$$g(\tau) = (-1)^k \sum_{\varepsilon} (-1)^{\sum \varepsilon_i} g(T_1^{\varepsilon_1} \times \cdots \times T_k^{\varepsilon_k}).$$

Since $g(\tau) \neq 0$, there exists a minor $T_1^{\varepsilon_1} \times \cdots \times T_k^{\varepsilon_k}$ such that $g(T_1^{\varepsilon_1} \times \cdots \times T_k^{\varepsilon_k}) \neq 0$.

Thus the minors of S^k are partitioned into sets of 2^k minors, each identified by some $T_1, \ldots, T_k$, and in each such set there is at least one minor T for which $g(T)$ is nonzero. $\square$

The error probability claimed in the theorem follows from the lemma by defining

$$g : S^3 \to \mathcal{S}/2,$$

$$g(i,j,k) = (i \circ j) \circ k - i \circ (j \circ k).$$

In the last line we have abbreviated notation by using the natural embedding $S \to \mathcal{S}/2$ sending $s \in S$ to $1s + \sum_{r \neq s} 0r$.

Remark. There is a similarity to the argument showing that Freivalds's [4] checker for matrix multiplication succeeds with probability at least 1/2. In that case, given matrices A, B, and C, a random vector v is multiplied by $AB - C$; if $AB \neq C$, then there is some vector u such that $u(AB - C) \neq 0$, and with every vector w such that $w(AB - C) = 0$, we associate the vector $w + u$ and note that $(w + u)(AB - C) \neq 0$.

3. Generalizations.

We have presented our method in the context of testing for associativity, that being a concrete and significant case, and the original problem we considered. However the method can be extended *mutatis mutandis* to more general situations.

Let $\{D_i\}_{i=1}^{c}$ be a collection of finite sets. If $\circ$ is a function on domain $\prod_{i=1}^{c} D_i$, we say that c is the *degree* of $\circ$. An *identity* is an equation involving one or more operations $\circ_j$, and which is required to hold for all instantiations of the variables, e.g., $\forall a, b, d, e \in D_1, c \in D_2$,

$$\circ_1(\circ_2(a,b), c, \circ_2(d,e)) = \circ_1(\circ_2(e,d), c, \circ_2(b,a)),$$

or, in the case of associativity,

$$\circ(\circ(a,b),c) = \circ(a, \circ(b,c)) \ \ \forall a,b,c \in S.$$

Note that each side of the equation may be viewed as a formula (in the circuit sense); we let ℓ be the total number of operations (internal nodes) occurring in the formulas. Thus $\ell = 6$ in the first example, and $\ell = 4$ for associativity. We let k be the total number of distinct variables occurring in the identity; thus $k = 5$ in the first example, and $k = 3$ for associativity.

A "read-once" identity is one in which every variable occurs exactly once on each side of the equation.

We have the following theorem.

THEOREM 3.1. *Let $\{D_i\}_{i=1}^{k}$ be finite sets, and let $\{\circ_j\}$ be a collection of operators, defined on various products of these sets; let the arguments to operator $\circ_j$ be drawn from the sets $D_{\sigma(j,1)}, \ldots, D_{\sigma(j,c_j)}$ where c_j is the degree of $\circ_j$. Let $M = \max_j \prod_{i=1}^{c_j} |D_{\sigma(j,i)}|$. A read-once identity with ℓ operations on k variables $\{x_i\}_{i=1}^{k}$ (each ranging in the corresponding D_i) can be verified in time $O(M \log(1/\delta) 2^k \ell)$ with failure probability at most δ.*

For comparison, supposing for simplicity that all the sets are of size n, this runtime is $O(n^{\max\{c_j\}} \log(1/\delta) 2^k \ell)$ whereas the naive method requires time $O(\ell n^k)$. The key gain is that the exponent of n is the maximum degree of the operations, rather than the number of variables in the identity.

This theorem relies upon the following.

LEMMA 3.2. *A read-once identity holds in S if and only if it holds in $\mathcal{S}/2$.*

Proof. If the identity holds in $\mathcal{S}/2$, then in particular it holds when each variable in the equation is a "singleton" element of the algebra, i.e., an element which has coefficient 1 on some element of S, and coefficient 0 elsewhere.

For the converse, note that each side of the identity can be expanded as a summation, over $(x_1, \ldots, x_k) \in D_1 \times \cdots \times D_k$, of terms each in exactly the same form as that side of the identity. Each corresponding pair of terms are equal in S, hence the summations are equal. ∎

Some examples:

Multiple domains. Let a finite state machine (S, Σ, δ) be given. Here S is the set of states of the machine (let $|S| = n$), Σ is the tape alphabet (let $|\Sigma| = m$), and $\delta : S \times \Sigma \to S$ is the transition function. Then the degree of the operator δ is 2, and it is possible to check in time $O(nm)$ (rather than the obvious $O(nm^2)$) that the operation of the machine is not dependent on the order of the input. (In other words, whether $\forall s \in S, a, b \in \Sigma, \delta(\delta(s,a),b) = \delta(\delta(s,b),a)$.) Testing for this property of the machine is sometimes called the diamond test in the CAD literature. We do this by extending $\mathbb{Z}/2$ with both S and Σ. Then we can extend δ implicitly to $\delta : (\mathbb{Z}/2)[S] \times (\mathbb{Z}/2)[\Sigma] \to (\mathbb{Z}/2)[S]$. We then verify the identity for a random $\mathbf{s}, \mathbf{a}$, and $\mathbf{b}$.

More generally, if $\circ$ is an operator from $X \times Y \to Z$, it can be naturally extended to an operator from $(\mathbb{Z}/2)[X] \times (\mathbb{Z}/2)[Y] \to (\mathbb{Z}/2)[Z]$, i.e.,

$$\left(\sum_x \alpha_x x\right) \circ \left(\sum_y \beta_y y\right) \doteq \sum_{xy} \alpha_x \beta_y x \circ y = \sum_z \gamma_z z,$$

where $\gamma_z = \sum_{x \circ y = z} \alpha_x \beta_y$. The algorithm extends to this setting. (In particular, if the identity is false, the probability of detecting this in one round is at least 1/8.)

Multiple operations. Consider two binary operations $\cup$ and $\cap$ and a unary operation $'$ over S (representing perhaps some kind of complementation). We wish to verify that for every $a, b, c \in S$, $(a \cap (b \cup c))' = a' \cup (b' \cap c')$. This is done in quadratic time by verifying the identity at random points over $(\mathbb{Z}/2)[S]$.

4. Witness identification.

The above method disproves identities without producing an explicit counterexample. However, if desired, it can be used easily in order to produce such a counterexample. (For example, for the purpose of debugging.) We illustrate this in the case of associativity.

Let $\mathbf{a}, \mathbf{b}, \mathbf{c}$ be a nonassociative triple in $\mathcal{S}/2$. Let A, B, and C be the sets indexed by $\mathbf{a}, \mathbf{b}$, and $\mathbf{c}$ (i.e., those elements occurring with coefficient 1). We know that there is a nonassociative triple in $A \times B \times C$. Because of Theorem 3.1, we can choose a new triple to be tested by the algorithm as follows: $\mathbf{a}', \mathbf{b}', \mathbf{c}'$ are i.i.d., with $\mathbf{a}'_i = 0$ if $\mathbf{a}_i = 0$, and otherwise $\mathbf{a}'_i$ is uniformly selected in $\{0, 1\}$. $\mathbf{b}'$ and $\mathbf{c}'$ are chosen similarly. The probability that $\mathbf{a}', \mathbf{b}', \mathbf{c}'$ is a nonassociative triple is at least 1/8. We repeat this process until a nonassociative triple $\mathbf{a}', \mathbf{b}', \mathbf{c}'$ is found, and then continue in like manner. Each of A, B, and C approximately halves in each successful round (analysis below), hence the number of rounds will be $O(\log n)$ with high probability. Thus, with a logarithmic increase in cost, we can pinpoint a nonassociative triple in S. Below we carry out the analysis up to the point that each of A, B, and C has been reduced to size $n^{2/3}$ or less; at that point all triples may be examined in time $O(n^2)$.

This argument, like Theorem 2.1, generalizes in all the ways described in the previous section.

THEOREM 4.1. *Beginning with sets A, B, C containing some nonassociative triple, the probability that more than $(1 + \frac{1}{\log^{1/3} n})\frac{8}{3}\log_2 n$ rounds of the above process are required to reduce all sets to size at most $n^{2/3}$ is at most* $\exp(-\Omega(\log^{1/3} n))$.

Proof. After one round we have new sets A', B', C'; if the round was successful (i.e., $\mathbf{a}', \mathbf{b}', \mathbf{c}'$ was a nonassociative triple), these will usually be strict subsets of A, B, and C, while if the round was unsuccessful, then $A' = A$, $B' = B$, and $C' = C$.

We are interested in the distribution of the random variables $|A'|/|A|$, $|B'|/|B|$, and $|C'|/|C|$ (in each round). With probability at most 7/8, the round is unsuccessful and the ratios equal 1.

We have shown earlier that for any $a \in A, b \in B, c \in C$ for which (a, b, c) is nonassociative, and for any $R \subseteq A - \{a\}$, $S \subseteq B - \{b\}$, $T \subseteq C - \{c\}$, at least one of the eight triples $\{R, R \cup \{a\}\} \times \{S, S \cup \{b\}\} \times \{T, T \cup \{c\}\}$ is a successful choice. In the worst case from the point of view of the sizes of A', B', and C', the successful triple is always $(R \cup \{a\}) \times (S \cup \{b\}) \times (T \cup \{c\})$. Therefore, as an upper bound on our analysis, we can suppose that the distribution of the sizes of A', B' and C' in successful rounds are independent and binomially distributed in the ranges $[1, |A|], [1, |B|], [1, |C|]$.

We focus on just one of these sequences of ratios, e.g., $|A'|/|A|$; the union bound accounts for a factor of 3 in the probability of failure. The probability that less than fraction $\frac{1}{8}(1 - \frac{1}{2\log^{1/3} n})$ of the $(1 + \frac{1}{\log^{1/3} n})\frac{8}{3}\log_2 n$ rounds are successful is at most $\exp(-\Omega(\log^{1/3} n))$. The probability that there exists any successful round in which $|A'|/|A| > (1 + \frac{1}{\log n})/2$ is at most $\log n \exp(-\Omega(n^{2/3}/\log^2 n))$. Therefore with probability at least $1 - \exp(-\Omega(\log^{1/3} n))$, there are at least $\frac{1}{3}(1 + \frac{1}{2\log^{1/3} n})\log_2 n$ rounds in which $|A'|/|A| \leq (1 + \frac{1}{\log n})/2$. The size of the set remaining after these rounds is at most $n((1 + \frac{1}{\log n})/2)^{\frac{1}{3}(1+\frac{1}{2\log^{1/3} n})\log_2 n} \leq n^{2/3}\exp(-\Omega(\log^{2/3} n))$.

5. The cancellative case.

We claim the following concerning this case.

THEOREM 5.1. *Let $\circ$ be cancellative.*

(1) *If $\circ$ is nonassociative, then it has at least $n - 2$ nonassociative triples.*

(2) *It is possible to compute a generating set of size $\lfloor \log_2 n \rfloor + 1$ in quadratic time.*

The first observation implies that picking a random triple and checking it for associativity works essentially optimally for cancellative operations. The second observation implies an $O(n^2 \log n)$ deterministic algorithm for verifying associativity for cancellative binary operations by taking into account Light's observation mentioned in the introduction.

Proof.

(1) Let (a, b, c) be nonassociative and let $a = a' \circ a''$. Consider the following *cycle:* $(a' \circ a'') \circ (b \circ c) = ((a' \circ a'') \circ b) \circ c = (a' \circ (a'' \circ b)) \circ c = a' \circ ((a'' \circ b) \circ c) = a' \circ (a'' \circ (b \circ c)) = (a' \circ a'') \circ (b \circ c)$.

Each of these equalities is an application of the associative identity, and since the first fails, one of the other four must fail as well. In other words, if (a, b, c) is nonassociative, then at least one of the following must be nonassociative:

(i) (a', a'', b),

(ii) $(a', a'' \circ b, c)$,

(iii) (a'', b, c),

(iv) $(a', a'', b \circ c)$.

Since $\circ$ is cancellative, a can be written as $a' \circ a''$ in n different ways. For each of these, associativity fails in at least one of the four categories above. Thus, there is a category for which there are $n/4$ failures. Each category identifies either a' or a'', so there can be no duplications among the nonassociative triples listed for that category.

To improve to a bound of $n - 2$, note that there must be a nonassociative triple in which not all three elements are equal. This follows once we know that there are at least two triples in one of the above categories. Now we suppose without loss of generality that there is a nonassociative triple (a, b, c) for which $b \neq c$; if this is not the case, then there is one for which $a \neq b$, and the remainder of the argument can be "reflected" accordingly.

For each of the n choices of a', a'' such that $a' \circ a'' = a$, fix a category (i-iv) in which the triple is nonassociative. Observe that among the triples listed in categories (i), (ii), and (iv), there can be no duplication, since a' is identified as the first element in each of those triples. The question that remains is how much duplication there can be between list (iii) and lists (i), (ii), and (iv).

Since $b \neq c$, there can be no duplication between lists (i) and (iii).

If there is a duplication between a triple $(a'_2, a''_2 \circ b, c)$ in list (ii) and a triple

(a_3'', b, c) in list (iii), then the value of a_2'' is implied by the value of $a_2'' \circ b$; this in turn implies the value of a_2', which must be equal to a_3'', and this in turn implies the value of a_3'. Hence there can be only one triple common to lists (ii) and (iii).

A common triple to lists (iii) and (iv) is possible only if $b \circ c = c$; in this case, if triples (a_3'', b, c) in list (iii) and $(a_4', a_4'', b \circ c)$ in list (iv) are equal, then a_4'' must equal b. This implies the value of a_4', which in turn is equal to a_3'', and this implies the value of a_3'. Hence there can be only one triple common to (iii) and (iv).

Hence there are at least $n - 2$ nonassociative triples.

The construction in section 6 will show that this bound is tight to within a constant factor.

(2) Let $A \subseteq S$ be arbitrary. Denote by $\langle A \rangle$ the closure of A under $\circ$. Thus a generating set G is one such that $\langle G \rangle = S$. Let A be any set such that $\langle A \rangle \neq S$ and let $b \in S - \langle A \rangle$. Then, $|\langle A \cup \{b\} \rangle| \geq 2|\langle A \rangle|$ because right cancellativity implies that the elements of $b \circ \langle A \rangle$ are all distinct, and left cancellativity and the fact that $\langle A \rangle$ is closed imply that each element of $b \circ \langle A \rangle$ is outside of $\langle A \rangle$. This implies the existence of a size $\lfloor \log_2 n \rfloor + 1$ generating set. Moreover, observe that we can keep track of the closure (in a greedy manner) in time $O(n^2)$. $\square$

If an operation $\circ$ on a finite set S is both cancellative and associative, then $(S, \circ)$ is a group. Hence the above process of testing first for cancellativity and then for the associative identity yields the following.

THEOREM 5.2. *There is a deterministic $O(n^2 \log n)$ time algorithm to test whether $(S, \circ)$ is a group.*

6. Lower bound for verifying associativity.

6. Lower bound for verifying associativity. An $\Omega(n^2)$ lower bound for checking for associativity is immediate: if some product of elements is not examined, it may be changed to destroy associativity. Indeed, this points out that a sub-$O(n^2)$ algorithm can be foiled by simply changing the product of a random pair of elements. Using Yao's lemma [8], the $\Omega(n^2)$ lower bound holds for randomized algorithms (even those tolerating constant error probability) as well.

With some more attention, we obtain an $\Omega(n^2)$ lower bound which holds even in case $\circ$ is assumed to be cancellative. (In the cancellative case, as we have pointed out, there are simpler quadratic time algorithms than ours to check associativity.) Again the method is to change just a few values of $\circ$; and again Yao's lemma implies that the lower bound holds for randomized algorithms.

The argument is as follows. Suppose the algorithm is deterministic. Let S be the hypercube $(\mathbb{Z}/2)^m$, and let $\circ$ be vector addition. Suppose there exist $a, b, c \in S$, with $a \neq 0^m$, such that the entries $b \circ c$, $b \circ (a+c)$, $(a+b) \circ c$, $(a+b) \circ (a+c)$ are not examined by the algorithm. Then the behavior of the algorithm on $\circ$ is indistinguishable from its behavior on the operation $\circ'$ which we obtain by modifying the following entries of $\circ$:

(1) $b \circ' c = a + b + c$,
(2) $b \circ' (a + c) = b + c$,
(3) $(a + b) \circ' c = b + c$,
(4) $(a + b) \circ' (a + c) = a + b + c$.

Observe that $\circ'$ is still cancellative, but it is not associative because

$$(c \circ' (a + b)) \circ' c = (a + b + c) \circ' c = a + b,$$

while

$$c \circ' ((a+b) \circ' c) = c \circ' (b+c) = b.$$

Now, for any fixed a, there is a set $R \subseteq S$ of size $|R| = |S|/2$ such that for all $r, r' \in R$, $r + a \neq r'$. Letting b and c range over R, we obtain $|S|^2/4$ disjoint quadruples $\{\{b, c\}, \{b, a+c\}, \{a+b, c\}, \{a+b, a+c\}\}$ in $S \times S$. If the algorithm does not examine at least one value of $\circ$ in each quadruple, then it cannot distinguish $\circ$ from $\circ'$. Hence the algorithm must perform at least $n^2/4$ operations.

We now note that Theorem 5.1(1) is tight up to a constant factor. If we pick a, b, c independently, uniformly at random, then since $\circ'$ is cancellative, each one of the four pairs $\{a, b\}$, $\{a \circ' b, c\}$, $\{b, c\}$, and $\{a, b \circ' c\}$ is uniformly distributed in $S \times S$. Therefore the probability that (a, b, c) is a nonassociative triple for $\circ'$ is at most $16/n^2$; in other words, the number of nonassociative triples is at most $16n$.

7. Grigni's modification. M. Grigni has pointed out that for large k (the number of variables in the identity) it is useful to run our algorithm using $\mathcal{S}/p = (\mathbb{Z}/p)[S]$ for prime p such that $p > k$ (in place of $\mathcal{S}/2$), where k is the number of variables occurring in the identity. At the modest price of keeping track of larger coefficients and using a little more randomness, the probability of detecting failure of the identity in one run of the process is now at least $1 - k/p$, rather than 2^{-k}. This is for the following reason: the result of the computation in our algorithm is a pair of elements of $\mathcal{S}/p$, one corresponding to the left-hand side of the identity being checked and another corresponding to the right-hand side. Subtracting one from the other, the algorithm obtains an element $\sum_s \omega_s s \in \mathcal{S}/p$ and reports nonassociativity if any ω_s is nonzero. Each such ω_s is defined by a polynomial over $\mathbb{Z}/p$ in the (random) variables (each in $\mathbb{Z}/p$) used in the algorithm. The degree of each of these polynomials is at most k, and if the operation is not associative, then at least one polynomial is nonzero. By a lemma of J. T. Schwartz [6], the fraction of assignments on which a nonzero polynomial is 0 is at most k/p.

8. Examples.

Example 1. Let $S = \{1, 2, \ldots, n\}$, with $x \circ y = x$ for every (x, y). The only set of generators is S. Note also that $\circ$ is associative.

Example 2. Let $S = \{1, 2, \ldots, n\}$, with n at least 3. Let $1 \circ 2 = 2$. Let $x \circ y = 3$ for every $(x, y) \neq (1, 2)$. The only nonassociative triple is $(1, 1, 2)$.

For $n = 2$, any nonassociative operation has at least two nonassociative triples.

9. Open questions. While a nonassociative operation has a short witness for this property—and we are able, in fact, to efficiently find such a witness—we do not know of any short witness for associativity or any sub-n^3 time (randomized or deterministic) algorithm which, if the given operation is associative, proves this fact. (An exception is cancellative operations which, from Theorem 5.2, we know to have associativity witnesses of length $O(n^2 \log n)$.)

It remains to make any progress on verification of identities which are not read-once. A key example is the "distributive" identity $a \cap (b \cup c) = (a \cap b) \cup (a \cap c)$; it is not known whether this can be verified in less than cubic time.

Finally, we recall the interesting question encountered in the context of Light's observation as to whether there is an efficient algorithm which, given a set S and a binary operation $\circ$ on S, finds a set of generators for S of optimal or nearly optimal size.

Acknowledgments. We wish to acknowledge helpful conversations with Manuel Blum, Michelangelo Grigni, Sampath Kannan, and Thomas Wilke. We also wish to thank Kousha Etessami for first bringing the question to our attention.

EXPLORING UNKNOWN ENVIRONMENTS*

SUSANNE ALBERS† AND MONIKA R. HENZINGER‡

Abstract. We consider exploration problems where a robot has to construct a complete map of an unknown environment. We assume that the environment is modeled by a directed, strongly connected graph. The robot's task is to visit all nodes and edges of the graph using the minimum number R of edge traversals. Deng and Papadimitriou [*Proceedings of the* 31*st Symposium on the Foundations of Computer Science*, 1990, pp. 356–361] showed an upper bound for R of $d^{O(d)}m$ and Koutsoupias (reported by Deng and Papadimitriou) gave a lower bound of $\Omega(d^2m)$, where m is the number of edges in the graph and d is the minimum number of edges that have to be added to make the graph Eulerian. We give the first subexponential algorithm for this exploration problem, which achieves an upper bound of $d^{O(\log d)}m$. We also show a matching lower bound of $d^{\Omega(\log d)}m$ for our algorithm. Additionally, we give lower bounds of $2^{\Omega(d)}m$, respectively, $d^{\Omega(\log d)}m$ for various other natural exploration algorithms.

1. Introduction.

Suppose that a robot has to construct a complete map of an unknown environment using a path that is as short as possible. In many situations it is convenient to model the environment in which the robot operates by a graph. This allows us to neglect geometric features of the environment and to concentrate on combinatorial aspects of the exploration problem. Deng and Papadimitriou [12] formulated thus the following exploration problem. A robot has to explore all nodes and edges of an unknown, strongly connected directed graph. The robot *visits* an edge when it traverses the edge. A node or edge is *explored* when it is visited for the first time. The goal is to determine a *map*, i.e., the adjacency matrix of the graph, using the minimum number R of edge traversals. At any point in time the robot knows (1) all visited nodes and edges and can recognize them when reencountered, and (2) the number of unvisited edges leaving any visited node. The robot does not know the head of unvisited edges leaving a visited node or the unvisited edges leading into a visited node. At each point in time, the robot visits a *current node* and has the choice of leaving the current node by traversing a specific known or an arbitrary (i.e., given by an adversary) unvisited outgoing edge. An edge can be traversed only from tail to head, not vice versa.

If the graph is Eulerian, $2m$ edge traversals suffice [12], where m is the number of edges. This immediately implies that undirected graphs can be explored with at most $4m$ traversals. In fact, using depth-first-search they can be explored using $2m$ edge traversals. For a non-Eulerian graph, let the *deficiency* d be the minimum number of edges that have to be added to make the graph Eulerian. Deng and

Papadimitriou [12] suggested studying the dependence of R on m and d and showed the first upper and lower bounds: they gave a graph such that any algorithm needs $\Omega(d^2m/\log d)$ edge traversals, and they also presented an algorithm that achieves an upper bound of $d^{O(d)}m$. Koutsoupias [16] improved the lower bound to $\Omega(d^2m)$. Deng and Papadimitriou asked the question whether the exponential gap between the upper and lower bound can be closed. Our paper is a first step in this direction: we give an algorithm that is subexponential in d; namely, it achieves an upper bound of $d^{O(\log d)}m$. We also show a matching lower bound for our algorithm and exponential lower bounds for various other exploration algorithms.

Note that d arises also in the complexity of the "offline" version of the problem: Consider a directed cycle with one edge replaced by $d+1$ parallel edges. On this graph any Eulerian traversal requires $\Omega(dm)$ edge traversals. A simple modification of the Eulerian online algorithm solves the offline problem on any directed graph with $O(dm)$ edge traversals.

Related work. Exploration and navigation problems for robots have been studied extensively in the past. The exploration problem in this paper was formulated by Deng and Papadimitriou based on a learning problem proposed by Rivest [19]. Betke, Rivest, and Singh [8] and Awerbuch et al. [1] studied the problem of exploring an undirected graph and requiring additionally that the robot returns to its starting point every so often. Bender and Slonim [9] showed how two cooperating robots can learn a directed graph with indistinguishable nodes, where each node has the same number of outgoing edges. Subsequent to the work in [12], Deng, Kameda, and Papadimitriou [11] investigated a geometric exploration problem, whose goal is to explore a room with or without polygonal obstacles. Hoffmann et al. [15] gave an improved exploration strategy for rooms without obstacles. More generally, theoretical studies of exploration and navigation problems in unknown environments were initiated by Papadimitriou and Yannakakis [18]. They considered the problem of finding a shortest path from a point s to a point t in an unknown environment and presented many geometric and graph-based variants of this problem. Blum, Raghavan, and Schieber [7] investigated the problem of finding a shortest path in an unfamiliar terrain with convex obstacles. More work on this problem includes [2, 5, 6].

Our results. Our main result is a new robot strategy that explores an arbitrary graph with deficiency d and traverses each edge at most $(d+1)^7d^{2\log d}$ times; see section 3. The algorithm does not need to know d in advance. The total number of traversals needed by the algorithm is also $O(\min\{nm, dn^2+m\})$, where n is the number of nodes. At the end of section 3 we show that any exploration algorithm that fulfills two intuitive conditions achieves an upper bound of $O(\min\{nm, dn^2+m\})$. A depth-first search strategy obtaining this bound was independently developed by Kwek [17].

In section 4 we demonstrate that our analysis of the new robot strategy is tight: There exists a graph that is explored by our algorithm using $d^{\Omega(\log d)}m$ edge traversals. We also show that various variants of the algorithm have the same lower bound. In section 2, we present lower bounds of $2^{\Omega(d)}m$, respectively, $d^{\Omega(\log d)}m$ for various other natural exploration algorithms, to give some intuition for the problem.

Our exploration algorithm tries to explore new edges that have not been visited so far. That is, starting at some visited node x with unvisited outgoing edges, the robot explores new edges until it gets *stuck* at a node y, i.e., it reaches y on an unvisited incoming edge and y has no unvisited outgoing edge. Since the robot is not allowed to traverse edges in the reverse direction, an adversary can always force the robot to visit unvisited nodes until it finally gets stuck at a visited node.

The robot then relocates, using visited edges, to some visited node z with unexplored outgoing edges and continues the exploration. The *choice* of z is the only difference between various algorithms and the *relocation* to z is the only step where the robot traverses visited edges. To minimize R we have to minimize the total number of edges traversed during all relocations. It turns out that a locally greedy algorithm that tries to minimize the number of traversed edges during each relocation is not optimal: it has a lower bound of $2^{\Omega(d)}m$ (see section 2).

Instead, our algorithm uses a divide-and-conquer approach. The robot explores a graph with deficiency d by exploring d^2 subgraphs with deficiencies $d/2$ each and uses the same approach recursively on each of the subgraphs. To create subgraphs with small deficiencies, the robot keeps track of visited nodes that have more visited outgoing than visited incoming edges. Intuitively, these nodes are *expensive* because the robot, when exploring new edges, can get stuck there. The relocation strategy tries to keep portions of the explored subgraphs "balanced" with respect to their expensive nodes. If the robot gets stuck at some node, then it relocates to a node z such that "its" portion of the explored subgraph contains the minimum number of expensive nodes.

2. Lower bounds for various algorithms. In this section we prove a lower bound of $2^{\Omega(d)}m$ for a locally greedy, a depth-first, and a breadth-first algorithm. We also give a lower bound of $d^{\Omega(\log d)}m$ for a generalized greedy strategy.

A related problem, for which lower bounds have been studied extensively, is the *s–t connectivity problem* in directed graphs; see [3, 4, 14] and references therein. Given a directed graph, the problem is to decide whether there exists a path from a distinguished node s to a distinguished node t. Most of the results are developed in the JAG model by Cook and Rackoff [10]. The best time–space tradeoffs currently known [4, 14] only imply a polynomial lower bound on the computation time if no upper bounds are imposed in the space used by the computation. Given the current knowledge of the s–t connectivity problem it seems unlikely that one can prove super-polynomial lower bounds for a *general* class of graph exploration algorithms.

In the following let G be a directed, strongly connected graph and let v be a node of G. Let $in(v)$ and $out(v)$ denote, respectively, the number of incoming and outgoing edges of v. Let the *balance* $bal(v) = out(v) - in(v)$. For a graph with deficiency d there exist at most d nodes s_i, $1 \leq i \leq d$, such that $bal(s_i) < 0$. Every node s_i with $bal(s_i) < 0$ is called a *sink*. Note that $-\sum_{s,bal(s)<0} bal(s) = d$. We use the term *chain* to denote a path. A chain is a sequence of nodes and edges $x_1, (x_1, x_2), x_2, (x_2, x_3), \ldots, (x_{k-1}, x_k), x_k$ for $k > 1$.

Greedy: If stuck at a node y, move to the nearest node z that has new outgoing edges.

Generalized-Greedy: At any time, for each path in the subgraph explored so far, define a lexicographic vector as follows. For each edge on the path, determine its current *cost*, which is the number of times the edge was traversed so far. Sort these costs in nonincreasing order and assign this vector to the path. Whenever stuck at a node y, out of all paths to nodes with new outgoing edges traverse the path whose vector is lexicographic minimum.

Depth-First: If stuck at a node y, move to the most recently discovered node z that can be reached and that has new outgoing edges.

Breadth-First: Let v be the node where the exploration starts initially. If stuck at a node y, move to the node z that has the smallest distance from v among all nodes with new outgoing edges that can be reached from y.

THEOREM 1. *For Greedy, Depth-First, and Breadth-First, and for every d, there exist graphs of deficiency d that require $2^{\Omega(d)}m$ edge traversals.*

Proof (*Greedy*). Basically *Greedy* fails since it is easy to "hide" a subgraph (see Figure 1). Whenever *Greedy* discovers this subgraph, the adversary can force it to repeat all the work done so far.

The graph G consists of two parts: (1) a cycle C_0 of three edges and nodes v, $v^1(C_0)$, and $v^2(C_0)$, and (2) a recursively defined problem P^d. A *problem* P^δ, for any integer $\delta \geq 2$, is a subgraph that has two *incoming* edges whose startnodes do not belong to P^δ but whose endnodes do, and δ *outgoing* edges whose startnode belongs to P^δ but whose endnodes do not. A *problem* P^1 is defined in the same way as a problem P^δ, $\delta \geq 2$, except that P^1 has only one incoming edge. In the case of P^d, the two incoming edges start at $v^1(C_0)$ and $v^2(C_0)$, respectively; the d outgoing edges all point to v.

For the description of P^δ we also need recursively defined problems Q^δ. These problems are identical to P^δ except that, for $\delta > 2$, Q^δ has exactly δ incoming edges.

A problem P^δ, $\delta = 1, 2$, consists of δ chains of three edges each. The first edge of each chain is an incoming edge into P^δ; the last edge of each chain is an outgoing edge. A problem Q^δ, $\delta = 1, 2$, is the same as P^δ.

We proceed to define P^δ, for $\delta > 2$. One of the incoming edges of P^δ is the first edge of a chain D^δ consisting of three edges and the other incoming edge is the first edge of a long chain C^δ. For each of these chains C^δ and D^δ, the last edge is an outgoing edge of P^δ. If $\delta = 3$, the last interior node of each of the chains C^δ and D^δ has an additional outgoing edge pointing into a problem P^1. If $\delta \geq 4$, then (a) the last two interior nodes of C^δ each have an additional outgoing edge pointing into a subproblem $P^{\delta-2}$, and (b) the last two interior nodes of D^δ each have an additional outgoing edge pointing into a subproblem $Q^{\delta-2}$. There are $\delta - 2$ edges leaving $P^{\delta-2}$, exactly $\max\{0, \delta - 4\}$ of which point to nodes of $Q^{\delta-2}$ such that each node in $Q^{\delta-2}$ that has k more outgoing than incoming edges, for some $0 \leq k \leq \max\{0, \delta - 4\}$, receives k incoming edges from $P^{\delta-2}$. The remaining outgoing edges of $P^{\delta-2}$ point to the interior nodes of D^δ that have additional outgoing edges. The problem $Q^{\delta-2}$ has $\delta - 2$ outgoing edges all of which are outgoing edges of P^δ. The total number of edges in C^δ is 2 plus the number of edges of D^δ plus the total number of edges contained in the subproblem $Q^{\delta-2}$ below D^δ.

A problem Q^δ, $\delta > 2$, is the same as P^δ except that the subproblem $P^{\delta-2}$ is replaced by another $Q^{\delta-2}$ problem. That is, Q^δ is composed of chains C^δ, D^δ, and problems $Q_i^{\delta-2}$, $i = 1, 2$. As mentioned before, Q^δ has exactly δ incoming edges.

Greedy is started at node v and traverses first chain C_0. Then it either explores C^d or D^d. In either case, afterwards *Greedy* explores all edges of Q^{d-2} since C^d is prohibitively long. Thus, P^{d-2} is "hidden" from *Greedy*. We exploit this in the analysis: Let $N(\delta)$ be the number of times that *Greedy* explores edges of a problem P^δ or Q^δ, gets stuck at some node, and cannot relocate to a suitable node by using only edges in P^δ, respectively, Q^δ. We show that $N(\delta) \geq 2^{\delta/2}$. Since the edge leaving v is traversed every time the algorithm cannot relocate by using only edges in P^d, the bound follows.

A problem P^δ contains two subproblems $P^{\delta-2}$ and $Q^{\delta-2}$. Note that (a) because of chain D^δ, no node in $Q^{\delta-2}$ can reach a node of $P^{\delta-2}$ without leaving P^δ, and (b) $Q^{\delta-2}$ is completely explored when the exploration of $P^{\delta-2}$ starts and all paths starting in $P^{\delta-2}$ lead through D^δ or $Q^{\delta-2}$. Thus, every time *Greedy* gets stuck in

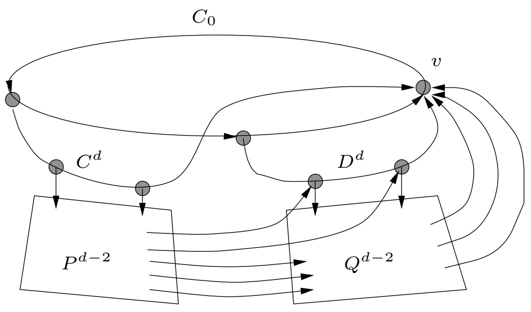

FIG. 1. *The graph for* Greedy.

a subproblem $P^{\delta-2}$ or $Q^{\delta-2}$ and has to leave $P^{\delta-2}$, respectively, $Q^{\delta-2}$ in order to resume exploration, it also has to leave P^{δ}. For $Q^{\delta-2}$ the statement follows from (a); for $P^{\delta-2}$ it follows from (a) and (b). In the same way, we can argue for a problem Q^{δ}. Thus, $N(\delta) \geq 2N(\delta-2)$. Since, for $\delta = 1, 2$, $N(\delta) \geq 1$, we obtain $N(\delta) \geq 2^{\delta/2}$.

This implies that the edge e on C_0 leaving v is traversed $2^{\Omega(d)}$ times. The desired bound follows by replacing e with a path consisting of $\Theta(m)$ edges.

Depth-First: We can use the same graph as in the case of the *Greedy* algorithm. *Depth-First* will explore all edges in Q^{d-2} before it will start exploring P^{d-2}.

Breadth-First: Again we can use the same graph as in the lower bound for *Greedy*. The last two interior nodes of C^d have a larger distance from the initial node v than all nodes on D^d and in Q^{d-2}. Thus Q^{d-2} is finished before *Breadth-First* starts exploring P^{d-2}. ∎

THEOREM 2. *For Generalized-Greedy and for every d, there exists a graph of deficiency d that requires $d^{\Omega(\log d)}m$ edge traversals.*

Proof. The graph used for the lower bound is outlined in Figure 2. The basic idea in the lower bound construction is as follows. *Generalized-Greedy* explores each subgraph Q_i^{γ} and its sibling R_i^{γ} "in parallel." Without loss of generality we can assume that the last chain traversed in the two subgraphs lies in Q_i^{γ} and the algorithm continues to explore Q_{i+1}^{γ} and R_{i+1}^{γ}. Let $N(\gamma)$ denote the number of times that the algorithm has to leave R_i^{γ} and traverse the root. We will show that $N(4\gamma) \geq \gamma N(\gamma)$, which implies that the root has to be traversed $N(d) \geq d^{\Omega(\log d)}$ times.

To be precise we show the bound for d being a power of 4. The bound for all values of d follows by rounding down to the largest power of 4 smaller than d. The graph G consists of two parts: (1) a cycle C_0 with nodes v, $v^1(C_0)$ and $v^2(C_0)$, and (2) a recursively defined subproblem P^d. Problem P^d has two incoming edges, one starting at $v^1(C_0)$ and one starting at $v^2(C_0)$. It also has d outgoing edges, all pointing to v. The subproblem P^d is a union of chains C, each of which consists of three edges, a startnode, an endnode, and two *interior nodes* $v^1(C)$ and $v^2(C)$. The interior nodes have at most one additional outgoing edge. We proceed to define P^{δ} and the "sibling" graphs Q^{δ} and R^{δ}, for all $\delta \leq d$ that are a power of 4, and then show the lower bound on this graph.

A *problem* P^{δ}, $\delta > 1$, is a graph with two incoming edges and exactly δ outgoing edges. A *problem* R^{δ}, $\delta > 1$, consists of P^{δ} with $\delta - 2$ additional incoming edges. The *problem* Q^{δ} consists of R^{δ} with two additional incoming and two additional outgoing edges.

$\delta = 1$: A problem P^1 consists of one chain. The incoming edge of P^1 is the first

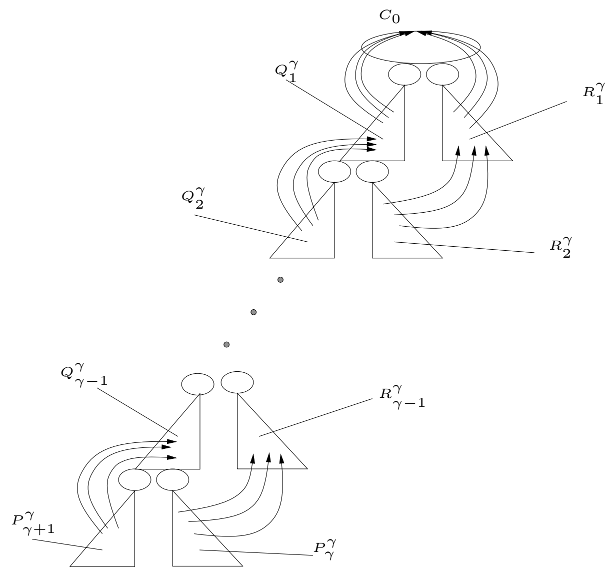

FIG. 2. *The graph for* Generalized-Greedy.

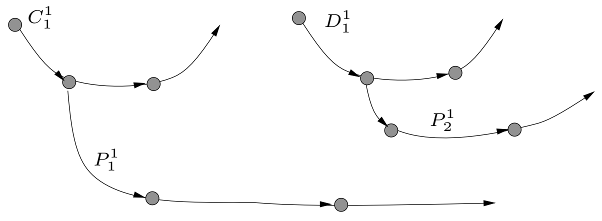

FIG. 3. *The subproblem* P^4.

edge of the chain and the outgoing edge of P^1 is the last edge of the chain. In P^1, the interior nodes of the chain have no additional outgoing edges; in Q^1, each interior node has one additional incoming and one additional outgoing edge. Problem R^1 is equal to P^1.

$\delta = 4$: A problem P^4 consists of two subproblems P_1^1 and P_2^1 and chains C_1^1 and D_1^1, whose first interior nodes have one additional outgoing edge (see Figure 3). The outgoing edge of C_1^1 is the incoming edge of P_1^1 and the corresponding edge of D_1^1 is the incoming edge of P_2^1. The last edge of C_1^1 and D_1^1 and the outgoing edges of P_1^1 and P_2^1 are outgoing edges of P^4. A problem R^4 is P^4 with two additional incoming edges, one at the startnode of P_1^1 and one at the startnode of P_2^1. A problem Q^4 is R^4 with two additional incoming and outgoing edges; each interior node of P_1^1 has an additional incoming and outgoing edge.

$\delta = 4^l$, for some $l \geq 2$: Let $\gamma = \delta/4$. It is simpler to describe Q^δ first. The construction is depicted in Figure 4. Every node has the same indegree as outdegree, i.e., there are no sinks. Problem Q^δ consists of subproblems Q_i^γ and R_i^γ, for $1 \leq i \leq \gamma$, connected by chains C_i^γ and D_i^γ, for $1 \leq i \leq \gamma$, whose interior nodes each have an additional outgoing edge.

The C-chains and Q-subproblems are interleaved as follows. The two edges leaving the interior nodes of C_1^γ point into Q_1^γ. In general, the edges leaving the interior nodes

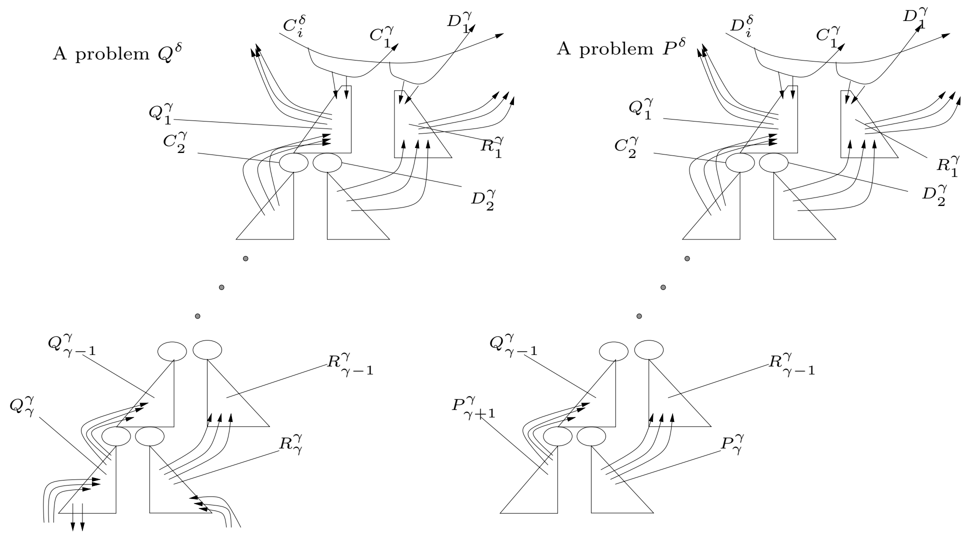

FIG. 4. *The subproblems Q^δ and P^δ.*

of C_i^γ point into Q_i^γ. The same holds for the D-chains and R-subproblems. The first edge of C_i^γ and of D_i^γ are incoming edges of Q^δ, for $i = 1$, and start in Q_{i-1}^γ, for $1 < i \leq \gamma$, on a node of the leftmost subproblem Q^1 contained in Q_{i-1}^γ. Recall that this problem consists of one chain with two additional incoming and outgoing edges. One of these outgoing edges is the first edge of C_i^γ and the second outgoing edge is the first edge of D_i^γ.

Additionally, the subproblems are connected as follows. Recall that γ edges leave R_i^γ. For $i = 1$, the edges leaving R_i^γ are outgoing edges of Q^δ. For $1 < i \leq \gamma$, two edges leaving R_i^γ point to the interior edges of D_{i-1}^γ. Additionally, there are $\gamma - 2$ edges leaving R_i^γ and pointing into R_{i-1}^γ such that every node in R_{i-1}^γ that has k more outgoing than incoming edges, for $k > 0$, receives k edges from R_i^γ. The same holds for Q_i^γ with C_{i-1}^γ. The problem Q_γ^γ has γ incoming edges which are incoming edges for Q^δ; the problem R_γ^γ has $\gamma - 2$ incoming edges which are incoming edges for Q^δ.

There are $4\gamma + 2 = \delta + 2$ outgoing edges in Q^δ: the last edge of C_i^γ and the last edge of D_i^γ, for $1 \leq i \leq \gamma$, all edges leaving R_1^γ, all but two edges leaving Q_1^γ (the other two are the incoming edges of D_2^γ and C_2^γ), and two edges leaving Q_γ^γ. There are also $\delta + 2$ incoming edges: the first edge of C_1^γ and of D_1^γ, the edges pointing to the two interior nodes of C_γ^γ and D_γ^γ, the γ incoming edges of Q_γ^γ, the $\gamma - 2$ incoming edges of R_γ^γ, and $2\gamma - 2$ incoming edges ending at the startnodes of C_i^γ and D_i^γ, for $2 \leq i \leq \gamma$.

A problem P^δ consists of 2γ chains C_i^γ and D_i^γ, $1 \leq i \leq \gamma$, as well as two subproblems P_i^γ, $\gamma \leq i \leq \gamma + 1$, and $2(\gamma - 1)$ subproblems Q_i^γ and R_i^γ, $1 \leq i \leq \gamma - 1$. These components are assembled in the same way as in Q^δ, except that Q_γ^γ is replaced by $P_{\gamma+1}^\gamma$ and R_γ^γ is replaced by P_γ^γ. Problems P_γ^γ and $P_{\gamma+1}^\gamma$ each have only two incoming edges from C_γ^γ and D_γ^γ, respectively.

There are $4\gamma = \delta$ outgoing edges in P^δ: the last edge of C_i^γ and the last edge of D_i^γ, for $1 \leq i \leq \gamma$, all but two edges leaving Q_1^γ (the other two are the incoming edges of D_2^γ and C_2^γ), all edges leaving R_1^γ. There are two incoming edges in P^δ. The first edge of C_1^γ and of D_1^γ are incoming edges in every problem P^δ. The following

$\delta - 2$ nodes are sources for P^δ: the two interior nodes of C_γ^γ and of D_γ^γ, the $2\gamma - 2$ startnodes of C_i^γ and D_i^γ, for $2 \le i \le \gamma$, the $\gamma - 2$ sources of P_γ^γ, and the $\gamma - 2$ sources of $P_{\gamma+1}^\gamma$.

A problem R^δ is a problem P^δ with an incoming edge into every source of P^δ. Thus there are δ incoming and δ outgoing edges.

We analyze *Generalized-Greedy* on G. For simplicity we only discuss the exploration of a problem Q^δ. The argument for P^δ and R^δ is analogous. As before, let $\gamma = \delta/4$. We show inductively that the symmetric construction of Q_i^γ and R_i^γ attached to C_i^γ and D_i^γ as well as the definition of *Generalized-Greedy* imply that Q_i^γ and R_i^γ are explored symmetrically. That is, during two consecutive traversals of C (in order to resume exploration in Q_i^γ or R_i^γ), *Generalized-Greedy* proceeds once into Q_i^γ and once into R_i^γ, where C is the chain at which chains C_i^γ and D_i^γ start. This obviously holds for $i = 1$. Assume it holds for i and we want to show it for $i + 1$. Note that Q_i^γ and R_i^γ differ only in the last chain that *Generalized-Greedy* explores in Q_i^γ, respectively, R_i^γ. Thus, until the traversal of the earlier of the last chain of Q_i^γ and the last chain of R_i^γ, *Generalized-Greedy* does not distinguish Q_i^γ from R_i^γ. Hence we can assume without loss of generality that *Generalized-Greedy* traverses first the last chain of R_i^γ, and afterwards the last chain of Q_i^γ. (Think of an adversary "giving" to *Generalized-Greedy* first the last chain of R_i^γ and then the last chain of Q_i^γ.) Then *Generalized-Greedy* explores C_{i+1}^γ and D_{i+1}^γ, and afterwards Q_{i+1}^γ and R_{i+1}^γ symmetrically. Thus, when *Generalized-Greedy* explores a subproblem R_i^γ, $1 \le i \le \gamma$, subproblems R_j^γ with $1 \le j < i$ are already finished.

Whenever *Generalized-Greedy* gets stuck in R_i^γ, $1 \le i \le \gamma$, and has to leave R_i^γ in order to resume exploration, it also has to leave the "parent problem" Q^δ (or P^δ, R^δ). This is because the chains D_i^γ, $1 \le i \le \gamma$, prevent the algorithm from reaching a chain in Q_j^γ, $1 \le j \le i$, from where unfinished chains in Q^δ, (P^δ, R^δ) can be reached. On the way from R_i^γ to an outgoing edge of the parent problem, *Generalized-Greedy* can traverse problems R_j^γ, $j \le i$. As shown in Figure 4, the subproblems are finished; no further exploration of R_j^γ is possible. The same arguments hold when the algorithm gets stuck in a problem P_γ^γ.

For any δ, $4 \le \delta \le d$, let $N(\delta)$ be the number of times *Generalized-Greedy* generates a chain in P^δ or R^δ, gets stuck, and has to leave P^δ or R^δ in order to continue exploration. Then $N(\delta) \ge \gamma N(\gamma) = \delta/4 N(\delta/4)$. Since $N(1) \ge 1$, we have $N(d) \ge d^{\Omega(\log d)}$ and hence the edge leaving node v is traversed $d^{\Omega(\log d)}$ times. $\square$

3. An algorithm for graphs with deficiency *d*.

3.1. The *Balance* algorithm. We present an algorithm that explores an unknown, strongly connected graph with deficiency d, without knowing d in advance. First we give some definitions. At the start of the algorithm, all edges are *unvisited* or *new*. An edge becomes *visited* whenever the robot traverses it. A node is *finished* whenever all its outgoing edges are visited. The robot is *stuck* at a node y if the robot enters a finished node y on an unvisited edge. A sink is *discovered* whenever the robot gets stuck at the sink for the first time. We assume that whenever the robot discovers a new sink, the subgraph of explored edges is strongly connected. This does not hold in general, but by properly restarting the algorithm, the problem can be reduced to the case described here. Details are given in section 3.2.

Assume the algorithm knew the d missing edges $(s_1, t_1), (s_2, t_2), \ldots, (s_d, t_d)$ and a path from each s_i to t_i. Then a modified version of the Eulerian algorithm could be executed: Whenever the original Eulerian algorithm traverses an edge (s_i, t_i), the modified Eulerian algorithm traverses the corresponding path from s_i to t_i. Obviously, the modified algorithm traverses each edge at most $2d + 2$ times. Thus, the problem is to find the missing edges and corresponding paths.

Our algorithm tries to find the missing edges by maintaining d edge-disjoint chains, such that the endnode of chain i is s_i and the startnode of chain i is our current *guess* of t_i. As the algorithm progresses, paths can be appended at the start of each chain. At termination, the startnode of chain i is indeed t_i. To mark chain i all edges on chain i are colored with color i.

The algorithm consists of two phases.

Phase 1. Run the algorithm of [12] for Eulerian graphs. Since G is not Eulerian, the robot will get stuck at a sink s. At this point stop the Eulerian graph algorithm and goto Phase 2. The part of the graph explored so far contains a cycle C_0 containing s [12]. We assume that at the end of Phase 1 all visited nodes and edges not belonging to C_0 are marked again as unvisited.

Phase 2. Phase 2 consists of *subphases*. During each subphase the robot visits a *current* node x of a *current* chain C and makes progress towards finishing the nodes of C. The current node of the first subphase is s, its current chain is C_0. The current node and current chain of subphase j depend on the outcome of subphase $j - 1$.

A chain can be in one of three states: *fresh*, *in progress*, or *finished*. A chain C is *finished* when all its nodes are finished; C is *in progress* in subphase j if C was a current chain in a subphase $j' \leq j$ and C is not yet finished; C is *fresh* if it is not finished and not yet in progress.

Up to $d+1$ chains in progress and up to d fresh chains can exist at the same time. The invariant that there are always at most $d+1$ chains in progress is convenient but not essential in the analysis of the algorithm. The invariant that there exist always at most d fresh chains is crucial. Every startnode of a fresh chain has more visited outgoing than visited incoming edges and, thus, the robot can get stuck there. In the analysis we require that there always exist at most d such nodes.

The algorithm marks the current guess for t_i with a *token* τ_i, for $1 \leq i \leq d$. In fact, every startnode of a fresh chain represents the current guess for some t_i, $1 \leq i \leq d$, and thus has a token τ_i. To simplify the description of the relocation process, each token is also assigned an *owner* which is a chain that contains the node on which the token is placed. More specifically, the owner of τ_i is the chain that was the current chain when the path from the current guess of t_i to s_i was extended last. Note that the owner is not the chain from the current guess of t_i to s_i. A node can be the current guess for more than one node t_i and, thus, have more than one token.

From a high-level point of view, at any time, the subgraph explored so far can be partitioned into chains, namely C_0 and the chains generated in Phase 2. During the actual exploration in the subphases, the robot travels between chains. While doing so, it generates or extends fresh chains, which will be taken into progress later, and finishes the chains currently in progress.

We give the details of a subphase. First, the algorithm tests if x has an unvisited outgoing edge.

1. If x does not have an unvisited outgoing edge and x is not the endnode of C, then the next node of C becomes the current node and a new subphase is started.
2. If x has no unvisited outgoing edge and x is the endnode of C, procedure *Relocate* is called to decide which chain becomes the current chain and to

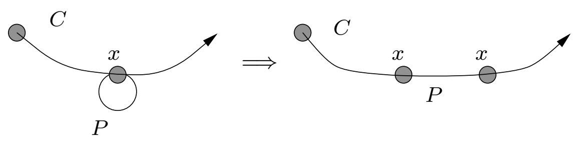

FIG. 5. *Case* 1.

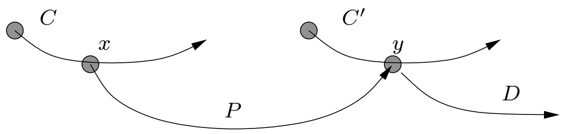

FIG. 6. *Case* 2.

move the robot to the startnode z of this chain. Node z becomes the current node.

3. If x has unvisited outgoing edges, the robot repeatedly explores unvisited edges until it gets stuck at a node y. Let P be the path traversed.
   We distinguish four cases.

Case 1. $y = x$. Cut C at x and add P to C (see Figure 5). The robot returns to x and the next phase has the same current node and current chain.

Case 2. $y \neq x$, y has a token τ_i and is the startnode of a fresh chain D (see Figure 6). Append P at D to create a longer fresh chain, and move the token from y to x. The current chain C becomes the *owner* of the token, the previous owner becomes the current chain, and y becomes the current node.

Case 3. $y \neq x$, y has a token τ_i but is not the startnode of a fresh chain. This is the same as Case 2 except that no fresh chain starts at y. The algorithm creates a new fresh chain of color i consisting of P. It moves the token from y to x and C becomes the owner of the token. The previous owner of the token becomes the current chain and y becomes the current node.

Case 4. $y \neq x$ and y does not own a token. In this case $bal(y) < 0$. If $bal(y) = -k$, then this case occurs k times for y. Let i be the number of existing tokens. The algorithm puts a new token τ_{i+1} on x with owner C, creates a fresh chain of color $i+1$ consisting of P (the first chain with color $i+1$), and moves the robot back to s. The initial chain C_0 becomes the current chain and s becomes the current node.

This leads to the algorithm given in Figure 7. We use x to denote the current node, C to denote the current chain, k the number of tokens used, and j the highest index of a chain. Lines 4–17 of the code correspond to item 3 above. Lines 6 and 7 correspond to Case 1, lines 8–13 correspond to Cases 2 and 3, and lines 14–16 correspond to Case 4. Lines 18 and 19 implement items 1 and 2, respectively. In line 13, C' is the chain that was the previous owner of τ_i and becomes the new current chain.

Additionally, the algorithm maintains a tree T, such that each chain C corresponds to a node $v(C)$ of T and $v(C')$ is a child of $v(C)$ if the last subpath appended to C' was explored while C was the current chain. Conversely, we use $C(v)$ to denote the chain represented by node v. For each chain there is exactly one node in the tree. Note that the tree changes dynamically. If in line 10 of the algorithm a path P is appended at a chain D, then the node representing the resulting chain becomes a child of $v(C)$, i.e., a child of the node representing the current chain C. The node $v(D)$ is removed. Since only fresh chains are reassigned, each added or removed node

 4.          while $\exists$ new outgoing edge at $x$ do
 5.              Traverse new edges starting at $x$ until stuck at a node $y$.
                 Call this path $P$.
 6.              if $y = x$ then
 7.                  Insert $P$ into $C$;
 8.              else if $y$ has a token $\tau_i$ then
 9.                      if $\exists$ chain $D$ of color $i$ starting in $y$ and $D$ is fresh then
10.                          Concatenate $P$ with $D$;
11.                      else
12.                          $j := j + 1$; $C_j :=$ chain that consists of $P$;
13.                      $C' := owner(\tau_i)$; Place $\tau_i$ on $x$; $owner(\tau_i) := C$; $x := y$;
                         $C := C'$;
14.                  else ($*$ $y \neq x$ and $y$ has no token $*$)
15.                      $j := j + 1$; $C_j :=$ chain that consists of $P$;
16.                      $k := k + 1$; Place token $\tau_k$ on $x$; $owner(\tau_k) := C$; $x := s$;
                         $C := C_0$;
17.                      Move robot to $x$;
18.          Move robot to first unfinished node $z$ that appears on $C$ after its
             startnode;  $x := z$;
19.      $C := Relocate(C)$;  $x :=$ startnode of $C$;
20.  until $C =$ empty_chain.
```

FIG. 7. *The Balance algorithm.*

is a leaf. This process ensures that the structure of nodes is indeed a tree.

We use T_v to denote the subtree of T rooted at v and say C is *contained* in T_v if $v(C)$ lies in T_v. We also say a token τ or an edge e is *contained* in T_v if $owner(\tau)$, respectively, the chain of e is contained in T_v. If all chains in T_v are finished, we say that T_v is *finished*. To represent T, the algorithm assigns a *parent* to each chain.

To relocate, the robot needs to be able to move on explored edges from the endpoint of a chain C to its startnode. This is always possible, since at the beginning of each subphase the explored edges form a strongly connected graph. To avoid an edge being traversed often for this purpose, we define for each chain C a path $closure(C)$ connecting the endnode of C with the startnode of C such that an edge belongs to $closure(C)$ for at most $d^{O(\log d)}$ chains C. Finally, we will show that $closure(C)$ is traversed at most $O(d^2)$ times.

A path Q is called a *C-completion* if it connects the endnode of a chain C with the startnode of C. A path Q in the graph is called *i-uniform* if it is a concatenation of chains of color i. Let u be a node of T. A path Q in the graph is *T_u-homogeneous* if any maximal subpath R of Q that does not belong to T_u is (a) i-uniform for some color i; (b) the edge of Q preceding R is the last edge of a chain of color i; and (c) the edge of Q after R is the first edge of a chain of color i. Intuitively, if a maximal subpath R of Q that does not belong to T_u is preceded by an edge of color i, then R is just the path of color i that leads to the previous chain of color i in T_u. In Figure 8 solid, dashed, and dotted lines denote different colors. In the corresponding tree,

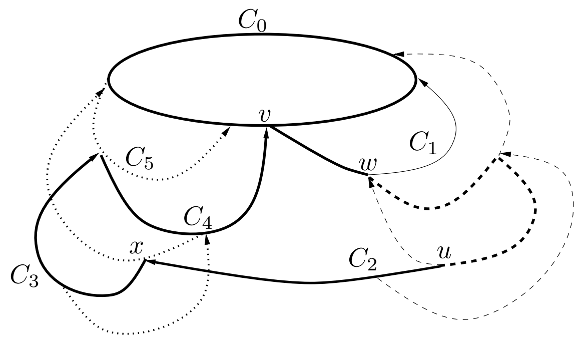

FIG. 8. *The path from x to u via v and w is $T_{v(C_1)}$-homogenous.*

the root $v(C_0)$ has two children, namely $v(C_1)$ and $v(C_5)$. Consider the path Q that starts at x, follows the solid chains to v and w, and then follows the dashed edges to u. (Path Q is shown in bold.) Path Q is a C_2-completion. It is also $T_{v(C_1)}$-homogenous because the two chains C_3 and C_4 not belonging to $T_{v(C_1)}$ have the same color as C_1 and C_2.

We try to choose *closure*(C) to be "as local to C" as possible: Let $S(C)$ be the set of explored edges when C becomes the current chain for the first time. Given $S(C)$, $a(C)$ is the lowest ancestor of $v(C)$ in T such that a $T_{a(C)}$-homogeneous completion of C exists in $S(C)$. Note that $a(C)$ is well defined since each chain has a $T_{v(C_0)}$-homogeneous completion. The path *closure*(C) is an arbitrary $T_{a(C)}$-homogeneous completion of C using only edges of $S(C)$. The algorithm can compute *closure*(C) whenever C becomes the current chain for the first time without moving the robot.

We describe the *Relocation* procedure; see Figure 9. In the relocation step, the robot repeatedly moves from the current chain to its parent until it reaches a chain C such that $T_{v(C)}$ is unfinished. To move from a chain X to its parent X', the robot proceeds along X to the endnode of X and traverses *closure*(X) to the startnode of X, which belongs to X'. When reaching C, the robot repeatedly moves from the startnode of the current chain X to the startnode of one of its children until it reaches the startnode of an unfinished chain. It chooses the child X' of X such that among all subtrees rooted at children of X and containing unfinished chains, $T_{v(X')}$ has the minimum number of tokens.

3.2. The analysis of the algorithm.

3.2.1. Correctness. Since the graph is strongly connected, all nodes of the graph must be visited during the execution of the algorithm. When the algorithm terminates, all visited nodes are finished. Thus, all edges must be explored. We show next that each operation and each move of the robot are well defined. Proposition 1 shows that if a chain of color i is fresh, then τ_i lies at the startnode of the chain. Thus, in line 10, token τ_i lies on y. By assumption, there exists a path from any finished node to s. Thus, the move in line 17 is well defined. In line 18, the robot moves to the next unfinished node of the current chain C. It would be possible to walk along *closure(C)*, but Propositon 1, part 4, shows later that *closure(C)* is not needed.

3.2.2. Fundamental properties of the algorithm.

LEMMA 1. *At most d tokens are introduced during the execution of the Balance algorithm.*

```
Procedure Relocate(C)
 1.  if all chains are finished then return(empty_chain).
 2.  else Move robot to the startnode of $C$ along $closure(C)$;
 3.      while $C \neq C_0$ and $T_{v(C)}$ is finished do
 4.          Move robot to the startnode of $parent(C)$ along $closure(parent(C))$;
 5.          $C := parent(C)$;
 6.      while $C$ is finished do
 7.          Let $C_1, C_2, \ldots, C_l$ be the chains with $parent(C_k) = C$, $1 \leq k \leq l$.
             Let $C_k$ be the chain such that $T_{v(C_k)}$ contains the smallest number
             of tokens among all $T_{v(C_1)}, \ldots, T_{v(C_l)}$ having unfinished chains;
 8.          $C := C_k$; $x :=$ startnode of $C$;
 9.          Move robot to $x$;
10.      if $C$ is not in progress then
11.          Compute $closure(C)$;
12.      return($C$)
```

FIG. 9. *The Relocation procedure.*

Proof. We say that the algorithm first introduces the token τ_k at y in line 16.

Let $in_v(v)$ and $out_v(v)$ denote the number of visited incoming and visited outgoing edges of v, respectively. Let $t(v)$ be the total number of tokens introduced on node v in line 16. We show inductively that $\max\{in_v(v) - out_v(v), 0\} = t(v)$. Since at termination $in_v(v) = in(v)$ and $out_v(v) = out(v)$, it follows that $-bal(v) \geq t(v)$ if $bal(v) < 0$ and $t(v) = 0$, otherwise. Thus, $d = -\sum_{v,with\ bal(v)<0} bal(v) \geq \sum_v t(v)$.

The claim $\max\{in_v(v) - out_v(v), 0\} = t(v)$ holds initially. Let P be the newly explored path when the first token is introduced on v, i.e., when the algorithm for the first time gets stuck at v and there is no token at v. Before P enters v, $in_v(v) = out_v(v)$. Traversing P increments $in_v(v)$ by 1 and sets $in_v(v) - out_v(v) = 1$. Thus, the claim holds. Let P be the newly explored path when the ith new token is introduced on v. It follows inductively that $in_v(v) - out_v(v) = i - 1$ before P enters v and traversing P increments the value by 1 as before. ∎

We prove next some invariants.

PROPOSITION 1.

1. *For every chain C that is in progress or that was in progress and is finished, parent(C) is finished.*
2. *Let C be a chain of color i, $1 \leq i \leq d$. (a) If C is fresh, C does not own a token, τ_i is located at the startnode of C, and parent(C) = owner(τ_i). (b) If C is in progress and not the current chain, then C is the owner of some token τ.*
3. *Every chain C is the parent of at most d chains.*
4. *If the Balance algorithm gets stuck at a node y of a chain C and y holds a token with C being the owner, then the startnode of C and all nodes of C lying between the startnode and y are finished.*

Proof (*Part* 1). Procedure *Relocate* ensures that *parent(C)* is finished before C is taken into progress.

Part 2a. When C is first created in line 12 or 15 of *Balance*, τ_i is placed on the startnode of C. Whenever the robot gets stuck at the current startnode of C and removes τ_i, chain C is extended by a path P because C is not in progress. Token τ_i is placed on the new startnode of C. Lines 13 and 16 ensure that the parent of C is always the owner of τ_i.

Part 2b. We show that whenever C is the current chain and *Balance* leaves C to continue work on another chain, C becomes the owner of a token. This suffices to prove part 2b because the children of a chain, and thus the corresponding tokens, can only be taken over by the current chain; see lines 13 and 16 of the algorithm.

Chain C is unfinished. Thus, if C is the current chain, *Balance* can only leave C to continue work on another chain during lines 5–17 of the algorithm. In this situation, *Balance* places a token on a node of C and C becomes the owner of that token.

Part 3. Chain C can become the parent of other chains while C is in progress and unfinished. During this time, every chain C' with $\mathit{parent}(C') = C$ is not in progress, see Part 1. By Part 2a, the startnode of such a chain C' holds a token and C is the owner of that token. Since there are only d tokens, the proposition follows.

Part 4. Since y holds a token, with C being the owner, y must have been the current node in a subphase when C was current chain. The node selection rule in line 18 of *Balance* ensures that the startnode of C and every node on C between the startnode and y are finished since, otherwise, the robot would have moved to an unfinished node z before y. ∎

The next lemma shows that our algorithm always balances the number of tokens contained in neighboring subtrees of T. For a subtree T_v of T, let the *weight* $w(T_v)$ be the number of tokens contained in T_v. Let $\mathit{active}(T_v) = 1$ if the current chain is in T_v; otherwise let $\mathit{active}(T_v) = 0$.

LEMMA 2. *Let $u, v \in T$ be siblings in T such that T_u and T_v contain unfinished chains. Then $|w(T_u) + \mathit{active}(T_u) - w(T_v) - \mathit{active}(T_v)| \leq 1$.*

Proof. Let $\mathit{active}(C) = 1$ iff C is the current chain, and let $\mathit{active}(C) = 0$ otherwise. Let $\mathit{token}(C)$ be the number of tokens owned by C and let $g(C) = \mathit{token}(C) + \mathit{active}(C)$. Finally, let $g(v) = \sum_{C, v(C) \in T_v} g(C) = w(T_v) + \mathit{active}(T_v)$. We show by induction on the steps of the algorithm that $|g(u) - g(v)| \leq 1$.

The claim holds initially. For a subtree T_v of T, the values $w(T_v)$ and $\mathit{active}(T_v)$ only change in lines 13, 16, and 19 of *Balance* and in lines 4 and 9 of procedure *Relocate*. Additionally, T changes in lines 10, 12, and 15.

Note first that changes in T do not affect the invariant: Whenever T changes, $v(C)$ receives a new child and C is not yet finished (or the algorithm has not yet determined that C is finished). Thus, the children of C are not yet in progress, i.e., they do not own any tokens by Proposition 1. Thus, the claim holds for any pair of children of $v(C)$.

We consider next all changes to $w(T_v)$ and $\mathit{active}(T_v)$.

Line 13: Let C be the current chain before the execution of line 13. Note that $\mathit{token}(C)$ increases by 1, $\mathit{active}(C)$ becomes 0, $\mathit{token}(C')$ decreases by 1, and $\mathit{active}(C')$ becomes 1. Thus, $g(C)$ and $g(C')$, and, hence, $g(v)$ is unchanged for every node $v \in T$.

Line 16: Note that (i) $g(C)$ is unchanged by the same argument as for line 13; (ii) $g(C')$ is unchanged, since $\mathit{token}(C')$ and $\mathit{active}(C')$ are unchanged; and (iii) $g(C_0)$ is increased by 1. Since C_0 only contributes to $g(v(C_0))$ and $v(C_0)$ is the root of T, the claim holds.

Line 19 *of Balance/line* 4 *and* 9 *of Relocate:* Let $\bar{C}$ be the current chain before the execution of line 3 or 7 and let C be the current chain afterwards. In line 3, the claim does not apply to $T_{v(C)}$, since $T_{v(C)}$ is finished. Thus, we are left with line 7. Note that $active(\bar{C})$ drops to 0 and $active(C)$ increases to 1. Thus, for every node v such that T_v contains either both the parent and its child or neither the parent nor its child, $g(v)$ is unchanged. The only remaining subtree is $T_{v(C)}$. Before the execution of line 7, for any sibling C' of C, $w(T_{v(C)}) \le w(T_{v(C')}) \le w(T_{v(C)}) + 1$. Since $active(C') = 0$, $|w(T_{v(C)}) - w(T_{v(C')}) + active(C) - active(C')| \le 1$. ☐

LEMMA 3. *Let C be a chain of color i, $1 \le i \le d$, and, at the time when C is taken in progress, let $u \in T$ be the closest ancestor of $v(C)$ that satisfies the following condition. The path from u to $v(C)$ in T contains d nodes $u_1, u_2, \ldots, u_d$ such that each u_j with $1 \le j \le d$ has a child v_j,* (a) *T_{v_j} contains a node of color i; and* (b) *$v(C) \notin T_{v_j}$. If there is no such ancestor u, then let u be $v(C_0)$. Then there exists a T_u-homogeneous C-completion.*

Proof. By assumption, the graph of explored edges is strongly connected, which implies that there exists a $T_{v(C_0)}$-homogeneous C-completion. Suppose that there are d nodes $u_1, \ldots, u_d$ satisfying (a) and (b). For $j = 1, \ldots, d$, let C_{u_j} be the chain corresponding to u_j. If one of the nodes $u_1, \ldots, u_d$, say u_k, is of color i, then there is the following T_{u_k}-homogeneous C-completion: Follow edges of color i until you reach the startnode of C_{u_k}, then walk "down" in T_{u_k} along ancestors of C to the startnode of C.

Thus, we are left with the case that none of the nodes $u_1, \ldots, u_d$ has color i. For $j = 1, \ldots, d$, let $C_{j,1} \in T_{v_j}$ be a chain of color i such that no ancestor of $C_{j,1}$ contained in T_{v_j} has color i. Let $C_{j,2}, \ldots, C_{j,l(j)}$ be the ancestors of $C_{j,1}$ in T_{u_j}. More precisely, for $k = 1, \ldots, l(j) - 1$, $C_{j,k+1} = parent(C_{j,k})$ and $C_{j,l(j)} = C_{u_j}$ is the chain corresponding to u_j.

Following the edges of color i gives a T_u-homogeneous path from C to every chain $C_{j,1}$ for $1 \le j \le d$. We want to show that there exists a T_u-homogenous path to a chain $C_{j,l(j)}$. We consider the following game on a $d \times \max_j l(j)$ grid, where for $1 \le j \le d$, square (j,k) has the color of $C_{j,k}$ for $1 \le k \le l(j)$ and no color for $k > l(j)$. Thus, all squares $(j,1)$ have color i and no other squares have color i. Initially all squares $(j,1)$ are checked; all other squares are unchecked. A square is checked if the robot can move to the startnode of the corresponding chain on a T_u-homogeneous path. The rules of the game are as follows (note that the startnode of $C_{j',k'-1}$ belongs to $C_{j',k'}$):

- *A square (j,k) of color i' gets checked whenever there exists a square (j',k') of color i' such that square $(j',k'-1)$ is checked and there exists a path of color-i' edges from the endnode of $C_{j',k'}$ to the startnode of $C_{j,k}$.*
- *The game terminates when one of the squares $(j,l(j))$ is checked or when no more squares can be checked.*

We will show that one of the squares $(j,l(j))$ can be checked. This shows that there is a T_u-homogeneous path from C to $C_{j,l(j)}$. Since u_j is an ancestor of $v(C)$, the same argument as above shows that there exists a T_u-homogeneous C-completion.

We employ the pigeonhole principle: Initially, there are d checked squares $(j,1)$ for $1 \le j \le d$ and each square $(j,2)$ has a color $i' \ne i$. Since there are at most $d-1$ other colors, there must be two squares $(s,2)$ and $(t,2)$ with the same color i'. Since the edges of color i' form a chain, there is either a path from $C_{s,2}$ to $C_{t,2}$ or vice versa. Thus, one of the two squares can be checked. Inductively, there are d checked squares $(j,k(j))$ such that $(j,k(j)+1)$ is unchecked. None of the squares $(j,k(j)+1)$ has color i and thus, there must be two squares $(j,k(j)+1)$ with the same color, which leads to checking one of the two squares. The game continues until one of the squares

$(j, l(j))$ has been checked. □

3.2.3. Counting the number of edge traversals.

LEMMA 4. *Each edge is traversed at most d times during executions of line* 17 *and at most $d+1$ times during executions of line* 18 *of the Balance algorithm.*

Proof. Let e be an arbitrary edge and let C be the chain e belongs to. Every time e is traversed during an execution of line 17, a new token is placed on the graph. Since a total of d tokens are placed, the first statement of the lemma follows.

Next we analyze executions of line 18. Let x and y be the tail and the head of e, i.e., $e = (x, y)$. Let C^1 be the portion of C that consists of the path from the startnode of C to x. Similarly, let C^2 be the path from y to the endnode of C.

By Proposition 1, part 4, e is traversed in line 18 when all nodes on C^1 are finished and the robot moves to the next unfinished node on C^2. Thus, e is traversed (a) if the robot gets stuck at a node on C^1 and moves to the next unfinished node of C, or (b) if the robot traverses C from its startnode, since procedure *Relocate* returned chain C. Every time case (a) occurs, a token is removed from C^1, and this token cannot be placed again on C^1. Whenever the robot interrupts the work on C^2, another token is placed on some node of C^2. Every time case (b) occurs, $\mathit{token}(C) + \mathit{active}(C)$ increases by 1, while no other step of the algorithm can decrease this value as long as C is unfinished. Note that a token is placed on a node of C^2. Since there are only d tokens, cases (a) and (b) occur a total of at most $d+1$ times. □

Thus, it only remains to bound how often an edge is traversed in *Relocate*. A chain C' is *dependent* on a chain C, $C \neq C'$, if $C' \in T_{v(C)}$ and $\mathit{closure}(C')$ is not T_u-homogeneous for any true descendant u of $v(C)$.

LEMMA 5. *For every chain C, there exist at most $d^{2\log d+1}$ chains $C' \in T_{v(C)}$ that are dependent on C.*

Proof. Let $n_i(C)$ be the total number of chains of color i dependent on C. For a color i, $1 \le i \le d$, and an integer δ, $1 \le \delta \le d$, let

$$N_i(\delta) = \max_C \{n_i(C); T_{v(C)} \text{ contains at most } \delta \text{ of the d tokens whenever } \mathit{active}\ (T_{v(C)}) = 1\}.$$

We will show that for any δ, $1 \le \delta \le d$, and any color i, (a) $N_i(\delta) \le d^2 N_i(\lfloor \delta/2 \rfloor)$ and (b) $N_i(1) = 1$. This implies $N_i(d) \le d^{2\log d}$. Since $\sum_{i=1}^{d} N_i(d) \le d \cdot d^{2\log d}$, the lemma follows.

To prove (1), fix a color i and an integer δ. Consider a subtree $T_{v(C)}$ that contains at most δ tokens when $\mathit{active}(T_{v(C)}) = 1$. Out of all chains of color i dependent on C, let C' be the chain whose closure is computed last. We show that when the algorithm computes $\mathit{closure}(C')$, then the number of chains of color i that are already dependent on C is at most $d(d-1)N_i(\lfloor \delta/2 \rfloor)$. Thus, $n_i(C) \le d(d-1)N_i(\lfloor \delta/2 \rfloor) + 1 \le d^2 N_i(\lfloor \delta/2 \rfloor)$.

Let $u_1, u_2, \ldots, u_l$ be the sequence of nodes (from lowest to highest) on the path from $v(C')$ to $v(C)$ such that every node u_j, $j = 1, 2, \ldots, l$, has a child v_j with (a) T_{v_j} containing a node of color i, and (b) $v(C') \notin T_{v_j}$. By Lemma 3, $l \le d$. Suppose that node u_j, $1 \le j \le l$, has $c(j)$ children, $v_{j,1}, v_{j,2}, \ldots, v_{j,c(j)}$ with $v \in T_{v_{j,1}}$. By condition (b), $2 \le c(j) \le d$.

For fixed j and $k \ge 2$, we have to show that up to the time when $\mathit{closure}(C')$ is computed, whenever $\mathit{active}(T_{v_{j,k}}) = 1$, then $w(T_{v_{j,k}}) \le \lfloor \delta/2 \rfloor$. Consider the point in time when $\mathit{closure}(C')$ is computed. Since $T_{v_{j,1}}$ contains C', $T_{v_{j,1}}$ is unfinished. By Lemma 2, *Balance* distributes the tokens contained in T_{u_j} evenly among the subtrees $T_{v_{j,1}}, T_{v_{j,2}}, \ldots, T_{v_{j,c(j)}}$ that contain unfinished chains. Thus, for each *unfinished* $T_{v_{j,k}}$

with $k \geq 2$, $w(T_{v_{j,k}})$ was up to now at most $\lfloor \delta/2 \rfloor$ whenever *active*$(T_{v_{j,k}}) = 1$. For each *finished* $T_{v_{j,k}}$, consider the last point of time when an unfinished chain of $T_{v_{j,k}}$ becomes the current chain. Since $v_{j,1}$ exists, $T_{v_{j,1}}$ is unfinished and, by Lemma 2, $w(T_{v_{j,k}})$ is up to this point in time at most $\lfloor \delta/2 \rfloor$ whenever *active*$(T_{v_{j,k}}) = 1$. We conclude that up to the time when *closure*(C') is computed, $T_{v_{j,k}}$ contains at most $N_i(\lfloor \delta/2 \rfloor)$ chains of color i that can be dependent on the chain corresponding to $v_{j,k}$, and, thus, can be dependent on C. Summing up, we obtain that $T_{v(C)}$ contains at most

$$\sum_{j=1}^{d} \sum_{k=2}^{c(j)} N_i(\lfloor \delta/2 \rfloor) \leq d(d-1)N_i(\lfloor \delta/2 \rfloor)$$

chains of color i that can be dependent on C.

Finally we show that $N_i(1) = 1$. If a subtree $T_{v(C)}$ contains at most one token whenever *active*$(T_{v(C)}) = 1$, then each node in $T_{v(C)}$ has only one child, by Proposition 1. Since $T_{v(C)}$ never branches, it can contain at most one chain of color i that is dependent on C. ∎

Lemma 6. *For every chain C, there exist at most $d^{2\log d+1}$ chains $C' \in T_{v(C)}$ such that closure(C') uses edges of C.*

Proof. Let C be an arbitrary chain and let $v \in T$ be the node corresponding to C. We show that if a chain $C' \in T_{v(C)}$ is not dependent on C, then *closure*(C') does not use edges of C. Lemma 6 follows immediately from Lemma 5.

If a chain $C' \in T_{v(C)}$ is not dependent on C, then the path *closure*(C') is T_u-homogeneous for a descendant u of v. Suppose that a T_u-homogeneous path P would use edges of C. Let i be the color of C. Chain C does not belong to T_u. Thus, after P has visited C, it may only traverse chains of color i until it reaches again a chain of color i that belongs to T_u. Note that all chains of color i that are reachable from C via edges of color i must have been generated earlier than C. However, all chains in T_u were generated later than C. We conclude that a T_u-homogeneous path cannot use edges of C. ∎

Lemma 7. *For every chain C, there exist at most $(d+2)d^{2\log d+2}$ chains $C' \notin T_{v(C)}$ such that closure(C') uses edges of C.*

Proof. A chain C' *needs* a chain C if *closure*(C') uses edges of C and C' is *u-hard* if *closure*(C') is T_u-homogeneous, but not T_v-homogeneous for any child v of u. For each chain C' there exists a unique node u of T such that C' is u-hard. If C' is dependent on chain C, then C' is $v(C)$-hard of u-hard for a true ancestor u of $v(C)$. If C' is u-hard and v is a descendant of u and an ancestor of $v(C')$, then C' is dependent on $C(v)$. To prove the lemma, it suffices to show the following two claims.

Claim 1. *There are at most $d^{2\log d+2}$ chains $C' \notin T_{v(C)}$ such that C' needs C and C' is u-hard for some ancestor u of $v(C)$.*

Claim 2. *There are at most $(d+1)d^{2\log d+2}$ chains $C' \notin T_{v(C)}$ such that C' needs C and C' is u-hard for some node u that is not an ancestor of $v(C)$.*

Proof of Claim 1. If C' needs C, then C' either does not yet exist or is unfinished when C is taken into progress. Consider the point in time when C is taken into progress. Let $u_1, u_2, \ldots, u_l$ be the ancestors of $v(C)$ in T that fulfill the following conditions: Each node u_j has a child v_j such that (a) T_{v_j} contains unfinished chains, and (b) $v(C) \notin T_{v_j}$. Thus, every chain that needs C lies in one of the subtrees T_{v_j}. Note that $l \leq d$, since by Proposition 1, every subtree that contains an unfinished chain not equal to the current chain must own a token. Assume C' belongs to T_{v_j}. Since u_j is the least common ancestor of $v(C)$ and $v(C')$, and C' is u-hard for an ancestor

u of $v(C)$, C' is dependent on $C(u_j)$. Since by Lemma 5 there are at most $d^{2\log d+1}$ chains that are dependent on $C(u_j)$, there can be at most $l \cdot d^{2\log d+1} \leq d^{2\log d+2}$ chains $C' \notin T_{v(C)}$ that need C and are u-hard for an ancestor of $v(C)$. ☐

Proof of Claim 2. Let i be the color of C. Let us denote the concatenation of all chains of color i as the *path of color i*. Note that the path of color i introduces a linear order on the chains of color i. We say a chain C *lies between* two other chains on the path of color i if C is not equal to one of the chains and lies between them in the linear order. We define first the nearest predecessor of a chain. Then we show (1) that for each chain $C' \notin T_{v(C)}$ that needs C and is u-hard for some node u that is not an ancestor of $v(C)$, there exists a chain C_1 of color i such that

- C lies on the path of color i between C_1 and its nearest predecessor, and
- C_1 fulfills the conditions of Claim 1, i.e., C' needs C_1 and u is an ancestor of $v(C_1)$.

We show next (2) that there exist at most d chains C_1 of color i for which C lies on the path of color i between C_1 and its nearest predecessor. By Claim 1 and Lemma 6, for each C_1 there exist at most $(d+1)d^{2\log d+1}$ closures that are hard for an ancestor of $v(C_1)$. It follows that there are at most $d(d+1) \cdot d^{2\log d+1}$ chains C' that need C and are u-hard for some node u that is not an ancestor of $v(C)$.

Consider the point in time when C is taken into progress. Let $a(C)$ be the closest ancestor of $v(C)$ such that $T_{a(C)}$ contains a node of color i that is not equal to $v(C)$. The *nearest predecessor* of C is the chain $C' \neq C$ of color i that was taken into progress most recently in $T_{a(C)}$.

(1) The closure of C' introduces an order on the chains belonging to it. Let C_1 be the last chain of T_u before C on *closure*(C') and let C_2 be the first chain of T_u after C on *closure*(C'), i.e., C lies on the path of color i edges between C_1 and C_2. We show below that the path of color i edges between C_1 and C_2 is contained in the path of color i edges between C_1 and its nearest predecessor. This implies that C lies on the path of color i edges between C_1 and its nearest predecessor and completes the proof of (1).

Since T_u is a subtree that contains C_1 and C_2, i.e., C_1 and another chain of color i that was taken into progress before C_1, T_u also must contain the nearest predecessor of C_1. Following the path of color i edges from C_1, C_2 is the first chain of T_u that is encountered. Thus, the color i path between C_1 and C_2 is contained in the color i path between C_1 and its nearest predecessor.

(2) We want to bound the number of color i chains C_1 such that C lies on the path of color i between C_1 and its nearest predecessor. Obviously, C_1 was created after C was taken in progress (otherwise, C_1 would have been appended to C). Consider the point in time when C is taken into progress. Let $\overline{C}_1, \ldots, \overline{C}_l$ be the chains that are parents of fresh chains. All chains created afterwards must belong to $T_{v(C)}$ or to $T_{v(\overline{C}_1)}, \ldots, T_{v(\overline{C}_l)}$. Note (a) that for no color i chain in $T_{v(C)}$, C can lie on the color i path between the chain and its nearest predecessor. Note (b) that for $k = 1, \ldots, l$, only for the color i chain $C^{(k)}$ in $T_{v(\overline{C}_k)}$ created first after C was taken into progress, C can lie between $C^{(k)}$ and its nearest predecessor. The nearest predecessor of every color i chain D created later belongs to $T_{v(\overline{C}_k)}$ and was created after C. Thus, C does not lie on the color i path between D and its predecessor. Thus, at most l chains exist such that C lies on the color i path between the chain and its predecessor. By Proposition 1, $l \leq d$. ☐

THEOREM 3. *Using the Balance algorithm and assuming that when a new sink is discovered the subgraph of explored edges is strongly connected, the robot explores* *an unknown graph with deficiency d and traverses each edge at most $(d+1)^5 d^{2\log d}$ times.*

Proof. Let e be an arbitrary edge of chain C. Edge e is traversed for the first time when it is explored during an execution of line 5 of the *Balance* algorithm. By Lemma 4, it can be traversed $2d+1$ times during executions of lines 17 and 18. By Lemmas 6 and 7, e belongs to at most $d^{2\log d+1} + (d+2)d^{2\log d+2}$ paths *closure*(C'). We show that each path *closure*(C') is traversed at most $d(d+1)$ times. The path *closure*(C') is used at most d times during an execution of line 2 of *Relocate* because each time a token is removed from the finished chain C'. The path *closure*(C') can also be used at most d^2 times in line 4 of *Relocate* because each time a token is removed from the finished subtree $T_{v(C'')}$ of a child C'' of C'.

Finally, the edge e might be traversed $d(d+1)$ times in line 9 of *Relocate*. When e is traversed in line 9, then (i) either the robot had moved to C_0 after the introduction of a new token (line 16) or (ii) there exists an ancestor u of $v(C)$ with a child x such that the robot was stuck at a node in T_x and T_x is finished. Thus, by going "up" the tree T in lines 3–5, the robot reached u. Case (i) occurs at most d times. When C becomes the current chain for the first time, let $u_1, \ldots, u_l$ be the ancestors of $v(C)$ such that each u_j has a child v_j with (a) T_{v_j} containing unfinished chains, and (b) $v \notin T_{v_j}$. By Proposition 1, the nodes $u_1, \ldots, u_l$ can have a total of d children satisfying (a) and (b). Since each subtree rooted at one of these children can contain at most d tokens, case (ii) occurs at most d^2 times.

Thus, edge e is traversed at most

$$(1)\quad 1 + 2d + 1 + d(d+1)(d^{2\log d+1} + (d+2)d^{2\log d+2}) + d(d+1) \le (d+1)^5 d^{2\log d}$$

times. □

3.3. The *Complete* algorithm. In subsections 3.1 and 3.2 we assumed that the subgraph of *explored* edges is strongly connected. We used this assumption only in line 16 of algorithm *Balance*. However, all that is needed in line 16 is that the algorithm "knows" a path from y to s, i.e., the robot can reach s from y. To achieve this we define a parametrized algorithm *P-Balance*$(\mathcal{P},\ s,\ C_0)$ as follows: in addition to s and C_0, it receives as input a set $\mathcal{P}$ of paths between various nodes in the graph. It executes algorithm *Balance* as before except when the robot gets stuck at y in line 16 and there is no path of explored edges from y to s. If there exists a path X from y to s consisting of (i) a (possibly empty) subpath of explored edges, followed by (ii) a path in $\mathcal{P}$, followed by (iii) another (possibly empty) subpath of explored edges, then a *fake* edge from y to s is added to the graph and traversed to reach s. Since the fake edge does not exist in the orginial graph the robot "simulates" traversing the fake edge by traversing X. The fake edge continues to exist (and might be traversed) in the graph until the end of algorithm *P-Balance*. We show below that at most $d-1$ fake edges are added during algorithm *P-Balance*.

We execute algorithm *P-Balance* repeatedly to construct an algorithm *Complete* that assumes only that the original graph is strongly connected and makes *no* assumption about the subgraph of explored edges. We call the edges traversed during execution $i \le k$ of algorithm *P-Balance*$(\mathcal{P},\ s,\ C_0)$ *k-visited.*

We describe algorithm *Complete* in detail: initially $\mathcal{P}$ is empty and Phase 1 (see subsection 3.1) is executed to determine s and C_0. Algorithm *Complete* then repeatedly executes algorithm *P-Balance*$(\mathcal{P},\ s,\ C_0)$ on the graph until *P-Balance* terminates or until while traversing path P the robot gets stuck at a node y in line 16 and cannot reach s. In the former case algorithm *Complete* terminates, in the latter case it adds to $\mathcal{P}$ a path of k-visited edges to y from each node in the subgraph traversed during the current or an earlier execution of algorithm *P-Balance*. Next all fake edges are discarded, all edges are marked as unvisited and unexplored, and all nodes are marked as unexplored and unfinished. Then s is set to y, the cycle C_0 is set to be the path between the first and the last occurrence of y on P, and algorithm *P-Balance*($\mathcal{P}$, s, C_0) is called.

Consider execution k of algorithm *P-Balance*. A *k-path* is a concatenation of three paths A_1, A_2, and A_3 such that A_1 and A_3 are possibly empty subpaths of edges explored during execution k and A_2 is a path of $\mathcal{P}$. Note that the concatenation of a k-path with edges explored during execution k (either at the beginning or at the end of the k-path) results again in a k-path. Note further that each k-path consists of k-visited edges.

Lemma 8 shows that if *P-Balance* gets stuck at a node y in line 16 and cannot reach s, then there exists a path of k-visited edges to y from each node in the subgraph traversed during the current or an earlier execution of algorithm *P-Balance* and that y appears at least twice on P. This proves that algorithm *Complete* is well defined.

LEMMA 8. *If while traversing path P during an execution of P-Balance($\mathcal{P}$, s, C_0) the robot gets stuck in line* 16 *at a node y and cannot reach s then*

1. *each node in the subgraph traversed during an earlier execution of algorithm P-Balance($\mathcal{P}$, s, C_0) can reach y on a path of k-visited edges;*
2. *each node in the subgraph traversed during the current execution of algorithm P-Balance($\mathcal{P}$, s, C_0) can reach y on a k-path;*
3. *y is a newly discovered sink;*
4. *y appears at least twice on P.*

Proof. Parts 1, 2, and 3: We use induction on the number k of calls to algorithm *P-Balance* to show the claim. Obviously the claim holds for $k = 0$. Consider next $k > 0$. Let s_k be the sink newly discovered by execution k of algorithm *P-Balance*. We show first that each node in the subgraph traversed during an earlier execution of algorithm *P-Balance* can reach y on a path of k-visited edges. There exists a path of k-visited edges from s_{k-1} to y, since execution k started at s_{k-1}. Inductively each node in the subgraph traversed during an earlier execution can reach s_{k-1} on a path of $(k-1)$-visited edges. Thus, by transitivity of the reachability relation and since all $(k-1)$-visited edges are also k-visited, each node in the subgraph traversed during an earlier execution of algorithm *P-Balance* can reach y on a path of k-visited edges.

We show next that each node in the subgraph traversed during the current execution of algorithm *P-Balance*($\mathcal{P}$, s, C_0) can reach y on a k-path. Since y is the last node on chain P every node on P can reach y following P. Each other node in the subgraph explored during algorithm *P-Balance*($\mathcal{P}$, s, C_0) belongs to a chain $Q \neq P$. We show by induction on the number of such chains Q created during the current execution that all nodes on such a chain Q can reach s by a k-path. Since execution k started at s, s can reach y on edges explored during execution k. It follows that each node in the subgraph traversed during algorithm *P-Balance*($\mathcal{P}$, s, C_0) can reach y on a k-path.

It remains to be shown that all nodes on a chain $Q \neq P$ created during the current execution can reach s by a k-path. This holds trivially before any chain is created. Consider a path P' that is part of Q. Then the endpoint y' of P' either belongs to an already existing chain or not. If y' belongs to a chain created earlier, then inductively y' and, thus, all nodes on P' can reach s by a k-path. If y' does not belong to a chain created earlier, then there exists a path in $\mathcal{P}$ from y' to s since $P' \neq P$. Thus there is a k-path from y' to s. It follows that every node on P' can reach s by a k-path.

We are left with showing that $y = s_k$, i.e., that y is a newly discovered sink. By the above proof, (a) if y was visited by an earlier execution of algorithm *P-Balance*, then there would exist a path from y to s in $\mathcal{P}$, and (b) if y belonged to a chain $Q \neq P$ in the current execution of algorithm *P-Balance*, then there would exist a k-path from y to s. Thus, algorithm *P-Balance*($\mathcal{P}$, s, C_0) would have been able to reach s from y. It follows that y was not visited before, i.e., that y is a newly discovered sink.

Part 4. Each node has outdegree at least 1. By the proof of part 1, y does not belong to a chain $Q \neq P$. Thus all of y's outedges must belong to P, i.e., y appeared at least twice on P. $\square$

Since there are only d sinks in the graph, part 3 of the above lemma shows that at most d executions of *P-Balance*($\mathcal{P}$, s, C_0) are made. Thus it follows that algorithm *Complete* terminates.

Now let us analyze the number of edge traversals. Algorithm *P-Balance* traverses the same path that algorithm *Balance* would have traversed on the graph consisting of the original graph and all fake edges. Since each fake edge connects two sinks, it does not change the deficiency of the graph. Thus, the previous analysis shows that each edge, including each fake edge, is traversed at most $(d+1)^5 d^{2\log d}$ times. The traversal of a fake edge corresponds to at most one traversal of every nonfake edge. We show below that there are at most $d-1$ fake edges. Thus the total number of traversals per edge is at most $(d-1)(d+1)^5 d^{2\log d}$ for each execution of algorithm *P-Balance*. Since there are at most d such executions, each edge is traversed at most $(d-1)d(d+1)^5 d^{2\log d}$ times during algorithm *Complete*.

It remains to show that there are at most $d-1$ fake edges. Each fake edge in execution k increases the number $in_v(s_i)$ of visited incoming edges for a sink s_i with $i < k$ without increasing the number $out_v(s_i)$ of visited outgoing edges. Since over all sinks s_i, $i < k$, there are at most $d-1$ more incoming than outgoing edges into these sinks, there are at most $d-1$ fake edges created during execution k.

We summarize our main result in the following theorem.

THEOREM 4. *Using the Complete algorithm, the robot explores an unknown graph with deficiency d and traverses each edge at most $(d+1)^7 d^{2\log d}$ times.*

The total number of edge traversals used by our algorithm is also $O(\min\{mn, dn^2 + m\})$, where n is the number of nodes in the graph. It is not hard to show that an upper bound of $O(\min\{mn, dn^2+m\})$ is achieved by any exploration algorithm satisfying the following two properties: (1) When the robot gets stuck, it moves on a cycle-free path to some arbitrary node with new outgoing edges. (2) When the robot is not relocating, it always traverses new edges whenever possible.

We show that any exploration algorithm satisfying (1) and (2) gets stuck at most $\min\{m, dn\}$ times. The bound follows because, by property (1), at most n edges are traversed during each relocation. Obviously, a robot gets stuck at most m times. For the proof of the second bound, let $in_u(v)$ and $out_u(v)$ be the number of unvisited incoming and unvisited outgoing edges of v, respectively. Let $def(v) = \max\{0, in_u(v) - out_u(v)\}$. We show inductively that $\sum_{v\in G} def(v) \leq d$. This implies that, for every node v, whenever the robot explores the last unvisited edge out of v, there are at most d unvisited incoming edges at v. Thus the robot gets stuck at most d times at any node v. Summing over all nodes in G gives the desired bound of dn.

The inequality $\sum_{v\in G} def(v) \leq d$ holds intitially. The invariant is maintained whenever the robot relocates from a node y, where it got stuck, to some node z with

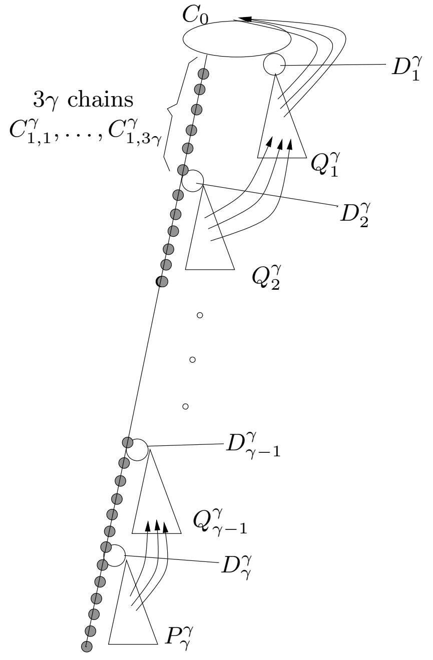

FIG. 10. *The graph G.*

new outgoing edges, because only visited edges are traversed. Whenever the robot starts a new exploration at a node z, visits a sequence of new edges, and gets stuck at a node x, *def*(z) increases by at most 1, $def(x)$ decreases by 1 while at no other node, and the *def*-value changes.

4. A tight lower bound for the *Balance* algorithm and modifications.

In this section we give first a lower bound for the *Balance* algorithm and we give afterwards lower bounds for modifications of *Balance*.

THEOREM 5. *For every $d \geq 1$, there exists a graph G of deficiency d that is explored by Balance using $d^{\Omega(\log d)} m$ edge traversals.*

Proof. We show that there exists a graph $G = (V, E)$ and an edge $e \in E$ that is traversed $d^{\Omega(\log n)}$ times while *Balance* explores G. The theorem follows by replacing e by a path of $\Theta(m)$ edges. We show the bound for d being a power of 5. The bound for all values of d follows by "rounding" down to the largest power of 5 smaller than d.

The graph is a union of chains C, each of which consists of three edges, a startnode, an endnode, and two *interior* nodes $v^1(C)$ and $v^2(C)$. The interior nodes belong to exactly one chain and have up to one additional outgoing edge. We describe G; see also Figure 10. Graph G contains (a) a cycle C_0 that starts and ends in a node v (*Balance* is started at v and finds C_0 during Phase 1) and (b) a recursively defined problem P^d attached to C_0.

In the following let δ, $1 \leq \delta \leq d$, be a power of 5. A *problem* P^δ, for any integer $\delta \geq 5$, is a subgraph that has two *incoming* edges whose startnodes do not belong to P^δ but whose endnodes do, and $\delta + 1$ *outgoing* edges whose startnodes belong to P^δ but whose endnodes do not. A problem P^1 has one incoming and one outgoing edge. In the case of P^d, the two incoming edges start at $v^1(C_0)$ and $v^2(C_0)$, respectively; d

outgoing edges point to v and one outgoing edge points to $v^1(C_0)$.

For the definition of P^δ we also need problems Q^δ. These problems are identical to P^δ except that, for $\delta > 1$, Q^δ has exactly $\delta + 1$ incoming edges.

A problem P^1 consists of a single chain; the first edge of the chain represents an incoming edge and the last edge represents an outgoing edge. The interior nodes have no additional outgoing edges. A problem Q^1 is identical to P^1.

For $\delta \geq 5$, let $\gamma = \delta/5$. Problem P^δ consists of $3\gamma^2$ chains $C^\gamma_{i,k}$, $1 \leq i \leq \gamma$, $1 \leq k \leq 3\gamma$, as well as γ chains D^γ_i and γ recursive subproblems Q^γ_i, $1 \leq i \leq \gamma - 1$, and P^γ_γ.

These components are assembled as follows. One of the incoming edges of P^δ is the first edge of $C^\gamma_{1,1}$. We assume that $v^1(C_0)$ is the startnode of $C^{d/5}_{1,1}$. Node $v^1(C^\gamma_{i,k})$ is the startnode of $C^\gamma_{i,k+1}$, $1 \leq i \leq \gamma$, $1 \leq k \leq 3\gamma - 1$. Node $v^1(C^\gamma_{i,3\gamma})$ is the startnode of $C^\gamma_{i+1,1}$, $1 \leq i \leq \gamma - 1$. The last edge of $C^\gamma_{1,k}$, $1 \leq k \leq 3\gamma$ is an outgoing edge of P^δ. The endnode of $C^\gamma_{i,k}$ is equal to the startnode of $C^\gamma_{i-1,k}$, $2 \leq i \leq \gamma$ and $1 \leq k \leq 3\gamma$. Note that the last edge of $C^\gamma_{2,1}$ is thus an outgoing edge of P^δ. Nodes $v^2(C^\gamma_{i,k})$, $1 \leq i \leq \gamma$, $1 \leq k \leq 3\gamma - 1$ have no additional outgoing edge but nodes $v^2(C^\gamma_{i,3\gamma})$, $1 \leq i \leq \gamma - 1$ do. Chain $C^\gamma_{\gamma,3\gamma}$ has no additional outgoing edges.

The second incoming edge of P^δ is the first edge of a chain D^γ_1 and, for $2 \leq i \leq \gamma$, the edge leaving $v^2(C^\gamma_{i-1,3\gamma})$ is the first edge of D^γ_i. For $1 \leq i \leq \gamma$ the last edge of D^γ_i is an outgoing edge of P^δ. If $\delta = 5$, then the first interior node of the chain $D^\gamma_i = D^\gamma_1$ has an additional outgoing edge pointing into a problem P^1. If $\delta > 5$, then the two interior nodes of D^γ_i, $1 \leq i \leq \gamma$ each have an additional outgoing edge. For $1 \leq i \leq \gamma - 1$, these two edges point into Q^γ_i and, for $i = \gamma$, they point into P^γ_γ.

If $\delta = 5$, then the outgoing edge of the only subproblem P^1 is an outgoing edge of $P^\delta = P^5$. If $\delta > 5$, the problems Q^γ_i, $1 \leq i \leq \gamma - 1$, and P^γ_γ each have $\gamma + 1$ outgoing edges. For Q^γ_1, γ of these edges are also outgoing edges of P^δ and one edge points to the interior node of D^γ_1 that is the startnode of $C^\gamma_{1,1}$. For $2 \leq i \leq \gamma - 1$, exactly $\gamma - 1$ edges leaving Q^γ_i point into Q^γ_{i-1} such that every node that has l more outgoing than incoming edges, for $l > 0$, receives l edges. One outgoing edge points to the interior nodes of D^δ_{i-1} that does not get an edge from Q^γ_{i-1} and the remaining edge points to the interior node of D^γ_i that is the startnode of $C^\gamma_{1,1}$. In the same way, the edges leaving P^γ_γ are connected with $Q^\gamma_{\gamma-1}$, $D^\gamma_{\gamma-1}$ and D^γ_γ.

We identify the sources of P^δ, i.e., the nodes having higher outdegree than indegree. At each source, outdegree and indegree differ by 1. The startnodes of the chains D^γ_i, $2 \leq i \leq \gamma$, and $C^\gamma_{\gamma,k}$, $1 \leq k \leq 3\gamma$, represent a total of $4\gamma - 1$ sources. One interior node of D^γ_γ represents a source. Finally, the subproblem P^γ_γ contains $\gamma - 1$ sources.

A problem Q^δ, $\delta \geq 5$ is the same as P^δ, except that the subproblem P^γ_γ is replaced by a problem Q^γ_γ. As mentioned before, a problem Q^δ receives $\delta - 1$ additional incoming edges. These edges point to the nodes that represent sources in P^δ.

We analyze the number of edge traversals used by *Balance* on G. Consider a problem P^δ, $\delta \geq 5$, and let $\gamma = \delta/5$. When *Balance* generates the strand of chains $C^\gamma_{i,1}, \ldots, C^\gamma_{i,3\gamma}$, for some $1 \leq i \leq \gamma$, this strand contains $3\gamma > \gamma + 1$ tokens. Since D^γ_i and the subproblem attached to it contain γ tokens *Balance* does not explore the unvisited edges out of $C^\gamma_{i,3\gamma}$ before the subproblem attached to D^γ_i is finished. In the same way we can argue for a problem Q^δ.

Let $N(\delta)$ be the number of times the following event happens while *Balance* works on a problem P^δ or Q^δ: *Balance* generates a new chain, gets stuck, and cannot reach a node with new outgoing edges by using only edges in P^δ, respectively, Q^δ. Problem P^δ contains γ subproblems $Q_1^\gamma, \ldots, Q_{\gamma-1}^\gamma$ and P_γ^γ. Every time *Balance* gets stuck in one of these subproblems and has to leave it in order to resume exploration, it also has to leave P^δ. This is because of the following facts: (1) When *Balance* explores Q_i^γ, $1 \leq i \leq \gamma - 1$, or P_γ^γ, the subproblems $Q_1^\gamma, \ldots, Q_{i-1}^\gamma$ respectively $Q_1^\gamma, \ldots, Q_{\gamma-1}^\gamma$ are already finished. (2) The chains $D_1^\gamma, \ldots, D_\gamma^\gamma$ ensure that *Balance* cannot reach any chain $C_{i,k}^\gamma$, $1 \leq i \leq \gamma$, $1 \leq k \leq 3\gamma$, from where the unfinished chains in P^δ can be reached. Again the same holds for a problem Q^δ. Thus, for $\delta \geq 5$, $N(\delta) \geq \gamma N(\gamma) = (\delta/5)N(\delta/5)$. Since $N(\delta) = 1$, for $\delta = 1$, we obtain $N(d) = d^{\Omega(\log d)}$. Finally, consider the edge e on C_0 that leaves v. *Balance* must traverse e at least $N(d) = d^{\Omega(\log d)}$ times. $\square$

We also modified the *Balance* algorithm by relocating to other nodes with new outgoing edges. Replace the choice of C_k in line 7 according to one of the following rules.

Round Robin. Let C_k be the chain among $C_1, \ldots, C_l$ that was selected least often in any execution of line 7.

Cheapest Subtree. Let C_k be the chain among $C_1, \ldots, C_l$, such that $T_{v(C_k)}$ contains the fewest number of dependent chains with respect to the current chain.

THEOREM 6. *For Round Robin and Cheapest Subtree and for all $d \geq 1$, there exist graphs of deficiency d that require $d^{\Omega(\log d)}m$ edge traversals.*

Proof. The proof is identical to that of *Generalized-Greedy* in Theorem 2. $\square$

Acknowledgments. We thank Prabhakar Raghavan for bringing to our attention the literature on the *s–t* connectivity problem. We also thank an anonymous referee for many helpful comments which improved the presentation of the paper.

REDUCIBILITY AND COMPLETENESS IN PRIVATE COMPUTATIONS[*]

JOE KILIAN[†], EYAL KUSHILEVITZ[‡], SILVIO MICALI[§], AND RAFAIL OSTROVSKY[¶]

Abstract. We define the notions of *reducibility* and *completeness* in (two-party and multiparty) private computations. Let g be an n-argument function. We say that a function f is *reducible* to a function g if n honest-but-curious players can compute the function f n-privately, given a black box for g (for which they secretly give inputs and get the result of operating g on these inputs). We say that g is *complete* (for private computations) if *every* function f is reducible to g.

In this paper, we characterize the complete boolean functions: we show that a boolean function g is complete if and only if g itself cannot be computed n-privately (when there is no black box available). Namely, for n-argument boolean functions, the notions of completeness and n-privacy are *complementary*. This characterization provides a huge collection of complete functions (*any* nonprivate boolean function!) compared to very few examples that were given (implicitly) in previous work. On the other hand, for nonboolean functions, we show that these two notions are *not* complementary.

Key words. private computation, reducibility, completeness, oblivious-transfer

1. Introduction.

We consider (two-party and multiparty) private computations. Quite informally, given an arbitrary n-argument function f, a t-private protocol for computing f should allow n players, each possessing an individual secret input, to satisfy simultaneously the following two constraints: (1) (correctness) all players learn the value of f and (2) (privacy) no set of at most t (faulty) players learns more about the initial inputs of other players than is implicitly revealed by f's output. This problem, also known as *secure computation*, has been examined in the literature with two substantially different types of faulty players—malicious (i.e., Byzantine) players and honest-but-curious players. Below we discuss some known results with respect to each of these two types of players.

Secure computation for malicious players. Malicious players may deviate from the prescribed protocol in an arbitrary manner in order to violate the correctness and privacy constraints. The first general protocols for secure computation were given in [Yao-82, Yao-86] for the two-party case and by [GMW-87] for the multiparty case. Other solutions were given in, e.g., [GHY-87, GV-87, BGW-88, CCD-88, BB-89,

Table 1.1
The number of faulty players, t, tolerable in the two basic secure-computation models (with n players).

	Honest-but-curious players	Malicious players
Computational model [Yao-82, GMW-87] (assuming trapdoor permutations exist)	$t \leq n$	$t < \frac{n}{2}$
Information-theoretic model [BGW-88, CCD-88]	$t < \frac{n}{2}$	$t < \frac{n}{3}$

RB-89, CKOR-97]; the various solutions differ from each other in the assumptions that are made—varying from intractability assumptions (such as the existence of trapdoor one-way permutations, e.g., in [GMW-87]) to physical assumptions (such as the existence of private (untappable) communication channels between each pair of players, e.g., in [BGW-88, CCD-88]). The above-mentioned solutions give t-private protocols for computing any n-argument function f for $t < \frac{n}{2}$ or $t < \frac{n}{3}$ depending on the assumption made. (See Table 1.1 for a summary of the main results.)

Secure computation for honest-but-curious players. Honest-but-curious players must always follow the protocol precisely but are allowed to "gossip" afterwards. Namely, some of the players may put together the information in their possession at the end of the execution in order to infer additional information about the original individual inputs. It should be realized that, in the case of honest-but-curious players, enforcing the *correctness* constraint is easy, and only enforcing the *privacy* constraint is hard. Honest-but-curious players are not only interesting on their own (e.g., for modeling security against outside listeners or against a passive adversary that wants to remain undetected); their importance also stems from "compiler-type" theorems, such as the one proved by [GMW-87][1] (with further extensions in many subsequent papers, for example, [BGW-88, CCD-88, RB-89]). This type of theorem provides algorithms for transforming any protocol that is t-private with respect to honest-but-curious players into a protocol that is t'-private with respect to malicious players (for some $t' \leq t$). In this paper we concentrate on honest-but-curious players.

Information-theoretic privacy. The first works on secure computation concentrated on the notion of *computational privacy*; roughly speaking, computational t-privacy requires that no coalition of t players can infer *in polynomial time* any additional information on the input of other players (that is not revealed by the output). The information-theoretic model was first examined by [BGW-88, CCD-88]; roughly speaking, information-theoretic t-privacy requires that no coalition of t players can infer any information on the input of other players, even if the players have unlimited computational power. In particular, [BGW-88, CCD-88] prove that if every two players are connected by a private channel, then every function is t-private for $t < n/2$ (with respect to honest-but-curious players; see Table 1.1). The information-theoretic model was then the subject of considerable work (e.g., [CKu-89, BB-89, CGK-90, CGK-92, KR-94, CFGN-96, KOR-96, HM-97, BW-98, KOR-98]). Particularly, [CKu-89] characterized the boolean functions for which n-private protocols exist: an n-argument boolean function f is n-private if and only if it can be represented as $f(x_1, x_2, \ldots, x_n) = f_1(x_1) \oplus f_2(x_2) \oplus \cdots \oplus f_n(x_n)$, where each f_i is boolean. Namely, f is n-private if and only if it is the exclusive-or of n local functions. An immediate

[1]The reader is referred to [G-98] for a fully detailed treatment of the [Yao-86, GMW-87] results.

corollary of this is that *most* boolean functions are *not* n-private (even with respect to honest-but-curious players).

Our contribution. We formally define the notion of *reducibility* among multiparty protocol problems. We say that a function f is reducible to a function g if there is a protocol that allows the n players to compute the value of f n-privately, in the information-theoretic sense, just by repeatedly using a black box (or a trusted party) for computing g. That is, in any round of the protocol, the players *secretly* supply arguments to the black box and then the black box *publicly* announces the result of operating g on these arguments. We stress that the only means of communication among the players is by interacting with the black box (i.e., evaluating g). For example, it is clear that *every* function f is reducible to itself (all players secretly give their private inputs $x_1, \dots, x_n$ to the black box and the black box announces the result $f(x_1, \dots, x_n)$). Naturally, we can also define the notion of *completeness.* A function g is complete if *every* function f is reducible to g. The importance of this notion relies on the following observation:

> If g is complete, and g can be computed t-privately in some "reasonable" setting[2] (such as the settings of [GMW-87, BGW-88], etc.), then any function f can be computed t-privately in the *same* setting. Moreover, from our construction a stronger result follows: if in addition the implementation of g is *efficient*, then so is the implementation of f (see below).

The above observation holds since our definition of reduction requires the highest level of privacy (i.e., n), the strongest notion of privacy (i.e., information-theoretic privacy), a simple use of g (i.e., as a black box), and that it avoid making any (physical or computational) assumptions. Hence the straightforward simulation, in which each invocation of the black box for g is replaced by an invocation of a "t-private" protocol for g, works in any "reasonable" setting (i.e., any setting that is not too weak to prevent simulation) and yields a "t-private" protocol for f in the same setting. Previously, there was no easy way to translate private protocols from one setting (such as the settings of [Yao-82, GMW-87, BGW-88, CCD-88, RB-89, FKN-94]) to other settings.

A simple observation regarding complete functions is that if g is complete, then g itself cannot be information-theoretic n-private. The inverse of this observation is the less obvious part: since the definition of completeness requires that the same function g will be used for computing *all* functions f, and since the definition of reductions seems very restrictive, it may be somewhat surprising that complete functions exist at all. Some examples of complete functions implicitly appear in the literature (without discussing the notions of reducibility and completeness). The first such results were shown in [Yao-82, GMW-87, K-88].

In this work we prove the existence of complete functions for n-party private computations. Moreover, while previous research concentrated on finding a *single* complete function, our main theorem *characterizes* all the *boolean* functions that are complete.

THEOREM 1.1 (main theorem). *For all $n \geq 2$, an n-argument boolean function g is complete if and only if g is* not *information-theoretic n-private.*

Our result thus shows a very strong dichotomy: every boolean function g is either "simple enough" so that it can be computed n-privately (in the information-theoretic

[2]A *setting* consists of defining the type of communication, type of privacy, type of players (e.g., honest-but-curious or malicious), the assumptions made, etc.

model), or it is "sufficiently expressive" so that a black box for it enables reducing every function (not only boolean) to g (i.e., g is complete). We stress that there is no restriction on g, besides being a non-n-private boolean function, and that no relation between the function g and the function f that we wish to compute is assumed. Note that using the characterization of n-private boolean functions by [CKu-89] it is easy to determine whether a given boolean function g is complete. That is, a boolean function g is complete if and only if it cannot be represented as $g(x_1, x_2, \ldots, x_n) = g_1(x_1) \oplus g_2(x_2) \oplus \cdots \oplus g_n(x_n)$, where each g_i is a boolean function.

Some features of our result. To prove the completeness of a function g as above, we present an appropriate construction with the following additional properties:

- We consider the most interesting scenario, where both the reduced function f and the black-box function g are n-argument functions (where n is the number of players). This enables us to organize the reduction in *rounds*, where in each round each player provides a value for a *single* argument of g (and the value of each argument is provided by exactly one player).[3] Thus, no player is "excluded" at any round from the evaluation of g. Our results, however, remain true even if the number of arguments of g is different from the number of arguments of f.
- Our construction evaluates the n-argument function g only on a *constant* number of n-tuples (hence, a partial implementation of g may be sufficient).
- When we talk about privacy, we put no computational restrictions on the power of the players; hence we get information-theoretic privacy. However, when we talk about protocols, we measure their *efficiency* in terms of the computational complexity of f (i.e., the size of the smallest circuit that computes f) and in terms of a confidence parameter k (our protocol allows error probability of $2^{-\Omega(k)}$). Our protocol is efficient (polynomial) in all these measures.[4] We stress, though, that the n-tuples with which we use the function g are chosen nonuniformly (namely, they are encoded in the protocol) for the particular choices of g and n (the size of the network). These n-tuples depend though neither on the size of the *inputs* to the protocol nor on the function f (or the confidence parameter k).

Our main theorem gives a full characterization of the boolean functions g that are complete (i.e., those that are not information-theoretic n-private). When nonboolean functions are considered, it turns out that the above simple characterization is no longer true. That is, we show that there are (nonboolean) functions that are not n-private, yet are *not* complete.

Overview of the proof of the main theorem. Our proof goes along the following lines:

1. We define the notion of embedded-OR for two-argument functions and appropriately generalize this notion to the case of n-argument functions. We then show that if an n-argument function is not private, then it contains an embedded-OR. For the case $n = 2$ this follows immediately from the characterization of n-private boolean functions by [CKu-89]; the case $n > 2$ requires some additional technical work.
2. We show how an embedded-OR can be used to implement an *oblivious transfer*

[3]Which player submits which argument is a permutation specified by the reduction.

[4]Evaluating g on any assignment is assumed to take unit time. All other operations (communication, computation steps, etc.) are measured in the regular way.

(OT) channel/primitive between any pair of players.[5] Finally, it follows from the work of [GMW-87, GHY-87, GV-87, K-88, BG-89, GL-90] that n-private computation of any function f can be implemented given such OT channels. All together, our main theorem follows.

Organization of the paper. In section 2 we specify our model and provide some necessary definitions. In section 3 we prove our main lemma, which shows the existence of an embedded-OR in every non-n-private, boolean function. In section 4 we use the main lemma (i.e., the existence of an embedded-OR) to implement OT channels between players. In section 5 we use the construction of OT channels to prove our main theorem. Finally, section 6 contains a discussion of the results and some open problems. For completeness, we include in the appendix a known protocol for private computations using OT channels (including its formal proof).

2. Model and definitions.

Let f be an n-argument function defined over a finite domain $\mathcal{D}$. Consider a collection of $n \geq 2$ synchronous, computationally unbounded players $P_1, \ldots, P_n$ that communicate using a black box for g, as described below. At the beginning of an execution, each player P_i has an input $x_i \in \mathcal{D}$. In addition, each player can flip unbiased and independent random coins. We denote by r_i the string of random bits flipped by P_i (sometimes we refer to the string r_i as the *random input* of P_i). The players wish to compute the value of a function $f(x_1, x_2, \ldots, x_n)$. To this end, they use a prescribed protocol $\mathcal{F}$. In the ith round of the protocol, every processor P_j secretly sends a message m_j^i to the black box g.[6] The protocol $\mathcal{F}$ specifies which argument to the black-box is provided by which player. The black box then publicly announces the result of evaluating the function g on the input messages.

Formally, with each round i the protocol associates a permutation π_i. The value computed by the black box at round i, denoted s_i, is $s_i = g(m^i_{\pi_i(1)}, m^i_{\pi_i(2)}, \ldots, m^i_{\pi_i(n)})$. Each message m_j^i, sent by P_j to the black box in the ith round, is determined by its input (i.e., x_j), its random input (i.e., r_j), and the output of the black box in previous rounds (i.e., $s_1, \ldots, s_{i-1}$). We say that the protocol $\mathcal{F}$ computes the function f if the last value (or the last sequence of values in the case of nonboolean f) announced by the black box equals the value of $f(x_1, x_2, \ldots, x_n)$ with probability $\geq 1 - 2^{-\Omega(k)}$, where k is a (confidence) parameter and the probability is over the choice of $r_1, \ldots, r_n$.

Let $\mathcal{F}$ be an n-party protocol as described above. The *communication* $\mathtt{S}(\vec{x}, \vec{r})$ is the concatenation of all messages announced by the black box while executing $\mathcal{F}$ on inputs $x_1, \ldots, x_n$ and random inputs $r_1, \ldots, r_n$. We often consider the communication $\mathbf{S}$ while fixing $\vec{x}$ and some of the r_i's; in this case, the communication should be thought of as a random variable, where each of the r_i's that were not fixed is chosen according to the corresponding probability distribution. For example, if T is a set of players, then $\mathbf{S}(\vec{x}, \langle r_i \rangle_{i \in T})$ is a random variable describing the communication when each player P_i holds input x_i, each player in T holds random input r_i, and the random inputs for all players in $\overline{T}$ are chosen randomly. The definition of privacy considers the distribution of such random variables.

[5]OT is a protocol for two players: a sender that holds two bits b_0 and b_1 and a receiver that holds a selection bit s. At the end of the protocol the receiver gets the bit b_s but has no information about the value of the other bit, while the sender has no information about the selection bit s. It should be emphasized that an OT channel in a multiparty setting has the additional requirement that listeners do not get any information; we prove, however, that this property is already implied by the basic properties of two-party OT.

[6]Notice that we do not assume private point-to-point communication among players. On the other hand, we do allow private communication between players and the black box for computing g.

Definition 2.1. *Let $\mathcal{F}$ be an n-party protocol that computes a function f and let $T \subseteq \{1, 2, \ldots, n\}$ be a set of players (coalition). We say that coalition T* does not learn any additional information *from the execution of $\mathcal{F}$ if the following holds: For every two input vectors $\vec{x}$ and $\vec{y}$ that agree on their T entries (i.e., $\forall\ i \in T : x_i = y_i$) and for which $f(\vec{x}) = f(\vec{y})$, for every choice of random inputs for the coalition's parties, $\langle r_i \rangle_{i \in T}$, and for every communication S,*

$$\Pr_{\langle r_i \rangle_{i \in \overline{T}}}(\mathbf{S}(\vec{x}, \langle r_i \rangle_{i \in T}) = S) \quad = \quad \Pr_{\langle r_i \rangle_{i \in \overline{T}}}(\mathbf{S}(\vec{y}, \langle r_i \rangle_{i \in T}) = S).$$

Informally, this definition implies that for all inputs that "look the same" from the coalition's point of view (and for which, in particular, f has the same value), the communication also "looks the same" (i.e., it is identically distributed). Therefore, by executing the protocol $\mathcal{F}$, the coalition T cannot infer any information on the inputs of $\overline{T}$ other than what follows from the inputs of T and the value of the function.

Definition 2.2. *A protocol $\mathcal{F}$ for computing f using a black box g is* t-private *if any coalition T of at most t players does not learn any additional information from the execution of the protocol. A function f is* t-private *(with respect to the black box g) if there exists a t-private protocol that uses the black box g and computes f.*

Definition 2.3. *Let g be an n-argument function. We say that the black box g (alternatively, the function g) is* complete *if every function f is n-private with respect to the black box g.*

OT is a protocol for two players $\mathcal{S}$, the *sender*, and $\mathcal{R}$, the *receiver*. It was first defined by Rabin [R-81] and since then was studied in many works (e.g., [EGL-82, W-83, FMR-85, K-88, IL-89, OVY-91]). The variant of OT protocol that we use here, which is often referred to as $\binom{2}{1}$-OT, was originally defined in [EGL-82]. It was shown equivalent to other notions of OT (see, for example, [R-81, EGL-82, BCR-86, B-86, C-87, K-88, CK-88]). The formalization of OT that we give is in terms of the probability distribution of the communication transcripts between the two players.

Definition 2.4 (OT).

Let k be a (confidence) parameter. The sender $\mathcal{S}$ initially has two bits b_0 and b_1 and the receiver $\mathcal{R}$ has a selection bit c. After the protocol completion the following holds:

- *Correctness: Receiver $\mathcal{R}$ gets the value of b_c with probability greater than $1-2^{-\Omega(k)}$, where the probability is taken over the coin tosses of $\mathcal{S}$ and $\mathcal{R}$. More formally, let $r_\mathcal{S}$, $r_\mathcal{R} \in \{0,1\}^{poly(k)}$ be the random tapes of $\mathcal{S}$ and $\mathcal{R}$ respectively, and denote the communication string by $\mathbf{comm}(\langle b_0, b_1, c\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) \in \{0,1\}^{poly(k)}$. (Again, when one (or both) of $r_\mathcal{S}, r_\mathcal{R}$ is unspecified, then* **comm** *becomes a random variable.) Then, for all k and for all $c, b_0, b_1 \in \{0,1\}$, the following holds:*

$$\Pr_{r_\mathcal{S}, r_\mathcal{R}}\left(\mathcal{R}(c, r_\mathcal{R},\ \mathbf{comm}(\langle b_0, b_1, c\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle)) = b_c\right) \quad \geq \quad 1 - \frac{1}{2^{\Omega(k)}}.$$

  *($\mathcal{R}(c, r_\mathcal{R},$ **comm**$)$ denotes the output of receiver $\mathcal{R}$ when it has a selection bit c and random input $r_\mathcal{R}$ and the communication in the protocol is* **comm***.)*

- *Sender's privacy: Receiver $\mathcal{R}$ does not get any information about b_{1-c}. (In other words, $\mathcal{R}$ has the "same view" in the case where $b_{1-c} = 0$ and in the case where $b_{1-c} = 1$). Formally, for all k, for all $c, b_c \in \{0,1\}$, for all $r_\mathcal{R}$, and for all communication comm,*

$$\begin{aligned}&\Pr_{r_\mathcal{S}}\left(\mathbf{comm}(\langle b_c, b_{1-c} = 0, c\rangle, r_\mathcal{R}) = comm\right)\\ &= \Pr_{r_\mathcal{S}}\left(\mathbf{comm}(\langle b_c, b_{1-c} = 1, c\rangle, r_\mathcal{R}) = comm\right).\end{aligned}$$

- *Receiver's privacy: Sender $\mathcal{S}$ does not get any information about c. (In other words, $\mathcal{S}$ has the "same view" in the case where $c = 0$ and in the case where $c = 1$.) Formally, for all k, for all $b_0, b_1 \in \{0, 1\}$, for all $r_{\mathcal{S}}$, and for all communication comm,*

$$\begin{aligned}&\Pr_{r_{\mathcal{R}}}\left(\mathbf{comm}(\langle b_0, b_1, c=0\rangle, r_{\mathcal{S}}) = \mathit{comm}\right)\\ &= \Pr_{r_{\mathcal{R}}}\left(\mathbf{comm}(\langle b_0, b_1, c=1\rangle, r_{\mathcal{S}}) = \mathit{comm}\right).\end{aligned}$$

Remark. We emphasize that both $\mathcal{S}$ and $\mathcal{R}$ are *honest* (but curious) and assumed to follow the protocol. When OT is defined with respect to *cheating* players, it is usually allowed that with probability $2^{-\Omega(k)}$ information will leak. This, however, is not needed for honest players.

3. A new characterization of n-private boolean functions. In this section we prove our main lemma, which establishes a new combinatorial characterization of the family of n-private boolean functions. First, we define what it means for a two-argument boolean function to contain an "embedded-OR" and use [CKu-89] to claim that any two-argument boolean function that is not 1-private contains an embedded-OR. We then generalize the definition and the claim to multiargument functions in the appropriate way.

DEFINITION 3.1. *We say that a two-argument function h contains an embedded-OR if there exist inputs x_0, x_1, y_0, y_1 ($x_0 \neq x_1$, $y_0 \neq y_1$) and an output value σ such that $h(x_1, y_1) = h(x_1, y_0) = h(x_0, y_1) = \sigma$ but $h(x_0, y_0) \neq \sigma$.*

DEFINITION 3.2. *We say that an n-argument ($n \geq 3$) function f contains an embedded-OR if there exist indices $1 \leq i < j \leq n$ and values a_k for all $k \notin \{i, j\}$ such that the two-argument function*

$$h(y, z) \overset{\triangle}{=} f(a_1, \ldots, a_{i-1}, y, a_{i+1}, \ldots, a_{j-1}, z, a_{j+1}, \ldots, a_n)$$

contains an embedded-OR.

The following facts are proven in [CKu-89].[7] Facts 1 and 2 give a characterization of the n-private boolean functions (these facts are relevant here since, as our main theorem shows, the characterization of the n-private boolean functions is also a characterization of the complete boolean functions). Facts 3 and 4 are used in [CKu-89] as technical lemmas and we use them here to prove Lemma 3.3 below.

1. An n-argument boolean function is $\lceil n/2 \rceil$-private if and only if it can be written as $f(x_1, \ldots, x_n) = f_1(x_1) \oplus \cdots \oplus f_n(x_n)$, where each f_i is boolean.
2. If an n-argument boolean function is $\lceil n/2 \rceil$-private, then it is n-private.
3. A two-argument boolean function f is not 1-private if and only if it contains an embedded-OR.
4. An n-argument boolean function f is $\lceil n/2 \rceil$-private if and only if in every partition of the indices $\{1, \ldots, n\}$ into two sets $S, \bar{S}$, each of size at most $\lceil n/2 \rceil$, the two-argument boolean function f_S defined by

$$f_S(\langle x_i \rangle_{i \in S}, \langle x_i \rangle_{i \in \bar{S}}) \overset{\triangle}{=} f(x_1, \ldots, x_n)$$

is 1-private.

[7]More specifically, the "only-if" part of fact 1 is Theorem 2 of [CKu-89]; the "if" parts of fact 1 and fact 2 is Theorem 3 of [CKu-89]; fact 3 is proved by Lemma 1 and Theorem 1 of [CKu-89]; and fact 4 is Lemma 5 of [CKu-89].

Our main lemma extends fact 3 above to the case of multiargument functions.

LEMMA 3.3 (main lemma). *Let $g(x_1, \ldots, x_n)$ be any boolean, n-argument function. The function g is not $\lceil n/2 \rceil$-private if and only if it contains an embedded-OR.*

Proof. Clearly, if g contains an embedded-OR, then there is a partition of the indices into two sets $S, \bar{S}$, each of size at most $\lceil n/2 \rceil$, such that the corresponding two-argument function g_S contains an embedded-OR (e.g., if i, j are the indices guaranteed by Definition 3.2, then include the index i in S, the index j in $\bar{S}$, and partition the other $n-2$ indices arbitrarily into two halves between S and $\bar{S}$). By fact 3, g_S is not 1-private and so, by fact 4, g itself is not $\lceil n/2 \rceil$-private.

For the other direction, since the function g is not $\lceil n/2 \rceil$-private, then, by fact 4, there is a partition $S, \bar{S}$ of the indices $\{1, \ldots, n\}$ such that the corresponding function g_S is not 1-private. For simplicity of notation, we assume that n is even and that $S = \{1, \ldots, n/2\}$. By fact 3, the two-argument function g_S contains an embedded-OR. Hence, by Definition 3.1, there exist inputs u, v, w, z and a value $\sigma \in \{0, 1\}$ that form the following structure:

$g_S(\cdot, \cdot)$	$w = w_{\frac{n}{2}+1}, \ldots, w_n$	$z = z_{\frac{n}{2}+1}, \ldots, z_n$
$u = u_1, \ldots, u_{\frac{n}{2}}$	σ	σ
$v = v_1, \ldots, v_{\frac{n}{2}}$	σ	$\bar{\sigma}$

where $u \neq v$ and $w \neq z$. To complete the proof, we will show below that it is possible to choose these four inputs so that $u_i \neq v_i$ for exactly one coordinate i and $w_j \neq z_j$ for exactly one coordinate j (this will show that g satisfies the condition of Definition 3.2). To this end, we will first show how, based on the inputs above, we can find u' and v', which differ from each other in exactly one coordinate (and such that u', v', w, z still form an embedded-OR, that is, $g(u', w) = g(u', z) = g(v', w) = \sigma$ and $g(v'z) = \bar{\sigma}$). Then, based on the new u', v' and a similar argument, we can find w', z', which differ from each other in exactly one coordinate. Again, this is done so that u', v', w', z' form the embedded-OR structure. Therefore, by using the above values of i, j and fixing all the other arguments in S to $u'_k = v'_k$ and all the other arguments in $\bar{S}$ to $w'_k = z'_k$, we get that g itself contains an embedded-OR.

Let $L \subseteq \{1, \ldots, \frac{n}{2}\}$ be the set of indices on which u and v disagree (i.e., indices k such that $u_k \neq v_k$). For every m $(0 \leq m \leq |L|)$, define T_m as the set of all vectors that can be obtained from the vector u by choosing a subset of m indices from L and replacing for each chosen index the value u_k by the value v_k (note that by the definition of L, we have $v_k \neq u_k$). In particular, $T_0 = \{u\}$, $T_{|L|} = \{v\}$, and $|T_m| = \binom{|L|}{m}$. In addition, we define the following two sets of vectors:

$$X_1 \stackrel{\triangle}{=} \{x = (x_1, \ldots, x_{n/2}) \mid g_S(x, w) = g_S(x, z)\}$$

and

$$X_2 \stackrel{\triangle}{=} \{x = (x_1, \ldots, x_{n/2}) \mid g_S(x, w) \neq g_S(x, z)\},$$

where w and z are the specific vectors we chose above. In particular, we have $u \in X_1$ and $v \in X_2$.

We now claim that there must exist u', v' as required. Namely, the vector u' is in X_1, the vector v' is in X_2, and u', v' differ in exactly one coordinate. Suppose, toward a contradiction, that this is not true, that is, for every pair u', v' that differ in exactly one coordinate, both u', v' are in the same set (X_1 or X_2). We claim that this implies that $T_m \subseteq X_1$ for all $0 \leq m \leq |L|$, contradicting the fact that v, which is in $T_{|L|}$, belongs to X_2. The proof is by induction. The claim is true for $m = 0$ since T_0 contains only the vector u, which is in X_1. Now, suppose the induction hypothesis holds for m. That is, $T_m \subseteq X_1$. For each vector x in T_{m+1}, there is a vector in T_m that differs from x in exactly one coordinate. By our assumption, this immediately implies that x is also in X_1 and hence $T_{m+1} \subseteq X_1$, as needed. Therefore, we reach a contradiction, which implies the existence of u', v' as required. That is, we found u', v' that differ in a single index i (i.e., $u'_i \neq v'_i$) and such that u', v', w, z still form an embedded-OR structure:

$g_S(\cdot,\cdot)$	$w = w_{\frac{n}{2}+1},\ldots,w_n$	$z = z_{\frac{n}{2}+1},\ldots,z_n$
$u' = u'_1,\ldots,u'_{i-1},u'_i,u'_{i+1},\ldots,u'_{\frac{n}{2}}$	σ	σ
$v' = u'_1,\ldots,u'_{i-1},v'_i,u'_{i+1},\ldots,u'_{\frac{n}{2}}$	σ	$\bar{\sigma}$

A similar argument shows the existence of w', z' that differ in a single index j and such that the above vectors u', v' together with the vectors w' and z' form an embedded-OR structure:

$g_S(\cdot,\cdot)$	$w' = w'_{\frac{n}{2}+1},\ldots,w'_{j-1},w'_j,w'_{j+1},\ldots,w'_n$	$z = w'_{\frac{n}{2}+1},\ldots,w'_{j-1},z'_j,w'_{j+1},\ldots,w'_n$
u'	σ	σ
v'	σ	$\bar{\sigma}$

This shows that g contains an embedded-OR (with indices i, j as required by Definition 3.2). ◻

4. Constructing embedded OT. The first, very simple observation is that given a black box for a function g that contains an embedded-OR, we can actually compute the OR of two bits. That is, suppose that the n players wish to compute $\text{OR}(b_k, b_\ell)$, where b_k is a bit held by player P_k and b_ℓ is a bit held by player P_ℓ. Let i, j, x_0, x_1, y_0, y_1 and $a_1,\ldots,a_{i-1},a_{i+1},\ldots,a_{j-1},a_{j+1},\ldots,a_n$ be the indices and inputs as guaranteed by Definitions 3.1 and 3.2. Then, player P_k will provide the black box with the ith argument which is x_{b_k} (i.e., if $b_k = 0$, then the argument provided by P_k is x_0 and if $b_k = 1$, then this argument is x_1) and player P_ℓ will provide the black box with the jth argument, which is y_{b_ℓ}. The other $n-2$ players will provide the $n-2$ fixed values $a_1,\ldots,a_{i-1},a_{i+1},\ldots,a_{j-1},a_{j+1},\ldots,a_n$. The black box will answer with the value

$$g(a_1,\ldots,a_{i-1},x_{b_k},a_{i+1},\ldots,a_{j-1},y_{b_\ell},a_{j+1},\ldots,a_n),$$

which is σ if $\text{OR}(b_k, b_\ell) = 1$ and is different from σ if $\text{OR}(b_k, b_\ell) = 0$. Hence, we have shown how to compute $\text{OR}(b_k, b_\ell)$.

Our main goal in this section is to show how, based on a black box that can compute OR, we can implement an OT protocol. We start with the two-party case ($n = 2$) and then proceed to the general case, which builds upon the two-party case.

4.1. The two-party case. In this section we show how to implement a two-party OT protocol. We start by implementing a variant of OT, called *random OT* (ROT), which is different from the standard OT (i.e., $\binom{2}{1}$-OT). In a ROT protocol the sender $\mathcal{S}$ has a bit s to be sent. At the end of the protocol, the receiver $\mathcal{R}$ gets a bit s' such that with probability $1/2$ the bit s' equals s and with probability $1/2$ the bit s' is random. The receiver knows which of the two cases happened but the sender has no idea which is the case. We start with a formal definition of the ROT primitive.

Definition 4.1 (ROT). *Let k be a (confidence) parameter. The sender $\mathcal{S}$ initially has a single input bit s (and the receiver has no input). A ROT protocol must satisfy the following four properties:*

- *Correctness. With probability greater than* $1 - 2^{-\Omega(k)}$*, receiver* $\mathcal{R}$ *outputs a pair of bits* (I, s')*, where* I *is referred to as the* indicator *(otherwise* $\mathcal{R}$ *outputs* **fail***). (As usual, the probability is taken over the coin tosses of* $\mathcal{S}$ *and* $\mathcal{R}$*, i.e.,* $r_{\mathcal{S}}$*,* $r_{\mathcal{R}} \in \{0,1\}^{poly(k)}$*.)*
- *Indicator's correctness. Whenever* $\mathcal{R}$ *outputs a pair of bits* (I, s') *such that the indicator* I *equals* 1 *(i.e.,* $\mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) = (1, s')$*), then* s' *is the correct input bit of the sender, i.e.,* $s' = s$*.*
- *Sender's privacy. If the protocol does not fail, then the probability that the receiver gets the sender's bit is exactly* $1/2$*; otherwise, the receiver gets a random bit. That is, the probability that* $\mathcal{R}$ *outputs a pair* (I, s') *such that* $I = 1$ *is exactly* $1/2$*. Formally,*

$$\begin{aligned}&\Pr_{r_{\mathcal{S}}, r_{\mathcal{R}}}(\mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) = (1, s') \mid \mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) \neq \mathbf{fail})\\ &= \Pr_{r_{\mathcal{S}}, r_{\mathcal{R}}}(\mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) = (0, s') \mid \mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) \neq \mathbf{fail})\\ &= \frac{1}{2}.\end{aligned}$$

  Moreover, if $\mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) = (0, s')$ *(i.e.,* $I = 0$*), then* s' *is random, namely,*

$$\Pr_{r_{\mathcal{S}}, r_{\mathcal{R}}}(s' = 1 | \mathcal{R}(r_{\mathcal{R}}, \mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}})) = (0, s')) \quad = \quad \frac{1}{2}.$$

- *Receiver's privacy. Sender* $\mathcal{S}$ *does not get any information about* I*, i.e., the sender does not know whether* $\mathcal{R}$ *received the bit* s *or a random bit. (In other words,* $\mathcal{S}$ *has the "same view" in the case where* $I = 0$ *and in the case where* $I = 1$*.) Formally, for all* k*, for all* $s \in \{0, 1\}$*, for all* $r_{\mathcal{S}}$*, and for all communication comm,*

$$\begin{aligned}&\Pr_{r_{\mathcal{R}}}(\mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}}) = comm \mid I = 0)\\ &= \Pr_{r_{\mathcal{R}}}(\mathbf{comm}(s, r_{\mathcal{S}}, r_{\mathcal{R}}) = comm \mid I = 1).\end{aligned}$$

Transformations of ROT protocols to $\binom{2}{1}$-OT protocols are well known [C-87].[8] Our ROT protocol is implemented, using a black box for OR, as follows:

a. The sender, $\mathcal{S}$, and the receiver, $\mathcal{R}$, repeat the following at most $m = \Theta(k)$ times:
   - $\mathcal{S}$ chooses a pair (a_1, a_2) out of the two pairs $\{(1, 0), (0, 1)\}$, each with probability $1/2$.
     $\mathcal{R}$ chooses a pair (b_1, b_2) out of the three pairs $\{(1, 0), (0, 1), (1, 1)\}$, each with probability $1/3$.
     $\mathcal{S}$ and $\mathcal{R}$ compute (using the black box) $c_1 = \mathrm{OR}(a_1, b_1)$ and $c_2 = \mathrm{OR}(a_2, b_2)$.

[8]Assume that the sender, $\mathcal{S}$, has two bits b_0, b_1 and the receiver, $\mathcal{R}$, has a selection bit c. The players $\mathcal{S}$ and $\mathcal{R}$ repeat the following for at most $m = \Theta(k)$ times: at each time, $\mathcal{S}$ tries to send to $\mathcal{R}$ a pair of random bits (s_1, s_2) using two invocations of ROT. If in both trials the receiver gets the actual bit or in both trials it gets a random bit, then they try again. If the receiver got exactly one of s_1 and s_2, it sends the sender a permutation of the indices π (i.e., either $(1, 2)$ or $(2, 1)$) such that $s_{\pi(c)}$ is known to it. The sender replies with $b_1 \oplus s_{\pi(1)}, b_2 \oplus s_{\pi(2)}$. The receiver can now retrieve the bit b_c and knows nothing about the other bit. The sender, by observing π, learns nothing about c (since it does not know from the invocation of the ROT protocols in which invocation the receiver got the actual bit and in which it got a random bit). Thus, we get a $\binom{2}{1}$-OT protocol based on the ROT protocol.

TABLE 4.1
Analyzing the six cases of (a single round of) the ROT protocol.

	$(b_1,b_2)=(1,0)$	$(b_1,b_2)=(0,1)$	$(b_1,b_2)=(1,1)$
$(a_1,a_2)=(1,0)$	$(c_1,c_2)=(1,0)$	$(c_1,c_2)=(1,1)$ $I=1$ $s'=s$	$(c_1,c_2)=(1,1)$ $I=0$ $s'=s$
$(a_1,a_2)=(0,1)$	$(c_1,c_2)=(1,1)$ $I=1$ $s'=s$	$(c_1,c_2)=(0,1)$	$(c_1,c_2)=(1,1)$ $I=0$ $s'=s\oplus 1$

- If $c_1=c_2=1$, then
  $\mathcal{S}$ sends $w=s\oplus a_1$ to $\mathcal{R}$.
  $\mathcal{R}$ outputs a pair (I,s') such that $s'=w\oplus b_2$, and $I=0$ if $(b_1,b_2)=(1,1)$ and $I=1$ otherwise.
  The protocol halts.

b. In the case that the protocol has not halted so far, $\mathcal{R}$ outputs **fail** and the protocol halts (this step is reached only if in all m times no choices (a_1,a_2) and (b_1,b_2) are such that $c_1=c_2=1$).

To analyze the protocol, we observe the following properties of it (the reader is referred to Table 4.1 for a summary of the protocol behavior in each of the six possible choices of (a_1,a_2), (b_1,b_2)):

1. If $(b_1,b_2)=(a_1,a_2)$, then one of c_1,c_2 is 0. This happens in two of the six choices of (a_1,a_2) and (b_1,b_2). In each of the other four choices we get $c_1=c_2=1$, and so at each round the protocol halts with probability 4/6. Therefore, the probability of failure in $m=\Theta(k)$ trials is exponentially small (in k), which implies the correctness property of the protocol.
2. Given that (a_1,a_2) and (b_1,b_2) are such that $c_1=c_2=1$ (which, as argued above, happens in four of the six cases), we have $(b_1,b_2)=(a_2,a_1)$ with probability 1/2 (two out of the four cases) and $(b_1,b_2)=(1,1)$ with probability 1/2. By the protocol, in the former case $\mathcal{R}$ outputs $I=1$ and in the latter $I=0$. Moreover, in the cases where $\mathcal{R}$ outputs $I=0$ (i.e., when $(b_1,b_2)=(1,1)$), each of the two choices of (a_1,a_2) is equally likely. Therefore, a_1 and hence also w and s' are random (that is, each has the value 0 with probability 1/2 and the value 1 with probability 1/2). This implies the sender's privacy property.
3. In the cases where $\mathcal{R}$ outputs $I=1$ (i.e., when $(b_1,b_2)=(a_2,a_1)$), then we have in particular $b_2=a_1$ and so $s'=w\oplus b_2=(s\oplus a_1)\oplus b_2=s$. This gives the indicator's correctness property.
4. As argued above, if the protocol does not fail, then $\mathcal{R}$ knows the "correct" value of I (since it knows the values of b_1,b_2,c_1, and c_2). The sender, on the other hand, based on (a_1,a_2), cannot know which of the two equally probable events, $(b_1,b_2)=(a_2,a_1)$ or $(b_1,b_2)=(1,1)$, happened and therefore it sees the same view whether $I=1$ or $I=0$. This gives the receiver's privacy property.

To conclude, the above four properties of the ROT protocol give the four properties required in Definition 4.1. Hence, combining the above construction (including the transformation of the ROT protocol to a $\binom{2}{1}$-OT protocol) with Lemma 3.3, we get the following lemma.

LEMMA 4.2. *An OT channel between two players is realizable given a black box g for any non-2-private function g.*

4.2. The multiparty case ($n > 2$). We have shown in our main lemma (Lemma 3.3) that any non-n-private function g contains an embedded-OR. Thus, as explained above, we can use the black box for g to compute the OR of two bits held by two players P_k and P_ℓ (where the other $n-2$ players assist by specifying the fixed arguments given by our main lemma). Then, based on the ability to compute OR, we showed in section 4.1 above how any two players can implement an OT channel between them in a way that satisfies the properties of OT (in particular, the privacy of the sender and the receiver with respect to each other). However, there is a subtle difficulty in implementing a private OT channel in a multiplayer system that we must address: besides the usual properties of an OT channel (as specified by Definition 2.4), we should guarantee that the information transmitted between the two owners of the channel will not be revealed to potential *listeners* (i.e., the other $n-2$ players). If the OT channel is implemented "physically," then clearly no information is revealed to the listeners. However, since we implement the OT protocol using a black box to some function g, which *publicly* announces each of its outcomes, we must also prove that this reveals no information to the listeners. That is, the communication seen during the execution of the OT protocol should be distributed in the same way for all values of b_1, b_2, and c.

The following lemma shows that the security of the OT protocol with respect to listeners is, in fact, already guaranteed by the basic properties of the OT protocol, namely, the security of the protocol with respect to both the receiver and the sender.

LEMMA 4.3. *Consider any (two-player) OT protocol. For every possible communication comm, the probability* $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0, b_1, c\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$ *is the same for all values* b_0 *and* b_1 *for the sender and* c *for the receiver. (In other words, a listener sees the same probability distribution of communications no matter what are the inputs held by the sender and the receiver in the OT protocol.)*

Proof. Consider the following eight probabilities corresponding to all possible values of the bits b_0, b_1, and c:

1. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 0, b_1 = 0, c = 0\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
2. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 0, b_1 = 0, c = 1\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
3. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 0, b_1 = 1, c = 0\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
4. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 0, b_1 = 1, c = 1\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
5. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 1, b_1 = 0, c = 0\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
6. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 1, b_1 = 0, c = 1\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
7. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 1, b_1 = 1, c = 0\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$,
8. $\Pr_{r_\mathcal{S}, r_\mathcal{R}}(\mathbf{comm}(\langle b_0 = 1, b_1 = 1, c = 1\rangle, \langle r_\mathcal{S}, r_\mathcal{R}\rangle) = comm)$.

The receiver's privacy property implies that the terms (1) and (2) are equal, (3) and (4) are equal, (5) and (6) are equal, and (7) and (8) are equal (since each of these four pairs of events differs only in the value of c). The sender's privacy property implies that the terms (1) and (3) are equal, (5) and (7) are equal, (2) and (6) are equal, and (4) and (8) are equal (since each of these four pairs of events differs only in the value of b_{1-c}). All together, we get that the eight probabilities are equal, as desired. □

5. A completeness theorem for multiparty boolean black-box reductions. In this section we state the main theorem and provide its proof. It is based on a protocol that can tolerate $n-1$ honest-but-curious players, assuming the existence of an OT channel between each pair of players. Such protocols appear in [GMW-87, GHY-87, GV-87, K-88, BG-89, GL-90] (these works deal also with malicious players). That is, by these works we get the following lemma. (For self-containment, both a protocol and its proof of security appear in the appendix.)

LEMMA 5.1. *Given OT channels between each pair of players, any n-argument function f can be computed n-privately (in time polynomial in the size of a boolean circuit for f).*

We are now ready to state our main theorem.

THEOREM 5.2 (main). *Let $n \geq 2$ and let g be an n-argument boolean function. The function g is complete if and only if it is* not *n-private.*

Proof.
($\Longrightarrow$) First, we show that any complete g cannot be n-private. Toward the contradiction let us assume that there exists such a function g, which is n-private and complete. This implies that all functions are n-private (as instead of using the black box g the players can evaluate g by using the n-private protocol for g). This, however, contradicts the results of [BGW-88, CKu-89] that show the existence of functions that are *not* n-private.
($\Longleftarrow$) Next (and this is where the bulk of the work is) we show how to compute any function n-privately, given a black box for any g that is not n-private. Recall that there exists a protocol that can tolerate $n-1$ honest-but-curious players, assuming the existence of OT channels (Lemma 5.1). Also, we have shown how a black box, computing *any* nonprivate function, can be used to simulate OT channels (Lemmas 4.2 and 4.3). Combining these we get the result. ∎

The theorem implies that "most" boolean functions are complete. That is, any boolean function that is not of the XOR-form of [CKu-89] is complete (see facts 1 and 2 in section 3).

6. Conclusions and further extensions.

6.1. Nonboolean functions. We have shown that *any* non-n-private boolean function g is complete. Namely, a black box for such a function g can be used for computing any function f n-privately. Let us now briefly turn our attention to nonboolean functions. First, we emphasize that if a function g contains an embedded-OR, then it is still complete even if it is nonboolean (all the arguments go through as they are; in particular note that Definitions 3.1 and 3.2 of embedded-OR apply for the nonboolean case as well). However, in the nonboolean case, not all nonprivate functions contain an embedded-OR and so their completeness does not necessarily follow.

PROPOSITION 6.1. *For every $n \geq 6$, there exists a (nonboolean) n-argument function g that is not n-private, yet such that g is* not *complete.*

Proof. In [CGK-92] it is shown that nonboolean functions form a "privacy hierarchy." That is, for every n and for every t such that $\lceil n/2 \rceil \leq t \leq n-2$, there exists a (nonboolean) n-argument function that is t-private but not $(t+1)$-private. Fix some t such that $\lceil n/2 \rceil < t \leq n-2$ (since $n \geq 6$, such t exists). By the above-mentioned result of [CGK-92], there exists an n-argument function g that is t-private and is not $(t+1)$-private (in particular, g is not n-private). However, such a function g cannot be complete since this would imply that every n-argument function is t-private which, again by [CGK-92], is not the case. ∎

The above proposition can be strengthened so that it applies to all $n \geq 2$ as follows: It is known that there are nonprivate two-argument functions that do not contain an embedded-OR. Examples of such functions were shown in [Ku-89] (see Table 6.1). We claim that with no embedded-OR one cannot compute the OR function. Assume, toward a contradiction, that there is some two-argument function f that does not have an embedded-OR, yet it could be used to compute the OR function. Since f can be used to compute the OR function, we can use it to implement OT (Lemma 4.2). Hence, there exists an implementation of OT based on some f that

Table 6.1
A nonprivate function which does not contain an embedded-OR.

	y_1	y_2	y_3
x_1	0	0	1
x_2	2	4	1
x_3	2	3	3

does not have an embedded-OR. However, [K-91] has shown that for two-argument functions, only the ones that contain an embedded-OR can be used to implement OT, deriving a contradiction. For n-argument functions ($n > 2$), notice that if we take a two-argument function g that is not 1-private and is also not complete, and we define an n-argument function $\hat{g}$ that depends only on its first two arguments by $\hat{g}(x_1, x_2, \ldots, x_n) = g(x_1, x_2)$, the resulting function $\hat{g}$ is not n-private yet it is not complete.

To conclude, we have shown that for the boolean case, the notions of completeness and privacy are *exactly complementary*, while for the nonboolean case they are *not*.

6.2. Additional remarks. In this section, we briefly discuss some possible extensions and easy generalizations of our results.

The first issue that we address is the need for the protocol to specify the permutation π_i that is used in each round i (for mapping the players to the arguments of the black box g). Note that in our construction, we use the black box only for computing the OR function on two arguments. For this, we need to map some two players P_k and P_ℓ, holding these two arguments to the special coordinates i, j guaranteed by the definition of embedded-OR. Therefore, without loss of generality, the sequence of permutations can be made oblivious (i.e., independent of the function f computed) at a price of $O(n^2)$ multiplicative factor to the rounds (and time). Moreover, at a price of $O(n^4)$ the sequence of permutations can even be made *independent* of the non-n-private function g. Finally, note that if g is a symmetric function (which is often the "interesting" case), then there is no need to permute the inputs to g.

Next, we recall the assumption that the number of arguments of g is the same as the number of arguments of f (i.e., n). Again, it follows from our constructions that this is not essential to any of our results: all that is needed is the ability for the two players P_k, P_ℓ that wish to compute the OR function in a certain step to do so by providing the two distinguished arguments i, j for g, and all the other (fixed) arguments can be provided by arbitrary players (e.g., all of them by P_1).

Finally, we note that the negative result of [CKu-89] allows a probability of error; hence, even a weaker notion of reduction that allows for errors in computing f does not change the family of complete functions. This impossibility result (i.e., first direction of the main theorem) still holds even if we allow the players to communicate not only using the black box but also using other types of communication such as point-to-point communication channels.

6.3. Open questions. The above results can be easily extended to show that any boolean g that is complete can also be used for a private computation of any *multioutput* function f (i.e., a function whose output is an n-tuple $(y_1, \ldots, y_n)$, where y_i is the output that should be given to P_i). This is so because Lemma 5.1 still holds. On the other hand, it is an interesting question to characterize the multioutput functions g that are complete (even in the boolean case where each output of g is in $\{0, 1\}$).

It is not clear how to extend the model and the results to the case of malicious players in its full generality. Notice, however, that under the appropriate definition of the model, if we are given as a black box the two-argument OR function, we can still implement private channels (see [KMO-94] for details), and hence by [BGW-88, CCD-88] can implement any f $n/3$-privately with respect to malicious players.

Suppose that we relax the notion of privacy to computational privacy (as in [Yao-82, GMW-87]). In such a case, any computationally n-private implementation of an (information-theoretically) non-n-private (equivalently, complete) boolean function g implies the existence of a one-way function. This is so since we have shown that such an implementation of g implies an implementation of OT, which in turn implies the existence of a one-way function by [IL-89]. However, the best-known implementation of such protocols for a function g as above requires *trapdoor* one-way permutations [GMW-87]. It is an important question whether there exists an implementation based on a one-way function (or permutation) for functions without a trapdoor. This question has only some partial answers. In particular, when one of the players has super-polynomial power, this is possible [OVY-91]. However, if we focus on polynomial-time players and protocols, then the result of our paper together with the work of [IR-89] implies that for all *complete* functions, if we use only black-box reductions, this is as difficult as separating $\mathcal{P}$ from $\mathcal{NP}$. Thus, using black-box reductions, *complete* functions seem to be hard to implement (with computational privacy) without a trapdoor property. Notice, however, that for nonboolean functions we have shown that there are functions that are not n-private and not complete. It is not known even if these functions can be implemented without using a trapdoor (the impossibility results of [IR-89] do not apply to this case).

Appendix. n-private protocols using embedded-OT channels. In this appendix, we present an n-private protocol that uses OT channels to compute an arbitrary n-argument function f. Our starting point is the protocol presented in [GMW-87, GHY-87, GV-87, GL-90, BG-89], which also deals with malicious players. Here we assume that players are honest. This enables us to use a simplified version of the protocol and prove Lemma 5.1.

Proof. The protocol goes as follows: given a circuit with addition and multiplication mod 2 gates that computes the function f, the players do the following. (All arithmetic operations in this protocol are modulo 2.)

1. *Sharing the inputs*: Each player P_i shares each bit $x_{i,k}$ of its input x_i by choosing, uniformly, at random a vector $(a_1^{i,k}, \ldots, a_n^{i,k})$ such that $\sum_{j=1}^{n} a_j^{i,k} = x_{i,k}$. Each such $a_j^{i,k}$ is called a *share* of the secret $x_{i,k}$. The player P_i sends the share $a_j^{i,k}$ to P_j (over their common private channel[9]).
2. *Evaluating the function*: The evaluation of the function is done in a bottom-up fashion. Each gate $c = a \circ b$ is evaluated using the shares corresponding to the inputs a and b of the gate. The evaluation of each gate ends with each player P_i holding a share c_i of the gate's output c, where the vector of shares $(c_1, \ldots, c_n)$ is uniformly distributed among the vectors whose sum is c. We distinguish between two cases according to the operation in the gate:
   - $c = a + b$: P_i computes its share of c by summing its shares of a and b, i.e., $c_i = a_i + b_i$. (No interaction is needed.)

[9]Note that, given an OT channel (as constructed in section 4.2), a private channel is easy to implement: for $\mathcal{S}$ to send a bit b to $\mathcal{R}$ it duplicates its bit twice, $\mathcal{R}$ chooses a selection bit arbitrarily, and they execute their OT protocol.

- $c = ab$: Note that $a \cdot b = (\sum_{i=1}^n a_i) \cdot (\sum_{j=1}^n b_j) = \sum_{1 \le i,j \le n} a_i \cdot b_j$. Each player P_i can compute (locally) $a_i b_i$. (However, if player P_i knew $a_i \cdot b_j$ (for $j \neq i$), it might be able to compute b_j, violating the privacy requirement.) Instead, we let P_i and P_j interact in a two-party protocol, so that at the end P_i will know $v_{i,j} \overset{\triangle}{=} (a_i \cdot b_j) - r_{i,j}$ and P_j will know $r_{i,j}$, where $r_{i,j}$ is a random bit (and so $v_{i,j} + r_{i,j}$ equals $a_i \cdot b_j$). This is done by letting P_j choose $r_{i,j}$ at random. Then, P_i receives from P_j, via their common OT channel, the a_ith element of the pair of values $((0 \cdot b_j) - r_{i,j}, (1 \cdot b_j) - r_{i,j})$ (this pair can be easily computed by P_j). Clearly, this element is exactly $(a_i \cdot b_j) - r_{i,j}$, as desired. As they use the OT channel, P_j has no idea which value P_i selected. We repeat this two-party protocol for each pair P_i, P_j. Each player computes $c_i = a_i \cdot b_i + \sum_{j \neq i} v_{i,j} + \sum_{j \neq i} r_{j,i}$. It can be verified that $c = \sum_{i=1}^n c_i$.

3. *Revealing* $f(x_1, \ldots, x_n)$. Each player P_i broadcasts its share of the output gate of the circuit. The sum of these shares is the desired value.

In the claims below, we verify (inductively) that during the computation, each vector of shares has the required sum and that the distribution in any proper subset of the shares is uniform. In addition, the interaction gives no information about previously computed shares. These properties give the correctness and privacy of the protocol.

Let $\mathbf{View}_f(T, \langle x_i \rangle, \langle R_i \rangle_{i \in T})$ denote the view that the set of players (coalition) T has on the communication in the above protocol for computing f, given that each player P_i ($1 \le i \le n$) has input x_i and that each player P_i in T has random string R_i. This is a random variable that is determined by the choice of random strings R_i for all players P_i not in T. We include in this view only messages that go from players in $\bar{T}$ to players in T. (Note that these messages together with the inputs and random strings of players in T completely define the messages sent among players in T and also messages sent from players in T to players in $\bar{T}$.) Similarly, $\mathbf{View}_C(T, \langle a_i, b_i \rangle, \langle R_i \rangle_{i \in T})$ denotes the view of T in a subprotocol evaluating a (multiplication) gate C (whose inputs a and b are shared by $(a_1, \ldots, a_n)$ and $(b_1, \ldots, b_n)$, respectively).

In the above protocol there is no communication for addition gates. Hence the view consists only of messages received during the sharing stage, during the evaluation of multiplication gates, and during the revealing stage. The first claim says that in a single evaluation of a multiplication gate no information is revealed.

Claim A.1. *Consider the subprotocol evaluating a multiplication gate C that computes a value $c = ab$. For every coalition T, for all sets of shares $(a_1, \ldots, a_n)$ $(b_1, \ldots, b_n)$ that are the input for this subprotocol (i.e., $\{a_i, b_i\}$ is the input for player P_i), for all choices of random strings for players in T, $\langle R_i \rangle_{i \in T}$, and for all communication $comm \in \{0,1\}^s$, where $s = |T|(n - |T|)$, we have*

$$\Pr[\mathbf{View}_C(T, \langle a_i, b_i \rangle, \langle R_i \rangle_{i \in T}) = comm] = 2^{-s},$$

where the probability goes over all choices of R_i for $i \in \bar{T}$.

Proof. The communication that goes from $\bar{T}$ to T during the evaluation of a multiplication gate C is as follows: for every $i \in T$ and $j \in \bar{T}$ the players P_i, P_j jointly "compute" $a_i b_j$ and $a_j b_i$. In computing $a_j b_i$ the player P_i does not get any message (its role is to pick a random $r_{j,i}$ and to send a message over their common OT channel). In computing $a_i b_j$ player P_i receives a one-bit message ($v_{i,j}$). Hence, the view of coalition T must be of size s. Moreover, as $r_{i,j}$ is chosen (by P_j) uniformly at random, then $v_{i,j}$ is also uniformly distributed in $\{0,1\}$ (independently of what a_i and b_j are). As all $r_{i,j}$'s are independent, the claim follows. $\square$

The next claim shows that at each stage of the computation the vector of shares is uniformly distributed. This is particularly important in the revealing stage, when we need to be sure that only the output is revealed.

CLAIM A.2. *Let $x_1, \ldots, x_n$ be an input to the protocol (i.e., x_i is the input for player P_i). Let C be a gate in the circuit and let c be the value of this gate when the input for the circuit is $x_1, \ldots, x_n$. Let $\vec{C}$ be a vector of shares that represents c in the above protocol. Then,*

- *$\sum_{i=1}^{n} C_i = c$ (correctness); and*
- *$\vec{C}$ is uniformly distributed among the vectors whose sum is c (privacy), i.e., let $c_1, \ldots, c_n$ satisfy $\sum c_i = c$ (there are 2^{n-1} such vectors). Then $\Pr[\vec{C} = (c_1, \ldots, c_n)|\vec{x}] = 1/2^{n-1}$.*

Proof. The first part easily follows from the description of the protocol, by induction. The second part is also proved by induction. The claim is certainly true after the sharing stage (as this is the way the shares are chosen). Now suppose we evaluate a gate. If the gate is an addition gate, computing $C = A + B$, then

$$\begin{aligned}\Pr[\vec{C} &= (c_1, \ldots, c_n)|\vec{x}] \\ &= \sum_{a_1, \ldots, a_n; \sum a_i = A} \Pr[\vec{A} = (a_1, \ldots, a_n)|\vec{x}] \cdot \Pr[\vec{B} = (c_1 - a_1, \ldots, c_n - a_n)|\vec{x}] \\ &= 2^{n-1} \frac{1}{2^{n-1}} \frac{1}{2^{n-1}} = \frac{1}{2^{n-1}}.\end{aligned}$$

If the gate computes $C = A \cdot B$, then we can fix $\vec{A} = (a_1, \ldots, a_n)$ and $\vec{B} = (b_1, \ldots, b_n)$ and now show that for any such fixed choice $\vec{C}$ still satisfies the requirement. In particular, it suffices to show (by induction on i) that the probability that $C_1 = c_1, \ldots, C_i = c_i$ for $i \leq n-1$ is $1/2^i$. To do so, we consider the bits $r_{i,j}$ $(j \neq i)$ and $r_{j,i}$ $(j \neq i)$ and assign random values to each of them (that were not assigned values so far). At least one of those random bits (e.g., $r_{n,i}$) is still "free." This implies that c_i will be uniformly distributed (as $r_{n,i}$ is one of the summands that construct c_i). Clearly, when we consider C_n, all the random bits already have values and hence the value of C_n is already determined. $\square$

We now turn to the proof of the privacy of the whole protocol.

CLAIM A.3. *For every coalition T (of size $1 \leq |T| \leq n-1$), for all input $x_1, \ldots, x_n$, for all choices of random strings for players in T, $\langle R_i \rangle_{i \in T}$, and for all possible communication comm,*[10]

$$\Pr[\mathbf{View}_f(T, \langle x_i \rangle, \langle R_i \rangle_{i \in T}) = comm] \quad = \quad 2^{-d}$$

for $d = |T| \cdot n_{\bar{T}} + m \cdot |T| \cdot (n - |T|) + (n - |T| - 1)$, where m is the number of multiplication gates in the circuit for f and $n_{\bar{T}}$ is the number of inputs for the circuit held by players in $\bar{T}$. (Again, the probability goes over all choices of R_i for $i \in \bar{T}$.)

Proof. In the sharing stage, each player in T receives a share (a bit) from each input to the circuit held by a player in $\bar{T}$ (by definition there are $n_{\bar{T}}$ such bits). The properties of the secret sharing guarantee that each of these bits is 0 with probability 1/2 and they are all independent. The evaluation of addition gates does not involve any communication. Claim A.1 guarantees that in the evaluation of any multiplication gate, no matter what are the shares that the players start with, the view of the

[10] A communication is *possible* for $x_1, \ldots, x_n$ if it is consistent with $f(x_1, \ldots, x_n)$.

players in T consists of a random string of length $|T|(n - |T|)$. Also, note that each of these evaluations makes use of new (independent) random bits. Finally, if $f_1, \ldots, f_n$ are the shares representing the outcome of the circuit, then by Claim A.2 this vector is uniformly distributed among the vectors whose sum equals $f(x_1, \ldots, x_n)$. Therefore, the players in T get in the revealing stage $n - |T|$ bits, which form $2^{n-|T|-1}$ combinations each with equal probability. Note that if $|T| = n - 1$, then in the revealing stage the players in T get only one bit, which is uniquely determined by $\vec{x}$. However, if $|T| < n - 1$, then the independence of the communication seen in the revealing stage and the communication seen in previous stages is guaranteed by the random bits $r_{i,j}$ for $i, j \in \bar{T}$. Combining all these we get the desired claim. ∎

COROLLARY A.4. *For every coalition T (of size $1 \leq |T| \leq n-1$), for all inputs $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$ such that $f(x_1, \ldots, x_n) = f(y_1, \ldots, y_n)$ and such that $x_i = y_i$ for all $i \in T$, for all choices of random strings for players in T, $\langle R_i \rangle_{i \in T}$, and for all communication comm,*

$$\Pr[\mathbf{View}_f(T, \langle x_i \rangle, \langle R_i \rangle_{i \in T}) = comm] \quad = \quad \Pr[\mathbf{View}_f(T, \langle y_i \rangle, \langle R_i \rangle_{i \in T}) = comm],$$

where the probability goes over all choices of R_i for $i \in \bar{T}$.

This completes the proof of Lemma 5.1. ∎

Acknowledgments. We wish to thank Oded Goldreich for helpful discussions and very useful comments. We thank Mihir Bellare for pointing out to us in 1991 that the works of Chor, Kushilevitz, and Kilian are complementary and thus imply a special case of our general result. Finally, we thank Amos Beimel and the anonymous referees for very helpful comments.

LOWER BOUNDS FOR ($\mathrm{MOD}_p - \mathrm{MOD}_m$) CIRCUITS[*]

VINCE GROLMUSZ[†] AND GÁBOR TARDOS[‡]

Abstract. Modular gates are known to be immune for the random restriction techniques of Ajtai (1983), Furst, Saxe, and Sipser (1984), Yao (1985), and Håstad (1986). We demonstrate here a random clustering technique which overcomes this difficulty and is capable of proving generalizations of several known modular circuit lower bounds of Barrington, Straubing, and Thérien (1990), Krause and Pudlák (1994), and others, characterizing symmetric functions computable by small ($\mathrm{MOD}_p, \mathrm{AND}_t, \mathrm{MOD}_m$) circuits.

Applying a degree-decreasing technique together with random restriction methods for the AND gates at the bottom level, we also prove a hard special case of the constant degree hypothesis of Barrington, Straubing, and Thérien (1990) and other related lower bounds for certain ($\mathrm{MOD}_p, \mathrm{MOD}_m, \mathrm{AND}$) circuits.

Most of the previous lower bounds on circuits with modular gates used special definitions of the modular gates (i.e., the gate outputs one if the sum of its inputs is divisible by m or is *not* divisible by m) and were not valid for more general MOD_m gates. Our methods are applicable, and our lower bounds are valid for the most general modular gates as well.

Key words. lower bounds, modular gates, composite modulus

1. Introduction.

Boolean circuits are perhaps the most widely examined models of computation. They gain application in diverse areas as VLSI design, complexity theory, and the theory of parallel computation.

A majority of the strongest and deepest lower bound results for computational complexity were proved using the Boolean circuit model of computation (for example, [12], [16], [8], [13], [14], or see [4] for a survey).

Unfortunately, lots of questions, even for very restricted circuit classes, have been unsolved for a long time.

Bounded depth and polynomial size is a natural restriction. Ajtai [1] and Furst, Saxe, and Sipser [6] proved that no polynomial sized, constant-depth circuit can compute the PARITY function. Yao [16] and Håstad [8] generalized this result for sublogarithmic depths. Their technique involved a sophisticated use of *random restriction techniques*, in which randomly assigned 0-1 values to the input variables fixed the output of large fan-in AND and OR Boolean gates.

Since the modular gates are very simple to define, and they are immune to the random restriction techniques in lower bound proofs for the PARITY function, the following natural question was asked by Barrington, Smolensky and others: How powerful will the Boolean circuits be if, beside the standard AND, OR, and NOT gates, MOD_m gates are also allowed in the circuit? Here, a MOD_m^A gate outputs 1 if the sum of its inputs is in a set $A \subset \{0, 1, 2, \ldots, m-1\}$ modulo m.

Razborov [13] showed that for computing MAJORITY with AND, OR, NOT, and MOD_2 gates, exponential size is needed with constant depth. This result was generalized by Smolensky [14] for MOD_p gates instead of MOD_2 gates, where p denotes a prime.

We know very little, however, if both MOD_p and MOD_q gates are allowed in the circuit for different primes p, q, or if the modulus is a nonprime power composite, e.g., 6. For example, it is consistent with our present knowledge that depth-3, linear-sized circuits with MOD_6 gates *only* recognize an NP-complete language (see [2]).

It is not difficult to see that constant-depth circuits with MOD_p gates only (p prime) cannot compute even very simple functions—the n-fan-in OR or AND functions—since they can compute only constant degree polynomials of the input variables over GF_p (see [14]).

But depth-2 circuits with MOD_2 and MOD_3 gates or MOD_6 gates can compute the n-fan-in OR and AND functions [9], [2]. Consequently, these circuits are more powerful than circuits with MOD_p gates only. The sketch of the construction is as follows: we take a MOD_3 gate at the top of the circuit and 2^n MOD_2 gates on the next level, where each subset of the n input variables is connected to exactly one MOD_2 gate, and then this circuit computes the n-fan-in OR, since if at least one of the inputs is 1, then exactly half of the MOD_2 gates evaluate to 1.

Barrington, Straubing, and Thérien [2] conjectured that any $(\mathrm{MOD}_p^B, \mathrm{MOD}_m^A, \mathrm{AND}_d)$ circuit needs exponential size to compute the n-fan-in AND function, where the prime p and the positive integers m and d are fixed and AND_d denotes the fan-in d AND function. They called it the *constant degree hypothesis* (CDH) and proved the $d = 1$ case, with highly nontrivial algebraic techniques. Their proof also works for depth-$(\ell + 1)$

$$(\overbrace{\mathrm{MOD}_{p^k}^B, \mathrm{MOD}_{p^k}^B, \ldots, \mathrm{MOD}_{p^k}^B}^{\ell}, \mathrm{MOD}_m^A) \tag{1.1}$$

circuits, computing the AND function.

Yan and Parberry [15], using Fourier-analysis, also proved the $d = 1$ case for $(\mathrm{MOD}_p^{\{1,2,\ldots,p-1\}}, \mathrm{MOD}_2^{\{1\}})$ circuits, but their method also works for the special case of the CDH where the sum of the degrees of the monomials g_i on the input-level satisfies

$$\sum_{\deg(g_i)\geq 1} (\deg(g_i) - 1) \leq \frac{n}{2(p-1)} - O(1).$$

Krause and Waack [11] applied communication-complexity techniques to show that any $(\mathrm{MOD}_m^{\{1,2,\ldots,m-1\}}, \mathrm{SYMMETRIC})$ circuit, computing the ID function

$$\mathrm{ID}(x, y) = \begin{cases} 1 \text{ if } x = y, \\ 0 \text{ otherwise} \end{cases}$$

for $x, y \in \{0, 1\}^n$, should have size at least $2^n / \log m$, where SYMMETRIC is a gate, computing an arbitrary symmetric Boolean function. Since (non-weighted) MOD_m gates are also SYMMETRIC gates, this lower bound is valid for $(\mathrm{MOD}_m^{\{1,2,\ldots,m-1\}}, \mathrm{MOD}_m^A)$ circuits. When mod m coefficients (or multiple wires) are allowed on the input-level, then the MOD_m gates are *not* SYMMETRIC gates, but the same proof techniques remain applicable. Caussinus [5] proved that the result of

[2] also implies a similar lower bound for the AND function. Unfortunately, results [11], [5] do not generalize for the more general MOD_m^A gates at the top.

Krause and Pudlák [10] proved that any $(\mathrm{MOD}_{p^k}^{\{0\}}, \mathrm{MOD}_q^{\{0\}})$ circuit which computes the $\mathrm{MOD}_r^{\{0\}}$ function has size at least 2^{cn}, for some $c > 0$, where p and r are different primes and q is not divisible by either of them.

Our main result is a characterization of those symmetric Boolean functions which are computable by quasi-polynomial-size

$$(\overbrace{\mathrm{MOD}_{p^k}^B, \mathrm{MOD}_{p^k}^B, \ldots, \mathrm{MOD}_{p^k}^B}^{\ell}, \mathrm{MOD}_m^A)$$

circuits. We prove (Theorem 2.5) that the *only* symmetric functions that are computable by such circuits are the MOD_{mp^j} functions with small j. Consequently, the nontrivial threshold functions (and thus also AND and OR) and the $\mathrm{MOD}_r^{\{0\}}$ functions if r does not divide $p^j m$ need exponential size on that circuits. Even MOD_4 requires exponential size $(\mathrm{MOD}_{3^r}, \mathrm{AND}_t, \mathrm{MOD}_2)$ circuits for constant t and r. Note the asymmetry: MOD_4 is easy to compute with a polynomial size $(\mathrm{MOD}_2, \mathrm{AND}_3)$ circuit. These results generalize the theorems of Barrington, Straubing, and Thérien [2] and Krause and Pudlák [10] and give a characterization of the computable symmetric functions, instead of singular lower bounds.

Grolmusz [7] generalized the results of [2], [15], [11], [10] for $(\mathrm{MOD}_q, \mathrm{MOD}_p, \mathrm{AND}_{cn})$ circuits, where the input-polynomials of each MOD_p gate are constructible from linear terms using at most $cn - 1$ multiplications (or, equivalently, can be computed by an arithmetic circuit of an arbitrary number of mod p additions and at most $cn-1$ fan-in 2 multiplications). In particular, one can allow the sum of *an arbitrary function* of cn variables and a linear polynomial of the n variables as inputs for each MOD_p gate. We generalize this result, too (Lemma 3.12). The main tool of the proof of [7] is a degree decreasing lemma, which we also generalize here for nonprime moduli (Lemma 3.9), and we use it both for lower and upper bound proofs.

Here we generalize the results of [7]: we prove a lower bound on the size of the $(\mathrm{MOD}_p, \mathrm{MOD}_m, \mathrm{AND})$ circuits computing AND_n if m is a positive integer, p is a prime, and each MOD_m gate has not-too-many AND gates as inputs and those AND gates have low fan-in. For the exact statement see Theorem 2.6. This is an important special case of the CDH of [2]. The lower bound also applies to circuits computing some other functions besides AND.

2. Our results.

2.1. Ideas. MOD_m gates are immune to random restriction techniques, since these gates remain MOD_m gates on the remaining variables after an arbitrary restriction, and thus (unless less than m variables remain unrestricted) the complexity does not decrease.

We overcome this difficulty by a *random clustering* technique, which forces some randomly chosen variables to be equal. Each equivalence class (or cluster) will make a new variable of the MOD_m gate, and each new variable will be invisible (i.e., its coefficient will be a multiple of m) for the gate with a constant probability (Lemma 3.4).

We use this for $(\mathrm{MOD}_p, \mathrm{AND}_t, \mathrm{MOD}_m)$ circuits, computing symmetric functions. Suppose that the equivalence classes are of size m; then the resulting function of the new, clustered variables is a unique symmetric function.

Almost all symmetric functions (except the $\mathrm{MOD}_{p^k m}$ functions) have large restrictions, whose unique factor resulting from the clustering above cannot be expressed as a modulo p sum of functions, none of which depends on all variables. An exponential lower bound follows for the number of AND gates on level 2 (Theorem 2.4).

If we have $o(n^2/\log n)$ constant-degree monomials as inputs for each MOD_m gates on level 2, then by random restrictions, one can essentially decrease their number, and a small number of low-degree monomials can be converted to linear polynomials with the help of the degree-decreasing lemma (Lemma 3.9), and we can apply Theorem 2.4 to get lower bounds. (Theorem 2.6)

2.2. Preliminaries.

Definition 2.1. *A fan-in n gate is an n-variable Boolean function. Let $G_1, G_2, \ldots, G_\ell$ be gates of unbounded fan-in. Then a $(G_1, G_2, \ldots, G_\ell)$-circuit denotes a depth-ℓ circuit with a G_1-gate on the top, G_2 gates on the second level, G_3 gates on the third level from the top,..., and G_ℓ gates on the last level.* AND_t *denotes the fan-in t* AND *gate. The size of a circuit is defined to be the total number of the gates in the circuit.*

All of our modular gates are of unbounded fan-in, and we allow for connecting inputs to gates or gates to gates with multiple wires. Note that, by this definition, our modular gates are not symmetric gates in general.

In the literature MOD_m gates are sometimes defined to be 1 iff the sum of their inputs is divisible by m, and sometimes they are defined to be 1 iff the sum of their inputs is not divisible by m. The following, more general definition covers both cases.

Definition 2.2. *We say that gate G is a* MOD_m-gate *if there exists $A \subset \{0, 1, \ldots, m-1\}$ such that*

$$G(x_1, x_2, \ldots, x_n) = \begin{cases} 1 & \textit{if } \sum_{i=1}^n x_i \bmod m \in A, \\ 0 & \textit{otherwise.} \end{cases}$$

A is called the 1*-set of G.* MOD_m *gates with* 1*-set A are denoted by* MOD_m^A.

Notation 2.3. *Let* $\Sigma_p(x_1, x_2, \ldots, x_s) = \sum_{i=1}^s x_i \bmod p$.

In general, Σ_p is not a Boolean gate, since its value is from $\{0, 1, \ldots, p-1\}$. However, in all of our statements, its value will be guaranteed to be 0 or 1.

2.3. Theorems. Here we list the three main results of this paper. To be concise we use $((\mathrm{MOD}_{p^k}^B)^\ell, \mathrm{MOD}_m^A)$ to denote circuits of type (1.1). Note that standard techniques (see Lemma 3.2) show that these circuits are equivalent to $(\sum_p, \mathrm{AND}_t, \mathrm{MOD}_m^A)$ circuits, and we could have stated Theorems 2.4 and 2.5 for those circuits instead.

Theorem 2.4. *Suppose that a circuit of type $((\mathrm{MOD}_{p^k}^B)^\ell, \mathrm{MOD}_m^A)$ with p prime computes a symmetric Boolean function f on n variables, such that $f \neq \mathrm{MOD}_{p^j m}^A$ for any A. Then its size S is exponential in p^j; i.e., there exists a number $c > 1$ depending on p, m, k, and ℓ such that $S > c^{p^j}$.*

As a special case we get that the size S of an n-variable circuit of type $((\mathrm{MOD}_{p^k}^B)^\ell, \mathrm{MOD}_m^A)$ with p prime computing any of the nontrivial threshold functions (including AND *and* OR*) or the $\mathrm{MOD}_r^{\{0\}}$ function (where r does not divide mp^j for any j) is exponential in n. We have $S > c^n$ for a number $c > 1$ depending only on p, m, k, and ℓ.*

Theorem 2.5. *Let the prime p and the positive integers m, k, and ℓ be fixed with m not a power of p. The symmetric functions computed by a type $((\mathrm{MOD}_{p^k}^B)^\ell, \mathrm{MOD}_m^A)$*

circuit of quasi-polynomial size are exactly the functions $\mathrm{MOD}^C_{mp^j}$ *with* $j = O(\log\log n)$ *and* $C \subset \{0, 1, \ldots, mp^j - 1\}$.

On the other hand, all the functions $\mathrm{MOD}^C_{mp^j}$ *with* $j = O(\log\log n)$ *can be computed by quasi-polynomial size* $(\sum_p, \mathrm{AND}_2, \mathrm{MOD}_m)$ *circuits.*

Our final result proves a special case of the CDH.

THEOREM 2.6. *Let* p *be prime and* m *a fixed positive integer. Suppose that a* $(\mathrm{MOD}^B_p, \mathrm{MOD}^A_m, \mathrm{AND})$ *circuit computes* AND_n. *If each* MOD_m *gate has fan-in* $o(n^2/\log n)$ *and each* AND *gate has constant fan-in, then the size of the circuit is super-polynomial.*

We remark that this result is a consequence of the tradeoff between the size of $(\Sigma_p, \mathrm{MOD}_m, \mathrm{AND})$ circuits computing AND and a new measure introduced here, the number of pairs of input variables the MOD_m gates relate (see Theorems 3.13 and 3.14). Note that similar bounds can be proved for circuits computing many other natural functions, like threshold or MOD_r functions.

3. The proofs.

3.1. Eliminating the top gate.

The top-gate elimination is widely used in the literature (cf. [10, Lemma 5.2] or [3]). It replaces the top MOD_{p^r} gate with constant fan-in AND gates and a simple summation modulo p with a polynomial increase in the size.

LEMMA 3.1. *Let* p *be a prime,* k *a positive integer, and* $A \subset \{0, 1, \ldots, p^k - 1\}$. *There is a modulo* p *polynomial of degree* $p^k - 1$ *computing the* $\mathrm{MOD}^A_{p^k}$ *function.* □

One can repeatedly use this lemma to eliminate a constant-depth subcircuit of MOD_{p^r} gates from the top of any circuit, as stated by the next lemma.

LEMMA 3.2. *Suppose that* $f : \{0, 1\}^n \to \{0, 1\}$ *is computed by a depth-*$(\ell + 1)$

$$(\overbrace{\mathrm{MOD}^A_{p^k}, \ldots, \mathrm{MOD}^A_{p^k}}^{\ell}, G)$$

circuit, where p *is a prime and on the input level we have arbitrary gates (or subcircuits)* G. *Suppose the number of these gates* G *is* S. *Then* f *can also be computed from the same gates* G *by a* $(\Sigma_p, \mathrm{AND}_t, G)$ *circuit, with* $t < p^{k\ell}$ *and at most* $S^{p^{k\ell}}$ AND_t *gates on the middle level.*

Proof. By Lemma 3.1 all $\mathrm{MOD}^A_{p^k}$ can be replaced by a modulo p polynomial of degree less than p^k; thus f is degree $< p^{k\ell}$ polynomial of the output of the G gates. The bound on the size comes from counting all the possible monomials in such a polynomial. □

Note that the size of the new circuit is still polynomial in S, and the fan-in of the AND gates is constant if the depth ℓ and the modulus p^k are constants. Note also that AND_t gates with $t < p^k$ can be considered as special MOD_{p^k} gates, and thus AND_t gates can be eliminated the same way.

3.2. Random clustering.

DEFINITION 3.3. *Let* $\sim$ *be an equivalence relation on the variables of a function* f. *By the factor* $f/\!\sim$ *of* f *we mean the function obtained from* f *by identifying variables according to* $\sim$. *The variables of* $f/\!\sim$ *correspond to the equivalence classes of* $\sim$. *For an integer* m *we call the* $f/\!\sim$ *an* m*-factor of* f *if each equivalence class in* $\sim$ *consists of* m *variables.*

We say that the Boolean function f is p-simple (p is a positive integer) if it can be expressed as a modulo p sum of functions, none of which depend on all of the variables.

Example. Suppose that f has six variables, and $x_1{\sim}x_2, x_3{\sim}x_4, x_5{\sim}x_6$. Then $f/{\sim}$ is a 2-factor of f, has three variables, and is defined as

$$f/{\sim}(y_1, y_2, y_3) = f(y_1, y_1, y_2, y_2, y_3, y_3).$$

Notice that any factor of the AND function is again an AND function. The m-factor of a symmetric function is unique and it is also a symmetric function. Note that for prime numbers p a function f is p-simple iff it can be expressed as a modulo p polynomial of degree less than the number of its variables.

Implicitly, a random clustering technique was used in the paper of Krause and Pudlák [10]. However, our method gives stronger results more directly.

The following lemma is about a special type of three level circuits. It is stated in a more general way, but the reader may think of polynomial size, $(\sum_p, \mathrm{AND}_t, \mathrm{MOD}_m^A)$ circuits with constant t.

LEMMA 3.4. *Let p, m, and t be positive integers, $1 \geq \varepsilon > 0$, and suppose the Boolean function f on n variables satisfies $f \equiv \sum_{i=1}^{S} f_i \pmod p$, where each f_i is computed in an arbitrary way from t of the functions f_{ij} and from $(1-\varepsilon)n$ of the input variables. Each of the functions f_{ij} is in turn a modulo m linear combination of the input variables. Here the functions f_i output modulo p values while f_{ij} output modulo m values. If n is large enough and divisible by m and $S < c^n$, then there exists a p-simple m-factor of f, where the constant $c > 1$ depends only on m, t, and ε.*

Proof. The idea is to observe that $f_{ij}/{\sim}$ is a modulo m linear combination of its variables, and the coefficient of a variable, corresponding to an equivalence class in a random $\sim$, is equal to zero with a positive constant probability. Thus $f_i/{\sim}$ depends on all of its variables with exponentially small probability. Then, with high probability, all the functions $f_i/{\sim}$ have an invisible variable, and thus $f/{\sim}$ is p-simple.

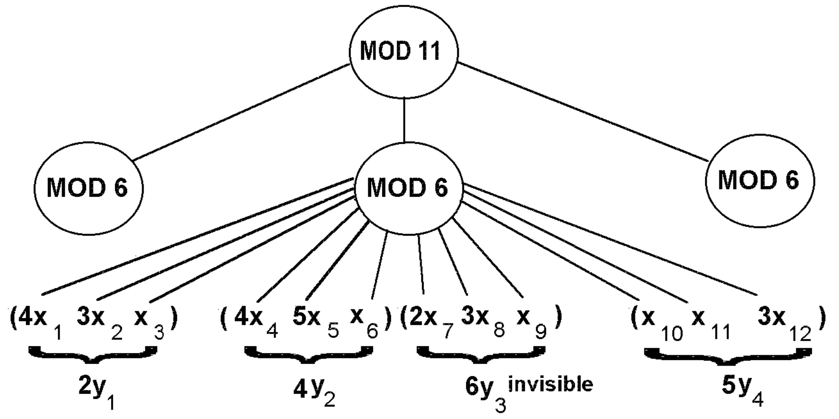

FIG. 3.1. *Random clustering in the simplest case: $t = 1, \varepsilon = 1$, and every f_{i1} is a* MOD_6 *gate.*

Let us choose $\sim$ uniformly at random from all the partitions of the variables into classes of size m. Consider choosing the equivalence classes one by one. Consider a fixed $1 \leq i \leq S$ and one of the first $\lceil \varepsilon n/(2m) \rceil$ classes. When we choose the variables of this class, there are less than $\varepsilon n/2$ variables already in previous classes and at most $(1-\varepsilon)n$ variables directly seen by f_i, so the set H of the remaining variables has at least $\varepsilon n/2$ elements. Each variable in H has a coefficient in each of the combinations f_{ij}. Let $(a_j)_{j=1}^t$ be a list of coefficients that are most popular, and call a variable in H good if its coefficient in f_{ij} is a_j for each value of j. There are at least $|H|/m^t \geq \epsilon n/(2m^t)$ good variables. When choosing the variables for our equivalence class each has a probability of at least $\epsilon/(2m^t)$ to be good. Despite the slight dependence among these events, the probability that each of them are good is still at least $(\epsilon/(4m^t))^m$ for large enough n. If this is the case, $f_i/{\sim}$ does not depend on the variable corresponding to this class, since f_i does not see it directly, and the coefficient of this variable in f_{ij} is $ma_j = 0 \bmod m$. Thus (using $(1-u)^k < e^{-uk}$) with probability at most $e^{-(\varepsilon n/(2m))\cdot(\varepsilon m^{-t}/4)^m}$ does $f_i/{\sim}$ depend on each of its variables. We choose $\ln c = (\varepsilon/4)^{m+1}/m^{tm+1}$. If $S < c^n$, then with positive probability none of the functions $f_i/{\sim}$ depend on all of the variables; consequently, $f/{\sim} \equiv \sum_{i=1}^S f_i/{\sim}$ $(\mathrm{mod}\ p)$ is p-simple. ∎

We remark here that the same proof gives that if S in the lemma is bounded by another exponential function of n, then a random m-factor of f can almost always be expressed as a modulo p sum of functions; none of the functions depends on an m^{-mt} fraction of their variables.

NOTATION 3.5. *Let $w(x)$ denote the weight of a zero-one vector x, i.e., the number of ones in x. Then $f(i)$ denotes the value of the symmetric Boolean function f on inputs of weight i.*

LEMMA 3.6. *Let p be a prime. If f is a symmetric Boolean function on p^k variables with $f(0) \neq f(p^k)$, then f is not p-simple.*

Proof. Notice that

$$\sum_{x\in\{0,1\}^n} (-1)^{w(x)} f(x) \equiv 0 \pmod p$$

for p-simple functions f. The left-hand side is zero for functions not depending on one of the input variables; thus it is divisible by p for a modulo p sum of such functions.

For a symmetric function on $n = p^k$ variables, the left-hand side of the last equation is

$$\sum_{i=0}^{n} (-1)^i \binom{n}{i} f(i) \equiv f(0) - f(n) \pmod p,$$

since p divides $\binom{p^k}{i}$ unless $i = 0$ or $i = p^k$. Thus $f(0) \neq f(n)$ implies that f has full p-degree as claimed. ∎

THEOREM 3.7. *Let p be a prime, m, t, k, and S positive integers, and $1 \geq \varepsilon > 0$. Suppose the symmetric Boolean function f on n variables is the modulo p sum of S of the functions f_i, where each of the f_i is computed in an arbitrary way from t of the functions f_{ij} and from $(1-\varepsilon)n$ of the input variables. Each of the functions f_{ij} is in turn a modulo m linear combination of the input variables. Here the functions f_i output modulo p values while f_{ij} output modulo m values. Suppose f is not equal to any MOD_{mp^k} gate. Then $S > c^{p^k}$ for a constant $c > 1$ depending only on m, t, and ε.*

Proof. Since f is not a MOD_{mp^k} gate, there exist numbers $0 \leq i < i + mp^k = j \leq n$ such that $f(i) \neq f(j)$. Restrict the function f by assigning 0 to $n - j$ of its variables and assigning 1 to i of them. The resulting function f' is a symmetric function of its mp^k variables satisfying $f'(0) \neq f'(mp^k)$. Notice that the restriction does not increase the size of the circuit computing the function. The unique m-factor of f' is a symmetric function f'' on p^k variables satisfying $f''(0) \neq f''(p^k)$. By Lemma 3.6, f'' is not p-simple. Thus Lemma 3.4 gives the claimed bound on S. ∎

We are ready now to prove Theorem 2.4.

Proof of Theorem 2.4. We apply Lemma 3.2 to get rid of the MOD_{p^k} gates and get a $(\sum_p, \mathrm{AND}_t, \mathrm{MOD}_m)$ circuit for our symmetric function. The size of the circuit blows up polynomially, i.e., it is bounded by S^b, where b and t depend on p, m, k, and ℓ. Then Theorem 3.7 bounds S. Notice that we did not use the feature of Theorem 3.7 that the middle gates can directly depend on many input variables.

The statement on the specific functions follows from the observation that every function mentioned there satisfies that it is not of the form $\mathrm{MOD}^A_{mp^j}$ unless $mp^j > n$. ∎

The following lemma nicely complements Theorem 3.7.

LEMMA 3.8. *Consider the Boolean function* $f(x_1, x_2, \ldots, x_n) = \mathrm{MOD}^A_{mp^k}(x_1, x_2, \ldots, x_n)$. *If m is not a power of the prime p, then f can be computed by a* $(\sum_p, \mathrm{AND}_2, \mathrm{MOD}_m)$ *circuit of size at most* $(mn)^{2p^{k'}}$, *where $p^{k'}$ is the largest power of p dividing mp^k.*

Notice that the assumption that m is not a power of p is necessary. Otherwise, if $m = p^\ell$, arbitrary size constant depth circuits of constant fan-in AND and arbitrary MOD_p and MOD_m gates could only compute Boolean functions expressible as constant degree modulo p polynomials, and that constant degree does not depend on k. Consequently, it cannot compute f, which is a degree-$(p^k - 1)$ polynomial.

Proof. Suppose first that all elements of the 1-set A are congruent to a single number a modulo m. There is a degree $p^{k'} - 1$ polynomial on the input computing $\mathrm{MOD}^A_{p^{k'}}$ modulo p (Lemma 3.1). This polynomial can be implemented by a modulo p sum of AND gates of at most $p^{k'} - 1$ variables. The number of AND gates is bounded by $n^{p^{k'}-1}$. Let q be prime factor of m different from p, and place a redundant $\mathrm{MOD}^{\{1\}}_q$ gate above each AND gate. Apply the degree decreasing lemma (Lemma 3.9) to replace each AND gate by a collection of at most $(2q)^{p^{k'}-2}$ MOD_q gates summing to the same value modulo p. First replace each MOD_q gate by a MOD_m gate computing the same function, then replace each MOD_m gate G by the AND of G and the $\mathrm{MOD}^{\{a\}}_m$ gate on all the inputs. The resulting circuit computes the AND of the $\mathrm{MOD}^{\{a\}}_m$ and the $\mathrm{MOD}^A_{p^{k'}}$ functions; thus it computes the $\mathrm{MOD}^A_{mp^k}$ function as desired.

To remove our assumption on A, notice that every set A can be decomposed into m sets A_i satisfying this assumption. The equation $\mathrm{MOD}^A_{mp^k} = \sum_i \mathrm{MOD}^{A_i}_{mp^k}$ proves the lemma. ∎

Consider the smallest $(\sum_p, \mathrm{AND}_t, \mathrm{MOD}_m)$ circuit computing the function $\mathrm{MOD}^{\{0\}}_{mp^j}$, and notice that the lower bound on the circuit size for this function in Theorem 3.7 is c^{p^j}, while the upper bound in Lemma 3.8 is $n^{c'p^j}$. The gap is too wide to characterize polynomial size circuits, but we can characterize quasi-polynomial-size circuits as in Theorem 2.5.

Proof of Theorem 2.5. Apply Lemma 3.2 as in Theorem 2.4 to eliminate the MOD_{p^k} gates. Use Theorem 3.7 and Lemma 3.8 to get the two sides of the characterization. ∎

3.3. The degree-decreasing lemma. Lemma 3.9 exploits a surprising property of (MOD$_s$, MOD$_m$)-circuits, which (MOD$_p$, MOD$_p$) circuits lack, since constant-depth circuits with MOD$_p$ gates and arbitrary size are only capable of computing constant-degree modulo p polynomials of the input. Here we generalize the original version [7] of the degree-decreasing lemma for nonprime moduli.

LEMMA 3.9 (degree-decreasing lemma). *Let p be a prime and $s, m > 1$ be integers, satisfying* $\gcd(s,p) = \gcd(s,m) = 1$. *Let x_1, x_2, x_3 be variables taking values from $\{0,1,\dots,p-1\}$, $x_1' \in \{0,1\}$. Then*

$$\mathrm{MOD}_p^A(x_1x_2 + x_3) \equiv H_0 + H_1 + \cdots + H_{p-1} + \beta \pmod{s}, \tag{3.1}$$

$$\mathrm{MOD}_m^A(x_1'x_2 + x_3) \equiv H_0' + H_1' + \beta' \pmod{s}, \tag{3.2}$$

where H_i abbreviates

$$H_i = \alpha \sum_{j=0}^{p-1} \mathrm{MOD}_p^A(ix_2 + x_3 + j(x_1 + (p-i)))$$

for $i = 0,1,\dots,p-1$; α is the multiplicative inverse of p modulo s: $\alpha p \equiv 1 \pmod{s}$; β is a positive integer satisfying $\beta = -|A|(p-1)\alpha \bmod s$; H_i' abbreviates

$$H_i' = \alpha' \sum_{j=0}^{m-1} \mathrm{MOD}_m^A(ix_2 + x_3 + j(x_1' + (m-i)))$$

for $i = 0,1$; and α' is the multiplicative inverse of m modulo s: $\alpha' m \equiv 1 \pmod{s}$; and β' is a positive integer satisfying $\beta' = -|A|\alpha \bmod s$.

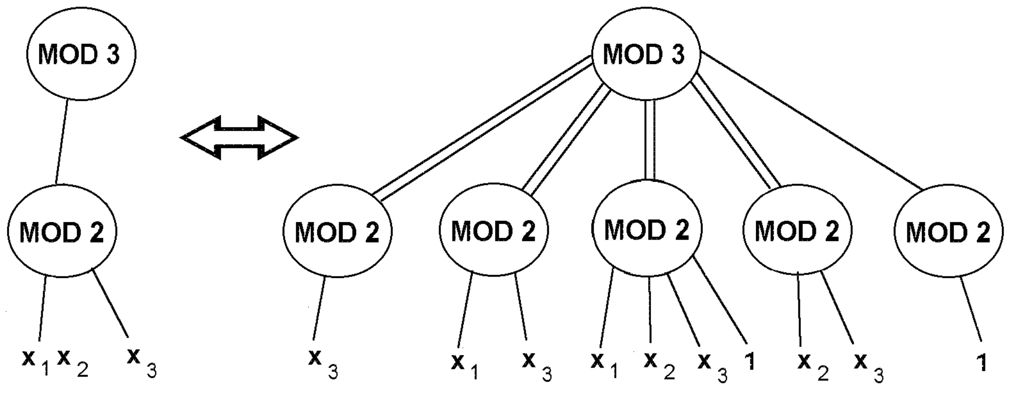

FIG. 3.2. *Degree decreasing in* (MOD$_3$, MOD$_2^{\{1\}}$) *case. On the left the input is a degree-2 polynomial, and on the right the input consists of linear polynomials.*

Proof. Let $x_1 = k$, and let $0 \le i \le p-1$, $k \ne i$. Then

$$H_k = \alpha \sum_{j=0}^{p-1} \mathrm{MOD}_p^A(kx_2 + x_3) = \alpha p \mathrm{MOD}_p^A(kx_2 + x_3) \equiv \mathrm{MOD}_p^A(x_1x_2 + x_3) \pmod{s}$$

and

$$H_i = \alpha \sum_{j=0}^{p-1} \mathrm{MOD}_p^A(ix_2 + x_3 + j(k-i)) = \alpha|A|,$$

since for any fixed x_2, x_3, i, k expression $kx_2+x_3+j(k-i)$ takes on every value exactly once modulo p while $j = 0, 1, \dots, p-1$; so $\mathrm{MOD}_p^A(ix_2+x_3+j(k-i))$ equals 1 exactly $|A|$ times. Consequently,

$$H_0 + H_1 + \cdots + H_{p-1} + \beta \equiv \mathrm{MOD}_p^A(x_1x_2+x_3) + (p-1)\alpha|A| + \beta \equiv \mathrm{MOD}_p^A(x_1x_2+x_3) \pmod{s}.$$

Similarly, let $x_1' = k \in \{0,1\}$, and let $i \in \{0,1\}$, $k \neq i$. Then

$$H_k' = \alpha' \sum_{j=0}^{m-1} \mathrm{MOD}_m^A(kx_2+x_3) = \alpha' m \mathrm{MOD}_m^A(kx_2+x_3) \equiv \mathrm{MOD}_p^A(x_1'x_2+x_3) \pmod{s}$$

and

$$H_i' = \alpha' \sum_{j=0}^{m-1} \mathrm{MOD}_m^A(ix_2 + x_3 + j(k-i)) = \alpha'|A|,$$

since for any fixed x_2, x_3, i, k, for $i \neq k$ $|i-k| = 1$, so expression $kx_2 + x_3 + j(k-i)$ takes on every value exactly once modulo m while $j = 0, 1, \dots, m-1$; so $\mathrm{MOD}_m^A(ix_2 + x_3 + j(k-i))$ equals 1 exactly $|A|$ times. Consequently,

$$H_0' + H_1' + \beta' \equiv \mathrm{MOD}_m^A(x_1'x_2+x_3) + \alpha'|A| + \beta' \equiv \mathrm{MOD}_p^A(x_1'x_2+x_3) \pmod{s}. \qquad \square$$

3.4. Random restriction. The CDH of [2] states that any $(\sum_p, \mathrm{MOD}_m, \mathrm{AND}_d)$ circuit computing AND has superpolynomial size if p is a prime and m and d are constants. We make progress toward this statement by proving Theorem 2.6 stating that AND requires superpolynomial size circuits of this type, if each MOD_m gate has fan-in $o(n^2/\log n)$. A stronger form of this statement (see Theorem 3.13) can be based on the following definition.

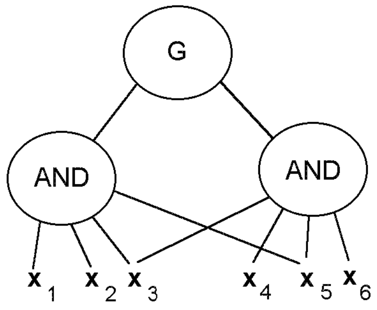

FIG. 3.3. *Gate G relates, e.g., x_1 and x_2 or x_3 and x_6 but does not relate x_1 and x_4.*

DEFINITION 3.10. *Let G be a gate of a circuit on the second level from the inputs computing some function of* AND*'s of variables. We say that G relates two input variables if they appear as inputs in a common* AND *gate below G.*

*We say that a gate G is H-*linear *if H is a subset of the input-variables, such that G does not relate two input variables outside H; i.e., the input of G is linear in the variables outside H with coefficients that are arbitrary functions of the variables in H. We call a gate ε-*linear *if it is H-linear with a set H containing at most an ε-fraction of all variables.*

We start with a simple application of the degree decreasing lemma (Lemma 3.9).

LEMMA 3.11. *Let p and m be relatively prime integers, and consider an n variable Boolean function f computed by a* (MOD_m^B, AND) *circuit, where the top* MOD_m^B *gate is H-linear. Then f can be computed by a* ($\sum_p$, MOD_m) *circuit with* $(2m)^{|H|}$ MOD_m *gates.*

Proof. We use induction on $|H|$. In the $|H| = 0$ case the AND gates have fan-in 1; thus they can be removed.

We can translate the AND gates to multiplications on the 0-1 variables. Consequently, the input of the MOD_m gate is a polynomial P of the input variables with all of its monomials having at most a single variable outside H. We may suppose that P is multilinear. If $x_i \in H$ for some $1 \leq i \leq n$, we can write this input in the form $P = Qx_i + R$, where the polynomials Q and R do not depend on x_i, and all their monomials contain at most a single variable outside H. We apply Lemma 3.9 to replace our MOD_m gate with the modulo p sum of $2m$ MOD_m gates. The inputs of these MOD_m gates are linear combinations of x_i, Q, and R. To finish the proof, we apply the inductive hypothesis with $H \setminus \{x_i\}$ to replace each of these new MOD_m gates with the modulo p sum of $(2m)^{|H|-1}$ MOD_m gates on the input variables. □

LEMMA 3.12. *Let the prime p and the positive integer m be fixed. Then there exist constants $c > 1$ and $\varepsilon > 0$ such that if a circuit* $((\mathrm{MOD}_{p^k}^A)^\ell, \mathrm{MOD}_m^B, \mathrm{AND})$ *computes* AND_n, *and every* MOD_m *gate is an ε-linear gate, then the size of the circuit is $S > c^n$.*

The proof of this lemma is simpler for the case when p is not dividing m. We need Theorem 3.7 in its full generality for the remaining case.

Proof. Suppose first that p does not divide m.

We apply Lemma 3.11 for the MOD_m gates. The resulting circuit computes a modulo p polynomial of degree less than $p^{k\ell}$ of the at most $S(2m)^{\varepsilon n}$ MOD_m gates (Lemma 3.2). The size is therefore at most $(S(2m)^{\varepsilon n})^{p^{k\ell}}$. But Theorem 2.4 claims an exponential lower bound on this size, thus for a small enough ε, size S must be exponential in n.

In the general case where p may divide m, we write $m = p^a m_0$ where p does not divide m_0. First we decompose each MOD_m^B gate into the sum of $\mathrm{MOD}_m^{\{b_i\}}$ gates for $B = \{b_1, b_2, \ldots, b_t\}$. Then $\mathrm{MOD}_m^{\{b_i\}}$ gates are converted to $\mathrm{MOD}_m^{\{0\}}$ gates, connecting bit 1 with multiple wires to the gate. Next, we exchange $\mathrm{MOD}_m^{\{0\}}$ gates to AND of the $\mathrm{MOD}_{m_0}^{\{0\}}$ and $\mathrm{MOD}_{p^a}^{\{0\}}$ gates. (We used a similar decomposition in the proof of Lemma 3.8.) We have increased the size of the circuit by a factor of at most $2m$ so far. We apply Lemma 3.11 to the MOD_{m_0} gates. This increases the size by a factor of at most $(2m)^{\varepsilon n}$. The resulting circuit has MOD_{m_0} and AND gates at the bottom level and MOD_{p^a}, MOD_p, $\sum_p$, and AND_2 gates everywhere else. As the last two types can be replaced with MOD_p gates, we can apply Lemma 3.2. We get a three level circuit computing AND_n with a $\sum_p$ gate on top and AND_t gates in the middle (with a constant t depending on m, p, k, and ℓ). The bottom gates are MOD_m and AND gates. Notice that the number S_2 of the gates in the middle level is at most S_1^t, where S_1 is the number of gates on the bottom level, and $S_1 \leq (2m)^{\varepsilon n+1}S$.

The fan-in of these bottom AND gates is bounded by $\varepsilon n+1$. We choose $\varepsilon < 1/4t$. Merging the bottom AND gates with the middle AND gates, one gets that AND_n is the modulo p sum of AND functions on at most $n/2$ inputs and at most t MOD_m gates. Applying Theorem 3.7, one gets that $S_2 > c^n$ with some $c > 1$ depending on p, m, k, and ℓ. Thus $S^t > c^n/(2m)^{t(\varepsilon n+1)}$ proving an exponential lower bound on S if $c > (2m)^{\varepsilon t}$. □

Now we turn to prove Theorem 2.6. It is a special case of the following result proving an optimal tradeoff between size and the new measure of the maximal number of related pairs.

THEOREM 3.13. *Let p be a prime and m, k, and ℓ positive integers. Suppose that a* $((\mathrm{MOD}^B_{p^k})^\ell, \mathrm{MOD}^A_m, \mathrm{AND})$ *circuit computes* AND_n. *If each* MOD_m *gate in the circuit relates at most $X \geq n$ pairs of input variables then the size of the circuit is at least $c_0^{n^2/X}$, with a constant $c_0 > 1$ depending on p, m, k, and ℓ.*

Proof. We fix the values c and ε claimed in Lemma 3.12. We take a restriction on the circuit by leaving a variable unrestricted with probability $P = \varepsilon n/(22X)$ independently for each of the variables. We assign 1 to the rest of the variables. Clearly, the restricted circuit computes the AND of the remaining variables.

With probability of at least 1/2, the number of the remaining variables is at least $n_0 = \lfloor Pn/2 \rfloor = \lfloor \varepsilon n^2/(44X) \rfloor$.

Exactly those pairs remained related in a MOD_m gate in the restricted circuit, whose both variables remained unrestricted.

The expected number of pairs related by a single gate in the restricted circuit is at most $XP^2 = \varepsilon n_0/11$. Unfortunately, the deviation can be large, it is easy to construct n gates, relating $n-1$ pairs each, such that *any* restriction to n' variables has a gate relating $n'-1$ pairs. Thus, it is important that, when using Lemma 3.12, we need not bound the number of related pairs, only the size of a set, covering each pair.

Lemma 3.12 easily implies the Theorem if there is a restriction leaving n_0 variables unrestricted, such that every MOD_m gate is ε-linear. In other words, for each G, we need the existence of a set H (depending on G) of size at most εn_0, which contains at least one of every pair related by G in the restricted circuit.

Let us bound the probability that this is not the case for a fixed MOD_m gate G. Take a maximal matching on pairs of unrestricted variables that are related by G. The set H of the endpoints of the matching-edges satisfies that no pair is related outside H, since otherwise, adding that pair to the matching would yield a larger matching. Thus it suffices to bound the probability that $|H| \geq \varepsilon n_0$, i.e., that all the variables involved in some $j = \lceil \varepsilon n_0/2 \rceil$ pairs of G-related variables forming a matching remain unrestricted. We bound this probability by the product of the number of choices for the matching and the probability that the variables remain unrestricted for a fixed matching. For a fixed gate G we get that the probability that at least n_0 variables remain unrestricted but G is not ε-linear after the restriction is at most $\binom{X}{j}P^{2j}$. Hence if $S\binom{X}{j}P^{2j} < 1/2$, where S is the size of our circuit, then Lemma 3.12 proves our theorem. The alternative is $S \geq (2\binom{X}{j}P^{2j})^{-1} \geq \left(\frac{j}{eXP^2}\right)^j$, which proves the same bound. □

Next we show that the logarithmic order of magnitude of the bound in Theorem 3.13 is tight.

THEOREM 3.14. *If m is not a power of the prime p, and $X > 0$ is arbitrary, then the n variable* AND *function is computable by a* $(\sum_p, \mathrm{MOD}_m, \mathrm{AND})$ *circuit of size* $(2m)^{n^2/(2X)}$ *such that the total number of pairs of variables related by any* MOD_m *gate in the circuit is at most X.*

Proof. Compute AND of the variables in two levels with AND gates, first computing the AND of $\lceil n^2/(2X) \rceil$ classes of at most $\lceil 2X/n \rceil$ variables each. Then place a $\mathrm{MOD}_m^{\{1\}}$ gate of fan-in 1 onto the top. Apply Lemma 3.11 to replace the top two levels by the modulo p sum of $(2m)^{n^2/(2X)}$ MOD_m gates. The inputs of these new gates are linear combinations of the outputs of the gates computing AND for a single class.

Note that Lemma 3.11 works only if m is not a multiple of p. Otherwise use that MOD_m gates can simulate MOD_q gates if q divides m. $\square$

We remark that the proofs of Lemma 3.12 and Theorem 3.13 use Theorem 3.7 for the lower bound, so they apply to circuits computing OR or MOD_r with r not dividing mp^s, not just for AND. The upper bound in Theorem 3.14 can also be applied to these functions.

Acknowledgment. We are grateful to Zoltán Király for helpful discussions.

SHORTEST PATH QUERIES AMONG WEIGHTED OBSTACLES IN THE RECTILINEAR PLANE[*]

DANNY Z. CHEN[†], KEVIN S. KLENK[†], AND HUNG-YI T. TU[‡]

Abstract. We study the problems of processing single-source and two-point shortest path queries among weighted polygonal obstacles in the rectilinear plane. For the single-source case, we construct a data structure in $O(n \log^{3/2} n)$ time and $O(n \log n)$ space, where n is the number of obstacle vertices; this data structure enables us to report the length of a shortest path between the source and any query point in $O(\log n)$ time, and an actual shortest path in $O(\log n + k)$ time, where k is the number of edges on the output path. For the two-point case, we construct a data structure in $O(n^2 \log^2 n)$ time and space; this data structure enables us to report the length of a shortest path between two arbitrary query points in $O(\log^2 n)$ time, and an actual shortest path in $O(\log^2 n + k)$ time. Our work improves and generalizes the previously best-known results on computing rectilinear shortest paths among weighted polygonal obstacles. We also apply our techniques to processing two-point L_1 shortest obstacle-avoiding path queries among arbitrary (i.e., not necessarily rectilinear) polygonal obstacles in the plane. No algorithm for processing two-point shortest path queries among weighted obstacles was previously known.

1. Introduction.

The problems of computing shortest paths among geometric obstacles are among the most fundamental topics in computational geometry. Given a *rectilinear* plane with disjoint weighted polygonal obstacles of n vertices in total, we study the problems of answering shortest path queries in this setting. A plane is rectilinear if all geometric objects (e.g., lines, obstacles, paths) in it are *rectilinear*, i.e., each line or edge of such an object is parallel to the x- or y-axis, and distances are measured based on the L_1 metric. No two obstacles intersect each other in their interior points. Every obstacle is *weighted*, i.e., it is associated with a nonnegative *weight* factor, so that a path in the plane, if it intersects the interior of an obstacle, is charged extra cost based on the weight of that obstacle in addition to the cost of the L_1 length of the path. A *shortest path* connecting two points in the plane is a path with the minimum total cost. Note that shortest paths of this kind are in fact a generalization of the shortest paths (that completely avoid the interior of obstacles) studied in classical geometric path planning problems; our shortest paths become obstacle-avoiding if the weight of each obstacle is $+\infty$. A shortest path query specifies two points, s and t, in the plane and requests a rectilinear shortest path (or its weighted total cost) connecting s and t. If the point s is always fixed and t is arbitrary, then the query is called a *single-source* query and the fixed point s is

called the *source point*. If both s and t are arbitrary points, then the query is called a *two-point* query. Our objective is to create data structures which enable shortest path queries to be answered efficiently.

Unlike shortest path problems in graph theory, in which both the single-source and two-point (or called all-pairs) versions are well studied, geometric shortest path query problems, especially the two-point query versions, are not yet well understood. Geometric shortest path queries can specify arbitrary points in the plane which consists of uncountable infinitely many points. Furthermore, it is still difficult in many situations to obtain good solutions to the two-point query versions even when efficient algorithms for the corresponding single-source query versions are known. The two-point Euclidean shortest path query problem is such an example, for which only efficient approximation results [6, 2] are known so far.

A number of algorithms have been discovered for computing rectilinear shortest obstacle-avoiding paths [3, 4, 8, 9, 10, 11, 13, 21, 22, 24, 25, 26, 31, 32, 33] and shortest paths among weighted obstacles [15, 24, 28, 32]. When the plane has only a single obstacle (i.e., a simple polygon), shortest path query problems are much easier and in fact are quite well studied (e.g., see [7, 16, 17, 18, 19, 23]). However, shortest path query problems become substantially harder in environments with multiple obstacles. There were only a few algorithms [10, 11, 20, 23, 25, 26, 27, 29] for *single-source obstacle-avoiding* path queries in multiple obstacle environments. Results on *two-point* queries in such environments were even rarer; the only such previous algorithms we know are for the special cases of *rectilinear* shortest obstacle-avoiding paths among *rectangular* obstacles [3, 4, 13] and among *rectilinear polygonal* obstacles [21]. For rectilinear shortest obstacle-avoiding path queries among rectilinear polygonal obstacles, Iwai, Suzuki, and Nishizeki [21] built a data structure in $O(n^2 \log^3 n)$ time and $O(n^2 \log^2 n)$ space, which supports each two-point length query in $O(\log^2 n)$ time. For shortest paths among weighted obstacles, very few algorithms were previously known [15, 24, 28, 32], and none of these results can handle arbitrary shortest path queries. In particular, Mitchell and Papadimitriou [28] solved the problem of determining shortest paths through a weighted planar polygonal subdivision; their algorithm takes a time of $O(n^8)$ times another factor based on the precision of the problem instance. Lee, Yang, and Chen [24] presented two algorithms for computing a rectilinear shortest path between two points among weighted rectilinear polygonal obstacles in the plane; their first algorithm takes $O(n \log^2 n)$ time and $O(n \log n)$ space and the second takes $O(n \log^{3/2} n)$ time and space.

In this paper, we present new techniques for processing single-source and two-point rectilinear shortest path queries among disjoint weighted rectilinear polygonal obstacles. Using these techniques, we are also able to obtain efficient algorithms for answering other path queries, including two-point L_1 shortest obstacle-avoiding path queries among arbitrary (not necessarily rectilinear) polygonal obstacles. Our techniques are based on numerous new geometric observations and the generalized visibility graph of Lee, Yang, and Chen [24]. We introduce the idea of "gateway points" which are used to control effectively the connection between any query points and the generalized visibility graph. We also present methods for computing single-source shortest path trees in the generalized visibility graph that are more efficient in both the time and space bounds than directly applying the best-known graphical shortest path algorithm by Fredman and Tarjan [14]. Our techniques and ideas could be useful in solving other shortest path query problems. Our main results are as follows:

- For single-source queries among weighted rectilinear obstacles in the rectilinear plane, we construct a data structure in $O(n \log^{3/2} n)$ time and $O(n \log n)$ space. This data structure supports each path length query in $O(\log n)$ time. An actual shortest path can be reported in $O(\log n + k)$ time, where k is the number of edges on the output path. An immediate consequence of this result is an improvement over the previously best-known algorithms in [24] for computing a rectilinear shortest path between two points among weighted rectilinear obstacles by a factor of $O(\log^{1/2} n)$ in either the time or space bound.

• For two-point queries among weighted rectilinear obstacles in the rectilinear plane, we construct a data structure in $O(n^2 \log^2 n)$ time and space. This data structure supports each path length query in $O(\log^2 n)$ time. An actual shortest path can be obtained in $O(\log^2 n + k)$ time.

• For two-point L_1 shortest *obstacle-avoiding* path queries among arbitrary (not necessarily rectilinear) polygonal obstacles in the plane, we build a data structure in $O(n^2 \log^2 n)$ time and $O(n^2 \log n)$ space. This data structure supports each path length query in $O(\log^2 n)$ time. An actual shortest path can be obtained in $O(\log^2 n + k)$ time.

Note that in comparison with the two-point result in [21], our algorithms work for more general geometric settings (*weighted* rectilinear obstacles or *arbitrary* polygonal obstacles) yet take less time (a factor of $\log n$) in constructing the data structures.

Unless otherwise specified, all geometric objects (e.g., lines, paths, polygons) are implicitly assumed to be rectilinear; i.e., each of their segments is parallel to one of the coordinate axes.

The rest of the paper is organized as follows. Section 2 reviews briefly the construction of the generalized visibility graph that is a basis for our data structures. Section 3 details our insights and procedures for efficiently processing path queries among weighted rectilinear obstacles. Section 4 presents our algorithms for creating the data structures for both the single-source and two-point queries among weighted rectilinear obstacles. Section 5 extends our work to two-point L_1 shortest obstacle-avoiding path queries among arbitrary polygonal obstacles.

2. Preliminaries.

Let the x- (resp., y-) coordinate of a point s on the plane be denoted by s_x (resp., s_y). For points s and t, the L_1 distance between s and t is $\text{dist}(s,t) = |s_x - t_x| + |s_y - t_y|$. A path P_{st} connecting s and t is a sequence of line segments $\overline{p_0p_1}$, $\overline{p_1p_2}$, …, $\overline{p_{m-1}p_m}$, with $p_0 = s$ and $p_m = t$. Let $d(P_{st})$ denote the (unweighted) length of P_{st}, i.e., the sum of the L_1 lengths of the segments on P_{st}. If P_{st} intersects the interior of some weighted obstacles, the *weighted length* of P_{st} is defined as follows: Partition P_{st} into subpaths $A_1, B_1, A_2, B_2, \ldots, A_k, B_k$, where A_i is a subpath without intersecting the interior of any obstacle, B_i is a subpath completely within the interior of some obstacle R_i, and subpaths A_1 and B_k may be of zero length; the weighted length of P_{st}, denoted by $d_w(P_{st})$, is $d_w(P_{st}) = \sum_{i=1}^{k}(d(A_i) + d(B_i)) + \sum_{i=1}^{k}(d(B_i) \times W(R_i))$, where $W(R_i)$ is the weight factor of R_i.

An obstacle R_i (a polygon, possibly with holes) is specified by a sequence of edges on each of its outer and inner boundaries. For each vertex u of R_i such that the interior angle of R_i at u is $3\pi/2$, we define the *internal projection points* of u as follows: Let $\overline{uv}$ be the horizontal (resp., vertical) edge of R_i containing u; shoot a horizontal (resp., vertical) ray from u along the direction opposite to that of v until the ray hits the first boundary point $p_h(u)$ (resp., $p_v(u)$) of R_i. We call $p_h(u)$ (resp., $p_v(u)$) the *horizontal* (resp., *vertical*) *internal projection point* of u. Internal projection points are useful for controlling shortest paths that penetrate weighted obstacles.

The notion of visibility is generalized to the rectilinear plane with weighted obstacles by Lee, Yang, and Chen [24]. Two points s and t are *visible* to each other if $\overline{st}$ is horizontal or vertical and $\overline{st}$ either does not intersect the interior of any obstacle or is completely contained in a single obstacle. A point p is *visible* from a horizontal or vertical line L if and only if p is visible from a finite point p' on L. A key component of our shortest path data structures is the generalized visibility graph $G = (V, E)$ defined in [24] which captures the necessary information about shortest paths among the n obstacle vertices. We denote the cost of each edge $e \in E$ by $w(e)$.

The vertex set V of the visibility graph G can be partitioned into three subsets: (i) V_O of obstacle vertices, (ii) V_I of internal projection points of the vertices in V_O, and (iii) V_S of *Steiner points*. We need to sketch the recursive procedure in [24] for generating Steiner points for graph G: (1) Draw a vertical (resp., horizontal) line L, which we call a *cut-line*, at the median of the x- (resp., y-) coordinates of all the vertices in $V_O \cup V_I$; (2) project the vertices in $V_O \cup V_I$ that are visible from the cut-line L onto L (the projection points of $V_O \cup V_I$ on L are the Steiner points of V_S on L); (3) use L to partition $V_O \cup V_I$ into two subsets S_1 and S_2, one on each side of L; (4) perform the procedure recursively on the subsets S_1 and S_2, resp., until the size of each such subset becomes 1. Because this procedure has $O(\log n)$ recursion levels, it clearly generates $O(n \log n)$ Steiner points in V_S. Since $|V_O \cup V_I| = O(n)$, there are totally $O(n \log n)$ vertices in $V = V_O \cup V_I \cup V_S$. We associate with each cut-line L a *level number* $LN(L)$, which is the number of the recursion level at which L is used in the above procedure (with the root level being level 1).

The edge set E of G consists of two subsets: (1) E_V of line segments between every Steiner point in V_S and its corresponding vertex in $V_O \cup V_I$, and (2) E_L of line segments connecting consecutive Steiner points on every cut-line. The weighted lengths of the edges in E_V can be easily determined and stored during the generation of the Steiner points. The weighted lengths of the edges in E_L are obtained by using Widmayer's algorithm [24, 30] in $O(n \log n)$ time.

It was shown in [24] that graph G so created captures the necessary information about shortest paths among points in the plane that are vertices of V. The first algorithm in [24] runs Fredman and Tarjan's shortest path algorithm [14] on G to find a shortest path between two points s and t (with both s and t being included in V), in $O(n \log^2 n)$ time and $O(n \log n)$ space.

The second algorithm in [24] improved the time bound of the first algorithm, based on Clarkson, Kapoor, and Vaidya's idea [8] of reducing the number of vertices (precisely, the Steiner points) in graph G by increasing the number of edges. Let the set of additional edges to G be E_S, and denote the graph so resulted by $G' = (V', E')$. G' was obtained from G in [24] as follows: (1) For every vertical (resp., horizontal) cut-line L, partition the plane into horizontal (resp., vertical) strips such that each strip contains $O(\log^{1/2} n)$ Steiner points of $L \cap V_S$; (2) within each strip, for every pair of vertices u and v in $V_O \cup V_I$ such that u and v are both visible from L and are on the opposite sides of L, add an edge (u, v) to E_S, and let the cost of (u, v) be the sum of the costs of the edges $(u, s(u))$, $(s(u), s(v))$, and $(s(v), v)$ in G, where $s(u)$ and $s(v)$ are Steiner points on L corresponding to u and v, resp.; (3) in each strip, retain the Steiner points that have the highest or lowest y- (resp., x-) coordinate among the Steiner points in $L \cap V_S$, and remove from V_S the rest of the Steiner points on L in that strip together with edges adjacent to any of the removed Steiner points. (The retained Steiner points play the role of maintaining communication between consecutive strips.)

Graph $G' = (V', E')$ created by this procedure has $|V'| = O(n \log^{1/2} n)$ and $|E'|$

$= O(n \log^{3/2} n)$. The second algorithm in [24] then runs the shortest path algorithm [14] on G', in $O(n \log^{3/2} n)$ time and space. Thus, there is a time-space trade-off between the first and second algorithm in [24].

Our algorithms for shortest path queries make use of both graphs G and G'. In particular, G is a key component of our shortest path data structures, and G' is used in *constructing* our shortest path data structures. We will also show (in section 4) that by using an *implicit* representation scheme for G', the time-space trade-off incurred by the algorithms in [24] can be eliminated, and hence the best time and space bounds of both these algorithms can be achieved simultaneously.

3. Shortest path queries among weighted rectilinear obstacles. We discuss in this section our algorithms for answering single-source and two-point shortest path queries among weighted rectilinear obstacles, while deferring the complete description of the desired shortest path data structures and their construction until the next section. This allows us to show an array of useful geometric structures of these shortest path query problems before giving the details of various components of our algorithmic solutions. Exploiting these new geometric observations is one of our main contributions in this paper.

3.1. Useful observations. We start with some notation and useful insights. For a query point z, we project z vertically (resp., horizontally) onto the first obstacle edge (if it exists) that is above (resp., below, to the left of, to the right of) z. Let $Q(z)$ be the set of the at most four projection points of z on obstacle boundaries.

A path P is *monotone* with respect to the x- (resp., y-) axis if and only if no vertical (resp., horizontal) line crosses P more than once. A path is called a *staircase* if it is monotone with respect to both the x-axis and the y-axis. Clearly, a staircase from a point p to a point q in an obstacle-free region is a shortest path between p and q since its length equals $\text{dist}(p, q)$.

The following lemmas specify various useful structures of shortest paths between two arbitrary points q and r.

LEMMA 3.1. *Suppose there is a shortest path P_{qr} connecting points q and r whose interior does not intersect any obstacle boundary. Then* (1) *P_{qr} is a staircase, and* (2) *there is a shortest path P'_{qr} between q and r such that P'_{qr} either contains an obstacle vertex or P'_{qr} consists of at most two edges.*

Proof. We prove (1) by contradiction. Assume the interior of a shortest path P_{qr} has no intersection with any obstacle boundary yet P_{qr} is not a staircase. Then P_{qr} must have three consecutive edges that form two right turns or two left turns. But, by moving the middle one of these three edges, one can obtain a shorter path between q and r than P_{qr}, a contradiction.

For proving (2), assume without loss of generality (WLOG) the staircase P_{qr} consists of at least three edges. Consider its first two edges $\overline{qq_1}$ and $\overline{q_1q_2}$ (see Figure 3.1). Since the interior of $\overline{qq_1}$ does not intersect any obstacle boundary, we can move $\overline{qq_1}$, until either the interior of the segment $\overline{q'q'_1}$ encounters some obstacle boundary or $q'_1 = q_2$. The path P'_{qr} obtained by replacing $\overline{qq_1}$ and $\overline{q_1q_2}$ of P_{qr} with $\overline{qq'}$, $\overline{q'q'_1}$, and $\overline{q'_1q_2}$ has the same length as P_{qr}. If the interior of $\overline{q'q'_1}$ encounters some obstacle boundary, then $\overline{q'q'_1}$ must contain a vertex of an obstacle edge e (because e does not intersect $\overline{q_1q_2}$), and hence the lemma is proved. If $q'_1 = q_2$, then the resulting shortest path P'_{qr} has one less edge than P_{qr}. By repeatedly applying this reduction to P'_{qr}, we obtain a shortest path between q and r that either passes through an obstacle vertex or consists of at most two edges. ∎

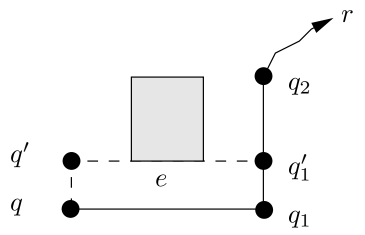

FIG. 3.1. *Moving the segment $\overline{qq_1}$ vertically up.*

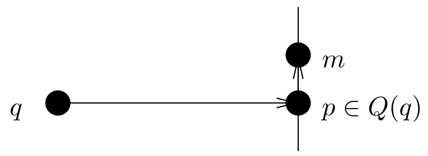

FIG. 3.2. *The two line segments of P_{qm} meeting at a point $p \in Q(q)$.*

LEMMA 3.2. *For two points q and r with q not on any obstacle boundary, if the interior of a shortest q-to-r path P_{qr} intersects the boundary of an obstacle, then there is a shortest q-to-r path that either goes through a point $p \in Q(q)$ (via the segment $\overline{qp}$) or goes through an obstacle vertex.*

Proof. Let m be the obstacle boundary point on the interior of P_{qr} such that the interior of the subpath P_{qm} of P_{qr} does not intersect any obstacle boundary point. By Lemma 3.1, P_{qm} is a staircase that can be made either to pass through an obstacle vertex or to consist of at most two line segments. WLOG, we assume that P_{qm} consists of at most two edges.

Let m be on an obstacle edge $e(m)$. Then either $e(m)$ contains a point $p \in Q(q)$, or $e(m)$ contains no point of $Q(q)$. It is not hard to see the following. If $e(m)$ contains a point $p \in Q(q)$, then the two edges of P_{qm} can be made to join together at $p \in Q(q)$ (e.g., Figure 3.2). If $e(m)$ contains no point of $Q(q)$, then a vertex of $e(m)$ must belong to P_{qm} (e.g., see Figure 3.3). ☐

LEMMA 3.3. *Suppose a point q is on an obstacle boundary. Then, for any point r, there is a shortest q-to-r path P_{qr} that either consists of at most two line segments or goes through an obstacle vertex.*

Proof. The proof is similar to that of Lemma 3.1. ☐

The significance of Lemmas 3.1, 3.2, and 3.3 to processing shortest path queries is as follows. Given two query points s and t, there are only three possibilities: (1) a shortest path P_{st} goes through an obstacle vertex and hence through a vertex of the generalized visibility graph G (by possibly going through a point in $Q(s) \cup Q(t)$); (2) P_{st} goes through a point in $Q(s) \cup Q(t)$ but not through any vertex of G; or (3) P_{st} consists of at most two line segments. In case 2, the path P_{qr}, for some $q \in Q(s)$ and $r \in Q(t)$, is one with at most two line segments.

Note that in the single-source case, a shortest path from any query point in the plane to the source point always goes through some vertices of graph G (e.g., the source vertex), and thus G can be used to effectively control single-source shortest paths for all query points. However, the two-point case may be different, because shortest paths between certain query points in the plane do not pass through any vertex of G. Therefore, our two-point query algorithms must account for both possibilities: (i) a sought path goes through a vertex of G, and (ii) no desired path goes through any

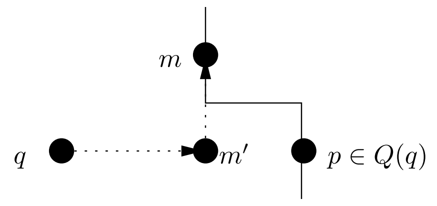

FIG. 3.3. *The segment $\overline{mm'} \subseteq e(m)$ of P_{qm} must contain an obstacle vertex.*

vertex of G. In the next subsection, we discuss our query algorithms for the possibility of a desired shortest path going through a vertex of G (i.e., case 1). The possibility of no desired shortest path going through any vertex of G is handled in section 3.5.2 (i.e., cases 2 and 3).

3.2. Main ideas and difficulties. In this subsection, we focus on two-point queries for which a desired shortest path goes through some vertices of G. Let s and t be two query points. Based on Lemmas 3.2 and 3.3, we need to compute the length of a shortest p-to-q path through a vertex of G for every $p \in Q(s) \cup \{s\}$ and $q \in Q(t) \cup \{t\}$.

Our main idea for computing a shortest p-to-q path that intersects some vertices of G is to identify a subset $V_{\mathrm{g}}(z)$ of vertices in G for each $z \in \{p, q\}$, such that a shortest p-to-q path must go through at least one pair v_q, v_p of vertices, with $v_q \in V_{\mathrm{g}}(q)$ and $v_p \in V_{\mathrm{g}}(p)$. We call the vertices of G in $V_{\mathrm{g}}(q)$ the *gateways* of q. If we know $V_{\mathrm{g}}(q)$ and $V_{\mathrm{g}}(p)$ and the weighted path between q (resp., p) and each vertex in $V_{\mathrm{g}}(q)$ (resp., $V_{\mathrm{g}}(p)$), then we can easily find a shortest p-to-q path by utilizing a data structure that maintains shortest path information for every pair of vertices in G. In this section, we simply assume that our two-point data structure can report the length of a shortest path between any two vertices of G in $O(1)$ time and a corresponding actual shortest path in an additional $O(k)$ time, where k is the number of edges of the output path.

For this idea to work, we must overcome two difficulties: (1) identifying $V_{\mathrm{g}}(q)$, and (2) determining the lengths of the weighted paths between q and the vertices in $V_{\mathrm{g}}(q)$. Note that it is possible for a path between q and a vertex in $V_{\mathrm{g}}(q)$ to penetrate a number of obstacles. For the efficiency of our query algorithms, it is certainly desirable that $|V_{\mathrm{g}}(q)|$ be small. Indeed, we will show that $|V_{\mathrm{g}}(q)| = O(\log n)$ for any point q and $V_{\mathrm{g}}(q)$ can be computed in $O(\log n)$ time. Furthermore, we show that the weighted paths between q and the vertices in $V_{\mathrm{g}}(q)$ and their lengths can also be computed in $O(\log n)$ time.

Our idea for computing the set $V_{\mathrm{g}}(q)$ of gateways for a point q is that of "inserting" q into graph G. We treat q as if it were one of the obstacle vertices and compute the edges in G adjacent to q that would have resulted if the procedure in [24] for constructing G were applied to q. Note that such an "insertion" of a point into G does not actually change the shortest path information contained in G (i.e., q is not a new obstacle); furthermore, the resulting graph (after the "insertions") contains shortest path information among the inserted points and the original vertices of G, if a shortest path between two inserted points does intersect G. Also, note that our "insertion" process does not actually modify graph G because the points are never truly inserted into G.

3.3. Characterization of gateways. To "insert" a point q into graph G, we project q onto the relevant cut-lines based on the graph construction procedure [24]. A fixed set of $O(n)$ cut-lines is used in constructing G, subdividing the plane recursively in [24]. Each cut-line can be associated with a particular recursion level. In consequence, all points in each region of the resulted planar subdivision are projected onto the same subset of cut-lines. If, according to the graph construction procedure [24], q would have been projected onto a cut-line L, then we say L is a *projection cut-line* of q. Note that if a cut-line L is a projection cut-line of q, then q is visible from L. But, not every cut-line visible from q is a projection cut-line of q. It is sufficient for us to discuss geometric observations with vertical cut-lines only (those with horizontal cut-lines are symmetric). In the rest of this section, we assume all the cut-lines are vertical unless otherwise specified.

LEMMA 3.4. *Suppose that the projection cut-lines of a point q are sorted in increasing order by their x-coordinates. Then the projection cut-lines of q that are to the right (resp., left) of q are simultaneously in the decreasing (resp., increasing) order of their level numbers.*

Proof. We prove the lemma only for the projection cut-lines of q that are to the right of q. Let L' and L'' be two projection cut-lines to the right of q with L' to the left of L''. Then the level number of L' must be bigger than that of L'' (otherwise, L' would have prevented the projection of q from reaching L'', a contradiction). Hence, the lemma follows. □

The gateway set $V_{\mathrm{g}}(q)$ of a point q is determined as follows: For each projection cut-line L of q, if z is the vertex of G on L that is immediately above (resp., below) $p_L(q)$, then $z \in V_{\mathrm{g}}(q)$, where $p_L(q)$ is the projection point of q on L. For $z \in V_{\mathrm{g}}(q)$, we denote the projection cut-line of q that contains z by L_z. Observe that if q were "inserted" into G, then the only edges adjacent to q in the graph would be those connecting q with its projection points. Because each projection point $p_L(q)$ of q is adjacent to at most two neighboring vertices of G on its cut-line L, $V_{\mathrm{g}}(q)$ controls every path in G from q to any other vertex of G. Since at each recursion level of the graph construction algorithm, q can be projected onto at most one cut-line, there are $O(\log n)$ projection cut-lines for q. Each such projection cut-line has at most two neighboring vertices of G for $p_L(q)$. Therefore, we have the next two lemmas.

LEMMA 3.5. *For each point q in the plane, $|V_{\mathrm{g}}(q)| = O(\log n)$.*

LEMMA 3.6. *For each point q and each vertex v of G, there is a shortest q-to-v path in the plane that goes through a vertex of $V_{\mathrm{g}}(q)$.*

For every gateway $z \in V_{\mathrm{g}}(q)$, we define an "edge" (q, z) in the graph as follows: Let z be on a projection cut-line L of q; then the edge (q, z) consists of the two segments $\overline{qp(q)}$ and $\overline{p(q)z}$.

By the definition of gateways, $V_{\mathrm{g}}(q)$ can be computed efficiently (e.g., in $O(\log^2 n)$ time by doing a binary search on the vertices of G along each projection cut-line of q, or in $O(\log n)$ time by using a fractional cascading data structure [5]). However, the real difficulty is that each edge connecting q with a vertex in $V_{\mathrm{g}}(q)$ can penetrate many obstacles, and straightforward methods fail to compute the weighted lengths of such edges efficiently. By exploiting a number of geometric observations, we show below how to compute $V_{\mathrm{g}}(q)$ and the weights of all these edges in $O(\log n)$ time.

A *gateway region* $\mathcal{R}(q)$ (Figure 3.4) of a point q is the area enclosed by an interconnection of the gateways in $V_{\mathrm{g}}(q)$. We show only how the set ${V_{\mathrm{g}}}^1(q)$ of gateways in the first quadrant of q are connected: (1) Let a vertical "pseudo" cut-line pass through q. (2) For each vertex v of ${V_{\mathrm{g}}}^1(q)$, project v horizontally to the projection cut-line L of q (on point $p_L(v)$) that is immediately to the left of v (it can be shown that such a projection is always possible among weighted obstacles). Note that L can be the

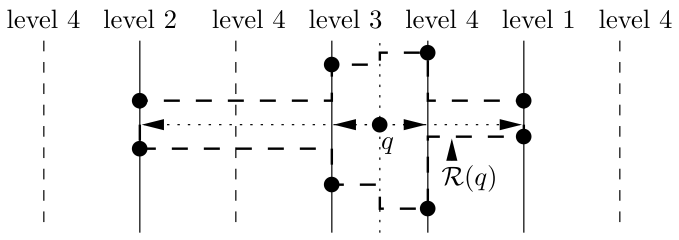

FIG. 3.4. *The gateway region $\mathcal{R}(q)$ for a point q.*

"pseudo" cut-line containing q. For v, let the vertex of $V_{\mathrm{g}}{}^1(q)$ on L be u (if u exists). (3) Connect u and v by line segments $\overline{up_L(v)}$ and $\overline{p_L(v)v}$. (4) If v is the rightmost gateway of $V_{\mathrm{g}}{}^1(q)$, then connect v with the point (v_x, q_y) by a segment. (5) If L is the "pseudo" cut-line containing q (and hence u does not exist on L), then connect v and $p_L(v)$ by a segment. The area in the first quadrant of q enclosed together by the polygonal chain so defined, the x-axis, and y-axis (with q as the origin) is part of $\mathcal{R}(q)$. $\mathcal{R}(q)$ is the union of the areas so defined in all four quadrants of q.

A planar region $\mathcal{R}$ is *rectilinearly convex* if $\mathcal{R}$ is connected and for any horizontal or vertical line L, $L \cap \mathcal{R}$ is also connected. The next two lemmas characterize some crucial structures of $\mathcal{R}(q)$.

LEMMA 3.7. *For any point q, the gateway region $\mathcal{R}(q)$ is rectilinearly convex; furthermore, for any point z in $\mathcal{R}(q)$, the points (z_x, q_y) and (q_x, z_y) are both in $\mathcal{R}(q)$.*

Proof. We know by Lemma 3.4 that the projection cut-lines of q are sorted by their level-numbers. It is sufficient to prove that in each quadrant of q, the gateways in sorted order form a sequence of "restricted" maximal elements. Let S be a point set in the first quadrant of q. We say a point $a \in S$ is a *restricted maximal element* of S if there is no other point $b \in S$ such that $a_x < b_x$ and $a_y < b_y$. The restricted maximal elements in other quadrants of q are defined in a symmetric fashion. WLOG, we prove only the case for the first quadrant of q.

This proof is by contradiction. Suppose the first quadrant of q contains two gateways a, $b \in V_{\mathrm{g}}(q)$ such that $a_x < b_x$ and $a_y < b_y$. Let a and b be on the projection cut-lines L_a and L_b of q, resp. Since $a_x < b_x$, by Lemma 3.4, L_a is at a higher recursion level than L_b (i.e., $LN(L_a) > LN(L_b)$). Let a be a projection point of vertex $v_a \in V_O \cup V_I$. But $a_y < b_y$ implies that v_a is not able to project on L_b. Furthermore, v_a must be to the left of L_b (otherwise, v_a would have been projected on L_b because L_a is to the left of L_b). Hence, the projection of v_a on L_b is blocked. There are two possible cases on blocking the projection of v_a from L_b: (i) blocking by a cut-line L^* such that $LN(L^*) \leq LN(L_b)$, or (ii) blocking by a vertical obstacle edge e that is to the left of L_b.

In (i), cut-line L^* would have also blocked q from being projected on L_b because of the level numbers of L^* and L_b, contradicting the assumption that $b \in V_{\mathrm{g}}(q)$. In (ii), let v be the lower vertex of the vertical edge e. Note that e cannot cross the horizontal line H_q that contains q. This implies that $v_y < b_y$ but v is also not able to project on L_b. Repeatedly applying the same argument on v, we must eventually have some vertical obstacle edge that either crosses the horizontal line H_q or is to the right of L_b since there are only finitely many obstacle edges. But that would contradict with either $b \in V_{\mathrm{g}}(q)$ or that such a vertical edge must be to the left of L_b. □

LEMMA 3.8. *The gateway region $\mathcal{R}(q)$ contains no vertices of $V_O \cup V_I$ in its*

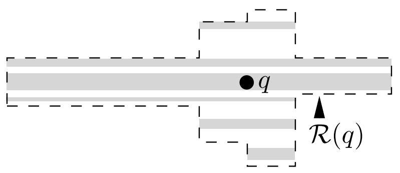

FIG. 3.5. *Horizontal obstacle strips inside the gateway region* $\mathcal{R}(q)$.

interior.

Proof. This can be proved by a contradiction argument similar to the proof of Lemma 3.7. ∎

To further discuss the properties of gateways of a point q, we distinguish three cases: (a) q is an obstacle vertex, (b) q is not an obstacle vertex but is on a vertical obstacle edge, and (c) q is not on any vertical obstacle edge. Case (a) can be readily handled. Hence we only focus on (b) and (c) in the following two subsections. We first discuss (c) and then show how to reduce (b) to (c).

3.3.1. Point q not on any vertical obstacle edge. Throughout this subsection, we assume that point q is not on any vertical obstacle edge.

The lemma below follows from Lemma 3.8 and it further characterizes $\mathcal{R}(q)$.

LEMMA 3.9. *There are three possible relations of obstacles to the gateway region* $\mathcal{R}(q)$*:* (1) *the interior of* $\mathcal{R}(q)$ *does not intersect any obstacle;* (2) $\mathcal{R}(q)$ *is completely contained within an obstacle; or* (3) $\mathcal{R}(q)$ *has horizontal obstacle strips running through it (e.g., see Figure* 3.5*).*

Proof. The interior of $\mathcal{R}(q)$ either intersects some obstacle edges or it does not. If the interior of $\mathcal{R}(q)$ does not intersect any obstacle edge, then clearly either case 1 or 2 holds. If the interior of $\mathcal{R}(q)$ does intersect an obstacle edge e, then by Lemma 3.8, no vertex of e can be in the interior of $\mathcal{R}(q)$. By the convexity of $\mathcal{R}(q)$ (Lemma 3.7), $e \cap \mathcal{R}(q)$ is a single line segment s_e. Segment s_e cannot be vertical because if it were, then it would have intersected the horizontal line containing q at a point inside $\mathcal{R}(q)$ and thus blocked the projection of q beyond s_e, contradicting that s_e is in the interior of $\mathcal{R}(q)$. Hence, s_e must be on the boundary of a horizontal obstacle strip across $\mathcal{R}(q)$. ∎

The following lemmas provide the basis for an efficient computation of $V_{\mathrm{g}}(q)$ and their weighted edges to q.

LEMMA 3.10. *For two gateways* $a, b \in V_{\mathrm{g}}(q)$ *that are both above the horizontal line* H_q *containing* q*, let* $LN(L_a) > LN(L_b)$*, with* L_a *not being the leftmost or rightmost projection cut-line of* q*. Then the set of horizontal obstacle strips penetrated by segment* $\overline{bb'}$ *is a subset of the horizontal obstacle strips penetrated by segment* $\overline{aa'}$*, where* $a' = (a_x, q_y)$ *and* $b' = (b_x, q_y)$ *(see Figure* 3.6*).*

Proof. WLOG, assume both a and b are above line H_q. If a and b are both to the left (resp., right) of q, then the lemma follows immediately from Lemmas 3.4, 3.7, and 3.9. If a and b are on the opposite sides of q, then based on Lemma 3.9, the lemma will follow if we can show $a_y \geq b_y$. We prove $a_y \geq b_y$ by contradiction. Assume $a_y < b_y$. WLOG, let a be to the right of q and b to the left of q (Figure 3.6), and let a be a projection point of a vertex $v_a \in V_O \cup V_I$.

First, we show that v_a is to the right of L_a. By Lemmas 3.8 and 3.9, v_a cannot be between L_a and L_b and cannot be on L_a. Also, v_a cannot be to the left of L_b (otherwise, a would have not been a projection point of v_a on L_a because $LN(L_b)$

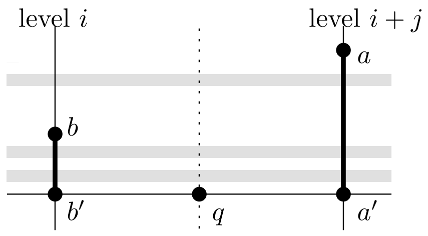

FIG. 3.6. *Illustration of Lemma* 3.10.

$< LN(L_a)$). Next, we show that a cannot be on a vertical obstacle edge. If a were on a vertical obstacle edge e, then, since L_a (which contains e) is neither the leftmost nor rightmost projection cut-line of q, e cannot cross line H_q; hence the lower vertex of e would be in the interior of $\mathcal{R}(q)$, a contradiction. Finally, we show that v_a cannot be blocked from being projected on L_b. By Lemma 3.4, no projection cut-line of q between L_a and L_b has a lower level number than L_b; hence no such projection cut-line can block the projection of v_a on L_b. Since a is not on a vertical obstacle edge, the projection of v_a can reach the left of L_a. The projection of v_a also cannot be blocked by obstacles between L_a and L_b by Lemma 3.9. Therefore, if $a_y < b_y$, then v_a would have been projected onto L_b, contradicting that b is a gateway of q on L_b. ∎

LEMMA 3.11. *For two gateways a, $b \in V_g(q)$ that are both above the horizontal line H_q containing q, let $LN(L_a) > LN(L_b)$. Then $a_y < b_y$ implies that L_a is the leftmost or rightmost projection cut-line of q and that a is on a vertical obstacle edge e such that e crosses H_q.*

Proof. WLOG, assume a and b are both above H_q and $a_y < b_y$. By Lemmas 3.4 and 3.7, a and b cannot be both to the left (resp., right) of q. Hence WLOG, assume a is to the right of q and b to the left of q. By the same argument as in the proof of Lemma 3.10, we can show that assuming a is not on any vertical obstacle edge leads to a contradiction. But if a is on a vertical obstacle edge e, then e must cross H_q (otherwise, the lower vertex of e on L_a would be above H_q, contradicting that $a \in V_g(q)$). This is possible only if e is on the rightmost projection cut-line of q. It is not difficult to see that in this case, a is actually a projection point of a vertex of $V_I \cup V_O$ to the right of e. ∎

COROLLARY 3.12. *For two gateways $a, b \in V_g(q)$ that are both above line H_q, suppose none of L_a or L_b contains a vertical obstacle edge that crosses H_q. Then $LN(L_a) > LN(L_b)$ implies $a_y \geq b_y$.*

Proof. An immediate consequence of Lemma 3.11. ∎

The ordering of the gateways of q by their y-coordinates is a key to our computation of $V_g(q)$ and its weighted edges to q. The next corollary shows that this ordering can be easily obtained.

COROLLARY 3.13. *Let $A(q)$ be the set of gateways of a point q above the horizontal line H_q, such that no gateway in $A(q)$ is on a vertical obstacle edge crossing H_q. If $A(q)$ is in increasing order of the level numbers of the projection cut-lines of q that contain the points of $A(q)$, then $A(q)$ is also in nondecreasing order of the y-coordinates of the points of $A(q)$.*

Proof. An immediate consequence of Corollary 3.12. ∎

The next lemma shows that the special case (i.e., for the at most two gateways on those projection cut-lines of q that contain a vertical obstacle edge crossing H_q)

can be handled easily.

LEMMA 3.14. *Let a be a gateway of a point q on a vertical obstacle edge e that crosses the horizontal line H_q. Then either q is in the obstacle that contains e or q is not contained in any obstacle.*

Proof. The proof follows immediately from Lemma 3.9. $\square$

Hence, computing the weight of the "inserted" edge (q, a), where a is defined in Lemma 3.14, is easy. The vertical segment contained in edge (q, a) is on an obstacle edge and the weighted horizontal segment of (q, a) is determined by Lemma 3.14. The following two lemmas lay the foundation for our iterative procedure to obtain $V_{\mathrm{g}}(q)$ and the weighted edges between q and other gateways in $V_{\mathrm{g}}(q)$.

LEMMA 3.15. *For gateway $a \in V_{\mathrm{g}}(q)$, suppose $LN(L_a)$ is the smallest among all projection cut-lines of q that do not contain a vertical obstacle edge crossing the horizontal line H_q. Let b be the point (a_x, q_y). Then either* (i) *the interior of the vertical segment $\overline{ab}$ does not intersect the interior of any obstacle, or* (ii) *segment $\overline{ab}$ is contained in the same obstacle that contains q.*

Proof. The interior of $\mathcal{R}(q)$ either intersects some horizontal obstacle edges or it does not. If the interior of $\mathcal{R}(q)$ intersects no obstacle edge, then clearly case i or ii holds. So assume the interior of $\mathcal{R}(q)$ does intersect a horizontal obstacle edge. Also, assume a is above line H_q.

Suppose we start at q and go vertically upward until we meet the first point z on any obstacle boundary. By Lemma 3.9, it is sufficient to show $z_y \geq a_y$. There are two cases to consider: (1) no projection cut-line of q contains a vertical obstacle edge that crosses H_q, and (2) a projection cut-line of q contains a vertical obstacle edge e that crosses H_q. WLOG, assume q is to the left of L_a.

To show case 1, we consider two subcases: (1.1) $LN(L_a) = 1$, and (1.2) $LN(L_a) > 1$.

Subcase 1.1. $LN(L_a) = 1$. Then no obstacle blocks q from being projected onto the level 1 cut-line L_a. Let v be the left vertex of the horizontal obstacle edge containing z. If v is projected onto L_a, then $z_y = v_y \geq a_y$ is true. Otherwise, the projection of v can only be blocked from L_a by a vertical obstacle edge e'. Edge e' must be between z and L_a, and it cannot cross H_q. By repeatedly applying this argument to the lower vertex u of e', we can show $z_y \geq u_y \geq a_y$.

Subcase 1.2. $LN(L_a) > 1$. Then a vertical obstacle edge e' must block q from being projected onto the level 1 cut-line. Let v be the upper vertex of edge e'. We have either $v_y \geq z_y$ or $v_y < z_y$. When $v_y < z_y$, if v is projected onto L_a, then the lemma holds; otherwise, v is blocked by a cut-line or a vertical obstacle edge from being projected onto L_a. If v is blocked by a cut-line L, then L must be between L_a and e', and $LN(L) < LN(L_a)$. But then q would have been projected onto L, contradicting that $LN(L_a)$ is the smallest among all the projection cut-lines of q. If the projection of v is blocked from L_a by a vertical obstacle edge e'', then the same argument can be applied to the lower vertex u of e'' to show $z_y \geq u_y \geq a_y$. When $v_y \geq z_y$, the right vertex u' of the horizontal obstacle edge containing z must be to the left of the vertical obstacle edge e', and by Lemma 3.9, u' can be projected onto L_a. Hence, $z_y = u'_y \geq a_y$.

In case 2, a projection cut-line of q contains a vertical obstacle edge e that crosses H_q. The following can be shown: (i) Let u be the upper vertex of e; then $u_y \geq z_y$. (ii) One vertex of the horizontal obstacle edge containing z must be projected onto L_a. The argument is similar to that for case 1. $\square$

LEMMA 3.16. *For two gateways $a, a' \in V_{\mathrm{g}}(q)$ that are both above line H_q, suppose*

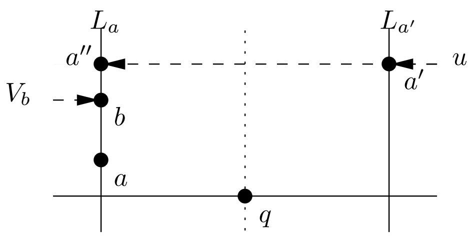

FIG. 3.7. *Illustration of Lemma* 3.16.

none of L_a and $L_{a'}$ contains a vertical obstacle edge crossing H_q, $LN(L_{a'}) > LN(L_a)$, and there is no projection cut-line L of q such that $LN(L_{a'}) > LN(L) > LN(L_a)$. Then the following are true (Figure 3.7*):* (1) *There is a Steiner point a'' on L_a such that $a'_y = a''_y$; furthermore, there is a vertex $u \in V_O \cup V_I$ such that u is projected on both a'' and a'.* (2) *For any Steiner point b on L_a such that $a''_y > b_y > a_y$, let vertex $v_b \in V_O \cup V_I$ be projected on b; then v_b and a' are on the opposite sides of L_a.* (3) *Let $p_1 = (a''_x, q_y)$ and $p_2 = (a'_x, q_y)$ be points on H_q; then segments $\overline{a''p_1}$ and $\overline{a'p_2}$ have the same weighted length.*

Proof. If $a_y = a'_y$, then (1) and (2) are trivially true, and (3) follows from Lemmas 3.9 and 3.10. So WLOG, assume $a_y < a'_y$ (Corollary 3.13) and L_a is to the left of $L_{a'}$. Let a'' be the point (a_x, a'_y).

The following claim is the key to proving (1), (2), and (3).

CLAIM. *Let $\mathcal{R}$ be the region enclosed by the boundary of $\mathcal{R}(q)$ and segments $\overline{a'a''}$ and $\overline{aa''}$, such that the interior of $\mathcal{R}$ does not intersect $\mathcal{R}(q)$. Then $\mathcal{R} - \overline{a'a''}$ does not intersect any vertical obstacle edge and does not contain any vertex in $V_O \cup V_I$.*

Proof of the claim. By contradiction. Suppose $\mathcal{R} - \overline{a'a''}$ contains a vertex $v \in V_O \cup V_I$. Then $a_y \le v_y < a'_y$ and v cannot be projected onto $L_{a'}$ because $a' \in V_{\mathrm{g}}(q)$. Hence the projection of v is blocked from $L_{a'}$ either by a cut-line $L \neq L_a$ with $LN(L) < LN(L_{a'})$, or by a vertical obstacle edge e not intersecting the interior of $\mathcal{R}(q)$ (by Lemma 3.9). In the former case, L must be between L_a and $L_{a'}$, and hence L cannot contain a vertical obstacle edge crossing H_q. If $LN(L) \le LN(L_a)$, then q would have not been projected onto either L_a or $L_{a'}$, a contradiction. If $LN(L) > LN(L_a)$ (but $LN(L) < LN(L_{a'})$), then q would have been projected on L, contradicting that there is no projection cut-line L of q such that $LN(L_{a'}) > LN(L) > LN(L_a)$. Hence, the projection of v cannot be blocked from $L_{a'}$ by a cut-line. If the projection of v is blocked from $L_{a'}$ by a vertical obstacle edge e which does not intersect the interior of $\mathcal{R}(q)$, then the lower vertex u' of e must be in $\mathcal{R} - \overline{a'a''}$. The argument can then be repeated on u', eventually showing that such a vertex u' must be projected on $L_{a'}$, a contradiction to $a' \in V_{\mathrm{g}}(q)$. Therefore, no obstacle vertex of $V_O \cup V_I$ can be in $\mathcal{R} - \overline{a'a''}$. This argument can also be used to show that no vertical obstacle edge intersects $\mathcal{R} - \overline{a'a''}$. ☐

Let $v_{a'} \in V_O \cup V_I$ be projected onto a'. Then $v_{a'}$ cannot be to the left of L_a; otherwise, since a' is to the right of L_a and $LN(L_a) < LN(L_{a'})$, $v_{a'}$ would have not been projected onto $L_{a'}$. So $v_{a'}$ must be to the right of L_a. Then by Lemma 3.9 and the above claim, $v_{a'}$ must be projected onto a'' on L_a as well. Hence, (1) is true (with $u = v_{a'}$).

For (2), if v_b is to the right of L_a (as a'), then v_b would have been projected onto L'_a because the interior of $\mathcal{R} \cup \mathcal{R}(q)$ contains no obstacle vertex and does not intersect any vertical obstacle edge, thus contradicting that $a' \in V_{\mathrm{g}}(q)$. Hence, v_b can only be to the left of L_a.

For (3), because any horizontal obstacle strip intersected by segment $\overline{a'p_2}$ cannot stop within $\mathcal{R}$ and must run through $\mathcal{R}$, segment $\overline{a''p_1}$ also intersects such a horizontal obstacle strip. By the same argument, if $\overline{a''p_1}$ intersects any horizontal obstacle strip, then such a horizontal strip must also be intersected by $\overline{a'p_2}$. Hence, the weighted lengths of both $\overline{a''p_1}$ and $\overline{a'p_2}$ are the same. $\square$

3.3.2. Point q on a vertical obstacle edge. If point q is on a vertical obstacle edge e, then we reduce this case to the case in which q is not on any vertical obstacle edge, as follows: Treat q as if q_x is perturbed to the left (resp., right) of e by some very small value $\epsilon > 0$, and then apply the observations and procedures for the case with q not on any vertical obstacle edge.

In the rest of this section, we assume WLOG that point q is not on any vertical obstacle edge.

3.4. Computing gateways and weighted edges to gateways. First, we need to find all projection cut-lines of point q. These cut-lines can be identified easily by using a data structure based on trapezoidal decomposition and planar point location [12] in $O(\log n)$ time. By Lemma 3.4, the x-coordinates of these cut-lines can be put in sorted order by bucket sort in $O(\log n)$ time. Let $L_{i_1}, L_{i_2}, \ldots, L_{i_g}$ be the sequence of all projection cut-lines of q in increasing order of their level numbers, and let $a_{i_j} \in V_{\mathrm{g}}(q)$ be on L_{i_j} that is above line H_q, with $g = O(\log n)$.

Next, we compute the gateways a_{i_j} and weighted edges (q, a_{i_j}). Let p_{i_j} be the projection point of q on projection cut-line L_{i_j} of q. Since edge (q, a_{i_j}) consists of two segments $\overline{qp_{i_j}}$ and $\overline{p_{i_j}a_{i_j}}$ and since the interior of $\overline{qp_{i_j}}$ is either contained completely in an obstacle or outside any obstacle, it is sufficient to show how to compute a_{i_j} and the weighted length $d_w(\overline{p_{i_j}a_{i_j}})$. We first find the gateways that are either on the projection cut-lines of q that contain a vertical obstacle edge crossing line H_q or on the projection cut-line of q that has the smallest level number among the projection cut-lines that do not contain a vertical obstacle edge crossing H_q. There are at most three such gateways and they can all be obtained by binary search on the vertices of G on the relevant projection cut-lines of q in $O(\log n)$ time. The weights of edges from q to these three gateways can be easily computed by Lemmas 3.14 and 3.15. Then, based on Lemma 3.16, we show that given a_{i_j} and $d_w(\overline{p_{i_j}a_{i_j}})$, $a_{i_{j+1}}$ and $d_w(\overline{p_{i_{j+1}}a_{i_{j+1}}})$ can both be obtained in $O(1)$ time. Our data structure for computing gateways and the weights of their edges to q maintains the following information for every cut-line L.

1. For any two vertices u and v of G on L, $d_w(\overline{uv})$ can be reported in $O(1)$ time. This is done by first using Widmayer's algorithm [30] to compute the weighted length between every two consecutive vertices of G on L and then by performing a prefix sum operation, along the vertices of G on L, to compute the weighted length from every vertex on L to the highest vertex on L. From the prefix sums of u and v, it is easy to find $d_w(\overline{uv})$ in $O(1)$ time.

2. Each vertex u of G on L keeps track of all vertices z in $V_O \cup V_I$ such that z is projected on u. Note that u can be the projections of vertices in $V_O \cup V_I$ on each side of L.

3. For each $z \in V_O \cup V_I$, maintain an array Proj_z of size $O(\log n)$. If z is projected to point $p(z)$ on cut-line L of level i, then $\mathrm{Proj}_z(i)$ has a pointer to $p(z)$ on L; otherwise, $\mathrm{Proj}_z(i)$ is undefined.

4. Each vertex u of G on L keeps track of the lowest vertex v of G on L such that $v_y \geq u_y$ and v is a projection of a vertex of $V_O \cup V_I$ that is to the left (resp., right) of L (v can be u).

Note that the graph construction procedure [24] can be easily modified to compute the information in items 1–4 above in $O(n\log n)$ time and space. Now based on Lemma 3.16, it is an easy matter to compute $a_{i_{j+1}}$ and $d_w(\overline{p_{i_{j+1}}a_{i_{j+1}}})$ from a_{i_j} and $d_w(\overline{p_{i_j}a_{i_j}})$, in $O(1)$ time. WLOG, assume L_{i_j} is to the left of $L_{i_{j+1}}$. We perform the following steps: (1) Find the lowest vertex a'' of G on L_{i_j} such that a'' is on or above a_{i_j} and that a'' is a projection point of a vertex $z \in V_O \cup V_I$ with z being to the right of L_{i_j}; (2) let $a_{i_{j+1}} = \mathrm{Proj}_z(LN(L_{i_{j+1}}))$ and $d_w(\overline{p_{i_{j+1}}a_{i_{j+1}}}) = d_w(\overline{p_{i_j}a_{i_j}}) + d_w(\overline{a_{i_j}a''})$.

Based on the above discussion, for any point q, we compute the gateway set $V_{\mathrm{g}}(q)$ and the weighted edges from all vertices of $V_{\mathrm{g}}(q)$ to q in $O(\log n)$ time.

3.5. Answering shortest path queries.

This subsection gives our procedures for answering single-source and two-point shortest path queries.

3.5.1. Single-source queries.

A single-source query requests a shortest path from the fixed source point s to an arbitrary query point t. Since s is fixed, it can be included as a vertex of graph G. The query procedure compares the lengths of the s-to-q shortest paths through the gateways of $V_{\mathrm{g}}(q)$ and selects the smallest path length for all $q \in Q(t) \cup \{t\}$. Precisely, the length of such a shortest s-to-q path is given by $\min\{d_w(P_{sv})+w(q,v) \mid v \in V_{\mathrm{g}}(q)\}$, where $d_w(P_{sv})$ is the length of a weighted shortest s-to-v path and $w(q,v)$ is the weight of the "inserted" edge connecting q and v. Since $|V_{\mathrm{g}}(q)| = O(\log n)$ and $V_{\mathrm{g}}(q)$ (together with the weighted edges between q and $V_{\mathrm{g}}(q)$) can be obtained in $O(\log n)$ time, a single-source length query is performed in $O(\log n)$ time.

An actual s-to-q shortest path consists of the path (with at most two segments) between q and a vertex $x \in V_{\mathrm{g}}(q)$ and a path in graph G from x to s. We already show how to compute the path between q and x in $O(\log n)$ time. The path between x and s in G can be reported by standard single-source shortest path tree methods in $O(k)$ time, where k is the number of edges on that path.

In the rest of the paper, we will no longer specify the details on reporting actual shortest paths, since these can all be carried out based on standard shortest path techniques.

3.5.2. Two-point queries.

A two-point query requests a shortest path between two arbitrary query points s and t. Our two-point query procedure must account for two cases: There is a shortest s-to-t path going through a vertex in G and there is no shortest s-to-t path going through any vertex of G. We then select the true shortest s-to-t path from the two candidates so obtained.

To obtain a shortest s-to-t path going through a vertex in G, we compute a shortest p-to-q path that goes through $V_{\mathrm{g}}(p)$ and $V_{\mathrm{g}}(q)$, for every pair p and q, $p \in Q(s) \cup \{s\}$ and $q \in Q(t) \cup \{t\}$. A shortest p-to-q path through $V_{\mathrm{g}}(p)$ and $V_{\mathrm{g}}(q)$ is computed as follows. First, compute $V_{\mathrm{g}}(p)$ (resp., $V_{\mathrm{g}}(q)$) for point p (resp., q) and the weighted edges between $V_{\mathrm{g}}(p)$ and p (resp., $V_{\mathrm{g}}(q)$ and q), as shown in section 3.4. Then, create a graph G_{pq} as follows: The vertices of G_{pq} are $\{p,q\} \cup V_{\mathrm{g}}(p) \cup V_{\mathrm{g}}(q)$; the edges of G_{pq} consist of the weighted edges between $V_{\mathrm{g}}(p)$ and p, the weighted edges between $V_{\mathrm{g}}(q)$ and q, and the edges (v_p, v_q), where $v_p \in V_{\mathrm{g}}(p)$, $v_q \in V_{\mathrm{g}}(q)$, and the weight of an edge (v_p, v_q) is the length of a shortest v_p-to-v_q path in G. It is easy to see that G_{pq} has $O(\log n)$ vertices and $O(\log^2 n)$ edges. Finally, find a shortest p-to-q path in G_{pq} by Fredman and Tarjan's shortest path algorithm [14]. This obtains the length of a shortest p-to-q path in $O(\log^2 n)$ time.

Computing a shortest s-to-t path not going through any vertex of G is much easier. By the lemmas in section 3.1, it is clear that such a path can be obtained from the shortest p-to-q path that consists of at most two line segments, for every pair p and q, $p \in Q(s) \cup \{s\}$ and $q \in Q(t) \cup \{t\}$. WLOG, assume p and q are not on the same vertical and horizontal line. Note that there can be only two such two-segment paths between p and q, one through the point (p_x, q_y) and the other through (q_x, p_y). Also, note that each such two-segment path may still penetrate many obstacles. Obviously, the following is a key operation for computing such two-segment paths: Given two points a and b that are on a same vertical or horizontal line, compute the weighted length of segment $\overline{ab}$. We use a grid-partition approach to perform this operation.

We partition the plane by using a set S_E of $O(n)$ lines such that each line in S_E contains a vertical or horizontal obstacle edge. The plane is thus divided into $O(n^2)$ rectangular grid cells with a weight factor associated with each cell. The following is easy to observe: Suppose we sweep a row (resp., column) of grid cells by a horizontal (resp., vertical) line L without letting L touch the horizontal (resp., vertical) boundaries of that row (resp., column); then for any two points a and b on L, the weighted length of segment $\overline{ab}$ remains unchanged during the sweeping.

We maintain the following information with the grid. (We only show the horizontal case.) (1) For every row X of the grid, let L_X be an arbitrary horizontal line strictly between the two horizontal boundaries of X; let S'_E be the set of such horizontal lines L_X for all the $O(n)$ rows of the grid. (2) The horizontal lines in $S_E \cup S'_E$ intersect the vertical lines in S_E at $O(n^2)$ points, which we call *special points.* (3) Along the row of special points on each horizontal line L in $S_E \cup S'_E$, perform a prefix sum computation on their weighted lengths along L to the leftmost special point. This grid-partitioning takes $O(n^2)$ time and space. Using the grid-based data structure, it is easy to compute the weighted length of any horizontal or vertical segment $\overline{ab}$ in $O(\log n)$ time.

In summary, each two-point path length query can be answered in $O(\log^2 n)$ time.

4. Constructing shortest path data structures.

This section focuses on the construction of our shortest path data structures. Our data structures for both single-source and two-point queries make use of graph G which has $O(n\log n)$ vertices and edges. If Fredman and Tarjan's shortest path algorithm [14] were directly applied to G, then computing a shortest path tree in G (for single-source queries) would take $O(n \log^2 n)$ time and $O(n\log n)$ space, and computing $O(n\log n)$ shortest path trees in G (for two-point queries) would take $O(n^2 \log^3 n)$ time and $O(n^2 \log^2 n)$ space. By using an implicit graph representation scheme and divide-and-conquer paradigms, we are able to construct the single-source data structure in $O(n \log^{3/2} n)$ time and $O(n \log n)$ space, and the two-point data structure in $O(n^2 \log^2 n)$ time and space. Note that graph G' (discussed in section 2) plays a crucial role in computing shortest path trees in G.

Since other components of our shortest path data structures have been discussed in section 3, this section only shows how to compute shortest path trees in G in the claimed time and space bounds.

4.1. Distance tables.

Recall that a major difference between graph G' and the generalized visibility graph G is the addition of a set E_S of $O(n \log^{3/2} n)$ edges to G'. The edges in E_S were represented *explicitly* using $O(n \log^{3/2} n)$ space in [24]. We use an *implicit* scheme to store E_S in $O(n\log n)$ space, which still enables us to retrieve information about G' as quickly (within a constant factor) as using the explicit representation. We call such a scheme *distance tables.*

The construction of G' is based on partitioning every cut-line L into strips, with each strip containing $O(\log^{1/2} n)$ Steiner points on L. Let S be the set of Steiner points on L within a strip of L, and let $PV_l(S)$ (resp., $PV_r(S)$) be an array containing the $O(\log^{1/2} n)$ vertices of $V_O \cup V_I$ within the strip that are to the left (resp., right) of L and are visible from L. We associate a distance table T_S with the strip of L for S. Note that for each vertex $u \in PV_l(S)$ and $v \in PV_r(S)$, there is an edge (u, v) in G' consisting of segments $\overline{up_L(u)}$, $\overline{p_L(u)p_L(v)}$, and $\overline{p_L(v)v}$, where $p_L(z)$ denotes the projection of a vertex $z \in PV_l(S) \cup PV_r(S)$ on L. Edges between $PV_l(S)$ and $PV_r(S)$ can be implicitly represented by arrays $PV_l(S)$ and $PV_r(S)$. The weights of these edges can also be represented implicitly, as follows: For every $z \in PV_l(S) \cup PV_r(S)$, store $p_L(z)$ and the weighted length of $\overline{zp_L(z)}$ in table T_S; for any $p_L(u)$ and $p_L(v)$ in S, use the prefix sums of weighted lengths discussed in section 3.4 to compute the weighted length of $\overline{p_L(u)p_L(v)}$, in $O(1)$ time. Hence, the weight of every edge (u, v), for $u \in PV_l(S)$ and $v \in PV_r(S)$, can be computed in $O(1)$ time via T_S. T_S uses $O(\log^{1/2} n)$ space. The distance tables for all $O(n \log^{1/2} n)$ strips of G use altogether $O(n\log n)$ space and can be trivially built in $O(n\log n)$ time. Running the shortest path algorithm of [14] on G' with edge set E_S being represented by distance tables is similar to the explicit representation of G' in [24], yet it takes $O(n \log^{3/2} n)$ (not $O(n \log^2 n)$) time and $O(n\log n)$ (not $O(n \log^{3/2} n)$) space.

4.2. Construction of the single-source data structure. The single-source shortest path tree in graph G rooted at the source vertex s is computed by making use of graph G'. The procedure for computing this shortest path tree in G consists of two steps.

1. Compute the single-source shortest path tree in G' rooted at s, in $O(n \log^{3/2} n)$ time and $O(n\log n)$ space (by using our distance table scheme). To obtain the shortest path tree in G rooted at s, we need to compute, for every cut-line L, the lengths of shortest paths from s to all Steiner points on L in each strip of L. Let S be the set of Steiner points on L within a strip of L, and let $PV(S)$ denote the vertices of $V_O \cup V_I$ within the strip that are visible from L. Observe that for each point $u \in S$, $PV(S)$ controls all paths in G from u to the source s, and that the lengths of shortest paths from the vertices in $PV(S)$ to s are already computed in this step.

2. Let u_m be the median Steiner point in S along L. Let $d_w(P^*_{u_m s}) = \min\{d_w(P_{u_m v}) + d_w(P^*_{vs}) \mid v \in PV(S)\}$, where P^*_{wz} denotes a shortest path between points w and z, and path $P_{u_m v}$ consists of segments $\overline{vp_L(v)}$ and $\overline{p_L(v)u_m}$. It is easy to compute $d_w(P^*_{u_m s})$ in $O(|PV(S)|)$ time. Next, use u_m to partition S into two subsets S_1 and S_2 of balanced sizes. Note that for a point $u' \in S_1$ (resp., S_2), all paths in G from u' to s are controlled by the vertices in $PV(S_1) \cup \{u_m\}$ (resp., $PV(S_2) \cup \{u_m\}$). Therefore, we recursively perform step 2 on S_1 and S_2, resp., until the size of each set becomes one.

The time bound of the divide-and-conquer procedure for step 2 obeys recurrence $T(N) = 2T(N/2) + cN$ for some constant $c > 0$. Because $|PV(S)| = O(\log^{1/2} n)$ for each strip, the time of the procedure taken on each strip is $O(\log^{1/2} n \log\log n)$. The total time of step 2 on all $O(n \log^{1/2} n)$ strips of G is $O(n\log n \log\log n) = o(n \log^{3/2} n)$, and the space is $O(n\log n)$.

4.3. Construction of the two-point data structure. For each of the $O(n\log n)$ vertices in G, we need to compute a single-source shortest path tree in G rooted at that vertex. The $O(n\log n)$ shortest path trees in G altogether take $O(n^2 \log^2 n)$ space. Applying the algorithm in section 4.2 for computing one shortest path tree to each vertex of G would take $O(n^2 \log^2 n \log\log n)$ time. We show here how to achieve an $O(n^2 \log^2 n)$ time and space algorithm for obtaining the $O(n\log n)$ shortest path trees in G. The algorithm consists of two steps.

1. Compute the lengths of shortest paths from all vertices in G' to all vertices in G. There are $O(n \log^{1/2} n) \times O(n\log n)$ path lengths to compute. By applying the algorithm in section 4.2 to each vertex of G', this step takes $O(n \log^{1/2} n) \times O(n \log^{3/2} n) = O(n^2 \log^2 n)$ time and $O(n^2 \log^{3/2} n)$ space.

2. Compute the lengths of shortest paths between the vertices of G that are not vertices of G'. Let S' (resp., S'') be the set of Steiner points on a cut-line L' (resp., L'') within a strip of L' (resp., L''). The $O(\log n)$ path lengths between the points in S' and the points in S'' are computed as follows: (2.1) Let u'_m (resp., u''_m) be the median Steiner point in S' (resp., S''), and compute the lengths of shortest paths from u'_m (resp., u''_m) to all the points in S'' (resp., S'). This can be done in $O(\log^{1/2} n \log\log n)$ time by using a divide-and-conquer procedure similar to the one in section 4.2. (2.2) Use u'_m (resp., u''_m) to partition S' (resp., S'') into two subsets S'_1 and S'_2 (resp., S''_1 and S''_2) of balanced sizes. (2.3) Recursively repeat this procedure on each pair of subsets S'_i and S''_j, with $i, j \in \{1, 2\}$, until the size of a set in the pair becomes one.

The time bound of the divide-and-conquer procedure for step 2 obeys recurrence $T(N) = 4T(N/2) + cN \log N$ for some constant $c > 0$, whose solution is $T(N) = O(N^2)$. Since there are $O(\log^{1/2} n)$ Steiner points in each strip of a cut-line, the time of the procedure for computing the $O(\log n)$ path lengths for each pair of strips is $T(\log^{1/2} n) = O(\log n)$. Hence, the total time of step 2 on all the $O(n^2\log n)$ pairs of strips of G is $O(n^2 \log^2 n)$, and the space is also $O(n^2 \log^2 n)$.

5. Shortest path queries among arbitrary polygonal obstacles.

This section focuses on processing two-point L_1 shortest obstacle-avoiding path queries among arbitrary (i.e., not necessarily rectilinear) polygonal obstacles. We call nonpenetrating obstacles *solid* obstacles. The query processing techniques that we will present have some similarity to those used in the previous sections, but nevertheless significant differences exist in our data structures and algorithms for this case. One notable difference in the solid polygonal obstacle case is that, corresponding to the nonrectilinear shape of obstacles, we will not limit ourselves to using rectilinear paths, although we still use the L_1 metric to measure the lengths of the (possibly nonrectilinear) paths. The line segments of nonrectilinear paths can be viewed as representing staircase subpaths consisting of many sufficiently short line segments (if rectilinear paths are desired).

We will show how to construct a two-point shortest path data structure in $O(n^2 \log^2 n)$ time and $O(n^2 \log n)$ space, which answers each two-point length query in $O(\log^2 n)$ time and reports an actual path in an additional $O(k)$ time, where k is the number of edges on the output path.

5.1. The visibility graph G^*.

In this section, we say a point q is *visible* from a point p iff line segment $\overline{qp}$ does not intersect the interior of any obstacle, and q is *rectilinearly visible* from p iff p and q are visible to each other and $\overline{pq}$ is horizontal or vertical. The visibility graph $G^* = (V^*, E^*)$, which we use for the solid polygonal obstacle case, is similar to graph G defined in section 2 for the weighted rectilinear obstacle case. But there are a few differences which account for the facts that the obstacles are solid and that the obstacle edges need not be rectilinear. This visibility graph was introduced in [8, 9]. The vertex set V^* of G^* includes: (i) the set of obstacle vertices and (ii) two sets of Steiner points.

As in [8, 9], there are two types of Steiner points in G^*: (1) projections of obstacle vertices onto cut-lines, and (2) projections of obstacle vertices onto obstacle boundaries. The first type of Steiner points (called *type*-1 *Steiner points*) are created in [8, 9] similar to the way sketched in section 2, building a graph with $O(n \log n)$ vertices and edges, as well as other information (e.g., cut-lines). The second type of Steiner points (called *type*-2 *Steiner points*) consists of horizontal and vertical projection points of each obstacle vertex p onto rectilinearly visible obstacle edges of p. Include edges in E^* between every obstacle vertex p and each of the (at most four) projection points of p. For each obstacle edge e, there is a linear ordering of the vertices in V^* which lie on e; include in E^* edges between every two consecutive vertices of V^* along e. Clearly, there are $O(n)$ type-2 Steiner points and they introduce $O(n)$ edges to E^*. These type-2 Steiner points and their edges can be created in $O(n \log n)$ time by a standard plane sweeping technique [8, 9].

5.2. Useful observations. We project each query point z vertically (resp., horizontally) onto the first point of the obstacle edge (if it exists) immediately above (resp., below, to the left of, to the right of) z. Let $Q(z)$ be the set of the (at most four) projection points of z on obstacle boundaries so resulted. The lemmas below show some useful structures of shortest paths between two points q and r.

LEMMA 5.1. *For two points q and r that are not visible to each other, there is a q-to-r shortest path whose interior passes through an obstacle vertex.*

Proof. The proof is obvious and omitted. □

Next, we characterize shortest paths between points that are visible to each other. Before doing so, we should point out that by simply performing a ray shooting operation (in any given direction), it is easy to find out whether two points in the plane are visible to each other, and if they are, give the shortest path (i.e., the segment) connecting the two points. Such a ray shooting data structure [1] takes $O(n^2)$ space and $O(n^2 \log n)$ time to construct, in order to support each operation in logarithmic time. In our case, it is possible to avoid such general ray shooting operations and use only special ray shooting (along the horizontal or vertical direction). We believe this simplifies the algorithm and even improves its implementation performance.

Let two points q and r be visible to each other. Then a shortest q-to-r path P_{qr} can be classified into one of three possible cases: (1) P_{qr} goes through an obstacle vertex and hence through a vertex of G^* (by possibly going through a point in $Q(q) \cup Q(r)$); (2) P_{qr} goes through a point in $Q(q) \cup Q(r)$ but not through any obstacle vertex of G^*; or (3) P_{qr} goes through neither a point in $Q(q) \cup Q(r)$ nor an obstacle vertex. Note that, even by using general ray shooting, it may be difficult to decide which case holds for each pair of mutually visible points. Fortunately, it turns out that it is not necessary to decide exactly which case holds. The next lemma shows that, for all practical purposes, case 1 can be differentiated from cases 2 and 3 without much trouble.

LEMMA 5.2. *Suppose two points q and r are visible to each other. By performing $O(1)$ special ray shooting operations (horizontal and vertical), it is possible to decide whether a shortest q-to-r path P_{qr} needs to be forced to go through an obstacle vertex.*

Proof. WLOG, assume r is in the first quadrant of q. In this case, what we need to do is to perform an upward (resp., downward) vertical ray shooting and a rightward (resp., leftward) horizontal ray shooting from q (resp., r). We only show how to analyze the information obtained by the leftward shooting from q and the downward shooting from r (the other case is similar).

There are three cases for the leftward shooting from q and the downward shooting from r: (a) The rays from q and r intersect each other before hitting an obstacle edge,

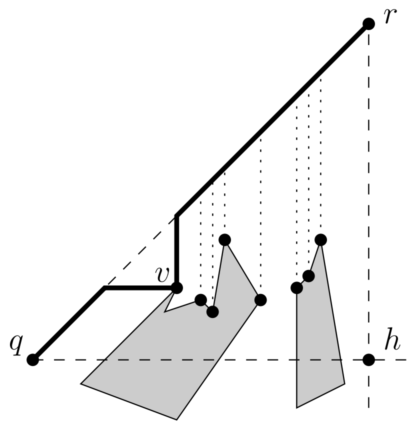

FIG. 5.1. *A shortest path P_{qr} goes through an obstacle vertex.*

(b) the rays hit the same obstacle edge e, and (c) the rays hit different obstacle edges.

In case (a), one can simply use a shortest q-to-r path that consists of segments $\overline{qh}$ and $\overline{hr}$, where h is the intersection point of the two rays. In case (b), a shortest q-to-r path consisting of three segments $\overline{qh_q}$, $\overline{h_qh_r}$, and $\overline{h_rr}$ can be used, where h_q (resp., h_r) is the hit point of the horizontal (resp., vertical) ray from q (resp., r) on the (same) obstacle edge e.

In case (c), a shortest q-to-r path P_{qr} can be forced to go through an obstacle vertex. Since q and r are visible to each other, segment $\overline{qr}$ does not intersect the interior of any obstacle. Let h be the intersection point of the two rays from q and r as if they are extended to infinity (Figure 5.1). Because the two rays do not hit the same obstacle edge before they intersect each other, the triangle $\triangle qrh$ must contain at least one obstacle vertex. Consider the obstacle vertices in $\triangle qrh$ that are vertically visible from a point on segment $\overline{qr}$. Let v be the first of such vertices in the left-to-right order based on their corresponding vertically visible points on $\overline{qr}$ (Figure 5.1). A shortest q-to-r path P_{qr} can then be obtained as in Figure 5.1, which goes through obstacle vertex v. $\square$

The horizontal and vertical ray shooting operations can be performed in $O(\log n)$ time each. This is done by using a planar point location data structure [12] which is based on a horizontal (resp., vertical) trapezoidal decomposition of the plane.

The significance of the above lemmas is as follows. For any two points q and r, regardless of whether they are visible to each other or not, a shortest q-to-r path can be obtained in one of two ways: (i) such a path can be forced to go through an obstacle vertex (Lemma 5.1 and case c in the proof of Lemma 5.2), and (ii) such a path need not go through any obstacle vertex (cases (a) and (b) in the proof of Lemma 5.2). Lemma 5.2 also shows how to handle paths of type ii efficiently. All other paths (i.e., type i) are captured by graph G^*, as shown in Lemma 5.1 and case (c) of the proof of Lemma 5.2. The next subsection further discusses how to handle two-point path queries of type i.

5.3. Characterization of gateways. Let p and q be any two query points. WLOG, we assume in this section a shortest p-to-q path goes through a vertex of G^*. As in the weighted rectilinear obstacle case, we want to compute a subset of vertices in G^* (the gateways) which captures a shortest p-to-q path. But our data structure for maintaining shortest path information for each pair of vertices in G^* is somewhat different from the weighted rectilinear obstacle case. Our two-point query procedure is also different. For the time being, we assume our data structure can report the length of a shortest path between any two vertices of G^* in $O(\log n)$ time. We again use the idea of "inserting" the query points into the visibility graph.

The set $V_{\mathrm{g}}(q)$ of gateways for a point q is defined similarly to the one for the weighted rectilinear obstacle case but differs in that the visibility graph for the solid polygonal obstacle case must account for the type-2 Steiner points. We therefore split $V_{\mathrm{g}}(q)$ into two subsets $V'_{\mathrm{g}}(q)$ of gateways with the type-1 Steiner points, and $V''_{\mathrm{g}}(q)$ of gateways with the type-2 Steiner points.

In the rest of this section, we assume WLOG that all cut-lines are vertical unless otherwise specified.

The set $V'_{\mathrm{g}}(q)$ of gateways for a point q is determined as follows: For each cut-line L of q that is horizontally visible from q, if z is the vertex of G^* on L that is immediately above (resp., below) the horizontal projection point $p_L(q)$ of q on L and if z is visible to $p_L(q)$, then $z \in V'_{\mathrm{g}}(q)$. For $V''_{\mathrm{g}}(q)$, shoot a ray from q onto the obstacle edge immediately above (resp., to the left of, to the right of, below) q; if u is the vertex of G^* that is immediately before (resp., after) the projection point of q on the obstacle edge, then $u \in V''_{\mathrm{g}}(q)$.

For each $z \in V'_{\mathrm{g}}(q)$ on a cut-line L of q, let an "edge" (q, z) in the graph consist of segments $\overline{qp_L(q)}$ and $\overline{p_L(q)z}$. If $z \in V''_{\mathrm{g}}(q)$, then edge (q, z) consists of segments $\overline{qp_e(q)}$ and $\overline{p_e(q)z}$, where $p_e(q)$ is the projection point of q on the obstacle edge e containing z. It is now easy to see that $V_{\mathrm{g}}(q)$ controls every path in G^* from q to any other vertex of G^*, and $|V_{\mathrm{g}}(q)| = O(\log n)$.

The *gateway region* $\mathcal{R}(q)$ of q (Figure 3.4) is defined and constructed in the same manner as the weighted rectilinear obstacle case (section 3.3), with the minor difference that here it is based on the vertices in $V'_{\mathrm{g}}(q)$ instead of $V_{\mathrm{g}}(q)$.

LEMMA 5.3. *The gateway region $\mathcal{R}(q)$ is rectilinearly convex and intersects no interior points of any obstacle. Furthermore, for any point z in $\mathcal{R}(q)$, the points (z_x, q_y) and (q_x, z_y) are both in $\mathcal{R}(q)$.*

Proof. The proof is similar to those of Lemmas 3.7 and 3.9. □

Comparing with the weighted case discussed in previous sections, it is straightforward to compute in this case $V_{\mathrm{g}}(q)$ and the L_1 distances from q to all points in $V_{\mathrm{g}}(q)$ in $O(\log n)$ time, by Lemma 5.3.

5.4. Construction of the data structure. In the weighted rectilinear obstacle case, our processing of queries depends on the ability to report efficiently the shortest paths (or their lengths) between any two vertices in the visibility graph. In the polygonal obstacle case, rather than applying graphical shortest path algorithms to graph G^* explicitly, we maintain needed path information by using the shortest path maps in [25, 26]. In effect, we need the geometric properties of graph G^* for query purposes, but we do not need its graph structures for computing our data structure for shortest paths between vertices of G^*.

Mitchell [25, 26] created an optimal single-source L_1 shortest path map in $O(n \log n)$ time and $O(n)$ space, where n is the number of obstacle vertices. Given any query point t, Mitchell's data structure can report the length of a shortest path from t to the source point s in $O(\log n)$ time (by planar point-location within the map), and an actual t-to-s shortest path in an additional $O(k)$ time, where k is the number of segments on the output path.

We apply Mitchell's algorithm [25, 26] to create $O(n \log n)$ L_1 single-source shortest path maps. In particular, we use each vertex $v \in V^*$ as a source point to construct a single-source shortest path map. Such a map is of size $O(n)$ because its geometric setting consists of n obstacle vertices (note that we need not use the $O(n \log n)$ Steiner points of V^* in building this shortest path map). This map allows us to handle single-source queries between the source $v \in V^*$ and any query point q.

Our two-point shortest path data structure for the solid polygonal obstacle case contains as a major component the $O(n \log n)$ shortest path maps. Using these maps, a length query of the shortest path between any vertex $v \in V^*$ and any query point p in the plane can be answered in $O(\log n)$ time. Our data structure can be created in altogether $O(n \log n) \times O(n \log n) = O(n^2 \log^2 n)$ time and $O(n \log n) \times O(n) = O(n^2 \log n)$ space. This is a savings of a factor of $\log n$ in space complexity over the methods we used in previous sections.

5.5. Answering shortest path queries. To answer a shortest path query for any two points p and q, we need to account for two cases: (i) a shortest p-to-q path goes through a vertex in G^*, and (ii) the shortest p-to-q path need not go through any vertex of G^*. The proof of Lemma 5.2 has shown how to distinguish these two cases. This subsection shows that a length query can be performed in $O(\log^2 n)$ time.

Suppose, by Lemma 5.2, we already know that a shortest p-to-q path goes through a vertex of G^* for two query points p and q. To obtain the length of such a shortest path, we use the shortest path maps constructed in section 5.4, as follows:

1. For one of the two query points, say q, compute $V_{\mathrm{g}}(q)$.
2. For each point $x \in V_{\mathrm{g}}(q)$, use p as a query point to find, in the shortest path map with x as the source point, the length of the shortest x-to-p path in the plane (in $O(\log n)$ time).
3. There are $O(\log n)$ paths, each consisting of the (trivial) shortest path from q to an $x \in V_{\mathrm{g}}(q)$ and the shortest x-to-p path. Find the length of the shortest p-to-q path among these paths.

This computation clearly takes altogether $O(\log^2 n)$ time. The correctness follows from the facts that a shortest p-to-q path goes through a point (say y) in $V_{\mathrm{g}}(q)$ and that the p-to-y-to-q path so obtained consists of a shortest q-to-y path and a shortest y-to-p path.

The computation of a shortest p-to-q path not going through any vertex of G^* is much simpler. From Lemma 5.2 in section 5.2, such a path and its length can be found in $O(\log n)$ time (by performing $O(1)$ horizontal and vertical ray shootings).

REDUCING RANDOMNESS VIA IRRATIONAL NUMBERS*

ZHI-ZHONG CHEN† AND MING-YANG KAO‡

Abstract. We propose a general methodology for testing whether a given polynomial with integer coefficients is identically zero. The methodology evaluates the polynomial at efficiently computable approximations of suitable irrational points. In contrast to the classical technique of DeMillo, Lipton, Schwartz, and Zippel, this methodology can decrease the error probability by increasing the precision of the approximations instead of using more random bits. Consequently, randomized algorithms that use the classical technique can generally be improved using the new methodology. To demonstrate the methodology, we discuss two nontrivial applications. The first is to decide whether a graph has a perfect matching in parallel. Our new NC algorithm uses fewer random bits while doing less work than the previously best NC algorithm by Chari, Rohatgi, and Srinivasan. The second application is to test the equality of two multisets of integers. Our new algorithm improves upon the previously best algorithms by Blum and Kannan and can speed up their checking algorithm for sorting programs on a large range of inputs.

1. Introduction.

Many algorithms involve checking whether certain polynomials with integer coefficients are identically zero. Oftentimes, these polynomials have exponential-sized standard representations while having succinct nonstandard representations [6, 17, 18, 22]. This paper focuses on testing such polynomials with integer coefficients.

Given a polynomial $Q(x_1, \ldots, x_q)$ in a succinct form, a naive method of testing it is to transform it into the standard simplified form and then test whether its coefficients are all zero. Since Q may have exponentially many monomials, this method may take exponential time. Let d_Q be the degree of Q. DeMillo and Lipton [6], Schwartz [18], and Zippel [22] proposed an advanced method, which we call *the DLSZ method*. It evaluates $Q(i_1, \ldots, i_q)$, where $i_1, \ldots, i_q$ are uniformly and independently chosen at random from a set S of $2d_Q$ integers. This method uses $q\lceil\log(2d_Q)\rceil$ random bits and has an error probability of at most $\frac{1}{2}$. (Every log in this paper is to base 2.) There are three general techniques that use additional random bits to lower the error probability to $\frac{1}{t}$ for any integer $t > 2$. These techniques have their own advantages and disadvantages in terms of the running time and the number of random bits used. The first performs $\lceil\log t\rceil$ independent evaluations of Q at $\lceil\log(2d_Q)\rceil$-bit integers, using $q\lceil\log(2d_Q)\rceil\lceil\log t\rceil$ random bits. The second enlarges the cardinality of S from $2d_Q$ to td_Q and performs one evaluation of Q at $\lceil\log(td_Q)\rceil$-bit integers, using $q\lceil\log d_Q + \log t\rceil$ random bits. The third is *probability amplification* [15]. A basic such technique works for $t \le 2^{q\lceil\log(2d_Q)\rceil}$ by performing t pairwise independent evaluations of Q at

$\lceil \log(2d_Q) \rceil$-bit integers, using $2q\lceil \log(2d_Q) \rceil$ random bits. Stronger amplification can be obtained by means of random walks on expanders [5, 1, 8].

In section 2, we propose a new general methodology for testing $Q(x_1, \ldots, x_q)$. Our methodology computes $Q(\pi_1, \ldots, \pi_q)$, where $\pi_1, \ldots, \pi_q$ are suitable irrational numbers such that $Q(\pi_1, \ldots, \pi_q) = 0$ if and only if $Q(x_1, \ldots, x_q) \equiv 0$. Since rational arithmetic is used in actual computers, we replace each π_i with a rational approximation π'_i. A crucial question is how many bits each π'_i needs to ensure that $Q(\pi'_1, \ldots, \pi'_q) = 0$ if and only if $Q(x_1, \ldots, x_q) \equiv 0$. We give an explicit answer to this question, from which we obtain a new randomized algorithm for testing Q. Our algorithm runs in polynomial time and uses $\sum_{i=1}^{q} \lceil \log(d_i + 1) \rceil$ random bits, where d_i is the degree of x_i in Q. Moreover, the error probability can be made inverse polynomially small by increasing the bit length of each π'_i. Thus, our methodology has two main advantages over previous techniques:

- It uses fewer random bits if some d_i is less than d_Q.
- It can reduce the error probability without using one additional random bit.

In general, randomized algorithms that use the classical DeMillo, Lipton, Schwartz, and Zippel (DLSZ) method can be improved using the new methodology. To demonstrate the methodology, we discuss two nontrivial applications. In section 3, the first application is to decide whether a given graph has a perfect matching. This problem has deterministic polynomial-time sequential algorithms but is not known to have a deterministic NC algorithm [7, 10, 13, 21]. We focus on solving it in parallel using as few random bits as possible. Our new NC algorithm uses fewer random bits while doing less work than the previously best NC algorithm by Chari, Rohatgi, and Srinivasan [4]. In section 4, the second application is to test the equality of two given multisets of integers. This problem was initiated by Blum and Kannan [3] for checking the correctness of sorting programs. Our new algorithm improves upon the previously best algorithms developed by them and can speed up their checking algorithm for sorting programs on a large range of inputs.

2. A new general methodology for testing polynomials.

The following notation is used throughout this paper.

- Let $Q(x_1, \ldots, x_q)$ be a polynomial with integer coefficients; we wish to test whether $Q(x_1, \ldots, x_q) \equiv 0$.
- For each x_i, let d_i be an upper bound on the degree of x_i in Q. Let $k_i = \lceil \log(d_i + 1) \rceil$.
- Let $k = \max_{i=1}^{q} k_i$ and $K = \sum_{i=1}^{q} k_i$; K is the number of random bits used by the methodology as shown in Theorem 2.3.
- Let d be an integer upper bound on the degree of Q; without loss of generality, we assume $d \geq \max_{i=1}^{q} d_i$.
- Let c be an upper bound on the absolute value of a monomial's coefficient in Q.
- Let Z be an upper bound on the number of monomials in Q; without loss of generality, we assume $Z \leq \sum_{i=0}^{d} q^i$.
- Let $\psi = \log c + \log Z + d(\log k + \frac{\log K}{2} + \log \ln K)$. Let ℓ be an integer at least $\psi + 1 + \log d$; ℓ determines the precision of our approximation to the irrational numbers chosen for the variables x_i.

For example, if all $d_i = 1$, then $k_i = 1$, $K = q$, and our goal is to use exactly q random bits, i.e., one bit per variable x_i.

Lemma 2.1. *Let $p_{1,1}, \ldots, p_{1,k_1}, \ldots, p_{q,1}, \ldots, p_{q,k_q}$ be K distinct primes. For each $p_{i,j}$, let $b_{i,j}$ be a bit. For each x_i, let $\pi_i = \sum_{j=1}^{k_i} (-1)^{b_{i,j}} \sqrt{p_{i,j}}$. Then $Q(x_1, \ldots, x_q) \not\equiv 0$*

if and only if $Q(\pi_1, \ldots, \pi_q) \neq 0$.

Proof. This lemma follows from Galois theory in algebra [14]. Let $A_0 = B_0$ be the field of rational numbers. For each x_j, let $K_j = \sum_{i=1}^{j} k_i$. Let A_j be the field generated by $\pi_1, \pi_2, \ldots, \pi_j$ over A_0. Let B_j be the field generated by $p_{1,1}, \ldots, p_{1,k_1}, \ldots, p_{j,1}, \ldots, p_{j,k_j}$ over B_0. By induction, $A_j = B_j$, the dimension of A_j over A_0 is 2^{K_j}, and the dimension of A_j over A_{j-1} is 2^{k_j}. Thus, π_j is not a root of any nonzero single variate polynomial over A_{j-1} that has a degree less than 2^{k_j}. Since $d_j < 2^{k_j}$, by induction, $Q(\pi_1, \ldots, \pi_j, x_{j+1}, \ldots, x_q) \not\equiv 0$. The lemma is proved at $j = q$. $\square$

In light of Lemma 2.1, the next algorithm tests $Q(x_1, \ldots, x_q)$ by approximating the irrational numbers $\sqrt{p_{i,j}}$ and randomizing the bits $b_{i,j}$.

ALGORITHM 1.

```
(1) Compute $q, d_1, \ldots, d_q, k_1, \ldots, k_q, K, d, c, Z$.
(2) Choose $p_{1,1}, \ldots, p_{1,k_1}, \ldots, p_{q,1}, \ldots, p_{q,k_q}$ to be the $K$ smallest primes.
(3) Choose each $b_{i,j}$ independently with equal probability for 0 and 1.
(4) Pick $\ell$, which determines the precision of our approximation to $\sqrt{p_{i,j}}$.
(5) For each $p_{i,j}$, compute a rational number $r_{i,j}$ from $\sqrt{p_{i,j}}$ by cutting off the
    bits after the $\ell$th bit after the decimal point.
(6) Compute $\Delta = Q(\sum_{j=1}^{k_1} (-1)^{b_{1,j}} r_{1,j}, \ldots, \sum_{j=1}^{k_q} (-1)^{b_{q,j}} r_{q,j})$.
(7) Output "$Q(x_1, \ldots, x_q) \not\equiv 0$" if and only if $\Delta \neq 0$.
```

The next lemma shows how to choose an appropriate ℓ at Step 1 of Algorithm 1.

LEMMA 2.2. *If* $Q(x_1, \ldots, x_q) \not\equiv 0$, *then* $|\Delta| \geq 2^{-\ell}$ *with probability at least* $1 - \frac{\psi}{\ell - 1 - \log d}$.

Proof. For each combination of the bits $b_{i,j}$, $Q(\pi_1, \ldots, \pi_q)$ is called a *conjugate.* By the prime number theorem [11], $\sqrt{p_{i,j}} \leq \sqrt{K} \ln K$ and thus $|\pi_i| \leq k\sqrt{K} \ln K$. Then, since Q has at most Z monomials, each conjugate's absolute value is at most $2^{\psi} = cZ(k\sqrt{K} \ln K)^d$. Let $\ell' = \ell - \psi - 1 - \log d$. Let α be the number of the conjugates that are less than $2^{-\ell'}$. Let $\beta = 2^K - \alpha$ be the number of the other conjugates. Let Π be the product of all the conjugates. By Lemma 2.1, $\Pi \neq 0$, and by algebra [9], Π is an integer. Thus, $|\Pi| \geq 1$ and $\alpha(-\ell') + \beta\psi \geq 0$. Hence, $\frac{\beta}{2^K} \geq \frac{\ell'}{\ell' + \psi}$; i.e., $|Q(\pi_1, \ldots, \pi_q))| \geq 2^{-\ell'}$ with the desired probability. We next show that if $|Q(\pi_1, \ldots, \pi_q)| \geq 2^{-\ell'}$, then $|\Delta| \geq 2^{-\ell}$. Since $r_{i,j} > \sqrt{p_{i,j}} - 2^{-\ell}$, $\sum_{j=1}^{k_i} r_{i,j} > |\pi_i| - k2^{-\ell}$. So approximating $p_{i,j}$ reduces each monomial term's absolute value in $Q(\pi_1, \ldots, \pi_q)$ by at most $c(k\sqrt{K} \ln K)^{d-1} dk 2^{-\ell}$. Thus, $|\Delta| \geq |Q(\pi_1, \ldots, \pi_q)| - cZ(k\sqrt{K} \ln K)^d 2^{-\ell + \log d} \geq |Q(\pi_1, \ldots, \pi_q)| - 2^{-\ell' - 1} \geq 2^{-\ell}$. $\square$

THEOREM 2.3. *For a given* $t > 1$, *set* $\ell \geq t\psi + 1 + \log d$. *If* $Q(x_1, \ldots, x_m) \equiv 0$, *Algorithm* 1 *always outputs the correct answer; otherwise, it outputs the correct answer with probability at least* $1 - \frac{1}{t}$. *Moreover, it uses exactly* K *random bits, and its error probability can be decreased by increasing* t *without using one additional random bit.*

Proof. This theorem follows from Lemma 2.2 immediately. $\square$

Let $||Q||$ be the size of the input representation of Q. The next lemma supplements Theorem 2.3 by discussing sufficient conditions for Algorithm 1 to be efficient.

LEMMA 2.4. *With* $Z = \sum_{i=1}^{d} q^i$, *Algorithm* 1 *takes polynomial time in* $||Q||$ *and* t *under the following conditions:*

- *The parameters* $q, d_1, \ldots, d_q, d$ *are at most* $(t||Q||)^{O(1)}$ *and are computable in time polynomial in* $t||Q||$.
- *The parameter* c *is at most* $2^{O(t||Q||)}$ *and is computable in time polynomial in* $t||Q||$.

- *Given ℓ'-bit numbers p'_i, $Q(p'_1, \ldots, p'_q)$ is computable in time polynomial in $t||Q||$ and ℓ'.*

Proof. The proof is straightforward based on the following key facts. There are at most $(t||Q||)^{O(1)}$ primes $p_{i,j}$, which can be efficiently found via the prime number theorem. Each $r_{i,j}$ has at most $(t||Q||)^{O(1)}$ bits and can be efficiently computed by, say, Newton's method. $\square$

We can scale up the rationals $r_{i,j}$ to integers and then compute Δ modulo a reasonably small random integer. As shown in later sections, this may considerably improve the efficiency of Algorithm 1 by means of the next fact.

FACT 1 (Thrash [19]). *Let $h \geq 3$ be an integer. If H is a subset of $\{1, 2, \ldots, h^2\}$ with $|H| \geq \frac{h^2}{2}$, then the least common multiple of the elements in H exceeds 2^h. Thus, for a given positive integer $h' \leq 2^h$, a random integer from $\{1, 2, \ldots, h^2\}$ does not divide h' with probability at least $\frac{1}{2}$.*

3. Application to perfect matching test.

Let $G = (V, E)$ be a graph with n vertices and m edges. Let $V = \{1, 2, \ldots, n\}$. Without loss of generality, we assume that n is even and $m \geq \frac{n}{2}$. A *perfect matching* of G is a set L of edges in G such that no two edges in L have a common endpoint and every vertex of G is incident to an edge in L.

Given G, we wish to decide whether it has a perfect matching. This problem is not known to have a deterministic NC algorithm. The algorithm of Chari, Rohatgi, and Srinivasan [4] uses the fewest random bits among the previous NC algorithms. This paper gives a new algorithm that uses fewer random bits while doing less work. For ease of discussion, a detailed comparison is made right after Theorem 3.2.

3.1. Classical ideas.

The *Tutte matrix* of G is the following $n \times n$ skew-symmetric matrix M of m distinct indeterminates $y_{i,j}$:

$$M_{i,j} = \begin{cases} y_{i,j} & \text{if } \{i,j\} \in E \text{ and } i < j, \\ -y_{j,i} & \text{if } \{i,j\} \in E \text{ and } i > j, \\ 0 & \text{otherwise.} \end{cases}$$

Let $L = \{\{i_1, j_1\}, \ldots, \{i_{\frac{n}{2}}, j_{\frac{n}{2}}\}\}$ be a perfect matching of G, where $i_1 < j_1, i_2 < j_2, \ldots, i_{\frac{n}{2}} < j_{\frac{n}{2}}$ and $i_1 < i_2 < \cdots < i_{\frac{n}{2}}$. Let $\pi(L) = y_{i_1,j_1} y_{i_2,j_2} \cdots y_{i_{\frac{n}{2}}, j_{\frac{n}{2}}}$. Let $\sigma(L) = 1$ or -1 if the following permutation is even or odd, respectively:

$$\begin{pmatrix} 1 & 2 & \cdots & n-1 & n \\ i_1 & j_1 & \cdots & i_{\frac{n}{2}} & j_{\frac{n}{2}} \end{pmatrix}.$$

Let $\mathrm{Pf}(G) = \sum_L \pi(L)\sigma(L)$, where L ranges over all perfect matchings in G.

FACT 2 (Fisher and Kasteleyn [2], Tutte [20]).

- $\det M = (\mathrm{Pf}(G))^2$.
- *G has a perfect matching if and only if* $\det M \not\equiv 0$.

Combining Fact 2 and the DLSZ method, Lovasz [12] gave a randomized NC algorithm for the matching problem. Since the degree of $\det M$ is at most n, this algorithm assigns to each $x_{i,j}$ a random integer from $\{1, 2, \ldots, 2n\}$ uniformly and independently and outputs "G has a perfect matching" if and only if $\det M$ is nonzero at the chosen integers. Its error probability is at most $\frac{1}{2}$, using $m\lceil\log(2n)\rceil$ random bits. The time and processor complexities are dominated by those of computing the determinant of an $n \times n$ matrix with $O(\log n)$-bit integer entries.

3.2. A new randomized NC algorithm. A direct application of Theorem 2.3 to $\det M$ uses $O(m)$ random bits, but our goal is $O(n + \log m/n)$ bits. Therefore, we need to reduce the number of variables in $\det M$.

- Let G' be the acyclic digraph obtained from G by orienting each edge $\{i, j\}$ into the arc $(\min\{i, j\}, \max\{i, j\})$.
- For each vertex i in G', let n_i be the number of outgoing arcs from i.
- Let $\hat{n}_i = 0$ if $n_i = 0$; otherwise, $\hat{n}_i = \lceil \log n_i \rceil$.
- Let $q = \sum_{i=1}^{n} \hat{n}_i$. Note that $q < n + n \log \frac{m}{n}$.
- Let $x_1, x_2, \ldots, x_q$ be q distinct new indeterminates.

We label the outgoing arcs of each vertex as follows. If $n_1 = 0$, vertex 1 has no outgoing arc in G'. If $n_1 = 1$, label its unique outgoing arc with 1. If $n_1 \geq 2$, label its n_1 outgoing arcs each with a distinct monomial in $\{(x_1)^{a_1}(x_2)^{a_2} \cdots (x_{\hat{n}_1})^{a_{\hat{n}_1}} \mid \text{each } a_h \text{ is } 0 \text{ or } 1\}$, which is always possible since $2^{\hat{n}_1} \geq n_1$. We label the n_2 outgoing arcs of vertex 2 in the same manner using $x_{\hat{n}_1+1}, x_{\hat{n}_1+2}, \ldots, x_{\hat{n}_1+\hat{n}_2}$. We similarly process the other vertices i, each using the next $\hat{n}_i$ available indeterminates x_h.

Let $f_{i,j}$ be the label of arc (i, j) in G'. Let $Q(x_1, \ldots, x_q)$ be the polynomial obtained from $\mathrm{Pf}(G)$ by replacing each indeterminate $y_{i,j}$ with $f_{i,j}$.

LEMMA 3.1. *G has a perfect matching if and only if $Q(x_1, \ldots, x_q) \not\equiv 0$.*

Proof. For each L as described in section 3.1, let $Q_L = \sigma(L) f_{i_1,j_1} f_{i_2,j_2} \cdots f_{i_{\frac{n}{2}},j_{\frac{n}{2}}}$. Then $Q = \sum_L Q_L$, where L ranges over all the perfect matchings of G. It suffices to prove that for distinct perfect matchings L_1 and L_2, the monomials Q_{L_1} and Q_{L_2} differ by at least one x_h. Let H be the subgraph of G induced by $(L_1 \cup L_2) - (L_1 \cap L_2)$. H is a set of vertex-disjoint cycles. Since $L_1 \neq L_2$, H contains at least one cycle C. Let C' be the acyclic digraph obtained from C by replacing each edge $\{i, j\}$ with the arc $(\min\{i, j\}, \max\{i, j\})$. C' contains two outgoing arcs (i, j_1) and (i, j_2) of some vertex i. So there is an indeterminate x_h used in arc labels for vertex i, whose degree is 1 in one of f_{i,j_1} and f_{i,j_2} but is 0 in the other. Hence, the degree of x_h is 1 in one of Q_{L_1} and Q_{L_2} but is 0 in the other, which makes Q_{L_1} and Q_{L_2} distinct as desired. ∎

To test whether G has a perfect matching, we use Algorithm 1 to test Q by means of Theorem 2.3 and Lemma 3.1. Below we detail each step of Algorithm 1.

Step 1. Compute q. Then set $d_1 = d_2 = \cdots = d_q = 1$, $k_1 = k_2 = \cdots = k_q = 1$, $K = q$, $d = q$, $c = 1$. Further set $Z = (\frac{2m}{n})^n$ since the number of perfect matchings in G is at most $\Pi_{i=1}^{n} m_i \leq (\frac{2m}{n})^n$, where m_i is the degree of node i in G.

Step 2. This step computes the q smallest primes $p_{1,1}, p_{2,1}, \ldots, p_{q,1}$, each at most $q \ln^2 q$. Since a positive integer p is prime if and only if it is indivisible by any integer i with $2 \leq i \leq \sqrt{p}$, these primes can be found in $O(\log q)$ parallel arithmetic steps on integers of at most $\lceil \log(1 + q \ln^2 q) \rceil$ bits using $O(q^{1.5} \log^3 q)$ processors.

Step 3. This step is straightforward.

Step 4. Set $\ell = \lceil t\psi \rceil + \lceil q \rceil + 1$, where $\psi = n \log \frac{2m}{n} + q \log(\sqrt{q} \ln q)$.

Step 5. We use Newton's method to compute $r_{i,1}$ from $p_{i,1}$. For the convenience of the reader, we briefly sketch the method here. We use $g_0 = p_{i,1}$ as the initial estimate. After the jth estimate g_j is obtained, we compute $g_{j+1} = \frac{1}{2}(g_j + \frac{p_{i,1}}{g_j})$, maintaining only the bits of g_{j+1} before the $(\ell + 1)$th bit after the decimal point. Thus, $g_{j+1} \leq \frac{1}{2}(g_j + \frac{p_{i,1}}{g_j})$. With g_{j+1} obtained, we check whether $g_{j+1}^2 > p_{i,1}$. If not, we stop; otherwise, we proceed to compute g_{j+2}. Since the convergence order of the method is 2, we take the $\lceil \log(\lceil \log p_{i,1} \rceil + \ell) \rceil$th estimate as $r_{i,1}$. Thus $r_{1,1}, \ldots, r_{q,1}$ can be computed in $O(\log(\ell + \log q))$ parallel arithmetic steps with q processors. Note that each g_j has at most $\lceil \log(1 + q \ln^2 q) \rceil + \ell$ bits.

Step 6. Evaluating Δ is equivalent to computing Δ^2. Δ^2 is the determinant of an $n \times n$ skew-symmetric matrix M' whose nonzero entries above the main diagonal in the ith row are either 1 or products of at most $\hat{n}_i$ rationals among $r_{1,1}, \dots, r_{q,1}$. Thus, each matrix entry has at most $\lceil \log n \rceil (\lceil \log(1 + q \ln^2 q) \rceil + \ell)$ bits. Setting up M' takes $O(\log n)$ arithemetic steps on $O(n^2)$ processors.

Step 7. This step is straightforward.

The next theorem summarizes the above discussion.

THEOREM 3.2. *For any given $t > 1$, whether G has a perfect matching can be determined in $O(\log(nt))$ parallel arithmetic steps on rationals of $O(tn \log^3 n)$ bits using $O(n^2)$ processors together with one evaluation of the determinant of an $n \times n$ matrix of $O(tn \log^3 n)$-bit rational entries. The error probability is at most $\frac{1}{t}$, using $q < n + n \log \frac{m}{n}$ random bits.*

Remark. The best known NC algorithm for computing the determinant of an $n \times n$ matrix takes $O(\log^2 n)$ parallel arithmetic steps using $O(n^{2.376})$ processors [16].

Proof. We separate the total complexity of Algorithm 1 into that for computing $\det M'$ and that for all the other computation. For the latter, the running time is dominated by that of Step 5; the bit length by that of the entries in M' at Step 6; and the processor count by that of setting up M'. $\square$

The work of Chari, Rohatgi, and Srinivasan [4] aims to use few random bits when the number of perfect matchings is small. Indeed, their algorithm uses the fewest random bits among the previous NC algorithms. For an error probability at most $\frac{3}{4}$, it uses $\min\{28 \sum_{i=1}^{n} \lceil \log \hat{d}_i \rceil, 6m + 4 \sum_{i=1}^{n} \lceil \log \hat{d}_i \rceil\} + O(\log n)$ random bits, where $\hat{d}_i$ is the degree of vertex i in G. It also computes the determinant of an $n \times n$ matrix with $O(n^7)$-bit entries. In contrast, with $t = 2$ in Theorem 3.2, Algorithm 1 has an error probability at most $\frac{1}{2}$ while using fewer random bits, i.e., $q < n + n \log \frac{m}{n}$ bits. Moreover, using the best known NC algorithm for determinants, the work of Algorithm 1 is dominated by that of computing the determinant of an $n \times n$ matrix with entries of shorter length, i.e., $O(n \log^3 n)$ bits.

The next theorem modifies the above implementation of Algorithm 1 by means of Fact 1 so that it computes the determinants of matrices with only $O(\log(nt))$-bit integer entries but uses slightly more random bits.

THEOREM 3.3. *For any given $t > 2$, whether G has a perfect matching can be determined in $O(\log(nt))$ parallel arithmetic steps on rationals of $O(tn \log^3 n)$ bits using $O(n^2)$ processors together with $\lceil \log t \rceil$ evaluations of the determinant of an $n \times n$ matrix of $O(\log(nt))$-bit integer entries. The error probability is at most $\frac{2}{t}$, using $q + O(\log t \log(nt))$ random bits, which is at most $n + n \log \frac{m}{n} + O(\log t \log(nt))$.*

Proof. We modify Steps 6 and 7 of the above implementation as follows.

Step 6.

- Compute M' as above.
- For each (i, j)th entry of M', we multiply it with $2^{(\hat{n}_i + \hat{n}_j)\ell}$ in $O(1)$ parallel arithmetic steps using $O(n^2)$ processors. Let M'' be the resulting matrix; note that $\det M'' = 2^{2q\ell} \det M'$ and each entry of M'' is an integer of at most $3\lceil \log n \rceil (\ell + \lceil \log n \rceil)$ bits.
- Let $\lambda = \lceil \log t \rceil$. Let $u = n! \cdot 2^{3n \lceil \log n \rceil (\ell + \lceil \log n \rceil)}$; note that $|\det M''| \le u$. We uniformly and independently choose λ random positive integers $w \le \lceil \log u \rceil^2$ using $O(\lambda \log(nt))$ random bits in $O(\lambda)$ steps on a single processor. For each chosen w, we first compute $M''' = M'' \bmod w$ in $O(1)$ parallel arithmetic steps using $O(n^2)$ processors; and then compute $\det M'''$ instead of $\det M'$.

Step 7. Output "G has a perfect matching" if and only if some $\det M'''$ is nonzero.

By Fact 1, if $\det M'' \neq 0$, then some chosen w does not divide $\det M''$ with probability at least $1-2^{-\lambda}$. Thus, the overall error probability is at most $\frac{1}{t}+2^{-\lambda} \leq \frac{2}{t}$. We separate the total complexity of Algorithm 1 into that for computing $\det M'''$ and that for all the other computation. As with Theorem 3.2, the running time of the latter remains dominated by that of Step 5, the bit length by that of the entries in M' at Step 6, and the processor count by that of setting up M'. $\square$

4. Application to multiset equality test. Let $A = \{a_1, \dots, a_n\}$ and $B = \{b_1, \dots, b_n\}$ be two multisets of positive integers. Let a be the largest possible value for any element of $A \cup B$. Given A, B, and a as input, the *multiset equality test problem* is that of deciding whether $A \equiv B$, i.e., whether they contain the same number of copies for each element in $A \cup B$. This problem was initiated by Blum and Kannan [3] to study how to check the correctness of sorting programs. They gave two randomized algorithms on a useful model of computation which reflects many sorting scenarios better than the usual RAM model. For brevity, we denote their model by MBK and the two algorithms by ABK_1 and ABK_2.

This section modifies the MBK model to cover a broader range of sorting applications. It then gives a new randomized algorithm, which improves upon ABK_1 and ABK_2 and can speed up the checking algorithm for sorting by Blum and Kannan [3] on a large range of inputs.

4.1. Models of computation and previous results. In both the MBK model and the modified model, the computer has $O(1)$ tapes as well as a random access memory of $O(\log n + \log a)$ words. The allowed elementary operations are $+$, $-$, $\times$, $/$, $<$, $=$, and two bit operations shift-to-left and shift-to-right, where $/$ is integer division. Each of these operations takes one step on integers that are one word long; thus the division of an integer of m_1 words by another of m_2 words takes $O(m_1 m_2)$ time. In addition, it takes one step to copy a word on tape to a word in the random access memory or vice versa.

The only difference between the two models is that the modified model has a shorter word length relative to a and therefore is applicable to sorting applications with a larger range of keys. To be precise, in the MBK model, each word has $1+\lfloor \log a \rfloor$ bits, and thus can hold a nonnegative integer at most a. In the modified model, each word has $\xi = 1 + \lfloor \log \max\{\lceil \log n \rceil, \lceil \log a \rceil\} \rfloor$ bits and thus can hold a nonnegative integer at most $\max\{\lceil \log n \rceil, \lceil \log a \rceil\}$.

Note that sorting A and B by comparison takes $O(n \log n)$ time in the MBK model and $O(\frac{\log a}{\xi} n \log n)$ time in the modified model. However, in both models, if $n \geq 2^a$, the equality of A and B can be tested in optimal $O(n)$ time with bucket sort. Hence, we hereafter assume $n < 2^a$. We briefly review ABK_1 and ABK_2 as follows.

Let $Q_1(x)$ be the polynomial $\sum_{i=1}^n x^{a_i} - \sum_{i=1}^n x^{b_i}$. ABK_1 selects a random prime $w \leq 3a\lceil \log(n+1) \rceil$ uniformly and computes $Q_1(n+1) \bmod w$ in a straightforward manner. It outputs "$A \equiv B$" if and only if $Q_1(n+1) \bmod w$ is zero. Excluding the cost of computing w, ABK_1 takes $O(n \log a)$ time in the MBK model and $O\big((\frac{\log a}{\xi})^2 n \log a\big)$ time in the modified model. The error probability is at most $\frac{1}{2}$.

Let $Q_2(x)$ be the polynomial $\Pi_{i=1}^n (x - a_i) - \Pi_{i=1}^n (x - b_i)$. ABK_2 uniformly selects a random positive integer $z \leq 4n$ and a random prime $w \leq 3n\lceil \log(a + 4n) \rceil$; and computes $P(z) \bmod w$ in a straightforward manner. It outputs "$A \equiv B$" if and only if $P(z) \bmod w$ is zero. Excluding the cost of computing w, ABK_2 takes $O\big(n \max\{1, (\frac{\log n}{\log a})^2\}\big)$ time in the MBK model and $O\big(n \frac{(\log n + \log a)(\log n + \log\log a)}{\xi^2}\big)$ time in the modified model. The error probability is at most $\frac{3}{4}$.

Generating the random primes w is a crucial step of ABK_1 and ABK_2. It is unclear how this step can be performed efficiently in terms of running time and random bits. We modify this step by means of Fact 1 as follows. In ABK_1, $|Q_1(n+1)| \leq 2^{1+a\log(n+1)+\log n}$; in ABK_2, $|Q_2(2n)| \leq 2^{1+n\log(a+4n)}$. Thus, we can replace w in ABK_1 and ABK_2 with two random positive integers $w_1 \leq (1+a\log(n+1)+\log n)^2$ and $w_2 \leq (1+n\log(a+4n))^2$, respectively. With these modifications, ABK_1 and ABK_2 use at most $2\log a + 2\log\log n + O(1)$ and $3\log n + 2\log\log(a+n) + O(1)$ random bits, respectively. The time complexities and error probabilities remain as stated above.

4.2. A new randomized algorithm. Our goal in this section is to design an algorithm for multiset equality test for the modified model that is faster than ABK_1 for $n = \omega((\log\log a)^2)$ and faster than ABK_2 for $n = \omega\left((\log a)^{\log\log a}\right)$. We can then use it to speed up the previously best checking algorithm for sorting [3].

- Let $q = \lfloor \log a \rfloor + 1$.
- Let $x_1, \ldots, x_q$ be q distinct indeterminates.
- For each $u \in A \cup B$, let f_u denote the monomial $(x_1)^{u_1}(x_2)^{u_2}\cdots(x_q)^{u_q}$, where $u_1u_2\cdots u_q$ is the standard q-bit binary representation of u.
- Let $Q(x_1,\ldots,x_q)$ denote the polynomial $\sum_{i=1}^n f_{a_i} - \sum_{i=1}^n f_{b_i}$.

Note that $Q(x_1,\ldots,x_q) \equiv 0$ if and only if $A \equiv B$. To test whether $A \equiv B$, we detail how to implement the steps of Algorithm 1 to test Q as follows. The algorithm is analyzed only with respect to the modified model.

Remark. In the implementation, the parameter t of Theorem 2.3 needs to be a constant so that the algorithm can be performed inside the random access memory together with straightforward management of the tapes. At the end of this section, we set $t = 4$, but for the benefit of future research, we analyze the running time and the random bit count in terms of a general t.

Step 1. Compute q by finding the index of the most significant bit in the binary representation of a. Since a takes up $O(\frac{\log a}{\xi})$ words, this computation takes $O(q)$ time by shifting the most significant nonzero word to the left at most ξ times. Afterwards, set $d_1 = d_2 = \cdots = d_q = k_1 = k_2 = \cdots = k_q = k = 1$, $K = d = q$, $c = n$, and $Z = 2n$ in $O(q)$ time. This step takes $O(q)$ time.

Step 2. Compute the q smallest primes $p_{1,1}, p_{2,1}, \ldots, p_{q,1} \leq q\ln^2 q$. We compute these primes by inspecting $i = 2, 3, \ldots$ one at a time up to $q\ln^2 q$ until exactly q primes are found. Since i can fit into $O(1)$ words, it takes $O(\sqrt{q}\log q)$ time to check the primality of each i using the square root test for primes in a straightforward manner. Thus, this step takes $O(q^{3/2}\log^3 q)$ time.

Step 3. This step is straightforward and uses q random bits and $O(\frac{q}{\xi})$ time.

Step 4. Set $\ell = \lceil t \rceil \psi' + \lceil q \rceil + 1$, where t is a given positive number and $\psi' = 2\lceil \log n \rceil + \lceil \frac{q\lceil \log q \rceil}{2} \rceil + q\lceil \log\lceil \log q \rceil \rceil + 1$. The number $\lceil \log n \rceil$ can be computed from the input in $O(n)$ time. The computations of $\lceil \frac{\log q}{2} \rceil$ and $\lceil \log\lceil \log q \rceil \rceil$ are similar to Step 1 and take $O(\log q)$ time. Thus, this step takes $O(n + \log q + \frac{\log t}{\xi})$ time.

Step 5. As at Step 5 in section 3.2, we use Newton's method to compute $r_{i,1}$ for each $p_{i,1}$. With only integer operations allowed, we use $2^\ell g_j$ as the jth estimate for $2^\ell\sqrt{p_{i,1}}$; i.e., $2^\ell g_{j+1} = (2^\ell g_j + 2^{2\ell}p_{i,1}/(2^\ell g_j))/2$. The last estimate computed in this manner is $2^\ell r_{i,1}$. Since 2^ℓ can be computed in $O((\frac{\ell}{\xi})^2)$ time using a doubling process, the first estimate $2^\ell p_{i,1}$ can be computed in the same amount of time. Since the other estimates all are $O(\frac{\ell}{\xi})$ words long, the $(j+1)$th estimate can be obtained from the jth in $O((\frac{\ell}{\xi})^2)$ time. Since only $O(\log \ell)$ iterations for each $2^\ell\sqrt{p_{i,1}}$ are needed, this step takes $O(q(\frac{\ell}{\xi})^2 \log \ell)$ time.

Step 6. We compute $\Delta = Q((-1)^{b_{1,1}} r_{1,1}, \ldots, (-1)^{b_{q,1}} r_{q,1})$ by means of Fact 1 as follows. Let $\lambda = \lceil \log t \rceil$. Since $|2^{q\ell}\Delta|$ is an integer at most $2^{\psi' + q\ell}$, we uniformly and independently select λ random positive integers $w \le (\psi' + q\ell)^2$ using $2\lambda(\log t + \log\log n + 2\log\log a + o(\log\log a))$ random bits and $O(\lambda \frac{\log \ell}{\xi})$ time. Note that if $2^{q\ell}\Delta \neq 0$, then with probability at least $1 - \frac{1}{t}$, some $2^{q\ell}\Delta \bmod w$ is nonzero. We next compute all $2^{ql}\Delta \bmod w$. For each element $u \in A \cup B$, let $e(u)$ be the number of 0's in the standard q-bit binary representation of u. Let $h(u) = f_u((-1)^{b_{1,1}} 2^\ell r_{1,1}, \ldots, (-1)^{b_{q,1}} 2^\ell r_{q,1})$. Then, $2^{q\ell}\Delta = \sum_{i=1}^n 2^{e(a_i)\ell} h(a_i) - \sum_{i=1}^n 2^{e(b_i)\ell} h(b_i)$, which we use to compute all $2^{q\ell}\Delta \bmod w$ as follows.

- Compute the numbers $e(u)$ for all $u \in A \cup B$ in $O(nq)$ time.
- For all w, compute all $2^\ell r_{i,1} \bmod w$ in $O(\lambda q \frac{\ell}{\xi} \frac{\log \ell}{\xi})$ time.
- For all w, use values obtained above to compute $h(u) \bmod w$ for all u in $O(\lambda nq(\frac{\log \ell}{\xi})^2)$ time.
- For all w, compute $2^\ell \bmod w$ in $O(\lambda \frac{\ell}{\xi} \frac{\log \ell}{\xi})$ time.
- For all w, use values obtained above to compute $2^{e(u)\ell} \bmod w$ for all u in $O(\lambda n(\frac{\log \ell}{\xi})^2 \log q)$ time.
- For all w, use values obtained above to compute $2^{q\ell}\Delta \bmod w$ in $O(\lambda n(\frac{\log \ell}{\xi})^2)$ time.

This step uses $2\lambda(\log t + \log\log n + 2\log\log a + o(\log\log a))$ random bits and takes $O(\lambda q \frac{\ell}{\xi} \frac{\log \ell}{\xi} + \lambda nq(\frac{\log \ell}{\xi})^2)$ time.

Step 7. Output "$A \not\equiv B$" if and only if some $2^{ql}\Delta \bmod w$ is nonzero.

The next theorem summarizes the above discussion.

THEOREM 4.1. *For any given $t > 2$, whether $A \equiv B$ can be determined in time*

$$O\left(q \log \ell \left(\frac{\ell}{\xi}\right)^2 + \lambda nq \left(\frac{\log \ell}{\xi}\right)^2\right),$$

where $q = \Theta(\log a)$; $\ell = \Theta(t(\log n + \log a \log\log a))$; $\xi = \Theta(\log\log(n+a))$; $\lambda = \Theta(\log t)$. The error probability is at most $\frac{2}{t}$ using $\log a + 2\lceil \log t \rceil(\log t + \log\log n + 2\log\log a + o(\log\log a))$ random bits.

Proof. The running time of Algorithm 1 is dominated by those of Steps 5 and 6. The error probability follows from Theorem 2.3 and Fact 1. $\square$

We use the next corollary of Theorem 4.1 to compare Algorithm 1 with ABK$_1$ and ABK$_2$ in the modified model.

COROLLARY 4.2. *With $t = 4$, Algorithm 1 has an error probability at most $\frac{1}{2}$ using $\log a + 4\log\log n + 8\log\log a + o(\log\log a)$ random bits, while running in time*

$$O\left(n \log a + \log a \frac{(\log n + \log a \log\log a)^2}{\log\log(n+a)}\right).$$

By Corollary 4.2, Algorithm 1 is faster than ABK$_1$ for $n = \omega((\log\log a)^2)$ and faster than ABK$_2$ for $n = \omega\left((\log a)^{\log\log a}\right)$. Thus, it can replace ABK$_1$ and ABK$_2$ to speed up the previously best checking algorithm for sorting [3] as follows. We use bucket sort for $2^a \le n$, Algorithm 1 for $(\log a)^{\log\log a} \le n < 2^a$, and ABK$_2$ otherwise.

Acknowledgments. We are very grateful to Steve Tate for useful discussions and to the anonymous referees for extremely thorough and helpful comments.

ON THE POWER OF LOGIC RESYNTHESIS*

WEI-LIANG LIN[†], AMIR H. FARRAHI[‡], AND M. SARRAFZADEH[§]

Abstract. A linear arrangement problem, called the minmax mincut problem, emerging from circuit design is investigated. Its input is a series-parallel directed hypergraph (SPDH), and the output is a linear arrangement (and a layout). The primary objective is to minimize the longest path, and the secondary objective is to minimize the cutwidth. It is shown that cutwidth D, subject to longest path minimization, is affected by two terms: *pattern number* k and *balancing number* m. Also, k and m are both lower bounds on the cutwidth. An algorithm, running in linear time, produces layouts with cutwidths $D \leq 2(k+m)$. There exist examples with $k = \Omega(N)$, where N is the number of vertices; however, m is always $O(\log N)$. We show that every SPDH, after *local logic resynthesis* (specifically, after reordering the serial paths), can be linearly placed with cutwidth $D = O(\log N)$. Simultaneously, its dual SPDH can be linearly placed with the same vertex order and with cutwidth $D = O(\log N)$. Therefore, after local resynthesis the area can be reduced by a factor of $N/\log N$.

Application to gate-matrix layout style is demonstrated.

1. Introduction.

This section begins by defining basic terms. Then we formulate the concerned problem and compare it with related problems in the literature.

1.1. Definitions.

The following definitions originate from a practical circuit application, which will be further explained in section 6. Most terms are natural extensions of terms from graph theory.

An *undirected hypergraph* $G = (V, E)$ consists of two sets V and E, where V is a set of vertices and E is a set of undirected hyperedges. An *undirected hyperedge* is a nonempty subset of V.

A *directed hypergraph* $H = (V, E)$ also consists of two sets V and E, where V is a set of vertices and E is a set of directed hyperedges. A *directed hyperedge* $e = (V_1, V_2)$ is an ordered pair of nonempty subsets of V, where V_1 is the *source set* of hyperedge (V_1, V_2) and V_2 is the *sink set* of hyperedge (V_1, V_2): $V_1 \cap V_2 = \emptyset$. Figure 1.1 shows a directed hypergraph $H = (V, E)$ with five vertices $V = \{a, b, c, d, e\}$ and two hyperedges $E = \{(\{a, b\}, \{c, d\}), (\{d\}, \{e\})\}$. $\{a, b\}$ and $\{c, d\}$ are the source set and the sink set of hyperedge $(\{a, b\}, \{c, d\})$, respectively. $\{d\}$ and $\{e\}$ are the source set and the sink set of hyperedge $(\{d\}, \{e\})$, respectively.

A *source* s of a directed hypergraph is a vertex without any incident hyperedge containing s in its sink set. Similarly, a *sink* t of a directed hypergraph is a vertex without any incident hyperedge containing t in its source set. Thus in Figure 1.1, a, b are sources and c, e are sinks.

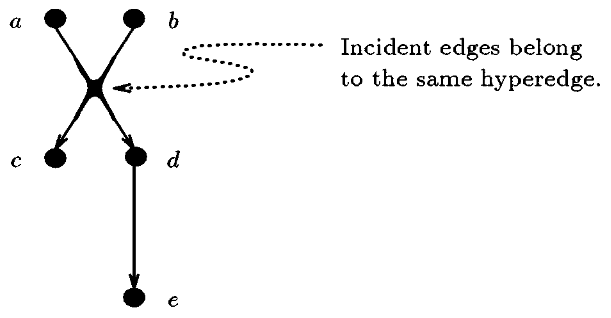

FIG. 1.1. *A directed hypergraph $H = (V, E)$ with five vertices $V = \{a, b, c, d, e\}$ and two hyperedges $E = \{(\{a, b\}, \{c, d\}), (\{d\}, \{e\})\}$. $\{a, b\}$ and $\{c, d\}$ are the only source set and the only sink set of hyperedge $(\{a, b\}, \{c, d\})$, respectively. $\{d\}$ and $\{e\}$ are the only source set and the only sink set of hyperedge $(\{d\}, \{e\})$, respectively. Also, a, b are sources and c, e are sinks.*

A *two-terminal directed hypergraph* is a directed hypergraph with only one source and only one sink. Notice that source sets and sink sets refer to hyperedges and sources and sinks refer to directed hypergraphs. A directed hypergraph is *acyclic* if there does not exist a sequence (with a cardinality larger than 1) of pairs of ordered vertices $(v_1, v_2), (v_2, v_3), \ldots, (v_m, v_{m+1} = v_1)$, where in (v_i, v_{i+1}), v_i and v_{i+1} belong to the source set and the sink set of a distinct hyperedge, respectively. Therefore, the directed hypergraph H in Figure 1.1 is acyclic but is not a two-terminal one.

We recursively define a *series-parallel directed hypergraph* (SPDH) as follows. A directed hypergraph, denoted as an *SPDH basis* (SPDHB), consisting of three vertices s, v, t connected by two hyperedges, as shown in Figure 1.2(a), is an SPDH. In addition to an SPDHB, an SPDH can be constructed by applying two operations, *series* and *parallel*, on two SPDHs, recursively. A *series* operation combines two SPDHs H_1, H_2 by removing the sink of H_1 and the source of H_2 and merging the remaining two "dangling" hyperedges into one hyperedge, as Figure 1.2(c) shows. A *parallel* operation combines two SPDHs by merging the two sources and the corresponding incident hyperedges and merging the two sinks and the corresponding hyperedges, as Figure 1.2(d) shows.

Obviously, an SPDH is acyclic. In addition, each vertex v has only two incident hyperedges: one *incoming hyperedge* containing vertex v in the sink set of the hyperedge and one *outgoing hyperedge* containing vertex v in the source set of the hyperedge. However, the source has only one incident hyperedge, called the *source hyperedge*, and the sink has also only one incident hyperedge, called the *sink hyperedge*.

A *series-parallel* (S-P) *tree* [13] T can represent an SPDH H. Since H is recursively constructed, we define T in a recursive manner. Each leaf of T corresponds to an SPDHB. Let H_1 and H_2 be two subgraphs of H that are combined either in series (labeled S) or in parallel (labeled P). The tree corresponding to the union of H_1 and H_2 consists of a node label S or P (depending on the combination step) with T_1 and T_2 as its subtrees, where T_1 and T_2 are trees corresponding to H_1 and H_2, respectively.

In order to simplify our discussion in linear arrangements of an SPDH, a modified S-P tree, called a "marked" S-P tree, is defined as follows. A double line below an S-type node is used to emphasize that the SPDH of the corresponding subtree should be located closer to the source. Figure 1.3(a) shows an SPDH constructed by applying 3 series and 3 parallel operations on 7 SPDHBs, and Figure 1.3(b) shows a corresponding

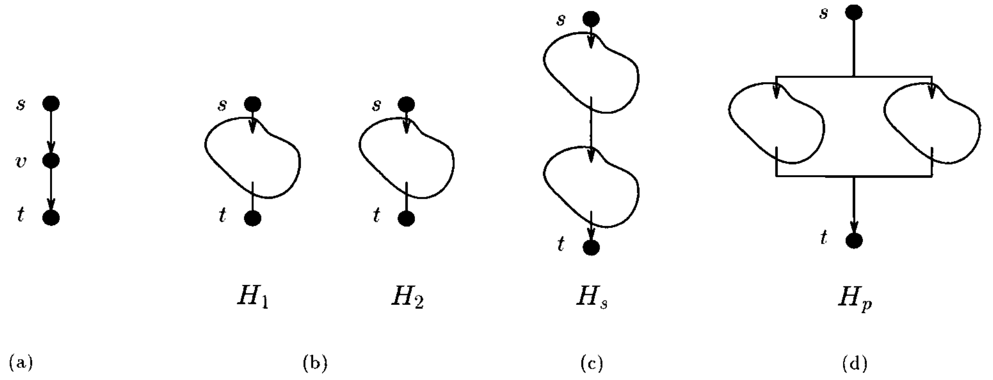

FIG. 1.2. (a) *An SPDHB.* (b) *Two SPDHs, H_1 and H_2, result in another SPDH,* (c) *H_s after a series operation or* (d) *H_p after a parallel operation.*

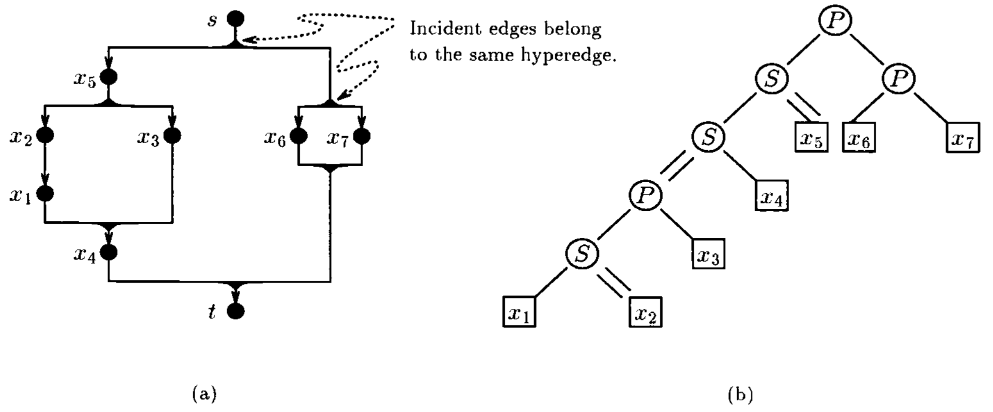

FIG. 1.3. (a) *An SPDH constructed by applying* 3 *series and* 3 *parallel operations on* 7 *SPDHBs.* (b) *A corresponding S-P tree. Notice that vertices s and t do not appear in the S-P tree because of the definition of an S-P tree.*

S-P tree.[1] The *dual* of an SPDH H is also an SPDH H_d constructed from a similar procedure as the one constructing H. However, when the procedure which constructs H employs a series operation, the dual procedure which constructs H_d employs a parallel operation, and vice versa. An S-P tree of H_d is a dual of an S-P tree of H. To clarify, we employ the name "nodes" instead of "vertices" in the context of S-P trees and employ "vertices" in the context of directed hypergraphs. Figures 1.4(a) and (b) show duals of the SPDH and S-P tree of Figure 1.3.

A *linear arrangement* (also called a *linear layout* or simply a *layout*) of a directed hypergraph H is a one-to-one function $L : V \to 1, 2, \ldots, |V|$. The cutwidth D of a layout is $D = \max(|E(i)| \mid 1 \leq i < |V|)$, where $E(i) = \{(V_1, V_2) \in E \mid \exists x \in V_1, y \in V_2, or, x \in V_2, y \in V_1$ such that $L(x) \leq i < L(y)\}$. In other words, $|E(i)|$ is the least number of tracks needed at position i in order to lay out all hyperedges crossing position i in distinct tracks. Figure 1.5 shows two layouts of the SPDH of Figure 1.3(a), where each filled circle represents a vertex: one layout needs three

[1]An SPDH may correspond to more than one S-P tree.

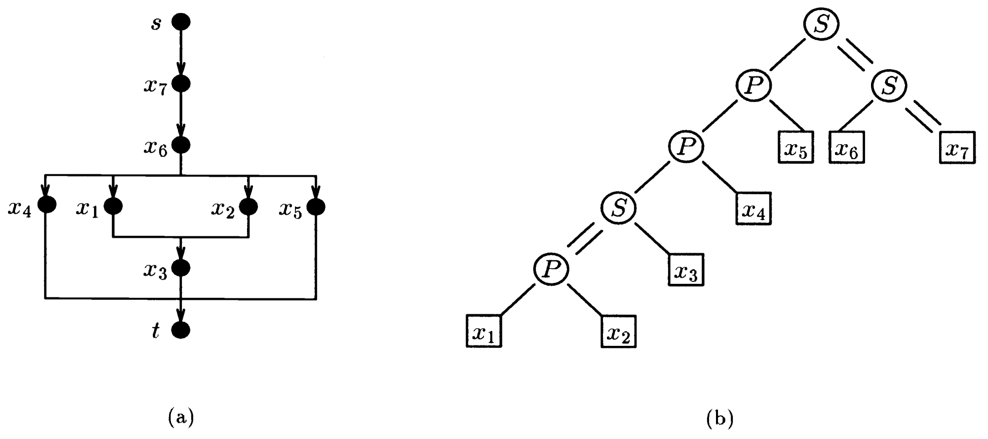

FIG. 1.4. (a) *A dual of the SPDH in Figure* 1.3(a). (b) *A dual of the S-P tree in Figure* 1.3(b).

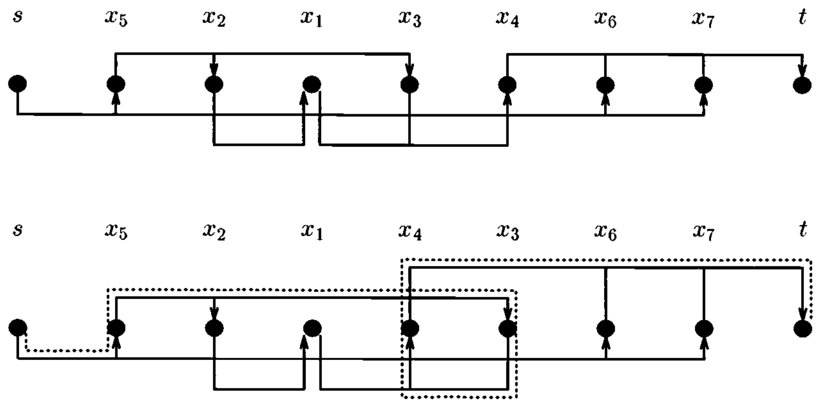

FIG. 1.5. *Two layouts for the SPDH in Figure* 1.3(a), *one with three tracks and the other with four tracks. Each filled circle represents a placed vertex, and the dotted line shows a path with a bend which will be discussed in section* 2.

tracks and the other needs four tracks.

1.2. Problem formulation. We formulate a novel linear arrangement problem as follows.

A minmax mincut problem.

Input: An SPDH.

Output: A minimum cutwidth layout with the constraints that the source is at the leftmost position, the sink is at the rightmost position, and the longest path[2] is minimized.

1.3. Related problems. In the literature, problems related to the minmax mincut problem are the single-machine sequencing with precedence relations problem [11], the mincut linear arrangement problem [4], and the gate-matrix area (height)

[2]Only horizontal lengths are taken into consideration since vertical lengths will become negligible when the number of vertices increases.

minimization problem [8]. However, there are no obvious methods to transform the minmax mincut problem to one of these problems.

The single-machine sequencing with precedence relations problem accepts an input of precedence relations, which forms a directed graph. The goal is to linearly arrange the vertices under the constraints of the precedence relations. Nevertheless, the problem of including the cutwidth in the cost function has not yet been addressed.

The mincut linear arrangement problem focuses on an undirected graph. The considered edges are not directed hyperedges. Minimizing the cutwidth of a linear layout of a general undirected graph is NP-complete [3]. If the graph is a tree, it can be solved in polynomial time [15].

In terms of our above definitions, the gate-matrix minimization problem is actually the "mincut linear arrangement of a general directed hypergraph" problem. However, it does not have the constraint of minimizing the longest path. The gate-matrix minimization problem is also NP-complete and a number of effective heuristics have been proposed [2, 5, 7, 6]. Also, a tight bound $\Theta(\log N)$ on the cutwidth was proved [12].

This paper is further organized as follows. Section 2 investigates the constraint of the longest path minimization problems. Section 3 shows that the *pattern number* k is a lower bound on the cutwidth D, and that there exist examples with $k = \Omega(N)$. An algorithm on the minmax mincut problem ensuring cutwidth $D \leq 2(k + m)$ is presented in section 4, where the *balancing number* m is also introduced. Section 5 proposes a reordering and layout algorithm, which reorders serial paths and simultaneously reduces the *pattern number*s of an SPDH and its dual from k to $O(\log N)$. The algorithm also lays out the SPDH and its dual in the same layout order. Therefore, every SPDH and its dual can be simultaneously laid out with cutwidth $O(\log N)$. Section 6 illustrates applications and shows two examples. The last section summarizes and concludes this paper.

2. Minimizing the longest path.

This section describes a class of layouts subject to two constraints: (1) the longest path is minimized, (2) the source is at the leftmost position and the sink is at the rightmost position.

THEOREM 2.1. *A layout of an SPDH, with the constraints that the source is at the leftmost position and the sink is at the rightmost position, has the minimum longest path if and only if it does not have any "bends" in its paths.*

Proof. There are two observations: (1) the source is at the leftmost position and the sink is at the rightmost position,[3] (2) since each path must begin at the source and end at the sink, the minimum path length is the straight-line distance from the source to the sink. If there is no bend in any path, each path (including the longest one) has the same minimum length, the straight-line distance from the source to the sink. Obviously, any bend will increase the lengths of some paths and, consequently, will violate the constraint of minimizing the longest path. Figure 1.5 shows layouts with and without bends. $\square$

It is not difficult to see that the set of all layouts produced by *topological sorting* [1] of directed hypergraphs is equal to the set of layouts without bends. (As will be discussed in section 6, layouts obtained from topological sorting are of particular importance in designing high-performance VLSI circuits.) A *topological sorting* of an acyclic directed hypergraph $H = (V, E)$ is a layout of its vertices such that if H contains a directed hyperedge (V_1, V_2), each vertex in V_1 will be laid out to the left of

[3]Recall that an SPDH has only one source and only one sink.

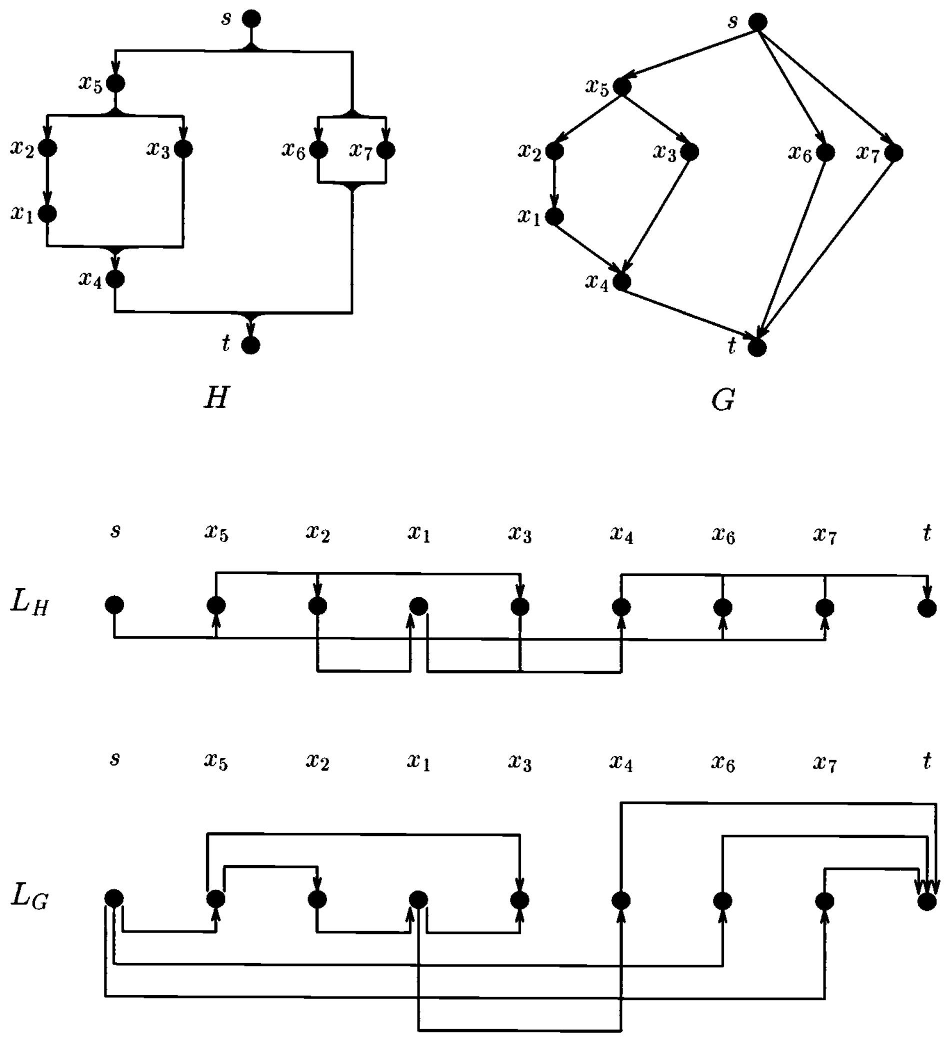

FIG. 2.1. *A directed hypergraph H is transformed to a directed graph G, and the topologically sorted layout L_H of H corresponds to the topologically sorted layout L_G of G.*

each vertex in V_2.

Notice that by substituting each directed hyperedge with two-terminal directed edges from each vertex of the source set to each vertex of the sink set, we transform any directed hypergraph H to a directed graph G. It is easy to see that there is a one-to-one relation between topological sortings of G and H. In Figure 2.1, a directed hypergraph H is transformed to a directed graph G and the topologically sorted layout L_H of H corresponds to the topologically sorted layout L_G of G.

3. Cutwidth consideration in topologically sorted layouts. Recall that for an SPDH layout the number of tracks needed is lower bounded by the cutwidth. In this section, among the *topologically sorted* (TS) *layouts* an SPDH with $D = \Omega(N)$ tracks is shown, where N is the number of vertices. In addition, the *pattern number* k is defined and shown to be a lower bound on the number of tracks D. However, this

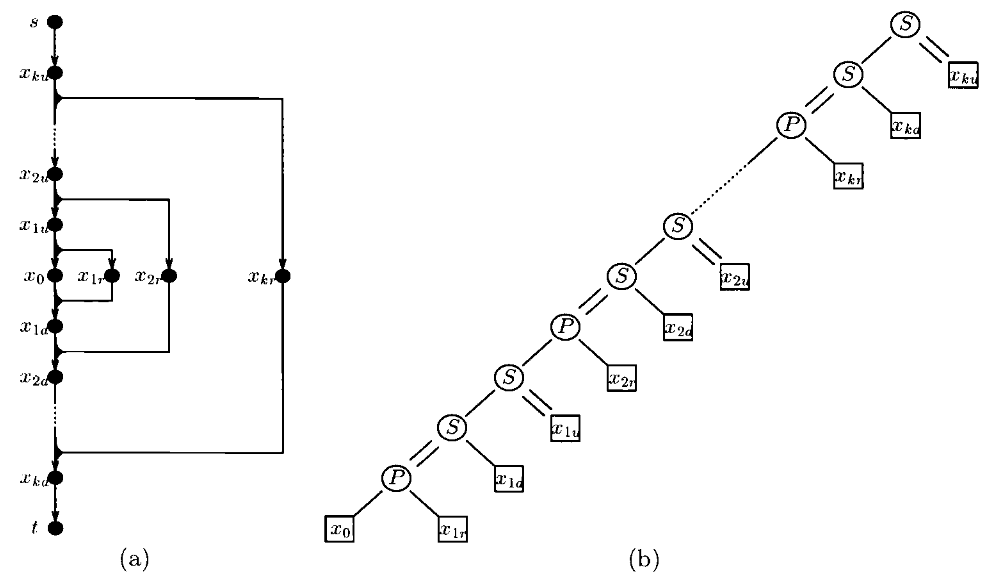

FIG. 3.1. (a) *A TS-difficult SPDH requiring $\Omega(N)$ tracks.* (b) *An S-P tree for the TS-difficult SPDH.*

bound is not tight.

Consider a class of SPDHs $TS\_d(k)$, called *TS-difficult SPDHs*, which is recursively defined as follows. The basis $TS\_d(0)$ is an SPDHB. $TS\_d(k)$ is constructed from $TS\_d(k-1)$ by adding an SPDHB in parallel and then serially merging an SPDHB to the source of the resulting SPDH and then adding another SPDHB to the sink of the resulting SPDH. The general form is shown in Figure 3.1(a) with $N = 3k + 3$.

LEMMA 3.1. *All TS-layouts of a TS-difficult SPDH $TS\_d(k)$ require $\Omega(N)$ tracks, where N is the number of vertices.*

Proof. Let $\mathrm{tr}(TS\_d(k))$ denote the minimum track number of $TS\_d(k)$ under TS. This lemma is proved by induction on k.

Basis: It is clear that $\mathrm{tr}(TS\_d(1)) = 2 \geq 1$.

Induction hypothesis: $\mathrm{tr}(TS\_d(k)) \geq k$.

Induction step: We need to show that $\mathrm{tr}(TS\_d(k+1)) \geq k+1$. Suppose TS_$d(k)$ has been laid out using the minimum number of tracks, as shown in Figure 3.2(a), where the only possible position for x_{ku} is at the leftmost and for x_{kd} is at the rightmost because of the TS constraint.

There are three possible positions for $x_{(k+1)r}$, as shown in Figure 3.2(b).

Case 1. *$x_{(k+1)r}$ is to the left of x_{ku}.*

Since $x_{(k+1)r}$ must be connected to $x_{(k+1)d}$ and this hyperedge is distinct from other hyperedges, we need a new track.

Case 2. *$x_{(k+1)r}$ is to the right of x_{kd}.*

Since $x_{(k+1)r}$ must be connected to $x_{(k+1)u}$ and this hyperedge is distinct from other hyperedges, we need a new track.

Case 3. *$x_{(k+1)r}$ is between x_{ku} and x_{kd}.*

If we can place the source hyperedge of $x_{(k+1)r}$, which is to the left of $x_{(k+1)r}$, in a track i and place the sink hyperedge of $x_{(k+1)r}$, which is to the right of $x_{(k+1)r}$ in another track j, these two tracks could be combined to reduce

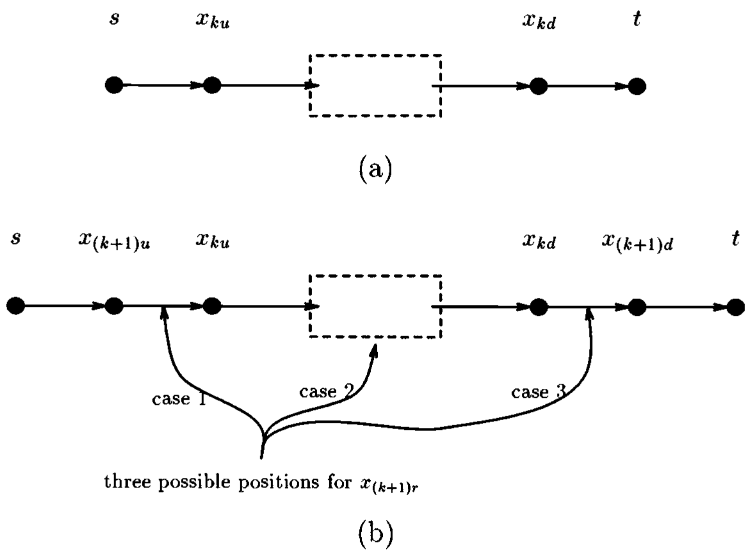

FIG. 3.2. (a) *A $TS\_d(k)$ layout with a minimal number of tracks.* (b) *There are three possible positions for the $x_{(k+1)r}$ of a $TS\_d(k+1)$.*

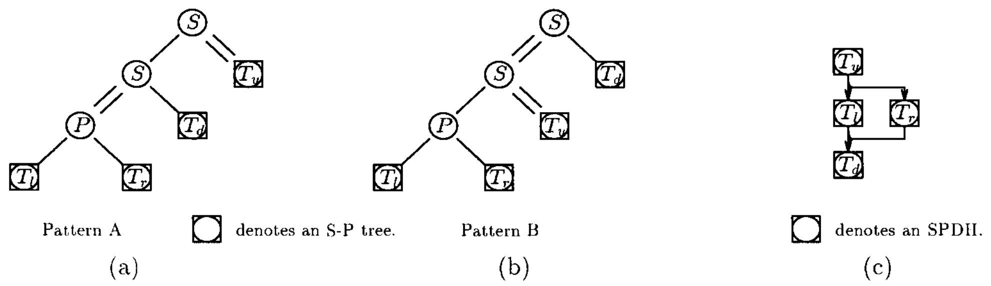

FIG. 3.3. (a) *Pattern A,* (b) *pattern B, and* (c) *the represented SPDH.*

tr($TS\_d(k)$) by 1. This is a contradiction to the assumption that $TS\_d(k)$ has been laid out using a minimal number of tracks. Therefore, we need a new track.

As discussed above, the number of tracks is bounded from below by $k = \frac{N-3}{3}$. That is, the lower bound is $\Omega(N)$. □

In Figure 3.1, a "pattern," called pattern A, depicted in Figure 3.3(a), is repeated along the longest path. Figure 3.3(b) shows an equivalent pattern, called pattern B. Patterns A and B are equivalent because the corresponding SPDHs, shown in Figure 3.3(c), are identical.

In an S-P tree, an *external path* is a path from a leaf to the root; it contains a sequence of inner nodes and a set of edges interconnecting the nodes. An external path can be decomposed into three kinds of elements as follows:

$$\left\{ \begin{matrix} P \\ | \end{matrix}, \begin{matrix} S \\ | \end{matrix}, \begin{matrix} S \\ || \end{matrix} \right\}.$$

We use $P|, S|, S||$ to represent these three elements. The *pattern number* of an external

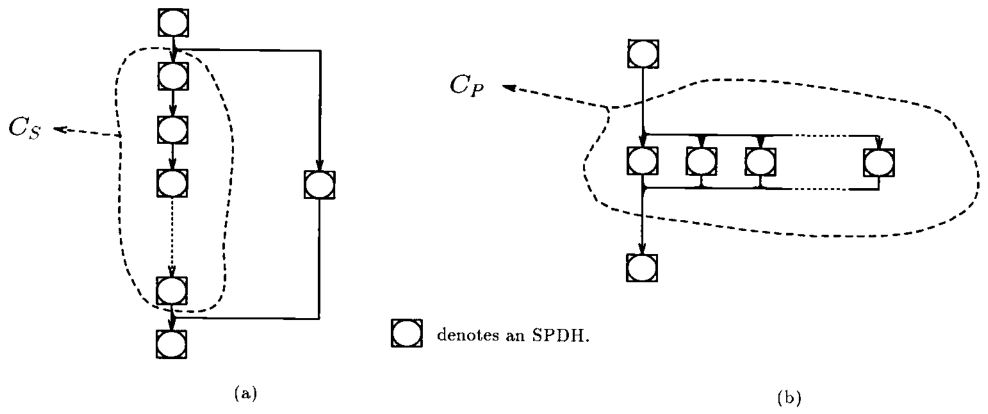

FIG. 3.4. (a) *A set of subgraphs are combined in series, called C_s.* (b) *Another set of subgraphs are combined in parallel, called C_p.*

path is defined in the following procedure:

0. Set the *pattern number* equal to 0.
1. Trace up the path from the corresponding leaf.
2. When encountering $P|$, consider it as part of a new pattern.
3. Continue to trace up until at least one $S|$ and at least one $S||$ (not necessarily in that order) are visited; call these two parts of the current pattern; add 1 to the *pattern number.*
4. Repeat steps 2 and 3 until the path ends.

Among the pattern numbers of external paths, the largest one defines the *pattern number* of an S-P tree and the corresponding SPDH. The following lemma essentially shows that the pattern number of an SPDH is well defined.

LEMMA 3.2. *All S-P trees corresponding to a given SPDH have a unique pattern number.*

Proof. When an S-P tree is constructed, either a set of subgraphs are combined in series, called C_s, or a set of subgraphs are combined in parallel, called C_p (see Figure 3.4).

For the series case, along any path from the corresponding subtree we meet a sequence of S-type nodes until another subgraph combines in parallel with C_s, and we will meet the same P-type node. If there is a construction of an S-P tree where along a specific subtree we meet only $S|$, but in another construction we meet $S||$, this means that in the previous SPDH other subgraphs need to be closer to the left in the final layout, but not in the latter SPDH. This is impossible for the same set of serially connected subgraphs. Using the same argument, we conclude that for an S-P tree, each path from subtrees of C_s meets at least one $S|$, one $S||$, or one $S|$ and one $S||$, which is independent of the construction method.

For the parallel case, each path from a subtree of C_p will meet at least a P-type node before this set of subgraphs is further combined in series. Consequently, any construction of this set will contribute the same to the pattern number of each path.

Therefore, each path has the same pattern number under any S-P tree construction algorithm, and the pattern number of an SPDH is unique. ◻

LEMMA 3.3. *The pattern number k of an S-P tree is a lower bound on the number of tracks needed to lay out the corresponding SPDH.*

Proof. The idea is to "peel" the S-P tree until it is isomorphic (including the labels) to the tree of a TS-difficult SPDH $TS\_d(k)$ (see Figure 3.1). This can be done by repeatedly deleting inner nodes which have either one or two leaves and which do not contribute to the pattern number and deleting one of the attached leaves which correspond to vertices in the SPDH.

Recall that in an SPDH, a vertex can have only two incident hyperedges, the incoming and the outgoing hyperedges. If a vertex v is attached to an S-type inner node, v has an incoming hyperedge of the form $(V_{i_s}, \{v\} \cup V_{i_t})$ and an outgoing hyperedge of the form $(\{v\} \cup V_{o_s}, V_{o_t})$, where V_{i_s}, V_{o_t} are nonempty vertex sets and V_{i_t}, V_{o_s} are general vertex sets. Deleting an S-type inner node and one of the attached leaves necessitates removing the corresponding vertex v in the SPDH such that the incoming and outgoing hyperedges $(V_{i_s}, \{v\} \cup V_{i_t})$, $(\{v\} \cup V_{o_s}, V_{o_t})$ are merged into one hyperedge $(V_{i_s} \cup V_{o_s}, V_{i_t} \cup V_{o_t})$.

If a vertex v is attached to a P-type inner node, the incoming hyperedge is of the form $(V_{i_s}, \{v\} \cup V_{i_t})$ and the outgoing hyperedge is of the form $(\{v\} \cup V_{o_s}, V_{o_t})$, where $V_{i_s}, V_{i_t}, V_{o_s}$, and V_{o_t} are nonempty vertex sets. Deleting a P-type inner node and one of the attached leaves means to delete the corresponding vertex v in the SPDH such that the incoming and outgoing hyperedges $(V_{i_s}, \{v\} \cup V_{i_t})$, $(\{v\} \cup V_{o_s}, V_{o_t})$ become (V_{i_s}, V_{i_t}) and (V_{o_s}, V_{o_t}), respectively.

As for the layout, in addition to removing corresponding vertices, in order not to change the number of tracks, the incident hyperedges are either connected using original tracks or remain the same. It depends on whether the deleted inner nodes are S-type or P-type, as shown in the following example.

Figure 3.5 gives an example of peeling. When x_1 and the related S-type inner node is peeled in the S-P tree, the corresponding vertex in the SPDH is removed, the corresponding vertex in the layout is deleted, and the incident hyperedges in the layout are merged. For x_6, which is connected to a P-type node, the corresponding vertices in the SPDH and in the layout are deleted. The resulting layout needs no more tracks than the original one because of the reduced constraints of merging and deleting.

If the original layout requires $o(k)$ tracks (i.e., less than $\Theta(k)$), the resulting SPDH, which has k patterns and is isomorphic to a TS-difficult SPDH shown in Figure 3.1, has $o(k)$ tracks. This is a contradiction of Lemma 3.1. $\square$

However, pattern number is not the only parameter that dictates the number of tracks. This is shown in the following lemma.

LEMMA 3.4. *There exist SPDHs with pattern number* 1 *that require* $\Omega(\log N)$ *tracks.*

Proof. [12] introduced a circuit which can be transformed, as will be mentioned in section 6, to a so-called difficult-SPDH. One of its S-P trees is shown in Figure 3.6. The pattern number is 1, but it was proved in [12] that $\Omega(\log N)$ tracks are necessary to lay it out. $\square$

4. A layout algorithm.

In this section, we propose a layout algorithm which traverses an S-P tree in a bottom-up manner. We will prove that the algorithm needs at most $2(k + m)$ tracks, where k is the pattern number of the given SPDH and the *balancing number* m (which will be defined in Theorem 4.1) is at most $\log N$ (but could be much less), where N is the number of vertices.

The proposed data structure is as follows. For each inner node n, two records, $D(n)$ and $pattern(n)$, are kept. $D(n)$ is the number of necessary tracks. $Pattern(n)$ is the *pattern configuration* of the larger track number of the two subgraphs of node n after tracing up to node n. The possible pattern configurations—denoted by

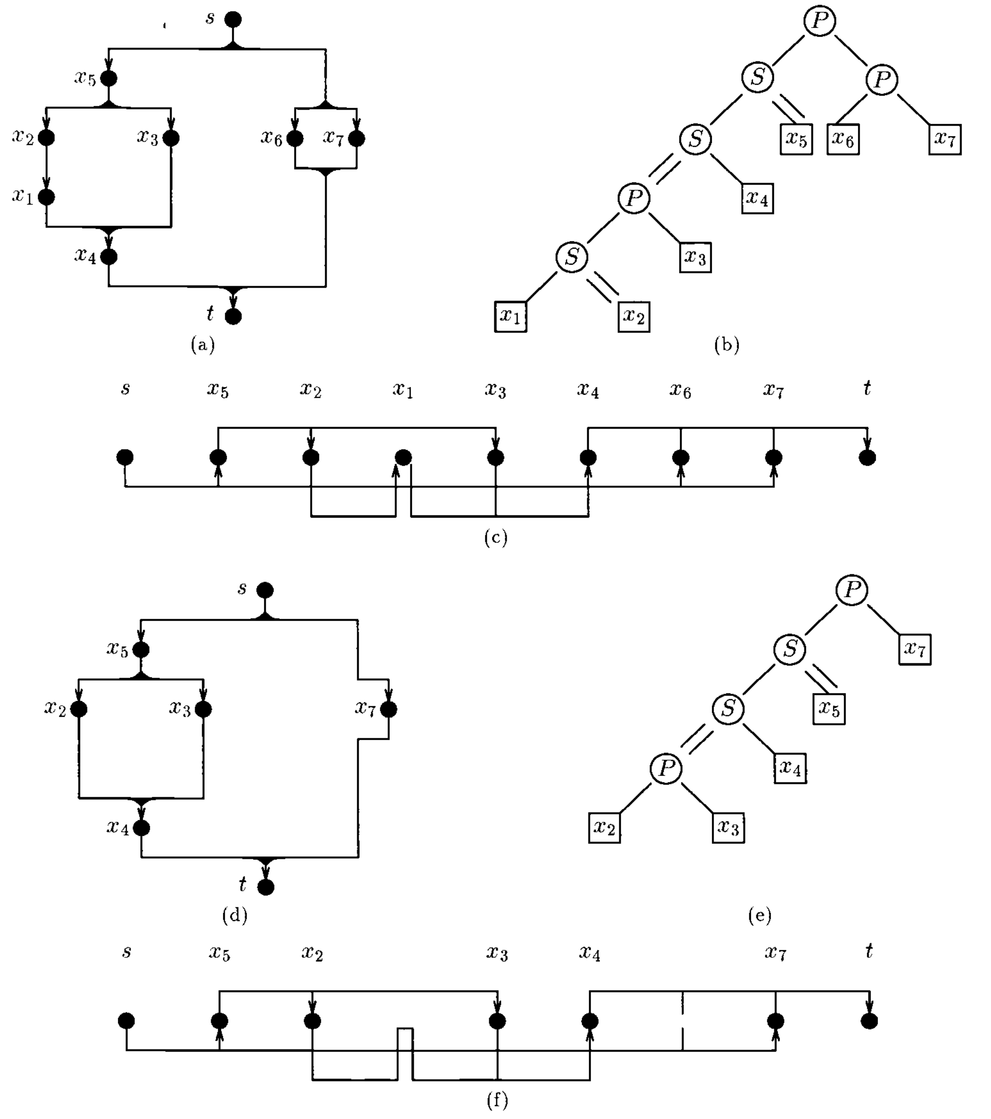

FIG. 3.5. (a) *An SPDH,* (b) *its S-P tree, and* (c) *one possible layout. After vertices* x_1 *and* x_6 *are peeled,* (d) *the resulting SPDH,* (e) *its S-P tree, and* (f) *one possible layout.*

pattern(n)—are $(k), (k, P|), (k, P|, S|)$, and $(k, P|, S||)$. The symbol (k) means that k patterns have been traversed and another $P|$ is now being looked for. $(k, P|)$ means that k patterns and an additional $P|$ have been traversed and another $S|$ or another $S||$ is being looked for. $(k, P|, S|)$ means that k patterns and an additional $P|$ and $S|$ have been traversed, while another $S||$ is being looked for. The last one, $(k, P|, S||)$, means that k patterns and an additional $P|$ and $S||$ have been traversed, while another $S|$ is being looked for.

In the algorithm, each pattern configuration is laid out with a special connection configuration, called a *layout representative.* Layout representatives are shown in

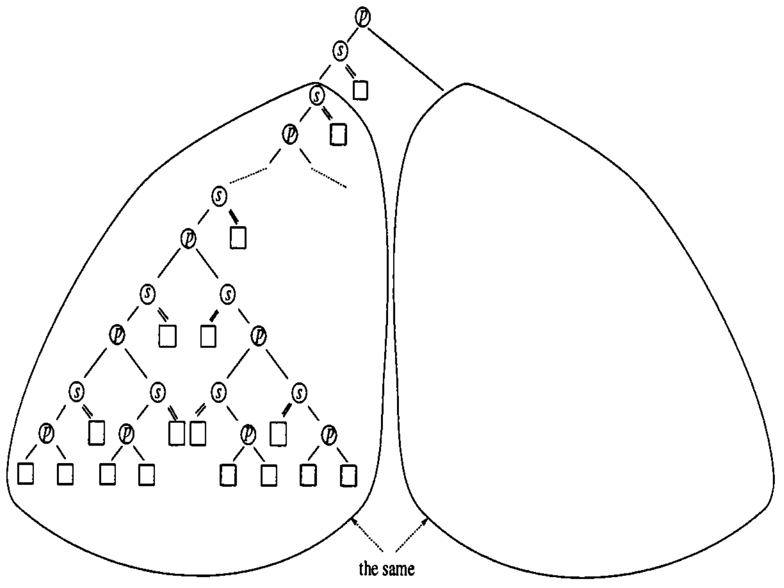

FIG. 3.6. *An S-P tree for a difficult-SPDH.*

Pattern Configuration	Layout Representative	k	Layout Basis
$\left\langle k \right\rangle$		0	$\left\langle k \overset{P}{\vert} \right\rangle$		0	$\left\langle k \overset{P}{\vert} \overset{S}{\vert} \right\rangle$		0	$\left\langle k \overset{P}{\vert} \overset{S}{\Vert} \right\rangle$		0	
FIG. 4.1. *Pattern configurations and layout representatives for the TS layout algorithm.*

Figure 4.1. For (k), the source and the sink hyperedges are available at the left and the right of the subgraph layout, respectively. For $(k, P|)$, both the source and the sink hyperedges are available at the left and the right. For $(k, P|, S|)$, both the source and the sink hyperedges are available at the left and only the sink hyperedge is available at the right. As for $(k, P|, S||)$, only the source hyperedge is available at the left, but both the source and the sink hyperedges are available at the right. In Figure 4.1, their basis configurations are shown.

We denote the left and the right children of n by l and r, respectively. Also, in order to simplify the proof, if the number of tracks is increased, two tracks will be added, by assigning pseudotrack in some cases (obviously, this is not done in practice). Thus, if $D(l) > D(r)$, $D(l) \geq D(r) + 2$. The main idea of the algorithm is to maintain layout representatives and to control the number of tracks.

TS LAYOUT ALGORITHM.

Input: An S-P tree.

Output: A TS layout.

Traverse each node in a bottom-up manner, and at the same time, lay out the corresponding subgraph according to the following cases until the entire S-P tree has been traversed. Furthermore, reduce the number of tracks by cleaning up the pseudotracks.

There are two cases according to the type of the currently traversed node n. Node n may be either an S-type node or a P-type node.

Case 1. *n is a P-type node.*

Rename n as P_n. According to whether P_n contributes to the pattern configuration or not, there are four cases.

Case 1.1. *P_n is in the pattern*[4] *of the left path but not in the pattern of the right path.*

This condition means that the pattern configuration of the left path below P_n is $(k(l))$ and that of the right path is $(k(r), P|)$, $(k(r), P|, S|)$, or $(k(r), P|, S||)$.

According to the relative values of $D(l)$ and $D(r)$, there are three cases.

Case 1.1.1. $D(l) > D(r)$.

The layout is shown in Figure 4.2, and the result of $D(P_n)$ and $pattern(P_n)$ is

$$D(P_n) = D(l) + 2, \tag{4.1}$$

$$pattern(P_n) = (k(l), P|). \tag{4.2}$$

We can see that the layout has the connection configuration of $(k(l), P|)$.

Case 1.1.2. $D(l) = D(r)$.

According to the pattern numbers, there are two cases.

Case 1.1.2.1. $k(l) \geq k(r)$.

It is similar to Case 1.1.1.

Case 1.1.2.2. $k(l) < k(r)$.

The layout is shown in Figure 4.2, and the result is

$$D(P_n) = D(r) + 2, \tag{4.3}$$

$$pattern(P_n) = pattern(r). \tag{4.4}$$

The three situations correspond to three possible pattern configurations of the right path. All the connection configurations remain the same as those of the layout of the right subgraphs.

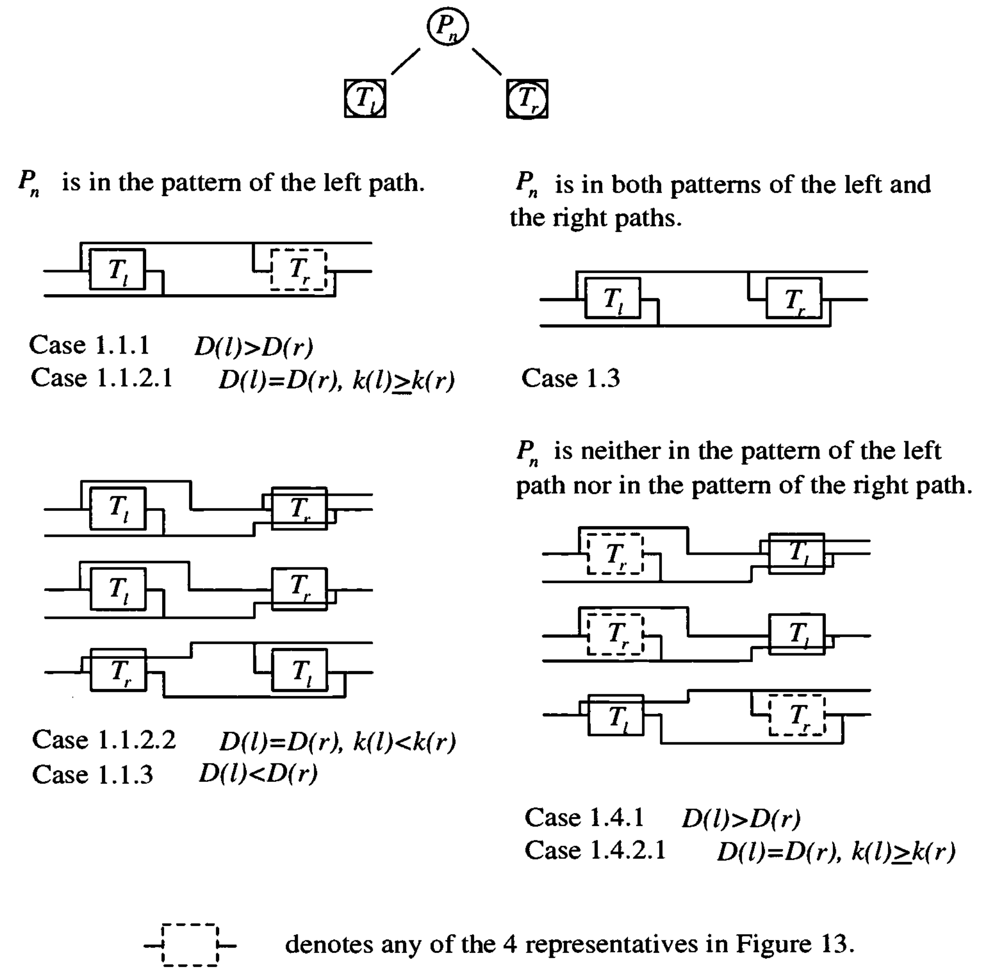
Case 1.1.3. $D(l) < D(r)$.

The layout is shown in Figure 4.2, and the result is

$$D(P_n) = D(r), \tag{4.5}$$

$$pattern(P_n) = pattern(r). \tag{4.6}$$

[4]Recall the definition of pattern number in section 3.



P_n
T_l
T_r
P_n is in the pattern of the left path.
Case 1.1.1 D(l)>D(r)
Case 1.1.2.1 D(l)=D(r), k(l)≥k(r)
Case 1.1.2.2 D(l)=D(r), k(l)<k(r)
Case 1.1.3 D(l)<D(r)
P_n is in both patterns of the left and the right paths.
Case 1.3
P_n is neither in the pattern of the left path nor in the pattern of the right path.
Case 1.4.1 D(l)>D(r)
Case 1.4.2.1 D(l)=D(r), k(l)≥k(r)
denotes any of the 4 representatives in Figure 13.

FIG. 4.2. *Layouts for P-type nodes.*

Case 1.2. *P_n is in the pattern of the right path but not in the pattern of the left path.*

It is similar to Case 1.1.

Case 1.3. *P_n is in both patterns of the left and the right paths.*

This condition means that the pattern configurations of the left path and the right path below P_n are $(k(l))$ and $(k(r))$, respectively.

Case 1.3.1. $D(l) > D(r)$.

It is similar to Case 1.1.1.

Case 1.3.2. $D(l) = D(r)$.

The layout is shown in Figure 4.2, and the result is

$$D(P_n) = D(l) + 2. \tag{4.7}$$

Case 1.3.2.1. $k(l) \geq k(r)$.

$$pattern(P_n) = (k(l), P|). \tag{4.8}$$

Case 1.3.2.2. $k(l) < k(r)$.

$$pattern(P_n) = (k(r), P|). \tag{4.9}$$

Case 1.3.3. $D(l) < D(r)$.

It is symmetrical to Case 1.3.1.

Case 1.4. *P_n is neither in the pattern of the left path nor in the pattern of the right path.*

This condition means that the pattern configuration of the left path below P_n is $(k(l), P|)$, $(k(l), P|, S|)$, or $(k(l), P|, S||)$ and that of the right path is $(k(r), P|)$, $(k(r), P|, S|)$, or $(k(r), P|, S||)$.

Case 1.4.1. $D(l) > D(r)$.

The layout is shown in Figure 4.2, and the result is

$$D(P_n) = D(l), \tag{4.10}$$

$$pattern(P_n) = pattern(l). \tag{4.11}$$

Case 1.4.2. $D(l) = D(r)$.

Case 1.4.2.1. $k(l) \geq k(r)$.

The layout is shown in Figure 4.2, and the result is

$$D(P_n) = D(l) + 2, \tag{4.12}$$

$$pattern(P_n) = pattern(l). \tag{4.13}$$

Case 1.4.2.2. $k(l) < k(r)$.

It is symmetrical to Case 1.4.2.1.

Case 1.4.3. $D(l) < D(r)$.

It is symmetrical to Case 1.4.1.

Case 2. *n is an S-type node.*

Rename n as S_n and put the subtree with the double line to the left side of S_n.

Case 2.1. *S_n is in the pattern of the left path but not in the pattern of the right path.*

This condition means that the pattern configuration of the left path below S_n is either $(k(l), P|)$ or $(k(l), P|, S|)$ and that of the right path is either $(k(r))$ or $(k(r), P|, S|)$.

Case 2.1.1. $D(l) > D(r)$.

The layout is shown in Figure 4.3, and the result is

$$D(S_n) = D(l), \tag{4.14}$$

$$pattern(S_n) = pattern(l) \cup (S||), \tag{4.15}$$

where $\cup$ means the original $pattern(l)$ meets one more $S||$. For now, that is either $(k(l), P|, S||)$ or $(k(l) + 1)$.

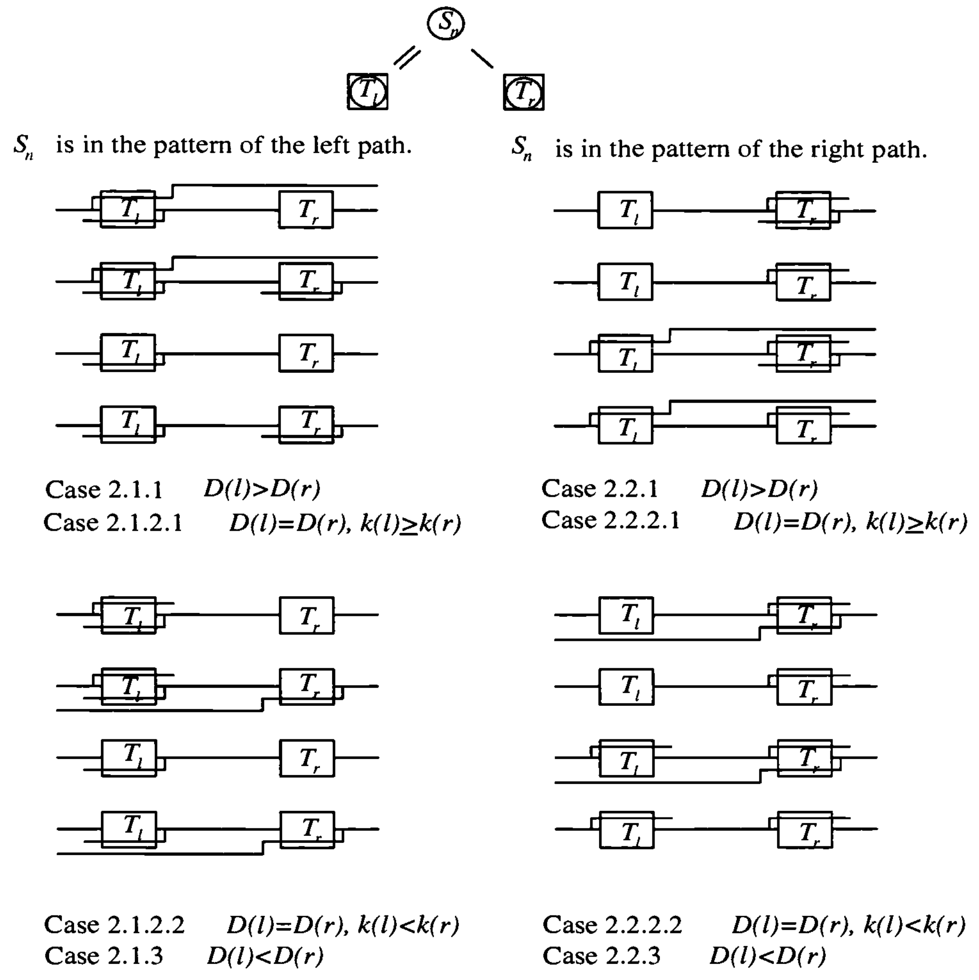
Case 2.1.2. $D(l) = D(r)$.

Case 2.1.2.1. $k(l) \geq k(r)$.

The layout is shown in Figure 4.3, and the result is

$$D(S_n) = D(l) + 2 \quad or \quad D(l), \tag{4.16}$$

$$pattern(S_n) = pattern(l) \cup (S||). \tag{4.17}$$



S_n
T_l
T_r
S_n is in the pattern of the left path.
S_n is in the pattern of the right path.
Case 2.1.1 D(l)>D(r)
Case 2.1.2.1 D(l)=D(r), k(l)≥k(r)
Case 2.2.1 D(l)>D(r)
Case 2.2.2.1 D(l)=D(r), k(l)≥k(r)
Case 2.1.2.2 D(l)=D(r), k(l)<k(r)
Case 2.1.3 D(l)<D(r)
Case 2.2.2.2 D(l)=D(r), k(l)<k(r)
Case 2.2.3 D(l)<D(r)

FIG. 4.3. *Layouts for S-type nodes: part* 1.

Case 2.1.2.2. $k(l) < k(r)$.
The layout is shown in Figure 4.3, and the result is

$$D(S_n) = D(r) + 2 \quad or \quad D(r), \tag{4.18}$$

$$pattern(S_n) = pattern(r). \tag{4.19}$$

Case 2.1.3. $D(l) < D(r)$.
The layout is shown in Figure 4.3, and the result is

$$D(S_n) = D(r), \tag{4.20}$$

$$pattern(S_n) = pattern(r). \tag{4.21}$$

Case 2.2. *S_n is not in the pattern of the left path but is in the pattern of the right path.*

This condition means that the pattern configuration of the left path below S_n is either $(k(l))$ or $(k(l), P|, S||)$ and that of the right path is either $(k(r), P|)$ or $(k(r), P|, S||)$. Therefore, there are four situations for different cases.

Case 2.2.1. $D(l) > D(r)$.

The layout is shown in Figure 4.3, and the result is

$$D(S_n) = D(l), \tag{4.22}$$

$$pattern(S_n) = pattern(l). \tag{4.23}$$

Case 2.2.2. $D(l) = D(r)$.

Case 2.2.2.1. $k(l) \geq k(r)$.

It is similar to Case 2.2.1, except that $D(S_n)$ is $D(l)+2$ in some cases.

Case 2.2.2.2. $k(l) < k(r)$.

The layout is shown in Figure 4.3, and the result is

$$D(S_n) = D(r) + 2 \quad or \quad D(r), \tag{4.24}$$

$$pattern(S_n) = pattern(r) \cup (S|). \tag{4.25}$$

Case 2.2.3. $D(l) < D(r)$.

It is similar to Case 2.2.2.2 except that $D(S_n)$ is only $D(l)$.

Case 2.3. *S_n is in both patterns of the left and the right paths.*

This condition means that the pattern configuration of the left path below S_n is either $(k(l), P|)$ or $(k(l), P|, S|)$ and that of right path below S_n is either $(k(r), P|)$ or $(k(r), P|, S||)$.

Case 2.3.1. $D(l) > D(r)$.

The layout is shown in Figure 4.4, and the result is

$$D(S_n) = D(l), \tag{4.26}$$

$$pattern(S_n) = pattern(l) \cup (S||). \tag{4.27}$$

Case 2.3.2. $D(l) = D(r)$.

Case 2.3.2.1. $k(l) \geq k(r)$.

It is similar to Case 2.3.1 except that $D(S_n)$ is $D(l)+2$ in some cases.

Case 2.3.2.2. $k(l) < k(r)$.

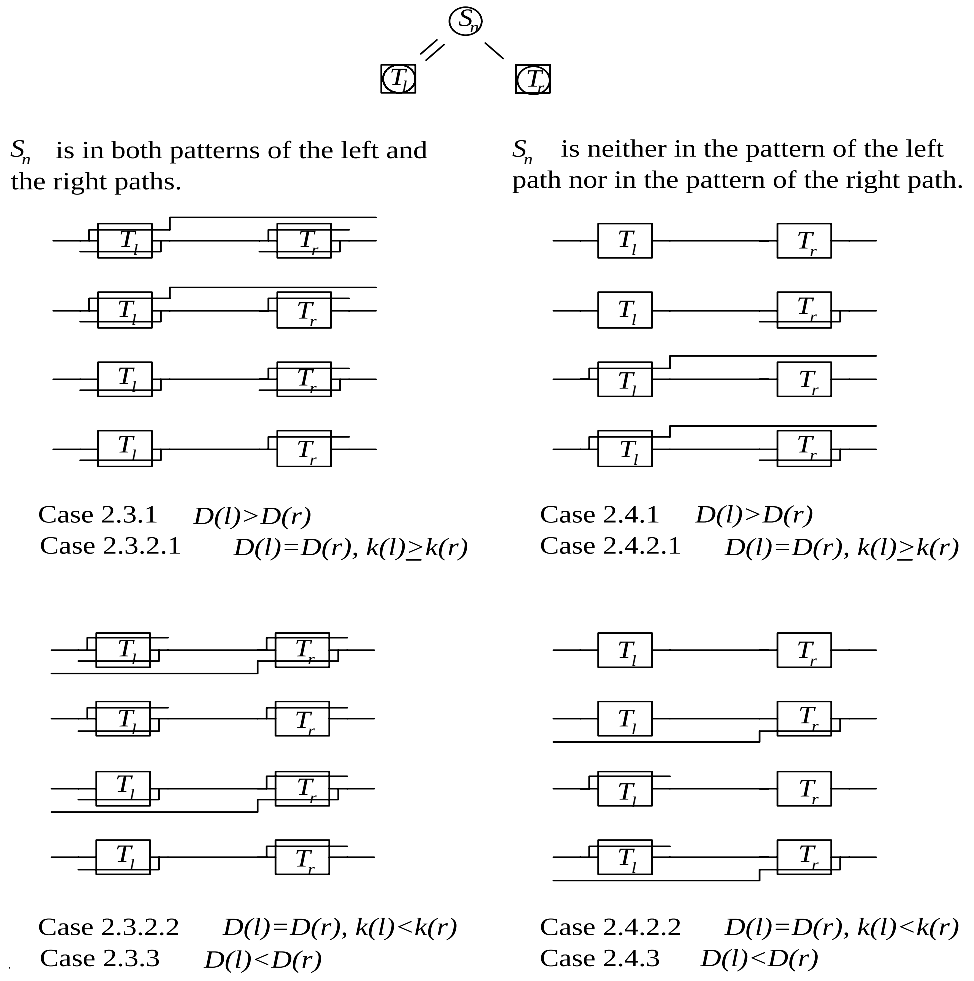
The layout is shown in Figure 4.4, and the result is

$$D(S_n) = D(r) + 2 \quad or \quad D(r), \tag{4.28}$$

$$pattern(S_n) = pattern(r) \cup (S|). \tag{4.29}$$

Case 2.3.3. $D(l) < D(r)$.

It is similar to Case 2.3.2.2 except that $D(S_n)$ is only $D(r)$.



S_n
T_l
T_r
S_n is in both patterns of the left and the right paths.

Case 2.4.3 D(l)<D(r)

FIG. 4.4. *Layouts for S-type nodes: part 2.*

Case 2.4. *S_n is neither in the pattern of the left path nor in the pattern of the right path.*

This condition means that the *pattern configuration* of the left path below S_n is either $(k(l))$ or $(k(l), P|, S||)$ and that of the right path is either $(k(r))$ or $(k(r), P|, S|)$.

Case 2.4.1. $D(l) > D(r)$.

The layout is shown in Figure 4.4, and the result is similar to Case 2.2.1.

Case 2.4.2. $D(l) = D(r)$.

Case 2.4.2.1. $k(l) \geq k(r)$.

The layout is shown in Figure 4.4, and the result is similar to Case 2.2.2.1.

Case 2.4.2.2. $k(l) < k(r)$.

The layout is shown in Figure 4.4, and the result is similar to Case 2.1.2.2.

Case 2.4.3. $D(l) < D(r)$.

The layout is shown in Figure 4.4, and the result is similar to Case 2.1.3.

Since this algorithm traverses each node only once and it takes constant time to process each node, it runs in linear time. After the above layout is obtained, we can trace down the S-P tree from the root and along the larger track number subtree. If the number of tracks is equal, we choose the one with the larger pattern number. In addition, if both track numbers and pattern numbers are the same, we choose the left one. We call this path the *largest track number path*. Along this path down, the number of tracks will decrease by two only if either of the following two events happen. We pass a $P|$ node which belongs to a pattern of the largest track number path or a node with the two subtrees having the same number of tracks.

THEOREM 4.1. *The layout produced by the TS layout algorithm uses at most $D = 2(k+m)$ tracks, where k is the pattern number and m is the balancing number; $m \leq \log N$.*

Proof. In the following, **A** represents a $P|$ which belongs to a pattern and during the layout procedure makes the number of tracks increase by two. **B** denotes a node with its two subtrees having the same number of tracks and it also causes the number of tracks to increase by two.

Suppose we already have a layout that is produced by the TS layout algorithm and the pattern number for the corresponding S-P tree is k. The minimal vertex number will occur when the largest track number path has k patterns and other paths have pattern numbers as small as possible. The reason is that the more patterns, the more tracks are needed for the layout. Thus, when the track number is fixed, fewer vertices are needed.

Here, $N(k,m)$ denotes the minimal vertex number when there are k **A**-type nodes and m **B**-type nodes in the largest track number path. The value m is called the *balancing number*.

Next, we apply induction on m to prove that $N(k,m) \geq 2^m$, where $k \geq 0$.

Basis: $m = 0$. It is clear that $N(k,0) \geq 2^0$.

Induction hypothesis: $N(k,m) \geq 2^m$.

Induction step: For $N(k,m+1)$, we trace down the largest track number path until we meet the first **B**-type node, meaning the subtrees of this **B**-type node have the same number of layout tracks. Suppose we have passed k_1 **A**-type nodes. The corresponding subtrees have $N(k_l,m_l)$ and $N(k_r,m_r)$ vertices, and the largest track number path is along the left path. Then $k_1 + k_l = k$ and $m_l = m$. The following two reasons show $m_r \geq m_l = m$. First, the right subtree needs to have the same number of tracks as the left subtree. Second, $k_r \leq k_l$, as a result of that the largest track number path chooses the larger pattern number under the situation of equal number of tracks. Therefore,

$$N(k,m+1) \geq N(k_l,m_l)+N(k_r,m_r) \geq N(k_l,m)+N(k_r,m) \geq 2^m+2^m \geq 2^{m+1} \tag{4.30}$$

We conclude that $D = 2(k+m) \leq 2k + 2\log N$. □

5. A reordering and layout algorithm for an SPDH and its dual. In this section we show how serial path reordering can reduce necessary layout tracks of an SPDH $\mathcal{P}$ and its dual $\mathcal{N}$ simultaneously to $O(\log N)$, where N is the number of vertices. In addition, we propose an algorithm which reorders and lays out an SPDH.

A *simultaneous layout* of an SPDH $\mathcal{P}$ consists of two layouts—one corresponding to $\mathcal{P}$ and the other corresponding to its dual $\mathcal{N}$—with the same vertex order. The

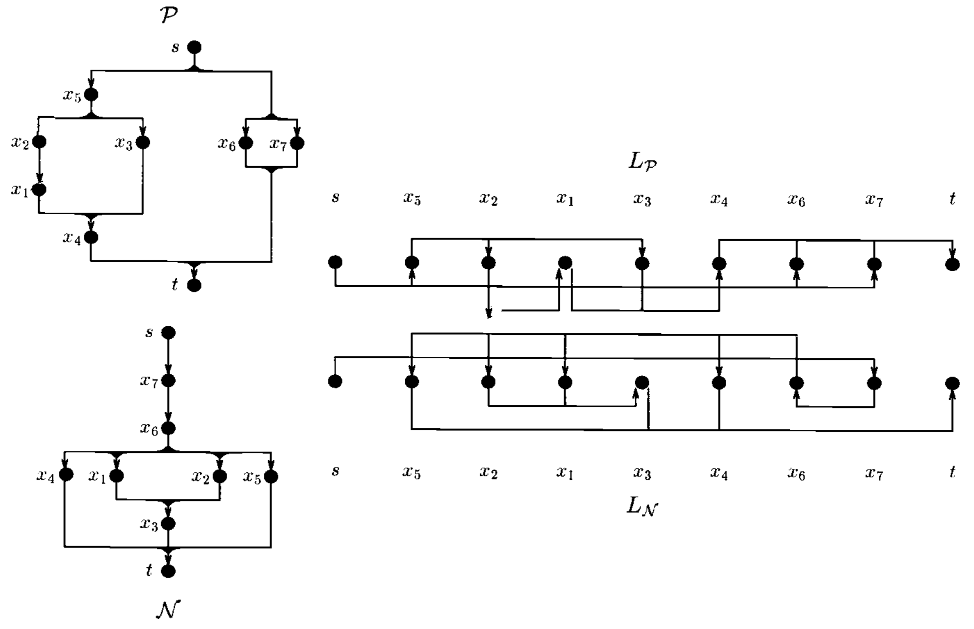

FIG. 5.1. *A simultaneous layout, including $L_{\mathcal{P}}$ and $L_{\mathcal{N}}$, of an SPDH $\mathcal{P}$ and its dual $\mathcal{N}$.*

names—$\mathcal{P}$ and $\mathcal{N}$—are motivated by applications in complementary metal oxide-silicon (CMOS) circuits, which consist of p-channel MOSFET (PMOS) and n-channel MOSFET (NMOS) parts. Figure 5.1 shows a simultaneous layout, consisting of $L_{\mathcal{P}}$ and $L_{\mathcal{N}}$, of an SPDH $\mathcal{P}$ and its dual $\mathcal{N}$. Notice that the ordering of the vertices in $L_{\mathcal{P}}$ and $L_{\mathcal{N}}$ is the same. *Serial path reordering* rearranges the serial connections of SPDHs. The effect of serial path reordering is illustrated in Figure 5.2, where the reordered SPDH needs only two tracks instead of the $O(N)$ tracks needed for the original TS-difficult SPDH of Figure 3.1. The resulting SPDH, S-P tree, and layout are also shown.

Recall the definitions of section 1.1. An SPDH and its dual have distinct S-P trees. These two trees are dual to each other. In our construction procedure, if one inner node in a tree is S-type, the corresponding inner node in the other tree is P-type, and vice versa.

The reordering and layout algorithm is summarized as follows:

1. Traverse each inner node of the S-P trees in a bottom-up manner.
2. Decide the relative positions of subtree layouts under the P-type node of the two currently traversed inner nodes.
3. Consequently, fix the single line and double line positions of the corresponding S-type node in the other tree.
4. Keep a *track number D* of necessary tracks for each node of each S-P tree.

There are only two types of layout representatives participating in the algorithm. Recall that a layout representative is a special connection configuration. These two layout representatives are shown in Figure 5.3. One is called a *Double-Double*, with both the source and the sink hyperedges available at the left and the right. The other is called a *Single-Double*, with only the source hyperedge available at the left but both the source and the sink hyperedges available at the right.

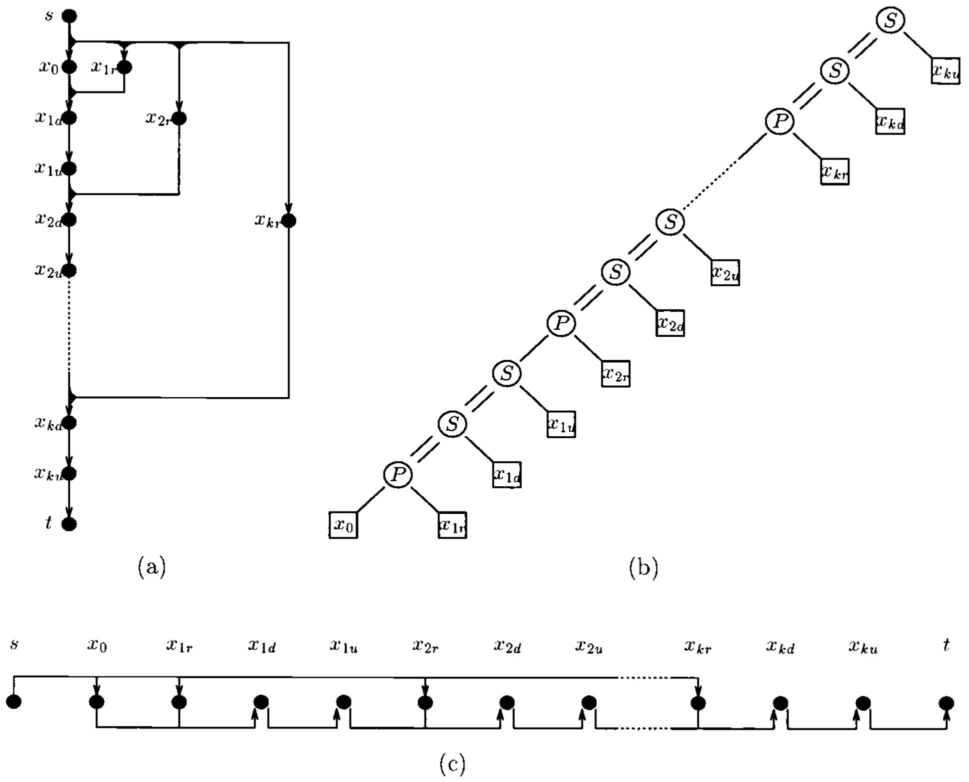

FIG. 5.2. *After reordering the TS-difficult SPDH in Figure* 3.1*, the corresponding* (a) *SPDH,* (b) *S-P tree, and* (c) *layout are shown.*

The algorithm has three characteristics:

1. During a bottom-up traversal of an inner node, each layout of its two subtrees are one of the two layout representatives, and the resulting layout will also be one of these two layout representatives.
2. The track number D of each P-type node is kept (by assigning pseudotracks in some cases) the same as that of the corresponding S-type node.
3. A track number is larger than the maximum of the track numbers of the two children if and only if the two subtrees of the corresponding node have the same track number. Also, all track numbers are kept odd.

We benefit from limiting the layout of each subtree to one of the two layout representatives as mentioned in the first characteristic and keeping track numbers as mentioned in the second characteristic. The benefit is that when traversing inner nodes we need to consider only three cases. These cases are divided according to the relative track numbers of the two subtrees of the currently traversed P-type inner node. The third characteristic (which is also about the track numbers) simplifies the proof of Theorem 5.1: this algorithm uses $O(\log N)$ tracks, where N is the vertex number of the input SPDH or its dual.

Regarding data structure, for each inner node n we keep two records: a track number, $D(n)$, and the layout representative for the n-rooted subtree, *layout-representative(n)*.

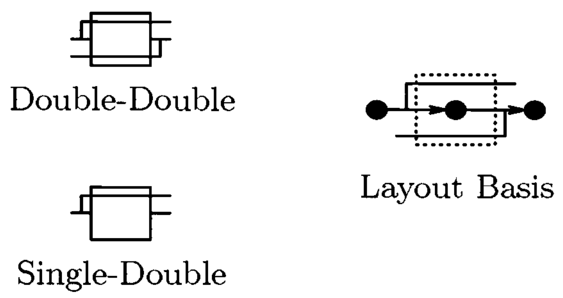

FIG. 5.3. *The two layout representatives and the layout basis.*

REORDERING AND LAYOUT ALGORITHM.

Input: An S-P tree and its dual.

Output: A TS simultaneous layout.

We lay out each vertex, a leaf in the trees, as a layout basis shown in Figure 5.3 and assign each layout basis $D = 3$ tracks. Then we traverse the nodes of both S-P trees simultaneously in a bottom-up manner and maintain the layout representatives according to the P-type node as in the cases described below. Finally, unnecessary tracks are cleaned up.

Case 1. *$D(P_l) = D(P_r)$ and $D(S_l) = D(S_r)$,*
where P_l, P_r are the left child and the right child of the P-type node P_n, respectively. Similarly, S_l, S_r are the left child and the right child of the corresponding S-type node S_n in the other S-P tree.
The resulting layouts are shown in Figure 5.4, and there are subcases depending on what the layout representatives of the corresponding subtrees are. The results of $D(P_n)$ and $D(S_n)$ are

$$D(P_n) = D(P_l) + 2 \ \ \textit{and} \ \ D(S_n) = D(S_l) + 2. \tag{5.1}$$

We can see that each of the resulting layout connections is one of the two types of layout representatives.

Case 2. *$D(P_l) > D(P_r)$ and $D(S_l) > D(S_r)$.*
The resulting layouts are also shown in Figure 5.4. The results of $D(P_n)$ and $D(S_n)$ are

$$D(P_n) = D(P_l) \ \ \textit{and} \ \ D(S_n) = D(S_l). \tag{5.2}$$

We can see that the resulting layout connections are still among the two layout representatives.

Case 3. *$D(P_l) < D(P_r)$ and $D(S_l) < D(S_r)$.*
It is similar to Case 2.

THEOREM 5.1. *The layout produced by the reordering and layout algorithm uses at most $D = 2\log(N-2) + 3$ tracks, where $N \geq 3$ is the number of vertices of SPDH $\mathcal{P}$ or SPDH $\mathcal{N}$.*

Proof. Assume $N(D)$ is the vertex number of an SPDH when the algorithm requires D tracks for the layout. Thus, $N' = N - 2$ is the number of vertices excluding the source and the sink. This lemma is proved by induction on N'.

Basis: $N' = 1$ and $D = 3$. It is clear that $N' = 1 \geq 2^0 = 2^{\frac{D-3}{2}}$.

Induction hypothesis: $N'(D) \geq 2^{\frac{D-3}{2}}$.

Case 1 When $D(P_l)=D(P_r)$ and $D(S_l)=D(S_r)$, assign $D(P_n)=D(P_l)+2$ and $D(S_n)=D(S_l)+2$
(c)
(d)
Case 2 When $D(P_l)>D(P_r)$ and $D(S_l)>D(S_r)$, assign $D(P_n)=D(P_l)$ and $D(S_n)=D(S_l)$

FIG. 5.4. (a), (c) *For a P-type node, there are two cases shown. Each case has four subcases of subtree layouts.* (b), (d) *The layouts of the corresponding S-type node are shown. Dashed lines are pseudotracks.*

Induction step: Because of the specific construction procedure in the algorithm, D is increased by 2 when the two subtrees have the same track number. Therefore,

$$N'(D+2) \geq N'(D) + N'(D) \geq 2^{\frac{(D+2)-3}{2}}, \tag{5.3}$$

and

$$D \leq 2\log N' + 3 = 2\log(N-2) + 3. \qquad \square \tag{5.4}$$

Similar to the TS layout algorithm, the reordering and layout algorithm also tra-

verses each node once, and it takes constant time to process each node. Consequently, it runs in linear time. The algorithm is demonstrated in the next section.

6. Applications and examples.

This section applies the minmax mincut algorithms to circuit design. This application produces layouts of CMOS functional cells using the gate-matrix layout style. Two circuits are used to demonstrate the reordering and layout algorithm.

In [10], the gate-matrix style was introduced to implement circuits. There, the "intersections" of polysilicon columns and diffusion rows form transistors and horizontal metal lines are used as connections. Gate-matrix design includes assigning transistors to columns and using metal lines to implement net lists. A CMOS functional cell is formed by series-parallel connections of transistors [14]; the PMOS and NMOS sides of the circuit are the dual of each other; a general CMOS circuit is an interconnection of CMOS functional cells.

Figures 6.1(a), (b), and Figure 6.2(b) show a function, a circuit which implements the function, and a layout of the circuit, respectively. Notice that since a MOSFET transistor is bidirectional, NMOS and PMOS circuits will function the same even if the positions of V_{DD} and V_{SS} are switched. Therefore, the NMOS layout of Figure 6.2(b) will function the same when current flows either from right to left or from left to right.

A CMOS functional cell is represented by two SPDHs as follows: Both the PMOS circuit and the NMOS circuit are represented by SPDHs. Each MOSFET transistor is represented by a vertex. A net is represented by a hyperedge. Node V_{DD} is represented by a source. The output of the CMOS functional cell is represented

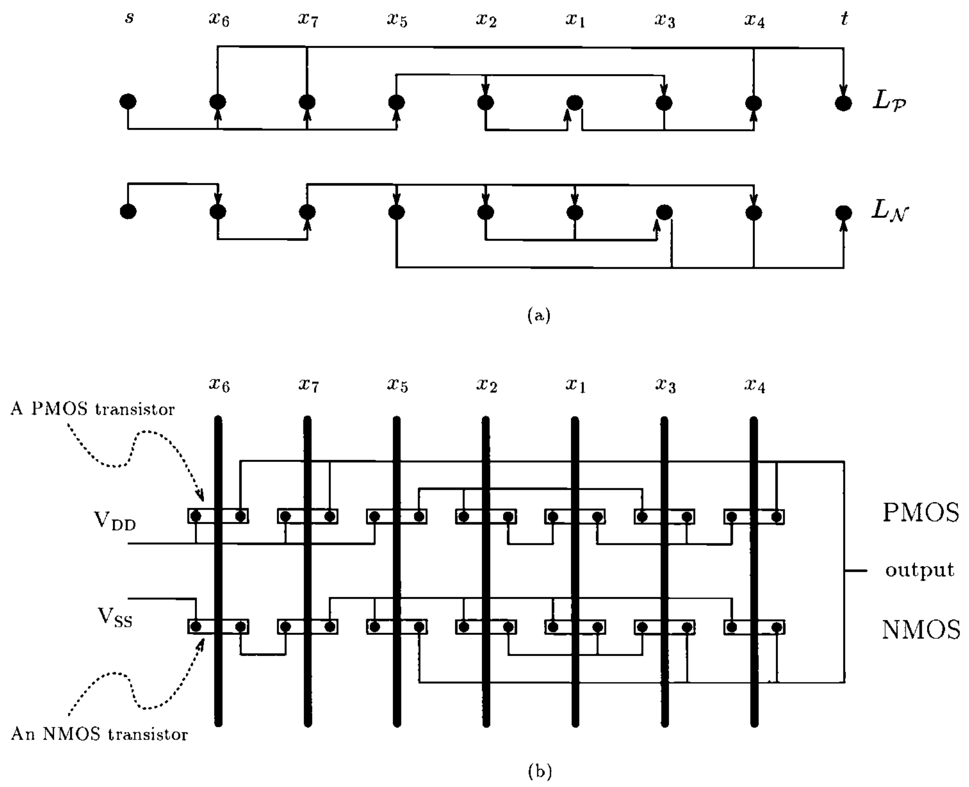

FIG. 6.2. (a) *A simultaneous layout of the SPDHs in Figure* 6.1(d). (b) *A layout of the circuit in Figure* 6.1(b).

by either the sink of an SPDH corresponding to the PMOS circuit or the source of an SPDH corresponding to the NMOS circuit. Node V_{SS} is represented by a sink. In this transformation, the gate-matrix area (height) minimization problem with CMOS functional cells as inputs is equal to the mincut linear arrangement of a SPDH problem.

Minimizing the longest path in an SPDH layout, which has been discussed in this paper, corresponds to minimizing the longest current path in circuit design. Such minimization speeds up the corresponding circuits. Furthermore, routing a path with bends usually requires more vias to connect horizontal and vertical wires than routing a path without any bends. Vias have high resistances, and thus they may slow the circuit. Therefore, our layouts, which are topologically sorted and have no bends, reduce resistances. Consequently, this reduction speeds up the corresponding circuits as well. In other words, the minmax mincut problem corresponds to an area minimization problem that addresses delay minimization. Timing issues in the gate-matrix layout style have not been addressed in the literature.

Notice that here we assume V_{DD} is at the leftmost upper position and V_{SS} is at the leftmost lower position, as shown in Figure 6.2(b). However, the power line may be available on the top and the ground line available on the bottom in some cases. In these cases, at most two tracks, the track for the power line and the track for the ground line, are saved. Therefore, the bounds mentioned remain the same.

Our timing-driven CMOS layout procedure is (conceptually) illustrated in Figures 6.1 and 6.2. The procedure is summarized as follows:

1. Accept an equation as an input (see Figure 6.1(a)).
2. Form a CMOS circuit to implement the function (Figure 6.1(b)).
3. Convert the circuit to two SPDHs: one corresponding to the PMOS circuit and the other corresponding to the NMOS circuit (Figure 6.1(c)).
4. Apply the reordering and layout algorithm to produce a simultaneous layout (Figures 6.1(d), 6.2(a)).
5. Finally, convert the simultaneous layout to a circuit layout (Figure 6.2(b)).

In circuit applications, we modify the reordering and layout algorithm to directly accept circuits as inputs and to produce circuit layouts as outputs. Two examples are demonstrated in the following.

Figure 6.3 shows a carry look-ahead circuit [14], an S-P tree corresponding to the PMOS circuit, and another S-P tree corresponding to the NMOS circuit. Figure 6.4 shows the resulting circuit and S-P trees after the reordering and layout algorithm is applied.

Figure 6.5(a) shows the resulting layouts after the first three steps of the reordering and layout algorithm. In the first step of the bottom-up traverse, the P-type node of the NMOS S-P tree belongs to Case 1 (see Figure 5.4). Both leaves are Double-Double-type layout representatives, and the resulting layouts are Double-Double type for both the NMOS and the PMOS circuits. In the second step, the P-type node of the PMOS S-P tree belongs to Case 2. The two subcircuits of the P-type node are Double-Double type. The resulting PMOS circuit layout is Double-Double type, and the resulting NMOS circuit layout is Single-Double type. The algorithm continues until it finishes traversing the S-P trees. Figure 6.5(b) shows the result, and Figure 6.5(c) shows the layout after redundant wires are cleaned up and the output signal line is connected.

Figure 6.6 shows another example from [12]. Its S-P trees corresponding to the PMOS circuit and the NMOS circuit are shown in Figures 6.7 and 6.8, respectively. Our layout of [12]'s circuit is shown in Figure 6.9. For either the PMOS or the NMOS circuit, 11 tracks are necessary for the 38 transistors. The layout in [12] uses the same number of tracks without minimizing the longest path. The number of tracks of our layout can be further reduced after the redundant wires are cleaned up. Notice that we have taken advantage of reordering the serial paths.

7. Summary and conclusion. After introducing the terminology, which basically defines what an SPDH and a layout are, we have formulated the minmax mincut problem. It accepts an SPDH and produces a minimum cutwidth linear layout subject to the constraints that the source is at the leftmost position, the sink is at the rightmost position, and the longest path is minimized.

The constraints of the minmax mincut problem limit the solution space to TS-layouts, which are created by topological sorting. To explore the possible cutwidths (the track numbers), we define the pattern number k and prove that it is a lower bound of the cutwidths for a specific instance. Another lower bound is the balancing number m.

We have proposed two algorithms; both algorithms traverse corresponding S-P trees in a bottom-up manner and run in linear time. The main idea is to maintain suitable layout representatives to ensure proper growth of the number of necessary tracks.

The TS layout algorithm lays out an SPDH with at most $2(k+m)$ tracks, where k

is the pattern number and m is the balancing number of the SPDH. If reordering the serial paths is allowed, the reordering and layout algorithm simultaneously lays out an SPDH and its dual with the same vertex order, and this algorithm uses $O(\log N)$ tracks, where N is the number of vertices.

We discussed CMOS circuits and their gate-matrix layout style. Then we interpreted the minmax mincut problem as a timing-driven gate-matrix layout problem for CMOS since a topologically sorted solution not only minimizes the longest path but also reduces resistances in circuit design. The timing-driven gate-matrix layout problem is an issue which has not been addressed in the literature.

One possible approach to reduce the number of tracks is as follows. We use the techniques proposed here to fix the ordering of the columns (or transistors). Then we use one of the classical channel routers (e.g., [9, 16]) to obtain a detour-free layout.

In short, motivated by CMOS circuit design we have formulated a novel linear arrangement problem, explored basic properties, and proposed two algorithms. Since performance issues are being paid close attention to, we expect more applications to emerge.

There are several possible research directions. To further improve the number of tracks is a problem that needs further research. To relax the input constraint from an SPDH to a general directed acyclic hypergraph remains open (e.g., interconnection of two or more functional cells).

APPLICATION-CONTROLLED PAGING FOR A SHARED CACHE*

RAKESH D. BARVE†, EDWARD F. GROVE‡, AND JEFFREY SCOTT VITTER§

Abstract. We propose a provably efficient application-controlled global strategy for organizing a cache of size k shared among P application processes. Each application has access to information about its own future page requests, and by using that local information along with randomization in the context of a global caching algorithm, we are able to break through the conventional $H_k \sim \ln k$ lower bound on the competitive ratio for the caching problem. If the P application processes always make good cache replacement decisions, our online application-controlled caching algorithm attains a competitive ratio of $2H_{P-1} + 2 \sim 2 \ln P$. Typically, P is much smaller than k, perhaps by several orders of magnitude. Our competitive ratio improves upon the $2P + 2$ competitive ratio achieved by the deterministic application-controlled strategy of Cao, Felten, and Li. We show that no online application-controlled algorithm can have a competitive ratio better than $\min\{H_{P-1}, H_k\}$, even if each application process has perfect knowledge of its individual page request sequence. Our results are with respect to a worst-case interleaving of the individual page request sequences of the P application processes.

We introduce a notion of fairness in the more realistic situation when application processes do not always make good cache replacement decisions. We show that our algorithm ensures that no application process needs to evict one of its cached pages to service some page fault caused by a mistake of some other application. Our algorithm not only is fair but remains efficient; the global paging performance can be bounded in terms of the number of mistakes that application processes make.

Key words. caching, application-controlled, competitive, online, randomized

1. Introduction.

Caching is a useful technique for obtaining high performance in these days where the latency of disk access is relatively high. Today's computers typically have several application processes running concurrently on them, by means of time sharing and multiple processors. Some processes have special knowledge of their future access patterns. Cao, Felten, and Li [CFL94a, CFL94b] exploit this special knowledge to develop effective file caching strategies.

An application providing specific information about its future needs is equivalent to the application having its own caching strategy for managing its own pages in cache. We consider the *multiapplication caching* problem, formally defined in section 3, in which P concurrently executing application processes share a common cache of size k. In section 4 we propose an online application-controlled caching scheme in which decisions need to be taken at two levels: when a page needs to be evicted from cache,

the global strategy chooses a victim process, but the process itself decides which of its pages will be evicted from cache.

Each application process may use any available information about its future page requests when deciding which of its pages to evict. However, we assume *no global information* about the interleaving of the individual page request sequences; all our bounds are with respect to a *worst-case interleaving* of the individual request sequences.

Competitive ratios smaller than the H_k lower bound for classical caching [FKL$^+$91] are possible for multiapplication caching, because each application may employ future information about its individual page request sequence.[1] The deterministic application-controlled algorithm proposed by Cao, Felten, and Li [CFL94a] achieves a competitive ratio of $2P+2$, which we prove in the appendix. We show in sections 5–7 that our new randomized online application-controlled caching algorithm improves the competitive ratio to $2H_{P-1}+2 \sim 2\ln P$, which is optimal up to a factor of 2 in the realistic scenario when $P < k$. (If we use the algorithm of [FKL$^+$91] for the case $P \geq k$, the resulting bound is optimal up to a factor of 2 for all P.) Our results are significant since P is often *much* smaller than k, perhaps by several orders of magnitude.

In the appendix, we also prove that no deterministic online application-controlled algorithm can have a competitive ratio better than $P+1$. Thus the difference between our competitive ratio and that attained by the algorithm by Cao, Felten, and Li is a further indication of the (well-known) power of randomization while solving online problems in general and online paging in particular.

In the scenario where application processes occasionally make bad page replacement decisions (or "mistakes"), we show in section 8 that our online algorithm incurs very few page faults globally as a function of the number of mistakes. Our algorithm is also *fair*, in the sense that the mistakes made by one processor in its page replacement decisions do not worsen the page fault rate of other processors.

2. Classical caching and competitive analysis.

The well-known *classical caching (or paging) problem* deals with a two-level memory hierarchy consisting of a fast *cache* of size k and *slow memory* of arbitrary size. A sequence of requests to pages is to be satisfied in their order of occurrence. In order to satisfy a page request, the page must be in fast memory. When a requested page is not in fast memory, a *page fault* occurs, and some page must be evicted from fast memory to slow memory in order to make room for the new page to be put into fast memory. The caching (or paging) problem is to decide which page must be evicted from the cache. The cost to be minimized is the number of page faults incurred over the course of servicing the page requests.

Belady [Bel66] gives a simple optimum offline algorithm for the caching problem; the page chosen for eviction is the one in cache whose next request is furthest in the future. In order to quantify the performance of an online algorithm, Sleator and Tarjan [ST85] introduce the notion of competitiveness, which in the context of caching can be defined as follows: for a caching algorithm A, let $F_A(\sigma)$ be the number of page faults generated by A while processing page request sequence σ. If A is a randomized algorithm, we let $F_A(\sigma)$ be the *expected* number of page faults generated by A on processing σ, where the expectation is with respect to the random choices made by the algorithm. An online algorithm A is called *c-competitive* if for every

[1] Here H_n represents the nth harmonic number $\sum_{i=1}^{n} 1/i \sim \ln n$.

page request sequence σ, we have $F_A(\sigma) \leq c \cdot F_{OPT}(\sigma) + b$, where b is some fixed constant. The constant c is called the *competitive ratio* of A. Under this measure, an online algorithm's performance needs to be relatively good on worst-case page request sequences in order for the algorithm to be considered good.

For cache size k, Sleator and Tarjan [ST85] show a lower bound of k on the competitive ratio of deterministic caching algorithms. Fiat et al. [FKL$^+$91] prove a lower bound of H_k if randomized algorithms are allowed. They also give a simple and elegant randomized algorithm for the problem that achieves a competitive ratio of $2H_k$. McGeoch and Sleator [MS91] give a rather involved randomized algorithm that attains the theoretically optimal competitive ratio of H_k.

3. Multiapplication caching problem.

In this paper we take up the theoretical issue of how best to use application processes' knowledge about their individual future page requests so as to optimize caching performance. For analysis purposes we use an online framework similar to that of [FKL$^+$91, MS91]. As mentioned before, the caching algorithms in [FKL$^+$91, MS91] use *absolutely no information* about future page requests. Intuitively, knowledge about future page requests can be exploited to decide which page to evict from the cache at the time of a page fault. In practice an application often has advance knowledge of its individual future page requests. Cao, Felten, and Li [CFL94a, CFL94b] introduced strategies that try to combine the advance knowledge of the processors in order to make intelligent page replacement decisions.

In the *multiapplication caching problem* we consider a cache capable of storing k pages that is shared by P different application processes, which we denote $P_1, P_2, \ldots, P_P$. Each page in cache and memory belongs to exactly one process. The individual request sequences of the processes may be interleaved in an arbitrary (worst-case) manner.

Worst-case measure is often criticized when used for evaluating caching algorithms for individual application request sequences [BIRS91, KPR92], but we feel that the worst-case measure is appropriate for considering a global paging strategy for a cache shared by concurrent application processes that have knowledge of their individual page request sequences. The locality of reference within each application's individual request sequence is accounted for in our model by each application process's knowledge of its own future requests. The worst-case nature of our model is that it assumes nothing about the order and duration of time for which application processes are active. In this model our worst-case measure of competitive performance amounts to considering a *worst-case interleaving* of individual sequences.

The approach of Cao, Felten, and Li [CFL94a] is to have the kernel deterministically choose the process owning the least recently used page at the time of a page fault and ask that process to evict a page of its choice (which may be different from the least recently used (LRU) page). In the appendix we show under the assumption that processes always make good page replacement decisions that Cao, Felten, and Li's algorithm has a competitive ratio between $P + 1$ and $2P + 2$. The algorithm we present in the next section and analyze thereafter improves the competitive ratio to $2H_{P-1} + 2 \sim 2 \ln P$.

4. Online algorithm for multiapplication caching.

Our algorithm is an online application-controlled caching strategy for an operating system kernel to manage a shared cache in an efficient and fair manner. We show in the subsequent sections that the competitive ratio of our algorithm is $2H_{P-1}+2 \sim 2 \ln P$ and that it is optimal to within a factor of about 2 among all online algorithms. (If $P \geq k$, we can use the algorithm of [FKL$^+$91].)

On a page fault, we first choose a victim process and then ask it to evict a suitable page. Our algorithm can detect mistakes made by application processes, which enables us to reprimand such application processes by having them pay for their mistakes. In our scheme, we mark pages as well as processes in a systematic way while processing the requests that constitute a phase.

DEFINITION 4.1. *The global sequence of page requests is partitioned into a consecutive sequence of* phases*; each phase is a sequence of page requests. At the beginning of each phase, all pages and processes are unmarked. A page gets marked during a phase when it is requested. A process is marked when all of its pages in cache are marked. A new phase begins when a page is requested that is not in cache and all the pages in cache are marked. A page accessed during a phase is called* clean *with respect to that phase if it was not in the online algorithm's cache at the beginning of a phase. A request to a clean page is called a* clean page request*. Each phase always begins with a clean page request.*

Our marking scheme is similar to the one in [FKL$^+$91] for the classical caching problem. However, unlike the algorithm in [FKL$^+$91], the algorithm we develop is a nonmarking algorithm, in the sense that our algorithm may evict marked pages. In addition, our notion of phase in Definintion 4.1 is different from the notion of phase in [FKL$^+$91], which can be looked upon as a special case of our more general notion. We put the differences into perspective in section 4.1.

Our algorithm works as follows when a page p belonging to process P_r is requested:

```
(1) If $p$ is in cache:
    (a) If $p$ is not marked, we mark it.
    (b) If process $P_r$ has no unmarked pages in cache, we mark $P_r$.
(2) If $p$ is not in cache:
    (a) If process $P_r$ is unmarked and page $p$ is *not* a clean page with respect
        to the ongoing phase (i.e., $P_r$ has made a mistake earlier in the phase
        by evicting $p$), then
        (i) We ask process $P_r$ to make a page replacement decision and evict
            one of its pages from cache in order to bring page $p$ into cache. We
            mark page $p$ and also mark process $P_r$ if it now has no unmarked
            pages in cache.
    (b) Else (process $P_r$ is marked or page $p$ is a clean page, or both)
        (i) If all pages in cache are marked, we remove marks from all pages
            and processes, and we start a new phase, beginning with the current
            request for $p$.
        (ii) Let $S$ denote the set of unmarked processes having pages in the
            cache. We randomly choose a process $P_e$ from $S$, each process being
            chosen with a uniform probability $1/|S|$.
        (iii) We ask process $P_e$ to make a page replacement decision and evict
            one of its pages from cache in order to bring page $p$ into cache. We
            mark page $p$ and also mark process $P_e$ if it now has no unmarked
            page in cache.
```

Note that in steps 2(a)(i) and 2(b)(iii) our algorithm seeks paging decisions from application processes that are unmarked. Consider an unmarked process P_i that has been asked to evict a page in a phase, and consider P_i's pages in cache at that time. Let u_i denote the *farthest unmarked* page of process P_i; that is, u_i is the unmarked page of process P_i whose next request occurs furthest in the future among all of P_i's unmarked cached pages. Note that process P_i may have marked pages in cache whose next requests occur after the request for u_i.

DEFINITION 4.2. *The* good set *of an unmarked process P_i at the current point in the phase is the set consisting of its farthest unmarked page u_i in cache and every marked page of P_i in cache whose next request occurs* after *the next request for page u_i. A page replacement decision made by an unmarked process P_i in either step* 2(a)(i) *or step* 2(b)(iii) *that evicts a page from its good set is regarded as a* good decision *with respect to the ongoing phase. Any page from the good set of P_i is a* good page *for eviction purposes at the time of the decision. Any decision made by an unmarked process P_i that is not a good decision is regarded as a* mistake *by process P_i.*

If a process P_i makes a mistake by evicting a certain page from cache, we can detect the mistake made by P_i if and when the same page is requested again by P_i in the same phase while P_i is still unmarked.

In sections 6 and 7 we specifically assume that application processes are always able to make good decisions about page replacement. In section 8 we consider fairness properties of our algorithm in the more realistic scenario where processes can make mistakes.

4.1. Relation to previous work on classical caching. Our marking scheme approach is inspired by a similar approach for the classical caching problem in [FKL$^+$91]. However, the phases defined by our algorithm are significantly different in nature from those in [FKL$^+$91]. Our phase ends when there are k distinct marked pages in cache; more than k distinct pages may be requested in the phase. The phases depend on the random choices made by the algorithm and are probabilistic in nature. On the other hand, a phase defined in [FKL$^+$91] ends when exactly k distinct pages have been accessed, so that given the input request sequence, the phases can be determined independently of the caching algorithm being used.

The definition in [FKL$^+$91] is suited to facilitate the analysis of online caching algorithms that never evict marked pages, called *marking algorithms.* In the case of marking algorithms, since marked pages are never evicted, as soon as k distinct pages are requested, there are k distinct marked pages *in* cache. This means that the phases determined by our definition for the special case of marking algorithms are exactly the same as the phases determined by the definition in [FKL$^+$91]. Note that our algorithm is in general *not* a marking algorithm since it may evict marked pages. While marking algorithms always evict unmarked pages, our algorithm always calls on unmarked processes to evict pages; the actual pages evicted may be marked.

4.2. Relation to the algorithm of Cao, Felten, and Li. The algorithm proposed by Cao, Felten, and Li [CFL94a] for the multiapplication caching problem amounts to evicting, at the time of a page fault, the farthest page from cache belonging to the process that owns the LRU page in cache. Thus, for a given interleaving of individual request sequences, the paging decisions made by that algorithm are deterministic. We prove in the appendix that no deterministic online algorithm for the multiapplication caching problem can have a competitive ratio better than $P+1$, and that the competitive ratio attained by the algorithm proposed by Cao, Felten, and Li [CFL94a] attains a competitive ratio of $2P+2$. Thus, the performance of the algorithm in [CFL94a] is within a factor of 2 of the best possible performance by any deterministic online algorithm for the multiapplication caching problem.

Given the notion of good pages that we developed above, it turns out that we can define a slightly more general version of the algorithm in [CFL94a] without changing its paging performance. Basically, in order to attain the competitive ratio of $2P + 2$, it is enough, at the time of a page fault, to evict from cache *any good page* belonging to the process that owns the LRU page in cache. We say that this is a slightly more general version than the algorithm presented in [CFL94a] because it may very often be the case that the good set of the process that owns the LRU page contains several pages other than the farthest page of that process.

5. Lower bounds for *OPT* and competitive ratio.

In this section we prove that the competitive ratio of any online caching algorithm can be no better than $\min\{H_{P-1}, H_k\}$. Let us denote by OPT the optimal offline algorithm for caching that works as follows: when a page fault occurs, OPT evicts the page whose next request is furthest in the future request sequence among all pages in cache.

As in [FKL$^+$91], we will compare the number of page faults generated by our online algorithm during a phase with the number of page faults generated by OPT during that phase. We express the number of page fronts as a function of the number of clean page requests during the phase. Here we state and prove a lower bound on the (amortized) number of page faults generated by OPT in a single phase. The proof is a simple generalization of an analogous proof in [FKL$^+$91], which deals only with the deterministic phases of marking algorithms.

LEMMA 5.1. *Consider any phase σ_i of our online algorithm in which ℓ_i clean pages are requested. Then OPT incurs an amortized cost of at least $\ell_i/2$ on the requests made in that phase.*[2]

Proof. Let d_i be the number of clean pages in OPT's cache at the beginning of phase σ_i; that is, d_i is the number of pages requested in σ_i that are in OPT's cache but not in our algorithm's cache at the beginning of σ_i. Let d_{i+1} represent the same quantity for the next phase σ_{i+1}. Let $d_{i+1} = d_m + d_u$, where d_m of the d_{i+1} clean pages in OPT's cache at the beginning of σ_{i+1} are marked during σ_i and d_u of them are not marked during σ_i. Note that $d_1 = 0$ and $d_i \le k$ for all i.

Of the ℓ_i clean pages requested during σ_i, only d_i are in OPT's cache, so OPT generates at least $\ell_i - d_i$ page faults during σ_i. On the other hand, while processing the requests in σ_i, OPT cannot use d_u of the cache locations, since at the beginning of σ_{i+1} there are d_u pages in OPT's cache that are not marked during σ_i. (These d_u pages would have to be in OPT's cache before σ_i even began.) There are k marked pages in our algorithm's cache at the end of σ_i, and there are d_m other pages marked during σ_i that are out of our algorithm's cache. So the number of distinct pages requested during σ_i is at least $d_m + k$. Hence, OPT serves at least $d_m + k$ requests corresponding to σ_i without using d_u of the cache locations. This means that OPT generates at least $(k + d_m) - (k - d_u) = d_{i+1}$ faults during σ_i. Therefore, the number of faults OPT generates on σ_i is at least

$$\max\{\ell_i - d_i, d_{i+1}\} \ge \frac{\ell_i - d_i + d_{i+1}}{2}. \tag{5.1}$$

Let us consider the number of page faults made by OPT in the first j phases of page request sequence σ. We can use the lower bound (5.1) for phases $2, 3, \dots, j-1$. In the jth phase, OPT makes at least $\ell_j - d_j \ge (\ell_j - d_j)/2$ faults. In the first phase, OPT generates k faults and we have $\ell_1 = k$. Thus the sum of OPT's faults over all

[2]By "amortized" in Lemma 5.1 we mean for each $j \ge 1$ that the number of page faults made by OPT while serving the first j phases is at least $\sum_{i=1}^{j} \ell_i/2$, where ℓ_i is the number of clean page requests in the ith phase.

j phases is at least

$$\ell_1 + \sum_{i=2}^{j-1} \frac{\ell_i - d_i + d_{i+1}}{2} + \frac{\ell_j - d_j}{2} \geq \sum_{i=1}^{j} \ell_i/2,$$

where we use the fact that $d_2 \leq k = \ell_1$. Thus by definition, the amortized number of faults OPT generates over any phase σ_i is at least $\ell_i/2$. ∎

Next we will construct a lower bound for the competitive ratio of *any* randomized online algorithm even when application processes have perfect knowledge of their individual request sequences. The proof is a straightforward adaptation of the proof of the H_k lower bound for classical caching [FKL+91]. However, in the situation at hand, the adversary has more restrictions on the request sequence that he can use to prove the lower bound, thereby resulting in a lowering of the lower bound.

Theorem 5.2. *The competitive ratio of any randomized algorithm for the multi-application caching problem is at least* $\min\{H_{P-1}, H_k\}$ *even if application processes have perfect knowledge of their individual request sequences.*

Proof. If $P > k$, the H_k lower bound on the classical caching problem from [FKL+91] is directly applicable by considering the case where each process accesses only one page each. This gives a lower bound of H_k on the competitive ratio.

In the case when $P \leq k$, we construct a multiapplication caching problem based on the nemesis sequence used in [FKL+91] for classical caching. In [FKL+91] a lower bound of $H_{k'}$ is proved for the special case of a cache of size k' and a total of $k'+1$ pages, which we denote $c_1, c_2, \ldots, c_{k'+1}$. All but one of the pages can fit in cache at the same time. Our corresponding multiapplication caching problem consists of $P = k'+1$ application processes $P_1, P_2, \ldots, P_P$ so that there is one process corresponding to each page of the classical caching lower bound instance for a k'-sized cache. Process P_i owns r_i pages $p_{i1}, p_{i2}, \ldots, p_{ir_i}$. The total number $\sum_{i=1}^{P} r_i$ of pages among all the processes is $k+1$, where k is the cache size; that is, all but one of the pages among all the processes can fit in memory simultaneously.

In the instance of the multiapplication caching problem we construct, the request sequence for each process P_i consists of repetitions of the double round-robin sequence

$$p_{i1}, p_{i2}, \ldots, p_{ir_i}, p_{i1}, p_{i2}, \ldots, p_{ir_i} \tag{5.2}$$

of length $2r_i$. We refer to the double round-robin sequence (5.2) as a *touch* of process P_i. When the adversary generates requests corresponding to a touch of process P_i, we say that it "touches process P_i."

Given an arbitrary adversarial sequence for the classical caching problem described above, we construct an adversarial sequence for the multiapplication caching problem by replacing each request for page c_i in the former problem by a touch of process P_i in the latter problem. We can transform an algorithm for this instance of multiapplication caching into one for the classical caching problem by the following correspondence: if the multiapplication algorithm evicts a page from process P_j while servicing the touch of process P_i, the classical caching algorithm evicts page c_j in order to service the request to page c_i. In Lemma 5.3 below, we show that there is an optimum online algorithm for the above instance of multiapplication caching that never evicts a page belonging to process P_i while servicing a fault on a request for a page from process P_i. Thus the transformation is valid, in that page c_i is always resident in cache after the page request to c_i is serviced. This reduction immediately implies that the competitive ratio for this instance of multiapplication caching must be at least $H_{k'} = H_{P-1}$. ∎

LEMMA 5.3. *For the above instance of multiapplication caching, any online algorithm A can be converted into an online algorithm A' that is at least as good in an amortized sense and that has the property that all the pages for process P_i are in cache immediately after a touch of P_i is processed.*

Proof. Intuitively, the double round-robin sequences force an optimal online algorithm to service the touch of a process by evicting a page belonging to *another* process. We construct online algorithm A' from A in an online manner. Suppose that both A and A' fault during a touch of process P_i. If algorithm A evicts a page of P_j, for some $j \neq i$, then A' does the same. If algorithm A evicts a page of P_i during the first round-robin while servicing a touch of P_i, then there will be a page fault during the second round-robin. If A then evicts a page of another process during the second round-robin, then A' evicts that page during the first round-robin and incurs no fault during the second round-robin. The first page fault of A was wasted; the other page could have been evicted instead during the first round-robin. If instead A evicts another page of P_i during the second round-robin, then A' evicts an arbitrary page of another process during the first round-robin, and A' incurs no page fault during the second round-robin. Thus, if A evicts a page of P_i, it incurs at least one more page fault than does A'.

If A faults during a touch of P_i, but A' doesn't, there is no paging decision for A' to make. If A does not fault during a touch of P_i, but A' does fault, then A' evicts the page that is not in A's cache. The page fault for A' is charged to the extra page fault that A incurred earlier when A' evicted one of P_i's pages.

Thus the number of page faults that A' incurs is no more than the number of page faults that A incurs. By construction, all pages of process P_i are in algorithm A''s cache immediately after a touch of process P_i. ◻

The double round-robin sequences in the above reduction can be replaced by single round-robin sequences by redoing the explicit lower bound argument of [FKL$^+$91].

6. Holes.

In this section, we introduce the notion of holes, which plays a key role in the analysis of our online caching algorithm. In section 6.2, we mention some crucial properties of holes of our algorithm under the assumption that applications always make good page replacement decisions. These properties are also useful in bounding the page faults that can occur in a phase when applications make mistakes in their page replacement decisions.

DEFINITION 6.1. *The eviction of a cached page at the time of a page fault on a clean page request is said to create a* hole *at the evicted page. Intuitively, a hole is the lack of space for some page, so that that page's place in cache contains a hole and not the page. If page p_1 is evicted for servicing the clean page request, page p_1 is said to be associated with the hole. If page p_1 is subsequently requested and another page p_2 is evicted to service the request, the hole is said to* move *to p_2, and now p_2 is said to be associated with the hole, and so on, until the end of the phase. We say that* hole h moves to process P_i *to mean that the hole h moves to some page p belonging to process P_i.*

6.1. General observations about holes.

All requests to clean pages during a phase are page faults and create holes. The number of holes created during a particular phase equals the number of clean pages requested during that phase. Apart from clean page requests, requests to holes also cause page faults to occur. By a *request to a hole* we mean a request for the page associated with that hole. As we proceed down the request sequence during a phase, the page associated with a particular hole varies with time. Consider a hole h that is created at a page p_1 that is evicted to serve a request for clean page p_c. When a request is made for page p_1, some page p_2 is evicted, and h moves to p_2. Similarly when page p_2 is requested, h moves to some p_3, and so on. Let $p_1, p_2, \ldots, p_m$ be the temporal sequence of pages all associated with hole h in a particular phase such that page p_1 is evicted when clean page p_c is requested, page p_i, where $i > 1$, is evicted when p_{i-1} is requested and the request for p_m falls in the next phase. Then the number of faults incurred in the particular phase being considered due to requests to h is $m - 1$.

6.2. Useful properties of holes. In this section we make the following observations about holes under the assumption that application processes make only good decisions.

LEMMA 6.2. *Let u_i be the farthest unmarked page in cache of process P_i at some point in a phase. Then process P_i is a marked process by the time the request for page u_i is served.*

Proof. This follows from the definition of farthest unmarked page and the nature of the marking scheme employed in our algorithm. □

LEMMA 6.3. *Suppose that there is a request for page p_i, which is associated with hole h. Suppose that process P_i owns page p_i. Then process P_i is already marked at the time of the present request for page p_i.*

Proof. Page p_i is associated with hole h because process P_i evicted page p_i when asked to make a page replacement decision in order to serve either a clean request or a page fault at the previous page associated with h. In either case, page p_i was a good page at the time process P_i made the particular paging decision. Since process P_i was unmarked at the time the decision was made, p_i was either the farthest unmarked page of process P_i then or some marked page of process P_i whose next request is after the request for P_i's farthest unmarked page. By Lemma 6.2, process P_i is a marked process at the time of the request for page p_i. □

LEMMA 6.4. *Suppose that page p_i is associated with hole h. Let P_i denote the process owning page p_i. Suppose page p_i is requested at some time during the phase. Then hole h does not move to process P_i subsequently during the current phase.*

Proof. The hole h belongs to process P_i. By Lemma 6.3 when a request is made to h, P_i is already marked and will remain marked until the end of the phase. Since only unmarked processes are chosen to evict pages, a request for h thereafter cannot result in eviction of any page belonging to P_i, so a hole can never move to a process more than once. □

Let there be R unmarked processes at the time of a request to a hole h. For any unmarked process P_j, $1 \leq j \leq R$, let u_j denote the farthest unmarked page of process P_j at the time of the request to hole h. Without loss of generality, let us relabel the processes so that

$$u_1, u_2, u_3, \ldots, u_R \tag{6.1}$$

is the temporal order of the first subsequent appearance of the pages u_j in the global page request sequence.

LEMMA 6.5. *In the situation described in* (6.1) *above, suppose during the page request for hole h that the hole moves to a good page p_i of unmarked process P_i to serve the current request for h. Then h can never move to any of the processes $P_1, P_2, \ldots, P_{i-1}$ during the current phase.*

Proof. The first subsequent request for the good page p_i that P_i evicts, by definition, must be the same as or must be after the first subsequent request for the farthest unmarked page u_i. So process P_i will be marked by the next time hole h is requested, by Lemma 6.3. On the other hand, the first subsequent requests of the respective farthest unmarked pages $u_1, \ldots, u_{i-1}$ appear before that of page u_i. Thus, by Lemma 6.2, the processes $P_1, P_2, \ldots, P_{i-1}$ are already marked before the next time hole h (page p_i) gets requested and will remain marked for the remainder of the phase. Hence, by the fact that only unmarked processes get chosen, hole h can never move to any of the processes $P_1, P_2, \ldots, P_{i-1}$. ☐

7. Competitive analysis of our online algorithm.

Our main result is Theorem 7.1, which states that our online algorithm for the multiapplication caching problem is roughly $2 \ln P$-competitive, assuming application processes always make good decisions (e.g., if each process knows its own future page requests). By the lower bound of Theorem 5.2, it follows that our algorithm is optimal in terms of competitive ratio up to a factor of 2.

THEOREM 7.1. *The competitive ratio of our online algorithm in section* 4 *for the multiapplication caching problem, assuming that good evictions are always made, is at most* $2H_{P-1} + 2$. *Our competitive ratio is within a factor of about* 2 *of the best possible competitive ratio for this problem.*

The rest of this section is devoted to proving Theorem 7.1. To count the number of faults generated by our algorithm in a phase, we make use of the properties of holes from the previous section. If ℓ requests are made to clean pages during a phase, there are ℓ holes that move about during the phase. We can count the number of faults generated by our algorithm during the phase as

$$\ell + \sum_{i=1}^{\ell} N_i, \tag{7.1}$$

where N_i is the number of times hole h_i is requested during the phase. Assuming good decisions are always made, we will now prove for each phase and for any hole h_i that the expected value of N_i is bounded by H_{P-1}.

Consider the first request to a hole h during the phase. Let R_h be the number of unmarked processes at that point in time. Let C_{R_h} be the random variable associated with the number of page faults due to requests to hole h during the phase.

LEMMA 7.2. *The expected number* $E(C_{R_h})$ *of page faults due to requests to hole h is at most* H_{R_h}.

Proof. We prove this by induction over R_h. We have $E(C_0) = 0$ and $E(C_1) = 1$. Suppose for $0 \leq j \leq R_h - 1$ that $E(C_j) \leq H_j$. Using the same terminology and notation as in Lemma 6.5, we let the farthest unmarked pages of the R_h unmarked processes at the time of the request for h appear in the temporal order

$$u_1, u_2, u_3, \ldots, u_{R_h}$$

in the global request sequence. We renumber the R_h unmarked processes for convenience so that page u_i is the farthest unmarked page of unmarked process P_i.

When the hole h is requested, our algorithm randomly chooses one of the R_h unmarked processes, say, process P_i, and asks process P_i to evict a suitable page. Under our assumption, the hole h moves to some good page p_i of process P_i. From Lemmas 6.4 and 6.5, if our algorithm chooses unmarked process P_i so that its good page p_i is evicted, then *at most* $R_h - i$ *processes remain unmarked* the next time h is requested. Since each of the R_h unmarked processes is chosen with a probability of $1/R_h$, we have

$$\begin{aligned} E(C_{R_h}) &\leq 1 + \frac{1}{R_h} \sum_{i=1}^{R_h} E(C_{R_h - i}) \\ &= 1 + \frac{1}{R_h} \sum_{i=0}^{R_h - 1} E(C_i) \\ &\leq 1 + \frac{1}{R_h} \sum_{i=0}^{R_h - 1} H_i \\ &= H_{R_h}. \end{aligned}$$

The last equality follows easily by induction and algebraic manipulations. □

Now let us complete the proof of Theorem 7.1. By Lemma 6.3 the maximum possible number of unmarked processes at the time a hole h is first requested is $P-1$. Lemma 7.2 implies that the average number of times any hole can be requested during a phase is bounded by H_{P-1}. By (7.1), the total number of page faults during the phase is at most $\ell(1 + H_{P-1})$. We have already shown in Lemma 5.1 that the *OPT* algorithm incurs an amortized cost of at least $\ell/2$ for the requests made in the phase. Therefore, the competitive ratio of our algorithm is bounded by $\ell(1+H_{P-1})/(\ell/2) = 2H_{P-1}+2$. Applying the lower bound of Theorem 5.2 completes the proof.

8. Application-controlled caching with fairness. In this section we analyze our algorithm's performance in the realistic scenario where application processes can make mistakes, as defined in Definition 4.2. We bound the number of page faults it incurs in a phase in terms of page faults caused by mistakes made by application processes during that phase. The main idea here is that if an application process P_i commits a mistake by evicting a certain page p and then during the same phase requests page p while process P_i is still unmarked, our algorithm makes process P_i pay for the mistake in step 2(a)(i).

On the other hand, if page p's eviction from process P_i was a mistake, but process P_i is marked when page p is later requested in the same phase, say, at time t, then process P_i's mistake is "not worth detecting" for the following reason: since evicting page p was a mistake, it must mean that at the time t_1 of p's eviction, there existed a set U of one or more unmarked pages of process P_i in cache whose subsequent requests appear *after* the next request for page p. Process P_i is marked at the time of the next request for p, implying that all pages in U were *evicted* by P_i at some times $t_2, t_3, \ldots, t_{|U|+1}$ after the mistake of evicting p. If instead at time $t_1, t_2, \ldots, t_{|U|+1}$ process P_i makes the specific good paging decisions of evicting the farthest unmarked pages, *the same set* $\{p\} \cup U$ *of pages will be out of cache at time* t. In our notion of fairness we choose to ignore all such mistakes and consider them "not worth detecting."

DEFINITION 8.1. *During an ongoing phase, any page fault corresponding to a request for a page* p *of an* unmarked *process* P_i *is called an* unfair fault *if the request for page* p *is not a clean page request. All faults during the phase that are not unfair are called* fair faults.

The unfair faults are precisely those page faults which are caused by mistakes considered "worth detecting." We state the following two lemmas that follow trivially from the definitions of mistakes, good decisions, unfair faults, and fair faults.

Lemma 8.2. *During a phase, all page requests that get processed in step* 2(a)(i) *of our algorithm are precisely the unfair faults of that phase. That is, unfair faults correspond to mistakes that get caught in step* 2(a)(i) *of our algorithm.*

Lemma 8.3. *All fair faults are precisely those requests that get processed in step* 2(b)(iii).

We now consider the behavior of holes in the current mistake-prone scenario.

Lemma 8.4. *The number of holes in a phase equals the number of clean pages requested in the phase.*

Lemma 8.5. *Consider a hole h associated with a page p of a process P_i. If a request for h is an unfair fault, process P_i is still unmarked and the hole h moves to some other page belonging to process P_i. If a request for hole h is a fair fault, then process P_i is already marked and the hole h can never move to process P_i subsequently during the phase.*

Proof. If the request for hole h is an unfair fault, then by definition process P_i is unmarked and by Lemma 8.2, h moves to some other page p' of process P_i. If the request for h is a fair fault, then by definition and the fact that the request for h is not a clean page request, process P_i is marked. Since our algorithm never chooses a marked process for eviction, it follows that h can never visit process P_i subsequently during the phase. □

During a phase, a hole h is created in some process, say, P_1, by some clean page request. It then moves around zero or more times within process P_1 on account of P_1's mistakes, until a request for hole h is a fair fault, upon which it moves to some other process P_2, never to come back to process P_1 during the phase. It behaves similarly in process P_2, and so on up to the end of the phase. Let T_h denote the total number of faults attributed to requests to hole h during a phase, of which F_h faults are fair faults and U_h faults are unfair faults. We have $T_h = F_h + U_h$.

By Lemma 8.5 and the same proof techniques as those in the proofs of Lemma 7.2 and Theorem 7.1, we can prove the following key lemma.

Lemma 8.6. *The expected number $E(F_h)$ of page requests to hole h during a phase that result in fair faults is at most H_{P-1}.*

By Lemma 8.4, our algorithm incurs at most $\ell + \sum_{i=1}^{\ell} T_{h_i}$ page faults in a phase with ℓ clean page requests. The expected value of this quantity is at most $\ell(H_{P-1} + 1) + \sum_{i=1}^{\ell} U_{h_i}$, by Lemma 8.6.

The expression $\sum_{i=1}^{\ell} U_{h_i}$ is the number of *unfair faults*, that is, the number of mistakes considered "worth detecting." Our algorithm is very efficient in that the number of unfair faults is an additive term. For any phase ϕ with ℓ clean requests, we denote $\sum_{i=1}^{\ell} U_{h_i}$ as M_ϕ.

Theorem 8.7. *The number of faults in a phase ϕ with ℓ clean page requests and M_ϕ unfair faults is bounded by $\ell(1 + H_{P-1}) + M_\phi$. At the time of each of the M_ϕ unfair faults, the application process that makes the mistake that causes the fault must evict a page from its own cache. No application process is ever asked to evict a page to service an unfair fault caused by some other application process.*

8.1. Extending fairness to the algorithm by Cao, Felten, and Li. It turns out that our notion of fairness extends, without any change, to the generalized version of the deterministic algorithm of [CFL94a] that we mentioned in section 4.2. It is easy to see that in the case of the generalized version of the algorithm of [CFL94a], a process incurs an unfair fault only if, at some time in the past, that process had the LRU page and the page it evicted was not a good page. Consequently, a result similar to Theorem 8.7 with $(1 + H_{P-1})$ replaced by $(1 + P)$ holds for the generalized version of the algorithm of [CFL94a].

9. Conclusions.

Cache management strategies are of prime importance for high performance computing. We consider the case where there are P independent processes running on the same computer system and sharing a common cache of size k. Applications often have advance knowledge of their page request sequences. In this paper we have addressed the issue of exploiting this advance knowledge to devise intelligent strategies to manage the shared cache, in a theoretical setting. We have presented a simple and elegant randomized application-controlled caching algorithm for the multiapplication caching problem that achieves a competitive ratio of $2H_{P-1}+2$. Our result is a significant improvement over the competitive ratios of $2P+2$ [CFL94a] for deterministic multiapplication caching and $\Theta(H_k)$ for classical caching, since the cache size k is often orders of magnitude greater than P. We have proven that no online algorithm for this problem can have a competitive ratio smaller than $\min\{H_{P-1}, H_k\}$, even if application processes have perfect knowledge of individual request sequences. We conjecture that an upper bound of H_{P-1} can be proven, up to second-order terms, perhaps using techniques from [MS91], although the resulting algorithm is not likely to be practical.

Using our notion of mistakes we are able to consider a more realistic setting when application processes make bad paging decisions and show that our algorithm is a fair and efficient algorithm in such a situation. No application needs to pay for some other application process's mistake, and we can bound the global caching performance of our algorithm in terms of the number of mistakes. Our notions of good page replacement decisions, mistakes, and fairness in this context are new.

One related area of possible future work is to consider alternative models to our model of worst-case interleaving. Another interesting area would be to consider caching in a situation where some applications have good knowledge of future page requests while other applications have no knowledge of future requests. We could also consider pages shared among application processes.

Appendix. The Cao, Felten, and Li algorithm.

The algorithm proposed by Cao, Felten, and Li [CFL94a] for the multiapplication caching problem amounts to evicting, at the time of a page fault, the *farthest* page from cache belonging to the process that owns the LRU page in cache.

THEOREM A.1. *The algorithm of Cao, Felten, and Li is* $(2P+2)$*-competitive. A generalized version of the algorithm of Cao, Felten, and Li, in which, at the time of a page fault, the process owning the LRU page in cache evicts any (deterministically chosen) good page, is also* $(2P+2)$*-competitive.*

Proof. Let there be ℓ clean page requests in a phase. Then there are ℓ faults due to clean page requests resulting in ℓ holes. The algorithm evicts only *good* pages from cache, so holes are associated only with such pages. By Lemma 6.4 we can conclude that each hole can result in at most one page fault per process up to the end of the phase, so that the total number of page faults in the phase is bounded by $\ell + \ell P$. Using Lemma 5.1 gives the above competitive factor. □

THEOREM A.2. *The competitive ratio of any deterministic online algorithm for the multiapplication caching problem is at least* $P+1$.

Proof. Since the algorithm is deterministic, we can construct an interleave that costs the algorithm a factor of $P+1$ times the number of faults that *OPT* will incur. For instance, consider a single clean request in each phase. On the basis of our knowledge of the deterministic choices made by the algorithm, we can easily make the resulting hole visit each process at least once so that the deterministic online algorithm incurs at least $P + 1$ faults per phase, whereas OPT incurs just one fault. $\square$

PERFECT-INFORMATION LEADER ELECTION WITH OPTIMAL RESILIENCE*

RAVI B. BOPPANA† AND BABU O. NARAYANAN‡

Abstract. This paper investigates the leader-election problem in the perfect-information model of distributed computing. It is shown that for every $\epsilon < \frac{1}{2}$, there exist leader-election protocols for n processors that tolerate ϵn faults.

Key words. distributed computing, fault tolerance, leader election, perfect information, probabilistic methods

1. Introduction.

1.1. Statement of problem.

A distributed system of computers often needs to designate one of its processors as the "leader." Some of the processors may be faulty, but the leader should be nonfaulty with probability bounded away from 0. We follow the perfect-information model of Ben-Or and Linial [4] in which a processor communicates only by broadcasting a message to every other processor; faulty processors are permitted unlimited computational power, and hence cryptographic techniques are useless.

Our main result is that for every $\epsilon < \frac{1}{2}$, there exist leader-election protocols for n processors that tolerate ϵn faults.

1.2. Relation to other work.

Ben-Or and Linial [4] introduced the perfect-information model of distributed computing; they constructed a leader-election protocol for n processors that tolerates $O(n^{\log_3 2}/\log n)$ faults. (Actually they constructed their protocol for the weaker problem of collective coinflipping, but their protocol works for leader election also.) Saks [16] constructed an election protocol called "pass the baton" that tolerates $O(n/\log n)$ faults; Ajtai and Linial [1] analyzed the baton-passing protocol in more detail. Subsequently, Alon and Naor [2] showed the existence of a protocol that tolerates ϵn faults for every $\epsilon < \frac{1}{3}$: their protocol is nonconstructive. (They designed a constructive protocol for some small but positive constant ϵ.) In [6], we showed that the (nonconstructive) Alon–Naor protocol tolerates ϵn faults for every $\epsilon < (2\sqrt{10} - 5)/3 \approx 0.44$. Finally, in the present paper, we show that the Alon–Naor protocol actually tolerates ϵn faults for every $\epsilon < \frac{1}{2}$.

Our bound of ϵn faults for every $\epsilon < \frac{1}{2}$ is asymptotically optimal: Saks [16] observed that no election protocol for n processors can tolerate $\lceil n/2 \rceil$ faults. (As Saks did not publish his proof, we present a proof in section 3.) These two bounds leave open the case of $n/2 - o(n)$ faults. Because our upper bound seems hard to improve, we conjecture that $n/2 - o(n)$ faults are impossible to tolerate.

Recently, researchers have investigated the running time of protocols. In each round, each processor may broadcast a message to every other processor. Cooper and Linial [9] constructed a protocol that runs in polylogarithmic time and yet tolerates ϵn faults for some positive constant ϵ.

After our work was completed, Ostrovsky, Rajagopalan, and Vazirani [14] showed nonconstructively the existence of a protocol with $O(\log n)$ rounds that tolerates ϵn faults for every $\epsilon < \frac{1}{2}$; they designed a constructive protocol for $\epsilon < 0.0045$. Later, Zuckerman [17] designed a constructive protocol with $O(\log n)$ rounds that tolerates ϵn faults for every $\epsilon < \frac{1}{2}$. After that, Russell and Zuckerman [15] designed a constructive protocol with $\log^* n + O(1)$ rounds that tolerates ϵn faults for every $\epsilon < \frac{1}{2}$. All three papers use our protocol as a subroutine for small subsets of processors.

For two delightful surveys of the perfect-information model and related topics, see Ben-Or, Linial, and Saks [5] and Linial [13].

The most common model in distributed computing is not the perfect-information model, but rather the message-passing model in which processors may send private messages to other processors. For that model, Feldman and Micali [10] present a randomized protocol for leader election that tolerates a linear number of faults and yet runs in a constant expected number of rounds. See Chor and Dwork [8] for an excellent survey of the message-passing model.

1.3. Organization. In section 2, we present the formal definition of election protocols. In section 3, we prove Saks's impossibility result. In section 4, we present the probabilistic construction of election protocols due to Alon and Naor. In section 5, we present an overview of the proof of our main result. In sections 6, 7, and 8, we give the actual proof.

2. Protocols.

In this section, we present the formal definition of election protocols, introduced by Saks [16]. Throughout this section, let X be a finite set of processors.

DEFINITION 2.1 (election protocol). (a) An *election protocol* for X is a nonempty, strictly-binary tree with each node labeled by a processor in X.

(b) Let P be an election protocol for X and $A \subseteq X$ be a set of faulty processors. We define $\mathrm{Pr}_A(P)$ recursively as follows. If P consists of a single node (with label x), then

$$\mathrm{Pr}_A(P) = \begin{cases} 1 & \text{if } x \notin A, \\ 0 & \text{if } x \in A. \end{cases}$$

If P consists of a root node (with label x), a left subprotocol L, and a right subprotocol R, then

$$\mathrm{Pr}_A(P) = \begin{cases} \frac{1}{2}(\mathrm{Pr}_A(L) + \mathrm{Pr}_A(R)) & \text{if } x \notin A, \\ \min(\mathrm{Pr}_A(L), \mathrm{Pr}_A(R)) & \text{if } x \in A. \end{cases}$$

Informally, think of an election protocol as a biased random tree process. The processor x at the root node is supposed to choose the left or right subtree uniformly at random. (If x is faulty, that is, if $x \in A$, then it makes an adversarial choice, not a random choice.) The process continues until we reach a leaf node; its processor is selected as the leader. The number $\mathrm{Pr}_A(P)$ is the minimum probability that the protocol P elects a nonfaulty leader.

For example, suppose that the processor set X is $\{1, 2, 3\}$. Suppose that the protocol P is the 3-node binary tree in which the root is labeled by 1, the root's left child is labeled by 2, and the root's right child is labeled by 3. If $A = \emptyset$ or $A = \{1\}$, then $\Pr_A(P) = 1$. If $A = \{2\}$ or $A = \{3\}$, then $\Pr_A(P) = \frac{1}{2}$. Finally, if $A = \{1, 2\}$ or $A = \{1, 3\}$ or $A = \{2, 3\}$ or $A = \{1, 2, 3\}$, then $\Pr_A(P) = 0$.

We could generalize election protocols to allow more than two subprotocols and a nonuniform distribution on the subprotocols, but we will not need these generalizations.

Next, we define the notion of resilience.

Definition 2.2 (resilience). (a) If P is an election protocol for X, and t is a nonnegative real number, then

$$\Pr_t(P) = \min \{\Pr_A(P) : A \subseteq X \wedge |A| \leq t\}.$$

(b) An election protocol P is *t-resilient* if $\Pr_t(P)$ is bounded away from 0. (Technically, for "bounded away from 0" to make sense, we should speak of a *sequence* $P(n)$ of protocols being $t(n)$-resilient. We shall ignore this technicality.)

To illustrate, let P be the previous example protocol. Then $\Pr_0(P) = 1$, $\Pr_1(P) = \frac{1}{2}$, $\Pr_2(P) = 0$, and $\Pr_3(P) = 0$.

3. Limitations.

Saks [16] states that an elementary argument shows that an election protocol cannot tolerate $\lceil n/2 \rceil$ faults. In this section, we provide the proof.

Theorem 3.1 (dichotomy). *If A and B are finite sets, and P is an election protocol for $A \cup B$, then* $\min(\Pr_A(P), \Pr_B(P)) = 0$.

Proof. Nonnegativity is trivial, so we prove only nonpositivity. The proof is by structural induction on P.

Base case (*P has exactly one node*). Let x be the processor of the root node of P. Because $x \in A \cup B$, either $x \in A$ or $x \in B$; without loss of generality, assume that $x \in A$. By the definitions of min and Pr, we have

$$\min(\Pr_A(P), \Pr_B(P)) \leq \Pr_A(P) = 0.$$

Inductive case (*P has more than one node*). In P, let x be the root processor, let L be the left subprotocol, and let R be the right subprotocol. Because $x \in A \cup B$, either $x \in A$ or $x \in B$; without loss of generality, assume that $x \in A$.

By the definition of Pr, we have

$$\begin{aligned} \Pr_B(P) &= \begin{cases} \frac{1}{2}(\Pr_B(L) + \Pr_B(R)) & \text{if } x \notin B, \\ \min(\Pr_B(L), \Pr_B(R)) & \text{if } x \in B \end{cases} \\ &\leq \frac{1}{2}(\Pr_B(L) + \Pr_B(R)) \\ &\leq \max(\Pr_B(L), \Pr_B(R)). \end{aligned} \tag{3.1}$$

By the definition of Pr and the assumption $x \in A$, we have

$$\Pr_A(P) = \min(\Pr_A(L), \Pr_A(R)). \tag{3.2}$$

Hence, by (3.1), the distributive law of min over max, (3.2), and the inductive hypothesis, we have

$$\begin{aligned}\min(\Pr_A(P), \Pr_B(P)) &\le \min(\Pr_A(P), \max(\Pr_B(L), \Pr_B(R)))\\ &= \max(\min(\Pr_A(P), \Pr_B(L)), \min(\Pr_A(P), \Pr_B(R)))\\ &\le \max(\min(\Pr_A(L), \Pr_B(L)), \min(\Pr_A(R), \Pr_B(R)))\\ &= \max(0, 0)\\ &= 0.\end{aligned}$$

This inequality completes the induction. □

The proof of the preceding theorem resembles the proof of a classical result in game theory: In every two-player, perfect-information game, one of the two players has a winning strategy. The resemblance is no accident: we could have derived our theorem as a consequence of the game-theoretic result.

We now derive Saks's impossibility result.

COROLLARY 3.2 (Saks). *If P is an election protocol for X, and $t \ge \lceil |X|/2 \rceil$, then $\Pr_t(P) = 0$.*

Proof. Nonnegativity is trivial, so we prove only nonpositivity. Let A and B be subsets of X such that $A \cup B = X$ and $|A| \le \lceil |X|/2 \rceil$ and $|B| \le \lceil |X|/2 \rceil$. Then by the definition of $\Pr_t$, and by Theorem 3.1, we have

$$\Pr_t(P) \le \min(\Pr_A(P), \Pr_B(P)) = 0.$$

This inequality completes the proof. □

4. Random protocols.

In this section we present the probabilistic construction of election protocols due to Alon and Naor [2]. For the remainder of this paper, let ϵ be a constant such that $0 \le \epsilon < \frac{1}{2}$. Let X be a nonempty finite set.

DEFINITION 4.1 (uniform distribution). The *uniform distribution* $\mathrm{Unif}(X)$ is the probability distribution on X that assigns each element of X the probability $1/|X|$.

DEFINITION 4.2 (function of distributions). Let f be a function on $A \times B$, and let C and D be probability distributions on A and B, respectively. Then $\widetilde{f}(C, D)$ is defined to be the probability distribution of the random variable $f(c, d)$, where c and d are independent random variables with distributions C and D, respectively. Although we presented this definition for a function with two arguments, we will generalize the definition in the obvious way to functions with fewer or more arguments.

DEFINITION 4.3 (random protocols). (a) If x is an element of X, and L and R are election protocols for X, then $f(x, L, R)$ is the election protocol for X whose root node is labeled x, whose left subprotocol is L, and whose right subprotocol is R.

(b) If D is a probability distribution on election protocols for X, then $F(D)$ is the probability distribution on election protocols for X defined by

$$F(D) = \widetilde{f}(\mathrm{Unif}(X), D, D).$$

(Here we are using Definition 4.2 to extend f to $\widetilde{f}$.) Informally, $F(D)$ has a random processor at its root and has independent copies of D as its left and right subprotocols.

(c) If i is a nonnegative integer, then $\mathcal{F}_i$ is the probability distribution on election protocols for X defined recursively as follows. If $i = 0$, then $\mathcal{F}_i$ ranges over trees with just one node, with that node labeled uniformly at random from X. If $i > 0$, then $\mathcal{F}_i = F(\mathcal{F}_{i-1})$. Informally, $\mathcal{F}_i$ is a full binary tree of height i, in which every node is labeled by a random processor.

We need to analyze the probability that the random protocol $\mathcal{F}_i$ elects a nonfaulty leader. It turns out, as Alon and Naor [2] observed, that this probability can be captured by a random number process that does not refer to protocols themselves. We now define this random process.

Definition 4.4 (common sets). Define $\mathbf{R}$ to be the set of real numbers. Define $\mathbf{R}^+$ to be the set of nonnegative real numbers. Define $\mathbf{B}$ to be the set $\{\text{true}, \text{false}\}$ of Boolean values.

Definition 4.5 (common distributions). Let p be a number between 0 and 1. Define the *Boolean distribution* $\text{Bool}(p)$ to be the distribution on $\mathbf{B}$ that assigns true the probability p and assigns false the probability $1-p$. Define the *Bernoulli distribution* $\text{Bern}(p)$ to be the distribution on $\{0,1\}$ that assigns 1 the probability p and assigns 0 the probability $1-p$.

Definition 4.6 (random numbers). (a) If b is a Boolean value, and x and y are [nonnegative] real numbers, then $g(b,x,y)$ is the [nonnegative] real number defined by

$$g(b,x,y) = \begin{cases} \min(x,y) & \text{if } b \text{ is true,} \\ (x+y)/2 & \text{otherwise.} \end{cases}$$

(b) If D is a probability distribution on $\mathbf{R}$ (or $\mathbf{R}^+$), then $G(D)$ is the probability distribution on $\mathbf{R}$ ($\mathbf{R}^+$) defined by

$$G(D) = \widetilde{g}(\text{Bool}(\epsilon), D, D).$$

Informally, given two independent arguments from D, we take their minimum with probability ϵ and their average with probability $1-\epsilon$.

(c) If i is a nonnegative integer, then $\mathcal{G}_i$ is the probability distribution on $\mathbf{R}^+$ defined recursively by

$$\mathcal{G}_i = \begin{cases} \text{Bern}(1-\epsilon) & \text{if } i = 0, \\ G(\mathcal{G}_{i-1}) & \text{if } i > 0. \end{cases}$$

Informally, $\mathcal{G}_i$ corresponds to a full binary tree of height i, in which each node is labeled randomly by a min or an average, with a bias toward averaging.

The following lemma shows that the distribution $\mathcal{G}_i$ of numbers is related to the distribution $\mathcal{F}_i$ of protocols.

Lemma 4.7 (protocols versus numbers). (a) *If A is a subset of X, and x is an element of X, and L and R are election protocols for X, then*

$$\Pr_A(f(x,L,R)) = g(x \in A, \Pr_A(L), \Pr_A(R)).$$

(b) *If A is a subset of X of size $\epsilon\,|X|$, and D is a probability distribution on election protocols for X, then*

$$\widetilde{\Pr_A}(F(D)) = G(\widetilde{\Pr_A}(D)).$$

(c) *If A is a subset of X of size $\epsilon\,|X|$, and i is a nonnegative integer, then*

$$\widetilde{\Pr_A}(\mathcal{F}_i) = \mathcal{G}_i.$$

Proof. (a) By the definitions of f and $\Pr_A$ and g, we have

$$\begin{aligned}\Pr_A(f(x,L,R)) &= \begin{cases} \min(\Pr_A(L), \Pr_A(R)) & \text{if } x \in A, \\ (\Pr_A(L) + \Pr_A(R))/2 & \text{otherwise} \end{cases} \\ &= g(x \in A, \Pr_A(L), \Pr_A(R)).\end{aligned}$$

(b) Because A has size $\epsilon\,|X|$, if x is uniformly distributed on X, then $x \in A$ has distribution $\mathrm{Bool}(\epsilon)$. By the definition of F, part (a), and the definition of G, we have

$$\begin{aligned}\widetilde{\mathrm{Pr}_A}(F(D)) &= \widetilde{\mathrm{Pr}_A}(\widetilde{f}(\mathrm{Unif}(X), D, D))\\ &= \widetilde{g}(\mathrm{Bool}(\epsilon), \widetilde{\mathrm{Pr}_A}(D), \widetilde{\mathrm{Pr}_A}(D))\\ &= G(\widetilde{\mathrm{Pr}_A}(D)).\end{aligned}$$

(c) The proof is by induction on i.

Base case $i = 0$. Recall that if x is uniformly distributed on X, then $x \in A$ has distribution $\mathrm{Bool}(\epsilon)$, and so $x \notin A$ has distribution $\mathrm{Bool}(1-\epsilon)$. Hence $\widetilde{\mathrm{Pr}_A}(\mathcal{F}_0)$ is the distribution $\mathrm{Bern}(1-\epsilon)$, which is $\mathcal{G}_0$.

Inductive case $i > 0$. By the definition of $\mathcal{F}_i$, part (b), the inductive hypothesis, and the definition of $\mathcal{G}_i$, we have

$$\widetilde{\mathrm{Pr}_A}(\mathcal{F}_i) = \widetilde{\mathrm{Pr}_A}(F(\mathcal{F}_{i-1})) = G(\widetilde{\mathrm{Pr}_A}(\mathcal{F}_{i-1})) = G(\mathcal{G}_{i-1}) = \mathcal{G}_i.$$

Hence all three parts of the lemma have been proved. ∎

5. Proof overview. In this section, we present an overview of our proof that the Alon–Naor random protocols tolerate ϵn faults (for every fixed $\epsilon < \frac{1}{2}$).

Throughout, let X be a finite nonempty set, of size n. We may assume that ϵn is an integer; otherwise we could use the smaller value $\lfloor \epsilon n \rfloor / n$ for ϵ.

Let A be a fixed subset of X of size ϵn. We will find a constant $\delta > 0$ (independent of n) such that for sufficiently large i, we obtain the tail bound

$$\mathrm{Pr}[\mathcal{G}_i \le \delta] < 1 \bigg/ \binom{n}{\epsilon n}. \tag{5.1}$$

By the definition of Pr_t, Boole's inequality, Lemma 4.7(c), and the tail bound (5.1), it would follow that

$$\begin{aligned}\mathrm{Pr}[\widetilde{\mathrm{Pr}_{\epsilon n}}(\mathcal{F}_i) \le \delta] &= \mathrm{Pr}\left[\bigvee_{|A|=\epsilon n} \widetilde{\mathrm{Pr}_A}(\mathcal{F}_i) \le \delta\right]\\ &\le \sum_{|A|=\epsilon n} \mathrm{Pr}[\widetilde{\mathrm{Pr}_A}(\mathcal{F}_i) \le \delta]\\ &= \sum_{|A|=\epsilon n} \mathrm{Pr}[\mathcal{G}_i \le \delta]\\ &< \sum_{|A|=\epsilon n} 1 \bigg/ \binom{n}{\epsilon n}\\ &= \binom{n}{\epsilon n} \bigg/ \binom{n}{\epsilon n}\\ &= 1.\end{aligned}$$

Hence there would be an election protocol P in the support of $\mathcal{F}_i$ such that $\mathrm{Pr}_{\epsilon n}(P) > \delta$; in other words, P would be ϵn-resilient, and we would be done.

To prove the tail bound (5.1) for $\epsilon < \frac{1}{3}$, Alon and Naor [2] used estimates on the expectation and variance of $\mathcal{G}_i$. To handle larger values of ϵ, we need to analyze higher moments of $\mathcal{G}_i$.

Definition 5.1 (expected value). If x is a random variable on $\mathbf{R}$, then $\mathrm{E}(x)$ denotes its expected value. If D is a probability distribution on $\mathbf{R}$, then $\mathrm{E}(D)$ denotes $\mathrm{E}(x)$, where x is a random variable with distribution D.

Definition 5.2 (moment). If D is a probability distribution on $\mathbf{R}$ and d is a nonnegative real number, then the dth *moment* of D is

$$\mathrm{M}_d(D) = \mathrm{E}(|x-y|^d),$$

where x and y are independent random variables with distribution D.

Our proof of the tail bound (5.1) divides into three steps:

(i) Our key step is to show that the higher moments of $\mathcal{G}_i$ are geometrically contracting in i; loosely speaking, each of these distributions is "concentrated" near one value.

(ii) Once we have this contraction result, we will show that the expectation of $\mathcal{G}_i$ is bounded away from 0; for small ϵ, this step is easy, but for large ϵ, we need to use a majorization argument that relates our random process to another process with smaller moments.

(iii) Once we know that the expectation of $\mathcal{G}_i$ is bounded away from 0, a simple argument using Chebyshev's inequality will give the tail bound (5.1).

In [7] we used the same outline of steps to analyze a biased-coin process, extending a result of Alon and Rabin [3]. The key difference between [7] and the present paper, besides the difference in problems, is in step (i): The contraction argument here is much more complicated than the one in [7], perhaps unavoidably so. Steps (ii) and (iii) resemble the corresponding steps in [7].

In section 6, we prove the contraction result. In section 7, we develop the majorization argument. Finally, in section 8, we prove the tail bound (5.1).

6. Contraction.

In this section, we prove that the higher moments of the distribution $\mathcal{G}_i$ geometrically contract with i. Let d be a nonnegative real number, the moment that we will focus on.

Definition 6.1 (Δ function). Let $x = (x_1, x_2, x_3, x_4)$ be a vector in $\mathbf{R}^4$. The function $\Delta\colon \mathbf{R}^4 \to \mathbf{R}$ is defined by

$$\Delta(x) = \Delta_1(x) + \Delta_2(x) + \Delta_3(x) + \Delta_4(x),$$

where

$$\Delta_1(x) = (1-\epsilon)^2 \left|\frac{x_1+x_2}{2} - \frac{x_3+x_4}{2}\right|^d,$$

$$\Delta_2(x) = \epsilon(1-\epsilon) \left|\frac{x_1+x_2}{2} - \min(x_3,x_4)\right|^d,$$

$$\Delta_3(x) = \epsilon(1-\epsilon) \left|\min(x_1,x_2) - \frac{x_3+x_4}{2}\right|^d,$$

and

$$\Delta_4(x) = \epsilon^2 \left|\min(x_1,x_2) - \min(x_3,x_4)\right|^d.$$

We defined Δ this way to get the following identity:

$$\mathrm{E}(|\widetilde{g}(\mathrm{Bool}(\epsilon), x_1, x_2) - \widetilde{g}(\mathrm{Bool}(\epsilon), x_3, x_4)|^d) = \Delta(x_1, x_2, x_3, x_4).$$

(Strictly speaking, for this identity to make sense, we should view g, and hence $\widetilde{g}$, as a function of just one argument, treating its last two arguments as constants. The identity follows from the definitions of g and Δ.)

Now let D be a probability distribution on $\mathbf{R}$. Let x be a random vector in $\mathbf{R}^4$ such that x_1, x_2, x_3, and x_4 are independent random variables with distribution D. Taking the expected value of the previous equation, and using the definition of G, we get the identity

$$\mathrm{M}_d(G(D)) = \mathrm{E}(\widetilde{\Delta}(D,D,D,D)). \tag{6.1}$$

The following lemma, an upper bound on Δ, is the key tool in proving our contraction result.

Lemma 6.2 (deterministic contraction). *If x is a vector in $\mathbf{R}^4$, then*

$$\begin{aligned}\Delta(x_1,x_2,x_3,x_4) + \Delta(x_3,x_2,x_1,x_4) + \Delta(x_1,x_3,x_2,x_4)&\\ \le \frac{1}{2}c \sum_{1\le i<j\le 4} \left|x_i - x_j\right|^d,&\end{aligned} \tag{6.2}$$

where $c = \max(2\epsilon, \frac{1+\epsilon}{2}) + 6(\frac{3}{4})^d$.

Proof. Throughout the proof we rely, without explicit mention, on the inequalities

$$\left|\frac{p+q}{2}\right|^d \le \frac{1}{2}\left[|p|^d + |q|^d\right]$$

and

$$\left|\frac{p+q+r+s}{4}\right|^d \le \frac{1}{4}\left[|p|^d + |q|^d + |r|^d + |s|^d\right],$$

which are special cases of the power mean inequality [12, Theorem 16].

Both sides of the inequality (6.2) are symmetric functions of x. Hence we may assume that $x_1 \le x_2 \le x_3 \le x_4$. The proof divides into two cases, depending on the value of x_2.

Case 1 ($x_2 \ge (x_1+x_3)/2$). Our first three steps are to develop an upper bound on each of the three Δ terms in (6.2); our last step is to add these three upper bounds to establish (6.2).

Step 1.1. We bound the four terms of $\Delta(x_1,x_2,x_3,x_4)$:

$$\begin{aligned}\Delta_1(x_1,x_2,x_3,x_4) &= (1-\epsilon)^2\left|\frac{x_3+x_4}{2} - \frac{x_1+x_2}{2}\right|^d\\ &\le (1-\epsilon)^2\left|\frac{x_3+x_4}{2} - \frac{x_1+(x_1+x_3)/2}{2}\right|^d\\ &= (1-\epsilon)^2\left|\frac{x_3+2x_4-3x_1}{4}\right|^d \le (1-\epsilon)^2\left(\frac{3}{4}\right)^d |x_4-x_1|^d\\ &\le \left(\frac{3}{4}\right)^d |x_4-x_1|^d;\end{aligned}$$

$$\begin{aligned}\Delta_2(x_1,x_2,x_3,x_4) &= \epsilon(1-\epsilon)\left|x_3 - \frac{x_1+x_2}{2}\right|^d \le \epsilon(1-\epsilon)\left|x_3 - \frac{x_1+(x_1+x_3)/2}{2}\right|^d\\ &= \epsilon(1-\epsilon)\left(\frac{3}{4}\right)^d |x_3-x_1|^d \le \left(\frac{3}{4}\right)^d |x_3-x_1|^d;\end{aligned}$$

$$\begin{aligned}\Delta_3(x_1,x_2,x_3,x_4) &= \epsilon(1-\epsilon)\left|\frac{x_3+x_4}{2}-x_1\right|^d = \epsilon(1-\epsilon)\left|\frac{x_3-x_1}{2}+\frac{x_4-x_1}{2}\right|^d \\ &\le \frac{1}{2}\epsilon(1-\epsilon)\left[|x_3-x_1|^d+|x_4-x_1|^d\right]; \\ \Delta_4(x_1,x_2,x_3,x_4) &= \epsilon^2|x_3-x_1|^d.\end{aligned}$$

Adding these four inequalities gives the bound

$$\begin{aligned}\Delta(x_1,x_2,x_3,x_4) \le{}& \frac{1}{2}\epsilon(1+\epsilon)|x_3-x_1|^d+\frac{1}{2}\epsilon(1-\epsilon)|x_4-x_1|^d \\ &+\left(\frac{3}{4}\right)^d|x_3-x_1|^d+\left(\frac{3}{4}\right)^d|x_4-x_1|^d.\end{aligned}\tag{6.3}$$

Step 1.2. We bound the four terms of $\Delta(x_3,x_2,x_1,x_4)$:

$$\begin{aligned}\Delta_1(x_3,x_2,x_1,x_4) &= (1-\epsilon)^2\left|\frac{x_1+x_4}{2}-\frac{x_3+x_2}{2}\right|^d \le (1-\epsilon)^2\left|\frac{x_4-x_1}{2}\right|^d \\ &= (1-\epsilon)^2\left(\frac{1}{2}\right)^d|x_4-x_1|^d \le (1-\epsilon)\left(\frac{3}{4}\right)^d|x_4-x_1|^d; \\ \Delta_2(x_3,x_2,x_1,x_4) &= \epsilon(1-\epsilon)\left|\frac{x_3+x_2}{2}-x_1\right|^d \le \frac{1}{2}\epsilon(1-\epsilon)\left[|x_2-x_1|^d+|x_3-x_1|^d\right]; \\ \Delta_3(x_3,x_2,x_1,x_4) &= \epsilon(1-\epsilon)\left|x_2-\frac{x_1+x_4}{2}\right|^d \le \epsilon(1-\epsilon)\left|\frac{x_4-x_1}{2}\right|^d \\ &= \epsilon(1-\epsilon)\left(\frac{1}{2}\right)^d|x_4-x_1|^d \le \epsilon\left(\frac{3}{4}\right)^d|x_4-x_1|^d; \\ \Delta_4(x_3,x_2,x_1,x_4) &= \epsilon^2|x_2-x_1|^d.\end{aligned}$$

Adding these four inequalities gives

$$\begin{aligned}\Delta(x_3,x_2,x_1,x_4) \le{}& \frac{1}{2}\epsilon(1+\epsilon)|x_2-x_1|^d+\frac{1}{2}\epsilon(1-\epsilon)|x_3-x_1|^d \\ &+\left(\frac{3}{4}\right)^d|x_4-x_1|^d.\end{aligned}\tag{6.4}$$

Step 1.3. We bound the four terms of $\Delta(x_1,x_3,x_2,x_4)$:

$$\begin{aligned}\Delta_1(x_1,x_3,x_2,x_4) &= (1-\epsilon)^2\left|\frac{x_1+x_3}{2}-\frac{x_2+x_4}{2}\right|^d \le (1-\epsilon)^2\left|\frac{x_4-x_1}{2}\right|^d \\ &= (1-\epsilon)^2\left(\frac{1}{2}\right)^d|x_4-x_1|^d \le \left(\frac{3}{4}\right)^d|x_4-x_1|^d; \\ \Delta_2(x_1,x_3,x_2,x_4) &= \epsilon(1-\epsilon)\left|\frac{x_1+x_3}{2}-x_2\right|^d \le \epsilon(1-\epsilon)\left|\frac{x_3-x_1}{2}\right|^d \\ &= \epsilon(1-\epsilon)\left(\frac{1}{2}\right)^d|x_3-x_1|^d \le \left(\frac{3}{4}\right)^d|x_3-x_1|^d; \\ \Delta_3(x_1,x_3,x_2,x_4) &= \epsilon(1-\epsilon)\left|\frac{x_4+x_2}{2}-x_1\right|^d \le \frac{1}{2}\epsilon(1-\epsilon)\left[|x_2-x_1|^d+|x_4-x_1|^d\right];\end{aligned}$$

$$\Delta_4(x_1, x_3, x_2, x_4) = \epsilon^2 |x_2 - x_1|^d \leq \epsilon^2 |x_4 - x_1|^d .$$

Adding these four inequalities gives

$$\begin{aligned}\Delta(x_1, x_3, x_2, x_4) \leq {} & \frac{1}{2}\epsilon(1-\epsilon)|x_2 - x_1|^d + \frac{1}{2}\epsilon(1+\epsilon)|x_4 - x_1|^d \\ & + \left(\frac{3}{4}\right)^d |x_3 - x_1|^d + \left(\frac{3}{4}\right)^d |x_4 - x_1|^d .\end{aligned} \tag{6.5}$$

Step 1.4. Adding the three bounds (6.3), (6.4), and (6.5), and using the definition of c, we obtain

$$\begin{aligned}&\Delta(x_1, x_2, x_3, x_4) + \Delta(x_3, x_2, x_1, x_4) + \Delta(x_1, x_3, x_2, x_4) \\ &\quad \leq \epsilon |x_2 - x_1|^d + \epsilon |x_3 - x_1|^d + \epsilon |x_4 - x_1|^d + 2\left(\frac{3}{4}\right)^d |x_3 - x_1|^d + 3\left(\frac{3}{4}\right)^d |x_4 - x_1|^d \\ &\quad \leq \left[\epsilon + 3\left(\frac{3}{4}\right)^d\right] \sum_{i<j} |x_i - x_j|^d \leq \frac{1}{2} c \sum_{i<j} |x_i - x_j|^d .\end{aligned}$$

This inequality is (6.2), which settles Case 1.

Case 2 ($x_2 \leq (x_1 + x_3)/2$). Again, our first three steps are to develop an upper bound on each of the three Δ terms in the inequality (6.2); our last step is to add these three upper bounds to establish (6.2).

Step 2.1 We bound the four terms of $\Delta(x_1, x_2, x_3, x_4)$:

$$\begin{aligned}\Delta_1(x_1, x_2, x_3, x_4) &= (1-\epsilon)^2 \left|\frac{x_1 + x_2}{2} - \frac{x_3 + x_4}{2}\right|^d \\ &= (1-\epsilon)^2 \left|\frac{x_4 - x_1}{4} + \frac{x_4 - x_2}{4} + \frac{x_3 - x_1}{4} + \frac{x_3 - x_2}{4}\right|^d \\ &\leq \frac{1}{4}(1-\epsilon)^2 \left[|x_4 - x_1|^d + |x_4 - x_2|^d + |x_3 - x_1|^d + |x_3 - x_2|^d\right]; \\ \Delta_2(x_1, x_2, x_3, x_4) &= \epsilon(1-\epsilon)\left|\frac{x_1 + x_2}{2} - x_3\right|^d \leq \frac{1}{2}\epsilon(1-\epsilon)\left[|x_3 - x_1|^d + |x_3 - x_2|^d\right]; \\ \Delta_3(x_1, x_2, x_3, x_4) &= \epsilon(1-\epsilon)\left|x_1 - \frac{x_3 + x_4}{2}\right|^d \leq \frac{1}{2}\epsilon(1-\epsilon)\left[|x_3 - x_1|^d + |x_4 - x_1|^d\right]; \\ \Delta_4(x_1, x_2, x_3, x_4) &= \epsilon^2 |x_3 - x_1|^d .\end{aligned}$$

Adding these four inequalities and using $|x_3 - x_1| \leq |x_4 - x_1|$ gives the bound

$$\begin{aligned}\Delta(x_1, x_2, x_3, x_4) &\leq \frac{1}{4}(1+\epsilon)^2 |x_3 - x_1|^d + \frac{1}{4}(1-\epsilon^2)|x_4 - x_1|^d \\ &\qquad + \frac{1}{4}(1-\epsilon^2)|x_3 - x_2|^d + \frac{1}{4}(1-\epsilon)^2 |x_4 - x_2|^d \\ &\leq \frac{1+\epsilon}{4}|x_3 - x_1|^d + \frac{1+\epsilon}{4}|x_4 - x_1|^d \\ &\qquad + \frac{1}{4}(1-\epsilon^2)|x_3 - x_2|^d + \frac{1}{4}(1-\epsilon)^2 |x_4 - x_2|^d \\ &\leq \frac{1+\epsilon}{4}\sum_{i<j}|x_i - x_j|^d .\end{aligned} \tag{6.6}$$

Step 2.2. We bound the four terms of $\Delta(x_3, x_2, x_1, x_4)$:

$$\begin{aligned}
\Delta_1(x_3,x_2,x_1,x_4) &= (1-\epsilon)^2 \left|\frac{x_3+x_2}{2} - \frac{x_1+x_4}{2}\right|^d \le (1-\epsilon)^2\left(\frac{1}{2}\right)^d |x_4-x_1|^d \\
&\le (1-\epsilon)\left(\frac{3}{4}\right)^d |x_4-x_1|^d; \\
\Delta_2(x_3,x_2,x_1,x_4) &= \epsilon(1-\epsilon)\left|\frac{x_3+x_2}{2} - x_1\right|^d = \epsilon(1-\epsilon)\left|\frac{x_3+(x_1+x_3)/2}{2} - x_1\right|^d \\
&= \epsilon(1-\epsilon)\left(\frac{3}{4}\right)^d |x_3-x_1|^d \le (1-\epsilon)\left(\frac{3}{4}\right)^d |x_3-x_1|^d; \\
\Delta_3(x_3,x_2,x_1,x_4) &= \epsilon(1-\epsilon)\left|x_2 - \frac{x_1+x_4}{2}\right|^d \le \epsilon(1-\epsilon)\left(\frac{1}{2}\right)^d |x_4-x_1|^d \\
&\le \epsilon\left(\frac{3}{4}\right)^d |x_4-x_1|^d; \\
\Delta_4(x_3,x_2,x_1,x_4) &= \epsilon^2 |x_2-x_1|^d \le \epsilon^2\left|\frac{x_1+x_3}{2} - x_1\right|^d \\
&\le \epsilon^2\left(\frac{1}{2}\right)^d |x_3-x_1|^d \le \epsilon\left(\frac{3}{4}\right)^d |x_3-x_1|^d.
\end{aligned}$$

Adding these four inequalities gives

$$\Delta(x_3,x_2,x_1,x_4) \le \left(\frac{3}{4}\right)^d |x_3-x_1|^d + \left(\frac{3}{4}\right)^d |x_4-x_1|^d. \tag{6.7}$$

Step 2.3. We bound the four terms of $\Delta(x_1, x_3, x_2, x_4)$:

$$\begin{aligned}
\Delta_1(x_1,x_3,x_2,x_4) &= (1-\epsilon)^2 \left|\frac{x_1+x_3}{2} - \frac{x_2-x_4}{2}\right|^d \le (1-\epsilon)^2\left(\frac{1}{2}\right)^d |x_4-x_1|^d \\
&\le (1-\epsilon)\left(\frac{3}{4}\right)^d |x_4-x_1|^d; \\
\Delta_2(x_1,x_3,x_2,x_4) &= \epsilon(1-\epsilon)\left|\frac{x_1+x_3}{2} - x_2\right|^d \le \epsilon(1-\epsilon)\left(\frac{1}{2}\right)^d |x_3-x_1|^d \\
&\le (1-\epsilon)\left(\frac{3}{4}\right)^d |x_3-x_1|^d; \\
\Delta_3(x_1,x_3,x_2,x_4) &= \epsilon(1-\epsilon)\left|x_1 - \frac{x_2+x_4}{2}\right|^d \le \epsilon(1-\epsilon)\left|x_1 - \frac{(x_1+x_3)/2+x_4}{2}\right|^d \\
&= \epsilon(1-\epsilon)\left|\frac{2x_4-x_3-3x_1}{4}\right|^d \le \epsilon(1-\epsilon)\left(\frac{3}{4}\right)^d |x_4-x_1|^d \\
&\le \epsilon\left(\frac{3}{4}\right)^d |x_4-x_1|^d;
\end{aligned}$$

$$\begin{aligned}\Delta_4(x_1, x_3, x_2, x_4) &= \epsilon^2 \left|x_2 - x_1\right|^d \le \epsilon^2 \left|\frac{x_1 + x_3}{2} - x_1\right|^d \\ &= \epsilon^2 \left(\frac{1}{2}\right)^d \left|x_3 - x_1\right|^d \le \epsilon \left(\frac{3}{4}\right)^d \left|x_3 - x_1\right|^d.\end{aligned}$$

Adding these four inequalities gives

$$\Delta(x_1, x_3, x_2, x_4) \le \left(\frac{3}{4}\right)^d \left|x_3 - x_1\right|^d + \left(\frac{3}{4}\right)^d \left|x_4 - x_1\right|^d. \tag{6.8}$$

Step 2.4. Adding the three bounds (6.6), (6.7), and (6.8), and using the definition of c, we obtain

$$\begin{aligned}&\Delta(x_1, x_2, x_3, x_4) + \Delta(x_3, x_2, x_1, x_4) + \Delta(x_1, x_3, x_2, x_4) \\ &\quad\le \frac{1}{4}(1+\epsilon)\sum_{i<j}\left|x_i - x_j\right|^d + 2\left(\frac{3}{4}\right)^d \left|x_3 - x_1\right|^d + 2\left(\frac{3}{4}\right)^d \left|x_4 - x_1\right|^d \\ &\quad\le \left[\frac{1+\epsilon}{4} + 2\left(\frac{3}{4}\right)^d\right]\sum_{i<j}\left|x_i - x_j\right|^d \le \frac{1}{2}c\sum_{i<j}\left|x_i - x_j\right|^d.\end{aligned}$$

This inequality is (6.2), which settles Case 2, which settles the lemma. ∎

Using the preceding lemma, we can prove the contraction result that we desire.

LEMMA 6.3 (contraction lemma). *If D is a probability distribution on $\mathbf{R}$ and d is a nonnegative real number, then*

$$\mathrm{M}_d(G(D)) \le c\,\mathrm{M}_d(D),$$

where $c = \max(2\epsilon, \frac{1+\epsilon}{2}) + 6(\frac{3}{4})^d$.

Proof. Let x be a random vector in $\mathbf{R}^4$ such that x_1, x_2, x_3, and x_4 are independent random variables with distribution D. Note that the three tuples (x_1, x_2, x_3, x_4), (x_3, x_2, x_1, x_4), and (x_1, x_3, x_2, x_4) are identically distributed. In particular, we have

$$\begin{aligned}\mathrm{E}(\widetilde{\Delta}(D, D, D, D)) &= \mathrm{E}(\Delta(x_1, x_2, x_3, x_4)) \\ &= \mathrm{E}(\Delta(x_3, x_2, x_1, x_4)) \\ &= \mathrm{E}(\Delta(x_1, x_3, x_2, x_4)).\end{aligned}$$

Hence, from the identity (6.1) and Lemma 6.2, we get

$$\begin{aligned}\mathrm{M}_d(G(D)) &= \mathrm{E}(\widetilde{\Delta}(D, D, D, D)) \\ &= \frac{1}{3}\left[\mathrm{E}(\Delta(x_1, x_2, x_3, x_4)) + \mathrm{E}(\Delta(x_3, x_2, x_1, x_4)) + \mathrm{E}(\Delta(x_1, x_3, x_2, x_4))\right] \\ &\le \frac{1}{6}c\sum_{1\le i<j\le 4}\mathrm{E}(\left|x_i - x_j\right|^d) \\ &= \frac{1}{6}c\sum_{1\le i<j\le 4}\mathrm{M}_d(D) \\ &= c\,\mathrm{M}_d(D).\end{aligned}$$

This inequality completes the proof. ∎

This lemma is a contraction result: The constant c can be made less than 1. Because $\epsilon < \frac{1}{2}$, every sufficiently large d makes $c < 1$. In fact, the choice $d = 8\ln\frac{6}{1-2\epsilon}$ works.

7. Majorization.

7. Majorization. In this section we relate our random process to another random process that is easier to analyze, using a concept called majorization. This argument is similar to the majorizing argument in Boppana and Narayanan [7].

DEFINITION 7.1 (majorization). Let C and D be probability distributions on $\mathbf{R}$. Say that C *majorizes* D, written $C \succeq D$, if there are random variables x and y such that

(i) the random variable x has distribution C,
(ii) the random variable y has distribution D, and
(iii) the inequality $x \geq y$ always holds.

Say that C is *majorized by* D, written $C \preceq D$, if D majorizes C.

Note that majorization is transitive. Also, if $C \succeq D$, then $\mathrm{E}(C) \geq \mathrm{E}(D)$.

We now show that the transformation G (from Definition 4.6) is "stochastically increasing."

LEMMA 7.2 (increasing). *If C and D are distributions on $\mathbf{R}$ such that $C \preceq D$, then $G(C) \preceq G(D)$.*

Proof. Note that $g(b, x, y)$ is increasing in x and y. By the definition of G and the hypothesis $C \preceq D$, it follows that

$$G(C) = \widetilde{g}(\mathrm{Bool}(\epsilon), C, C) \preceq \widetilde{g}(\mathrm{Bool}(\epsilon), D, D) = G(D).$$

That inequality completes the proof. □

We next define a random process $\mathcal{G}'_i$ that is majorized by our original process $\mathcal{G}_i$ but which can be analyzed exactly. (Compare the next definition with Definition 4.6.)

DEFINITION 7.3 (smaller random numbers). (a) If b is a Boolean value, and x and y are (nonnegative) real numbers, then $g'(b, x, y)$ is the (nonnegative) real number defined by

$$g'(b, x, y) = \begin{cases} \min(x, y)/2 & \text{if } b \text{ is true,} \\ \max(x, y)/2 & \text{otherwise.} \end{cases}$$

(b) If D is a probability distribution on $\mathbf{R}$ (or $\mathbf{R}^+$), then $G'(D)$ is the probability distribution on $\mathbf{R}$ ($\mathbf{R}^+$) defined by

$$G'(D) = \widetilde{g'}(\mathrm{Bool}(\epsilon), D, D).$$

(c) If i is a nonnegative integer, then $\mathcal{G}'_i$ is the probability distribution on $\mathbf{R}^+$ defined recursively by

$$\mathcal{G}'_i = \begin{cases} \mathrm{Bern}(1-\epsilon) & \text{if } i = 0, \\ G'(\mathcal{G}'_{i-1}) & \text{if } i > 0. \end{cases}$$

We now compare the unprimed distributions $\mathcal{G}_i$ to the primed distributions $\mathcal{G}'_i$.

LEMMA 7.4 (majorization). (a) *If b is a Boolean value, and x and y are nonnegative real numbers, then $g(b, x, y) \geq g'(b, x, y)$.*

(b) *If D is a distribution on $\mathbf{R}^+$, then $G(D) \succeq G'(D)$.*

(c) *If i is a nonnegative integer, then $\mathcal{G}_i \succeq \mathcal{G}'_i$.*

Proof.

(1) By the definitions of g and g', and the nonnegativity of x and y, we have

$$g(b, x, y) = g'(b, x, y) + \frac{1}{2}\min(x, y) \geq g'(b, x, y).$$

(2) Let b, x, and y be independent random variables such that b has distribution $\mathrm{Bool}(\epsilon)$, and x and y have distribution D. By the definition of G [or G'], the random variable $g(b,x,y)$ [$g'(b,x,y)$] has distribution $G(D)$ [$G'(D)$]. But $g(b,x,y) \geq g'(b,x,y)$ by part (a). The definition of majorization implies that $G(D) \succeq G'(D)$.

(3) The proof is by induction on i.

Base case ($i = 0$). By the definitions of $\mathcal{G}_0$ and $\mathcal{G}'_0$, we have

$$\mathcal{G}_0 = \mathrm{Bern}(1-\epsilon) = \mathcal{G}'_0.$$

Inductive case ($i > 0$). By the definition of $\mathcal{G}_i$, Lemma 7.2 and the inductive hypothesis, part (b), and the definition of $\mathcal{G}'_i$, we have

$$\mathcal{G}_i = G(\mathcal{G}_{i-1}) \succeq G(\mathcal{G}'_{i-1}) \succeq G'(\mathcal{G}'_{i-1}) = \mathcal{G}'_i.$$

Hence all three parts of the lemma have been proved. $\square$

We next show that the primed distributions $\mathcal{G}'_i$ are simple two-point distributions.

DEFINITION 7.5 (probability recurrence). If i is a nonnegative integer, then p_i is the nonnegative real number defined recursively by

$$p_i = \begin{cases} \epsilon & \text{if } i = 0; \\ 2\epsilon p_{i-1} + (1-2\epsilon)p_{i-1}^2 & \text{if } i > 0. \end{cases}$$

LEMMA 7.6 (two-point distribution). *If i is a nonnegative integer, then the distribution $\mathcal{G}'_i$ maps $1/2^i$ to $1 - p_i$ and maps 0 to p_i.*

Proof. The proof is by induction on i.

Base case ($i = 0$). By the definitions of $\mathcal{G}'_0$ and p_0, we have

$$\mathcal{G}'_0 = \mathrm{Bern}(1-\epsilon) = \mathrm{Bern}(1-p_0),$$

which completes the base case.

Inductive case ($i > 0$). Let b, x, and y be independent random variables such that b has distribution $\mathrm{Bool}(\epsilon)$, and x and y have distribution $\mathcal{G}'_{i-1}$. By the definitions of $\mathcal{G}'_i$ and G' and g', by independence, by the inductive hypothesis, and finally by the definition of p_i, we have

$$\begin{aligned}
\mathcal{G}'_i(0) &= G'(\mathcal{G}'_{i-1})(0) \\
&= \widetilde{g'}(\mathrm{Bool}(\epsilon), \mathcal{G}'_{i-1}, \mathcal{G}'_{i-1})(0) \\
&= \Pr[\, g'(b,x,y) = 0 \,] \\
&= \Pr[\, b \wedge \min(x,y) = 0 \,] + \Pr[\, \bar{b} \wedge \max(x,y) = 0 \,] \\
&= \Pr[\, b \,] \cdot \Pr[\, \min(x,y) = 0 \,] + \Pr[\, \bar{b} \,] \cdot \Pr[\, \max(x,y) = 0 \,] \\
&= \Pr[\, b \,] \cdot \Pr[\, x = 0 \vee y = 0 \,] + \Pr[\, \bar{b} \,] \cdot \Pr[\, x = 0 \wedge y = 0 \,] \\
&= \epsilon[1 - (1-p_{i-1})^2] + (1-\epsilon)p_{i-1}^2 \\
&= 2\epsilon p_{i-1} + (1-2\epsilon)p_{i-1}^2 \\
&= p_i.
\end{aligned}$$

Similarly, we can calculate that $\mathcal{G}'_i(1/2^i) = 1 - p_i$. This calculation completes the induction. $\square$

Next we show that the probabilities p_i are approaching 0.

LEMMA 7.7 (vanishing probability). *If i is a nonnegative integer, then $p_i \leq \epsilon(3\epsilon - 2\epsilon^2)^i$.*

Proof. The proof is by induction on i.

Base case ($i = 0$). This case holds (with equality) from the definition of p_0.

Inductive case ($i > 0$). By the definition of p_i, and by the inductive hypothesis, and because $3\epsilon - 2\epsilon^2 < 1$, we have

$$\begin{aligned} p_i &= 2\epsilon p_{i-1} + (1-2\epsilon)p_{i-1}^2 \\ &\leq 2\epsilon^2(3\epsilon - 2\epsilon^2)^{i-1} + (1-2\epsilon)\epsilon^2(3\epsilon - 2\epsilon^2)^{2(i-1)} \\ &\leq 2\epsilon^2(3\epsilon - 2\epsilon^2)^{i-1} + (1-2\epsilon)\epsilon^2(3\epsilon - 2\epsilon^2)^{(i-1)} \\ &= \epsilon(3\epsilon - 2\epsilon^2)^i. \end{aligned}$$

This inequality completes the induction. ☐

Because $3\epsilon - 2\epsilon^2 < 1$, the preceding lemma implies that $\lim_{i\to\infty} p_i = 0$.

As i approaches infinity, the good news is that $\mathcal{G}'_i$ is mostly concentrated on one value, so that $\mathcal{G}'_i$ has small moments (even relative to its expectation). The bad news is that the expectation of $\mathcal{G}'_i$ approaches 0. Therefore we introduce a hybrid of $\mathcal{G}_i$ and $\mathcal{G}'_i$ that preserves the good news but avoids the bad news.

Choose a nonnegative integer j so that $p_j \leq \frac{1}{2}[(1 - c^{1/d})/(2\epsilon)]^d$. Such a j exists because $\lim_{i\to\infty} p_i = 0$.

DEFINITION 7.8 (hybrid distribution). If i is a nonnegative integer, then the probability distribution $\mathcal{H}_i$ on $\mathbf{R}^+$ is defined recursively by

$$\mathcal{H}_i = \begin{cases} \mathcal{G}'_i & \text{if } i \leq j, \\ G(\mathcal{H}_{i-1}) & \text{if } i > j. \end{cases}$$

As $\mathcal{G}_i \succeq \mathcal{G}'_i$ (Lemma 7.4), and as G is stochastically increasing (Lemma 7.2), it follows (by induction on i) that $\mathcal{G}_i \succeq \mathcal{H}_i$.

8. Tail bound. In this section, we finally prove the tail bound (5.1), completing the proof of our main result on the existence of ϵn-resilient election protocols (for every fixed $\epsilon < \frac{1}{2}$).

It is easy to see, from the definition of g, that

$$g(b, x, y) = \frac{1}{2}(x + y) - \frac{1}{2}[b]\,|x - y|\,,$$

where $[b]$ is the *indicator* of b—namely 1 if b is true and 0 otherwise. From the definition of G, it follows that if D is a distribution on $\mathbf{R}$, then

$$\mathrm{E}(G(D)) = \mathrm{E}(D) - \frac{1}{2}\epsilon\,\mathrm{M}_1(D). \qquad (8.1)$$

(Recall that the expected value of a distribution is just the expected value of a random variable with that distribution.)

We need the following relation between moments. The power mean inequality [12, Theorem 16] implies the inequality

$$\mathrm{M}_\alpha(D)^{1/\alpha} \leq \mathrm{M}_\beta(D)^{1/\beta},$$

whenever $0 < \alpha \leq \beta$.

By Lemmas 7.6 and 7.7, we have

$$\mathrm{E}(\mathcal{G}_i') = (1-p_i)/2^i \geq (1-\epsilon)/2^i \geq 1/2^{i+1} \tag{8.2}$$

and

$$\mathrm{M}_d(\mathcal{G}_i') = 2p_i(1-p_i)/2^{id} \leq 2p_i/2^{id}. \tag{8.3}$$

Next, we show that the expectations of $\mathcal{G}_i$ are bounded away from 0. By replacing $\mathcal{G}_k$ with $\mathcal{H}_k$, iterating the identity (8.1), applying the power mean inequality and the contraction lemma, summing the geometric series, applying the bounds (8.2) and (8.3), and finally plugging in the definition of j, we obtain

$$\begin{aligned}
\mathrm{E}(\mathcal{G}_k) &\geq \mathrm{E}(\mathcal{H}_k)\\
&= \mathrm{E}(\mathcal{H}_j) - \frac{1}{2}\epsilon \sum_{i=j}^{k-1} \mathrm{M}_1(\mathcal{H}_i)\\
&\geq \mathrm{E}(\mathcal{H}_j) - \frac{1}{2}\epsilon \sum_{i=j}^{k-1} \mathrm{M}_d(\mathcal{H}_i)^{1/d}\\
&\geq \mathrm{E}(\mathcal{H}_j) - \frac{1}{2}\epsilon \sum_{i=j}^{k-1} \left(c^{i-j}\,\mathrm{M}_d(\mathcal{H}_j)\right)^{1/d}\\
&\geq \mathrm{E}(\mathcal{H}_j) - \frac{1}{2}\epsilon \frac{\mathrm{M}_d(\mathcal{H}_j)^{1/d}}{1-c^{1/d}}\\
&= \mathrm{E}(\mathcal{G}_j') - \frac{1}{2}\epsilon \frac{\mathrm{M}_d(\mathcal{G}_j')^{1/d}}{1-c^{1/d}}\\
&\geq \frac{1}{2^{j+1}} - \frac{1}{2}\epsilon \frac{(2p_j)^{1/d}/2^j}{1-c^{1/d}}\\
&= \frac{1}{2^{j+1}}\left[1 - \epsilon \frac{(2p_j)^{1/d}}{1-c^{1/d}}\right]\\
&\geq \frac{1}{2^{j+2}}.
\end{aligned} \tag{8.4}$$

Because j is fixed, the expectation is indeed bounded away from 0.

Finally we prove the tail bound (5.1). By the expectation bound (8.4), Chebyshev's inequality [11, section IX.6], the power mean inequality, and the contraction lemma, we have

$$\begin{aligned}
\Pr[\mathcal{G}_k \leq 1/2^{j+3}] &\leq \Pr[\mathcal{G}_k \leq \mathrm{E}(\mathcal{G}_k)/2]\\
&\leq \Pr[|\mathcal{G}_k - \mathrm{E}(\mathcal{G}_k)| \geq \mathrm{E}(\mathcal{G}_k)/2]\\
&\leq \mathrm{Var}(\mathcal{G}_k)/(\mathrm{E}(\mathcal{G}_k)/2)^2\\
&= 2\,\mathrm{M}_2(\mathcal{G}_k)/\,\mathrm{E}(\mathcal{G}_k)^2\\
&\leq 2\,\mathrm{M}_d(\mathcal{G}_k)^{2/d}/\,\mathrm{E}(\mathcal{G}_k)^2\\
&\leq 2c^{2k/d}\,\mathrm{M}_d(\mathcal{G}_0)^{2/d}/\,\mathrm{E}(\mathcal{G}_k)^2\\
&= 2c^{2k/d}[2\epsilon(1-\epsilon)]^{2/d}/\,\mathrm{E}(\mathcal{G}_k)^2\\
&\leq 2c^{2k/d}[2\epsilon(1-\epsilon)]^{2/d}2^{2(j+2)}.
\end{aligned}$$

As k gets large, the right side approaches 0, and in particular becomes less than $1/\binom{n}{\epsilon n}$ for k on the order of n. We thus obtain the tail bound (5.1). As discussed in section 5, this bound implies the existence of an ϵn-resilient election protocol, which proves our main result.

Acknowledgments. We thank Noga Alon for suggesting this problem to us, Nati Linial for some valuable discussions, and the two referees for useful comments.

NODE-DISJOINT PATHS ON THE MESH AND A NEW TRADE-OFF IN VLSI LAYOUT[*]

ALOK AGGARWAL[†], JON KLEINBERG[‡], AND DAVID P. WILLIAMSON[†]

Abstract. A number of basic models for VLSI layout are based on the construction of node-disjoint paths between terminals on a multilayer grid. In this setting, one is interested in minimizing both the number of *layers* required and the *area* of the underlying grid. Building on work of Cutler and Shiloach [*Networks*, 8 (1978), pp. 253–278], Aggarwal et al. [*Proc. 26th IEEE Symposium on Foundations of Computer Science*, Portland, OR, 1985; *Algorithmica*, 6 (1991), pp. 241–255], and Aggarwal, Klawe, and Shor [*Algorithmica*, 6 (1991), pp. 129–151], we prove an upper-bound trade-off between these two quantities in a general multilayer grid model. As a special case of our main result, we obtain significantly improved bounds for the problem of routing a full permutation on the mesh using node-disjoint paths; our new bound here is within polylogarithmic factors of the bisection bound. Our algorithms involve some new techniques for analyzing the structure of node-disjoint paths in planar graphs and indicate some respects in which this problem, at least in the planar case, is fundamentally different from its edge-disjoint counterpart.

Key words. combinatorial optimization, VLSI layout, disjoint paths problem

1. Introduction.

The basic node-disjoint paths problem is as follows. We are given a graph G and pairs of vertices in G. The two natural objectives we consider are to

(1) simultaneously route as many pairs as possible on node-disjoint paths in G;
(1′) route all pairs in as few "rounds of communication" as possible, where all paths routed in a single round must be node-disjoint.

Finding node-disjoint paths between designated pairs of vertices in a planar graph is fundamental to a number of routing and embedding problems. In particular, in many models of VLSI layout, effective layout strategies rely on heuristics for finding node-disjoint paths; many current routing software systems rely extensively on such an approach (see also [13]). Node-disjointness constraints can arise as well in the context of virtual circuit routing in networks, when one requires paths to be node-disjoint for the sake of fault tolerance or because of bottlenecks involving switches rather than links.

At the same time, the basic node-disjoint paths problem is NP-hard even for the two-dimensional mesh [10], and very little is known in the way of reasonable approximation algorithms for the problem. Given the basic nature of the problem,

we are interested in looking for techniques with provable performance guarantees for constructing node-disjoint paths in planar graphs, as such techniques may help in answering questions of the form (1) and (1′) as they arise in practice.

The study of this problem is also interesting to us precisely because its structure, in the case of planar graphs, is very different from the analogous edge-disjoint paths problem. This is true even in a technical sense; for example, work of Kleinberg and Tardos [9] has shown that for many planar graphs including the mesh, a natural *cut condition* is sufficient to within polylogarithmic factors for the feasibility of edge-disjoint paths. But this is far from true in the node-disjoint case, where one encounters a variety of "topological" obstructions to the existence of the paths. See section 1.1 for a discussion of some of these issues.

Let us discuss a very basic problem that arises in this setting. We say a set of terminal pairs in a graph is a *permutation* if each vertex of the graph appears in exactly one pair. If G denotes the $n \times n$ two-dimensional mesh graph, and we are given a permutation in which every pair needs to cross the center column, then the standard bisection bound says that at most n terminal pairs can be routed simultaneously, and so at least $\frac{1}{2}n$ rounds, in the sense of (1′), are required.

The lack of understanding of this area is such that the following has remained open; again, let G denote the mesh:

> (2) For every permutation on G, does there exist a set of $\Omega(n^{1-\varepsilon})$ pairs that can be simultaneously routed on node-disjoint paths for every $\varepsilon > 0$?
>
> (2′) Can every permutation on G be routed in $O(n^{1+\varepsilon})$ rounds for every $\varepsilon > 0$?

Again, by way of contrast, these questions are straightforward to resolve in the affirmative when one requires only edge-disjoint paths.

These latter questions turn out to be closely related to open problems of Aggarwal et al. [1] in the setting of *multilayer* VLSI layout. In multilayer VLSI layouts, typically a *pin* (a *node*, in our terminology) goes through several layers at the same location, and the routing among pins at each layer is planar. If a routing wire needs to change a layer, then a *via* (or *contact cut*) has to be made between two layers, and this usually affects the yield of the output chip (as well as affecting the general quality of the circuit). Consequently, it is practically useful to route as many connections on a single layer as possible (in order to reduce the vias); for more details see [1, 6, 15]. These constraints thus result directly in problems of the type (1) and (1′), with layers now playing the role of "rounds."

One typically reduces the number of layers by introducing spacing between the terminals. In the model of [1, 6], for a parameter d, consider a $dn \times dn$ mesh G_d, with an $n \times n$ grid of terminals at a *uniform spacing* of d. By this we mean that terminals are placed at the set of nodes of G_d whose row and column numbers are multiples of d; thus, $d-1$ paths can now be routed between adjacent terminals. The goal in this model is to find the tightest trade-off possible between the spacing d and the number of layers required in the worst case.

Cutler and Shiloach [6] showed that spacing $d = O(n^2)$ suffices to route all pairs in a single layer; and [1, 2, 8] showed that this value of d was tight up to constant factors. In terms of a general trade-off between d and the minimum number of layers required, the techniques of [6, 1] are sufficient only to show that, for spacing d, $O((\frac{n}{\sqrt{d}})^{4/3})$ layers are sufficient. However, guided by (2′), a reasonable question is the following:

> (3′) With spacing d, are $O((\frac{n}{\sqrt{d}})^{1+\varepsilon})$ layers sufficient to route any

permutation on the mesh, for every $\varepsilon > 0$?

This contains the result of [6] in the case $d = \Theta(n^2)$ and question ($2'$) in the case $d = 1$.

The main results of this paper provide affirmative answers to questions (2), ($2'$), and ($3'$). Specifically, we prove the following theorems.

THEOREM 1.1. *Every permutation on the mesh contains a set of* $\Omega(n/\log n)$ *terminal pairs that can be simultaneously routed on node-disjoint paths. Moreover, every permutation on the mesh can be routed in* $O(n \log^2 n)$ *rounds.*

THEOREM 1.2. *With spacing d, every permutation on the mesh contains a set of* $\Omega(n\sqrt{d}/\log n)$ *pairs that can be routed in one layer, and the entire permutation can be routed in* $O(nd^{-\frac{1}{2}} \log^2 n)$ *layers.*

This strengthens the bounds of [6, 1] on the number of layers required for routing a permutation. Within the context of VLSI, where the number of layers is typically a fixed small number, the "dual" maximization versions of these theorems may in fact be of greater interest. Namely, these are the first algorithms that can provably extract from any permutation on the mesh a routable set of terminal pairs whose size is within polylogarithmic factors of the bisection bound. Moreover, the approach we develop is fundamentally different from that of Cutler and Shiloach [6], which was essentially the only previous method applicable in this setting. Given the basic importance of the problem, we feel that the introduction of new techniques for constructing node-disjoint paths with improved performance guarantees could be of value in suggesting additional heuristic approaches to these problems.

We mentioned above that questions (2) and ($2'$) are easy in the case of edge-disjoint paths; in fact, one can construct a set of paths meeting the bisection bound using only one bend in each path. On the other hand, the paths in the Cutler–Shiloach construction, as well as our constructions in Theorems 1.1 and 1.2, use many bends. Thus it is natural to ask how many rounds are required with a routing that uses only a constant number of bends. Getting $o(n^2)$ rounds is not immediate, and it appears that no previous construction in the literature achieves it. We address this in the following theorem.

THEOREM 1.3. *Every permutation on the mesh can be routed in* $O(n^{7/5})$ *rounds, with each path in the routing using only six bends.*

1.1. The node-disjoint paths problem. For the sake of concreteness, we give some definitions. Throughout this paper, let $G = (V, E)$ denote the $n \times n$ two-dimensional mesh. Let $\mathcal{T} = \{(s_1, t_1), \ldots, (s_m, t_m)\}$ denote a set of *terminal pairs*, where each $s_i, t_i \in V$. A permutation is a set $\mathcal{T}$ of terminal pairs that partitions the vertex set; a *partial permutation* is a set of terminal pairs in which each node appears at most once. These are the only types of sets $\mathcal{T}$ we will be considering.

We say that a subset $\mathcal{T}'$ of $\mathcal{T}$ is *realizable* in G if all pairs in $\mathcal{T}'$ can be simultaneously connected by node-disjoint paths, and we define $\chi(\mathcal{T})$ to be the minimum size of a partition of $\mathcal{T}$ into realizable sets. This corresponds to the minimum number of rounds of communication—or the minimum number of layers—required, in the sense of ($1'$).

In this language, Theorem 1.1 simply says that for any permutation $\mathcal{T}$, we have $\chi(\mathcal{T}) = O(n \log^2 n)$. For the model of [6, 1], with a $dn \times dn$ mesh and terminals evenly spaced at distance d, we use $\chi_d(\mathcal{T})$ to denote the minimum size of a partition of $\mathcal{T}$ into routable sets. Thus our second result is that $\chi_d(\mathcal{T}) = O(nd^{-\frac{1}{2}} \log^2 n)$ for any permutation $\mathcal{T}$.

In addition to connections with VLSI and network routing, we mention that in the context of edge-disjoint paths the quantity $\chi(\mathcal{T})$ can also be viewed as the minimum number of *wavelengths* required to route $\mathcal{T}$ under an optical routing model in which two paths can share an edge as long as they are assigned different wavelengths. Bounds for $\chi(\mathcal{T})$ for permutations $\mathcal{T}$ on a d-dimensional mesh are a result of Raghavan and Upfal [14], and our work here can be seen to provide node-disjoint analogues of some of these bounds. However, optical routing is not, strictly speaking, a motivation of this work, since we do not know of proposals for architectures based on optical routing in which paths sharing a wavelength must remain node-disjoint.

When the number of terminal pairs is restricted to be a fixed constant, and the graph is planar, a polynomial-time algorithm for (1) and (1′) was first given by Robertson and Seymour in [16]. A more practically efficient algorithm for this case was subsequently given by Schrijver [17], who also gave a polynomial-time algorithm for the case in which all terminals lie on the boundaries of a designated set of faces, and the homotopies of the paths with respect to these faces is fixed. This extends work by Cole and Siegel [4] and Leiserson and Maley [12] for the mesh. This approach based on homotopy appears not to be directly applicable to our problem, for although we could test any fixed choice of homotopies for our paths in polynomial time, there are exponentially many choices of homotopies to try.

Let us also indicate some ways in which the node-disjoint paths problem on the mesh differs fundamentally from its edge-disjoint counterpart. First of all, letting $v_{i,j}$ denote the node at row i and column j of the mesh, consider the set $\mathcal{T}$ of consisting of all pairs of the form $(v_{i,1}, v_{n,i})$, $i = 1, \ldots, n$. This set of terminal pairs satisfies the usual cut condition, stating that there is no way to delete k nodes and separate $k+1$ pairs of terminals, and in fact the set $\mathcal{T}$ is routable in one round on edge-disjoint paths. However, since any two paths in a routing of $\mathcal{T}$ must cross, $\mathcal{T}$ requires n rounds when paths must be node-disjoint.

This example actually does not rely on the terminals being positioned near the boundary of the mesh. Consider an infinite grid graph; let $p = m^2$ for some parameter m and let $\mathcal{T}$ denote the set of all pairs of the form $(v_{im+j,0}, v_{jm+i,p})$, with $1 \leq i, j \leq m$. Then it is not hard to show by a crossing number argument (using a lemma of [11]) that $\chi(\mathcal{T}) = \Theta(\sqrt{p})$, although $\mathcal{T}$ is again routable in a single round using edge-disjoint paths.

As a final example, we show that while Theorem 1.3 implies that six bends are sufficient to route any permutation in $O(n^{7/5})$ rounds, there exist partial permutations that require $\Omega(n^2)$ rounds in any one-bend routing.

PROPOSITION 1.4. *There exists a partial permutation $\mathcal{T}$ on G for which there is no one-bend routing using fewer than $\frac{1}{8}n^2$ rounds.*

Proof. Assume for simplicity that n is even; so $n = 2m$. Let $\mathcal{T}$ consists of all pairs of the form $(v_{i,j}, v_{m+j,m+i})$, where $1 \leq i, j \leq m$. Let

$$X = \{v_{i,j} : 1 \leq i \leq m < j \leq 2m\},$$

$$Y = \{v_{i,j} : 1 \leq j \leq m < i \leq 2m\}.$$

Then in any one-bend routing of $\mathcal{T}$, at least $\frac{1}{8}n^2$ of the paths pass though either X or Y, and every pair of such paths must cross at some node.

1.2. Sketch of the algorithm.

We will show that it is possible, with a constant-factor loss in the bound, to reduce the problem for an arbitrary set of terminals to one in which there are two $k \times k$ subsquares of G, denoted A and B, which are spaced $4k$ apart from one another; also, every terminal pair has one end in A and the other in B. If there are p terminal pairs, we will show how to route $p/(k \log k)$ of them simultaneously; applying this process greedily gives the bound of Theorem 1.1.

The approach of Cutler and Shiloach [6] requires, in order to route q terminals in a single round, that the interterminal spacing be at least q. Using this, one can therefore be sure only of routing a set of size $p^{1/3}$, resulting in an overall bound of $n^{4/3}$ for $\chi(\mathcal{T})$.

We start by considering the following simple notion: Suppose we tried choosing at most one terminal from each row of A and at most one from each row of B, and then join as many of these terminals as possible in the region between A and B. There are a number of difficulties with this; in particular, there may be no way to choose terminals in this way so that nearly p/k can be joined in node-disjoint fashion. Let us call this above approach *row-selection*—one tries to pick a unique terminal from each row so that the selected terminals in A can be routed out of A on their rows and then joined with their selected counterparts in B, in such a way that no paths cross.

Our main technique is the following generalization of row selection: Although there may be no good way to choose unique terminals from the rows of A and B, we show that there exists a "rotation" of A and a "rotation" of B, so that the resulting set of rows allows for such a good selection. Now, meshes are discrete objects, so the notion of rotation has to be defined carefully—we use monotone random walks of varying biases as a basic way of "rotating" A and B.

Having chosen a candidate pair of rotations, we decompose A and B into *pseudorows*. The task of *pseudorow selection*—choosing a unique terminal from each pseudorow—is based on analyzing the bipartite graph H on the set of pseudorows, in which a pseudorow of A is joined to a pseudorow of B if there is some terminal pair with one end in each. We show that one can choose rotations of A and B so that this bipartite graph contains a large *monotone matching*—one in which no edges cross. The pairs corresponding to the edges of this matching can be routed in a single round.

With interterminal spacing of $d > 1$, a very similar approach is applicable. The main difference is that we can now afford to choose edge sets of the bipartite graph H which are not necessarily monotone matchings; we can handle a limited amount of nonmonotonicity using the technique of Cutler–Shiloach within each pseudorow.

2. Preliminaries.

In this section we develop some basic lemmas that will be useful in analyzing our algorithms. In section 3 we consider the basic problem of a permutation on the mesh, and we prove Theorem 1.1. In section 4 we give our algorithm for routing with interterminal spacing in the model of [6, 1]. Finally, in section 5 we discuss algorithms for routing with only a constant number of bends per path.

LEMMA 2.1. *Let $x_1, \ldots, x_d$ be positive integers for which $\sum_i x_i = a$ and $\sum_i x_i^2 = b$. Then $d \geq a^2 b^{-1}$.*

Proof. $a^2 = (\sum_i x_i)^2 \leq d \sum_i x_i^2 = db$. □

The following is easily proved by induction on b.

LEMMA 2.2. *For nonnegative integers a and b, one has*

$$\int_0^1 x^a (1-x)^b \, dx = (a+b+1)^{-1} \binom{a+b}{b}^{-1}.$$

LEMMA 2.3. *Consider the following random experiment: We first choose a bias α for a coin uniformly from the interval $[0, 1]$ and then flip the coin n times. The probability that the number of heads is k is equal to $\frac{1}{n+1}$.*

Proof. The probability is equal to

$$\binom{n}{k} \int_0^1 \alpha^k (1-\alpha)^{n-k} \, d\alpha,$$

which by Lemma 2.2 is equal to $\frac{1}{n+1}$. ∎

There is also a purely combinatorial proof of this, which we leave as an exercise for the reader.

2.1. Monotone matchings. We make use of a notion that we call a monotone matching. Here we define and develop some basic facts about monotone matchings at a general level.

In this section, let H denote a bipartite graph with bipartition (U, V), $U = \{u_1, \ldots, u_n\}$, $V = \{v_1, \ldots, v_n\}$, and let e denote the number of edges of H. As usual, by a *matching* in H we mean a set of edges that have no endpoints in common, and we let $\mu(H)$ denote the size of the largest matching in H.

DEFINITION 2.4. *A matching in H is said to* monotone *if it consists of edges $(u_{i_1}, v_{j_1}), \ldots, (u_{i_k}, v_{j_k})$ such that the sequence $i_1, \ldots, i_k$ is increasing and the sequence $j_1, \ldots, j_k$ is either increasing or decreasing. We say the matching is* increasing *in the former case and* decreasing *in the latter.*

We give two lower bounds on the size of the largest monotone matching in H.

LEMMA 2.5. *H has a monotone matching of size at least $\sqrt{\mu(H)}$.*

Proof. Let M be a matching of maximum size in H, and order its edges so that their endpoints in U have increasing indices. Consider the resulting sequence of indices in V. By a lemma due to Erdös and Szekeres [7], this sequence must have either an increasing sequence or a decreasing sequence of length at least $\sqrt{|M|} = \sqrt{\mu(H)}$. The edges corresponding to this sequence constitute a monotone matching. ∎

LEMMA 2.6. *H has an increasing monotone matching of size at least $e/2n$.*

Proof. Let M_k denote the set of all edges (u_i, v_j) for which $j = i + k \bmod n$. Let M_k' denote the subset of M_k in which $j \geq i$ and M_k'' the subset of M_k in which $j < i$. Now, each M_k' and M_k'' is a monotone matching, and since they are all disjoint one has size at least $e/2n$. ∎

An example by Coppersmith [5] shows that for every $d \leq n$ there exist d-regular bipartite graphs on $2n$ nodes with no monotone matching of size greater than $O(\max(d, \sqrt{n}))$.

Finally, it is also useful to establish "covering" versions of these lemmas. The edges of a bipartite graph of maximum degree Δ can be partitioned into Δ matchings; from the proof of Lemma 2.5, it follows that any matching can be partitioned into $O(\sqrt{n})$ monotone matchings. Thus we have the following lemma.

LEMMA 2.7. *The edges of H can be covered by $O(\Delta\sqrt{n})$ monotone matchings, where Δ is the maximum degree of H.*

The monotone matchings constructed in the proof of Lemma 2.6 cover the edges of H; thus we have the following.

LEMMA 2.8. *The edges of H can be covered by $2n$ increasing monotone matchings.*

3. The bound for $\chi(\mathcal{T})$.

For vertices $x, y \in G$, let $d(x, y)$ denote the shortest-path distance between them. As indicated above, we will first consider the following special case: There are $k \times k$ subsquares A and B of G, with $d(A, B) \geq 4k$, each terminal pair has one end in A and the other in B, and we must use paths that stay

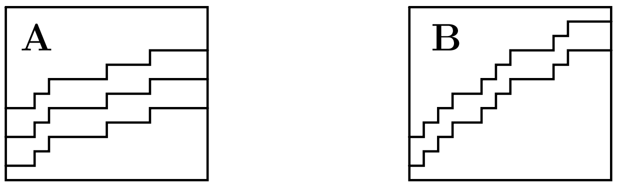

FIG. 3.1. *Decomposing into pseudorows.*

within $d(A,B)$ of $A \cup B$. Below we show how a bound for this special case can be used to prove Theorem 1.1.

We represent A as a union of pseudorows, as follows. Let v_1 denote the lower left vertex of A. We choose $\alpha \in [0,1]$ uniformly at random and perform the following random walk for k time steps starting from v_1:

(i) With probability $1-\alpha$, move one step to the right.

(ii) With probability α, move one step up and then one step to the right.

Let L_1^α denote the path traversed by this walk; note that it is contained in A. For $-k \le i \le k$, define L_i^α to be a copy of this path translated $(i-1)$ steps upward and then intersected with A. The sets L_i^α will be called pseudorows.

See Figure 3.1 for an example of such pseudorows.

For $x \in A$, let $R_x^\alpha = \{i : x \in L_i^\alpha\}$. The following is immediate from the construction but worth noting.

LEMMA 3.1. *If $v \in A$ belongs to both L_i^α and L_j^α, then $|j-i| = 1$. Thus $|R_v^\alpha| \le 2$ (v belongs to at most two of these sets) and, in particular, $E|R_v^\alpha| \le 2$.*

We say that $x, y \in A$ are *collinear* if there is some pseudorow that contains them both; in this case we write $x \sim y$.

For a vertex $x \in G$, let $a(x)$ denote its row number and $b(x)$ denote its column number. For two vertices x and y, let $d_\infty(x,y)$ denote the L_∞ distance between them; that is,

$$d_\infty(x,y) = \max\left(|a(x)-a(y)|, |b(x)-b(y)|\right).$$

LEMMA 3.2. *The probability that $x, y \in A$ are collinear is at most $\frac{2}{d_\infty(x,y)}$.*

Proof. Suppose without loss of generality that $b(x) \le b(y)$. We have

$$\begin{aligned}
Pr(x \sim y) &= \int_0^1 Pr(x \sim y \mid \alpha = t)\, dt \\
&\le \int_0^1 \sum_i Pr(x, y \in L_i^t)\, dt \\
&= \int_0^1 \sum_i Pr(x \in L_i^t) \cdot Pr(y \in L_i^t \mid x \in L_i^t)\, dt \\
&= \int_0^1 Pr(y \in L_i^t \mid x \in L_i^t) \cdot \sum_i Pr(x \in L_i^t)\, dt \\
&= \int_0^1 Pr(y \in L_i^t \mid x \in L_i^t) \cdot E|R_x^t|\, dt \\
&\le 2\int_0^1 Pr(y \in L_i^t \mid x \in L_i^t)\, dt.
\end{aligned}$$

If it is not the case that $b(y) - b(x) \geq a(x) - a(y) \geq 0$, then this last integral is 0. Otherwise, it is simply the probability, over a uniformly distributed bias, that a given number of heads will come up when a coin with that bias is flipped $d_\infty(x, y)$ times. By Lemma 2.3, this is $\frac{1}{1+d_\infty(x,y)}$. The lemma follows. $\square$

LEMMA 3.3. *There is an absolute constant c' so that if there are p terminal pairs with ends in A and B, then there is a realizable subset of size at least $p/(c'k \log k)$.*

Proof. We first choose a random α and decompose A into pseudorows. We do the same for B, using a random β. Now, by Lemma 3.1 we can choose half the pseudorows of A and half the pseudorows of B so that all pseudorows are disjoint and at least $q = p/4$ of the terminal pairs have both ends in these chosen pseudorows. Let $\mathcal{T}'$ denote a set of q such pairs.

Define a *collineation* to be a pair i, j such that s_i and s_j are collinear in A and t_i and t_j are collinear in B. We wish to bound the expected number of collineations among the pairs in $\mathcal{T}'$; this is simply the sum

$$\sum_{i,j} Pr(s_i \sim s_j) \cdot Pr(t_i \sim t_j).$$

By the Cauchy–Schwarz inequality, this dot product will be maximized if $Pr(s_i \sim s_j) = Pr(t_i \sim t_j)$ for all pairs i, j.

Thus the expected number of collineations is bounded by the largest possible sum

$$\sum_{x,y \in S} Pr(x \sim y)^2,$$

where S is a subset of A of size q. We can write this sum as

$$\frac{1}{2} \sum_{x \in S} \sum_{y \in S \setminus \{x\}} Pr(x \sim y)^2 \leq \frac{1}{2} \sum_{x \in S} \sum_{y \in S \setminus \{x\}} \frac{4}{d_\infty(x,y)^2},$$

with the inequality following from Lemma 3.2. This inner sum is maximized by having the vertices y fill in an L_∞ ball centered at x, in which case its value is bounded by

$$\sum_{i=1}^{\frac{1}{2}\sqrt{q}} \frac{32i}{i^2} \leq 32 + 16 \ln q \leq c \ln q$$

for an absolute constant c. Thus, summing over all x, we see that the expected number of collineations in $\mathcal{T}'$ is at most $\frac{1}{2} cq \ln q$.

Thus there exist α, β and decompositions of A and B into pseudorows for which there is a subset $\mathcal{T}'$ of q terminal pairs whose number of collineations is at most $\frac{1}{2} cq \ln q$. For this set $\mathcal{T}'$, let us build the following bipartite multigraph H. There is one vertex u_i on the left for each chosen pseudorow A and one vertex v_j on the right for each chosen pseudorow B. We now put w_{ij} parallel edges from u_i to v_j if there are w_{ij} terminals with one end in the pseudorow u_i and the other end in v_j. From H, we build a simple graph H' which contains an edge (u_i, v_j) iff $w_{ij} > 0$.

We claim that the number of edges of H' is at least $q/(2c \ln q)$. To see this, note that the number of collineations in $\mathcal{T}'$ is precisely

$$\sum_{i,j} \binom{w_{ij}}{2},$$

whence we have $\sum_{i,j} w_{ij}^2 \leq 2cq \ln q$. Since $q = |T'| = \sum_{i,j} w_{ij}$, the claim follows from Lemma 2.1.

Finally, the number of vertices in each half of the bipartition of H' is at most k, so by Lemma 2.6 H' has a monotone matching of size at least

$$\frac{q}{4ck \ln q} \geq \frac{p}{16ck \ln q} \geq \frac{p}{32ck \log k}.$$

We can route one terminal for each edge of the monotone matching, which implies the lemma with $c' = 32c$. Note that we need $d(A, B) = \Omega(k)$ in order to ensure that we correctly align the matched pseudorows of A with the corresponding pseudorows of B. ∎

LEMMA 3.4. *All terminal pairs with ends in A and B can be routed in $O(k \log^2 k)$ rounds.*

Proof. We produce the partition into realizable sets greedily, using Lemma 3.3. The bound follows since the number of remaining terminals goes down by a $(1 - \frac{c'}{k \log k})$ fraction for each realizable set we produce. ∎

Proof of Theorem 1.1. For an integer τ, let $\mathcal{T}_\tau$ denote the set of terminal pairs (s_i, t_i) for which $\frac{1}{2}\tau \leq d(s_i, t_i) \leq \tau$. We prove that $\mathcal{T}_\tau$ can be routed in $O(\tau \log^2 \tau)$ rounds; the overall bound on the number of rounds then follows since, for an absolute constant c'',

$$\begin{aligned} \chi(\mathcal{T}) &\leq \sum_{i=0}^{\lceil \log n \rceil} \chi(\mathcal{T}_{2^i}) \\ &\leq \sum_{i=0}^{\lceil \log n \rceil} c'' 2^i \log^2(2^i) \\ &\leq 4c'' n \log^2 n. \end{aligned}$$

To prove that $\chi(\mathcal{T}_\tau) = O(\tau \log^2 \tau)$, we show that $\mathcal{T}_\tau$ can be partitioned into a constant number of sets, and each of these sets can be partitioned into pairs of well-separated squares; we then invoke the algorithm of Lemma 3.4 on all the pairs in a single set simultaneously.

Choose $\tau' = \frac{1}{16}\tau$ and define S_{ij} to be the $\tau' \times \tau'$ subsquare of G whose upper-left corner lies in row $i\tau'$ and column $j\tau'$. Each pair of squares $(S_{ij}, S_{\ell m})$ defines a subset of $\mathcal{T}_\tau$, consisting of those terminal pairs with one end in S_{ij} and the other in $S_{\ell m}$. We call such a pair *active* if it contains a terminal pair in $\mathcal{T}_\tau$. By definition, any active pair $(S_{ij}, S_{\ell m})$ satisfies

$$6 \leq |\ell - i| + |m - j| \leq 16.$$

Thus, by Lemma 3.4, we can route all the terminal pairs in the set defined by any active pair in $O(\tau \log^2 \tau)$ rounds.

We say that active pairs $(S_{ij}, S_{\ell m})$ and $(S_{i'j'}, S_{\ell' m'})$ *interfere* with one another if there is some vertex within distance τ of both $S_{ij} \cup S_{\ell m}$ and $S_{i'j'} \cup S_{\ell' m'}$. Let us build a graph $\mathcal{K}$ on the set of active pairs, joining two by an edge if they interfere with one another. This graph has constant degree and hence can be colored with a constant number of colors. But we can use the same set of rounds for routing *all* the active pairs in a single color class, and thus $\chi(\mathcal{T}_\tau) = O(\tau \log^2 \tau)$.

The proof of the other statement of Theorem 1.1, that every permutation contains a routable set of size $\Omega(n/\log n)$, is strictly analogous. We first argue, using the interference graph $\mathcal{K}$ and Lemma 3.3 instead of Lemma 3.4, that $\mathcal{T}_\tau$ contains a routable set of size $\Omega(|\mathcal{T}_\tau|/\tau \log \tau)$. The bound now follows since for some $\tau \in \{2^i : 0 \le i \le \lceil \log n \rceil\}$ we have $|\mathcal{T}_\tau| = \Omega(n\tau)$. □

4. Terminals with spacing. The proof of Theorem 1.2 is essentially that of Theorem 1.1, with one additional step. As before, we can specialize to the case of two $kd \times kd$ squares A and B that contain p terminal pairs. To construct pseudorows, we first partition A and B into disjoint $d \times d$ subsquares, contract these subsquares, and then use the previous construction.

LEMMA 4.1. *There is an absolute constant c' so that if there are p terminals with ends in A and B, then there is a realizable subset of size at least $p\sqrt{d}/(c'k \log k)$.*

Proof. We follow the proof of Lemma 3.3 up through the construction of the bipartite graph H' with at most k vertices in each half of its bipartition, and with at least $q/(c \ln q)$ edges. Now define a *slice* in H' to be a set of the form $U' \cup V'$, where U' is a set of $\sqrt{d}$ consecutive vertices on the left side of H' and V' is a set of $\sqrt{d}$ consecutive vertices on the right side. The crucial point is that there are only d edges of H' with both ends in a given slice, and so using the technique of [1, 6], we can route one terminal pair for each of these edges in a single round.

We now construct a graph H'' by identifying blocks of $\sqrt{d}$ consecutive vertices of H' on the left and on the right. (We can essentially think of edges of H'' as corresponding to particular slices of H'.) Let us give each edge (u^*, v^*) in H'' a weight equal to the number of edges of H' that have ends in the supernodes u^* and v^*; thus these weights are integers between 0 and d. By the weighted analogue of Lemma 2.6, H'' has a monotone matching of weight at least

$$\frac{\text{weight}(H'')}{2|V(H'')|} = \frac{|E(H')|}{2|V(H'')|} \ge \frac{q\sqrt{d}\log k}{4ck \ln q} \ge \frac{p\sqrt{d}}{32ck \log k}.$$

We can route a number of terminals equal to the weight of any monotone matching in H'', as argued above; this implies the lemma. □

Proof of Theorem 1.2. Again reducing to the case of $kd \times kd$ squares A and B, we use a greedy approach based on Lemma 4.1. Each time, we reduce the number of remaining terminals by a factor of at least $(1 - \frac{c'\sqrt{d}}{k \log k})$; thus we route all terminal pairs in $O(kd^{-\frac{1}{2}} \log^2 k)$ rounds. □

5. Constant-bend routing. As in the previous sections, let us first consider the case in which all terminal pairs have ends in $k \times k$ squares A and B, with $d(A, B) \ge 4k$. Here, we additionally assume that A and B are each at a distance of at least $\Omega(k^{7/10})$ from the boundary of the mesh. Let us suppose that the lowest column number of a node in A is less than or equal to the lowest column number of a node in B.

The main difficulty we encounter here is this: Since we wish to use only a constant number of bends, the approach based on pseudorows appears to be inherently inapplicable, as it involves partitioning A and B into paths with many bends. Thus, in this case, we build a graph H with a vertex u_i for each row of A, and a vertex v_j for each row of B. We give the edge (u_i, v_j) a weight w_{ij} equal to the number of terminal pairs with one end in each row.

To give a sense of the algorithm, we first mention a very easy algorithm for routing in $O(k^{3/2})$ rounds. This is as follows. First replace each edge (u_i, v_j) of H with w_{ij} parallel edges. Now by Lemma 2.7 the edges of H can be covered by $O(k^{3/2})$ monotone matchings. Moreover, we may assume that each matching in the cover contains at most $O(k^{1/2})$ edges. We claim that all the terminal pairs corresponding to a single one

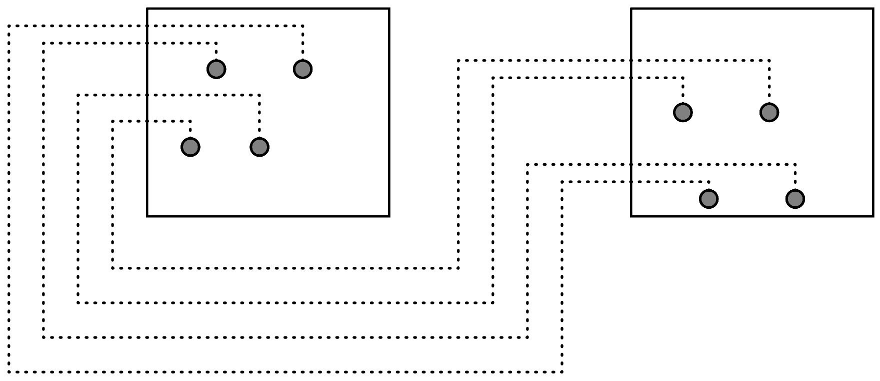

Fig. 5.1. *Routing with a constant number of bends.*

of these matchings can be routed in a single round. If the matching is increasing, then the pairs can be routed by having each terminal leave A along its row through the east wall, and enter B along the matching row through the west wall; if the matching is decreasing, then the pairs can be routed by having each terminal leave A along its row through the west wall and enter B along the matching row through the west wall. (See Figure 5.1 for a version of the latter case.) Moreover, since A and B are at least $\Omega(k^{1/2})$ distance from the boundary of the mesh, there is room for all the paths corresponding to a single matching to be routed in the region outside $A \cup B$.

To get a bound of $O(k^{7/5})$, we need a slight strengthening of this technique. We divide the edges into $\log k$ classes, by assigning each edge to the smallest power of 2 greater than its weight. Let H_w denote the subgraph of H consisting only of edges that are assigned the weight w, and let $\mathcal{T}_w$ denote the set of terminals corresponding to edges of H_w.

Lemma 5.1. *$\mathcal{T}_w$ can be routed in at most $2kw$ rounds, using at most four bends.*

Proof. Using Lemma 2.8, we can partition the edges of H_w into $2k$ (increasing) monotone matchings. Each edge of H_w corresponds to at most w terminals, so all terminals can be routed in $2kw$ rounds. It is easy to construct paths for these terminals using at most four bends. □

Lemma 5.2. *$\mathcal{T}_w$ can be routed in at most*

$$\max[O(k^{3/2}/w^{1/4}), O(k^{13/10})]$$

rounds, using at most six bends.

Proof. Since each edge of H_w corresponds to at least $w/2$ terminals, the maximum degree of a vertex in H_w is at most $2k/w$; thus we can partition the edges of H_w into $2k/w$ matchings. Let us say that a matching M is *well spaced* if for edges (u_i, v_j) and (u_k, v_ℓ) of M the difference between i and k is at least $\sqrt{w}$ and the distance between j and ℓ is at least $\sqrt{w}$. By an easy coloring argument, we can partition any matching in H_w into $O(\sqrt{w})$ well-spaced matchings, and thus we can partition the edges of H_w into $O(k/\sqrt{w})$ well-spaced matchings. Finally, each of these well-spaced matchings is only on $O(k/\sqrt{w})$ vertices, so by Lemma 2.7 we can partition each one into $O(\sqrt{k}/w^{1/4})$ monotone matchings.

Thus we now have a total of $O(k^{3/2}/w^{3/4})$ monotone matchings covering the edges of H_w, and each has the property that the endpoints of its edges are mutually at distance $\sqrt{w}$. We use a different set of rounds for routing each monotone matching.

Now, how many rounds are needed for a single monotone matching M? (Recall that each edge of M represents up to w terminals.) Let A_i (resp., B_i) denote the set of vertices in the ith row of A (resp., B). Since the edges of M are anchored in rows of A and B that are mutually $\sqrt{w}$ apart, we can assign to each edge $e = (u_i, v_j)$ a "band" of rows of width $\Omega(\sqrt{w})$ around row A_i and a similar band around row B_j. The pairs corresponding to an edge e are themselves a matching on the vertex set $A_i \cup B_j$. Thus these pairs can be partitioned, again by Lemma 2.7, into $O(\sqrt{w})$ monotone matchings, and each of *these* monotone matchings can be routed in a single round in the bands surrounding rows A_i and B_j.

Finally, we can do this simultaneously (i.e., using the same set of rounds) for all edges of a single well-spaced monotone matching, provided there is sufficient room between the squares A and B and the boundary of the mesh for routing all the paths. If there is sufficient room, then the number of rounds used is $O(k^{3/2}/w^{1/4})$. Otherwise, we must break up the rounds that use too many paths into subrounds that route only $O(k^{7/10})$ terminals at a time; the resulting bound is $O(k^{13/10})$ rounds. ∎

LEMMA 5.3. *The set of terminals with ends in A and B can be routed in $O(k^{7/5})$ rounds, using at most six bends.*

Proof. Let $r(\mathcal{T})$ denote the total number of rounds required for routing $\mathcal{T}$ with six bends. Then

$$\begin{aligned} r(\mathcal{T}) &\leq \sum_{w=2^i} r(\mathcal{T}_w) \\ &\leq \sum_{w=2^i \leq k^{2/5}} r(\mathcal{T}_w) + \sum_{k^{2/5} \leq w=2^i \leq k^{4/5}} r(\mathcal{T}_w) + \sum_{w=2^i \geq k^{4/5}} r(\mathcal{T}_w) \\ &\leq O(k) \sum_{w=2^i \leq k^{2/5}} w + O(k^{3/2}) \sum_{k^{2/5} \leq w=2^i \leq k^{4/5}} w^{-1/4} + O(k^{13/10}) \sum_{w=2^i \geq k^{4/5}} 1. \end{aligned}$$

Since all three of the terms in this last sum are easily seen to be $O(k^{7/5})$, the bound follows. ∎

Proof of Theorem 1.3. We use the notion of an interference graph $\mathcal{K}$ on pairs of subsquares as in the proof of Theorem 1.1. The only change is that we can now work only with $k \times k$ squares that have either no row or no column within $O(k^{7/10})$ of the boundary. (It is enough to have this guarantee for either rows *or* columns, since we just as well could have built our graph H on the set of columns of one of the squares.) To handle this, we define G' to be the subgraph of G induced by all nodes within distance $O(n^{2/5})$ of the boundary, or within distance $O(n^{7/10})$ of a corner of the mesh. Since $|G'| = O(n^{7/5})$, we can use a different round for each terminal pair with an end in G'; we then run the algorithm above (using the interference graph $\mathcal{K}$) in $G \setminus G'$. ∎

6. Conclusion.

There are a number of natural questions suggested by this work. First, the algorithm of Theorem 1.2 routes a permutation with spacing d in $O(nd^{-1/2} \log^2 n)$ rounds and thereby gives an upper-bound trade-off between inter-terminal spacing and the number of rounds required. However, we do not know how close to optimal this trade-off is for all values of d. At the extreme ends of the range $0 \leq d \leq n^2$, the number of rounds used by our algorithm is tight to within polylogarithmic factors—this follows from the bisection bound when $d = \Theta(1)$ and from [1] when $d = \Theta(n^2)$. While it is possible that the trade-off is tight to within polylogarithmic factors for all values of d, we are not able to prove this.

For constant-bend routing, we do not know whether there is an absolute constant b such that every permutation on the mesh can be routed in $O(n \log^{O(1)} n)$ rounds using at most b bends per path. It would also be interesting to understand the quantitative trade-off between the number of bends and the number of rounds needed.

In a somewhat different direction, the algorithm of Theorem 1.1 gives a routing for a set $\mathcal{T}$ of terminal pairs for which the number of rounds used is close to the best possible in the worst case. However, it is not an *approximation algorithm*, since we do not have a result relating the number of rounds we require for a given set $\mathcal{T}$ to the optimal value $\chi(\mathcal{T})$. It would be very interesting to obtain such an algorithm, since it would appear to require new techniques for analyzing $\chi(\mathcal{T})$ in cases when the cut condition gives no information.

Finally, it would be interesting to decide whether $\chi(\mathcal{T}) = O(n)$ for every permutation on the mesh.

Acknowledgments. We would like to thank Don Coppersmith, Tom Leighton, Baruch Schieber, and Madhu Sudan for valuable discussions on these problems.

QUALITY MESH GENERATION IN HIGHER DIMENSIONS*

SCOTT A. MITCHELL† AND STEPHEN A. VAVASIS‡

Abstract. We consider the problem of triangulating a d-dimensional region. Our mesh generation algorithm, called QMG, is a quadtree-based algorithm that can triangulate any polyhedral region including nonconvex regions with holes. Furthermore, our algorithm guarantees a bounded aspect ratio triangulation provided that the input domain itself has no sharp angles. Finally, our algorithm is guaranteed never to overrefine the domain, in the sense that the number of simplices produced by QMG is bounded above by a factor times the number produced by any competing algorithm, where the factor depends on the aspect ratio bound satisfied by the competing algorithm. The QMG algorithm has been implemented in C++ and is used as a mesh generator for the finite element method.

1. Introduction.

The *finite element method* refers to a family of numerical methods for solving boundary value problems and is used extensively in electromagnetics, thermodynamics, structural analysis, acoustics, chemistry, and astronomy. A crucial preprocessing step is mesh generation. A *mesh generator* is an algorithm for subdividing a finite subset of $\mathbf{R}^2$ or $\mathbf{R}^3$ into small convex cells, typically triangles or quadrilaterals in two dimensions and tetrahedra or hexahedra (brick shapes) in three dimensions.

We propose a mesh generation algorithm called QMG for nonconvex polyhedral regions in any dimension. QMG takes as input a representation of a polyhedral region in $\mathbf{R}^d$ and produces as output a simplicial complex that is a subdivision of the input region. QMG uses a quadtree technique: the domain is covered with a large d-dimensional cube, and then cubes are recursively split into 2^d subcubes until each subcube is triangulated.

For good accuracy bounds in the finite element method, it is necessary that the tetrahedra have bounded *aspect ratio.* The aspect ratio of a simplex is defined as its maximum side length divided by its minimum altitude. For an analysis of the accuracy of the finite element method, see Johnson [9].

The mesh produced by QMG is guaranteed to have good aspect ratio. Let ρ_{QMG} be the worst aspect ratio among all simplices in the QMG triangulation of a particular input polyhedron P. Let ρ_S be the worst aspect ratio among all simplices in any other

triangulation $\mathcal{S}$ of P, where $\mathcal{S}$ is produced by some other competing algorithm. Then Theorem 15.2 says that $\rho_{\mathrm{QMG}} \leq c\rho_{\mathcal{S}}$, where c is a universal constant, in the case $d = 2$ or $d = 3$. The technique used to prove this theorem is as follows. First, a lower bound is proved stating that any triangulation $\mathcal{S}$ of P must have at least one simplex with aspect ratio at least as large as $c/\theta(P)$, where $\theta(P)$ denotes the sharpest angle of P and c is some other constant. Then we prove that QMG's aspect ratio is bounded above by $c/\theta(P)$. In the case $d > 3$, a weaker version of this result is proved.

Our second main theorem is that the number of simplices generated by QMG is the smallest possible; that is, the mesh is as coarse as possible, in the following sense. Let n_{QMG} be the number of simplices produced by QMG when applied to a particular polyhedral domain P, and let $n_{\mathcal{S}}$ be the number of simplices in some other triangulation $\mathcal{S}$ of P. Then $n_{\mathrm{QMG}} \leq f(d, \rho_{\mathcal{S}}) \cdot n_{\mathcal{S}}$, where f is some function of d, the dimension, and of $\rho_{\mathcal{S}}$, the aspect ratio bound satisfied by the competing triangulation. In other words, n_{QMG} is much larger than $n_{\mathcal{S}}$ only in the case when $\mathcal{S}$ has simplices with poor aspect ratio. The precise values of the constants present in these two main results are not worked out explicitly in this article but are expected to be quite large.

The importance of bounding the number of tetrahedra is as follows. The running time of the finite element method is a function of the number of nodes and elements in the triangulation. In particular, if n is the number of nodes (or elements—for bounded aspect ratio triangulations, the number of nodes and elements are within a constant factor of each other), then the running time of the finite element method is $O(n^{\alpha})$, where α is at least 1 and depends on the method used for solving the sparse linear equations. Thus, there is a significant penalty for meshes with too many elements. On the other hand, small elements are necessary for high accuracy with the finite element method. Practitioners usually address this tradeoff by using meshes with varying degrees of refinement: such a mesh has small elements in the part of the domain of interest where high accuracy is desired, and larger elements are used elsewhere. Because QMG generates the coarsest mesh possible (up to the multiplicative factor $f(d, \rho_{\mathcal{S}})$), it can be used as the starting point for further refinement. Indeed, the implementation of QMG allows a user-specified refinement function to control the degree of refinement.

Our work is closely related to earlier work by Bern, Eppstein, and Gilbert [4], who solved the corresponding problem for two-dimensional (2D) polygonal domains. These authors also used a quadtree approach, but the extension of their technique to higher dimensions is far from straightforward. Our QMG algorithm differs in many ways from that earlier paper.

Other work on triangulation problems with optimality guarantees is the result of Baker, Grosse, and Rafferty [1], whose algorithm triangulates 2D polygons with nonobtuse angles and Chew's [7] triangulation of 2D polygons with guaranteed aspect ratio using a Delaunay approach. Chew's work was extended by Ruppert [14] to handle varying degrees of refinement (and thus establishing the Bern et al. optimality properties), and later by Chew also [8] to curved surfaces.

In three dimensions, no work previous to ours guaranteed bounded aspect ratio triangulations, although Chazelle and Palios [6] developed an algorithm with the best possible bound (up to a constant factor) on the cardinality of the triangulation in terms of reflex angles.

Our triangulation uses *Steiner points*, meaning that it introduces new vertices into the domain not present in the original input. Indeed, as shown by Schönhardt [15], Steiner points are necessary for triangulating nonconvex polyhedra in three dimensions and higher. For additional background on optimal triangulation, we refer the reader to the excellent surveys of Bern and Eppstein [3] and Bern and Plassmann [5]. Note that, because of the importance of mesh generation, there is a vast body of literature on mesh generation algorithms. We do not attempt to survey this literature here because the majority of these papers are not concerned with mathematical quality guarantees.

The remainder of this article is organized as follows. In section 2 we describe the class of allowable input domains for QMG. In sections 3 and 4 we present a high-level description of the QMG algorithm. In sections 5–7 we provide more details about the algorithm. In sections 8 and 9 we formally define aspect ratio and sharp angles and establish some results about them. In sections 10–17 we provide the analysis of QMG, including the proofs of the two main optimality properties mentioned above. In section 18, we consider the asymptotic running time of QMG, and in section 19 we briefly describe the implementation.

This article has a companion paper [12] that describes how to triangulate a grid of uniform boxes cut by a k-affine space. The method in that paper is used as a subroutine here, and we need some of the results of the analysis in that other paper for the analysis in section 10.

Besides the QMG algorithm and its analysis, the other main contribution of this paper is a series of new bounds that apply to any possible triangulation of a polyhedral domain (see section 9) and other results that apply to any possible bounded aspect ratio triangulation of a polyhedral domain (see section 16). The results in these sections act as lower bounds for proving QMG's optimality, but they would be useful for the analysis of other triangulation algorithms.

This article, along with the companion [12], supersedes our earlier work [13]. We briefly summarize the difference between this article and the earlier work. First, this work applies to d-dimensional regions for any d, whereas the earlier work was limited to three dimensions. A consequence of this generalization is that we have discarded the case-based proofs used in [13] in favor of more uniform treatment here. The notion of enforcing a "balance" condition in the quadtree has been dropped. Further, the idea of "warping" has been replaced by the approach in the companion paper, together with the "alignment" procedure described here.

2. Nonconvex polyhedra.

Recall that the input to our algorithm is a nonconvex polyhedron P in R^d. Mathematically, a nonconvex polyhedron is the set resulting from a finite number of union and intersection operations applied to halfspaces. We assume P is compact. We assume that P is presented via a *boundary representation*; in fact, from now on, we refer to polyhedra as "b-reps." The b-rep of P consists of a lattice of faces: zero-dimensional faces are called vertices, one-dimensional (1D) faces are called edges, and the d-dimensional face is P itself. Each face of dimension 1 or higher has boundaries that are faces of one lower dimension. Thus, a b-rep is stored as a layered directed acyclic graph with one node for each face, and with arcs to indicate the "is-a-boundary-of" relation. Nodes at level 0 (vertices) have coordinates stored with them.

Finally, to simplify our presentation, we assume that P is a d-manifold with boundary, although the implementation of QMG allows many nonmanifold features, such as internal boundaries.

3. Boxes.

The main data structure of QMG is a box. A *box* is a d-dimensional cube embedded in an axis-parallel manner in $\mathbf{R}^d$. Our algorithm is a *quadtree*-based algorithm, meaning that it starts with a single d-cube and then subdivides it into 2^d equal-size smaller cubes. The subdivision continues recursively.

Boxes of dimension less than d occur as separate data items. These lower-dimensional boxes are discussed in more detail in section 7. We ignore the existence of these lower-dimensional boxes until section 7 to allow a simplified presentation of QMG's quadtree generation in the next three sections.

Initially, there is one large d-dimensional box, called the *top box*, which contains all of P and also a neighborhood around P. This box is considered *active*. Other boxes are generated from the top box by applying one of three operations recursively. First, an active box may be *split*, meaning that it is replaced by 2^d smaller boxes each of equal size, as mentioned above. Second, a box may be *duplicated*, meaning that it is replaced by two or more boxes with the same size and position as the original box. Third, an active box may be *protected*, in which case it is no longer active and no longer available for splitting or duplicating. The collection of boxes is called a *quadtree*.

The data items stored with a box are as follows. QMG stores its position and size. Because of the dyadic nature of the quadtree, the position and size are both represented exactly (as integers). As mentioned in the last paragraph, boxes are either *active* or *protected*. An active box B has stored with it its *content*, which is denoted $\mathrm{co}(B)$. The definition of content is as follows. Let $\mathrm{ex}(B)$ denote a cube in $\mathbf{R}^d$ that is concentric with B but has a diameter larger by a constant factor $1+\gamma$, where γ is defined below. Note that $P \cap \mathrm{ex}(B)$ is a polyhedral region. If $P \cap \mathrm{ex}(B)$ is connected (in the topological sense), then we define $\mathrm{co}(B) = P \cap \mathrm{ex}(B)$. If $P \cap \mathrm{ex}(B)$ is not connected, then QMG makes duplicates of B, one for each component of $P \cap \mathrm{ex}(B)$, and assigns one component to each duplicate. Thus, $\mathrm{co}(B)$ is always a connected polyhedral region. More details are given in section 5.

A protected box is always associated with a particular face F of P, and F must meet $\mathrm{ex}(B)$. Thus, a protected box has stored with it a reference to F and also a close point. The *close point* is a point in $\mathbf{R}^d$ lying in $F \cap \mathrm{ex}(B)$. The coordinates of the close points are stored in an auxiliary table, and the protected box stores an index into this table. (This is because several protected boxes can share the same close point.) The collection of close points makes up the vertices of the final triangulation.

4. High-level description of the quadtree generation.

The mesh generation algorithm has two parts: quadtree generation and triangulation. See Figures 4.1–4.2 for the high-level outline of quadtree generation. Triangulation is described in section 7. Not all the terms in these figures have been defined yet.

Quadtree generation is divided into $d+1$ *phases* numbered $0, \ldots, d$. We use k throughout the article to denote the current phase. Phase k works primarily with the k-dimensional faces of P. (Thus, in phase d we look at P itself.) Each phase is subdivided into two *stages*, the separation stage and the alignment stage. During the separation stage, active boxes are split. There is also splitting of active boxes during the alignment stage. The alignment stage also turns some active boxes into protected boxes.

5. Separation stage.

In this section we describe the separation stage of phase k in more detail. At the start of the phase there is a list of active boxes I_k and the (initially empty) idle list I_{k+1}. During the phase we repeatedly remove one active box, say, B, from I_k and test it for crowdedness (defined below). If B is crowded, it is split. Let us use the term *children* to denote the boxes on the next deeper level resulting from the split. All the children with a nonempty content are inserted back

```
/* **Quadtree generation** */.
Initialize $I_0 := \{\text{top\_box}\}$.
Initialize $J := \{\}$.
for $k := 0, \ldots, d$ do
    Initialize $I_{k+1} := \{\}$.
    Initialize $O_F := \{\}$ for each $k$-dimensional $P$-face $F$.
    /* **Phase $k$ separation stage.** */
    while $I_k$ is nonempty do
        Remove an active box $B$ from $I_k$.
        if $B$ is crowded or too big for the size function then
            Split $B$ into $B_1, \ldots, B_{2^d}$; duplicate as necessary.
            Delete $B_i$'s with empty content.
            Put remaining $B_i$'s into $I_k$.
        elseif co($B$) contains a (necessarily unique) $k$-face $F$ of $P$ then
            $O_F := O_F \cup \{B\}$.
        else
            $I_{k+1} := I_{k+1} \cup \{B\}$.
        end if
    end while
```

FIG. 4.1. *High-level description of QMG's quadtree generation (continued in Figure* 4.2*).*

into I_k. Box B itself is deleted, and the children with empty content are deleted. On the other hand, if B is not crowded, we check whether it has a P-face of dimension k, say, F, in its content. If so, the box is transferred to orbit O_F. If not, the box is transferred to the idle list. In this manner I_k is eventually emptied.

We now explain the terms "content" and "crowdedness." First, we define ex(B) for an active box B to be a d-dimensional cube in $\mathbf{R}^d$ concentric with B but expanded in each dimension by a multiplicative factor $1+\gamma$. Parameter γ must satisfy $\gamma \geq \epsilon_{0,F}$ for each P-face F, where $\epsilon_{0,F}$ is the tolerance for alignment described in section 6. For instance, $\gamma = 0.5$ is acceptable.

The *content* of an active box B, denoted co(B), is a b-rep and is typically $P \cap$ ex(B). However, if $P \cap \text{ex}(B)$ has more than one connected component, we identify the components of $P \cap \text{ex}(B)$, say, $C_1, \ldots, C_p$, and we replace B with p copies of itself, say, $B_1, \ldots, B_p$. Then we define $\text{co}(B_i) = C_i$ for $i = 1, \ldots, p$.

Say B is split, and say B' is one of the child boxes. We compute co(B') by intersecting co(B) with ex(B'). (Notice that our definition of ex(B) guarantees that ex(B') is a proper subset of ex(B).) In particular, we do not compute co(B') by intersecting the original b-rep P with ex(B'). This is because this latter approach could reintroduce connected components that were duplicated into a box different from B at some earlier level of splitting.

We say that a box B is *crowded* if either

- co(B) meets any P-face of dimension $k-1$ or less, or
- co(B) meets a P-face F of dimension k, and co(B) meets another P-face G that is not a superface of F.

Thus, a box B is not crowded during phase k if either co(B) does not meet any P-faces of dimension k or lower, or co(B) meets exactly one P-face F of dimension k, no P-faces of dimension less than k, and every P-face of dimension higher than k

```
        /* **Phase $k$ alignment stage.** */
        for each $k$-dimensional $P$-face $F$ do
            while $O_F$ is nonempty do
                Remove the highest-precedence box $B$ from $O_F$.
                Find the highest-priority subface $B'$ of $B$ that is close to $F$.
                if $B$ has no such close subface then
                    $I_{k+1} := I_{k+1} \cup \{B\}$.
                elseif the alignment condition is satisfied for $B$ then
                    Protect $B$; its associated $P$-face is $F$.
                    Find the close point on $F$ for $B$ (near $B'$).
                    $J := J \cup \{B\}$.
                else
                    Split $B$ into $B_1, \ldots, B_{2^d}$; duplicate as necessary.
                    Delete the $B_i$'s with no content.
                    Put remaining $B_i$'s into $O_F$.
                end if
            end while
        end for
    end for /* **end of $k$ loop** */
```

FIG. 4.2. *High-level description of QMG's quadtree generation (continued from Figure* 4.1*).*

in co(B) is a superface of F. A box that is not crowded is transferred either to I_{k+1} in the first case (i.e., when co(B) does not meet any P-faces of dimension k or lower) or to O_F in the second case. Some examples of crowdedness are given in Figure 5.1.

Another rule used in the separation stage is that we split boxes if their side length is greater than the user-specified mesh refinement function that was mentioned in the introduction. We do not say any more about this here, since the analysis in subsequent sections does not involve a user-specified mesh refinement function.

The reader may notice that there appears to be a potential infinite loop: if an active box B in phase k has a P-face of dimension $k-1$ or less in its interior, this will cause an infinite recursion of splitting because there will always be a crowded subbox. Fortunately, this situation can never occur. The reason is that a box whose interior meets a P-face of dimension $k-1$ or less would have had a close subface identified in an earlier phase and would have become protected or would have been crowded in an earlier phase. (See the next section for a description of close subfaces.) Therefore, it could never end up in I_k. It is possible, however, for a box in I_k to have a face of dimension $k-1$ or less inside ex(B) but outside B. This can happen because, in the previous phase, a $(k-1)$-face F could lie in the content of B and yet not be close enough to come close to a subface of B. In this case the box will be split until the d-cubes ex(B) have shrunk enough that they do not meet the low-dimensional P-face. The number of times that a box can be split is analyzed in subsequent sections.

The computation of co(B) (that is, computing the geometric intersection co(B')$\cap$ ex(B), where B' is the parent of B, and then checking whether this intersection is connected) is among the most computationally intensive tasks of QMG. We carry out the search for connected components with a ray-shooting algorithm that we do not describe here. The worst-case running time of this ray-shooting algorithm is $O(n^2)$, where n is the total combinatorial complexity of co(B) (i.e., the total number of

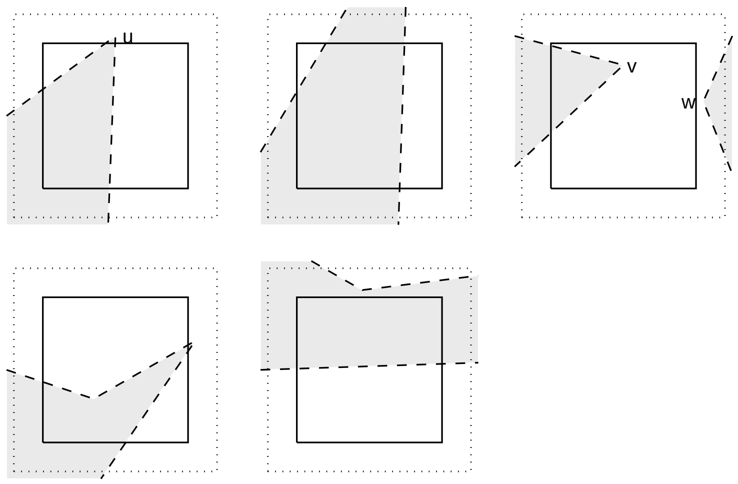

Fig. 5.1. *Examples of crowdedness: solid lines indicate boxes, dotted lines indicate* ex(B) *for these boxes, dashed lines indicate the boundary of P, and shading represents the interior of P. Suppose we are in the separation stage of the phase 0 in the case $d = 2$. All boxes in the top row are uncrowded. The first box would be placed into $O_{\boldsymbol{u}}$. The second box would be placed into I_1. The third box in the top row must be duplicated, and then one duplicate would go into $O_{\boldsymbol{v}}$ and the other into $O_{\boldsymbol{w}}$. Both boxes in the bottom row are crowded and must be split.*

boundary faces), but in practice the running time will usually be closer to $O(n)$.

In the case $d = 2$, it is possible to find connected components of co(B) via a plane sweep in $O(n \log n)$ operations. In the case $d = 3$, an $O(n \log n)$ plane sweep can also be used provided that P is preprocessed with $O(N^2)$ preprocessing steps, where N is the combinatorial complexity of the input polyhedron P. This efficient algorithm for $d = 3$ is described in our earlier paper [13]. We have not implemented a plane-sweep procedure for either $d = 2$ or $d = 3$.

6. Alignment.

In this section we describe the alignment stage. Recall that the alignment stage processes each orbit independently. For this section, assume we are in phase k and are processing orbit O_F of P-face F whose dimension is k.

First, a sequence of parameters

$$0 = \epsilon_{d,F} = \epsilon_{d-1,F} = \cdots = \epsilon_{d-k,F} < \epsilon_{d-k-1,F} < \epsilon_{d-k-2,F} < \cdots < \epsilon_{0,F} < 0.5$$

is chosen for F. The method for choosing positive scalars $\epsilon_{d-k-1,F}, \epsilon_{d-k-2,F}, \ldots, \epsilon_{0,F}$ is described in [12], which must be slightly modified to take into account the containment relationship between P-faces of different dimensions. These parameters have positive upper and lower bounds depending only on d and k.

We now process boxes in O_F in the order described below. Let B be the high-precedence box in the orbit. Let B' be any subface of B. We construct the ∞-norm neighborhood of radius $\epsilon_{r,F}$ around B', denoted $N(B')$, where r stands for the dimension of B'. Thus, this neighborhood is an axis-parallel parallelepiped (which could be degenerate if $\epsilon_{r,F} = 0$). If F meets $N(B')$, then F is said to be *close* to B'. The *close subface* of B is the box subface of lowest dimension that is close to F. If there is a tie (i.e., there are several faces of the same lowest dimension all close to F), then we break the tie with a priority rule, which is described below. A box with no close subface is transferred to I_{k+1}.

Because $\gamma \geq \epsilon_{0,F}$, if F is close to B (i.e., if B has a close subface), then F must meet $\mathrm{ex}(B)$. Thus, we can check whether B has a subface close to F by examining $\mathrm{co}(B)$. Indeed, it is important that we query $\mathrm{co}(B)$ rather than the original P, because it might be difficult to determine from queries on P whether the P-face in question is associated with B or with a duplicate of B.

Next we claim a partial converse: if F meets $\overline{\mathrm{ex}}(B)$, then B has a subface close to F. We define $\overline{\mathrm{ex}}(B)$ to be a cube concentric with B and expanded by $\epsilon_{d-k-1,F}$ in each dimension. Because $0 < \epsilon_{d-k-1,F} < \gamma$, it follows that $B \subset \overline{\mathrm{ex}}(B) \subset \mathrm{ex}(B)$. Furthermore, it follows from Lemmas 1 and 2 of [12] that if any P-face F meets $\overline{\mathrm{ex}}(B)$, then B has a subface close to F. The cube $\overline{\mathrm{ex}}(B)$ is not used in our algorithm, but it plays a role in the analysis below.

Once every box in the orbit has chosen its close subface, we now test the *alignment condition*. The alignment condition is as follows. Define the *extended orbit* of F to be O_F united with protected boxes from earlier phases that are associated with proper subfaces of F. For every active box B in the orbit, the close subface of B must be completely covered by boxes in the extended orbit (either active or protected) that are the same size or larger. For an example of the alignment condition, see Figure 6.1. We provide motivation for the alignment condition in section 7.

Let us now comment further on the alignment condition. First, we have to explain what is meant by "completely covered." We say that a box subface B' is *completely covered* by some collection of boxes $\{B_1, \ldots, B_n\}$ provided that for any point $\boldsymbol{p}$ in the relative interior of B', there exists an open neighborhood N of $\boldsymbol{p}$ such that $N \subset B_1 \cup \cdots \cup B_n$. (Note that if B' is a 0-dimensional box subface, i.e., a vertex, then its relative interior is B' itself.)

With these definitions of "extended orbit" and "completely covered," we can now state the priority rule for choosing a close subface. Recall that the close subface of B is the box subface of lowest dimension close to F. Let l be the dimension of this subface. If there is a tie (i.e., there is more than one face of B of the dimension l close to F), then we favor the subfaces that are completely covered by boxes the same size or larger in the extended orbit (i.e., those close subfaces of dimension l for which the alignment condition holds). If there is still a tie, we use a lexicographic tie-breaking rule.

Recall that boxes can get duplicated during the separation stage, and thus several active boxes can cover the same geometric region in $\mathbf{R}^d$. We claim that two boxes with overlapping geometric regions in $\mathbf{R}^d$ cannot end up in the same orbit. (This fact simplifies the sorting necessary to check the alignment condition.) The reason is as follows. Suppose B and B' are two boxes whose interiors have a common point in $\mathbf{R}^d$, and suppose both $\mathrm{co}(B)$ and $\mathrm{co}(B')$ contain a point of P-face F. By the tree-nature of the quadtree, two boxes that share a common interior point must have the property that one is contained in the other.

We claim that $\mathrm{co}(B)$ and $\mathrm{co}(B')$ both must meet a proper subface of F. If not, then $\mathrm{co}(B)$ would have to contain the intersection of $\mathrm{ex}(B)$ with the entire affine hull of F (because no boundaries of F are in $\mathrm{co}(B)$). Similarly, $\mathrm{co}(B')$ also would contain the intersection $\mathrm{ex}(B')$ with the hull of F. (See section 8 for definition of "affine hull" and other mathematical terminology.) Since one box contains the other, this means that one box contains points from F that the other box also contains. But then there could not be two distinct connected components of P in $\mathrm{co}(B)$ and $\mathrm{co}(B')$, so duplication would not have taken place.

Thus, $\mathrm{co}(B), \mathrm{co}(B')$ each contain proper subfaces of F. But in this case, the boxes

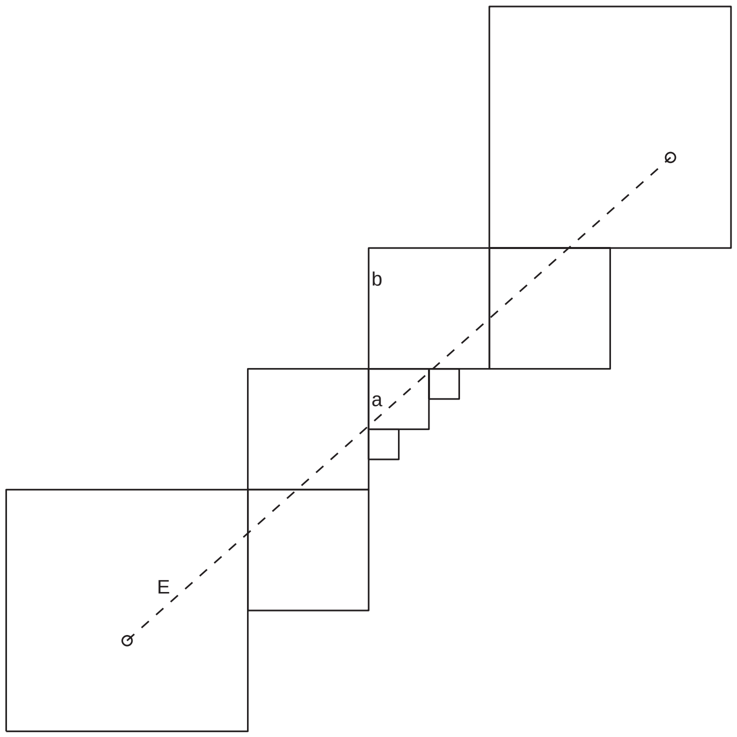

Fig. 6.1. *The alignment condition in the case $d = 2, k = 1$: the boxes in this figure are the extended orbit of a P-edge E, which is the dashed line. The two large boxes at the ends are protected boxes for the endpoints of E, protected from phase 0. In this figure, box a must be split because the alignment condition does not hold for this box. Its close subface, which could be either its lower left-hand corner or upper right-hand corner, is contained by another box smaller than a. All other boxes satisfy the alignment condition. For example, box b does not have to be split; its close subface could be either its bottom edge or right edge. The right edge will have higher priority, since the alignment condition holds for that edge.*

could not end up in O_F (i.e., if they were still active in phase $\dim(F)$, they would be crowded).

As mentioned earlier, a box is protected if the alignment condition holds for its close subface. We make the following claim: if the alignment condition holds for B at the time it is protected, then the condition continues to hold for the remainder of the algorithm. In other words, the following situation cannot occur: a box B with close subface B' is deemed to satisfy the alignment condition and becomes protected. Later a neighboring box $\bar{B}$ also containing B' as a subface gets split because the alignment condition does not hold for $\bar{B}$, thus causing the alignment condition to be violated for B.

To prove the claim in the last paragraph, we must describe the order in which QMG processes the boxes in an orbit O_F. "Process" means that QMG determines whether the box satisfies the alignment condition; if so, then protect it, and if not, then split it. The correct order is to start with the largest boxes in the orbit, working down to the smallest. Within the set of boxes of the same size, we process those with the lowest-dimensional close subfaces first, working toward highest-dimensional close subfaces.

We claim that this order assures that if the alignment condition holds for a box B at the time it is processed, then the alignment condition holds for B for the remainder of the algorithm. Suppose we are at the step when B is processed and the alignment condition is satisfied. Let B' be the close subface of B, and let l be the dimension of B'. Let $B_1, \ldots, B_n$ be the boxes in the extended orbit that cover B'. Some of $B_1, \ldots, B_n$ will be larger than B' and hence already protected. Protected boxes are not split again, so they will continue to cover B' for the rest of the algorithm. Consider a box B_i that is the same size as B. If B_i has a close face of dimension less than l, then B_i is already protected (because we process boxes with lower-dimensional close faces first). The dimension of the close face of B_i cannot be greater than l, because B' is a subface of B_i and has higher priority than any subface of B_i of dimension $l+1$ or more. Therefore, the only remaining possibility is that B_i is the same size as B and that the close subface of B_i has dimension exactly l. But then this subface, if it is not B', must also be completely covered by boxes in the orbit because otherwise B' would have higher priority. (Recall that faces that are completely covered have higher priority.) So we see that B_i will become protected as well and cannot be split.

When a box B is protected, as mentioned above, we have identified a close subface B' of B. This subface has the property that F meets an ∞-norm neighborhood of B'. We now select a point lying on F in this neighborhood (see [12] for more details on selecting the close point). The rule used for choosing the close point has the property that any other box B'' that is the same size as B and also has B' as its close subface will choose the same close point. Thus, several adjacent boxes that are in the same orbit and are the same size might share a close point.

The alignment stage continues until there are no boxes left to process; every box is either protected or has been moved to the idle list. When O_F is empty, the alignment moves onto a different orbit. Once the orbits of all dimension-k faces of P are empty, the phase is over.

7. Triangulation.

After phase d of quadtree generation, QMG triangulates the quadtree. In the triangulation procedure, the collection of protected boxes is triangulated into a simplicial complex.

To describe the triangulation procedure, we must first bring lower-dimensional boxes into the picture. In this section, we revisit some of the concepts from earlier sections and revise some of the algorithm steps to take into account lower-dimensional boxes. The lower-dimensional boxes serve two purposes: first, they simplify the data structures needed for checking the alignment condition, and second, they serve as the basis for generating the final triangulation.

In QMG, boxes can have dimension 0 up to d. Initially, there is only one active box of dimension d, namely, the top box. Lower-dimensional boxes get created each time a box is protected by QMG. At the moment an i-dimensional active box B is changed from active to protected during the alignment stage for orbit O_F, all its faces of dimension $i-1$ are launched as new active boxes (there are $2i$ such faces). Let B' be one of these new active boxes. It is dealt with in a manner analogous to the way QMG handles subboxes after a split. We compute $\mathrm{co}(B')$ as the intersection $\mathrm{co}(B) \cap \mathrm{ex}(B')$. We determine the disposition of B' using the same rules as before: if $\mathrm{co}(B')$ is empty, then we delete B'. If $\mathrm{co}(B) \cap \mathrm{ex}(B')$ has more than one connected component, then we duplicate B'. If $\mathrm{co}(B')$ does not meet F (and hence meets only P-faces of dimension $k+1$ and higher), then we place B' in I_{k+1}. If $\mathrm{co}(B')$ meets F, then we place B' in O_F.

It is possible that B' will also become immediately protected; this happens, for instance, when the close subface of B is also a subface of B'.

The same operations are performed on an i-dimensional box as are performed on a full-dimensional box: such a box can be tested for crowdedness, split for separation, protected, and so on. When an i-dimensional box is split, 2^i new subboxes are created. If B is i-dimensional, it is said to *extend over* i of the possible d coordinate axes, and it is *flat* over the remaining $d - i$ coordinate axes.

The definition of $\mathrm{ex}(B)$ for a box of dimension less than d is as follows. Every box B has associated with it a number called its *size*, which we denote $\mathrm{size}(B)$ and which is the side length of B in a dimension over which it extends. The size of every box is equal to the size of the top box multiplied by a factor 2^{-p}, where p is the number of times the top box was split to reach this box. If B is a box, then $\mathrm{ex}(B)$ is an axis-parallel full-dimensional parallelepiped in $\mathbf{R}^d$ concentric with B, with side lengths $(1 + \gamma)\,\mathrm{size}(B)$ for axes over which B extends, and side length $\gamma\,\mathrm{size}(B)$ for the axes in which B is flat. This choice ensures that all properties of $\mathrm{ex}(B)$ asserted earlier are still valid, namely, if B has a subface close to F, then the subface meets $\mathrm{ex}(B)$. Also, if B is split, then $\mathrm{ex}(B')$ for each subbox B' is contained in $\mathrm{ex}(B)$. Finally, if subfaces of B are launched as new active boxes when B is protected, then each new subface B' also satisfies $\mathrm{ex}(B') \subset \mathrm{ex}(B)$. Note that for consistency, even zero-dimensional boxes must have a size. When a zero-dimensional box B is split, there is only one child, but splitting still has significance because the size is halved, which diminishes $\mathrm{ex}(B)$ and therefore $\mathrm{co}(B)$.

Earlier, when describing the alignment condition, we introduced the terms "extended orbit" and "completely cover." Recall that we defined extended orbit to be the union of the orbit O_F of a face F united with the protected boxes for all proper subfaces of F from previous phases. In fact, QMG never forms extended orbits; instead, the lower-dimensional active box faces of protected boxes act as proxies for the protected boxes. A system of weights is used to determine the complete coverage condition. In particular, every active box in QMG stores a weight associated with each of its subfaces. Thus, an i-dimensional active box has 3^i weights stored with it. Each weight is a number between 0 and 1 that indicates what fraction of the subface is "owned" by that active box. Initially, the top box owns all of its subfaces. When a box is split, the weights are divided up among children. We omit the details of how the weights get split up, but the upshot is that QMG can test whether a box subface is completely covered by boxes in its orbit by adding up the weights associated with that subface contributed by all the boxes containing it; complete coverage is indicated by a weight sum of 1.0.

Although many details are omitted, we do mention one key point that reduces the amount of searching and sorting in QMG. When testing the complete coverage rule, it is necessary to look only at boxes of a single size. This means that the complete coverage condition can be tested with a simple hash table. Consider the example in Figure 7.1.

It can be shown that these more complicated rules introduced in this section are equivalent to the definitions in the preceding sections in the following sense. For a given input P, the quadtree generation procedure produces the same sequence of full-dimensional boxes whether we follow the rules of this section or preceding sections.

The protected boxes are linked together by pointers; in particular, a protected box of dimension i has pointers to all the protected boxes of dimension $i + 1$ of which it is a subface. This data structure serves as the basis for triangulation.

The triangulation algorithm is based on our other paper [12] and is as follows.

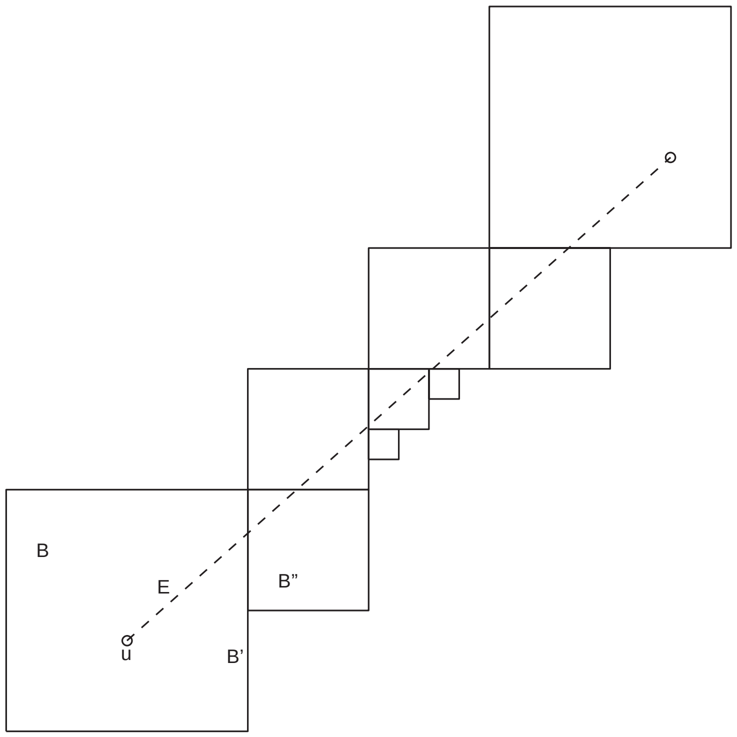

FIG. 7.1. *The alignment condition taking into account lower-dimensional boxes. The lower left-hand box B is protected in phase 0 for the vertex u of P in its interior. The right edge of this box—call it B'—becomes a new active box. It is uncrowded; its associated P-face is E (E is the dashed segment); and its close subface is the whole box B'. During the alignment phase 1, this 1D box is split because the weight of B' associated with B' itself is only 0.5. Once B' is split in half, its lower half no longer meets E and hence is placed into I_2. Its upper half, together with the full-dimensional active box labeled B'', completely covers the upper half of B' so the alignment condition is satisfied.*

Let a *chain* be a sequence of nested boxes $B_0, \ldots, B_d$ such that the dimension of B_i is i. “Nested” means that, for each i, B_i is a face or subset of a face of B_{i+1}. Let $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_d$ be the close points of $B_0, \ldots, B_d$. Then the simplex whose vertices are $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_d$ is put in the triangulation. Thus, the triangulation has one simplex for each chain. The only exception is when a close point is repeated in this chain; in this case, the simplex is said to be *null* and is not included in the triangulation. QMG enumerates all possible chains with a stack-based search algorithm. An example of the triangulation algorithm is presented in Figure 7.2.

We can now explain the importance of the alignment condition in Figure 7.3. As is seen from the figure, if the alignment condition were not enforced, then the triangulation algorithm described in the preceding paragraph would be invalid.

8. Aspect ratio.

In our analysis of QMG, which begins in section 10, we demonstrate two optimality properties: the triangulation generated by QMG has optimal aspect ratio, up to a certain factor, and also optimal cardinality (compared with all other bounded aspect ratio triangulations), up to a certain factor. Before demonstrating these properties, we must provide definitions for aspect ratio, sharp angle, and so on. This mathematical background is the topic of this section and the next

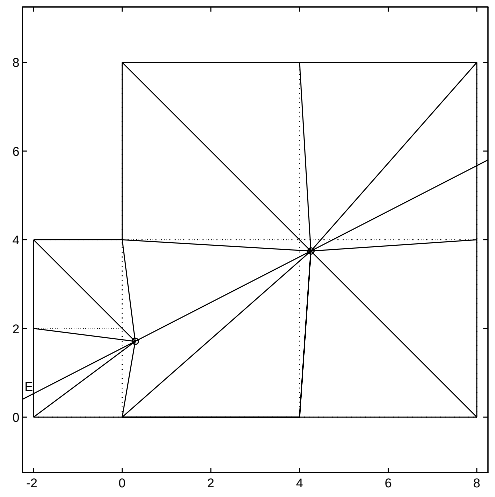

FIG. 7.2. *An example of the triangulation procedure in the case* $d = 2$. *All six full-dimensional protected boxes in this figure are associated with* P*-edge* E. *The dotted lines are boundaries of boxes that are not present in the final triangulation. The solid segments are all part of the triangulation. The close point for the two small boxes on the left is the point near* $(0, 2)$ *marked in the figure. An example of a nonnull chain in this figure would be starting from the vertex* $(0, 0)$ *(whose close point is at* $(0, 0)$ *and is associated with the* $2D$ *face* P *itself), then the edge* $\{0\} \times [0, 2]$ *containing it, whose close point is the marked point on* E *near* $(0, 2)$*, and finally the box* $[0, 4] \times [0, 4]$*, whose close point is the marked point near* $(4, 4)$ *on* E. *An example of a null chain would be the vertex at* $(4, 0)$ *(whose close point is at* $(4, 0)$*), the edge* $\{4\} \times [0, 4]$ *(whose close point is on* E *near* $(4, 4)$*), and finally the box* $[4, 8] \times [0, 4]$*, which has the same close point near* $(4, 4)$. *This figure shows a triangulation on both sides of* E *for illustrative purposes, although if* E *were a boundary edge, in fact only one side of* E *would be triangulated. As mentioned in the introduction, however, the actual implementation of QMG allows internal boundaries, so the above situation of triangulating both sides of an edge does occur with QMG.*

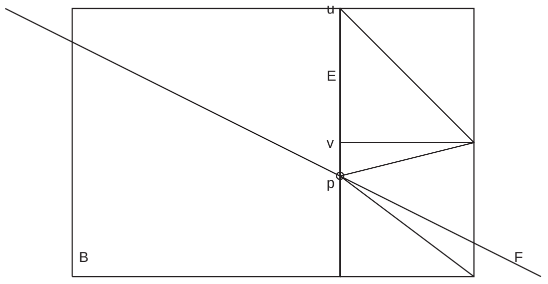

FIG. 7.3. *An inconsistency that would arise during triangulation if the alignment condition were not enforced. In particular, the close point of box* B *is point* $\boldsymbol{p}$*, which lies on* P*-face* F *and also on the right edge of box* B. *Thus, the close face for* B *is this edge. The alignment condition does not hold; that is, the close face of* B *is covered by smaller boxes on the right. If the triangulation algorithm were applied despite the violation of the alignment condition, then an illegal triangulation would result. For instance, the close point of edge* E *is one of its endpoints, say, endpoint* $\boldsymbol{v}$. *Then the chain consisting of* $\boldsymbol{u}$*, then* E *(whose close point is* $\boldsymbol{v}$*), and then* B *(whose close point is* $\boldsymbol{p}$*) is a flat simplex, that is, a triangle with collinear vertices. Such a simplex has infinite aspect ratio and must not be allowed in a triangulation. Note that a degenerate simplex like this is not a null simplex as defined in section 7: this degenerate simplex does not have any repeated vertex, and hence it cannot be legally dropped from the triangulation.*

section. In this section, all norms are assumed to be Euclidean norms (i.e., 2-norms), although most of the bounds are valid for other standard norms as well (since the bounds include a multiplicative factor depending on d).

First, we provide some standard definitions from linear algebra. An *affine set* X is the solution to a system of linear equations, that is, $X = \{\boldsymbol{x} \in \mathbf{R}^d : A\boldsymbol{x} = \boldsymbol{b}\}$ for some $m \times d$ matrix A with linearly independent rows and some m-vector $\boldsymbol{b}$. The *dimension* of this affine set is $d - m$. Let Y be any subset of $\mathbf{R}^d$. The *affine hull* of Y is defined to be the lowest-dimensional affine set that contains Y and is denoted $\operatorname{aff}(Y)$. It can be shown that $\operatorname{aff}(Y)$ is uniquely determined by this definition. In particular, it can be shown that $\operatorname{aff}(Y)$ is the set of all points that can be written in the form $\alpha_1\boldsymbol{y}_1 + \cdots + \alpha_s\boldsymbol{y}_s$, where s is an arbitrary positive integer, $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s \in Y$, and $\alpha_1, \ldots, \alpha_s$ is an arbitrary sequence of real numbers that add up to 1. Let F be a face of P. Since P is polyhedral, $\operatorname{aff}(F)$ and F have the same dimension.

We now define aspect ratio.

DEFINITION 8.1. *Let T be a d-simplex in $\mathbf{R}^d$ with vertices $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_d$. Then the* altitude *of T at $\boldsymbol{v}_i$ is defined to be* $\operatorname{dist}(\boldsymbol{v}_i, \operatorname{aff}(\boldsymbol{v}_0, \ldots, \boldsymbol{v}_{i-1}, \boldsymbol{v}_{i+1}, \ldots, \boldsymbol{v}_d))$. *The* minimum altitude *of T, denoted* $\operatorname{minalt}(T)$, *is the minimum altitude over all choices of $\boldsymbol{v}_i$ for $i = 0, \ldots, d$.*

DEFINITION 8.2. *For a d-simplex T in $\mathbf{R}^d$, the* maximum side length *of T, denoted* $\operatorname{maxside}(T)$, *is defined to be*

$$\max\{\|\boldsymbol{v}_i - \boldsymbol{v}_j\| : i, j = 0, \ldots, d\},$$

where $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_d$ are the vertices of T.

DEFINITION 8.3. *The* aspect ratio *of a simplex T is defined to be*

$$\operatorname{asp}(T) = \operatorname{maxside}(T)/\operatorname{minalt}(T).$$

Thus, the aspect ratio is always at least 1, and large aspect ratios indicate poor-quality elements.

In the remainder of this section, we characterize aspect ratio in terms of matrix norms. Given a d-simplex T, we define its associated matrix M_T to be the $d \times d$ matrix whose ith column, $i = 1, \ldots, d$, is $\boldsymbol{v}_i - \boldsymbol{v}_0$. Thus, M_T depends on the numbering of the vertices, and in particular, $\boldsymbol{v}_0$ plays a distinguished role. However, we note the following: if we define M_T' according to a different numbering of the vertices, the columns of M_T' can be obtained from the columns of M_T by subtracting pairs of columns in M_T and then permuting. In linear algebra terms, there exists a $d \times d$ matrix L all of whose entries are 0's except for possibly one 1 and one -1 in each column such that $M_T' = M_T L$, and such that L^{-1} has the same properties (all 0's except for possibly one 1 and one -1 per column).

The following two results hold for any numbering. These lemmas use the following well-known linear algebra fact. The norm of a $d \times d$ matrix is bounded above and below by constant multiples (where the constant depends on d) of the maximum norm among its columns, and also above and below by constant multiples of the maximum norm among its rows. In the remainder of this article, c_d denotes a constant depending only on d, which may change from formula to formula.

LEMMA 8.4. *Let σ denote* $\operatorname{maxside}(T)$. *Then*

$$c_d\sigma \le \|M_T\| \le C_d\sigma,$$

where c_d, C_d are two constants depending only on d.

Proof. There are two cases, depending on whether σ is the length of a side adjacent to $\boldsymbol{v}_0$. In the first case, say that $\sigma = \|\boldsymbol{v}_1 - \boldsymbol{v}_0\|$. Then both inequalities are easy because σ is the norm of the first column of M_T, and all the other columns of M_T have norms bounded above by σ.

The other case is that σ is the length of a side not adjacent to $\boldsymbol{v}_0$. We can reduce to the first case by renumbering the vertices and noting that the norms of the transformation matrices mentioned above, $\|L\|$ and $\|L^{-1}\|$, are bounded above by constants depending only on d. □

LEMMA 8.5. *Let* $\mu = \operatorname{minalt}(T)$. *Then*

$$c_d/\mu \leq \|M_T^{-1}\| \leq C_d/\mu,$$

where c_d, C_d *are two constants depending only on* d *(not necessarily the same constants as in the previous lemma).*

Proof. Let $\boldsymbol{u}^{\mathrm{T}}$ be the ith row of M_T^{-1}. Then $M_T^{\mathrm{T}}\boldsymbol{u}$ is a column of the identity matrix. (The superscript T denotes transpose. The subscript T indicates the association of M with simplex T.) Geometrically, this means that $\boldsymbol{u}$ is orthogonal to $d-1$ columns of M_T; in particular, $\boldsymbol{u}$ is orthogonal to the plane $\operatorname{aff}(\boldsymbol{v}_0, \ldots, \boldsymbol{v}_{i-1}, \boldsymbol{v}_{i+1}, \ldots, \boldsymbol{v}_d)$. Thus, $\boldsymbol{u}$ is parallel to the altitude from vertex i. Its length is chosen so that its inner product with $\boldsymbol{v}_i - \boldsymbol{v}_0$ is 1, which implies that its inner product with the true altitude vector is 1. Thus, the ith row of M_T^{-1} is parallel to the altitude vector from $\boldsymbol{v}_i$ but is scaled so that its length is the reciprocal of the altitude.

Then we see that the rows of M_T^{-1} have lengths equal to reciprocals of altitudes from $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d$, with the shortest altitude being the reciprocal of the norm of the largest row. This proves the lemma, provided that the minimum altitude is not adjacent to $\boldsymbol{v}_0$. The case when the minimum altitude is adjacent to $\boldsymbol{v}_0$ is handled by renumbering as in the previous proof. □

We conclude from these two lemmas that $\operatorname{asp}(T)$ is within a constant factor of $\|M_T\| \cdot \|M_T^{-1}\|$, that is, the condition number $\kappa(M_T)$. Combining these lemmas with the Hadamard inequality yields the following well-known result:

$$c_d \operatorname{minalt}(T)^d \leq \operatorname{vol}(T) \leq C_d \operatorname{maxside}(T)^d. \tag{8.1}$$

9. Angles and PL paths. In the preceding section, we defined "aspect ratio." It turns out that we can show that QMG produces triangulations whose aspect ratio is bounded above in terms of the sharpest angle of the input domain P. In this section, we provide the definition of "sharpest angle" and a theorem stating that *any possible* triangulation of P has aspect ratio bounded below in terms of the sharpest angle. Thus, the theorem in this section is the lower bound necessary to prove that the QMG triangulation is optimal.

Let $\boldsymbol{x}, \boldsymbol{y}$ be two points in P. A *piecewise linear* (PL) path Π from $\boldsymbol{x}$ to $\boldsymbol{y}$ is a path composed of a finite number of line segments. The endpoints of the segments are the *breakpoints* of Π. The *length* of this path, denoted $\operatorname{lth}(\Pi)$, is the sum of the lengths of the individual segments. Suppose that $\boldsymbol{x} \in F$ and $\boldsymbol{y} \in G$, where F and G are two faces of P. We will say that Π is *contractible* if there exists a point $\boldsymbol{z}$ such that the segment $\boldsymbol{xz}$ lies in F, the segment $\boldsymbol{yz}$ lies in G, and for all $\boldsymbol{v} \in \Pi$, the segment $\boldsymbol{vz}$ lies in P. Note that this definition forces $\boldsymbol{z}$ to lie in both F and G. Thus, a necessary condition for contractibility is that F and G have a nonempty common subface.

Note that we should really apply this term "contractible" to a triplet (Π, F, G), since the definition depends on the specification of F and G as well as on the path Π.

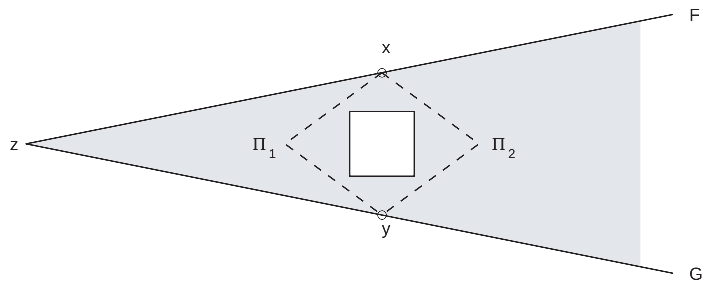

FIG. 9.1. *In the $d = 2$ case, F and G are two boundary segments meeting at boundary vertex $\boldsymbol{z}$. The polygon has a square hole in it: the interior of P is shaded. The PL path Π_1 connects a point $\boldsymbol{x} \in F$ to $\boldsymbol{y} \in G$. This path is contractible to $\boldsymbol{z}$. On the other hand, path Π_2 is incontractible.*

When we use the term, the choice of F and G will be understood from context. The opposite of contractible is *incontractible.*

Let $\mathcal{T}$ be an arbitrary triangulation of P (not necessarily the triangulation produced by QMG). If a path Π is contractible, we can obtain a lower bound on the aspect ratios of simplices of $\mathcal{T}$ that meet Π. On the other hand, if Π is incontractible, we can obtain an upper bound on the minimum altitude of simplices that meet Π. The remainder of this section is devoted to stating and proving these two results.

We start with the definition of the "angle" between two P-faces F and G, which is defined by contractible paths.

DEFINITION 9.1. *Let F, G be two faces of P, and suppose $\boldsymbol{x} \in F$ and $\boldsymbol{y} \in G$. Let Π be a contractible PL path from $\boldsymbol{x}$ to $\boldsymbol{y}$. Let A be the affine set* $\mathrm{aff}(F) \cap \mathrm{aff}(G)$. *The* angle *determined by* $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ *is*

$$\theta = \frac{\mathrm{lth}(\Pi)}{\min(\mathrm{dist}(\boldsymbol{x}, A), \mathrm{dist}(\boldsymbol{y}, A))}. \tag{9.1}$$

We say that the sharpest angle *formed by F and G is the infimum of* (9.1) *over all contractible paths from F to G (assuming that at least one contractible path from F to G exists). Finally, we say that the sharpest angle in P is the infimum over all angles.*

In the denominator of (9.1), "dist" denotes ordinary Euclidean distance. Note that $\boldsymbol{z}$, the base of the contraction, does not appear in (9.1). An example of a contractible path is given in Figure 9.1. We are concerned with the case when this angle is small, so large angles have no significance. Thus, the degenerate case when the denominator of (9.1) is 0 (which happens, for instance, if F is a superface of G or vice versa) is not relevant for our analysis.

In the case $d = 2$, the previous definition is within a constant factor of the ordinary notion of an angle between two edges of a polygon, since only the case $\dim(F) = \dim(G) = 1$ matters when $d = 2$.

Now for the first main result of this section: we show that if there is a contractible path Π forming an angle θ, then θ^{-1} is a lower bound on the aspect ratio of at least one simplex in every possible triangulation of P.

THEOREM 9.2. *Let F, G be two P-faces, and assume there is a contractible path from F to G. Let θ be the value of the sharpest angle between F and G. Let $\mathcal{T}$ be an arbitrary triangulation of P. Then there is a simplex T in the triangulation with a vertex lying on $F \cap G$ such that* $\mathrm{asp}(T) \geq c_d/\theta$.

Proof. Let $(\boldsymbol{x}, \boldsymbol{y}, \Pi)$ be the triple defining the sharpest angle θ between F and G, and let $\boldsymbol{z}$ be the point in $F \cap G$ to which we can contract Π. (Stating this more carefully, since sharpest angle is defined as an infimum, we should say that $(\boldsymbol{x}, \boldsymbol{y}, \Pi)$ defines an angle of size $(1+\epsilon)\theta$, where $\epsilon > 0$ is arbitrarily small. But the $1+\epsilon$ factor can be absorbed by the c_d factor.) Let H be the P-face contained in $F \cap G$ that contains $\boldsymbol{z}$. (If there is more than one P-face H satisfying $\boldsymbol{z} \in H \subset F \cap G$, choose any such H.) Let $A = \mathrm{aff}(F) \cap \mathrm{aff}(G)$. Note that $H \subset A$, since $H \subset F \cap G$.

In the triangulation of P, restrict attention to simplices of $\mathcal{T}$ that have at least one vertex on H. Call this collection of simplices $\mathcal{T}'$. Since $\mathcal{T}'$ is a finite set, there is an $\epsilon > 0$ such that every point in $\boldsymbol{v} \in P$ satisfying $\mathrm{dist}(\boldsymbol{v}, \boldsymbol{z}) \le \epsilon$ and $\boldsymbol{v}\boldsymbol{z} \subset P$ is contained in a simplex from $\mathcal{T}'$. Then we can contract $(\boldsymbol{x}, \boldsymbol{y}, \Pi)$ toward $\boldsymbol{z}$ (i.e., replace $\boldsymbol{x}$ by $(1-\lambda)\boldsymbol{z} + \lambda\boldsymbol{x}$, $\boldsymbol{y}$ by $(1-\lambda)\boldsymbol{z} + \lambda\boldsymbol{y}$, and each point $\boldsymbol{v} \in \Pi$ by $(1-\lambda)\boldsymbol{z} + \lambda\boldsymbol{v}$ for some fixed $\lambda \in (0, 1]$) so that, without loss of generality, all of Π is covered by simplices in $\mathcal{T}'$. Note that the contraction operation does not affect the value of θ because the numerator and denominator of (9.1) scale by the same amount when we contract toward $\boldsymbol{z}$.

Without loss of generality, $\mathrm{dist}(\boldsymbol{x}, A) \ge \mathrm{dist}(\boldsymbol{y}, A)$; define $\alpha = \mathrm{dist}(\boldsymbol{y}, A)$. Define $\beta = \mathrm{lth}(\Pi)$. Thus, $\theta = \beta/\alpha$ is the sharpest angle. Now define a continuous piecewise linear function $f : P \to \mathbf{R}$ as follows. We first define f on the vertices of $\mathcal{T}$ as follows. For each $\mathcal{T}$-vertex $\boldsymbol{v} \in G$ we define $f(\boldsymbol{v}) = \mathrm{dist}(\boldsymbol{v}, A)$ where distance is measured in the ordinary Euclidean sense. Since $H \subset A$, this fixes $f(\boldsymbol{v}) = 0$ for vertices $\boldsymbol{v} \in H$. For all other vertices $\boldsymbol{v}$ of $\mathcal{T}$ we define $f(\boldsymbol{v}) = 0$. Notice that all vertices $\boldsymbol{v}$ of F have $f(\boldsymbol{v}) = 0$ because the intersection of F and G is contained in A. Now extend f to all of P by linearly interpolating over each simplex. This yields a uniquely determined piecewise linear function $f : P \to \mathbf{R}$. Notice that f is identically 0 on F.

Next, we claim that $f(\boldsymbol{y}) \ge \alpha$. Notice that for points on G, f is a linear interpolation of the function $\boldsymbol{u} \mapsto \mathrm{dist}(\boldsymbol{u}, A)$. This latter function is a convex function because A is convex. A linear interpolant of a convex function is always greater than or equal to the function value itself; thus $f(\boldsymbol{y}) \ge \mathrm{dist}(\boldsymbol{y}, A) = \alpha$.

On the other hand, $f(\boldsymbol{x}) = 0$ because $\boldsymbol{x} \in F$. Let $f|_\Pi$ be the restriction of f to Π; then $f|_\Pi$ is PL and continuous and increases by α. The length of Π is β. Therefore, there is a point $\boldsymbol{u}$ where the directional derivative of f at $\boldsymbol{u}$ parallel to Π is at least α/β in magnitude. Let T be the simplex of $\mathcal{T}$ containing $\boldsymbol{u}$ (if there is more than one such T, choose arbitrarily). Note that $T \in \mathcal{T}'$ because we are assuming Π is covered by $\mathcal{T}'$. On this simplex T, since the gradient is constant, $\|\nabla f\| \ge \alpha/\beta$.

There is an analytic expression for ∇f on T as follows. Let us number the vertices of T with $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_d$ so that $\boldsymbol{v}_0$ is a vertex on H. (Recall that every simplex in $\mathcal{T}'$ has at least one vertex on H.) Let $r_i = f(\boldsymbol{v}_i)$ for $i = 0, \ldots, d$. Thus, $r_0 = 0$ because f is zero on H, as noted above. Then one checks that $f(\boldsymbol{u})$ on T is given by the linear mapping $f(\boldsymbol{u}) = \boldsymbol{r}^{\mathrm{T}} M_T^{-1}(\boldsymbol{u} - \boldsymbol{v}_0)$, where M_T was defined earlier, and $\boldsymbol{r}^{\mathrm{T}}$ denotes $(r_1, \ldots, r_d)$. Then we see that ∇f on T is given by $(M_T^{\mathrm{T}})^{-1}\boldsymbol{r}$, so

$$\|\nabla f\| \le \|M_T^{-1}\| \cdot \|\boldsymbol{r}\| \le c_d \cdot (\max |r_i|)/\operatorname{minalt}(T).$$

Notice that $\max |r_i|$ is the maximum distance of a vertex of T from A, but this is at most $\operatorname{maxside}(T)$, since T has an edge from each of its vertices to $\boldsymbol{v}_0$, which lies on A. Thus,

$$\begin{aligned} \|\nabla f\| &\le c_d \operatorname{maxside}(T)/\operatorname{minalt}(T) \\ &= c_d \operatorname{asp}(T). \end{aligned}$$

On the other hand, we showed in the previous paragraph that $\|\nabla f\| \geq \alpha/\beta$, which is the reciprocal of θ. Thus, we have proved that the aspect ratio of T is bounded below by the reciprocal of the sharpest angle between F and G. ∎

The previous result shows that the presence of a contractible path gives a useful bound that is applicable to any triangulation $\mathcal{T}$. On the other hand, the presence of an incontractible path also gives a useful bound. We start with a lemma and then prove the main result.

LEMMA 9.3. *Let Π be an incontractible path from $\boldsymbol{x} \in F$ to $\boldsymbol{y} \in G$. Let $\mathcal{T}$ be an arbitrary triangulation of P. Let $F_1, \ldots, F_m$ be an enumeration of all the faces (of all dimensions including d) of $\mathcal{T}$ that meet Π. Then $F_1 \cap \cdots \cap F_m = \emptyset$.*

Proof. Suppose that $F_1, \ldots, F_m$ have a common point $\boldsymbol{z}$. Since the triangulation is boundary conforming, $\boldsymbol{z}$ lies on a common subface of F and G (because the lowest-dimensional triangulation face meeting $\boldsymbol{x}$ must be a subface of F, and similarly for the lowest-dimensional face meeting $\boldsymbol{y}$). Furthermore, every point $\boldsymbol{v}$ on Π is covered by a simplex that also covers $\boldsymbol{z}$. Since simplices are convex, this simplex also covers the segment $\boldsymbol{vz}$. Thus, Π is contractible to $\boldsymbol{z}$, contradicting the assumption. ∎

THEOREM 9.4. *Let F, G be two P-faces, and let Π be an incontractible path from $\boldsymbol{x} \in F$ to $\boldsymbol{y} \in G$. Let $\mathcal{T}$ be an arbitrary triangulation of P. Then $\mathcal{T}$ contains a simplex T meeting Π such that*

$$\operatorname{minalt}(T) \leq c_d \operatorname{lth}(\Pi).$$

Proof. Let $F_1, \ldots, F_m$ be an enumeration of faces of $\mathcal{T}$ meeting Π. By the preceding lemma, $F_1 \cap \cdots \cap F_m = \emptyset$. Let the vertices of F_1 be denoted $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_s$, where $s \leq d$. Since Π meets F_1, there is a point, say, $\boldsymbol{z}$, on Π that can be written as a convex combination of the vertices of F_1:

$$\boldsymbol{z} = \lambda_0 \boldsymbol{v}_0 + \cdots + \lambda_s \boldsymbol{v}_s,$$

where each λ_i is nonnegative, and $\lambda_0 + \cdots + \lambda_s = 1$. Therefore, for some i, $\lambda_i \geq 1/(s+1) \geq 1/(d+1)$. Without loss of generality, say that $\lambda_0 \geq 1/(d+1)$. Note that since the F_i's are disjoint, there is some F_i that does not contain $\boldsymbol{v}_0$. Let this other face be denoted F_2.

Let $f : P \to \mathbf{R}$ be a PL continuous function defined as follows. We set $f(\boldsymbol{v}_0) = 1$. For all other vertices $\boldsymbol{v}$ of $\mathcal{T}$, set $f(\boldsymbol{v}) = 0$. Now extend f to all of P by linear interpolation over the simplices in $\mathcal{T}$. Note that $f(\boldsymbol{z}) = \lambda_0 f(\boldsymbol{v}_0) + \cdots + \lambda_s f(\boldsymbol{v}_s)$, and hence $f(\boldsymbol{z}) \geq 1/(d+1)$. On the other hand, let $\boldsymbol{w}$ be the point where Π meets F_2; note that $f(\boldsymbol{w}) = 0$ since f is identically zero on F_2 (because f is defined to be zero on all vertices of F_2).

We now conclude the proof using the same technique as in Theorem 9.2. Along path Π, f is PL and continuous and decreases by at least $1/(d+1)$ (from $\boldsymbol{z}$ to $\boldsymbol{w}$). Therefore, there is a point $\boldsymbol{u}$ on Π such that f has a directional derivative at $\boldsymbol{u}$ parallel to Π whose magnitude is at least $(1/(d+1))/\operatorname{lth}(\Pi)$. Let T be the simplex containing $\boldsymbol{u}$. Then on this simplex T, since the gradient is constant, $\|\nabla f\| \geq 1/((d+1)\operatorname{lth}(\Pi))$.

We obtain an analytic expression for ∇f on T as follows. Let us number the vertices of T with $\boldsymbol{v}_0, \ldots, \boldsymbol{v}_d$. Let $r_i = f(\boldsymbol{v}_i) - f(\boldsymbol{v}_0)$ for $i = 0, \ldots, d$. Thus, $|r_i| \leq 1$ for each i. As earlier, ∇f on T is given by $(M_T^{\mathrm{T}})^{-1}\boldsymbol{r}$, so

$$\|\nabla f\| \leq \|M_T^{-1}\| \cdot \|\boldsymbol{r}\| \leq c_d / \operatorname{minalt}(T).$$

Combining this inequality with the inequality proved in the previous paragraph proves the theorem. ∎

10. QMG aspect ratio in terms of neighboring box sizes. In this section we begin our analysis of the aspect ratio bound for QMG. In general, we cannot establish a universal constant upper bound on the aspect ratio of the triangulation produced by QMG because if P has sharp angles, then any possible triangulation, including QMG, will have poor aspect ratio near the sharp angle, as proved by Theorem 9.2. Thus, we want to show that the sharpest angle of any simplex-generated QMG is very sharp only if the input polyhedron itself has a sharp angle.

In this section we argue that the worst-case aspect ratio produced by QMG is bounded in terms of the ratio of sizes of neighboring boxes. This section requires an understanding of the analysis in our paper [12]. In subsequent sections, we bound this box-size ratio in terms of the sharpest angle. Thus, the combination of these arguments bounds the aspect ratio of QMG in terms of $\theta(P)$.

From now on, we denote the sharpest angle in P by $\theta(P)$. In particular,

$$\theta(P) = \min(1, \min\{\theta(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)\}), \tag{10.1}$$

where $\theta(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ is defined as in (9.1) and the inner min is taken over all allowable choices of $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ for (9.1). The outer min is included because, as mentioned above, we are concerned only about the case of small angles. If the minimum angle is large, then it has no impact on our bounds.

Let B be a box. As above, we define $\operatorname{size}(B)$ to be the length of a side of B. Let B, B' be two neighboring protected boxes such that $\operatorname{co}(B)$ and $\operatorname{co}(B')$ have a common point. (Here, $\operatorname{co}(B)$ refers to the content of B at the time it became protected. The contents of two neighboring boxes might not have a common point if the boxes' common subface is completely outside P because of boundaries that cut through the boxes or because of duplication.) Suppose $\operatorname{size}(B) \geq \operatorname{size}(B')$. These boxes have *box-size ratio* $\operatorname{size}(B)/\operatorname{size}(B')$. Let r be the maximum box-size ratio in the whole triangulation produced by QMG. We argue in this section that the worst aspect ratio in QMG is at most $c_d r$.

Consider a simplex T generated by QMG. As in [12], this simplex comes from a chain of $d+1$ nested box subfaces. Unlike [12], these box subfaces can have different sizes; in particular, the subfaces in the chain can grow in size as the dimension of the box face increases.

A consequence of the alignment condition presented in section 6 is as follows. Let B_i, B_{i+1} be two boxes in a chain, so that $\dim(B_i) = i$ and $\dim(B_{i+1}) = i+1$. Let the close points of these boxes be $\boldsymbol{v}_i, \boldsymbol{v}_{i+1}$. Then either $\boldsymbol{v}_i = \boldsymbol{v}_{i+1}$ or

$$\operatorname{dist}(\boldsymbol{v}_{i+1}, \operatorname{aff}(B_i)) \geq c_d \operatorname{size}(B_{i+1}). \tag{10.2}$$

The reason is as follows. Let C be the close face of B_{i+1}. Let B^* be the i-dimensional face of B_{i+1} that contains B_i. If C is a subface of B^*, then the alignment condition implies that B^* must also be protected, and hence $B^* = B_i$ and $\boldsymbol{v}_i = \boldsymbol{v}_{i+1}$. Else C is not a subface of B^*, which means that $\boldsymbol{v}_i$ is bounded away by $c_d \operatorname{size}(B_{i+1})$ from B^* as argued in [12], because the neighborhoods $N(\cdot)$ defined earlier create an exclusion zone around B^*.

Let M_T be the $d \times d$ matrix associated with T defined above, with columns ordered according to the chain order. Because of (10.2), M_T, when scaled to unit box size, satisfies analogues of the inequalities that were developed in [12] in the case of unit box size.

In particular, let S_T be the $d \times d$ diagonal matrix whose ith entry is the box side length of the ith box face in the chain defining T. Then the matrix $N = M_T S_T^{-1}$

has its columns rescaled so that each column corresponds to a difference between two vertices in a unit-size cube. Slight generalizations of the bounds proved in [12] apply to N (actually, that paper considered the transpose N^{T}). In particular, the bounds in [12] imply that $\|N\|$ and $\|N^{-1}\|$ are at most c_d.

Since $\kappa(M_T) \leq \kappa(N)\kappa(S_T)$, we have from the last paragraph that $\kappa(M_T) \leq c_d\kappa(S_T)$. Note that all the box faces in a chain come from mutual neighboring cubes, so $\kappa(S_T) \leq r$. Therefore, $\kappa(M_T) \leq c_d r$. This argument has established the following theorem.

THEOREM 10.1. *Let $\rho_{\mathrm{QMG}}(P)$ denote the worst-case aspect ratio produced by QMG when applied to polyhedral domain P. Then there exist two neighboring protected boxes B, B' such that* $\mathrm{co}(B) \cap \mathrm{co}(B') \neq \emptyset$ *and such that*

$$\rho_{\mathrm{QMG}}(P) \leq c_d \cdot \mathrm{size}(B)/\,\mathrm{size}(B').$$

In subsequent sections, we bound the maximum box-size ratio in terms of the sharpest angle $\theta(P)$. The ultimate goal is Theorem 15.1, which bounds $\rho_{\mathrm{QMG}}(P)$ in terms of $\theta(P)$.

11. A bound on splitting for alignment.

As we saw in the preceding section, the aspect ratio of QMG can be bounded if we can bound the number of times boxes are split. The following is the key theorem about how many times a box can be split. The proof of Theorem 11.1 will be the topic of this and the next few sections.

THEOREM 11.1. *Let P be the input polyhedral region, whose sharpest angle is $\theta(P)$ defined by* (10.1). *Let B be a protected box produced by QMG. Then there exists an active box B_a that is an ancestor of B such that*

$$\mathrm{size}(B_a) \leq c_d\theta(P)^{-\phi(d)}\,\mathrm{size}(B), \tag{11.1}$$

where $\phi(d) = (d-1)(d-2)/2 + 1$, *and such that* $\mathrm{co}(B_a)$ *contains an incontractible path* Π *satisfying* $\mathrm{lth}(\Pi) \leq c_d\,\mathrm{size}(B_a)$. *We call B_a the* anchor *of B.*

Recall that QMG splits boxes in both the separation and alignment stages. The purpose of this section is to show that the amount of splitting for alignment is bounded by c_d, which is one step in the proof of Theorem 11.1. We start with two preliminary lemmas, which lead to the main result, Lemma 11.4, at the end of this section. That lemma is one step in the proof of Theorem 11.1.

LEMMA 11.2. *Let B be a box with a neighbor B' such that* $\mathrm{co}(B) \cap \mathrm{co}(B') \neq \emptyset$. *There is a constant c_d such that if* $\mathrm{size}(B') \leq c_d\,\mathrm{size}(B)$, *then* $\mathrm{co}(B') \subset \mathrm{co}(B)$.

Proof. Let $s = \mathrm{size}(B)$ and $s' = \mathrm{size}(B')$. Then $\mathrm{ex}(B)$ extends out by γs from all sides of B. Hence $\mathrm{ex}(B)$ contains any point within ∞-norm distance γs from B. In particular, if $(1+\gamma)s' \leq \gamma s$, then $\mathrm{ex}(B')$ would be completely contained in $\mathrm{ex}(B)$; let c_d in the lemma be this factor $\gamma/(1+\gamma)$. Let $\boldsymbol{x}$ be a point in $\mathrm{co}(B') \cap \mathrm{co}(B)$. Then every point in $\mathrm{co}(B')$ is reachable by a PL path in $\mathrm{co}(B')$ from $\boldsymbol{x}$. This means that all of $\mathrm{co}(B')$ is contained in the component of $P \cap \mathrm{ex}(B)$ that contains $\boldsymbol{x}$, which must be $\mathrm{co}(B)$. ∎

LEMMA 11.3. *Let B be a box that is split for alignment: in particular, say B is split during processing of O_F in phase k for some face F. Then there exists another active box B^* created by QMG such that* (1) $\mathrm{size}(B^*) = \mathrm{size}(B)$, (2) *$B^*$ was split before the phase k alignment stage (i.e., B^* was split during phases $0, \ldots, k-1$ or in the phase k separation stage), and* (3) *there is a PL path in P from* $\mathrm{co}(B)$ *to* $\mathrm{co}(B^*)$ *of length at most* $c_d\,\mathrm{size}(B)$.

Proof. Let us first prove the lemma for the simplified version of QMG in which all the boxes are full dimensional. In this case, the alignment condition was described in section 6 as follows: B is split for alignment because its high-priority close face, say, C, is not completely covered by (full-dimensional) boxes in the extended orbit of F the same size or larger when B is processed.

Consider the collection of boxes obtained by taking all boxes produced by any step of simplified QMG that are the same size as B. Consider also all those boxes larger than B that are leaf boxes (i.e., protected). Notice that this collection of boxes, say, Q, completely covers the input domain; some parts of $\mathbf{R}^d$ could be double covered because of duplication.

Let the enumeration of all boxes in Q that cover C be denoted $B_1, \ldots, B_m$; exclude B itself from this enumeration. Since F is close to C, F meets $N(C)$ and hence also $\mathrm{co}(B)$. Let $\boldsymbol{x}$ be a point where F meets $N(C)$. Among $B_1, \ldots, B_m$, consider only those B_i such that $\boldsymbol{x} \in \mathrm{co}(B_i)$. The case when $\boldsymbol{x} \notin \mathrm{co}(B_i)$ could occur only because of duplication; there could be duplicates of neighbors of B that do not contain $\boldsymbol{x}$.

Rename the remaining boxes again as $B_1, \ldots, B_m$; note that these boxes together with B must cover C. Since the alignment condition does not hold for B, one of them, say, B_i, is already split at the time B is processed. The box that is already split must have the same size as B (i.e., it cannot be one of the larger boxes in Q because those boxes are all protected). Without loss of generality, B_i is the earliest box among $B_1, \ldots, B_m$ to be split.

Case 1 is that this box B_i was split during a phase $0, \ldots, k-1$, or during phase k separation. In this case the lemma is proved with $B^* = B_i$; note that the two boxes contain $\boldsymbol{x}$ in their content so that condition (3) of the lemma is trivial.

The remaining case, case 2, is that B_i is split during the phase k alignment stage before B is processed. Rename B_i as B'. Note that since $\mathrm{co}(B')$ meets F, then B' must be in O_F. Since B' is the first box among $B_1, \ldots, B_m$ to be split during phase k alignment, C is still covered by boxes in the orbit of the same size or larger at the time the alignment condition is checked for B'. Let C' be the close face of B'. Note that C' is not covered by boxes in the orbit of the same size or larger, since we are assuming B' is split for alignment in phase k. It is not possible that $\dim(C') \geq \dim(C)$ because then C would have higher priority than C' and hence C' would not be selected as the close face of B'. (Recall that the priority rule favors faces of lower dimension and, among faces of the same dimension, favors faces completely covered by boxes in the orbit.) Thus, $\dim(C') < \dim(C)$. Start the proof of this lemma over again with B' and C'. In other words, consider the boxes in the quadtree at the level of B' that cover C'. Either for B' we will "exit" this argument in case 1 (i.e., we find a box B^* that satisfies the lemma for B'), or we will have to restart the argument another time.

But note that each time we restart the above argument, the dimension of the close face in question decreases by 1. Thus, we can repeat the argument at most d times before terminating at case 1. Let the sequence of boxes constructed by repeating this argument be $B, B', B'', \ldots, B^{(r)}, B^*$, where B^* is a box split before phase k alignment. Note that $r \leq d$ as just mentioned. Also, all boxes in this sequence are the same size, and $B^{(i)}$ is adjacent to $B^{(i+1)}$ for each i. Furthermore, $\mathrm{co}(B^{(r)})$ has a common point with $\mathrm{co}(B^*)$, and all of $B^{(1)}, \ldots, B^{(r)}$ are in O_F. This means that we can find a PL path in P from B to $B^{(r)}$ by traversing F through each box. (Recall that a box in O_F cannot meet any boundaries of F in its content.) The length of the PL path constructed in this manner is at most $c_d\,\mathrm{size}(B)$. This proves the lemma.

If we wanted to extend this proof to the case of the complete version of QMG (including lower-dimensional boxes), we would use the same proof as above, except that we would have to restate the meaning of "completely covered" in terms of the weight system mentioned in section 7. Because we have incompletely described the weight system and skipped the lemmas showing that lower-dimensional boxes do indeed act like proxies for the full-dimensional boxes that contain them, we do not have enough machinery to prove this lemma in the general case; hence we merely assert it. ∎

The preceding lemma now leads to the main result of this section, which says that during splitting for alignment, boxes can become only a constant factor smaller.

LEMMA 11.4. *Let B be a box that results from splitting for alignment during the processing of O_F for some k-face F. Then B is descended from an active box B' at the start of the phase k alignment stage such that* $\operatorname{size}(B') \le c_d \operatorname{size}(B)$.

Proof. Let B_0 be a parent of B, so that B_0 was split for alignment during the processing of O_F and so that $\operatorname{size}(B_0) = 2\operatorname{size}(B)$. By the preceding lemma, there is another box B^* that was either protected from an earlier phase or was split for separation such that there is a PL path Π in P from $\operatorname{co}(B^*)$ to $\operatorname{co}(B_0)$ of length at most $c_d \operatorname{size}(B_0)$.

Let B' be the ancestor of B_0 at the beginning of phase k alignment in O_F. Observe that there is a constant χ_d depending on d such that if B' satisfied $\operatorname{size}(B') \ge \chi_d \operatorname{size}(B_0)$, then $\operatorname{co}(B')$ would contain $\operatorname{co}(B^*)$ as a subset. This follows from the same proof technique used for Lemma 11.2; in particular, if B' were sufficiently larger than B_0, it would contain the whole path Π and also $\operatorname{co}(B^*)$.

On the other hand, it is impossible that $\operatorname{co}(B')$ contains $\operatorname{co}(B^*)$. This is because B^* was split for separation in phase k or was split in a phase earlier than k. Whatever P-faces caused B^* to be split would cause B' to be crowded, and hence B' could not end up in O_F.

Thus, we conclude $\operatorname{size}(B') < \chi_d \operatorname{size}(B_0)$, which proves the lemma. ∎

This lemma shows that all splitting for alignment can be lumped into the factor c_d in (11.1).

12. Splitting boxes for weak crowding.

Recall that a box is split for separation if and only if it is crowded. Recall also that there are two ways that B can be crowded in phase k: (1) $\operatorname{co}(B)$ contains a P-face of dimension $k-1$ or lower, or (2) $\operatorname{co}(B)$ contains a P-face F of dimension k, and another P-face G of dimension k or greater that is not a superface of F.

We call the former "weak crowding" and the latter "strong crowding." In this section we show that all splitting for weak crowding can also be lumped into the factor c_d in (11.1), which is another step toward proving Theorem 11.1.

LEMMA 12.1. *Let B be a box that is split for weak crowding; that is, in the phase k separation stage,* $\operatorname{co}(B)$ *meets a P-face of dimension $k-1$ or lower. Then B has an ancestor B_0 that is an active box at the beginning of phase k such that* $\operatorname{size}(B) \ge c_d \operatorname{size}(B_0)$.

Proof. The assumption implies that the P-face F of dimension $k-1$ or lower meets $\operatorname{ex}(B)$. Let B_0 be the ancestor of B from the beginning of phase k. We claim that B_0 can be at most a constant factor c_d larger than B. This is because the expansion factors for $\operatorname{ex}(B)$ and $\overline{\operatorname{ex}}(B)$ are off by a constant c_d. Recall that $\overline{\operatorname{ex}}(B)$ was defined in section 6 and is applied here with respect to face F. Therefore, the ancestor of B_0, if it is much larger than B, would contain this P-face F in $\overline{\operatorname{ex}}(B_0)$. Recall that if F meets $\overline{\operatorname{ex}}(B_0)$, then B_0 has a subface close to F. Hence B_0 would have been protected in phase $\dim(F)$, which is less than k, or would have been split for separation. Thus, B_0 is at most c_d larger than B. ∎

Thus, all splitting for weak crowding can also be lumped into the factor c_d in (11.1).

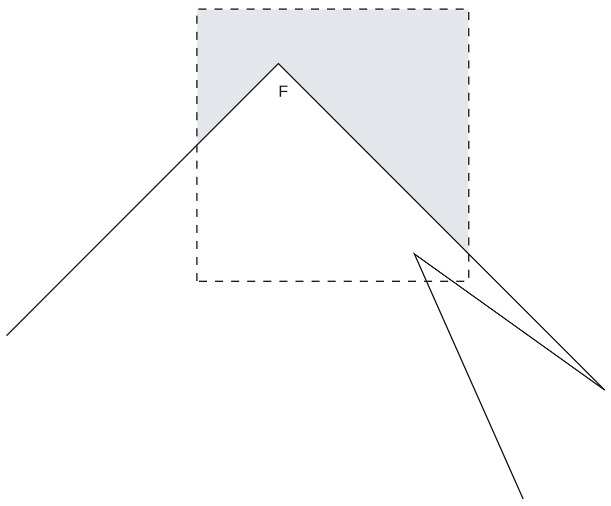

FIG. 13.1. *Lemma* 13.1 *in the case $k = d = 2$. Face F is a single vertex. The boundary of P is the solid line. The convex set C is the dashed square in the figure. The shaded region is U. Notice that every point in U is visible to F.*

13. Splitting for strong crowding.

13. Splitting for strong crowding. In this section we analyze splitting for strong crowding and finally prove Theorem 11.1. Recall that "strongly crowded" means that there is a P-face F of dimension k in co(B), and another P-face G of dimension $l \geq k$ in co(B) that is not a superface of F. From now on, we say that G is "foreign" to F if G is not a superface of F. We say that two points $\boldsymbol{x}$ and $\boldsymbol{y}$ are "visible" to each other with respect to P if segment $\boldsymbol{xy}$ lies in P. We start with two lemmas about visibility.

LEMMA 13.1. *Let P be a k-dimensional polyhedral domain in $\mathbf{R}^d$, and let C be a closed convex subset of $\mathbf{R}^d$. Suppose $P \cap C$ is not empty, and let U be a component of $P \cap C$. Suppose that U meets a P-face F and that U does not meet any faces of P that are foreign to F. Then every point in U is visible to every point in $F \cap U$, where "visibility" is with respect to U.*

See Figure 13.1 for an illustration of this lemma.

Proof. Let $\boldsymbol{x}$ be a point in $F \cap U$ and $\boldsymbol{y}$ a point in U. Consider the segment $L = \boldsymbol{xy}$; suppose that this segment is not contained in U. We will derive a contradiction. Since $\boldsymbol{y} \in U$ and U is closed, there must be some point $\boldsymbol{z} \in L$ different from $\boldsymbol{x}$ such that $\boldsymbol{z}$ is in U, but there is a sequence of points $\boldsymbol{z}_1, \boldsymbol{z}_2, \ldots$ lying on L and converging to $\boldsymbol{z}$ that are not in U. Note that all of these points lie in C because C is convex and L joins two points in C. Thus, since these points are not in $P \cap C$, we conclude that they are not in P. This means that there is at least one facet H of P (where "facet" refers to a face of dimension $k-1$) passing through $\boldsymbol{z}$ such that aff(H) does not contain L as a subset.

But this is impossible, because every facet of P meeting U in this component is a superface of F by assumption. This means in particular that for H in the last paragraph, $\boldsymbol{x} \in$ aff(H). But since aff(H) is convex and contains $\boldsymbol{x}$ and $\boldsymbol{z}$, it also contains L. ∎

LEMMA 13.2. *Let P be a k-dimensional polyhedral domain in $\mathbf{R}^d$, and let C be a closed convex subset of $\mathbf{R}^d$. Suppose $P \cap C$ is not empty, and let U be a component of $P \cap C$. Suppose that U meets a P-face F, and suppose that U also meets a face*

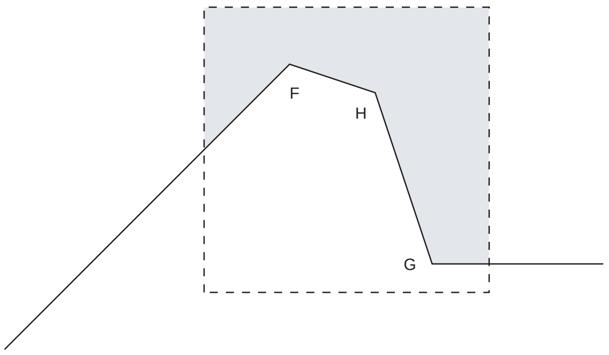

Fig. 13.2. *Lemma 13.2 for $d = 2$. Face F is a single vertex. The convex set C is the dashed square in the figure. The shaded region is U. Note that there is a vertex G of P that is foreign to F. This means that there is a face, namely, vertex H in U, that is also foreign to F but is visible to $F \cap U$.*

G of P foreign to F. Then for any point $\boldsymbol{x} \in F \cap U$, there is a point $\boldsymbol{y} \in U$ that is visible to $\boldsymbol{x}$ (with respect to U) such that $\boldsymbol{y}$ lies on a P-face foreign to F (which may or may not be G).

See Figure 13.2 for an illustration.

Proof. For $\lambda \in [0, 1]$, let $C(\lambda)$ denote the contraction by λ of C toward $\boldsymbol{x}$ (i.e., $\boldsymbol{v} \in C$ iff $\lambda\boldsymbol{v} + (1-\lambda)\boldsymbol{x} \in C(\lambda)$). Let $U(\lambda)$ be the component of $C(\lambda) \cap P$ that contains $\boldsymbol{x}$. Find the parameter value $\lambda^* > 0$, such that $U(\lambda^*)$ still meets a foreign face, but $U(\lambda^* - \epsilon)$ meets no faces foreign to F for all small $\epsilon > 0$. By the preceding lemma, every point in $U(\lambda^* - \epsilon)$ is visible to $\boldsymbol{x}$. Since the set of points visible to $\boldsymbol{x}$ is closed, this means that every point in $U(\lambda^*)$ is also visible to $\boldsymbol{x}$, and this set includes a point from a foreign face. $\square$

We now conclude the proof of Theorem 11.1. Let B be a protected box that is produced by QMG. Write down its sequence of ancestors $B_0, B_1, \ldots, B_r$, where $B_r = B$ and B_0 is the top box. This sequence is not necessarily unique if B_r is not full dimensional, in which case any sequence of ancestors will do. Now, delete boxes B_i in this sequence such that B_{i+1} arises from B_i via subface launching. Denote the new list $B_0, \ldots, B_r$ again. Each box is now a factor 2 smaller than its predecessor. From this list, delete boxes that are split either for alignment or for weak crowding, and denote the new list again as $B_0, B_1, \ldots, B_r$. This new list contains boxes that are split only for strong crowding, as well as the protected box B_r, which is not split. By Lemmas 11.4 and 12.1, in this new sequence of boxes, each box differs from its predecessor in size by a factor at most c_d.

Each box $B_0, \ldots, B_{r-1}$ is split during some phase 0 to $d - 1$. (There cannot be any strong crowding in phase d by definition of strong crowding.) Therefore, mark the location where each phase begins and ends in the sequence $B_0, \ldots, B_{r-1}$. This divides the sequence $B_0, \ldots, B_{r-1}$ into *periods*, where the kth period consists of boxes split during phase k.

Now subdivide each period into *subperiods*, using the following procedure. Focus on one particular period k, and suppose it starts at B_l and ends with B_m (i.e., B_l is the first box of the sequence split in phase k, and B_m is the last). Since B_m is strongly crowded, there is a k-face of P, say, F, meeting $\mathrm{co}(B_m)$, and there is another face G foreign to F meeting $\mathrm{co}(B_m)$. Pick a point $\boldsymbol{x} \in F \cap \mathrm{co}(B_m)$. Without loss of generality, by Lemma 13.2, we can assume that there is a segment in $\mathrm{co}(B_m)$ from $\boldsymbol{x}$

to a point $\boldsymbol{y} \in G$ (else choose a different G). Similarly, without loss of generality, $\boldsymbol{y}$ is not in any proper subface of G. (If $\boldsymbol{y}$ is in a proper subface of G, simply reselect G to be the subface: because G is foreign to F, every subface of G is also foreign to F.)

We will construct a PL path Π in $\mathrm{co}(B_m)$. The first segment of the path is $\boldsymbol{xy}$. Consider whether G has any boundary faces that meet $\mathrm{co}(B_m)$. If not, then the construction of Π is complete, and we let $\Pi = \boldsymbol{xy}$. The other case is that a boundary of G meets $\mathrm{co}(B_m)$. By Lemma 13.2, there is a segment in $\mathrm{co}(B_m)$ from $\boldsymbol{y}$ to a boundary face of G. (In this application of Lemma 13.2, the "polyhedral domain" in the lemma is G itself. Note that a boundary of G is foreign to G, i.e., is not a superface.) Append this new segment to Π. We can continue in this manner until we reach a point to which we will now reassign the name $\boldsymbol{y}$, such that $\boldsymbol{y}$ lies on P-face foreign to F, which we rename G, such that G does not have any boundaries that meet $\mathrm{co}(B_m)$. Note that $\mathrm{lth}(\Pi)$ is at most $d \cdot \sqrt{d}(1+\gamma)\,\mathrm{size}(B_m)$. The factor $\sqrt{d}(1+\gamma)\,\mathrm{size}(B_m)$ is the diameter of $\mathrm{ex}(B_m)$ (in the worst case when B_m is full dimensional) and hence is the maximum length of any segment in $\mathrm{co}(B_m)$, and the factor d comes from the fact that Π has at most d segments in it. This is because in the preceding construction of Π, each time a new segment is added, the dimension of the boundary face in question decreases by at least 1. Thus, $\mathrm{lth}(\Pi) \le c_d\,\mathrm{size}(B_m)$.

Note that $\Pi \subset \mathrm{co}(B_i)$ for each $i = l, \ldots, m$, since $\mathrm{co}(B_m) \subset \mathrm{co}(B_{m-1}) \subset \cdots \subset \mathrm{co}(B_l)$. On the other hand, in an ancestor of B_m, it might be possible to extend Π with one or more additional segments so that it reaches a lower-dimensional boundary face of G. Find the lowest numbered box B_q (largest in size) in the period $B_l, \ldots, B_m$ such that it is *not* possible to extend Π to a P-face of lower dimension that is a boundary of G. We will say that the subsequence $B_q, B_{q+1}, \ldots, B_m$ is one *subperiod* of period k. Each box in this subperiod is associated with the quintuple $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ defined in the last paragraph. If $q = l$, we are done; this is the only subperiod of period k.

On the other hand, if $q > l$, then in B_{q-1} it is possible to extend Π to reach a face of lower dimension than was reached in B_q. Extend Π with one or more additional segments, yielding a path Π' to a face G' that is a proper subface of G. Now we repeat the above argument to find the predecessor of B_{q-1}, say, $B_{q'}$, such that Π cannot be extended in $B_{q'}$ but can be extended in $B_{q'-1}$ (or else $q' = l$), and we let $B_{q'}, B_{q'+1}, \ldots, B_{q-1}$ be another subperiod of period k, associated with $(\boldsymbol{x}, \boldsymbol{y}', F, G', \Pi')$. We continue in this manner until we finally get back to B_l. The maximum number of subperiods in period k is seen to be $d - k$. The reason is that each time we back up to a new subperiod, the dimension of the face reached by Π decreases by at least 1. The maximum possible dimension of G initially is $d - 1$, and the minimum possible dimension is k (because no box among $B_l, \ldots, B_m$ is weakly crowded).

Thus, we have divided the sequence of boxes $B_0, \ldots, B_{r-1}$ into at most d periods numbered $0, \ldots, d-1$, and period k is divided into at most $d - k$ subperiods. We have also associated with each box a choice of $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$.

Now we can classify each box in the sequence according to whether its associated path Π is contractible or not. Let B_a be the highest numbered (smallest) box in $B_0, \ldots, B_{r-1}$ such that its associated path is incontractible. (Notice that B_a exists because B_0 certainly satisfies this condition.) Thus, B_a satisfies the conditions of Theorem 11.1 that it contains an incontractible path of length at most $c_d\,\mathrm{size}(B_a)$, and that it is an ancestor of B. All that remains is to establish (11.1). Note that the anchor box must be the last one in its subperiod, because all boxes in a subperiod have the same associated path. From now on, we consider only the portion $B_a, \ldots, B_r$

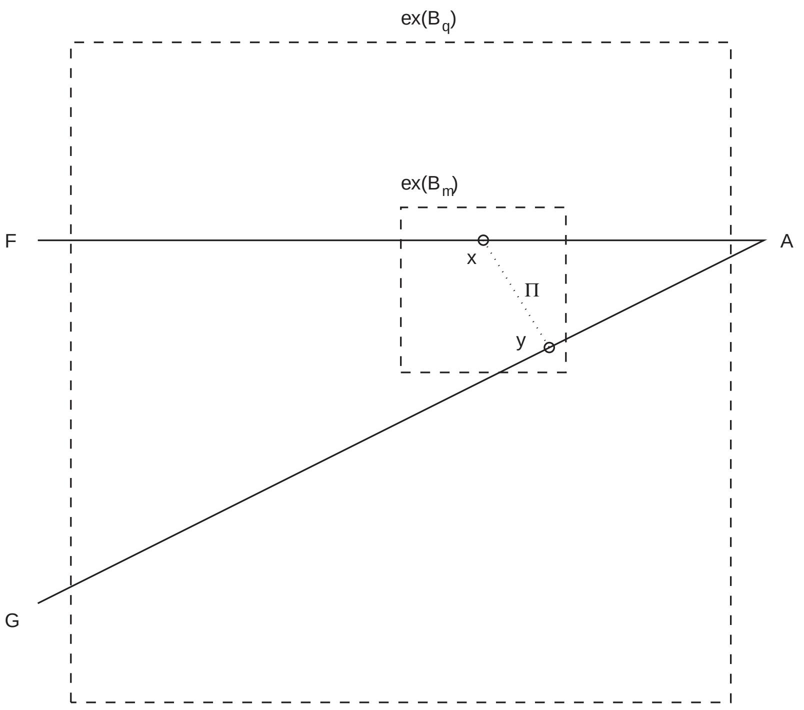

FIG. 13.3. *Items $\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi, A$ arising in the proof of* (13.1). *The boundaries of* $\mathrm{ex}(B_q)$ *and* $\mathrm{ex}(B_m)$ *are the dashed lines. In this figure A is zero dimensional and is equal to $F \cap G$, but in general A will be a superset of $F \cap G$.*

of the original sequence.

We start with the following intermediate result. Let B_m be a box in the sequence with $m > a$, and suppose it is contained in a subperiod beginning with B_q (so $a < q \leq m$). Then we claim

$$\mathrm{size}(B_m) \geq c_d \cdot \theta(P) \cdot \mathrm{size}(B_q). \tag{13.1}$$

Let us assume that B_m is a proper descendent of B_q because when $m = q$, (13.1) is trivially true. Let $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ be the quintuple associated with B_m; by definition of subperiod, the same quintuple is associated with B_q. Since Π is contractible (by choice of B_a), $F \cap G$ is nonempty. Let A denote $\mathrm{aff}(F) \cap \mathrm{aff}(G)$. We claim that A does not meet $\mathrm{ex}(B_q)$. See Figure 13.3 for an illustration of the items constructed in the proof of this claim. Note that no boundary face of F meets $\mathrm{co}(B_q)$, because $\mathrm{co}(B_q)$ does not meet any P-faces of dimension $k-1$ or less (because it is not weakly crowded). Thus, $\mathrm{co}(B_q)$ must contain all of $\mathrm{aff}(F) \cap \mathrm{ex}(B_q)$. Similarly, $\mathrm{co}(B_q)$ does not contain any boundary faces of G by construction of Π (else Π could be extended). Thus, $\mathrm{co}(B_q)$ also contains all of $\mathrm{aff}(G) \cap \mathrm{ex}(B_q)$. Suppose that $\mathrm{aff}(F) \cap \mathrm{aff}(G)$ met $\mathrm{ex}(B_q)$; then $\mathrm{co}(B_q)$ would have to contain all of $\mathrm{aff}(F) \cap \mathrm{aff}(G) \cap \mathrm{ex}(B_q) = A \cap \mathrm{ex}(B_q)$ by the foregoing argument. In particular, F and G would meet in $\mathrm{co}(B)$ at all points in $A \cap \mathrm{ex}(B_q)$. But this is impossible, because neither has any boundaries in $\mathrm{co}(B_q)$.

Since A does not meet $\mathrm{ex}(B_q)$, there is a lower bound of the form $c_d\,\mathrm{size}(B_q)$ on the distance from A to $\mathrm{ex}(B_m)$. This is because $\mathrm{ex}(B_q)$ extends a small fraction c_d multiplied by $\mathrm{size}(B_q)$ beyond $\mathrm{ex}(B')$ for any proper descendant B' of B_q. In particular, this means $\operatorname{dist}(\boldsymbol{x}, A) \geq c_d \operatorname{size}(B_q)$ and $\operatorname{dist}(\boldsymbol{y}, A) \geq c_d \operatorname{size}(B_q)$. On the other hand, $\operatorname{lth}(\Pi) \leq c_d \operatorname{size}(B_m)$, as argued above. Thus, in the definition of sharp angle (9.1) applied to $(\boldsymbol{x}, \boldsymbol{y}, \Pi)$, we see that F and G make an angle less than or equal to $c_d \operatorname{size}(B_m)/\operatorname{size}(B_q)$. Since $\theta(P)$ is the sharpest angle,

$$\theta(P) \leq c_d \operatorname{size}(B_m)/\operatorname{size}(B_q).$$

This equation proves (13.1).

We now deduce (11.1) from (13.1). If B_q is the beginning of a subperiod with $q > a$, and B_m is its end, then $\operatorname{size}(B_q) \leq c_d\theta(P)^{-1} \operatorname{size}(B_m)$ from (13.1). Thus, if ϕ stands for the total number of subperiods between B_{a+1} and B_r, then $\operatorname{size}(B_a) \leq (c_d\theta(P))^{-\phi} \operatorname{size}(B_r)$, where $c_d^{-\phi}$ accounts for the factor in box size shrinkage between the end of one subperiod and the beginning of the next, and $\theta(P)^{-\phi}$ accounts for box shrinkage within the ϕ subperiods. Since there are at most $d - k$ subperiods in period k, the total number of subperiods ϕ can be bounded $\phi(d) = d(d+1)/2$. Thus, $\operatorname{size}(B_a) \leq c_d\theta(P)^{-d(d+1)/2} \operatorname{size}(B_r)$ (where we have renamed $c_d^{-\phi(d)}$ as c_d).

In fact, we can immediately improve this estimate on $\phi(d)$ with the following observation. Note that if B_i is in period 0, then its path Π constructed above cannot be contractible. This is because F in phase 0 is a vertex and hence is disjoint from any foreign face G. Thus, the anchor box B_a either is the last box of period 0 or is in a later period. This means that the only subperiods that matter are in period 1 or later. Thus, we can improve the estimate to $\phi(d) = (d-1)d/2$.

We can further improve the estimate to (13.2) below with the following more complicated analysis. We claim that in period 1, a single subperiod suffices. The proof is as follows. Assume that the anchor box is in period 0 or 1 (else we would not need to include subperiods of period 1 in the count of ϕ, so (13.2) holds already). Let us review why we constructed subperiods in the first place. Let B_m be the box at the end of a subperiod, let $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ be its associated quintuple such that Π is contractible, and let B_q be the first box in the subperiod ending at B_m. In the above derivation of (13.1), we used the fact $\operatorname{aff}(F) \cap \operatorname{aff}(G)$ cannot meet $\operatorname{ex}(B_q)$. To derive this fact, we needed to know that G does not have any boundaries in $\operatorname{co}(B_q)$. The above method of constructing subperiods indeed assures that G does not have boundaries in $\operatorname{co}(B_q)$.

But consider the special case of period 1, so that $\dim(\operatorname{aff}(F)) = 1$. Let B_m be the last box in period 1, and redefine B_q to be the first box of period 1, or the child of the anchor B_a, whichever comes later. Let $(\boldsymbol{x}, \boldsymbol{y}, F, G, \Pi)$ be the quintuple for B_m. Since $\dim(F) = 1$, $\dim(\operatorname{aff}(F) \cap \operatorname{aff}(G))$ is either 0 or 1. The case when $\dim(\operatorname{aff}(F) \cap \operatorname{aff}(G)) = 1$ cannot occur by the way we construct Π. In particular, if $\dim(\operatorname{aff}(F) \cap \operatorname{aff}(G)) = 1$, then $\operatorname{aff}(F) \subset \operatorname{aff}(G)$, which means that G either is a superface of F (contradicting the choice of G as a foreign face) or has a boundary in $\operatorname{co}(B_m)$ (contradicting the fact that Π reaches a face of minimal dimension).

The other case is that $\dim(\operatorname{aff}(F) \cap \operatorname{aff}(G)) = 0$; in other words, $\operatorname{aff}(F) \cap \operatorname{aff}(G)$ is a single point $\{\boldsymbol{v}\}$. Since Π is contractible, F and G have a common subface which must therefore be $\{\boldsymbol{v}\}$ itself. Thus $\{\boldsymbol{v}\}$ is a face of P. But since B_q is not weakly crowded, $\operatorname{co}(B_q)$ cannot contain a 0-dimensional face of P. Thus, without making any assumption about whether G has boundaries in $\operatorname{co}(B_q)$, we have determined that $\operatorname{aff}(F) \cap \operatorname{aff}(G)$ does not meet $\operatorname{ex}(B_q)$. Therefore, a single subperiod suffices for period 1.

Thus, we have the following improved estimate for ϕ, which is the total number

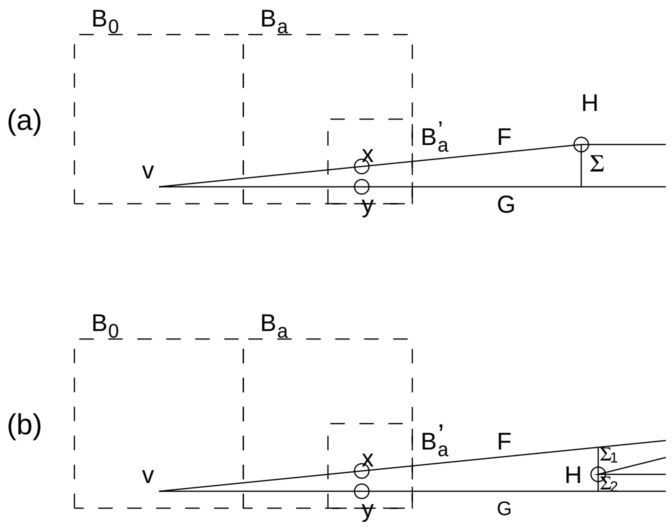

FIG. 13.4. *Faces arising in the proof of the strengthened version of Corollary* 13.3 *when* $d = 2$. *Box* B *and path* Π *are not depicted; both are enclosed in* B'_a *in the figure.*

of subperiods after B_a:

$$\phi(d) = (d-1)(d-2)/2 + 1. \tag{13.2}$$

This concludes the proof of Theorem 11.1.

Notice that by combining Theorems 9.4 and 11.1 we immediate obtain the following corollary.

COROLLARY 13.3. *Let* B *be a protected box generated by QMG. Then there exists an ancestor* B_a *of* B *such that* (11.1) *holds and such that for any triangulation* $\mathcal{T}$ *of* P*, there is a simplex* T *meeting* $\operatorname{co}(B_a)$ *such that* $\operatorname{minalt}(T) \le c_d \operatorname{size}(B_a)$.

In fact, we can strengthen Corollary 13.3 (though not Theorem 11.1) in the case $d = 2$. The strengthened version of Corollary 13.3 asserts that

$$\operatorname{size}(B_a) \le c \operatorname{size}(B) \tag{13.3}$$

holds when $d = 2$, in place of (11.1) (i.e., the factor of $\theta(P)^{-1}$ goes away). The argument for this strengthening is as follows. In the following argument, c denotes an absolute constant whose value may change from formula to formula.

Consider how the factor $\theta(P)^{-1}$ arises in the first place. Let B be a protected box and B_a its anchor. This factor comes when anchor B_a is from period 0, and then in period 1 we split a strongly crowded box that has a contractible path that defines a sharp angle θ. Since (11.1) and (13.3) are equivalent when $\theta(P)$ is large, let us assume that $\theta \le 0.1$. Let B'_a be the last box that is split for strong crowding at the end of period 1. Clearly (13.3) holds for this choice of B'_a (since splitting for alignment, as well as all splitting in phase 2, incurs only an additional factor c). The contractible path Π in B'_a is from $\boldsymbol{x}$ to $\boldsymbol{y}$. See Figure 13.4. We now must prove that for an arbitrary triangulation $\mathcal{T}$, there is a simplex T meeting Π satisfying $\operatorname{minalt}(T) \le c_d \operatorname{size}(B'_a)$.

In the figure, B_0 denotes a protected box for $\boldsymbol{v}$, the common subface of F and G. Note that there must be an incontractible path from $\boldsymbol{v}$ to a foreign face H whose length is at most a factor c more than $\operatorname{size}(B_0)$ by the preceding analysis. Thus, $\boldsymbol{x}$

and $\boldsymbol{y}$ must both be separated from $\boldsymbol{v}$ by at least $c_d \operatorname{dist}(\boldsymbol{v}, H)$. There are two possible ways to choose H; either it is a subface of one of F or G, which is (a) in the figure, or it is does not meet F and G, which is (b) in the figure.

Let $\mathcal{T}$ be an arbitrary triangulation. Let $T_1, \ldots, T_s$ be the triangles of T that meet Π. Take two cases. In the first case, suppose that at least one of $T_1, \ldots, T_s$, say, T_1, meets the segment denoted by Σ in (a) or that it meets the PL path $\Sigma_1 \cup \Sigma_2$ in (b). Since $\Sigma, \Sigma_1, \Sigma_2$ are all incontractible, this means by Theorem 9.4 that $\operatorname{minalt}(T_1) \le c \operatorname{lth}(\Sigma)$ for (a) or $\operatorname{minalt}(T_1) \le c \operatorname{lth}(\Sigma_1 \cup \Sigma_2)$ for (b). But now it is clear that $\operatorname{lth}(\Sigma), \operatorname{lth}(\Sigma_1), \operatorname{lth}(\Sigma_2)$ are all at most $c\theta \operatorname{dist}(\boldsymbol{v}, H)$, that is, less than or equal to $c \operatorname{size}(B'_a)$. Thus, $\operatorname{minalt}(T_1) \le c \operatorname{size}(B'_a)$, proving the corollary.

The other case is that none of $T_1, \ldots, T_s$ meet Σ in (a) or $\Sigma_1 \cup \Sigma_2$ in (b). But this means all of $T_1, \ldots, T_s$ are contained in the polygonal region bounded by $F \cup G \cup \Sigma$ in (a) or $F \cup G \cup \Sigma_1 \cup \Sigma_2$ in (b). The width of this polygonal region is at most $c \operatorname{size}(B'_a)$, so any triangle in this region has minalt at most $c \operatorname{size}(B'_a)$. This concludes the proof that Corollary 13.3 may be strengthened in the case $d = 2$.

14. Maximizing the minimum altitude.

In this section we consider the problem of computing a triangulation that maximizes the minimum altitude. Although this is not the problem for which QMG is intended, we nonetheless can obtain an interesting consequence from Corollary 13.3. Suppose we want to compute the triangulation of P that maximizes the minimum altitude. In other words, for a triangulation $\mathcal{T}$ of P, define

$$\mu_{\mathcal{T}}(P) = \min\{\operatorname{minalt}(T) : T \in \mathcal{T}\}$$

and then consider the triangulation $\mathcal{T}^*$ that solves

$$\mu(P) = \max\{\mu_{\mathcal{T}}(P) : \mathcal{T} \text{ is a triangulation of } P\}.$$

It follows from Corollary 13.3 that QMG solves this problem to within a factor $c_d \theta(P)^{-\phi(d)}$ for $d > 2$ and within a factor c (a universal constant) when $d = 2$. This is because the minimum altitude among all triangles produced by QMG is within a factor c_d of the smallest protected box generated by QMG. But, by the corollary, the smallest protected box is within a factor of $c_d \theta(P)^{-\phi(d)}$ of the minimum altitude of any possible triangulation.

Thus, in the case $d = 2$, $\mu_{\text{QMG}}(P) \ge c\mu(P)$, and for $d = 3$, $\mu_{\text{QMG}}(P) \ge c\theta(P)^2 \mu(P)$. In the case $d = 2$, more is known about this problem. In particular, the algorithm of Bern, Dobkin, and Eppstein [2] produces a triangulation $\mathcal{T}$ also satisfying $\mu_{\mathcal{T}}(P) \ge c\mu(P)$, and also $\mathcal{T}$ has an optimal (linear) number of triangles.

In the case $d = 3$, much less is known. For instance, we do not know whether the bound $c\theta(P)^{-2}$ is tight for QMG. We have constructed an example where the minimum altitude of the triangulation produced by QMG is off from $\mu(P)$ by a factor $c\theta(P)^{-1}$, but we have not found an example attaining the bound $c\theta(P)^{-2}$.

Another open question concerns a geometric characterization of $\mu(P)$. It follows from the optimality of QMG in the case $d = 2$ that $\mu(P)$ is within a constant factor of the minimum geodesic distance between P-faces that do not meet each other. Is there a similar simple geometric characterization of $\mu(P)$ for $d = 3$? For any d, Theorem 9.4 implies that the minimum geodesic distance between two nonmeeting faces of P is an upper bound on $\mu(P)$ (to within a constant c_d), but it is not known whether this bound is tight.

15. A bound on the QMG aspect ratio. This section establishes the optimality of the QMG aspect ratio using Theorem 11.1 and Corollary 13.3.

THEOREM 15.1. *Let $\rho_{\mathrm{QMG}}(P)$ denote the worst-case aspect ratio produced by QMG when applied to polyhedral domain P. Then*

$$\rho_{\mathrm{QMG}}(P) \le c_d \theta(P)^{-\phi(d)}.$$

Proof. Let B_1, B_2 be two neighboring protected boxes such that $\mathrm{co}(B_1)$ and $\mathrm{co}(B_2)$ have a common point. Assume that B_1 is protected in phase k and lies in O_F, assume B_2 is protected in phase l and lies in O_G, and assume $\mathrm{size}(B_1) > \mathrm{size}(B_2)$. By Theorem 10.1, it suffices to obtain an upper bound on $\mathrm{size}(B_1)/\,\mathrm{size}(B_2)$.

We can assume that $\mathrm{co}(B_2) \subset \mathrm{co}(B_1)$. If this relation did not hold, then by Lemma 11.2 we could immediately conclude that there is a bound of the form c_d on $\mathrm{size}(B_1)/\,\mathrm{size}(B_2)$.

By Theorem 11.1, B_2 has an anchor B_a containing an incontractible path such that

$$c_d \theta(P)^{-\phi(d)}\,\mathrm{size}(B_2) \ge \mathrm{size}(B_a). \tag{15.1}$$

Because B_1 is protected, every point in $\mathrm{co}(B_1)$ is visible to every point in $F \cap \mathrm{co}(B_1)$ by Lemma 13.1, and this includes $\mathrm{co}(B_2)$ as well. Therefore, any PL path inside $\mathrm{co}(B_1)$ is contractible to any point of $F \cap \mathrm{co}(B_1)$. Since $\mathrm{co}(B_a)$ contains an incontractible path, it cannot be a subset of $\mathrm{co}(B_1)$. Hence, $\mathrm{size}(B_a) \ge c_d\,\mathrm{size}(B_1)$. Combining this with (15.1) shows that $\mathrm{size}(B_1)/\,\mathrm{size}(B_2) \le c_d \theta(P)^{-\phi(d)}$. ◻

When $d = 2$, Theorem 15.1 shows that QMG is optimal because we already know that for any triangulation $\mathcal{T}$, $\rho_{\mathcal{T}}(P) \ge c\theta(P)^{-1}$ by Theorem 9.2, and $\phi(2) = 1$.

When $d = 3$, Theorem 15.1 shows that QMG has an aspect ratio bound of $c\theta(P)^{-2}$, whereas the lower bound from Theorem 9.2 is $c\theta(P)^{-1}$. In fact, a more complicated analysis of QMG for the $d = 3$ case establishes an upper bound of $c\theta(P)^{-1}$ on $\rho_{\mathrm{QMG}}(P)$. Here is a sketch of this analysis. Recall that the only case that needs attention is the case of a large protected box B_1 next to a much smaller protected box B_2, such that $\mathrm{co}(B_2) \subset \mathrm{co}(B_1)$. Suppose, for instance, that B_1 is protected in phase 0 (a similar argument applies to the case when B_1 is protected in phase 1), and suppose that B_2 is protected in phases 1 or 2. Find the largest ancestor B^* of B_2 with the property that $\mathrm{co}(B^*) \subset \mathrm{co}(B_1)$; as above, $\mathrm{size}(B_1)/\,\mathrm{size}(B^*) \le c$. Consider the chain of strongly crowded boxes from B^* down to B_2. Let P' be the intersection of P with the facet of B_1 separating it from B^*. Observe that splitting strongly crowded boxes in phases 1 and 2 of three-dimensional (3D) QMG applied to the chain of boxes B^* down to B_2 is very similar to phases 0 and 1 of 2D QMG running on the polygon P'. In other words, with a correct modification to the definition of $\mathrm{ex}(B)$ in two dimensions, whenever a 3D box on the boundary of B_1 is split for strong crowding, the corresponding 2D box would be split for strong crowding of P'.

Since 2D QMG is optimal with respect to maximizing the minimum altitude, we conclude that $\mathrm{size}(B_2)$ is bounded below by the minimum geodesic distance δ in P' between two faces that do not meet. But now it is easy to see that $\delta/\,\mathrm{size}(B_1)$ is bounded above by the sharpest angle θ at $\boldsymbol{v}$. Thus, $\mathrm{size}(B_1)/\,\mathrm{size}(B_2) \le c\theta(P)^{-1}$.

It is likely that this line of reasoning extends to higher dimensions, although we do not know the exact improvement to Theorem 15.1 possible with this analysis. Furthermore, we do not know whether our lower bound from Theorem 9.2 on the best attainable aspect ratio is tight in dimensions higher than 3.

We can summarize the conclusions of this section with the following theorem.

THEOREM 15.2. *Let $\mathcal{T}$ be an arbitrary triangulation of P with worst-case aspect ratio denoted $\rho_{\mathcal{T}}(P)$. Then*

$$\rho_{\mathrm{QMG}}(P) \le c_d \cdot (\rho_{\mathcal{T}}(P))^{\psi(d)},$$

where $\psi(d) = 1$ for $d = 2, 3$ and $\psi(d) \le \phi(d)$ for higher dimensions.

16. Bounded aspect ratio triangulations.

In the preceding section we showed that the QMG triangulation has an aspect ratio bound. In the next section we will show that, among all triangulations with bounded aspect ratio, QMG has the minimum cardinality, up to a constant factor. First, we present some preliminary lemmas that apply generally to any triangulation with bounded aspect ratio.

LEMMA 16.1. *Let $\mathcal{T}$ be a triangulation of a polyhedral region P whose aspect ratio is at most ρ. Let T_1, T_2 be two simplices that share a common vertex $\boldsymbol{v}$. Then* $\operatorname{minalt}(T_1) \le \zeta_1(\rho, d) \operatorname{minalt}(T_2)$, *where the function $\zeta_1(\cdot,\cdot)$ is defined below.*

We omit the proof of this lemma, which is contained in [10]. Here is a sketch. Two simplices S_1, S_2 of $\mathcal{T}$ that share an edge $\boldsymbol{v}_1\boldsymbol{v}_2$ satisfy $\operatorname{minalt}(S_1) \le \rho \operatorname{minalt}(S_2)$ by the chain of inequalities:

$$\begin{aligned} \operatorname{minalt}(S_1) &\le \|\boldsymbol{v}_1 - \boldsymbol{v}_2\| \\ &\le \operatorname{maxside}(S_2) \\ &= \operatorname{asp}(S_2) \operatorname{minalt}(S_2) \\ &\le \rho \operatorname{minalt}(S_2). \end{aligned} \tag{16.1}$$

Two simplices T_1, T_2 that share a vertex $\boldsymbol{v}$ are connected by a chain of simplices $S_1 (= T_1), S_2, \ldots, S_p (= T_2)$ that all share $\boldsymbol{v}$ and such that S_i and S_{i+1} have a common edge. This is because $\mathcal{T}$ is a triangulation of P, which is a manifold with boundary. It can be shown that the number of simplices p that can share a common vertex is bounded above in terms of ρ because the solid angle of each S_i at $\boldsymbol{v}$ is bounded below in terms of ρ. Thus, p is bounded above in terms of ρ: it turns out that $p \le c_d \rho^{d-1}$. Thus, the lemma is true with $\zeta_1(\rho, d) = \rho^{c_d \rho^{d-1}}$.

Now for the first result of the section. This lemma bounds the rate at which simplices can grow in a bounded aspect ratio triangulation.

LEMMA 16.2. *Let $\mathcal{T}$ be a triangulation of P whose aspect ratio bound is ρ. Let Π be a PL path in P from $\boldsymbol{x}$ to $\boldsymbol{y}$. Suppose that $\boldsymbol{x}$ is contained in a simplex T. Then every simplex T' containing $\boldsymbol{y}$ satisfies*

$$\operatorname{minalt}(T') \le c_d \zeta_1(\rho, d) \max(\operatorname{minalt}(T), \operatorname{lth}(\Pi)). \tag{16.2}$$

Proof. Let $F_1, \ldots, F_s$ be an enumeration of the faces of $\mathcal{T}$ met by Π. Let F_s be the lowest-dimensional face of $\mathcal{T}$ containing $\boldsymbol{y}$.

Case 1. *F_s has a vertex in common with T.* Since every simplex containing $\boldsymbol{y}$ also contains F_s, then T' has a common vertex with T. In this case the lemma is true with the first term of the max in (16.2) by the preceding lemma.

Case 2. *F_s does not have a vertex in common with T.* In this case, define a PL continuous function $f : P \to \mathbf{R}$ that is 1 on vertices of F_s and 0 on all other vertices and is linearly interpolated by $\mathcal{T}$. Then, as in the proof of Theorem 9.4, there must be a simplex S that meets Π such that the gradient of f on S is at least $1/\operatorname{lth}(\Pi)$, and hence this simplex satisfies $\operatorname{minalt}(S) \le c_d \operatorname{lth}(\Pi)$. Notice that S and F_s must have a common vertex because if not, the gradient of f on S would be 0. Since S and

T' have a common vertex, we apply the preceding lemma to bound $\text{minalt}(T')$ by the second term of the max in (16.2), proving the lemma. $\square$

Here is our other main result about bounded aspect ratio triangulations.

LEMMA 16.3. *Let C be a cube in $\mathbf{R}^d$ of side length s. Let $T_1, \ldots, T_n$ be a set of n simplices with pairwise disjoint interiors, satisfying* $\text{minalt}(T_i) \geq \mu$ *and* $\text{asp}(T_i) \leq \rho$ *for each i. Suppose each T_i meets C. Then*

$$n \leq c_d \rho^d + c_d s^d / \mu^d. \tag{16.3}$$

Proof. For each T_i, identify a point $\boldsymbol{x}_i \in T_i \cap C$. Now contract each T_i about $\boldsymbol{x}_i$ until we obtain a new simplex T_i' such that $\text{minalt}(T_i') = \mu$. Since $T_i' \subset T_i$, the set $T_1', \ldots, T_n'$ still enjoys the property that interiors are pairwise disjoint. Since $\boldsymbol{x}_i \in T_i'$, each T_i' still meets C. Finally, contraction affects maxside and minalt by the same scale factor, so $\text{asp}(T_i') = \text{asp}(T_i)$.

We know that $\text{maxside}(T_i') = \text{asp}(T_i')\,\text{minalt}(T_i') \leq \rho\mu$. Therefore, for every point $\boldsymbol{y}$ in T_i', $\text{dist}(\boldsymbol{y}, \boldsymbol{x}_i) \leq \rho\mu$. Let $\boldsymbol{x}_0$ be the centroid of C. Then we have for each i that $\text{dist}(\boldsymbol{x}_i, \boldsymbol{x}_0) \leq c_d s$. Combining these inequalities yields the bound that for every point $\boldsymbol{y} \in T_i'$ for each i, $\text{dist}(\boldsymbol{y}, \boldsymbol{x}_0) \leq \rho\mu + c_d s$. Thus, all of $T_1', \ldots, T_n'$ are contained in a ball B of radius $\rho\mu + c_d s$ around $\boldsymbol{x}_0$. The volume of this ball is at most $c_d(\rho^d\mu^d + s^d)$. Each simplex has volume at least $c_d\mu^d$ by equation (8.1). Since the simplices have disjoint interiors, their number is bounded above by $\text{vol}(B)/(c_d\mu^d)$, which proves the lemma. $\square$

17. A bound on the cardinality of QMG.

In this section we show that the cardinality of the triangulation produced by QMG is always within a constant factor of optimal among all bounded aspect ratio triangulations, where the constant depends on the aspect ratio. We start with the following lemma.

LEMMA 17.1. *Let $\boldsymbol{x}$ be an arbitrary point in P, and let T be the simplex generated by QMG that contains $\boldsymbol{x}$. (If there is more than one, the result holds for any choice of T.) Let $\mathcal{S}$ be some other triangulation of P with aspect ratio bound $\rho_{\mathcal{S}}$, and let S be the simplex in $\mathcal{S}$ that contains $\boldsymbol{x}$. (If there is more than one, then the result holds for any choice of S.) Then*

$$\text{minalt}(S) \leq c_d \zeta_1(\rho_{\mathcal{S}}, d) \cdot \theta(P)^{-(2d+2)\phi(d)} \cdot \text{minalt}(T). \tag{17.1}$$

Proof. Recall that each simplex generated by QMG is associated with a full-dimensional protected box, namely, the last box in its chain. Furthermore, each full-dimensional protected box is associated with a full-dimensional anchor box as in Theorem 11.1. Therefore, transitively, each simplex generated by QMG is associated with an anchor box.

Let T be such a simplex, and B_a its anchor box. Clearly

$$\text{minalt}(T) \leq c_d \,\text{size}(B_a), \tag{17.2}$$

since T lies in $\text{ex}(B_a)$. On the other hand, there is also an inequality in the other direction. The reason is as follows. Let B be the full-dimensional protected box containing T. Then, as argued in section 10, $\text{minalt}(T)$ is bounded below by the size of the smallest neighbor of B, which, by the proof of Theorem 15.1, is bounded below by $c_d\theta(P)^{\phi(d)}\,\text{size}(B)$. There is a lower bound on $\text{size}(B)$ in terms of $\text{size}(B_a)$ given by (11.1). Combining these bounds yields

$$\text{minalt}(T) \geq c_d \theta(P)^{2\phi(d)}\,\text{size}(B_a). \tag{17.3}$$

Let $\boldsymbol{x}$ be the arbitrary point in P specified by the lemma. Let T be the simplex generated by QMG that contains $\boldsymbol{x}$, let B be the protected box associated with T, and let B_a be the anchor of B. In the next few paragraphs we will construct a PL path Σ from $\boldsymbol{x}$ to a simplex $\bar{S} \in \mathcal{S}$ satisfying $\text{minalt}(\bar{S}) \leq \text{size}(B_a)$ and such that $\text{lth}(\Sigma)$ is bounded above in terms of $\text{size}(B_a)$.

Observe that $\text{co}(B_a)$ contains an incontractible path Π_1 by definition of "anchor." Therefore, let S_1 be the simplex in $\mathcal{S}$ that meets Π_1 and satisfies $\text{minalt}(S_1) \leq c_d \, \text{size}(B_a)$, as specified in Theorem 9.4. Let $\boldsymbol{y}$ be a point in $\Pi_1 \cap S_1$. Construct the shortest PL path (the geodesic path) from $\boldsymbol{x}$ to $\boldsymbol{y}$ lying in $\text{co}(B_a)$, and call it Σ_1. Note that there is no a priori upper bound on $\text{lth}(\Sigma_1)$ in terms of $\text{size}(B_a)$ because $\text{co}(B_a)$ could contain geodesic paths possibly much longer than $\text{size}(B_a)$.

Let $T_1, T_2, \ldots, T_p$ be an enumeration of the QMG simplices met by Σ_1, listed in the order they are encountered starting with $\boldsymbol{x}$. Note that no simplex can appear twice in this enumeration; this is because Σ_1 is a geodesic path and therefore would not return to the same simplex more than once.

Let T_q be the first simplex in the sequence that fails to satisfy (17.3). If there is no such q, then take $q = p + 1$. Thus, $T_1, \ldots, T_{q-1}$ all satisfy (17.3). We claim that $q - 1 \leq c_d \theta(P)^{-2d\phi(d)}$. This follows from (16.3). Observe that $T_1, \ldots, T_{q-1}$ is a set of simplices with disjoint interiors all meeting $\text{ex}(B_a)$. We use (17.3) as a lower bound on the minimum altitudes of $T_1, \ldots, T_{q-1}$, $c_d \, \text{size}(B_a)$ as the size of $\text{ex}(B_a)$, and Theorem 15.1 to get upper bounds on aspect ratios. In this use of (16.3), the second term dominates the first on the right-hand side.

Suppose that $q = p+1$; in other words, every simplex in the enumeration satisfies (17.3). Then define $\Sigma = \Sigma_1$; we claim that

$$\text{lth}(\Sigma) \leq c_d \theta(P)^{-2d\phi(d)} \, \text{size}(B_a). \tag{17.4}$$

This is because Σ passes through $q-1$ simplices, and the length of its segment in each simplex is at most $c_d \, \text{size}(B_a)$. This choice of Σ has all the properties named above: it connects $\boldsymbol{x}$ to a point on a simplex S_1 (which satisfies $\text{minalt}(S_1) \leq c_d \, \text{size}(B_a)$) and satisfies (17.4). This concludes the construction of $\bar{S}$ for the case $q = p + 1$; in particular, we take $\bar{S} = S_1$.

The other case is that $q < p-1$. In this case, we truncate Σ_1 at the point where it enters T_q, which we denote $\boldsymbol{x}_1$; call the truncated path Σ'_1. Clearly Σ'_1 satisfies (17.4) by the same argument as in the last paragraph. Now notice that the anchor box for T_q cannot be B_a because T_q does not satisfy (17.3) by choice of q.

Therefore, identify the anchor of T_q, which we will call B_b, and start the construction anew from $\boldsymbol{x}_1$. In other words, find the incontractible path Π_2 in $\text{co}(B_b)$, find the simplex S_2 of $\mathcal{S}$ that meets the incontractible path and has altitude at most $c_d \, \text{size}(B_b)$, and let Σ_2 be the path $\boldsymbol{x}_1$ to a point in $S_2 \cap \Pi_2$. Note that $\text{size}(B_b) \leq \text{size}(B_a)/2$, because B_b must be smaller than B_a so that (17.3) can be satisfied for the new anchor. Find the first simplex in this new path that fails to satisfy (17.3) for B_b and so on. Notice that Σ'_2, the truncation of Σ_2, satisfies (17.4) with $\text{size}(B_b)$ taking the place of $\text{size}(B_a)$ on the right-hand side. Therefore, the upper bounds given by the right-hand side of (17.4) on $\text{lth}(\Sigma'_1), \text{lth}(\Sigma'_2), \ldots$ form a series decreasing by a factor of 2 each time. Eventually the procedure terminates at Σ_l because there is a finite lower bound on the smallest protected box in QMG. When the procedure terminates, concatenate $\Sigma'_1, \Sigma'_2, \ldots, \Sigma'_{l-1}, \Sigma_l$ into a PL path Σ. (This concatenation is possible because Σ'_1 ends at $\boldsymbol{x}_1$, which is where Σ'_2 begins, and so on.)

This path Σ has the following properties. It satisfies (17.4) with the original B_a on the right-hand side, multiplied by an additional factor of 2 that arises from summing a decreasing geometric series. It connects $\boldsymbol{x}$, the given point in P contained in a simplex T of QMG anchored at B_a, to a point $\boldsymbol{y}$ that is in a simplex S_l in triangulation $\mathcal{S}$ and that satisfies $\operatorname{minalt}(S_l) \le c_d \operatorname{size}(B_a)$. In this case, we take $\bar{S} = S_l$ to satisfy the conditions mentioned above.

This is exactly the setup we need to apply Lemma 16.2. Let S be the simplex in $\mathcal{S}$ that contains $\boldsymbol{x}$. From Lemma 16.2 applied to Σ we conclude that

$$\begin{aligned}\operatorname{minalt}(S) &\le c_d\zeta_1(\rho_{\mathcal{S}}, d) \cdot \max(\operatorname{lth}(\Sigma), \operatorname{minalt}(\bar{S}))\\ &\le c_d\zeta_1(\rho_{\mathcal{S}}, d) \cdot \theta(P)^{-2d\phi(d)} \operatorname{size}(B_a).\end{aligned} \tag{17.5}$$

The second line was obtained by substituting the bound (17.4) for $\operatorname{lth}(\Sigma)$ and then noting that this bound dominates the upper bound of $c_d \operatorname{size}(B_a)$ that applies to $\operatorname{minalt}(\bar{S})$.

Now the lemma is proved because we combine (17.5) with the bound on $\operatorname{size}(B_a)$ in terms of $\operatorname{minalt}(T)$ given by (17.3). □

THEOREM 17.2. *Let $n_{\mathrm{QMG}}(P)$ be the number of simplices in the triangulation produced by QMG. Let $\mathcal{S}$ be some other triangulation of P with aspect ratio bound $\rho_{\mathcal{S}}$, and let the cardinality of $\mathcal{S}$ be $n_{\mathcal{S}}$. Then*

$$n_{\mathrm{QMG}}(P) \le c_d\zeta_1(\rho_{\mathcal{S}}, d)^d \rho_{\mathcal{S}}^d \cdot \theta(P)^{-(2d+2)d\phi(d)} \cdot n_{\mathcal{S}}. \tag{17.6}$$

Proof. Let $f_{\mathrm{QMG}} : P \to \mathbf{R}$ be the piecewise constant function defined as follows. Let T be a simplex generated by QMG. The value of f_{QMG} on T is defined to be $1/\operatorname{vol}(T)$. On boundaries of simplices, a measure-zero set, we leave f_{QMG} undefined. Function $f_{\mathcal{S}} : P \to \mathbf{R}$ is defined similarly in terms of $\mathcal{S}$. Note that

$$n_{\mathrm{QMG}} = \int_{\boldsymbol{x}\in P} f_{\mathrm{QMG}}(\boldsymbol{x})\, d\boldsymbol{x}$$

because the value of the integral over each individual simplex is exactly 1. A similar expression holds for $n_{\mathcal{S}}$.

Define piecewise constant functions $g_{\mathrm{QMG}} : P \to \mathbf{R}$ to be $1/\operatorname{minalt}(T)^d$ on T, where T is a simplex in QMG, $g_{\mathcal{S}}$ similarly for $\mathcal{S}$. Finally, define $h_{\mathcal{S}}$ to the piecewise constant function that is $1/\operatorname{maxside}(S)^d$ on S, as S ranges over simplices in $\mathcal{S}$.

Then we have the following chain of inequalities.

$$\begin{aligned}n_{\mathrm{QMG}} &= \int_{\boldsymbol{x}\in P} f_{\mathrm{QMG}}(\boldsymbol{x})\, d\boldsymbol{x}\\ &\le c_d \int_{\boldsymbol{x}\in P} g_{\mathrm{QMG}}(\boldsymbol{x})\, d\boldsymbol{x}\\ &\le c_d\zeta_1(\rho_{\mathcal{S}}, d)^d \cdot \theta(P)^{-(2d+2)d\phi(d)} \cdot \int_{\boldsymbol{x}\in P} g_{\mathcal{S}}(\boldsymbol{x})\, d\boldsymbol{x}\\ &\le c_d\zeta_1(\rho_{\mathcal{S}}, d)^d \rho_{\mathcal{S}}^d \cdot \theta(P)^{-(2d+2)d\phi(d)} \cdot \int_{\boldsymbol{x}\in P} h_{\mathcal{S}}(\boldsymbol{x})\, d\boldsymbol{x}\\ &\le c_d\zeta_1(\rho_{\mathcal{S}}, d)^d \rho_{\mathcal{S}}^d \cdot \theta(P)^{-(2d+2)d\phi(d)} \cdot \int_{\boldsymbol{x}\in P} f_{\mathcal{S}}(\boldsymbol{x})\, d\boldsymbol{x}\\ &= c_d\zeta_1(\rho_{\mathcal{S}}, d)^d \rho_{\mathcal{S}}^d \cdot \theta(P)^{-(2d+2)d\phi(d)} \cdot n_{\mathcal{S}}.\end{aligned}$$

In these inequalities, we used (8.1) to obtain the second line, (17.1) for the third line, the aspect ratio bound for $\mathcal{S}$ for the fourth line, and (8.1) again for the fifth line. This proves the theorem. □

Note that this theorem allows the ratio $n_{\text{QMG}}/n_{\mathcal{S}}$ to be arbitrarily large if the competing triangulation $\mathcal{S}$ has bad aspect ratio. This is not merely an artifact of our analysis but is a feature of bounded aspect ratio triangulations, as illustrated by the following example. Consider a $p \times 1$ rectangle with $p \gg 1$. On such a domain, QMG would require $\Omega(p)$ triangles (as would any algorithm guaranteeing bounded aspect ratio), but this domain can be triangulated with just two triangles by inserting a diagonal. This latter triangulation has aspect ratio of $\Omega(p)$.

Note also that $\rho_{\mathcal{S}} \geq c_d\theta^{-1}$ by Theorem 9.2. Thus, the entire right-hand side of (17.6) can be bounded above with the more compact formula $f(\rho_{\mathcal{S}}, d) \cdot n_{\mathcal{S}}$.

18. Running time analysis. In this section we briefly discuss the running time of QMG. The running time for the separation stages is proportional to the number of boxes created multiplied by the time per box. There is no prior upper bound on the number of boxes in terms of the input. There is also no prior upper bound on the number of boxes in terms of the output, that is, in terms of the number of simplices produced, which we denote s. However, a modification to QMG would allow us to claim that the total number of boxes is bounded above by a multiple of s. The modification would be an additional operation to short circuit a series of splitting operations that make no progress. More specifically, the modification is as follows. When we split a box, we check whether only one of its children has nonempty content. If so, we discard the other children, and we immediately shrink that box by a power-of-two factor, until it is sufficiently small that we can be guaranteed that the next split will produce more than one child with nonempty content.

The amount of time to process a box depends on the combinatorial complexity of its content. A crude upper bound is that the complexity of the content is bounded by $O(N)$, where N is the complexity of the input domain P. Processing the content requires a connected component computation; the time for this computation in higher dimensions is $O(N^2)$, although, as mentioned in section 5, more efficient algorithms are available for two and three dimensions.

Thus, an estimate for the separation stage running time, using the modification mentioned above, is $O(N^2 s)$ operations. The operations in the alignment stage (checking complete coverage) can be done with a hash table as mentioned in section 7. Thus, alignment requires $O(s)$ operations. Finally, the triangulation part of the algorithm also requires $O(s)$ operations. Thus, the total running time is $O(N^2 s)$.

19. Implementation. A 2D version of QMG, called "tripoint," was implemented by S. Mitchell in C++ and is available on the World Wide Web [11]. A full version of QMG has been implemented in C++ by S. Vavasis; the implementation QMG1.1 is more general than the version described in this paper because it can also handle nonmanifold features, including several kinds of internal boundaries. QMG1.1 is available on the Web [16]. The implementation is slightly different from the algorithm described in this article; in particular, the alignment procedure uses an adaptive method for selecting tolerances and a different rule for choosing a close face. Computational experiments will be described elsewhere.

20. Open questions. Some of the open questions raised by this work include the following:

(1) Is there a triangulation algorithm with stronger optimality properties? For instance, the QMG aspect ratio is optimal (up to a constant factor) only in two and three dimensions.

(2) Several open questions were posed in section 14. For instance, is there a

characterization of the maximal value of the min-altitude in a triangulation of 3D polyhedra?

(3) Can this work be extended to curved boundaries? It appears that the main bottleneck is a solution to the subproblem of triangulating a uniform grid of boxes posed in the companion paper [12].

(4) Is there a mesh generation algorithm for three-dimensional domains that guarantees dihedral angles bounded by $\pi/2$? Such a bound is important for some finite element problems [17]. It is known [3] how to solve the corresponding problem in two dimensions.

(5) Can the running time bound be improved?

(6) The optimality properties demonstrated here all involve constant factors that are apparently very large. The QMG implementation in practice often produces meshes that are factors of 50 off from the minimum number of tetrahedra, and also factors of 50 off from the best aspect ratio. This leads to the following practical open question: Is there a mesh generation algorithm with theoretical guarantees comparable to QMG's, and yet with better theoretical constants or better performance in practice?

Acknowledgments. Preparation of this article has been an on-again, off-again process spanning a number of years. Several people have given us very useful comments on earlier versions, including Chandrajit Bajaj, Marshall Bern, Paul Chew, John Gilbert, Joe Mitchell, and the two referees of [13]. We thank Gail Pieper of Argonne and an anonymous referee for a careful reading of an earlier draft of this article.

CONTAINMENT AND OPTIMIZATION OF OBJECT-PRESERVING CONJUNCTIVE QUERIES*

EDWARD P. F. CHAN† AND RON VAN DER MEYDEN‡

Abstract. In the optimization of queries in an object-oriented database (OODB) system, a natural first step is to use the typing constraints imposed by the schema to transform a query into an equivalent one that logically accesses a minimal set of objects. We study a class of queries for OODBs called *conjunctive queries*. Variables in a conjunctive query range over heterogeneous sets of objects. Consequently, a conjunctive query is equivalent to a union of conjunctive queries of a special kind, called *terminal* conjunctive queries. Testing containment is a necessary step in solving the equivalence and minimization problems. We first characterize the containment and minimization conditions for the class of terminal conjunctive queries. We then characterize containment for the class of all conjunctive queries and derive an optimization algorithm for this class. The equivalent optimal query produced is expressed as a union of terminal conjunctive queries, which has the property that the number of variables as well as their search spaces are minimal among all unions of terminal conjunctive queries. Finally, we investigate the complexity of the containment problem. We show that it is complete in Π_2^p.

Key words. object-oriented database, query optimization, conjunctive queries, containment, equivalence, minimization, complexity

1. Introduction. The initial attempts at constructing object-oriented databases (OODBs) provided only navigational programming languages for manipulating data [21, 5]. The lack of query languages like those available in relational systems has been criticized as a major drawback of the object-oriented approach [30, 4]. Consequently, most, if not all, commercial OODBs now provide, or will provide, some form of high-level declarative query language (e.g., [23, 13, 22, 17, 18]). These query languages, like those of the relational model, transfer the burden of choosing an efficient execution plan for a query to the database system. This has led to a resurrection of the study of query optimization in the object-oriented setting (e.g., [26, 7, 6, 27, 15, 19, 10, 12]). Most of these papers develop transformations that reduce the cost of evaluating a given query but do not necessarily produce an *optimal* equivalent query.

In the setting of relational databases, a well-accepted notion of query optimality exists for the class of *conjunctive* queries [11], and the classical theory is based on the notion of query *containment*. A query Q_1 is said to be contained in a query Q_2 if, in every database instance, the set of answers to Q_1 is a subset of the set of answers to Q_2. In this paper, we study the containment and optimization problems for a class of conjunctive queries in an object-oriented setting. The closely related *equivalence* problem has previously been addressed for object-oriented queries by Hull and Yoshikawa [15]. Our results are complementary to their work, in that the language in [15] is object-generating, while our language is *object-preserving*. Our language enables a user to retrieve objects from a database, but not to create new complex

objects. Moreover, our language, like the one in [7], is defined on an inheritance hierarchy, whereas most languages studied in the literature are basically languages for complex objects without inheritance. The need to deal with inheritance introduces an extra level of complexity into the containment and optimization problems.

In an OODB, classes are named collections of similar objects. A class C may be refined into subclasses. Conversely, the class C is said to be a superclass of its subclasses. Subclasses are specializations of their superclasses. Consequently, objects in a class are also contained in its superclasses. Specialization of a class is often achieved by refining and/or adding properties to its superclasses. Since properties of a superclass are also properties of its subclasses, a subclass is said to inherit the properties of its superclasses. Class–subclass relationships form an acyclic directed graph called an inheritance or generalization hierarchy.

Inheritance is a powerful modeling tool because it allows for a better structured and more concise description of the schema and helps in factoring out shared implementations in applications [3]. Objects belonging to the same class share some common properties. Properties are attributes or methods defined on types; they are applicable only to instances of the types. In effect, therefore, types are constraints imposed on objects in the classes. Properties are formally denoted as attribute type pairs in this paper. A natural first step in query optimization is to use the typing constraints implied by the schema to minimize the search space for variables involved in the query. The following example illustrates how this idea may be applied to the kind of object-oriented conjunctive query we consider.

Example 1.1. Figure 1 is a schema for a vehicle rental database. It keeps track of all rental transactions for vehicles in the company. In this application, Auto, Trailer, and Truck are subclasses of the superclass Vehicle. There are clients, called discount customers, who are known to the company and receive special treatment. Discount customers receive a special rate and are not required to pay a deposit on the vehicles rented. However, discount customers are only allowed to rent automobiles and not other types of vehicles. Note that this constraint is captured by the more restrictive typing of the attribute VehRented in the subclass Discount of the class Client. Let us assume further that all superclasses are partitioned by their respective subclasses.

Suppose we want to find all those vehicles that have been rented to a discount client. Expressed in a calculus-like language, the query looks like the following:

$$Q_1 : \{x \mid \exists y\ (x \in \text{Vehicle}\ \&\ y \in \text{Discount}\ \&\ x \in y.\text{VehRented})\}.$$

Since discount clients are allowed to rent automobiles only, the above query is equivalent to the following query:

$$Q_2 : \{x \mid \exists y\ (x \in \text{Auto}\ \&\ y \in \text{Discount}\ \&\ x \in y.\text{VehRented})\}.$$

Q_2 is considered to be more optimal since the number of variables as well as their search spaces are minimal, given the typing constraints implied by the schema. Let us consider another query. Assume that we want to find those clients who rented a truck. It can be expressed as follows:

$$Q_3 : \{x \mid \exists y\ (x \in \text{Client}\ \&\ y \in \text{Truck}\ \&\ y \in x.\text{VehRented})\}.$$

Since discount clients are allowed to rent automobiles only (but not other kinds of vehicles); Q_3 is the same as the following query:

$$Q_4 : \{x \mid \exists y\ (x \in \text{Normal}\ \&\ y \in \text{Truck}\ \&\ y \in x.\text{VehRented})\}. \qquad \square$$

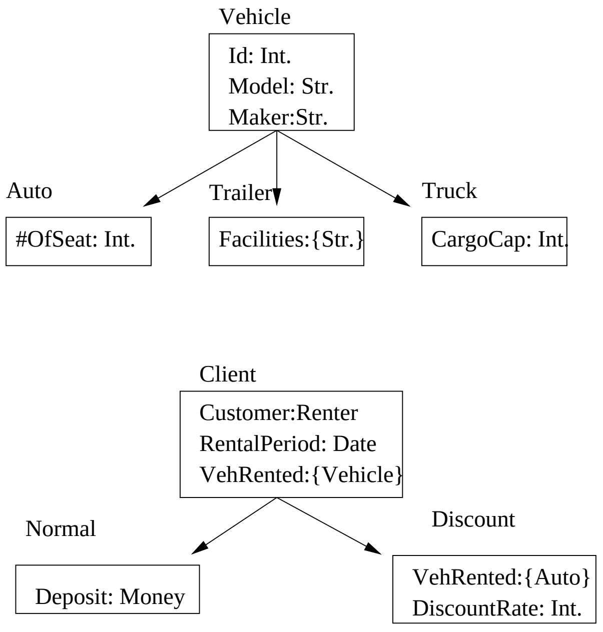

FIG. 1. *A vehicle rental database.*

Relational conjunctive queries have been studied extensively in the literature. A variable in a relational query ranges over a homogeneous relation. On the other hand, as illustrated by the above example, variables in an object-oriented query range over classes which could consist of heterogeneous sets of objects. This is because a class may be refined to various subclasses in which shared attribute names may correspond to different types or classes. For example, the variable x in Q_3 in Example 1.1 ranges over a heterogeneous set *Client* = *Normal* $\cup$ *Discount*. All the members of this set have the attribute *VehRented*, but only for members x of *Normal* can x.VehRented contain an element of the class *Truck*. This implies that clients who rent a truck are normal clients. This constitutes a significant divergence from the relational case. For instance, syntactically correct relational conjunctive queries are always satisfiable, but this is not true for object-oriented conjunctive queries [9]. The additional complexity is also reflected in the containment problem, as illustrated by the following example.

Example 1.2. The schema in Figure 2 records the employer–employee relationships among a group of people. The Employee attribute indicates the set of employees hired by a person.

Consider the following two queries defined on the above inheritance hierarchy. Q_1 retrieves all people x who hire a person u and a male v such that u is also an employee of v and u hires a female employee w. Q_2 finds all those people x who hire a male employee y who in turn hires a female employee z. Expressed in our language, they are as follows.

$$\begin{aligned} Q_1 : \{x \mid \exists u\, \exists v\, \exists w\ (&x \in \text{Person} \;\&\; u \in \text{Person} \;\&\; v \in \text{Male} \;\&\; w \in \text{Female} \\ &\& u \in x.\text{Employee} \;\&\; v \in x.\text{Employee} \;\&\; u \in v.\text{Employee} \\ &\&\; w \in u.\text{Employee})\}. \end{aligned}$$

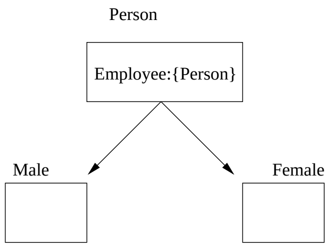

FIG. 2. *An employer-employee schema.*

$$Q_2 : \{x \mid \exists y\, \exists z\ (x \in \text{Person} \ \&\ y \in \text{Male} \ \&\ z \in \text{Female} \ \&\ y \in x.\text{Employee} \ \&\ z \in y.\text{Employee})\}.$$

The above two queries are best visualized as the two graphs in Figure 3.

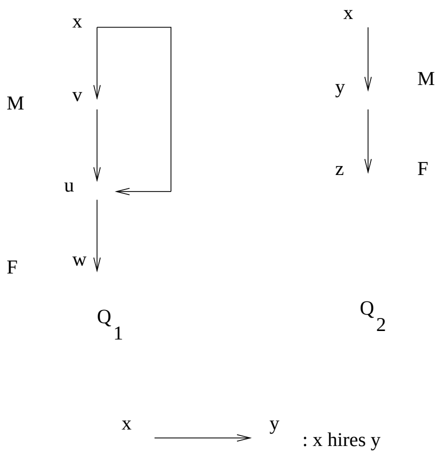

FIG. 3. *A query graph.*

We claim that Q_2 contains Q_1, meaning that whenever there is an answer for Q_1, it will also be an answer for Q_2. The person u is either a male or a female. If u is a male, then y and z in Q_2 can be mapped to u and w, respectively. Similarly if u is a female, variables y and z in Q_2 can be mapped to v and u, respectively. Thus, whenever there is an answer for Q_1, it will also be an answer for Q_2. $\square$

The above examples illustrate the kind of conjunctive queries we are interested in. Examples 1.1 and 1.2 demonstrate that the analysis of containment of conjunctive queries is more difficult than its counterpart in the relational case. This is due to the fact that the domains of attributes impose certain constraints on a query, and the analysis of the containment problem also involves analysis of disjunctive information.

The following is an overview of the problem and the approach we took in solving it. Given a conjunctive query $Q(\mathbf{S})$, where $\mathbf{S}$ is an object-oriented database schema denoted by an inheritance hierarchy, we want to find an equivalent query $Q'(\mathbf{S})$ that is, in some sense, optimal. Moreover, we are interested in determining when a conjunctive query is contained in another one. Both problems require an understanding of what a conjunctive query represents. We first observe that a conjunctive query, like the ones in Examples 1.1 and 1.2, can be decomposed as a union of a special kind of conjunctive queries called terminal conjunctive queries. As typing constraints in an inheritance hierarchy are restrictions on objects in a database, not every terminal conjunctive query is satisfiable. With typing constraints implied by an inheritance hierarchy, unsatisfiable terminal conjunctive queries can be determined and are eliminated from a union. Having removed unsatisfiable terminal conjunctive queries, characterization of containment and optimization are then derived. The technique employed and the result obtained are similar to those in select-project-join-union (SPJU)-expressions in the relational theory [24].

Most work on query optimization in OODBs concentrates on complex object optimization without considering the typing constraints imposed by the inheritance hierarchy (e.g., [26, 6, 27, 15, 19, 12]). Type checking of queries in the presence of *nonstrict* inheritance hierarchy was studied in [7]. Our work is different from all previous approaches in several important respects. First, we use the typing constraints imposed by an inheritance hierarchy to study the containment, equivalence, and optimization of queries. Second, our optimization is an exact minimization while most of the previous work deals with algebraic transformations and/or heuristics (e.g., [26, 27, 6, 19, 12]). Third, with reasons similar to those noted in [24], characterizing equivalence does not suffice to solve the optimization problem. Instead, we need to understand the containment problem as well. This work, to our best knowledge, is the first work that provides a characterization for containment of queries in an object-oriented setting. This result could also find applications in a view definition and classification in an OODB. For instance, to correctly integrate a virtual class or view into an inheritance hierarchy, it is imperative to resolve the containment problem for the view definition language [25]. Last, we demonstrate that the idea of containment mappings of relational conjunctive queries [11] can be extended to its object-oriented counterpart. Our proposed language, on the other hand, is perhaps more restrictive than some other query languages studied in the literature.

The next section defines the class of conjunctive queries and the basic notation needed throughout the discussion. In characterizing the containment and equivalence of terminal conjunctive queries, it is assumed that the query involved is satisfiable. We present an efficient algorithm for solving the satisfiability problem for terminal conjunctive queries in section 3. The results in that section were proven in [9] and are needed in the subsequent discussions. Sections 4 and 5 characterize the containment, equivalence, and minimization conditions for *terminal* conjunctive queries. In section 6, we solve the containment problem and derive an algorithm for optimizing the class of all conjunctive queries. The notion of optimization captures the intuition of minimization of the number of variables as well as their search spaces. In section 7, we analyse the complexity of testing containment of conjunctive queries. The main result shows that the problem is Π_2^p-complete. Finally, we give our conclusions in section 8.

2. Definitions and notation.

In this section, we introduce notation that is necessary for the rest of the discussion.

2.1. Types, classes, and schemas.

We suppose, given the following pairwise disjoint sets:

1. A set $\mathcal{T}$ of *atomic type domains*, where each atomic type domain is an *infinite* set of *atomic values*. Examples of atomic type domains are the set of integers

and the set of strings over some alphabet. We asssume distinct atomic type domains are disjoint.
2. A countably infinite set $\mathcal{O}$ of symbols which are called *object identifiers*.
3. A set $\mathcal{B}$ of *atomic types*, containing for each atomic type domain $T \in \mathcal{T}$, a symbol $\mathbf{T}$ naming that type domain. For brevity, we abuse notation by using the same symbol T for a type domain and its name. Thus $\mathcal{B} = \mathcal{T}$.
4. A countably infinite set $\mathcal{A}$ of symbols, the *attributes*.
5. A countably infinite set $\mathcal{C}$ of symbols which are called *classes*.

The set $\bigcup_{T \in \mathcal{T}} T$ is said to be the set of *atomic values*. The elements of $\mathcal{A}$ will be used as attribute names in tuple types, and the elements of $\mathcal{C}$ serve as names for user-defined classes.

A *type expression* over a set $\mathbf{C} \subseteq \mathcal{C}$ of class names is an expression defined as follows:

1. Every element of $\mathcal{B}$ is a type expression, called an *atomic type*.
2. Every element of $\mathbf{C}$ is a type expression, called a *class*.
3. If t is an atomic type or a class, then $\{t\}$ is type expression, called a *set* type.
4. If $a_1, \dots, a_n$ are distinct attributes in $\mathcal{A}$ and $t_1, \dots, t_n$ are atomic types, set types or classes, where $n \geq 0$, then $[a_1 : t_1, \dots, a_n : t_n]$ is a type expression, called a *tuple* type. As in a relation scheme, the order of attributes is immaterial. The empty tuple [] is also a tuple type. The type t_i is said to be the *type* of the attribute a_i, for each $i = 1, \dots, n$.

We write *type-expr*$(\mathbf{C})$ for the set of all type expressions over $\mathbf{C}$.

Following [20, 8], we introduce the notion of schema. A *schema* $\mathbf{S}$ is a triple $(\mathbf{C}, \sigma, \prec)$, where $\mathbf{C}$ is a finite subset of $\mathcal{C}$, σ is a function from $\mathbf{C}$ to tuple types, and $\prec$ is a partial order on $\mathbf{C}$. The mapping σ associates to each class in $\mathbf{C}$ a tuple type in *type-expr*$(\mathbf{C})$, which describes its structure. As noted in [14], there is no loss of representational power in restricting the structures of classes to be tuple types. The relationship $\prec$ among classes represents the user-defined *inheritance hierarchy*. We assume that the hierarchy has no cycle of length greater than 1. A class $A \in \mathbf{C}$ is said to be *terminal* if there is no class $B \neq A$ such that $B \prec A$. Otherwise, A is *nonterminal*. A class B is a *descendant* (or an *ancestor*) of a class A if $B \prec A$ (or $A \prec B$, respectively).

Following [1, 20], we derive from this hierarchy a subtyping relation $\leq$ among expressions in *type-expr*$(\mathbf{C})$. Let $\mathbf{S} = (\mathbf{C}, \sigma, \prec)$ be a schema. The *subtyping* relation among expressions in *type-expr*$(\mathbf{C})$ is the smallest ordering $\leq$, which satisfies the following axioms:

1. $A \leq A$ if $A \in \mathcal{B}$.
2. $B \leq C$ if $B \prec C$, for all classes B and C in $\mathbf{C}$.
3. $\{t\} \leq \{s\}$, for all types s, t such that $t \leq s$.
4. $[a_1 : t_1, \dots, a_n : t_n, \dots, a_{n+p} : t_{n+p}] \leq [a_1 : s_1, \dots, a_n : s_n]$, for all atomic types, set types or classes $t_1, \dots, t_n, s_1, \dots, s_n$ such that $t_i \leq s_i$, for all $i = 1, \dots, n$.

The order of arguments in a tuple type is immaterial, so we have $[a_3 : C_3, a_2 : C_2, a_1 : C_1] \leq [a_1 : C_1, a_2 : C_2]$.

For any expressions E_1 and E_2 in *type-expr*$(\mathbf{C})$, E_1 is a *subtype* of E_2 if $E_1 \leq E_2$. It is worth noting that the subtyping relation is a reflexive and transitive relation. As inheritance hierarchies are given by users, some schemas may not be meaningful. Let $\mathbf{S} = (\mathbf{C}, \sigma, \prec)$ be a schema. $\mathbf{S}$ is *consistent* if, for all classes B and C such that $B \prec C$, we have $\sigma(B) \leq \sigma(C)$. We consider only consistent schemas throughout this paper. The schemas we have defined are essentially the same as those defined in ODMG-93 [8]. Thus, our results are applicable to systems conforming to this standard. Let $C \in \mathbf{C}$. Attributes in $\sigma(C)$ are called the *attributes* of C. The *type of* $C.A$, denoted *type*$(C.A)$, is the type t of A in $\sigma(C)$. In consistent schemas, subclasses are specializations of their superclasses. Specialization of subclasses is represented formally by refining types of inherited attributes and/or adding new attribute type pairs.

2.2. States, domains, and objects. Let $\mathbf{S} = (\mathbf{C}, \sigma, \prec)$ be a schema and $\leq$ be the subtyping relation on *type-expr*$(\mathbf{C})$. Let $\mathbf{O}$ be a finite subset of $\mathcal{O}$ and $\mathbf{I}_c$ be a function from $\mathbf{O}$ to $\mathbf{C}$. Given $\mathbf{O}$ and $\mathbf{I}_c$, each type expression T in *type-expr*$(\mathbf{C})$ is interpreted as a set of possible values, called the *domain* of T, denoted as *dom*(T). In order to represent inapplicable attributes, we introduce a new symbol "Λ." The *domain* of a type with respect to $\mathbf{O}$ and $\mathbf{I}_c$ is defined as follows:

1. If $\mathbf{T} \in \mathcal{B}$ is an atomic type naming the type domain T, then $dom(\mathbf{T}) = T$.
2. For each class $D \in \mathbf{C}$, we define $dom(D) = \{o \mid o \in \mathbf{O}$ and $\mathbf{I}_c(o) = E$, where $E \prec D\}$.
3. For each set type $\{t\}$, we define $dom(\{t\}) = \{v \mid v \subseteq dom(t)\}$.
4. For each tuple type $[a_1 : t_1, \ldots, a_n : t_n]$, we define $dom([a_1 : t_1, \ldots, a_n : t_n]) = \{[a_1 : v_1, \ldots, a_n : v_n] \mid v_i \in dom(t_i) \cup \{\Lambda\}$ for all $i = 1, \ldots, n\}$.

Note that the value of an attribute of a tuple may be the null value Λ. This is to be interpreted as the attribute being inapplicable.

A *state* $\mathbf{s}$ on a schema $\mathbf{S} = (\mathbf{C}, \sigma, \prec)$ is a triple $(\mathbf{O}, \mathbf{I}_c, \mathbf{I}_v)$, where $\mathbf{O}$ is a finite subset of $\mathcal{O}$, $\mathbf{I}_c$, which is a function from $\mathbf{O}$ to $\mathbf{C}$, and $\mathbf{I}_v$ is a function from $\mathbf{O}$ to tuple values in domains of types with respect to $\mathbf{O}$ and $\mathbf{I}_c$. The function $\mathbf{I}_v$ maps each element in $\mathbf{O}$ to a tuple value which satisfies the following:

$$\forall o \in \mathbf{O},\ \mathbf{I}_v(o) \in dom\left(\sigma\big(\mathbf{I}_c(o)\big)\right).$$

That is, $\mathbf{I}_v$ defines the data value of an object and the (tuple) value of an object defined on a class must satisfy the type specification associated with the class. The set $\{\langle o, \mathbf{I}_v(o)\rangle \mid o \in \mathbf{O}\}$ is the set of objects in the state $\mathbf{s}$. Two objects in a state are *identical* if and only if they have the same identifier, so we may sometimes abuse terminology by referring to the identifier o as an *object* of $\mathbf{s}$.

Let $[a_1 : v_1, \ldots, a_n : v_n]$ be a tuple value. Then $[a_1 : v_1, \ldots, a_n : v_n].a_i$ is v_i. We call v_i the value of attribute a_i in the tuple. If the attribute a does not occur in a tuple, then the value of attribute a in the tuple is Λ.

In many, if not most, existing object-oriented database systems (e.g., [22, 17, 23]), an object is defined on exactly one most specialized class in an inheritance hierarchy. Consequently, as in [1, 17], we assume the following throughout the discussion.

2.2.1. Terminal class partitioning assumption. Given any state $\mathbf{s} = (\mathbf{O}, \mathbf{I}_c, \mathbf{I}_v)$ on a schema $\mathbf{S}$, the class $\mathbf{I}_c(o)$ is a terminal class in $\mathbf{S}$ for every object o in $\mathbf{O}$. That is, every nonterminal class is partitioned by its terminal descendants.

2.3. A class of object-preserving conjunctive queries. In this subsection, we define a calculus-like query language for an object-oriented database.

Queries are constructed from a set of variables, symbols from the set of atomic values, the equality operator "$=$," the membership operator "$\in$," the OR operator "$\sqcup$," the logical operator "&," as well as the existential quantifier "$\exists$." The set of variables is assumed to be disjoint from other sets of symbols.

First we define the concept of term. Terms enable us to refer to an object or a component of an object. A *term* is an expression of one of the following forms: c or x or $x.A$, where c is an atomic value, i.e., c is in some atomic type domain, x is a variable, and A is an attribute. A term of the form x or $x.A$ is called a *variable term.* An *attribute term* is of the form $x.A$.

An *atom* or an *atomic formula* is defined to be one of the following:

1. $x \in C_1 \sqcup \cdots \sqcup C_n$, where the C_i's are classes or atomic types, and x is a variable. An atom $x \in C_1 \sqcup \cdots \sqcup C_n$ is called a *range* atom and it asserts that the variable x denotes an object in the class C_i or a value in the atomic type C_i, for some $1 \leq i \leq n$.
2. $t_1 = t_2$, where t_1 and t_2 are terms. Such an atom is called an *equality* atom. An equality atom asserts that the operands denote identical objects or are of the same atomic value.
3. $x \in y.A$, where x and y are variables. The atom $x \in y.A$ is called a *membership* atom. A membership atom asserts that the object or atomic value denoted by x is a member of the *set object* denoted by $y.A$.

It is worth noting that path expressions of the form $x.A_1 \dots A_n$ (as used in [33]) and of the form $x.A_1[y_1] \dots A_n[y_n]$ (as used in [16]), where x and y_i's are variables or atomic values, can all be represented indirectly in our language. Likewise, atoms of the forms $c \in x.A$ and $y.A \in C_1 \sqcup \cdots \sqcup C_n$, and of the form $x.A \in y.B$, where x and y are variables and c is an atomic value, can again be expressed indirectly in our language.

A *formula* is constructed from atomic formulas, the logical operator "&," as well as existential quantifiers. *Bound* and *free* variables are defined in the usual manner. A *query* is an expression of the form $\{\ t \mid \Phi(t)\}$, where t is either a variable or an atomic value and $\Phi(t)$ is a formula. The term t is called the *distinguished term* of the query. A query $\{s_0 \mid \Phi(t)\}$ is called *conjunctive* if $\Phi(t)$ is of the form $\exists s_1 \cdots \exists s_m(M)$, where M is a formula containing no quantifier that is a conjunction of atomic formulas.[1] $\exists s_1 \cdots \exists s_m$ is called the *prefix* and M is called the *matrix* of the formula or of the query. We also make use of *union queries*, which are expressions of the form $Q_1 \cup \cdots \cup Q_n$, where each Q_i is a conjunctive query.

2.4. Semantics of queries. We now give the semantics of queries and define the notion of query containment. It is convenient, for technical reasons that will become apparent below, to state the semantics in terms of a mapping to a language that uses the objects and atomic values of a state as basic syntactic entities. We remark that the semantics are slightly nonstandard, in that they require that the terms occurring in an atom have a nonnull value in order for the atom to be true: this was handled in [9] using a three-valued logic, but since only the truth of atoms is relevant to the containment question for conjunctive queries, we simplify this here.

Define a *term over a state* $\mathbf{s} = (\mathbf{O}, \mathbf{I}_c, \mathbf{I}_v)$ to be an expression of one of the following forms: an atomic value c, an object $o \in \mathbf{O}$, or an expression $o.A$, where $o \in \mathbf{O}$ is an object and A is an attribute. The *value* $Val(t)$ of a term t over $\mathbf{s}$ is defined as follows:

1. If t is an atomic value c, then $Val(t) = c$.
2. If t is an object $o \in \mathbf{O}$, then $Val(t) = o$.
3. If t is the expression $o.A$, where $o \in \mathbf{O}$ is an object and A is an attribute, then $Val(t)$ is the value of attribute A in $\mathbf{I}_v(o)$.

Note that $Val(t)$ may be an atomic value, object, set, or the null value Λ.

[1]The results in this paper can be extended to conjunctive queries with more than one free variable.

An *atom over* $\mathbf{s}$ is an expression of one of the following forms:

1. $t \in C_1 \sqcup \cdots \sqcup C_n$, where t is a term over $\mathbf{s}$ and the C_i are classes or atomic types;
2. $t_1 = t_2$, where t_1 and t_2 are terms over $\mathbf{s}$, or
3. $t \in o.A$, where t is a term over $\mathbf{s}$, where o is an object of $\mathbf{s}$, and where A is an attribute.

We define certain atoms $\mathbf{A}$ over a state $\mathbf{s}$, to be *satisfied* in $\mathbf{s}$, written $\mathbf{s} \models \mathbf{A}$, as follows:

1. $\mathbf{s} \models t \in C_1 \sqcup \cdots \sqcup C_n$, where t is a term over $\mathbf{s}$ and each C_i is a class or atomic type, if $\mathit{Val}(t) \in \mathit{dom}(C_i)$ for some $i = 1, \dots, n$;
2. $\mathbf{s} \models t_1 = t_2$, where t_1 and t_2 are terms over $\mathbf{s}$, if $\mathit{Val}(t_1) = \mathit{Val}(t_2)$ and neither value is equal to Λ;
3. $\mathbf{s} \models t \in o.A$, where t is a term over $\mathbf{s}$, the o is an object of $\mathbf{s}$, and A is an attribute, if $\mathit{Val}(t)$ is not equal to Λ and $\mathit{Val}(o.A)$ is a set that contains $\mathit{Val}(t)$.

Note that in order for an atom to be satisfied, all of its terms must have nonnull values.

An *assignment* for a query Q in a state $\mathbf{s} = (\mathbf{O}, \mathbf{I}_c, \mathbf{I}_v)$ is a function α mapping each variable of Q either to an atomic value or to an object in $\mathbf{O}$. Assignments may be extended to mappings from the terms and atoms of Q to terms and atoms over $\mathbf{s}$, respectively, as follows:

1. for terms which are atomic values c we define $\alpha(c) = c$,
2. for terms of the form $x.A$, where x is a variable, we define $\alpha(x.A)$ to be the expression $o.A$, where $o = \alpha(x)$, and
3. for atoms $\mathbf{A}$ of Q we define $\alpha(\mathbf{A})$ to be the atom over $\mathbf{s}$ obtained by substituting for each term t in $\mathbf{A}$ the term $\alpha(t)$.

Using the notion of satisfaction of atoms over a state in that state, we now define a formula Φ to be satisfied in a state $\mathbf{s}$ with respect to an assignment α, written $\mathbf{s}, \alpha \models \Phi$, in the usual way. For atomic formulae $\mathbf{A}$ we have $\mathbf{s}, \alpha \models \mathbf{A}$ if $\mathbf{s} \models \alpha(\mathbf{A})$. The cases of Boolean operators and quantifiers are as in the standard semantics of first order logic, where the universe consists of the union of the sets $\mathit{dom}(T)$, where T ranges over all type expressions.

A query $Q = \{t \mid \Phi(t)\}$ is said to be *satisfied in a state* $\mathbf{s}$ *with respect to an assignment* α, written $\mathbf{s}, \alpha \models Q$, if $\mathbf{s}, \alpha \models \Phi(t)$. The assignment α is called a *satisfying* assignment for Q in this case. We say that the object or value a is an *answer* of Q with respect to $\mathbf{s}$ if there exists a satisfying assignment α for Q such that $a = \alpha(t)$, where t is the distinguished term of Q. If Q is a query and $\mathbf{s}$ is a state, we write $Q(\mathbf{s})$ for the set of all answers of Q with respect to $\mathbf{s}$. For union queries Q of the form $Q_1 \cup \cdots \cup Q_n$ we define $Q(\mathbf{s})$ to be the set $Q_1(\mathbf{s}) \cup \cdots \cup Q_n(\mathbf{s})$.

A query Q is said to be *satisfiable* if there is a state $\mathbf{s}$ such that $Q(\mathbf{s})$ is nonempty. Given two queries Q_1 and Q_2 (on a schema $\mathbf{S}$), Q_1 is said to *contain* Q_2 with respect to $\mathbf{S}$, denoted $Q_1 \supseteq Q_2$, if $Q_1(\mathbf{s}) \supseteq Q_2(\mathbf{s})$, for all states $\mathbf{s}$ on $\mathbf{S}$. Two queries Q_1 and Q_2 are said to be *equivalent* with respect to schema $\mathbf{S}$, denoted $Q_1 \equiv Q_2$, if they contain each other with respect to $\mathbf{S}$.

We note that for conjunctive queries, the existential quantifiers are not strictly essential: the query $\{t \mid \exists x_1 \cdots \exists x_n(\Phi)\}$ is equivalent to the query $\{t \mid \Phi\}$. Consequently, we assume henceforth, for purposes of analysis, that queries do not contain existential quatifiers. This yields the following simple characterization of satisfaction: α is a satisfying assignment for a conjunctive query Q in a state $\mathbf{s}$ if and only if

$\mathbf{s} \models \alpha(\mathbf{A})$ for all atoms $\mathbf{A}$ of Q. (It is still sometimes convenient to write formulae with quantifiers in order to scope variables and avoid naming conflicts.)

2.5. Well-formed conjunctive queries. We consider only those queries in which each term either denotes an object or a value, or a set of objects or values, but not both. We call such queries *well-formed.* The following defines when a query is well formed. First we note that, given a conjunctive query, additional equalities among terms could be inferred with the following algorithm. It is easy to see that the inferences performed in the algorithm are correct.

```
ALGORITHM EQUALITYGRAPH. Given a conjunctive query, generate additional
implied equality edges.
 Input: A conjunctive query $Q$.
 Output: An undirected graph $E(Q)$, called the complete equality relationship graph
         for $Q$.
 Method: The edges $\{x, y\}$ in the graph $E(Q)$ are called equality edges, and are also
         denoted by '$x = y$'.
   (1) Generate a graph with terms in $Q$ as nodes. (If $x.A$ is a term of $Q$, then
       so is $x$.) Generate additional nodes and equality edges by applying the
       following three steps exhaustively to the graph until no more edges can
       be derived.
       (i) For each node $t$, derive the equality edge $t = t$. For each equality
           atom "$s = t$" of $Q$, generate an equality edge between the node $s$
           and the node $t$.
       (ii) If $s = t$ and $t = u$ are equality edges, then derive the equality edge
            $s = u$.
       (iii) If $x$ and $y$ are variable nodes, $x = y$ is an equality edge, and $x.A$ is
             a node in the graph, then add the node $y.A$, if it does not already
             exist, and derive the equality edge $x.A = y.A$.
   (2) Output the graph constructed.
```

By substeps (i) and (ii), the complete equality relationship graph $E(Q)$ for a conjunctive query Q yields an equivalence relation R, defined by tRt', if there exists an equality edge between t and t'. For each term t in $E(Q)$, the equivalence class $[t]$ of R containing t is the set $\{t' \mid t'$ is a node in $E(Q)$ and there is an equality edge between t and $t'\}$. These sets are said to be the *equivalence classes* of $E(Q)$.

Let Q be a query. An occurrence of a term $x.A$ in the matrix of Q is a *set occurrence* if the occurrence appears on the right-hand side of a membership atom. All other occurrences of terms in the matrix of Q are *object occurrences.* A term s is an *object* term if some term t in the equivalence class $[s]$ has an object occurrence in the query. A term s is a *set* term if there is a set occurrence in the query of some term $t \in [s]$. Intuitively, a set term is one that *must* denote a set, and an object term is one that *must* denote an object or atomic value. A conjunctive query Q is *well formed* if

(i) every term in Q is either an object term or a set term, but *not* both,
(ii) each object term of the form $x.A$ is equated, directly or indirectly, to some variable or atomic value; that is, there is a variable or an atomic value in the equivalence class $[x.A]$, and

(iii) every variable in Q ranges over exactly one disjunction of classes or atomic types; that is, there is exactly one range atom associated with each variable.

Condition (i) is necessary for the satisfiability of the query and arises from the obvious constraint that no term can simultaneously denote both an object and a set. It is worth remarking that this condition implies that a set term cannot occur within an equality atom in the query, for such an occurrence would be an object occurrence, making the term simultaneously a set term and and object term. Note, moreover, that no object term can ever denote a set, for, by conditions (ii) and (iii), an object term must denote an element of some union of classes and atomic types.

For terms denoting objects or atomic values, condition (ii) is not a real restriction, since such a term can always be equated to some new existentially quantified variable ranging over all classes and atomic types. This condition is needed to simplify the discussion in the subsequent sections. In the case of condition (iii), note that because of the terminal class partitioning assumption, a query is unsatisfiable if it contains both $x \in C$ and $x \in D$, where C and D are distinct terminal classes. Such a query may be satisfiable if C and D are nonterminal classes, but in this case the two range atoms can be replaced (given a schema) with the single atom $x \in C_1 \sqcup \cdots \sqcup C_n$, where $C_1, \ldots, C_n$ are the common terminal descendants of C and D. Moreover, if the variable x occurs in no range atom, then we may clearly add the atom $x \in C_1 \sqcup \cdots \sqcup C_n$, where $C_1, \ldots, C_n$ are all terminal classes and atomic types, without changing the meaning of the query.

For the rest of this paper, we use the term *conjunctive queries* to denote well-formed conjunctive queries. Well-formed queries include *safe* as well as *unsafe* queries that produce infinite answers [31].

2.6. Terminal conjunctive queries. A *terminal* conjunctive query is a conjunctive query in which every range atom is of the form "$x \in C$," where C is a terminal class or an atomic type.

Every conjunctive query can be expressed as a union of terminal conjunctive queries, as follows. First, define an *expansion* of a query Q to be a query obtained by replacing each range atom of the form $x \in C_1 \sqcup \cdots \sqcup C_n$ by one of the atoms $x \in C_i$. For example, the query

$$\{x \mid (x \in C \sqcup D) \wedge (y \in E \sqcup F) \wedge (x.A = y)\}$$

has four expansions, one of which is the query

$$\{x \mid x \in D \wedge y \in E \wedge x.A = y\}.$$

Note that every expansion of a conjunctive query is a terminal conjunctive query.

PROPOSITION 2.1. *Let Q be a conjunctive query and let $Q_1, \ldots, Q_n$ be all the expansions of Q. Then Q is equivalent to $Q_1 \cup \cdots \cup Q_n$.*

Proof. See [9]. $\square$

This result states that, semantically, a conjunctive query corresponds to a union of terminal conjunctive queries. Each terminal conjunctive query in a union could have variables defined on different domains. To solve the containment and equivalence problems, it is necessary to solve the satisfiability problem and to identify exactly the set of objects or values over which a variable is ranging. In section 3, we present an algorithm for solving these problems for the terminal conjunctive queries. This algorithm employs typing constraints to determine satisfiability of a terminal conjunctive query. Queries that are not terminal could, by Proposition 2.1, first be decomposed into a union of terminal conjunctive queries. We can then apply the algorithm in section 3 to each subquery in the union to determine its satisfiability and delete the unsatisfiable subqueries from the union. In sections 4 and 5, we shall derive algorithms for testing containment and for minimizing terminal conjunctive queries. Section 6.1 deals with containment of unions of conjunctive queries, which can be used to determine containment of arbitrary conjunctive queries.

3. An efficient algorithm for testing satisfiability of terminal conjunctive queries.

Testing the satisfiability of restricted classes of conjunctive queries is an NP-complete problem [9]. However, determining if a terminal conjunctive query is satisfiable is tractable. We present in this section an algorithm that solves this problem in polynomial time, from [9], along with a sketch of its correctness proof. The aspect of this proof that is germane to our purposes in the present paper is that if the input query is satisfiable, it is possible to construct a "minimal" state with respect to which the query returns a nonempty result. Various properties of the state constructed are needed in the proof of the characterization of containment of terminal conjunctive queries.

One of the reasons for unsatisfiability of a query is the incompatibility of the typing of its terms implied by the schema. Note that a query Q and schema $\mathbf{S} = (\mathbf{C}, \sigma, \prec)$ together determine a type $\mathit{type}(t)$ for every term t of the query. (In every case, this type is in fact a class or atomic type.) For every atomic value c in an atomic type T, we define $\mathit{type}(c) = T$. For every variable x in Q, define $\mathit{type}(x)$ to be the unique class or atomic type C such that Q contains an atom of the form $x \in C$. For every term of the form $x.A$ in Q, define $\mathit{type}(x.A)$ as the type of attribute A in $\sigma(\mathit{type}(x))$, if $\mathit{type}(x)$ is a class and A is an attribute of $\sigma(\mathit{type}(x))$, and undefined otherwise.

In order for the query to be satisfiable, the type assigned to its terms must be consistent. By the terminal class partitioning assumption, terms denoting the same object must belong to the same terminal class or atomic type, and an object belonging to a set must be of a type admissible for that set. The following definition helps to check these conditions. If T is an atomic type or a class, we say D is a *terminal subtype* of T if either T is an atomic type and D is T, or D is a terminal descendant of T. Let t be an object term in Q. Define $\mathit{SatType}(t)$ to be the set of all D such that

1. for all terms $u \in [t], D$ is a terminal subtype of $\mathit{type}(u)$, and
2. for every '$u \in z.A$' in Q, where $u \in [t], D$ is a terminal subtype of C, where $\mathit{type}(z.A)$ is $\{C\}$.

Intuitively, $\mathit{SatType}(t)$ is the set of terminal types that are consistent with all the typing information on t derivable from the query. Since every object term must be equated to some variable, which must range over a terminal type, or to an atomic value, $\mathit{SatType}(t)$ contains at most a single element. Note that the definition depends only on the equivalence class of t, so we may also write $\mathit{SatType}([t])$ for $\mathit{SatType}(t)$. Note also that if Q is satisfiable, then $\mathit{SatType}(t)$ is a singleton set for every variable object term t in Q. For if $\mathit{SatType}(t)$ were empty, then it would be impossible to construct a satisfying assignment.

```
ALGORITHM SATTESTUT. Verify if a terminal conjunctive query $Q$ is satisfiable.
Input: A terminal conjunctive query $Q$ on $\mathbf{S}$.
Output: yes if $Q$ is satisfiable, and no otherwise.
Method: Compute the complete equality relationship graph $E(Q)$ for $Q$.
    (1) If there is an object term of the form $x.A$ for which $type(x.A)$ is undefined
        or equal to a set type, or there is a set term of the form $x.A$, for which
        $type(x.A)$ is undefined or is not equal to a set type, then output no and
        exit.
    (2) If there is an object term $t$ in $Q$ such that $SatType(t)$ is empty, then
        output no and exit.
    (3) If there is an object term $t$ with two distinct atomic values $c_1$ and $c_2$
        both in $[t]$, then output no and exit.
    (4) Output yes.
```

LEMMA 3.1. *If the algorithm SatTestUT outputs yes, then Q is satisfiable.*

Proof. Suppose the algorithm outputs *yes.* We construct a state $\mathbf{s}_Q$ and a satisfying assignment α for Q in $\mathbf{s}_Q$. This assignment will be called the *canonical* asssignment for Q in $\mathbf{s}_Q$. The details of the construction will be applied in later results.

First, to each equivalence class $[t]$ of the complete equality relationship graph of Q, we associate a distinct value $[t]_\alpha$ and a terminal class or an atomic type $type_\alpha([t])$. The type $type_\alpha([t])$ is defined to be $type(s)$ for any term s of the query in $[t]$. This is well defined in the case of object terms by statement (2). For set terms $x.A$, note that if $t \in [x.A]$, then t must be of the form $y.A$ for some variable $y \in [x]$, by the fact that set terms do not occur in equations in Q and construction of $E(Q)$. Thus $type_\alpha([x.A])$ may be defined to be $type(x.A)$ in this case. The values $[t]_\alpha$ are assigned as follows.

Val1: If $type_\alpha([t])$ is an atomic type, and there is an atomic value c in $[t]$, then $[t]_\alpha = c$. By statement (3), c is the unique atomic value in $[t]$.

Val2: If $type_\alpha([t])$ is an atomic type and there is no atomic value in $[t]$, then take $[t]_\alpha$ to be any value of type $type_\alpha([t])$, such that no two distinct equivalence classes are assigned the same value. (This is possible because the atomic types are infinite.)

Val3: If $type_\alpha([t])$ is a terminal class, then the value $[t]_\alpha$ is defined to be just the equivalence class $[t]$ itself. In this case these values will be interpreted below as objects in the state to be constructed.

Val4: If none of the above cases apply, then $type_\alpha([t])$ is a set type. In this case $[t]_\alpha$ is defined to be the set $\{[v]_\alpha \mid$ "$v \in z.A$" is an atom in Q for some variable z in $[t]\}$. (Note that the variables v must be object variables, so the values $[v]_\alpha$ are already defined by cases Val1–Val3.)

Observe that it follows from this definition that distinct equivalence classes are assigned distinct values.

We now construct a state $\mathbf{s}_Q = (\mathbf{O}, \mathbf{I}_c, \mathbf{I}_v)$. We take the set of objects $\mathbf{O}$ of this state to be $\{[t] \mid [t]$ is an equivalence class of Q such that $type_\alpha([t])$ is a terminal class$\}$. These objects are assigned to terminal classes by putting $\mathbf{I}_c([t]) = type_\alpha([t])$, for every $[t] \in \mathbf{O}$. The mapping $\mathbf{I}_v$, defined below, maps each $[t] \in \mathbf{O}$ to a tuple value on $type_\alpha([t])$. First, for each $[t] \in \mathbf{O}$, define $attr([t])$ to be the set of attributes A such that $x.A$ is a term of Q for some variable $x \in [t]$. We now define attribute values for the object $[t]$ as follows. Note that by conditions (1) and (2), the set $attr([t])$ is a subset of the set of attributes in $\mathbf{I}_c([t])$. For each attribute $A \in attr([t])$, the value assigned to the attribute A for the object $[t]$ is $[x.A]_\alpha$, where x is any variable in $[t]$ such that $x.A$ is a term of Q. (Note that the definition of the complete equality relationship graph ensures that if x and y are variables in $[t]$ such that $x.A$ and $y.A$ are terms of Q, then $[x.A] = [y.A]$, so this definition is independent of the choice of x.) If A is an attribute in $type_\alpha([t])$ but not in $attr([t])$, a null value is assigned to A for the object $[t]$. This completes the definition of the state $\mathbf{s}$.

Finally, we define a mapping α from the variables of Q to this state. For each variable x, we let $\alpha(x)$ be the value $[x]_\alpha$. By Lemma 3.2, Q is satisfiable. ☐

LEMMA 3.2. *The query Q is satisfied in the state $\mathbf{s}_Q$ under the assignment α.*

See [9] for more details (on a slightly different approach to the proof).

THEOREM 3.3. *A terminal conjunctive query Q on $\mathbf{S}$ is satisfiable if and only if the algorithm SatTestUT outputs yes.*

Proof. See [9]. ☐

Unless otherwise stated, we consider only satisfiable terminal conjunctive queries for the rest of this paper.

4. Containment of terminal conjunctive queries. We now set about developing a condition that characterizes containment of terminal conjunctive queries. We remark that some of the results of this section depend crucially on the notion of atoms over a state defined in section 2.4. For the rest of sections 4 and 5, a query Q refers to a terminal conjunctive query Q.

We begin by defining a relation that is intended to capture the equations that must be satisfied under any satisfying assignment for a query. Recall that the terms in an equation must have nonnull interpretations for the equation to hold. Given a query Q, define the relation $\approx$ on the set of terms by $s \approx t$ if either

1. s and t are both terms in the complete equality relationship graph of Q and $[s] = [t]$, or
2. s and t are the same term, which is an atomic value.

Note that the relation $\approx$ is an equivalence relation when restricted to the set of terms of the complete equality relationship graph of Q. However, $\approx$ is not an equivalence relation in general, since we do not have $t \approx t$ for terms t that are not an atomic value or in the complete equality relationship graph of Q. Intuitively, this reflects the fact that such terms may have interpretation Λ under a satisfying assignment, so that the equation $t = t$ does not hold. (We do have $c \approx c$ for atomic values c because the equation $c = c$ will hold under every satisfying assignment.)

We can extend the relation $\approx$ on terms to a relation on atoms by defining $\mathbf{A} \approx \mathbf{A}'$ if $\mathbf{A}$ and $\mathbf{A}'$ are atoms of the same syntactic form and the terms in corresponding positions are $\approx$-related. (For example, if $[x] = [y]$ and $z.A$ is a term of the complete equality relationship graph, then we have $x \in z.A \approx y \in z.Z$, but not $x = z.A \approx y \in z.Z$, because these atoms are of different syntactic forms.)

LEMMA 4.1. *If α is a satisfying assignment for Q in a state $\mathbf{s}$, then*

(i) *If s and t are terms with $s \approx t$, then both $Val(\alpha(s))$ and $Val(\alpha(t))$ are nonnull and $Val(\alpha(s)) = Val(\alpha(t))$.*

(ii) *If $\mathbf{A}$ and $\mathbf{A}'$ are atoms with $\mathbf{A} \approx \mathbf{A}'$, then $\mathbf{s} \models \alpha(\mathbf{A})$ if and only if $\mathbf{s} \models \alpha(\mathbf{A}')$.*

Proof. The claim of part (i) is trivial for constants c, since we always have that $Val(\alpha(c)) = c$ is nonnull. The case where s and t are terms of the complete equality relationship graph with $[s] = [t]$ is by induction on the construction of the complete equality relationship graph, proving also the additional property that $Val(\alpha(t))$ is nonnull for any term in the complete equality relationship graph.

Note that for all terms t of Q, we must have that $Val(\alpha(t))$ is nonnull, since this is required for the atom in which t occurs to be satisfied under α. (There is one exception to this observation, the case in which t is the distinguished term and not equal to a variable. But then t must be an atomic value c, for which $Val(\alpha(t)) = c$ is nonnull.) For equations $s = t$ in Q we must have $Val(\alpha(s)) = Val(\alpha(t))$ in order for α to be satisfying. It is trivial that for an equality edge $t = t$ we have $Val(\alpha(t)) = Val(\alpha(t))$. This establishes the base case of the induction. (The case of equations $t = t$, for terms introduced later in the construction, is similar but uses the additional property.)

Consider next the case of edges $t_1 = t_2$ and $t_2 = t_3$ inducing an edge $t_1 = t_3$. Since we have $[t_1] = [t_2]$ and $[t_2] = [t_3]$, it follows from the inductive hypothesis that $Val(\alpha(t_i))$ is nonnull for $i = 1, \ldots, 3$ and $Val(\alpha(t_1)) = Val(\alpha(t_2))$ and $Val(\alpha(t_2)) = Val(\alpha(t_3))$. It is immediate that $Val(\alpha(t_1)) = Val(\alpha(t_3))$.

Finally, suppose that x and y are variables with $x = y$, an edge of the complete equality relationship graph, and that $x.A$ is a node of the complete equality relationship graph. By the induction hypothesis $Val(\alpha(x))$ and $Val(\alpha(y))$ are nonnull and equal, and $Val(\alpha(x).A)$ is nonnull. It follows that $Val(\alpha(y.A)) = Val(\alpha(y).A)$ is equal to $Val(\alpha(x).A)$ and hence nonnull, and equal to $Val(\alpha(x.A))$.

Part (ii) follows directly from part (i) using the fact that the definition of satisfaction depends only on the values of the terms in the atoms $\mathbf{A}$ and $\mathbf{A}'$. $\square$

In addition to the atoms in a query, certain other atoms will always be satisfied with respect to any satisfying assignment for the query. For example, if a query contains atoms $x = y$ and $y \in C$, then every satisfying assignment also makes the atom $x \in C$ true. The following notion is intended to characterize such atoms. A query Q is said to *derive* an atom $\mathbf{A}$ if

1. $\mathbf{A}$ is of the form $t \in T$ where T is a basic type and $t \approx c$ for some atomic value c of type T, or
2. $\mathbf{A}$ is of the form $t_1 = t_2$, where t_1 and t_2 are terms satisfying $t_1 \approx t_2$, or
3. Q contains an atom $\mathbf{A}'$ such that $\mathbf{A}' \approx \mathbf{A}$.

We write $Q \vdash \mathbf{A}$ if Q derives the atom $\mathbf{A}$. The following result shows that every atom derived by a query in fact holds under any satisfying assignment.

LEMMA 4.2. *Let α be any satisfying assignment for the query Q in the state $\mathbf{s}$. If $\mathbf{A}$ is an atom such that $Q \vdash \mathbf{A}$, then $\mathbf{s} \models \alpha(\mathbf{A})$.*

Proof. We consider each clause of the definition of derivation:

1. Suppose $\mathbf{A}$ is of the form $t \in T$, where T is an atomic type and $t \approx c$, where c is an atomic value of type T. By Lemma 4.1, we have $Val(\alpha(t)) = Val(\alpha(c)) = c$. It follows that $\mathbf{s} \models \alpha(\mathbf{A})$.
2. If $\mathbf{A}$ is of the form $s = t$ with $s \approx t$, then by Lemma 4.1(i), $Val(\alpha(s)) = Val(\alpha(t))$, with both nonnull, so $\mathbf{s} \models \alpha(\mathbf{A})$ by definition.
3. Otherwise, Q contains an atom $\mathbf{A}'$ such that $\mathbf{A}' \approx \mathbf{A}$. Since α is a satisfying assignment, we have that $\mathbf{s} \models \alpha(\mathbf{A}')$. By Lemma 4.1(ii), it follows that $\mathbf{s} \models \alpha(\mathbf{A})$ also. $\square$

We now set about showing that a converse to this result holds for the state $\mathbf{s}_Q$ constructed form a query Q. We begin by relating atoms over this state to atoms of the query. Define an *inverse* of the canonical mapping α for the query Q to be a function ω mapping each object of $\mathbf{s}_Q$ and each atomic value to either a variable of Q or an atomic value, such that

1. for all atomic values c such that there exists a variable y of Q with $\alpha(y) = c$, we have that $\omega(c)$ is a variable with this property,
2. for all atomic values c such that there exists no variable y of Q with $\alpha(y) = c$,

we have $\omega(c) = c$, and

3. for all objects $[t]$ of $\mathbf{s}_Q$ we have that $\omega([t])$ is a variable in $[t]$. (Note that each object of $\mathbf{s}_Q$ is an equivalence class of terms that must contain a variable by condition (ii) of the definition of well-formed queries.)

We may extend ω to a mapping from terms over the state $\mathbf{s}_Q$ to terms formed using the variables of Q by defining $\omega([t].A) = \omega([t]).A$ for all terms of the form $[t].A$. The following result explains why we call such a mapping an inverse of α. (To understand the condition on (ii), observe that ω is not defined on sets occurring in $\mathbf{s}_Q$.)

LEMMA 4.3. *If ω is an inverse of the canonical mapping α from Q to $\mathbf{s}_Q$, then*

(i) *for all terms t of Q we have $\omega(\alpha(t)) \approx t$,*

(ii) *for all terms t over $\mathbf{s}_Q$ for which $Val(t)$ is nonnull and not equal to a set, we have $\omega(Val(t)) \approx \omega(t)$, and*

(iii) *for all terms t over $\mathbf{s}_Q$ for which $Val(t)$ is nonnull, $\omega(t)$ is either an atomic value or a term in the complete equality relationship graph of Q.*

Proof. For (i) we consider three cases, according to whether $\alpha(t)$ is an atomic value, object, or attribute term.

Consider first the case where $\alpha(t)$ is the atomic value c. Note that t cannot be an attribute term since these must be mapped to attribute terms. If t is an atomic value, t must be equal to c, so $\omega(\alpha(t)) = c \approx c = t$. If t is a variable, there exists a variable y with $\alpha(y) = c$ and $\omega(c) = y$. Since the construction guarantees that distinct equivalence classes are mapped by α to distinct values, we must have $t \in [y]$. Thus $\omega(\alpha(t)) = y \approx t$.

Next, consider the case in which $\alpha(t)$ is the object $[x]$. As this case can only arise from case Val3 of the construction, we have $t \in [x]$, so $\omega(\alpha(t)) = \omega([x]) \approx t$.

Finally, if $\alpha(t)$ is of the form $o.A$, where o is an object of $\mathbf{s}_Q$, then t is a term of the form $x.A$, where x is a variable, and $o = [x]$. Thus $\omega(\alpha(t)) = \omega([x].A) = \omega([x]).A$. Let $\omega([x])$ be the variable y. Because y must be in $[x]$ and $x.A$ is a term of the complete equality graph, $y.A$ is also a term of the complete equality graph, with $[x.A] = [y.A]$. Hence we have that $\omega(\alpha(t)) = y.A \approx x.A = t$.

We prove (ii) and (iii) together. Note that if t is an atomic value or an object of $\mathbf{s}_Q$, then $\omega(t)$ is a variable of Q or an atomic value, so the claim of (iii) holds. In this case we also have $Val(t) = t$, so the claim of (ii) follows directly from the fact that $\omega(t)$ is an atomic value or a term of the complete equality relationship graph, so that $\omega(t) \approx \omega(t)$.

Suppose next that t is a term over $\mathbf{s}_Q$ of the form $[x].A$ (where, without loss of generality, x is a variable) for which $Val(t)$ is defined and not equal to a set. By definition, $\omega([x].A) = \omega([x]).A = y.A$ for some variable $y \in [x]$. Moreover, by construction of $\mathbf{s}_Q$, there exists a variable $z \in [x]$ such that $z.A$ is a term in the complete equality relationship graph. It follows that $\omega([x].A)$ are in the complete equality relationship graph, establishing the claim of (iii) in this case. (Note also that $x.A$ is in the complete equality relationship graph.)

Moreover, we have either $Val(t) = [x.A]$ or $Val(t) = c$ for some atomic value c. To complete the proof of (ii) we consider each of these cases individually.

Suppose first that $Val(t) = [x.A]$. Let $\omega([x])$ be the variable $y \in [x]$. Then $x \approx y$. Hence $\omega(Val(t)) = \omega([x.A]) \approx x.A \approx y.A = \omega(t)$. Next, if $Val(t)$ is the atomic value c then, by construction of $\mathbf{s}_Q$, one of the following cases applies:

1. In case (Val1) of the construction, we have $c \in [x.A]$. Thus $\omega(Val(t)) = \omega(c)$. If there does not exist a variable v with $\omega(v) = c$, then $\omega(c) = c \approx x.A$. If there does exist such a variable, and $\omega(c) = v$, then we must have $v \in [x.A]$.

Hence, here $\omega(c) = v \approx x.A$. In either case, it follows that $\omega(\mathit{Val}(t)) \approx \omega(t)$.

2. In case (Val2) of the construction, $x.A$ is of atomic type, but $[x.A]$ contains no atomic value. In this case, there exists a variable y in $[x.A]$, for which we must have $\alpha(y) = c$. Without loss of generality, take y to be the variable such that $\omega(c) = y$. Then $\omega([x].A) = \omega([x]).A \approx x.A \approx y = \omega(\mathit{Val}(t))$. ☐

We may extend an inverse ω of α to a mapping from atoms $\mathbf{A}$ over $\mathbf{s}_Q$ to atoms over the variables of Q by defining $\omega(\mathbf{A})$ to be the atom obtained by substituting for each term t over $\mathbf{s}_Q$ in $\mathbf{A}$ the term $\omega(t)$.

We now show that the atoms derived by a query Q completely capture the set of atoms of a certain form holding in the state $\mathbf{s}_Q$. Define an atom over $\mathbf{s}_Q$ to be *terminal* if it is of one of the following forms:

1. $t \in T$, where t is a term over $\mathbf{s}_Q$ and T is an atomic type or terminal class,
2. $s = t$, where s and t are terms over $\mathbf{s}_Q$ such that neither $\mathit{Val}(s)$ nor $\mathit{Val}(s)$ is a set, and
3. $t \in o.A$, where t is a term over $\mathbf{s}_Q$ and o is an object of $\mathbf{s}_Q$.

Intuitively, the terminal atoms are those that may occur as images under satisfying assigments of a well-formed query.

LEMMA 4.4. *Let ω be any inverse of α. Then for all* terminal *atoms A over $\mathbf{s}_Q$ such that $\mathbf{s}_Q \models \mathbf{A}$ we have $Q \vdash \omega(\mathbf{A})$.*

Proof. We consider each of the possible cases for the atom A.

1. If $\mathbf{A}$ is of the form $c \in T$, where c is an atomic value of type T, then $Q \vdash \omega(\mathbf{A})$ by the first clause of the definition of derivation.
2. Suppose $\mathbf{A}$ is of the form $[t] \in C$, where C is a terminal class and $[t]$ is an object of $\mathbf{s}_Q$, with $I_c([t]) = C$. By construction of $\mathbf{s}_Q$, there exists a variable $x \in [t]$ such that $x \in C$ is an atom of Q. Since $\omega([t])$ is also an element of the equivalence class $[t]$, we have $x \approx \omega([t])$, so the atom $\omega(A)$ is $\approx$-related to the atom $x \in C$. Hence, $Q \vdash \omega(\mathbf{A})$ by the third clause of the definition of derivation.
3. Suppose that $\mathbf{A}$ is of the form $s = t$, where s and t are terms over $\mathbf{s}_Q$. For this equation to hold in $\mathbf{s}_Q$, we must have $\mathit{Val}(s) = \mathit{Val}(t)$, with both nonnull. Since the atom is terminal, neither value is a set. Hence, by Lemma 4.3(ii), we have $\omega(s) \approx \omega(\mathit{Val}(s)) = \omega(\mathit{Val}(s)) \approx \omega(t)$. It follows that $Q \vdash \omega(s) = \omega(t)$ by the second clause of the definition of derivation.
4. Suppose that $\mathbf{A}$ is an atom of the form $a \in b.A$, where a is a value or object of $\mathbf{s}_Q$ and b is an object of $\mathbf{s}_Q$. By construction of $\mathbf{s}_Q$, for this atom to hold in $\mathbf{s}_Q$ there must exist an object term t in Q and a set term $x.A$ such that $t \in x.A$ is an atom of Q and $\alpha(t) = a$ and $\alpha(x) = b$. Since $\omega(a) = \omega(\alpha(t)) \approx t$ and $\omega(b) = \omega(\alpha(x)) \approx x$ by Lemma 4.3(i), it follows the third clause of the definition of derivation that $Q \vdash \omega(t) \in \omega(b).A$, i.e., $Q \vdash \omega(\mathbf{A})$. ☐

We note that the corresponding property could not be established for atoms over $\mathbf{s}_Q$ expressing equations between sets. For example, for the query $Q = \{x \mid 1 \in x.A \wedge 1 \in y.B\}$ we find that in $\mathbf{s}_Q$ we have $\mathbf{s}_Q \models [x].A = [y].B$, since $\mathit{Val}([x].A) = \{1\} = \mathit{Val}([y].B)$, but not $Q \vdash x.A = y.B$, since $[x.A] \neq [y.B]$.

We are now ready to state the characterization of containment of queries. First, define a *variable mapping* from a query Q_2 to a query Q_1 to be a function μ mapping each variable of Q_2 to either a variable of Q_1 or to an atomic value. Such a mapping can be extended to a mapping from terms in the complete equality graph of Q_2 to expressions formed from atomic values and variables of Q_1 by taking $\mu(c) = c$ for all atomic values c, and $\mu(x.B) = \mu(x).B$ for all variables x. (Note that the expression $\mu(x).B$ need not be a term of the complete equality graph of Q_1, or even a term. For example, if $\mu(x)$ is the atomic value c, then this expression is $c.B$, which is not a term, and is uninterpretable in our language, since atomic values do not have attributes.)

We will deal with the composition of various such mappings. Recall that if $f : X \to Y$ and $g : Y \to Z$ are functions, then the composition $g \circ f$ is the function from X to Z defined by $g \circ f(x) = g(f(x))$.

Define a *containment mapping* μ from a query Q_2 to a query Q_1 to be a variable mapping from Q_2 to Q_1 such that

1. if t_1 is the distinguished term of Q_1 and t_2 is the distinguished term of Q_2, then $\mu(t_2) \approx_1 t_1$ (where $\approx_1$ is the relation derived from Q_1), and
2. for every atom A of Q_2, we have $Q_1 \vdash \mu(A)$.

The following result shows that containment mappings characterize containment between terminal conjunctive queries.

THEOREM 4.5. *If Q_1 and Q_2 are terminal conjunctive queries, then $Q_1 \subseteq Q_2$ if and only if there exists a containment mapping from Q_2 to Q_1.*

Proof. Suppose first that μ is a containment mapping from Q_2 to Q_1. We need to show that $Q_1 \subseteq Q_2$. For this, let $\mathbf{s}$ be any state and suppose that α is a satisfying assignment for Q_1 in the state $\mathbf{s}$, so that $\alpha(t_1) \in Q_1(\mathbf{s})$, where t_1 is the distinguished term of Q_1. We show that $\alpha(t_1)$ is also in $Q_2(\mathbf{s})$. Define the assignment β for Q_2 in $\mathbf{s}$ by $\beta = \alpha \circ \mu$. If $\mathbf{A}$ is an atom of Q_2, then since μ is a containment mapping we have by definition of containment that $Q_1 \vdash \mu(\mathbf{A})$. By Lemma 4.2 it follows that $\mathbf{s} \models \alpha(\mu(\mathbf{A}))$, i.e., that $\mathbf{s} \models \beta(\mathbf{A})$. Since this holds for every atom of Q_2 it follows that β is a satisfying assignment of Q_2 in $\mathbf{s}$. Thus $Q_2(\mathbf{s})$ contains $\beta(t_2)$, where t_2 is the distinguished term of Q_2. Because μ is a containment mapping, we have $\mu(t_2) \approx t_1$. Thus, by Lemma 4.1 we have that $\beta(t_2) = \alpha(\mu(t_2)) = \alpha(t_1)$ is in $Q_2(\mathbf{s})$, as promised. This completes the proof that $Q_1 \subseteq Q_2$, establishing the implication from right to left in the lemma.

To prove the converse, assume that there exists no containment mapping from Q_2 to Q_1. We show that Q_1 is not contained in Q_2 by establishing that $Q_1(\mathbf{s}_{Q_1})$ is not a subset of $Q_2(\mathbf{s}_{Q_1})$. In particular, we argue that if α is the canonical assignment of Q_1 in $\mathbf{s}_{Q_1}$ and t_1 is the distinguished term of Q_1, then $\alpha(t_1)$ is not in $Q_2(\mathbf{s}_{Q_1})$. Note that, on the other hand, $\alpha(t_1)$ is an element of $Q_1(\mathbf{s}_{Q_1})$ by Lemma 3.2.

To show that $\alpha(t_1)$ is not in $Q_2(\mathbf{s}_{Q_1})$, assume to the contrary that β is a satisfying assignment for Q_2 in $\mathbf{s}_{Q_1}$ with $\beta(t_2) = \alpha(t_1)$, where t_2 is the distinguished term of Q_2. We derive a contradiction to the assumption that there exists no containment mapping from Q_2 to Q_1. In particular, let ω be any inverse of α and consider the mapping $\mu = \omega \circ \beta$. Note that this must be a variable mapping from Q_2 to Q_1. We claim that μ is a containment mapping from Q_2 to Q_1.

To see this, note first that $\mu(t_2) = \omega(\beta(t_2)) = \omega(\alpha(t_1)) \approx t_1$. Thus μ satisfies the first clause of the definition of containment mapping. Next, note that if $\mathbf{A}$ is an atom of Q_2, then since β is a satisfying assignment we have that $\mathbf{s}_{Q_1} \models \beta(\mathbf{A})$. Since $\beta(\mathbf{A})$ is a terminal atom over $\mathbf{s}_{Q_1}$ we have by Lemma 4.4 that $Q_1 \vdash \omega(\beta(\mathbf{A}))$, i.e., that $Q_1 \vdash \mu(\mathbf{A})$. Thus μ satisfies the second condition of the definition of containment mapping, completing the proof that μ is a containment mapping from Q_2 to Q_1 and yielding the desired contradiction. $\square$

5. Minimization of terminal conjunctive queries.

In this section, we define a notion of minimality of terminal conjunctive queries and derive an algorithm that, given a terminal conjunctive query as input, finds a minimal equivalent query among all terminal conjunctive queries.

Let Q be a terminal conjunctive query. A *minimal* terminal conjunctive query of Q is a terminal conjunctive query equivalent to Q with the number of variables minimal among such terminal conjunctive queries. We now show how to find minimal queries.

We begin with a number of lemmas concerning containment mappings. In the rest of the discussion, we use subscripting to indicate the query with respect to which we compute the equivalence classes.

LEMMA 5.1. *Let μ be a containment mapping from the satisfiable terminal conjunctive query Q_2 to the satisfiable terminal conjunctive query Q_1.*

(i) *If t is a term of the complete equality relationship graph of Q_2, then $\mu(t)$ is either an atomic value or a term of the complete equality relationship graph of Q_1.*

(ii) *Let $\approx_1$ and $\approx_2$ be the relations on terms corresponding to the queries Q_1, Q_2, respectively. For all terms s and t, if $s \approx_2 t$ then $\mu(s) \approx_1 \mu(t)$.*

Proof. We establish (i) and (ii) simultaneously. If $s \approx_2 t$ because both s and t are the atomic value c, then we have $\mu(s) = \mu(t) = c$, so $\mu(s) \approx_1 \mu(t)$. It therefore remains to show that if $[s]_2 = [t]_2$, where s and t are terms of the complete equality relationship graph of Q_2, then $\mu(s)$ and $\mu(t)$ are terms of the complete equality relationship graph of Q_1 and $[\mu(s)]_1 = [\mu(t)]_1$. We prove this by induction on the construction of the complete equality relationship graph of query Q_2. Note that it is immediate from the fact that μ is a containment mapping that for all terms s of Q such that $\mu(s)$ is not an atomic value, we have $\mu(s)$ equal to a term in the complete equality relationship graph of Q_1. This is because s occurs in an atom $\mathbf{A}$ of Q_2 and Q_1 derives the atom $\mu(\mathbf{A})$.

In the case of edges $s = s$, we clearly have $\mu(s) \approx_1 \mu(s)$. For edges $s = t$ corresponding to atoms of Q_2, we have $\mu(s) \approx_1 \mu(t)$ because μ is a containment mapping. Suppose that an edge $s = u$ is derived from edges $s = t$ and $t = u$ of the complete equality relationship graph of Q_2 for which we have $\mu(s) \approx_1 \mu(t)$ and $\mu(t) \approx_1 \mu(u)$. Since all the latter terms are in Q_1, it follows from the fact that $\approx_1$ is an equivalence relation on the terms of Q_1 that $\mu(s) \approx_1 \mu(u)$.

Finally, suppose that an edge $x.A = y.A$ is derived from an edge $x = y$ and a term $x.A$ of the complete equality relationship graph of Q_2. We assume by way of induction that $\mu(x) \approx_1 \mu(y)$ and that the term $\mu(x.A)$ occurs in the complete equality relationship graph of Q_1. Now $\mu(x.A) = \mu(x).A$, so $\mu(x)$ must be a variable, else Q_1 would not be satisfiable. Since $\mu(x) \approx_1 \mu(y)$, it follows similarly that $\mu(y)$ must be a variable. Thus, $\mu(y.A) = \mu(y).A$ is a term of the complete equality relationship graph of Q_1 and $\mu(x).A \approx_1 \mu(y).A$, by the inductive hypothesis and the construction of the complete equality relationship graph of Q_1. ▯

LEMMA 5.2. *Let μ be a containment mapping from the satisfiable terminal conjunctive query Q_2 to the satisfiable terminal conjunctive query Q_1. If $\mathbf{A}$ is an atom such that $Q_1 \vdash \mathbf{A}$, then $Q_2 \vdash \mu(\mathbf{A})$.*

Proof. We consider the three cases of the definition of derivation. First, suppose $\mathbf{A}$ is of the form $t \in T$, where T is an atomic type and t is $\approx$-related to the atomic value c of type T. Then by Lemma 5.1(ii) we have $\mu(t) \approx_1 c$, so $Q_1 \vdash \mu(t) \in T$. Second, if $\mathbf{A}$ is the atom $s = t$ and $s \approx_2 t$, then by Lemma 5.1(ii) we have $\mu(s) \approx_1 \mu(t)$, so $Q_1 \vdash \mu(s) = \mu(t)$. Finally, if Q_2 contains the atom $\mathbf{A}' \approx_2 \mathbf{A}$, then by Lemma 5.1(ii) we have $\mu(\mathbf{A}') \approx_1 \mu(\mathbf{A})$. Since μ is a containment mapping it is also the case that $Q_1 \vdash \mu(\mathbf{A}')$. It follows using the definition of derivation and the fact that $\approx_1$ is an equivalence relation on terms of the complete equality relationship graph that $Q_1 \vdash \mu(\mathbf{A})$. ☐

LEMMA 5.3. *Let Q_1, Q_2, and Q_3 be satisfiable terminal conjunctive queries. If μ_1 is a containment mapping from Q_1 to Q_2 and μ_1 is a containment mapping from Q_2 to Q_3, then $\mu_2 \circ \mu_1$ is a containment mapping from Q_1 to Q_3.*

Proof. Let t_1, t_2, and t_3 be the distinguished terms of Q_1, Q_2, and Q_3, respectively, and let $\approx_1, \approx_2$, and $\approx_3$ be the relations on terms derived form these queries. Since μ_1 and μ_2 are containment mappings, we have $\mu_1(t_1) \approx_2 t_2$ and $\mu_2(t_2) \approx_3 t_3$. It follows, using Lemma 5.1(ii), that $\mu_2 \circ \mu_1(t_1) \approx_3 \mu_2(t_2) \approx_3 t_3$. This establishes that $\mu_2 \circ \mu_1$ satisfies the first condition of the definition of containment mapping.

It remains to show that if $\mathbf{A}$ is an atom of Q_1, then $Q_3 \vdash \mu_2 \circ \mu_1(\mathbf{A})$. Since μ_1 is a containment mapping we have that $Q_2 \vdash \mu_1(\mathbf{A})$. It follows, using Lemma 5.2 and the fact that μ_2 is a containment mapping, that $Q_3 \vdash \mu_2 \circ \mu_1(\mathbf{A})$. ☐

Let $Q = \{t \mid M\}$ be a conjunctive query and suppose μ is a variable mapping on Q. Define $\mu(Q)$ to be the conjunctive query with the distinguished term $\mu(t)$ obtained by replacing each atom $\mathbf{A}$ of Q by the atom $\mu(\mathbf{A})$.

PROPOSITION 5.4. *Let Q be a terminal conjunctive query. Suppose there is a containment mapping μ from Q to itself. Then $\mu(Q)$ is equivalent to Q.*

Proof. It is easy to check that μ is a containment mapping from Q to $\mu(Q)$, so we have by Theorem 4.5 that $\mu(Q) \subseteq Q$. To show $Q \subseteq \mu(Q)$, we show that there is a containment mapping from $\mu(Q)$ to Q. We claim that the identity mapping i is such a mapping. Note first that the distinguished term of $\mu(Q)$ is $\mu(t)$, where t is the distinguished term of Q, and we have $i(\mu(t)) = \mu(t) \approx t$, because μ is a containment mapping. It remains to show that for every atom $\mathbf{A}$ of Q, we have for the corresponding atom $\mu(\mathbf{A})$ of $\mu(Q)$ that $Q \vdash i(\mu(\mathbf{A}))$. That is, we need $Q \vdash \mu(\mathbf{A})$. This is immediate from the fact that μ is a containment mapping. ☐

The following describes how to obtain a minimal terminal conjunctive query. Say that a variable mapping μ from a query Q_1 to a query Q_2 is *bijective* if $\mu(x)$ is a variable of Q_2 for every variable x of Q_1 and the restriction of μ to the set of variables of Q_1 is a bijective mapping to the set of variables of Q_2.

THEOREM 5.5. *A terminal conjunctive query Q is minimal if all containment mappings from Q to itself are bijective.*

Proof. Suppose that all containment mappings from Q to itself are bijective, but that Q is not minimal. We establish a contradiction. Since Q is not minimal, there is a minimal terminal conjunctive query Q' equivalent to Q which has fewer variables. Now by Theorem 4.5, the fact that $Q' \equiv Q$ implies that there is a containment mapping μ from Q to Q' and also that there is a containment mapping ω from Q' to Q. It follows from Lemma 5.3 that the composite mapping $\omega \circ \mu$ is a variable mapping from Q to itself. By the assumption, $\omega \circ \mu$ is bijective. But this means that the number of variables of Q' is at least as large as the number of variables of Q, contradicting the choice of Q'. ☐

The converse to Theorem 5.5 follows from the following.

THEOREM 5.6. *Let Q_1 and Q_2 be minimal terminal conjunctive queries. Suppose $Q_1 \equiv Q_2$. Then every containment mapping from one query to the other is bijective.*

Proof. Let μ be a containment mapping from Q_1 to Q_2. Since these queries are equivalent, there also exists a containment mapping ω from Q_2 to Q_1. By Lemma 5.3, the composite mapping $\mu \circ \omega$ is a containment mapping from Q_2 to itself. Suppose that the image of the set of variables of Q_2 under $\mu \circ \omega$ does not contain all the variables of Q_2. Then the query $(\mu \circ \omega)(Q_2)$, which is equivalent to Q_2 by Proposition 5.4, has fewer variables than Q_2. This contradicts the minimality of Q_2. This shows that the image of the set of variables of Q_2 under $\mu \circ \omega$ contains all the variables of Q_2. It follows that Q_1 has at least as many variables as Q_2. A similar argument using the containment mapping $\omega \circ \mu$ from Q_1 to Q_1 shows that Q_2 has at least as many variables as Q_1. Since $\mu \circ \omega$ covers the variables of Q_2, it now follows that μ must in fact be a bijection between the variables of Q_1 and Q_2. $\square$

Given a satisfiable terminal conjunctive query Q, the algorithm to find a minimal terminal conjunctive query Q' equivalent to Q is as follows. Consider all containment mappings μ from Q to itself. Choose Q' to be one of the queries $\mu(Q)$ that has the fewest variables among such queries. The minimality of Q' follows from Theorem 5.6.

Note that there may be some further optimizations possible for the query Q' so obtained, since this may contain atoms of the form $c \in T$ or $c = c$, where c is an atomic value of type T. Such atoms, since they are derivable even from an empty query, can be deleted, yielding an equivalent query.

6. Containment and optimization of conjunctive queries. In this section, we study the containment of conjunctive queries and show how to obtain optimal conjunctive queries. The optimal conjunctive queries obtained are expressed as unions of terminal conjunctive queries and are optimal among all unions of terminal conjunctive queries. In section 6.1, we characterize containment of conjunctive queries by solving the containment problem for unions of terminal conjunctive queries. In section 6.2, we give our notion of optimality. In section 6.3, we derive an algorithm, given a conjunctive query, for finding an optimal union of terminal conjunctive queries. We first use an example to illustrate our notion of optimality and the approach taken in obtaining an optimal query.

Example 6.1. Let us consider the following query defined on the schema in Example 1.1.

$$Q_1 : \{x \mid \exists y\, \exists z\ (x \in \text{Vehicle}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Client}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$

This query retrieves all those vehicles that have been rented to a discount client. By Proposition 2.1, Q_1 is equivalent to the union of the following terminal conjunctive queries:

$$S_1 : \{x \mid \exists y\, \exists z\ (x \in \text{Auto}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Normal}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$
$$S_2 : \{x \mid \exists y\, \exists z\ (x \in \text{Auto}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Discount}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$
$$S_3 : \{x \mid \exists y\, \exists z\ (x \in \text{Trailer}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Normal}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$
$$S_4 : \{x \mid \exists y\, \exists z(x \in \text{Trailer}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Discount}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$
$$S_5 : \{x \mid \exists y\, \exists z(x \in \text{Truck}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Normal}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$
$$S_6 : \{x \mid \exists y\, \exists z(x \in \text{Truck}\ \&\ y \in \text{Discount}\ \&\ z \in \text{Discount}\ \&\ x \in y.\text{VehRented}\ \&\ x \in z.\text{VehRented})\}.$$

With algorithm SatTestUT, it can be shown that S_3, S_4, S_5, and S_6 are unsatisfiable. The reason for this is that discount clients are only allowed to rent automobiles and not other types of vehicles. Hence Q_1 is equivalent to $S_1 \cup S_2$. There is a containment mapping from S_2 to S_1; the mapping is to map x to x and y and z to y. By Theorem 4.5, S_1 is redundant and is removed from the union. S_2 can further be minimized by mapping x to x and y and z to y. The resulting optimal query obtained is as follows:

$$S_2' : \{x \mid \exists y(x \in \text{ Auto } \& \ y \in \text{ Discount } \& \ x \in y.\text{VehRented})\}. \qquad \square$$

6.1. A characterization of containment of unions of terminal conjunctive queries. By Proposition 2.1, understanding containment of unions of terminal conjunctive queries suffices to solve the containment problem of conjunctive queries. We have found a characterization of containment for terminal conjunctive queries. We are now ready to state the containment condition for two unions of terminal conjunctive queries.

THEOREM 6.1. *Let $M = Q_1 \cup \cdots \cup Q_s$ and $N = P_1 \cup \cdots \cup P_t$ be two unions of terminal conjunctive queries. $M \subseteq N$ if and only if for each Q_i in M there is a P_j in N such that $Q_i \subseteq P_j$.*

Proof. "If." This part is trivial.

"Only if." Let Q_i be a subquery in M. Let $\mathbf{s}_{Q_i}$ be the state constructed for Q_i. Suppose α is a satisfying assignment from Q_i to $\mathbf{s}_{Q_i}$ and let ω be an inverse of α. Since $M \subseteq N$, there is some P_j such that there is a satisfying assignment γ of object identifiers and atomic values in the state $\mathbf{s}_{Q_i}$ to variables in P_j that gives rise to the answer $\alpha(t_i)$, where t_i is the distinguished term of Q_i. Then $\omega o \gamma$ is a variable mapping from P_j to Q_i. We show that the mapping $\omega o \gamma$ is a containment mapping.

Let $\omega o \gamma(t_j) = v$, where t_j is the distinguished term of P_j. Then $\gamma(t_j) = \alpha(t_i)$. Hence, $\omega(\gamma(t_j)) = \omega(\alpha(t_i))$. By Lemma 4.3(i), $\omega(\alpha(t_i)) \approx t_j$. Let $\mathbf{A}$ be an atom of P_j. Then $\gamma(\mathbf{A})$ is a terminal atom over $\mathbf{s}_{Q_i}$ and $\mathbf{s}_{Q_i} \models \gamma(\mathbf{A})$. By Lemma 4.4, $Q_i \vdash \omega$ $(\gamma(\mathbf{A}))$. Hence $\omega o \gamma$ is a containment mapping. By Theorem 4.5, $Q_i \subseteq P_j$. $\square$

As a corollary, we solve the problem of determining when one conjunctive query contains the other one.

6.2. Search-space-optimal queries. We now introduce our notion of optimality, which tries to capture the intuition that the number of variables as well as their search spaces are minimal among all equivalent queries. In a conjunctive query, each variable is associated with a set of terminal classes or atomic types which denotes the search space of the variable. Without knowing the physical data organization for various classes, a good criterion of evaluating various equivalent queries is by comparing the set of variables in a query and their associated search spaces.

Example 6.2. Let us consider again the vehicle rental schema. The following three queries can be shown to be equivalent:

$$\begin{aligned} Q_1 : \{x \mid \exists y \exists z \ (&x \in \text{Auto} \ \& \ y \in \text{Discount} \ \& \ z \in \text{Vehicle} \ \& \ x \in y.\text{VehRented} \\ &\& \ z \in y.\text{VehRented})\}. \\ Q_2 : \{x \mid \exists y \ (&x \in \text{Vehicle} \ \& \ y \in \text{Discount} \ \& \ x \in y.\text{VehRented})\}. \\ Q_3 : \{x \mid \exists y \ (&x \in \text{Auto} \ \& \ y \in \text{Discount} \ \& \ x \in y.\text{VehRented})\}. \end{aligned}$$

If we consider the domain of the type of a variable as its search space, then Q_1 has more variables and has a larger search space than Q_2. Although Q_2 and Q_3 have the same number of variables, the search space associated with variables in Q_2 is greater than that in Q_3. Q_3 is considered to be more optimal since the number of variables as well as the search space are minimal. $\Box$

Existing work on exact minimization tries to minimize the number of joins in an expression [2]. The notion of optimality we shall propose attempts to generalize that idea.

A *multiset* is a set or bag of elements in which *duplicate* elements are allowed. Let S and T be two multisets. The *bag union* of S and T, denoting $S \uplus T$, is a multiset obtained from merging elements in the operands, such that for every element x in S or T, the number of occurrences of x in the bag union is the sum of the numbers of occurrences of x in S and in T. Clearly the bag union operator is commutative and associative. We say S is a *bag subset* of T and denotes $S \sqsubseteq T$ if for every element x in S, if there are n occurrences of x in S, then there are at least n occurrences of x in T.

Let Q be a conjunctive query and x a variable in Q. Define *term-class*(Q, x) $=\{E \mid x \in C_1 \sqcup \cdots \sqcup C_n$ is the range atom in Q associated with the variable x, and E is a terminal subtype of C_i, for some $1 \leq i \leq n\}$. Informally, *term-class*(Q, x) gives the terminal descendent classes or atomic types over which the variable x is ranging in the query. Let $x_1, \ldots, x_n$ be the set of variables in Q. Then *term-class*(Q) is a multiset defined as *term-class*$(Q, x_1) \uplus \cdots \uplus$ *term-class*(Q, x_n).

We are now ready to define our notion of optimality. Let $Q = Q_1 \cup \cdots \cup Q_n$ and $P = P_1 \cup \cdots \cup P_m$ be two unions of conjunctive queries. Q is said to be *at least as optimal* as P, denotes $Q \leq P$, if *term-class*$(Q_1) \uplus \cdots \uplus$ *term-class*$(Q_n) \sqsubseteq$ *term-class*$(P_1) \uplus \cdots \uplus$ *term-class*(P_m).

A query Q is *search-space-optimal* among a set of queries $\mathbf{S}$ if for all P in $\mathbf{S}$ such that P is equivalent to $Q, P \leq Q$ implies $Q \leq P$. For search-space-optimal queries, the object search spaces are minimal among all equivalent queries in the set $\mathbf{S}$. The query Q_3 in Example 6.2 is a search-space-optimal query.

COROLLARY 6.2. *If Q is a minimal terminal conjunctive query, then Q is a search-space-optimal query among all terminal conjunctive queries.*

Proof. The proof of the corollary follows from Theorem 5.6 and the derivability of range atoms. $\Box$

6.3. Optimization of unions of terminal conjunctive queries. In this subsection, we study the optimization of unions of terminal conjunctive queries. We show how to obtain a search-space-optimal query among all unions of terminal conjunctive queries.

A union of terminal conjunctive queries $Q_1(\mathbf{s}, t) \cup \cdots \cup Q_n(\mathbf{s}, t)$ is *nonredundant* if there are no Q_i and $Q_j, i \neq j$, such that $Q_i \subseteq Q_j$. We can transform a union of terminal conjunctive queries to an equivalent nonredundant union by finding Q_i and Q_j, $i \neq j$, such that $Q_i \subseteq Q_j$ and deleting Q_i from the union until no more subquery can be removed.

The following is an important property about nonredundant unions of terminal conjunctive queries.

THEOREM 6.3. *Let $M = Q_1 \cup \cdots \cup Q_s$ and $N = P_1 \cup \cdots \cup P_t$ be two nonredundant unions of terminal conjunctive queries. Then $M \equiv N$ if and only if for each Q_i in M, there is a unique P_j in N such that $Q_i \equiv P_j$ and vice versa. Moreover, $s = t$.*

Proof. "If" follows from Theorem 6.1.

For "Only if", suppose $M \equiv N$. Let Q_i be a subquery in M. By Theorem 6.1, there is a P_j in N such that $Q_i \subseteq P_j$. By the assumption on equivalence and by

Theorem 6.1, there is Q_p in M such that $P_j \subseteq Q_p$. If $i \neq p$, then $Q_i \subseteq P_j$ and $P_j \subseteq Q_p$. This implies $Q_i \subseteq Q_p$ and contradicts the nonredundancy of M. Hence $i = p$ and $Q_i \equiv P_j$. If $s \neq t$, say, $s < t$, then there is a P_j which is redundant. This is a contradiction. It follows that $s = t$. ☐

The following is an algorithm for finding an optimal union of terminal conjunctive queries for a conjunctive query.

Algorithm Optimization. Given a conjunctive query Q, find an equivalent union of terminal conjunctive queries which is search-space-optimal among all unions of terminal conjunctive queries.

Input: A conjunctive query Q.
Output: An equivalent union of terminal conjunctive queries.
Method:
(1) Convert Q into an equivalent union of terminal conjunctive queries.
(2) Remove unsatisfiable subqueries from the union using the algorithm *SatTestUT*.
(3) Remove any redundant subqueries from the union.
(4) Minimize each of the remaining subqueries.
(5) Output the union of resulting terminal conjunctive queries.

Theorem 6.4. *The union of terminal conjunctive queries output by Algorithm Optimization is equivalent to Q and is a search-space-optimal query among all unions of terminal conjunctive queries.*

Proof. By Proposition 2.1, Theorem 3.3, and definitions of redundancy and minimization, the union, say Q', output is equivalent to the input Q. Let $P = P_1 \cup \cdots \cup P_n$ be a union of terminal conjunctive queries that is equivalent to Q. Without loss of generality, let us assume that P is nonredundant and each subquery is minimal. By Theorem 6.3, there is a one-to-one correspondence between the two unions. By Theorem 5.6 and the fact that both unions are unions of terminal conjunctive queries, $Q' \leq P$. ☐

Let us look at the following example.

Example 6.3. Let us consider a query defined on the schema in Figure 4:

$$Q_1 : \{x \mid \exists y\, \exists s\ (x \in N \ \&\ y \in H \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$

By Proposition 2.1, Q_1 is equivalent to the union of the following terminal conjunctive queries:

$$S_1 : \{x \mid \exists y\, \exists s\ (x \in T_1 \ \&\ y \in I \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$
$$S_2 : \{x \mid \exists y\, \exists s\ (x \in T_2 \ \&\ y \in I \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$
$$S_3 : \{x \mid \exists y\, \exists s\ (x \in T_3 \ \&\ y \in I \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$
$$S_4 : \{x \mid \exists y\, \exists s\ (x \in T_1 \ \&\ y \in J \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$
$$S_5 : \{x \mid \exists y\, \exists s\ (x \in T_2 \ \&\ y \in J \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$
$$S_6 : \{x \mid \exists y\, \exists s\ (x \in T_3 \ \&\ y \in J \ \&\ s \in J \ \&\ y = x.B \ \&\ y \in x.A \ \&\ s \in x.A)\}.$$

With algorithm SatTestUT, S_2, S_3, S_4, and S_5 are unsatisfiable. Hence Q_1 is equivalent to $S_1 \cup S_6$. Neither subquery in the union contains the other and hence the union is nonredundant. Since variables in S_1 range over different terminal classes, S_1 is minimal. It can easily be shown that S_6 can be minimized further. A minimal form is as follows:

$$S'_6 : \{x \mid \exists y\ (x \in T_3 \ \&\ y \in J \ \&\ y = x.B \ \&\ y \in x.A)\}.$$

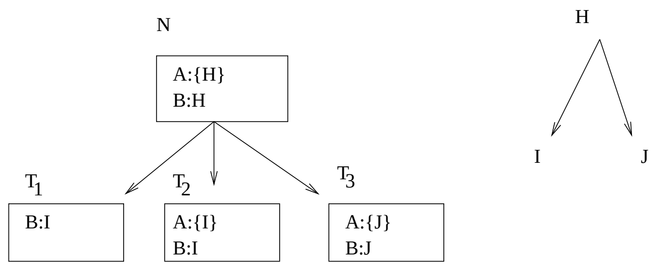

FIG. 4. *An inheritance hierarchy.*

The union of terminal conjunctive queries output by the algorithm is $S_1 \cup S'_6$, which is a search-space-optimal query for Q_1 among all unions of terminal conjunctive queries. □

Algorithm *Optimization* only produces an optimal query expressed as a union of terminal conjunctive queries. This form need not be the most desirable form to be executed. For instance, Q_1 in Example 6.3 is equivalent to the following query:

$$Q_2 : \{x \mid \exists y \, \exists s \; (x \in T_1 \sqcup T_3 \;\&\; y \in H \;\&\; s \in J \;\&\; y = x.B \;\&\; y \in x.A \;\&\; s \in x.A)\}.$$

Throughout the discussion, we made *no* assumption on how data are being physically organized. It could be the case that, given certain information on data organization, Q_2 is a better form to be evaluated than the union produced by the algorithm. However, the union of terminal conjunctive queries produced could be used as a basis to generate an equivalent query in a more desirable form. It would be interesting to see how other information could be used to synthesize a more optimal query for the union.

7. Complexity of the containment problem. In this section, we investigate the time complexity for determining containment of conjunctive queries. We begin with the simple case of terminal conjunctive queries. The containment problem for terminal conjunctive queries is clearly in NP. A relational query is called a select-project-join (SPJ)-query if only selections with constant, projection, and natural join are used in the query. It is well known that the class of relational SPJ-expressions can be expressed as a tagged tableau [2]. Every such tagged tableau can be translated into a conjunctive query without the set membership construct. In [2], it was shown that the problem of determining containment of SPJ-expressions is an NP-complete problem. Consequently, the containment problem of terminal conjunctive queries is also NP-complete. In fact, it can be shown that the containment problem of terminal conjunctive queries involving only range and set membership atoms is NP-complete.

COROLLARY 7.1. *The problem of determining containment for terminal conjunctive queries is an NP-complete problem.*

Proof. The proof follows from the argument above. □

Corollary 7.1 implies that testing containment of conjunctive queries is NP-hard. We shall show that the problem is in Π_2^P of the polynomial hierarchy [28]. The proof of this result is similar to a proof in [24]. A language L is in Π_2^P if its complement is in Σ_2^P, the class of languages which can be recognized by a nondeterministic polynomial-time algorithm with an oracle from NP. An *oracle* for a class of decision problems **C** enables one to decide any problem in **C** in unit time. The classes Σ_2^P and Π_2^P contain NP and are contained in PSPACE.

THEOREM 7.2. *The problem of determining containment for conjunctive queries is in* Π_2^P.

Proof. Let E_1 and E_2 be two conjunctive queries. We describe a nondeterministic polynomial-time algorithm with an oracle from NP that answers "yes" if and only if $E_1 \not\subseteq E_2$. By Theorem 6.1, $E_1 \not\subseteq E_2$ if and only if there is a terminal conjunctive query in the union for E_1, say E_3, such that $E_3 \not\subseteq E_2$. E_3 can be guessed nondeterministically from E_1 by assigning terminal classes or atomic types to variables involved. After guessing the query, we test if E_3 is satisfiable. Testing satisfiability of terminal conjunctive queries can be performed in polynomial time [9]. If E_3 is satisfiable, then we ask the oracle if $E_3 \subseteq E_2$. If the oracle answers "no," then the algorithm answers "yes." It remains to show that determining $E_3 \subseteq E_2$ is in NP. By Theorem 6.1, $E_3 \subseteq E_2$ if and only if there is a terminal conjunctive query in the union for E_2, say E_4, such that $E_3 \subseteq E_4$. Thus we can guess E_4 as before and then check in nondeteministic polynomial time that $E_3 \subseteq E_4$. Hence our claim is proved. ◻

We are now ready to show that the containment problem is Π_2^P-hard.

A Π_2 formula of quantified propositional logic is an expression,

$$\varphi = \forall p_1 \cdots p_n \exists p_{n+1} \cdots p_{n+m}[\alpha],$$

where α is a formula of propositional logic containing only the propositional variables $p_1, \ldots, p_{n+m}$. Such an expression is true if for every assignment of Boolean truth value to the variables $p_1, \ldots, p_n$, there exists an assignment of truth values to the variables $p_{n+1}, \ldots, p_{n+m}$ under which the formula α is true. The set Π_2-SAT is the set of all true Π_2 formulae. This is a generalization of the problem of satisfiability to the polynomial hierarchy. It is known that the set Π_2-SAT is complete for the level Π_2^p of this hierarchy [29, 32].

THEOREM 7.3. *There exists a fixed schema* **S** *such that problem of deciding, given queries* Q_1 *and* Q_2 *on* **S**, *whether* $Q_1 \subseteq Q_2$ *is* Π_2^p*-hard.*

Proof. By reduction from Π_2-SAT. We show that for every Π_2 formula φ, there is a pair of conjunctive queries Q_1, Q_2 such that φ is true if and only if Q_1 is contained in Q_2.

Define the schema **S** to contain classes C, R, G, V, AND, and NOT. The subclass relationships between these classes are given by $R \prec C$ and $G \prec C$. Thus, the terminal classes are R, G, V, AND, and NOT. The tuple type for both R and G is $[a : C,\ b : INT,\ c : V]$, for V is the empty tuple type $[]$, for AND is $[in_1 : V, in_2 : V, out : V]$, and for NOT is $[in : V, out : V]$.

We first describe the query Q_1. Part of this query will encode the truth tables for conjunction and negation. Intuitively, there are (four) variables ranging over AND which represent the lines of the truth table for "$\wedge$," there are (two) variables ranging over NOT which represent the lines of the truth table of "$\neg$," and there are variables t and f in V which denote the truth values *true* and *false*, respectively. We write $TT(t, f)$ for the following formula:

$$\begin{aligned}
&\exists u_1 \in AND[u_1.\,in_1 = t \;\&\; u_1.\,in_2 = t \;\&\; u_1.\,out = t] \;\&\\
&\exists u_2 \in AND[u_2.\,in_1 = t \;\&\; u_2.\,in_2 = f \;\&\; u_2.\,out = f] \;\&\\
&\exists u_3 \in AND[u_3.\,in_1 = f \;\&\; u_3.\,in_2 = t \;\&\; u_3.\,out = f] \;\&\\
&\exists u_4 \in AND[u_4.\,in_1 = f \;\&\; u_4.\,in_2 = f \;\&\; u_4.\,out = f] \;\&\\
&\exists v_1 \in NOT[v_1.\,in = t \;\&\; v_1.\,out = f] \;\&\\
&\exists v_2 \in NOT[v_2.\,in = f \;\&\; v_2.\,out = t].
\end{aligned}$$

Next, suppose φ has n universally quantified variables. Part of the query Q_1 will have the function of assigning a truth value to each of these variables. We construct for each $i = 1, \ldots, n$ the query $ASGN_i(t, f)$ given by

$$\exists w_{i1} \in R \exists w_{i2} \in C \exists w_{i3} \in G\big[w_{i1}.a = w_{i2} \;\&\; w_{i2}.a = w_{i3} \;\&\; w_{i2}.b = i \;\&\; w_{i3}.b = i \;\&\; w_{i2}.c = t \;\&\; w_{i3}.c = f\big].$$

We now define the query Q_1 to be

$$\{t \mid t \in V \;\&\; \exists f \in V[TT(t, f) \;\&\; ASGN_1(t, f) \;\&\; \cdots \;\&\; ASGN_n(t, f)]\}.$$

After moving the quantifiers to the front, it is clear that Q_1 is a conjunctive query.

Let α be a formula of propositional logic in the propositional constants $p_1, \ldots, p_{n+m}$. We define inductively the formula Φ_α with free variables amongst $\mathbf{x} = x_{p_n}, \ldots, x_{p_{n+m}}$ and x_α. If α is the propositional constant p_i, where $i = 1, \ldots, n$, then

$$\Phi_\alpha = \exists z_{i1} \in R \exists z_{i2} \in G\big[z_{i1}.a = z_{i2} \;\&\; z_{i2}.b = i \;\&\; z_{i2}.c = x_{p_i}\big].$$

If α is the propositional constant p_i, where $i = n+1, \ldots, n+m$, then Φ_α is the null formula **true**. (Note that the variable x_α is x_{p_i} in these cases.) If $\alpha = \beta \& \gamma$, then $\Phi_\alpha(\mathbf{x}, x_\alpha)$ is

$$\exists y_\beta \in AND\, \exists x_\beta x_\gamma \in V \left[\begin{array}{l} y_\beta.\,in_1 = x_\beta \;\&\; y_\beta.\,in_2 = x_\gamma \;\&\; y_\beta.\,out = x_\alpha \;\&\; \\ \Phi_\beta(\mathbf{x}, x_\beta) \;\&\; \Phi_\gamma(\mathbf{x}, x_\gamma) \end{array} \right].$$

If $\alpha = \neg\beta$, then $\Phi_\alpha(\mathbf{x}, x_\alpha)$ is

$$\exists y_\beta \in NOT\, \exists x_\beta \in V\big[x.\,in = x_\beta \;\&\; y_\beta.\,out = x_\alpha \;\&\; \Phi_\beta(\mathbf{x}, x_\beta)\big].$$

We define Q_2 to be the query

$$\big\{x_\alpha \mid x_\alpha \in V \;\&\; \exists x_{p_1} \cdots x_{p_n} \in V\big[\Phi_\alpha(\mathbf{x}, x_\alpha)\big]\big\}.$$

Observe that the class C does not occur in Q_2. Thus, after moving the quantifiers to the front, this query is a terminal conjunctive query.

Note that expansions of Q_1 are obtained by replacing each of the n range atoms $w_{i2} \in C$ by either $w_{i2} \in R$ or $w_{i2} \in G$. There are therefore 2^n such expansions. We first show that each of these expansions uniquely determines an assignment of truth values to the propositional constants $p_1, \ldots, p_n$.

Suppose $1 \leq i \leq n$. Because the constant i has only two occurrences in Q_1, if μ is a mapping from the variables z_{i1}, z_{i2}, x_{p_i} to the variables of an expansion E of Q_1 that preserves the atom $z_{i2}.b = i$ of the formula Φ_{p_i}, then we must have $\mu(z_{i2}) = w_{i2}$ or $\mu(z_{i2}) = w_{i3}$. In case the atom $w_{i2} \in C$ of $ASGN_i$ is expanded as $w_{i2} \in G$, the mapping $z_{i1} \mapsto w_{i1}, z_{i2} \mapsto w_{i2}, x_{p_i} \mapsto t$, is the only mapping that preserves all the equality and range atoms of Φ_{p_i}. This determines the assignment of *true* to p_i. Similarly, in case $w_{i2} \in C$ is expanded as $w_{i2} \in R$, the mapping $z_{i1} \mapsto w_{i2}, z_{i2} \mapsto w_{i3}, x_{p_i} \mapsto f$ is the only such mapping. This determines the assignment of *false* to p_i.

Next, suppose that μ is a mapping from the variables of the formulae Φ_{p_i} for $i = 1, \ldots, n$ and the variables $x_{p_{n+1}}, \ldots, x_{p_{n+m}}$ to the variables of an expansion E of Q_1, such that the atoms of Q_2 containing these variables are preserved. As noted above, this implies that the variables $x_{p_1}, \ldots, x_{p_n}$ are mapped to either t or f. The same holds for the variables $x_{p_{n+1}}, \ldots, x_{p_{n+m}}$, because of the range atoms $x_{p_i} \in V$ in Q_2. Let θ be the truth value assignment that assigns the constant p_i to be *true* if and only if $\mu(x_{p_i}) = t$. Under these conditions, a straightforward induction on the complexity of α shows that there exists a unique extension of the mapping μ to a mapping from the variables of Q_2 to the variables of Q_1 that preserves all the atoms of Q_2. Furthermore, we have $\mu(x_\alpha) = t$ if and only if the formula α is true with respect to the assignment θ. Note also that this mapping μ is a containment mapping from Q_2 to the expansion E if and only if $\mu(x_\alpha) = t$.

It now follows from the observations above that there exists a containment mapping from Q_2 to E for each expansion E of Q_1 if and only if the quantified formula φ is true. □

THEOREM 7.4. *The problem of determining containment for conjunctive queries is complete in* Π_2^P.

Proof. The proof follows from Theorems 7.2 and 7.3. □

8. Conclusion. Query optimization is an important and yet difficult problem in an OODB. The types of attributes in an inheritance hierarchy can be considered as constraints imposed on objects in a state. In this paper, we studied the containment, equivalence, and optimization problems for a class of natural queries called conjunctive queries. A conjunctive query can be expressed as a union of terminal conjunctive queries. We first characterized containment and minimization for terminal conjunctive queries. We then solved the problems of containment and optimization for the class of object-preserving conjunctive queries. The optimal queries are expressed as unions of terminal conjunctive queries. The notion of optimality captures the intuition that an optimal equivalent query logically accesses, in certain sense, the least number of objects in a database. It was shown that testing containment of terminal conjunctive queries is an NP-complete problem. Moreover, the containment problem of conjunctive query in general is Π_2^p-complete.

ROBUST PLANE SWEEP FOR INTERSECTING SEGMENTS[*]

JEAN-DANIEL BOISSONNAT[†] AND FRANCO P. PREPARATA[‡]

Abstract. In this paper, we reexamine in the framework of robust computation the Bentley–Ottmann algorithm for reporting intersecting pairs of segments in the plane. This algorithm has been reported as being very sensitive to numerical errors. Indeed, a simple analysis reveals that it involves predicates of degree 5, presumably never evaluated exactly in most implementations. Within the exact-computation paradigm we introduce two models of computation aimed at replacing the conventional model of real-number arithmetic. The first model (predicate arithmetic) assumes the exact evaluation of the signs of algebraic expressions of some degree, and the second model (exact arithmetic) assumes the exact computation of the value of such (bounded-degree) expressions. We identify the characteristic geometric property enabling the correct report of all intersections by plane sweeps. Verification of this property involves only predicates of (optimal) degree 2, but its straightforward implementation appears highly inefficient. We then present algorithmic variants that have low degree under these models and achieve the same performance as the original Bentley–Ottmann algorithm. The technique is applicable to a more general case of curved segments.

1. Introduction.

As is well known, computational geometry has traditionally adopted the arithmetic model of exact computation over the real numbers. This model has been extremely productive in terms of algorithmic research, since it has permitted a vast community to focus on the elucidation of the combinatorial (topological) properties of geometric problems, thereby leading to sophisticated and efficient algorithms. Such an approach, however, has a substantial shortcoming, since all computer calculations have finite precision, a feature which affects not only the quality of the results but even the validity of specific algorithms. In other words, in this model, algorithm correctness does not automatically translate into program correctness. In fact, there are several reports of failures of implementations of theoretically correct algorithms (see, e.g., [For87, Hof89]). This state of affairs has engendered a vigorous debate within the research community, as is amply documented in the literature. Several proposals have been made to remedy this unsatisfactory situation. They can be split into two broad categories according to whether they perform exact computations (see, e.g., [BKM$^+$95, FV93, Yap97, She96]) or approximate computations (see, e.g., [Mil88, HHK89, Mil89]).

This paper fine-tunes the exact-computation paradigm. The numerical computations of a geometric algorithm are basically of two types: tests (predicates) and constructions, each with clearly distinct roles. Tests are associated with branching

decisions in the algorithm that determine the flow of control, whereas constructions are needed to produce the output data. While approximations in the execution of constructions are often acceptable, approximations in the execution of tests may produce incorrect branching, leading to the inconsistencies which are the object of the criticisms leveled against geometric algorithms. The exact-computation paradigm therefore requires that tests be executed with total accuracy. This will guarantee that the result of a geometric algorithm will be topologically correct albeit geometrically approximate. This also means that robustness is in principle achievable if one is willing to employ the required precision. The reported failures of structurally correct algorithms are entirely attributable to noncompliance with this criterion.

Therefore, geometric algorithms can also be characterized on the basis of the complexity of their predicates. The complexity of a predicate is expressed by the degree of a homogeneous polynomial embodying its evaluation. The degree of an algorithm is the maximum degree of its predicates, and an algorithm is robust if the adopted precision matches the degree requirements.

The "degree criterion" is a design principle aimed at developing low-degree algorithms. This approach involves reexamining under the degree criterion the rich body of geometric algorithms known today, possibly without negatively affecting traditional algorithmic efficiency. A previous paper [LPT96] considered as an illustration of this approach the issue of proximity queries in two and three dimensions. As an additional case of degree-driven algorithm design, in this paper we confront another class of important geometric problems, which have caused considerable difficulties in actual implementations: plane sweep problems for sets of segments. As we shall see, plane sweep applications involve a number of predicates of different degree and algorithmic power. Their analysis not only will lead to new and robust implementations (an outcome of substantial practical interest) but will elucidate on a theoretical level some deeper issues pertaining to the structure of several related problems and the mechanism of plane sweeps.

2. Three problems associated with intersecting segments.

Given is a finite set $\mathcal{S}$ of line segments in the plane. Each segment is defined by the coordinates of its two endpoints. We discuss the three following problems (see Figure 2.1):

- Pb1: Report the pairs of segments of $\mathcal{S}$ that intersect.
- Pb2: Construct the arrangement $\mathcal{A}$ of $\mathcal{S}$, i.e., the incidence structure of the graph obtained interpreting the union of the segments as a planar graph.
- Pb3: Construct the trapezoidal map $\mathcal{T}$ of $\mathcal{S}$. $\mathcal{T}$ is obtained by drawing two vertical line segments (*walls*), one above and one below each endpoint of the segments and each intersection point. The walls are extended either until they meet another segment of $\mathcal{S}$ or to infinity.

Let $S_1, \ldots, S_n$ be the segments of $\mathcal{S}$, and let k be the number of intersecting pairs. We say that the segments are in *general position* if any two intersecting segments intersect in a single point, and all endpoints and intersection points are distinct.

The number of intersection points is no more than the number of intersecting pairs of segments, and both are equal if the segments are in general position. Therefore, the number of vertices of $\mathcal{A}$ is at most k, the number of edges of $\mathcal{A}$ is at most $n+2k$, and the number of vertical walls in $\mathcal{T}$ is at most $2(n+k)$, the bounds being tight when the segments are in general position. Thus the sizes of both $\mathcal{A}$ and $\mathcal{T}$ are $O(n+k)$. We didn't consider here the two-dimensional faces of either $\mathcal{A}$ or $\mathcal{T}$. Including them would not change the problems we address.

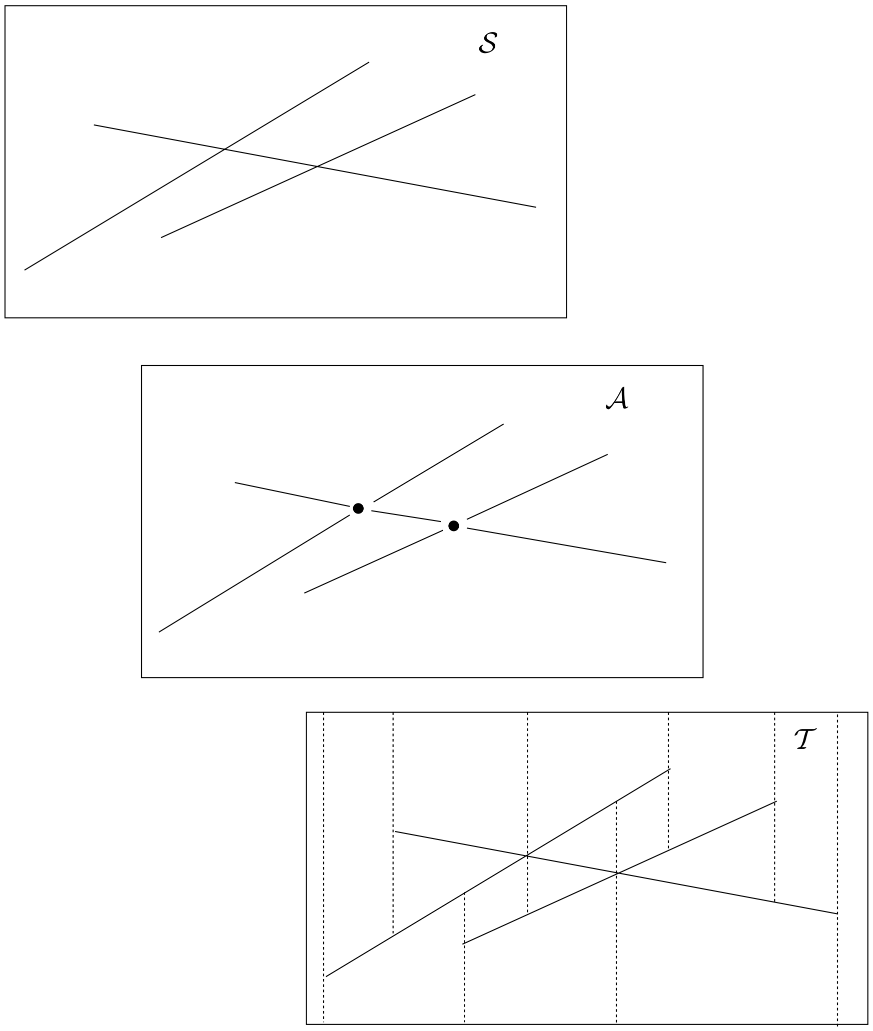

Fig. 2.1. *A set of segments $\mathcal{S}$, the corresponding arrangement $\mathcal{A}$ and its trapezoidal map $\mathcal{T}$.*

3. Algebraic degree and arithmetic models.

It is well known that the efficient algorithms that solve Pb1–Pb3 are very unstable when implemented using nonexact arithmetic, and several frustrating experiences have been reported [For85]. This motivates us to carefully analyze the predicates involved in those algorithms. We first introduce here some terminology borrowed from [LPT96]. See also [Bur96, For93]. We consider each input data (i.e., coordinates of an endpoint of some segment of $\mathcal{S}$) as a *variable.*

An *elementary predicate* is the sign $-$, 0, or $+$ of a homogeneous multivariate polynomial whose arguments are a subset of the input variables. The degree of an elementary predicate is defined as the maximum degree of the irreducible factors (over the rationals) of the polynomials that occur in the predicate and that do not have a constant sign. A *predicate* is more generally a Boolean function of elementary predicates. Its degree is the maximum degree of its elementary predicates.

The *degree of an algorithm* A is defined as the maximum degree of its predicates.

The *degree of a problem* P is defined as the minimum degree of any algorithm that solves P.

In most problems in computational geometry, $d = O(1)$. However, as d affects the speed and/or robustness of an algorithm, it is important to measure d precisely.

In the rest of this paper we consider the degree as an additional measure of algorithmic complexity. Note that, qualitatively, degree and memory requirements are similar, since the arithmetic capabilities demanded by a given degree must be available, albeit they may be never resorted to in an actual run of the algorithm (since the input may be such that predicates may be evaluated reliably with lower precision).

We will consider two arithmetic models. In the first one, called the *predicate arithmetic of degree* d, the only numerical operations that are allowed are the evaluations of predicates of degree at most d. Algorithms of degree d can therefore be implemented exactly in the predicate arithmetic model of degree d. This model is motivated by recent results that show that evaluating the sign of a polynomial expression may be faster than computing its value (see [ABD+97, BY97, BEPP97, Cla92, She96]). This model, however, is very conservative since the nonavailability of the arithmetics required by a predicate is assimilated to an entirely random choice of the value of the predicate.

The second model, called the *exact arithmetic of degree* d, is more demanding. It assumes that values (and not just signs) of polynomials of degree at most d be represented and computed exactly (i.e., roughly as d-fold precision integers). However, higher-degree operations (e.g., a multiplication operation of whose factors is a d-fold precision integer) are appropriately rounded. Typical rounding is rounding to the nearest representable number, but less accurate rounding can also be adequate as will be demonstrated later.

Let P be a predicate (polynomial) of degree d. We ignore for simplicity the size of the coefficients of P, because they are typically small constants; if the input data are all b-bit integers, the size of each monomial in predicate P is upper bounded by 2^{bd}. Moreover, let v be the number of variables that occur in a predicate; for most geometric problems and, in particular, for those considered in this paper, v is a small number. Since the polynomial P is homogeneous, it may contain only highest-degree monomials, whose number is bounded by v^d. It follows that an algorithm of degree d requires precision $p \leq db + d \log v = db + O(1)$ in the exact arithmetic model of degree d.

4. The predicates and the degree of problems Pb1–Pb3. In this section, we analyze the degree of problems Pb1–Pb3 (in subsections 4.1–4.3) and of the standard algorithms for solving these problems (in subsection 4.4).

We use the following notations. The coordinates of point A_i are denoted x_i and y_i. $A_i <_x A_j$ means that the x-coordinate of point A_i is smaller than the x-coordinate of point A_j. The same is true for $<_y$. $[A_i A_j]$ denotes the line segment whose left and right endpoints are, respectively, A_i and A_j, while $(A_i A_j)$ denotes the line containing $[A_i A_j]$. $A_i <_y (A_j A_k)$ means that point A_i lies below line $(A_j A_k)$.

4.1. Predicates. Pb1 requires only that we check if two line segments intersect (Predicate $2'$ below).

Pb2 requires in addition the ability to sort intersection points along a line segment (Predicate 4 below).

Pb3 requires the ability to execute all the predicates listed below.

Predicate 1: $A_0 <_x A_1$.
Predicate 2: $A_0 <_y (A_1A_2)$.
Predicate 2′: $[A_0A_1] \bigcap [A_2A_3] \neq \emptyset$.
Predicate 3: $A_0 <_x [A_1A_2] \bigcap [A_3A_4]$.
Predicate 4: $[A_0A_1] \bigcap [A_2A_3] <_x [A_0A_1] \bigcap [A_4A_5]$.
Predicate 5: $[A_0A_1] \bigcap [A_2A_3] <_x [A_4A_5] \bigcap [A_6A_7]$.

Two other predicates appear in some algorithms that report segment intersections.

Predicate 3′: $(x = x_0) \bigcap [A_1A_2] <_y (x = x_0) \bigcap [A_3A_4]$.
Predicate 4′: $[A_0A_1] \bigcap [A_2A_3] <_y (A_4A_5)$.

4.2. Algebraic degree of the predicates. We now analyze the algebraic degree of the predicates introduced above.

PROPOSITION 4.1. *The degree of Predicates i and i' ($i = 1, \ldots, 5$) is i.*

Proof. We first provide explicit formulae for the predicates.

Evaluating Predicate 2 is equivalent to evaluating the sign of

$$\mathrm{orient}(A_0A_1A_2) = \begin{vmatrix} x_0 & x_1 & x_2 \\ y_0 & y_1 & y_2 \\ 1 & 1 & 1 \end{vmatrix} = \begin{vmatrix} x_1 - x_0 & x_2 - x_0 \\ y_1 - y_0 & y_2 - y_0 \end{vmatrix}.$$

Predicate 2′ can be implemented as follows for the case $A_0 <_x A_2$ (otherwise we exchange the roles of $[A_0A_1]$ and $[A_2A_3]$):

```
if $A_1 <_x A_2$ then return false
if $A_3 <_x A_1$
    if orient$(A_0A_1A_2) \times$ orient$(A_0A_1A_3) < 0$ then return true
    else return false
else
    if orient$(A_0A_1A_2) \times$ orient$(A_2A_3A_1) > 0$ then return true
    else return false
```

Therefore, in all cases, Predicate 2′ reduces to Predicate 2.

The intersection point $I = [A_iA_j] \bigcap [A_kA_l]$ is given by

$$I = A_i + (A_j - A_i)\frac{N_I}{D_I} \tag{4.1}$$

with $N_I = \mathrm{orient}(A_iA_kA_l)$ and

$$\begin{aligned} D_I &= \begin{vmatrix} x_j - x_i & x_k - x_l \\ y_j - y_i & y_k - y_l \end{vmatrix} \\ &= \mathrm{orient}(A_iA_jA_k) - \mathrm{orient}(A_iA_jA_l) \\ &\overset{def}{=} \mathrm{Orient}(A_iA_jA_kA_l). \end{aligned}$$

Predicate 4′ reduces to evaluating orient(I, A_0, A_1), where I is the intersection of $[A_2A_3]$ and $[A_4A_5]$. It follows from (4.1) that this is equivalent to evaluating the sign of orient$(A_2A_3A_4A_5)$ and of

$$\mathrm{orient}(A_0A_1A_2) \times \mathrm{Orient}(A_2A_3A_4A_5) - \mathrm{orient}(A_2A_4A_5) \times \mathrm{Orient}(A_0A_1A_2A_3).$$

Predicates 3–5: Explicit formulas for Predicates 3, 4, and 5 can be immediately deduced from the coordinates of the intersection points $I = [A_0A_1] \bigcap [A_2A_3]$ and $J = [A_4A_5] \bigcap [A_6A_7]$ which are given by (4.1). If $A_4A_5 = A_0A_1$, it is clear from (4.1) that $(x_1 - x_0)$ is a common factor of $x_I - x_0$ and $x_J - x_0$.

If $[A_1A_2]$ and $[A_3A_4]$ do not intersect, Predicate $3'$ reduces to Predicate 2. Otherwise, it reduces to Predicate 3.

The above discussion shows that the degree of predicates i and i' is *at most* i. To establish that it is *exactly* i, we have shown in the appendix that the polynomials of Predicates 2, 3, $4'$, and 5, as well as the factor other than $(x_1 - x_0)$ involved in Predicate 4, are irreducible over the rationals.

It follows that the proposition is proved for all predicates. □

Recalling the requirements of the various problems in terms of predicates, we have the following proposition.

PROPOSITION 4.2. *The algebraic degrees of* Pb1, Pb2, *and* Pb3 *are, respectively,* 2*,* 4*, and* 5.

4.3. Implementation of Predicate 3 with exact arithmetic of degree 2. As they will be useful in section 7, in this subsection we present two approximate implementations of Predicate 3 (of degree 3) under the exact arithmetic of degree 2.

From (4.1) we know that Predicate 3 can be written as

$$x_{01}\, D < x_{21}\, N, \tag{4.2}$$

where $x_{01} = x_0 - x_1$, $x_{21} = x_2 - x_1$, $D = |\ \mathrm{Orient}(A_1A_2A_3A_4)|$, and $N = \mathrm{sign}(D)\times$ $\mathrm{orient}(A_1A_3A_4)$.

We stipulate to employ floating-point arithmetic conforming to the IEEE 754 standard [Gol91]. In this standard, simple precision allows us to represent b-bit integers with $b = 24$ and double precision allows us to represent b'-bit integers with $b' = 2b+5 = 53$. The coordinates of the endpoints of the segments are represented in simple precision, and the computations are carried out in double precision. We denote $\oplus$, $\otimes$, and $\oslash$ the rounded arithmetic operations $+, \times$, and $/$. In the IEEE 754 standard, all four arithmetic operations are exactly rounded; i.e., the computed result is the floating-point number that best approximates the exact result.

Since $\mathrm{Orient}(A_1A_2A_3A_4)$ and $\mathrm{orient}(A_1A_3A_4)$ are $(2b+3)$-bit integers, the four terms x_{01}, x_{21}, N, and D in inequality (4.2) can be computed exactly in double precision, and the following monotonicity property is a direct consequence of exact rounding of arithmetic operations.

Monotonicity property 1: $x_{01} \otimes D < x_{21} \otimes N \Longrightarrow x_{01} \times D < x_{21} \times N$.

This implies that the comparison between the two computed expressions $x_{01} \otimes D$ and $x_{21} \otimes N$ evaluates Predicate 3 except when these numbers are equal.

Since in most algorithms, an intersection point is compared with many endpoints, it is more efficient to compute and store the coordinates of each intersection point and to perform comparisons with the computed abscissae rather than to evaluate (4.2) repeatedly. We now illustrate an effective rounding procedure of the x-coordinates of intersection points which gives an alternative approximate implementation of Predicate 3.

LEMMA 4.3. *If the coordinates of the endpoints of the segments are simple precision integers, then the abscissa x_I of an intersection point can be rounded to one of its two nearest simple precision integers using only double precision floating-point arithmetic operations.*

Proof. We assume that the coordinates of the endpoints of the segments are represented as b-bit integers stored as simple precision floating-point numbers. The computations are carried out in double precision.

The rounded value $\tilde{x}_I$ of x_I is given by

$$\tilde{x}_I = \lfloor((x_{21} \otimes N) \oslash D)\rceil \oplus x_1,$$

where $\lfloor X \rceil$ denotes the integer nearest to X (with any tie-breaking rule). If $\varepsilon = 2^{-b'}$ is a strict bound to the modulus of the relative error of all arithmetic operations, $\tilde{X} = (x_{21} \otimes N) \oslash D$ satisfies the following relations:

$$\frac{x_{21}N}{D}(1-2\varepsilon) \approx \frac{x_{21}N}{D}(1-\varepsilon)^2 < \tilde{X} < \frac{x_{21}N}{D}(1+\varepsilon)^2 \approx \frac{x_{21}N}{D}(1+2\varepsilon).$$

As $\frac{x_{21}N}{D} = x_I - x_1 \leq 2^{b+1}$, we obtain

$$|(x_{21} \otimes N) \oslash D - x_{21}N/D)| \lesssim 2^{b+1}22^{-b'} = 2^{-b-3} \ll 1.$$

We round $\tilde{X}$ to the nearest integer $\lfloor \tilde{X} \rceil$. Since $\lfloor \tilde{X} \rceil$ and x_1 are $(b+1)$-bit integers, there is no error in the addition. Therefore, $\tilde{x}_I$ is a $(b+2)$-bit integer and the absolute error on $\tilde{x}_I$ is smaller than 1. □

It follows that, under the hypothesis of the lemma, if E is an endpoint, I is an intersection point, and $\tilde{I}$ is the corresponding rounded point, the following monotonicity property holds.

Monotonicity property 2: $\tilde{I} <_x E \Longrightarrow I <_x E,$
$E <_x \tilde{I} \Longrightarrow E <_x I.$

This implies that the comparison between the x-coordinates of $\tilde{I}$ and E evaluates Predicate 3, except when the abscissae of $\tilde{I}$ and E coincide.

Notice that the monotonicity property does not necessarily hold for two intersection points.

Remark 1. A result similar to Lemma 4.3 has been obtained by Priest [Pri92] for points with floating-point coordinates. More precisely, if the endpoints of the segments are represented as simple precision floating-point numbers, Priest [Pri92] has proposed a rather complicated algorithm that uses double precision floating-point arithmetic and rounds x_I to the nearest simple precision floating-point number. Since it applies to the integers as well, this stronger result also implies the monotonicity property.

4.4. Algebraic degree of the algorithms. The naive algorithm for detecting segment intersections (Pb1) evaluates $\Theta(n^2)$ Predicates $2'$ and thus is of degree 2, which is degree-optimal by the proposition above. Although the time-complexity of the naive algorithm is worst-case optimal, since $0 \leq k \leq \frac{1}{2}n(n-1)$, it is worth looking for an output sensitive algorithm whose complexity depends on both n and k. Chazelle and Edelsbrunner [CE92] have shown that $\Omega(n \log n + k)$ is a lower bound for Pb1 and therefore also for Pb2 and Pb3. A very recent algorithm of Balaban [Bal95] solves Pb1 optimally in $O(n \log n + k)$ time using $O(n)$ space. This algorithm does not solve Pb2 nor Pb3 and, since it uses Predicate $3'$, its degree is 3.

Pb2 can be solved by first solving Pb1 and subsequently sorting the reported intersection points along each segment. This can easily be done in $O((n+k) \log n)$ time by a simple algorithm of degree 4 using $O(n)$ space. A direct (and asymptotically more efficient) solution to Pb2 has been proposed by Chazelle and Edelsbrunner [CE92]. Its time complexity is $O(n \log n + k)$, and it uses $O(n + k)$ space. Their algorithm, which constructs the arrangement of the segments, is of degree 4.

A solution to Pb3 can be deduced from a solution to Pb2 in $O(n + k)$ time using a very complicated algorithm of Chazelle [Cha91]. A deterministic and simple algorithm due to Bentley and Ottmann [BO79] solves Pb3 in $O((n + k) \log n)$ time, which is slightly suboptimal, using $O(n)$ space. This classical algorithm uses the sweep-line paradigm and evaluates $O((n+k)\log n)$ predicates of all types discussed above, and therefore has degree 5. Incremental randomized algorithms [CS89, BDS$^+$92] construct the trapezoidal map of the segments and thus solve Pb3 and have degree 5. Their time complexity and space requirements are optimal (although only as expected performances).

In this paper, we revisit the Bentley–Ottmann algorithm and show that a variant of degree 3 (instead of 5) [Mye85, Sch91] can solve Pb1 with no sacrifice of performance (section 6.1). Although this algorithm is slightly suboptimal with respect to time complexity, it is much simpler than Balaban's algorithm. We also present two variants of the sweep-line algorithm. The first one (section 6.2) uses only predicates of degree at most 2 and applies to the restricted but important special case where the segments belong to two subsets of nonintersecting segments. The second one (section 7) uses the exact arithmetic of degree 2. All these results are based on a (nonefficient) lazy sweep-line algorithm (to be presented in section 5) that solves Pb1 by evaluating predicates of degree at most 2.

Remark 2. When the segments are not in general position, the number s of intersection points can be less than the number k of intersecting pairs. In the extreme, $s = 1$ and $k = n(n-1)/2$. Some algorithms can be adapted so that their time complexities depend on s rather than k [BMS94]. However, a lower bound on the degree of such algorithms is 4 since they must be able to detect if two intersection points are identical, therefore to evaluate Predicate 4′.

5. A lazy sweep-line algorithm.

Let $\mathcal{S}$ be a set of n segments whose endpoints are $E_1, \ldots, E_{2n}$. For a succinct review, the standard algorithm first sorts $E_1, \ldots, E_{2n}$ by increasing x-coordinates and stores the sorted points in a priority queue X, called the *event* schedule. Next, the algorithm begins sweeping the plane with a vertical line L and maintains a data structure Y that represents a subset of the segments of $\mathcal{S}$ (those currently intersected by L, ordered according to the ordinates of their intersections with L). Intersections are detected in correspondence of adjacencies created in Y, either by insertion/deletion of segment endpoints or by order exchanges at intersections. An intersection, upon detection, is inserted into X according to its abscissa. Of course, a given intersection may be detected several times. Multiple detections can be resolved by performing a preliminary membership test for an intersection in X and omitting insertion if the intersection has been previously recorded. An intersection is reported when the sweep-line reaches its abscissa. We stipulate to use another policy to resolve multiple detections, namely to remove from X an intersection point I whose associated segments are no longer adjacent in Y. Event I will be reinserted in X when the segments become again adjacent in Y. This policy has also the advantage of reducing the storage requirement of Bentley–Ottmann's algorithm to $O(n)$ [Bro81].

5.1. Description of the lazy algorithm.

We now describe a modification of the sweep-line algorithm that does not need to process the intersection points by increasing x-coordinates.

First, the algorithm sorts the endpoints of the segments by increasing x-coordinates into an array X. Let $E_1, \ldots, E_{2n}$ be the sorted list of endpoints.

Then the algorithm starts processing *events* and maintains a dictionary Y that stores an ordered subset of the line segments. The events consist of the endpoints and of a subset of the pairs of segments that intersect and are adjacent in Y. Such pairs are called *processable* and will be precisely defined below. The algorithm processes the endpoints by increasing order of their x-coordinates, but, contrary to the standard algorithm, the processable pairs are processed in any order. As a consequence, two intersection points or even an intersection point and an endpoint won't necessarily be processed in the order of their x-coordinates, and Y won't necessarily represent the ordered set of segments intersecting some vertical line L (as in the standard algorithm).

The events are processed in the same way as in the standard algorithm, i.e., processing an endpoint means either the insertion of the corresponding segment into Y or its deletion from it (as appropriate), and processing an intersection means its report and the exchange of the two segments involved. The only difference is that we maintain a set P of processable pairs: each time a pair of intersecting segments become adjacent in Y, we check whether the pair is processable and, in the affirmative, add it to P.

While there are processable pairs, the algorithm extracts any of them from P and processes it. When there are no more processable pairs, the algorithm proceeds to the next endpoint. When there are no more processable pairs and no more endpoints to be processed, the algorithm stops.

To complete the description of the algorithm, we need to define the *processable* pairs. The definition rests on the notions of *active* and *prime* pairs to be given below. We need the following notations. We denote by $L(E_i)$ the vertical line passing through E_i. Slab (E_i, E_{i+1}) denotes the open vertical slab bounded by $L(E_i)$ and $L(E_{i+1})$, and $(E_i, E_{i+1}]$ denotes the semiclosed slab obtained by adjoining line $L(E_{i+1})$ to the open slab (E_i, E_{i+1}). For two segments S_k and S_l, we denote by A_{kl} their rightmost left endpoint, by B_{kl} their leftmost right endpoint, and by I_{kl} their intersection point when they intersect (see Figure 5.1). In addition, W_{kl} denotes the set of segment endpoints that belong to the (closed) region bounded by the vertical lines $L(A_{kl})$ and $L(B_{kl})$ and by the two segments (a trapezoid if the two segments do not intersect, a double-wedge otherwise). We denote by E_{kl} the most recently processed element of W_{kl} and by F_{kl} the element of W_{kl} to be processed next. (Note that E_{kl} and F_{kl} are always defined, since they may respectively coincide with A_{kl} and B_{kl}.) Last, we define sets $W^+_{kl}(E_{kl})$ and $W^-_{kl}(E_{kl})$ as follows. If S_k and S_l do not intersect, $W^+_{kl}(E_{kl}) = \emptyset$ and $W^-_{kl}(E_{kl})$ consists of all points $E \in W_{kl}$, $E_{kl} \leq_x E$. Otherwise, an endpoint $E \in W_{kl}$ belongs to $W^+_{kl}(E_{kl})$ (respectively, to $W^-_{kl}(E_{kl})$) if $E_{kl} \leq_x E$ and if the slab $(E_{kl}, E]$ does (respectively, does not) contain I_{kl}.[1]

DEFINITION 5.1. *Let (S_k, S_l) be a pair of segments, and assume without loss of generality that $S_k \bigcap L(E_{kl}) <_y S_l \bigcap L(E_{kl})$. The pair is said to be* active *if the following conditions are satisfied:*

(1) *S_k and S_l are adjacent in Y,*

(2) *$S_k < S_l$ in Y,*

(3) $F_{kl} \in W^+_{kl}(E_{kl})$ (emptiness condition).

Observe that the emptiness condition implies that the segments intersect (since $W^+_{kl}(E_{kl}) = \emptyset$ if they do not). We now identify a subset of the active pairs, whose processing, as we shall see, has priority.

DEFINITION 5.2. *An active pair of segments (S_k, S_l) is said to be* prime *if the next endpoint to be processed belongs to W_{kl} (i.e., it coincides with $F_{kl} \in W^+_{kl}(E_{kl})$).*

It should be noted that deciding if a pair of intersecting segments is active or prime reduces to the evaluation of Predicates 2 only and the condition $F_{kl} \in W^+_{kl}(E_{kl})$ should

[1]For line segments or even pseudosegments, $W^-_{kl}(E_{kl})$ and $W^+_{kl}(E_{kl})$ do not depend on E_{kl}. However, we keep E_{kl} as a parameter in preparation for the more general case of monotone arcs. See Remark 4 at the end of this section.

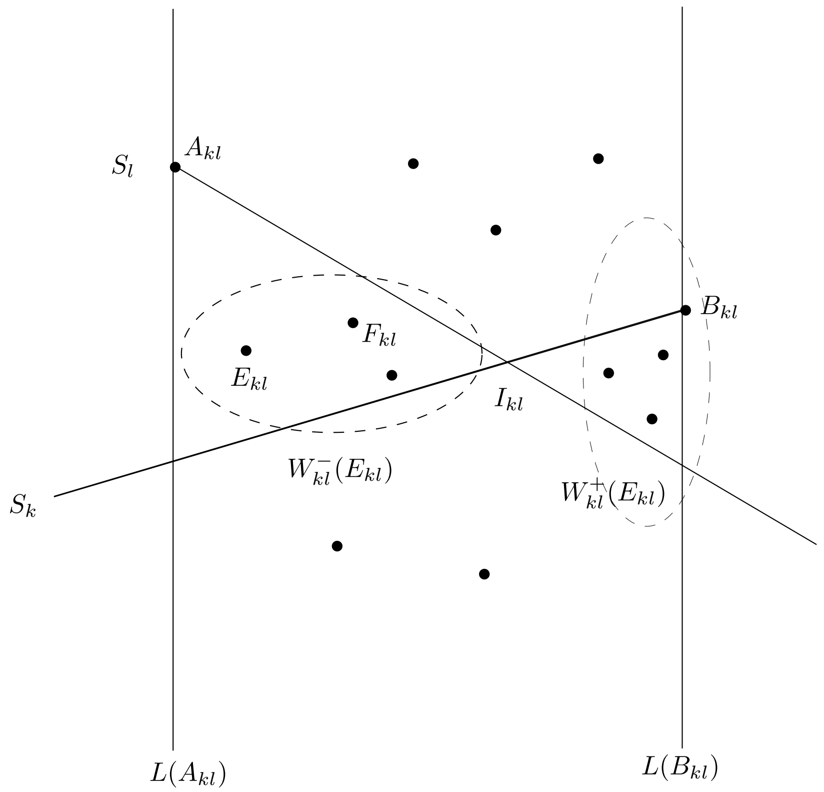

FIG. 5.1. *For the definitions of* $W^-_{kl}(E_{kl})$ *and* $W^+_{kl}(E_{kl})$.

not be construed as implying the comparison of the abscissae of I_{kl} and F_{kl} (Predicate 3). Indeed, if $S_k \bigcap L(A_{kl}) <_y S_l \bigcap L(A_{kl})$ (which can be decided by Predicate 2), then the emptiness condition corresponds to $F_{kl} <_y S_k$ and $S_l <_y F_{kl}$.

For reasons that will be clear below, the set of processable pairs is not specified in the finest detail in this section, since several different implementations are possible. We require only that, at any time, the two following assertions remain true.

(1) All prime pairs are processable.

(2) All processable pairs are active.

In other words, the next endpoint may be processed once there are no more prime pairs, without placing any deadline on the processing of the current active pairs as long as they are not prime.

In the rest of this section, we will simply assume that we have an oracle at our disposal that can decide if a given pair is processable. Clearly, for some instances of the lazy algorithm (e.g., when considering all active pairs as processable), the oracle can be implemented with Predicates 2 only. In such a case, the lazy algorithm involves only Predicates 1 and 2 and is of degree 2 by Proposition 4.1. We will prove its correctness in the next subsection.

The important issue of efficiently detecting the processable pairs will be considered in sections 6 and 7 where several oracles will be introduced. These instances of the lazy algorithm will still be correct but, in some cases, will have a degree higher than 2.

5.2. Correctness of the lazy algorithm. Let $Y^-(E_i)$ and $Y^+(E_i)$ be, respectively, snapshots of the data structure Y immediately before and after processing event E_i, $i = 1, \dots, 2n$. Observe that $Y^-(E_i)$ and $Y^+(E_i)$ differ only by the segment S that has E_i as one of its endpoints. Let $Y(E_i) = Y^-(E_i) \bigcup Y^+(E_i)$. The order relation in Y is denoted by $<$.

THEOREM 5.3. *If Predicates* 1 *and* 2 *are evaluated exactly, the described lazy sweep-line algorithm will detect all pairs of segments that intersect.*

Proof. The algorithm (correctly) sorts the endpoints $E_1, \dots, E_{2n}$ of the segments by increasing x-coordinates into X. Consequently, the set of segments that intersect $L(E)$ and the set of segments in $Y(E)$ coincide for any endpoint E. The proof of the theorem is articulated now as two lemmas and their implications.

LEMMA 5.4. *Two segments have exchanged their positions in Y if and only if they intersect and if the pair has been processed.*

Proof. Let us consider two segments, say S_k and S_l, that do not intersect. Without loss of generality, let $S_k < S_l$ in $Y(A_{kl})$. Assume for a contradiction that $S_l < S_k$ in $Y^-(B_{kl})$. S_k and S_l cannot exchange their positions because they will never form an active pair. Therefore, $S_l < S_k$ in $Y^-(B_{kl})$ can happen only if there exists a segment S_m, $m \neq k, l$, that at some stage in the execution of the algorithm was present in Y together with S_k and S_l and caused one of the following two events to occur.

(1) $S_m > S_l$ and the positions of S_m and S_k are exchanged in Y.

(2) $S_m < S_k$ and the positions of S_m and S_l are exchanged in Y.

In both cases, the segments that exchange their positions are not consecutive in Y, violating condition 1 of Definition 5.1.

Therefore, two segments can exchange their positions in Y only if they intersect and this can happen only when their intersection is processed. Moreover, when the intersection has been processed, the segments are no longer active and cannot exchange their positions a second time. ∎

We say that an endpoint E of S is *correctly placed* if and only if the subset of the segments that are below E (in the plane) coincides with the subset of the segments $< S$ in $Y(E)$, i.e.,

$$\forall S' \in Y(E), \qquad S' < S \Longleftrightarrow S' \bigcap L(E) <_y S \bigcap L(E).$$

Otherwise, E is said to be *misplaced.* (Note that $S \bigcap L(E)$ coincides with E.)

LEMMA 5.5. *If Predicates* 1 *and* 2 *are evaluated exactly, both endpoints of every segment are correctly placed.*

Proof. Assume, for a contradiction, that E of S is the *first* endpoint to be misplaced by the algorithm.

CLAIM 1. *E can be misplaced only if there exist at least two intersecting segments S_k and S_l in $Y^-(E)$ such that E belongs to W_{kl}.*

Proof. First recall that Predicate 2 is the only predicate involved in placing S in Y.

Consider first the case where E is the left endpoint of S. Let (S_k, S_l) be *any* pair of segments in $Y^-(E)$. If $E \notin W_{kl}$, then both S_l and S_k are either above or below E, and their relative order does not affect the placement of E. This establishes that E will be correctly placed in $Y^+(E)$ (i.e., the contrapositive of the necessary condition expressed by the claim).

Suppose now that E is a right endpoint. In this case we shall establish the lemma in its direct form. The left endpoint of S has been correctly placed since it was processed earlier and E is the first one to be misplaced. If E has been misplaced, then, by Lemma 5.4, there exists a segment $S' \in Y^-(E)$ intersecting S to the left of E such that the relative positions of S and S' in $Y^+(A)$ and $Y^-(E)$ are the same (A is the rightmost left endpoint of S and S'), i.e., their order in Y has not been reversed by the algorithm. In this case, $E = B_{kl} \in W_{kl}$ for $S_k = S$ and $S_l = S'$, thus proving that there exists a pair S_l and S_k such that S_l and S_k intersect and $E \in W_{kl}$. ◻

Let S_k and S_l be two segments of $Y^-(E)$ such that $E \in W_{kl}$. Assume without loss of generality that $S_k < S_l$ in $Y(E_{kl})$. Since E is the first endpoint to be misplaced, we have $S_k \bigcap L(E_{kl}) <_y S_l \bigcap L(E_{kl})$. For convenience, we will say that two segments S_p and S_q have been *exchanged between* E' and E'' for two endpoints $E' <_x E''$ if $S_p < S_q$ in $Y^+(E')$ and $S_q < S_p$ in $Y^-(E'')$.

The case where $E \in W^-_{kl}(E_{kl})$ cannot cause any difficulty since S_k and S_l cannot be active between E_{kl} and E, and therefore, S_k and S_l cannot be exchanged between E_{kl} and E, which implies that E is correctly placed with respect to S_k and S_l.

The case where $E \in W^+_{kl}(E_{kl})$ is more difficult. E is not correctly placed only if S_k and S_l are not exchanged between E_{kl} and E, i.e., $S_k < S_l$ in both $Y^+(E_{kl})$ and $Y^-(E)$. We shall prove that this is not possible and therefore conclude that S is correctly placed into Y in this case as well.

Assume, for a contradiction, that S_k and S_l have not been exchanged between E_{kl} and E. As E belongs to $W^+_{kl}(E_{kl})$, S_k and S_l cannot be adjacent in $Y^-(E)$ since otherwise they would constitute a prime pair and they would have been exchanged. Let $(S_k = S_{k_0}, S_{k_1}, \ldots, S_{k_r}, S_{k_{r+1}} = S_l)$ $(r \geq 1)$ be the subsequence of segments of $Y^-(E)$ occurring between S_k and S_l with the further (legitimate) assumption that (S_k, S_l) is a pair of intersecting segments such that $E \in W^+_{kl}(E_{kl})$, for which r is *minimal* (i.e., for which the above subsequence is shortest). For an arbitrary $1 \leq i \leq r$, consider segment S_{k_i} and assume, without loss of generality, that $E <_y S_{k_i}$. As a direct consequence of the fact that $(S_k, S_{k_1}, \ldots, S_{k_r}, S_l)$ is shortest, we observe that E cannot belong to $W^+_{kk_i}(E_{kk_i})$ nor to $W^+_{k_il}(E_{k_il})$. We distinguish two cases.

(i) $E <_y S_{k_i}$ (see Figure 5.2). Clearly, $E \in W_{k_il}$, and, by the above observation, we must have $E \in W^-_{k_il}(E_{k_il})$. It follows that the relative y-orders of S_{k_i} and S_l along $L(E_{k_il})$ and $L(E)$ are the same, hence $S_l \bigcap L(E_{k_il}) <_y S_{k_i} \bigcap L(E_{k_il})$. As E is the first endpoint to be misplaced, the order in $Y^+(E_{k_il})$ agrees with the geometry; i.e., we have $S_l < S_{k_i}$ in $Y^+(E_{k_il})$. Moreover, since the pair (S_{k_i}, S_l) is not active (between E_{k_il} and E, because $E \in W^-_{k_il}(E_{k_il})$) and therefore cannot be exchanged, the same inequality holds in $Y^-(E)$, which contradicts the definition of S_{k_i}.

(ii) $S_{k_i} <_y E$. This case is entirely symmetric to the previous one. It suffices to exchange the roles of S_k and S_l and to reverse the relations $<$ and $<_y$.

Since a contradiction has been reached in both cases, the lemma is proved. ◻

We now complete the proof of the theorem. The previous lemma implies that the endpoints are correctly processed. Indeed let E_i be an endpoint. If E_i is a right endpoint, we simply remove the corresponding segment from Y and update the set of active segments. This can be done exactly since predicates of degree ≤ 2 are evaluated correctly. If E_i is a left endpoint, it is correctly placed in Y on the basis of the previous lemma.

The lemma also implies that all pairs that intersect have been processed. Indeed if S_p and S_q are two intersecting segments such that $S_p \bigcap L(A_{pq}) <_y S_q \bigcap L(A_{pq})$ and $S_q \bigcap L(B_{pq}) <_y S_p \bigcap L(B_{pq})$, the lemma shows that $S_p < S_q$ in $Y^+(A_{pq})$ and $S_p > S_q$ in $Y^-(B_{pq})$, which implies that the pair (S_p, S_q) has been processed (Lemma 5.4).

This concludes the proof of the theorem. ◻

Remark 3. Handling the degenerate cases does not cause any difficulty, and the

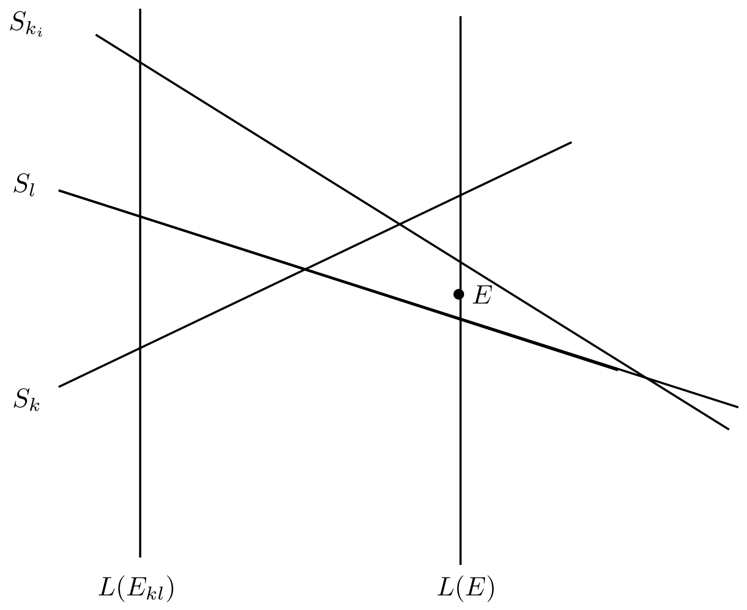

FIG. 5.2. *For the proof of correctness of the lazy algorithm.*

previous algorithm will work with only minor changes. For the initial sorting of the endpoints, we can take any order relation compatible with the order of their x-coordinates, e.g., the lexicographic order.

Remark 4. Theorem 5.3 applies directly to pseudosegments, i.e., curved segments that intersect in at most one point. Lemmas 5.4 and 5.5 also extend to the case of monotone arcs that may intersect at more than one point. To be more precise, in Lemma 5.4, we have to replace "intersect" with "intersect an odd number of times"; Lemma 5.5 and its proof are unchanged provided that we define $W^+_{kl}(E_{kl})$ (respectively, $W^-_{kl}(E_{kl})$) as the subset of W_{kl} consisting of the endpoints E, $E_{kl} \leq_x E$, such that the slab $(E_{kl}, E]$ contains an odd number (respectively, none or an even number) of intersection points. As a consequence, the lazy algorithm (which still uses only Predicates 1, 2, and $2'$) will detect all pairs of arcs that intersect an odd number of times.

Remark 5. For line segments, observe that checking whether a pair of segments is active does not require knowing (and therefore maintaining) E_{kl}. In fact, we can replace condition 3 in the definition of an active pair by the following condition: $S_l <_y F_{kl} <_y S_k$ and $I_{kl} <_x F_{kl}$. If $E_{kl} <_x I_{kl}$, the two definitions are identical and if $I_{kl} <_x E_{kl}$, the pair is not active since, by Lemma 5.5, condition 2 of the definition won't be satisfied.

6. Efficient implementations of the lazy algorithm in the predicate arithmetic model. The difficulty of efficiently implementing the lazy sweep-line algorithm using only predicates of degree at most 2 (i.e., in the predicate arithmetic model of degree 2) is due to verification of the emptiness condition in Definition 5.1 and of the prime-pair condition expressed by Definition 5.2: both conditions require examination of all endpoints that have not been processed yet. One can easily check that various known implementations of the sweep achieve straightforward verification of the emptiness condition by introducing algorithmic complications. The following subsection describes an efficient implementation of the lazy algorithm in the predicate arithmetic model of degree 3. The second subsection improves on this result in a special but important instance of Pb1, namely the case of two sets of nonintersecting segments. The algorithm presented there uses only predicates of degree at most 2.

6.1. Robustness of the standard sweep-line algorithm. We shall run our lazy algorithm under the predicate arithmetic model of degree 3. We then have the capability to correctly compare the abscissae of an intersection and of an endpoint. We refine the lazy algorithm in the following way. Let E_i be the last processed endpoint and let E_{i+1} be the endpoint to be processed next. An active pair (S_k, S_l) that occurs in Y between $Y(E_i)$ and $Y^-(E_{i+1})$ will be processed if and only if its intersection point I_{kl} lies to the right of E_i and not to the right of E_{i+1}. As the slab is free of endpoints in its interior, any pair of adjacent segments encountered in Y (between $Y(E_i)$ and $Y^-(E_{i+1})$) and that intersect within the slab is active. Moreover the intersection points of all prime pairs belong to the slab. It follows that this instance of the lazy algorithm need not explicitly check whether a pair is active or not and therefore is much more efficient than the lazy algorithm of section 5. This algorithm is basically what the original algorithm of Bentley–Ottmann[2] becomes when predicates of degree at most 3 are evaluated. (Recall that the standard algorithm requires the capability to correctly execute predicates of degree up to 5.)

We therefore conclude with the following theorem.

THEOREM 6.1. *If Predicates* 1, 2, *and* 3 *are evaluated exactly, the standard sweep-line algorithm will solve* Pb1 *in* $O((n + k) \log n)$ *time.*

It is now appropriate to briefly comment on the implementation details of the just described modified algorithm. Data structure Y is implemented as usual as a dictionary. Data structure X, however, is even simpler than in the standard algorithm (which uses a priority queue with dictionary access). Here X has a primary component realized as a static search tree on the abscissae of the endpoints $E_1, \ldots, E_{2n}$. Leaf E_j points to a secondary data structure $\mathcal{L}(E_j)$ realized as a conventional linked list, containing (in an arbitrary order) adjacent intersecting pairs in slab $(E_j, E_{j+1}]$. Remember that, when E_j has been processed, all intersecting pairs of $\mathcal{L}(E_j)$ are active. Insertion into $\mathcal{L}(E_j)$ is performed at one of its ends, and so is access for reporting (when the plane sweep reaches slab $(E_j, E_{j+1}]$). Since access to events occurs in data structure X, each pair in X must have pointers to the two corresponding segments in Y, in order to enable the necessary updates. In addition, to effect constant-time removal of a pair (S_h, S_k) due to loss of adjacency, all that is needed is to make bidirectional the mentioned pointers. Notice that the elements of X correspond to pairs of adjacent segments in Y, so that at most two records in X are pointed to by any member of Y. We finally observe that a segment adjacency arising in Y during the execution of the algorithm must be tested for intersection; however, an intersecting pair of adjacent segments is eligible for insertion into X only as long as the plane sweep has not gone beyond the slab containing the intersection in question. As regards the running time, beside the initial sorting of the endpoints and the creation of the corresponding primary tree in time $O(n \log n)$, it is easily seen that each intersection uses $O(\log n)$ time (amortized), thereby achieving the performance of the standard algorithm.

[2]With the policy concerning multiple detections of intersections that is stipulated at the beginning of section 5.

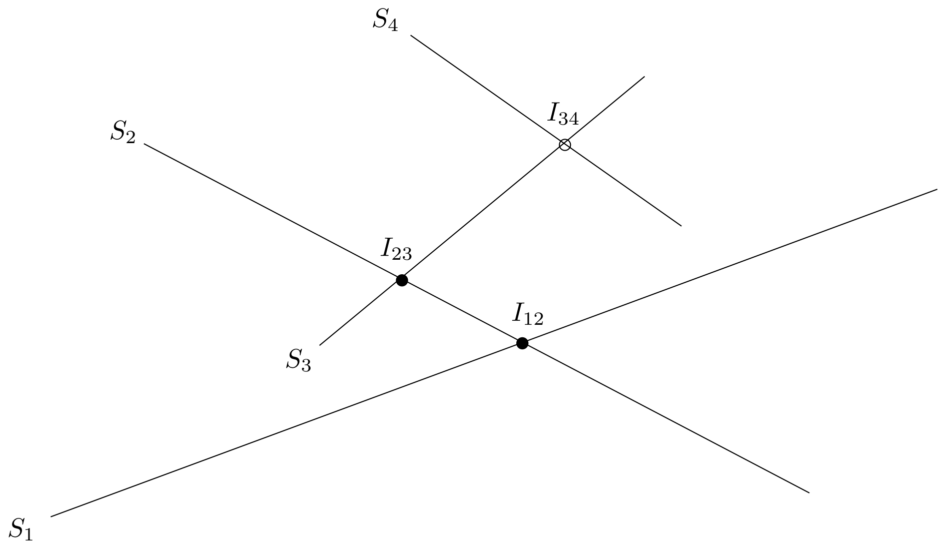

FIG. 6.1. *Assume that the computed x-coordinate of the intersection I_{12} of S_1 and S_2 is (erroneously) found to be smaller than the x-coordinate of the left endpoint of S_3. Y is implemented as a balanced binary search tree. The key associated to a node is the $\lceil \frac{n}{2} \rceil$th element of the corresponding subtree. If all predicates of degree at most 2 are evaluated exactly, S_3 is correctly inserted below S_2, and S_4 is correctly inserted above S_1 and S_2. The different states of Y are (S_1), (S_1, S_2), (S_2, S_1), (S_3, S_2, S_1), and (S_3, S_2, S_1, S_4). Since segments S_3 and S_4 are never adjacent, their intersection I_{34} will not be detected. Observe that the missed intersection point can be arbitrarily far from the intersection point involved in the wrong decision.*

Finally, we note that if only predicates of degree ≤ 2 are evaluated correctly, the algorithm of Bentley–Ottmann may fail to report the set of intersecting pairs of segments. See Figure 6.1 for an example.

Remark 6. The fact that the sweep-line algorithm does not need to sort intersection points had already been observed by several authors including Myers [Mye85], Schorn [Sch91], and Hobby [Hob93]. Myers does not use it for solving robustness problems but for developing an algorithm with an expected running time of $O(n \log n + k)$. Schorn uses this fact to decrease the precision required by the sweep-line algorithm from fivefold to threefold; i.e., Schorn's algorithm uses exact arithmetic of degree 3. Using Theorem 5.3, we will show in section 7 that double precision suffices.

6.2. Reporting intersections between two sets of nonintersecting line segments. In this subsection, we consider two sets of line segments in the plane, $\mathcal{S}_b$ (the blue set) and $\mathcal{S}_r$ (the red set), where no two segments in $\mathcal{S}_b$ (similarly, in $\mathcal{S}_r$) intersect. Such a problem arises in many applications, including the union of two polygons and the merge of two planar maps. We denote by n_b and n_r the cardinalities of $\mathcal{S}_b$ and $\mathcal{S}_r$, respectively, and let $n = n_b + n_r$.

Mairson and Stolfi [MS88] have proposed an algorithm that works for arcs of curve as well as for line segments. Its time complexity is $O(n \log n+k)$, which is optimal, and requires $O(n + k)$ space ($O(n)$ in case of line segments). The same asymptotic time-bound has been obtained by Chazelle et al. [CEGS94] and by Chazelle and Edelsbrunner [CE92]. The latter algorithm is not restricted to two sets of nonintersecting line segments. Other algorithms have been proposed by Nievergelt and Preparata [NP82] and by Guibas and Seidel [GS87] in the case where the segments of $\mathcal{S}_b$ (and $\mathcal{S}_r$) are

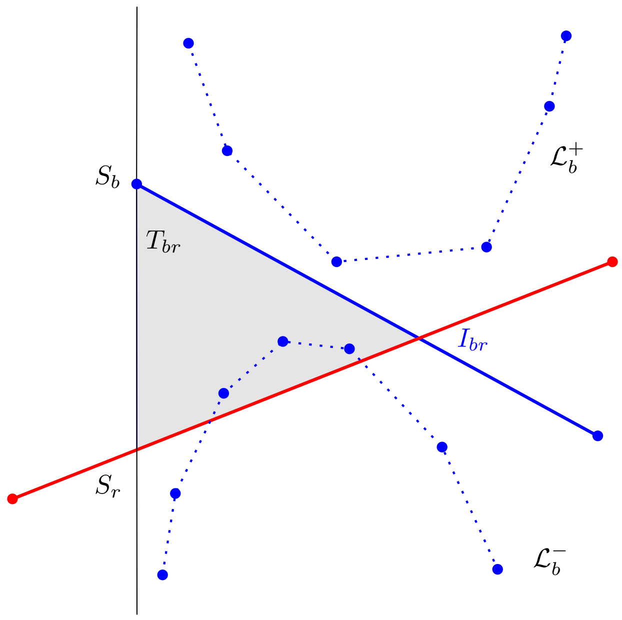

FIG. 6.2. *Notations for the case of two sets of nonintersecting line segments.*

the edges of a subdivision with convex faces. With the exception of the algorithm of Chazelle et al. [CEGS94], all these algorithms construct the resulting arrangement and therefore have degree 4. The algorithm of Chazelle et al. requires comparing the ordinates of the intersections of two segments with a vertical line passing through an endpoint. Therefore it is of degree 3.

We propose here an algorithm that computes all the intersections but not the arrangement. This algorithm uses only predicates of degree ≤ 2 and has time complexity $O((n+k)\log n)$.

Segments are assumed to be nonvertical since intersections with vertical segments can be easily handled with predicates of degree ≤ 2. We say that a point E_i is *vertically visible* from a segment $S_b \in \mathcal{S}_b$ if the vertical line segment joining E_i with S_b does not intersect any other segment in $\mathcal{S}_b$ (the same notion is applicable to $\mathcal{S}_r$). For two intersecting segments $S_b \in \mathcal{S}_b$ and $S_r \in \mathcal{S}_r$, let L be a vertical line to the right of A_{br} such that no other segment intersects L between S_b and S_r (i.e., S_b and S_r are adjacent). We let T_{br} denote the wedge defined by S_b and S_r in the slab between L and $L(I_{br})$ (see Figure 6.2). For a point set $\mathcal{F}$, we let $CH^+(\mathcal{F})$ and $CH^-(\mathcal{F})$ denote its upper and lower convex hulls, respectively.

Our algorithm is based on the following observation.

LEMMA 6.2. *T_{br} contains blue endpoints if and only if it contains a blue endpoint that is vertically visible from S_b. Similarly, T_{br} contains red endpoints if and only if it contains a red endpoint vertically visible from S_r.*

Proof. The sufficient condition is trivial, so we prove only necessity. Assume without loss of generality that $S_r \bigcap L(A_{br}) <_y S_b \bigcap L(A_{br})$. Let $\mathcal{E}$ be the subset of the blue endpoints that belong to T_{br}. Clearly, all vertices of $CH^+(\mathcal{E})$ are vertically visible from S_b. $\square$

Our algorithm has two phases. The second one is the lazy algorithm of section

5. The first one can be considered as a preprocessing step that will help to efficiently find active pairs of segments.

More specifically, our objective is to develop a quick test of the emptiness condition based on the previous lemma. The preprocessing phase is aimed at identifying the candidate endpoints for their potential belonging to wedges formed by intersecting adjacent pairs. Referring to $\mathcal{S}_b$ (and analogously for $\mathcal{S}_r$), we first sweep the segments of $\mathcal{S}_b$ and construct for each blue segment S_b the lists $\mathcal{L}_b^-$ and $\mathcal{L}_b^+$ of blue endpoints that are vertically visible from S_b and lie respectively below and above S_b. The sweep takes time $O(n \log n)$ and the constructed lists are sorted by increasing abscissa. Since there is no intersection point, only predicates of degree ≤ 2 are used. The total size of the lists $\mathcal{L}_b^-$, $\mathcal{L}_b^+$, $\mathcal{L}_r^-$, and $\mathcal{L}_r^+$ is $O(n)$.

As mentioned above, the crucial point is to decide whether or not the wedge T_{br} of a pair of intersecting segments S_b and S_r, adjacent in Y, contains endpoints of other segments. Again, we assume that $S_r < S_b$ in Y. If such endpoints exist, then T_{br} contains either a blue vertex of $CH^+(\mathcal{L}_b^- \cap L^+)$ or a red vertex of $CH^-(\mathcal{L}_b^+ \cap L^+)$. ($L^+$ is the half-plane to the right of line L.)

We will show below that, using predicates of degree ≤ 2, the lists can be preprocessed in time $O(n \log n)$ and that deciding whether or not T_{br} contains endpoints can be done in time $O(\log n)$, using only predicates of degree at most 2.

Assuming for the moment that this primitive is available, we can execute the plane sweep algorithm described earlier. Specifically, we sweep $\mathcal{S}_b$ and $\mathcal{S}_r$ simultaneously, using the lazy sweep-line algorithm of section 5.[3] Each time we detect a pair of (adjacent) intersecting segments S_b and S_r, we can decide in time $O(\log n)$ whether they are "active" or "not active," using only predicates of degree ≤ 2.

We sum up the results of this section in the following theorem.

THEOREM 6.3. *Given n line segments in the plane belonging to two sets $\mathcal{S}_b$ and $\mathcal{S}_r$, where no two segments in $\mathcal{S}_b$ (analogously, in $\mathcal{S}_r$) intersect, there exists an algorithm of optimal degree 2 that reports all intersecting pairs in $O((n+k)\log n)$ time using $O(n)$ storage.*

We now return to the implementation of the primitive described above. Suppose that, for some segment S_i ($i = b$ or r) we have constructed the upper hull $\mathrm{CH}^+(\mathcal{L}_i^- \cap L^+)$. Then we can detect in $O(\log n)$ time if an element of a list, say $\mathcal{L}_b^-$, lies above some segment S_r. More specifically, we first identify among the edges of $CH^+(\mathcal{L}_b^- \cap L^+)$ the two consecutive edges whose slopes are, respectively, smaller and greater than the slope of S_r. This requires only the evaluation of $O(\log |\mathcal{L}_b^-|)$ predicates of degree 2. It then remains to decide whether the common endpoint E of the two reported edges lies above or below the line containing S_r. This can be answered by evaluating the orientation predicate $\mathrm{orient}(E, A_r, B_r)$.

The crucial requirement of the adopted data structure is the ability to efficiently maintain $\mathrm{CH}^+(\mathcal{L}_i^- \cap L^+)$. To this purpose, we propose the following solution.

The data structure associated with a list $\mathcal{L}_i^-$ ($i = b$ or r) represents the upper convex hull $\mathrm{CH}^+(\mathcal{L}_i^-)$ of $\mathcal{L}_i^-$. (Similarly, the data structure associated with a list $\mathcal{L}_i^+$ represents the lower convex hull $\mathrm{CH}^-(\mathcal{L}_i^+)$ of $\mathcal{L}_i^+$.) This implies that a binary search on the convex hull slopes uniquely identifies the test vertex. Since the elements of each list are already sorted by increasing x-coordinates, the data structures can be constructed in time proportional to their sizes and therefore in $O(n)$ time in total. It can be easily checked that only orientation predicates (of degree 2) are involved in this process. To guarantee the availability of $\mathrm{CH}^+(\mathcal{L}_i^- \cap L^+)$, we have to ensure

[3]We can adopt the policy of processing all active pairs before the next endpoint.

that our data structure can efficiently handle the deletion of elements. As elements are deleted in order of increasing abscissa, this can be done in amortized $O(\log |S|)$ time per deletion [HS90, HS96]. It follows that preprocessing all lists takes $O(n)$ time, uses $O(n)$ space, and requires only the evaluation of predicates of degree ≤ 2.

7. An efficient implementation of the lazy algorithm under the exact arithmetic model of degree 2. We shall run the lazy algorithm of section 6.1 under the exact arithmetic model of degree 2, i.e., Predicates 1 and 2 are evaluated exactly but Predicate 3 is implemented with exact arithmetic of degree 2 as explained in section 4.3. Several intersection points may now be found to have the same abscissa as an endpoint. We refine the lazy algorithm in the following way. Let E_i be the last processed endpoint and let E_{i+1} be the endpoint with an abscissa strictly greater than the abscissa of E_i to be processed next. An active pair (S_k, S_l) will be processed if and only if its intersection point is found to lie to the right of E_i and not to the right of E_{i+1}.

We claim that this policy leads to efficient verification of the emptiness condition. Indeed, the intersections of all prime pairs belong to $(E_i, E_{i+1}]$, because $E_{i+1} \in W^+_{kl}(E_{kl}) \Longrightarrow I_{kl} \leq_x E_{i+1}$, and, by the monotonicity property, both implementations of Predicate 3 of section 4.3 will report that $I_{kl} \leq_x E_{i+1}$.

The crucial observation that drastically reduces the time complexity is the following. A pair of adjacent segments (S_k, S_l) encountered in Y between $Y(E_i)$ and $Y(E^-_{i+1})$ whose intersection point is reported to lie in slab $(E_i, E_{i+1}]$ is active if and only if $E_{i+1} \notin W^-_{kl}(E_{kl})$. Indeed, since I_{kl} is found to be $<_x E_{i+2}$, the monotonicity property implies that $I_{kl} <_x E_{i+2}$. Therefore, when checking if a pair is active, it is sufficient to consider just the next endpoint, not all of them.

Theorem 5.3 therefore applies. If no two endpoints have the same x-coordinate, the algorithm is the same as the algorithm in section 6.1 apart from the implementation of Predicate 3. Otherwise, we construct X on the distinct abscissae of the endpoints and store all endpoints with identical x-coordinates in a secondary search structure with endpoints sorted by y-coordinates. This secondary structure will allow us to determine if a pair is active in logarithmic time by binary search. We conclude with the following theorem.

THEOREM 7.1. *Under the exact arithmetic model of degree* 2*, the instance of the lazy algorithm described above solves* $Pb1$ *in* $O((n+k)\log n)$ *time.*

8. Conclusion. Further pursuing our investigations in the context of the exact-computation paradigm, in this paper we have illustrated that important problems on segment sets (such as intersection report, arrangement, and trapezoidal map), which are viewed as equivalent under the Real-RAM model of computation, are distinct if their algebraic degree is taken into account. This sheds new light on robustness issues which are intimately connected with the notion of algebraic degree and illustrates the richness of this new direction of research.

For example, we have shown that the well-known plane sweep algorithm of Bentley–Ottmann uses more machinery than strictly necessary and can be appropriately modified to report segment intersections with arithmetic capabilities very close to optimal and no sacrifice in performance.

Another result of our work is that exact solutions of some problems can be obtained even if approximate (or even random) evaluations of some predicates are performed. More specifically, using less powerful arithmetic than demanded by the application, we have been able to compute the vertices of an arrangement of line segments by constructing an arrangement which may be different from the actual one (and may not even correspond to any set of straight line segments) but still has the same vertex set.

Our work shows that the sweep-line algorithm is more robust than usually believed, proposes practical improvements leading to robust implementations, and provides a better understanding of the sweeping line paradigm. The key to our technique is to relax the horizontal ordering of the sweep. This is one step further after similar attempts, aimed though at different purposes [Mye85, MS88, EG89].

A host of interesting open questions remain. One such question is to devise an output-sensitive algorithm for reporting segment intersections with optimal time complexity and with optimal algebraic degree (that is, 2). It would also be interesting to examine the plane sweep paradigm in general. For example, with regard to the construction of Voronoi diagrams in the plane, one should elucidate the reasons for the apparent gap between the algebraic degrees of Fortune's plane sweep solution and of the (optimal) divide-and-conquer and incremental algorithms.

Appendix. In connection with reducibility of polynomials over a domain of rationality, we choose the rationals as the latter. "Reducible" means "reducible over the rationals."

We first recall that a general determinant is irreducible if its entries are regarded as independent variables [Boc07]. This suffices to prove directly that the degree of Predicate 2 is 2 and will be crucial for completing the proof of irreducibility of the polynomials pertaining to the other predicates. Use will be made of the following theorem.

Let $p(x_1, \ldots, x_n)$ be a multivariate homogeneous polynomial, and let I be a subset of $\{1, \ldots, n\}$, such that for any $j \in I$, x_j is a variable of degree 1 in p. For $i \in \{1, \ldots, n\}$ p can be expressed as

$$p = p_i x_i + p_{i0},$$

where p_i and p_{i0} are polynomials in all variables except x_i. Two polynomials are not considered distinct if they differ just by a multiplicative constant. We have the following.

THEOREM 8.1. *Let $p(x_1, \ldots, x_n)$ be a multivariate homogeneous polynomial with degree at least 3 and $|I| \geq 2$. If for some $i, j \in I$, coefficients p_i and p_j are distinct and irreducible, then p is irreducible.*

Proof. Assume, for a contradiction, that p is reducible. This means that p can be expressed as $p = \phi\psi$, where ϕ and ψ are multivariate homogeneous polynomials over the same variables satisfying $1 \leq degree(\phi), degree(\psi) < degree(p)$. Each degree-1 variable obviously appears in exactly one of the factors. With complete generality, assume that x_i appears in ϕ. We distinguish two cases.

(1) $degree(\phi) > 1$. Expanding ϕ around x_i we obtain $\phi = \phi_i x_i + \phi_{i0}$, so that

$$p = \phi\psi = (\phi_i x_i + \phi_{i0})\psi = \phi_i \psi x_i + \phi_{i0}\psi.$$

This means that $p_i = \phi_i \psi$, with $degree(\phi_i), degree(\psi) \geq 1$, i.e., p_i is reducible, a contradiction.

(2) $degree(\phi) = 1$. Variable x_j appears either in ϕ or in ψ. In the first case, p_i and p_j are both proportional to ψ, i.e., they may differ only by a multiplicative constant and are not distinct, a contradiction.

In the second case, by an argument analogous to that of Case 1, we reach the conclusion that $p_j = \phi\psi_j$ and that $degree(\psi_j) = degree(p) - degree(\phi) - 1 \geq$

$3-1-1=1$. Since $p_j=\phi\psi_j$ and $degree(\phi), degree(\psi_j) \geq 1$, p_j is reducible, another contradiction.

This completes the proof of the theorem. □

The calculation of coefficients p_i, p_j corresponds to taking formal derivatives of p with respect to x_i,x_j. Notice that a derivation reduces the degree by 1. The reader may verify, by explicit and not very enlightening calculations, that the following schedules of derivations lead to irreducible 2×2 determinants. The indices conform with the notation of section 4.1.

Predicate 3: Apply Theorem 8.1 to the pair (x_1, x_2).

Predicate 4: Apply Theorem 8.1 first to (x_2, x_3) and then to (y_6, y_7).

Predicate 4′: Apply Theorem 8.1 first to (x_0, x_1) and then to (x_2, x_3)

Predicate 5: Apply Theorem 8.1 first to (x_1, x_2), next to (x_7, x_8), and finally to (y_5, y_6).

Acknowledgments. We are indebted to H. Brönnimann for having pointed out an error in a previous version of this paper and to O. Devillers for discussions that lead to Lemma 4.3. S. Pion, M. Teillaud, and M. Yvinec are also gratefully acknowledged for their comments on this work. Special thanks are due to two anonymous referees, whose insightful comments have significantly contributed to the quality of the paper.

BINARY SPACE PARTITIONS FOR FAT RECTANGLES[*]

PANKAJ K. AGARWAL[†], EDWARD F. GROVE[‡], T. M. MURALI[§], AND JEFFREY SCOTT VITTER[¶]

Abstract. We consider the practical problem of constructing binary space partitions (BSPs) for a set S of n orthogonal, nonintersecting, two-dimensional rectangles in $\mathbb{R}^3$ such that the aspect ratio of each rectangle in S is at most α, for some constant $\alpha \geq 1$. We present an $n2^{O(\sqrt{\log n})}$-time algorithm to build a binary space partition of size $n2^{O(\sqrt{\log n})}$ for S. We also show that if m of the n rectangles in S have aspect ratios greater than α, we can construct a BSP of size $n\sqrt{m}2^{O(\sqrt{\log n})}$ for S in $n\sqrt{m}2^{O(\sqrt{\log n})}$ time. The constants of proportionality in the big-oh terms are linear in $\log \alpha$. We extend these results to cases in which the input contains nonorthogonal or intersecting objects.

1. Introduction.

Rendering a set of opaque or partially transparent objects in $\mathbb{R}^3$ quickly and in a visually realistic way is a fundamental problem in computer graphics [15]. A central component of this problem is *hidden-surface removal*: given a set of objects, a viewpoint, and an image plane, compute the scene visible from the viewpoint as projected onto the image plane. Because of its importance, the hidden-surface removal problem has been studied extensively in both the computer graphics and the computational geometry communities [14, 15, 28]. One of the conceptually simplest solutions to this problem is the z-buffer algorithm [8, 15]. This algorithm sequentially processes the objects; for each object, it updates the pixels of the image plane covered by the object, based on the distance information stored in the z-buffer. A very fast hidden-surface removal algorithm can be obtained by implementing the z-buffer in hardware. However, only special-purpose and costly graphics engines contain fast z-buffers, and z-buffers implemented in software are generally inefficient. Even

when fast hardware z-buffers are present, they are not fast enough to handle the huge models (containing hundreds of millions of polygons) that often have to be displayed in real time. As a result, other methods have to be developed either to "cull away" a large subset of invisible polygons so as to decrease the rendering load on the graphics pipeline (when models are large; see, e.g., [29]) or to completely solve the hidden-surface removal problem (when there are very slow or no z-buffers).

One technique to handle both of these problems is the *binary space partition* (BSP), a data structure introduced by Fuchs, Kedem, and Naylor [16] that is based on work by Schumacker et al. [27]. Fuchs, Kedem, and Naylor use the BSP to implement the so-called "painter's algorithm" for hidden-surface removal; the painter's algorithm draws the objects to be displayed on the screen in a back-to-front order (in which no object is occluded by any object earlier in the order). In general, it is not possible to find a back-to-front order from a given viewpoint for an arbitrary set of objects. By fragmenting the objects, the BSP ensures that a back-to-front order from *any* viewpoint can be determined for the fragments [16].

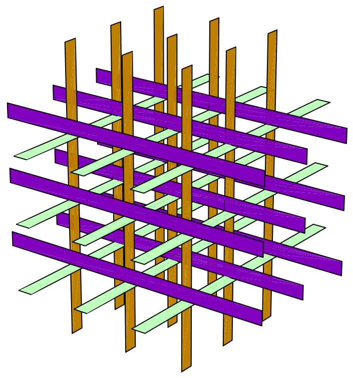
The BSPs have subsequently proven to be versatile, with applications in many other problems—global illumination [6], shadow generation [10, 11], visibility problems [4, 29], solid modeling [22, 24, 30], geometric data repair [19], ray tracing [21], robotics [5], approximation algorithms for network design [17], and surface simplification [3]. Algorithms have also been developed to construct BSPs for moving objects [1, 2, 12, 23, 31].

Informally, a BSP $\mathcal{B}$ for a set of $(d-1)$-dimensional objects in $\mathbb{R}^d$ is a binary tree. Each node v of $\mathcal{B}$ is associated with a convex region $\mathcal{R}_v$. The regions associated with the children of v are obtained by splitting $\mathcal{R}_v$ with a hyperplane. If v is a leaf of $\mathcal{B}$, then the interior of $\mathcal{R}_v$ does not intersect any object. The regions associated with the leaves of the tree form a convex decomposition of $\mathbb{R}^d$. The $(d-1)$-dimensional faces of the cells of this decomposition intersect the objects and divide them into fragments; these fragments are stored at appropriate nodes of the BSP.

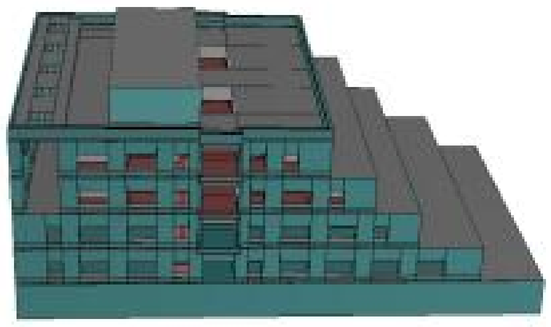
The efficiency of most algorithms that use BSPs depends on the number of nodes in the BSP. As a result, there has been a lot of effort to construct BSPs of small size. Although several simple heuristics have been developed for constructing BSPs of reasonable sizes [4, 7, 16, 20, 29, 30], provable bounds were first obtained by Paterson and Yao. They show that a BSP of size $O(n \log n)$ can be constructed for n disjoint segments in $\mathbb{R}^2$; they also show that a BSP of size $O(n^2)$ can be constructed for n disjoint triangles in $\mathbb{R}^3$, which is optimal in the worst case [25]. But in graphics-related applications, many common environments like buildings are composed largely of orthogonal rectangles, and nonorthogonal objects are approximated by their orthogonal bounding boxes [15]. Paterson and Yao [26] prove that a BSP of size $O(n)$ exists for n nonintersecting, orthogonal segments in $\mathbb{R}^2$, and a BSP of size $O(n\sqrt{n})$ exists for n nonintersecting, orthogonal rectangles in $\mathbb{R}^3$. These bounds are optimal in the worst case.

In all known lower bound examples of orthogonal rectangles in $\mathbb{R}^3$ requiring BSPs of size $\Omega(n\sqrt{n})$, most of the rectangles are "thin." For example, the lower bound proof presented by Paterson and Yao uses a configuration of $\Theta(n)$ orthogonal rectangles, arranged in a $\sqrt{n} \times \sqrt{n} \times \sqrt{n}$ grid, for which any BSP has size $\Omega(n\sqrt{n})$ (see Figure 1.1).All rectangles in their construction have aspect ratio $\Omega(\sqrt{n})$. Such configurations of thin rectangles rarely occur in practice. Many real databases consist mainly of "fat" rectangles; i.e., the aspect ratios of these rectangles are bounded by a constant.

It is natural to ask whether BSPs of near-linear size can be constructed if most



(a)



(b)

FIG. 1.1. (a) *Lower bound for orthogonal rectangles.* (b) *Model of a building—*85% *of the rectangles have aspect ratio at most* 25.

of the rectangles are "fat." We call a rectangle *fat* if its aspect ratio (the ratio of the longer side to the shorter side) is bounded by a fixed constant; for specificity, we use $\alpha \geq 1$ to denote this constant. A rectangle is said to be *thin* if its aspect ratio is greater than α. In this paper, we consider the following problem:

> *Given a set S of n nonintersecting, orthogonal, two-dimensional rectangles in $\mathbb{R}^3$, of which m are thin and the remaining $n-m$ are fat, construct a BSP for S.*

We first show how to construct a BSP of size $n2^{O(\sqrt{\log n})}$ for n fat rectangles in $\mathbb{R}^3$ (i.e., when $m = 0$). We then show that if $m > 0$, a BSP of size $n\sqrt{m}2^{O(\sqrt{\log n})}$ can be built. We also prove a lower bound of $\Omega(n\sqrt{m})$ on the size of such a BSP.

We finally prove two important extensions to these results. If p of the n input objects are nonorthogonal, we show that an $np2^{O(\sqrt{\log n})}$-size BSP exists. Unlike in the case of orthogonal objects, fatness does not help in reducing the worst-case size of BSPs for nonorthogonal objects. In particular, we prove that there exists a set of n fat triangles in $\mathbb{R}^3$ for which any BSP has $\Omega(n^2)$ size. However, nonorthogonal objects can be approximated by orthogonal bounding boxes. The resulting bounding boxes might intersect each other. Motivated by this observation, we also consider the problem in which n fat rectangles contain k intersecting pairs of rectangles, and we show that we can construct a BSP of size $(n+k)\sqrt{k}2^{O(\sqrt{\log n})}$.

In all cases, the constant of proportionality in the big-oh terms is linear in $\log \alpha$, where α is the maximum aspect ratio of the fat rectangles. Our algorithms to construct these BSPs run in time proportional to the size of the BSPs they build. Experiments demonstrate that our algorithms work well in practice and construct BSPs of near-linear size when most of the rectangles are fat, and perform better than most known algorithms for constructing BSPs for orthogonal rectangles [18].

As far as we are aware, ours is the first work to consider BSPs for the practical and common case of (two-dimensional) fat polygons in $\mathbb{R}^3$. De Berg considers a weaker model, the case of (three-dimensional) fat polyhedra in $\mathbb{R}^3$ (a polyhedron is said to be *fat* if its volume is at least a constant fraction of the volume of the smallest sphere enclosing it), although his results extend to higher dimensions [13].

One of the main ingredients of our algorithm is the construction of an $O(n \log n)$-size BSP for a set of n fat rectangles that are "long" with respect to a box B; i.e., none of the vertices of the rectangles lie in the interior of B. To prove this result, we crucially use the fatness of the rectangles. We then develop an algorithm to construct a BSP of size $n2^{O(\sqrt{\log n})}$ for n fat rectangles by simultaneously simulating the algorithm for long rectangles and partitioning the vertices of rectangles in S in a clever manner.

The rest of the paper is organized as follows: section 2 gives some preliminary definitions. In section 3, we show how to build an $O(n \log n)$-size BSP for n long rectangles. Sections 4 and 5 present and analyze our algorithm to construct a BSP of size $n2^{O(\sqrt{\log n})}$ for n fat rectangles. We extend this result in section 6 to construct BSPs for cases in which some objects in the input are thin or nonorthogonal. We conclude in section 7 with some open problems.

2. Geometric preliminaries. A *binary space partition* $\mathcal{B}$ for a set S of pairwise-disjoint, $(d-1)$-dimensional, polyhedral objects in $\mathbb{R}^d$ is a tree defined as follows: Each node v in $\mathcal{B}$ represents a convex polytope $\mathcal{R}_v$ and a set of objects $S_v = \{s \cap \mathcal{R}_v \mid s \in S\}$ that intersect $\mathcal{R}_v$. The region associated with the root is $\mathbb{R}^d$ itself. If S_v is empty, then node v is a leaf of $\mathcal{B}$. Otherwise, we partition $\mathcal{R}_v$ into two convex polytopes by a *cutting hyperplane* H_v. At v, we store the equation of H_v and $\{s \mid s \in S_v, s \subseteq H_v\}$, the subset of objects in S_v that lie in H_v. If we let H_v^+ be the positive halfspace and H_v^- the negative halfspace bounded by H_v, the polytopes associated with the left and right children of v are $\mathcal{R}_v \cap H_v^-$ and $\mathcal{R}_v \cap H_v^+$, respectively. The left subtree of v is a BSP for the set of objects $S_v^- = \{s \cap H_v^- \mid s \in S_v\}$ and the right subtree of v is a BSP for the set of objects $S_v^+ = \{s \cap H_v^+ \mid s \in S_v\}$. The size of $\mathcal{B}$ is the sum of the number of nodes in $\mathcal{B}$ and the total number of faces of all dimensions of the objects stored at all the nodes in $\mathcal{B}$.

In our case, S is a set of orthogonal rectangles in $\mathbb{R}^3$. In our algorithms, we will use orthogonal cutting planes. Therefore, the region $\mathcal{R}_v$ associated with each node v in $\mathcal{B}$ is a *box* (rectangular parallelepiped). We say that a rectangle r is *long* with respect to a box B if none of the vertices of r lie in the interior of B. Otherwise, r is said to be *short* (see Figure 2.1). A long rectangle is *free* if none of its edges lies in the interior of B; otherwise it is *nonfree*. A *free cut* is a cutting plane that does not cross any rectangle in S and that either divides S into two nonempty sets or contains

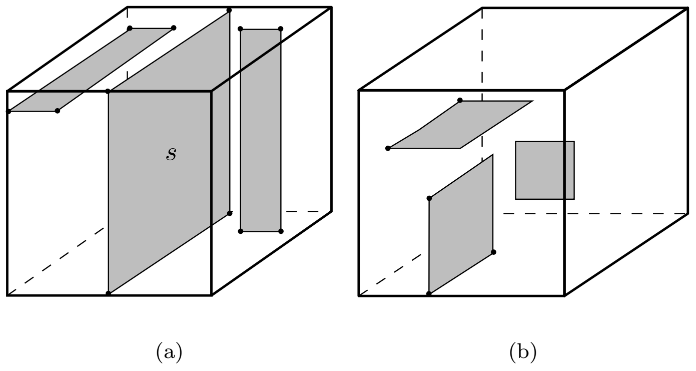


FIG. 2.1. (a) *Long and* (b) *short rectangles. Heavy dots indicate the vertices of these rectangles that lie on the boundary of the box. Rectangle s is a free rectangle.*

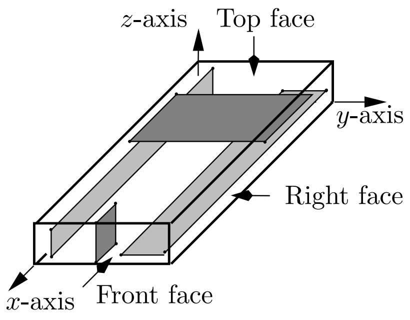

FIG. 2.2. *Different classes of rectangles.*

a rectangle in S. Note that the plane containing a free rectangle is a free cut. Free cuts play a critical role in preventing excessive fragmentation of the rectangles in S.

We will often focus on a box B and construct a BSP for the rectangles intersecting it. Given a set of rectangles R, let

$$R_B = \{s \cap B \mid s \in R\}$$

be the set of rectangles obtained by clipping the rectangles in R within B. For a set of points P, let P_B be the subset of P lying in the interior of B.

A box B has six faces: *top, bottom, front, back, right,* and *left*, as shown in Figure 2.2. We assume, without loss of generality, that the back, bottom, left corner of B is the origin (i.e., the back face of B lies on the yz-plane). A rectangle s that is long with respect to B belongs to the *top class* if two parallel edges of $s \cap B$ are contained in the top and bottom faces of B. We similarly define the *front* and *right* classes. A long rectangle belongs to at least one of these three classes; a nonfree long rectangle belongs to a unique class. See Figure 2.2 for examples of rectangles belonging to different classes.

Although a BSP is a tree, we will often discuss just how to partition the box represented by a node into two boxes. We will not explicitly detail the associated construction of the actual tree itself, since the construction is straightforward once we specify the cutting plane. Sometimes we will abuse notation and use B to refer to

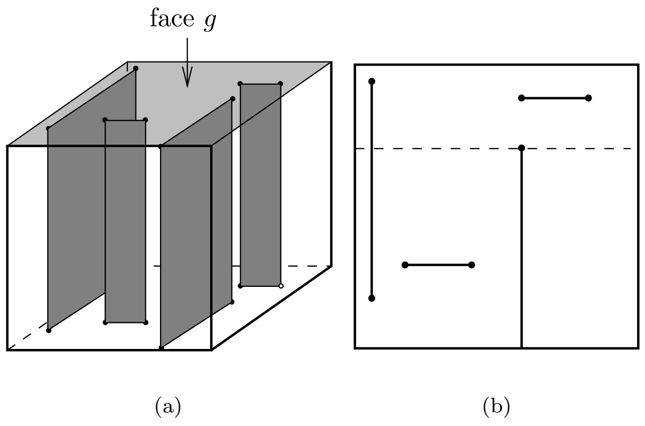

FIG. 2.3. (a) *Long rectangles in the top class.* (b) *Projections of the rectangles in* (a) *onto the top face g; heavy dots indicate the vertices of these rectangles that lie in the interior of g. The dashed line is the cut satisfying* (2.1).

the corresponding node in the BSP as well.

In the rest of the paper, we assume that the vertices of the rectangles in S are sorted by x-, y-, and z-coordinates, and that for each axis, the rectangles perpendicular to that axis are sorted by intercept. The cost of this sort will not affect the asymptotic running times of our algorithms.

We now state two preliminary lemmas that we will use in our algorithms. The first lemma characterizes a set of rectangles that are long with respect to a box and belong to one class. The second lemma applies to two classes of long rectangles.

LEMMA 2.1. *Let C be a box, P a set of points in the interior of C, R a set of rectangles long with respect to C, and $w \geq 1$ a real number. If the rectangles in R_C belong to one class, then the following two conditions hold (see Figure* 2.3*):*

(i) *There exists a face g of the box C that contains exactly one of the edges of each rectangle in R_C. Let V be the set of those vertices of the rectangles in R_C that lie in the interior of g.*

(ii) *We can find a plane that partitions C into two boxes C_1 and C_2 so that for $i = 1, 2$,*

$$|V \cap C_i| + w|P_{C_i}| \leq \frac{|V| + w|P|}{2}. \tag{2.1}$$

If the rectangles in R_C and the points in P are sorted along each of the three axes, the partitioning plane can be computed in $O(|R_C| + |P|)$ time.

Proof. (i) follows from the definition of a class. To prove part (ii) of the lemma, let P^* be the set of projections of the points in P onto g. Assume g is the top face of C. If we associate a weight of 1 with each point in V and a weight w with each point in P^*, the total weight of the points in $V \cup P^*$ is $|V| + w|P|$. By sweeping g, we can find a line l lying in g and parallel to the x-axis that contains a point in $V \cup P^*$ and divides $V \cup P^*$ into two sets, each with weight at most $(|V| + w|P|)/2$. We split C into two boxes C_1 and C_2 using the plane containing l that is orthogonal to g. By construction, C_1 and C_2 satisfy (2.1). The time bound follows easily. ∎

LEMMA 2.2. *Let C be a box, P a set of points in the interior of C, R a set of* *rectangles long with respect to C, and $w \geq 1$ a real number. If the rectangles in R_C belong to two classes, then one of the following two conditions holds (see Figure 2.4):*

(i) *We can find one free cut that partitions C into two boxes C_1 and C_2 so that*

$$|R_{C_i}| + w|P_{C_i}| \leq \frac{2\left(|R_C| + w|P|\right)}{3} \tag{2.2}$$

for $i = 1, 2$.

(ii) *We can find two parallel free cuts that divide C into three boxes C_1, C_2, and C_3 such that all rectangles in R_{C_2} belong to the same class and such that*

$$|R_{C_2}| + w|P_{C_2}| \geq \frac{|R_C| + w|P|}{3}. \tag{2.3}$$

If the rectangles in R_C and the points in P are sorted along each of the three axes, these free cuts can be computed in $O(|R_C| + |P|)$ time.

Proof. We assume without loss of generality that the rectangles in R_C belong to the top and right classes. Let $\bar{r}$ denote the projection of a rectangle $r \in R_C$ onto the x-axis: $\bar{r}$ is either a point or an interval. Similarly, let $\bar{p}$ denote the projection of a point $p \in P$ onto the x-axis. Set

$$U = \left\{ \left(\bigcup_{r \in R_C} \bar{r} \right) \cup \left(\bigcup_{p \in P} \bar{p} \right) \right\}.$$

The set U is a collection of disjoint intervals, some of which may be single points. Let r_1 (resp., r_2) be a rectangle in R_C belonging to the top (resp., right) class. Since the rectangles in R_C are disjoint, it is easily seen that $\bar{r}_1$ and $\bar{r}_2$ are also disjoint. Hence, each connected component of U contains the projections of rectangles belonging to at most one class. For any connected component I of U define

$$\mu(I) = |\{r \in R_C \mid \bar{r} \subseteq I\}| + w|\{p \in P \mid \bar{p} \subseteq I\}|.$$

Set $W = |R_C| + w|P|$. If U contains a connected component $I = [\beta, \gamma]$ with $\mu(I) > W/3$, then the two free cuts are $x = \beta$ and $x = \gamma$. The cuts partition the box C into three boxes C_1, C_2, and C_3, where C_2 denotes the middle box. By construction, all rectangles in R_{C_2} belong to at most one class. Hence, condition (ii) holds. [1]

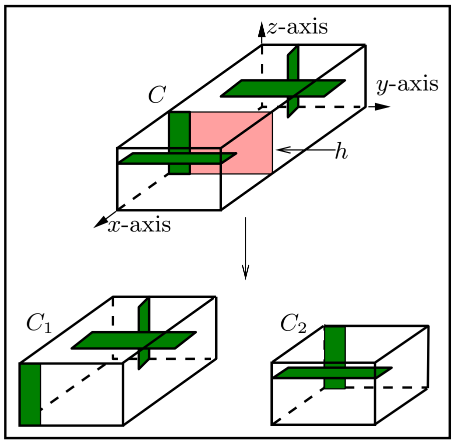
If there is no such connected component of U, then let $I = [\beta, \gamma]$ be the leftmost connected component of U with $\sum_{I' \leq I} \mu(I') > W/3$ (we say that $I' \leq I$ if I' lies to the left of I). Since $\mu(I) \leq W/3$ and $\sum_{I' < I} \mu(I') < W/3$,

$$\sum_{I' \leq I} \mu(I') \leq 2W/3.$$

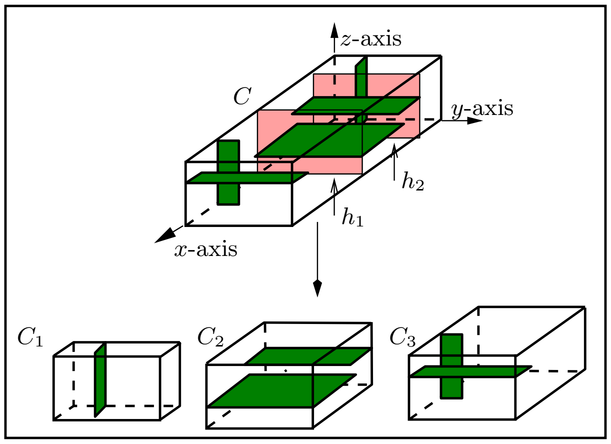
We partition C into two boxes C_1 and C_2 using the cut $x = \gamma$. In this case, condition (i) holds.

If the rectangles in R_C and the points in P are sorted along the x-axis, it is clear that the components in U can be computed and sorted in $O(|R_C| + |P|)$ time. The free cut(s) used to partition C can be found in the same time by sweeping the components of U. ◻

[1]If $\beta = \gamma$, i.e., I is a point, then C_2 is regarded as a degenerate box. If I is the first (resp., last) connected component of U, then C_1 (resp., C_3) may be a degenerate box.



(a)



(b)

FIG. 2.4. (a) *Free cut h partitions box C into two boxes C_1 and C_2.* (b) *Two parallel free cuts h_1 and h_2 partition C into three boxes: C_1, C_2, and C_3.*

3. BSPs for long fat rectangles. Let S be a set of fat rectangles. Assume that all the rectangles in S are long with respect to a box B. In this section, we show how to build a BSP for S_B, the set of rectangles clipped within B. In general, S_B can have all three classes of rectangles. We first exploit the fatness of the rectangles to prove that whenever all three classes are present in S_B, a small number of cuts can divide B into boxes, each of which has only two classes of rectangles. Then we describe an algorithm that constructs a BSP for rectangles belonging to only two classes.

3.1. Reducing three classes to two classes. Assume, without loss of generality, that the longest edge of B is parallel to the x-axis. The rectangles in S_B that

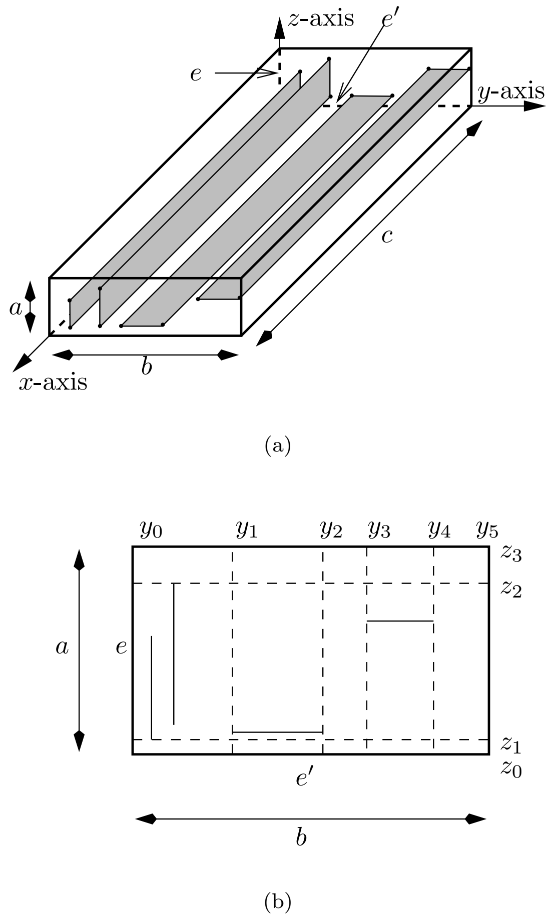


FIG. 3.1. (a) *Rectangles belonging to the sets R and T.* (b) *The back face of B; dashed lines are intersections of the back face with the α-cuts.*

belong to the front class can be partitioned into two subsets: the set R of rectangles that are vertical (and parallel to the right face of B) and the set T of rectangles that are horizontal (and parallel to the top face of B); see Figure 3.1. Let e be the edge of B that lies on the z-axis, and let e' be the edge of B that lies on the y-axis. The intersection of each rectangle in R with the back face of B is a segment parallel to the z-axis. Let $\bar{r}$ denote the projection of such a segment r onto the z-axis, and let $\bar{R} = \{\bar{r} \mid r \in R\}$. Let $z_1 < z_2 < \cdots < z_{k-1}$ be the endpoints of intervals in $\bar{R}$ that lie in the interior of e but not in the interior of any interval of $\bar{R}$. Note that $k-1$ may be less than $2|R|$, as in Figure 3.1, if some of the projected segments overlap. If no two intervals in $\bar{R}$ share an endpoint, then $\{z_1, z_2, \ldots, z_{k-1}\}$ is the set of vertices of the union of the intervals in $\bar{R}$; otherwise, $\{z_1, z_2, \ldots, z_{k-1}\}$ includes endpoints common to two intervals in $\bar{R}$ and not lying in the interior of any other interval in $\bar{R}$. Similarly, for each rectangle t in the set T, let $\bar{t}$ be the projection of t onto the y-axis, and let $\bar{T} = \{\bar{t} \mid t \in T\}$. Let $y_1 < y_2 < \cdots < y_{l-1}$ be the endpoints of intervals in $\bar{T}$ that lie in the interior of e' but not in the interior of any interval of $\bar{T}$.

We divide B into kl boxes by drawing the planes $z = z_i$ for $1 \leq i < k$ and the planes $y = y_j$ for $1 \leq j < l$; see Figure 3.1. This decomposition of B into kl boxes can easily be constructed in a treelike fashion by performing $(k-1)(l-1)$ cuts. We refer to these cuts as *α-cuts*. If any resulting box has a free rectangle, we divide that box into two boxes by applying the free cut along the free rectangle. Let $\mathcal{C}$ be the set of boxes into which B is partitioned in this manner. We can prove the following lemma about the decomposition of B into $\mathcal{C}$.

LEMMA 3.1. *The set $\mathcal{C}$ of boxes formed by the above process satisfies the following properties:*

(i) *Each box C in $\mathcal{C}$ has only two classes of rectangles,*
(ii) *there are at most $26\alpha^2 n$ boxes in $\mathcal{C}$, and*
(iii) $\sum_{C \in \mathcal{C}} |S_C| \leq 16\alpha n$.

Proof. Let z_0 and z_k, where $z_0 < z_k$, be the endpoints of e, the edge of the box B that lies on the z-axis. Similarly, define y_0 and y_l, where $y_0 < y_l$, to be the endpoints of the edge of B that lies on the y-axis.

(i) Let C be a box in $\mathcal{C}$. If C does not contain a rectangle from $T \cup R$, the claim is obvious since the rectangles in T and R together constitute the front class. Suppose C contains rectangles from the set R. Rectangles in R belong to the front class and are parallel to the right face of B. We claim that C cannot have any rectangles from the right class. Indeed, consider an edge of C parallel to the z-axis. The endpoints of this edge have z-coordinates z_i and z_{i+1}, for some $0 \leq i < k$. Since C contains a rectangle from R, by construction, the interval $z_i z_{i+1}$ must be covered by projections of rectangles in R (onto the z-axis). If C also contains a rectangle r belonging to the right class, then let $z_i < z < z_{i+1}$ be the z-coordinate of a point in $r \cap C$. Let r' be a rectangle in R whose projection on the z-axis contains z. Since both r and r' are long with respect to C, the interiors of r and r' intersect, which contradicts the fact that the rectangles in S are nonintersecting. A similar proof shows that if C contains rectangles from T, then C does not contain any rectangle in the top class.

(ii) We first show that both k and l are at most $2\lfloor\alpha\rfloor + 3$. Let a (resp., b, c) denote the length of the edges of B parallel to the z-axis (resp., y-axis, x-axis). By assumption, $a, b \leq c$. Let $r \in R$ be a rectangle with dimensions β and γ, where $\beta \leq \gamma$. Consider $\bar{r}$, the projection of r onto the z-axis. Suppose that $\bar{r} \subseteq z_i z_{i+1}$, for some $0 < i < k-1$, i.e., $\bar{r}$ lies in the interior of the edge e of B lying on the z-axis. Since r is a rectangle in the front class and is parallel to the right face of B, we have $\beta \leq a \leq c = \gamma$. If $\hat{r}$, the rectangle supporting r in the set S, has dimensions $\hat{\beta}$ and $\hat{\gamma}$, where $\hat{\beta} \leq \hat{\gamma} \leq \alpha\hat{\beta}$, we have $\beta = \hat{\beta}$ (since $\bar{r} \subseteq \mathrm{int}(e)$) and $\gamma \leq \hat{\gamma}$. (If i is 0 or $k-1$, we cannot claim that $\beta = \hat{\beta}$; in these cases, it is possible that $\beta \ll \hat{\beta}$.) See Figure 3.2. Thus, we obtain

$$a \leq c = \gamma \leq \hat{\gamma} \leq \alpha\hat{\beta} = \alpha\beta.$$

It follows that the length of the interval $\bar{r}$, and hence the length of $z_i z_{i+1}$, is at least a/α. Since every alternate interval $z_i z_{i+1}, 0 < i < k-1$ contains the projection of at least one rectangle of R, we have $k \leq 2\lfloor\alpha\rfloor + 3$. In a similar manner, $l \leq 2\lfloor\alpha\rfloor + 3$. Hence, the planes $z = z_i, 1 \leq i \leq k-1$ and the planes $y = y_j, 1 \leq j \leq l-1$ partition B into at most $kl \leq (2\lfloor\alpha\rfloor + 3)^2$ boxes. Each such box C can contain at most n rectangles. Hence, at most n free cuts can be made inside C. The free cuts can divide C into at most $n+1$ boxes. This implies that the set $\mathcal{C}$ has at most $kl(n+1) \leq 26\alpha^2 n$ boxes.

(iii) Each rectangle r in S_B is cut into at most kl pieces. The edges of these pieces

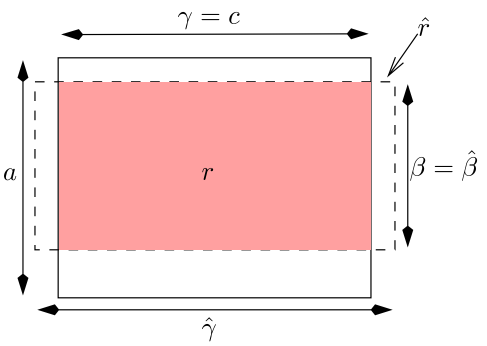

FIG. 3.2. *Projections of $\hat{r}$ (the dashed rectangle), $r = \hat{r} \cap B$ (the shaded rectangle), and the right face of B onto the zx-plane.*

form an arrangement on r. Each face of the arrangement is one of the at most kl rectangles that r is partitioned into. Only $2(k + l - 2)$ faces of the arrangement have an edge on the boundary of r. All other faces can be used as free cuts. Hence, after all possible free cuts are made in the boxes into which B is divided by the $(k-1)(l-1)$ cuts, only $2(k + l - 2)$ pieces of each rectangle in S_B survive. This proves that $\sum_{C \in \mathcal{C}} |S_C| \leq 16\alpha n$. ◻

Remark. The only place in the whole algorithm where we use the fatness of the rectangles in S is in the proof of Lemma 3.1. If the rectangles in S are thin, then Lemma 3.1(ii) is not true; both k and l can be $\Omega(n)$.

If S_B contains a short rectangle, the α-cuts partition the short rectangle into a constant number of pieces. Hence, Lemma 3.1(ii) and 3.1(iii) hold even when S_B contains short rectangles.

3.2. BSPs for two classes of long rectangles. Let C be one of the boxes into which B is partitioned by the α-cuts. We now present an algorithm for constructing a BSP for the set of clipped rectangles S_C, which has only two classes of long rectangles. We recursively apply the following steps to each of the boxes produced by the algorithm until no box contains a rectangle.

1. If S_C has a free rectangle, we use the free cut containing that rectangle to split C into two boxes.
2. If S_C has two classes of rectangles, we use Lemma 2.2 (with $R = S$ and $P = \emptyset$) to split C into at most three boxes, using at most two parallel free cuts.
3. If S_C has only one class of rectangles, we split C into two by a plane, using Lemma 2.1 (with $R = S$ and $P = \emptyset$).

In steps 2 and 3, since $P = \emptyset$, we can use any value of w in Lemmas 2.2 and 2.1.

We first analyze the algorithm for two classes of long rectangles. The BSP produced has the following structure: If step 3 is executed at a node v, then step 2 is not invoked at any descendant of v. Note that the cutting planes used in steps 1 and 2 do not intersect any rectangle of S_C, so only the cuts made in step 3 increase the number of rectangles. Hence, repeated execution of steps 1 or 2 on S_C constructs a top subtree $\mathcal{T}_C$ of the BSP with $O(|S_C|)$ nodes such that each leaf in $\mathcal{T}_C$ has only one class of rectangles and the total number of rectangles in all the leaves is at most $|S_C|$. The operations at a box D in $\mathcal{T}_C$ involve determining the cuts to be made at D, partitioning D according to these cuts, identifying the resulting free rectangles and applying free cuts containing them, and partitioning the rectangles in S_D into the new boxes.

Since we assume that we have sorted the vertices of the rectangles in S at the very beginning, Lemmas 2.1 and 2.2 imply that the cuts to be made at B can be determined in $O(|S_D|)$ time. The free cuts resulting after partitioning D according to these cuts are parallel to each other. Hence, all free cuts can be applied in $O(|S_D|)$ time. Further, the number of rectangles at each child of D is at most $2|S_D|/3$. Hence, $\mathcal{T}_C$ can be constructed in $O(|S_C|\log|S_C|)$ time. At each leaf v of the tree $\mathcal{T}_C$, recursive invocations of steps 1 and 3 build a BSP of size $O(|S_v|\log|S_v|)$ in $O(|S_v|\log|S_v|)$ time (see [25] for details). Since $\sum_v S_v \le |S_C|$, where the sum is taken over all leaves v of $\mathcal{T}_C$, the total size of the BSP constructed inside C is $O(|S_C|\log|S_C|)$. It also follows that the BSP inside C can be constructed in $O(|S_C|\log|S_C|)$ time.

We now analyze the overall algorithm for long rectangles. The algorithm first applies the α-cuts to the rectangles in S_B, as described in section 3.1. Consider the set of boxes $\mathcal{C}$ produced by the α-cuts. Each of the boxes in $\mathcal{C}$ contains only two classes of rectangles (by Lemma 3.1(i)). In view of the above discussion, for each box $C \in \mathcal{C}$, we can construct a BSP for S_C of size $O(|S_C|\log|S_C|)$ in time $O(|S_C|\log|S_C|)$. Lemma 3.1(ii) and (iii) imply that the total size of the BSP is

$$O(n)+\sum_{C\in\mathcal{C}} O(|S_C|\log|S_C|) = O(n\log n).$$

The time spent in building the BSP is also $O(n\log n)$. We can now state the following theorem.

THEOREM 3.2. *Let S be a set of n fat rectangles and B a box so that all rectangles in S are long with respect to B. An $O(n\log n)$-size BSP for the clipped rectangles S_B can be constructed in $O(n\log n)$ time. The constants of proportionality in the big-oh terms are linear in α^2, where α is the maximum aspect ratio of the rectangles in S.*

Remark. We can show that the height of the BSP constructed by the above algorithm is $O(\log n)$. We can also modify our algorithm to construct a BSP of size $O(n)$ for n long rectangles as follows: If a box C has two classes of long rectangles, we apply step 1 or 2 of the previous algorithm. If the rectangles in C belong to one class, we use the algorithm of Paterson and Yao for constructing BSPs for orthogonal segments in the plane [26] to construct a BSP of linear size for S_C. However, the height of the BSP can now be $\Omega(n)$ in the worst case.

4. BSPs for fat rectangles.

We now describe our main algorithm for constructing a BSP for a set S of n fat nonintersecting rectangles, in which we simultaneously simulate the algorithm for long fat rectangles presented in section 3 and partition the vertices of the rectangles in S. The algorithm proceeds in rounds. Each round simulates a few steps of the algorithm for long rectangles and partitions the vertices of the rectangles in S into a small number of sets of approximately equal size. At the beginning of the ith round, for $i > 0$, the algorithm has a top subtree $\mathcal{B}_i$ of the BSP for S. Let Q_i be the set of boxes associated with the leaves of $\mathcal{B}_i$ containing at least one rectangle. The initial tree $\mathcal{B}_1$ consists of one node and Q_1 consists of one box that contains all the input rectangles. Our algorithm maintains the invariant that for each box $B \in Q_i$, all long rectangles in S_B are nonfree. If Q_i is empty, we are done. Otherwise, in the ith round, for each box $B \in Q_i$, we construct a top subtree $\mathcal{T}_B$ of the BSP for the set S_B and attach it to the corresponding leaf of $\mathcal{B}_i$. This gives us the new top subtree $\mathcal{B}_{i+1}$. Thus, it suffices to describe how to build the tree $\mathcal{T}_B$ on a box B during a round.

Let $F \subseteq S_B$ be the set of rectangles that are long with respect to B. Set $f = |F|$, and let k be the number of vertices of rectangles in S_B that lie in the interior of B

(note that each such vertex is a vertex of an original rectangle in the input set S). By assumption, all rectangles in F are nonfree. We choose a parameter a, which remains fixed throughout the round. We pick

$$a = 2^{\sqrt{\log(f+k)}}$$

to optimize the size of the BSP that the algorithm creates. We now describe the ith round in detail. See Figure 4.1 for an outline of $\mathcal{B}$'s structure.

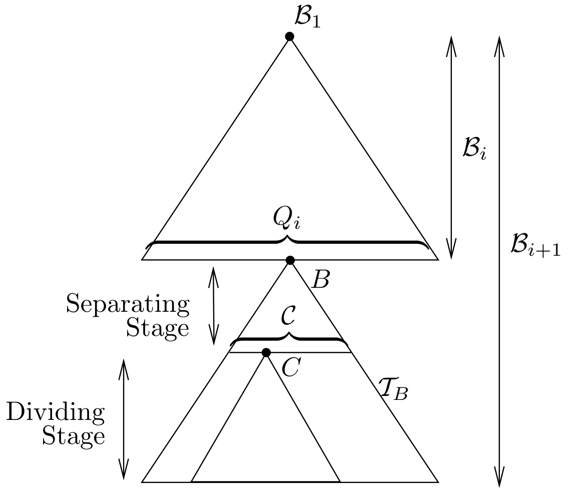

FIG. 4.1. *Overall structure of $\mathcal{B}$.*

If $k = 0$ (i.e., if all rectangles in S_B are long), we use Theorem 3.2 to construct a BSP for S_B. Otherwise, we perform a sequence of cuts in two stages that partition B as follows:

Separating stage. We apply the α-cuts, as described in section 3.1. We make these cuts with respect to the rectangles in F, i.e., we consider only those rectangles of S_B that are long with respect to B. Let $\mathcal{C}$ be the set of boxes into which B is partitioned by the α-cuts.

Dividing stage. We refine each box C in $\mathcal{C}$ by applying cuts similar to the ones made in section 3.2, as described below. Let k_C denote the number of vertices of rectangles in S_C that lie in the interior of C. Recall that F_C is the set of rectangles in F that are clipped within C. We recursively invoke the dividing stage until $|F_C| + 2ak_C \leq (f + ak)/a$ and S_C does not contain any free rectangles.

1. If C has any free rectangle, we use the free cut containing that rectangle to split C into two boxes.
2. If the rectangles in F_C belong to two classes, let P_C denote the set of vertices of the rectangles in S_C that lie in the interior of C. We apply at most two parallel free cuts that satisfy Lemma 2.2, with $R = F, P = P_C$, and $w = 2a$.
3. If the rectangles in F_C belong to just one class, we apply one cut using Lemma 2.1, with $R = F, P = P_C$, and $w = 2a$.

The cuts introduced during the dividing stage can be made in a treelike fashion. At the end of the dividing stage, we have a set of boxes so that for each box D in this set, S_D does not contain any free rectangle and $|F_D| + ak_D \leq (f + ak)/a$. Notice that as we apply cuts in C and in the resulting boxes, rectangles that are short with respect to C may become long with respect to the new boxes. We ignore these new long rectangles until the next round, unless they induce a free cut.

5. Analysis of the algorithm.

We now analyze the size of the BSP constructed by the algorithm and the time complexity of the algorithm. In a round, the algorithm constructs a top subtree $\mathcal{T}_B$ of the BSP for the set of clipped rectangles S_B. Recall that F is the set of rectangles that are long with respect to B, $f = |F|$, and k is the number of vertices of rectangles in S_B that lie in the interior of B. For a node C in $\mathcal{T}_B$, recall that k_C denotes the number of vertices of rectangles in S_C that lie in the interior of C.

We now define some more notation that we need for the analysis. For a node C in $\mathcal{T}_B$, let $\mathcal{T}_C$ be the subtree of $\mathcal{T}_B$ rooted at C, L_C be the set of leaves in $\mathcal{T}_C$, ϕ_C be the number of long rectangles in F_C (recall that F_C is the set of rectangles in F that intersect C and are clipped within C), and ν_C be the number of long rectangles in $S_C \setminus F_C$ (recall that a rectangle in $S_C \setminus F_C$ is a portion of a rectangle in S_B that is short with respect to B). For a box D corresponding to a leaf of $\mathcal{T}_B$, let f_D be the number of long rectangles in S_D. Note that f_D counts both the "old" long rectangles in F_D (pieces of rectangles that were long with respect to B) and the "new" long rectangles in $S_D \setminus F_D$ (pieces of rectangles that were short with respect to B, but became long with respect to D due to the cuts made during the round); $f_D = \phi_D + \nu_D$.

In a round, the separating stage first splits B into a set of boxes $\mathcal{C}$. For each box $C \in \mathcal{C}$, F_C has only two classes of long rectangles. The algorithm then executes the dividing stage on each such box C. As in the case of the algorithm for long rectangles (see section 3), the subtree constructed in C has the following property: if step 4 is executed at a node v, then step 4 is not executed at any descendent of v. In Lemma 5.1, we prove a bound on the total number of long rectangles at each leaf of $\mathcal{T}_B$. For a box $C \in \mathcal{C}$, we bound the number of long rectangles at the leaves of $\mathcal{T}_C$ in Lemmas 5.2 and 5.3. In Lemma 5.4, we prove a bound on the size of the tree $\mathcal{T}_B$. Finally, we use these lemmas to establish bounds on the size of the BSP constructed by our algorithm and the running time of our algorithm (see Theorem 5.5).

LEMMA 5.1. *For a box D associated with a leaf of $\mathcal{T}_B$,*

$$f_D + 2ak_D \leq \frac{f + 2ak}{a}.$$

Proof. We know that ν_D is at most k (since a rectangle in $S_D \setminus F_D$ must be a piece of a rectangle short with respect to B, and there are at most k short rectangles in B). Since $f_D + 2ak_D \leq \phi_D + 2ak_D + \nu_D$ and $\phi_D + 2ak_D \leq (f + ak)/a$ (by construction), the lemma follows. □

LEMMA 5.2. *Let C be a box associated with a node in $\mathcal{T}_B$. If all rectangles in F_C belong to one class, then*

$$\sum_{D \in L_C} f_D \leq 2\phi_C + 2\nu_C \max\left\{\frac{2(\phi_C + ak_C)}{\mu}, 1\right\} + 4k_C\left(\frac{\phi_C + ak_C}{\mu}\right),$$

where $\mu = (f + ak)/a$.

Proof. Assume, without loss of generality, that all rectangles in F_C belong to the top class, and let g be the top face of C. By Lemma 2.1(i), g contains an edge of every rectangle in F_C. Let ρ_C be the number of vertices of the nonfree long rectangles in F_C that lie in the interior of g; obviously, $\phi_C \leq \rho_C \leq 2\phi_C$. Set

$$\Phi(\rho_C, \nu_C, k_C) = \max \sum_{D \in L_C} f_D,$$

where the maximum is taken over all boxes C and over all sets S of rectangles with ρ_C vertices of rectangles in F_C lying in the interior of the top face of C, ν_C long rectangles in $S_C \setminus F_C$, and k_C vertices in the interior of C. We claim that

$$\Phi(\rho_C, \nu_C, k_C) \leq \rho_C + 2\nu_C \max\left\{\frac{\rho_C + 2ak_C}{\mu}, 1\right\} + 2k_C \left(\frac{\rho_C + 2ak_C}{\mu}\right), \tag{5.1}$$

which implies the lemma, because $\rho_C \leq 2\phi_C$.

Note that if S_C contains $m \geq 1$ free rectangles, we apply the free cuts containing these rectangles to partition C (by repeatedly invoking step 4 of the dividing stage) until the resulting boxes do not contain any free rectangle. The free cuts partition C into a set $\mathcal{E}$ of $m+1$ boxes. Since we have created the boxes in $\mathcal{E}$ using free cuts,

$$\rho_E + 2ak_E \leq \rho_C + 2ak_C, \qquad \text{for any box } E \text{ in } \mathcal{E}, \tag{5.2}$$

$$\sum_{E \in \mathcal{E}} \nu_E \leq \nu_C, \qquad \sum_{E \in \mathcal{E}} k_E \leq k_C, \qquad \sum_{E \in \mathcal{E}} \rho_E \leq \rho_C. \tag{5.3}$$

These inequalities imply that if (5.1) holds for each box in $\mathcal{E}$, then (5.1) holds for C as well. Therefore, we prove (5.1) for all boxes C such that F_C contains only one class of rectangles and S_C does not contain any free rectangle. We proceed by induction on $\rho_C + 2ak_C$.

Base case. $0 \leq \rho_C + 2ak_C \leq \mu$. Since $0 \leq \rho_C + 2ak_C \leq \mu$ and S_C does not contain any free rectangle, C is a leaf of $\mathcal{T}_B$, i.e., $L_C = \{C\}$. We have

$$\Phi(\rho_C, \nu_C, k_C) = \sum_{D \in L_C} f_D = f_C = \phi_C + \nu_C \leq \rho_C + \nu_C, \tag{5.4}$$

which implies (5.1).

Induction step. $\rho_C + 2ak_C > \mu$. In this case, C is split into two subboxes C_1 and C_2 by a cutting plane h. Since $\sum_{D \in L_C} f_D = \sum_{D \in L_{C_1}} f_D + \sum_{D \in L_{C_2}} f_D$,

$$\Phi(\rho_C, \nu_C, k_C) = \Phi(\rho_{C_1}, \nu_{C_1}, k_{C_1}) + \Phi(\rho_{C_2}, \nu_{C_2}, k_{C_2}),$$

where $k_{C_1} + k_{C_2} \leq k_C$ and $\rho_{C_1} + \rho_{C_2} \leq \rho_C$.

Note that h does not contain a free rectangle. For $i = 1, 2$, each long rectangle in $S_{C_i} \setminus F_{C_i}$ is contained either in a long rectangle in $S_C \setminus F_C$ or in a short rectangle in S_C. Since h intersects each rectangle in S_C at most once and a short rectangle intersected by h is divided into one short and one long rectangle,

$$\nu_{C_1} + \nu_{C_2} \leq 2\nu_C + k_C. \tag{5.5}$$

By Lemma 2.1(ii), we have

$$\rho_{C_i} + 2ak_{C_i} \leq \frac{\rho_C + 2ak_C}{2}, \qquad \text{for } i = 1, 2. \tag{5.6}$$

Let $\mathcal{E}_1$ (resp., $\mathcal{E}_2$) be the set of boxes obtained by applying all the free cuts in S_{C_1} (resp., S_{C_2}) in step 4 of the dividing stage. Clearly,

$$\Phi(\rho_C, \nu_C, k_C) = \sum_{E \in \mathcal{E}_1} \Phi(\rho_E, \nu_E, k_E) + \sum_{E \in \mathcal{E}_2} \Phi(\rho_E, \nu_E, k_E).$$

We consider two cases.

Case (i). $\mu < \rho_C + 2ak_C \leq 2\mu$. For each $i = 1, 2$

$$\rho_{C_i} + 2ak_{C_i} \leq \frac{\rho_C + 2ak_C}{2} \leq \mu.$$

As a result, all boxes in $\mathcal{E}_1$ and $\mathcal{E}_2$ are leaves of $\mathcal{T}_B$. Using (5.3) and (5.4), we obtain

$$\begin{aligned}\Phi(\rho_C, \nu_C, k_C) &\leq \sum_{E \in \mathcal{E}_1} f_E + \sum_{E \in \mathcal{E}_2} f_E \leq \sum_{E \in \mathcal{E}_1} (\rho_E + \nu_E) + \sum_{E \in \mathcal{E}_2} (\rho_E + \nu_E) \\ &\leq \rho_{C_1} + \nu_{C_1} + \rho_{C_2} + \nu_{C_2}.\end{aligned}$$

It now follows from (5.5) that

$$\Phi(\rho_C, \nu_C, k_C) \leq \rho_C + 2\nu_C + k_C, \tag{5.7}$$

which implies (5.1), because $\rho_C + 2ak_C > \mu$.

Case (ii). $\rho_C + 2ak_C > 2\mu$. For any box E in $\mathcal{E}_1 \cup \mathcal{E}_2$, by (5.2) and (5.6),

$$\max\left\{\frac{\rho_E + 2ak_E}{\mu}, 1\right\} \leq \max\left\{\frac{\rho_C + 2ak_C}{2\mu}, 1\right\} = \frac{\rho_C + 2ak_C}{2\mu}.$$

By (5.2) and the induction hypothesis,

$$\begin{aligned}\Phi(\rho_C, \nu_C, k_C) \leq& \sum_{E \in \mathcal{E}_1} \left(\rho_E + 2\nu_E \left(\frac{\rho_C + 2ak_C}{2\mu}\right) + 2k_E \left(\frac{\rho_C + 2ak_C}{2\mu}\right)\right) \\ &+ \sum_{E \in \mathcal{E}_2} \left(\rho_E + 2\nu_E \left(\frac{\rho_C + 2ak_C}{2\mu}\right) + 2k_E \left(\frac{\rho_C + 2ak_C}{2\mu}\right)\right) \\ \leq& \left(\rho_{C_1} + \rho_{C_2}\right) + 2\left(\nu_{C_1} + \nu_{C_2}\right)\left(\frac{\rho_C + 2ak_C}{2\mu}\right) \\ &+ 2\left(k_{C_1} + k_{C_2}\right)\left(\frac{\rho_C + 2ak_C}{2\mu}\right).\end{aligned}$$

Using (5.5), we obtain

$$\begin{aligned}\Phi(\rho_C, \nu_C, k_C) &\leq \rho_C + 2\left(2\nu_C + k_C\right)\left(\frac{\rho_C + 2ak_C}{2\mu}\right) + 2k_C\left(\frac{\rho_C + 2ak_C}{2\mu}\right) \\ &= \rho_C + 2\nu_C\left(\frac{\rho_C + 2ak_C}{\mu}\right) + 2k_C\left(\frac{\rho_C + 2ak_C}{\mu}\right),\end{aligned}$$

which implies (5.1). ∎

LEMMA 5.3. *Let C be a box associated with a node in $\mathcal{T}_B$. If all rectangles in F_C belong to two classes, then*

$$\sum_{D \in L_C} f_D \leq O\left(\phi_C + (\nu_C + k_C)\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right),$$

where $\mu = (f + ak)/a$.

Proof. Similar to the proof of Lemma 5.2. See the Appendix for details. ∎

LEMMA 5.4. *The tree $\mathcal{T}_B$ constructed on box B in a round has the following properties:*

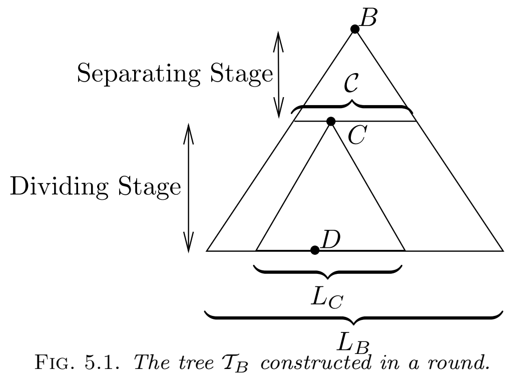

FIG. 5.1. *The tree $\mathcal{T}_B$ constructed in a round.*

(i) $\sum_{D \in L_B} k_D \leq k$,

(ii) $\sum_{D \in L_B} f_D = O(f + a^3 k)$, *and*

(iii) $|\mathcal{T}_B| = O((f + a^3 k) \log a)$.

Proof. The bound on $\sum_{D \in L_B} k_D$ is obvious, since each vertex in the interior of S_B lies in the interior of at most one box of L_B. Next, we use Lemma 5.3 to prove a bound on $\sum_{D \in L_B} f_D$.

Let $\mathcal{C}$ be the set of boxes into which B is partitioned by the separating stage; see Figure 5.1. Obviously, $\sum_{D \in L_B} f_D = \sum_{C \in \mathcal{C}} \sum_{D \in L_C} f_D$. For each box $C \in \mathcal{C}$, Lemma 3.1(i) implies that all rectangles in F_C belong to at most two classes. Hence, by Lemma 5.3,

$$\sum_{D \in L_B} f_D \leq \sum_{C \in \mathcal{C}} O\left(\phi_C + (\nu_C + k_C)\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right).$$

Arguing as in the proof of Lemma 3.1(3), we can show that $\sum_{C \in \mathcal{C}} \phi_C = O(f)$ and that $\sum_{C \in \mathcal{C}} \nu_C = O(k)$. We also know that $\sum_{C \in \mathcal{C}} k_C \leq k$ and $\mu = (f + ak)/a$. Therefore,

$$\sum_{D \in L_B} f_D = O\left(f + k\left(\frac{f + 2ak}{\mu}\right)^3\right) = O\left(f + a^3 k\right).$$

We now sketch the proof that $|\mathcal{T}_B| = O((f + a^3 k) \log a)$. Following the same argument as in the proof of Lemma 3.1(2), we can show that the separating stage creates a tree with $O(f + k)$ nodes. We now count the number of nodes in $\mathcal{T}_B$ that are created by the dividing stage. Let $D \in \mathcal{T}_B$ be such a node. If D is partitioned by a cut containing a free rectangle (i.e., step 4 of the dividing stage is invoked at D), we charge D to its nearest ancestor $C \in \mathcal{T}_B$ such that C is not partitioned by a free cut (i.e., step 4 or 4 of the dividing stage is executed at C). Otherwise, we charge a cost of 1 to D itself. Let C be a node in $\mathcal{T}_B$ that is not partitioned by a free cut. Since a free rectangle can be created only by partitioning a long rectangle, the cut used to partition C creates $O(\phi_C + \nu_C)$ free rectangles, which implies that C is charged $O(\phi_C + \nu_C + 1)$ times by the above argument. Hence,

$$|\mathcal{T}_B| = O\left(\sum_C (\phi_C + \nu_C + 1)\right),$$

where C ranges over all nodes in $\mathcal{T}_B$ where step 4 or 4 of the dividing stage is executed. By following an inductive argument similar to the ones used to prove Lemmas 5.2 and 5.3, we can show that $|\mathcal{T}_B| = O((f + a^3k)\log a)$. Informally, the charging scheme compresses $\mathcal{T}_B$ by collapsing all nodes that are split by free cuts. Lemma 2.1 and 2.2 imply that the height of the compressed tree is $O(\log a)$. We can show that $\sum_C(\phi_C + \nu_C + 1)$ is roughly the product of the height of the tree and $\sum_D f_D$, the total number of long rectangles intersecting the leaves of the tree. $\square$

We now present our main result regarding the performance of our algorithm.

THEOREM 5.5. *Given a set S of n rectangles in $\mathbb{R}^3$ such that the aspect ratio of each rectangle in S is bounded by a constant $\alpha \geq 1$, we can construct a BSP of size $n2^{O(\sqrt{\log n})}$ for S in time $n2^{O(\sqrt{\log n})}$. The constants of proportionality in the big-oh terms are linear in* $\log \alpha$.

Proof. We first bound the size of the BSP constructed by the algorithm. Let $S(f, k)$ denote the maximum size of the BSP produced by the algorithm for a box B that contains f long rectangles and k vertices in its interior. If $k = 0$, Theorem 3.2 implies that $S(f, k) = O(f \log f)$. For $k > 0$, by Lemma 5.4(iii), we construct the subtree $\mathcal{T}_B$ on B of size $O((f + a^3k)\log a)$ in one round, and recursively construct subtrees for each box in the set of leaves L_B. Therefore, there exist constants $c_1, c_2, c_3 > 0$ so that the size $S(f, k)$ satisfies the following recurrence:

$$S(f,k) \leq \begin{cases} c_1 f \log f & \text{for} \quad k = 0, \\ \displaystyle\sum_{D \in L_B} S(f_D, k_D) + c_2(f + a^3k)\log a & \text{for} \quad k > 0, \end{cases}$$

where

$$f_D + 2ak_D \leq \frac{f + 2ak}{a}$$

for every box D in L_B (by Lemma 5.1), and

$$\sum_D k_D \leq k, \qquad \sum_D f_D \leq c_3(f + a^3k)$$

(by Lemma 5.4(i) and 5.4(ii). Using induction on $f + 2ak$, we can prove that the solution to the above recurrence is

$$S(f,k) = (f + k)2^{O(\sqrt{\log(f+k)})},$$

where the constant of proportionality is linear in $\log \alpha$. Intuitively, the algorithm constructs the BSP for B in $O(\log a) = O(\sqrt{\log(f + k)})$ rounds, and the total number of long rectangles increases roughly by a constant factor in each round. The $n2^{O(\sqrt{\log n})}$ bound on the size of the BSP constructed by the algorithm follows, since $f \leq n$ and $k \leq 4n$ at the beginning of the first round.

We now bound the running time of our algorithm. Recall that we initially sorted the vertices of the rectangles in S by x-, y-, and z-coordinates. Suppose S_B does not contain a free rectangle. By Lemmas 2.1 and 2.2, the cuts to be made at B can be determined in $O(|S_B|)$ time. Suppose C is a box obtained by partitioning B according to these cuts; we can easily obtain the sorted order of the vertices of the rectangles in S_C from the sorted order in B. Let $\mathcal{E}$ be the set of boxes obtained by applying C using all the free rectangles in S_C. Since the free rectangles in S_C are parallel to each other, we can partition the rectangles in S_C among the boxes in $\mathcal{E}$ in $O(|S_C|)$ time. Therefore, we can construct the tree representing the partition of B into the set of boxes E in $O(|S_B|)$ time. Hence, we obtain the same $n2^{O(\sqrt{\log n})}$ bound for the running time of the algorithm. $\square$

Remark. We can modify our algorithm to prove that the height of the BSP constructed is $O(\log n)$: if S_B contains free rectangles, we assign appropriate weights to the free rectangles, and partition B using the weighted median of the free rectangles. We leave the details to the reader. Paterson and Yao [25] use a similar idea to bound the height of BSP they construct for segments in the plane.

6. Extensions.

In this section, we extend the algorithm of section 4 to the following two cases: (i) some of the input rectangles are thin and (ii) some of the input polygons are triangles.

6.1. Fat and thin rectangles.

Let us assume that the input $S = F \cup T$ has n rectangles, consisting of $m \geq 1$ thin rectangles in T and $n - m$ fat rectangles in F. We first describe our algorithm and then construct a set of rectangles for which any BSP has size $\Omega(n\sqrt{m})$. The algorithm we use now is very similar to the algorithm for fat rectangles. Given a box B, let f be the number of long rectangles in F_B, k the number of vertices of rectangles in F_B that lie in the interior of B, and t the number of rectangles in T_B. We fix a parameter $a = 2^{\sqrt{\log(f+k)}}$ and perform the following steps:

1. If S_B contains a free rectangle, we use the corresponding free cut to split B into two boxes.
2. If $k = t = 0$, we use the algorithm for long rectangles to construct a BSP for the set of clipped rectangles S_B.
3. If $t \geq (f + k)$, we use the algorithm by Paterson and Yao for orthogonal rectangles in $\mathbb{R}^3$ to construct a BSP for S_B [26].
4. If $(f + k) > t$, we perform one round of the algorithm described in section 4, with the difference that we also use thin rectangles to make free cuts.

This algorithm is recursively invoked on all the resulting subboxes. Let $S(f, k, t)$ be the maximum size of the BSP produced by this algorithm for a box B with k vertices in its interior, f long rectangles in F_B, and t thin rectangles in T_B. Note that in section 5, during the analysis of a round, we did not use the fact that the short rectangles were fat. As a result, Lemmas 5.2 and 5.3 hold for step 6.1 above, with $\nu_C + k_C + t_C$ replacing the term $\nu_C + k_C$. We can similarly extend Lemma 5.4 to obtain the following recurrence for $S(f, k, t)$. Here D ranges over all the boxes that B is divided into by a round of cuts, as described above in step 6.1.

$$S(f,k,t) = \begin{cases} O(f \log f), & \text{for} \quad k = t = 0, \\ O(t\sqrt{t}), & \text{for} \quad t \geq f + k, \\ \sum_D S(f_D, k_D, t_D) + O(f \log a + a^3 k + a^3 t), & \text{for} \quad f + k > t, \end{cases}$$

where $\sum_D k_D \leq k$, $f_D + 2ak_D \leq (f + 2ak)/a$, $\sum_D f_D = O(f + a^3 k)$, and $\sum_D t_D = O(a^3 t)$.

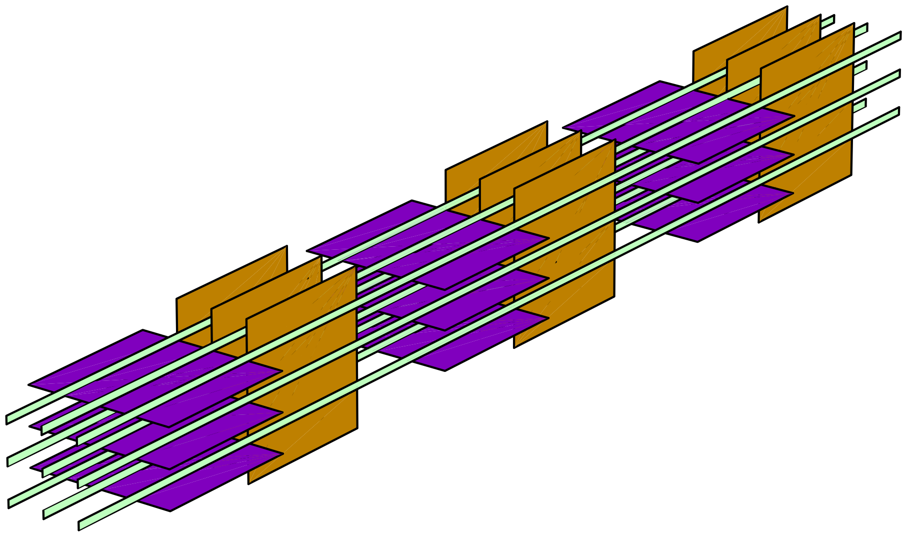

FIG. 6.1. *Lower bound construction for thin and fat rectangles.*

We can analyze this recurrence as in section 5 and show that its solution is

$$S(f,k,t) = (f+k)\sqrt{t}2^{O(\sqrt{\log(f+k)})},$$

where the constant of proportionality is linear in $\log \alpha$. The following theorem is immediate.

THEOREM 6.1. *Let S be a set of n rectangles in $\mathbb{R}^3$, of which $m \geq 1$ are thin. A BSP of size $n\sqrt{m}2^{O(\sqrt{\log n})}$ for S can be constructed in $n\sqrt{m}2^{O(\sqrt{\log n})}$ time. The constants of proportionality in the big-oh terms are linear in $\log \alpha$, where α is the maximum aspect ratio of the fat rectangles.*

We can show that Theorem 6.1 is almost optimal by constructing a set of n rectangles of which m are thin, for which any BSP has size $\Omega(n\sqrt{m})$. Recall that there exists a set of m thin rectangles in $\mathbb{R}^3$ for which any BSP has size $\Omega(m\sqrt{m})$ [26]. To complete the proof of the lower bound, we now exhibit a set $S = T \cup F$ of n rectangles, where T is a set of m thin rectangles and F is a set of $n-m$ fat rectangles, for which any BSP has size $\Omega((n-m)\sqrt{m})$. The rectangles in T are arranged in a $\sqrt{m}\times\sqrt{m}$ grid; each rectangle in T is a segment of length $n-m+5(n-m)/(2\sqrt{m})+1$ perpendicular to the yz-plane. The rectangles in F are divided into $(n-m)/(2\sqrt{m})$ sets, each consisting of $2\sqrt{m}$ squares with side length $\sqrt{m}+2$. Each set consists of $\sqrt{m}$ squares parallel to the xy-plane and $\sqrt{m}$ squares parallel to the xz-plane so that the following three conditions are satisfied (see Figure 6.1).

1. In each set, a square parallel to the xy-plane is at a distance of 2ε from any square parallel to the xz-plane,
2. For any square, the closest square in a different set is at a distance of $1-2\varepsilon$, and
3. For any square, the closest thin rectangle is at a distance of ε.

We can show that there are $(n-m)\sqrt{m}/2$ points such that a cube of side 2ε centered at any such point intersects a thin rectangle t of T and two squares r and s of F. For each such cube ψ, we can show that at least one edge of r, s, or t is crossed in the interior of ψ by a cutting plane of $\mathcal{B}$, which implies that the cutting planes in $\mathcal{B}$ and the edges of the rectangles in S cross at $\Omega((n-m)\sqrt{m})$ points, thus proving the lower bound on the size of $\mathcal{B}$.

6.2. Fat rectangles and triangles. Suppose that $p \geq 1$ polygons in the input S are (nonorthogonal) triangles and that the rest are fat rectangles. To construct a BSP for S, we use nonorthogonal cutting planes; hence, each region is a convex polytope and the intersection of a triangle with a region is a polygon, possibly with more than three edges. We can extend the algorithm of section 6.1 to this case as follows: In step 6.1, we check whether we can make free cuts through the nonorthogonal polygons too. In step 6.1, if the number of triangles at a node is greater than the number of fat rectangles, we use the algorithm of Agarwal et al. for triangles in $\mathbb{R}^3$ to construct a BSP of size quadratic in the number of triangles in near-quadratic time [2]. Proceeding as in the previous section, we can prove the following theorem.

THEOREM 6.2. *A BSP of size* $np2^{O(\sqrt{\log n})}$ *can be constructed in* $np2^{O(\sqrt{\log n})}$ *time for* n *polygons in* $\mathbb{R}^3$*, of which* $p \geq 1$ *are nonorthogonal and the rest are fat rectangles. The constants of proportionality in the big-oh terms are linear in* $\log \alpha$*, where* α *is the maximum aspect ratio of the fat rectangles.*

Unlike the case of rectangles, the fatness assumption does not help in constructing BSPs of small size for triangles. More specifically, we can show that there exists a set of n fat triangles in $\mathbb{R}^3$ such that any BSP for these triangles has $\Omega(n^2)$ size by modifying Chazelle's construction for proving a quadratic lower bound on the size of convex decompositions of polyhedra in $\mathbb{R}^3$ [9].

7. Conclusions. In this paper, we have studied the problem of constructing BSPs for orthogonal rectangles under the natural assumption that most rectangles are fat. Our result shows that this assumption allows a smaller worst-case size of BSPs. Our algorithm constructs a BSP for any set of orthogonal rectangles; it is only the analysis of the algorithm that depends on the fatness of the input rectangles. We have implemented a variant of our algorithm and compared its performance to that of other known algorithms [18]. Our algorithm is indeed practical: it constructs a BSP of near-linear size on real data sets. It performs better than not only Paterson and Yao's algorithm [26] but also most heuristics described in the literature [4, 16, 30].

We now briefly mention another extension to our algorithms. If the n fat rectangles contain $k \geq 1$ crossing pairs, we can construct a BSP of size $(n+k)\sqrt{k}2^{O(\sqrt{\log n})}$ for these rectangles as follows: for each crossing pair r and s, we partition one of the rectangles (say, r) into two smaller rectangles that do not intersect s. We construct a BSP for the resulting $n + O(k)$ rectangles by invoking our algorithm for a set of fat and thin triangles. We can also construct a set of n fat rectangles with k crossing pairs for which any BSP has size $\Omega(n + k\sqrt{k})$.

It seems very probable that BSPs of a size smaller than $n2^{O(\sqrt{\log n})}$ can be built for n fat rectangles in $\mathbb{R}^3$. The only lower bound we have is the trivial $\Omega(n)$ bound. It would be interesting to see if simple heuristics (e.g., choose the next splitting plane to be one that intersects the smallest number of rectangles) can be proven to construct BSPs of (close to) optimal size. An even more challenging open problem is determining the right assumptions that should be made about the input objects and the graphics display hardware so that provably fast and *practically efficient* algorithms can be developed for doing hidden-surface elimination of these objects.

Appendix. Proof of Lemma 5.3.

Lemma 5.3. *Let C be a box associated with a node in $\mathcal{T}_B$. If all rectangles in F_C belong to two classes, then*

$$\sum_{D \in L_C} f_D \le O\left(\phi_C + (\nu_C + k_C)\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right),$$

where $\mu = (f + ak)/a$.

Proof. Let

$$\Psi(\phi_C, \nu_C, k_C) = \max \sum_{D \in L_C} f_D,$$

where the maximum is taken over all boxes C and over all sets S of rectangles with ϕ_C long rectangles in F_C, ν_C long rectangles in $S_C \setminus F_C$, and k_C vertices in the interior of C. The rectangles in F_C belong to at most two classes. We claim that

(A.1)
$$\Psi(\phi_C, \nu_C, k_C) \le 2\phi_C + 5\nu_C \max\left\{\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3, 1\right\} + 6k_C\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3,$$

which proves the lemma.

If S_C contains $m \ge 1$ free rectangles, we apply the free cuts containing these rectangles to partition C (by repeatedly invoking step 4 of the dividing stage) until the resulting boxes do not contain any free rectangles. Let $\mathcal{E}$ be the set of boxes into which C is so partitioned. Then

(A.2) $$\phi_E + 2ak_E \le \phi_C + 2ak_C, \qquad \text{for any box } E \text{ in } \mathcal{E},$$

(A.3) $$\sum_{E \in \mathcal{E}} \phi_E \le \phi_C \qquad \sum_{E \in \mathcal{E}} \nu_E \le \nu_C \qquad \sum_{E \in \mathcal{E}} k_E \le k_C.$$

These inequalities imply that if (A.1) holds for each box in $\mathcal{E}$, then (A.1) holds for C as well. Therefore, we prove (A.1) for all boxes C such that F_C contains at most two classes of rectangles and S_C does not contain any free rectangles. We proceed by induction on $\phi_C + 2ak_C$.

Base case. $\phi_C + 2ak_C \le \mu$. Since $\phi_C + 2ak_C \le \mu$ and S_C does not contain any free rectangles, C is a leaf of $\mathcal{T}_B$. We have

(A.4) $$\Psi(\phi_C, \nu_C, k_C) = \sum_{D \in L_C} f_D = f_C = \phi_C + \nu_C,$$

which implies (A.1).

Induction step. $\phi_C + 2ak_C > \mu$. The cuts made in step 4 of the dividing stage fall into one of two categories (see Lemma 2.2). Note that none of these cuts contains a free rectangle.

Case (i). We divide C into two boxes, C_1 and C_2, using a plane h that does not cross any rectangle in F_C. As a result,

$$\phi_{C_1} + \phi_{C_2} \le \phi_C \qquad \text{and} \qquad k_{C_1} + k_{C_2} \le k_C.$$

Since h intersects each rectangle in S_C at most once, (5.5) holds in this case too; i.e.,

(A.5) $$\nu_{C_1} + \nu_{C_2} \le 2\nu_C + k_C.$$

Lemma 2.2 implies that

$$\phi_{C_i} + 2ak_{C_i} \leq \frac{2(\phi_C + 2ak_C)}{3} \qquad \text{for } i = 1, 2. \tag{A.6}$$

Let $\mathcal{E}_1$ (resp., $\mathcal{E}_2$) be the set of boxes obtained by applying all the free cuts in S_{C_1} (resp., S_{C_2}) in step 4 of the dividing stage. Clearly,

$$\Psi(\phi_C, \nu_C, k_C) \leq \sum_{E \in \mathcal{E}_1} \Psi(\phi_E, \nu_E, k_E) + \sum_{E \in \mathcal{E}_2} \Psi(\phi_E, \nu_E, k_E).$$

We consider two cases.

(a) $\mu \leq \phi_C + 2ak_C \leq 3\mu/2$. In this case, by (A.2) and (A.6),

$$\phi_E + 2ak_E \leq \frac{2(\phi_C + 2ak_C)}{3} \leq \mu,$$

for each box E in $\mathcal{E}_1$ and $\mathcal{E}_2$. Since E does not contain a free rectangle, E is a leaf of $\mathcal{T}_B$. Using (A.5), (A.3), and (A.4), we obtain

$$\begin{aligned}\Psi(\phi_C, \nu_C, k_C) &\leq \sum_{E \in \mathcal{E}_1} f_E + \sum_{E \in \mathcal{E}_2} f_E \\ &\leq \sum_{E \in \mathcal{E}_1} (\phi_E + \nu_E) + \sum_{E \in \mathcal{E}_2} (\phi_E + \nu_E) \\ &\leq \phi_{C_1} + \nu_{C_1} + \phi_{C_2} + \nu_{C_2} \\ &\leq \phi_C + 2\nu_C + k_C,\end{aligned}$$

which implies (A.1), because $\phi_C + 2ak_C > \mu$.

(b) $\phi_C + 2ak_C > 3\mu/2$. For a box E in $\mathcal{E}_1 \cup \mathcal{E}_2$, by (A.2) and (A.6), we have

$$\max\left\{\left(\frac{\phi_E + 2ak_E}{\mu}\right)^3, 1\right\} \leq \max\left\{\left(\frac{2}{3}\left(\frac{\phi_C + 2ak_C}{\mu}\right)\right)^3, 1\right\} = \frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3.$$

By the induction hypothesis, and by using (A.3) and (A.5),

$$\begin{aligned}\Psi(\phi_C, \nu_C, k_C) \leq &\sum_{E \in \mathcal{E}_1} \left(2\phi_E + 5\nu_E \left(\frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right) + 6k_E \left(\frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right)\right) \\ &+ \sum_{E \in \mathcal{E}_2} \left(2\phi_E + 5\nu_E \left(\frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right) + 6k_E \left(\frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right)\right) \\ \leq &\; 2\left(\phi_{C_1} + \phi_{C_2}\right) + 5\left(\nu_{C_1} + \nu_{C_2}\right)\left(\frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right) \\ &\quad + 6\left(k_{C_1} + k_{C_2}\right)\left(\frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right) \\ \leq &\; 2\phi_C + 5 \cdot \frac{8}{27}\left(2\nu_C + k_C\right)\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 + 6 \cdot \frac{8}{27} k_C \left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 \\ \leq &\; 2\phi_C + 5\nu_C \left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 + 6k_C \left(\frac{\phi_C + 2ak_C}{\mu}\right)^3,\end{aligned}$$

which implies (A.1).

Case (ii). We find two parallel planes h_1 and h_2 that divide C into three boxes C_1, C_2, and C_3 (in this order) so that all rectangles in F_{C_2} belong to one class. Lemma 2.2 implies that the rectangles in F_C are partitioned among C_1, C_2, and C_3. Moreover, h_1 and h_2 partition the vertices in the interior of C. Thus,

$$\phi_{C_1} + \phi_{C_2} + \phi_{C_3} \leq \phi_C \qquad \text{and} \qquad k_{C_1} + k_{C_2} + k_{C_3} \leq k_C.$$

The planes h_1 and h_2 can intersect the rectangles in $S_C \setminus F_C$. Each long rectangle in $S_C \setminus F_C$ is partitioned into at most three long rectangles. Each short rectangle in S_C is partitioned into at most three rectangles; if two of these rectangles are long, then one of the long rectangles must be in S_{C_2}, since C_2 is sandwiched between C_1 and C_3 (see the proof of Lemma 2.2). In other words,

$$\nu_{C_1} + \nu_{C_3} \leq 2\nu_C + k_C \qquad \text{and} \qquad \nu_{C_2} \leq \nu_C + k_C. \tag{A.7}$$

Lemma 2.2 also implies that

(A.8)
$$\phi_{C_i} + 2ak_{C_i} \leq \frac{2(\phi_C + 2ak_C)}{3}, \qquad \text{for } i = 1, 3, \text{ and } \phi_{C_2} + 2ak_{C_2} \leq \phi_C + 2ak_C.$$

Let $\mathcal{E}_i, 1 \leq i \leq 3$ be the set of boxes obtained by applying all the free cuts in S_{C_i} in step 4 of the dividing stage. Note that for each box $E \in \mathcal{E}_2$, F_E contains only one class of rectangles. It is clear that

$$\Psi(\phi_C, \nu_C, k_C) \leq \sum_{E \in \mathcal{E}_1} \Psi(\phi_E, \nu_E, k_E) + \sum_{E \in \mathcal{E}_2} \Phi(2\phi_E, \nu_E, k_E) + \sum_{E \in \mathcal{E}_3} \Psi(\phi_E, \nu_E, k_E),$$

where $\Phi(\,)$ is as defined in the proof of Lemma 5.2. We again consider two cases.

(a) $\mu < \phi_C + 2ak_C \leq 3\mu/2$. By (A.8), each box in $\mathcal{E}_1$ and $\mathcal{E}_3$ is a leaf of $\mathcal{T}_B$. Therefore, by (A.4),

$$\begin{aligned}\Psi(\phi_C, \nu_C, k_C) &\leq \sum_{E \in \mathcal{E}_1} f_E + \sum_{E \in \mathcal{E}_2} \Phi\left(2\phi_E, \nu_E, k_E\right) + \sum_{E \in \mathcal{E}_3} f_E \\ &\leq \sum_{E \in \mathcal{E}_1} (\phi_E + \nu_E) + \sum_{E \in \mathcal{E}_3} (\phi_E + \nu_E) + \sum_{E \in \mathcal{E}_2} \Phi\left(2\phi_E, \nu_E, k_E\right) \\ &\leq (\phi_{C_1} + \phi_{C_3}) + (\nu_{C_1} + \nu_{C_3}) + \sum_{E \in \mathcal{E}_2} \Phi\left(2\phi_E, \nu_E, k_E\right).\end{aligned}$$

For each box $E \in \mathcal{E}_2$, $\phi_E + 2ak_E \leq 3\mu/2$. Hence, by (5.7), we have

$$\Phi\left(2\phi_E, \nu_E, k_E\right) \leq 2\phi_E + 2\nu_E + k_E.$$

As a result,

$$\begin{aligned}\Psi(\phi_C, \nu_C, k_C) &\leq (\phi_{C_1} + \phi_{C_3}) + (\nu_{C_1} + \nu_{C_3}) + \sum_{E \in \mathcal{E}_2} (2\phi_E + 2\nu_E + k_E) \\ &\leq (\phi_{C_1} + \phi_{C_3}) + (\nu_{C_1} + \nu_{C_3}) + (2\phi_{C_2} + 2\nu_{C_2} + k_{C_2}) \\ &\leq 2\phi_C + 4\nu_C + 4k_C,\end{aligned}$$

where the last inequality follows from (A.7). This inequality implies (A.1).

(b) $\phi_C + 2ak_C > 3\mu/2$. For a box $E \in \mathcal{E}_1 \cup \mathcal{E}_3$,

$$\max\left\{\left(\frac{\phi_E + 2ak_E}{\mu}\right)^3, 1\right\} \le \max\left\{\left(\frac{2}{3}\left(\frac{\phi_C + 2ak_C}{\mu}\right)\right)^3, 1\right\} = \frac{8}{27}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3.$$

Similarly, for a box $E \in \mathcal{E}_2$,

$$\max\left\{2\left(\frac{\phi_E + ak_E}{\mu}\right), 1\right\} \le 2\left(\frac{\phi_C + 2ak_C}{\mu}\right).$$

By the induction hypothesis and (5.1),

$$\begin{aligned}\Psi(\phi_C, \nu_C, k_C) \le &\sum_{E \in \mathcal{E}_1}\left(2\phi_E + 5 \cdot \frac{8}{27}\nu_E\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 + 6 \cdot \frac{8}{27}k_E\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right)\\ &+ \sum_{E \in \mathcal{E}_2}\left(2\phi_E + 4\nu_E\left(\frac{\phi_C + 2ak_C}{\mu}\right) + 4k_E\left(\frac{\phi_C + 2ak_C}{\mu}\right)\right)\\ &+ \sum_{E \in \mathcal{E}_3}\left(2\phi_E + 5 \cdot \frac{8}{27}\nu_E\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 + 6 \cdot \frac{8}{27}k_E\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\right).\end{aligned}$$

Since $\phi_C + 2ak_C > 3\mu/2$,

$$\frac{\phi_C + 2ak_C}{\mu} \le \frac{4}{9}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3.$$

Therefore, using (A.7), we have

$$\begin{aligned}\Psi(\phi_C, \nu_C, k_C) &\le 2\left(\phi_{C_1} + \phi_{C_2} + \phi_{C_3}\right) + 5 \cdot \frac{8}{27}\left(\nu_{C_1} + \nu_{C_3}\right)\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\\ &\quad + \frac{16}{9}\nu_{C_2}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 + 6 \cdot \frac{8}{27}\left(k_{C_1} + k_{C_3}\right)\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\\ &\quad + \frac{16}{9}k_{C_2}\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3\\ &\le 2\phi_C + 5\nu_C\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3 + 6k_C\left(\frac{\phi_C + 2ak_C}{\mu}\right)^3,\end{aligned}$$

which implies (A.1). ☐

Acknowledgments. We would like to thank Seth Teller for providing us with the Soda Hall dataset (shown in Figure 1.1) created at the Department of Computer Science, University of California at Berkeley.

WAIT-FREE k-SET AGREEMENT IS IMPOSSIBLE: THE TOPOLOGY OF PUBLIC KNOWLEDGE*

MICHAEL SAKS† AND FOTIOS ZAHAROGLOU‡

Abstract. In the classical consensus problem, each of n processors receives a private input value and produces a decision value which is one of the original input values, with the requirement that all processors decide the same value. A central result in distributed computing is that, in several standard models including the asynchronous shared-memory model, this problem has no deterministic solution. The k-set agreement problem is a generalization of the classical consensus proposed by Chaudhuri [*Inform. and Comput.*, 105 (1993), pp. 132–158], where the agreement condition is weakened so that the decision values produced may be different, as long as the number of distinct values is at most k. For $n > k \geq 2$ it was not known whether this problem is solvable deterministically in the asynchronous shared memory model. In this paper, we resolve this question by showing that for any $k < n$, there is no deterministic wait-free protocol for n processors that solves the k-set agreement problem. The proof technique is new: it is based on the development of a topological structure on the set of possible processor schedules of a protocol. This topological structure has a natural interpretation in terms of the knowledge of the processors of the state of the system. This structure reveals a close analogy between the impossibility of wait-free k-set agreement and the Brouwer fixed point theorem for the k-dimensional ball.

Key words. distributed computing, consensus, Sperner's lemma, wait-free

1. Introduction.

1.1. Wait-free algorithms and the k-set agreement problem.

In totally asynchronous multiprocessor systems without global clocks, the execution speed of each processor may fluctuate widely. A highly desirable property for protocols in such a system is that no processor ever wait indefinitely for an action by another processor, that is, unless a processor fails (stops running) it is guaranteed to complete its task regardless of the relative speeds of the other processors, even if other processors stop participating. Protocols with this property are said to be *wait-free*.

We are interested in the standard model of shared-memory distributed systems with atomic registers [20]; an essentially equivalent model has been studied as *asynchronous parallel random access machines (PRAMs)* (e.g., [12, 22]). We restrict consideration to the case where each processor is deterministic. Informally such a system consists of a set of processors each with its own local memory accessible only to itself, and a set of shared registers. Each shared register supports atomic read and write operations, which means that (1) if two processors access a register simultaneously, the register automatically serializes the accesses, so there are no collisions, and (2)

a processor cannot simultaneously both read and write to a register. A protocol is defined by a set of programs, one for each processor, where each program involves "private computations," together with reads and writes to the shared memory. The system is completely asynchronous and the protocol makes no reference to a clock.

In executing a particular protocol the system may exhibit a wide range of behavior, depending on the relative speeds of the processors. The execution thus depends on the *schedule* of the processors, i.e., the way in which the program steps of the individual processors are interleaved. For a protocol to be correct, it should be correct for *all* schedules. A useful way to think about this requirement is to view the schedule as being chosen by an adversary who seeks to force the protocol to behave incorrectly.

Effective computation in such systems requires some coordination among the processors. The *consensus* problem was introduced as an abstraction of one coordination problem. In this problem, each processor p receives a private input x_p and must produce as output a *decision value* d_p, subject to the following requirements:

Validity. Each decision value is the input value of some processor.

Consistency. All processors that decide must decide the same value.

A fundamental result for the deterministic shared memory model outlined above is that there is no wait-free protocol that solves the consensus problem. This result was proven for this model by Herlihy [16] and independently by Loui and Abu-Amara [21] by adapting the proof of the seminal impossibility result for consensus in message passing systems with one failing processor proved by Fischer, Lynch, and Paterson [15].

This impossibility result spawned considerable activity along several fronts. One direction is to strengthen the model (i.e., introduce randomization, strengthen the shared memory primitives) so as to make consensus achievable. A second direction, pioneered by Herlihy, is the classification of data objects according to the number of processors that can achieve consensus using this data object [16]. A third direction has been to understand fully what can and can't be done in the deterministic atomic register shared-memory model.

As a step toward this third goal, it is natural to consider a weaker version of the consensus problem called the *k-set agreement problem.* This problem is identical to the consensus problem except that the *consistency* condition is replaced by a weaker condition:

k-Consistency. The set of decision values produced by the processors has cardinality at most k.

This problem was proposed and studied by Chaudhuri [10], who considered it in the message passing model and obtained some results relating the difficulty of this problem to various other related problems. In the shared atomic register model the main question is, For which values of n and k is there a wait-free algorithm for n processors to achieve k-set agreement in the shared-memory model? Trivially such an algorithm is possible for $n \leq k$ and (by the result for consensus) is impossible for $k = 1$ and $n > 1$. Chaudhuri conjectured that k-set agreement is impossible for any $n > k$. To appreciate the deceptive difficulty of the problem, the reader may consider the first previously unsolved case $k = 2$ and $n = 3$. This seemingly elementary brain teaser is already quite challenging.

1.2. Main results.

In this paper we prove the following theorem.

THEOREM 1.1. *For $k < n$, there is no deterministic wait-free protocol in the shared atomic registers model which solves the k-set agreement problem in a system of n processors.*

The first step in the proof is the formulation of a new formal model for shared-memory atomic register systems, called the *weakly synchronous model.* For our purposes, this model is at least as powerful as the standard ones (so impossibility proofs for this model apply to those) but it has the advantage of a particularly simple combinatorial structure. This allows us to reformulate the given problem in purely combinatorial terms.

We then develop a new approach for reasoning about computability issues in distributed systems. The basis of this approach is to shift focus from the structure of protocols for a distributed system to the structure of the set of possible schedules of a distributed system. To accomplish this shift for a given protocol, we fix ("hardwire") a particular set of input values to the processors and observe that having done this, the processor schedule now completely determines the output values of the processors and thus can be viewed as the "input" to the system. We introduce two key notions: (i) two schedules are "indistinguishable" if for any protocol they exhibit the same output behavior, (ii) a set S of schedules is "knowable" if there is a protocol which "recognizes" it, in the sense that for some specified output symbol, the protocol produces that symbol during an execution if and only if the execution proceeds according to some schedule from S.

These two concepts lead naturally to the definition of a topology on the set of schedules, and Theorem 1.1 is proved by analyzing this topology. Our approach reveals and exploits a close analogy between the impossibility of wait-free k-set agreement and a lemma of Knaster, Kuratowski, and Mazurkiewicz (KKM lemma) [1], which is equivalent to the fixed point theorem for the closed unit ball B_m in m-dimensional Euclidean space: if f is a continuous map from B_m to itself, then there exists a point $x \in B_m$ such that $f(x) = x$. Very roughly, f corresponds to a distributed protocol Π, and the fixed point x corresponds to the schedule for which Π fails to solve the k-set agreement. The increase in difficulty of the k-set agreement proof in going from the case $k = 1$ to the case $k > 1$ corresponds to the increase in difficulty in going from the fixed point theorem for the interval $[-1, 1]$, which is very simple, to the theorem for balls in higher dimension, which, while elementary, is considerably harder. An additional obstacle in our work is that, while the topological structure of B_m is well understood, we must develop the topological structure for the set of schedules from scratch.

While the explicit use of topology can be avoided, we have retained the topological structure of the proof, because this is what drove the proof and it provides important insight into what is going on. Our topological structure has an intuitive interpretation in terms of the information about an execution which is "public knowledge." We believe that it will be worthwhile to explore the connection with the formal theory of distributed knowledge [14].

The inspiration for the topological approach came from Chaudhuri's work [10], in which the combinatorial properties of triangulations in $\mathbf{R}^k$ were used to obtain certain reductions among various decision problems. There is a considerable literature concerning topologies underlying computation in general [27] and distributed computing in particular [26]. The main body of this work seems to center on the use of topology as a tool for describing various semantic constructs in distributing computing, rather than as a tool for proving impossibility results.

Two other research teams—Borowsky and Gafni [7] and Herlihy and Shavit [17]—independently discovered the topological approach to proving impossibility theorems and proved Theorem 1.1. Borowsky and Gafni [7] considered a class of protocols that is similar to our *weakly synchronous* model, and Herlihy and Shavit [17] considered *full information* protocols that bear similarities to both. The proof of Borowsky and Gafni [7] is similar to ours but does not make the explicit connection to topology. By an additional computational reduction they extend the result to prove the impossibility of k-set agreement for n processors in the presence of k faults. Herlihy and Shavit [17] developed a more general technique for proving impossibility results in this model based on simplicial homology theory. Subsequent developments along these lines include the papers [8, 11, 18].

This paper is organized as follows. In section 2, we formalize the model, the problem, and the above-mentioned notions of indistinguishable schedules and knowable sets. We also present a proof of the impossibility of (1-set) consensus using the new terminology. In section 3, we use this notation to reformulate Theorem 1.1, and we observe a close analogy between this reformulation and the aforementioned KKM lemma. In section 4, we provide an explicit bijection between the set of 2-processor schedules and the points of the closed unit interval that provides an alternative, albeit more complicated, proof of the impossibility of 2-processor consensus, and we sketch an (unproved) correspondence between n-processor schedules and the n-vertex simplex. This informal sketch motivates the combinatorial constructions discussed later. Section 5 contains an outline of the steps that we will follow to emulate the proof of the KKM lemma. Section 6 contains the proof of the main theorem. Some additional facts about the underlying topological structure in our proof are given in an appendix.

2. Definitions and preliminary results.

2.1. Input-output problems and *k*-set agreement. We fix, once and for all, the set $P = \{1, 2, \ldots, n\}$ of processors. The k-set agreement problem for P is a special case of a larger class of *input-output* problems [23, 6, 5]. In an input-output problem, each processor receives an input value from some set I and must produce an output value from some set D, where the output values must satisfy certain restrictions depending on the input. Formally, such a problem is specified by the input set I, output set D, and a relation $R \subset I^n \times D^n$.

For the k-set agreement problem, we take $I = D = \mathbf{N}$, the set of natural numbers, and the relation consists of pairs $(\vec{x}, \vec{d})$ satisfying the following: The set of values appearing in $\vec{d}$ has size at most k and is a subset of the set of values appearing in $\vec{x}$.

2.2. Informal description of the model. The results in this work will be proved for a specific formalization of the general model of asynchronous distributed computing described in the introduction. For reasons that will be apparent, we call this model the *weakly synchronous model.* This formalization was chosen because it is technically simple and is well suited to formal impossibility proofs. Informally the features of the model are as follows.

WS.1 Each register is a single-writer–multiple-reader register. The unique processor who may write to a register is referred to as the *owner* of the register.

WS.2 We assume that each process can simultaneously write to all of the registers it owns in a single atomic step. We model this by having each processor own only one register, whose set of allowed values is an arbitrary infinite set. Thus an arbitrary amount of information can be encoded in a single write.

WS.3 Each register holds an ordered list of values. When a value v is written to the register it is appended to the list rather than overwriting the existing values. Thus the register contains a record of all the writes ever done to it. At all times, the length of this list is equal to the total number of write operations that have been performed by the owner.

WS.4 When a processor performs a read operation, it reads the entire shared memory in one atomic step.

WS.5 Each processor's program consists of an infinite loop. Each iteration of the loop consists of a write to its shared register, followed by a read of the entire shared memory, followed by some arbitrary private computation.

WS.6 In solving a decision problem each processor p starts with a private initial input x_p from some input domain I. Each processor must write its decision value in the shared register that it owns. If D is the set of possible decision values, then the first element of D (if any) that the processor writes is considered to be its decision.

WS.7 The system satisfies a weak synchronicity condition. The processors execute their programs in a sequence of synchronous rounds. For each round the scheduling adversary chooses an arbitrary nonempty subset of processors to be active and each active processor executes one iteration of its loop. Since the round is synchronous all active processor writes are completed before any read begins.

We make the informal claim that our model is at least as powerful as other shared-memory models (e.g., [20, 16, 5]). It has been shown in [25] and [19, 13] that restricting to single-writer registers does not reduce the power of the model. Intuitively features 2, 3, and 4 provide more power than the standard models. Features 5 and 6 provide a "normal form" for protocols that solve input-output problems; a program in some other model can easily be converted to one of this form. Feature 7 restricts the power of the adversary by limiting the possible behaviors of the system. Note that this makes it *easier* for a protocol to be correct and thus *harder* for there to be an impossibility proof. We will not present a formal justification of these claims; the interested reader can do this for a favorite model.

2.3. Formal description of the model. A *protocol* Π for a processor set $P = \{1, \dots, n\}$ and an input domain I is referred to as a (P, I)-protocol and it is specified by a tuple (S, V, e, w, u), where

(1) S is an arbitrary set. S corresponds to the set of possible states for each processor.

(2) V is an arbitrary set. V corresponds to the set of possible values that a processor can write in a register. Thus by WS.2 each register holds an element of V^*, which is the set of finite lists of elements of V.

(3) e is a map from $I \times P$ to S. It determines the initial state of each processor from the processor's input value and the processor's ID.

(4) w is a map from S to V. It determines the value a processor will write in its register on the next step.

(5) u is a map from $S \times (V^*)^n$ to S. It determines the next state of a processor after executing a read operation. The evaluation of u corresponds to an arbitrary private computation by a processor.

A *system configuration* is a pair $(\vec{s}; \vec{l})$, where $\vec{s} = (s_1, \dots, s_n) \in S^n$ is called the *state configuration* and $\vec{l} = (l_1, \dots, l_n) \in (V^*)^n$ is called the *memory configuration*. Here s_i is the state of the ith processor and $l_i = v_1; \dots; v_k \in V^*$ is the list stored in the ith register.

A *block* J is a nonempty subset of P. The *configuration update operator* $\lhd = \lhd_\Pi$ takes as operands a system configuration and a block $J \subset P$ and produces a system configuration as follows:

$$(\vec{t}, \vec{m}) = (\vec{s}, \vec{l}) \lhd J,$$

where

$$\begin{array}{rcll} m_i &=& l_i & \text{if } i \notin J, \\ m_i &=& l_i, w(s_i) & \text{if } i \in J, \\ t_i &=& s_i & \text{if } i \notin J, \\ t_i &=& u(s_i, \vec{m}) & \text{if } i \in J. \end{array}$$

The operator corresponds to the modification of the system configuration which occurs after the synchronous execution of a program loop by the set J of processors. This corresponds to condition WS.7 in the informal description.

A *schedule* is an infinite sequence of blocks $\sigma = \sigma_1\sigma_2\sigma_3\dots$. For a nonempty $J \subseteq P$, $\Sigma(J) = \{\sigma = \sigma_1\sigma_2\dots | \sigma_i \subseteq J, \sigma_i \neq \emptyset\ \}$ denotes the set of all schedules whose blocks are subsets of J. If $p \in \sigma_i$ we say that processor p takes a step at time i. If $p \in P$ and σ is a schedule, then $steps_p(\sigma)$ is equal to the (possibly infinite) number of steps that p takes in σ. We say that p is

- *active* in σ if $steps_p(\sigma) \geq 1$, i.e., p appears in at least one block. Active(σ) is the set of active processors.
- *inactive* in σ if $steps_p(\sigma) = 0$, i.e., p appears in no block. Inactive(σ) is the set of inactive processors.
- *nonfaulty* in σ if $steps_p(\sigma)$ is infinite. Nonfaulty(σ) is the set of nonfaulty processors.
- *faulty* in σ if $steps_p(\sigma)$ is finite. Faulty(σ) is the set of faulty processors.

Observe that $\Sigma(J)$ consists of those schedules whose set of active processors is a subset of J.

A schedule is always an infinite sequence of blocks. A finite sequence of blocks is called a *fragment*. $\Phi(J)$ denotes the set of fragments whose blocks are subsets of J. The above definitions of $steps_p(\sigma)$, active, and inactive can be extended to fragments, but faulty and nonfaulty make sense only for schedules. If τ is a fragment and ϕ is a schedule or fragment, then $\tau\phi$ represents their concatenation and is a schedule or fragment. If $\sigma = \tau\phi$ we say that τ is a *prefix* of σ or that σ is an *extension* of τ.

If J is a subset of P, we denote by $[J]$ the schedule whose blocks are all equal to J. If J is equal to the singleton set $\{p\}$, we typically write $[p]$ for $[\{p\}]$.

A *run* (resp., *partial run*) is a triple $(\Pi, \vec{x}, \sigma)$, where Π is a (P, I) protocol, $\vec{x} \in I^n$ is the input, and σ is a schedule (resp., a fragment). The *execution* (resp., *partial execution*) $E = E(\Pi, \vec{x}, \sigma)$ associated to a run (resp., partial run) is defined as the infinite (resp., finite) sequence of configurations $C_0C_1C_2\dots$, where $C_0 = C_0(\Pi, \vec{x}) = (\vec{s}^{\,0}, \vec{l}^{\,0})$ is the *initial configuration* defined by $\vec{s}^{\,0} = (e(i_1, 1), \dots, e(i_n, n))$ and $\vec{l}^{\,0} = (\perp, \dots, \perp)$, where $\perp$ denotes the empty list, and $C_{i+1} = C_i \lhd \sigma_{i+1}$. The *public record* of the run or partial run $(\Pi, \vec{x}, \sigma)$ is a vector

$$Pub(\Pi, \vec{x}, \sigma) \ = \ (Pub_1(\Pi, \vec{x}, \sigma), \dots, Pub_n(\Pi, \vec{x}, \sigma)),$$

where $Pub_p(\Pi, \vec{x}, \sigma)$ is the (possibly infinite) list of all writes performed by p in the execution. Note that $Pub_p(\Pi, \vec{x}, \sigma)$ is infinite if and only if σ is a schedule and p is nonfaulty in σ. If $Pub_p(\Pi, \vec{x}, \sigma)$ is finite, then its length is the number of steps that p takes in σ.

Next, we define what it means for a protocol to *compute* a relation $R \subseteq I^n \times D^n$ for some arbitrary set D. The *D-decision value* of p on the run $(\Pi, \vec{x}, \sigma)$, denoted

$d_p^D(\Pi, \vec{x}, \sigma)$, is the first element $d \in D$ that appears on its list, or Λ(null) if none exists. If the element $d \in D$ first appears in the sth item of its list we say that p *D-decides* at step s. The vector of the D-decision values is the *D-decision vector* $\vec{d}^D(\Pi, \vec{x}, \sigma)$.

A vector $\vec{b} \in D^n$ is *compatible* with $\vec{d}$ if it can be obtained from $\vec{d}$ by replacing each Λ by some element of D. An input $\vec{x}$ is *R-permissible* if there is at least one vector $\vec{d} \in D^n$ such that $(\vec{x}, \vec{d}) \in R$. Protocol Π *computes* the relation R on schedule σ if for all R-permissible inputs $\vec{x}$

(1) the D-decision value of every nonfaulty processor is not null,

(2) there is a vector $\vec{b} \in D^n$ with $(\vec{x}, \vec{b}) \in R$ which is compatible with the decision vector $\vec{d}^D(\Pi, \vec{x}, \sigma)$.

A protocol Π is an *f-fault tolerant protocol* for R if it computes R on σ for all σ such that $|\text{Faulty}(\sigma)| \leq f$. A protocol that is $(n-1)$-fault tolerant, i.e., one that computes R on every schedule σ, is said to be *wait-free.* A protocol Π is a *bounded wait-free* protocol for R if there is a B such that for every run, each processor that takes at least B steps D-decides. It is easy to see (and is well known) that a wait-free protocol is bounded wait-free. It is also known (see [9] and the remark following Lemma 6.1 below) that for k-set consensus the existence of a wait-free protocol implies the existence of a bounded wait-free protocol.

Finally, a (P, I) protocol Π is *input-free* if the initial state of each processor depends on the processor ID only, that is, e is a map from P to S instead of from $I \times P$ to S. For an input-free protocol Π we write (Π, σ) for the run or partial run, $E(\Pi, \sigma)$ for the execution or partial execution, and $Pub(\Pi, \sigma)$ for the public record. Intuitively, input-free protocols are obtained from arbitrary ones by "hardwiring" a specific set of inputs to the individual processors.

PROPOSITION 2.1. *Let Π be a (P, I) protocol and let $\vec{x} \in I^n$ be some fixed input vector. Then there exists an input-free protocol Π' such that for all $\sigma \in \Sigma(P) \cup \Phi(P)$,*

$$E(\Pi, \vec{x}, \sigma) = E(\Pi', \sigma)$$

2.4. Impossibility of consensus. For illustration purposes we show how to adapt the proof of the consensus impossibility result [15, 16, 21] to prove that wait-free consensus is impossible in the weakly synchronous model. The previous proofs in the literature give a stronger result: there is no consensus protocol that is even 1-fault tolerant. It is possible to strengthen the following proof to give this result, but we do not do this here. This section is not needed for the development of the rest of the paper.

THEOREM 2.2. *In the weakly synchronous model, for $n > 1$ there is no deterministic wait-free protocol for n-processor consensus.*

Proof. Assume the set of possible inputs is $I = \{a, b\}$. Suppose, for contradiction, that Π is a protocol that solves consensus for all $\vec{x} \in I^n$ and all schedules σ. Each run $(\Pi, \vec{x}, \sigma)$ may be classified uniquely as a-deciding or b-deciding depending on the decision value.

PROPOSITION 2.3. *There is an input vector $\vec{y}$ and two schedules σ and ϕ such that $(\Pi, \vec{y}, \sigma)$ is a-deciding and $(\Pi, \vec{y}, \phi)$ is b-deciding.*

Proof. Let $\vec{y} \in I^n$ be an input vector with the minimum number of a's such that there exists a schedule σ such that $(\Pi, \vec{y}, \sigma)$ is a a-deciding; $\vec{y}$ has at least one a in it, say, in coordinate p. Define ϕ to be the schedule with repeated blocks $P - \{p\}$. We claim that $(\Pi, \vec{y}, \phi)$ is b-deciding. Let $\vec{w}$ be the vector obtained from $\vec{y}$ by changing the entry in coordinate p to b. Both of the runs $(\Pi, \vec{y}, \phi)$ and $(\Pi, \vec{w}, \phi)$ have the same public record. Furthermore the latter is b-deciding since $\vec{w}$ has fewer a's from $\vec{y}$ which was selected to have the minimum possible such number. Therefore $(\Pi, \vec{y}, \phi)$ is also b-deciding. $\square$

We restrict our attention to runs with input $\vec{y}$ given by Proposition 2.3. We say that a fragment τ is a-valent (resp., b-valent) if for every schedule ρ, $(\Pi, \vec{y}, \tau\rho)$ is a-deciding (resp., b-deciding). It is *bivalent* if it is neither a-valent nor b-valent, i.e., if there are schedules ρ and μ such that $(\Pi, \vec{y}, \tau\rho)$ is an a-deciding and $(\Pi, \vec{y}, \tau\mu)$ is a b-deciding. Clearly, no processor reaches a decision on the partial execution corresponding to a bivalent fragment. By choice of $\vec{y}$, the empty fragment is *bivalent.*

LEMMA 2.4. *For any bivalent fragment τ there exists a block J such that the fragment τJ is bivalent.*

Proof. Let τ be a bivalent fragment. Assume for contradiction that τJ is not bivalent for any block J. Thus for each J, τJ is either a- or b-valent. Without loss of generality suppose that τP (where P is the set of all processors) is a-valent. We will show that τJ is a-valent for every J in P which would imply τ is a-valent, a contradiction. Let J be arbitrary and $\bar{J} = P - J$. It is easy to see that the state of the shared memory and the internal states of processors in $\bar{J}$ are identical for the partial executions $PE(\Pi, \vec{y}, \tau P)$ and $PE(\Pi, \vec{y}, \tau J\bar{J})$. (Note, however, that the internal states of processors in J may differ between the two partial executions.) Recall that $[\bar{J}]$ denotes the schedule consisting of repeated $\bar{J}$ blocks. Then schedules $\tau J\bar{J}[\bar{J}]$ and $\tau P[\bar{J}]$ have identical public records. Since by our assumption τJ is not bivalent it must be a-valent, giving the desired contradiction. $\square$

By using the above lemma, one can construct an (infinite) schedule such that any prefix is bivalent, which contradicts that Π is a wait-free algorithm for consensus. $\square$

2.5. Tallies and the counting protocol. We now introduce a specific protocol, called the *counting protocol,* which will play a special role in our analysis. This is an input-free protocol which we denote by Γ.

To describe this protocol, we need to introduce the notion of a *tally vector*, which is a vector indexed by P whose entries are nonnegative integers. For a tally vector v, and $p \in P$, we write $v[p]$ for the $[p]$ entry of v. We define the partial order on tally vectors with $v \leq w$ if $v[p] \leq w[p]$ for all $p \in P$. Two tally vectors that are comparable under this ordering are said to be *noncrossing* and they are *crossing* otherwise. If τ is a fragment, the *tally* of τ, denoted $t(\tau)$, is the tally vector such that $t(\tau)[q]$ is equal to the number of steps q takes in τ. If $\sigma = \sigma_1, \sigma_2, \ldots$ is a schedule or fragment, the *tally sequence* associated with σ, denoted $\mathrm{T}(\sigma)$, is the sequence $T_0, T_1, T_2, \ldots$ of tally vectors, where T_i is the tally of the fragment $\sigma_1\sigma_2\ldots\sigma_i$. For example, the fragment $\{1,2\}\{3\}\{1,3\}\{1,2,3\}\{1\}\{2\}$ has tally sequence $(0,0,0), (1,1,0), (1,1,1), (2,1,2), (3,2,3), (4,2,3), (4,3,3)$. Observe that the tally vectors in the tally sequence of σ are noncrossing and that σ is trivially determined by $\mathrm{T}(\sigma)$.

We can now define the counting protocol Γ. As stated before, it takes no input. The state of each processor p is a tally vector $tally_p$. Initially all entries of $tally_p$ are 0. Each time p executes a step, p writes (appends) $tally_p$ to its public register. It then reads all of the shared registers and sets $tally_p$ so that $tally_p[q]$ is equal to the number of steps that have been taken by processor q (which is equal to the length of the list in processor q's public register). We define $Count(\sigma)$ to be the public record, $Pub(\Gamma, \sigma)$, of the counting protocol on schedule or fragment σ and call this the *public tally* of σ. Thus for each $p \in P$, $Count_p(\sigma)$ is a (possibly infinite) list of length $steps_p(\sigma)$, where each element of the list is itself a vector indexed by P. For $i \leq \mathit{steps}_p(\sigma)$, we denote by $\mathit{Count}_{p,i}(\sigma)$ the vector corresponding to the ith write by p, and for $q \in P$, $\mathit{Count}_{p,i}(\sigma)[q]$ is the value of this vector in position q. For example, on the fragment $\{1,2\}\{3\}\{1,3\}\{1,2,3\}\{1\}\{2\}$, we have

$$\begin{aligned}
\mathit{Count}_1(\sigma) &= (0,0,0);(1,1,0);(2,1,2);(3,2,3),\\
\mathit{Count}_2(\sigma) &= (0,0,0);(1,1,0);(3,2,3),\\
\mathit{Count}_3(\sigma) &= (0,0,0);(1,1,1);(2,1,2).
\end{aligned}$$

Note that the ith write by processor p is $t(\tau)$, where τ is the prefix up to the $(i-1)$st step of p. Note also that the final values of the internal states of the processors, tally_1, tally_2, and tally_3, are, respectively, $(4,2,3)$, $(4,3,3)$, and $(3,2,3)$, which do not appear in the public record.

By definition, each tally that appears in the public tally of σ also appears in its tally sequence $\mathrm{T}(\sigma)$. In particular, the set of all tally vectors that appear in the public tally is noncrossing. We will need the following lemma.

Lemma 2.5. *Let σ and ϕ be two schedules such that $\mathit{Count}(\sigma) \neq \mathit{Count}(\phi)$. Then at least one of the following holds:*

(1) *There exists a processor p and an integer i such that p takes at least i steps in both σ and ϕ and the tally vectors $\mathit{Count}_{p,i}(\sigma)$ and $C_{p,i}(\phi)$ are different.*

(2) *There exists a pair of crossing tally vectors v and w so that v appears in $\mathit{Count}(\sigma)$ and w appears in $\mathit{Count}(\phi)$.*

Proof. First consider the case that each processor takes exactly the same number of steps in σ as in ϕ. Then since $\mathit{Count}(\sigma) \neq \mathit{Count}(\phi)$, the first conclusion must hold.

Next, suppose that some processor p takes a total of i steps in σ and takes at least $i+1$ steps in ϕ. Let r be a processor that takes infinitely many steps in ϕ and let w be a tally vector written by r on schedule ϕ such that $w(p) \geq i+1$. Such a w must exist since p takes at least $i+1$ steps and r takes infinitely many steps. Let q be a processor that takes infinitely many steps in σ and let v be the tally vector written by q on schedule σ at its $w(q)+2$ step. Then $v(q) = w(q)+1$ and $v(p) \leq i < w(p)$, and so v and w are crossing tally vectors. ◻

2.6. Indistinguishable schedules. Two schedules or fragments σ and τ are *publicly indistinguishable* if for any protocol Π and input vector $\vec{x}$, the public records $\mathit{Pub}(\Pi, \vec{x}, \sigma)$ and $\mathit{Pub}(\Pi, \vec{x}, \tau)$ are the same. Intuitively, this says that there is no protocol Π and input $\vec{x}$ that will enable an "outside observer" looking at the "final" lists in the registers to distinguish between the schedules σ and τ. This is clearly an equivalence relation on the set all schedules and fragments. The structure of this equivalence relation is fundamental to the proofs of our results.

If σ and τ are publicly indistinguishable, then they must have the same public tallies, i.e., $\mathit{Count}(\sigma) = \mathit{Count}(\tau)$. As we will see in Theorem 2.12, this condition is also sufficient for public indistinguishability. This theorem will also provide another combinatorial characterization based on a notion called *compression*. To introduce this notion we will need some additional definitions.

If τ is a fragment, its length $|\tau|$ is the number of blocks in it, and its *weight*, $w(\tau)$, is the sum of the block sizes. Associated to each schedule or fragment σ is its *site sequence* $s(\sigma) = (s_1, s_2, \ldots)$ of length $|\sigma|$, where s_i is the weight of the first i blocks. We will also refer to s_i as the *site* of the ith block of σ.

Example 2.6. *$P = \{1,2,3\}$ and τ is the fragment $\{1,2,3\}\{1,2\}\{2,3\}\{2\}\{3\}$. Then $|\tau| = 5$, $w(\tau) = 9$, and $s(\tau) = (3,5,7,8,9)$.*

Let σ be a schedule or fragment. Then a block σ_i of σ is *hidden* if σ_i is not the last block and no processor in σ_i appears in any later block. Note that any two hidden blocks are necessarily disjoint and that whether σ is a schedule or a fragment, at least one processor belongs to no hidden block. Thus we have the following proposition.

PROPOSITION 2.7. *A schedule or fragment σ has at most $|P|-1$ hidden blocks.*

A schedule or fragment that has no hidden blocks is said to be *compressed*.

We now define operators for "eliminating" hidden blocks. For a positive integer s, the *merge* operator M_s is defined as follows. If σ is a schedule or fragment, $M_s(\sigma)$ is the schedule or fragment obtained as follows: if there is a block σ_i at site s and the block is hidden, then replace σ_i and σ_{i+1} by their union; otherwise, $M_s(\sigma) = \sigma$. The following facts are easy to verify.

PROPOSITION 2.8.

(1) *If σ is compressed, then $M_s(\sigma) = \sigma$ for all s.*
(2) *The operators M_s and M_r commute for all integers r and s.*
(3) *If σ is a schedule or fragment and $r_1, r_2, \ldots, r_k$ are the sites of its hidden blocks, then $M_{r_1}M_{r_2}\ldots M_{r_k}(\sigma)$ is a compressed sequence.*

The compressed sequence obtained from σ in the third part of Proposition 2.8 is called the *compression* of σ and is denoted $\hat{\sigma}$. More generally, a sequence τ which can be obtained from σ by application of some sequence of merge operators is said to be a *partial compression* or σ. An easy consequence of Proposition 2.8 is the following.

COROLLARY 2.9. *If τ is a partial compression of σ, then $\hat{\tau} = \hat{\sigma}$. Thus $\hat{\sigma}$ is the unique compressed sequence that can be obtained from σ by applying merge operators.*

The compression map $\sigma \longrightarrow \hat{\sigma}$ defines an equivalence relation on $\Sigma(P) \cup \Phi(P)$: σ and τ are *compression equivalent* if $\hat{\sigma} = \hat{\tau}$. The equivalence class of σ is called the *compression class* of σ and is denoted $\langle\sigma\rangle$.

Let σ be a compressed schedule, let χ be the smallest prefix of σ containing all faulty processors, and write $\sigma = \chi\phi$. Then any schedule that compresses to σ is of the form $\tau\phi$, where τ is a fragment of the same weight as χ. In particular, this implies the following.

PROPOSITION 2.10. *The compression class $\langle\sigma\rangle$ of any schedule is finite.*

EXAMPLE 2.11. *Suppose $P = \{1,2,3,4\}$ and let σ be the compressed schedule $\{1,2\}\{1,3,4\}\{1,2,3\}[3] = \{1,2\}\{1,3,4\}\{1,2,3\}\{3\}\{3\}\ldots$. There are eleven uncompressed schedules whose compression is σ:*

$$\begin{aligned}
\sigma^1 &= \{1,2\}\{1,3,4\}\{1\}\{2,3\}[3],\\
\sigma^2 &= \{1,2\}\{1,3,4\}\{2\}\{1,3\}[3],\\
\sigma^3 &= \{1,2\}\{1,3,4\}\{1\}\{2\}[3],\\
\sigma^4 &= \{1,2\}\{1,3,4\}\{2\}\{1\}[3],\\
\sigma^5 &= \{1,2\}\{1,3,4\}\{12\}[3],\\
\sigma^6 &= \{1,2\}\{4\}\{1,3\}\{1,2,3\}[3],\\
\sigma^7 &= \{1,2\}\{4\}\{1,3\}\{1\}\{2,3\}[3],\\
\sigma^8 &= \{1,2\}\{4\}\{1,3\}\{2\}\{1,3\}[3],\\
\sigma^9 &= \{1,2\}\{4\}\{1,3\}\{1\}\{2\}[3],\\
\sigma^{10} &= \{1,2\}\{4\}\{1,3\}\{2\}\{1\}[3],\\
\sigma^{11} &= \{1,2\}\{4\}\{1,3\}\{1,2\}[3].
\end{aligned}$$

In σ^{10}, for instance, the hidden blocks are at sites 3, 6, *and* 7. *Applying M_6 yields σ^{11}, and then applying M_7 yields σ^6, and applying M_3 yields σ.*

The following result characterizes public indistinguishability. Recall the definition of the public tally vector $Count(\sigma)$ from the previous section as the public record of the counting protocol Γ.

THEOREM 2.12. *Let σ and τ be schedules or fragments. Then the following are equivalent:*

(1) *σ is publicly indistinguishable from τ,*

(2) *$Count(\sigma) = Count(\tau)$,*

(3) *$\hat{\sigma} = \hat{\tau}$.*

Proof. (3) $\Rightarrow$ (1). Assume that $\hat{\sigma} = \hat{\tau}$; we will show that σ and τ are publicly indistinguishable.

LEMMA 2.13. *σ is publicly indistinguishable from $M_s(\sigma)$ for all s.*

Proof. The result is trivial if $\sigma = M_s(\sigma)$, so assume they are distinct. Then σ has a hidden block σ_k at site s and

$$\begin{array}{rcll} \phi_i & = & \sigma_i & \text{if } i < k, \\ \phi_k & = & \sigma_k \cup \sigma_{k+1}, & \\ \phi_i & = & \sigma_{i+1} & \text{if } i > k. \end{array}$$

Let $C(\sigma, i)$ be the configuration of the protocol Π on schedule σ after the execution of i blocks. Clearly $C(\phi, i) = C(\sigma, i)$ for every $i < k$. The configuration $C(\sigma, k+1)$ and $C(\phi, k)$ have exactly the same memory configuration but they may differ on the state configuration of the processors in the set σ_k. But these processors will not execute another step later in any of the schedules. Therefore, for $i > k$, $C(\phi, i)$ differs from $C(\sigma, i+1)$ only in the state of the processors in σ_k. Therefore σ and ϕ are publicly indistinguishable. □

COROLLARY 2.14. *σ is publicly indistinguishable from $\hat{\sigma}$.*

Proof. Let $r_1, r_2, \ldots, r_k$ be the sites of the hidden blocks of σ. Then by proposition 2.8, $\hat{\sigma} = M_{r_1} M_{r_2} \ldots M_{r_k}(\sigma)$ and the result follows by applying the previous lemma and induction. □

Therefore σ is publicly indistinguishable from $\hat{\sigma}$ and τ is publicly indistinguishable from $\hat{\tau}$. Since $\hat{\sigma} = \hat{\tau}$, then σ and τ are publicly indistinguishable.

(1) $\Rightarrow$ (2). This is trivial since if σ is publicly indistinguishable from τ, then by definition every protocol, including Γ, has the same public record on σ as τ.

(2) $\Rightarrow$ (3). Let σ and τ be schedules such that $Count(\sigma) = Count(\tau)$. From Corollary 2.14 and the fact that (1) $\Rightarrow$ (2) we have $Count(\sigma) = Count(\hat{\sigma})$ and $Count(\tau) = Count(\hat{\tau})$, hence $Count(\hat{\sigma}) = Count(\hat{\tau})$.

Now suppose for contradiction that $\hat{\sigma} \neq \hat{\tau}$. Write $\phi = \hat{\sigma}$ and $\mu = \hat{\tau}$ and consider the least k such that $\phi_k \neq \mu_k$. Let ϕ' and μ' be the prefixes ending with ϕ_k and μ_k, respectively. Then the tally vectors $t(\phi')$ and $t(\mu')$ are different; we may assume that either $t(\phi') < t(\mu)$ or $t(\phi')$ and $t(\mu')$ are crossing vectors (defined in section 2.5). Then the vector $t(\phi')$ does not appear in the tally sequence of μ and does not appear in $Count(\mu)$. On the other hand, since ϕ is compressed, we may choose a processor q in ϕ_k that writes again. Its next write in the counting protocol will be $t(\phi')$, contradicting that $Count(\phi) = Count(\mu)$.

This completes the proof of Theorem 2.12. □

2.7. Quasi extensions of fragments. We have defined the notion of a public record associated to an execution as the vector $\vec{R}$ indexed by p, where the entry $\vec{R}_p$ is the list of all writes done by p during the execution. It is convenient to call any such vector $\vec{R}$ indexed by P, where the entry $\vec{R}_p$ is an arbitrary list of elements, a *public record*. A public record is *finite* if each list is finite and infinite otherwise. If $\vec{R}$ and $\vec{R}'$ are public records, then we say that $\vec{R}'$ is an extension of $\vec{R}$ if each of the lists $\vec{R}_p$ is a prefix of the corresponding list $\vec{R}'_p$.

Now if τ is a fragment which is a prefix of the schedule or fragment σ, then clearly the following condition holds:

(QE) For any protocol Π and input $\vec{x}$, the public record of the execution $(\Pi, \vec{x}, \sigma)$ is an extension of the public record of the execution $(\Pi, \vec{x}, \tau)$.

We say that a schedule or fragment σ is a *quasi extension* of the fragment τ if condition (QE) holds. For a fragment τ, Q_τ denotes the set of schedules that are quasi extensions of τ.

Condition (QE) does not imply that τ is a prefix of σ. For instance, we have the following.

LEMMA 2.15. *Let ρ be a fragment, ϕ a schedule or fragment, and $Y \subseteq Active(\phi)$. If $\sigma = \rho\phi$ and $U \subseteq Active(\phi)$, then σ quasi-extends ρU.*

Proof. For any protocol, the public records of $\rho\phi$ and ρU trivially agree up through the end of ρ. Now in ρU, each of the processors in U write once more, and they write the view observed during their last step in ρ. But for each $p \in U$, the same write will occur when executing $\rho\phi$ since $p \in Active(\phi)$. $\square$

We have the following combinatorial characterization of quasi extension, which is analogous to Theorem 2.12.

THEOREM 2.16. *Let μ be a fragment and let σ be a schedule or a fragment. Then the following are equivalent:*

(1) *σ is a quasi extension of μ.*

(2) *$Count(\sigma)$ extends $Count(\mu)$.*

(3) *There exists a prefix ρ of σ, a schedule or fragment ϕ, and a subset U of $Active(\phi)$ such that $\sigma = \rho\phi$ and $\hat{\mu} = \widehat{\rho U}$.*

Proof. (1) $\Rightarrow$ (2). This follows from the definition of quasi extension and the fact that $Count(\sigma)$ and $Count(\mu)$ are the respective public records arising from a protocol.

(2) $\Rightarrow$ (3). Write $\hat{\mu}$ as τU, where U is the last block of $\hat{\mu}$. By hypothesis, and the fact that μ is publicly indistinguishable from $\hat{\mu}$, we have that $Count(\sigma)$ extends $Count(\tau U)$. Since τU is compressed, there is a processor $p \in U$ that also appears in the last block of τ. Let i be the number of steps that p makes in τ. By definition of the counting protocol, $Count_{p,i+1}(\tau U) = t(\tau)$, where $t(\tau)$ is the tally vector associated with fragment τ. By hypothesis, $Count_{p,i+1}(\sigma) = Count_{p,i+1}(\tau U)$. Let ρ be the minimal prefix of σ containing the first i steps of p. Again, by the definition of the counting protocol, $Count_{p,i+1}(\sigma) = t(\rho)$. Hence $t(\tau) = t(\rho)$. Write $\sigma = \rho\phi$. Now, since $Count(\rho\phi)$ extends $Count(\tau U)$ it is clear that each processor in U must take a step in ϕ, so $U \subseteq Active(\phi)$. Finally, we claim that $\widehat{\rho U} = \tau U$, and for this it is enough, by Theorem 2.12, to show that $Count(\rho U) = Count(\tau U)$. By Lemma 2.15, $Count(\rho\phi)$ extends $Count(\rho U)$ and since $Count(\rho\phi)$ also extends $Count(\tau U)$ (by hypothesis) and every processor takes the same number of steps in ρU as in τU, we must have $Count(\rho U) = Count(\tau U)$, as required.

(3) $\Rightarrow$ (1). Assume that (3) holds. By Lemma 2.15, σ is a quasi extension of ρU. But since $\widehat{\rho U} = \hat{\mu}$, ρU and μ are publicly indistinguishable and so σ is also a quasi extension of μ. $\square$

2.8. Knowable sets. For a set of schedules S, let $\hat{S} = \{\hat{\sigma} | \sigma \in S\}$. In particular, $\hat{\Sigma}$ is the set of all compressed schedules. By Theorem 2.12, to check that a protocol for an input-output problem is correct, it suffices to check it for schedules in $\hat{\Sigma}$.

In this subsection, we are interested in the dependence of the public record of a run $(\Pi', \vec{x}, \sigma)$ on σ while holding Π' and $\vec{x}$ fixed. Therefore it is easier to consider the corresponding input-free protocol Π given by Proposition 2.1.

In an input-free protocol, each processor's decision depends only on the schedule. One can view the computational steps taken by the processors as "collecting information" about the schedule. When a processor "knows enough" about the schedule, it can make a decision. Let $K(\Pi, d)$ be the set of all compressed schedules on which some processor running the input-free protocol Π writes d on its list. The pair (Π, d) is an *acceptor* and d is its *accepting* value. We say that (Π, d) *accepts schedule* σ if $\sigma \in K(\Pi, d)$. A set $K \subseteq \hat{\Sigma}$ is *publicly knowable* or simply *knowable* if it equals $K(\Pi, d)$ for some acceptor (Π, d). Below we give several examples. In each example, $d =$ "@."

EXAMPLE 2.17. *$\hat{\Sigma}$ is knowable. If Π is the protocol where every processor writes* "@" *at every opportunity, then $\hat{\Sigma} = K(\Pi, @)$.*

EXAMPLE 2.18. *$\emptyset$ is knowable. If Π is the protocol where every processor writes* "0" *at every opportunity, then $K(\Pi, @) = \emptyset$.*

EXAMPLE 2.19. *For each integer k and processor p, let $S_{p,k}$ be the set of compressed schedules in which processor p takes at least k steps. It is easy to see that $S_{p,k}$ is knowable; a simple input-free protocol that accepts this set is the one where processor p writes* "0" *for its first $k - 1$ steps and* "@" *thereafter, and all other processors always write* "0."

EXAMPLE 2.20. *Let S_i be the set of schedules where every processor takes at least i steps. S_i is a knowable set. The protocol that accepts the set is as follows: Each processor has two possible states, "continue" and "accept." While in the "continue" state, each processor appends* "0" *to the list in its shared register, reads the shared memory, and enters the "accept" state if all of the processors took i steps (have output list of length at least i). Once the processor is in the "accept" state, it writes* "@."

EXAMPLE 2.21. *Let τ be any fragment. The set $\hat{Q}_\tau$ of compressed schedules that are quasi extensions of τ is knowable. Define the following modification of the counting protocol defined in section* 2.5*: if any processor ever observes that the public record is an extension of $Count(\tau)$, then it writes* "@" *at its next opportunity. When this protocol is run on an (infinite) compressed schedule σ,* "@" *is written if and only if $Count(\sigma)$ is an extension of $Count(\tau)$. By Theorem* 2.16 *this is equivalent to $\sigma \in \hat{Q}_\tau$.*

For contrast, we give some examples of sets that are not knowable.

EXAMPLE 2.22. *Let $T_{p,k}$ be the set of compressed schedules where processor p takes* exactly *k steps for some k. Then $T_{p,k}$ is* not *a knowable set. Suppose to the contrary that (Π, d) is an acceptor for $T_{p,k}$. Let $\sigma \in T_{p,k}$ be arbitrary; then d is written in the public record of the run (Π, σ). Now the first write of (a, "d") occurs at some finite block σ_m of σ, so if we define $\phi = \sigma_1, \sigma_2, \ldots, \sigma_m, \{p\}, \{p\}, \ldots,$ then ϕ is also accepted by (Π, d). Then $\hat{\phi}$ is a compressed schedule accepted by (Π, d) but not in $T_{p,k}$, a contradiction.*

EXAMPLE 2.23. *The complement of a knowable set need not be knowable, e.g., consider the complement of $S_{p,k}$ and apply an argument analogous to the previous one.*

EXAMPLE 2.24. *Let N_p be the set of compressed schedules that do not begin with $\{p\}$. Then N_p is not knowable. Suppose to the contrary that (Π, d) is an acceptor for N_1. Let $\sigma \in N_1$ be the schedule $\{1, 2\}, \{2\}, \{2\}, \ldots.$ Then there is a block σ_k of σ such that d is first written in the public record of the run (Π, σ). If*

$\phi = \{1\}, \{2\}^k, \{1, 2\}\{2\}, \{2\}, \{2\}, \ldots,$ *then the public record corresponding to its first* $k+1$ *blocks will match the public record of the first* k *blocks of* σ*. Thus* ϕ *is compressed, is not in* N_1*, and is accepted by* (Π, d)*, a contradiction.*

The last example illustrates an important point: it is not hard to construct a protocol such that for any schedule σ in N_p, the fact "$\sigma \in N_p$" is recorded in the local state of at least one processor q. (Each processor $q \neq p$ records "yes" in its local state, if its first read does not see a write by p, and p records "yes" in its local state if its first read sees at least one write other than its own.) However, in this case, if p appears in the first block and never writes again, this fact does not become "public." The term *publicly knowable* reflects the fact that the value v is written in the memory and thus every nonfaulty processor "eventually knows" that the schedule belongs to K.

An acceptor (Π, d) is said to accept a *fragment* τ if d appears in the public record of Π on τ. The definition of a run of a protocol implies the following.

Proposition 2.25. *Let* K *be a knowable set. Then a compressed schedule* σ *belongs to* K *if and only if for some fragment* τ *of* σ, $\hat{Q}_\tau \subseteq K$*.*

The concept of knowable set allows us to reformulate the impossibility result for a k-set agreement problem. We do this in the next section.

3. Reformulating Theorem 1.1 and a topological analogy.

We want to prove that, in the weakly synchronous model, there is no wait-free protocol that solves the k-set agreement problem in a system of n processors for any $k < n$. Clearly it suffices to prove the impossibility result for $k = n - 1$. As a first step in the proof of Theorem 1.1, we use the notation of the previous section to reformulate it.

Assume, for contradiction, that there exists a wait-free protocol Π that solves the $(n-1)$-set agreement problem for a processor set $P = \{1, \ldots, n\}$. Consider the behavior of Π on the input $\vec{x} = (1, \ldots, n) \in I^n$. For each $i \in P$, let D_i be the set of compressed schedules σ such that on the run $(\Pi, \vec{x}, \sigma)$ at least one processor reaches decision i. By definition, each D_i is a knowable subset of $\hat{\Sigma}$. Also, if Π is correct, then for any schedule σ, at least one processor decides some value in $\{1, \ldots, n\}$, so the sets $D_1, D_2, \ldots, D_n$ together cover $\hat{\Sigma}$. An arbitrary sequence $A_1, A_2, \ldots, A_n$ of subsets of $\hat{\Sigma}$ *satisfies the activity property* if for each $p \in P$, processor p is active in each $\sigma \in A_p$. In other words A_p is disjoint from $\hat{\Sigma}(P - \{p\})$.

Proposition 3.1. *If* Π *is a fully fault-tolerant protocol for* k*-set agreement, then the sequence of sets* $D_1, D_2, \ldots, D_n$ *satisfies the activity property.*

Proof. Assume for the sake of contradiction that for some schedule $\sigma \in D_p$, processor p is not active. Consider a run of protocol Π on σ with the input vector $\vec{y}$ defined by $y_p = n + 1$ and $y_q = x_q$ for $q \neq p$. Then $Pub(\Pi, \vec{x}, \sigma) = Pub(\Pi, \vec{y}, \sigma)$; therefore, on input $\vec{y}$ some processor decides p although p does not appear in $\vec{y}$, which violates the validity condition. □

Our main theorem will thus follow from the following general result about knowable sets.

Theorem 3.2. *If* $K_1, \ldots, K_n$ *is a collection of knowable subsets of* $\hat{\Sigma}(P)$ *that cover* $\hat{\Sigma}$ *and satisfy the activity property, then*

$$\bigcap_{p=1}^{n} K_p \neq \emptyset.$$

Applying this to the sets $D_1, D_2, \ldots, D_n$, we obtain that there is a single schedule σ in which every possible decision $1, 2, \ldots, n$ is reached, contradicting that Π solves the $(n-1)$-set agreement problem.

$Hull(E^P)$	$\longleftrightarrow$	$\hat{\Sigma}(P)$
point $\vec{z} \in Hull(E^P)$	$\longleftrightarrow$	compressed schedule σ
relatively open subset of $Hull(E^P)$	$\longleftrightarrow$	knowable subset of $\hat{\Sigma}(P)$
$Hull(E^{P-\{p\}})$	$\longleftrightarrow$	$\hat{\Sigma}(P - \{p\})$
boundary property	$\longleftrightarrow$	activity property
vertex $\vec{e}^p$	$\longleftrightarrow$	schedule $[p] = \{p\}\{p\}\dots$

There is a striking analogy between the statement of Theorem 3.2 and a well-known theorem concerning the topology of Euclidean space. Let $Hull(Z)$ denote the convex hull of a set of points Z in the Euclidean space. Let $E^P = \{\vec{e}^p | p \in P\}$ be the set of standard unit basis vectors of $\mathbf{R}^P$, which we identify with $\mathbf{R}^n$. Note that $Hull(E^P)$ is the $(n-1)$-dimensional simplex consisting of the set of nonnegative vectors whose coordinates sum to 1. We say that a sequence of subsets $A_1, A_2, \dots, A_n$ of $Hull(E^P)$ *satisfies the boundary property* if for each $p \in \{1, \dots, n\}$, A_p is disjoint from $Hull(E^{P-\{p\}})$, which is the face of $Hull(E^P)$ opposite the vertex $\vec{e}^p$, i.e, each vector $\vec{z} \in A_p$ has positive pth coordinate. Finally, a subset U is *relatively open* in $Hull(E^P)$ if it is the intersection of $Hull(E^P)$ with an open subset of $\mathbf{R}^n$.

The following theorem is essentially equivalent to the Brouwer fixed point theorem for the $(n-1)$-dimensional closed ball.

THEOREM 3.3 (KKM theorem; see [1]). *If $U_1, \dots, U_n$ is a collection of relatively open subsets of $Hull(E^P)$ that cover $Hull(E^P)$ and satisfy the boundary property, then*

$$\bigcap_{i=1}^{n} U_i \neq \emptyset.$$

There is a tight syntactic correspondence between the two situations described by Theorems 3.2 and 3.3, which is given in Table 1.

The obvious question is, Is there some way to make use of this correspondence to prove the desired result for knowable sets? The natural way to do this would be to find a bijection between $\hat{\Sigma}(P)$ and $Hull(E^P)$ which obeys the syntactic correspondence. Given such a bijection Theorem 3.2 would follow from Theorem 3.3. In fact, we believe that there is such a bijection and that we have an existential argument for this. But the technical details involved in turning this argument into a rigorous proof seem to be considerable and except for the case $n = 2$, we have not completed such a proof.

It turns out we don't really need such a bijection. We prove Theorem 3.2 directly by analyzing and imitating the proof of Theorem 3.3. Nevertheless, the ideas of the proof are based on the intuition we developed in trying to construct an appropriate bijection between $\hat{\Sigma}(P)$ to $Hull(E^P)$. In the next section, we discuss some of these intuitions and give an explicit bijection for the $n = 2$ case (which corresponds to the impossibility of 2-processor consensus), a not-so-explicit bijection for the $n = 3$ case, and a glimpse at the $n > 3$ case. While our proofs do not explicitly depend on this section, it provides the key intuitions which motivate the succeeding sections.

4. Bijections between $\hat{\Sigma}(P)$and $Hull(E^P)$.

As described in the previous section, the most natural way to prove our result would be to provide a bijection f obeying the syntactic correspondence. For $n = 2$ we can explicitly construct such a map. For higher dimensions we have no explicit map, although we are fairly certain that the facts we develop later could, if one wanted, be used to prove existence of such a map. We emphasize that the proofs of our results do not rely on this section, and so we freely make claims here without proof.

The conditions we need on a bijection between $\hat{\Sigma}(P)$ and $Hull(E^P)$ are

(A) for $J \subseteq P$, each compressed schedule $\sigma \in \hat{\Sigma}(P)$ is mapped to the simplex $Hull(\{e^i : i \in J\})$;

(B) the image of any knowable set of $\hat{\Sigma}(P)$ is a relatively open subset of $Hull(E^P)$.

The first condition is fairly explicit; it says, for instance, that schedules of the form $(p)(p)(p)\dots$ must be mapped to a corner vertex $\vec{e}^{\,p}$. The second relies on the notion of knowable sets, whose definition in terms of protocols is hard to deal with directly. We now state a combinatorial characterization of knowability. We don't prove this now, but we note that it is equivalent to the characterization proved below as Theorem A.4. If τ is a schedule fragment, the *cylinder* of τ, B_τ is the collection of all schedules that have τ as a prefix.

THEOREM 4.1. *A set S of compressed schedules is knowable if and only if the set $\{\sigma \in \Sigma(P) | \hat{\sigma} \in S\}$ can be expressed as a (possibly infinite) union of cylinders.*

Now suppose we can find a function f whose domain is the set $\Sigma(P)$ of all schedules (not just compressed ones), such that f satisfies the following four conditions:

(1) f maps $\Sigma(P)$ onto $Hull(E^P)$.

(2) Each schedule σ is mapped to the simplex $Hull(\{e^i : i \in J\})$, where $J = Active(\sigma)$.

(3) $f(\sigma) = f(\tau)$ if and only if σ and τ have the same compression.

(4) f maps schedules with a "large" common prefix to points that are "close." More precisely, there exists a function $\alpha(j)$ on the nonnegative integers that tends to 0 such that for any two schedules σ and ϕ, if σ and ϕ have a common prefix of j blocks, then $\|f(\sigma) - f(\phi)\| \leq \alpha(j)$, where $\|\cdot\|$ denotes the usual Euclidean length.

The second condition is just condition (A) above. It is not hard to show that conditions (1), (3), and (4) together with Theorem 4.1 imply condition (B). Note that given a map f satisfying (1) and (3), its restriction to the set $\hat{\sigma}$ of compressed schedules is a bijection.

The following definitions will be useful. A schedule σ is *degenerate* if it has a unique nonfaulty processor. Such a schedule is uniquely of the form $\tau[p]$ for some segment τ and processor p, where either τ is the null fragment or the last block B of τ is not equal to $\{p\}$. Writing τ as μB, we say that μ is the *fundamental fragment* of σ and B is the fundamental block. We also say that σ is p-degenerate. A degenerate schedule whose fundamental fragment has weight at most w is said to be *w-admissible.*

We now describe such a function f for the $n = 2$ case and give some indication how it can be extended to the $n \geq 3$ case.

4.1. A bijection for the 2-processor case.

For simplicity, in the description of f, we consider the range to be the interval $[0, 1]$ instead of $Hull(E^{\{1,2\}})$.

Let us start by describing a mapping that does not work. Take each schedule σ and interpret it as an infinite ternary string $t = t(\sigma)$ by mapping $\{1\}$ to 0, $\{1, 2\}$ to 1, and $\{2\}$ to 2. Then any schedule can be interpreted as a real number between 0 and 1. Furthermore, this mapping is easily seen to satisfy properties (1), (2), and (4) above: the map is onto, it sends the schedule $[1] = \{1\}\{1\}\dots$ to the endpoint 0 and $[2]$ to endpoint 1, and two schedules with a common prefix of j blocks map to points that differ by at most $(1/3)^j$. The problem is condition (3). The map sends the schedules $\{1\}[2]$ and $\{1, 2\}[1]$ to the point 1/3, yet they do not have the same

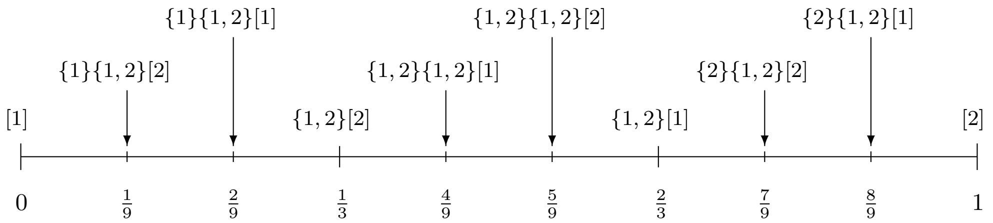

FIG. 1. *The map from* $\hat{\Sigma}(\{1,2\})$ *to the* $[0,1]$ *interval.*

compression, and $\{1\}[2]$ and $\{1,2\}[2]$ which have the same compression are mapped to $1/3$ and $2/3$, respectively. To fix this problem we modify $t = t(\sigma)$. Given $t = t(\sigma)$, define the infinite sequence a by $a_i = t_i$ if $t_1, t_2, \ldots, t_{i-1}$ has an even number of 1's and $a_i = 2 - t_i$ otherwise. Interpret a as a real number between 0 and 1 written in base 3. The map f is now defined to take $f(\sigma) = a$. It still satisfies (1), (2), and (4), but now it can also be shown to satisfy (3).

Figure 1 depicts the restriction of the mapping to compressed schedules. Under this map, degenerate schedules get mapped to rational numbers whose denominators are powers of 3. Observe that for $n = 2$, a compressed schedule σ is equal to the compression of some other schedule if and only if it is degenerate, in which case there is exactly one uncompressed schedule whose compression is σ. The mapping sends these two schedules to the same point. For example, the inverse image of $2/9$ is $\{1\}\{1,2\}[1]$ and $\{1\}\{2\}[1]$.

The bijection has a geometric description. Each prefix τ is associated with an interval R_τ which corresponds to the schedules that start with this prefix. The endpoints of the interval τ are the images of the schedules $\tau[1]$ and $\tau[2]$. The empty prefix corresponds to the entire interval, and if τ is a prefix of μ, then the interval corresponding to μ is a subinterval of that corresponding to τ. In general, the interval corresponding to τ is divided into three subintervals, corresponding to $\tau\{1\}, \tau\{1,2\}$, and $\tau\{2\}$.

It will be useful to describe this process of subdivision in *levels.* The level 0 subdivision is the subdivision into three intervals, corresponding to the prefixes $\{1\}, \{1,2\}$, and $\{2\}$. The level i subdivision is obtained from the level $i-1$ subdivision by taking each interval corresponding to a prefix of weight i (that is, the sum of the block sizes is i) and subdividing it into three subintervals as above. Thus the level 1 subdivision consists of the subdivision of the intervals $[0, 1/3]$ and $[2/3, 1]$ into three parts and the level 2 subdivision subdivides each of the intervals $[0, 1/9]$, $[2/9, 1/3]$, $[1/3, 2/3]$, $[2/3, 7/9]$, and $[8/9, 1]$ into three intervals.

4.2. The case of more than two processors. For $P = \{1,2\}$ we were able to give an explicit map from schedules to $Hull(E^P)$. For $|P| > 2$, we don't know how to do this. However, in the 2-processor case, we saw that the map can be defined by a process of successive subdivision. For each fragment τ we defined an interval R_τ which is the image of all schedules with prefix τ. For each schedule σ, the sequence of regions R_{σ^i}, where σ^i is the unique prefix of σ that appears in the level i subdivision, are nested, and their intersection is the image of σ. It should also be apparent that the lengths of the intervals into which we subdivided each interval are not critical; all we really needed was that the length of R_τ goes to 0 as we take larger and larger prefixes.

For $|P| \geq 3$ we will attempt to construct a map along similar lines. We will

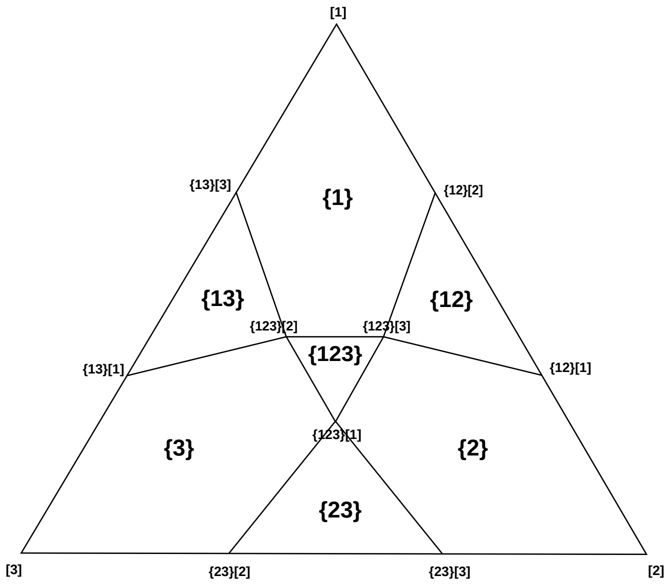

FIG. 2. *The subdivision* $D_0(\{1,2,3\})$.

construct a sequence $D_m(P)$ of decompositions of the simplex $Hull(E^P)$. The decomposition $D_0(P)$ consists of $2^{|P|}-1$ regions R_J, one for each nonempty subset of J of P; all schedules with first block J are mapped to R_J. This tiling is called the *level* 0 *decomposition* of the simplex. More generally, in the level m decomposition $D_m(P)$, $m \geq 0$, the regions correspond to fragments that are minimal subject to their weight being greater than m. The level $m+1$ decomposition is obtained from the level m decomposition by taking each region corresponding to a fragment τ of weight exactly m and tiling it by 2^n-1 regions corresponding to the fragments of the form τJ, where J is a block. The region R_τ is the image of the map applied to schedules with prefix τ. Given the level m decomposition for all m, the image of a schedule σ is determined as follows: for each m, σ is assigned to a unique $R_m(\sigma)$ region in the level m decomposition corresponding to the appropriate prefix of σ. The sequence of regions $R_m(\sigma)$ is nested and their diameters tend to 0, so σ is mapped to the unique point in their intersection. A key property will be that a point on the boundary of two or more regions will correspond to a set of schedules all having the same compression, where each schedule corresponds to one of the regions. The "vertices" of the decomposition $D_m(P)$ will correspond to schedules whose compression is an m-admissible degenerate schedule.

We now sketch how this can be done for $|P|=3$; the same approach would also seem to work for higher dimensions. The combinatorial structure underlying the map is regular, but it is sufficiently complicated that writing a complete description and a rigorous proof that it works seems to be a very tedious undertaking, which is why we do not rely explicitly on this construction in the proof of our main result. The development in the later sections is closely related to the present construction; the reader will see that this construction is the basis for the "triangulation graphs" presented in section 6.2. Conversely, the interested reader can use the precise description of the triangulation graphs to get a precise description of the map in higher dimensions.

Let $P=\{1,2,3\}$. Figure 2 shows the level 0 decomposition, $D_0(P)$ into seven regions. Each region is labeled by a nonempty subset of P. Each singleton set corresponds to a pentagonal region and each other set corresponds to a triangular region. All 0-admissible compressed degenerate schedules map to vertices in the figure. Each vertex is labeled by the unique compressed schedule that maps to it, and for each such vertex its inverse image is the set of all schedules whose compression is equal to its label. For example, the vertex labeled $\{1,2,3\}[2]$ lies on the boundary of the four regions $\{1\},\{3\},\{1,3\},\{1,2,3\}$ and for each such region there is a corresponding schedule that maps to that vertex: of $\{1\}\{2,3\}[2],\{3\}\{1,2\}[2],\{1,3\}[2]$, and $\{1,2,3\}[2]$. Consider a segment that separates two regions. Each point on the segment corresponds to two schedules, one that begins with the fragment defining the first region and one that begins with the fragment defining the other region. For example, the segment joining $\{1,2,3\}[2]$ and $\{1,3\}[1]$ separates the regions $\{3\}$ and $\{1,3\}$ and each point on the segment is the image of exactly two schedules $\{1,3\}\sigma$ and $\{3\}\{1\}\sigma$, where $\sigma \in \Sigma(\{1,2\})$.

In the higher level decompositions, we successively subdivide each region into seven subregions. When we focus on a region associated to fragment τ, it is useful to relabel each vertex of the region by the unique schedule beginning with τ that maps to that vertex. Thus, for instance, for the region $\{1,2\}$, we can view its vertices as $\{1,2\}[1]$, $\{1,2\}[2]$, and $\{1,2\}[3]$. When we subdivide this region we do it in a way analogous to the level 0 decomposition of the entire triangle, with $\{1,2\}[i]$ corresponding to the schedule $[i]$. Any triangular region is subdivided in this way.

To decompose a pentagonal region we treat it as a "distorted" triangle. In general, a pentagonal region will correspond to a fragment τ whose last block is a singleton set $\{i\}$. (The reader should follow this for the region labeled $\{1\}$.) The vertices of the region will correspond to the schedules $\tau[i]$, $\tau[j], \tau\{j,k\}[k], \tau\{j,k\}[j], \tau[k]$. When we subdivide, we view $\tau[i], \tau[j], \tau[k]$ as the vertices of the distorted triangle. The three segments joining $\tau[j]$ and $\tau[k]$ are together viewed as one "side" of the triangle. The two intermediate vertices $\tau\{j,k\}[k]$ and $\tau\{j,k\}[j]$ play the role of the vertices that are added when we subdivide that side.

Figure 3 depicts the level 1 decomposition with the vertices labeled and Figure 4 shows the decomposition with faces labeled. Note that the level 1 decomposition is produced from the level 0 decomposition by decomposing each of the three pentagons corresponding to regions whose fragment has weight 1.

The level 2 decomposition is not shown; it is obtained from the level 1 decomposition by subdividing each of the 12 regions that correspond to fragments of weight 2.

This completes our discussion of our attempt to prove Theorem 3.2 by an appropriate bijection between $Hull(E^P)$ and $\hat{\Sigma}(P)$. While we did not complete this approach, the constructions motivate much of what comes in the proof.

5. Reviewing the geometric case.

As we stated, the proof of Theorem 3.2 is obtained by following closely the proof of its geometric analog Theorem 3.3. It is useful to review the outline of that proof.

Recall that we have a cover of the simplex $Hull(E^P)$ by relatively open sets $U_1, \dots, U_n$ that satisfy the boundary property and we want to show that there is a point belonging to all of the sets. We begin with a lemma which applies to an arbitrary open cover of $Hull(E^P)$. For $\vec{x} \in Hull(E^P)$, let $B(x,\epsilon)$, the *closed ϵ-ball around x*, denote the set of points $\vec{y} \in Hull(E^P)$ within Euclidean distance ϵ of $\vec{x}$.

LEMMA 5.1. *For any finite collection $\mathcal{U}$ of open sets that covers $Hull(E^P)$ there is an $\epsilon = \epsilon(\mathcal{U}) > 0$ such that for each point $\vec{x} \in Hull(E^P)$, some member of $\mathcal{U}$ contains $B(\vec{x},\epsilon)$.*

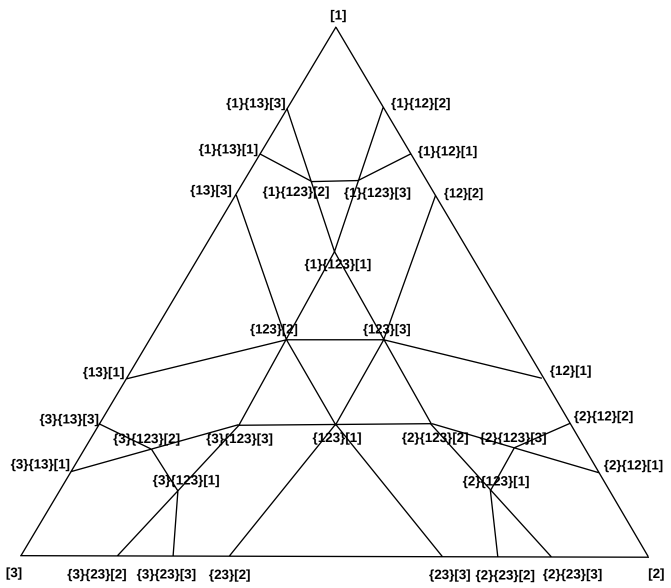

FIG. 3. *The subdivision $D_1(\{1,2,3\})$ with vertex labels.*

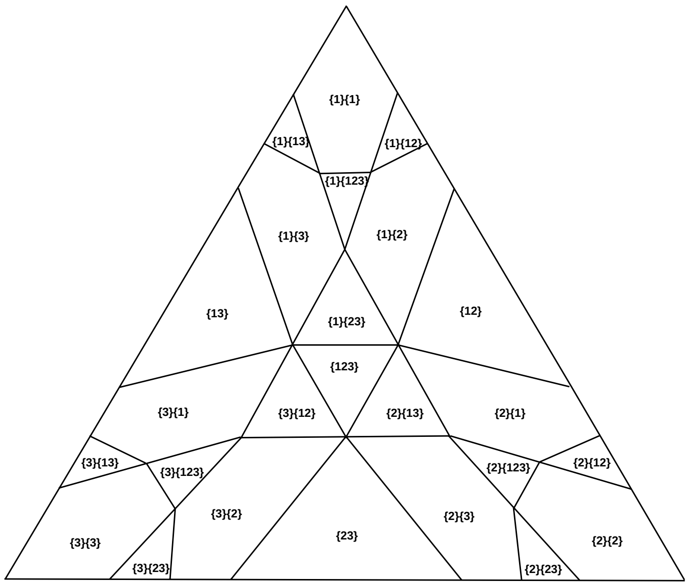

FIG. 4. *The subdivision $D_1(\{1,2,3\})$ with face labels.*

The key point is that the same ϵ works for all $\vec{x}$. Now given our covering $U_1, \ldots, U_n$ satisfying the boundary property we choose an $\epsilon > 0$ for which the conclusion of the above lemma is satisfied. We then define a function (labeling) λ of the points of $Hull(E^P)$ to $[n] = \{1, \ldots, n\}$ as follows: $\lambda(\vec{x})$ is the minimum j such that $B(\vec{x}, \epsilon) \subseteq U_j$. Note that, by the boundary property, this labeling satisfies the following *coherence condition*: for each $J \subset P$, each point of $Hull(E^J)$ is labeled by an element of J. It suffices to show that

(**) for some $\vec{y} \in Hull(E^P)$, $B(\vec{y}, \epsilon)$ contains n points with distinct labels, since then $\vec{y} \in \bigcap_{i=1}^{n} U_i$.

The proof of (**) relies on the notion of a *triangulation* of the simplex. Roughly, a triangulation T of $Hull(E^P)$ is a decomposition into a finite collection of n-vertex simplices with the property that any two simplices in the triangulation are disjoint or their intersection is a face of each (where by a face, we mean a subsimplex spanned by a subset of the vertices). The set of all simplices in T and faces of simplices in T are the *faces of T*.

For the ϵ given by Lemma 5.1, we construct a triangulation T satisfying the following.

LEMMA 5.2. *For each positive ϵ there exists a triangulation T of $Hull(E^P)$ all of whose simplices have diameter at most ϵ.*

Consider the labeling λ restricted to the vertices of T. The following lemma now completes the proof of (**) and Theorem 3.3.

LEMMA 5.3 (Sperner's lemma [1]). *Let $\lambda : Hull(E^P) \longrightarrow [n]$ be a coherent labeling and let T be a triangulation of $Hull(E^P)$. Then some n-vertex simplex of T has all of its vertices distinctly labeled.*

6. Proof of Theorem 3.2.

Recall that we have knowable sets $K_1, K_2, \ldots, K_n$ that cover $\hat{\Sigma}(P)$ and satisfy the activity property. We wish to show that they have a nonempty intersection.

The first step in adapting the proof of Theorem 3.3 is to prove an analog of Lemma 5.1. Recall that for a fragment τ the set of schedules that are quasi extensions of τ is denoted Q_τ, and $\hat{Q}_\tau = \hat{\Sigma}P \cap Q_\tau$. The sets $\hat{Q}_\tau$ play the role of ϵ-balls. For example, for each compressed schedule ϕ, and for each integer w, let $\phi^{(w)}$ denote the maximal prefix of ϕ whose weight (sum of block sizes) is at most w. If we consider the sequence of sets $\hat{Q}_{\phi^{(w)}}$ we see that $\hat{Q}_{\phi^{(1)}} \supseteq \hat{Q}_{\phi^{(2)}} \supseteq \cdots$ and that the intersection of all of them is just ϕ itself. This is analogous to a sequence of balls of decreasing radius around a particular point. The analog of Lemma 5.1 is the following.

LEMMA 6.1. *Let $\mathcal{K}$ be a collection of knowable sets that covers $\hat{\Sigma}(P)$. Then there is an integer $w = w(\mathcal{K})$ with the property that for each schedule ϕ, some member of $\mathcal{K}$ contains $\hat{Q}_{\phi^{(w)}}$.*

Proof. Suppose for contradiction that for each w there is a schedule $\phi(w)$ such that the set $\hat{Q}_{\phi(w)^{(w)}}$ is not contained in any member of $\mathcal{K}$. Let $\Phi = \{\phi(w) : w \geq 1\}$. Construct a schedule σ as follows. Let σ_1 be any set that is the first block of infinitely many members of Φ, and inductively for $i > 1$, having defined $\sigma_1 \ldots \sigma_{i-1}$, let σ_i be a set such that $\sigma_1\sigma_2 \ldots \sigma_i$ is a prefix of infinitely many members of Φ. The compression $\hat{\sigma}$ must belong to some member $K \in \mathcal{K}$. By Proposition 2.25, there is a fragment τ of $\hat{\sigma}$ such that $\hat{Q}_\tau \subseteq K$. By construction of σ, τ is a prefix of infinitely many members of Φ. In particular, it belongs to some $\phi(w)$ with $w > w(\tau)$. Then $\hat{Q}_{\phi(w)^{(w)}} \subseteq \hat{Q}_\tau \subseteq K$ contradicts the choice of $\phi(w)$. ∎

Remark. The above result implies the fact mentioned in section 2.1 that the existence of a wait-free protocol Π for k-set agreement implies the existence of a bounded wait-free protocol. Given Π, define protocol Π', where each processor behaves as in Π except that if it sees that any processor has decided before it has decided, it immediately takes the lowest decision value it sees as its decision value. Clearly Π' is correct if Π is. Letting D_i be the set of schedules where some processor decides i, the above Lemma implies that there is a w such that after at most w total steps (by all of the processors) some processor has reached a decision. Thus, after taking at most $w + 2$ steps a processor will have decided and written its decision value.

Now given our covering $K_1, \ldots, K_n$ satisfying the activity property we choose an m for which the conclusion of the above lemma is satisfied. We then define a function (labeling) λ of the points of $\hat{\Sigma}(\Sigma^P)$ to $[n] = \{1, \ldots, n\}$ as follows: $\lambda(\hat{\sigma})$ is the minimum j such that $\hat{Q}_{\hat{\sigma}^{(m)}} \subseteq U_j$. Note that, by the activity property, this labeling satisfies the following *coherence condition*: for each $J \subset B$, each $\hat{\sigma} \in \hat{\Sigma}(\Sigma_J)$ is labeled by an element of J. It suffices to show the following analog of (**).

LEMMA 6.2. *Let $K_1, \ldots, K_n$ be knowable sets that cover $\hat{\Sigma}(P)$ and let λ be a labeling of the schedules that satisfies the coherence condition. Then for any integer $m \geq 1$, there is a fragment τ of weight at least m that is a prefix of n schedules having different labels.*

The proof of this relies on abstracting the notion of a *triangulation* for the set of compressed schedules and proving an analog of Sperner's lemma.

6.1. Triangulation graphs.

By analyzing the proof of Sperner's lemma, it can be seen that the lemma can be interpreted as a statement about graphs embedded in $Hull(E^P)$ that have certain properties. This motivates the definition of the following class of graphs defined on $\hat{\Sigma}(P)$.

A *triangulation graph* on $\hat{\Sigma}(P)$ is a finite graph $G = (V, E)$ whose vertex set is a subset of $\hat{\Sigma}(P)$ and which satisfies the following properties:

(1) For each $p \in P$, the schedule $[p] = \{p\}\{p\}\{p\} \ldots$ is a vertex.
(2) If C is a clique contained in $\hat{\Sigma}(J)$ of size $|J| - 1$, then
   (a) if C is contained in $\hat{\Sigma}(I)$ for any proper subset I of J, then there is a unique clique of size $|J|$ in $\hat{\Sigma}(J)$ that contains C;
   (b) if C is not contained in $\hat{\Sigma}(I)$ for any proper subset I of J, then there are exactly two cliques of size $|J|$ in $\hat{\Sigma}(J)$ that contain C.

Here we use *clique* to mean a not necessarily maximal complete subgraph.

These conditions correspond to those satisfied by the skeleton of a triangulation in the geometric case. The first condition comes by associating the schedules $[p]$ to the generators $\vec{e}^p$ of the simplex $Hull(E^P)$, which are necessarily vertices of any triangulation. The second condition corresponds to the fact that in any triangulation of the simplex, if a $(|J| - 1)$-vertex face of T lies in $Hull(E^J)$, then (i) if it lies on the boundary of $Hull(E^J)$, then it is a face of a unique $|J|$-vertex face of T, while (ii) if it lies in the interior of $Hull(E^J)$, then it is the common boundary of a pair of $|J|$-vertex faces of T.

These conditions are sufficient to prove an analog of Sperner's lemma.

LEMMA 6.3. *Let $\lambda : \hat{\Sigma}(P) \longrightarrow [n]$ be a coherent labeling and let G be a triangulation graph on $\hat{\Sigma}([n])$. Then some n-vertex clique of G has all of its vertices labeled differently.*

Proof. For $k \in [n]$, let $g(k)$ be the number of k vertex cliques in $\hat{\Sigma}([k])$ whose vertices are labeled differently. Since λ is coherent these labels must be $\{1, 2, \ldots, k\}$. The key step is the following claim.

Claim. For each k between 2 and n, $g(k) \equiv g(k-1) \mod 2$.

It then follows that $g(n) \equiv g(1) \equiv 1 \mod 2$ since the schedule $[1]$ is the unique vertex in $\hat{\Sigma}([1])$, and we conclude that $g(n) \neq 0$.

It suffices to prove the claim. For k between 2 and n, define $p(k)$ to be the number of pairs (C', C), where C is a k-clique in $\hat{\Sigma}([k])$ and C' is a $(k-1)$-clique contained in C that is distinctly labeled $1, 2, \ldots, k-1$. Then the claim follows from

$$\begin{aligned} g(k) &\equiv p(k) \mod 2, \\ p(k) &\equiv g(k-1) \mod 2. \end{aligned}$$

The first relation is obtained by computing $p(k)$ in the following manner. Each k-clique C in $\hat{\Sigma}([k])$ which is not distinctly labeled contains either 0 or 2 cliques of size $k-1$ that are labeled $1, 2, \ldots, k-1$ and so contribute $0 \mod (2)$ to $p(k)$. On the other hand, each distinctly labeled k-clique C has a unique subclique of size $k-1$ that is labeled $1, 2, \ldots, k-1$ and so contributes 1 to $p(k)$.

The second relation follows by considering, for each $(k-1)$-clique C' with labels $1, 2, \ldots, k-1$, the number of k-cliques of $\hat{\Sigma}([k])$ to which it belongs. By the definition of triangulation graph, if C' does not lie in $\hat{\Sigma}(I)$ for some proper subset I of $[k]$, then it belongs to exactly two cliques C of size k in $\hat{\Sigma}([k])$ and so contributes 0 mod (2) to $p(k)$. On the other hand, if $C' \subset \hat{\Sigma}(I)$ for some proper subset I of $[k]$, then the definition of triangulation graph implies that C' is in a unique k-vertex clique $C \subset \hat{\Sigma}([k])$ and so contributes exactly 1 to $p(k)$. Thus $p(k) \mod 2$ counts the parity of the number of $(k-1)$-cliques C' labeled by $1, 2, \ldots, k-1$ that are in $\hat{\Sigma}(I)$ for some I properly contained in $[k]$. But the fact that C' contains all labels $1, 2, \ldots, k-1$ implies, by the coherence of λ, that I contains $[k-1]$ and so C' must be in $\hat{\Sigma}([k-1])$. Therefore, $p(k) \equiv g(k-1)$ mod 2. □

Next we will prove the following lemma.

LEMMA 6.4. *For any integer w, there exists a triangulation graph G on $\hat{\Sigma}(P)$ with the property that for any clique of G there is a fragment τ of weight at least w such that every vertex of the clique is contained in $\hat{Q}_\tau$.*

Together with Lemma 6.3, this lemma completes the proof of Lemma 6.2 and hence of Theorems 3.2 and 1.1.

Finally, it remains to show the existence of the desired triangulation graphs. This turns out to be the most technically arduous part of the proof.

6.2. Constructing triangulation graphs. We will define a sequence of triangulation graphs $\{G_m(P) | m \geq 0\}$ on $\hat{\Sigma}(P)$ with the property that any clique of $G_m(P)$ is a subset of $\hat{Q}_\tau$ for some fragment τ of weight at least $w = m - n$ (where $n = |P|$).

The precise description of $G_m(P)$ is technical, but the "picture" of the construction is nice. The graph $G_m(P)$ is closely related to the decomposition $D_m(P)$, described in section 4, but since we have only given a hint as to the general construction of $D_m(P)$, we cannot use the $D_m(P)$ explicitly in our formal description of the $G_m(P)$. Nevertheless to help understand the technical description, the reader should compare the graphs $G_0(P)$ and $G_1(P)$ depicted in Figures 5 and 6 with the pictures of $D_0(P)$ and $D_1(P)$ in section 4. The following properties are evident from the examples and will also hold in general:

(1) The vertex set of $G_m(P)$ corresponds to the vertex set of $D_m(P)$, i.e., it is the set $V_m(P)$ of m-admissible compressed degenerate schedules in $\Sigma(P)$.
(2) The graph $G_m(P)$ is obtained from the decomposition $D_m(P)$ by adding edges in order to triangulate the pentagonal regions in $D_m(P)$. Recall that each pentagonal face is labeled by a fragment that ends with a singleton block, i.e., one of the form $\tau = \mu\{i\}$. The pentagon is triangulated by connecting the vertex corresponding to (the compression of) $\tau[i]$ to the vertices corresponding to (the compression of) $\tau\{j,k\}[j]$ and $\tau\{j,k\}[k]$.

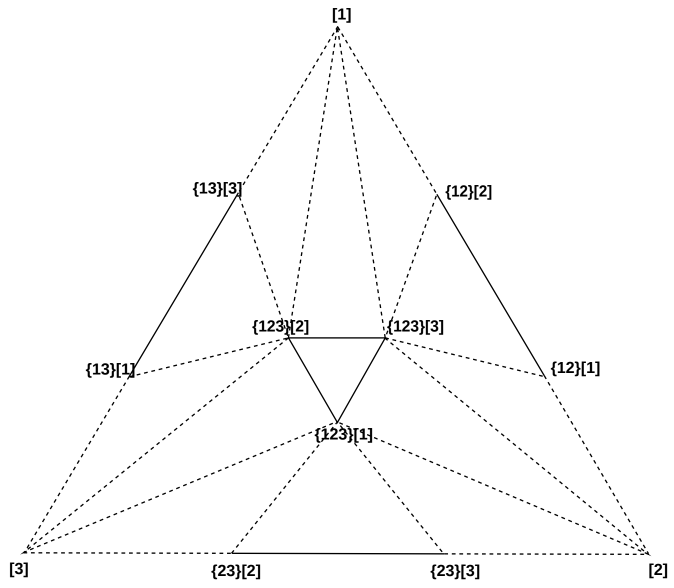

Fig. 5. *The graph* $G_0(\{1,2,3\})$.

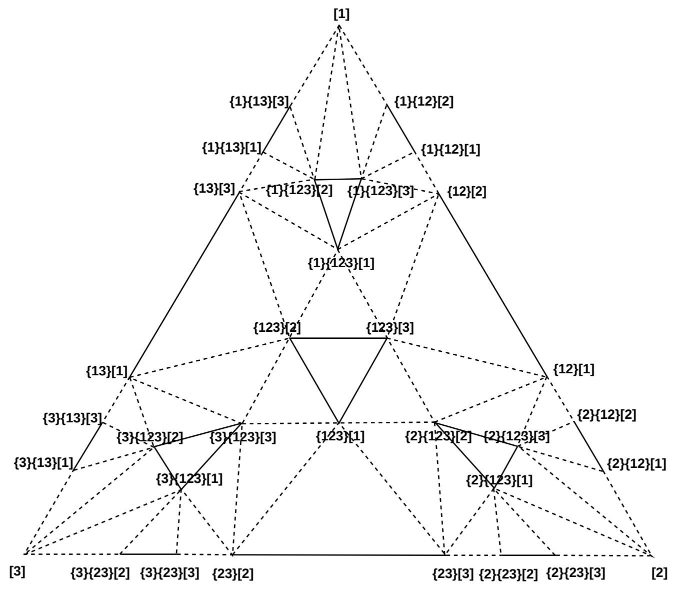

Fig. 6. *The graph* $G_1(\{1,2,3\})$.

(3) The edges in $G_m(P)$ are depicted as either solid or dashed lines. The reason for this distinction will be clear only after we give a precise definition of the graphs.

Let us now give the formal definition of the graphs $G_m(P)$. A schedule σ is *degenerate* if it has a unique nonfaulty processor. Let $V(J)$ denote the set of compressed degenerate schedules σ with $\mathit{Active}(\sigma) \subseteq J$. We say that $\sigma \in V(J)$ is p-degenerate if p is the unique nonfaulty processor, and we denote by $V^p(J)$ the set of p-degenerate schedules. Note that a p-degenerate schedule can be written in the form $\tau[p]$, where τ is a fragment and $[p]$ denotes the schedule all of whose blocks are singleton p blocks.

Recall that the weight of a fragment is the sum of its block sizes. For an arbitrary schedule σ and nonnegative integer m, let $\sigma^{(m)}$ be the maximal prefix of σ having weight less than or equal to m and let $B_m(\sigma)$ be the block of σ following $\sigma^{(m)}$. We say that σ is *m-admissible* if (i) it belongs to $V(P)$ and (ii) all blocks after $B_m(\sigma)$ are singleton p blocks. (This definition is equivalent to the definition of m-admissible given in section 4.) Thus an m-admissible schedule is of the form $\sigma^{(m)}B_m(\sigma)[p]$. Note that if σ is m-admissible, then it is j-admissible for all $j \geq m$. Also, observe that since σ is compressed, $p \in B_m(\sigma)$. We denote by $V^p_m(J)$ the set of m-admissible p-degenerate schedules in $V(J)$ and $V_m(J)$ is the union over p of $V^p_m(J)$. $V_m(P)$ is the vertex set of $G_m(P)$. Note that for $j \geq m$, this implies that the vertex set of $G_m(P)$ is a subset of the vertex set of $G_j(P)$.

We now define the edge set of $G_m(P)$. The edge set is the union of two relations: m-similarity, which is an equivalence relation, and m-shadowing, which is acyclic.

Two m-admissible schedules σ and ϕ in $V_m(P)$ are *m-similar* if $\sigma^{(m)} = \phi^{(m)}$ and $B_m(\phi) = B_m(\sigma)$. This is clearly an equivalence relation.

If $\sigma \in V^p_m(P)$ and $\phi \in V^q_m(P)$, we say that *σ m-shadows ϕ* if there is a set T satisfying $q \in T \subseteq B_m(\sigma) - \{p\}$ such that the compression of the fragment $\sigma^{(m)}T$ is equal to $\phi^{(m)}B_m(\phi)$. In particular this implies that ϕ is equal to the compression of $\sigma^{(m)}T[q]$. The m-shadow relation is acyclic since σ m-shadows ϕ implies that $w(\sigma^{(m)}B_m(\sigma)) > w(\phi^{(m)}B_m(\phi))$.

EXAMPLE 6.1. *Consider the compressed schedules:*

$$\begin{aligned}
\sigma &= \{1,2\}\{2,3\}\{1,2\}[2],\\
\rho &= \{1,2\}\{1,2,3\}[1],\\
\phi &= \{1,2\}\{1,2,3\}[2],\\
\nu &= \{1,2\}\{1,3\}[3],\\
\mu &= \{1,2\}[1].
\end{aligned}$$

Each of the schedules is in $V_m(P)$ for $m \geq 4$, all but σ also belong to $V_2(P)$ and $V_3(P)$, and μ belongs to $V_0(P)$ and $V_1(P)$. σ 4-shadows ρ, and is otherwise unrelated to all other schedules. ρ is m-similar to ϕ for $2 \leq m \leq 4$ and does not m-shadow any of the other schedules for any m. ϕ 2-shadows both μ and ν and 3-shadows ν. ν 2-shadows μ.

We can now define the edge set $E_m(P)$ of the graph $G_m(P)$. The pair $(\sigma, \phi) \in E_m(P)$ if either (i) σ and ϕ are m-similar, (ii) σ m-shadows ϕ, or (iii) ϕ m-shadows σ. In Figures 5 and 6, the solid edges correspond to those that come from m-similarity and the dashed edges arise from m-shadowing. It should be emphasized that while $V_i(P) \subset V_j(P)$ for $i < j$, the edge sets are not nested.

To complete the proof of Lemma 6.4 and hence the proof of the impossibility of wait-free m-set agreement it is now enough to prove two facts, as follows.

LEMMA 6.5.

(1) *The graph G_m is a triangulation graph for $\hat{\Sigma}(P)$.*

(2) *For any clique C in $G_m(P)$, C is contained in a set of the form $\hat{Q}_\tau$ for some fragment τ with $m - n < w(\tau)$.*

$G_m(P)$ trivially satisfies the first condition of triangulation graphs since $[p]$ is m-admissible for all $m \geq 0$.

Table 2
Summary of terminology for cliques and flags.

$\sigma^{(m)}$	the largest prefix of σ with weight $\leq m$
$B_m(\sigma)$	the first block of σ following $\sigma^{(m)}$
σ is m-admissible	σ is compressed and of the form $\sigma^{(m)} B_m(\sigma)[p]$
flag $\mathcal{F}$	a finite family of nested sets including $\emptyset$
$\mathcal{F}$ is a J-flag	the largest set in $\mathcal{F}$ is J
$\mathcal{F}^+(p)$	the unique smallest set in $\mathcal{F}$ containing element p
I-clique	consists of a p-degenerate vertex for each $p \in I$
(I, J)-clique	I-clique contained in $V_m(J)$
$(\tau, \mathcal{F})$ is (m, J)-admissible	τ a fragment, $\mathcal{F}$ a J-flag, $Active(\tau) \subseteq J$, $w(\tau) \leq m$, and $w(\tau F) > m$ for $F \in \mathcal{F} - \{\emptyset\}$
$C_I(\tau, \mathcal{F})$	$\{\sigma^p \vert p \in I\}$ where σ^p is the compression of $\tau \mathcal{F}^+(p)[p]$
$(\tau, \mathcal{F})$ is a (m, J)-flag representation of I-clique C	$C = C_I(\tau, \mathcal{F})$ and $(\tau, \mathcal{F})$ is (m, J)-admissible

The hard part is proving that $G_m(P)$ satisfies the second condition of triangulation graphs. The key is to obtain a complete characterization of the cliques of $G_m(J)$. Along the way we will also prove the second part of Lemma 6.5 (which will follow from Lemma 6.7). We advise the reader to refer frequently to Figure 6 to help in understanding what follows.

Alas, we need some more definitions. (Table 2 provides a summary of some of the key definitions.) Let $J \subseteq P$. A *flag* is a finite family $\mathcal{F}$ of sets that are totally ordered by inclusion and includes the emptyset. The unique maximal set of $\mathcal{F}$ is denoted $\mathcal{F}^M$. If $J = \mathcal{F}^M$ we say that $\mathcal{F}$ is a J-flag. For $p \in J$, $\mathcal{F}^+(p)$ denotes the unique smallest set containing p, and $\mathcal{F}^-(p)$ denotes the unique largest set not containing p.

By the definition of the edge set, any clique C consists of schedules that are p-degenerate for distinct p. If $I \subseteq P$ and C is a clique that consists of one p-degenerate schedule for each $p \in I$, then C is a called an *I-clique*. We typically denote such a clique by $\{\sigma(p) \vert p \in I\}$, where $\sigma(p)$ denotes a p-degenerate schedule.[1] As noted when defining m-admissibility, each $\sigma(p)$ is equal to $\sigma(p)^{(m)} B_m(\sigma(p))[p]$. If C is an I-clique all of whose vertices belong to $V_m(J)$, we say that C is an (I, J)-clique.

Let $C = \{\sigma(p) \vert p \in I\}$ be an (I, J)-clique. A processor $q \in I$ is said to be *dominant* in C if it maximizes $w(\sigma(p)^{(m)} B_m(\sigma(p)))$ among all $p \in I$. The following lemma provides a simple combinatorial representation for (I, J)-cliques.

Lemma 6.6. *Let $C = \{\sigma(p) \vert p \in I\}$ be an I-clique in $G_m(J)$. Let q be a dominant processor and $\tau = \sigma(q)^{(m)}$. Then*

(1) *for each $p \in I$, there is a subset F_p of J containing p such that $\sigma(p)$ is equal to the compression of $\tau F_p[p]$;*

[1] A remark on notation: The (p) in $\sigma(p)$ is simply an index, and so $\sigma(p)$ in this case stands for a p-degenerate schedule. This should not be confused with the notation $\sigma[p]$, which denotes a schedule consisting of a *fragment* σ followed by an infinite sequence of $\{p\}$ blocks.

(2) *the family of sets* $\mathcal{F} = \{F_p | p \in I\} \cup \{\emptyset, J\}$ *is a* J*-flag;*

(3) *for each* $p \in I$, $F_p = \mathcal{F}^+(p)$, *and* $w(\tau F_p) > m$.

Proof. Since q is dominant in C, then for each $p \in I - \{q\}$, $\sigma(q)$ either is m-similar to or m-shadows $\sigma(p)$, which implies that for $p \neq q$, $\sigma(p)$ is the compression of a schedule of the form $\tau F_p[p]$, where $p \in F_p \subset J$. This proves the first part. For the second part, let $p, r \in I$. If $\sigma(p)$ is m-similar to $\sigma(r)$, then the condition that the compression of τF_p is equal to the compression of τF_r implies $F_p = F_r$. Otherwise $\sigma(p)$ m-shadows $\sigma(r)$, which means that $\sigma(r)^{(m)} B_m(\sigma(r))$ can be written as the compression of $\sigma(p)^{(m)}B$ for some $B \subseteq B_m(\sigma(p)) - \{p\}$. Since τF_r and $\sigma(p)^{(m)}B$ have the same compression and τF_p and $\sigma(p)^{(m)} B_m(\sigma(p))$ have the same compression (by comparing the total number of steps taken by each processor in each of these fragments), we conclude that $F_r \subseteq F_p - \{p\}$. From this it follows that $\mathcal{F} = \{F_p | p \in I\} \cup \{\emptyset, J\}$ is a J-flag and for each $p \in I$, $F_p = \mathcal{F}^+(p)$, completing the second part. Finally, the m-admissibility of the vertices in C implies that $w(\tau F) \geq m$ for all nonempty $F \in \mathcal{F}^+(p)$. □

This motivates the following definitions. An (m, J)*-admissible pair* is a pair $(\tau, \mathcal{F})$, where $\tau \in \Phi(J)$ (recall that $\Phi(J)$ is the set of fragments whose blocks are subsets of J) and $\mathcal{F}$ is a J-flag such that $w(\tau) \leq m$ and $w(\tau F) > m$ for all nonempty $F \in \mathcal{F}$. For such a pair, we define $C_I(\tau, \mathcal{F})$ to be the set $\{\sigma(p) | p \in I\}$ of schedules where $\sigma(p)$ is the compression of the schedule $\tau \mathcal{F}^+(p)[p]$. Note that since $p \in \mathcal{F}^+(p)$ this is equal to the schedule obtained by compressing the fragment $\tau \mathcal{F}^+(p)$ and appending $[p]$.

From Lemma 6.6 we have that every (I, J)-clique is of the form $C_I(\tau, \mathcal{F})$ for some (m, J)-admissible pair. In fact, the converse of this statement also holds and we state them together in the following lemma.

LEMMA 6.7.

(1) *For* $I \subseteq J \subseteq P$, *each* (I, J) *clique of* $G_m(P)$ *has the form* $C_I(\tau, \mathcal{F})$ *for some* (m, J) *admissible pair* $(\tau, \mathcal{F})$.

(2) *If* $(\tau, \mathcal{F})$ *is an* (m, J)*-admissible pair and* $I \subseteq J$, *then* $C_I(\tau, \mathcal{F})$ *is an* (I, J)*-clique.*

Proof. The first part follows from Lemma 6.6. To prove the second part, suppose that $(\tau, \mathcal{F})$ is m-admissible. We first must show that each schedule in $C_I(\tau, \mathcal{F}) = \{\sigma(p) | p \in I\}$ is a vertex of $V_m(J)$. Proposition 6.8 follows easily from the definition of compression.

PROPOSITION 6.8. *If* $(\tau, \mathcal{F})$ *is* (m, J) *admissible,* $F = \mathcal{F}^+(p)$, *and* $p \in J$, *then the compression of* $\tau F[p]$ *can be written in the form* $\mu B[p]$, *where* $w(\mu) \leq w(\tau)$ *and* $w(\mu B) = w(\tau F)$. *Thus* $\sigma(p)$ *is* m*-admissible and so belongs to* $V_m(J)$.

Next we must show that for $p, q \in I$, $\sigma(p)$ and $\sigma(q)$ are adjacent in $G_m(P)$, i.e., either they are m-similar or one m-shadows the other. Let $A = \mathcal{F}^+(p)$ and $B = \mathcal{F}^+(q)$. Thus $\sigma(p)$ is the compression of $\tau A[p]$ and $\sigma(q)$ is the compression of $\tau B[q]$, and also $w(\tau A)$ and $w(\tau B)$ are both greater than m. If $A = B$, then $\tau A[p]$ and $\tau A[q]$ have exactly the same hidden blocks, and so $\sigma(p)$ and $\sigma(q)$ are clearly m-similar. If $A \neq B$, then without loss of generality $A \subset B$. Furthermore, $p \in A$ and $q \in B - A$, since $A = \mathcal{F}^+(p)$ and $B = \mathcal{F}^+(q)$. Let $\sigma(q) = \mu B'[q]$ be the compression of $\tau B[q]$. Then $B' = B \cup C$, where C is the union of some number of blocks (possibly 0) at the end of τ. Also, $w(\mu B') = w(\tau B)$. Every hidden block of $\tau B[q]$ is also hidden in $\tau A[p]$, and so $\tau A[q]$ can be partially compressed to $\mu A'[p]$, where $A' = A \cup C$. This implies that $p \in A' \subseteq B' - \{q\}$, and so $\sigma(q)$ m-shadows $\sigma(p)$. □

This lemma provides a nice combinatorial characterization of cliques. If C is an I-clique and $C = C_I(\tau, \mathcal{F})$, where $(\tau, \mathcal{F})$ is an (m, J)-admissible pair, then $(\tau, \mathcal{F})$

is called an (m, J)-*flag representation* of C. This representation is in general not unique. Lemma 6.6 gave such a representation for each I-clique C in $V_m(J)$. This construction has the properties that τ is equal to the prefix $\sigma(q)^{(m)}$ for some (in fact, any) dominant processor q and that $\mathcal{F}$ consists exactly of those sets F_p for $p \in I$, where F_p is the unique set such that $\sigma(p)$ is the compression of $\tau F_p[p]$. In particular, $\mathcal{F}$ is the unique minimal J-flag for which $(\tau, \mathcal{F})$ is a (k, J)-flag representation of C. We call this representation the (m, J)-*canonical* representation of C. It is clear that the (m, J)-canonical representation of the I-clique C is unique.

EXAMPLE 6.2. *Let* $m = 2$ *and* $P = \{1, 2, 3, 4, 5\}$. *The set consisting of* $\{1, 2, 3\}[3]$, $\{1, 2\}\{1, 3\}[1]$, *and* $\{1, 2\}\{1, 5, 3, 4\}[4]$ *has four* $(2, P)$-*flag representations:* $(\tau, \mathcal{F})$, $(\mu, \mathcal{F})$, $(\tau, \mathcal{G})$, *and* $(\mu, \mathcal{G})$, *where* $\mathcal{F} = \{\emptyset, \{3\}, \{1, 3\}, \{1, 3, 4, 5\}, \{1, 2, 3, 4, 5\}\}$, $\mathcal{G} = \{\emptyset, \{3\}, \{1, 3\}, \{1, 3, 5\}, \{1, 3, 4, 5\}, \{1, 2, 3, 4, 5\}\}$, $\tau = \{1, 2\}$, *and* $\mu = \{2\}\{1\}$. *The canonical representation is* $(\tau, \mathcal{F})$.

We can now prove the second part of Lemma 6.5. If C is any I-clique, let $(\tau, \mathcal{F})$ be an (m, P)-flag representation of C. The (m, P)-admissibility of $(\tau, \mathcal{F})$ implies that $w(\tau) > m - n$. Every schedule in C is the compression of a schedule of the form $\tau F[p]$ for some $F \in \mathcal{F}$ and $p \in I$ and is thus a quasi extension of τ. Thus $\sigma \in \hat{Q}_\tau$ as required.

It remains only to check that $G_m(P)$ satisfies the third condition of the definition of triangulation graphs. We will prove the following.

LEMMA 6.9. *Let* $I \subseteq J \subseteq P$ *and let* C *be an* I-*clique in* $G_m(J)$. *Then the number of* (J, J)-*cliques that contain* C *is equal to the number of distinct* J-*flag representations of* C.

In light of this lemma, the two parts of the second property of triangulation graphs follow, respectively, from the two parts of the following lemma.

LEMMA 6.10. *Let* $J \subseteq P$, $p \in J$, *and* $I = J - \{p\}$. *Let* C *be an* I-*clique that is contained in* $V_m(J)$.

(1) *If* C *is contained in* $V_m(I)$, *then* C *has a unique* J-*flag representation.*

(2) *If* C *is not contained in* $V_m(I)$, *then* C *has exactly two* J-*flag representations.*

Thus, all that remains is to prove Lemmas 6.9 and 6.10, which we now do. We first make some preliminary observations about flags and flag representations.

PROPOSITION 6.11. *Let* $\mathcal{F}$ *and* $\mathcal{H}$ *be* J-*flags. If* $\mathcal{H}^+(r) = \mathcal{F}^+(r)$ *for every* $r \in J$, *then* $\mathcal{H} = \mathcal{F}$.

Proof. Suppose that $\mathcal{H} \neq \mathcal{F}$ are J-flags and let A be a set that is in one but not the other, say, it is in $\mathcal{H}$ but not in $\mathcal{F}$. Then there is an element r such that $\mathcal{H}^+(r) = A$, and so $\mathcal{H}^+(r) \neq \mathcal{F}^+(r)$. $\square$

LEMMA 6.12. *Let* $C = \{\sigma(p) | p \in I\}$ *be an* (I, J)-*clique and let* q *be a dominant processor. Let* $(\tau, \mathcal{F})$ *be the canonical* (m, J)-*flag representation of* C. *Let* $(\mu, \mathcal{H})$ *be an arbitrary* (m, J)-*flag representation of* C. *Then*

(1) $\sigma(q) = \tau\mathcal{F}^+(q)[q]$.

(2) μ *can be written in the form* $\nu\lambda$, *where* ν *is a fragment such that the compression of* $\nu\mathcal{F}^+(q)$ *is* $\tau\mathcal{F}^+(q)$ *and* λ *is a possibly empty fragment consisting of pairwise disjoint blocks.*

(3) *Let* B *denote the union of the blocks of* λ. *Then* $B \subseteq J - I$ *and* $\mathcal{H}^+(p) = \mathcal{F}^+(p) - B$ *for each* $p \in I$.

(4) $I \subseteq \mathcal{H}^+(q) \subseteq \mathcal{F}^+(q) \subseteq J$.

Proof. The first part follows immediately from the definition of the canonical (m, J)-flag representation. For the second part, note that $\mu\mathcal{H}^+(q)[q]$ must compress to $\sigma(q) = \tau\mathcal{F}^+(q)[q]$, which means that $\mu\mathcal{H}^+(q)$ must compress to $\tau\mathcal{F}^+(q)$. Let ν be the portion of μ that compresses to τ and let λ be the portion of μ that is merged with $\mathcal{H}^+(q)$ to form $\mathcal{F}^+(q)$. Then $\mu = \nu\lambda$, and λ must consist of disjoint blocks. For the third part, if $p \in I$, then $\tau\mathcal{F}^+(p)$ must have the same compression as $\nu\lambda\mathcal{H}^+(p)$, which means that $\lambda\mathcal{H}^+(p)$ must compress to $\mathcal{F}^+(p)$, so $\mathcal{H}^+(p) = \mathcal{F}^+(p) - B$. Since $p \in \mathcal{H}^+(p)$, we must have $p \notin B$, so $B \subset J - I$. For the fourth part, $\mathcal{H}^+(q)$ contains $\mathcal{H}^+(p)$ for all $p \in I$, so $I \subseteq \mathcal{H}^+(q)$. ☐

LEMMA 6.13. *Each (J, J)-clique has a unique (m, J)-flag representation.*

Proof. Let $C = \{\sigma(p) : p \in J\}$ be a J-clique contained in $V_m(J)$ and let $(\tau, \mathcal{F})$ be its J-canonical representation. Suppose that $(\mu, \mathcal{H})$ is any other J-flag representation. Since $\mathcal{H}$ is a J-flag, there must be $q \in J$ such that $\mathcal{H}^+(q) = J$. Then $\mu J[q]$ is compressed and must be equal to $\sigma(q)$. Furthermore q is dominant in C, so by the definition of the canonical representation $\tau = \mu$.

By Proposition 6.11, if $\mathcal{G} \neq \mathcal{F}$, then there exists r such that $\mathcal{F}^+(r) \neq \mathcal{G}^+(r)$. But then the compression of $\tau\mathcal{F}^+(r)[r]$ cannot be equal to the compression of $\tau\mathcal{G}^+(r)[r]$. Therefore $\mathcal{F} = \mathcal{G}$ and the (m, J)-flag representation is unique. ☐

Now we are ready to prove Lemmas 6.9 and 6.10, to finish the proof of the main theorem.

Proof of Lemma 6.9. Let C be an (I, J)-clique, and let $C^1, C^2, \ldots, C^r$ be the distinct (J, J)-cliques that contain C. By Lemma 6.13, each of the C^i has a unique (m, J)-flag representation, $(\tau_i, \mathcal{F}_i)$, and by the definition of the representation, $(\tau_i, \mathcal{F}_i)$ is also an (m, J)-flag representation of C, i.e., $C = C_I(\tau_i, \mathcal{F}_i)$. Also, these are the only (m, J)-flag representations of C, since any such representation for C is also an (m, J)-flag representation of some J-clique containing C. ☐

Proof of Lemma 6.10. Let $C = \{\sigma(r) | r \in I\}$ be an $I = J - \{p\}$-clique and let $(\mu, \mathcal{H})$ denote an arbitrary (m, J)-flag representation of C. Let q denote a dominant processor of C. From Lemma 6.12, $I \subseteq \mathcal{H}^+(q) \subseteq J$.

To prove the first part of the lemma, suppose that C is contained in $V_m(I)$. Then $\mathcal{H}^+(q) \neq J$ so $\mathcal{H}^+(q) = I$. Let $\mathcal{G} = \mathcal{H} - \{J\}$. Then $(\mu, \mathcal{G})$ is a (m, I)-flag representation of C. But, by Lemma 6.13, there is only one such representation, so this implies that $(\mu, \mathcal{H})$ must be the unique (m, J)-flag representation.

We proceed to the second part of the lemma. Let $(\tau, \mathcal{F})$ be the canonical (m, J)-flag representation of C and let q be a dominant processor of C. We want to show that there is exactly one other representation. Now, by Lemma 6.12, either $\mathcal{F}^+(q) = J$ or $\mathcal{F}^+(q) = I$. We proceed by analyzing these two cases separately.

Case I. $\mathcal{F}^+(q) = I$. First we construct another (m, J)-flag representation. Let S be the last block of τ that contains p. There is such a block since, by hypothesis, $C \not\subset V_m(J - \{p\})$. If $S = \{p\}$, then $\tau\mathcal{F}^+(q)$ would not be compressed, contradicting the definition of the canonical representation. So $S \neq \{p\}$. Let ψ be the sequence obtained by replacing the block S by $\{p\}$ followed by $S - \{p\}$. Then $(\psi, \mathcal{F})$ is also an (m, J)-representation of C.

Now we show that this is the only other (m, J)-flag representation of C. Let $(\mu, \mathcal{H})$ be an arbitrary (m, J)-flag representation of C. Then, by Lemma 6.12, $I \subseteq \mathcal{H}^+(q) \subseteq \mathcal{F}^+(q)$ implies that $\mathcal{H}^+(q) = \mathcal{F}^+(q) = I$. Defining ν, λ, B as in Lemma 6.12 we must have $B = \emptyset$ and λ is the empty string. Then $\mathcal{H}^+(r) = \mathcal{F}^+(r)$ for all $r \in I$, and also $\mathcal{H}^+(p) = \mathcal{F}^+(p) = J$, so Proposition 6.11 implies $\mathcal{H} = \mathcal{F}$. Finally, $\mu I[q]$ must compress to $\tau I[q]$. Then either $\mu I[q]$ is already compressed (and $\mu = \tau$) or μ contains a hidden block. But a block in $\mu I[q]$ can be hidden only if it is disjoint from I, i.e., it is a singleton p block, and it must be the last appearance of p. This means that μ is equal to ψ above and so $(\mu, \mathcal{H}) = (\psi, \mathcal{F})$.

Case II. $\mathcal{F}^+(q) = J$. Then $J - \{p\}$ is not in $\mathcal{F}$. Again, we must construct another (m, J)-flag representation of C and show that this is the only other one. First note the following.

PROPOSITION 6.14. *If* $(\mu, \mathcal{H})$ *is any* (m, J)*-representation of* C*, then either* $\mu = \tau$ *or* $\mu = \tau\{p\}$*.*

To see this, note that by Lemma 6.12, either $\mathcal{H}^+(q) = J$ or $\mathcal{H}^+(q) = I$. Also $\sigma(q) = \tau J[q]$ is the compression of $\mu\mathcal{H}^+(q)[q]$. Thus if $\mathcal{H}^+(q) = J$, then $\mu = \tau$, and if $\mathcal{H}^+(q) = I$, then μ must be $\tau\{p\}$.

Now we proceed with constructing an alternative representation of C. Let $A = \mathcal{F}^-(p) \cup \{p\}$. Note that $A \notin \mathcal{F}$ since in the canonical representation, every set in $\mathcal{F}$ is of the form $\mathcal{F}^+(r)$ for some $r \neq p$. Let $\mathcal{G} = \mathcal{F} \cup \{A\}$; then $\mathcal{G}^+(r) = \mathcal{F}^+(r)$ for each $r \neq p$. Thus $(\tau, \mathcal{G})$ would seem to be another (m, J)-representation of C. This is indeed true, except in one case. The problem is that the definition of (m, J) representation requires that $(\tau, \mathcal{G}^+(s))$ be m-admissible for all $s \in J$, which means that $w(\tau) \leq m < w(\tau\mathcal{G}^+(s))$. Now, this is true for all $s \neq p$, since it was true for $(\tau, \mathcal{F})$. However, it is possible that $w(\tau\mathcal{G}^+(p)) \leq m$. This happens if and only if $w(\tau) < m$ and $\mathcal{F}^-(p) = \emptyset$ so that $A = \{p\}$. So we consider two subcases, depending on whether this happens.

Subcase II*a*: $(\tau, \mathcal{G})$ *is* (m, J)*-admissible.* As we have just discussed, this means that either $\mathcal{F}^-(p) \neq \emptyset$ or $\mathcal{F}^-(p) = \emptyset$ and $w(\tau) = m$. Then $(\tau, \mathcal{G})$ is a second (m, J)-representation of $(\tau, \mathcal{F})$; we need to prove that there are no others.

If $(\mu, \mathcal{H})$ is an (m, J)-flag representation of C, then let ν, λ, B be as in Lemma 6.12. Then $B = \{p\}$ or $B = \emptyset$. We claim $B = \emptyset$. If $B = \{p\}$, then $w(\mu) = w(\tau) + 1$ and so the (m, J)-admissibility of $(\mu, \mathcal{H})$ requires $w(\tau) < m$ and so $\mathcal{F}^-(p) \neq \emptyset$. Let $s \in \mathcal{F}^-(p)$; then $\mathcal{F}^+(s) \subseteq \mathcal{F}^-(p)$. But $\tau\{p\}\mathcal{H}^+(s)$ must compress to $\tau\mathcal{F}^+(s)$, which is impossible since $p \notin \mathcal{F}^+(s)$.

Thus $B = \emptyset$, and so $\mathcal{H}^+(q) = \mathcal{F}^+(q) = J$, which means by Proposition 6.14 that $\mu = \tau$. We now need to show that $\mathcal{H} = \mathcal{F}$ or $\mathcal{H} = \mathcal{G}$, i.e., $\mathcal{F} \subseteq \mathcal{H} \subseteq \mathcal{G}$. $\mathcal{H}$ must contain $\mathcal{F}$, since $\mathcal{H}^+(r) = \mathcal{F}^+(r)$ for all $r \in I$ and $\mathcal{F}$ was defined only to contain $\emptyset$, J, and the sets $\mathcal{F}^+(r)$ for $r \in I$. If $\mathcal{H}$ is not a subset of $\mathcal{G}$ let D be the minimal member of $\mathcal{H} - \mathcal{G}$ and let D_0 be the largest subset of D in $\mathcal{G}$. Choose $x \in D - D_0$ and note that $x \neq p$, since $\mathcal{F}^-(p)$ and A are both in $\mathcal{G}$. Then $\mathcal{H}^+(x) = D \neq \mathcal{G}^+(x)$, which contradicts that $(\tau, \mathcal{H})$ and $(\tau, \mathcal{G})$ both are (m, J) representations of C.

Subcase II*b*: $(\tau, \mathcal{G})$ *is not* (m, J)*-admissible.* This means that $\mathcal{F}^-(p) = \emptyset$ and $w(\tau) < m$. Thus $(\tau\{p\}, \mathcal{E})$ is another (m, J)-flag representation, where $\mathcal{E}$ is obtained from $\mathcal{F}$ by deleting p from each set in $\mathcal{F}$ and adding the set J.

Suppose that $(\mu, \mathcal{H})$ is any (m, J)-flag representation of C; we want to show that $(\mu, \mathcal{H}) = (\tau, \mathcal{F})$ or $(\mu, \mathcal{H}) = (\tau\{p\}, \mathcal{E})$. Let ν, λ, B be as in Lemma 6.12. Once again we have either $\mu = \tau$ and $B = \emptyset$ or $\mu = \tau\{p\}$ and $B = \{p\}$.

In the case $\mu = \tau$, we also have that $\mathcal{F}^+(r) = \mathcal{H}^+(r)$ for all $r \neq p$. We claim that $\mathcal{F}^+(p) = \mathcal{H}^+(p)$, which would imply that $\mathcal{F} = \mathcal{H}$. To see the claim, observe that $\mathcal{F}^+(p)$ is the smallest nonempty set of $\mathcal{F}$, and it belongs to $\mathcal{H}$ since $\mathcal{F} \subseteq \mathcal{H}$. Thus it suffices to show that $\mathcal{H}$ contains no smaller set. $\mathcal{H}$ cannot contain $\{p\}$ since $w(\tau p) \leq m$ would violate m-admissibility of $(\tau, \mathcal{H})$. $\mathcal{H}$ cannot contain any other subset of $\mathcal{H}$ because $\mathcal{H}^+(r) = \mathcal{F}^+(r)$ for all $r \neq p$. Thus $\mathcal{F} = \mathcal{H}$, and $(\mu, \mathcal{H}) = (\tau, \mathcal{F})$.

In the case that $\mu = \tau\{p\}$, for any $r \neq q$ we must have that $\tau\mathcal{F}^+(r)$ and $\tau\{p\}\mathcal{H}^+(r)$ compress to the same vertex of C. Then for every $r \neq p$, $\mathcal{H}^+(r) = \mathcal{F}^+(r) - \{p\} = \mathcal{E}^+(r)$. We also have $\mathcal{H}^+(p) = \mathcal{E}^+(p) = J$ since $J - \{p\}$ is a member of both of them. From Proposition 6.11, $\mathcal{H} = \mathcal{E}$, and thus $(\mu, \mathcal{H}) = (\tau\{p\}, \mathcal{E})$. $\square$

This completes the proof of Lemma 6.10 which, as explained, completes the proof that G_m is a triangulation graph and thus completes the proof of the main theorem.

Appendix. The topology of knowable sets. In this appendix, we look more closely at the structure of the collection of knowable sets, $\mathcal{K} = \{K | K \subseteq \hat{\Sigma} \text{ is a knowable set}\}$. In particular, we prove that $\mathcal{K}$ defines a compact Hausdorff topological space on $\hat{\Sigma}(P)$. Along the way we give two characterizations of this space: (i) we give a nice basis for $\mathcal{K}$, and (ii) we show that $\mathcal{K}$ is the quotient of the Cantor topology on $\Sigma(P)$ with respect to the compression map.

Notions from point set topology are briefly reviewed as needed. For more details, see [24].

A.1. $\mathcal{K}$ is a Hausdorff topology. Recall that formally, a topological space on a set X is a collection $\mathcal{U}$ of subsets of X that includes $\emptyset$ and X and is closed under arbitrary union and finite intersection. The members of $\mathcal{U}$ are the *open sets* of the topology, and complements of members of $\mathcal{U}$ are the *closed sets* of the topology.

THEOREM A.1. *$\mathcal{K}$ is a topology on the set $\hat{\Sigma}$.*

Proof. We observed in section 2.8 that $\emptyset$ and $\hat{\Sigma}$ are both in $\mathcal{K}$. We need to show that the union of an arbitrary collection of knowable sets is knowable and the intersection of a finite collection of knowable sets is knowable.

Let $\{K^i\}_{i\in\Lambda}$ be an arbitrary collection of knowable sets. We will show that $K^{\cup} = \cup_{i\in\Lambda}K^i$ is a knowable set. Let (Π^i, d^i) be an acceptor for K_i and V^i be the set of values that can be written to the registers by this protocol. We exhibit an acceptor $(\Pi^{\cup}, d)$ for $K^{\cup}$. Informally the protocol simulates all the protocols in the above collection in parallel and a processor writes the accept value d when it sees that at least one of accept values d^i has been written.

More formally protocol $\Pi^{\cup}$ is defined as follows. The set of processor states S consists of the (possibly infinite) product set $\prod_{i\in\Lambda}(S^i)$ together with a special state $s^\star$. Thus a state value s is either $s^\star$ or a tuple $(s^i | i \in \Lambda)$, where $s^i \in S^i$. (A state value of $s^\star$ will mean that a processor is ready to write the accept value d.) The initial state e_p is the tuple $(e^i_p | i \in \Lambda)$. The set of write values V is the product set $\prod_{i\in\Lambda} V^i$ together with the accept value d. If no processor has ever written d, then the contents of shared memory $\vec{l}$ can be viewed as a tuple $(\vec{l}^{\,i} : i \in \Lambda)$, where $\vec{l}^{\,i}$ corresponds to the run of Π^i. The write map w is defined as $w(s) = d$ if $s = s^\star$ and otherwise $w(s)$ is the tuple $(w^i(s^i) : i \in \Lambda)$. The state update map u is defined as $u(s, \vec{l}) = s^\star$ if d appears in $\vec{l}$ or there is at least one $i \in \Lambda$ such that d^i appears in $\vec{l}^{\,i}$; otherwise $u(s, \vec{l}) = (u^i(s^i, \vec{l}^{\,i}) : i \in \Lambda)$. It is easy to see that the accept value d is written by $\Pi^{\cup}$ on schedule σ if and only if there is an $i \in \Lambda$ such that d^i is written by Π^i on σ. Thus the set $K^{\cup}$ is knowable.

Next we want to show that the intersection of a finite collection of knowable sets is knowable. As above, let $\{K^i\}_{i\in\Lambda}$ be a collection of knowable sets and (Π, d^i) be acceptors. We define a protocol $\Pi^{\cap}$ by a minor modification of $\Pi^{\cup}$. The only difference is in the state update map u. The condition for a processor to enter state $s^\star$ is either that some processor has written d or *for every* $i \in \Lambda$, d_i appears in $\vec{l}^{\,i}$.

It is easy to see that if the accept value d is written by $\Pi^{\cap}$ on schedule σ, then for all $i \in \Lambda$, d^i is written by Π^i on σ and thus $K(\Pi^{\cap}, d)$ is a subset of $K^{\cap}$. The reverse containment holds if Λ is finite (although it need not hold if Λ is infinite; see below). For $\sigma \in K^{\cap}$ let j^i be the index of the block of σ in which d^i is first written and let j be the maximum of the j^i. Then any processor taking a step subsequent to block j will see all of the decision values d^i and thus move to state $s^\star$. At least one such processor will take another step and will thus write d. □

Observe that this final argument fails when the collection $\{K^i\}$ is infinite because the index j may not be defined. As an example, let K^i be the set of compressed schedules where processor p takes at least i steps, and let i range over the positive integers.

Next, recall that a topological space $(X, \mathcal{U})$ is a *Hausdorff space* if for any two distinct points $x, y \in X$ there are disjoint open sets U_x and U_y with $x \in U_x$ and $y \in U_y$.

LEMMA A.2. *$(\Sigma, \mathcal{K})$ satisfies the Hausdorff condition.*

Proof. In this case the Hausdorff condition means that if σ and ϕ are distinct compressed schedules, then there is a pair of acceptors (Π, d) and (Φ, d') such that Π accepts σ and Φ accepts ϕ and no schedule is accepted by both. We will take Π and Φ to be a minor modification of the counting protocol: when processor p writes for the ith time, it writes (T, p), where T is its current tally vector (instead of just T).

Now we need to choose the accepting values for Φ and Π, which will be of the form (T, p). Since σ and ϕ are distinct compressed schedules, Theorem 2.12 implies that their tally records must be different. Apply Lemma 2.5. Under the first conclusion of this lemma, there is a processor p and a positive integer i such that p takes at least i steps in both schedules and tally vectors $Count_{p,i}(\phi)$ and $Count_{p,i}(\phi)$ are different. Thus take $d = (Count_{p,i}(\sigma), p)$ and $d' = (Count_{p,i}(\phi), p)$. Note that for any schedule ρ, at most one of d and d' can appear in its public tally since both can appear only in the list of processor p, and that list can contain only one vector that has an $i - 1$ in position p, while both of these vectors have an $i - 1$ in that position.

Under the second conclusion of Lemma 2.5 there is a pair of crossing vectors v and w such that v appears in the public tally corresponding to σ and w appears in the public tally corresponding to ϕ. Let q be a processor that writes v during σ and r be a processor that writes w during ϕ. Let $d = (v, q)$ and $d' = (w, r)$; the fact that v and w are crossing ensures that no schedule can be accepted by both protocols. □

A.2. A basis for $\mathcal{K}$. A basis for a topology $(X, \mathcal{U})$ is a collection $\mathcal{B}$ of open sets with the property that every open set is a union of members of $\mathcal{B}$. Equivalently, $\mathcal{B}$ is a basis if for any point x and open set U containing x, there is a $B \in \mathcal{B}$ such that $x \in B \subseteq U$.

Recall that for a fragment τ, the set Q_τ is the set of schedules that are quasi extensions of τ, and $\hat{Q}_\tau = Q_\tau \cap \hat{\Sigma}(P)$. Then Example 2.21 and Proposition 2.25 imply the following.

THEOREM A.3. *The set $\{\hat{Q}_\tau : \tau$ a fragment$\}$ is a basis for the knowable set topology.*

A.3. Representing $\mathcal{K}$ as a quotient topology. Let $(X, \mathcal{U})$ be a topological space and $f : X \longrightarrow Y$ be any surjective map. It is easily checked that the collection $\mathcal{U}/f = \{W \subseteq Y : f^{-1}(W) \in \mathcal{U}\}$ defines a topology on Y, called the *quotient* of $(X, \mathcal{U})$ by f. Here we represent the knowable set topology on $\hat{\Sigma}(P)$ as a quotient of a simple topology on $\Sigma(P)$.

For a fragment τ, let B_τ be the set of all schedules that have τ as a prefix. Let $(\Sigma(P), \mathcal{S})$ be the topology whose open sets are unions of sets B_τ. (This is called the *Cantor topology* on $\Sigma(P)$.)

Consider the map $f : \Sigma \longrightarrow \hat{\Sigma}$, where $f(\sigma) = \hat{\sigma}$. In this case, the quotient topology $\mathcal{R} = \mathcal{S}/f$ is defined on $\hat{\Sigma}$ and is given by $\mathcal{R} = \{U \subset \hat{\Sigma} | f^{-1}(U) \in \mathcal{S}\}$.

THEOREM A.4. *$\mathcal{K}$ and $\mathcal{R}$ define the same topology on $\hat{\Sigma}$.*

Proof. (1) $\mathcal{K} \subseteq \mathcal{R}$. Since $\{\hat{Q}_\tau | \tau \in \Phi(P)\}$ is a basis for $\mathcal{K}$, it suffices to show that for each fragment τ, $\hat{Q}_\tau$ is in $\mathcal{R}$, i.e., that $f^{-1}(\hat{Q}_\tau)$ is open in the Cantor topology. For this, it suffices to show that if $\sigma \in f^{-1}(\hat{Q}_\tau)$, then there is a fragment μ so that $\sigma \in B_\mu \subseteq f^{-1}(\hat{Q}_\tau)$. Since σ is in $f^{-1}(\hat{Q}_\tau)$ it is a quasi extension of τ, which by Theorem 2.16 means that its public tally is an extension of the public tally of τ. Since τ is finite, there is a prefix μ of σ such that the public tally of μ extends the public tally of τ. This implies that any schedule in B_μ is a quasi extension of τ, i.e., $B_\mu \subseteq f^{-1}(\hat{Q}_\tau)$.

(2) $\mathcal{R} \subseteq \mathcal{K}$. Let $S \subset \hat{\Sigma}$ be a set such that $f^{-1}(S)$ is an open set in the Cantor topology. We will prove that S is a knowable set. Let $\sigma \in S$ be arbitrary. It suffices to show that there is a knowable set K containing σ such that $K \subset S$.

Let $f^{-1}(\sigma) = \{\sigma^1, \ldots, \sigma^k\}$, which is a finite set by Proposition 2.10. For each $\sigma^i \in f^{-1}(\sigma)$ let B_{ρ_i} be a basis set in the Cantor topology such that $\sigma^i \in B_{\rho_i} \subset f^{-1}(S)$.

Choose a prefix ρ of σ that has greater weight (total number of steps) than each of the ρ_i and also contains all of the steps of the faulty processors of σ. We write $\sigma = \rho\chi$, where Active(χ) is equal to N, the set of nonfaulty processors of σ. Hence, ρN is compressed since $\rho\chi$ is. By Lemma 2.15, $\sigma \in \hat{Q}_{\rho N}$. We claim that $\hat{Q}_{\rho N} \subseteq S$, which will complete the proof.

Let γ be an arbitrary schedule in $\hat{Q}_{\rho N}$; we show that $\gamma \in S$. For this it suffices to find a j such that $\gamma \in B_{\rho_j}$, i.e., ρ_j is a prefix of γ. By Theorem 2.16 there is a prefix τ of γ, a schedule ϕ, and a subset U of Active(ϕ) such that $\gamma = \tau\phi$ and $\widehat{\tau U} = \rho N$. Since $\widehat{\tau U} = \rho N$ we must have $U \subseteq N$ and $\tau = \beta\zeta$, where ζ consists of some sequence of disjoint blocks whose union is $U - N$ and the last block of β has nonempty intersection with N. Thus $\widehat{\beta N} = \widehat{\tau U} = \rho N$.

We now claim that $\widehat{\beta\chi} = \sigma$. Now, since σ is compressed, so is χ. It is easy to see that a block is hidden in $\beta\chi$ if and only if it is hidden inside β within the fragment βN, and since the compression of βN is ρN, we have $\widehat{\beta\chi} = \rho\chi = \sigma$. Hence $\beta\chi \in f^{-1}(\sigma)$, and $\beta\chi \in B_{\rho_j}$ for some j. Since β and ρ have the same weight, which is at least the weight of ρ_j, we have that ρ_j is a prefix of β. Therefore $\gamma = \beta\zeta\phi \in B_{\rho_j}$. ☐

A topological space $(X, \mathcal{U})$ is *compact* if for any collection of open sets whose union is X there is a finite subcollection whose union is X. We remark that since the Cantor topology is known to be compact, and a quotient of a compact topology is compact, we have the following.

COROLLARY A.5. *The topological space $(\hat{\Sigma}, \mathcal{K})$ is compact.*

Acknowledgments. We would like to express our appreciation to Soma Chaudhuri for introducing us to this problem and for several enlightening discussions. We thank Shlomo Moran for helpful comments on an earlier draft. We thank two anonymous referees for numerous helpful suggestions. Thanks to Shiyu Zhou and Sri Divakaran for help in making several of the figures.

AN OPTIMAL ALGORITHM FOR MONTE CARLO ESTIMATION*

PAUL DAGUM†, RICHARD KARP‡, MICHAEL LUBY§, AND SHELDON ROSS¶

Abstract. A typical approach to estimate an unknown quantity μ is to design an experiment that produces a random variable Z distributed in $[0,1]$ with $\mathbf{E}[Z]=\mu$, run this experiment independently a number of times, and use the average of the outcomes as the estimate. In this paper, we consider the case when no a priori information about Z is known except that is distributed in $[0,1]$. We describe an approximation algorithm $\mathcal{AA}$ which, given ϵ and δ, when running independent experiments with respect to any Z, produces an estimate that is within a factor $1+\epsilon$ of μ with probability at least $1-\delta$. We prove that the expected number of experiments run by $\mathcal{AA}$ (which depends on Z) is optimal to within a constant factor for every Z.

Key words. stopping rule, approximation algorithm, Monte Carlo estimation, sequential estimation, stochastic approximation

1. Introduction.

The choice of experiment, or experimental design, forms an important aspect of statistics. One of the simplest design problems is that of deciding when to stop sampling. For example, suppose $Z_1, Z_2, \ldots$ are independently and identically distributed according to Z in the interval $[0,1]$ with mean μ_Z. From Bernstein's inequality, we know that if N is fixed proportional to $\ln(1/\delta)/\epsilon^2$ and $S_N = Z_1 + \cdots + Z_N$, then with probability at least $1-\delta$, S/N approximates μ_Z with absolute error ϵ. Often, however, μ_Z is small and a good absolute error estimate of μ_Z is typically a poor relative error approximation of μ_Z.

We say $\tilde{\mu}_Z$ is an (ϵ,δ)-approximation of μ_Z if

$$\mathbf{Pr}[\mu_Z(1-\epsilon) \le \tilde{\mu}_Z \le \mu_Z(1+\epsilon)] \ge 1-\delta.$$

In engineering and computer science applications, we often desire an (ϵ,δ)-approximation of μ_Z in problems where exact computation of μ_Z is NP-hard. For example, many researchers have devoted substantial effort to the important and difficult problem of approximating the permanent of $0-1$ valued matrices [1, 4, 5, 9, 10, 13, 14]. Researchers have also used (ϵ,δ)-approximations to tackle many other difficult problems,

such as approximating probabilistic inference in Bayesian networks [6], approximating the volume of convex bodies [7], solving the Ising model of statistical mechanics [11], solving for network reliability in planar multiterminal networks [15, 16], approximating the number of solutions to a DNF formula [17] or, more generally, to a GF[2] formula [18], and approximating the number of Eulerian orientations of a graph [19].

Define

$$\lambda = (\mathrm{e} - 2) \approx .72,$$
$$\Upsilon = 4\lambda \ln(2/\delta)/\epsilon^2$$

and let σ_Z^2 denote the variance of Z. Define

$$\rho_Z = \max\{\sigma_Z^2, \epsilon\mu_Z\}.$$

We first prove a slight generalization of the zero-one estimator theorem [12, 15, 16, 17]. The new theorem, the generalized zero-one estimator theorem, proves that if

$$N = \Upsilon \cdot \rho_Z/\mu_Z^2, \tag{1}$$

then S_N/N is an (ϵ, δ)-approximation of μ_Z.

To apply the generalized zero-one estimator theorem we require the values of the unknown quantities μ_Z and σ_Z^2. Researchers circumvent this problem by computing an upper bound κ on ρ_Z/μ_Z^2 and using κ in place of ρ_Z/μ_Z^2 to determine a value for N in (1). An a priori upper bound κ on ρ_Z/μ_Z^2 that is close to ρ_Z/μ_Z^2 is often very difficult to obtain, and a poor bound leads to a prohibitive large bound on N.

To avoid the problem encountered with the generalized zero-one estimator theorem, we use the outcomes of previous experiments to decide when to stop iterating. This approach is known as *sequential analysis* and originated with the work of Wald on statistical decision theory [22]. Related research has applied sequential analysis to specific Monte Carlo approximation problems such as estimating the number of points in a union of sets [17] and estimating the number of self-avoiding walks [20]. In other related work, Dyer et al. describe a stopping rule–based algorithm that provides an upper bound estimate on μ_Z [8]. With probability $1 - \delta$, the estimate is at most $(1 + \epsilon)\mu_Z$, but the estimate can be arbitrarily smaller than μ in the challenging case when μ is small.

We first describe an approximation algorithm based on a simple stopping rule. Using the stopping rule, the approximation algorithm outputs an (ϵ, δ)-approximation of μ_Z after an expected number of experiments proportional to Υ/μ_Z. The variance of the random variable Z is maximized subject to a fixed mean μ_Z if Z takes on value 1 with probability μ_Z and 0 with probability $1-\mu_Z$. In this case, $\sigma_Z^2 = \mu_Z(1-\mu_Z) \approx \mu_Z$, and the expected number of experiments run by the stopping rule–based algorithm is within a constant factor of optimal. In general, however, σ_Z^2 is significantly smaller than μ_Z, and for small values of σ_Z^2 the stopping rule–based algorithm performs $1/\epsilon$ times as many experiments as the optimal number.

We describe a more powerful algorithm, the $\mathcal{AA}$ algorithm that, on inputs ϵ, δ, and independently and identically distributed outcomes $Z_1, Z_2, \ldots$ generated from any random variable Z distributed in $[0, 1]$, outputs an (ϵ, δ)-approximation of μ_Z after an expected number of experiments proportional to $\Upsilon \cdot \rho_Z/\mu_Z^2$. Unlike the simple, stopping rule–based algorithm, we prove that for all Z, $\mathcal{AA}$ runs the optimal number of experiments to within a constant factor. Specifically, we prove that if $\mathcal{BB}$ is any algorithm that produces an (ϵ, δ)-approximation of μ_Z using the inputs ϵ, δ, and

$Z_1, Z_2, \dots$, then $\mathcal{BB}$ runs an expected number of experiments proportional to at least $\Upsilon \cdot \rho_Z/\mu_Z^2$. (Canetti, Even, and Goldreich prove the related lower bound $\Omega(\ln(1/\delta)/\epsilon^2)$ on the number of experiments required to approximate μ_Z with absolute error ϵ with probability at least $1-\delta$ [2].) Thus we show that for any random variable Z, $\mathcal{AA}$ runs an expected number of experiments that is within a constant factor of the minimum expected number.

The $\mathcal{AA}$ algorithm is a general method for optimally using the outcomes of Monte Carlo experiments for approximation—that is, to within a constant factor, the algorithm uses the minimum possible number of experiments to output an (ϵ, δ)-approximation on each problem instance. Thus, $\mathcal{AA}$ provides substantial computational savings in applications that employ a poor upper bound κ on ρ_Z/μ_Z^2. For example, the best known a priori bound on κ for the problem of approximating the permanent of size n is superpolynomial in n [13]. Yet for many problem instances of size n, the number of experiments run by $\mathcal{AA}$ is significantly smaller than this bound. Other examples exist where the bounds are also extremely loose for many typical problem instances [7, 10, 11]. In all those applications, we expect $\mathcal{AA}$ to provide substantial computational savings, and possibly render problems that were intractable because of the poor upper bounds on ρ_Z/μ_Z^2, amenable to efficient approximation.

2. Approximation algorithm.

In subsection 2.1, we describe a stopping rule algorithm for estimating μ_Z. This algorithm is used in the first step of the approximation algorithm $\mathcal{AA}$ that we describe in subsection 2.2.

2.1. Stopping Rule Algorithm.

Let Z be a random variable distributed in the interval $[0,1]$ with mean μ_Z. Let $Z_1, Z_2, \dots$ be independently and identically distributed according to Z.

Stopping Rule Algorithm.

```
Input parameters: $(\epsilon, \delta)$ with $0 < \epsilon < 1$, $\delta > 0$.
Let $\Upsilon_1 = 1 + (1+\epsilon)\Upsilon$.

Initialize $N \leftarrow 0$, $S \leftarrow 0$
While $S < \Upsilon_1$ do: $N \leftarrow N + 1$; $S \leftarrow S + Z_N$

Output: $\tilde{\mu}_Z \leftarrow \Upsilon_1/N$
```

Stopping Rule Theorem. *Let Z be a random variable distributed in $[0,1]$ with $\mu_Z = \mathbf{E}[Z] > 0$. Let $\tilde{\mu}_Z$ be the estimate produced and let N_Z be the number of experiments that the Stopping Rule Algorithm runs with respect to Z on input ϵ and δ. Then,*

(1) $\mathbf{Pr}[\mu_Z(1-\epsilon) \le \tilde{\mu}_Z \le \mu_Z(1+\epsilon)] > 1-\delta$,

(2) $\mathbf{E}[N_Z] \le \Upsilon_1/\mu_Z$.

The proof of this theorem can be found in section 5.

2.2. Approximation Algorithm $\mathcal{AA}$.

The (ϵ, δ)-approximation algorithm $\mathcal{AA}$ consists of three main steps. The first step uses the stopping rule–based algorithm to produce an estimate $\hat{\mu}_Z$ that is within a constant factor of μ_Z with probability at least $1-\delta$. The second step uses the value of $\hat{\mu}_Z$ to set the number of experiments to run in order to produce an estimate $\hat{\rho}_Z$ that is within a constant factor of ρ with probability at least $1-\delta$. The third step uses the values of $\hat{\mu}_Z$ and $\hat{\rho}_Z$ produced in the first two steps to set the number of experiments and runs this number of experiments to produce an (ϵ, δ)-estimate of $\tilde{\mu}_Z$ of μ_Z.

Let Z be a random variable distributed in the interval $[0,1]$ with mean μ_Z and variance σ_Z^2. Let $Z_1, Z_2, \ldots$ and $Z'_1, Z'_2, \ldots$ denote two sets of random variables independently and identically distributed according to Z.

APPROXIMATION ALGORITHM $\mathcal{AA}$.

```
**Input Parameters:** $(\epsilon,\delta)$, with $0<\epsilon\le 1$ and $0<\delta\le 1$.
Let $\Upsilon_2 = 2(1+\sqrt{\epsilon})(1+2\sqrt{\epsilon})(1+\ln(\frac{3}{2})/\ln(\frac{2}{\delta}))\Upsilon \approx 2\Upsilon$ for small $\epsilon$ and $\delta$.

**Step 1:** Run the Stopping Rule Algorithm using $Z_1, Z_2 \ldots$ with input parameters
$\min\{1/2,\sqrt{\epsilon}\}$ and $\delta/3$. This produces an estimate $\hat{\mu}_Z$ of $\mu_Z$.

**Step 2:** Set $N = \Upsilon_2 \cdot \epsilon/\hat{\mu}_Z$ and initialize $S \leftarrow 0$.
For $i = 1,\ldots,N$ do: $S \leftarrow S + (Z'_{2i-1} - Z'_{2i})^2/2$.
$\hat{\rho}_Z \leftarrow \max\{S/N, \epsilon\hat{\mu}_Z\}$.

**Step 3:** Set $N = \Upsilon_2 \cdot \hat{\rho}_Z/\hat{\mu}_Z^2$ and initialize $S \leftarrow 0$.
For $i = 1,\ldots,N$ do: $S \leftarrow S + Z_i$.
$\tilde{\mu}_Z \leftarrow S/N$.

**Output:** $\tilde{\mu}_Z$
```

$\mathcal{AA}$ THEOREM. *Let Z be any random variable distributed in $[0,1]$, $\mu_Z = \mathbf{E}[Z] > 0$ be the mean of Z, σ_Z^2 be the variance of Z, and $\rho_Z = \max\{\sigma_Z^2, \epsilon\mu_Z\}$. Let $\tilde{\mu}_Z$ be the approximation produced by $\mathcal{AA}$ and let N_Z be the number of experiments run by $\mathcal{AA}$ with respect to Z on input parameters ϵ and δ. Then,*

(1) $\mathbf{Pr}[\mu_Z(1-\epsilon) \le \tilde{\mu}_Z \le \mu_Z(1+\epsilon)] \ge 1-\delta$.

(2) *There is a universal constant c' such that* $\mathbf{Pr}[N_Z \ge c'\Upsilon \cdot \rho_Z/\mu_Z^2] \le \delta$.

(3) *There is a universal constant c' such that* $\mathbf{E}[N_Z] \le c'\Upsilon\rho_Z/\mu_Z^2$.

We prove the $\mathcal{AA}$ theorem in section 6.

3. Lower bound. Algorithm $\mathcal{AA}$ is able to produce a good estimate of μ_Z using no a priori information about Z. An interesting question is, What is the inherent number of experiments needed to produce an (ϵ,δ)-approximation of μ_Z? In this section, we state a lower bound on the number of experiments needed by any (ϵ,δ)-approximation algorithm to estimate μ_Z when there is no a priori information about Z. This lower bound shows that, to within a constant factor, $\mathcal{AA}$ runs the minimum number of experiments for every random variable Z.

To formalize the lower bound, we introduce the following natural model. Let $\mathcal{BB}$ be any algorithm that on input (ϵ,δ) works as follows with respect to Z. Let $Z_1, Z_2, \ldots$ denote independently and identically distributed according to Z with values in the interval $[0,1]$. $\mathcal{BB}$ runs an experiment, and on the Nth run $\mathcal{BB}$ receives the value Z_N. The measure of the running time of $\mathcal{BB}$ is the number of experiments it runs, i.e., the time for all other computations performed by $\mathcal{BB}$ is not counted in its running time. $\mathcal{BB}$ is allowed to use any criteria it wants to decide when to stop running experiments and produce an estimate, and in particular $\mathcal{BB}$ can use the outcome of all previous experiments. The estimate that $\mathcal{BB}$ produces when it stops can be any function of the outcomes of the experiments it has run up to that point. The requirement of $\mathcal{BB}$ is that it produces an (ϵ,δ)-approximation of μ_Z for any Z.

This model captures the situation where the algorithm can only gather information about μ_Z through running random experiments and where the algorithm has no a priori knowledge about the value of μ_Z before starting. This is a reasonable pair of assumptions for practical situations. It turns out that the assumption about a priori knowledge can be substantially relaxed: the algorithm may know a priori that the outcomes are being generated according to some known random variable Z or to some closely related random variable Z', and still the lower bound on the number of experiments applies.

Note that Algorithm $\mathcal{AA}$ fits into this model, and thus the average number of experiments it runs with respect to Z is minimal for all Z to within a constant factor among all such approximation algorithms.

Lower Bound Theorem. *Let $\mathcal{BB}$ be any algorithm that works as described above on input (ϵ, δ). Let Z be a random variable distributed in $[0,1]$, μ_Z be the mean of Z, σ_Z^2 be the variance of Z, and $\rho_Z = \max\{\sigma_Z^2, \epsilon\mu_Z\}$. Let $\tilde{\mu}_Z$ be the approximation produced by $\mathcal{BB}$ and let N_Z be the number of experiments run by $\mathcal{BB}$ with respect to Z. Suppose that $\mathcal{BB}$ has the the following properties:*

(1) *For all Z with $\mu_Z > 0$, $\mathbf{E}[N_Z] < \infty$.*

(2) *For all Z with $\mu_Z > 0$,*

$$\mathbf{Pr}[\mu_Z(1-\epsilon) \le \tilde{\mu}_Z \le \mu_Z(1+\epsilon)] > 1 - \delta.$$

Then, there is a universal constant $c > 0$ such that for all Z, $\mathbf{E}[N_Z] \ge c\Upsilon \cdot \rho_Z/\mu_Z^2$.

We prove this theorem in section 7.

4. Preliminaries for the proofs.

We begin with some notation that is used hereafter. Let $\xi_0 = 0$ and for $k > 0$ let

$$\xi_k = \sum_{i=1}^{k}(Z_i - \mu_Z). \tag{2}$$

For fixed $\alpha, \beta \ge 0$, we define the random variables

$$\zeta_k^+ = \xi_k - \alpha - \beta k, \tag{3}$$

$$\zeta_k^- = -\xi_k - \alpha - \beta k. \tag{4}$$

The main lemma we use to prove the first part of the Stopping Rule Theorem provides bounds on the probabilities that the random variables ζ_k^+ and ζ_k^- are greater than zero. We first form the sequences of random variables $\mathrm{e}^{d\zeta_0^+}, \mathrm{e}^{d\zeta_1^+}, \ldots$ and $\mathrm{e}^{d\zeta_0^-}, \mathrm{e}^{d\zeta_1^-}, \ldots$ for any real-valued d. We prove that these sequences are *supermartingales* when $0 \le d \le 1$ and $\beta \ge d\sigma_Z^2$, i.e., for all $k > 0$

$$\mathbf{E}[\mathrm{e}^{d\zeta_k^+} | \mathrm{e}^{d\zeta_{k-1}^+}, \ldots, \mathrm{e}^{d\zeta_0^+}] \le \mathrm{e}^{d\zeta_{k-1}^+},$$

and similarly,

$$\mathbf{E}[\mathrm{e}^{d\zeta_k^-} | \mathrm{e}^{d\zeta_{k-1}^-}, \ldots, \mathrm{e}^{d\zeta_0^-}] \le \mathrm{e}^{d\zeta_{k-1}^-}.$$

We then use properties of supermartingales to bound the probabilities that the random variables ζ_k^+ and ζ_k^- are greater than zero. For these and subsequent proofs, we use the following two inequalities.

Inequality 4.1. *For all α, $\mathrm{e}^{\alpha} \ge 1 + \alpha$.*

Inequality 4.2. *Let $\lambda = (\mathrm{e} - 2) \approx .72$. For all α with $|\alpha| \le 1$,*

$$1 + \alpha + \alpha^2/(2+\lambda) \le \mathrm{e}^{\alpha} \le 1 + \alpha + \lambda \cdot \alpha^2.$$

LEMMA 4.3. *For $|d| \leq 1$, $\mathbf{E}[\mathrm{e}^{dZ}] \leq \mathrm{e}^{d\mu_Z + \lambda d^2 \sigma_Z^2}$.*

Proof. Observe that $E[e^{dZ}] = \mathrm{e}^{d\mu_Z} E[\mathrm{e}^{d(Z-\mu_Z)}]$. But from Inequality 4.2,

$$\mathrm{e}^{d(Z-\mu_Z)} \leq 1 + d(Z-\mu_Z) + \lambda d^2 (Z-\mu_Z)^2.$$

Taking expectations and applying Inequality 4.1 completes the proof. □

LEMMA 4.4. *For $0 \leq d \leq 1$, and for $\beta \geq \lambda d \sigma_Z^2$, the sequences of random variables $\mathrm{e}^{d\zeta_0^+}, \mathrm{e}^{d\zeta_1^+}, \ldots$ and $\mathrm{e}^{d\zeta_0^-}, \mathrm{e}^{d\zeta_1^-}, \ldots$ form supermartingales.*

Proof. For $k \geq 1$

$$\mathrm{e}^{d\zeta_k^+} = \mathrm{e}^{d\zeta_{k-1}^+} \cdot \mathrm{e}^{-d\beta} \cdot \mathrm{e}^{d(\xi_k - \xi_{k-1})}$$

and thus

$$\mathbf{E}[\mathrm{e}^{d\zeta_k^+} | \mathrm{e}^{d\zeta_{k-1}^+}, \ldots, \mathrm{e}^{d\zeta_0^+}] = \mathrm{e}^{d\zeta_{k-1}^+} \cdot \mathrm{e}^{-d\beta} \mathbf{E}[\mathrm{e}^{d(\xi_k - \xi_{k-1})}].$$

Similarly, for $k \geq 1$

$$\mathbf{E}[\mathrm{e}^{d\zeta_k^-} | \mathrm{e}^{d\zeta_{k-1}^-}, \ldots, \mathrm{e}^{d\zeta_0^-}] = \mathrm{e}^{d\zeta_{k-1}^-} \cdot \mathrm{e}^{-d\beta} \mathbf{E}[\mathrm{e}^{-d(\xi_k - \xi_{k-1})}].$$

But $\xi_k - \xi_{k-1} = Z_k - \mu_Z$ and thus from Lemma 4.3,

$$\mathbf{E}[\mathrm{e}^{d(\xi_k - \xi_{k-1})}] \leq \mathrm{e}^{\lambda d^2 \sigma_Z^2}$$

and

$$\mathbf{E}[\mathrm{e}^{-d(\xi_k - \xi_{k-1})}] \leq \mathrm{e}^{\lambda d^2 \sigma_Z^2}.$$

Thus, for $\beta \geq \lambda d \sigma_Z^2$,

$$\mathbf{E}[\mathrm{e}^{d\zeta_k^+} | \mathrm{e}^{d\zeta_{k-1}^+}, \ldots, \mathrm{e}^{d\zeta_0^+}] \leq \mathrm{e}^{d\zeta_{k-1}^+} \cdot \mathrm{e}^{d(\lambda d \sigma_Z^2 - \beta)} \leq \mathrm{e}^{d\zeta_{k-1}^+}$$

and

$$\mathbf{E}[\mathrm{e}^{d\zeta_k^-} | \mathrm{e}^{d\zeta_{k-1}^-}, \ldots, \mathrm{e}^{d\zeta_0^-}] \leq \mathrm{e}^{d\zeta_{k-1}^-} \cdot \mathrm{e}^{d(\lambda d \sigma_Z^2 - \beta)} \leq \mathrm{e}^{d\zeta_{k-1}^-}. \qquad \square$$

Lemma 4.5, needed for the proof of Lemma 4.6, follows directly from the properties of conditional expectations and of martingales.

LEMMA 4.5. *If $\eta_0, \ldots, \eta_k$ is a supermartingale, then for all $0 \leq i \leq k$*

$$\mathbf{E}[\eta_i | \eta_0] \leq \eta_0. \qquad \square$$

We next prove Lemma 4.6. This lemma is the key to the proof of the first part of the Stopping Rule Theorem. In addition, from this lemma we easily prove a slightly more general version of the zero-one estimator theorem.

LEMMA 4.6. *For any fixed $N > 0$, for any $\beta \leq 2\lambda\rho_Z$,*

$$\mathbf{Pr}[\xi_N / N \geq \beta] \leq \mathrm{e}^{\frac{-N\beta^2}{4\lambda\rho_Z}} \tag{5}$$

and

$$\mathbf{Pr}[\xi_N / N \leq -\beta] \leq \mathrm{e}^{\frac{-N\beta^2}{4\lambda\rho_Z}}. \tag{6}$$

Proof. Recall the definitions of ζ_N^+ and ζ_N^- from (3) and (4). Let $\alpha = 0$. Then, the left-hand side of (5) is equivalent to $\mathbf{Pr}[\zeta_N^+ \geq 0]$ and the left-hand side of (6) is equivalent to $\mathbf{Pr}[\zeta_N^- \geq 0]$. Let $\alpha' = \beta N/2$ and $\beta' = \beta/2$. For $0 \leq i \leq N$, let $\zeta_i'^+ = \xi_i - \alpha' - \beta' i$ and $\zeta_i'^- = -\xi_i - \alpha' - \beta' i$. Thus, $\zeta_N'^+ = \zeta_N^+$ and $\zeta_N'^- = \zeta_N^-$.

We now give the remainder of the proof of (5), using $\zeta_N'^+$, and omit the remainder of the analogous proof of (6) which uses $\zeta_N'^-$ in place of $\zeta_N'^+$. For any $N > 0$,

$$\mathbf{Pr}[\zeta_N'^+ \geq 0] = \mathbf{Pr}[\mathrm{e}^{d\zeta_N'^+} \geq 1] \leq \mathbf{E}[\mathrm{e}^{d\zeta_N'^+}].$$

Set $d = \beta'/(\lambda\rho_Z) = \beta/(2\lambda\rho_Z)$. Note that $\beta \leq 2\lambda\rho_Z$ implies that $d \leq 1$. Note also that since $\rho_Z \geq \sigma_Z^2$, $\beta' \geq \lambda d \sigma_Z^2$. Thus, by Lemma 4.4, $\mathrm{e}^{d\zeta_0'^+}, \ldots, \mathrm{e}^{d\zeta_N'^+}$ is a supermartingale. Thus, by Lemma 4.5

$$\mathbf{E}[\mathrm{e}^{d\zeta_N'^+} | \mathrm{e}^{d\zeta_0'^+}] \leq \mathrm{e}^{d\zeta_0'^+} = \mathrm{e}^{\frac{-\alpha'\beta'}{\lambda\rho_Z}} = \mathrm{e}^{\frac{-N\beta^2}{4\lambda\rho_Z}}.$$

Since $\mathrm{e}^{d\zeta_0'^+}$ is a constant,

$$\mathbf{E}[\mathrm{e}^{d\zeta_N'^+} | \mathrm{e}^{d\zeta_0'^+}] = \mathbf{E}[\mathrm{e}^{d\zeta_N'^+}],$$

completing the proof of (5). □

We use Lemma 4.6 to generalize the zero-one estimator theorem [17] from $\{0,1\}$-valued random variables to random variables in the interval $[0,1]$.

Generalized zero-one estimator theorem. *Let $Z_1, Z_2, \ldots, Z_N$ denote random variables that are independent and identically distributed according to Z. If $\epsilon < 1$ and*

$$N = 4\lambda \ln(2/\delta) \cdot \rho_Z/(\epsilon\mu_Z)^2,$$

then

$$\mathbf{Pr}\left[(1-\epsilon)\mu_Z \leq \sum_{i=1}^{N} Z_i/N \leq (1+\epsilon)\mu_Z\right] > 1 - \delta.$$

Proof. The proof follows directly from Lemma (4.6), using $\beta = \epsilon\mu_Z$, noting that $\epsilon\mu_Z \leq 2\lambda\rho_Z$ and that $N \cdot (\epsilon\mu_Z)^2/(4\lambda\rho_Z) = \ln(2/\delta)$. □

5. Proof of the Stopping Rule Theorem.

We next prove the Stopping Rule Theorem. Recall that $\lambda = (\mathrm{e}-2) \approx .72$ and $\Upsilon_1 = 1 + (1+\epsilon)\Upsilon = 1 + 4\lambda\ln(2/\delta)(1+\epsilon)/\epsilon^2$.

Proof of part (1). Recall that $\tilde{\mu}_Z = \Upsilon_1/N_Z$. It suffices to show that

$$\mathbf{Pr}[N_Z < \Upsilon_1/(\mu_Z(1+\epsilon))] + \mathbf{Pr}[N_Z > \Upsilon_1/(\mu_Z(1-\epsilon))] \leq \delta.$$

We first show that $\mathbf{Pr}[N_Z < \Upsilon_1/(\mu_Z(1+\epsilon))] \leq \delta/2$. Let $L = \lfloor \Upsilon_1/(\mu_Z(1+\epsilon)) \rfloor$. Assuming that $\mu_Z(1+\epsilon) \leq 1$, the definition of Υ_1 and L implies that

$$L \geq \frac{4\lambda\ln(2/\delta)}{\epsilon^2\mu_Z}. \tag{7}$$

Since N_Z is an integer, $N_Z < \Upsilon_1/(\mu_Z(1+\epsilon))$ if and only if $N_Z \leq L$. But $N_Z \leq L$ if and only if $S_L \geq \Upsilon_1$. Thus,

$$\mathbf{Pr}[N_Z < \Upsilon_1/(\mu_Z(1+\epsilon))] = \mathbf{Pr}[N_Z \leq L] = \mathbf{Pr}[S_L \geq \Upsilon_1].$$

Let $\beta = \Upsilon_1/L - \mu_Z$. Then,

$$\mathbf{Pr}[S_L \geq \Upsilon_1] = \mathbf{Pr}[S_L - \mu_Z L - \beta L \geq 0] = \mathbf{Pr}[\xi_L/L \geq \beta].$$

Noting that $\epsilon\mu_Z \leq \beta \leq 2\lambda\rho_Z$, Lemma (4.6) implies that

$$\mathbf{Pr}[\xi_L/L \geq \beta] \leq \mathrm{e}^{\frac{-L\beta^2}{4\lambda\rho_Z}} \leq \mathrm{e}^{\frac{-L(\epsilon\mu_Z)^2}{4\lambda\rho_Z}}.$$

Using inequality (7) and noting that $\rho_Z \leq \mu_Z$, it follows that this is at most $\delta/2$.

The proof that $\mathbf{Pr}[N_Z > \Upsilon_1/(\mu_Z(1-\epsilon))] \leq \delta/2$ is similar. □

Proof of part (2). The random variable N_Z is the stopping time such that

$$\Upsilon_1 \leq S_{N_Z} < \Upsilon_1 + 1.$$

Using Wald's equation [22] and $\mathbf{E}[N_Z] < \infty$, it follows that

$$\mathbf{E}[S_{N_Z}] = \mathbf{E}[N_Z]\mu_Z$$

and thus,

$$\Upsilon_1/\mu_Z \leq \mathbf{E}[N_Z] < (\Upsilon_1 + 1)/\mu_Z. \qquad \square$$

Similar to the proof of the first part of the Stopping Rule Theorem, we can show that

$$\mathbf{Pr}[N_Z > (1+\epsilon)\Upsilon_1/\mu_Z] \leq \delta/2, \tag{8}$$

and therefore with probability at least $1 - \delta/2$ we require at most $(1+\epsilon)\Upsilon_1/\mu_Z$ experiments to generate an approximation. The following lemma is used in the proof of the $\mathcal{AA}$ Theorem in section 6.

Stopping Rule Lemma.

(1) $\mathbf{E}[1/\tilde{\mu}_Z] = \mathcal{O}(1/\mu_Z)$.

(2) $\mathbf{E}[1/\tilde{\mu}_Z^2] = \mathcal{O}(1/\mu_Z^2)$.

Proof of the Stopping Rule Lemma. $\mathbf{E}[1/\tilde{\mu}_Z] = \mathcal{O}(1/\mu_Z)$ follows directly from part (2) of the Stopping Rule Theorem and the definition of N_Z. $\mathbf{E}[1/\tilde{\mu}_Z^2] = \mathcal{O}(1/\mu_Z^2)$ can be easily proved based on the ideas used in the proof of part (2) of the Stopping Rule Theorem. □

6. Proof of the $\mathcal{AA}$ Theorem.

$\mathcal{AA}$ theorem. *Let Z be any random variable distributed in $[0,1]$, μ_Z be the mean of Z, σ_Z^2 be the variance of Z, and $\rho_Z = \max\{\sigma_Z^2, \epsilon\mu_Z\}$. Let $\tilde{\mu}_Z$ be the approximation produced by $\mathcal{AA}$ and let N_Z be the number of experiments run by $\mathcal{AA}$ with respect to Z on input parameters ϵ and δ. Then*

(1) $\mathbf{Pr}[\mu_Z(1-\epsilon) \leq \tilde{\mu}_Z \leq \mu_Z(1+\epsilon)] \geq 1-\delta$,

(2) *there is a universal constant c' such that* $\mathbf{Pr}[N_Z \geq c'\Upsilon \cdot \rho_Z/\mu_Z^2] \leq \delta$,

(3) *there is a universal constant c' such that* $\mathbf{E}[N_Z] \leq c'\Upsilon\rho_Z/\mu_Z^2$.

Proof of part (1). From the Stopping Rule Theorem, after step (1) of $\mathcal{AA}$, $\mu_Z(1-\sqrt{\epsilon}) \leq \hat{\mu}_Z \leq \mu_Z(1+\sqrt{\epsilon})$ holds with probability at least $1-\delta/3$. Let $\Phi = 2(1+\sqrt{\epsilon})^2$. We show next that if $\mu_Z(1-\sqrt{\epsilon}) \leq \hat{\mu}_Z \leq \mu_Z(1+\sqrt{\epsilon})$, then in step (2) the choice of Υ_2 guarantees that $\hat{\rho}_Z \geq \rho_Z/2$. Thus, after steps (1) and (2), $\Phi\hat{\rho}_Z/\hat{\mu}_Z^2 \geq \rho_Z/\mu_Z^2$ with probability at least $1-\delta/3$. But by the generalized zero-one estimator theorem, for $N = (1+\ln(\frac{3}{2})/\ln(\frac{2}{\delta}))\Upsilon \cdot \rho_Z/\mu_Z^2 \leq \Phi(1+\ln(\frac{3}{2})/\ln(\frac{2}{\delta}))\Upsilon \cdot \hat{\rho}_Z/\hat{\mu}_Z^2 \leq \Upsilon_2 \cdot \hat{\rho}_Z/\hat{\mu}_Z^2$, step

(3) guarantees that the output $\tilde{\mu}_Z$ of $\mathcal{AA}$ satisfies $\mathbf{Pr}[\mu_Z(1-\epsilon) \le \tilde{\mu}_Z \le \mu_Z(1+\epsilon)] \ge 1 - 2\delta/3$.

For all i, let $\xi_i = (Z_{2i-1} - Z_{2i})^2/2$, and observe that, $\mathbf{E}[\xi] = \sigma_Z^2$. First assume that $\sigma_Z^2 \ge \epsilon\mu_Z$, and hence $\rho_Z = \sigma_Z^2$. If $\sigma_Z^2 \ge 2(1-\sqrt{\epsilon})\epsilon\mu_Z$, then from the generalized zero-one estimator theorem, after at most $(2/(1-\sqrt{\epsilon}))(1+\ln(\frac{3}{2})/\ln(\frac{2}{\delta}))\cdot\Upsilon\cdot\epsilon/\mu_Z \le \Upsilon_2\cdot\epsilon/\hat{\mu}_Z$ experiments, $\rho_Z/2 \le S/N \le 3\rho_Z/2$ with probability at least $1-2\delta/3$. Thus $\hat{\rho}_Z \ge \rho_Z/2$. If $\epsilon\mu_Z \le \sigma_Z^2 \le 2(1-\sqrt{\epsilon})\epsilon\mu_Z$, then $\epsilon\mu_Z \ge \sigma_Z^2/(2(1-\sqrt{\epsilon}))$, and therefore, $\hat{\rho}_Z \ge \epsilon\hat{\mu}_Z \ge \rho_Z/2$.

Next, assume that $\sigma_Z^2 \le \epsilon\mu_Z$ and thus $\rho_Z = \epsilon\mu_Z$. But steps (1) and (2) guarantee that $\hat{\rho}_Z \ge \epsilon\hat{\mu}_Z \ge \rho_Z(1-\sqrt{\epsilon})$, with probability at least $1-\delta/3$.

Proof of part (2). $\mathcal{AA}$ may fail to terminate after $\mathcal{O}(\Upsilon\cdot\rho_Z/\mu_Z^2)$ experiments either because step (1) failed with probability at least $\delta/2$ to produce an estimate $\hat{\mu}_Z$ such that $\mu_Z(1-\sqrt{\epsilon}) \le \hat{\mu}_Z \le \mu_Z(1+\sqrt{\epsilon})$, or, because in step (2), for $\sigma_Z^2 \le 2(1-\sqrt{\epsilon})\epsilon\mu_Z$, $\hat{\rho}_Z = S/N$ and S/N is not $\mathcal{O}(\epsilon\mu_Z)$ with probability at least $1-\delta/2$.

But (8) guarantees that step (1) of $\mathcal{AA}$ terminates after $\mathcal{O}(\Upsilon\cdot\rho_Z/\mu_Z^2)$ experiments with probability at least $1-\delta/2$. In addition, we can show similarly to Lemma 4.6, that if $\sigma_Z^2 \le 2\epsilon\mu_Z$, then

$$\mathbf{Pr}[S/N \ge 4\epsilon\mu_Z] \le \mathrm{e}^{-N\epsilon\mu_Z/2}.$$

Thus, for $N \ge 2\Upsilon\cdot\epsilon/\mu_Z$, we have that $\mathbf{Pr}[S/N \ge 4\epsilon\mu_Z] \le \delta/2$.

Proof of part (3). Observe that from the Stopping Rule Theorem, the expected number of experiments in step (1) is $\mathcal{O}(\ln(1/\delta)/(\epsilon\mu_Z))$. From the Stopping Rule Lemma, the expected number of experiments in step (2) is $\mathcal{O}(\ln(1/\delta)/(\epsilon\mu_Z))$. Finally, in step (3) we observe that $\mathbf{E}[\hat{\rho}_Z/\hat{\mu}_Z^2] = \mathbf{E}[\hat{\rho}_Z]\mathbf{E}[1/\hat{\mu}_Z^2]$ since $\hat{\rho}_Z$ and $\hat{\mu}_Z$ are computed from disjoint sets of independently and identically distributed random variables. From the Stopping Rule Lemma $\mathbf{E}[1/\hat{\mu}_Z^2]$ is $\mathcal{O}(\ln(1/\delta)/\mu_Z^2)$. Furthermore, observe that $\mathbf{E}[\hat{\rho}_Z] \le \mathbf{E}[S/N] + \mathbf{E}[\epsilon\hat{\mu}_Z]$. But $\mathbf{E}[S/N] = \sigma_Z^2$ and $\mathbf{E}[\epsilon\hat{\mu}_Z] = \mathcal{O}(\epsilon\mu_Z)$. Thus, if $\sigma_Z^2 \ge \epsilon\mu_Z$, then $\rho_Z = \sigma_Z^2$ and $\mathbf{E}[\hat{\rho}_Z] = \mathcal{O}(\sigma_Z^2) = \mathcal{O}(\rho_Z)$. If $\sigma_Z^2 \le \epsilon\mu_Z$, then $\rho_Z = \epsilon\mu_Z$ and $\mathbf{E}[\hat{\rho}_Z] = \mathcal{O}(\epsilon\mu_Z) = \mathcal{O}(\rho_Z)$. Thus, the expected number of experiments in step (3) is $\mathcal{O}(\ln(1/\delta)\cdot\rho_Z/(\epsilon\mu_Z)^2)$ □

7. Proof of the Lower Bound Theorem.

LOWER BOUND THEOREM. *Let $\mathcal{BB}$ be any algorithm that works as described above on input (ϵ,δ). Let Z be a random variable distributed in $[0,1]$, μ_Z be the mean of Z, σ_Z^2 be the variance of Z, and $\rho_Z = \max\{\sigma_Z^2, \epsilon\mu_Z\}$. Let $\tilde{\mu}_Z$ be the approximation produced by $\mathcal{BB}$ and let N_Z be the number of experiments run by $\mathcal{BB}$ with respect to Z. Suppose that $\mathcal{BB}$ has the the following properties:*

(1) *For all Z with $\mu_Z > 0$, $\mathbf{E}[N_Z] < \infty$.*

(2) *For all Z with $\mu_Z > 0$, $\mathbf{Pr}[\mu_Z(1-\epsilon) \le \tilde{\mu}_Z \le \mu_Z(1+\epsilon)] > 1-\delta$.*

Then there is a universal constant $c > 0$ such that for all Z, $\mathbf{E}[N_Z] \ge c\Upsilon\cdot\rho_Z/\mu_Z^2$.

Let $f_Z(x)$ and $f_{Z'}(x)$ denote two given distinct probability mass (or in the continuous case, density) functions. Let $Z_1, Z_2, \ldots$ denote independent and identically distributed random variables with probability density $f(x)$. Let H_Z denote the hypothesis $f = f_Z$ and let $H_{Z'}$ denote the hypothesis $f = f_{Z'}$. Let α denote the probability that we reject H_Z under f_Z and let β denote the probability that we accept $H_{Z'}$ under $f_{Z'}$.

The sequential probability ratio test minimizes the number of expected sample size under both H_Z and $H_{Z'}$ among all tests with the same error probabilities α and β. Theorem 7.1 states the result of the sequential probability ratio test. We prove the result for completeness, although similar proofs exist [21].

THEOREM 7.1. *If T is the stopping time of any test of H_Z against $H_{Z'}$ with error probabilities α and β, and $\mathbf{E}_Z[T], \mathbf{E}_{Z'}[T] < \infty$, then*

$$\mathbf{E}_Z[T] \geq \frac{1}{\omega_Z}\left(\alpha \ln \frac{1-\beta}{\alpha} + (1-\alpha)\ln\frac{\beta}{1-\alpha}\right)$$

and

$$\mathbf{E}_{Z'}[T] \geq \frac{1}{\omega_{Z'}}\left((1-\beta) \ln \frac{1-\beta}{\alpha} + \beta\ln\frac{\beta}{1-\alpha}\right),$$

where $\omega_Z = \mathbf{E}_Z[\ln(f_{Z'}(x)/f_Z(x))]$ and $\omega_{Z'} = \mathbf{E}_{Z'}[\ln(f_{Z'}(x)/f_Z(x))]$.

Proof. For the independent and identically distributed random variables $Z_1, Z_2, \ldots$, let $\lambda_k(Z_k) = \ln(f_{Z'}(Z_k)/f_Z(Z_k))$. Define $\zeta_k^+ = \lambda_k + \cdots + \lambda_1$ and $\zeta_k^- = \zeta_k^+$.

For stopping time T, we get from Wald's first identity

$$\mathbf{E}_Z[\zeta_T^+] = \mathbf{E}_Z[T]\mathbf{E}_Z[\lambda_1]$$

and

$$\mathbf{E}_{Z'}[\zeta_T^-] = \mathbf{E}_{Z'}[T]\mathbf{E}_{Z'}[\lambda_1].$$

Next, let Ω denote the space of all inputs on which the test rejects H_Z, and let Ω^c denote its complement. Thus by definition, we require that $\mathbf{Pr}_Z[\Omega] = \alpha$ and $\mathbf{Pr}_Z[\Omega^c] = 1-\alpha$. Similarly, we require that $\mathbf{Pr}_{Z'}[\Omega] = 1-\beta$ and $\mathbf{Pr}_{Z'}[\Omega^c] = \beta$. From the properties of expectations we can show that

$$\mathbf{E}_Z[\zeta_T^+] = \mathbf{E}_Z[\zeta_T^+|\Omega]\mathbf{Pr}_Z[\Omega] + \mathbf{E}_Z[\zeta_T^+|\Omega^c]\mathbf{Pr}_Z[\Omega^c].$$

We can decompose $\mathbf{E}_{Z'}[\zeta_T^-]$ similarly. Let $\mu = \mathbf{E}_Z[\zeta_T^+|\Omega]$ and observe that from Inequality 4.1, $\mathbf{E}_Z[\mathrm{e}^{\zeta_T^+ - \mu}|\Omega] \geq 1$. Thus

$$\mu \leq \ln \mathbf{E}_Z[\mathrm{e}^{\zeta_T^+}|\Omega].$$

But

$$\mathbf{E}_Z[\mathrm{e}^{\zeta_T^+}|\Omega] = \mathbf{E}_Z[\mathrm{e}^{\zeta_T^+}I_\Omega]/\mathbf{Pr}_Z[\Omega],$$

where I_Ω denotes the characteristic function for the set Ω. Thus, since

$$\mathrm{e}^{\zeta_T^+} = \prod_{i=1}^{T}\frac{f_{Z'}(Z_i)}{f_Z(Z_i)},$$

we can show that

$$\mathbf{E}_Z[\mathrm{e}^{\zeta_T^+}I_\Omega] = \mathbf{Pr}_{Z'}[\Omega],$$

and finally,

$$\mathbf{E}_Z[\zeta_T^+|\Omega] \leq \ln \mathbf{E}_Z[\mathrm{e}^{\zeta_T^+}|\Omega] = \ln\frac{1-\beta}{\alpha}.$$

Similarly, we can show that

$$\mathbf{E}_Z[\zeta_T^+|\Omega^c] \leq \ln \frac{\beta}{1-\alpha},$$
$$\mathbf{E}_{Z'}[\zeta_T^-|\Omega] \leq \ln \frac{\alpha}{1-\beta},$$

and

$$\mathbf{E}_{Z'}[\zeta_T^-|\Omega^c] \leq \ln \frac{1-\alpha}{\beta}.$$

Thus,

$$-\mathbf{E}_Z[T]\mathbf{E}_Z[\lambda_0] \leq \alpha \ln \frac{1-\beta}{\alpha} + (1-\alpha) \ln \frac{\beta}{1-\alpha},$$

which proves the first part of the lemma. Similarly,

$$-\mathbf{E}_{Z'}[T]\mathbf{E}_{Z'}[\lambda_0] \leq (1-\beta) \ln \frac{\alpha}{1-\beta} + \beta \ln \frac{1-\alpha}{\beta},$$

proves the second part of the lemma. □

COROLLARY 7.2. *If T is the stopping time of any test of H_Z against $H_{Z'}$ with error probabilities α and β such that $\alpha + \beta = \delta$, then*

$$\mathbf{E}_Z[T] \geq -\frac{1-\delta}{\omega_Z} \ln \frac{2-\delta}{\delta}$$

and

$$\mathbf{E}_{Z'}[T] \geq \frac{1-\delta}{\omega_{Z'}} \ln \frac{2-\delta}{\delta}.$$

Proof. If $\alpha + \beta = \delta$, then

$$(1-\beta) \ln \frac{1-\beta}{\alpha} + \beta \ln \frac{\beta}{1-\alpha} = -\alpha \ln \frac{1-\beta}{\alpha} - (1-\alpha) \ln \frac{\beta}{1-\alpha}$$

achieves a minimum at $\alpha = \beta = \delta/2$. Substitution of $\alpha = \beta = \delta/2$ completes the proof. □

Before we present Lemma 7.5 that proves the Lower Bound Theorem for $\sigma_Z^2 \geq \epsilon\mu_Z$, we begin with some definitions. Let $\xi = Z - \mu_Z$ and for any $0 \leq d \leq 1$ let

$$\psi = \mathbf{E}_0[\mathrm{e}^{d\xi}].$$

Define $\zeta = d\xi - \ln \psi$ and

$$f_{Z'}(x) = f_Z(x) \cdot e^{\zeta}.$$

LEMMA 7.3. $1 + d^2\sigma_Z^2/(2+\lambda) \leq \psi \leq 1 + \lambda d^2 \sigma_Z^2$.

Proof. Since $\psi = \mathbf{E}_Z[\mathrm{e}^{d\xi}]$ we use Inequality 4.2 to show that

$$1 + d\xi + d^2\xi^2/(2+\lambda) \leq \mathrm{e}^{d\xi} \leq 1 + d\xi + \lambda d^2 \xi^2.$$

Taking expectations completes the proof. ∎

LEMMA 7.4. $2d\sigma_Z^2/((2+\lambda)\psi) \le \mathbf{E}_{Z'}[\xi] \le 2\lambda d\sigma_Z^2/\psi$.

Proof. Since $\mathbf{E}_{Z'}[\xi] = \psi^{-1}\psi'$, where ψ' denotes the derivative of ψ with respect to d, the proof follows directly from Lemma 7.3. ∎

LEMMA 7.5. *If* $\sigma_Z^2 \ge \epsilon\mu_Z$, *then for* $\epsilon < 1$, $\mathbf{E}[N_Z] \ge (1-\delta)(1-\epsilon)^2 \ln(\frac{2-\delta}{\delta}) \cdot \sigma_Z^2/((2+\lambda)2\epsilon\mu_Z)^2$,

Proof. Let T denote the stopping time of any test of H_Z against $H_{Z'}$. Note that $\mathbf{E}_{Z'}[Z] - \mathbf{E}_Z[Z] = \mathbf{E}_{Z'}[Z] - \mu_Z = \mathbf{E}_{Z'}[\xi]$. If we set $d = \epsilon\mu_Z/\sigma_Z^2$, then, by Lemmas 7.3 and 7.4, $\mathbf{E}_{Z'}[Z] - \mu_Z > \epsilon\mu_Z/(2+\lambda)$. Thus to test H_Z against H_Z', we can use the $\mathcal{BB}$ with input ϵ^* such that $\mu_Z(1+\epsilon^*) \le \mu_Z(1+\epsilon/(2+\lambda))(1-\epsilon^*) < \mu_{Z'}(1-\epsilon^*)$. Solving for ϵ^* we obtain $\epsilon^* \le \epsilon/(2(2+\lambda)+\epsilon)$. But Corollary 7.2 gives a lower bound on the expected number of experiments $\mathbf{E}[N_Z^*]$ run by $\mathcal{BB}$ with respect the Z. We observe that

$$-\omega_Z = \mathbf{E}_Z[\zeta] = \ln\psi \le d^2\sigma_Z^2,$$

where the inequality follows from Lemma 7.3. We let $d = \epsilon\mu_Z/\sigma_Z^2$ and substitute $\epsilon = 2(2+\lambda)\epsilon^*/(1-\epsilon^*)$ to complete the proof. ∎

We now prove the Lower Bound Theorem that holds also when $\sigma_Z^2 < \epsilon\mu_Z$. We define the density

$$f_{Z'}(x) = f_Z(x)\cdot(1-\epsilon\mu_Z) + \epsilon\mu_Z.$$

LEMMA 7.6. *If* $\mu_Z \le 1/4$, *then* $\mathbf{E}_{Z'}[Z] - \mu_Z \ge \epsilon\mu_Z/4$.

Proof. Observe that $\mathbf{E}_{Z'}[Z] = (1-\epsilon\mu_Z)\mathbf{E}_Z[Z] + \epsilon\mu_Z/2$ and therefore $\mathbf{E}_{Z'}[Z] - \mu_Z = \epsilon\mu_Z(1/2-\mu_Z)$. ∎

LEMMA 7.7. $-\mathbf{E}_Z[\ln\frac{f_{Z'}(x)}{f_Z(x)}] \le \frac{\epsilon\mu_Z}{1-\epsilon\mu_Z}$.

Proof. Observe that

$$-\ln\frac{f_{Z'}(x)}{f_Z(x)} \le -\ln(1-\epsilon\mu_Z) \le \frac{\epsilon\mu_Z}{1-\epsilon\mu_Z}.$$

Taking expectations completes the proof. ∎

LEMMA 7.8. *If* $\mu_Z \le 1/4$, *then* $\mathbf{E}[N_Z] \ge (1-\delta)(1-\epsilon)\ln(\frac{2-\delta}{\delta})/(16\epsilon\mu_Z)$.

Proof. Let T denote the stopping time of any test of H_Z against $H_{Z'}$. From Lemma 7.6, and since $\mu_Z \le \frac{1}{4}$, $\mathbf{E}_{Z'}[Z] - E_Z[Z] > \epsilon\mu_Z/4$. Thus to test H_Z against H_Z', we can use the $\mathcal{BB}$ with input ϵ^* such that $\mu_Z(1+\epsilon^*) \le \mu_Z(1+\epsilon/4)(1-\epsilon^*) < \mu_{Z'}(1-\epsilon^*)$. Solving for ϵ^* we obtain $\epsilon^* \le \epsilon/(8+\epsilon)$. But Corollary 7.2 gives a lower bound on the expected number of experiments $\mathbf{E}[N_Z^*]$ run by $\mathcal{BB}$ with respect the Z. Next observe that, by Lemma 7.7, $-\omega_Z$ in Corollary 7.2 is at most $2\epsilon\mu_Z$. Substitution of $\epsilon = 8\epsilon^*/(1-\epsilon^*)$ completes the proof. ∎

Proof of the Lower Bound Theorem. The proof follows from Lemma 7.5 and Lemma 7.8. ∎

SEPARATING COMPLEXITY CLASSES USING AUTOREDUCIBILITY[*]

HARRY BUHRMAN[†], LANCE FORTNOW[‡], DIETER VAN MELKEBEEK[§], AND LEEN TORENVLIET[¶]

Abstract. A set is autoreducible if it can be reduced to itself by a Turing machine that does not ask its own input to the oracle. We use autoreducibility to separate the polynomial-time hierarchy from exponential space by showing that all Turing complete sets for certain levels of the exponential-time hierarchy are autoreducible but there exists some Turing complete set for doubly exponential space that is not.

Although we already knew how to separate these classes using diagonalization, our proofs separate classes solely by showing they have different structural properties, thus applying Post's program to complexity theory. We feel such techniques may prove unknown separations in the future. In particular, if we could settle the question as to whether all Turing complete sets for doubly exponential time are autoreducible, we would separate either polynomial time from polynomial space, and nondeterministic logarithmic space from nondeterministic polynomial time, or else the polynomial-time hierarchy from exponential time.

We also look at the autoreducibility of complete sets under nonadaptive, bounded query, probabilistic, and nonuniform reductions. We show how settling some of these autoreducibility questions will also lead to new complexity class separations.

Key words. complexity classes, completeness, autoreducibility, coherence

1. Introduction.

While complexity theorists have made great strides in understanding the structure of complexity classes, they have not yet found the proper tools to do nontrivial separation of complexity classes such as $\mathcal{P}$ and $\mathcal{NP}$. They have developed sophisticated diagonalization, combinatorial and algebraic techniques, but none of these ideas have yet proven very useful in the separation task.

Back in the early days of computability theory, Post [13] wanted to show that the set of noncomputable computably enumerable sets strictly contains the Turing complete computably enumerable sets. In what we now call "Post's program" (see

[11, 15]), Post tried to show these classes differ by finding a property that holds for all sets in the first class but not for some set in the second.

We would like to resurrect Post's program for separating classes in complexity theory. In particular we will show how some classes differ by showing that their complete sets have different structures. While we do not separate any classes not already separable by known diagonalization techniques, we feel that refinements to our techniques may yield some new separation results.

In this paper we will concentrate on the property known as "autoreducibility." A set A is autoreducible if we can decide whether an input x belongs to A in polynomial-time by making queries about membership of strings different from x to A.

Trakhtenbrot [16] first looked at autoreducibility in both the unbounded and space-bounded models. Ladner [10] showed that there exist Turing complete computably enumerable sets that are not autoreducible. Ambos-Spies [1] first transferred the notion of autoreducibility to the polynomial-time setting. More recently, Yao [18] and Beigel and Feigenbaum [5] have studied a probabilistic variant of autoreducibility known as "coherence."

In this paper, we ask for what complexity classes do all the complete sets have the autoreducibility property. In particular we show the following.

(i) All Turing complete sets for $\Delta_k^{\mathcal{EXP}}$ are autoreducible for any constant k, where $\Delta_{k+1}^{\mathcal{EXP}}$ denotes the sets that are exponential-time Turing reducible to $\Sigma_k^{\mathcal{P}}$.

(ii) There exists a Turing complete set for doubly exponential space that is not autoreducible.

Since the union of all sets $\Delta_k^{\mathcal{EXP}}$ coincides with the exponential-time hierarchy, we obtain a separation of the exponential-time hierarchy from doubly exponential space and thus of the polynomial-time hierarchy from exponential space. Although these results also follow from the space hierarchy theorems [9] which we have known for a long time, our proof does not directly use diagonalization, but rather separates the classes by showing that they have different structural properties.

Issues of relativization do not apply to this work because of oracle access (see [8]): a polynomial-time autoreduction cannot view as much of the oracle as an exponential or doubly exponential computation. To illustrate this point we show that there exists an oracle relative to which some complete set for exponential time is not autoreducible.

Note that if we can settle whether the Turing complete sets for doubly exponential time are all autoreducible one way or the other, we will have a major separation result. If there exists a Turing complete set for doubly exponential time that is not autoreducible, then we get that the exponential-time hierarchy is strictly contained in doubly exponential time and hence that the polynomial-time hierarchy is strictly contained in exponential time. If all of the Turing complete sets for doubly exponential time are autoreducible, we get that doubly exponential time is strictly contained in doubly exponential space, and thus polynomial time strictly in polynomial space. We will also show that this assumption implies a separation of nondeterministic logarithmic space from nondeterministic polynomial time. Similar implications hold for space-bounded classes (see section 5). Autoreducibility questions about doubly exponential time and exponential space thus remain an exciting line of research.

We also study the nonadaptive variant of the problem. Our main results scale down one exponential as follows:

(i) All truth-table complete sets $\Delta_k^{\mathcal{P}}$ are truth-table autoreducible for any constant k, where $\Delta_{k+1}^{\mathcal{P}}$ denotes the sets polynomial-time Turing reducible to $\Sigma_k^{\mathcal{P}}$.

(ii) There exists a truth-table complete set for exponential space that is not truth-table autoreducible.

Again, finding out whether all truth-table complete sets for intermediate classes, namely polynomial space and exponential time, are truth-table autoreducible, would have major implications.

In contrast to the above results we exhibit the limitations of our approach: For the restricted reducibility where we are only allowed to ask two nonadaptive queries, all complete sets for $\mathcal{EXP}$, $\mathcal{EXPSPACE}$, $\mathcal{EEXP}$, $\mathcal{EEXPSPACE}$, etc., are autoreducible.

We also argue that uniformity is crucial for our technique of separating complexity classes, because our nonautoreducibility results fail in the nonuniform setting. Razborov and Rudich [14] show that if strong pseudorandom generators exist, "natural proofs" cannot separate certain nonuniform complexity classes. Since this paper relies on uniformity in an essential way, their result does not apply.

Regarding the probabilistic variant of autoreducibility mentioned above, we can strengthen our results and construct a Turing complete set for doubly exponential space that is not even probabilistically autoreducible. We leave the analog of this theorem in the nonadaptive setting open: Does there exist a truth-table complete set for exponential space that is not probabilistically truth-table autoreducible? We do show that every truth-table complete set for exponential time is probabilistically truth-table autoreducible. Thus, a positive answer to the open question would establish that exponential time is strictly contained in exponential space. A negative answer, on the other hand, would imply a separation of nondeterministic logarithmic space from nondeterministic polynomial time.

Here is the outline of the paper: First, we introduce our notation and state some preliminaries in section 2. Next, in section 3 we establish our negative autoreducibility results, for the adaptive as well as the nonadaptive case. Then we prove the positive results in section 4, where we also briefly look at the randomized and nonuniform settings. Section 5 discusses the separations that follow from our results and would follow from improvements on them. Finally, we conclude in section 6 and mention some possible directions for further research.

1.1. Errata to conference version.

A previous version of this paper [6] erroneously claimed proofs showing all Turing complete sets for $\mathcal{EXPSPACE}$ are autoreducible and all truth-table complete sets for $\mathcal{PSPACE}$ are nonadaptively autoreducible. Combined with the additional results in this version, we would have a separation of $\mathcal{NL}$ and $\mathcal{NP}$ (see section 5).

However the proofs in the earlier version failed to account for the growth of the running time when recursively computing previous players' moves. We use the proof technique in section 3 though unfortunately we get weaker theorems. The original results claimed in the previous version remain important open questions as resolving them either way will yield new separation results.

2. Notation and preliminaries.

Most of our complexity theoretic notation is standard. We refer the reader to the textbooks by Balcázar, Díaz, and Gabarró [4, 3], and by Papadimitriou [12].

We use the binary alphabet $\Sigma = \{0, 1\}$. We denote the difference of a set A with a set B, i.e., the subset of elements of A that do not belong to B, by $A \setminus B$.

For any integer $k \geq 0$, a Σ_k-formula is a Boolean expression of the form

$$\exists\, y_1 \in \Sigma^{n_1}, \forall\, y_2 \in \Sigma^{n_2}, \ldots, Q_k\, y_k \in \Sigma^{n_k} : \phi(y_1, y_2, \ldots, y_k, z), \tag{2.1}$$

where ϕ is a Boolean formula, Q_i denotes $\exists$ if i is odd, and $\forall$ otherwise, and the n_i's are positive integers. We say that (2.1) has $k-1$ alternations. A Π_k-formula is just like (2.1) except that it starts with a $\forall$-quantifier. It also has $k-1$ alternations. A QBF$_k$-formula is a Σ_k-formula (2.1) or a Π_k-formula without free variables z.

For any integer $k \geq 0$, $\Sigma_k^{\mathcal{P}}$ denotes the kth Σ-level of the polynomial-time hierarchy. We define these levels recursively by $\Sigma_0^{\mathcal{P}} = \mathcal{P}$ and $\Sigma_{k+1}^{\mathcal{P}} = \mathcal{NP}^{\Sigma_k^{\mathcal{P}}}$. The Δ-levels of the polynomial-time and exponential-time hierarchy are defined as $\Delta_{k+1}^{\mathcal{P}} = \mathcal{P}^{\Sigma_k^{\mathcal{P}}}$ and $\Delta_{k+1}^{\mathcal{EXP}} = \mathcal{EXP}^{\Sigma_k^{\mathcal{P}}}$, respectively. The polynomial-time hierarchy $\mathcal{PH}$ equals the union of all sets $\Delta_k^{\mathcal{P}}$, and the exponential-time hierarchy $\mathcal{EXPH}$ similarly equals the union of all sets $\Delta_k^{\mathcal{EXP}}$.

A *reduction* of a set A to a set B is a polynomial-time oracle Turing machine M such that $M^B = A$. We say that A reduces to B and write $A \leq_{\mathrm{T}}^{\mathcal{P}} B$ ("T" for Turing). The reduction M is *nonadaptive* if the oracle queries M makes on any input are independent of the oracle, i.e., the queries do not depend upon the answers to previous queries. In that case we write $A \leq_{\mathrm{tt}}^{\mathcal{P}} B$ ("tt" for truth-table). Reductions of functions to sets are defined similarly. If the number of queries on an input of length n is bounded by $q(n)$, we write $A \leq_{q(n)-\mathrm{T}}^{\mathcal{P}} B$ and $A \leq_{q(n)-\mathrm{tt}}^{\mathcal{P}} B$, respectively; if it is bounded by some constant, we write $A \leq_{\mathrm{btt}}^{\mathcal{P}} B$ ("b" for bounded). We denote the set of queries of M on input x with oracle B by $Q_{M^B}(x)$; in case of nonadaptive reductions, we omit the oracle B in the notation. If the reduction asks only one query and answers the answer to that query, we write $A \leq_{\mathrm{m}}^{\mathcal{P}} B$ ("m" for many-one).

For any reducibility $\leq_r^{\mathcal{P}}$ and any complexity class $\mathcal{C}$, a set C is $\leq_r^{\mathcal{P}}$*-hard* for $\mathcal{C}$ if we can $\leq_r^{\mathcal{P}}$-reduce every set $A \in \mathcal{C}$ to C. If in addition $C \in \mathcal{C}$, we call C $\leq_r^{\mathcal{P}}$*-complete* for $\mathcal{C}$. For any integer $k \geq 0$, the set TQBF$_k$ of all true QBF$_k$-formulae is $\leq_{\mathrm{m}}^{\mathcal{P}}$-complete for $\Sigma_k^{\mathcal{P}}$. For $k = 1$, this reduces to the fact that the set SAT of satisfiable Boolean formulae is $\leq_{\mathrm{m}}^{\mathcal{P}}$-complete for $\mathcal{NP}$.

Now we get to the key concept of this paper in the following definition.

DEFINITION 2.1. *A set A is* autoreducible *if there is a reduction M of A to itself that never queries its own input, i.e., for any input x and any oracle B, $x \notin Q_{M^B}(x)$. We call such M an* autoreduction *of A.*

We will also discuss randomized and nonuniform variants. A set is *probabilistically autoreducible* if it has a probabilistic autoreduction with bounded two-sided error. Yao [18] first studied this concept under the name "coherence." A set is *nonuniformly autoreducible* if it has an autoreduction that uses polynomial advice. For all these notions, we can consider both the adaptive and the nonadaptive case. For randomized autoreducibility, nonadaptiveness means that the queries only depend on the input and the random seed.

3. Nonautoreducibility results.

In this section, we show that large complexity classes have complete sets that are not autoreducible.

THEOREM 3.1. *There is a $\leq_{2-\mathrm{T}}^{\mathcal{P}}$-complete set for $\mathcal{EEXPSPACE}$ that is not autoreducible.*

Most natural classes containing $\mathcal{EEXPSPACE}$, e.g., triply exponential time and triply exponential space, also have this property.

We can even construct the complete set in Theorem 3.1 to defeat every probabilistic autoreduction.

THEOREM 3.2. *There is a $\leq_{2-\mathrm{T}}^{\mathcal{P}}$-complete set for $\mathcal{EEXPSPACE}$ that is not probabilistically autoreducible.*

In the nonadaptive setting, we obtain the following theorem.

THEOREM 3.3. *There is a $\leq_{3-\mathrm{tt}}^{\mathcal{P}}$-complete set for $\mathcal{EXPSPACE}$ that is not nonadaptively autoreducible.*

Unlike the case of Theorem 3.1, our construction does not seem to yield a truth-table complete set that is not probabilistically nonadaptively autoreducible. In fact, as we shall show in section 4.3, such a result would separate $\mathcal{EXP}$ from $\mathcal{EXPSPACE}$; see also section 5.

We will detail in section 4.3 that our nonautoreducibility results do not hold in the nonuniform setting.

3.1. Adaptive autoreductions. Suppose we want to construct a nonautoreducible Turing complete set for a complexity class $\mathcal{C}$, i.e., a set A such that

1. A is not autoreducible,
2. A is Turing hard for $\mathcal{C}$,
3. A belongs to $\mathcal{C}$.

If $\mathcal{C}$ has a $\leq_{\mathrm{m}}^{\mathcal{P}}$-complete set K, realizing goals 1 and 2 is not too hard: We can encode K in A, and at the same time diagonalize against all autoreductions. A straightforward implementation would be to encode $K(y)$ as $A(\langle 0, y\rangle)$, and stagewise diagonalize against all $\leq_{\mathrm{T}}^{\mathcal{P}}$-reductions M by picking for each M an input x not of the form $\langle 0, y\rangle$ that is not queried during previous stages, and setting $A(x) = 1 - M^A(x)$. However, this construction does not seem to achieve goal 3. In particular, deciding the membership of a diagonalization string x to A might require computing $A(\langle 0, y\rangle) = K(y)$ on inputs y of length $|x|^c$, assuming M runs in time n^c. Since we have to do this for all potential autoreductions M, we can only bound the resources (time, space) needed to decide A by a function in $t(n^{\omega(1)})$, where $t(n)$ denotes the amount of resources some deterministic Turing machine accepting K uses. That does not suffice to keep A inside $\mathcal{C}$.

To remedy this problem, we will avoid the need to compute $K(y)$ on large inputs y, say of length at least $|x|$. Instead, we will make sure we can encode the membership of such strings to *any* set, not just K, and at the same time diagonalize against M on input x. We will argue that we can do this by considering two possible coding regions at every stage as opposed to a fixed one: the left region L, containing strings of the form $\langle 0, y\rangle$, and the right region R, similarly containing strings of the form $\langle 1, y\rangle$. The following states that we can use one of the regions to encode an arbitrary sequence, and set the other region such that the output of M on input x is fixed and indicates the region used for encoding.

STATEMENT 3.4. *Either it is the case that for any setting of L there is a setting of R such that $M^A(x)$ accepts, or for any setting of R there is a setting of L such that $M^A(x)$ rejects.*

This allows us to achieve goals 1 and 2 from above as follows. In the former case, we will set $A(x) = 0$ and encode K in L (at that stage); otherwise we will set $A(x) = 1$ and encode K in R. Since the value of $A(x)$ does not affect the behavior of M^A on input x, we diagonalize against M in both cases. Also, in any case,

$$K(y) = A(\langle A(x), y\rangle),$$

so deciding K is still easy when given A. Moreover—and crucially—in order to compute $A(x)$, we no longer have to decide $K(y)$ on large inputs y, of length $|x|$ or more. Instead, we have to check whether the former case in Statement 3.4 holds or not. Although quite complex a task, it only depends on M and on the part of A constructed so far, not on the value of $K(y)$ for any input of length $|x|$ or more: We verify whether we can encode *any* sequence, not just the characteristic sequence of K for lengths at least $|x|$, and at the same time diagonalize against M on input x.

Provided the complexity class $\mathcal{C}$ is sufficiently powerful, we can perform this task in $\mathcal{C}$.

There is still a catch, though. Suppose we have found out that the former case in Statement 3.4 holds. Then we will use the left region L to encode K (at that stage), and we know we can diagonalize against M on input x by setting the bits of the right region R appropriately. However, deciding exactly how to set these bits of the noncoding region requires, in addition to determining which region we should use for coding, the knowledge of $K(y)$ for all y such that $|x| \leq |y| \leq |x|^c$. In order to also circumvent the need to decide K for too large inputs here, we will use a slightly stronger version of Statement 3.4 obtained by grouping quantifiers into blocks and rearranging them. We will partition the coding and noncoding regions into intervals. We will make sure that for any given interval, the length of a string in that interval (or any of the previous intervals) is no more than the square of the length of any string in that interval. Then we will blockwise alternately set the bits in the coding region according to K, and the corresponding ones in the noncoding region so as to maintain the diagonalization against M on input x as in Statement 3.4. This way, in order to compute the bit $A(\langle 1, z\rangle)$ of the noncoding region, we will only have to query K on inputs y with $|y| \leq |z|^2$, as opposed to $|y| \leq |z|^c$ for an arbitrarily large c depending on M as was the case before.

This is what happens in the next lemma, which we prove in a more general form, because we will need the generalization later on in section 5.

LEMMA 3.5. *Fix a set K, and suppose we can decide it simultaneously in time $t(n)$ and space $s(n)$. Let $\alpha : \mathbb{N} \to (0, \infty)$ be a constructible monotone unbounded function, and suppose there is a deterministic Turing machine accepting TQBF that takes time $t'(n)$ and space $s'(n)$ on QBF-formulae of size $2^{n^{\alpha(n)}}$ with at most* $\log \alpha(n)$ *alternations. Then there is a set A such that*

1. *A is not autoreducible;*
2. *$K \leq^{\mathcal{P}}_{2-\mathrm{T}} A$;*
3. *We can decide A simultaneously in time $O(2^{n^2} \cdot t(n^2) + 2^n \cdot t'(n))$ and space $O(2^{n^2} + s(n^2) + s'(n))$.*

Proof. Fix a function α satisfying the hypotheses of the lemma, and let $\beta = \sqrt{\alpha}$. Let $M_1, M_2, \ldots$ be a standard enumeration of autoreductions clocked such that M_i runs in time $n^{\beta(i)}$ on inputs of length n. Our construction starts out with A being the empty set, and then adds strings to A in subsequent stages $i = 1, 2, 3, \ldots$ defined by the following sequence:

$$\begin{cases} n_0 &= 0, \\ n_{i+1} &= n_i^{\beta(n_i)} + 1. \end{cases}$$

Note that since M_i runs in time $n^{\beta(i)}$, M_i cannot query strings of length n_{i+1} or more on input 0^{n_i}.

Fix an integer $i \geq 1$ and let $m = n_i$. For any integer j such that $0 \leq j \leq \log \beta(m)$, let I_j denote the set of all strings with lengths in the interval $[m^{2^j}, \min(m^{2^{j+1}}, m^{\beta(m)} + 1))$. Note that $\{I_j\}_{j=0}^{\log \beta(m)}$ forms a partition of the set I of strings with lengths in $[m, m^{\beta(m)} + 1) = [n_i, n_{i+1})$ with the property that for any $0 \leq k \leq \log \beta(m)$, the length of any string in $\cup_{j=0}^{k} I_j$ is no more than the square of the length of any string in I_k.

During the ith stage of the construction, we will encode the restriction $K|_I$ of K to I into $\{\langle b, y\rangle \mid b \in \{0, 1\}$ and $y \in I\}$, and use the string 0^m for diagonalizing against

```
if formula (3.1) holds
  then for $j = 0, \dots, \log\beta(m)$
        $(\ell_y)_{y\in I_j} \leftarrow (K(y))_{y\in I_j}$
        $(r_y)_{y\in I_j} \leftarrow$ the lexicographically first value satisfying
              $(\forall\,\ell_y)_{y\in I_j+1}, (\exists\,r_y)_{y\in I_{j+1}}, (\forall\,\ell_y)_{y\in I_{j+2}}, (\exists\,r_y)_{y\in I_{j+2}},$
                $\dots, (\forall\,\ell_y)_{y\in I_{\log\beta(m)}}, (\exists\,r_y)_{y\in I_{\log\beta(m)}} : M_i^{A'}(0^m)$ accepts,
           where $A' = A \cup \{\langle 0, y\rangle \mid y \in I \text{ and } \ell_y = 1\} \cup \{\langle 1, y\rangle \mid y \in I \text{ and } r_y = 1\}$
        end for
      $A \leftarrow A \cup \{\langle 0, y\rangle \mid y \in I \text{ and } \ell_y = 1\} \cup \{\langle 1, y\rangle \mid y \in I \text{ and } r_y = 1\}$
  else { formula (3.2) holds }
      for $j = 0, \dots, \log\beta(m)$
        $(r_y)_{y\in I_j} \leftarrow (K(y))_{y\in I_j}$
        $(\ell_y)_{y\in I_j} \leftarrow$ the lexicographically first value satisfying
              $(\forall\,r_y)_{y\in I_{j+1}}, (\exists\,\ell_y)_{y\in I_{j+1}}, (\forall\,r_y)_{y\in I_{j+2}}, (\exists\,\ell_y)_{y\in I_{j+2}},$
                $\dots, (\forall\,r_y)_{y\in I_{\log\beta(m)}}, (\exists\,\ell_y)_{y\in I_{\log\beta(m)}} : M_i^{A'}(0^m)$ accepts,
           where $A' = A \cup \{\langle 0, y\rangle \mid y \in I \text{ and } \ell_y = 1\} \cup \{\langle 1, y\rangle \mid y \in I \text{ and } r_y = 1\}$
        end for
      $A \leftarrow A \cup \{0^m\} \cup \{\langle 0, y\rangle \mid y \in I \text{ and } \ell_y = 1\} \cup \{\langle 1, y\rangle \mid y \in I \text{ and } r_y = 1\}$
  end if
```

FIG. 3.1. *Stage i of the construction of the set A in Lemma* 3.5.

M_i, applying the next strengthening of Statement 3.4 to do so.

CLAIM 3.6. *For any set A, at least one of the following holds:*

$$(\forall\,\ell_y)_{y\in I_0}, (\exists\,r_y)_{y\in I_0}, (\forall\,\ell_y)_{y\in I_1}, (\exists\,r_y)_{y\in I_1}, \dots, (\forall\,\ell_y)_{y\in I_{\log\beta(m)}}, (\exists\,r_y)_{y\in I_{\log\beta(m)}} : M_i^{A'}(0^m) \text{ accepts} \tag{3.1}$$

or

$$(\forall\,r_y)_{y\in I_0}, (\exists\,\ell_y)_{y\in I_0}, (\forall\,r_y)_{y\in I_1}, (\exists\,\ell_y)_{y\in I_1}, \dots, (\forall\,r_y)_{y\in I_{\log\beta(m)}}, (\exists\,\ell_y)_{y\in I_{\log\beta(m)}} : M_i^{A'}(0^m) \text{ rejects}, \tag{3.2}$$

where A' denotes $A \cup \{\langle 0, y\rangle \mid y \in I$ and $\ell_y = 1\} \cup \{\langle 1, y\rangle \mid y \in I$ and $r_y = 1\}$.

Here we use $(Q\,z_y)_{y\in Y}$ as a shorthand for $Q\,z_{y_1}, Q\,z_{y_2}, \dots, Q\,z_{y_{|Y|}}$, where $Y = \{y_1, y_2, \dots, y_{|Y|}\}$ and all variables are quantified over $\{0, 1\}$. Without loss of generality we assume that the range of the pairing function $\langle\cdot,\cdot\rangle$ is disjoint from 0^*.

Proof of Claim 3.6. Fix A. If (3.1) does not hold, then its negation holds, i.e,

$$(\exists\,\ell_y)_{y\in I_0}, (\forall\,r_y)_{y\in I_0}, (\exists\,\ell_y)_{y\in I_1}, (\forall\,r_y)_{y\in I_1}, \dots, (\exists\,\ell_y)_{y\in I_{\log\beta(m)}}, (\forall\,r_y)_{y\in I_{\log\beta(m)}} : M_i^{A'}(0^m) \text{ rejects}. \tag{3.3}$$

Switching the quantifiers $(\exists\,\ell_y)_{y\in I_j}$ and $(\forall\,r_y)_{y\in I_j}$ pairwise for every $0 \le j \le \log\beta(m)$ in (3.3) yields the weaker statement (3.2). ☐

Figure 3.1 describes the ith stage in the construction of the set A. Note that the lexicographically first values in this algorithm always exist, so the construction works fine. We now argue that the resulting set A satisfies the properties of Lemma 3.5:

1. The construction guarantees that $A(0^m) = 1 - M_i^{A\setminus\{0^m\}}(0^m)$ holds by the end of stage i. Since M_i on input 0^m cannot query 0^m (because M_i is an autoreduction)

nor any of the strings added during subsequent stages (because M_i does not even have the time to write down any of these strings), $A(0^m) = 1 - M_i^A(0^m)$ holds for the final set A. Thus, M_i is not an autoreduction of A. Since this is true of any autoreduction M_i, the set A is not autoreducible.

2. During stage i, we encode $K|_I$ in the left region iff we do not put 0^m into A; otherwise we encode $K|_I$ in the right region. Thus, for any $y \in I$, $K(y) = A(\langle A(0^m), y\rangle)$. Therefore, $K \leq_{2-\mathrm{T}}^{\mathcal{P}} A$.

3. First note that A only contains strings of the form 0^m with $m = n_i$ for some integer $i \geq 1$, and strings of the form $\langle b, y\rangle$ with $b \in \{0,1\}$ and $y \in \Sigma^*$. Assume we have executed the construction of A up to but not including stage i and stored the result in memory. The additional work to decide the membership to A of a string belonging to the ith stage is as follows.

(i) *Case* 0^m. Since $0^m \in A$ iff formula (3.1) does not hold and (3.1) is a $\mathrm{QBF}_{2\log\beta(m)}$-formula of size $2^{O(m^{\beta(m)})} \leq 2^{m^{\alpha(m)}}$, we can decide whether $0^m \in A$ in time $O(t'(m))$ and space $O(s'(m))$.

(ii) *Case* $\langle b, z\rangle$ *where* $b = A(0^m)$ *and* $z \in I$. Then $\langle b, z\rangle \in A$ iff $z \in K$, which we can decide in time $t(|z|)$ and space $s(|z|)$.

(iii) *Case* $\langle b, z\rangle$ *where* $b = 1 - A(0^m)$ *and* $z \in I$. Say $z \in I_k$, $0 \leq k \leq \log\beta(m)$. In order to compute whether $\langle b, z\rangle \in A$, we run the part of stage i corresponding to the values of j in Figure 3.1 up to and including k, and store the results in memory. This involves computing K on $\cup_{j=0}^{k} I_j$ and deciding $O(2^{|z|})$ $\mathrm{QBF}_{2\log\beta(m)}$-formulae of size $2^{O(m^{\beta(m)})} \leq 2^{m^{\alpha(m)}}$, namely one formula for each $y \in \cup_{j=0}^{k} I_j$ which precedes or equals z in lexicographic order. The latter takes $O(2^{|z|} \cdot t'(m))$ time and $O(2^{|z|} + s'(m))$ space. Since every string in $\cup_{j=0}^{k} I_j$ is of size no more than $|z|^2$, we can do the former in time $O(2^{|z|^2} \cdot t(|z|^2))$ and space $O(2^{|z|^2} + s(|z|^2))$. So, the requirements for this stage are $O(2^{|z|^2} \cdot t(|z|^2) + 2^{|z|} \cdot t'(|z|))$ time and $O(2^{|z|^2} + s(|z|^2) + s'(|z|))$ space.

A similar analysis also shows that we can perform the stages up to but not including i in time $O(2^m \cdot (t(m) + t'(m)))$ and space $O(2^m + s(m) + s'(m))$. All together, this yields the time and space bounds claimed for A. $\square$

Using the upper bound $2^{n^{\alpha(n)}}$ for $s'(n)$, the smallest standard complexity class to which Lemma 3.5 applies, seems to be $\mathcal{EEXPSPACE}$. This results in Theorem 3.1.

Proof of Theorem 3.1. In Lemma 3.5, set K a $\leq_{\mathrm{m}}^{\mathcal{P}}$-complete set for $\mathcal{EEXPSPACE}$, and $\alpha(n) = n$. $\square$

In section 4.2, we will see that $\leq_{2-\mathrm{T}}^{\mathcal{P}}$ in the statement of Theorem 3.1 is optimal: Theorem 4.6 shows that Theorem 3.1 fails for $\leq_{2-\mathrm{tt}}^{\mathcal{P}}$.

We note that the proof of Theorem 3.1 carries through for $\leq_{\mathrm{T}}^{\mathcal{EXPSPACE}}$-reductions with polynomially bounded query lengths. This implies the strengthening given by Theorem 3.2.

3.2. Nonadaptive autoreductions. Diagonalizing against nonadaptive autoreductions M is easier. If M runs in time $\tau(n)$, there can be no more than $\tau(n)$ coding strings that interfere with the diagonalization, as opposed to $2^{\tau(n)}$ in the adaptive case. This allows us to reduce the complexity of the set constructed in Lemma 3.5 as follows.

LEMMA 3.7. *Fix a set K, and suppose we can decide it simultaneously in time $t(n)$ and space $s(n)$. Let $\alpha : \mathbb{N} \to (0, \infty)$ be a constructible monotone unbounded function, and suppose there is a deterministic Turing machine accepting TQBF that takes time $t'(n)$ and space $s'(n)$ on QBF-formulae of size $n^{\alpha(n)}$ with at most* $\log\alpha(n)$ *alternations. Then there is a set A such that*

1. *A is not nonadaptively autoreducible;*
2. *$K \leq^{\mathcal{P}}_{3-\mathrm{tt}} A$;*
3. *We can decide A simultaneously in time $O(2^n + n^{\alpha(n)}) \cdot (t(n^2) + t'(n)))$ and space $O(2^n + n^{\alpha(n)} + s(n^2) + s'(n))$.*

Proof. The construction of the set A is the same as in Lemma 3.5 (see Figure 3.1) apart from the following differences.

(i) $M_1, M_2, \ldots$ now is a standard enumeration of nonadaptive autoreductions clocked such that M_i runs in time $n^{\beta(i)}$ on inputs of length n. Note that the set $Q_M(x)$ of possible queries M makes on input x contains no more than $|x|^{\beta(i)}$ elements.

(ii) During stage $i \geq 1$ of the construction, I denotes the set of all strings y with lengths in $[m, m^{\beta(m)} + 1) = [n_i, n_{i+1})$ such that $\langle 0, y\rangle \in Q_{M_i}(0^m)$ or $\langle 1, y\rangle \in Q_{M_i}(0^m)$, and I_j for $0 \leq j \leq \log \beta(m)$ denotes the set of strings in I with lengths in $[m^{2^j}, \min(m^{2^{j+1}}, m^{\beta(m)} + 1))$. Note that the only ℓ_y's and r_y's that affect the validity of the predicate "$M_i^{A'}(0^m)$ accepts" in formula (3.1) and the corresponding formulae in Figure 3.1, are those for which $y \in I$.

(iii) At the end of stage i in Figure 3.1, we add the following line:

$$A \leftarrow A \cup \{\langle b, y\rangle \mid b \in \{0,1\}, y \in \Sigma^* \text{ with } m \leq |y| < m^{\beta(m)} + 1, y \notin I \text{ and } K(y) = 1\}.$$

This ensures coding $K(y)$ for strings y with lengths in $[n_i, n_{i+1})$ such that neither $\langle 0, y\rangle$ nor $\langle 1, y\rangle$ are queried by M_i on input 0^m. Although not essential, we choose to encode them in both the left and the right region.

The proof that A satisfies the three properties claimed carries over. Only the time and space analysis in the third point needs modification. The crucial simplification over the adaptive case lies in the fact that (3.1) and the similar formulae in Figure 3.1 now become $\mathrm{QBF}_{2\log\beta(n)}$-formulae of size $n^{O(\beta(m))}$ as opposed to of size $2^{O(m^{\beta(m)})}$ in Lemma 3.5. More specifically, referring to the proof of Lemma 3.5, we have the following cases regarding the work at stage i of the construction.

(i) *Case 0^m.* The above mentioned simplification takes care of this case.

(ii) *Case $\langle b, z\rangle$, where $b = A(0^m)$ and $z \in I$.* The argument of Lemma 3.5 carries over as such.

(iii) *Case $\langle b, z\rangle$, where $b = 1 - A(0^m)$ and $z \in I$.* Computing K on $\cup_{j=0}^{k} I_j$ and storing the result can be done in time $O(m^{\beta(m)} \cdot t(|z|^2))$ and space $O(m^{\beta(m)} + s(|z|^2))$. Deciding the $O(m^{\beta(m)})$ $\mathrm{QBF}_{2\log\beta(m)}$-formulae of size $m^{O(\beta(m))} \leq m^{\alpha(m)}$ involved requires no more than $O(m^{\beta(m)} \cdot t'(m))$ time and $O(m^{\beta(m)} + s'(m))$ space.

(iv) *Case $\langle b, z\rangle$ where $b \in \{0,1\}$, $m \leq |z| \leq m^{\beta(m)} + 1$, and $z \notin I$.* This is an additional case. By construction, $\langle b, z\rangle \in A$ iff $z \in K$, which we can decide in time $t(|z|)$ and space $s(|z|)$.

By similar analysis, a rough estimate of the resources required for the previous stages of the construction is $O(2^m \cdot (t(m) + t'(m)))$ time and $O(2^m + s(m) + s'(m))$ space, resulting in a total as stated in the lemma. ∎

As a consequence, we can lower the space complexity in the equivalent of Theorem 3.1 from doubly exponential to singly exponential, yielding Theorem 3.3. In section 4.2 we will show we cannot reduce the number of queries from three to two in Theorem 3.3.

If we restrict the number of queries the nonadaptive autoreduction is allowed to make to some fixed polynomial, the proof technique of Theorem 3.3 also applies to $\mathcal{EXP}$. In particular, we obtain the following theorem.

THEOREM 3.8. *There is a $\leq^{\mathcal{P}}_{3-\mathrm{tt}}$-complete set for $\mathcal{EXP}$ that is not $\leq^{\mathcal{P}}_{\mathrm{btt}}$-autoreducible.*

4. Autoreducibility results.

For small complexity classes, all complete sets turn out to be autoreducible. Beigel and Feigenbaum [5] established this property of all levels of the polynomial-time hierarchy as well as of $\mathcal{PSPACE}$, the largest class for which it was known to hold before our work. In this section, we will prove it for the Δ-levels of the exponential-time hierarchy.

As to nonadaptive reductions, the question was even open for all levels of the polynomial-time hierarchy. We will show here that the $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for the Δ-levels of the polynomial-time hierarchy are nonadaptively autoreducible. For any complexity class containing $\mathcal{EXP}$, we will prove that the $\leq_{2-\mathrm{tt}}^{\mathcal{P}}$-complete sets are $\leq_{2-\mathrm{tt}}^{\mathcal{P}}$-autoreducible.

Finally, we will also consider nonuniform and randomized autoreductions.

Throughout this section, we will assume without loss of generality an encoding γ of a computation of a given oracle Turing machine M on a given input x with the following properties. γ will be a marked concatenation of successive instantaneous descriptions of M, starting with the initial instantaneous description of M on input x, such that:

(i) Given a pointer to a bit in γ, we can find out whether that bit represents the answer to an oracle query by probing a constant number of bits of γ.

(ii) If it is the answer to an oracle query, the corresponding query is a substring of the prefix of γ up to that point, and we can easily compute a pointer to the beginning of that substring without probing γ any further.

(iii) If it is not the answer to an oracle query, we can perform a local consistency check for that bit which only depends on a constant number of previous bit positions of γ and the input x. Formally, there exist a function g_M and a predicate e_M, both polynomial-time computable, and a constant c_M such that the following holds: For any input x, any index i to a bit position in γ, and any j, $1 \leq j \leq c_M$, $g_M(x; i, j)$ is an index no larger than i, and

$$e_M(x; i, \gamma_{g_M(x;i,1)}, \gamma_{g_M(x;i,2)}, \ldots, \gamma_{g_M(x;i;c_M)}) \tag{4.1}$$

indicates whether γ passes the local consistency test for its ith bit γ_i. Provided the prefix of γ up to but not including position i is correct, the local consistency test is passed iff γ_i is correct.

We call such an encoding a *valid computation* of M on input x iff the local consistency tests (4.1) for all the bit positions i that do not correspond to oracle answers, are passed, and the other bits equal the oracle's answer to the corresponding query. Any other string we will call a *computation.*

4.1. Adaptive autoreductions.

We will first show that every $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set for $\mathcal{EXP}$ is autoreducible, and then generalize to all Δ-levels of the exponential-time hierarchy.

THEOREM 4.1. *Every $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set for $\mathcal{EXP}$ is autoreducible.*

Here is the proof idea: For any of the standard deterministic complexity classes $\mathcal{C}$, we can decide each bit of the computation on a given input x within $\mathcal{C}$. Thus, if A is a $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set for $\mathcal{C}$ that can be decided by a machine M within the confines of the class $\mathcal{C}$, then we can $\leq_{\mathrm{T}}^{\mathcal{P}}$-reduce deciding the ith bit of the computation of M on input x to A. Now, consider the two (possibly invalid) computations we obtain by applying the above reduction to every bit position, answering all queries except for x according to A, assuming $x \in A$ for one computation and $x \notin A$ for the other.

Note that the computation corresponding to the right assumption about $A(x)$ is certainly correct. Thus, if both computations yield the same answer (which we

```
if $R_\mu^{A\setminus\{x\}}(\langle x, 2^{p(|x|)}\rangle) = R_\mu^{A\cup\{x\}}(\langle x, 2^{p(|x|)}\rangle)$
  then accept iff $R_\mu^{A\cup\{x\}}(\langle x, 2^{p(|x|)}\rangle) = 1$
  else $i \leftarrow R_\sigma^{A\cup\{x\}}(x)$
      accept iff $e_M(x; i, R_\mu^{A\setminus\{x\}}(\langle x, g_M(x;i;1)\rangle), R_\mu^{A\setminus\{x\}}(\langle x, g_M(x;i,2)\rangle), \ldots,$
                                  $\ldots, R_\mu^{A\setminus\{x\}}(\langle x, g_M(x;i,c_M)\rangle)) = 0$
  end if
```

FIG. 4.1. *Autoreduction for the set A of Theorem* 4.1 *on input x.*

can efficiently check using A without querying x), that answer is correct. If not, the other computation contains a mistake. We cannot check both computations entirely to see which one is right, but given a pointer to the first incorrect bit of the wrong computation, we can efficiently verify that it is mistaken by checking only a constant number of bits of that computation. The pointer is again computable within $\mathcal{C}$.

In case $\mathcal{C} \subseteq \mathcal{EXP}$, using a $\leq_{\mathrm{T}}^{\mathcal{P}}$-reduction to A and assuming $x \in A$ or $x \notin A$ as above, we can determine the pointer with oracle A (but without querying x) in polynomial time, since the pointer's length is polynomially bounded.

We now fill out the details.

Proof of Theorem 4.1. Fix a $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set A for $\mathcal{EXP}$. Say A is accepted by a Turing machine M such that the computation of M on an input of size n has length $2^{p(n)}$ for some fixed polynomial p. Without loss of generality the last bit of the computation gives the final answer. Let g_M, e_M, and c_M be the formalization of the local consistency test for M as described by (4.1).

Let $\mu(\langle x, i\rangle)$ denote the ith bit of the computation of M on input x. We can compute μ in $\mathcal{EXP}$, so there is an oracle Turing machine R_μ $\leq_{\mathrm{T}}^{\mathcal{P}}$-reducing μ to A.

Let $\sigma(x)$ be the first i, $1 \leq i \leq 2^{p(|x|)}$, such that $R_\mu^{A\setminus\{x\}}(\langle x, i\rangle) \neq R_\mu^{A\cup\{x\}}(\langle x, i\rangle)$, provided it exists. Again, we can compute σ in $\mathcal{EXP}$, so there is a $\leq_{\mathrm{T}}^{\mathcal{P}}$-reduction R_σ from σ to A.

Consider the algorithm in Figure 4.1 for deciding A on input x. The algorithm is a polynomial-time oracle Turing machine with oracle A that does not query its own input x. We now argue that it correctly decides A on input x. We distinguish between two cases.

(i) *Case* $R_\mu^{A\setminus\{x\}}(\langle x, 2^{p(|x|)}\rangle) = R_\mu^{A\cup\{x\}}(\langle x, 2^{p(|x|)}\rangle)$. Since at least one of the computations $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ or $R_\mu^{A\cup\{x\}}(\langle x, \cdot\rangle)$ coincides with the actual computation of M on input x, and the last bit of the computation equals the final decision, correctness follows.

(ii) *Case* $R_\mu^{A\setminus\{x\}}(\langle x, 2^{p(|x|)}\rangle) \neq R_\mu^{A\cup\{x\}}(\langle x, 2^{p(|x|)}\rangle)$. If $x \in A$, $R_\mu^{A\setminus\{x\}}(\langle x, 2^{p(|x|)}\rangle) = 0$, so $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ contains a mistake. Variable i gets the correct value of the index of the first incorrect bit in this computation, so the local consistency test for $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ being the computation of M on input x fails on the ith bit, and we accept x. If $x \notin A$, then $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is a valid computation, so no local consistency test fails, and we reject x. ▯

The local checkability property of computations used in the proof of Theorem 4.1 does not relativize, because the oracle computation steps depend on the entire query, i.e., on a number of bits that is only limited by the resource bounds of the base machine, in this case exponentially many. We next show that Theorem 4.1 itself also does not relativize.

THEOREM 4.2. *Relative to some oracle, $\mathcal{EXP}$ has a $\leq_{2-\mathrm{T}}^{\mathcal{P}}$-complete set that is* *not autoreducible.*

Proof. Note that $\mathcal{EXP}$ has the following property.

PROPERTY 4.3. *There is an oracle Turing machine N running in $\mathcal{EXP}$ such that for any oracle B, the set accepted by N^B is $\leq_{\mathrm{m}}^{\mathcal{P}}$-complete for $\mathcal{EXP}^B$.*

Without loss of generality, we assume that N runs in time 2^n. Let K^B denote the set accepted by N^B.

We will construct an oracle B and a set A such that A is $\leq_{2-\mathrm{T}}^{\mathcal{P}}$-complete for $\mathcal{EXP}^B$ and is not $\leq_{\mathrm{T}}^{\mathcal{P}^B}$-autoreducible.

The construction of A is the same as in Lemma 3.5 (see Figure 3.1) with $\beta(n) = \log n$ and $K = K^B$, except that the reductions M_i now also have access to the oracle B.

We will encode in B information about the construction of A that reduces the complexity of A relative to B but do it high enough so as not to destroy the $\leq_{2-\mathrm{T}}^{\mathcal{P}}$-completeness of A for $\mathcal{EXP}^B$ nor the diagonalizations against $\leq_{\mathrm{T}}^{\mathcal{P}^B}$-autoreductions.

We construct B in stages along with A. We start with B empty. Using the notation of Lemma 3.5, at the beginning of stage i, we add 0^{2^m} to B iff property (3.1) does not hold, and at the end of substage j, we join B with

$$\left\{\left\langle 0^{2^{m^{2^{j+1}}}}, y\right\rangle \mid y \in I_j \text{ and } r(y) = 1\right\} \text{ if (3.1) holds at stage } i,$$
$$\left\{\left\langle 0^{2^{m^{2^{j+1}}}}, y\right\rangle \mid y \in I_j \text{ and } \ell(y) = 1\right\} \text{ otherwise.}$$

Note that this does not affect the value of $K^B(y)$ for $|y| < m^{2^{j+1}}$ nor the computations of M_i on inputs of size at most m (for sufficiently large i such that $m^{\log m} < 2^m$). It follows from the analysis in the proof of Lemma 3.5 that the set A is $\leq_{2-\mathrm{T}}^{\mathcal{P}}$-hard for $\mathcal{EXP}^B$ and not $\leq_{\mathrm{T}}^{\mathcal{P}^B}$-autoreducible.

Regarding the complexity of deciding A relative to B, note that the encoding in the oracle B allows us to eliminate the need for evaluating $\mathrm{QBF}_{\log\beta(n)}$-formulae of size $2^{n^{\beta(n)}}$. Instead, we just query B on easily constructed inputs of size $O(2^{n^2})$. Therefore, we can drop the terms corresponding to the $\mathrm{QBF}_{\log\beta(n)}$-formulae of size $2^{n^{\beta(n)}}$ in the complexity of A. Consequently, $A \in \mathcal{EXP}^B$. ☐

Theorem 4.2 applies to any complexity class containing $\mathcal{EXP}$ that has Property 4.3, e.g., $\mathcal{EXPSPACE}$, $\mathcal{EEXP}$, $\mathcal{EEXPSPACE}$, etc.

Sometimes, the structure of the oracle allows us to get around the lack of local checkability of oracle queries. This is the case for oracles from the polynomial-time hierarchy, and leads to the following extension of Theorem 4.1.

THEOREM 4.4. *For any integer $k \geq 0$, every $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set for $\Delta_{k+1}^{\mathcal{EXP}}$ is autoreducible.*

The proof idea is as follows: Let A be a $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set accepted by the deterministic oracle Turing machine M with oracle TQBF_k. First note that there is a polynomial-time Turing machine N such that a query q belongs to the oracle TQBF_k iff

$$\exists\, y_1, \forall\, y_2, \ldots, Q_k\, y_k : N(q, y_1, y_2, \ldots, y_k) \text{ accepts,} \tag{4.2}$$

where the y_ℓ's are of size polynomial in $|q|$.

We consider the two purported computations of M on input x constructed in the proof of Theorem 4.1. One belongs to a party assuming $x \in A$, the other to a party assuming $x \notin A$. The computation corresponding to the right assumption is correct; the other one might not be.

Now suppose the computations differ and we are given a pointer to the first bit position where they disagree, which turns out to be the answer to an oracle query q. Then we can have the two parties play the k-round game underlying (4.2): The party claiming $q \in \mathrm{TQBF}_k$ plays the existentially quantified y_ℓ's, the other one the universally quantified y_ℓ's. The players' strategies will consist of computing the game history so far, determining their optimal next move, $\leq_{\mathrm{T}}^{\mathcal{P}}$-reducing this computation to A, and finally producing the result of this reduction under their respective assumption about $A(x)$. This will guarantee that the party with the correct assumption plays optimally. Since this is also the one claiming the correct answer to the oracle query q, he will win the game, i.e., $N(q, y_1, y_2, \ldots, y_k)$ will equal his answer bit.

The only thing the autoreduction for A has to do is determine the value of $N(q, y_1, y_2, \ldots, y_k)$ in polynomial time using A as an oracle but without querying x. It can do that along the lines of the base case algorithm given in Figure 4.1. If during this process the local consistency test for N's computation requires the knowledge of bits from the y_ℓ's, we compute these via the reduction defining the strategy of the corresponding player. The bits from q we need we can retrieve from the M-computations, since both computations are correct up to the point where they finished generating q. Once we know $N(q, y_1, y_2, \ldots, y_k)$ we can easily decide the correct assumption about $A(x)$.

The construction hinges on the hypothesis that we can $\leq_{\mathrm{T}}^{\mathcal{P}}$-reduce determining the player's moves to A. Computing these moves can become quite complex, though, because we have to recursively reconstruct the game history so far. The number of rounds k being constant seems crucial for keeping the complexity under control. The conference version of this paper [6] erroneously claimed the proof works for $\mathcal{EXPSPACE}$, which can be thought of as alternating exponential time with an exponential number of alternations. Establishing Theorem 4.4 for $\mathcal{EXPSPACE}$ would actually separate $\mathcal{NL}$ from $\mathcal{NP}$, as we will see in section 5.

Proof of Theorem 4.4. Let A be a $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete set for $\Delta_{k+1}^{\mathcal{EXP}} = \mathcal{EXP}^{\Sigma_k^{\mathcal{P}}}$ accepted by the exponential-time oracle Turing machine M with oracle TQBF_k. Let g_M, e_M, and c_M be the formalization of the local consistency test for M as described by (4.1). Without loss of generality there is a polynomial p and a polynomial-time Turing machine N such that on inputs of size n, M makes exactly $2^{p(n)}$ oracle queries, all of the form

$$\exists\, y_1 \in \Sigma^{2^{p(n)}}, \forall\, y_2 \in \Sigma^{2^{p(n)}}, \ldots, Q_k\, y_k \in \Sigma^{2^{p(n)}} : N(q, y_1, y_2, \ldots, y_k) \text{ accepts}, \tag{4.3}$$

where q has length $2^{p^2(n)}$. Moreover, the computations of N in (4.3) each have length $2^{p^3(n)}$, and their last bit represents the answer; the same holds for the computations of M on inputs of length n. Let g_N, e_N, and c_N be the formalization of the local consistency test for N.

We first define a bunch of functions computable in $\Delta_{k+1}^{\mathcal{EXP}}$. For each of them, say ξ, we fix an oracle Turing machine R_ξ that $\leq_{\mathrm{T}}^{\mathcal{P}}$-reduces ξ to A, and which the final autoreduction for A will use. The proofs that we can compute these functions in $\Delta_{k+1}^{\mathcal{EXP}}$ are straightforward.

Let $\mu(\langle x, i\rangle)$ denote the ith bit of the computation of M^{TQBF_k} on input x, and $\sigma(x)$ the first i (if any) such that $R_\mu^{A \setminus \{x\}}(\langle x, i\rangle) \neq R_\mu^{A \cup \{x\}}(\langle x, i\rangle)$. The roles of μ and σ are the same as in the proof of Theorem 4.1: We will use R_μ to figure out whether both possible answers for the oracle query "$x \in A$?" lead to the same final answer, and if not, use R_σ to find a pointer i to the first incorrect bit (in any) of the simulated computation getting the negative oracle answer $x \notin A$. If i turns out not to point to an oracle query, we can proceed as in the proof of Theorem 4.1. Otherwise, we will make use of the following functions and associated reductions to A.

We define the functions η_ℓ and y_ℓ inductively for $\ell = 1, \ldots, k$. At each level ℓ we first define η_ℓ, which induces a reduction R_{η_ℓ}, and then define y_ℓ based on R_{η_ℓ}. All of these functions take an input x such that the ith bit of $R_\mu^{A \setminus \{x\}}(\langle x, \cdot \rangle)$ is the answer to an oracle query (4.3), where $i = R_\sigma^{A \cup \{x\}}(x)$. We define $\eta_\ell(x)$ as the lexicographically least $y_\ell \in \Sigma^{2^{p(|x|)}}$ such that

$$\begin{aligned}&\chi[Q_{\ell+1}\, y_{\ell+1}, Q_{\ell+2}\, y_{\ell+2}, \ldots, Q_k\, y_k :\\ &\quad N(q, y_1(x), y_2(x), \ldots, y_{\ell-1}(x), y_\ell, y_{\ell+1}, \ldots, y_k) \text{ accepts}] \equiv \ell \bmod 2;\end{aligned} \tag{4.4}$$

if this value does not exist, we set $\eta_\ell(x) = 0^{2^{p(|x|)}}$. Note that the right-hand side of (4.4) is 1 iff y_ℓ is existentially quantified in (4.3).

$$y_\ell(x) = \begin{cases} R_{\eta_\ell}^{A \cup \{x\}}(x) & \text{if } \ell \equiv R_\mu^{A \cup \{x\}}(\langle x, i \rangle) \bmod 2, \\ R_{\eta_\ell}^{A \setminus \{x\}}(x) & \text{otherwise.} \end{cases} \tag{4.5}$$

The condition on the right-hand side of (4.5) means that we use the hypothesis $x \in A$ to compute $y_\ell(x)$ from R_{η_ℓ} in case

(i) either y_ℓ is existentially quantified in (4.3) and the player assuming $x \in A$ claims (4.3) holds,

(ii) or else y_ℓ is universally quantified and the player assuming $x \in A$ claims (4.3) fails.

Otherwise we use the hypothesis $x \notin A$.

In case i points to the answer to an oracle query (4.3), the functions η_ℓ and the reductions R_{η_ℓ} incorporate the moves during the successive rounds of the game underlying (4.3). The reduction R_{η_ℓ}, together with the player's assumption about membership of x to A, determines the actual move $y_\ell(x)$ during the ℓth round, namely $R_{\eta_\ell}^{A \cup \{x\}}(x)$ if the ℓth round is played by the opponent assuming $x \in A$, and $R_{\eta_\ell}^{A \setminus \{x\}}(x)$ otherwise. The condition on the right-hand side of (4.5) guarantees that the existentially quantified variables are determined by the opponent claiming the query (4.3) is a true formula, and the universally quantified ones by the other opponent. In particular, (4.5) ensures that the opponent with the correct claim about (4.3) has a winning strategy. Provided it exists, the function η_ℓ defines a winning move during the ℓth round of the game for the opponent playing that round, given the way the previous rounds were actually played (as described by the $y(x)$'s). For odd ℓ, i.e., y_ℓ is existentially quantified, it tries to set y_ℓ such that the remainder of (4.3) holds; otherwise it tries to set y_ℓ such that the remainder of (4.3) fails. The actual move may differ from the one given by η_ℓ in case the player's assumption about $x \in A$ is incorrect. The opponent with the correct assumption plays according to η_ℓ. Since that opponent also makes the correct claim about (4.3), he will win the game. In any case, $N(q, y_1, y_2, \ldots, y_k)$ will hold iff (4.3) holds.

Finally, we define the functions ν and τ, which have a similar job as the functions μ and σ, respectively, but this time for the computation of $N(q, y_1, y_2, \ldots, y_k)$ instead of the computation of $M_k^{\mathrm{TQBF}}(x)$. More precisely, $\nu(\langle x, r \rangle)$ equals the rth bit of the computation of $N(q, y_1(x), y_2(x), \ldots, y_k(x))$, where the $y_\ell(x)$'s are defined by

```
if $R_\mu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) = R_\mu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$
  then accept iff $R_\mu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) = 1$
  else $i \leftarrow R_\sigma^{A\cup\{x\}}(x)$
    if the $i$th bit of $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is not the answer to an oracle query
      then accept iff $e_M(x; i, R_\mu^{A\setminus\{x\}}(\langle x, g_M(x; i, 1)\rangle), R_\mu^{A\setminus\{x\}}(\langle x, g_M(x; i, 2)\rangle),$
                          $\ldots, R_\mu^{A\setminus\{x\}}(\langle x, g_M(x; i, c_M)\rangle)) = 0$
      else if $R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) = R_\nu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$
        then accept iff $R_\mu^{A\setminus\{x\}}(\langle x, i\rangle) \neq R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$
        else $r \leftarrow R_\tau^{A\cup\{x\}}(x)$
          accept iff
            $e_N(q, y_1, y_2, \ldots, y_k; r, R_\nu^{A\setminus\{x\}}(\langle x, g_N(q, y_1, y_2, \ldots, y_k; r, 1)\rangle),$
                 $R_\nu^{A\setminus\{x\}}(\langle x, g_N(q, y_1, y_2, \ldots, y_k; r, 2)\rangle),$
                 $\ldots, R_\nu^{A\setminus\{x\}}(\langle x, g_N(q, y_1, y_2, \ldots, y_k; r, c_N)\rangle)) = 0$
          where $q$ denotes the query described in $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$
                to which the $i$th bit in this computation is the answer
            and
            $y_\ell = \begin{cases} R_{\eta_\ell}^{A\cup\{x\}}(x) & \text{if } \ell \equiv R_\mu^{A\cup\{x\}}(\langle x, i\rangle) \bmod 2, \\ R_{\eta_\ell}^{A\setminus\{x\}}(x) & \text{otherwise} \end{cases}$
      end if
    end if
end if
```

FIG. 4.2. *Autoreduction for the set A of Theorem* 4.4 *on input x.*

(4.5), and the bit with index $i = R_\sigma^{A\cup\{x\}}(x)$ in the computation $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is the answer to the oracle query (4.3). We define $\tau(x)$ to be the first r (if any) for which $R_\nu^{A\setminus\{x\}}(\langle x, r\rangle) \neq R_\nu^{A\cup\{x\}}(\langle x, r\rangle)$, provided the bit with index $i = R_\sigma^{A\cup\{x\}}(x)$ in the computation $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is the answer to an oracle query.

Now that we have these functions and corresponding reductions, we can describe an autoreduction for A. On input x, it works as described in Figure 4.2. We next argue that the algorithm correctly decides A on input x. Checking the other properties required of an autoreduction for A is straightforward.

We only consider the cases where $R_\mu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) \neq R_\mu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$ and i points to the answer to an oracle query in $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$. We refer to the analysis in the proof of Theorem 4.1 for the remaining cases.

(i) *Case* $R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) = R_\nu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$. If $x \in A$, variable i points to the first incorrect bit of $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$, which turns out to be the answer to an oracle query, say (4.3). Since $R_\nu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$ yields the correct oracle answer to (4.3),

$$R_\mu^{A\setminus\{x\}}(\langle x, i\rangle) \neq R_\nu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) = R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle),$$

and we accept x.

If $x \notin A$, both $R_\mu^{A\setminus\{x\}}(\langle x, i\rangle)$ and $R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$ give the correct answer to the oracle query i points to in the computation $R_\mu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$. Thus, they are equal, and we reject x.

(ii) *Case* $R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle) \neq R_\nu^{A\cup\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$. As described in Figure 4.2, we will use the local consistency test for $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ being the computation of $N(q, y_1(x), y_2(x), \ldots, y_k(x))$. Apart from bits in the purported computation $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$, this test may also need bits from q and from the $y_\ell(x)$'s. The $y_\ell(x)$'s can be computed straightforwardly using their definition (4.5). The bits from q we might need can be retrieved from $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$. This is because our encoding scheme for computations has the property that the query q is a substring of the prefix of the computation up to the position indexed by i. Since either $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is correct everywhere, or else i is the first position where it is incorrect, the description of q in $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is correct in any case. Moreover, we can easily compute a pointer to the beginning of the substring q of $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ from i.

If $x \in A$, $R_\nu^{A\setminus\{x\}}(\langle x, 2^{p^3(|x|)}\rangle)$ is incorrect, so $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ has an error as a computation of $N(q, y_1(x), y_2(x), \ldots, y_k(x))$. Variable r gets assigned the index of the first incorrect bit in this computation, so the local consistency check fails, and we accept x.

If $x \notin A$, $R_\nu^{A\setminus\{x\}}(\langle x, \cdot\rangle)$ is a valid computation of $N(q, y_1(x), y_2(x), \ldots, y_k(x))$, so every local consistency test is passed, and we reject x. $\square$

4.2. Nonadaptive autoreductions. Thus far, we have constructed autoreductions for $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete sets A. On input x we looked at the two candidate computations obtained by reducing to A, answering all oracle queries except for x according to A, and answering query x positively for one candidate, and negatively for the other. If the candidates disagreed, we tried to find out the right one, which always existed. We managed to get the idea to work for quite powerful sets A, e.g., $\mathcal{EXP}$-complete sets, by exploiting the local checkability of computations. That allowed us to figure out the wrong computation without going through the entire computation ourselves: With help from A, we first computed a pointer to the first mistake in the wrong computation, and then verified it locally.

We cannot use this adaptive approach for constructing nonadaptive autoreductions. It seems like figuring out the wrong computation in a nonadaptive way requires the autoreduction to perform the computation of the base machine itself, so the base machine has to run in polynomial time. Then checking the computation essentially boils down to verifying the oracle answers. Using the game characterization of the polynomial-time hierarchy along the same lines as in Theorem 4.4, we can do this for oracles from the polynomial-time hierarchy.

THEOREM 4.5. *For any integer $k \geq 0$, every $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete set for $\Delta_{k+1}^{\mathcal{P}}$ is nonadaptively autoreducible.*

Parallel to the adaptive case, an earlier version of this paper [6] stated Theorem 4.5 for unbounded k, i.e., for $\mathcal{PSPACE}$. However, we only get the proof to work for constant k. In section 5, we will see that proving Theorem 4.5 for $\mathcal{PSPACE}$ would separate $\mathcal{NL}$ from $\mathcal{NP}$.

The only additional difficulty in the proof is that in the nonadaptive setting, we do not know which player has to perform the even rounds, and which one the odd rounds in the k-round game underlying a query like (4.2). But we can just have them play both scenarios, and afterwards figure out the relevant run.

Proof of Theorem 4.5. Let A be a $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete set for $\Delta_{k+1}^{\mathcal{P}} = \mathcal{P}^{\Sigma_k^{\mathrm{P}}}$ accepted by the polynomial-time oracle Turing machine M with oracle TQBF$_k$. Without loss of generality there is a polynomial p and a polynomial-time Turing machine N such that on inputs of size n, M makes exactly $p(n)$ oracle queries q, all of the form

$$(4.6)\quad \exists\, y_1 \in \Sigma^{p(n)}, \forall\, y_2 \in \Sigma^{p(n)}, \ldots, Q_k\, y_k \in \Sigma^{p(n)} : N(q, y_1, y_2, \ldots, y_k) \text{ accepts},$$

where q has length $p^2(n)$. Let $q(x,i)$ denote the ith oracle query of M^{TQBF_k} on input x. Note that $q \in \mathrm{FP}^{\Sigma_k^{\mathcal{P}}}$.

Let $Q = \{\langle x,i\rangle \mid q(x,i) \in \mathrm{TQBF}_k\}$. The set Q belongs to $\Delta_{k+1}^{\mathcal{P}}$, so there is a $\leq_{\mathrm{tt}}^{\mathcal{P}}$-reduction R_Q from Q to A.

If for a given input x $R_Q^{A\cup\{x\}}$ and $R_Q^{A\setminus\{x\}}$ agree on $\langle x,j\rangle$ for every $1 \leq j \leq p(|x|)$, we are home: We can simulate the base machine M using $R_Q^{A\cup\{x\}}(\langle x,j\rangle)$ as the answer to the jth oracle query.

Otherwise, we will make use of the following functions $\eta_1, \eta_2, \dots, \eta_k$ computable in $\Delta_{k+1}^{\mathcal{P}}$, corresponding oracle Turing machines $R_{\eta_1}, R_{\eta_2}, \dots, R_{\eta_k}$ defining $\leq_{\mathrm{tt}}^{\mathcal{P}}$-reductions to A, and functions $y_1, y_2, \dots, y_k$ also computable in $\Delta_{k+1}^{\mathcal{P}}$. As in the proof of Theorem 4.4, we define η_ℓ and y_ℓ inductively for $\ell = 1, \dots, k$. They are defined for inputs x such that there is a smallest $1 \leq i \leq p(|x|)$ for which $R_Q^{A\setminus\{x\}}(\langle x,i\rangle) \neq R_Q^{A\cup\{x\}}(\langle x,i\rangle)$. The value of $\eta_\ell(x)$ equals the lexicographically least $y_\ell \in \Sigma^{p(|x|)}$ such that

$$\begin{aligned}&\chi[Q_{\ell+1}\, y_{\ell+1}, Q_{\ell+2}\, y_{\ell+2}, \dots, Q_k\, y_k :\\ &\quad N(q(x,i), y_1(x), y_2(x), \dots, y_{\ell-1}(x), y_\ell, y_{\ell+1}, \dots, y_k) \text{ accepts}] \equiv \ell \bmod 2;\end{aligned} \tag{4.7}$$

we set $\eta_\ell(x) = 0^{p(|x|)}$ if such string does not exist. The right-hand side of (4.7) is 1 iff y_ℓ is existentially quantified in (4.6).

$$y_\ell = \begin{cases} R_{\eta_\ell}^{A\cup\{x\}}(x) & \text{if } \ell \equiv R_Q^{A\cup\{x\}}(\langle x,i\rangle) \bmod 2,\\ R_{\eta_\ell}^{A\setminus\{x\}}(x) & \text{otherwise.}\end{cases} \tag{4.8}$$

The condition on the right-hand side of (4.8) means that we use the hypothesis $x \in A$ to compute $y_\ell(x)$ from R_{η_ℓ} in case

(i) either y_ℓ is existentially quantified in (4.6) and the assumption $x \in A$ leads to claiming that (4.6) holds,

(ii) or else y_ℓ is universally quantified and the assumption $x \in A$ leads to claiming that (4.6) fails.

The intuitive meaning of the functions η_ℓ and the reductions R_{η_ℓ} is similar to in the proof of Theorem 4.4: They capture the moves during the ℓth round of the game underlying (4.6) for $q = q(x,i)$. The function η_ℓ encapsulates an optimal move during round ℓ if it exists, and the reduction R_{η_ℓ} under the player's assumption regarding membership of x to A produces the actual move in that round. The condition on the right-hand side of (4.8) guarantees the correct alternation of rounds. We refer to the proof of Theorem 4.4 for more intuition.

Consider the algorithm in Figure 4.3. Note that the only queries to A the algorithm in Figure 4.3 needs to make are the queries of R_Q different from x on inputs $\langle x,j\rangle$ for $1 \leq j \leq p(|x|)$ and the queries of R_{η_ℓ} different from x on input x for $1 \leq \ell \leq k$. Since R_Q and the R_{η_ℓ}'s are nonadaptive, it follows that Figure 4.3 describes a $\leq_{\mathrm{tt}}^{\mathcal{P}}$-reduction to A that does not query its own input. A similar but simplified argument as in the proof of Theorem 4.4 shows that it accepts A. Thus, A is nonadaptively autoreducible. ∎

Next, we consider more restricted reductions. Using a different technique, we arrive at the following theorem.

THEOREM 4.6. *For any complexity class $\mathcal{C}$, every $\leq_{2-\mathrm{tt}}^{\mathcal{P}}$-complete set for $\mathcal{C}$ is $\leq_{2-\mathrm{tt}}^{\mathcal{P}}$-autoreducible, provided $\mathcal{C}$ is closed under exponential-time reductions that only ask one query which is smaller in length.*

```
if $R_Q^{A\setminus\{x\}}(\langle x,j\rangle) = R_Q^{A\cup\{x\}}(\langle x,j\rangle)$ for every $1 \le j \le p(|x|)$
  then accept iff $M$ accepts $x$ when the $j$th oracle query is answered $R_Q^{A\cup\{x\}}(\langle x,j\rangle)$
  else $i \leftarrow$ first $j$ such that $R_Q^{A\setminus\{x\}}(\langle x,j\rangle) \neq R_Q^{A\cup\{x\}}(\langle x,j\rangle)$
      accept iff $N(q, y_1, y_2, \dots, y_k) = R_Q^{A\cup\{x\}}(\langle x,i\rangle)$
                 where $q$ denotes the $i$th query of $M$ on input $x$
                       when the answer to the $j$th oracle query is given by $R_Q^{A\cup\{x\}}(\langle x,j\rangle)$
                 and
                 $y_\ell = \begin{cases} R_{\eta_\ell}^{A\cup\{x\}}(x) & \text{if } \ell \equiv R_Q^{A\cup\{x\}}(\langle x,i\rangle) \bmod 2, \\ R_{\eta_\ell}^{A\setminus\{x\}}(x) & \text{otherwise} \end{cases}$
  end if
```

```
case truth-table of $M_i$ on input $\langle 0^i, x\rangle$ with the truth-value of query $x$ set to $A(x)$
  constant:
    accept iff $M_i^A$ rejects $\langle 0^i, x\rangle$
  of the form "$y \notin A$":
    accept iff $x \notin A$
  otherwise:
    accept iff $x \in A$
  end case
```

FIG. 4.4. *Algorithm for the set D of Theorem* 4.6 *on input $\langle 0^i, x\rangle$.*

In particular, Theorem 4.6 applies to $\mathcal{C} = \mathcal{EXP}$, $\mathcal{EXPSPACE}$, and $\mathcal{EEXPSPACE}$. In view of Theorems 3.1 and 3.3, this implies that Theorems 3.1, 3.3, and 4.6 are optimal.

The proof exploits the ability of $\mathcal{EXP}$ to simulate all polynomial-time reductions to construct an auxiliary set D within $\mathcal{C}$ such that any $\le_{2-\mathrm{tt}}^{\mathcal{P}}$-reductions of D to some fixed complete set A has a property that induces an autoreduction on A.

Proof of Theorem 4.6. Let $M_1, M_2, \dots$ be a standard enumeration of $\le_{2-\mathrm{tt}}^{\mathcal{P}}$-reductions such that M_i runs in time n^i on inputs of size n. Let A be a $\le_{2-\mathrm{tt}}^{\mathcal{P}}$-complete set for $\mathcal{C}$.

Consider the set D that only contains strings of the form $\langle 0^i, x\rangle$ for $i \in \mathbb{N}$ and $x \in \Sigma^*$, and is decided by the algorithm of Figure 4.4 on such an input. Except for deciding $A(x)$, the algorithm runs in exponential time. Therefore, under the given conditions on $\mathcal{C}$, $D \in \mathcal{C}$, so there is a $\le_{2-\mathrm{tt}}^{\mathcal{P}}$-reduction M_j from D to A.

The construction of D diagonalizes against every $\le_{2-\mathrm{tt}}^{\mathcal{P}}$-reduction M_i of D to A whose truth-table on input $\langle 0^i, x\rangle$ would become constant once we filled in the membership bit for x. Therefore, for every input x, one of the following cases holds for the truth-table of M_j on input $\langle 0^j, x\rangle$.

(i) The reduced truth-table is of the form "$y \in A$" with $y \neq x$. Then $y \in A \Leftrightarrow M_j$ accepts $\langle 0^j, x\rangle \Leftrightarrow x \in A$.

(ii) The reduced truth-table is of the form "$y \notin A$" with $y \neq x$. Then $y \notin A \Leftrightarrow M_j$ accepts $\langle 0^j, x\rangle \Leftrightarrow x \notin A$.

(iii) The truth-table depends on the membership to A of two strings different from x. Then M_j^A does not query x on input $\langle 0^j, x\rangle$, and accepts iff $x \in A$.

The above analysis shows that the algorithm of Figure 4.5 describes a $\le_{2-\mathrm{tt}}^{\mathcal{P}}$-

```
if $|Q_{M_j}(\langle 0^j, x\rangle) \setminus \{x\}| = 2$
   then accept iff $M_j^A$ accepts $\langle 0^j, x\rangle$
   else { $|Q_{M_j}(\langle 0^j, x\rangle) \setminus \{x\}| = 1$ }
         $y \leftarrow$ unique element of $Q_{M_j}(\langle 0^j, x\rangle) \setminus \{x\}$
         accept iff $y \in A$
   endif
```

FIG. 4.5. *Autoreduction constructed in the proof of Theorem* 4.6.

reduction of A. ∎

4.3. Probabilistic and nonuniform autoreductions. The previous results in this section trivially imply that the $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete sets for the Δ-levels of the exponential-time hierarchy are probabilistically autoreducible, and the $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for the Δ-levels of the polynomial-time hierarchy are probabilistically nonadaptively autoreducible. Randomness allows us to prove more in the nonadaptive case.

First, we can establish Theorem 4.5 for $\mathcal{EXP}$.

THEOREM 4.7. *Let f be a constructible function. Every $\leq_{f(n)-\mathrm{tt}}^{\mathcal{P}}$-complete set for $\mathcal{EXP}$ is probabilistically $\leq_{O(f(n))-\mathrm{tt}}^{\mathcal{P}}$-autoreducible. In particular, every $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete set for $\mathcal{EXP}$ is probabilistically nonadaptively autoreducible.*

Proof. Let A be a $\leq_{f(n)-\mathrm{tt}}^{\mathcal{P}}$-complete set for $\mathcal{EXP}$. We will apply the PCP Theorem for $\mathcal{EXP}$ [2] to A.

LEMMA 4.8 (see [2]). *There is a constant k such that for any set $A \in \mathcal{EXP}$, there is a polynomial-time Turing machine V and a polynomial p such that for any input x:*

(i) *If $x \in A$, then there exists a proof oracle π such that*

$$\Pr_{|r|=p(|x|)}[V^{\pi}(x,r) \text{ accepts }] = 1. \tag{4.9}$$

(ii) *If $x \notin A$, then for any proof oracle π*

$$\Pr_{|r|=p(|x|)}[V^{\pi}(x,r) \text{ accepts }] \leq \frac{1}{3}.$$

Moreover, V never makes more than k proof oracle queries, and there is a proof oracle $\tilde{\pi} \in \mathcal{EXP}$ independent of x such that (4.9) *holds for $\pi = \tilde{\pi}$ in case $x \in A$.*

Translating Lemma 4.8 into our terminology, we obtain the following lemma.

LEMMA 4.9. *There is a constant k such that for any set $A \in \mathcal{EXP}$ there is a probabilistic $\leq_{k-\mathrm{tt}}^{\mathcal{P}}$-reduction N, and a set $B \in \mathcal{EXP}$ such that for any input x:*

(i) *If $x \in A$, then $N^B(x)$ always accepts.*

(ii) *If $x \notin A$, then for any oracle C, $N^C(x)$ accepts with probability at most $\frac{1}{3}$.*

Let R be a $\leq_{f(n)-\mathrm{tt}}^{\mathcal{P}}$-reduction of B to A, and consider the probabilistic reduction M^A that on input x, runs N on input x with oracle $R^{A\cup\{x\}}$. M^A is a probabilistic $\leq_{k\cdot f(n)-\mathrm{tt}}^{\mathcal{P}}$-reduction to A that never queries its own input. The following shows it defines a reduction from A:

(i) If $x \in A$, then $R^{A\cup\{x\}} = R^A = B$, so $M^A(x) = N^B(x)$ always accepts.

(ii) If $x \notin A$, then for $C = R^{A\cup\{x\}}$, $M^A(x) = N^C(x)$ accepts with probability at most $\frac{1}{3}$. ∎

Note that Theorem 4.7 makes it plausible why we did not manage to scale down Theorem 3.2 by one exponent to $\mathcal{EXPSPACE}$ in the nonadaptive setting, as we were able to do for our other results in section 3 when going from the adaptive to the nonadaptive case: This would separate $\mathcal{EXP}$ from $\mathcal{EXPSPACE}$.

We suggest the extension of Theorem 4.7 to the Δ-levels of the exponential-time hierarchy as an interesting problem for further research.

Second, Theorem 4.5 also holds for $\mathcal{NP}$.

THEOREM 4.10. *All $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for $\mathcal{NP}$ are probabilistically nonadaptively autoreducible.*

Proof. Fix a $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete set A for $\mathcal{NP}$. Let R_A denote a length nondecreasing $\leq_{\mathrm{m}}^{\mathcal{P}}$-reduction of A to SAT.

Define the set

$$W = \{\langle \phi, 0^i \rangle \mid \phi \text{ is a formula with say } m \text{ variables and } \exists\, a \in \Sigma^m : [\phi(a) \text{ and } a_i = 1]\}.$$

Since $W \in \mathcal{NP}$, there is a $\leq_{\mathrm{tt}}^{\mathcal{P}}$-reduction R_W from W to A.

We will use the following probabilistic algorithm by Valiant and Vazirani [17].

LEMMA 4.11 (see [17]). *There exists a polynomial-time probabilistic Turing machine N that on input a Boolean formula φ with n variables, outputs another quantifier free Boolean formula $\phi = N(\varphi)$ such that:*

(i) *If φ is satisfiable, then with probability at least $\frac{1}{4n}$, ϕ has a unique satisfying assignment.*

(ii) *If φ is not satisfiable, then ϕ is never satisfiable.*

Now consider the following algorithm for A: On input x, run N on input $R_A(x)$, yielding a Boolean formula ϕ with, say m variables, and it accepts iff

$$\phi(R_W^{A\cup\{x\}}(\langle \phi, 0\rangle), R_W^{A\cup\{x\}}(\langle \phi, 00\rangle), \ldots, R_W^{A\cup\{x\}}(\langle \phi, 0^i\rangle), \ldots, R_W^{A\cup\{x\}}(\langle \phi, 0^m\rangle))$$

evaluates to true. Note that this algorithm describes a probabilistic $\leq_{\mathrm{tt}}^{\mathcal{P}}$-reduction to A that never queries its own input. Moreover, we have the following:

(i) If $x \in A$, then with probability at least $\frac{1}{4|x|}$, the Valiant–Vazirani algorithm N produces a Boolean formula ϕ with a unique satisfying assignment $\tilde{a}_\phi$. In that case, $(R_W^{A\cup\{x\}}(\langle \phi, 0\rangle), R_W^{A\cup\{x\}}(\langle \phi, 00\rangle), \ldots, R_W^{A\cup\{x\}}(\langle \phi, 0^i\rangle), \ldots, R_W^{A\cup\{x\}}(\langle \phi, 0^m\rangle))$ equals $\tilde{a}_\phi$, and we accept x.

(ii) If $x \notin A$, any Boolean formula ϕ which N produces has no satisfying assignment, so we always reject x.

Executing $\Theta(n)$ independent runs of this algorithm, and accepting iff any of them accepts, yields a probabilistic nonadaptive autoreduction for A. ∎

Thus, for probabilistic autoreductions, we get similar results as for deterministic ones: Low end complexity classes turn out to have the property that their complete sets are autoreducible, whereas high end complexity classes do not. As we will see in more detail in the next section, this structural difference yields separations.

If we allow nonuniformity, the situation changes dramatically. Since probabilistic autoreducibility implies nonuniform autoreducibility [5], all our positive results for small complexity classes carry over to the nonuniform setting. But, as we will see next, the negative results do not, because also the complete sets for large complexity classes become autoreducible, both in the adaptive and in the nonadaptive case. Thus, uniformity is crucial for separating complexity classes using autoreducibility, and the Razborov–Rudich result [14] does not apply.

Feigenbaum and Fortnow [7] define the following concept of $\#\mathcal{P}$-robustness, of which we also consider the nonadaptive variant.

Table 5.1
Separation results using autoreducibility.

question	yes	no
Are all $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete sets for $\mathcal{EXPSPACE}$ autoreducible?	$\mathcal{NL} \neq \mathcal{NP}$	$\mathcal{PH} \neq \mathcal{PSPACE}$
Are all $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete sets for $\mathcal{EEXP}$ autoreducible?	$\mathcal{NL} \neq \mathcal{NP}$ $\mathcal{P} \neq \mathcal{PSPACE}$	$\mathcal{PH} \neq \mathcal{EXP}$
Are all $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for $\mathcal{PSPACE}$ $\leq_{\mathrm{tt}}^{\mathcal{P}}$-autoreducible?	$\mathcal{NL} \neq \mathcal{NP}$	$\mathcal{PH} \neq \mathcal{PSPACE}$
Are all $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for $\mathcal{EXP}$ $\leq_{\mathrm{tt}}^{\mathcal{P}}$-autoreducible?	$\mathcal{NL} \neq \mathcal{NP}$ $\mathcal{P} \neq \mathcal{PSPACE}$	$\mathcal{PH} \neq \mathcal{EXP}$
Are all $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for $\mathcal{EXPSPACE}$ probabilistically $\leq_{\mathrm{tt}}^{\mathcal{P}}$-autoreducible?	$\mathcal{NL} \neq \mathcal{NP}$	$\mathcal{P} \neq \mathcal{PSPACE}$

Definition 4.12. *A set A is* $\#\mathcal{P}$-robust *if* $\#\mathcal{P}^A \subseteq \mathcal{FP}^A$; *A is* nonadaptively $\#\mathcal{P}$-robust *if* $\#\mathcal{P}_{\mathrm{tt}}^A \subseteq \mathcal{FP}_{\mathrm{tt}}^A$.

Nonadaptive $\#\mathcal{P}$-robustness implies $\#\mathcal{P}$-robustness. For the usual deterministic and nondeterministic complexity classes containing $\mathcal{PSPACE}$, all $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete sets are $\#\mathcal{P}$-robust. For the deterministic classes containing $\mathcal{PSPACE}$, it is also true that the $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets are nonadaptively $\#\mathcal{P}$-robust.

The following connection with nonuniform autoreducibility holds.

Theorem 4.13. *All $\#\mathcal{P}$-robust sets are nonuniformly autoreducible. All nonadaptively $\#\mathcal{P}$-robust sets are nonuniformly nonadaptively autoreducible.*

Proof. Feigenbaum and Fortnow [7] show that every $\#\mathcal{P}$-robust language is random-self-reducible. Beigel and Feigenbaum [5] prove that every random-self-reducible set is nonuniformly autoreducible (or "weakly coherent," as they call it). Their proofs carry over to the nonadaptive setting. □

It follows that the $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for the usual deterministic complexity classes containing $\mathcal{PSPACE}$ are all nonuniformly nonadaptively autoreducible. The same holds for adaptive reductions, in which case the property is also true of nondeterministic complexity classes containing $\mathcal{PSPACE}$. In particular, we get the following corollary.

Corollary 4.14. *All $\leq_{\mathrm{T}}^{\mathcal{P}}$-complete sets for $\mathcal{NEXP}$, $\mathcal{EXPSPACE}$, $\mathcal{EEXP}$, $\mathcal{NEEXP}$, $\mathcal{EEXPSPACE}$,... are nonuniformly autoreducible. All $\leq_{\mathrm{tt}}^{\mathcal{P}}$-complete sets for $\mathcal{PSPACE}$, $\mathcal{EXP}$, $\mathcal{EXPSPACE}$,... are nonuniformly nonadaptively autoreducible.*

5. Separation results.

In this section, we will see how we can use the structural property of all complete sets being autoreducible to separate complexity classes. Based on the results of sections 3 and 4, we only get separations that were already known: $\mathcal{EXPH} \neq \mathcal{EEXPSPACE}$ (by Theorems 4.4 and 3.1), $\mathcal{EXP} \neq \mathcal{EEXPSPACE}$ (by Theorems 4.7 and 3.2), and $\mathcal{PH} \neq \mathcal{EXPSPACE}$ (by Theorems 4.5 and 3.3, and also by scaling down $\mathcal{EXPH} \neq \mathcal{EEXPSPACE}$). However, settling the question for certain other classes would yield impressive new separations.

We summarize the implications in Table 5.1.

Theorem 5.1. *In Table* 5.1, *a positive answer to a question from the first column implies the separation in the second column, and a negative answer implies the separation in the third column.*

Most of the entries in Table 5.1 follow directly from the results of the previous sections. In order to finish the table, we use the next lemma.

LEMMA 5.2. *If $\mathcal{NP} = \mathcal{NL}$, we can decide the validity of QBF-formulae of size t and with γ alternations on a deterministic Turing machine M_1 in time $t^{O(c^\gamma)}$ and on a nondeterministic Turing machine M_2 in space $O(c^\gamma \log t)$, for some constant c.*

Proof. Since $co\mathcal{NP} = \mathcal{NP}$, by Cook's theorem we can transform in polynomial time a Π_1-formula with free variables into an equivalent Σ_1-formula with the same free variables, and vice versa. Since $\mathcal{NP} = \mathcal{P}$, we can decide the validity of Σ_1-formulae in polynomial-time. Say both the transformation algorithm T and the satisfiability algorithm S run in time n^c for some constant c.

Let ϕ be a QBF-formula of size t with γ alternations. Consider the following algorithm for deciding ϕ: Repeatedly apply the transformation T to the largest suffix that constitutes a Σ_1- or Π_1-formula until the whole formula becomes Σ_1, and then run S on it.

This algorithm correctly decides the truth of ϕ. Since the number of alternations decreases by one during every iteration, it makes at most γ calls to T, each time at most raising the length of the formula to the power c. It follows that the algorithm runs in time $t^{O(c^\gamma)}$.

Moreover, since $\mathcal{P} = \mathcal{NL}$, a padding argument shows that DTIME$[\tau]$ is contained in NSPACE$[\log \tau]$ for any time constructible function τ. Therefore, the result holds. ∎

This allows us to improve Theorems 3.2 and 3.3 as follows under the hypothesis $\mathcal{NP} = \mathcal{NL}$.

THEOREM 5.3. *If $\mathcal{NP} = \mathcal{NL}$, there is a $\leq^{\mathcal{P}}_{2-\mathrm{T}}$-complete set for $\mathcal{EXPSPACE}$ that is not probabilistically autoreducible. The same holds for $\mathcal{EEXP}$ instead of $\mathcal{EXPSPACE}$.*

Proof. Combine Lemma 5.2 with the probabilistic extension of Lemma 3.5 used in the proof of Theorem 3.2. ∎

THEOREM 5.4. *If $\mathcal{NP} = \mathcal{NL}$, there is a $\leq^{\mathcal{P}}_{3-\mathrm{tt}}$-complete set for $\mathcal{PSPACE}$ that is not nonadaptively autoreducible. The same holds for $\mathcal{EXP}$ instead of $\mathcal{PSPACE}$.*

Proof. Combining Lemma 5.2 with Lemma 3.7 for $\alpha(n) = n$ yields the result for $\mathcal{EXP}$. The one for $\mathcal{PSPACE}$ follows, since $\mathcal{NP} = \mathcal{NL}$ implies that $\mathcal{EXP} = \mathcal{PSPACE}$. ∎

Now, we have all ingredients for establishing Table 5.1.

Proof of Theorem 5.1. The $\mathcal{NL} \neq \mathcal{NP}$ implications in the "yes"-column of Table 5.1 immediately follow from Theorems 5.3 and 5.4 by contraposition.

By Theorem 3.1, a positive answer to the second question in Table 5.1 would yield $\mathcal{EEXP} \neq \mathcal{EEXPSPACE}$, and by Theorem 3.3, a positive answer to the fourth question would imply $\mathcal{EXP} \neq \mathcal{EXPSPACE}$. By padding, both translate down to $\mathcal{P} \neq \mathcal{PSPACE}$.

Similarly, by Theorem 4.4, a negative answer to the second question would imply $\mathcal{EXPH} \neq \mathcal{EEXP}$, which pads down to $\mathcal{PH} \neq \mathcal{EXP}$. A negative answer to the fourth question would yield $\mathcal{PH} \neq \mathcal{EXP}$ directly by Theorem 4.5. By the same token, a negative answer to the first question results in $\mathcal{EXPH} \neq \mathcal{EXPSPACE}$ and $\mathcal{PH} \neq \mathcal{PSPACE}$, and a negative answer to the third question in $\mathcal{PH} \neq \mathcal{PSPACE}$. By Theorem 4.7, a negative answer to the last question implies $\mathcal{EXP} \neq \mathcal{EXPSPACE}$ and $\mathcal{P} \neq \mathcal{PSPACE}$. ∎

We note that we can tighten all of the separations in Table 5.1 a bit, because we can apply Lemmas 3.5 and 3.7 to smaller classes than in Theorems 3.1 and 3.3, respectively. One improvement along these lines that warrants attention is replacing "$\mathcal{NL} \neq \mathcal{NP}$" in Table 5.1 with "$co\mathcal{NP} \not\subseteq \mathcal{NP} \cap \mathrm{NSPACE}[\log^{O(1)} n]$." This is because that condition suffices for Theorems 5.3 and 5.4, since we can strengthen Lemma 5.2 as follows.

LEMMA 5.5. *If co$\mathcal{NP} \subseteq \mathcal{NP} \cap \mathrm{NSPACE}[\log^{O(1)} n]$, we can decide the validity of QBF-formulae of size t and with γ alternations on a deterministic Turing machine M_1 in time $t^{O(c^\gamma)}$ and on a nondeterministic Turing machine M_2 in space $O(d^\gamma \log^d t)$, for some constants c and d.*

6. Conclusion.

We have studied the question of whether all complete sets are autoreducible for various complexity classes and various reducibilities. We obtained a positive answer for lower complexity classes in section 4 and a negative one for higher complexity classes in section 3. This way we separated the lower complexity classes from the higher ones by highlighting a structural difference. The resulting separations were not new, but we argued in section 5 that settling the very same question for intermediate complexity classes would provide major new separations.

We believe that refinements to our techniques may lead to these separations, and we would like to end with some thoughts in that direction.

One does not have to look at complete sets only. Let $\mathcal{C}_1 \subseteq \mathcal{C}_2$. Suppose we know that all complete sets for $\mathcal{C}_2$ are autoreducible. Then it suffices to construct, e.g., along the lines of Lemma 3.5, a hard set for $\mathcal{C}_1$ that is not autoreducible, in order to separate $\mathcal{C}_1$ from $\mathcal{C}_2$.

As we mentioned at the end of section 5, we can improve Theorem 3.1 a bit by applying Lemma 3.5 to smaller space-bounded classes than $\mathcal{EEXPSPACE}$. We cannot hope to gain much, though, since the coding in the proof of Lemma 3.5 seems to be $\mathrm{DSPACE}[2^{n^{\beta(n)}}]$-complete because of the $\mathrm{QBF}_{2\log\beta(n)}$-formulae of size $2^{O(n^{\beta(n)})}$ involved for inputs of size n. The same holds for Theorem 3.3 and Lemma 3.7.

Generalizations of autoreducibility may allow us to push things further. For example, one could look at $k(n)$-autoreducibility where $k(n)$ bits of the set remain unknown to the querying machine. Theorem 4.4 goes through for $k(n) \in O(\log n)$. Perhaps one can exploit this leeway in the coding of Lemma 3.5 and narrow the gap between the positive and negative results. As discussed in section 5, this would yield interesting separations.

Finally, one may want to look at other properties than autoreducibility to realize Post's program in complexity theory. Perhaps another concept from computability theory or a more artificial property can be used to separate complexity classes.

Acknowledgments. We would like to thank Manindra Agrawal and Ashish Naik for very helpful discussions. We are also grateful to Carsten Lund and Muli Safra for answering questions regarding the PCP theorem. We thank the anonymous referees for their nice suggestions on how to present our results and for their meticulous proofreading.

MAINTENANCE OF 2- AND 3-EDGE-CONNECTED COMPONENTS OF GRAPHS II*

HAN LA POUTRÉ†

Abstract. Data structures and algorithms are presented to efficiently maintain the 2- and 3-edge-connected components of a general graph, under insertions of edges and nodes in the graph. At any moment, the data structure can answer whether two nodes are 2- or 3-edge-connected. The algorithms run in $O(n+m.\alpha(m,n))$ time, where m is the total number of queries and edge insertions. Furthermore, a linear-time algorithm is presented for maintaining the 2-edge-connected components in case the initial graph is connected. Finally, a new solution is presented for the 2-vertex-connected components of a graph.

1. Introduction. A graph algorithm is called dynamic if it maintains some information related to a graph while the graph is being changed. Dynamic algorithms are known for several graph problems. Examples are, e.g., maintenance of transitive closures [16, 17, 18, 27], minimal spanning trees [7, 8], planarity testing [3, 4, 6, 25, 33], shortest paths [1, 2, 29], k-connectivity [4, 5, 8, 9, 14, 21, 23, 24, 28, 32, 34, 35], and nearest common ancestors in trees [12].

The general problem of maintaining the k-edge- or k-vertex-connected components of a graph ($k \geq 1$) starts with an "empty" graph of n nodes[1] (i.e., a graph with no edges) and allows subsequent edge insertions and queries that ask whether two nodes are k-edge/vertex-connected.[2] For these problems, a lower bound of $\Omega(n+m.\alpha(m,n))$ [32] exists,[3] which is induced by lower bounds for set merging algorithms [10, 20]. Here m is the number of insertions and queries. So it is important to know whether there exist algorithms that actually run in this time. For $k=2$, Westbrook and Tarjan [32] obtained the optimal running time of $O(n+m.\alpha(m,n))$. For 3-edge-connectivity, however, only combinatorial and special-case results exist. In our companion paper [21], we developed combinatorial and special-case results for 2- and 3-edge-connectivity; we will further use these in this paper. These special-case results concern maintaining the 3-edge-connectivity relation in 2-edge-connected graphs and give an implementation in $O((n+m).\alpha(m,n))$ time. In [14], Galil and Italiano obtained comparable results with this complexity for maintaining the 3-edge-connectivity relation in connected graphs.

[1]In this paper, n is the number of nodes.

[2]For definitions, see subsection 2.5.

[3]$\alpha(m,n)$ is the inverse Ackermann function.

Although [21] presents a solution for 3-edge-connectivity which works in time $O(n \log n + m)$, it still leaves the problem whether the α-bound is achievable for the general case. The general problem appears to be substantially more difficult than the special-case problems, which can make use of the preset combinatorial structure of the special graphs. This is also sustained by a coresult of this paper, which shows that maintaining 2-edge-connected components in connected graphs can be done in linear time, while in general graphs this cannot. Therefore, the important issue remains whether the (actually more involved) 3-edge-connectivity relation can be maintained within the α-bound.

The main objectives of this paper are presenting algorithms and data structures that maintain the 3-edge-connectivity relation in general graphs with a running time of $O(n + m.\alpha(m, n))$. To achieve this, we develop extended combinatorial structures (augmented cycle forests and basic cluster trees), and we present new data structures (fractionally rooted trees). We thus construct a solution consisting of different data structure layers to maintain the 3-edge-connectivity relation. For practical applications, however, the structures seem very well suited for implementation. Furthermore, we also present a linear-time solution for maintaining 2-edge-connected components in connected graphs. Since there is a nonlinear lower bound of $\Omega(n + m.\alpha(m, n))$ for maintaining 2-*vertex*-connectivity in connected graphs, this seems to be the first result that reveals a difference in computational complexity between 2-edge- and 2-vertex-connectivity. Finally, we also give new solutions[4] for maintaining the 2-edge- and 2-vertex-connected components of a graph, which also makes use of the above data structures and with a similar running time of $O(n + m.\alpha(m, n))$. This integrates the approaches for 2- and 3-edge-connectivity and also connects those for 2- and 3-vertex-connectivity (see [24]). We remark that all our results allow the insertion of nodes as well.

The paper is organized as follows. Section 2 contains the preliminaries. In section 3, the specifications of the operations on a new data structure, called fractionally rooted trees, are given. In section 4, the maintenance of 2-edge-connected components is considered, including the special case for connected graphs. In section 5–7, the fractionally rooted tree is presented. To be precise, observations and ideas are given in section 5; the building elements for fractionally rooted trees, called division trees, are described in section 6; and the fractionally rooted trees themselves are presented in section 7. Their complexity is considered in section 8. The final results for fractionally rooted trees are in section 9. In section 10, the optimal solution for maintaining the 3-edge-connected components is presented. Furthermore, in section 11, the maintenance of 2-vertex-connected components is briefly considered. Finally, section 12 contains concluding remarks. Readers interested in the main outlines of the paper can skip sections 6.2, 8.1, and 9 (except for the theorems in section 9). Readers interested in 3-edge-connectivity only can skip subsection 4.2.

2. Preliminaries.

2.1. Graphs and terminology. Let $G = \langle V, E \rangle$ be an undirected graph with V the set of vertices and E the set of edges. We denote an edge as a triple (e, x, y), where e is a unique edge name and x and y are the end nodes of the edge. A graph is called *empty* if it consists of nodes without edges. We use the standard terminology (see also [15]). A path is *simple* if no node occurs twice in it. Two paths are called *edge disjoint* if they do not have a common edge. Two (different) paths are called

[4]Obtained independently from [32].

vertex disjoint if they do not have a common vertex except for their end vertices. Two nodes are called *connected* if there exists a path between them. An (elementary) *cycle* is a path of which the end nodes are equal and in which no edge occurs twice. A cycle is *simple* if no node occurs twice except for the end nodes.

We extend the terminology. Consider a tree T. A set of nodes of T *induces a subtree* of T if these nodes are the nodes of a subtree of T; this is similar for a set of edges. Suppose the vertex set of T is partitioned into disjoint subsets, where each set induces a subtree of T. Let each induced subtree of T be contracted to a new node, called *contraction node*. For an edge (e,x,y), where x and y are contracted to p and q, $p \neq q$, the edge (e,p,q) is called the *contraction (edge)* of (e,x,y), and (e,x,y) is called the *original* of (e,p,q). (Both edges are given the same name.)

The tree CT consisting of the contraction nodes and the contraction edges is called *a contraction tree of* T. For a class D of edges in T, the class of edges in CT *inherited from* D consists of the contractions of edges in D. When we consider classes of nodes in a graph, we often refer to a class that is represented by a node c by "class c." A *singleton* class, set, or tree is a class, set, or tree that consists of one element or node, respectively. For a set or list L, $|L|$ denotes the number of elements in L. (If a sublist is attached to each element in L, then these sublists are not considered for $|L|$.)

Consider a tree T that is rooted at node r. (This just means that node r is a distinguished node.) The *father node of an edge* is the end node of the edge that is closest to the root. Then *father edge of a node* x is the edge between x and the father node of x. The *father edge of an edge* is the father edge of the father node of that edge. For a subtree S of T, the *maximal* node of that subtree is the (unique) node that is nearest to the root. We call an edge of subtree S a *maximal edge* if it is incident with the maximal node of S.

2.2. Connectivity. Two nodes x and y are *k-edge-connected* ($k \geq 1$) iff there exist k edge-disjoint paths between x and y, and x and y are *k-vertex-connected* iff there exist k different vertex-disjoint paths between x and y (Menger; see [26]). It is well known that k-edge-connectivity is an equivalence relation on the set of nodes of a graph.

Henceforth, we will usually call an equivalence class for 2-edge-connectivity a 2*ec-class*, and an equivalence class for 3-edge-connectivity a 3*ec-class*. The 2-edge-connected components of a graph $G = \langle V, E\rangle$ are the subgraphs of G that are induced by the 2ec-classes, i.e., subgraph $\langle C, \{(e,x,y) \in E | x,y \in C\}\rangle$ for each 2ec-class C.

Lemma 2.1 (see [21]). *Let $G = \langle V, E\rangle$ be a graph. Let H be a 2-edge-connected component of G. Then H is a 2-edge-connected graph. Moreover, nodes $x, y \in H$ are k-edge-connected in H iff they are k-edge-connected in G ($k \geq 1$).*

The notion of a 3-edge-connected component can be defined such that Lemma 2.1 holds for 3-edge-connectivity too. We refer to [21]. In our observations, we will represent the 2ec-classes and the 3ec-classes of a graph by means of a "super" graph. To this end, we use the notion of a *class node*, which is a new node (or "name") that represents a class.

Lemma 2.2 (see [21]). *Let $G = \langle V, E\rangle$ be a graph and let $k \geq 1$. Let V be partitioned into classes, where any two nodes in the same class are k-edge-connected. Let a new class node be related to each class. Let k' satisfy $1 \leq k' \leq k$. Then two nodes are k'-edge-connected in G iff the class nodes of their classes are k'-edge-connected in the graph obtained from G by contracting each class to its class node.*

We call a set S of at least two nodes a 2*vc-class* if the nodes are 2-vertex-connected, and if there does not exist a node outside S that is 2-vertex-connected with the nodes of S (i.e., the class is maximal). Furthermore we define a *quasi class* to be any set of two nodes that are the end nodes of a cut edge. The 2-*vertex-connected components* of a graph G are the subgraphs of G that are induced by the 2vc-classes of nodes. (Note that the 2-vertex-connected components and the subgraphs induced by quasi classes as we defined them are usually called the blocks of a graph.)

In the sequel, we will often denote 2-edge-connectivity by "2ec-," etc., when we consider components or relations. For example, 3ec-components denotes 3-edge-connected components, and 2vc-relation denotes 2-vertex-connectivity relation.

2.3. Problem description. The problems that we consider in this paper are as follows. Let a graph be given. Then the following operations may be applied on the graph.

insert$((e,x,y))$. Insert the edge (e,x,y) in the graph.

2*ec-comp*(x). Output the name of the 2ec-component (2ec-class) which contains x.

3*ec-comp*(x). Output the name of the 3ec-component (3ec-class) which contains x.

*Is*2*vc*(x,y). Output whether x and y are two nodes in the graph that are 2-vertex-connected and output the name of the 2vc-component (2vc-class) in which they both are contained (if any).

We call a problem the 2*ec-problem* if operations *insert* and 2*ec-comp* are considered; the 3*ec-problem* if operations *insert*, 2*ec-comp*, and 3*ec-comp* are considered; and the 2*vc-problem* if operations *insert* and $Is2vc$ are considered. In these problems, we normally start with an empty graph with n nodes (unless stated otherwise). In addition, the above collection of operations can be extended with the insertion of a new (isolated) node in the graph. We will consider this operation only in the last steps of our solutions.

We call the insertion of an edge an *essential insertion* for a given problem, if in the graph either the connectivity relation changes or, for the 2ec-problem, the 2ec-relation changes, or, for the 3ec-problem, the 2ec- or 3ec-relation changes, or, for the 2vc-problem, the 2vc-relation changes. An insertion is called *nonessential* otherwise. Note that nonessential insertions can be omitted, which is known after a proper couple of queries. (Thus such an insertion does not need to take more than the time for those queries.)

2.4. The Ackermann function. The *Ackermann function* A is defined as follows. For $i, x \geq 0$ function A is given by

$$\begin{array}{rcll} A(0,x) & = & 2x & \text{for } x \geq 0, \\ A(i,0) & = & 1 & \text{for } i \geq 1, \\ A(i,x) & = & A(i-1, A(i,x-1)) & \text{for } i \geq 1,\ x \geq 1. \end{array} \tag{1}$$

The *row inverse* a of A and the *functional inverse* α of A are defined in correspondence to [11, 12, 19, 23] by

$$a(i,n) = \min\{x \geq 0 | A(i,x) \geq n\} \quad (i \geq 0,\ n \geq 0), \tag{2}$$

$$\alpha(m,n) = \min\{i \geq 1 | a(i,n) \leq 4.\lceil m/n \rceil\} \quad (m \geq 0,\ n \geq 1). \tag{3}$$

Here we take $\lceil 0 \rceil = 1$. For more technical insight on these functions, we refer to [19]. Here we quote that

$$a(i, A(i,x)) = x \quad (i \geq 0,\ x \geq 0), \tag{4}$$

and also that for *any* practical n, we have $\alpha(m,n) \leq 3$. Also, $A(i,1) = 2$ and $A(i,2) = 4$ $(i \geq 0)$, and $A(0,x) = 2x$, $A(1,x) = 2^x$, and $A(2,x) = \left.2^{2^{2^{\cdot^{\cdot^{2}}}}}\right\}^{x \text{ 2s}}$.
Similarly we have

$$\begin{array}{rclcl}
a(0,n) & = & \lceil \frac{n}{2} \rceil, & & \\
a(1,n) & = & \lceil \log n \rceil & = & \min\{j | \lceil \frac{n}{2^j} \rceil = 1\}, \\
a(2,n) & = & \log^* n & = & \min\{j | \lceil \log^{(j)} n \rceil = 1\}, \\
a(3,n) & = & & & \min\{j | \log^{*^{(j)}} n = 1\},
\end{array}$$

where the superscript (j) denotes the j consecutive applications. For simplicity, we extend the Ackermann function by $A(i,-1) = 0$ for all $i \geq 0$.

2.5. Representation and data structures. The algorithms and data structures that we present (except for the algorithm in subsection 4.2) can be implemented on *both* a pointer machine and a random access machine (RAM) with the same complexity. Nodes and edges of a graph are represented in memory by records, which we will consider to be the actual nodes and edges. Each vertex has an incidence list consisting of pointers to the incident edges. Also, each edge contains pointers to its two end nodes. If we consider a tree T rooted at some node r, then for each node in T, its father node and father edge are related to it by appropriate pointers. An edge that has to be inserted is given by its record with the pointers to its end nodes as input for the algorithms.

In the following, the Union-Find structure is used to maintain the equivalence classes for connectivity, 2-edge-, and 3-edge-connectivity. These structures are denoted by UF_c, UF_{2ec}, and UF_{3ec}, respectively, where the corresponding Finds on elements x are denoted by $c(x)$, $2ec(x)$, and $3ec(x)$, respectively. Many solutions have been proposed for the Union-Find problem [19, 30, 31]: these solutions all take $O(n + m.\alpha(m,n))$ time for all Unions and m Finds on n elements, which is optimal [10, 20]. The solution of [19] ensures that, in addition, the fth Find can be done in $O(\alpha(f,n))$ worst-case time. We call such structures *α-UF structures.* In this paper, we will also make use of a class of structures UF(i) ($i \geq 1$), as defined in [19].

THEOREM 2.3 (see [19]). *Structure UF(i) takes $O(n.a(i,n))$ time for all Unions on n elements, where a Find takes $O(i)$ worst-case time $(i \geq 1)$.*

We consider the *connectivity problem* for edge insertions. Let $G = \langle V, E \rangle$ be a graph. Suppose a sequence of edge insertions in G and queries about whether two nodes are connected are performed. If an edge (e,x,y) is inserted, there are two cases. If $c(x) = c(y)$, then nothing needs to be done. Otherwise, if $c(x) \neq c(y)$, then x and y are not connected yet and the equivalence classes $c(x)$ and $c(y)$ are joined. Since apart from these Unions, each insertion takes $O(1)$ time, it follows that all insertions and queries can be performed in $O(|E|)$ time plus the time needed for the Union and Find operations. In the sequel, we use this algorithm for maintaining connectivity, but we will not make the above computations explicit any more.

3. Fractionally rooted trees: Concept and operations. We give a formal description of the operations supported by the data structure called *fractionally rooted tree*, without considering the data structure itself yet. Let a forest F be given. Suppose the collection of edges is partitioned into disjoint classes such that each class induces some subtree of F. Such a partition is called an *admissible partition.*

We first define some notions. Let x and y be two nodes in the same tree of F, and let P be the tree path between x and y. By "edge classes on P," we mean the edge classes of which an edge is on P. An edge class is *incident* with node x if it contains an edge with x as end node. We call a node x on P a *boundary node* of P if it is incident with two classes on P or if it is one of the end nodes of P. We call a node of P an *internal node* otherwise. A *boundary edge set* for a boundary node z on P is a set of (0, 1, or 2) edges incident with z: one from each class that is incident with z and that is on P. (See Figure 1, where path P is drawn with heavy lines, C_1 and C_2 are two different edge classes, $\{e_1, e_2\} \subseteq C_1$ and $\{e_3, e_4\} \subseteq C_2$, and where $\{e_1, e_3\}$, $\{e_1, e_4\}$, $\{e_2, e_3\}$, and $\{e_2, e_4\}$ are the possible boundary edge sets for z on P.) A *boundary list* for the two nodes x and y is a list consisting of the boundary nodes of P, where each boundary node has a sublist that contains a boundary edge set for it on P. (Note that in a boundary list for x and y with $x \neq y$, all nodes have a sublist with two edges except for nodes x and y that each have one edge in their sublist.) We say that x and y are *related nodes*, denoted by $x \sim y$, if $x = y$ or if all the edges on P are in the same edge class. (Hence $x \sim y$ iff x and y are the only nodes in a boundary list for x and y.)

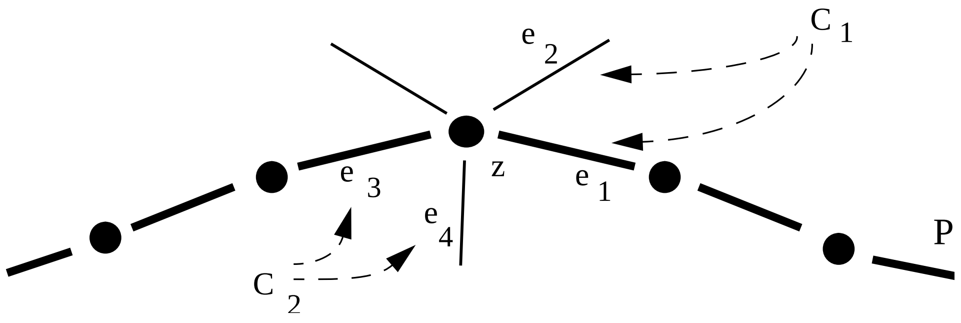

FIG. 1. *Boundary edge sets.*

We say that an edge class *occurs* in a list consisting of sublists of edges if an edge of it occurs in some sublist. A *joining list* J is a list of nodes with sublists of edges such that the union of the classes occurring in J induces some subtree in F. (Hence it yields a new admissible partition of the edge set.) In addition, the nodes in J must be the nodes incident with at least two classes occurring in J, and the sublist for each node contains an edge for each class in J incident with the node.

The following operations, called *FRT operations*, may be performed on a forest F.

link$((e, x, y))$. Let x and y be nodes in different trees of forest F. Then link the two trees containing x and y by inserting the edge (e, x, y), where (e, x, y) forms a new singleton class.

boundary(x, y). Let x and y be in the same tree of F with $x \neq y$. Then output a boundary list for x and y.

joinclasses(J). Let J be a joining list. Then join all the edge classes of which an edge occurs in the list.

candidates(x, y). Return an edge incident with x and return an edge incident with y; these edges (the candidates) are in the same class if such edges exist (i.e., $x \sim y$). Return the names of the edge classes in which the edges are contained.

Finally, we define some notions that will be used in the sequel. We say that a call *boundary*(x, y) is *essential* if $\neg(x \sim y)$ and it is *nonessential* if $x \sim y$. An *essential sequence* is a sequence of *link*, *boundary*, and *joinclasses*, where every call of *boundary* is essential and is followed by a call *joinclasses*(J) such that all the edge classes occurring in the output of *boundary* also occur in J. A *matching sequence* is a sequence of FRT-operations where the subsequence of calls of *link*, essential calls of *boundary*, and calls of *joinclasses* forms an essential sequence.

4. Two-edge-connectivity.

In this section, we consider the problem of maintaining the 2ec-components in a graph, and we will present algorithms that run in $O(n + m.\alpha(m, n))$ time for n nodes and m queries and insertions using fractionally rooted trees. Thus we present a solution that is different from that given in [32] but whose approach is closer to the approach for maintaining the 3ec-relation in general graphs (section 10), and that we will use there too. We also present a linear-time solution for maintaining the 2ec-components in case the initial graph is connected.

4.1. Graph observations.

In this subsection, we recall from the companion paper [21] the observations for inserting edges in a graph $G = \langle V, E\rangle$. The set V can be partitioned into equivalence classes for 2-edge-connectivity: the 2ec-classes. Let each 2ec-class C be represented by a new (distinct) node c, called the *class node* of C. Let $2ec(x)$ be the class node of the 2ec-class in which the node x is contained. We define the contracted graph $2ec(G)$ as follows:

$$2ec(G) = \langle 2ec(V), \{(e, 2ec(x), 2ec(y)) | (e, x, y) \in E \wedge 2ec(x) \neq 2ec(y)\}\rangle.$$

For example, $2ec(G)$ is the graph that is obtained if we contract each 2ec-class into one class node. By Lemma 2.2, $2ec(G)$ is a forest (for a figure, see [21]). An edge (e, x, y) in G is called an *interconnection edge* between (classes) $2ec(x)$ and $2ec(y)$ if $2ec(x) \neq 2ec(y)$.

We consider the 2ec-relation under edge insertions by means of the graph $2ec(G)$. Suppose a new edge $(e, x, y) \notin E$ is inserted in graph $G = \langle V, E\rangle$. We distinguish three cases and apply Lemma 2.2.

1. $c(x) \neq c(y)$. Then $(e, 2ec(x), 2ec(y))$ connects two trees in $2ec(G)$ that have to be joined into one tree.
2. $2ec(x) \neq 2ec(y) \wedge c(x) = c(y)$. Then edge $(e, 2ec(x), 2ec(y))$ connects $2ec(x)$ and $2ec(y)$ in a tree of $2ec(G)$, and all class nodes on the tree path P from $2ec(x)$ to $2ec(y)$ become 2-edge-connected in $2ec(G)$. Thus all the classes "on" P must be joined.
3. $2ec(x) = 2ec(y)$. Then nothing happens.

4.2. Algorithms for initially connected graphs.

We consider the 2ec-problem in case the initial graph is connected. We represent the graph $2ec(G)$ by means of a spanning tree of G, denoted by $ST(G)$. Note that a 2ec-class induces a subtree in $ST(G)$. Since the tree $ST(G)$ can be constructed in advance, we can use the Union-Find algorithms of [13] to maintain the 2-edge-connected classes: this algorithm runs in $O(n + m)$ time for m Finds for this special case. (It runs on a RAM but not on a pointer machine.) Moreover, as remarked in [19], a Find can be performed in $O(1)$ worst-case time.

We give the algorithms in case the graph G initially is a tree. We implement the tree as a rooted tree and initialize the Union-Find structure of [13] accordingly. We recall from [13] that the name of a set in the Union-Find structure is the (unique) node in the set that is closest to the root. Suppose an edge (e, x, y) is inserted. If $c(x) = c(y) \wedge 2ec(x) \neq 2ec(y)$, then the tree path between $2ec(x)$ and $2ec(y)$ is obtained as in [21] by traversing the root paths of $2ec(x)$ and $2ec(y)$ in $2ec(G)$ stepwise in an alternating way, where we use $ST(G)$ with the Union-Find structure as representation for $2ec(G)$. This is stopped if a class name *top* has been visited by both traversals; path P between $2ec(x)$ and $2ec(x)$ consists of the two parts of these root paths up to and including *top*.

We consider the time complexity. A computation of a tree path P is done in $O(|P|)$ time, since one of the two traversals contains nodes of P only. Since the number of classes decreases by $|P| - 1$, all path computations take $O(n)$ time altogether. All Unions and m Finds take $O(n+m)$ time. Finally, each insertion takes two Finds and $O(1)$ time, apart from the above cost.

In case the initial graph is connected but it is not a tree, then we do the following. First obtain a spanning tree of the graph, and initialize the structure for this tree. Then insert the edges of the graph that are not in the tree by means of the above algorithm. Then the actual insertions can be performed.

THEOREM 4.1. *The* $2ec$*-problem for graphs that are initially connected can be solved such that a sequence of* m *insert operations takes* $O(n + m)$ *time, where a query takes* $O(1)$ *time. The structure can be initialized* $O(e_0)$ *time and takes* $O(n)$ *space, where* e_0 *is the number of edges in the initial graph.*

The above theorem can be augmented to allow attachment of a single new node by an edge connecting it with an existing node in the graph, within the same time complexity. (Thus, the graph remains connected.) This can be done by [13, section 3].

4.3. Algorithms and data structures for general graphs. In this subsection, we will give a solution for the general 2ec-problem with a time complexity of $O(n + m.\alpha(m, n))$ for n nodes and m queries and insertions.

We represent the structure $2ec(G)$ by means of a forest of spanning trees of G. We denote the forest together with additional information (defined below) by $SF(G)$. $SF(G)$ is augmented with *edge classes* induced by the 2ec-relation.

Let (e, x, y) be an edge in $SF(G)$. If $2ec(x) = 2ec(y)$, then (e, x, y) is in the edge class named $2ec(x)$. Otherwise, edge (e, x, y) forms a singleton class on its own, which we call a *quasi class*.

An edge class that is not a quasi class is called a *real class*. Note that interconnection edges form quasi classes and vice versa.

As observed in subsection 4.2, a 2ec-class (of nodes) induces some subtree in $SF(G)$. Therefore, each edge class induces a subtree in $SF(G)$. Also, if each subtree in $SF(G)$ induced by a real edge class is contracted to some node, then we obtain the forest $2ec(G)$, where the quasi edge classes in $SF(G)$ correspond to the edges in $2ec(G)$.

We consider the insertion of edge (e, x, y). If x and y are in different trees of $SF(G)$, then these trees need to be linked. Now suppose x and y are in the same tree T of $SF(G)$. Let P be the tree path in T between x and y. We use the terminology of section 3. By the definition of edge classes, a boundary node of P is either one of the end nodes x or y, or it is a node for which its two neighbors on P are not both in the same 2ec-class as itself. The two neighbors of an internal node z on P are inside class $2ec(z)$ too. Therefore, if we compute the boundary nodes of P only, then we obtain one or two nodes of each 2ec-class (of nodes) that need to be joined.

We need some tree representation to compute boundary sequences efficiently while trees are linked from time to time. One solution is to use rooted trees and, in the case of linkings of trees, to redirect the smallest one of the two trees that are linked.

However, this takes $O(n.\log n)$ for the linkings. To improve the time complexity, we use the fractionally rooted trees (FRT) structure.

We solve the 2ec-problem by the so-called 2EC structure, which is given as follows. We use the above forest $SF(G)$ with the 2ec-classes and the above edge classes. A node x in $SF(G)$ that is not in a singleton 2ec-class has a pointer *assoc* to an edge that is incident with x and that is in the class named $2ec(x)$. (Such an edge exists.) We call such an edge an *associated edge* for x. Forest $SF(G)$ is implemented as a FRT structure, denoted by FRT_{2ec}. Moreover, all 2ec-classes of nodes (in $SF(G)$) are implemented by a Union-Find structure, denoted by UF_{2ec}. All connected components of nodes are implemented by a Union-Find structure, denoted by UF_c.

The initialization and the queries are straightforward. The insertion of edge (e, x, y) in graph G is done by procedure $insert_{2ec}((e, x, y))$ as follows.

1. If $c(x) \neq c(y)$, then $link((e, x, y))$ is performed, and the two connected components $c(x)$ and $c(y)$ are joined (in UF_c).
2. If $c(x) = c(y) \wedge 2ec(x) \neq 2ec(y)$, then the following is done. First, operation $boundary(x, y)$ is performed, returning boundary list BL. All the (node) classes in which the boundary nodes are contained are joined in UF_{2ec}. For each node z in BL, the associated edge e of z (if any) is obtained. If edge e is not in an edge class occurring in the sublist of z in BL, then e is inserted in its sublist. (This ensures that $2ec(e) = 2ec(z)$ remains true after subsequent joinings.) The end nodes of BL are removed in case their sublists contain one edge only. Then, if $BL \neq \emptyset$, operation $joinclasses(BL)$ is performed. Finally, for each node z in BL without an associated edge, an edge in its (old) sublist is made its associated edge.
3. If $2ec(x) = 2ec(y)$, nothing is done.

Note that starting from a graph with n nodes, there are at most $2(n-1)$ essential insertions, since in each essential insertion at least two connected components or 2ec-classes are joined.

OBSERVATION 4.2. *In a 2EC structure, the time needed for a sequence of essential insertions is linear to the time for a matching sequence of $O(n)$ operations on n nodes in FRT_{2ec} and for $O(n)$ Unions and Finds in UF_c and UF_{2ec}. Each nonessential insertion takes time linear to $\theta(1)$ Finds in UF_c and UF_{2ec}.*

A $2EC(i)$ structure is the structure described above, where $FRT_{2ec} = FRT(i)$ (see section 9), $UF_{2ec} = UF(i)$, and $UF_c = UF(i)$.

THEOREM 4.3. *A $2EC(i)$ structure solves the 2ec-problem such that the total time for all essential insertions is $O(n.i.a(i, n))$, where a query and a nonessential insertion can be performed in $O(i)$ time, and where the data structure can be initialized in $O(n)$ time and takes $O(n)$ space ($i \geq 1$, $n \geq 2$).*

Proof. Theorem 4.3 can be proved by Observation 4.2, Theorem 2.3, and Theorem 9.1. ▯

We denote the Union-Find structures UF_{2ec} and UF_c together by UF. We consider the UF structures to be one structure on $O(n)$ elements. Now take FRT$(\alpha(n, n))$ as FRT_{2ec} for a graph with n nodes, where $\alpha(n, n)$ is obtained as in [19], and take for UF the α-UF structure (see subsection 2.5). Then we obtain the following.

THEOREM 4.4. *The 2ec-problem can be solved such that the time is $O(m.\alpha(m, n))$ in total (where m is the number of edge insertions and queries), where the fth query takes $O(\alpha(f, n))$ time. The data structure can be initialized in $O(n)$ time and takes $O(n)$ space.*

Proof. Each query and nonessential insertion corresponds to $O(1)$ Finds in the

UF structures. Moreover, all essential insertions take at most $O(n)$ Finds. Hence by [19] the fth operation is performed in $O(\alpha(f,n))$ time if it is a query or nonessential insertion. The remaining statements follow by Theorem 9.1 (with $n' \leq \min\{2m, n\}$), by (3), and by subsection 2.5. $\square$

The above theorem can be augmented to allow insertion of new nodes in the graph with a time complexity of $O(n + m.\alpha(m,n))$: then α-FRT is used instead of FRT$(\alpha(n,n))$ (cf. section 9).

5. Fractionally rooted trees: Observations and ideas. We give some of the ideas and observations regarding *fractionally rooted trees*. We consider a forest F, with an admissible partition of the edge set (see section 3).

A tree T in F is partitioned into subtrees that all are (locally) rooted, i.e.; each subtree has its own root independent of the remainder of the tree and subtrees. Each subtree is contracted to a new node, which yields a contracted tree T'. The collection of edges of T' is partitioned into edge classes *inherited from* the edge classes of T.

A boundary list B between two nodes x and y in T can now be obtained as follows. Let c and d be the nodes in T' to which x and y are contracted, respectively. Suppose $c \neq d$. Let P be the tree path between x and y in T. Let P' be the tree path between c and d in T'. Since an edge class induces a subtree, it follows that each boundary node of P' contains a boundary node of P, and the other way around. For a boundary node b on P', let P_b be the part of P inside b, and let s and t be its end nodes. Then, obviously, for a node $z \notin \{s,t\}$ contained in b, z is a boundary node of P_b iff it is one of P. If we extend P_b to P_{bb} with the other edges e_s and e_t on P incident with s and t, respectively (if they exist), then it follows that *a node contained in b is a boundary node of P_{bb} iff it is one of P.*

Now suppose that e_s exists. Then the boundary set for b contains an edge that is in the same edge class as the contraction of e_s. Let f_s be the original of this edge. Then e_s and f_s are in the same class, and, hence, the tree path connecting them consists of edges in this class only. Therefore, if we change P_b by replacing the "end edge" e_s by f_s, the boundary nodes contained inside b remain unchanged. We can do the same for t. Hence, *the boundary nodes contained in b are those contained in the local tree path between the originals of the edges in the boundary edge set of b or x or y (if x or y are contained in b).* (See Figure 2 for an illustration within T, where the subtree of T that is contracted to b in T' is surrounded by an ellipsoid.)

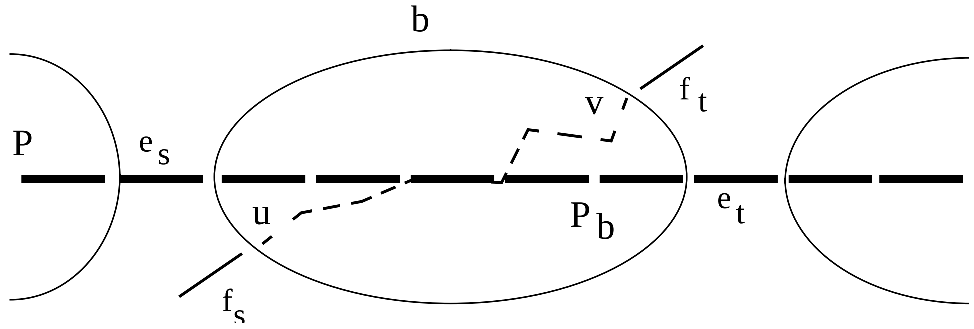

FIG. 2. *Boundary nodes in b.*

Hence we can *compute* a *boundary list B* for x and y as follows. First we compute a boundary list B' in T' for the nodes c and d. Then for each boundary node b in B', we obtain the nodes u and v in b that are x, y, or end nodes of the originals of the edges in the boundary edge set of b. Subsequently, we compute the "local" boundary list $bl(b)$ for u and v. Finally, we extend the sublists of the end nodes u and v with the appropriate originals of the edges in the boundary edge set of b; if u (or v) is not a boundary node for x and y after all, then it is removed from $bl(b)$. Then these local boundary lists $bl(b)$ together form B.

6. Division trees.

6.1. Description. Division trees form the base of the fractionally rooted trees. For the terminology regarding contractions we refer to section 2.1.

Let F be a forest with an admissible partition of the edge set into edge classes, distinguished as *global edge classes*. Let T be a tree in F. Let $CT(T)$ be a contraction tree of T, where $CN(T)$ is the collection of contraction nodes and for each $b \in CN(T)$, $tree(b)$ is the subtree of T that is contracted to b. Then T together with set $CN(T)$ and with subtrees $tree(b)$ is called a *division tree*. An edge is called *internal* if it is contained in some $tree(b)$, and *external* otherwise. For a contraction node b, the *extended tree* $extree(b)$ is $tree(b)$ extended with the external edges incident with $tree(b)$. The edge set of a $extree(b)$ is partitioned into *local edge classes* induced by the global edge classes of T. This yields an admissible partition. Tree $extree(b)$ is rooted at some node.

An external edge (e, x, y) may contain different information pertaining to the two extended subtrees in which it is contained. Therefore, we distinguish two representatives called *(edge) sides*, one for each of its end nodes $(e, x, y)_x$ and $(e, x, y)_y$. For external edge (e, x, y), $(e, x, y)_x$ is the representative for $extree(contr(x))$, where $contr(x)$ is the node to which x is contracted. For internal edges, both sides are considered to be identical. We often omit referring to the proper side, however.

The class of edge e in $extree(b)$ is denoted by $class(e)$. Every edge class contains at most one edge that is marked by a so-called *d-mark*, which must be an external edge and which contains a direct pointer $d(e)$ to the name of the edge class. (So, the class name can be obtained fast.) For each edge class C in $extree(b)$, the following edges are distinguished (with direct pointers to them):

- $\max(C)$ is a maximal edge of C in the rooted tree $extree(b)$. Such an edge is then called *the* maximal edge of that class and is marked by an *m-mark* (which is done implicitly).
- $ext(C)$ is an external edge in it (if there exists any).
- $direct(C)$ is the d-marked edge in it (if it exists).

For a node x in $extree(b)$, the father edge of x or an m-marked edge incident with x is called a *preferred edge for x*. Note that for node x and a class C incident with x, there is *exactly one* preferred edge for x in C.

We describe the operations that we want to perform on F.

basic-external-link$((e, x, y))$. Let x and y be nodes in two different trees T_x and T_y. Then link these trees by the edge (e, x, y), yielding tree T, where the partition of the node set remains unchanged. This means that $CN(T) = CN(T_x) \cup CN(T_y)$, and for each $b \in CN(T)$, $tree(b)$ is not affected by the operation. The new edge (e, x, y) forms a new singleton class on its own.

basic-internal-link$((e, x, y), y)$. Let x and y be nodes in two different trees T_x and T_y. Let $c = contr(x)$. Then link these trees by the edge (e, x, y), yielding tree T, where $tree(c)$ is extended with edge (e, x, y) and tree T_y. For example, $CN(T) = CN(T_x)$, and $tree(b)$ remain unchanged for $b \in CN(T_x)\backslash\{c\}$. The new edge (e, x, y) forms a new singleton class on its own. The edges in T_y are called *affected*.

basic-integrate(x, f). Let x be a node in tree T, and let f be a (possibly new) contraction node not occurring in $CN(T)$. Then change the partition of T such that it consists of just one subtree, with contraction node f. For example, afterward $CN(T) = \{f\}$. The edges in T are called *affected.*

basic-boundary(x, y). Let $contr(x) = contr(y)$. Then return a boundary list BL for x and y, where the edges in BL are preferred.

basic-joinclasses(J). Let J be a joining list with one node such that there is at most one edge class occurring in J that contains a d-marked edge. Then join the edge classes occurring in J.

Note that for affected edges, the father relations and m-marks of these edges (edge sides) may change during these calls.

6.2. Implementation. We implement the structures as follows. A tree T in F is implemented in the common way. Each node x in T contains a pointer $contr(x)$ to the contraction node in which it is contained, and, conversely, for each contraction node b, the list $nodes(b)$ consists of the nodes in $tree(b)$. Similarly, each external edge has a pointer to its contraction edge and vice versa. An edge is marked external or internal. The edge classes in $extree(b)$ are represented by a Union-Find structure, called the *local class Union-Find structure.* The initialization of a division tree with one contraction node is straightforward.

The operations are implemented as follows. We omit straightforward implementation details regarding, e.g., handling marks, (special) pointers, lists, etc. Note that converting an edge from external to internal may have consequences for classes, marks, and pointers.

basic-external-link$((e, x, y))$ *and basic-integrate*(x, f). The implementation of these operations is obvious. Note that maximal edges can be found by checking for each edge whether its father edge is in the same class.

basic-internal-link$((e, x, y), y)$. Let $c = contr(x)$. First, *basic-integrate*(y, c) is performed, edge (e, x, y) is inserted, and x is made the father of y. Then $\max(class(e))$ is set to (e, x, y).

basic-boundary(x, y). If $x = y$, then return the boundary list BL consisting of node x with empty sublist. Otherwise, the following is done. First, two boundary lists $s(x)$ and $s(y)$ for the root paths of x and y are stepwisely computed in an alternating way, until a node *top* has been visited by both computations. This is as follows. List $s(x)$ starts with visiting node x, and a step for $s(x)$ is as follows: obtain the father edge (e, z, z') of the node z that is visited (if any), obtain the edge $\max(class(e)) = (e', u, v)$, and visit the father node of e'. Shorten the lists $s(x)$ and $s(y)$ such that they are boundary lists for x and *top* and for y and *top* respectively. Boundary list BL is created from $s(x)$ and $s(y)$, where if $top \notin \{x, y\}$ and the two edges related to *top* are in the same edge class, then *top* is removed from the list (since it cannot be a boundary node of P).

basic-joinclasses(J). First a list CJ is created consisting of all (names of) edge classes occurring in J. Then the classes in CJ are joined, and the edges e_d, e_m, and e_{ex} (given below) are related to this new class appropriately. Edge e_m is the maximum edge of the class of the father edge of x if this class occurs in CJ, and of any class in CJ otherwise. Edge e_d is the (unique) d-marked edge in one of the classes in CJ (if it exists), and e_{ex} is the external edge of some class in CJ (if any).

7. Fractionally rooted trees: The data structure. We present the recursive data structure called the fractionally rooted trees. We consider a dynamic forest F_0 with an admissible partition of its edge set.

Let $i \geq 1$. Let F_i consist of contractions of a number of trees in F_0. The edge set of forest F_i is partitioned into the edge classes that are inherited from the edge classes of F_0 We introduce the structures FRT(i) for F_i for $i \geq 1$.

Each tree of F_i has a name in FRT(i) being some (new) unique node. For each tree in F_i, its data structure contains its tree name s and a collection of at most i layers, numbered from i in a decreasing order (say, down to $down(s)$). Each existing layer j consists of a division tree, denoted by $tree(s, j)$. For layer i, $tree(s, i)$ is the tree in F_i with name s. For existing layer $j < i$, $tree(s, j)$ is the contraction of $tree(s, j+1)$, and its global edge classes are inherited from those of $tree(s, j + 1)$. Finally, tree name s forms the contraction tree of $tree(s, down(s))$. (The above number $down(s)$ is only used in the description.) We denote by $tree_0(s)$ the original in F_0 of $tree(s, i)$ in F_i. To each tree name some parameters are associated, which will be given in the following sections. The structure FRT(i) allows the operations on F_i as described in section 3, where we add the parameter i to easily allow recursion. Thus we have (with the following modifications) the operations $link((e, x, y), s, t, i)$, where $x \in tree(s, i)$ and $y \in tree(t, i)$; $boundary(x, y, i)$, where the returned boundary list consists of *preferred* edges; $joinclasses(J, i)$; and $candidates(x, y, i)$, which does not return the names of edges classes, and where the returned edges are *preferred.* In addition, we have an operation $treename(x)$ that trivially outputs the name s of the tree in which a node x occurs.

For implementation purposes, we mention that the edge classes in F_0 are represented by a Union-Find structure UF_0. If FRT(i) is used as a complete structure, directly on F_0 (i.e., $F_i = F_0$), then $UF_0 = UF(i)$ (see subsection 2.5), and each operation $joinclasses(J, i)$ also joins all classes in F_0 occurring in J (in UF_0).

The structures FRT(i) are defined inductively (in terms of divisions trees). The method of induction has relations to those in [11, 12, 19, 23]. We start from a base structure FRT(1) that corresponds to the idea using ordinary rooted trees. This structure takes $O(n. \log n)$ time for an essential sequence of operations.

7.1. The structure FRT(1). Structure FRT(1) is a structure for a forest F_1 that satisfies the following conditions. For each tree name s, we have a parameter $weight(s, 1)$ that contains the number of nodes in $tree(s, 1)$. The local class Union-Find structure for F_1 is UF(1). FRT(1) is initialized as a forest of division trees with one contraction node each. The algorithms for the operations are as follows.

$link((e, x, y), s, t, 1)$. W.l.o.g. suppose that $weight(s, 1) \leq weight(t, 1)$. Then $basic\text{-}internal\text{-}link((e, x, y), x)$ is performed.

$boundary(x, y, 1)$. Boundary list BL is obtained by a call $basic\text{-}boundary(x, y)$.

$joinclasses(J, 1)$. The joining of classes is performed by calls $basic\text{-}joinclasses(J_x)$ for each node x in J, where J_x consists of x and its sublist in J.

$candidates(x, y, 1)$. Let e_x and e_y be the father edges of x and y, respectively (if they exist). Obtain the edges $m_x := \max(class(e_x))$ and $m_y := \max(class(e_y))$. If m_x is incident with y, then $e'_y := m_x$ (now e'_y is m-marked for y), otherwise $e'_y := e_y$; this is similar for e'_x. Output e'_x and e'_y. (Now e'_x and e'_y are preferred.)

We remark that procedure $candidates(x, y, 1)$ yields a correct pair of edges, since if x and y are incident with the same edge class C, at least one of the father edges of x and y must be in C, and if the father edge of, say, x is not in C, then the m-marked edge of C is incident with x.

7.2. The structure FRT(i) for $i > 1$. Let $i > 1$. Structure FRT(i) is a structure for a forest F_i that satisfies the following conditions. For each tree name

s, we keep a parameter $\mathit{weight}(s,i)$ that contains the number of nodes of $\mathit{tree}(s,i)$. Also, we have a parameter $\mathit{lowindex}(s,i)$ which is an integer ≥ -1 that satisfies

$$2.A(i, \mathit{lowindex}(s,i)) \leq \mathit{weight}(s,i). \tag{5}$$

(The parameter *lowindex* is incremented from time to time by the algorithms.) The Union-Find structure for local classes in F_i is UF(i).

Two cases are distinguished.

- If $\mathit{weight}(s,i) = 1$, then $\mathit{down}(s) = i$. Hence $CN(\mathit{tree}(s,1)) = \{s\}$.
- Otherwise, if $\mathit{weight}(s,i) > 1$, then $\mathit{down}(s) < i$. A contraction node $b \in CN(\mathit{tree}(s,i))$ satisfies (besides $\mid \mathit{nodes}(b) \mid \geq 2$)

  $$\mid \mathit{nodes}(b) \mid \geq 2.A(i, \mathit{lowindex}(s,i)). \tag{6}$$

  If layer i is removed, then the remaining part, starting from $\mathit{tree}(s, i-1)$ in layer $i-1$, is an FRT($i-1$)-structure. For an external edge (e,x,y) in $\mathit{tree}(s,i)$, side $(e,x,y)_x$ is *d-marked* if its contraction edge is preferred for $\mathit{contr}(x)$.

Note that every edge class C in $\mathit{extree}(b)$ for some $b \in CN(\mathit{tree}(s,i))$ contains at most one d-marked edge, since every edge class in $\mathit{tree}(s,i-1)$ contains at most one preferred edge incident with b.

7.2.1. Implementation. The initialization is done by initializing a forest of division trees with one contraction node each. For singleton trees, the contraction node is the tree name, where for nonsingleton trees, new tree names are recursively related to them in the next layer. All the corresponding *lowindex*-values are set to -1.

We give the algorithms for the operations. Note that, by (5), $\mathit{lowindex}(s,i) \geq 0$ implies that $\mathit{down}(s) < i$.

$\mathit{link}((e,x,y),s,t,i)$. W.l.o.g., we assume that $\mathit{lowindex}(s,i) \geq \mathit{lowindex}(t,i)$.

Let $\mathit{newweight} := \mathit{weight}(s,i) + \mathit{weight}(t,i)$ and let $\mathit{ls} := \mathit{lowindex}(s,i)$. There are three cases. (For more intuition behind this operation, we refer to the comments and figures in [19].)

- $\mathit{lowindex}(s,i) > \mathit{lowindex}(t,i)$. A call *basic-internal-link*$((e,x,y),y)$ is performed. (Now, $\mathit{tree}(t,i)$ is contracted to $\mathit{contr}(x)$.) Then t and its related layers j with $j < i$ are disposed.
- $\mathit{lowindex}(s,i) = \mathit{lowindex}(t,i) \wedge \mathit{newweight} \geq 2.A(i, \mathit{ls}+1)$. Then a *new* contraction node f is created in layer $i-1$. Then *basic-external-link*(e,x,y) and $\mathit{basic} - \mathit{integrate}(x,f)$ are called, and $\mathit{contr}(f) := s$. (Now, $\mathit{tree}(f)$ consists of the former $\mathit{tree}(s,i)$, $\mathit{tree}(t,i)$, and (e,x,y).) The old existing layers j related to s and t with $j < i$ are disposed, including tree name t. Finally, $\mathit{lowindex}(s,i) := \mathit{lowindex}(s,i) + 1$ and $\mathit{lowindex}(s,i-1) := -1$.
- $\mathit{lowindex}(s,i) = \mathit{lowindex}(t,i) \wedge \mathit{newweight} < 2.A(i, \mathit{ls}+1)$. Then we want to do the actual linking on a lower layer. Therefore, first *basic-external-link*$((e,x,y))$ is executed. Then the contraction edge (e,c,d) of (e,x,y) is created, and a recursive call $\mathit{link}((e,c,d),s,t,i-1)$ is performed, where all the affected edges in layer $i-1$ are obtained. For each edge (e',u,v) in layer i that is (e,x,y) or the original of an affected edge in layer $i-1$, the d-marks are updated: if its contraction edge is preferred for $\mathit{contr}(u)$, then $(e',u,v)_u$ is d-marked; otherwise, $(e',u,v)_u$ is un-d-marked. The same is done for v.

boundary(x, y, i). Perform *candidates*(x, y, i) yielding edges e_x and e_y. If e_x and e_y are in the same edge classes in F_0, then the desired boundary list consists of x and y with e_x and e_y in their sublists. Otherwise, let $c = contr(x)$ and $d = contr(y)$. Then the boundary list BB for c and d in layer $i-1$ is (recursively) computed: if $c = d$, then BB contains just c, and otherwise a recursive call *boundary*$(c, d, i-1)$ is performed, returning BB. For each boundary node b in BB, we obtain the nodes u and v in *tree*(b) that are x, y, or end nodes of the originals of the edges in the boundary edge set of b. Then a "local" boundary list for u and v in *tree*(b) is computed by *basic-boundary*(u, v), where the sublists of the end nodes u and v are extended with the originals of the (at most 2) appropriate edges in BB: if u (or v) is not a boundary node for x and y after all, then it is removed from the local list. These local boundary lists are concatenated, yielding the desired boundary list.

joinclasses(J, i). First a list JJ for layer $i-1$ is made, consisting of the nodes $contr(x)$ for nodes $x \in J$, where the sublist for c is the concatenation of all sublists for $x \in J$ with $contr(x) = c$. Then, for each node $c \in JJ$, the classes occurring in its sublist are obtained, and its sublist is replaced by a sublist that contains for each such class one external edge (if any). All nodes of JJ with a sublist containing at most one edge are removed. If $JJ \neq \emptyset$, then *joinclasses*$(JJ, i-1)$ is called. All the original edge sides of the edges that have been un-m-marked in layer $i-1$ are un-d-marked in layer i. Finally, for each node x in J, *basic-joinclasses*(J_x) is executed, where J_x contains x and its sublist in J.

candidates(x, y, i). Let $c = contr(x)$ and $d = contr(y)$. If $c = d$, then do the same as for $i = 1$. Otherwise, perform candidates$(c, d, i-1)$ that returns the (preferred) edges e_c and e_d. Let edge $e_1 \in extree(c)$ be the (d-marked) original of e_c. Let $e_2 := \max(d(e_1))$. If e_2 is incident with x, then $e_x := e_2$ (e_x is m-marked w.r.t. x); otherwise, e_x is the father edge of x. The same is done for y, yielding e_y. Return the edges e_x and e_y. This is a correct pair of edges, which follows by the specification of *candidates*$(i-1)$ and similar observations as for $i = 1$. Note that by using $d(e_1)$ instead of *class*(e_1), we need to follow *one* pointer only, instead of performing a Find.

We are left with the problem of how to obtain and store the values *weight*, *lowindex*, and the Ackermann values. All these values depend on both the tree name and the layer number. The values *lowindex*(s, j) and *weight*(s, j) for all relevant j are stored in a list for s. For further details and for the problem of how to obtain Ackermann values for all the structures (viz., by means of one "Ackermann net" for $2n$), we refer to [19].

8. Complexity of FRT(i).

We consider the time and space complexity of FRT(i) structures ($i \geq 1$). In the notation, we omit the procedure parameters except for the layer number i. Operations *treename* and *candidates*(i) can be performed in $O(i)$ time, and a nonessential call *boundary*(i) can be done in $O(i)$ time plus $O(1)$ Finds in UF_0. For *candidates*, this is seen as follows. If $contr(x) = contr(y)$, it takes one Find in UF(i), which is $O(i)$ time. Otherwise, all instructions except for the recursive call can be done in constant time (because of the d-marks and preferred edges), giving $O(i)$ time by induction. For a nonessential call *boundary*, we see that if $i = 1$ then $x \sim y$, and thus *basic-boundary*(x, y) is similar to *candidates*$(x, y, 1)$, while if $i > 1$, then *candidates*(x, y, i) is executed together with two Finds.

In the sequel, we consider the complexity of essential sequences (see section 3). We determine the time complexity in steps, where one *step* denotes a Find operation (in any involved Union-Find structure), a *candidates* operation, a nonessential *boundary* operation, or one ordinary elementary computation step not included in these three operations. Hence each *candidates* operation and each nonessential call of *boundary* takes 1 step.

We obtain the following result. The proof is given in subsection 8.1 (which can be skipped at first reading). Note that if $F_i = F_0$, then $UF_0 = UF(i)$ and the set unions take $O(n.a(i,n))$ time (see Theorem 2.3).

LEMMA 8.1. *An essential sequence in an FRT(i) structure with n nodes needs a total of $O(n.a(i,n))$ steps, except for joining edge classes in F_0 ($i \geq 1$, $n \geq 2$).*

8.1. Proof of Lemma 8.1. Lemma 8.1 is proved by induction in a way similar to the proof in [19]. We first consider the *net cost* of the basic operations, i.e., the cost of the operations *except* for the cost of set unions. Then *basic-integrate*(y, f) and *basic-internal-link*$((e, x, y), y)$ take net $O(|T_y|)$ steps, where T_y is the tree containing y; *basic-external-link*$((e, x, y))$ takes net $O(1)$ steps. A call *basic-boundary*(x, y) takes $O(|BL|)$ steps if BL is the resulting boundary list, and *basic-joinclasses*(J) takes $O(|E_J|)$ net steps, where E_J is the number of edges in J.

We now consider the complexity of the structures FRT(i). As in [19], we do not need to consider the complexity of storing and obtaining the information for each layer related to a tree name, since this can be charged easily to other operations. We show that an essential sequence in FRT(i) takes $O(n.a(i,n))$ steps on n nodes (except for the cost on F_0). Moreover, we show that the number of times that an edge becomes affected (see section 6) is at most $a(i,n)$. We prove all this by considering the procedures *link*(i), (essential) *boundary*(i), and *joinclasses*(i), where the cost of set union or essential recursive calls is considered separately. Here an *essential recursive call* is any recursive call of these procedures with the restriction that recursive *boundary* calls are essential.

8.1.1. FRT(1). We consider the cost of an essential sequence on n nodes ($n > 1$) in FRT(1) by determining for each procedure the cost of all its calls.

Procedure *link*$((e, x, y), s, t, 1)$ takes at most $O(|weight(t, 1)|)$ steps, where, w.l.o.g. *tree*(t, i) is the smallest of the two sets to be joined. Charge each node in *tree*$(t, 1)$ for $O(1)$ cost. Since the nodes in *tree*$(t, 1)$ become elements of a tree with at least double size, all calls take at most $\lfloor \log n \rfloor \leq a(1, n)$ steps together. Similarly, the number of times that an edge is affected is at most $a(1, n)$.

A call *boundary*$(x, y, 1)$ takes $O(|BL|)$ steps. Note that at least $|BL| - 1$ different classes occur in BL. Charge $O(1)$ cost to the encountered classes. In the essential sequence, all these classes are subsequently joined by a call *joinclasses*. This gives at most $O(n)$ steps.

Procedure call *joinclasses*$(J, 1)$ takes $O(1)$ steps for each class that is joined; thus the total amount of steps is $O(n)$ steps apart from the joinings.

Finally, since there are at most $2n$ edge sides, the time for set unions in UF(1) is $O(n.a(1,n))$ (Theorem 2.3).

Therefore, FRT(1) takes at most $d.n.a(1, n)$ steps for an essential sequence on n nodes ($n > 1$) for some constant d. Moreover, the number of times that a node is affected is at most $a(1, n)$.

8.1.2. FRT(i) for $i > 1$. We consider the cost for an essential sequence on n nodes ($n > 1$) in FRT(i) with $i > 1$. We perform the analysis by means of induction on i. Suppose FRT$(i - 1)$ takes at most $c.k.a(i - 1, k)$ steps in an essential sequence on k nodes ($k > 1$), where c is some arbitrary constant. Moreover, suppose that the number of times that an edge in the FRT$(i - 1)$ structure is affected is at most

$a(i-1,k)$. For each procedure or specific part of the computation, we determine the cost of all its calls.

For an essential call of $boundary(i)$, we have the following. First, the calls of $candidates(i)$ and the recursive call $boundary(i-1)$ take $O(1)$ net steps. (The call $boundary(i-1)$ takes net $O(1)$ steps if it is nonessential and it takes no steps if it is essential.) Then local boundary lists are computed and manipulated (but do not become empty, see section 5). Hence the net cost is $O(|BL|)$ steps. Since afterward all classes occurring in BL must be joined by a call of $joinclasses$ in the essential sequence, it follows that the total net amount of steps is $O(n)$.

Procedure $joinclasses(i)$ takes a net number of steps linear to the number of classes that will be joined, apart from the recursive call. Hence this is $O(n)$ in total.

We divide *link* $((e,x,y),s,t,i)$ into several parts and compute the net cost of each of these parts for all executions together. First, the removal of parts of structures can be charged to their creation. Second, the calls of procedure *basic-internal-link* and *basic-integrate* take at most $O($*the number of processed nodes*$)$ steps. Therefore, we charge these steps to the processed nodes. Note that in both cases the processed nodes will (henceforth) be contained in a new tree with higher $lowindex$ value and that there are at most $a(i,\lceil\frac{n+1}{2}\rceil)+2 \le 3.a(i,n)$ different $lowindex$ values (cf. (5)). Therefore, the total cost of these calls is $O(n.a(i,n))$ steps. Similarly, it follows that an edge is affected is at most $a(i,n)$ times. Third, the cost for changing d-marks of edges in procedure $link(i)$ is linear to the number of times that contraction edges are affected in the recursive call $link(i-1)$. In Observation 8.4 we will show that this is at most $\frac{1}{2}.n.a(i,n)$. Hence this takes $O(n.a(i,n))$ steps altogether. Last, the rest of the procedure requires $O(1)$ net time per call of link(i), which gives $O(n)$ time altogether. In conclusion, all calls of *link* take at most $O(n.a(i,n))$ steps net and affect an edge at most $a(i,n)$ times.

The required time for set unions in UF(i) is $O(n.a(i,n))$ (Theorem 2.3), since there are at most $2n$ edge sides.

Finally, we consider the essential recursive calls (performed on contraction nodes). We first have two observations (the latter can be proved as in [19]).

OBSERVATION 8.2. *The operations on contraction trees (for layer i) by procedure link*$((e,x,y),i)$ *are the creation of a singleton tree and the linking and removal of trees; procedures* $joinclasses(i)$ *and* $boundary(i)$ *only change edge classes in contraction trees.*

OBSERVATION 8.3. *In link*$((e,x,y),s,t,i)$*, a recursive call is performed only if*

$$\begin{aligned}&1 < lowindex(s,i) = lowindex(t,i) \le a(i,n)\\ &\wedge weight(s,i)+weight(t,i) < 2.A(i,lowindex(s,i)+1).\end{aligned}$$

For a contraction node $c \in CN(tree(s,i))$, we denote by $lowindex(c)$ the value $lowindex(s,i)$, which is fixed during its existence. We call c an l-contraction node if $lowindex(c) = l$. Similarly, we say that a recursive call $link((e,c,d),s,t,i-1)$ is an l-call if $l = lowindex(s,i) = lowindex(t,i)$. A recursive call $boundary(i-1)$ or $joinclasses(i-1)$ is an l-call if $l = lowindex(s,i)$, where s is the name of the tree on which the operation is applied. Obviously an l-call operates on l-contraction nodes only, and vice versa. We compute the cost of all l-calls for fixed value l, $-1 \le l \le a(i,n)$. Note that any tree of l-contraction nodes with $l \le 0$ consists of one contraction node. Hence an l-call of $boundary(i-1)$ and $joinclasses(i-1)$ occurs only if $l \ge 1$. By Observation 8.3 and since $|nodes(b)| \ge 2$ for each contraction node b, it follows in case of an l-call *link* $(s,t,i-1)$ that $l > 1$, and that $weight(s,i-1)+$

$weight(t, i-1) < A(i, l+1)$. By this and by Observation 8.2, the maximal size of any tree of l-contraction nodes is $< A(i, l+1)$.

Now let l be fixed number with $1 \leq l \leq a(i, n)$. Partition the total collection of all l-contraction nodes involved in l-calls into the existing maximal sets. Then the size of such a maximal set is at most $A(i, l+1)$. It easily follows that the sequence of essential recursive l-calls on the nodes of a maximal set in FRT$(i-1)$ is an essential sequence. For each such maximal set of k contraction nodes, the cost of all (previous) essential l-calls on these nodes in FRT$(i-1)$ is at most $c.k.a(i-1, k) \leq c.k.\ a(i-1, A(i, l+1))$. Hence the total cost of all essential l-calls in FRT$(i-1)$ on l-cluster nodes is at most $c.(\textit{number of l-cluster nodes}).\ a(i-1, A(i, l+1))$. By (6), there are at most $n/(2.A(i, l))$ l-contraction nodes. Therefore, this cost is at most $c.\frac{n}{2.A(i,l)}.\ a(i-1, A(i, l+1))$, which is at most $\frac{1}{2}c.n$ by using $i > 1$ and equations (1) (on $A(i, l+1)$) and (4), respectively.

Since at most $a(i, n)$ values l of *lowindex* occur, the cost of all these FRT$(i-1)$-calls is at most $\frac{1}{2}c.n.a(i.n)$.

Similar to the above, by the induction hypothesis, the number of times that l-contraction edges are affected in the l-calls *link*$(i-1)$ is at most $\frac{1}{2}.n$ for fixed l.

OBSERVATION 8.4. *The number of times that contraction edges are affected in recursive calls at most link$(i-1)$ is $\frac{1}{2}.n.a(i, n)$.*

Combining all the above results yields that the total number of steps is at most $c_1.n + c_2.n.a(i, n) + \frac{1}{2}c.n.a(i, n)$ for some c_1 and c_2 (independent of c). By taking $c = \max\{d, 2.(c_1 + c_2)\}$, it follows by induction that an essential sequence in FRT(i) takes at most $c.n.a(i, n)$ steps and affects an edge at most $a(i, n)$ times. This concludes the proof of Lemma 8.1.

9. FRT structures. We consider FRT(i)-structures with $F_i = F_0$ and express the operations of section 3 in terms of section 7. It is easily seen how to use the latter for the former; we may only need an additional call of *treename* or $O(1)$ Finds in UF$_0$ for the proper result. Thus Lemma 8.1 remains valid for the operations in section 3 (in order of magnitude). Note that by Theorem 2.3, a step, as defined in the previous subsection, is $O(i)$ time.

THEOREM 9.1. *An essential sequence in FRT(i) on n nodes needs a total time of $O(n.i.a(i, n))$ $(i \geq 1,\ n \geq 2)$. Each candidates operation and each nonessential call boundary takes $O(i)$ time. The structure can be initialized in $O(n)$ time and takes $O(n)$ space.*

Note that if n' is the number of nodes that are not still contained in singleton trees after the execution of the above sequence (thus $n' \leq n$), then the total time is even $O(n'.i.a(i, n'))$. Also, the theorem can be extended with the insertion of new (isolated) nodes in the structure with the same complexity bounds, where the insertion of a new node takes $O(1)$ time (see also [19]).

We define an α-FRT structure as follows. Initially, FRT$(\alpha(n, n))$ is used. From time to time, a transformation is performed, replacing an FRT(i) structure by an FRT$(i-1)$ structure, viz., each time that $\alpha(q, n)$ decreases by one, where at any moment q is the number of queries *candidates* performed until then. This is performed in a way similar to the proof of Theorem 5.2 of [19] (full paper), where now the query *candidates* plays the role of the Finds, and where *link* and *joinclasses* play the role of the Union operations. The building of a new FRT$(i-1)$ is done similar to Theorem 5.2 in [19], but instead of building just parts of FRT$(i-1)$ during *candidates* operations, we have for all pointers in F_0 two versions, and we build and handle FRT$(i-1)$ with the unused pointer version. (This duplication is only relevant in case we want a single *candidates* query to have $O(\alpha(q,n))$ worst-case time.) Then we obtain the following result.

THEOREM 9.2. *Let an α-FRT structure for an "empty" forest with n nodes be given. Then a matching sequence in α-FRT needs a total of $O((n+m).\alpha(m,n))$ time (where m is the number of operations candidates and boundary that is performed), where the qth call of candidates takes $O(\alpha(q,n))$ time. The structure can be initialized in $O(n)$ time and takes $O(n)$ space.*

Proof. The proof is related to the proof of Theorem 5.2 in [19]. We leave this as an exercise for the reader (and refer to [22, 23]). □

Note that if n' is defined as before (and, hence, the essential subsequence of the matching sequence consists of $\theta(n')$ operations), then the total time is even $O((n'+m).\alpha(m,n))$ time. Also, by using the same transformation techniques as in Theorem 6.2 in [19], the above theorem can be extended with the insertion of new (isolated) nodes in the structure with the corresponding complexity bound $O((n+m).\alpha(m,n))$ (where m and n denote the current number at the time of consideration), where the insertion of a new node takes $O(1)$ time. We will not give details here but refer to [22, 23]. (We want to remark that if at any time $m = O(n)$, as for the 2ec-and the 3ec-problem, then only rebuildings from FRT(i) to FRT($i+1$) are needed.)

In practice there is no need to perform transformations of FRT-structures or to compute Ackermann values [19]. This is because $\alpha(m,n) \leq 3$ for any practical n. Thus, structures FRT(i) with $i \in \{2,3\}$ are suited for all practical situations and only need the nontrivial Ackermann values $A(2,3) = 16$ and $A(2,4) = A(3,3) = 65536$. An essential sequence in FRT(2) takes $\leq c.2.n.a(2,n) = 2cn.\log^* n$ time, which is $\leq 8cn$ for $n \leq 2^{16}$ and $\leq 10cn$ for $n \leq 2^{65536}$, where c is not too large a constant (see section 8). Therefore, we conjecture that FRT(2) can be implemented as a fast structure for all *practical* situations, with constant-time queries.

10. 3-edge-connectivity.

We will now extend the results to the maintenance of 3ec-components in a graph, with a time complexity of $O(n + m.\alpha(m,n))$ for n nodes and m queries and insertions. In subsection 10.1 we consider maintaining the 3ec-relation within 2-edge-connected graphs and, subsequently, in subsection 10.2 we consider the problem for general graphs.

Let $G = \langle V, E\rangle$ be a graph. The set V can be partitioned into equivalence classes for 3-edge-connectivity, called *3ec-classes*. Each 3ec-class C is represented by a new node c, called the *class node* of C. Let $3ec(x)$ be the class node of the 3ec-class in which the vertex x is contained. We define the graph $3ec(G)$ as follows.

$$3ec(G) = \langle 3ec(V), \{(e, 3ec(x), 3ec(y)) | (e,x,y) \in E \wedge 3ec(x) \neq 3ec(y)\}\rangle.$$

Hence, $3ec(G)$ is the graph that is obtained if we contract each 3ec-class into one class node (see Figure 3 if G is 2-edge-connected). No two nodes in $3ec(G)$ are 3-edge-connected (by Lemma 2.2).

10.1. 2-edge-connected graphs.

In this subsection, we suppose that graph G is 2-edge-connected, and we state results from the companion paper [21]. Every two distinct class nodes must lie on a common elementary cycle in $3ec(G)$, while simple cycles in $3ec(G)$ cannot intersect in more than one class node.

Let $Cyc(3ec(G))$ be the graph that is constructed from $3ec(G)$ as follows. Each nontrivial simple cycle is represented by a distinct node called a *cycle node*. Let $cn(3ec(G))$ be the set of cycle nodes. For a cycle node s, let $cycle(s)$ be the set of all class nodes that are on the cycle s. The graph $Cyc(3ec(G))$ consists of the class nodes and cycle nodes of $3ec(G)$, where a class node c is adjacent to a cycle node s in $Cyc(3ec(G))$ iff c lies on cycle s in $3ec(G)$. Therefore, graph $Cyc(3ec(G))$ shows the incidence relation for class nodes and cycles. Moreover, graph $Cyc(3ec(G))$ is a tree called the *cycle tree* of G. The structure of $Cyc(3ec(G))$ is illustrated in Figure 3, where the cycle nodes are drawn as boxes.

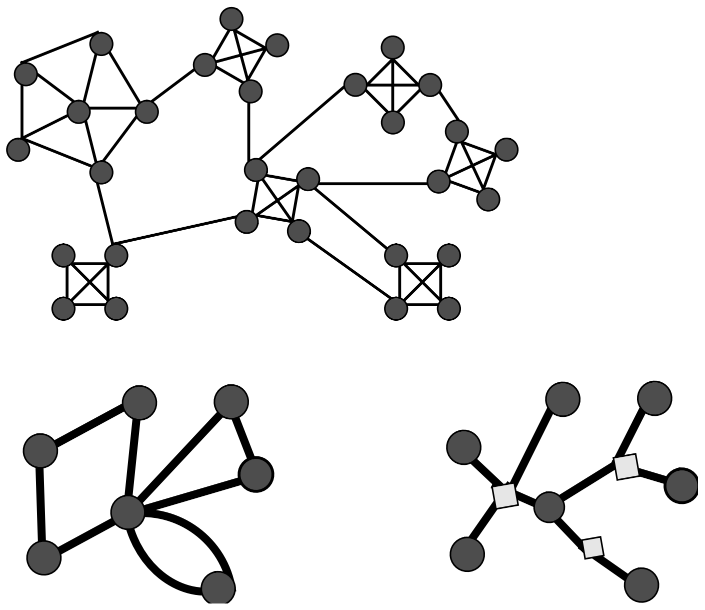

FIG. 3. *A* 2*-edge-connected graph* G *and the related graphs* $3ec(G)$ *and* $Cyc(3ec(G))$*.*

10.1.1. Edge insertions. We maintain the 3ec-relation under edge insertions by means of $Cyc(3ec(G))$. Suppose a new edge (e,x,y) is inserted in G. If $3ec(x) = 3ec(y)$, then by Lemma 2.2, the 3ec-relation, $3ec(G)$, and $Cyc(3ec(G))$ remain unchanged. So, we can assume that $3ec(x) \neq 3ec(y) \wedge 2ec(x) = 2ec(y)$. Then edge $(e, 3ec(x), 3ec(y))$ arises as a new edge in $3ec(G)$.

LEMMA 10.1 (see [21]). *Let G be a* 2*-edge-connected graph. Suppose that an edge* $(e, 3ec(x), 3ec(y))$ *is inserted to the graph* $3ec(G)$*. Then all the class nodes on the tree path P from* $3ec(x)$ *to* $3ec(y)$ *in* $Cyc(3ec(G))$ *become* 3*-edge-connected in* $3ec(G)$*, while the other pairs of distinct class nodes in* $3ec(G)$ *stay only* 2*-edge-connected.*

Thus, for all class nodes on P, all the corresponding classes form a new class (by Lemma 2.2). The update can now be performed as follows:

- obtain the tree path P between $3ec(x)$ and $3ec(y)$ in $Cyc(3ec(G))$,
- join all the classes "on" P into one new class C', and
- adapt the cycle tree $Cyc(3ec(G))$ accordingly.

The update heavily changes the structure of $Cyc(3ec(G))$. (For illustrations, we refer to [21].) The cycle tree changes as follows. Consider the simple cycle s and the class nodes c and d ($c \neq d$) such that s, c, and d are on P and $c, d \in cycle(s)$. Then classes c and d are joined into the new class c'. The original simple cycle s splits into two "smaller" simple cycles, each one consisting of the class node c' and of one of the two parts of the former cycle *between* c and d (we refer to [21]).

LEMMA 10.2 (see [21]). *Given a* 2*-edge-connected graph G of n nodes with a cycle tree, there exists a data structure for the* 3*ec-problem (that also maintains a* *cycle tree) such that the following holds. The total time for m insertions and queries is $O(m+n)$ time plus the time needed to perform $O(m+n)$ Finds and $O(n)$ Unions and Splits in a Union-Find or a Circular Split-Find structure for $O(n)$ elements. The data structure takes $O(n)$ space.*

Here, the *Circular Split-Find problem* [23] is a problem closely related to the Split-Find problem [11]. It deals with splitting cyclic lists into two new cyclic lists, determined by two splitting nodes. In [23], solutions for this problem are given with similar complexities as the UF-structures (cf. section 2.5). (They are closely related to [11].) We denote such structures similarly by GSF(i) and α-GSF structures. Later, we choose appropriate structures when applying Lemma 10.2.

10.2. General graphs.

10.2.1. Observations. We extend the solution of the previous section to general graphs. We first state observations of [21] (to which we refer for further details and figures). For detecting the 3ec-classes it suffices to detect the 3ec-classes inside the 2ec-components. Therefore, our algorithms for general graphs maintain the 2ec-classes (as in section 4), and they maintain the 3ec-classes within 2ec-components. We consider the forest of all cycle trees for the 2ec-components, called the *cycle forest* $Cyc(3ec(G))$ of G.

Suppose edge (e, x, y) is inserted in graph G yielding graph G'. If $c(x) \neq c(y)$, then the 2ec-classes and the 3ec-classes do not change. Otherwise, if $2ec(x) = 2ec(y)$, then (e, x, y) is inserted inside a 2ec-component and the changes as described in subsection 10.1.1 occur. Otherwise, we have $2ec(x) \neq 2ec(y) \wedge c(x) = c(y)$. Consider $2ec(G)$. Let P_2 be the tree path between $2ec(x)$ and $2ec(y)$ in $2ec(G)$ (see subsection 4.1). Then the major changes are that

1. all 2ec-classes corresponding to class nodes on P_2 form one new 2ec-class,
2. for each 2ec-class C on P_2, the 3ec-classes inside C are changed, and
3. a new cycle s of 3ec-classes arises; the new cycle node s links the (updated) cycle trees that are contained in the 2ec-classes on P_2.

We consider the changes more precisely. The first part is identical to subsection 4.1. For the second part, we consider the changes of the 3ec-classes that occur in 2ec-classes on P_2. Consider a 2ec-class C on P_2 in $2ec(G)$. Let u and v be the two nodes in C that are x, y, or end nodes of interconnection edges between C and other classes on P. (We call u and v the *interconnection nodes* for C.) Then there is a new path between u and v in G' that does not intersect with C except for u and v, where such a path did not previously exist in G. Hence, considered within C only, this corresponds to inserting a temporary edge between the nodes u and v, since the 3ec-classes are completely determined by the 2ec-components in which they are contained (see Lemma 2.1). For the third part, now suppose all these "local" insertions are performed in the 2ec-classes on P_2. Then the two interconnection nodes in a 2ec-class C on P_2 are in the same (updated) 3ec-class in C, called the *interconnection* 3*ec-class* in C. All these interconnection 3ec-classes form a new cycle s. Then in the cycle forest s must be linked to these interconnection 3ec-classes, and thus it links the corresponding cycle trees.

10.2.2. Data structures and approach. We observe that when an edge (e, x, y) is inserted in a 2ec-component H, the changes in the 3ec-relation and $Cyc(3ec(H))$ are fully determined by just the 3ec-classes in which x and y are contained.

Consider a graph $G = \langle V, E \rangle$. We change the cycle forest $Cyc(3ec(G))$ by augmenting the collection of nodes of G and partitioning the thus-obtained 3ec-classes into subclasses. We do this as follows. Each 3ec-class in G may be extended with an arbitrary number of new, auxiliary nodes that are considered to be nodes in that 3ec-class (conceivably by means of artificial edges). The auxiliary nodes are not distinguished from the original nodes.

Each (extended) 3ec-class C of G is partitioned into *subclasses* of nodes. To each subclass a (new) distinct node is related called the *subclass node*. We call these the subclass nodes for C. The subclass node of the subclass to which x belongs is denoted by $sub(x)$. Now an *augmented cycle forest* AF_G for G is a forest on the subclass nodes and the cycle nodes of $Cyc(3ec(G))$ such that for each 3ec-class C of G the subclass nodes for C induce a subtree of AF_G and such that $Cyc(3ec(G))$ is obtained if for each 3ec-class C its subclass nodes are contracted into one node. We call an edge that links two subclass nodes of a 3ec-class C a *connector* for 3ec-class C. The set of all the connectors for C is called the *connector class* for C. Stated informally, AF_G can be obtained by replacing each class node in $Cyc(3ec(G))$ by some tree of subclass nodes and connectors. See Figure 4, where cycle nodes are drawn as boxes and (sub)class nodes as dots.

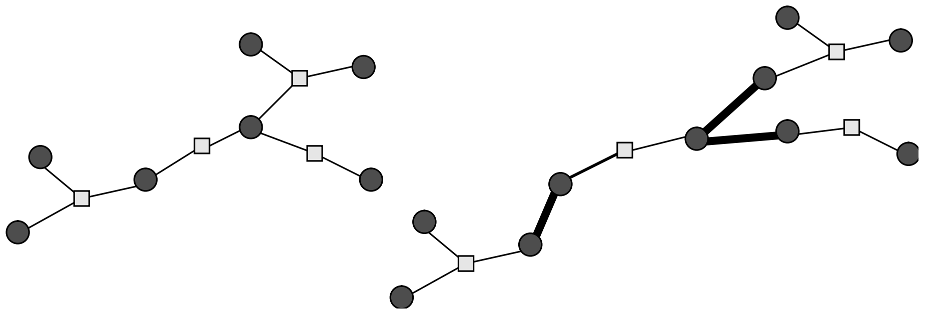

FIG. 4. *Graphs* $Cyc(3ec(G))$ *and* AF_G.

We consider the insertion of an edge (e, x, y) in a 2-edge-connected graph G in terms of AF_G. Let $2ec(x) = 2ec(y) \wedge 3ec(x) \neq 3ec(y)$. The 3ec-classes on the tree path from $3ec(x)$ to $3ec(y)$ in $Cyc(3ec(G))$ correspond to the 3ec-classes that have at least one subclass on the tree path P between $sub(x)$ and $sub(y)$ in AF_G. Hence we can update the structure according to the following observations (also cf. subsection 10.1.1).

- Two successive subclass nodes on P (without a cycle node in between) correspond to the same class. Hence it suffices to obtain just the subclass nodes on P that are adjacent to a cycle node on P.
- All the classes of which a subclass node is "on" P must be joined into one new class C'.
- The augmented cycle tree AF_G must be adapted. Hence, all subclass nodes for C' must form a (sub)tree. This can be done by splitting each cycle s occurring on P and by joining the two subclasses that are the neighbors of s on P. (These updates can be performed locally as for cycle trees for each part of P without adjacent subclass nodes.)

Our goal structure is now as follows. To a graph G we relate a forest $bc(G)$ and an augmented cycle forest AF_G that satisfy the following. The graph $G = \langle V, E \rangle$ is extended with an (incremental) collection of auxiliary nodes, which are 3-edge-connected to least one original node. The (thus extended) vertex set is partitioned into disjoint sets, called *basic-clusters.* Each basic-cluster has a (new) unique node called *cluster node.* The nodes of forest $bc(G)$ are these cluster nodes. We call the edges of $bc(G)$ *bc-edges.* The following constraints are satisfied.

- Each 3ec-class C is partitioned into subclasses by intersecting C with the basic clusters. Then AF_G is an augmented cycle forest for G, based on this partition into subclasses.
- Each subclass node is considered to be contained in the basic cluster that contains its subclass. Then for a basic-cluster b, the subclass nodes that are contained in b together with appropriate cycle nodes of AF_G induce a subtree of AF_G denoted by $tree(b)$.
- Every connector in AF_G corresponds to exactly one edge in $bc(G)$ (and vice versa).

It follows that for a cluster b, $tree(b)$ does not have two adjacent subclass nodes. Therefore, $tree(b)$ is a cycle tree of some 2-edge-connected graph that has the nodes of basic-cluster b as its nodes together with a number of appropriate edges that induce the 3ec-relation as represented by $tree(b)$.

We observe that $bc(G)$ can be obtained from AF_G by contracting all subclass nodes in a basic-cluster b to cluster node b. Thus $bc(G)$ is an other contraction of AF_G (different from $Cyc(G)$). See Figure 5 for the example of Figure 4. We now define edge classes on $bc(G)$ as the classes inherited from the connector classes in AF_G (see section 2.1). Note that if two bc-edges incident with a cluster node b are in the same bc-edge class, then their originals in AF_G must have the same end node (a subclass node) in cluster b.

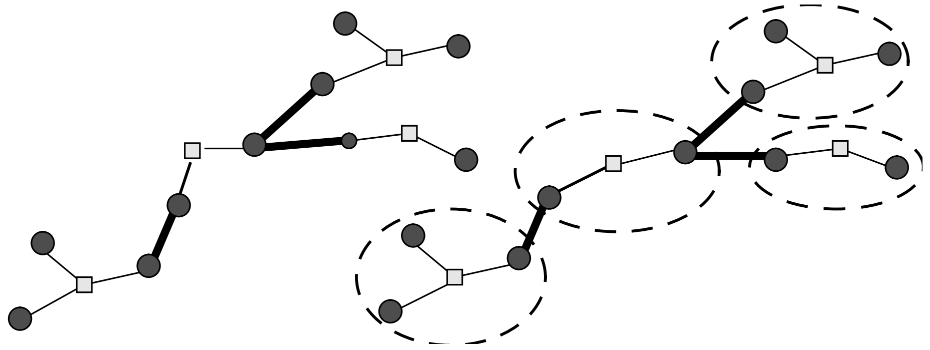

FIG. 5. *Forests AF_G and $bc(G)$.*

Now the strategy for inserting an edge (e, x, y) in 2-edge-connected graph G can be put in terms of $bc(G)$ as follows. Let c and d be the basic clusters containing x and y, respectively. Suppose that $c \neq d$.

- Let P' be the tree path in $bc(G)$ between c and d. Let P be the tree path in AF_G between $sub(x)$ and $sub(y)$. To obtain the relevant parts of P, it suffices to obtain a boundary list BL for c and d in $bc(G)$. This is seen as follows. The two incident bc-edges of an internal node b on P' are in the same bc-edge class. Hence their originals (which lie on P) have the same end node sb in b, which, therefore, is not adjacent to a cycle node on P. Note that for a boundary node $b \notin \{c, d\}$ of P', its two incident bc-edges on P' are not in the same bc-edge class, and thus cluster b contains at least two subclass nodes and one cycle node of P.

- For each such cluster b with $b \in BL$, a local update of the local cycle tree must be performed by joining all subclasses on the part P_b of P inside cluster b and by updating the local cycle tree correspondingly. The end nodes sb_1 and sb_2 of P_b are $sub(x)$, $sub(y)$, or the end nodes in cluster b of the originals of the bc-edges on P'. The latter can also be obtained from the bc-edges in the sublist of b in BL. The update thus corresponds to the update for inserting a temporary edge between any two nodes of G that are contained in subclasses sb_1 and sb_2.

10.2.3. Data structures and algorithms. In this section, we describe a data structure for the 3ec-problem, called *3EC structure*. We distinguish between the different layers of *representation*.

The representation of graph G is as follows. The vertex set of G may be extended from time to time with auxiliary nodes. There is a structure $2EC$ to maintain the 2ec-classes of G. This structure works on the regular nodes only, and, hence, the additional nodes are not involved. There is a "global" Union-Find structure UF_{3ec} for implementing the 3ec-classes of nodes of G. We recall that in the $2EC$ structure, there are Union-Find structures UF_c and UF_{2ec}.

Each node x has a pointer $clus(x)$ to the cluster node in which it is contained. Forest $bc(G)$ is implemented as a fractionally rooted tree structure (FRT) denoted by FRT_{3ec}.

The augmented cycle forest AF_G is not implemented as a whole. In fact, it is implemented in parts, viz., by cycle trees inside basic-clusters and by separate connectors. To be precise, we have the following implementation. Instead of a subclass node s as the end node of a connector, we take a node in subclass s as an end node. This is because subclasses are joined from time to time. Then the subclasses that are the ends of a connector (e, x, y) are $sub(x)$ and $sub(y)$. For a basic-cluster b, $tree(b)$ is implemented and maintained as a cycle tree as in Lemma 10.2. We refer to this as the *local structure*. The Union-Find and Circular Split-Find structures used in the local structure are denoted by UF_{loc} and GSF_{loc}. To each subclass, we relate a connector that has one of its end nodes in that subclass (if it exists) its *associated connector*.

The initialization for an empty graph is straightforward: each basic cluster contains one node. Also, a query corresponds to a Find in UF_{3ec}.

Suppose some new edge (e, x, y) is inserted in G, resulting in graph G'. Let the corresponding clusters for x and y be c and d. Then procedure $insert_3((e, x, y))$ updates the structure as follows if $3ec(x) \neq 3ec(y)$.

1. $c(x) \neq c(y)$. Then $insert_2((e, x, y))$ is performed
2. $c(x) = c(y) \wedge 2ec(x) = 2ec(y) \wedge 3ec(x) \neq 3ec(y)$. If $c = d$, then list BL is the list consisting of c with empty sublist; otherwise, $boundary(c, d)$ is performed in FRT_{3ec}, yielding boundary list BL in $bc(G)$. List BL is copied as list J but with empty sublists.
   For each basic cluster b in BL, the following is done. First, the nodes u and v in $tree(b)$ are obtained that are x, y, or end nodes of the originals of the bc-edges in the sublist of b (if any). If $3ec(u) \neq 3ec(v)$, then the following is done. A local insertion (Lemma 10.2) of a temporary edge (e', u, v) in basic-cluster b is performed to update $tree(b)$. Then an associated connector is obtained for each of the subclasses that are joined in cluster b, and the corresponding bc-edges are put in the sublist for b in J (since all classes must be joined later in the global structure). One of these connectors (if any) is assigned to the resulting subclass as its associated edge.

All the 3ec-classes of which a subclass was involved in the joinings are joined in UF_{3ec} (e.g., by taking a node from each subclass). Finally, the FRT_{3ec} structure is updated by means of call $joinclasses(J)$ (where if the sublist of node c or d is empty, then this node is removed from J.)

3. $c(x) = c(y) \wedge 2ec(x) \neq 2ec(y)$. First, the 2ec-classes that will be joined into one new class are determined. This is done as follows. A boundary list BL for x and y is computed in $2EC$ (this is only the first part of the call $insert_2((e, x, y))$). Subsequently, the names of the 2ec-classes are obtained. Then a linear list L is constructed that consists of these names and of those edges in BL with end nodes in different 2ec-classes: the names and edges alternate in L such that an edge is bracketed by the two corresponding 2ec-classes. Now L contains the tree path between $2ec(x)$ and $2ec(y)$ in $2ec(G)$ in the proper order.
For each 2ec-class C in L the following is done. We obtain the nodes u and v in C that are x, y, or the end nodes of the surrounding edges in L. If $3ec(u) \neq 3ec(v)$ then a temporary edge between u and v in C is inserted by a call $insert_3((e', u, v))$. Afterward, a new, auxiliary node z_C is created, and it is inserted in the interconnection 3ec-class $3ec(u)$. A connector (e'_C, z_C, z'_C) is created between z_C and some node z'_C of 3ec-class $3ec(u)$.
The nodes z_C $(C \in L)$ together form a new basic cluster b. Thus a cycle tree corresponding to the cycle of the new subclasses $\{z_C\}$ $(C \in L)$ is initialized in cluster b (in the same order as the 2ec-components C in L).
Cluster node b is linked with the involved trees in $bc(G)$ by means of new bc-edges as follows. For each z_C and connector (e'_C, z_C, z'_C), let $b' = clus(z'_C)$. Then a bc-edge (e'_C, b, b') is created for this connector, and a call $link((e'_C, b, b'))$ is performed in $bc(G)$. Edge (e'_C, z_C, z'_C) is associated with $sub(z_C)$ and $sub(z'_C)$. If $sub(z'_C)$ already had an associated edge (e'', z'', z'''), then (e'_C, b, b') is put in the class containing $(e'', clus(z''), clus(z'''))$ by a call of $joinclasses$.
The 2ec-classes in L are joined by performing a real call $insert_2((e, x, y))$ in $2EC$.

10.2.4. Complexity. We consider the complexity of the above algorithm. Regarding the creation of auxiliary nodes, suppose the initial graph G_0 has n (regular) nodes. The total number of new nodes created by the algorithm is at most $2n-1$, since a new node is created for each 2ec-class that is joined. Similarly, the total number of created clusters is at most $n-1$. Hence we only need FRT and Union-Find structures for $O(n)$ nodes. We denote all the Union-Find structures used independently in 3EC (not as part of FRT_{3ec} or FRT_{2ec}) by UF. We consider the UF structures to be one structure, on $O(n)$ elements. Obviously, a nonessential insertion takes time linear to $O(1)$ Finds.

LEMMA 10.3. *In a 3EC structure, the time for a sequence of essential insertions is at most linear to the time for a matching sequence of $O(n)$ operations on $O(n)$ nodes in FRT_{3ec} and FRT_{2ec} and for $O(n)$ Unions, Splits, and Finds in the UF and GSF_{loc} structures.*

Proof. We define a step to be an ordinary computational step or a Find operation in any UF or GSF_{loc} structure. We consider a collection of essential $insert_3$ operations, including the $insert_3$ calls during the execution of an $insert_3$ itself. Therefore, we do not consider the cost of an essential call $insert_3$ inside $insert_3$. Obviously, there are at most $O(n)$ essential insertions possible. So the essential $insert_3$ operations yield a matching sequence of $O(n)$ operations in FRT_{3ec}. Also, all calls $insert_2$

in the calls $insert_3$ are essential. Therefore, by Observation 4.2, the lemma holds for the operations in $2EC$.

We consider the *net cost* of the sequence of essential $insert_3$ calls: i.e., the cost of the parts of the computations apart from the computations considered above, from $O(1)$ steps per call $insert_3$, and from the Unions and Splits in the UF and GSF_{loc} structures.

1. Case $c(x) \neq c(y)$. Then there is no net cost.
2. Case $2ec(x) = 2ec(y) \wedge 3ec(x) \neq 3ec(y)$. We consider the net cost of a call $insert_3$. One part corresponds to the cost of essential local insertions inside clusters. This takes $O(1)$ steps for each such cluster and for each subclass that is joined. These $O(1)$ steps are considered to be included in the cost for joining two subclasses by a local insertion (at most 2 of these clusters have no subclasses that are joined).
   Since, in total, at most $O(n)$ essential local insertions can occur, the *net* cost is linear to $O(n)$ Finds in these structures (by Lemma 10.2).
3. $c(x) = c(y) \wedge 2ec(x) \neq 2ec(y)$. The computation of a boundary list in 2EC is a part of an essential call $insert_2$. The remainder takes $O(|L|)$ steps, plus a number of (other) $insert_3$ calls (this latter cost is included in case 2). Since the 2ec-classes in L are joined, the total net cost is $O(n)$ steps. ∎

A $3EC(i)$ *structure* is a 3EC structure where $FRT_{3ec} = FRT(i)$, $FRT_{2ec} = FRT(i)$, $UF = UF(i)$, and $GSF = GSF(i)$.

THEOREM 10.4. *A $3EC(i)$ structure solves the $3ec$-problem such that the following holds. The total time that is needed for all essential insertions is $O(n.i.a(i,n))$, whereas a query and nonessential insertion can be performed in $O(i)$ time. The structure can be initialized in $O(n)$ time and takes $O(n)$ space ($i \geq 1$, $n \geq 2$).*

Proof. By Lemma 10.3, Theorems 2.3 and 9.1, and [23] (for GSF(i)), the theorem follows. ∎

The α-$3EC$ structure is a 3EC structure with $FRT_{3ec} = FRT(\alpha(n,n))$, $FRT_{2ec} = FRT(\alpha(n,n))$, $UF = \alpha$-UF, and $GSF = \alpha$-GSF, where in the latter structures the number of Finds is replaced by the number of *insert* operations and queries. Then, similarly as for Theorem 4.4, we obtain the following.

THEOREM 10.5. *The $3ec$-problem can be solved in $O(m.\alpha(m,n))$ total time (where m is the number of edge insertions and queries), where the fth query can be performed in $O(\alpha(f,n))$ time. The structure can be initialized in $O(n)$ time and takes $O(n)$ space.*

By using the α-$3EC$ structure where $FRT_{3ec} = \alpha$-FRT and $FRT_{2ec} = \alpha$-FRT instead, the above theorem can be augmented to allow insertions of new nodes in the graph with a time complexity of $O(n + m.\alpha(m,n))$ (cf. section 9).

11. A solution for 2-vertex-connectivity.

We consider the problem of maintaining the 2-vertex-connected components in a graph, and we will present algorithms with a time complexity of $O(n+m.\alpha(m,n))$ for n nodes and m queries and insertions using fractionally rooted trees. Similar to 2-edge-connectivity, we thus present a solution that is different from that given in [32] but whose approach is closer to the approach for maintaining the 3-vertex-connectivity relation in general graphs [24].

11.1. Graph observations.

Let $G = \langle V, E \rangle$ be a graph. We define the graph $2vc(G)$ as follows. For each 2vc-class or quasi class, there is a unique node related to that class called the class node. The vertices of $2vc(G)$ are the nodes of G together with these class nodes. For each node x, there is an edge between x and each class node c such that x is contained in 2vc-class c. (Thus we obtain a collection of trees corresponding to so-called block trees.) Hence $2vc(G)$ is a forest, where each tree in $2vc(G)$ corresponds to a connected component in G. For the insertion of an edge (e, x, y) in G, we have that all the classes of which the class node is on the tree path P between x and y in $2vc(G)$ form one new 2vc-class together (if P exists), while the other 2vc-classes and quasi classes remain unchanged.

We represent $2vc(G)$ by means of a spanning forest $SF(G)$ of G. We augment $SF(G)$ with edge classes on its set of edges. An edge class contains all the edges that connect two vertices that are in some 2vc-class or quasi class. An edge class consisting of a cut edge of G is called a *quasi* edge class, and a *real* edge class otherwise. Hence, a class of edges together with the end nodes of these edges induces a subtree in $SF(G)$, since for two 2-vertex-connected nodes x and y, all nodes on the tree path between x and y are 2-vertex-connected with them too. Also, two nodes x and y are 2-vertex-connected iff x and y are incident with 2 edges of the same real edge class. We use names of edge classes as the names of the corresponding 2vc-classes and quasi classes. Note that if each edge (e, x, y) in $SF(G)$ is replaced by two edges connecting class node C with x and y, where C is the edge class containing (e, x, y), then we obtain $2vc(G)$.

For the insertion of a new edge $(e, x, y) \notin E$ in G, we now have the following. If $c(x) \neq c(y)$, then (e, x, y) connects two connected components, and it thus connects two trees in $SF(G)$. If $\neg Is2vc(x, y) \wedge c(x) = c(y)$, then all edge classes occurring on the tree path between x and y in $SF(G)$ must be joined. Otherwise, we have $Is2vc(x, y) \wedge c(x) = c(y)$, and the insertion of (e, x, y) will not affect the 2vc-relation.

11.2. Algorithms. We use a fractionally rooted tree structure FRT on forest $SF(G)$, denoted by FRT_{2vc}. All quasi edge classes are marked as being quasi. All other classes are not marked. There is a Union-Find structure for connected components denoted by UF_c. The initialization for an empty graph is straightforward. A query $Is2vc(x, y)$ is performed by first performing a call *candidates*; then $false$ is returned if the returned edge-class names are distinct or correspond to a quasi edge class, while *true* and the (common) edge-class name are returned otherwise. For the insertion of a new edge (e, x, y) in G, we distinguish the two relevant cases.

1. $c(x) \neq c(y)$. Then $link((e, x, y))$ is performed, and the two connected components $c(x)$ and $c(y)$ are joined (in UF_c).
2. $\neg Is2vc(x, y) \wedge c(x) = c(y)$. Then a boundary list BL for x and y in $SF(G)$ is obtained by $boundary(x, y)$. If BL contains nodes x and y only, then x and y form a quasi class; then the edge class obtained in the call $Is2vc(x, y)$ is unmarked, reflecting that the edge class is real now. Otherwise, nodes x and y are deleted from BL (their sublists contain one edge only), and $joinclasses(BL)$ is called.

A $2VC(i)$ structure is the above structure where $FRT_{2vc} = FRT(i)$ and where $UF_c = UF(i)$. Then we obtain the following result in a way similar to subsection 4.3.

THEOREM 11.1. *A $2VC(i)$ structure solves the 2vc-problem such that the following holds. The total time that is needed for all essential insertions is $O(n.i.a(i, n))$, where a query and a nonessential insertion can be performed in $O(i)$ time. The structure can be initialized in $O(n)$ time and takes $O(n)$ space ($i \geq 1$, $n \geq 2$).*

Now take α-FRT as FRT_{2vc} for a graph with n nodes, and take α-UF for UF_c. Then we obtain the following result in a way similar to subsection 4, where now Theorem 9.2 is used instead of Theorem 9.1.

THEOREM 11.2. *The 2vc-problem can be solved in $O(m.\alpha(m, n))$ total time (where m is the number of edge insertions and queries), where the fth query can* *be performed in $O(\alpha(f,n))$ time. The structure can be initialized in $O(n)$ time and takes $O(n)$ space.*

The above theorem can be augmented to allow insertion of new nodes in the graph with a time complexity of $O(n + m.\alpha(m,n))$ (cf. section 9).

12. Concluding remarks. We have presented solutions for maintaining the 2-edge and the 3-edge-connected components of graphs under insertion of edges and vertices and for the 2-vertex-connected components. The solutions take $O(n + m.\alpha(m,n))$ time in total and are optimal on pointer machines and cell probe machines. The optimality follows from the $\Omega(n + m.\alpha(m,n))$ lower bound for k-edge/vertex-connectivity ($k \geq 1$) in general graphs [32]. Also, for all practical problem sizes, there is no need to perform transformations of FRT-structures; we recall that $a(2,n) = \log^* n$ and refer to section 9. Therefore, we conjecture that FRT(2), 2EC(2), 3EC(2), and 2VC(2) can be implemented as fast and easy structures in *practical* situations as well, with constant-time queries.

We have also presented linear-time algorithms for maintaining 2-*edge*-connectivity in a connected graph on a RAM. Since there is a nonlinear lower bound of $\Omega(n + m.\alpha(m,n))$ for maintaining 2-*vertex*-connectivity in connected graphs on a RAM [32], this shows an interesting difference in computational complexity between 2-edge-connectivity and 2-vertex-connectivity.

Finally, we remark that the problem of maintaining the 3-vertex-connected components of general graphs can be solved with the optimal complexity of $O(n + m.\alpha(m,n))$ time for m insertions and queries. This generalizes the special-case result in [4] for maintaining the 3-vertex-connectivity relation inside 2-vertex-connected graphs with such a time bound. We refer to [24].

RESTRUCTURING PARTITIONED NORMAL FORM RELATIONS WITHOUT INFORMATION LOSS[*]

MILLIST W. VINCENT[†] AND MARK LEVENE[‡]

Abstract. Nested relations in partitioned normal form (PNF) are an important subclass of nested relations that are useful in many applications. In this paper we address the question of determining when every PNF relation stored under one nested relation scheme can be transformed into another PNF relation stored under a different nested relation scheme without loss of information, referred to as the two schemes being data equivalent. This issue is important in many database application areas such as view processing, schema integration, and schema evolution. The main result of the paper provides two characterizations of data equivalence for nested schemes. The first is that two schemes are data equivalent if and only if the two sets of multivalued dependencies induced by the two corresponding scheme trees are equivalent. The second is that the schemes are equivalent if and only if the corresponding scheme trees can be transformed into the other by a sequence of applications of a local restructuring operator and its inverse.

1. Introduction.

It is widely accepted now that the flat relational model, as defined by [5], needs to be extended or modified to cater to the demands of new application areas such as those involving textual, spatial, or scientific data [4, 17, 22, 25, 27]. One of the most important of these extensions is the *nested relational model*, originally proposed in [14], which removes the 1NF restriction that attributes values to be atomic and instead allows sets and relations as attribute values. Many aspects of nested relational databases have been investigated in the last decade including query languages and algebras, query optimization, normalization, and user interfaces [12, 13, 17, 19, 23, 24, 29]. Several research prototypes of nested databases have been implemented [20, 23, 26] and several major commercial database systems, such as ORACLE System 8 and ILLUSTRA [27], support nested relations.

Several subclasses of nested relations have also been investigated [29] and one subclass that has received considerable attention is the class of *partitioned normal form* (PNF) nested relations [1, 12, 21]. In a PNF relation the set of atomic attributes at every level of the nested relation must be a key. It has been shown that PNF relations possess several desirable properties that nested relations in general do not possess, such as nesting and unnesting operations commuting, which results in the semantics of PNF nested relations and their query languages being more transparent than for general nested relations [18]. It has been suggested that PNF relations are sufficient to model all practical applications of nested relations [7]. The issue that is investigated in this paper is determining when every PNF nested relation stored under one nested relation scheme can be transformed into another PNF nested relation stored under a different nested relation scheme without loss of semantic content, re-

ferred to as the two schemes being *data equivalent*. Determining whether two schemes are data equivalent is an important issue in all data models, not only the nested relational model, and has impact on a variety of areas such as view processing, scheme integration, schema evolution, and schema translation in heterogeneous database systems [9, 10, 15, 16]. In particular, the recent work in [15, 16] has highlighted the importance of data equivalence, and the more general notion of data dominance, in the development of correct techniques for schema integration and schema translation and demonstrated that several existing methodologies were incorrect because of insufficient attention being paid to the issues of data equivalence and data dominance.

The approach to formalizing the notion of data equivalence used in this paper is based on the seminal work in [9, 11]. The essential idea of data equivalence is that two database schemes are data equivalent if there exists a bijection which maps from every instance of one scheme to an instance in the other. If this property is satisfied, then every instance of one scheme can be mapped to an instance in the other scheme and then recovered since the mapping is 1–1. If no restriction is placed on the instance mapping apart from the requirement that it be a bijection, then this notion of data equivalence is referred to as *absolute equivalence*. Several more restrictive notions of data equivalence were also introduce in [9, 11] based on further restricting the instance mapping. In particular, the other types of data equivalence introduced were (in increasing order of restrictiveness) *internal equivalence* (which does not allow the instance mapping "invent" more than a fixed set of constants), *generic equivalence* (which requires that the instance mapping commutes with permutations of the data values which leave the instances unchanged), and *query equivalence* (which requires that the instance mapping be a query in the data model). It has been shown that in the case of the relational model, the different notions of data equivalence are not identical, whereas in the format model introduced in [9, 11], absolute equivalence, internal equivalence, and generic equivalence are identical. In this paper, we will show that all four notions of data equivalence are identical for single nested relational schemes.

The main result of this paper is to provide two characterizations of absolute equivalence for PNF schemes. The first shows that two PNF schemes are absolutely equivalent if and only if the sets of *multivalued dependencies* (MVDs) induced by the corresponding scheme trees are equivalent. This result confirms the importance of considering dependencies in restructuring, an observation that had been previously made but not fully investigated [10]. For the second characterization, we introduce a local restructuring operator for the tree corresponding to a PNF scheme, called COMPRESS, which merges a parent node having a single child node with the child node. We then show that two PNF schemes are absolutely equivalent if and only if one tree can be transformed into the other by a sequence of applications of the COMPRESS operator and its inverse. Finally, we use these results to develop a polynomial time algorithm for testing whether two nested schemes are absolutely equivalent. We also point out that in the characterizing absolute equivalence we explicitly derive a 1–1 mapping between the PNF instances of the schemes expressed as a sequence of unnest and nest operations. The benefit of deriving an instance mapping, and especially one that is expressible as a query, is that the instance mapping can be used in database translation tools to translate any query expressed against one scheme into another query expressed against an equivalent scheme [9, 10, 15, 16]. We also note that the technique we use in proving the main result, using combinatorial methods and the path properties of balanced scheme trees, is a novel one and differs from the techniques used to characterize data equivalence in related data models [1, 2, 11].

The rest of the paper is organized as follows. In section 2 we introduce basic definitions and notations. In section 3 we derive the main result of the paper on characterizing absolute equivalence on nested schemes. In section 4 we discuss related work and section 5 contains concluding comments.

2. Definitions and notation.

We now introduce the definitions and notation to be used in later sections. More complete presentations can be found in standard references such as [3, 18].

2.1. Trees.

A *tree* is a finite, acyclic, directed graph in which there is a unique node, called the *root*, with indegree 0 and every other node has indegree 1. A node n' is a *child* of a node n (or equivalently, n is the *parent* of n') if there is a directed edge from n to n'. A pair of nodes are *siblings* if they are children of the same node. A node is a *leaf* if it has no children. A node n' is recursively defined to be a *descendant* of a node n (or equivalently, n is an *ancestor* of n') if either n' is a child of n, or n has a child n'' such that n' is a descendant of n''. The *height* of a tree T is the number of nodes on the longest path from the root to a leaf node.

A tree T' is a *subtree* of a tree T if the nodes of T' are a subset of those of T and for every pair of nodes n' and n, n' is a child of n in T if and only if n' is a child of n in T'. A subtree T' is a *principal subtree* of T if the root of T' is a child of the root of T. A tree T is *balanced* if every nonleaf node has at least two children.

2.2. Scheme trees and nested relations.

Let U be a fixed countable set of atomic attribute names. Associated with each attribute name $A \in U$ is a countably infinite set of values denoted by $\mathrm{DOM}(A)$ and the set $\mathbf{DOM}$ is defined by $\mathbf{DOM} = \cup\,\mathrm{DOM}(A_i)$ for all $A_i \in U$. We assume that $\mathrm{DOM}(A_i) \cap \mathrm{DOM}(A_j) = \emptyset$ if $i \neq j$. A *scheme tree* is a tree containing at least one node and whose nodes are labeled with nonempty sets of attributes that form a partition of a finite subset of U. If n denotes a node in a scheme tree T, then

$\mathrm{ATT}(n)$ is the set of attributes associated with n;
$\mathrm{ATT}(T)$ is the union of $\mathrm{ATT}(n)$ for all $n \in T$;
$\mathrm{ANC}(n)$ is the set of all ancestor nodes of n, including n;
$\mathrm{A}(n)$ is the union of $\mathrm{ATT}(n')$ for all $n' \in \mathrm{ANC}(n)$;
$\mathrm{DESC}(n)$ is the set of all descendant nodes of n, including n;
$\mathrm{D}(n)$ is the union of $\mathrm{ATT}(n')$ for all $n' \in \mathrm{DESC}(n)$;
$\mathrm{ROOT}(T)$ denotes the root node of T;
$\mathrm{HEIGHT}(T)$ denotes the height of T.

Figure 2.1 illustrates an example scheme tree defined over the set of attributes {STUDENT, MAJOR, CLASS, EXAM, PROJECT}.

If S and T are two scheme trees, then S and T are *isomorphic* if there exists a bijection τ from the nodes of S to those of T such that

(i) for any pair of nodes n' and n in S, n' is a child of n in T if and only if $\tau(n')$ is a child of $\tau(n)$ in S;

(ii) for every node $n \in S$, $\mathrm{ATT}(n) = \mathrm{ATT}(\tau(n))$.

We note that it follows from this definition that if scheme trees S and T are isomorphic, then $\mathrm{ATT}(S) = \mathrm{ATT}(T)$. It also follows that the scheme tree resulting from interchanging in a scheme tree of any pair of subtrees whose roots are siblings is isomorphic to the original tree. If a scheme tree T has leaf nodes $\{n_1, \ldots, n_m\}$, then the *path set* of T, $\mathrm{P}(T)$, is defined by $\mathrm{P}(T) = \{A(n_1), \ldots, A(n_m)\}$. For instance, the

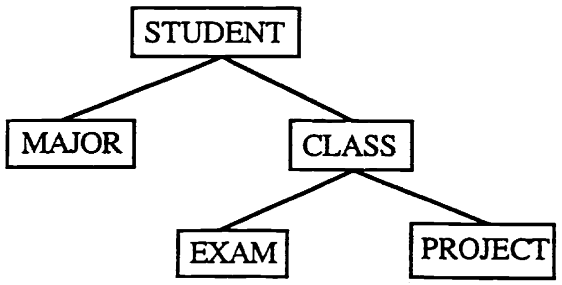

FIG. 2.1. *An example scheme tree.*

path set of the scheme tree in Figure 2.1 is {{STUDENT, MAJOR}, {STUDENT, CLASS, EXAM}, {STUDENT, CLASS, PROJECT}}.

A *nested relation scheme* (NRS) for a scheme tree T, denoted by $\mathrm{N}(T)$, is the set defined recursively by the following:

(i) if T consists of a single node u, then $\mathrm{N}(T) = \mathrm{ATT}(u)$;

(ii) if $A = \mathrm{ATT}(\mathrm{ROOT}(T))$ and $T_1, \ldots, T_k, k \geq 1$, are the principal subtrees of T, then $\mathrm{N}(T) = A \cup \{\mathrm{N}(T_1)\} \cup \cdots \cup \{\mathrm{N}(T_k)\}$.

For example, for the scheme tree T shown in Figure 2.1, $\mathrm{N}(T)$ = {STUDENT, {MAJOR},{CLASS, {EXAM}, {PROJECT}}}.

We now recursively define the domain of a scheme tree T, denoted by $\mathrm{DOM}(\mathrm{N}(T))$, by the following:

(i) if T consists of a single node n with $\mathrm{ATT}(n) = \{A_1, \ldots, A_n\}$, then $\mathrm{DOM}(\mathrm{N}(T)) = \mathrm{DOM}(A_1) \times \cdots \times \mathrm{DOM}(A_n)$;

(ii) if $A = \mathrm{ATT}(\mathrm{ROOT}(T))$ and $T_1, \ldots, T_p$ are the principal subtrees of T, then $\mathrm{DOM}(\mathrm{N}(T) = \mathrm{DOM}(A) \times \mathrm{P}(\mathrm{DOM}(\mathrm{N}(T_1))) \times \cdots \times \mathrm{P}(\mathrm{DOM}(\mathrm{N}(T_p)))$, where $\mathrm{P}(S)$ denotes the set of all *nonempty*, finite subsets of a set S.

We note in the above definition that, in contrast to the VERSO model defined in [1], we do not allow empty sets. A discussion of the effects of this assumption on our results is contained in section 4.

The set of atomic attributes in $\mathrm{N}(T)$, denoted by $\mathrm{Z}(\mathrm{N}(T))$, is defined by $\mathrm{Z}(\mathrm{N}(T)) = \mathrm{N}(T) \cap U$. The set of higher-order attributes in $\mathrm{N}(T)$, denoted by $\mathrm{H}(\mathrm{N}(T))$, is defined by $\mathrm{H}(\mathrm{N}(T)) = \mathrm{N}(T) - \mathrm{Z}(\mathrm{N}(T))$. For instance, for the example shown in Figure 2.1, $\mathrm{Z}(\mathrm{N}(T))$ = {STUDENT} and $\mathrm{H}(\mathrm{N}(T))$ = {{MAJOR}, {CLASS, {EXAM}, {PROJECT}}}. Also, if V is a subset of $\mathrm{N}(T)$ given by $V = \{A_1, \ldots, A_k, \{Y_1\}, \ldots, \{Y_p\}\}$, where $A_1, \ldots, A_k$ are the atomic attributes of V and $\{Y_1\}, \ldots, \{Y_p\}$ are the higher-order attributes, then the atomic attributes in V, denoted by $\mathrm{ATOM}(V)$, are recursively defined by $\mathrm{ATOM}(V) = \{A_1, \ldots, A_k\} \cup \mathrm{ATOM}(Y_1) \cdots \cup \mathrm{ATOM}(Y_p)$.

Finally we define a nested relation over a nested relation scheme $\mathrm{N}(T)$, denoted by $r(\mathrm{N}(T))$, or often simply by r when $\mathrm{N}(T)$ is understood, to be a finite nonempty set of elements from $\mathrm{DOM}(\mathrm{N}(T))$. If t is a tuple in r and Y is a nonempty subset of $\mathrm{N}(T)$, then $t[Y]$ denotes the restriction of t to Y and the restriction of r to Y is then the nested relation defined by $r[Y] = \{t[Y] \mid t \in r\}$. An example of a nested relation over the scheme tree shown in Figure 2.1 is shown in Table 2.1. The active domain of a nested relation r, denoted by $\mathrm{ACT}(r)$, is the subset of **DOM** containing atomic values appearing in r.

2.3. Nested operators. We now define the two restructuring operators for nested relations, nest and unnest [28].

Let Y be a nonempty proper subset of $\mathrm{N}(T)$. Then the operation of *nesting* a relation r on Y, denoted by $\nu_Y(r)$, is defined to be a nested relation over the scheme $(\mathrm{N}(T) - Y) \cup \{Y\}$ and a tuple $t \in \nu_Y(r)$ if and only if (1) there exists $t' \in r$ such that $t[\mathrm{N}(T) - Y] = t'[\mathrm{N}(T) - Y]$ and (2) $t[Y] = \{t''[Y] \mid t'' \in r \text{ and } t''[\mathrm{N}(T) - Y] = t[\mathrm{N}(T) - Y]\}$.

Unnesting is defined as follows. Let $r(\mathrm{N}(T))$ be a relation and $\{Y\}$ an element of $\mathrm{H}(\mathrm{N}(T))$. Then the unnesting of r on $\{Y\}$, denoted by $\mu_{\{Y\}}(r)$, is a relation over the nested scheme $(\mathrm{N}(T) - \{Y\}) \cup Y$ and a tuple $t \in \mu_{\{Y\}}(r)$ if and only if there exists $t' \in r$ such that $t'[\mathrm{N}(T) - \{Y\}] = t[\mathrm{N}(t) - \{Y\}]$ and $t[Y] \in t'[\{Y\}]$.

More generally, one can define the total unnest of a relation, $\mu^*(r)$, as the flat relation defined recursively by the following:

(1) if r is a flat relation, then $\mu^*(r) = r$;

(2) otherwise $\mu^*(r) = \mu^*(\mu_{\{Y\}}(r))$, where $\{Y\}$ is a higher-order attribute in the NRS for r.

It can be shown [28] that the order of unnesting is immaterial and so μ^* is uniquely defined.

2.4. Constraints. We now define dependencies in a nested relation in a similar fashion to the way they are defined in flat relations. If $r(\mathrm{N}(T))$ is a nested relation and Y and Z are subsets of $\mathrm{N}(T)$, then r satisfies the *functional dependency* (FD) $Y \rightarrow Z$ if and only if for all tuples $t, t' \in r$, if $t[Y] = t'[Y]$, then $t[Z] = t'[Z]$. The MVD $Y \rightarrow\rightarrow Z$ is satisfied in r if and only if for all $t, t' \in r$ such that $t[Y] = t'[Y]$ there exists $s \in r$ such that $s[Y] = t[Y]$, $s[Z] = t[Z]$, and $s[\mathrm{N}(T) - Z] = t'[\mathrm{N}(T) - Z]$. Given a set Σ of FDs and MVDs and an FD $Z \rightarrow W$ (or MVD $Z \rightarrow\rightarrow W$), Σ *implies* the FD $Z \rightarrow W$ (or MVD $Z \rightarrow\rightarrow W$) if every relation in $\mathrm{SAT}(\Sigma)$ also satisfies $Z \rightarrow W$ (or $Z \rightarrow\rightarrow W$). The *closure* of a set Σ of a FDs and MVDs, denoted by Σ^+, is the set of FDs and MVDs implied by Σ. Two sets of dependencies, Σ and Ψ, are *equivalent*, written as $\Sigma \equiv \Psi$, if $\Sigma^+ = \Psi^+$. In some places in the rest of the paper we wish to consider only flat relations and we denote by $\mathrm{SAT}(\Sigma)$ the set of all *flat relations* which satisfy a set Σ of FDs and MVDs.

The set of MVDs induced by a scheme tree T is defined as follows [17]. If (n, n') is an edge in T, then the MVD associated with this edge is the MVD $\mathrm{A}(n) \rightarrow\rightarrow \mathrm{D}(n')$ and $\mathrm{MVD}(T)$ is the set of all such MVDs associated with all the edges in T. For example, if T is the scheme tree in Figure 2.1, then $\mathrm{MVD}(T) = \{$STUDENT $\rightarrow\rightarrow$ MAJOR, STUDENT $\rightarrow\rightarrow$ CLASS EXAM PROJECT, STUDENT CLASS $\rightarrow\rightarrow$ EXAM, STUDENT CLASS $\rightarrow\rightarrow$ PROJECT$\}$. A *join dependency* (JD), denoted by $\bowtie [R_1, \ldots, R_p]$, where $R_i \subseteq U$ for $1 \leq i \leq p$, is satisfied in a flat relation r if $r = \pi_{R_1}(r) \bowtie \cdots \bowtie \pi_{R_p}(r)$, where π denotes the projection operator.

The subclass of nested relations we investigate in the paper, PNF relations, was introduced in [21]. If T is a scheme tree and $\mathrm{PNF}(T)$ denotes the set of all PNF nested relations over T, then a relation $r \in \mathrm{PNF}(T)$ if and only if the following conditions hold:

(i) r is a nested relation defined over $\mathrm{N}(T)$;

(ii) $\mathrm{Z}(\mathrm{N}(T))$ is a key for r, i.e., satisfies the FD $\mathrm{Z}(\mathrm{N}(T)) \rightarrow \mathrm{H}(\mathrm{N}(T))$;

(iii) for every $Y \in \mathrm{H}(\mathrm{N}(T))$ and $t \in r, t[Y]$ is in PNF.

3. Absolute equivalence for PNF schemes. In this section we establish the main results of the paper on characterizing absolute equivalence for scheme trees. First, we recall the definition of absolute equivalence between schemes [9].

DEFINITION 3.1. *Let T and S be scheme trees where $\mathrm{ATT}(T) = \mathrm{ATT}(S) = U$ and let $X \subseteq \mathbf{DOM}$. The set $\mathrm{DOM}_X(T)$ is defined by $\mathrm{DOM}_X(T) = \{r \mid r \in \mathrm{PNF}(T)$ and $\mathrm{ACT}(r) \subseteq X\}$. Then T is* absolutely equivalent *to S if there exists a positive integer N such that for all $X \subseteq \mathbf{DOM}$ such that $|X \cap \mathrm{DOM}(A_i)| \geq N$* [1] *for every $A_i \in U$, there exists a bijection from $\mathrm{DOM}_X(T)$ to $\mathrm{DOM}_X(S)$ ($|X|$ denotes the cardinality of a set X).*

A simple consequence of Definition 3.1 is the following alternative characterization [9] of absolute equivalence in terms of domain sizes. This characterization is fundamental to the later results in this paper.

LEMMA 3.2. *Let T and S be scheme trees where $\mathrm{ATT}(T) = \mathrm{ATT}(S)$ and let $X \subseteq \mathbf{DOM}$. Then T and S are absolutely equivalent if and only if there exists a positive integer N such that for all $X \subseteq \mathbf{DOM}$ such that $|X \cap \mathrm{DOM}(A_i)| \geq N$ for every $A_i \in U, |\mathrm{DOM}_X(T)| = |\mathrm{DOM}_X(S)|$.*

We now show that $|\mathrm{DOM}_X(T)|$ can be computed by the following recursively defined integer function.

DEFINITION 3.3. *If T is a scheme tree and $X \subseteq \mathbf{DOM}$, then the integer function $\alpha_X(T)$ is recursively defined as follows:*

(i) *if T consists of a single node with attributes $A_1, \ldots, A_k$, then*

$$\alpha_X(T) = 2^{x_1 \cdots x_k} - 1,$$

where $x_i = |X \cap \mathrm{DOM}(A_i)|, 1 \leq i \leq k$;

(ii) *otherwise if T has a root node n with attributes $A_1, \ldots, A_m$ and nonempty principal subtrees $T_1, \ldots, T_p$, then*

$$\alpha_X(T) = (\alpha_X(T_1) \cdots \alpha_X(T_p) + 1)^{x_1 \cdots x_m} - 1.$$

For example, given the scheme trees S and T shown in Figure 3.1,

$$\alpha_X(T) = 2^{x_1 x_2 x_3} - 1,$$

$$\alpha_X(S) = ((2^{x_2 - 1})(2^{x_3} - 1) + 1)^{x_1} - 1.$$

LEMMA 3.4. *If T is scheme tree and $X \subseteq \mathbf{DOM}$, then $|\mathrm{DOM}_X(T)| = \alpha_X(T)$.*

Proof. Part (i) of Definition 3.3 follows immediately from the fact that for any set with x elements, the number of nonempty subsets is $2^x - 1$. Part (ii) follows

[1]This is done to avoid combinatorial interaction that can occur with small domains [2].

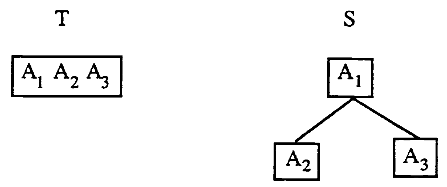

FIG. 3.1. *Example scheme trees.*

from the following combinatorial argument. There are $x_1 \cdots x_m$ distinct values for the set of attributes $A_1 \cdots A$ (we will also refer to this set of attributes as the key for T) and so, by the PNF assumption, any relation in PNF(T) can contain at most $x_1 \cdots x_m$ tuples. To count the number of possible relations, each key value is either not present in a relation or, if it is, it can be associated with $\alpha_X(T_1) \cdots \alpha_X(T_p)$ distinct values for the other attributes. There are thus $\alpha_X(T_1) \cdots \alpha_X(T_p) + 1$ different tuples involving a key value (the $+1$ for the case where the key value is missing from a relation). Then since there are $x_1 \cdots x_m$ possible tuples in a relation, there are $(\alpha_X(T_1) \cdots \alpha_X(T_p) + 1)^{x_1 \cdots x_m} - 1$ possible relations (the -1 is because we do not permit empty sets) [9]. $\square$

A straightforward corollary of the previous Lemma 3.2 is the following which characterizes absolute equivalence using $\alpha_X(T)$.

LEMMA 3.5. *Let T and S be scheme trees where* $\mathrm{ATT}(T) = \mathrm{ATT}(S)$ *and let* $X \subseteq \mathbf{DOM}$. *Then T is absolutely equivalent to S if and only if there exists a positive integer N such that for all* $X \subseteq \mathbf{DOM}$ *such that* $|X \cap \mathrm{DOM}(A_i)| \geq N$ *for every* $A_i \in U, \alpha_X(S) = \alpha_X(T)$.

Another interesting corollary of Lemma 3.4 is the following result which provides a characterization of the number of flat relations which satisfy MVD(T); a result that the reader can verify is not easy to obtain directly.

COROLLARY 3.6. *If* $\mathrm{DOM}_X(\mathrm{MVD}(T)) = \{r \mid r \in \mathrm{SAT}(\mathrm{MVD}(T))$ *and* $\mathrm{ACT}(r) \subseteq X$ *where* $X \subseteq \mathbf{DOM}\}$*, then* $|\mathrm{DOM}_X(\mathrm{MVD}(T))| = \alpha_X(T)$.

Proof. From Lemma 3.18 (see later), there exists a bijection from PNF(T) to SAT(MVD(T)) which preserves active values and so $|\mathrm{DOM}_X(\mathrm{MVD}(T))| = |\mathrm{DOM}_X(T)|$ and the result follows from Lemma 3.4. $\square$

We now introduce a restructuring operator for PNF scheme trees, called COMPRESS.[2] As will be shown shortly, the application of the COMPRESS operator yields a scheme tree which is absolutely equivalent to the original scheme tree. We will also show later, in the main result of the paper, that the COMPRESS operator is complete in the sense that two scheme trees are absolutely equivalent only if one can be transformed into the other by repeated application of the COMPRESS operator and its inverse.

DEFINITION 3.7. *Let T be a scheme tree and n a node in T with a single child node n' having children $n_1, \ldots, n_k$. Then the* COMPRESS *operator results in replacing the subtree with root n by a subtree with root containing* $\mathrm{ATT}(n) \cup \mathrm{ATT}(n')$ *and having children $n_1, \ldots, n_k$.*

The COMPRESS operator is illustrated in Figure 3.2.

Next, we show that the number of PNF instance of a scheme tree is invariant under the COMPRESS operator and so COMPRESS preserves absolute equivalence.

[2]The inverse of COMPRESS is referred to as elementary compaction in [1]

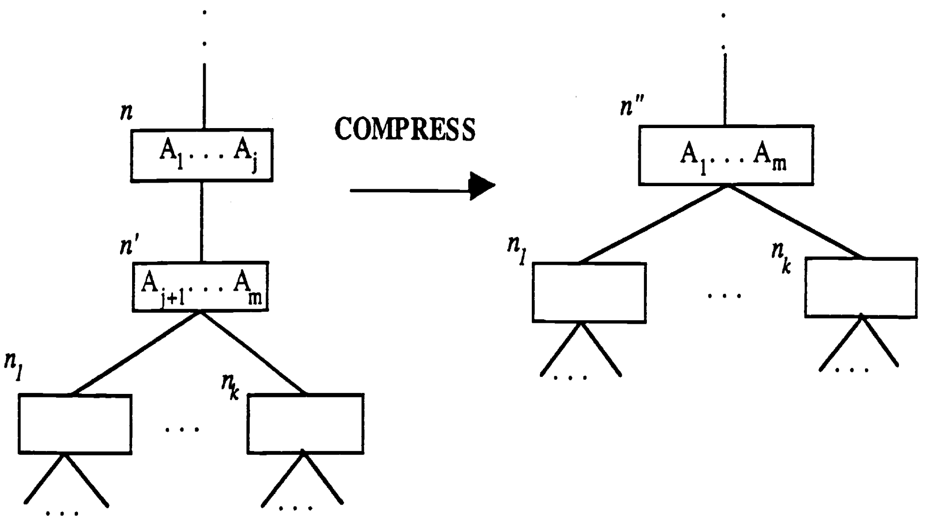

FIG. 3.2. *COMPRESS operator.*

LEMMA 3.8. *If T is a scheme tree, then $\alpha_X(T) = \alpha_X(\mathrm{COMPRESS}(T))$, where* COMPRESS$(T)$ *denotes the scheme tree obtained by applying the COMPRESS operator to an arbitrary node in the tree.*

Proof. From Definition 3.3, it suffices to show that $\alpha_X(T) = \alpha_X(S)$ where, from Figure 3.2, T is the subtree rooted at node n and S is the subtree rooted at node n''. From Definition 3.3 we have

$$\alpha_X(T) = (\alpha_X(T') + 1)^{x_1 \cdots x_j} - 1,$$

where T' is subtree at n'. If n' has no children, then $\alpha_X(T)$ can be written as

$$\begin{aligned}\alpha_X(T) &= (2^{x_{j+1} \cdots x_m} - 1 + 1)^{x_1 \cdots x_j} - 1\\ &= 2^{x_1 \cdots x_m} - 1\\ &= \alpha_X(S).\end{aligned}$$

Alternatively, if n' has children $n_1, \dots, n_k$ and corresponding subtrees $T_1, \dots, T_k$ rooted at these nodes, then $\alpha_X(T)$ can be written as

$$\begin{aligned}&= ((\alpha_X(T_1) \cdots \alpha_X(T_k) + 1)^{x_{j+1} \cdots x_m} - 1 + 1)^{x_1 \cdots x_j} - 1\\ &= (\alpha_X(T_1) \cdots \alpha_X(T_k) + 1)^{x_1 \cdots x_m} - 1\\ &= \alpha_x(S). \qquad \square\end{aligned}$$

It follows from this result that by repeatedly applying the COMPRESS operator to a scheme tree T until no more applications can be applied, a balanced tree is obtained which is absolutely equivalent to the original tree. In the terminology of [11], this tree can be considered as a *normal form tree* for T. We now show the crucial result that for balanced scheme trees, the absolute equivalence property coincides with the trees being isomorphic. It is interesting to note that the property of a scheme tree being balanced is unique to the context of PNF relations, since the property does not arise in the normal form trees developed in related nested data models which do not enforce PNF [2, 11].

THEOREM 3.9. *If S and T are balanced scheme trees such that* $\mathrm{ATT}(S) = \mathrm{ATT}(T)$*, then S and T are absolutely equivalent if and only if S and T are isomorphic.*

The proof of the "only if" part this theorem (the "if" part is trivial) requires several steps in the form of several preliminary lemmas and so we first summarize these steps. We first show that if S and T are not isomorphic, then there exist attributes A and B such that A and B belong to the same path in one scheme tree, say S, but not in T. We then establish lower and upper bounds for $\alpha_X(S)$ and $\alpha_X(T)$ and show that if we construct a domain X where the number of attribute values of any attribute in X, except for those of A and B, is fixed the number of A and B values in X are allowed to be large but identical, then $\alpha_X(S) > \alpha_X(T)$ and so S and T cannot be absolutely equivalent. To establish the first preliminary lemma on the relationship between isomorphisms and path sets in scheme trees, we need the following definitions.

DEFINITION 3.10. *For any pair of attributes A and B in a scheme tree $T, A \sim B$ denotes that there exists an element of* $\mathrm{P}(T)$ *to which they both belong, and $A \not\sim B$ denotes the converse. If S and T are scheme trees such that* $\mathrm{ATT}(S) = \mathrm{ATT}(T)$*, then S and T are defined to be* path equivalent*, denoted by $S \sim T$, if for all $A, B \in$* $\mathrm{ATT}(S)$*, $A \sim B$ in T if and only if $A \sim B$ in S. We denote by $S \not\sim T$ the fact that S and T are not path equivalent.*

For example, in the scheme tree S in Figure 3.1, $A_1 \sim A_2, A_1 \sim A_3$, but $A_2 \not\sim A_3$ and so $S \not\sim T$ since $A_2 \sim A_3$ in T. We now show that for two balanced scheme trees, path equivalence coincides with the trees being isomorphic.

LEMMA 3.11. *If T and S are balanced scheme trees such that* $\mathrm{ATT}(T) = \mathrm{ATT}(S)$*, then S and T are isomorphic if and only if $T \sim S$.*

Proof. If: the proof is by induction on Max $(\mathrm{HEIGHT}(T), (\mathrm{HEIGHT}(S))$. The result clearly holds when Max $(\mathrm{HEIGHT}(T), (\mathrm{HEIGHT}(S)) = 1$, so assume inductively that the result is true for all trees where Max $(\mathrm{HEIGHT}(T), (\mathrm{HEIGHT}(S)) < k, k > 1$, and we shall establish the result is true when Max $(\mathrm{HEIGHT}(T), (\mathrm{HEIGHT}(S)) = k$.

We first prove that the sets of attributes belonging to leaf nodes in S and T are the same. If not, there exists an attribute A which, without loss of generality, is in a leaf node of S but in a nonleaf node n in T. From the balanced assumption, n has at least two children and so there exists an attribute B in one child of n and an attribute C in another and so $B \not\sim C$ in T. This is a contradiction since by assumption $S \sim T$ and so $A \sim B$ and $A \sim C$, but this implies that $B \sim C$ in S since an attribute in a leaf node belongs to at most one element of the path set of a scheme tree.

Next we claim that there is a bijection ρ from the leaf nodes of S to the leaf nodes of T such that $\mathrm{ATT}(n) = \mathrm{ATT}(\rho(n))$ for every leaf node n in S. Otherwise, since the sets of attributes in leaf nodes are the same, there must exist a pair of attributes A and B such that A and B are in the same leaf node in S but in different leaf nodes of T thus contradicting the assumption that $S \sim T$.

Since the sets of leaf attributes are the same in both trees, the sets of attributes in nonleaf nodes are the same and so by the induction hypothesis the scheme trees S' and T' are isomorphic, where S' and T' are the trees obtained by removing the leaf nodes from S and T, respectively. Hence there exists a bijection τ from the nodes of S' to those of T'. Consider the mapping from the nodes of S to those in T defined by $\sigma(n) = \rho(n)$ if n is a leaf node in S and $\tau(n)$ otherwise. It is clear that σ satisfies property (ii) of a scheme tree isomorphism from the induction hypothesis and the property of ρ established above. Also, by the induction hypothesis, σ satisfies the property (i) for any pair of nodes in S' and so to complete the proof it suffices to show that a leaf node n' in S has a parent node n if and only if $\sigma(n')$ has parent node $\sigma(n)$ in T. If this is not the case, then by the induction hypothesis $\sigma(n)$ must be a leaf node in T' such that $\mathrm{ATT}(n) = \mathrm{ATT}(\rho(n))$ and so $A \sim B$ in S for any $A \in \mathrm{ATT}(n)$ and $B \in \mathrm{ATT}(n')$, but $A \not\sim B$ in T which completes the proof of the "if" part.

Only if: This part is immediate from the definition of isomorphism between scheme trees. $\square$

We note that the previous result holds only if the trees are balanced. For example, if S and T are scheme trees such that $\mathrm{N}(S) = \{A, \{B\}\}$ and $\mathrm{N}(T) = \{B, \{A\}\}$, then $T \sim S$ but S and T are not isomorphic. We next introduce two auxiliary functions and show that they are upper and lower bounds for $\alpha_X(T)$.

Definition 3.12. *If T is a scheme tree with* $\mathrm{ATT}(T) = \{A_1, \ldots, A_n\}$ *and* $X \subseteq$ **DOM**, *then the integer function $\beta_X(T)$ is defined by*

$$\beta_X(T) = 2^{p_X(T)},$$

where $p_X(T)$ is defined recursively by

$$p_X(T) = x_1 \cdots x_n \quad \textit{if } T \textit{ consists of a single node};$$

otherwise

$$p_X(T) = x_1 \cdots x_m (p_X(T_1) + \cdots + p_X(T_k) + 1),$$

where $\mathrm{ATT}(\mathrm{ROOT}(T)) = \{A_1, \ldots, A_m\}$, $x_i = |X \cap \mathrm{DOM}(A_i)|$, $1 \leq i \leq n$, *and* $T_1, \ldots, T_k$ *denote the principal subtrees of* T.

For example, for the scheme trees S and T shown in Figure 3.1,

$$\beta_X(T) = 2^{x_1 x_2 x_3} \quad \text{and} \quad \beta_X(S) = 2^{(x_2 + x_3 + 1)x_1}.$$

Definition 3.13. *If T is a scheme tree with* $\mathrm{ATT}(T) = \{A_1, \ldots, A_n\}$ *and* $X \subseteq$ **DOM**, *then the integer function $\delta_X(T)$ is defined by*

$$\delta_X(T) = 2^{q_X(T)}$$

and $q_X(T)$ is defined recursively by

$$q_X(T) = x_1 \cdots x_n - 1 \textit{ if } T \textit{ consists of a single node};$$

otherwise

$$q_X(T) = (x_1 \cdots x_m - 1)(q_X(T_1) + \cdots + q_X(T_k)),$$

where $\mathrm{ATT}(\mathrm{ROOT}(T)) = \{A_1, \ldots, A_m\}$, $x_i = |X \cap \mathrm{DOM}(A_i)|$, $1 \leq i \leq n$, *and* $T_1, \ldots, T_k$ *denote the principal subtrees of* T.

For example, for the scheme trees S and T shown in Figure 3.1,

$$\delta_X(T) = 2^{x_1 x_2 x_3 - 1} \quad \text{and} \quad \delta_X(S) = 2^{(x_2 - 1 + x_3 - 1)(x_1 - 1)}.$$

Lemma 3.14. *If T is a scheme tree where* $\mathrm{ATT}(T) = \{A_1, \ldots, A_n\}$ *and* $|X \cap \mathrm{DOM}(A_i)| > 1$, $1 \leq i \leq n$, *then* $\delta_X(T) < \alpha_X(T) < \beta_X(T)$.

Proof. We shall first show that $\alpha_X(T) < \beta_X(T)$ by induction on HEIGHT(T). The result clearly holds for the case where the height of tree is 1 so assume inductively that it holds for trees of height less than some positive integer p. Then

$$\begin{aligned}
\alpha_X(T) &= (\alpha_X(T_1)\cdots\alpha_X(T_k)+1)^{x_1\cdots x_m} - 1 && \text{by definition}\\
&< (\alpha_X(T_1)\cdots\alpha_X(T_k)+1)^{x_1\cdots x_m} \\
&< (\beta_X(T_1)\cdots\beta_X(T_k)+1)^{x_1\cdots x_m} && \text{by the induction hypothesis}\\
&= (2^{p_X(T_1)+\cdots+p_X(T_k)}+1)^{x_1\cdots x_m} && \text{by definition of } \beta_X(T)\\
&\le (2^{p_X(T_1)+\cdots+p_X(T_k)+1})^{x_1\cdots x_m} && \text{since } 2^a+1 \le 2^{a+1} \text{ for } 0 \le a\\
&= 2^{(p_X(T_1)+\cdots+p_X(T_k)+1)x_1\cdots x_m}\\
&= \beta_X(T).
\end{aligned}$$

We now show $\delta_X(T) < \alpha_X(T)$ again by induction on the HEIGHT(T). First, one can establish by a simple induction argument, which we omit, that $\alpha_X(T) > 1$. In the case that HEIGHT$(T) = 1, \delta_X(T) < \alpha_X(T)$ since $a^b - 1 > a^{b-1}$ when $a > 1$ and $b > 1$. Assume inductively that $\delta_X(T) < \alpha_X(T)$ holds for trees of height less than some positive integer p. Then

$$\begin{aligned}
\alpha_X(T) &= (\alpha_X(T_1)\cdots\alpha_X(T_k)+1)^{x_1\cdots x_m} - 1 && \text{by definition}\\
&> (\alpha_X(T_1)\cdots\alpha_X(T_k))^{x_1\cdots x_m} - 1\\
&> (\alpha_X(T_1)\cdots\alpha_X(T_k))^{x_1\cdots x_m - 1} && \text{since } \alpha_X(T) > 1 \text{ and } a^b - 1\\
& && \quad > a^{b-1} \text{ when } a > 1 \text{ and } b > 1\\
&> (\delta_X(T_1)\cdots\delta_X(T_k))^{x_1\cdots x_m - 1} && \text{by the induction hypothesis}\\
&= (2^{q_X(T_1)+\cdots+q_X(T_k)})^{x_1\cdots x_m - 1} && \text{from the definition of } \delta_X(T)\\
&= 2^{(q_X(T_1)+\cdots+q_X(T_k))(x_1\cdots x_m - 1)}\\
&= \delta_X(T). \qquad \square
\end{aligned}$$

We now use Lemma 3.14 to provide upper and lower bounds for $\alpha_X(T)$. $\square$

LEMMA 3.15. *Let T be a scheme tree,* ATT$(T) = \{A_1, \dots, A_n\}$*, and* $A_i, A_j \in$ ATT(T).

(i) *If $A_i \sim A_j$ in T and if $x_i = x_j = x$ and $x_k > 1$ for all k, $1 \le k \le n$, then* $\alpha_X(T) > 2^{(x-1)^2}$.

(ii) *If $A_i \not\sim A_j$ in T and if $x_i = x_j = x$ and $x_k > 1$ for all $k, 1 \le k \le n$, then there exist expressions C_1 and C_2, independent of x, such that $\alpha_X(T) < 2^{C_1 x + C_2}$.*

Proof. (i) We first note that one can easily see by an inductive argument that $q_X(T) > 1$, where $q_X(T)$ is defined in Definition 3.13. Next we prove by induction on the height of T that $q_X(T) > (x_i - 1)$ for all $i, 1 \le i \le n$. This result clearly holds when HEIGHT$(T) = 1$. Assume inductively then that the result holds for all trees of height up to k and consider the case where the height of T is $k+1$. If A_i is in the root of T, then

$$\begin{aligned}
q_X(T) &= (x_1 \cdots x_i \cdots x_m - 1)(q_X(T_1) + \cdots + q_X(T_k))\\
&> x_i - 1 && \text{since } q_X\text{'s} > 1 \text{ and all the } x\text{'s are} > 1 \text{ by assumption.}
\end{aligned}$$

If instead A_i is in a principal subtree T_p, then

$$\begin{aligned} q_X(T) &= (x_1 \cdots x_m - 1)(q_X(T_1) + \cdots + q_X(T_p) \ldots + q_X(T_k)) \\ &> (x_1 \cdots x_m - 1) q_X(T_p) \\ &> q_X(T_p) \\ &> x_i - 1 \qquad \text{by the induction hypothesis.} \end{aligned}$$

We now complete the proof of (i) by using induction on HEIGHT(T) to show that $p_X(T) > (x-1)^2$ from which (ii) follows using Lemma 3.14. In the case where HEIGHT(T) = 1, then A_i and A_j must both be in ROOT(T), and so

$$\begin{aligned} q_X(T) &= x_1 \cdots x_i \cdots x_j \cdots x_m - 1 \\ &> x^2 - 1 \qquad \text{since all the } x\text{'s are} > 1 \\ &> (x-1)^2 \qquad \text{since } x > 1. \end{aligned}$$

Assume inductively then that the result holds for all trees up to height k, and let T be of height $k+1$. If A_i and A_j are both in ROOT(T), then

$$\begin{aligned} q_X(T) &= (x_1 \cdots x_i \cdots x_j \cdots x_m - 1)(q_X(T_1) + \cdots + q_X(T_k)) \\ &> (x-1)^2 (q_X(T_1) + \cdots + q_X(T_k)) \\ &> (x-1)^2 \qquad \text{since } q_X(T) > 1 \text{ as noted above.} \end{aligned}$$

Alternatively, suppose that A_i is in ROOT(T) and A_j is in a principal subtree T_p. Then

$$\begin{aligned} q_X(T) &= (x_1 \cdots x_i \cdots x_m - 1)(q_X(T_1) + \cdots + q_X(T_p) \cdots + q_X(T_k)) \\ &> (x-1) q_X(T_p) \\ &> (x-1)^2 \qquad \text{since } q_X(T_p) > (x-1). \end{aligned}$$

Alternatively, suppose that A_i and A_j are both in a principal subtree T_p. Then $q_X(T) > q_X(T_p)$ from the definition of $q_X(T)$ and so $q_X(T) > (x-1)^2$ by the induction hypothesis. The other case, where A_i and A_j are in different principal subtrees cannot occur because $A_i \sim A_j$.

To prove (ii), we first note that one can prove, using a similar method to the one used above in proving $q_X(T) > (x_i - 1)$, that $p_X(T) = B_1 x_i + B_2$, where B_1 and B_2 are arithmetic expressions which do not involve x_i. We next show by induction on HEIGHT(T) that $p_X(T) < C_1 x + C_2$ from which (ii) follows using Lemma 3.14. Consider the case where HEIGHT(T) = 2. Then A_i and A_j must be in different children of the root and so, by Definition 3.12, $p_X(T) = D_1(D_2 x + D_3 x + 1)$ where D_1, D_2, and D_3 are arithmetic expressions which do not contain x and so, by simple rearrangement of terms, the induction hypothesis is satisfied. Assume inductively then that the result holds for all trees up to height k and let T be of height $k+1$.

If A_i and A_j belong to different principal subtrees of T, which without loss of generality we denote by T_i and T_j, respectively, then $p_X(T) = C(p_X(T_i) + p_X(T_j) + D)$, where C and D are expressions not containing x, and so the result follows using the above result that both $p_X(T_i)$ and $p_X(T_j)$ are equal to expressions which are linear in x. Alternatively, if A_i and A_j occur in the same principal subtree of T, then the result follows by the inductive hypothesis and rearranging terms in the expression for $p_X(T)$. ◻

Finally, we complete the proof of Theorem 3.9.

Proof of Theorem 3.9. *If*: This part is immediate.

Only if: We prove the contrapositive that if S and T are not isomorphic, then they are not absolutely equivalent. Let $\mathrm{ATT}(T) = \{A_1, \ldots, A_n\}$. If S and T are not isomorphic, then by Lemma 3.11 there exist attributes A_i and A_j such that, without loss of generality, $A_i \sim A_j$ in S but $A_i \not\sim A_j$ in T. So by Lemma 3.15, $\alpha_X(S) > 2^{(x-1)^2}$ and $2^{C_2 x + C_2} > \alpha_X(T)$. It follows by elementary properties of the exponential function that there exists a constant N such that $2^{(x-1)^2} > 2^{C_2 x + C_2}$ for $x > N$ and so $\alpha_X(S) > \alpha_X(T)$ when $x_k > 1$ for all k, $1 \leq k \leq n$, and $x_i = x_j = x$. This contradicts Lemma 3.5 and so S and T cannot be absolutely equivalent. ∎

We note that Theorem 3.9 is not valid if the scheme trees are not balanced. For example, if one takes scheme trees S and T, where $\mathrm{N}(S) = \{A, \{B\}\}$ and $\mathrm{N}(T) = \{A, B\}$, then it follows from Definition 3.3 and Lemma 3.5 that S and T are absolutely equivalent yet they are not isomorphic. It also follows from this theorem that the scheme trees S and T in Figure 3.1 are not absolutely equivalent since they are balanced but not isomorphic.

We now use Theorem 3.9 to show that the (balanced) normal form tree for T, denoted by $\mathrm{B}(T)$, is unique (up to an isomorphism). We write $S \Rightarrow T$ if there exists a sequence of scheme trees $S_1, \ldots, S_n$ such that $S_1 = S, \ldots, S_n = T$ and $S_i = \mathrm{COMPRESS}(S_{i-1}), n \geq i > 1$.

LEMMA 3.16. *If S is a scheme tree and S_1 and S_2 are balanced scheme trees such that $S \Rightarrow S_1$ and $S \Rightarrow S_2$, then S_1 and S_2 are isomorphic.*

Proof. It suffices to show that $\Rightarrow$ is Church–Rosser, i.e.,

(i) every sequence of COMPRESS operation terminates;

(ii) if $S \Rightarrow S_1$ and $S \Rightarrow S_2$, then there is a pair of isomorphic trees T_1 and T_2 such that $S_1 \Rightarrow T_1$ and $S_2 \Rightarrow T_2$.

Since COMPRESS reduces the number of nodes in the scheme tree by 1, (i) follows immediately. For (ii), it follows from (i) that there exist balanced scheme trees T_1 and T_2 such that $S \Rightarrow S_1 \Rightarrow T_1$ and $S \Rightarrow S_2 \Rightarrow T_2$. Applying Lemmas 3.5 and 3.8 shows that T_1 and T_2 are absolutely equivalent and so they are isomorphic by Theorem 3.9. ∎

To complete the preliminaries needed to prove the main result of the paper, we follow the approach of [29] and define a generalized nest operator and then show that it can be used to construct a bijection between PNF instances of two scheme trees whose induced sets of scheme trees are equivalent.

DEFINITION 3.17. *Let T be a scheme tree and s be a flat relation defined over U. Then nesting s according to T, denoted by $\nu^*_T(s)$, is defined by $\nu^*_T(s) = \nu_{X_k} \cdots \nu_{X_0}(s)$ such that*

(i) *for every nonroot node $n \in T$ there exist one and only one X_i such that $\mathrm{N}(T_n) = X_i$, where T_n is the subtree of T with root n;*

(ii) *if node n is a descendent of node n' in T, then the nest operation on the set corresponding to n is performed before the nest operation on the set corresponding to n'.*

For example, given the scheme tree T in Figure 2.1, then one nest sequence to construct $\nu^*_T(s)$ is $\nu_{\mathrm{MAJOR}}\ \nu_{\mathrm{CLASS},\{\mathrm{EXAM}\},\{\mathrm{PROJECT}\}}\ \nu_{\mathrm{EXAM}}\ \nu_{\mathrm{PROJECT}}(r)$. The following properties of $\nu^*_T(s)$ can be easily shown using the results in [28, 29].

LEMMA 3.18. *If s is a flat relation in $\mathrm{SAT}(\mathrm{MVD}(T))$, then*

(i) *$\nu^*_T(s)$ is uniquely defined;*

(ii) *if $r \in \mathrm{PNF}(T)$, then $\nu^*_T(\mu^*(r)) = r$;*

(iii) $\mu^*(\nu_T^*(s)) = s$.

We use this result to show that if MVD(S) and MVD(T) are equivalent, then there exists a bijection from PNF(S) to PNF(T).

LEMMA 3.19. *If S and T are scheme trees where* ATT(T) = ATT(S) *and* MVD(S) $\equiv$ MVD(T)*, then the mapping from* PNF(S) *to* PNF(T) *defined by* $F(r) = \nu_T^*(\mu^*(r))$*,* $r \in$ PNF(S)*, is a bijection.*

Proof. We shall verify that F has each of the properties of a bijection.

(i) *F is total.* If $r \in$ PNF(S), then $\mu^*(r) \in$ SAT(MVD(S)) (Theorem 7.5 in [18]) and so $\mu^*(r) \in$ SAT(MVD(T)) since MVD(S) $\equiv$ MVD(T) and hence $\nu_T^*(\mu^*(r)) \in$ PNF(T) (again by Theorem 7.5 in [18]).

(ii) *F is onto.* Let $r \in$ PNF(T) and consider the relation r_1 where $r_1 = \nu_S^*(\mu^*(r))$. From the same argument as in (i), $r_1 \in$ PNF(S). By Lemma 3.18(iii), $\mu^*(\nu_S^*(\mu^*(r))) = \mu^*(r)$ and so $F(r_1) = \nu_T^*(\mu^*(\nu_S^*(\mu^*(r)))) = \nu_T^*(\mu^*(r))$, and by Lemma 3.18(ii), $\nu_T^*(\mu^*(r)) = r$ and so F is onto.

(iii) *F is* 1–1. Suppose that there are relations r_1 and $r_2 \in$ PNF(S) such that $F(r_1) = F(r_2)$, i.e., $\nu_T^*(\mu^*(r_1)) = \nu_T^*(\mu^*(r_2))$. Then applying μ^* to both sides and using Lemma 3.18(iii) shows that $\mu^*(r_1) = \mu^*(r_2)$ and applying ν_S^* to both sides and using Lemma 3.18(ii) shows that $r_1 = r_2$ and so F is 1–1. □

Combining these preliminary results now leads to the main result of this paper which provides two characterization of absolute equivalence for nested schemes.

THEOREM 3.20. *If T and S are scheme trees where* ATT(S) = ATT(T)*, then the following statements are equivalent:*

(i) *S and T are absolutely equivalent;*

(ii) B(S) *and* B(T) *are isomrphic;*

(iii) MVD(S) $\equiv$ MVD(T).

Proof. We shall show that (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) $\Rightarrow$ (i).

(i) $\Rightarrow$ (ii). From Lemmas 3.5 and 3.8, if S and T are absolutely equivalent, then B(S) and B(T) are absolutely equivalent and so B(S) and B(T) are isomorphic by Theorem 3.9.

(ii) $\Rightarrow$ (iii). It follows directly from the definition of a scheme tree isomorphism that if B(S) and B(T) are isomorphic, then MVD(B(S)) = MVD(B(T)) and so it suffices to show that MVD(T') $\equiv$ MVD(COMPRESS(T')), where COMPRESS(T') denoted the tree obtained by any application of the COMPRESS operator to an arbitrary scheme tree T'. This follows immediately from the observation that P(T') = P(COMPRESS(T')) and the result [18] that MVD(T') $\equiv \bowtie$ [P(T')].

(iii) $\Rightarrow$ (i). This is immediate from Lemma 3.19 and noting that for any $r \in$ PNF(S), ACT(r) = ACT($F(r)$). □

Some observations on this theorem and its consequences are appropriate at this point. We first note that a consequence of the equivalence of (i) and (ii) is that the COMPRESS operator (and its inverse) are complete in the sense that two scheme trees are absolutely equivalent if and only if one tree can be obtained from the other by a sequence of applications of the COMPRESS operator and its inverse. Second, from (i) $\Rightarrow$ (iii) and Lemma 3.19 it follows that absolute equivalence implies query equivalence in the context of the nested query language of [28]. So all the types of data equivalence coincide for nested schemes since it is well known that query equivalence $\Rightarrow$ generic equivalence $\Rightarrow$ internal equivalence $\Rightarrow$ absolute equivalence [10].

The theorem also results in two polynomial time algorithms for testing scheme tree equivalence, one by checking for the equivalence of the sets of MVDs and the other by converting each scheme tree to a balanced tree and then checking if the trees are isomorphic. Using the MVD approach, it follows from the results in [6] that the implication problem of testing whether a set of MVDs Σ implies an MVD $Z \rightarrow\rightarrow W$ can be solved in at worst in $\mathrm{O}(N \log |U|)$ time, where N is the total number of occurrences of attributes in Σ. Testing whether two sets of MVDs are equivalent then reduces to running the membership test for each MVD in both sets and can be solved in at worst in $\mathrm{O}(|\Sigma| N \log |U|)$ time, assuming that $|\Sigma|$ and N are upper bounds for both MVD sets.

The alternative approach can be implemented by first imposing an arbitrary total ordering on U and thereafter sorting first the attributes in each node of the scheme tree and then the children of each node according to the first attribute in a child. This sort can be done in at worst in time $t = \Sigma_i (c_i \log c_i + k_i \log k_i)$ where the sum is taken over all the nodes in the tree and c_i and k_i represent the number of attributes in node i of the tree and the number of children of node i, respectively. Using the properties of the log function we can derive $t = \log(\Pi_i c_i^{c_i} k_i^{k_i})$ and so $t \leq \mathrm{O}(|U| \log |U|)$ because $\Sigma_i c_i = |U|$ and $\Sigma_i k_i \leq |U|$. After sorting the scheme tree, compressing them can be done in at worst in $\mathrm{O}(|U|)$ time since there are at most $|U|$ nodes in the tree. Finally, testing if the trees are isomorphic can be done in at worst $\mathrm{O}(|U|)$ time since each attribute needs to be checked at most once and appears only once in a scheme tree. Hence the total cost of testing for absolute equivalence using this method is at worst $\mathrm{O}(|U| \log |U|)$ time. This compares favorably with the MVD approach when $|U| < |\Sigma|\ N$, which one expects normally to hold. The next lemma summarizes this result.

LEMMA 3.21. *Testing whether two PNF scheme trees are absolutely equivalent can be done in* $\mathrm{O}(|U| \log |U|)$ *time.*

4. Related work.

The concept of absolute equivalence and the investigation of necessary and sufficient conditions for absolute equivalence for a nested-type model, called the format model, was first carried out in [11]. The format model uses three data constructors—collection (which corresponds to set construction), composition (which corresponds to tuple construction), and classification (an alternate construction similar to a variant record construction). A set of local restructuring operators was then defined and proven to be complete for preserving absolute equivalence between formats. The format model is a more general model than the nested model used in this paper in a number of aspects. First, the nested model does not use the classification construction; second, the nested model requires that the collection and composition operators alternate, which is not required in the format model; and last, the nested model requires the PNF condition, whereas the format model does not. As a consequence, while the essential problem addressed in this paper and [11] is the same, the results differ because of the different underlying models. In particular, none of the restructuring operators in [11] is equivalent to our COMPRESS operator and the balanced property of a normal form tree in this paper is not a property of the normal form trees in [11]. The work in [11] was later extended in [2], where the problem of restructuring and data equivalence of the format model was extended to include finite attribute domains. Also, restructuring operators which augment the data capacity of a scheme were introduced. Once again, the results in [2] differ from the results in this paper because of the different model assumptions.

The work in [1] examined data equivalence in the context of the VERSO model. The VERSO model is closer to the one used in this paper than those in [2, 11] but there are still two important differences. First, the VERSO model allows empty sets at all levels in a relation, whereas the model used in this paper, based on [28], does not permit empty sets. Second, the data manipulation language in VERSO differs from that of the nested model used in this paper and, in particular, does not include the nest and unnest operators for restructuring. Instead, the effect of restructuring an instance of a VERSO scheme is defined indirectly via a set of flat relations corresponding to the instance. As a result, the restructuring between two arbitrary VERSO schemes defined over the same set of atomic attributes may not be defined and so the VERSO restructuring operator is less powerful than the unnest and nest operators. For instance, given the scheme trees S and T with $\mathrm{N}(S) = \{A, B, C\}$ and $\mathrm{N}(T) = \{A, \{B\}, \{C\}\}$, then a relation defined over S can be transformed into one over T by two applications of the nest operator but S cannot be transformed into T with the VERSO restructuring [10]. As a result, the notion of data equivalence between two schemes in [1] is restricted to those schemes for which the VERSO restructuring operator is defined. In contrast, we place no restrictions on the nested schemes apart from the obvious requirement of them being defined over the same set of atomic attributes. It is interesting to then compare the results on data equivalence in [1] with ours. Their main result shows that two VERSO schemes are data equivalent if and only if they are identical apart from the trivial restructuring operations of permuting the order of attributes within a node of the scheme tree or permuting the left-to-right ordering of the children of a node. This is a more negative result than ours which allows nontrivial restructuring of the scheme tree using the COMPRESS operator and its inverse. The other difference between the work in [1] and ours is that they consider the issue of data dominance, a more general notion than data equivalence, whereas we have only considered data equivalence.

A different aspect to restructuring PNF relations was investigated in [8]. The motivation for the work was based on the observation that if empty sets are permitted, then restructuring using the nest and unnest operators may result in losing more information than is necessary. A restructuring operator was then defined which maps directly from one nested scheme to another without the use of the nest and unnest operator, using a similar but more general approach to that used in [1], with the aim of minimizing information loss in the restructuring. However, this paper did not address the question of characterizing when the new restructuring operator preserved information content and this was posed as an open problem.

In [12] two restructuring operations were considered in the context of nested relations not necessarily in PNF. The first operation, called *empty node insertion*, allows the insertion of a node with the empty set of attributes between two other nodes in the path of a scheme tree. Empty node insertion preserves absolute equivalence but is not considered herein, since nodes having an empty set of attributes are disallowed. The motivation for allowing such nods in [12] is the restructuring of a forest of scheme trees so that they be joinable. The second operation, called *root weighting*, is a generalization of the COMPRESS operator which allows us to remove a node in the scheme tree and add its attributes to one of its ancestor nodes. As a result of Theorem 3.20 it is easy to verify that any root weighting not corresponding to an application of the COMPRESS operator does not preserve absolute equivalence, resulting in dominance instead.

5. Conclusion.

In this paper we have investigated the problem of when two nested relational schemes are data equivalent and provided two characterizations of data equivalence. The first is that two nested schemes are data equivalent if and only if the sets of MVDs induced by the corresponding scheme trees are equivalent. The second is that two schemes are data equivalent if and only if the corresponding scheme trees can be transformed into each other by a sequence of applications of a tree restructuring operator called COMPRESS (and its inverse). The COMPRESS operator merges a parent and child nodes in a scheme tree if the parent has only one child node. We also used these characterizations to derive two polynomial time algorithms for determining when two nested schemes are data equivalent.

There are several other related topics that also warrant further investigation. Data equivalence can be viewed as a special case of data dominance [8] which holds if there is 1–1 (but not necessarily onto) mapping from the instances of one scheme to the instances of another scheme. Then finding a complete set of restructuring operators for a scheme tree which preserve data dominance is an important question that arises in contexts such as schema integration where one often wants to ensure that the integrated scheme dominates the original schemes. The approach in this paper has also assumed that attribute domains are disjoint and it would be useful to characterize data equivalence and dominance if this assumption is dropped. Another aspect that needs further investigation is to extend the approach in this paper, which has characterized data equivalence for only a single nested scheme, to characterizing absolute equivalence and dominance for nested database schemes.

LINEAR-TIME APPROXIMATION ALGORITHMS FOR COMPUTING NUMERICAL SUMMATION WITH PROVABLY SMALL ERRORS*

MING-YANG KAO† AND JIE WANG‡

Abstract. Given a multiset $X = \{x_1, \ldots, x_n\}$ of real numbers, the *floating-point set summation* problem asks for $S_n = x_1 + \cdots + x_n$. Let E_n^* denote the minimum worst-case error over all possible orderings of evaluating S_n. We prove that if X has both positive and negative numbers, it is NP-hard to compute S_n with the worst-case error equal to E_n^*. We then give the first known polynomial-time approximation algorithm that has a provably small error for arbitrary X. Our algorithm incurs a worst-case error at most $2(\lceil \log(n-1) \rceil + 1)E_n^*$. (All logarithms log in this paper are base 2.) After X is sorted, it runs in $O(n)$ time. For the case where X is either all positive or all negative, we give another approximation algorithm with a worst-case error at most $\lceil \log \log n \rceil E_n^*$. Even for unsorted X, this algorithm runs in $O(n)$ time. Previously, the best linear-time approximation algorithm had a worst-case error at most $\lceil \log n \rceil E_n^*$, while E_n^* was known to be attainable in $O(n \log n)$ time using Huffman coding.

1. Introduction.

Summation of floating-point numbers is ubiquitous in numerical analysis and has been extensively studied (for example, see [2, 4, 5, 6, 7, 8, 10, 11, 12]). This paper focuses on the *floating-point set summation* problem which, given a multiset $X = \{x_1, \ldots, x_n\}$ of real numbers, asks for $S_n = x_1 + x_2 + \cdots + x_n$. Without loss of generality, let $x_i \neq 0$ for all i throughout the paper. Here X may contain both positive and negative numbers. For such a general X, previous studies have discussed heuristic methods and obtained statistical or empirical bounds for their errors. We take a new approach by designing efficient algorithms whose worst-case errors are provably small.

Our error analysis uses the standard model of floating-point arithmetic with unit roundoff $\alpha \ll 1$:

$$\mathrm{fl}(x + y) = (x + y)(1 + \delta_{xy}), \quad \text{where } |\delta_{xy}| \leq \alpha.$$

Since the operator $+$ is applied to two operands at a time, an ordering for adding X corresponds to a binary addition tree of n leaves and $n - 1$ internal nodes, where a leaf is an x_i and an internal node is the sum of its two children. Different orderings yield different addition trees, which may produce different computed sums $\hat{S}_n$ in floating-point arithmetic. We aim to find an optimal ordering that minimizes the

error $E_n = |\hat{S}_n - S_n|$. Let $I_1, \ldots, I_{n-1}$ be the internal nodes of an addition tree T over X. Since α is very small even on a desktop computer, any product of more than one α is negligible in our consideration. Using this approximation,

$$\hat{S}_n \approx S_n + \sum_{i=1}^{n-1} I_i \delta_i.$$

Hence $E_n \approx |\sum_{i=1}^{n-1} I_i \delta_i| \leq \alpha \sum_{i=1}^{n-1} |I_i|$, giving rise to the following definitions.

- The *worst-case error* of T, denoted by $E(T)$, is $\alpha \sum_{i=1}^{n-1} |I_i|$.
- The *cost* of T, denoted by $C(T)$, is $\sum_{i=1}^{n-1} |I_i|$.

Our task is to find a fast algorithm that constructs an addition tree T over X such that $E(T)$ is small. Since $E(T) = \alpha \cdot C(T)$, minimizing $E(T)$ is equivalent to minimizing $C(T)$. We further adopt the following notations.

- E_n^* (respectively, C_n^*) is the minimum worst-case error (respectively, minimum cost) over all orderings of evaluating S_n.
- $T_{\min}$ denotes an optimal addition tree over X, i.e., $E(T_{\min}) = E_n^*$ or, equivalently, $C(T_{\min}) = C_n^*$.

In section 2, we prove that if X contains both positive and negative numbers, it is NP-hard to compute a $T_{\min}$. In light of this result, we design an approximation algorithm in section 3.1 that computes a tree T with $E(T) \leq 2(\lceil \log(n-1) \rceil + 1)E_n^*$. After X is sorted, this algorithm takes only $O(n)$ time. This is the first known polynomial-time approximation algorithm that has a provably small error for arbitrary X. For the case where X is either all positive or all negative, we give another approximation algorithm in section 3.2 that computes a tree T with $E(T) \leq (1 + \lceil \log \log n \rceil)E_n^*$. This algorithm takes only $O(n)$ time even for unsorted X. Previously [5], the best linear-time approximation algorithm had a worst-case error at most $\lceil \log n \rceil E_n^*$, while E_n^* was known to be attainable in $O(n \log n)$ time using Huffman coding [9].

2. Minimizing the worst-case error is NP-hard.

If X contains both positive and negative numbers, we prove that it is NP-hard to find a $T_{\min}$. We first observe the following properties of $T_{\min}$.

LEMMA 2.1. *Let z be an internal node in $T_{\min}$ with children z_1 and z_2, sibling u, and parent r.*

1. *If $z > 0$, $z_1 \geq 0$, and $z_2 > 0$, then $u \geq 0$ or $r < 0$.*
2. *If $z < 0$, $z_1 \leq 0$, and $z_2 < 0$, then $u \leq 0$ or $r > 0$.*

Proof (By symmetry). We prove only the first statement. $C(T_r) = |r| + |z| + C_f$, where $C_f = C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. Assume to the contrary that $u < 0$ and $r \geq 0$. Then $z \geq |u|$. We swap T_{z_1} with T_u. Let $z' = u + z_2$. Now r becomes the parent of z' and z_1. This rearrangement of nodes does not affect the value of node r, and the costs of T_{z_1}, T_{z_2}, and T_u remain unchanged. Let T'_r be the new subtree with root r. Let T' be the entire new tree from the swapping. Since u and z_2 have the opposite signs, $|z'| < \max\{|u|, z_2\} \leq z$. Hence, $C(T'_r) = r + |z'| + C_f < r + z + C_f = C(T_r)$. Thus, $C(T') < C(T_{\min})$, contradicting the optimality of $T_{\min}$. This completes the proof. $\square$

For the purpose of proving that finding a $T_{\min}$ is NP-hard, we restrict all x_i to nonzero integers and consider the following optimization problem.

MINIMUM ADDITION TREE (MAT).

Input: A multiset X of n nonzero integers $x_1, \ldots, x_n$.

Output: Some $T_{\min}$ over X.

The following problem is a decision version of MAT.

ADDITION TREE (AT).

Instance: A multiset X of n nonzero integers $x_1, \dots, x_n$, and an integer $k \geq 0$.

Question: Does there exist an addition tree T over X with $C(T) \leq k$?

LEMMA 2.2. *If* MAT *is solvable in time polynomial in n, then* AT *is also solvable in time polynomial in n.*

Proof. The proof is straightforward. □

In light of Lemma 2.2, to prove that MAT is NP-hard, it suffices to reduce the following NP-complete problem [3] to AT.

3-PARTITION (3PAR).

Instance: A multiset B of $3m$ positive integers $b_1, \dots, b_{3m}$, and a positive integer K such that $K/4 < b_i < K/2$ and $b_1 + \cdots + b_{3m} = mK$.

Question: Can B be partitioned into m disjoint sets $B_1, \dots, B_m$ such that for each B_i, $\sum_{b \in B_i} b = K$? (B_i must therefore contain exactly three elements from B.)

Given an instance (B, K) of 3PAR, let

$$W = 100(5m)^2K; \qquad a_i = b_i + W; \qquad A = \{a_1, \dots, a_{3m}\}; \qquad L = 3W + K.$$

LEMMA 2.3. *(A, L) is an instance of* 3PAR. *Furthermore, it is a positive instance if and only if (B, K) is a positive instance.*

Proof. Since $K/4 < b_i < K/2$, $K/4 + W < a_i < K/2 + W$, and thus $L/4 < a_i < L/2$. Next, $a_1 + a_2 + \cdots + a_{3m} = 3mW + mK = mL$. This completes the proof of the first statement. The second statement follows from the fact that $b_i + b_j + b_k = K$ if and only if $a_i + a_j + a_k = L$. □

Write

$$\epsilon = \frac{1}{400(5m)^2}; \qquad h = \lfloor 4\epsilon L \rfloor; \qquad H = L + h;$$

$$h = \beta_0 H; \quad a_i = \left(\frac{1}{3} + \beta_i\right) H; \quad a_i = \left(\frac{1}{3} + \epsilon_i\right) L; \quad a_M = \max\{a_i : i = 1, \dots, 3m\}.$$

LEMMA 2.4.

1. $|\epsilon_i| < \epsilon$ *for* $i = 1, \dots, 3m$.
2. $0 < \beta_0 < 4\epsilon$, *and* $|\beta_i| < 4\epsilon$ *for* $i = 1, \dots, 3m$.
3. $3a_M < H$.

Proof. Statement 1. Note that $b_i + W = (1/3 + \epsilon_i)(3W + K)$. Thus, $b_i = K/3 + \epsilon_i(300(5m)^2 + 1)K$. Since $K/4 < b_i < K/2$, $-1/12 < \epsilon_i(300(5m)^2 + 1) < 1/6$. Hence $4(5m)^2|\epsilon_i| < 10^{-2}$, i.e., $|\epsilon_i| < \epsilon$.

Statement 2. Since $4\epsilon L > 1$, we have $\beta_0 > 0$. Also, since $H > L$ and $\beta_0 H = \lfloor 4\epsilon L \rfloor$, we have $\beta_0 < 4\epsilon$. Next, for each a_i, we have $\beta_i = (\epsilon_i L - h/3)/(L + h)$. Then by the triangular inequality and Statement 1, $|\beta_i| < 7\epsilon/3 < 4\epsilon$.

Statement 3. By Statement 1, $a_i < (1/3 + \epsilon)L$. Thus $3a_M < L + 3\epsilon L$. Then, since $3\epsilon L < 3K \leq h$, $3a_M < L + h = H$. □

To reduce (A, L) to an instance of AT, we consider a particular multiset

$$X = A \cup \{-H, \dots, -H\} \cup \{h, \dots, h\}$$

with m copies of $-H$ and h each. Given a node s in $T_{\min}$, let T_s denote the subtree rooted at s. For convenience, also let s denote the value of node s. Let $v(T_{\min})$ denote the value of the root of $T_{\min}$, which is always 0. For brevity, we use λ with or without scripts to denote the sum of at most $5m$ numbers in the form of $\pm\beta_i$. Then all nodes are in the form of $(N/3 + \lambda)H$ for some integer N and some λ. Since by Lemma 2.4,

$|\lambda| \le (5m)(4\epsilon) = (500m)^{-1}$, the terms N and λ of each node are uniquely determined. The nodes in the form of λH are called the *type*-0 nodes. Note that $T_{\min}$ has m type-0 leaves, i.e., the m copies of h in X.

LEMMA 2.5. *In $T_{\min}$, type-0 nodes can only be added to type-0 nodes.*

Proof. Assume to the contrary that a type-0 node z_1 is added to a node z_2 in the form of $(\pm N/3 + \lambda)H$ with $N \ge 1$. Then $|z_1 + z_2| \ge (1/3 + \lambda')H$ for some λ'. Let z be the parent of z_1 and z_2. Since $v(T_{\min}) = 0$, z cannot be the root of $T_{\min}$. Let u be the sibling of z. Let r be the parent of z and u. Let t be the root of $T_{\min}$. Let P_r be the path from t to r in $T_{\min}$. Let m_r be the number of nodes on P_r. Since $T_{\min}$ has $5m - 1$ internal nodes, $m_r < 5m - 1$.

We rearrange $T_{\min}$ to obtain a new tree T' as follows. First, we replace T_z with T_{z_2}; i.e., r now has subtrees T_{z_2} and T_u. Let T'' be the remaining tree; i.e., T'' is $T_{\min}$ after removing T_{z_1}. Next, we create T' such that its root has subtrees T_{z_1} and T''. This tree rearrangement eliminates the cost $|z_1 + z_2|$ from T_r but may result in a new cost in the form of λH on each node of P_r. The total of these extra costs, denoted by C_λ, is at most $m_r(5m)(4\epsilon)H < (5m-1)(5m)(4\epsilon)H$. Then, $C(T') = C(T_{\min}) - |z_1 + z_2| + C_\lambda \le C(T_{\min}) - (1/3 + \lambda')H + C_\lambda < C(T_{\min}) + (-1/3 + (5m)^2(4\epsilon))H = C(T_{\min}) + (-1/3 + 10^{-2})H < C(T_{\min})$, contradicting the optimality of $T_{\min}$. This completes the proof. ∎

LEMMA 2.6. *Let z be a node in $T_{\min}$.*

1. *If $z < 0$, then $|z| \le H$.*
2. *If $z > 0$, then $z < H$.*

Proof. Statement 1. Assume that the statement is untrue. Then, since all negative leaves have values $-H$, some negative internal node z has an absolute value greater than H and two negative children z_1 and z_2. Since $v(T_{\min}) = 0$, some z has a positive sibling u. We pick such a z at the lowest possible level of $T_{\min}$. Let r be the parent of z and u. By Lemma 2.1(1), $r > 0$. Then $u > |z| > H$. Since all positive leaves have values less than H, u is an internal node with two children u_1 and u_2. Since $u > 0$, $z < 0$, and $r > 0$, by Lemma 2.1(1), u must have a positive child and a negative child. Without loss of generality, let u_1 be positive and u_2 be negative. Then $u = u_1 - |u_2|$. Since z is at the lowest possible level, $|u_2| \le H$, for otherwise we could find a z at a lower level under u_2. We swap T_z with T_{u_2}. Let T'_r be the new subtree rooted r. Let $u' = u_1 + z$. Since $u_2 + u' = r > 0$ and $u_2 < 0$, we have $u' > 0$. Since $|u_2| \le H < |z|$, we have $u' = u_1 - |z| < u_1 - |u_2| = u$. Let $C_f = C(T_z) + C(T_{u_1}) + C(T_{u_2})$. Then $C(T'_r) = r + u' + C_f < r + u + C_f = C(T_r)$, which contradicts the optimality of $T_{\min}$ because the costs of the internal nodes not mentioned above remain unchanged.

Statement 2. Assume that this statement is false. Then, since all positive leaves have values less than H, some internal node z has a value of at least H as well as two positive children. Since $v(T_{\min}) = 0$, some such z has a negative sibling u. By Statement 1, $|u| \le H$. Hence $z + u \ge 0$, contradicting Lemma 2.1(1). ∎

The following lemma strengthens Lemma 2.6.

LEMMA 2.7.

1. *Let z be a node in $T_{\min}$. If $z > 0$, then z is in the form of λH, $(1/3 + \lambda)H$, or $(2/3 + \lambda)H$.*
2. *Let z be an internal node in $T_{\min}$. If $z < 0$, then z is in the form of λH, $(-1/3 + \lambda)H$, or $(-2/3 + \lambda)H$.*

Proof. Statement 1. By Lemma 2.6, $z < H$. Thus $z = (N/3 + \lambda)H$ with $0 \le N \le 3$. To rule out $N = 3$ by contradiction, assume $z = (1 + \lambda)H$ with $\lambda < 0$. Since by Lemma 2.4 all positive leaves have values less than $(1/3 + 4\epsilon)H$, z is an internal node. By Lemmas 2.5 and 2.6, z has two children $z_1 = (2/3 + \lambda')$ and $z_2 = (1/3 + \lambda'')$. Since $v(T_{\min}) = 0$, z is not the root, and by Lemmas 2.5 and 2.6, z has a negative sibling u. By Lemma 2.6, $|u| \le H$. Let r be the parent of z and u. Then $C(T_r) = |r| + z + C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. We swap T_{z_2} with T_u. Let z' be the parent of z_1 and u. Now r is the parent of z' and u. Let T'_r be the new subtree rooted at r after the swapping. Since r remains the same, $C(T'_r) = |r| + |z'| + C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. If $|u| \ge z_1$, then $|z'| = |u| - z_1 \le H - z_1 = (1/3 - \lambda')H < z_1 < z$; otherwise, $|u| < z_1$ and thus $|z'| = z_1 - |u| < z_1 < z$. In either case, $C(T'_r) < C(T_r)$, contradicting the optimality of $T_{\min}$.

Statement 2. The proof is similar to that of Statement 1. By Lemma 2.6, $z = (-N/3 + \lambda)H$ with $0 \le N \le 3$. To rule out $N = 3$ by contradiction, assume $z = (-1+\lambda)H$ with $\lambda < 0$. By Lemmas 2.5 and 2.6, z has a positive sibling $u < H$ and two children $z_1 = (-2/3 + \lambda')H$ and $z_2 = (-1/3 + \lambda'')H$. Let r be the parent of z and u. Then $C(T_r) = |r| + |z| + C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. We swap T_{z_2} with T_u. Let z' be the parent of z_1 and u. Now r is the parent of z' and u. Let T'_r be the new subtree rooted at r after the swapping. Since r is the same, $C(T'_r) = |r| + |z'| + C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. If $u \ge |z_1|$, then $|z'| = u - |z_1| < (1/3 - \lambda')H < |z|$; otherwise, $u < |z_1|$ and thus $|z'| = |z_1| - u < |z_1| < |z|$. So $C(T'_r) < C(T_r)$, contradicting the optimality of $T_{\min}$. ∎

The following lemma supplements Lemma 2.7(1).

Lemma 2.8. *Let z be a node in $T_{\min}$. If $z = (1/3 + \lambda)H$, then z is a leaf.*

Proof. Assume to the contrary that $z = (1/3 + \lambda)H$ is not a leaf. By Lemmas 2.5 and 2.7, z has two children $z_1 = (2/3 + \lambda_1)H$ and $z_2 = (-1/3 + \lambda_2)H$. By Lemmas 2.5 and 2.7, z_1 has two children $z_3 = (1/3 + \lambda_3)H$ and $z_4 = (1/3 + \lambda_4)H$, contradicting Lemma 2.1(1). ∎

The following lemma strengthens Lemma 2.7(2).

Lemma 2.9. *Let z be an internal node in $T_{\min}$. If $z < 0$, then z can be only in the form of λH or $(-1/3 + \lambda)H$.*

Proof. To prove the lemma by contradiction, by Lemma 2.7, we assume $z = (-2/3 + \lambda)H$. Let z_1 and z_2 be the two children of z. Let u be the sibling of z; by Lemmas 2.5 and 2.7, $u = (2/3 + \lambda')H$ or $(1/3 + \lambda')H$. Let r be the parent of z and u. Then $C(T_r) = |r| + |z| + C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. By Lemmas 2.5 and 2.7, there are two cases based on the values of z_1 and z_2 with the symmetric cases omitted.

Case 1. $z_1 = (-1/3 + \lambda_1)H$ and $z_2 = (-1/3 + \lambda_2)H$. Swap T_u with T_{z_2}. Let z' be the new parent of z_1 and u. Then r is the parent of z' and u. Let T'_r be the new subtree rooted at r. Then $C(T'_r) = |r| + |z'| + C(T_{z_1}) + C(T_{z_2}) + C(T_u)$. Whether $u = (2/3 + \lambda')H$ or $(1/3 + \lambda')H$, we have $|z'| < |z|$ and thus $C(T'_r) < C(T_r)$, which contradicts the optimality of $T_{\min}$.

Case 2. $z_1 = (1/3 + \lambda_1)H$ and $z_2 = -H$. There are two subcases based on u.

Case 2A. $u = (2/3 + \lambda')H$. We swap T_{z_1} with T_u. Let z' be the new parent of z_2 and u. Then $|z'| < |z|$.

Case 2B. $u = (1/3 + \lambda')H$. We swap T_{z_2} with T_u. Let z' be the new parent of z_1 and u. By Lemma 2.8, both z_1 and u are leaves, and thus by Lemma 2.4, $2z_1 + u < H$. Therefore, $|z'| = z_1 + u < H - z_1 = |z|$.

Therefore, in either subcase of Case 2, the swapping results in an addition tree over X with a smaller cost than $T_{\min}$, reaching a contradiction. ∎

Lemma 2.10. *$C(T_{\min}) \ge m(H + h)$. Moreover, $C(T_{\min}) = m(H + h)$ if and only if (A, L) is a positive instance of* 3PAR .

Proof. By Lemmas 2.5, 2.7, 2.8, and 2.9, each $a_i \in A$ can be added only to some $a_j \in A$ or to some $z_1 = (-1/3 + \lambda_1)H$. In turn, z_1 can be only the sum of $-H$ and some $z_2 = (2/3 + \lambda_2)H$. In turn, z_2 is the sum of some a_k and $a_\ell \in A$. Hence in $T_{\min}$, $2m$ leaves in A are added in pairs. The sum of each pair is then added to a leaf node $-H$. This sum is then added to a leaf node in A. This sum is a type-0 node with value $-|\lambda'|H$, which can be added only to another type-0 node. Let $a_{p,1}, a_{p,2}$, and $a_{p,3}$ be the three leaves in A associated with each $-H$ and added together as $((a_{p,1}+a_{p,2})+(-H))+a_{p,3}$ in $T_{\min}$. The cost of such a subtree is $2H-(a_{p,1}+a_{p,2}+a_{p,3})$. There are m such subtrees R_p. Their total cost is $2mH - \sum_{i=1}^{3m} a_i = mH+mh$. Hence $C(T_{\min}) \geq mH + mh$.

If (A, L) is not a positive instance of 3PAR, then for any $T_{\min}$, there is some subtree R_p with $a_{p,1} + a_{p,2} + a_{p,3} \neq L$. Then, the value of the root r_i of R_p is $a_{p,1} + a_{p,2} + a_{p,3} - H \neq -h$. Since r_i is a type-0 node, it can be added only to a type-0 node. No matter how the m root values r_k and the m leaves h are added, some node resulting from adding these $2m$ numbers is nonzero. Hence $C(T_{\min}) > mH + mh$.

If (A, L) is a positive instance of 3PAR, let $\{a_{p,1}, a_{p,2}, a_{p,3}\}$ with $1 \leq p \leq m$ form a 3-set partition of A; i.e., A is the union of these m 3-sets and for each p, $a_{p,1} + a_{p,2} + a_{p,3} = L$. Then each 3-set can be added to one $-H$ and one h as $(((a_{p,1} + a_{p,2}) + (-H)) + a_{p,3}) + h$, resulting in a node of value zero and contributing no extra cost. Hence $C(T_{\min}) = mH + mh$. This completes the proof. ∎

THEOREM 2.11. *It is NP-hard to compute an optimal addition tree over a multiset that contains both positive and negative numbers.*

Proof. By Lemma 2.2, it suffices to construct a reduction f from 3PAR to AT. Let $f(B, K) = (X, mH + mh)$, which is polynomial-time computable. By Lemma 2.10, $(X, mH + mh)$ is a positive instance of AT if and only if (A, L) is a positive instance of 3PAR. Then, by Lemma 2.3, f is a desired reduction. ∎

3. Approximation algorithms.

In light of Theorem 2.11, for X with both positive and negative numbers, no polynomial-time algorithm can find a $T_{\min}$ unless P = NP [3]. This motivates the consideration of approximation algorithms.

3.1. Linear-time approximation for general X.

This section assumes that X contains at least one positive number and one negative number. We give an approximation algorithm whose worst-case error is at most $2(\lceil \log(n-1) \rceil + 1)E_n^*$. If X is sorted, this algorithm takes only $O(n)$ time.

In an addition tree, a leaf is *critical* if its sibling is a leaf with the opposite sign. Note that if two leaves are siblings, then one is critical if and only if the other is critical. Hence an addition tree has an even number of critical leaves.

LEMMA 3.1. *Let T be an addition tree over X. Let $y_1, \ldots, y_{2k}$ be its critical leaves, where y_{2i-1} and y_{2i} are siblings. Let $z_1, \ldots, z_{n-2k}$ be the noncritical leaves. Let $\Pi = \sum_{i=1}^{k} |y_{2i-1} + y_{2i}|$ and $\Delta = \sum_{j=1}^{n-2k} |z_j|$. Then $C(T) \geq (\Pi + \Delta)/2$.*

Proof. Let x be a leaf in T. There are two cases.

Case 1. x is some critical leaf y_{2i-1} or y_{2i}. Let r_i be the parent of y_{2i-1} and y_{2i} in T for $1 \leq i \leq k$. Then $|r_i| = |y_{2i-1} + y_{2i}|$.

Case 2. x is some noncritical leaf z_j. Let w_j be the sibling of z_j in T. Let q_j be the parent of z_j and w_j. There are three subcases.

Case 2A. w_j is also a leaf. Since z_j is noncritical, w_j has the same sign as z_j and is also a noncritical leaf. Thus $|q_j| = |z_j| + |w_j|$.

Case 2B. w_j is an internal node with the same sign as z_j. Then $|q_j| \geq |z_j|$.

Case 2C. w_j is an internal node with the opposite sign to z_j. If $|w_j| \geq |z_j|$, then $|q_j| + |w_j| \geq |z_j|$; if $|w_j| < |z_j|$, then $|q_j| + |w_j| = |z_j|$. So, we always have $|q_j| + |w_j| \geq |z_j|$.

Observe that

$$C(T) \geq \sum_{i=1}^{k} |r_i| + \frac{1}{2}\left(\sum_{z_j \text{ in Case 2A}} |q_j|\right) + \sum_{z_j \text{ in Case 2B}} |q_j| + \sum_{z_j \text{ in Case 2C}} |q_j|;$$

$$C(T) \geq \sum_{z_j \text{ in Case 2C}} |w_j|.$$

Simplifying the sum of these two inequalities based on the case analysis, we have $2C(T) \geq \Pi + \Delta$ as desired. $\square$

In view of Lemma 3.1, we desire to minimize $\Pi + \Delta$ over all possible T. Given $x_t, x_{t'} \in X$ with $t \neq t'$, $(x_t, x_{t'})$ is a *critical pair* if x_t and $x_{t'}$ have the opposite signs. A *critical matching* R of X is a set $\{(x_{t_{2i-1}}, x_{t_{2i}}) : i = 1, \ldots, k\}$ of critical pairs where the indices t_j are all distinct. For simplicity, let $y_j = x_{t_j}$. Let $\Pi = \sum_{i=1}^{k} |y_{2i-1} + y_{2i}|$ and $\Delta = \sum_{z \in X - \{y_1, \ldots, y_{2k}\}} |z|$. If $\Pi + \Delta$ is the minimum over all critical matchings of X, then R is called a *minimum critical matching* of X. Such an R can be computed as follows. Assume that X consists of ℓ positive numbers $a_1 \leq \cdots \leq a_\ell$ and m negative numbers $-b_1 \geq \cdots \geq -b_m$.

Algorithm 1.

```
1. If $\ell = m$, let $R = \{(a_i, -b_i) : i = 1, \ldots, \ell\}$.
2. If $\ell < m$, let $R = \{(a_i, -b_{i+m-\ell}) : i = 1, \ldots, \ell\}$.
3. If $\ell > m$, let $R = \{(a_{i+\ell-m}, -b_i) : i = 1, \ldots, m\}$.
```

Lemma 3.2. *If X is sorted, then Algorithm 1 computes a minimum critical matching R of X in $O(n)$ time.*

Proof. By case analysis, if $a_i \leq a_j$ and $b_{i'} \leq b_{j'}$, then $|a_i - b_{i'}| + |a_j - b_{j'}| \leq |a_i - b_{j'}| + |a_j - b_{i'}|$. Thus if $\ell = m$, then pairing a_i with $-b_i$ returns the minimum $\Pi + \Delta$. For the case $\ell < m$, let ϵ be an infinitesimally small positive number. Let X' be X with additional $m - \ell$ copies of ϵ. Then $\sum_{i=1}^{\ell} |a_i - b_{i+m-\ell}| + \sum_{i=1}^{m-\ell} |\epsilon - b_i| = (\ell - m)\epsilon + \Pi + \Delta$ is the minimum over all possible critical matchings of X'. Thus $\Pi + \Delta$ is the minimum over all possible critical matching of X. The case $\ell > m$ is symmetric to the case $\ell < m$. Since X is sorted, the running time of Algorithm 1 is $O(n)$. $\square$

We now present an approximation algorithm to compute the summation over X.

Algorithm 2.

```
1. Use Algorithm 1 to find a minimum critical matching $R$ of $X$. The numbers
   $x_i$ in the pairs of $R$ are the critical leaves in our addition tree over $X$, and
   those not in the critical pairs are the noncritical leaves.
2. Add each critical pair of $R$ separately.
3. Construct a balanced addition tree over the resulting sums of step 2 and the
   noncritical leaves.
```

Theorem 3.3. *Let T be the addition tree over X constructed by Algorithm 2. If X is sorted, then T can be obtained in $O(n)$ time and $E(T) \leq 2(\lceil \log(n-1) \rceil + 1)E(T_{\min})$.*

Proof. Steps 2 and 3 of Algorithm 2 both take $O(n)$ time. By Lemma 3.2, step 1 also takes $O(n)$ time and thus Algorithm 2 takes $O(n)$ time. As for the error analysis, let T' be the addition tree constructed at step 3. Then $C(T) = C(T') + \Pi$. Let h be the number of levels of T'. Since T' is a balanced tree, $C(T') \leq (h-1)(\Pi + \Delta)$ and thus $C(T) \leq h(\Pi + \Delta)$. By assumption, X has at least two numbers with the opposite signs. So there are at most $n - 1$ numbers to be added pairwise at step 3. Thus $h \leq \lceil \log(n-1) \rceil + 1$. Next, by Lemma 3.1, since R is a minimum critical matching of X, we have $C(T_{\min}) \geq (\Pi + \Delta)/2$. In summary, $E(T) \leq 2(\lceil \log(n-1) \rceil + 1)E(T_{\min})$. ∎

3.2. Improved approximation for single-sign X. This section assumes that all x_i are positive; the symmetric case where all x_i are negative can be handled similarly.

Let T be an addition tree over X. Observe that $C(T) = \sum_{i=1}^{n} x_i d_i$, where d_i is the number of edges on the path from the root to the leaf x_i in T. Hence finding an optimal addition tree over X is equivalent to constructing a Huffman tree to encode n characters with frequencies $x_1, \ldots, x_n$ into binary strings [9].

FACT 3.1. *If X is unsorted (respectively, sorted), then a $T_{\min}$ over X can be constructed in $O(n \log n)$ (respectively, $O(n)$) time.*

Proof. If X is unsorted (respectively, sorted), then a Huffman tree over X can be constructed in $O(n \log n)$ [1] (respectively, $O(n)$ [9]) time. ∎

For the case where X is unsorted, many applications require a faster running time than $O(n \log n)$. Previously, the best $O(n)$-time approximation algorithm used a balanced addition tree and thus had a worst-case error at most $\lceil \log n \rceil E_n^*$. Here we provide an $O(n)$-time approximation algorithm to compute the sum over X with a worst-case error at most $\lceil \log \log n \rceil E_n^*$. More generally, given an integer parameter $t > 0$, we wish to find an addition tree T over X such that $C(T) \leq C(T_{\min}) + t \cdot |S_n|$.

ALGORITHM 3.

```
1. Let $m = \lceil n/2^t \rceil$. Partition $X$ into $m$ disjoint sets $Z_1, \ldots, Z_m$ such that each $Z_i$ has exactly $2^t$ numbers, except possibly $Z_m$, which may have less than $2^t$ numbers.
2. For each $Z_i$, let $z_i = \max\{x : x \in Z_i\}$. Let $M = \{z_i : 1 \leq i \leq m\}$.
3. For each $Z_i$, construct a balanced addition tree $T_i$ over $Z_i$.
4. Construct a Huffman tree $H$ over $M$.
5. Construct the final addition tree $T$ over $X$ from $H$ by replacing $z_i$ with $T_i$.
```

THEOREM 3.4. *Assume that $x_1, \ldots, x_n$ are all positive. For any integer $t > 0$, Algorithm 3 computes an addition tree T over X in $O(n + m \log m)$ time with $C(T) \leq C(T_{\min}) + t|S_n|$, where $m = \lceil n/2^t \rceil$. Since $|S_n| \leq C(T_{\min})$, $E(T) \leq (1+t)E(T_{\min})$.*

Proof. For an addition tree L and a node y in L, the *depth* of y in L, denoted by $d_L(y)$, is the number of edges on the path from the root of L to y. Since H is a Huffman tree over $M \subseteq X$ and every $T_{\min}$ is a Huffman tree over X, there exists some $T_{\min}$ such that for each z_j, its depth in $T_{\min}$ is at least its depth in H. Furthermore, in $T_{\min}$, the depth of each $y \in Z_i$ is at least that of z_i. Therefore,

$$\sum_{i=1}^{m} \sum_{x_j \in Z_i} x_j \cdot d_H(z_i) \leq C(T_{\min}).$$

Also note that for $x_j \in Z_i$, $d_T(x_j) - d_H(z_i) \leq \log 2^t = t$. Hence

$$\begin{aligned} C(T) &= \sum_{x_i \in X} x_i \cdot d_T(x_i) \\ &= \sum_{i=1}^{m} \sum_{x_j \in Z_i} x_j \cdot d_H(z_i) + \sum_{i=1}^{m} \sum_{x_j \in Z_i} x_j \cdot (d_T(x_j) - d_H(z_i)) \\ &\leq C(T_{\min}) + t \sum_{x_i \in X} x_i. \end{aligned}$$

In summary, $C(T) \leq C(T_{\min}) + tS_n$. Since step 4 takes $O(m \log m)$ time and the others take $O(n)$ time, the total running time of Algorithm 3 is as stated. ∎

COROLLARY 3.5. *Assume that $n \geq 4$ and all $x_1, \ldots, x_n$ are positive. Then, setting $t = \lfloor \log((\log n) - 1) \rfloor$, Algorithm 3 finds an addition tree T over X in $O(n)$ time with $E(T) \leq \lceil \log \log n \rceil E(T_{\min})$.*

Proof. The proof follows from Theorem 3.4. ∎

PRECISION-SENSITIVE EUCLIDEAN SHORTEST PATH IN 3-SPACE*

JÜRGEN SELLEN†, JOONSOO CHOI‡, AND CHEE-KENG YAP§

Abstract. This paper introduces the concept of *precision-sensitive algorithms*, analogous to the well-known output-sensitive algorithms. We exploit this idea in studying the complexity of the 3-dimensional *Euclidean shortest path* problem. Specifically, we analyze an incremental approximation approach and show that this approach yields an asymptotic improvement of running time. By using an optimization technique to improve paths on fixed edge sequences, we modify this algorithm to guarantee a relative error of $O(2^{-r})$ in a time polynomial in r and $1/\delta$, where δ denotes the relative difference in path length between the shortest and the second shortest path.

Our result is the best possible in some sense: if we have a *strongly precision-sensitive* algorithm, then we can show that unambiguous SAT (USAT) is in polynomial time, which is widely conjectured to be unlikely.

Finally, we discuss the practicability of this approach. Experimental results are provided.

1. Introduction.

1.1. Precision-sensitivity versus output-sensitivity.

The complexity of geometric algorithms generally falls under one of two distinct computational frameworks. In the *algebraic framework*, the (time) complexity of an algorithm is measured by the number of algebraic operations (such as $+, -, \times, \div, \sqrt{\cdot}$) on real-valued variables, assuming exact computations. In simple cases, the input size has one parameter n corresponding to the number of input values. In the *bit framework*, (time) complexity is measured by the number of bitwise Boolean operations, assuming input values are encoded as binary strings. The input size parameter n above is usually supplemented by an additional parameter L which is an upper bound on the bit-size of any input value; see [6].

Currently, practically every computational geometry algorithm is based on the algebraic model. For instance, we usually say that the planar convex hull problem can be solved in optimal $O(n \log n)$ time. This presumes the algebraic framework. What about the bit framework? One can easily deduce that the bit complexity is $O(n \log n \mu(L))$, where $\mu(L)$ is the bit complexity of multiplying two L-bit integers. However, it is not clear that this is optimal. Thus the possibility for faster planar convex hull algorithms seems wide open in the bit model. Of course, the situation with other problems in computational geometry is similar.

This paper is interested in bit complexity and may be seen as a follow-up to [6]. Besides its inherent interest, there are other reasons for believing that the bit model will become more important for computational geometry in the future. As the field now begins to address implementation issues in earnest, it must focus on low-level operations (what was previously dismissed as "constant time operations"). In low-level operations, it is the bit-size of numbers that is the main determinant of complexity. Second, there are reasons to think that "exact computation" (see [16]) will be an important paradigm for future implementations of geometric algorithms. (The emphasis here is on "implementations" since exact computation is already the de facto standard in theoretical algorithms.) In exact computation, complexity crucially depends on the bit-sizes of input numbers.

The main conceptual contribution in this paper is the idea of *precision-sensitive* algorithms. Today, the concept of *output-sensitive* algorithms has become an important pillar of computational geometry. But output-sensitivity is basically a concept in the algebraic framework. We suggest that precision-sensitivity is the analogous concept in the bit framework. As in output-sensitive algorithms, we may define some implicit parameter $\delta = \delta(I)$ for any input instance I. Instead of measuring the output size, δ now measures the "precision-sensitivity" of I. Intuitively, the parameter δ measures the precision or number of bits needed for output. We seek to design algorithms that can take advantage of this parameter δ. (Our idea is related to recent work in numerical analysis which quantifies the distance from an input instance to the nearest singularity.)

As an example, consider the well-studied 2-dimensional Euclidean shortest path problem. In the algebraic model, the time complexity of this problem was recently shown to be $O(n \log n)$ [8], a significant improvement upon the previous $O(n^2)$ techniques. But little is known about this problem in the bit model. Here, the question reduces to whether we can compare the sums of n square roots of integers in polynomial time. This problem may require exponential time because the difference between two such sums, as far as we know, may be as small as $2^{-2^{Cn}}$ for some $C > 0$. Blömer [3, 4] considers this problem[1] and its extensions. We may let the precision-sensitive parameter δ be the difference in path length between the sought shortest path and the next shortest path. In practical situations, the gap δ is unlikely to be exponentially small. For such inputs, it may be possible to compute the shortest path in time polynomial in n (the number of obstacle vertices), L (the bit length of input numbers) and δ, provided our algorithm is "precision-sensitive."

The introduction of precision-sensitivity paves the way for studying problems that were previously considered hopeless or "solved." Notice that the same situation arises with the introduction of output-sensitivity. To take one example, the hidden surface elimination which is trivially $\Theta(n^2)$ in the usual complexity model (ergo, "uninteresting") becomes very interesting when we consider output-sensitive algorithms. See [1, 2] for some interesting results that exploit output-sensitivity in this problem.

1.2. Precision-sensitive approach to 3ESP. This paper focuses on the 3-dimensional *Euclidean shortest path* (3ESP) problem: given a collection of polyhedral obstacles in $\mathbf{R}^3$, and source and target points $s, t \in \mathbf{R}^3$, construct an obstacle-avoiding polygonal path

$$p_{min} = (s, x_1, \ldots, x_k, t), \tag{1}$$

[1] Interestingly, Blömer and Yap noted that the equality of two sums of square roots can be decided in polynomial time.

$k \geq 0$, from s to t with minimal Euclidean length. Here, the x_i's are called *breakpoints* of the path and are required to lie on edges of the obstacles. This problem is ideal for introducing precision-sensitivity because conventional approaches are doomed to failure due to the problem's NP-hardness, a result of Canny and Reif [5]. It is also useless to introduce output-sensitivity here because the output-size is $O(n)$.

On the other hand, something interesting is going on in the bit model: the algebraic numbers that describe the lengths of the shortest paths may have exponential degrees (see section 2.2). This means that to compare the lengths of two *combinatorially distinct* shortest paths may require exponentially many bits. "Combinatorially distinct" means that the respective paths pass through different sequences of edges, and each is shortest for its edge sequence. In this paper, we use the relative difference between the length d_1 of a shortest path and the length d_2 of the combinatorially distinct next shortest path as our measure of "precision-sensitivity,"

$$\delta = \delta(I) := (d_2 - d_1)/d_1. \tag{2}$$

It should be noted that δ may be 0. One possibility for $\delta = 0$ is when the shortest path passes through a concave corner. Taking δ into account is a crucial step towards a practical 3ESP algorithm.

First we clarify some further aspects of 3ESP. The exponential behavior of 3ESP has two sources: not only is the bit complexity apparently exponential, the number of combinatorially distinct shortest paths can also be exponential. In fact, Canny and Reif's NP-hardness construction exploits the latter property of 3ESP. We can separate the combinatorial aspects from the algebraic aspects as follows. Define the *combinatorial* 3*ESP problem* which, with input as in 3ESP, asks for a *shortest edge sequence*

$$S_{min} = (e_1, \dots, e_k), \tag{3}$$

such that $x_i \in e_i$ for $i = 1, \dots, k$, where the x_i are the breakpoints of some shortest path p_{min} given by (1). Once S_{min} is obtained, there are effective numerical methods to zoom into the actual breakpoints $x_1, \dots, x_k$, as we shall see. Thus the "purely" numerical part of ESP is delegated to a subsequent phase of computation.

How hard is the combinatorial 3ESP problem? Define the implicit parameter $s(I)$ of an input I to 3ESP to be $s = s(I) = |\log(|d_1 - d_2|)|$. We say an algorithm for the combinatorial 3ESP problem is *strongly precision-sensitive* if it is polynomial-time in the parameters n, L, s. By a careful analysis of the Canny–Reif proof, we show the following theorem.

THEOREM 1. *If there exists a strongly precision-sensitive algorithm for the combinatorial* 3*ESP problem, then USAT can be solved in polynomial-time.*

Here *USAT* is the *unambiguous satisfiability problem*, commonly believed not to be in polynomial-time [11, 14]. Note that the parameter $s(I)$ is an absolute measure while our sensitivity parameter $\delta(I)$ is a relative one. But this difference is not crucial. What is more important is the fact that $s(I)$ is roughly logarithmic in $\delta(I)$. In some sense, this theorem justifies our choice of $\delta(I)$.

1.3. Towards a practical algorithm. In hopes of developing a "practical algorithm," Papadimitriou [10] introduces the *approximate* 3*ESP* problem. The input is as in 3ESP plus a new input parameter $\varepsilon > 0$. The problem is to compute an ε-*approximate shortest path*, i.e., one whose length is at most $(1 + \varepsilon)$ times the length of the shortest path. The bit-complexity of this approach is resolved in [6], yielding an algorithm with time

$$T(n, M, W) = O((n^3 M \log M + (nM)^2) \cdot \mu(W)), \tag{4}$$

where $M = O(nL/\epsilon)$, $W = O(\log(n/\epsilon) + L)$ and $\mu(W) = O(W \log W \log\log W)$ is the complexity of multiplying two W-bit numbers. Despite initial hopes, this result is still impractical, even for small examples, because the stated complexity is, roughly speaking, achieved for every input instance. Our goal is to remedy this by introducing precision-sensitivity.

Recall that Papadimitriou's approach is to subdivide each obstacle edge into *segments* in a clever way and, by treating these segments as nodes in a weighted graph, to reduce the problem to finding the shortest path in a graph.

In order to introduce precision-sensitivity, we exploit the alternative scheme introduced in [6] for subdividing edges into segments. The subdivision is parameterized by a choice of $\epsilon > 0$. Our scheme has the property that the $\epsilon/2$-subdivision is a refinement of the ϵ-subdivision and hence we can incrementally reduce the approximation error. The idea is to discard in each refinement step all segments that are provably not used by the shortest path; what remains are called *essential* segments. While it is obvious that such an implementation can drastically decrease running time in practice, we show that, depending on the parameter δ, this improvement is also asymptotical.

Assuming *nondegeneracy* (see section 2.1) of S_{min} in (3), we prove the following theorem.

THEOREM 2. *There is an incremental algorithm to compute an ε-approximate shortest path in time that is polynomial in $1/\delta$ and $1/\varepsilon$. Omitting logarithmic factors, the dependency on $1/\varepsilon$ is only linear rather than quadratic.*

In case the shortest path sequence S_{min} is unique (i.e., $\delta > 0$), we can use techniques from mathematical optimization as soon as we have reached a refinement in which only S_{min} is left. The convergence depends on the spectral bounds μ, ρ corresponding to the minimum and maximum (respectively) eigenvalue of the Hessian H of the path length function $l(\lambda_1, \dots, \lambda_k)$, where $\lambda_1, \dots, \lambda_k \in \mathbf{R}$ parameterize the points $x_1, \dots, x_k$ on S_{min}.

THEOREM 3. *The length of the shortest path can be approximated to relative error ε in time polynomial in $1/\delta, \log(1/\varepsilon), n, L$ and the spectral bounds μ, ρ.*

This theorem and the remark in Theorem 2 about a linear dependency on $1/\varepsilon$ are of practical significance.

It is important to note that the given running times in Theorems 2 and 3 are upper bounds, they are tight only for $\varepsilon \le \delta$. For $\varepsilon > \delta$, and in particular for $\delta = 0$, the running time of both algorithms can be bounded by the running time of the nonincremental approach in [6].

In section 5 we shall provide some experimental results, addressing the practicability of the incremental technique.

2. Preliminaries.

Throughout the paper, we assume that the input is given by a source point s, a target point t, and a set of pairwise disjoint polyhedral obstacles, with a total of less than n edges. For each obstacle edge e, denote its endpoints by $s(e)$, $t(e)$ and write $e = \overline{s(e)t(e)}$. Let $[e]$ denote the infinite line through e. We assume that s, t as well as endpoints of edges are specified by L-bit rational numbers. For any point $q \in \mathbf{R}^3$, $\|q\|$ denotes its Euclidean norm. The scalar product of two k-tuples x, y is denoted $\langle x, y \rangle$.

2.1. Basic properties. We assume the notation in the preceding introduction. In particular, p_{min} is a *global shortest path* from s to t in the free space FS defined by the obstacles. Here, FS is defined as the closure of the complement of the union of the obstacles.

First we fix an *edge sequence* $S = (s, e_1, \dots, e_k, t)$. The sequence S is *degenerate* if $s \in [e_1]$, $t \in [e_k]$, or $[e_j] = [e_{j+1}]$ for some $j \in \{1, \dots, k-1\}$. Note that nondegeneracy of S excludes two edges e_i and e_j from lying in a common line $[e_i] = [e_j]$ only when $|i - j| = 1$, but not if $|i - j| > 1$.

A path

$$p = (s, x_1, \dots, x_k, t)$$

is called an *S-path* if $x_i \in [e_i]$ for all i. An S-path p is *admissible* if $x_i \in e_i$ for all i.

A breakpoint x_i of p that lies on the line between its neighboring vertices, $x_i \in \overline{x_{i-1}x_{i+1}}$, is called *redundant*. Without loss of generality we may assume that p_{min} in (1) contains no redundant vertices.

We will parameterize points $x_i \in [e_i]$ by a scalar λ_i according to the equation

$$x_i = s(e_i) + \lambda_i u(e_i), \text{ with } u(e_i) = \frac{t(e_i) - s(e_i)}{\|t(e_i) - s(e_i)\|}.$$

Let $x_0 = s$ and $x_{k+1} = t$. Then the polygonal path $p = (s, x_1, \dots, x_k, t)$ over S has length

$$l_S(\lambda_1, \dots, \lambda_k) = \sum_{i=0}^{k} \|x_{i+1} - x_i\|.$$

We also write $|p|$ for $l_S(\lambda_1, \dots, \lambda_k)$. Let $p_{min}(S)$ be defined to be the path p over S that minimizes the function $l_S(\lambda_1, \dots, \lambda_k)$, *without consideration of the obstacles and without requiring admissibility.*

A necessary condition for $l_S : \mathbf{R}^k \to \mathbf{R}$ to take its global minimum at $\lambda = (\lambda_1, \dots, \lambda_k)$ is that all partial derivatives vanish at λ. This condition can be interpreted as *Snell's law*, and, as the next lemma will reveal, is also a sufficient condition to specify shortest paths.

LEMMA 1. *The function $l_S : \mathbf{R}^k \to \mathbf{R}$ is convex. If the shortest path over the lines $[e_i]$ has no redundant breakpoints, then l_S has a unique minimizer $\zeta \in \mathbf{R}^k$.*

Proof. (1) Let $l = l_S = \sum_{i=0}^{k} l_i$, where

$$l_i(\lambda_1, \dots, \lambda_k) := ||x_{i+1} - x_i||.$$

We may interpret l_i as a function in two variables λ_i and λ_{i+1} (unless $i = 0$ or k, in which case l_i depends on a single variable λ_1 or λ_k).

To show that l is convex, it suffices to show that each of the l_i is convex (the sum of convex functions is convex). The convexity of l_i is a special case of a general result in convex analysis: for any norm $||.|| : \mathbf{R}^k \to \mathbf{R}$ and any linear function $f : \mathbf{R}^m \to \mathbf{R}^k$, the function $||f|| : \mathbf{R}^m \to \mathbf{R}$ is convex (see, e.g., [12]).

(2) The convexity of l guarantees that every local minimum of l is a global minimum, say, d_S, and that the set of points $\lambda \in \mathbf{R}^k$ satisfying $l(\lambda) = d_S$ (the set of minimizers) is convex.

Assume that there are two distinct minimizers $\zeta_1, \zeta_2 \in \mathbf{R}^k$. Then every $\mu(t) = (\mu_1(t), \ldots, \mu_k(t)) := \zeta_1 + t(\zeta_2 - \zeta_1)$, $t \in [0,1]$, is a minimizer, and hence $l(\mu(t)) \equiv$ const. But

$$l(\mu(t)) = \sum_{i=0}^{k} l_i(\mu(t)),$$

where

$$l_i(\mu(t)) = \sqrt{A_i(t - B_i)^2 + C_i}$$

with $A_i \geq 0$ and $C_i \geq 0$. This can be constant only if each of the functions $l_i(\mu(t))$ is linear in t, i.e., $A_i = 0$ or $C_i = 0$ (this directly follows from $\partial^2 l(\mu(t))/\partial t^2 \equiv 0$).

Now let j be the first index for which $\mu_i(t)$ is not constant, i.e., $\mu_i(t) \equiv$ const $\forall\, i = 1, \ldots, j-1$ and $\mu_j(t) \not\equiv$ const (j may be equal to 1).

The fact that $l_j(\mu(t))$ is linear then implies that $x_{j-1} \in [e_j]$: the point $x_j(t) := s(e_j) + \mu_j(t) u(e_j)$ is moving on the line $[e_j]$ while keeping distance $l_j(\mu(t))$ to the fixed point $x_{j-1} = s(e_{j-1}) + \mu_{j-1}(t) u(e_{j-1})$.

Thus x_{j-1} and $x_j(t)$ lie on the same line $[e_j]$ for all $t \in [0,1]$. From Snell's law it follows that also $x_{j+1}(t)$ must lie on this line, showing that the vertex $x_j(t)$ is redundant. $\square$

Note that, in contrast to this proof, the known proof for the uniqueness of the shortest path [13] (see also [16, appendix]) uses geometrical arguments.

LEMMA 2. *Let $S = (s, e_1, \ldots, e_k, t)$ be nondegenerate.*

(i) *If $[e_i] \cap [e_{i+1}] = \emptyset$ $\forall i$, then the Hessian $H = H(\lambda)$ of $l_S = l_S(\lambda)$ is positive-definite.*

(ii) *If a path $p = (s, x_1, \ldots, x_k, t)$ is such that*

$$x_i \notin [e_{i-1}] \cup [e_{i+1}], \quad i = 1, \ldots, k,$$

then $H(\lambda)$ is locally positive-definite at p.

Proof. The Hessian $H = H(\lambda)$ of $l = l_S$ is a tridiagonal $k \times k$-matrix

$$H = \begin{pmatrix} a_1 & b_1 & & & \\ b_1 & a_2 & b_2 & & \\ & b_2 & \ddots & & \\ & & & & b_{k-1} \\ & & & b_{k-1} & a_k \end{pmatrix}.$$

Let H_i be the Hessian of the function $l_i = ||x_{i+1} - x_i||$, interpreted as function over λ_i and λ_{i+1} if $1 \leq i \leq k-1$, and over λ_1 (resp., λ_k) if $i = 0$ (resp., $i = k$):

$$H_0 = (a_1^-), \quad H_i = \begin{pmatrix} a_i^+ & b_i \\ b_i & a_{i+1}^- \end{pmatrix}, \quad H_k = (a_k^+),$$

with

$$a_i^+ = \frac{\partial^2 l_i}{\partial \lambda_i^2}\ , \ a_{i+1}^- = \frac{\partial^2 l_i}{\partial \lambda_{i+1}^2}\ , \ b_i = \frac{\partial^2 l_i}{\partial \lambda_i \partial \lambda_{i+1}}.$$

Then H and the H_i are related by $a_i = a_i^- + a_i^+$. Abusing the notation, we may write $H = H_0 + \cdots + H_k$.

To prove that H is positive-definite, it remains to show that the determinant of H is not zero. Write

$$H = \left(\begin{array}{c|c} a_1 & b_1 \quad\quad \\ \hline b_1 & \\ & H' \\ & \end{array}\right), \quad H^+ = \left(\begin{array}{c|c} a_1^+ & b_1 \quad\quad \\ \hline b_1 & \\ & H' \\ & \end{array}\right),$$

where H' is the matrix obtained by deleting the first row and first column of H. Then

$$\det(H) = \det(H^+) + a_1^- \det(H').$$

As all H_i are positive-semidefinite, it follows $H^+ = H_1 + \cdots + H_k$ is positive-semidefinite, and thus $\det(H^+) \geq 0$.
This implies

$$\det(H) \geq a_1^- \det(H').$$

Continuing recursively, we finally get

$$\det(H) \geq a_1^- \cdot \cdots \cdot a_k^-.$$

Abbreviating

$$v_i = \frac{x_{i+1} - x_i}{||x_{i+1} - x_i||},$$

we have

$$a_i^- = \frac{1 - \langle v_{i-1}, u(e_i)\rangle^2}{||x_i - x_{i-1}||}.$$

This is strictly positive under conditions (i) or (ii) in the statement of the lemma. Hence $\det(H) > 0$. ◻

2.2. Bit complexity. The goal of this section is to provide some background on the algebraic complexity of 3ESP.

First, we specify shortest paths over edge sequences algebraically. Let $S = (s, e_1, \ldots, e_k, t)$ be a fixed edge sequence.

For given intervals $I_i \in \{ \{0\}, \{|e_i|\}, [0, |e_i|] \}$, we define a Boolean formula (in the free variables $\lambda_1, \ldots, \lambda_k$)

$$B_S(I_1, \ldots, I_k) : \quad \bigwedge_{i=1}^{k} (\mathit{Essential}_i \ \wedge \ \mathit{Optimal}_i)$$

with the predicate

$$\mathit{Essential}_i \Leftrightarrow \left\langle \frac{x_{i+1} - x_i}{\|x_{i+1} - x_i\|}, \frac{x_i - x_{i-1}}{\|x_i - x_{i-1}\|} \right\rangle^2 \neq 1,$$

specifying that x_i is nonredundant, and the predicate

$$\mathit{Optimal}_i \Leftrightarrow \begin{cases} \mathit{Snell}(e_i), & I_i = [0, |e_i|] \\ \lambda_i = 0, & I_i = \{0\} \\ \lambda_i = |e_i|, & I_i = \{|e_i|\}, \end{cases}$$

specifying that — according to I_i — the point x_i is fixed at an endpoint of e_i or obeys Snell's law *Snell*(e_i) at some point in the relative interior of e_i (so I_i only serves as a "flag").

It is obvious that the predicates *Essential*$_i$ and *Optimal*$_i$ can be written as a Boolean combination of a constant number of polynomial inequalities of bounded degree over the variables $\lambda_{i-1}, \lambda_i, \lambda_{i+1}$ and a constant number of "additional variables." (Note that roots $\sqrt{r}$ can be eliminated by introducing a new variable a, substituting $\sqrt{r}$ by a and adding $(a^2 = r \ \wedge \ a \geq 0)$ to the formula. The variable a may be introduced by the quantifier $\exists$.)

As a corollary of Lemma 1, we get the following lemma.

LEMMA 3. *For any fixed edge sequence S and intervals $I_1, \ldots, I_k$, the formula $B_S(I_1, \ldots, I_k)$ is satisfied by at most one algebraic point $\lambda = (\lambda_1, \ldots, \lambda_k)$. If $p_{min}(S)$ is a shortest path over S with nonredundant vertices $x_i = s(e_i) + \lambda_i u(e_i)$, then there exist intervals $I_1, \ldots, I_k$ such that λ satisfies $B_S(I_1, \ldots, I_k)$.*

In particular, there exists a sequence $S = (s, e_1, \ldots, e_k, t)$ and there exist intervals $I_1, \ldots, I_k$ such that the shortest path p_{min} is parameterized by the single solution λ of $B_S(I_1, \ldots, I_k)$.

To derive some upper bounds on the bit complexity of the 3ESP problem, we shall use several results on quantifier elimination and root separation (see, e.g., [9]):

- *Quantifier elimination*: Given a Tarski formula with free variable y
$$\text{(P)} \quad \exists x \in \mathbf{R}^n : \bigvee_i \bigwedge_j p_{ij}(x, y) \Delta_{ij} 0$$
with $\leq m$ polynomials $p_{ij}(x, y)$ each of degree $\leq d$, with integer coefficients of bit-size $\leq L$, and $\Delta_{ij} \in \{>, \geq, =\}$, then there exists an equivalent predicate
$$\text{(P}'\text{)} \quad \bigvee_i \bigwedge_j h_{ij}(y) \Delta'_{ij} 0$$
with $(md)^{O(n)}$ polynomials h_{ij} of degree $(md)^{O(n)}$ and coefficients of bit-size $L(md)^{O(n)}$. ("Equivalent" means that (P) is true for a fixed $y = c$ if and only if (P$'$) is true for $y = c$.) The predicate (P$'$) can be constructed in time polynomial in L and $(md)^{O(n)}$.
- *Cauchy's bound*: Given any univariate polynomial $A(y) = \sum_{i=0}^{d} a_i y^i$ with integer coefficients a_i of bit-size $\leq L$, every root $\alpha \neq 0$ of A satisfies $|\alpha| \geq 2^{-2L}$.
- *Root separation*: If α and β are two distinct roots of $A(y)$, then $|\alpha - \beta| \geq (d2^L)^{-Cd}$ (for some $C > 0$ that does not depend on A). Isolating intervals for all roots of $A(y)$ can be computed in time polynomial in L and d.

Let us consider the formula $B_S(I_1, \ldots, I_k)$ from Lemma 3. With the above results we immediately get the following lemma.

LEMMA 4. *Every coordinate λ_i of a parameter tuple λ satisfying $B_S(I_1, \ldots, I_k)$ has a defining polynomial h_{λ_i} of degree $n^{O(n)}$ with integer coefficients of bit-size $Ln^{O(n)}$. The polynomial h_{λ_i} together with an isolating interval for λ_i can be computed in time polynomial in L and $n^{O(n)}$.*

Proof. Consider the formula
$$\text{(P1)} \quad \exists \lambda_1 \ldots \exists \lambda_{i-1} \exists \lambda_{i+1} \ldots \exists \lambda_k : \ B_S(I_1, \ldots, I_k).$$

The formula (P1) contains $O(n)$ polynomials in $O(n)$ variables of bounded degree with rational (resp., integer) coefficients of size $O(L)$. The stated quantifier elimination result provides $n^{O(n)}$ polynomials h_{ij} of degree $n^{O(n)}$, with integer coefficients of bit-size $Ln^{O(n)}$.

If there is a tuple λ satisfying (P1), then λ_i will be a root of one of the polynomials h_{ij} (recall that λ is unique).

Now consider the product

$$h := \prod_{i,j} h_{ij}.$$

Using root separation, we compute isolating intervals for each of the $n^{O(n)}$ roots of h. For each root, we can check if it satisfies (P1).

Clearly, the whole computation can be done in time polynomial in L and $n^{O(n)}$. ▯

To determine which choice of intervals $I_1, \dots, I_k$ specifies the shortest path over a given sequence S and to determine the shortest path p_{min} we need to compute and compare shortest path lengths.

Lemma 5. *Let λ and λ' be solutions of $B_S(I_1, \dots, I_k)$ and $B_{S'}(I'_1, \dots, I'_{k'})$, respectively, and let p and p' be the corresponding paths. Then $|p| = |p'|$ or*

$$|(|p| - |p'|)| \geq 2^{-Ln^{Cn}}$$

(for a global constant $C > 0$).

Proof. The difference in path length between p and p' is the unique solution y of

$$\text{(P2)} \quad \begin{aligned} &\exists \lambda_1 \dots \lambda_k \exists \lambda'_1 \dots \lambda'_{k'} : \\ &y = \sum_{i=0}^{k} ||x_{i+1} - x_i|| - \sum_{i=0}^{k'} ||x'_{i+1} - x'_i|| \\ &\wedge\ B_S(I_1, \dots, I_k)\ \wedge\ B_{S'}(I'_1, \dots, I'_{k'}) \end{aligned}$$

The formula (P2) can again be written as a Tarski formula. Analogous to Lemma 4, one can use quantifier elimination to obtain a polynomial h with $h(y) = 0$. The coefficients of h are of bit-size $Ln^{O(n)}$. The claim follows immediately from Cauchy's bound. ▯

In order to actually compute the shortest path p_{min}, we have to filter out those shortest paths, or solutions to $B_S(I_1, \dots, I_k)$, which would collide with obstacles. Having calculated the parameter λ satisfying $B_S(I_1, \dots, I_k)$, this amounts to answering the query "$\overline{x_i x_{i+1}} \in FS$?", for $i = 0, \dots, k$. But this query can be expressed as a Tarski sentence in a fixed number of variables and can be decided in time polynomial in L and $n^{O(n)}$. We finally obtain the following theorem.

Theorem 4. *It is possible to compute algebraic representations of all combinatorially distinct shortest paths in time polynomial in L and $n^{O(n)}$.*

In this theorem, we may assume that each shortest path is represented by a sequence $(S, I_1, \dots, I_k, \lambda_1, \dots, \lambda_k)$, where $S = (s, e_1, \dots, e_k, t)$ is an edge sequence, the I_j's are interval flags for S, and the λ_j satisfy the formula $B_S(I_1, \dots, I_k)$. Furthermore, each λ_j is represented by one of its isolated interval representations.

3. Combinatorial 3ESP is as hard as USAT. Recall that the exponential complexity of the 3ESP problem has a combinatorial and an algebraic source. We give evidence that 3ESP remains intractable even after eliminating the algebraic source of complexity.

We briefly review the Canny–Reif construction (see [5, section 2.5]): Given a 3SAT formula f in conjunctive form with m clauses and n variables $b_1, \dots, b_n$, it is possible to construct an environment $E(f)$ such that the following holds for a fixed "reference length" $l = 2^{3n}$ and $\Delta = 2^{-nm-3n-4}$: To each instantiation of $(b_1, \dots, b_n)$ there corresponds an edge sequence $S = S(b_1, \dots, b_n)$ such that the shortest path p over S lies in free space and satisfies

$$|p| \in \begin{cases} [l, l+\Delta] & \text{if } f(b_1, \dots, b_n) = 1, \\ [l+2\Delta, \infty) & \text{if } f(b_1, \dots, b_n) = 0. \end{cases}$$

The number of edges of $E(f)$ as well as the maximal bit-size of coordinates is polynomial in n and m. Deciding the satisfiability of f is reduced to deciding if the shortest path in $E(f)$ has length $\le l + \Delta$.

A careful analysis shows the following property of $E(f)$: if the formula f is uniquely satisfiable, i.e., by exactly one instantiation of $(b_1, \dots, b_n)$, then the shortest path in $E(f)$ is unique and the gap in length between this path and any path that passes over a different edge sequence is single-exponential (i.e., $> c^{-nm}$ for some $c > 1$).

The argument is as follows: The basic construction elements in [5] are parallel, 2-dimensional plates with (for ease of description) 1-dimensional slots. The construction is based on a scene with 2^n shortest paths, with length $l' \le l + \Delta$. In the final step, obstacles are introduced which stretch all paths that correspond to nonsatisfying instances by at least Δ. It remains to verify that there are no further locally shortest paths that use other edge sequences and have length close to l'. The use of parallel plates ensures that these paths would have additional legs between slots. The spacing between plates and between the breakpoints of the shortest paths in the slots gives a lower bound on the additional length and is again roughly Δ. Finally, the gap Δ is single-exponential.

Now assume that we have a strongly precision-sensitive algorithm as defined in section 1.2. Consider the satisfiability problem restricted to 3SAT formulas that are satisfiable by at most one variable instance, known as the *unambiguous satisfiability problem USAT*. Assume we are given such a formula f. By constructing $E(f)$ and running our algorithm, we would be able to decide the satisfiability of f in polynomial time. This proves Theorem 1.

4. Approximation. For simplicity, we shall describe algorithms in this section in the algebraic framework. It is important to note that the hardness result of section 3 is not valid in this model. However, as in [6], the technique extends to the bit framework. In particular, it suffices to compute intermediate numbers to precision $W = O(\log(n/\varepsilon) + L)$.

We review the approximation scheme for 3ESP in [6]: the algorithm mainly consists of three steps. In the first step, the edges are subdivided into segments using a method that depends on some given parameter $\varepsilon' > 0$. This ε'-*subdivision* (as it is called) satisfies the properties given in the following lemma.

LEMMA 6 (see [6]).

(1) *Each edge is divided into $O(L/\varepsilon')$ segments.*

(2) *Each segment σ of the subdivision satisfies $|\sigma| \le \varepsilon' \mathit{dist}(s, \sigma)$.*

(3) *The $\varepsilon'/2$-subdivision is a refinement of the ε'-subdivision.*

In the second step of the algorithm, the *visibility graph* $G_0 = (V_0, E_0)$ of the segments is constructed. The nodes of the graph comprise the subdivision segments including s and t. The edges comprise pairs (σ, σ') of segments that can "see each other," meaning that there exists $x \in \sigma$ and $x' \in \sigma'$ such that $\overline{xx'} \in FS$. In the third step, the visibility graph G_0 is weighted by assigning to each edge (σ, σ') the Euclidean distance between the midpoints of σ and σ'. Finally, the shortest path Σ in G_0 is computed by running Dijkstra's shortest path algorithm. This path is a *segment sequence* $\Sigma = (s, \sigma_1, \dots, \sigma_k, t)$. Its "weight" according to the midpoint distances is further denoted as $|\Sigma|$.

The following lemma relates $|\Sigma|$ to $|p_{min}|$ (and shows the correctness of the approximation scheme).

LEMMA 7. *For $\varepsilon' = \varepsilon/Cn$, C a given constant, Σ satisfies $|\Sigma| \le (1+2\varepsilon/C)|p_{min}|$ and $|p_{min}| \le (1+2\varepsilon/C)|\Sigma|$.*

Proof. Consider the path Σ_{min} in G_0 which corresponds to p_{min} (Σ_{min} is equivalent to a path that connects the midpoints of the segments used by p_{min}). By the triangle inequality the weight of each leg (σ_i, σ_{i+1}) of Σ_{min} can be bounded by the length of the corresponding leg of p_{min}, plus the length of the segments σ_i and σ_{i+1}. Hence, we obtain

$$|\Sigma| \le |\Sigma_{min}| \le |p_{min}| + 2\sum_{j=1}^{k} |\sigma_j|.$$

With $k \le n$, $|\sigma_j| \le \varepsilon' \mathrm{dist}(s, \sigma_j)$, and $\mathrm{dist}(s, \sigma_j) \le |p_{min}|$, we get

$$|\Sigma| \le (1 + 2\varepsilon/C)|p_{min}|.$$

To prove the second inequality, we consider the path p over Σ which connects pairwise visible points $x_i^1 \in \sigma_i$, $x_{i+1}^2 \in \sigma_{i+1}$, and which connects the points x_i^1, x_i^2 on each σ_i by additional legs. By the triangle inequality, we obtain

$$|p_{min}| \le |p| \le |\Sigma| + 2\sum_{j=1}^{k} |\sigma_j|.$$

With $k \le n$, $|\sigma_j| \le \varepsilon' \mathrm{dist}(s, \sigma_j)$, and $\mathrm{dist}(s, \sigma_j) \le |\Sigma|$, we finally get

$$|p_{min}| \le (1 + 2\varepsilon/C)|\Sigma|. \qquad \square$$

4.1. An incremental algorithm. The above algorithm uses a fixed subdivision. In the following, we shall exploit property (3) in Lemma 6 by successively halving the error bound ε and by refining only those segments which the global shortest path could potentially use.

Let $\varepsilon_i = 2^{-i}$ and $\varepsilon_i' = \varepsilon_i/Cn$, for the fixed constant $C = 32$. (This is a significant improvement to the conference version of this paper, where we divide by Cn^2 instead of Cn.) Let $G_i = (V_i, E_i)$ be the weighted visibility graph for any set of segments V_i fulfilling the basic inequality (2) of Lemma 6, and let l_i denote the length of the shortest path from s to t in G_i. By Lemma 7, we get $l_i \le (1 + \varepsilon_i/16)|p_{min}|$ and $|p_{min}| \le (1 + \varepsilon_i/16)l_i$.

LEMMA 8. *If $\Sigma = (s, \sigma_1, \dots, \sigma_k, t)$, $k \le n$, is a path in G_i with $|\Sigma| > (1+\varepsilon_i/4)l_i$, then any path p over Σ satisfies $|p| > |p_{min}|$.*

Proof. Assume $|p| \leq |p_{min}|$. By the triangle inequality, we get

$$|\Sigma| \leq |p| + 2\sum_{j=1}^{k} |\sigma_j|.$$

With $k \leq n$, $|\sigma_j| \leq \varepsilon_i \mathrm{dist}(s, \sigma_j)/32n$, and $\mathrm{dist}(s, \sigma_j) \leq |p| \leq |p_{min}|$, we get

$$|\Sigma| \leq (1 + \varepsilon_i/16)|p_{min}|.$$

With $|p_{min}| \leq (1 + \varepsilon_i/16)l_i$, we finally get

$$|\Sigma| \leq (1 + \varepsilon_i/4)l_i,$$

a contradiction. □

We define the *essential subgraph* $G_i^{ess} = (V_i^{ess}, E_i^{ess})$ of G_i to be the subgraph which is spanned by the union of all (s,t)-paths Σ in G_i with $|\Sigma| \leq (1 + \varepsilon_i/4)l_i$.

LEMMA 9. *If p_{min} leads over a segment sequence $\Sigma = (s, \sigma_1, \ldots, \sigma_k, t)$ in G_i, then Σ is in G_i^{ess}.*

To approximate a shortest path p_{min} by successive refinement, we need thus only to consider the segments in V_i^{ess} in the next step.

We can compute G_i^{ess} as follows: run Dijkstra's single source shortest path algorithm on G_i twice, starting at s and starting at t, and assign to each $\sigma \in V_i$ the distances $d_s(\sigma)$ (resp., $d_t(\sigma)$) to s (resp., t) in G_i. This implies $l_i = d_s(t) = d_t(s)$. Let the weight of edge (σ, σ') in G_i be denoted by $\omega(\sigma, \sigma')$. Then we can choose E_i^{ess} to be the set of all $(\sigma, \sigma') \in E_i$ that satisfy

$$d_s(\sigma) + d_t(\sigma') + \omega(\sigma, \sigma') \leq (1 + \varepsilon_i/4)l_i.$$

In practice, G_i^{ess} should be significantly smaller than G_i. In fact, it approaches the 1-dimensional skeleton formed by all global shortest paths as $\varepsilon_i \to 0$. In the next lemma we show that, depending on the precision-sensitivity parameter δ, the incremental construction of G_i^{ess} will eventually resolve the edge sequence S_{min} of the global shortest path p_{min}.

LEMMA 10. *Let $\varepsilon_i < \delta$ and let (σ, σ') be an arbitrary edge of G_i^{ess} with $\sigma \in e, \sigma' \in e'$ (e and e' are obstacle edges). Then either $e = e'$ or (e, e') is an edge of S_{min}.*

Proof. The graph G_i^{ess} contains a path $\Sigma = \Sigma_1 \cdot (\sigma, \sigma') \cdot \Sigma_2$, where Σ_1 is a shortest path from s to σ and Σ_2 is a shortest path from σ' to t. By construction of G_i^{ess}, Σ satisfies $|\Sigma| \leq (1 + \varepsilon_i/4)l_i$. Let $p = p_1 \cdot (x, x') \cdot p_2$ be an admissible path over Σ, i.e., a path which realizes the visibility relation (p is a zig-zag path which uses additional legs on segments). As Σ_m, $m = 1, 2$, is a shortest path in G_i^{ess}, Σ_m enters and leaves an obstacle edge e at most once (otherwise, there would be a cycle and a shortcut on e). Hence, each Σ_m leads over $k \leq n$ segments σ_j. By the triangle inequality, we get

$$|p| \leq |\Sigma| + 4\sum_{j=1}^{k} |\sigma_j|.$$

With $|\sigma_j| \leq \varepsilon_i \mathrm{dist}(s, \sigma_j)/32n$ and $\mathrm{dist}(s, \sigma_j) \leq |\Sigma|$, we get

$$|p| \leq (1 + \varepsilon_i/4)|\Sigma|.$$

With $|\Sigma| \le (1+\varepsilon_i/4)l_i$ and $l_i \le (1+\varepsilon_i/4)|p_{min}|$, we obtain $|p| < (1+\varepsilon_i)|p_{min}|$. By definition of δ, p must lie on S_{min}. Finally, the edge (σ, σ') used by p must lie on the same obstacle edge e of S_{min} or must correspond to an edge (e, e') of S_{min}. ∎

We are now ready to formulate the *incremental algorithm* to get a relative error of $\varepsilon = 2^{-r}$:

```
(1)  $i := 0;\ \varepsilon'_0 := 1/Cn;$
(2)  Compute the initial $\varepsilon'_0$-subdivision $V_0$;
(3)  Repeat
(4)      Construct the visibility graph $G_i = (V_i, E_i)$;
(5)      Compute $G_i^{ess} = (V_i^{ess}, E_i^{ess})$;
(6)      Compute $V_{i+1}$ by refining $V_i^{ess}$;
(7)      $i := i+1;\ \varepsilon'_i := \varepsilon'_{i-1}/2;$
(8)  Until $i = r+1$.
```

4.2. Spectral analysis. Our first goal in this section is to characterize the behavior of the incremental algorithm for a fixed edge sequence S.

Let $l = l_S$, and let again H be the Hessian of l with spectral bounds μ and ρ. Let $\zeta = (\zeta_1, \ldots, \zeta_k)$ be the parameter tuple specifying $p_{min}(S)$, and z_j the breakpoint of $p_{min}(S)$ on e_j, specified by ζ_j. Our goal is to show that a path p over S whose length differs only slightly from $|p_{min}(S)|$ must also have a parameter λ which is close to ζ. Taylor's theorem shows that for any $\lambda \in \mathbf{R}^k$, there exists $\tau \in \mathbf{R}^k$ such that

$$l(\lambda) - l(\zeta) = \langle \nabla l(\zeta), \lambda - \zeta \rangle + \frac{1}{2}\langle \lambda - \zeta, H(\tau)(\lambda - \zeta)\rangle. \tag{5}$$

The first term is equal to zero as ζ minimizes the function l_S (see section 2.1). The second term can be bounded by the "spectrum" of H:

$$\mu\|\lambda - \zeta\|^2 \ \le\ \langle \lambda - \zeta, H(\tau)(\lambda - \zeta)\rangle \ \le\ \rho\|\lambda - \zeta\|^2. \tag{6}$$

This implies

$$l(\lambda) - l(\zeta) \ge \frac{\mu}{2}\|\lambda - \zeta\|^2.$$

Thus, the parameter λ of any path p over S with $|p| - |p_{min}(S)| \le \tilde{\varepsilon}$ satisfies $\|\lambda - \zeta\|^2 \le 2\tilde{\varepsilon}/\mu$ (for any $\tilde{\varepsilon} > 0$).

In the next lemma, we consider G_i^{ess} after the edge sequence S_{min} of the unique shortest path has been resolved.

LEMMA 11. *Let $\varepsilon_i < \delta$, let $\sigma \in G_i^{ess}$ be a segment with $\sigma \subseteq e$, let $x \in \sigma$ be an arbitrary point, and let $z \in e$ be the breakpoint of the shortest path p_{min} on e. Then*

$$||x - z|| \le \left(2\varepsilon_i \frac{|p_{min}|}{\mu}\right)^{\frac{1}{2}}.$$

Proof. By Lemma 10, we can assume that $x = x_j$ is the jth vertex of a path p over S_{min} with $|p| \le (1+\varepsilon)|p_{min}|$. Accordingly, let $z = z_j$ be the jth vertex of p_{min}. Now, let λ be the parameter of p, and let ζ be the parameter of p_{min}. Setting $\tilde{\varepsilon} = \varepsilon_i|p_{min}|$, we get

$$\begin{aligned} ||x_j - z_j|| &= |\lambda_j - \zeta_j| \le ||\lambda - \zeta|| \\ &\le \left(2\varepsilon_i \frac{|p_{min}|}{\mu}\right)^{\frac{1}{2}}. \end{aligned}$$ ∎

Now assume we run our incremental algorithm for the fixed edge sequence S_{min} and are in step i (i.e., the ith iteration step). Then on each edge e_j those segments whose distance from z_j is more than const $\cdot \sqrt{\varepsilon_i}$ will automatically not be considered. Here, const $= \sqrt{2|p_{min}|/\mu}$ depends on S but not on i.

By construction, each segment σ on e_j has length $|\sigma| \geq a_j\varepsilon_i/32n$ (with a_j the distance from e_j to the source s). Thus we refine at most

$$C(S) \cdot n\varepsilon_i^{-\frac{1}{2}}$$

segments on each e_j in the ith step, with

$$C(S) = \frac{32}{a}\sqrt{2\frac{|p_{min}|}{\mu}}$$

and $a = \min_j\{a_j\}$.

Let $\varepsilon = 2^{-r}$ be the desired relative error. Summing over $i = 1, \ldots, r$, we produce a total of $O(r\sqrt{1/\varepsilon_r})$ segments. This is a significant improvement to the original (not precision-sensitive) scheme, which would produce $O(1/\varepsilon_r)$ segments.

The described effect occurs in the overall algorithm as soon as $\varepsilon_i < \delta$. Lemmas 10 and 11 then imply that the essential subgraph G_i^{ess} contains less than $O(nC(S_{min})2^{i/2})$ segments per edge. On the other hand, if $\varepsilon_i > \delta$, then G_i^{ess} contains $O(nL/\varepsilon_i) = O(nL/\delta)$ segments per edge. (This is the number of segments produced by the non-incremental scheme in [6].) This yields the following lemma.

LEMMA 12. *The essential subgraph G_i^{ess} contains less than*

$$M_i = O\left(n\left(\frac{L}{\delta} + C(S_{min}) \cdot 2^{\frac{i}{2}}\right)\right)$$

segments per edge.

We note that the number of segments per edge which are produced by the algorithm in [6] is also an upper bound for M_i.

The visibility relation between segments can be computed separately for each of the $O(r)$ refinement steps by a sweep algorithm, as described in [6]. The cost of this algorithm dominates the computation of G_i^{ess}. Thus, the running time of the ith step is $T(n, M_i, W)$, with T as in (4). The running time of the total algorithm can be bounded by

$$O(r \cdot T(n, M_r, W)).$$

Thus, we have proven Theorem 2.

4.3. Path optimization. With the incremental approach above, we have a tool to determine S_{min} in (3) in time polynomial in $1/\delta$. As soon as there is only one possible edge sequence (or only a few combinatorially distinct sequences) left, it is however more efficient to use an optimization technique to approximate the actual shortest path. We propose to use a steepest descend method (see, e.g., [7, section C-5]):

Let the spectrum of H be bounded below by $\mu > 0$ and above by ρ (choose μ as the smallest, and ρ as the biggest eigenvalue of H). We can derive explicit values for these bounds (especially for ρ) as described in section 4.4.

Let $I = [\frac{1}{2\rho}, \frac{3}{2\rho}]$. Define the sequence

$$\lambda^{i+1} = \lambda^i - \kappa \nabla l(\lambda^i),$$

with $\kappa \in I$ and λ^0 the known approximation. Then this sequence converges to the unique minimizer ζ of l at the rate of a geometric progression with ratio $q = 1 - \mu/\rho$:

$$||\lambda^{i+1} - \zeta|| \leq q||\lambda^i - \zeta|| \leq q^{i+1}||\lambda^0 - \zeta||.$$

With

$$||l(\lambda^i) - l(\zeta)|| \leq \frac{\rho}{2}||\lambda^i - \zeta||^2$$

and

$$||\lambda^0 - \zeta||^2 \leq \frac{2}{\mu}(l(\lambda^0) - l(\zeta)) \leq \frac{2\delta}{\mu} l(\zeta),$$

we get

$$||l(\lambda^i) - l(\zeta)|| \leq \frac{\rho\delta}{\mu} q^{2i} |p_{min}|.$$

To achieve $||l(\lambda^i) - l(\zeta)|| < 2^{-r}|p_{min}|$, it is sufficient to choose $i > N$ with

$$N = \Theta\left(\frac{\rho}{\mu}\left(r + |\log\delta| + \left|\log\frac{\rho}{\mu}\right|\right)\right).$$

Again, it is important to note that this method — e.g., because of the freedom of choice for κ — easily extends to the bit framework. The running time of the whole algorithm can be resolved as

$$O(\log(1/\delta) \cdot T(n, M_\delta, W) + Nn\mu(W)),$$

where $M_\delta = O(nL/\delta)$. This finally proves Theorem 3.

4.4. Spectral bounds. In this section, we discuss two different methods to get bounds on the spectrum of the Hessian H of the path length function $l = l_{S_{min}}$. We shall use the notations of section 2.

By the theory of Gerschgorin circles, the eigenvalues of H are bounded above by $\rho = \max_i\{\ a_i + |b_i| + |b_{i-1}|\ \}$, with a_i and b_i as in the proof of Lemma 2.

With the help of ρ, we can directly give a bound on μ. As the determinant of H is equal to the product of all k eigenvalues of H, we get

$$\mu \geq \frac{\det(H)}{\rho^{k-1}},$$

where the determinant of H satisfies the inequality

$$\det(H) \geq \prod_{i=1}^{k} a_i^-.$$

A crucial deficiency of the above bound is that it is exponential in k, the number of intermediate vertices of p_{min}.

A bound on μ not depending on k can be obtained by a method based on the theorem of Courant–Fischer (see [15, pp. 101–102]):

Let A, B and C be positive-semidefinite symmetric matrices with $C = A + B$, and α (resp., β) the smallest eigenvalue of A (resp., B). Then each eigenvalue γ of C satisfies $\gamma \geq \alpha + \beta$. Assuming k to be even (the case of odd k can be similarly treated), we split $H = A + B$ according to

$$A = \sum_{i=0}^{k/2} H_{2i} \ , \quad B = \sum_{i=1}^{k/2} H_{2i-1}.$$

The matrices A and B are block matrices, and the eigenvalues are the eigenvalues of the H_i. It follows that

$$\mu \geq \min\{ \ \mu_i \ ; \ i = 0, \ldots, k \ \},$$

where μ_i is the smallest eigenvalue of H_i. This bound has the nice property that it depends only on pairs of edges of S_{min}.

5. Experimental results. The preceding algorithms for the approximate 3ESP problem have a high polynomial dependency on the number of edges n or the desired error bound ε. But these theoretical bounds need not reflect the "average behavior" or practical situations. This suggests some empirical studies.

To verify the practicability of our incremental approach, we implemented a simplified version of the proposed algorithm. The simplification is based on the observation that for certain special cases, the visibility relation between segments can be replaced by the visibility of segment midpoints:

Let the obstacles be 2-dimensional facets arranged in h parallel planes separating the start and target points. Let $\varepsilon' = \varepsilon/h$, and consider the subdivision defined in section 4. Then the following lemma holds.

LEMMA 13. *There exists a free polygonal path p from s to t, which connects segment midpoints and satisfies $|p| \leq (1+\varepsilon)|p_{min}|$.*

Proof. The shortest path p_{min} from s to t is strictly monotone in the direction of the normal vector of the planes containing the obstacle facets. Now pick an arbitrary vertex v of p_{min} and move this vertex on the incident edge in either direction while keeping the other path vertices fixed. We continue this deformation until the (deformed) path hits another obstacle facet or until v hits a segment midpoint. In the first case, we consider the intersection point as a further path vertex, and in the latter case we continue the process by picking another path vertex until all vertices coincide with segment midpoints. It is easy to see that this process terminates after at most h deformation steps, introducing an absolute error of at most $h\varepsilon'|p_{min}|$. $\square$

Further, we used a uniform subdivision for each edge by starting with the edges as segments and successively halving the segments.

Tables 1 and 2 show the result of the incremental algorithm for the situation in Figures 1 and 2. The figures visualize the situation after 10 iteration steps: the essential segments are the solid black parts of the edges, and the shortest paths from start to goal determined so far are drawn dashed. In the first example there are two shortest paths, which are resolved after the 8th iteration step. In the second example,

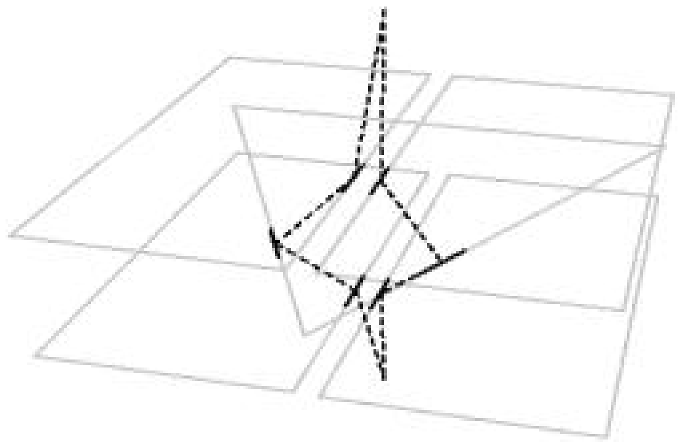

FIG. 1. *Horizontal obstacles 1.*

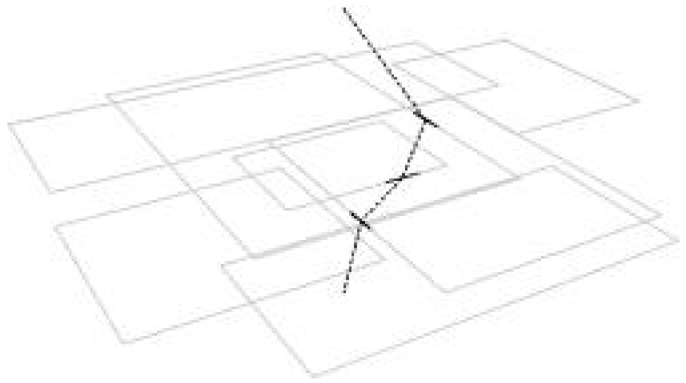

FIG. 2. *Horizontal obstacles 2.*

the unique shortest path is resolved after the 10th step.

The tables show the guaranteed relative error in path length, the length of the shortest path in the current visibility graph, and the number of the essential segments. The running time of the algorithm is mostly quadratic in this number, and was, for these examples, in the range of seconds on a state-of-the-art workstation.

The following behavior has been typical for the examples we tried: until the error bound ε_i is small enough to discard, the number of essential segments is doubled per step. Then comes a phase where the segment number does not change significantly. Once the shortest paths are resolved, the number of essential segments is doubled every two iteration steps, as predicted by the theoretical results.

6. Final remarks. We have developed the first precision-sensitive algorithms for 3ESP. Beyond its intrinsic interest, it demonstrates a critical exploitation of precision-sensitivity. We conjecture that other previously intractable problems may likewise yield to this approach.

If the sensitivity parameter δ is zero, we can modify our approach to take advantage of the "next sensitivity" parameter, namely, the gap between the second and the third shortest path, etc. A general treatment of this may be interesting.

We note that attention has to be paid to degenerate situations in this problem. But it seems unavoidable to take this into account because degeneracy seems to be one cause of intrinsic complexity in 3ESP. Note that there has been some recent literature on degeneracy in geometric problems.

The merits of the incremental 3ESP seem evident: in our examples, there would have been no chance to detect the shortest path by the exhaustive approach [6]. Our algorithm is a useful tool when a researcher needs to determine the real shortest path in a particular small environment.

OPTIMAL INFORMATION GATHERING ON THE INTERNET WITH TIME AND COST CONSTRAINTS*

OREN ETZIONI†, STEVE HANKS†, TAO JIANG‡, AND OMID MADANI†

Abstract. The World Wide Web provides access to vast amounts of information, but content providers are considering charging for the information and services they supply. Thus the consumer may face the problem of balancing the benefit of asking for information against the cost (in terms of both money and time) of acquiring it. We study information-gathering strategies that maximize the expected value to the consumer. In our model there is a single information request, which has a known *benefit* to the consumer. To satisfy the request, *queries* can be sent simultaneously or in sequence to any of a finite set of independent *information sources.* For each source we know the monetary cost of making the query, the amount of time it will take, and the probability that the source will be able to provide the requested information. A *policy* specifies which sources to contact at which times, and the *expected value* of the policy can be defined as some function of the likelihood that the policy will yield an answer, the expected benefit, and the monetary cost and time delay associated with executing the policy. The problem is to find an expected-value-maximizing policy.

We explore four variants of the objective function V: (i) V consists only of the benefit term subject to threshold constraints on both total cost and total elapsed time, (ii) V is linear in the expected total cost of the policy subject to the constraint that the total elapsed time never exceeds some deadline, (iii) V is linear in the expected total elapsed time subject to the constraint that the total cost never exceeds some threshold, and (iv) V is linear in the expected total monetary cost and the expected time delay of the policy. The problems of devising an optimal querying policy for all four variants and approximating an optimal querying policy for variants (iii) and (iv) are shown to be NP-hard. For (i), and with a mild simplifying assumption for (iii), we give a fully polynomial time approximation scheme. For (ii), we consider *batched* querying policies, and design an $O(n^2)$ time approximation algorithm with ratio $\frac{1}{2}$ and a polynomial time approximation scheme for optimal single-batch policies, and an $O(kn^2)$ time approximation algorithm with ratio $\frac{1}{5}$ for optimal k-batch policies.

1. Introduction.

The Internet is rapidly becoming the foundation of an information economy. Valuable information sources include online travel agents, nationwide yellow pages, job listing services, online malls, and many more. Currently, most of this information is available free of charge, and as a result parallel search tools such as MetaCrawler [16] and BargainFinder [9] respond to requests by querying numerous information sources simultaneously to maximize the information provided and minimize delay. However, information providers may start charging for their services [7, 11]. Billing protocols to support an "information marketplace" have been announced by large players such as Visa and Microsoft [15] and by researchers [18].

Once billing mechanisms are in place, consumers of information may face the problem of balancing the benefit of obtaining information against the cost (both monetary and temporal) of obtaining it. Information providers will differ in the quality of the information they provide as well as the amount they charge and the speed at which they deliver information. The consumer thus faces the problem of developing a schedule of queries to the providers that maximizes expected value, which can be expressed in terms of (1) the benefit associated with a successful query, (2) the likelihood that a particular query will yield successful results, (3) the cost of making a query, and (4) the amount of time it takes.

This paper analyzes the "query scheduling" problem for a number of variants of the objective function. We begin by stating the problem precisely and then summarize our main results.

1.1. The model. The basic problem is to find a *policy* for obtaining the answer to a (single) query. The policy will dictate which information source will be queried and when. To define a policy we begin with a (finite) set of information sources, $s_1, \ldots, s_n$. For each source s_i we introduce a cost parameter c_i and a duration parameter d_i. The former is the monetary cost assessed when the source is activated and the latter is the amount of time it takes the source to process the query. The cost and duration are known with certainty and are charged whether or not the source returns an answer to the query.[1] Finally we have p_i, the probability that s_i will return an answer to the query. Success probabilities are independent for distinct sources, and whether or not s_i will answer a query is uncertain but consistent: if s_i successfully answers a query it will always do so subsequently, and if it fails to answer a query it will always fail to do so subsequently.[2] We assume that accurate estimates of these parameters are obtainable from the history of the interactions with the information sources.

A policy can be represented as a sequence of pairs $\mathcal{P} = (s_{i_1}, t_1), \ldots, (s_{i_m}, t_m)$, where $t_1 \leq t_2 \leq \cdots \leq t_m$. This specifies that source s_{i_1} will be initiated at t_1, s_{i_2} will be initiated at t_2, and so on. An execution of the policy is terminated either when some source returns a correct answer or when the policy has been exhausted. Since each source in a policy succeeds probabilistically, a policy generates a probability distribution over *outcomes*, where each outcome is one possible way that the policy might be played out. We use $S(\mathcal{O})$, $C(\mathcal{O})$, and $T(\mathcal{O})$ to denote the outcome's success (1 or 0), total cost, and duration, respectively. The *value* of an outcome $\mathcal{O}$ is a function of $S(\mathcal{O})$, $C(\mathcal{O})$, and $T(\mathcal{O})$. The first component of the value function of an outcome $\mathcal{O}$ is always a constant reward R if the query was answered and 0 otherwise. The function additionally contains two additive components, one a function of $C(\mathcal{O})$ and one a function of $T(\mathcal{O})$. The *expected value* of a policy $\mathcal{P}$, denoted $V(\mathcal{P})$, is simply the expectation of the values of all its outcomes.

Our objective is to find a policy to maximize the expected value. We will consider four versions of the objective function: linear and threshold versions of the cost and time components. With suitable scaling of the monetary and time costs, the four objective functions assume the forms given in Table 1.1. We will hereafter refer to the four problems by their acronyms: TT for threshold in cost and time, LT for linear in cost and threshold in time, TL for threshold in cost and linear in time, and LL for linear in cost and time. Note that in the threshold cases we try to find a policy with

[1] All our results can be extended to the case when the cost is charged only if the query is successful. Cost *expectations* in place of costs should be used in a few of the models.

[2] As a result it is never profitable to query a source more than once.

TABLE 1.1
The four objective functions. Here, $\mathcal{O}$ denotes a possible outcome of the policy $\mathcal{P}$ to be found.

Objective	Time threshold	Linear in time
Cost threshold	TT: max $\mathbf{E}[R \cdot S(\mathcal{O})]$ s.t. $\forall \mathcal{O}\ \ C(\mathcal{O}) \leq \varsigma$ and $T(\mathcal{O}) \leq \tau$	TL: max $\mathbf{E}[R \cdot S(\mathcal{O}) - T(\mathcal{O})]$ s.t. $\forall \mathcal{O}\ \ C(\mathcal{O}) \leq \varsigma$
Linear in cost	LT: max $\mathbf{E}[R \cdot S(\mathcal{O}) - C(\mathcal{O})]$ s.t. $\forall \mathcal{O}\ \ T(\mathcal{O}) \leq \tau$	LL: max $\mathbf{E}[R \cdot S(\mathcal{O}) - C(\mathcal{O}) - T(\mathcal{O})]$

the maximum expected value subject to the constraint that the policy never violates the threshold. In the remainder of the paper, assume without loss of generality that $R = 1$, unless otherwise stated.

1.2. "Batched" policies. The results in this paper concerning the model LT will reflect one more simplifying assumption: that the duration parameters d_i are the same for each source. This assumption is powerful because it allows us to consider scheduling sources in simultaneous "batches": all sources will be scheduled at $t = 0, d, 2d, \ldots$, where d is the common duration.

Although not fully general, this is a reasonable model of the current and probable future state of information access on the Internet. The current common mode of providing information is to supply small amounts of information quickly and cheaply (rather than process large-scale lengthy requests) [16]. As a result the duration for processing a single query relative to the user's time threshold is typically small. Furthermore, the number of providers continues to grow dramatically. In the case in which there are many information providers but each takes a short amount of time, the assumption of equal process duration may be an excellent approximation: the error introduced by assuming equal times will tend to be small relative to the amount of time the user is willing to wait for his information (and thus will not affect the quality of the schedule significantly), yet the sheer number of potential providers will still require an algorithm to choose carefully among its sources since a simple policy of completely serial or parallel queries is liable to be a very bad one.

1.3. Summary of our results. We show that finding an optimal policy is NP-hard for models TT and LT. Reductions from the problems in LT and TT show that even approximating an optimal policy for models LL and TL is NP-hard. A fully polynomial time approximation scheme (FPTAS) is obtained for the model TT, using an extension of the well-known rounding technique for Knapsack [6]. The FPTAS also works for the model TL under a weak assumption: every source is "profitable" individually according to the TL objective function, i.e., for every source s_i, $Rp_i - d_i \geq 0$. The approximation algorithms for the case LT, where the objective function is linear in total cost subject to a time threshold, are perhaps the most interesting technically. We assume that all sources have the same time duration and consider batched policies with a bounded number of batches. We will first present an $O(n^2)$ time approximation algorithm for optimal single-batch policies with ratio $\frac{1}{2}$, and then extend it to a polynomial time approximation scheme (PTAS). For any constant $r > 1$, the PTAS runs in time $O(n^{r+1})$ to achieve an approximation ratio $\frac{r-1}{r+1}$. The algorithms are simple and are similar to the ones in [14] for Knapsack, but the analyses are more sophisticated. We then design an approximation algorithm with ratio $\frac{1}{5}$ for optimal k-batch policies, running in time $O(kn^2)$. The algorithm is based on the ratio $\frac{1}{2}$ algorithm for single-batch policies, but it also involves some new ideas.

1.4. Related work. Scheduling problems have been studied in many contexts including job-shop scheduling, processor allocation, etc. However, our Internet-inspired query scheduling problem has a unique flavor due to the need to balance the competing time and cost constraints on policies with unbounded parallelism. We here consider a number of alternative models that have appeared in the literature, underscoring the difference from our own. If we constrain the policies to be serialized, then an optimal solution can be found in polynomial time (see section 4 for the LT case). Similar problems have been addressed in [4, 8, 12, 17] and elsewhere. The difference in this paper is the ability to query any number of sources in parallel. Papers [3, 5] study scheduling tasks with unlimited parallelism, but their models are different because all tasks have to be executed successfully, whereas in our model a successful answer from any single source suffices. Furthermore, the positive results in [3, 5] are restricted to an exponential time dynamic programming algorithm and some heuristics. Another model of optimal information gathering has recently been studied in [2]. There, the objective is to find a query policy that minimizes the expected value of a linear combination of the total dollar cost and total time cost. A constant ratio approximation algorithm is obtained. Note that their model omits the positive reward associated with the successful completion of a query, which changes the nature of the problem as far as the design of approximation algorithms is concerned.

This paper provides complete proofs and adds new results to the work appearing in [1]. The paper is organized as follows. The hardness results for all four models are given in the next section. Sections 3 and 4 present the approximation algorithms with their analyses for optimal single-batch policies and optimal k-batch policies in the LT model. The FPTASs for the two models involving a cost threshold are given in section 5. The proofs of some technical claims are provided in the appendix.

2. The complexity of computing optimal querying policies.

We first prove that computing an optimal policy in models TT and LT is NP-hard. The proofs are reductions from the Partition problem: Given a finite multiset S of positive integers $w_i \in S$, is there a subset $I \subset S$ such that $\sum_{w_i \in I} w_i = \frac{1}{2}\sum_{w_i \in S} w_i$? The only subtlety is that we have to use exponential numbers in the constructions.

THEOREM 2.1. *Finding an optimal policy in model* TT *is NP-hard.*

Proof. It is clear that any optimal policy in this model is in fact a single-batch policy. Hence we need only to consider single-batch policies. We show that Partition reduces to this problem. Assume that the duration parameters of all the sources are less than the deadline. Then, the expected value of any policy $\mathcal{P}$ in this model is

$$V(\mathcal{P}) = 1 - \prod_{s_i \in \mathcal{P}} (1 - p_i).$$

Thus, maximizing $V(\mathcal{P})$ subject to a cost threshold is equivalent to minimizing $\prod_{s_i \in \mathcal{P}}(1 - p_i)$ under the same constraint, which in turn means maximizing $\sum_{s_i \in \mathcal{P}} - \ln(1 - p_i)$ under the same constraint.

Consider an instance of Partition consisting of a set $S = \{w_1, \dots, w_n\}$ of integers, and let $C = \sum_{i=1}^{n} w_i$. For each source s_i, let its cost $c_i = w_i$, success probability $p_i = 1 - (1 + 1/C)^{-w_i}$, and time duration $d_i = 0$. Take the cost threshold to be $C/2$, and the time threshold to be some positive number. The expression $(1 + 1/C)^{-w_i}$ can be evaluated using the standard repeated squaring technique or a binomial series expansion approximation. It will become clear that we have only to keep at most $3 \log C + \log n$ precision bits during the process.

Clearly, $V(\mathcal{P}) \leq 1-(1+1/C)^{-\frac{C}{2}}$ for any feasible policy $\mathcal{P}$. Now, let $x = \sum_{w_i \in \mathcal{P}} w_i$

and treat x as a continuous variable. Consider function $h(x) = 1-(1+1/C)^{-x}$, which is clearly increasing in x. Since

$$(1+1/C)^{-\frac{C}{2}+1} - (1+1/C)^{-\frac{C}{2}} = (1+1/C)^{-\frac{C}{2}}(1/C) > 1/(\sqrt{e}C),$$

where e is the natural constant, there is a separation of at least $1/(\sqrt{e}C)$ in the value of the function $h(x)$ between point $\frac{C}{2}$ and any point less than or equal to $\frac{C}{2}-1$. If we keep $3\log C + \log n$ bits during calculation of each $1-(1+1/C)^{-w_i}$, then each p_i would have $2\log C + \log n$ precision bits. Thus, the precision of our evaluation of $V(\mathcal{P}) = 1 - \prod_{s_i\in\mathcal{P}}(1-p_i)$ is at least $2\log C$ bits, which is sufficient to allow us to distinguish between the case $\sum_{s_i\in\mathcal{P}} c_i = \frac{C}{2}$ and the case $\sum_{s_i\in\mathcal{P}} c_i < \frac{C}{2}$, due to the above $1/(\sqrt{e}C)$ separation. □

For the problem instance LT we prove a stronger result by showing that a special case of the problem is NP-hard.

THEOREM 2.2. *Finding an optimal single-batch policy for the* LT *objective function is NP-hard.*

Proof. Note that the objective in the single-batch case is to find a set $\mathcal{P}$ of sources to query in parallel such that the function

$$V(\mathcal{P}) = R\left(1 - \prod_{s_i\in\mathcal{P}}(1-p_i)\right) - \sum_{s_i\in\mathcal{P}} c_i \tag{2.1}$$

is maximized. This is equivalent to minimizing the quantity $R\prod_{s_i\in\mathcal{P}}(1-p_i)+\sum_{s_i\in\mathcal{P}} c_i$ over all possible sets of sources.

Consider an instance of Partition consisting of a set $S=\{w_1,\ldots,w_n\}$ of integers, and let $C=\sum_{i=1}^n w_i$. Define the parameters for the optimal single-batch policy problem as follows:

$$\begin{aligned} &c_i = w_i,\\ &p_i = 1-(1+1/C)^{-w_i},\\ &R = [\ln(1+1/C)]^{-1}(1+1/C)^{\frac{C}{2}}. \end{aligned}$$

Again, it will become clear that only $4\log C + \log n$ bits must be kept in the calculation of p_i's and R. For any subset $S_1 \subseteq S$ we have

$$\begin{aligned} \sum_{w_i\in S_1} c_i + R\prod_{w_i\in S_1}(1-p_i) &= \sum_{w_i\in S_1} w_i + [\ln(1+1/C)]^{-1}(1+1/C)^{\frac{C}{2}}\prod_{w_i\in S_1}(1+1/C)^{-w_i}\\ &= \sum_{w_i\in S_1} w_i + [\ln(1+1/C)]^{-1}(1+1/C)^{\frac{C}{2}-\sum_{w_i\in S_1} w_i}. \end{aligned}$$

Again, let $x=\sum_{w_i\in S_1} w_i$ and treat x as a continuous variable. We want to locate the minimum of the following function:

$$h(x) = x + [\ln(1+1/C)]^{-1}(1+1/C)^{\frac{C}{2}-x}.$$

Setting the derivative to zero,

$$\begin{aligned} &h'(x) = 1 + [\ln(1+1/C)]^{-1}[-\ln(1+1/C)](1+1/C)^{\frac{C}{2}-x} = 0\\ \Rightarrow\quad & 1 = [\ln(1+1/C)]^{-1}\ln(1+1/C)(1+1/C)^{\frac{C}{2}-x}\\ \Rightarrow\quad & 1 = (1+1/C)^{\frac{C}{2}-x}\\ \Rightarrow\quad & x = \frac{C}{2}. \end{aligned}$$

We also note that the second derivative of $h(x)$ is always positive, which shows the convexity of the function:

$$h''(x) = [\ln(1+1/C)]^{-1}[\ln(1+1/C)]^2(1+1/C)^{\frac{C}{2}-x} > 0.$$

The following shows that there is a separation of $\Omega(1/C^2)$ in the value of the function $h(x)$ between the points $\frac{C}{2}$ and $\frac{C}{2} \pm 1$(assume that $C > 2$):

$$\begin{aligned}
h\left(\frac{C}{2}-1\right) - h\left(\frac{C}{2}\right) &= C^{-1}[\ln(1+1/C)]^{-1} - 1\\
&> C^{-1}\left(\frac{6C^3}{6C^2-3C+2}\right) - 1\\
&= \frac{3C-2}{6C^2-3C+2}\\
&> 1/(6C^2),\\
h\left(\frac{C}{2}+1\right) - h\left(\frac{C}{2}\right) &= 1 - \left(\frac{1}{C+1}\right)(\ln(1+1/C))^{-1}\\
&> 1 - \left(\frac{1}{C+1}\right)\left(\frac{2C^2}{2C-1}\right)\\
&> 1/(6C^2).
\end{aligned}$$

Therefore, we have only to keep $4\log C + \log n$ precision bits in the calculation of R and p_i's. Hence the reduction can be done in polynomial time. ∎

Hence the problem of deciding whether the expected value of some policy for the single-batch case exceeds a certain threshold is NP-hard. This problem readily reduces to a problem in the LL model where the duration parameters of the sources are all set to the threshold in question. In this case, it is not hard to see that there is a policy with a positive value for the LL model problem if and only if there is a policy for the single-batch model problem with expected value greater than the threshold. Below, by a *positive approximation* we mean constructing a policy which has positive expected value if and only if the value of an optimal policy is positive. Positive approximation is a very relaxed approximation criterion, and we just argued that even positively approximating the optimal in model LL is hard. A similar reduction from model TT shows that positively approximating problems in model TL is NP-hard as well.

THEOREM 2.3. *Positively approximating an optimal policy for the objective functions in the models* TL *or* LL *is NP-hard.*

3. Approximating optimal single-batch policies.

In this and the following sections our focus is on the LT model. In this section we consider policies that send out all their queries in a single batch, i.e., all queries are sent in parallel at time $t = 0$. We present an algorithm that approximates the optimal single-batch policy with ratio 1/2 and then develop a PTAS. Although the PTAS is a straightforward extension of the ratio 1/2 algorithm, its analysis is very different.

Recall again that a single-batch policy is just a set of sources, and our goal is to maximize the objective function in equality (2.1).

The following simple facts and definitions will be useful in this and the next sections. The first lemma shows the subadditivity of the objective function for batched policies.

LEMMA 3.1. *Let* OPT_0 *be an optimal* k*-batch policy. For any partition of* OPT_0 *into two subpolicies* OPT_1 *and* OPT_2*, where the sources in* OPT_1 *and* OPT_2 *are scheduled in the same batches as they are in* OPT_0*,* $V(\mathrm{OPT}_0) \le V(\mathrm{OPT}_1) + V(\mathrm{OPT}_2)$*.*

Proof. We prove it for $k = 2$; the extension to the general k is straightforward. For each $i = 0, 1, 2$ and $j = 1, 2$, let $P_{i,j}$ and $C_{i,j}$ be the collective success probability and cost of the sources in batch j of OPT_i, respectively. Then

$$\begin{aligned}V(\mathrm{OPT}_0) &= P_{0,1} - C_{0,1} + (1 - P_{0,1})(P_{0,2} - C_{0,2})\\ &= P_{1,1} - C_{1,1} + P_{0,1} - P_{1,1} - C_{2,1} + (1 - P_{0,1})(P_{0,2} - C_{0,2}).\end{aligned}$$

Since $P_{0,1} = P_{1,1} + P_{2,1} - P_{1,1}P_{2,1}$,

$$P_{0,1} - P_{1,1} = P_{2,1}(1 - P_{1,1}) \le P_{2,1}.$$

Hence

$$P_{1,1} - C_{1,1} + P_{0,1} - P_{1,1} - C_{2,1} \le P_{1,1} - C_{1,1} + P_{2,1} - C_{2,1}.$$

Similarly, we have

$$P_{0,2} - C_{0,2} \le P_{1,2} - C_{1,2} + P_{2,2} - C_{2,2}.$$

Because OPT_0 is optimal, $P_{1,2} - C_{1,2} \ge 0$ and $P_{2,2} - C_{2,2} \ge 0$. Therefore,

$$\begin{aligned}V(\mathrm{OPT}_0) &\le (P_{1,1} - C_{1,1} + P_{2,1} - C_{2,1}) + (1 - P_{0,1})(P_{1,2} - C_{1,2} + P_{2,2} - C_{2,2})\\ &= (P_{1,1} - C_{1,1} + (1 - P_{0,1})(P_{1,2} - C_{1,2})) + P_{2,1} - C_{2,1}\\ &\quad + (1 - P_{0,1})(P_{2,2} - C_{2,2})\\ &\le (P_{1,1} - C_{1,1} + (1 - P_{1,1})(P_{1,2} - C_{1,2})) + P_{2,1} - C_{2,1}\\ &\quad + (1 - P_{2,1})(P_{2,2} - C_{2,2}),\end{aligned}$$

and thus

$$V(\mathrm{OPT}_0) \le V(\mathrm{OPT}_1) + V(\mathrm{OPT}_2). \qquad \square$$

LEMMA 3.2. *Suppose that* $\mathcal{P}$ *is any* k*-batch policy,* i *is an index between* 1 *and* k*, and* s_j *is a source not appearing in* $\mathcal{P}$*. Let* $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$ *denote the subpolicies consisting of the first* $i - 1$ *batches, the* i*th batch, and the last* $k - i$ *batches of* $\mathcal{P}$*, respectively. Also denote the expected cost and collective success probability of the sources in policy* $\mathcal{P}_l$ *as* C_l *and* P_l*,* $l = 1, 2, 3$*. Then adding* s_j *to the* i*th batch of policy* $\mathcal{P}$ *increases its expected value by*

$$\begin{aligned}V(\mathcal{P} \cup \{s_j\}) - V(\mathcal{P}) &= (1 - P_1)(p_j(1 - P_2)(1 - P_3 + C_3) - c_j)\\ &= (1 - P_1)p_j((1 - P_2)(1 - P_3 + C_3) - c_j/p_j).\end{aligned} \tag{3.1}$$

In particular, if $k = i = 1$*, the net increase is*

$$V(\mathcal{P} \cup \{s_j\}) - V(\mathcal{P}) = p_j(1 - P_2) - c_j = p_j(1 - P_2 - c_j/p_j). \tag{3.2}$$

Proof. The expected values of the policies $\mathcal{P}$ and $\mathcal{P} \cup \{s_j\}$ can be written as

$$V(\mathcal{P}) = (P_1 - C_1) + (1 - P_1)((P_2 - C_2) + (1 - P_2)(P_3 - C_3)),$$

```
1.   Sort the sources so that $c_1/p_1 \leq \cdots \leq c_n/p_n$.
2.   APPR = $\emptyset$.   (* APPR is the best policy found so far. *)
3.   For $i := 1$ to $n$
4.     $S := \{s_i\}$.   (* $S$ is the current policy constructed. *)
5.     $Q := 1 - p_i$.   (* $Q$ is the collective failure probability of $S$. *)
6.     For $j := 1$ to $n$, where $j \neq i$
7.       If $Q \geq c_j/p_j$ then (* profitability check *)
8.         $S := S \cup \{s_j\}$.
9.         $Q := Q(1 - p_j)$.
10.      else exit to step 11.
11.    If $V(\text{APPR}) < V(S)$ then APPR := $S$.
12.  Output policy APPR.
```

FIG. 3.1. *The algorithm Pick-a-Star.*

$$V(\mathcal{P}\cup\{s_j\}) = (P_1-C_1)+(1-P_1)((P_2+p_j-P_2p_j-C_2-c_j)+(1-P_2)(1-p_j)(P_3-C_3)).$$

Taking the difference gives us the lemma. □

Thus, in the case of $k = 1$, adding s_j to the policy $\mathcal{P}$ results in an increased expected value if and only if the collective failure probability $1 - P_2$ of the sources in $\mathcal{P}$ is strictly greater than the cost-to-success-probability ratio c_j/p_j of source s_j. Observe that the increased value $p_j(1 - P_2 - c_j/p_j)$ is proportional to the success probability p_j as long as the ratio c_j/p_j is kept constant. Also observe that, for general k, $1 - P_3 + C_3 = 1 - (P_3 - C_3) = 1 - V(\mathcal{P}_3)$. It follows from Lemma 3.2 that a source s_i with $c_i > p_i$ is not useful if $V(\mathcal{P}_3) \geq 0$. Hence we can assume from now on that $p_i \geq c_i$ for all i.

We say that a source s is *profitable in a policy* $\mathcal{P}$ if s is queried in $\mathcal{P}$ and dropping it from $\mathcal{P}$ would not increase the expected value of $\mathcal{P}$. The above lemma states that source s_j in batch i of the k-batch policy $\mathcal{P}$ is profitable in $\mathcal{P}$ if and only if $c_j/p_j \leq (1 - P_{2,j})(1 - V(\mathcal{P}_3))$, where $P_{2,j}$ is the collective success probability of sources in batch i *excluding* source s_j. A policy $\mathcal{P}$ is *irreducible* if every source in $\mathcal{P}$ is profitable in $\mathcal{P}$. Clearly, every optimal k-batch policy is irreducible.

3.1. A ratio $\frac{1}{2}$ approximation algorithm. Our algorithm, as shown in Figure 3.1, is somewhat similar to the greedy approximation algorithm for Knapsack given in [14], though the analysis of its performance is more complex.

The algorithm Pick-a-Star sorts the sources in ascending order of the ratio c_i/p_i. It then goes over each source s_i, picks it, and then picks the rest from the sorted list (with s_i removed) until either the list is exhausted or it reaches a source s_j which cannot be profitable, meaning that the profitability criterion

$$\prod_{k=i \text{ or } k<j} (1 - p_k) \geq c_j/p_j$$

is not satisfied. Equality (3.2) in Lemma 3.2 and the comments following the lemma explain the choice of the criterion. Pick-a-Star keeps track of the policy with the highest expected value over the iterations. Clearly the running time is $O(n^2)$.

Now we analyze the performance of Pick-a-Star and show that it results in an expected value that is at least half of the optimum. Let APPR be the policy obtained by Pick-a-Star and OPT be an optimal single-batch policy. Since Pick-a-Star picks the first source optimally (i.e., through exhaustive search), $V(\text{APPR}) \geq V(\{s_i\}) = p_i - c_i$

for all $i \leq n$. Thus, without loss of generality, we may assume $|\text{APPR}| > 1$. Moreover, we will assume henceforth that the first source picked by Pick-a-Star is the "most profitable" source in OPT, i.e., some source s_i with the maximum $V(\{s_i\})$ over all sources in OPT. Let s_{last} be the last source picked by Pick-a-Star. We can assume that the collective failure probability of APPR is at least the ratio c_{last}/p_{last}, because otherwise we could modify APPR by decreasing p_{last} while keeping c_{last}/p_{last} constant until the collective failure probability of APPR becomes equal to c_{last}/p_{last}. This is possible since the collective failure probability of $\text{APPR} - \{s_{last}\}$ is greater than c_{last}/p_{last}. By Lemma 3.2 such modification could only worsen the expected value of APPR. Note that if s_{last} appears also in OPT, then it is treated as a different copy and kept intact. Hence we do not change the expected value of OPT in this case (or in any other case). Note also that this potential modification does not affect the first source picked by Pick-a-Star since $|\text{APPR}| > 1$.

Define $S_0 = \text{APPR} \cap \text{OPT}$, $S_1 = \text{APPR} - S_0$, and $S_2 = \text{OPT} - S_0$. For each $i = 0, 1, 2$, let C_i and P_i be the collective cost and success probability of the sources in S_i. Note that if the success probability of source s_{last} is modified in APPR as mentioned above and s_{last} also appears in OPT, then the two copies of s_{last} in APPR and OPT are viewed as distinct sources and thus s_{last} will not be included in S_0. On the other hand, if s_{last} is not modified in APPR and s_{last} appears in OPT, then the two copies of s_{last} in APPR and OPT are viewed as the same source and thus s_{last} will be included in S_0. Observe that

$$\forall s_i \in S_1 \forall s_j \in S_2, \frac{c_i}{p_i} \leq \frac{c_j}{p_j}. \tag{3.3}$$

Let us first consider the (easier) case in which $S_2 = \emptyset$. Observe that $S_1 \subseteq \{s_1, \ldots, s_{last}\}$. Since the collective failure probability of $\text{APPR} - \{s_{last}\}$ is greater than $c_{last}/p_{last} \geq \cdots \geq c_1/p_1$, every element of S_1 is profitable in the set $\text{APPR} - \{s_{last}\}$. By Lemma 3.2, $V(\text{APPR} - \{s_{last}\}) \geq V(\text{OPT} - \{s_{last}\})$. We also know that $V(\text{APPR}) \geq V(\text{APPR} - \{s_{last}\})$ by Lemma 3.2. Since $V(\text{APPR}) \geq V(\{s_{last}\})$ and $V(\text{OPT}) \leq V(\text{OPT} - \{s_{last}\}) + V(\{s_{last}\})$ by Lemma 3.1,

$$2V(\text{APPR}) \geq V(\text{OPT} - \{s_{last}\}) + V(\{s_{last}\}) \geq V(\text{OPT}).$$

Now suppose that $S_2 \neq \emptyset$. Since OPT is irreducible and Pick-a-Star picks sources until no remaining source can be profitable, $S_1 \neq \emptyset$. Let $m = |S_2|$ and $l = |S_1|$. Let

$$\alpha_1 = \max_{s_i \in S_1} \frac{c_i}{p_i(1-P_0)} \leq \frac{c_{last}}{p_{last}(1-P_0)},$$
$$\alpha_2 = \min_{s_i \in S_2} \frac{c_i}{p_i(1-P_0)}.$$

By relation 3.3, clearly $\alpha_1 \leq \alpha_2$. The next lemma relating α_1, α_2 to P_1, P_2 is a key to our analysis.

LEMMA 3.3. (i) $\alpha_1 \leq 1 - P_1 \leq \alpha_2$ *and* (ii) $1 - P_2 \geq \alpha_2^{\frac{m}{m-1}}$.

Proof. Recall that we have assumed that $(1 - P_0)(1 - P_1) \geq c_{last}/p_{last}$. Thus $1 - P_1 \geq \alpha_1$. Since Pick-a-Star stopped before picking anything from S_2, $(1 - P_0)(1 - P_1) \leq c_i/p_i$ for any $s_i \in S_2$. These prove (i). To prove (ii), let $p_{min} = \min_{s_i \in S_2} p_i$. Since OPT is irreducible, $(1 - P_0)(1 - P_2)/(1 - p_{min}) \geq c_{min}/p_{min} \geq (1 - P_0)\alpha_2$. So,

$$(1 - P_2)^{\frac{m-1}{m}} \geq (1 - P_2)/(1 - p_{min}) \geq \alpha_2,$$

i.e., $1 - P_2 \geq \alpha_2^{\frac{m}{m-1}}$. ◻

Now we want to find a lower bound for the ratio

$$\frac{V(\text{APPR})}{V(\text{OPT})} = \frac{P_0 - C_0 + (1-P_0)P_1 - C_1}{P_0 - C_0 + (1-P_0)P_2 - C_2}. \tag{3.4}$$

Since $V(S_0) \geq V(S_2)/m$ by the choice of the first source picked by Pick-a-Star and the fact that S_0 is irreducible,

$$V(\text{OPT}) \leq V(S_0) + V(S_2) \leq (m+1)V(S_0).$$

This implies

$$\frac{(1-P_0)P_2 - C_2}{P_0 - C_0 + (1-P_0)P_2 - C_2} \leq \frac{m}{m+1}.$$

Define

$$r = \frac{(1-P_0)P_1 - C_1}{(1-P_0)P_2 - C_2}. \tag{3.5}$$

To obtain a lower bound of 1/2 for the ratio in equality (3.4), we need

$$\frac{1}{m+1} + r\frac{m}{m+1} \geq \frac{1}{2}, \quad \text{i.e.,} \quad r \geq \frac{m-1}{2m}, \tag{3.6}$$

which we show below. The following lemma gives a clean lower bound for ratio r.

LEMMA 3.4.

$$r \geq \min_{\alpha_1 \leq 1-P_1 \leq \alpha_2} \frac{P_1 - l(1-(1-P_1)^{1/l})\alpha_1}{(1-\alpha_2^{m/(m-1)})(1-\alpha_2)}.$$

Proof. Observe that

$$\begin{aligned} r &= \frac{(1-P_0)P_1 - (\sum_{s_i \in S_1} p_i \frac{c_i}{p_i})}{(1-P_0)P_2 - C_2} \\ &\geq \frac{(1-P_0)P_1 - (\sum_{s_i \in S_1} p_i)(1-P_0)\alpha_1}{(1-P_0)P_2 - C_2} \\ &\geq \frac{P_1 - (\sum_{s_i \in S_1} p_i)\alpha_1}{P_2 - C_2/(1-P_0)} \\ &\geq \frac{P_1 - (\sum_{s_i \in S_1} p_i)\alpha_1}{P_2 - P_2\alpha_2} \\ &\geq \frac{P_1 - (\sum_{s_i \in S_1} p_i)\alpha_1}{(1-\alpha_2^{m/(m-1)})(1-\alpha_2)}. \end{aligned}$$

The last step follows from (ii) of Lemma 3.3. Since

$$\sum_{s_i \in S_1} (1-p_i) \geq l \left[\prod_{s_i \in S_1} (1-p_i) \right]^{1/l} = l(1-P_1)^{1/l},$$

$\sum_{s_i \in S_1} p_i \leq l - l(1-P_1)^{1/l}$. Hence the lemma follows from (i) of Lemma 3.3. ◻

Now we try to simplify the lower bound function.[3]

CLAIM 3.5. *The ratio*

$$\frac{P_1 - l(1-(1-P_1)^{1/l})\alpha_1}{(1-\alpha_2^{m/(m-1)})(1-\alpha_2)}$$

is increasing in P_1 when $1 - P_1 \geq \alpha_1$.

By Lemma 3.3, the smallest P_1 can be is $1 - \alpha_2$. The above ratio is clearly decreasing in $\alpha_1 \leq \alpha_2$. For convenience, let $x = \alpha_2$. We set $P_1 = 1 - x$ and $\alpha_1 = x$, and we get

$$r \geq \frac{1}{1-x^{m/(m-1)}}\left[\frac{1-x-l(1-x^{1/l})x}{1-x}\right]. \tag{3.7}$$

CLAIM 3.6. *The right-hand side of inequality* (3.7) *is nonincreasing in l.*

Taking the limit

$$\lim_{l\to\infty} l(1-x^{1/l}) = \lim_{l\to\infty}\frac{1-x^{1/l}}{1/l} = \lim_{l\to\infty}\frac{(-x^{1/l})(\ln x)(-1/l^2)}{-1/l^2} = -\ln x,$$

we get

$$r \geq \frac{1}{1-x^{m/(m-1)}}\left[\frac{1-x+x\ln x}{1-x}\right]. \tag{3.8}$$

CLAIM 3.7. *The right-hand side of inequality* (3.8) *is decreasing in $x \in (0,1)$.*

Since the right-hand side expression is undefined at $x = 1$, we take the limit

$$\begin{aligned}
r &\geq \lim_{x\to1}\left[\frac{1}{1-x^{m/(m-1)}}\left(\frac{1-x+x\ln x}{1-x}\right)\right]\\
&= \lim_{x\to1}\frac{1-x+x\ln x}{1-x-x^{\frac{m}{m-1}}+x^{\frac{2m-1}{m-1}}}\\
&= \lim_{x\to1}\frac{-1+\ln x+x/x}{-1-\frac{m}{m-1}x^{\frac{1}{m-1}}+\frac{2m-1}{m-1}x^{\frac{m}{m-1}}}\\
&= \lim_{x\to1}\frac{1/x}{-\frac{m}{m-1}\frac{1}{m-1}x^{\frac{2-m}{m-1}}+\frac{2m-1}{m-1}\frac{m}{m-1}x^{\frac{1}{m-1}}}\\
&= \frac{1}{-\frac{m}{(m-1)^2}+\frac{m(2m-1)}{(m-1)^2}} = \frac{1}{\frac{m}{m-1}(\frac{-1+2m-1}{m-1})}\\
&= \frac{m-1}{2m}.
\end{aligned}$$

This verifies inequality (3.6) and completes the proof that $V(\text{APPR})/V(\text{OPT}) \geq 1/2$.

THEOREM 3.8. *Pick-a-Star produces a single-batch policy with an expected value that is at least half of the optimum.*

[3]The proofs of the claims appear in the appendix.

3.2. Extending Pick-a-Star to a PTAS. The extension of the algorithm is straightforward. Let $r \geq 1$ be any fixed constant. The new algorithm iterates over all possible choices of at most r sources and schedules the rest of the sources based on the cost-to-success probability ratio using the same stopping criterion. It then outputs the best policy found in all iterations. Call the new algorithm Pick-r-Stars. Clearly, it runs in $O(n^{r+1})$ time. We show that Pick-r-Stars achieves an approximation ratio of $\frac{r-1}{r+1}$. The analysis is different from the previous subsection in that we will make use of the r sources in the optimal policy with the highest success probability instead of the the most profitable ones. We would like to remark here that this new strategy does not work for Pick-a-Star, nor does our analysis of Pick-a-Star work for general r because the best lower bound that the analysis yields for the ratio defined in equality (3.5) is $\frac{m-1}{2m}$.

Let APPR be the policy found by Pick-r-Stars and OPT an optimal policy. As in the previous subsection, we assume without loss of generality that (i) $|\text{APPR}| > r$ and $|\text{OPT}| > r$, (ii) APPR contains the r sources in OPT with the highest success probability, and (iii) the collective failure probability of APPR is at least the ratio c_{last}/p_{last}, where s_{last} is the last source picked by Pick-r-Stars. Since OPT is irreducible, we can also assume that APPR $\not\subseteq$ OPT, because otherwise APPR = OPT.

Again, let $S_0 = \text{APPR} \cap \text{OPT}$, $S_1 = \text{APPR} - S_0$, and $S_2 = \text{OPT} - S_0$ and the corresponding collective costs and success probabilities C_i and P_i, for each $i = 0, 1, 2$. We also have $c_i/p_i \leq c_j/p_j$ for all $s_i \in S_1, s_j \in S_2$. Define $l = |S_1|$, $m = |S_2|$, and

$$\begin{aligned}
\alpha_0 &= \max_{s_i \in S_0} \frac{c_i}{p_i}, \\
\alpha_1 &= \max_{s_i \in S_1} \frac{c_i}{p_i} \leq \frac{c_{last}}{p_{last}(1-P_0)}, \\
\alpha_2 &= \min\left\{1,\ \min_{s_i \in S_2} \frac{c_i}{p_i}\right\}.
\end{aligned}$$

Then we again have

$$\alpha_1 \leq (1-P_0)(1-P_1) \leq \alpha_2. \tag{3.9}$$

To obtain a clean lower bound for the approximation ratio $V(\text{APPR})/V(\text{OPT})$, we go through a sequence of simplifying steps. In the process we will guarantee that the ratio $V(\text{APPR})/V(\text{OPT})$ never improves and inequality (3.9) always holds.

First, we will assume that $|S_0| = r$, i.e., APPR and OPT share exactly r common sources, by the following argument. Let $s_i \in S_0$ be any source. Then

$$\begin{aligned}
\frac{V(\text{APPR})}{V(\text{OPT})} &= \frac{1-(1-P_0)-C_0+(1-P_0)P_1-C_1}{1-(1-P_0)-C_0+(1-P_0)P_2-C_2} \\
&= \frac{\frac{1}{1-p_i}-\frac{1-P_0}{1-p_i}-\frac{C_0}{1-p_i}+\frac{(1-P_0)P_1}{1-p_i}-\frac{C_1}{1-p_i}}{\frac{1}{1-p_i}-\frac{1-P_0}{1-p_i}-\frac{C_0}{1-p_i}+\frac{(1-P_0)P_2}{1-p_i}-\frac{C_2}{1-p_i}} \\
&= \frac{\frac{1-c_i}{1-p_i}-\frac{1-P_0}{1-p_i}-\frac{C_0-c_i}{1-p_i}+\frac{(1-P_0)P_1}{1-p_i}-\frac{C_1}{1-p_i}}{\frac{1-c_i}{1-p_i}-\frac{1-P_0}{1-p_i}-\frac{C_0-c_i}{1-p_i}+\frac{(1-P_0)P_2}{1-p_i}-\frac{C_2}{1-p_i}} \\
&> \frac{1-\frac{1-P_0}{1-p_i}-\frac{C_0-c_i}{1-p_i}+\frac{(1-P_0)P_1}{1-p_i}-\frac{C_1}{1-p_i}}{1-\frac{1-P_0}{1-p_i}-\frac{C_0-c_i}{1-p_i}+\frac{(1-P_0)P_2}{1-p_i}-\frac{C_2}{1-p_i}}.
\end{aligned}$$

The last step holds because $p_i - c_i = V(\{s_i\}) > 0$ and thus $1 - c_i > 1 - p_i$. Hence we can define a new pair of APPR and OPT by removing the source s_i and dividing the cost of every remaining source in S_0 by $1 - p_i$. Clearly inequality (3.9) still holds for the new pair.

Second, we can assume that $\alpha_1 = \alpha_2 = (1 - P_0)(1 - P_1)$. This can be achieved by increasing the cost of each source in S_1 and decreasing the cost of each source in S_2. So now, $c_i = \alpha_1 p_i$ for each $s_i \in S_1 \cup S_2$.

Third, we assume without loss of generality that the r sources in S_0 have the same success probability $p = 1 - (1 - P_0)^{1/r}$. Since these sources are assumed to have the largest success probability in OPT, $p_i \le p$ for each $s_i \in S_2$. Moreover, we can assume that $p_i = p$ for each $s_i \in S_2$ by the following argument. If $p_i < p$, we increase p_i to p and c_i to $\alpha_1 p$. By Lemma 3.2, this improves $V(\text{OPT})$ because the set OPT is irreducible. If this results in a set that is not irreducible, we can make it irreducible by dropping some sources in S_2, again improving the expected value of OPT.

Fourth, we can assume that $c_i/p_i = \alpha_0$ for all $s_i \in S_0$. The condition can be achieved by increasing the costs of the sources in S_0. This would decrease the expected value of both APPR and OPT by the same amount and thus decrease the ratio $V(\text{APPR})/V(\text{OPT})$.

Finally, we can worsen APPR by assuming that

$$p_i = 1 - (1 - P_1)^{1/l} = 1 - (\alpha_1/(1 - P_0))^{1/l} = 1 - (\alpha_1/(1 - p)^r)^{1/l}$$

for each $p_i \in S_1$, as mentioned in the previous subsection.

Now we have clean formulas for the expected values:

$$\begin{aligned} V(\text{APPR}) &= 1 - (1 - p)^r \frac{\alpha_1}{(1 - p)^r} - \alpha_0 r p - l\alpha_1 \left[1 - \left(\frac{\alpha_1}{(1 - p)^r}\right)^{1/l}\right], \\ V(\text{OPT}) &= 1 - (1 - p)^{r+m} - \alpha_0 r p - \alpha_1 m p. \end{aligned}$$

We further simplify the formulas by getting rid of l and m.

LEMMA 3.9.

$$V(\text{APPR}) \ge 1 - \alpha_1 - \alpha_0 r p + \alpha_1 \ln\left(\frac{\alpha_1}{(1 - p)^r}\right).$$

Proof. Since $\alpha_1/(1 - p)^r < 1$ by inequality 3.9, the function $-l\alpha_1[1 - (\frac{\alpha_1}{(1-p)^r})^{1/l}]$ is nonincreasing in l by Claim 3.6 in the last subsection. Taking the limit, we get $V(\text{APPR}) \ge \lim_{l\to\infty} 1 - \alpha_1 - \alpha_0 r p - l\alpha_1(1 - (\frac{\alpha_1}{(1-p)^r})^{1/l})$ or

$$V(\text{APPR}) \ge 1 - \alpha_1 - \alpha_0 r p + \alpha_1 \ln\left(\frac{\alpha_1}{(1 - p)^r}\right). \qquad \square$$

LEMMA 3.10.

$$V(\text{OPT}) \le 1 + \frac{\alpha_1 p}{\ln(1 - p)} - \alpha_0 r p - \frac{\alpha_1 p}{\ln(1 - p)} \ln\left[\frac{-\alpha_1 p}{(1 - p)^r \ln(1 - p)}\right].$$

Proof. We can treat m as a continuous variable and maximize $1 - (1 - p)^{r+m} - \alpha_0 r p - \alpha_1 m p$ over all real values of m. Taking the derivative with respect to m and setting it to 0, we get

$$m = \frac{1}{\ln(1 - p)} \ln\left(\frac{-\alpha_1 p}{(1 - p)^r \ln(1 - p)}\right).$$

Hence

$$\max_m 1-(1-p)^{r+m}-\alpha_0 rp-\alpha_1 mp = 1+\frac{\alpha_1 p}{\ln(1-p)}$$
$$-\alpha_0 rp-\frac{\alpha_1 p}{\ln(1-p)}\ln\frac{-\alpha_1 p}{(1-p)^r\ln(1-p)}. \qquad \square$$

Now we are ready to show that $V(\text{APPR})/V(\text{OPT}) \geq (r-1)/(r+1)$. It suffices to prove that

$$\frac{V(\text{OPT})-V(\text{APPR})}{V(\text{APPR})} \leq \frac{2}{r-1}. \tag{3.10}$$

We first give an overestimate of the difference $V(\text{OPT})-V(\text{APPR})$. The following simple mathematical facts for $0<p<1$ will be useful:

$$\begin{aligned}
p \ < \ -\ln(1-p) &= p+\frac{p^2}{2}+\frac{p^3}{3}+\cdots < \ \frac{p}{1-p},\\
0 \ < \ 1+\frac{p}{\ln(1-p)} &= 1-\frac{1}{1+p/2+p^2/3+\cdots}\\
&< 1-\frac{1}{1+p+p^2+\cdots}\\
&= p\\
-\ln\left(\frac{-p}{\ln(1-p)}\right) &= -\ln\left(1-\left(1+\frac{p}{\ln(1-p)}\right)\right)\\
&> 1+\frac{p}{\ln(1-p)}.
\end{aligned}$$

Let $f_1(\alpha_1)=\alpha_1 p^2-\alpha_1 p\ln(\frac{\alpha_1}{(1-p)^r})$.

LEMMA 3.11. $V(\text{OPT})-V(\text{APPR})<f_1(\alpha_1)$.

Proof. From Lemmas 3.9 and 3.10, we know

$$\begin{aligned}
V(\text{OPT})-V(\text{APPR}) \leq{}& \alpha_1\left(1+\frac{p}{\ln(1-p)}\right)-\alpha_1\left(1+\frac{p}{\ln(1-p)}\right)\ln\left(\frac{\alpha_1}{(1-p)^r}\right)\\
&-\frac{\alpha_1 p}{\ln(1-p)}\ln\left(\frac{-p}{\ln(1-p)}\right).
\end{aligned}$$

Therefore,

$$\begin{aligned}
V(\text{OPT})-V(\text{APPR}) &< \alpha_1\left(1+\frac{p}{\ln(1-p)}\right)-\alpha_1 p\ln\left(\frac{\alpha_1}{(1-p)^r}\right)\\
&\quad+\frac{\alpha_1 p}{\ln(1-p)}\left(1+\frac{p}{\ln(1-p)}\right)\\
&= \alpha_1\left(1+\frac{p}{\ln(1-p)}\right)^2-\alpha_1 p\ln\left(\frac{\alpha_1}{(1-p)^r}\right)
\end{aligned}$$

or

$$V(\text{OPT})-V(\text{APPR}) \leq \alpha_1 p^2-\alpha_1 p\ln\left(\frac{\alpha_1}{(1-p)^r}\right). \qquad \square$$

Next we find an underestimate of $V(\text{APPR})$. Observe that the following conditions follow from inequality (3.9), the simplifying assumptions on the sources in S_i (e.g., $\forall\, s_i \in S_0, c_i/p_i = \alpha_0$), and the arguments for the second claim of Lemma 3.3:

$$(1-p)^r > \alpha_1,$$

$$(1-p)^{r-1} = ((1-p)^r)^{\frac{r-1}{r}} > \alpha_0.$$

Let $f_2(\alpha_1) = \frac{r(r-1)}{2}(1-p)^{r-2}p^2 + \alpha_1 \ln(\frac{\alpha_1}{(1-p)^r}) + (1-p)^r - \alpha_1$.

Lemma 3.12.

$$V(\text{APPR}) > f_2(\alpha_1) = \frac{r(r-1)}{2}(1-p)^{r-2}p^2 + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + (1-p)^r - \alpha_1.$$

Proof.

$$\begin{aligned} V(\text{APPR}) &\geq 1 - \alpha_1 - \alpha_0 rp + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) \\ &= 1 - (1-p)^r - \alpha_0 rp + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + (1-p)^r - \alpha_1 \\ &> 1 - (1-p)^r - (1-p)^{r-1} rp + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + (1-p)^r - \alpha_1 \\ &= p^2(1 + 2(1-p) + \cdots + (r-1)(1-p)^{r-2}) + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) \\ &+ (1-p)^r - \alpha_1. \end{aligned}$$

Thus

$$V(\text{APPR}) > \frac{r(r-1)}{2}(1-p)^{r-2}p^2 + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + (1-p)^r - \alpha_1. \qquad \square$$

Hence we have the following clean lower bound on the ratio $\frac{V(\text{OPT})-V(\text{APPR})}{V(\text{APPR})}$.

Lemma 3.13.

$$\frac{V(\text{OPT}) - V(\text{APPR})}{V(\text{APPR})} > \min_{\alpha_1 < (1-p)^r} \frac{f_1(\alpha_1)}{f_2(\alpha_1)}.$$

Lemma 3.14. *For all* $\alpha_1 < (1-p)^r$, $f_1(\alpha_1)/f_2(\alpha_1) > 1/(r-1)$.

Proof. First consider the case $\alpha_1 \geq (1-p)^{2r-1}$. Let $\alpha_1 = (1-p)^x$. Hence $r < x \leq 2r-1$. Observe that because the function $y \ln y + 1 - y$ is positive for all $y > 0$,

$$\alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + (1-p)^r - \alpha_1 = (1-p)^r \left(\frac{\alpha_1}{(1-p)^r} \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + 1 - \frac{\alpha_1}{(1-p)^r}\right) > 0.$$

This means $f_2(\alpha_1) > \frac{r(r-1)}{2}(1-p)^{r-2}p^2$. Thus

$$\frac{f_1(\alpha_1)}{f_2(\alpha_2)} < \frac{(1-p)^x p^2 - (x-r)(1-p)^x p \ln(1-p)}{\frac{r(r-1)}{2}(1-p)^{r-2}p^2}$$

$$
\begin{aligned}
&< \frac{(1-p)^x p^2 + (x-r)(1-p)^{x-1}p^2}{\frac{r(r-1)}{2}(1-p)^{r-2}p^2} \\
&< \frac{1+x-r}{r(r-1)/2} \\
&\le \frac{2r}{r(r-1)} \\
&= \frac{2}{r-1}.
\end{aligned}
$$

When $\alpha_1 \le (1-p)^{2r-1}$, we claim that the function $f_2(\alpha_1) - \frac{r-1}{2} f_1(\alpha_1)$ is decreasing in α_1.

CLAIM 3.15. *The function*

$$
\begin{aligned}
f_2(\alpha_1) - \frac{r-1}{2} f_1(\alpha_1) = {}& \frac{r(r-1)}{2}(1-p)^{r-2}p^2 + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) \\
&+ (1-p)^r - \alpha_1 - \frac{r-1}{2}\left(\alpha_1 p^2 - \alpha_1 p \ln\left(\frac{\alpha_1}{(1-p)^r}\right)\right)
\end{aligned}
$$

is decreasing in α_1 *for* $\alpha_1 \le (1-p)^{2r-1}$.

Hence, for any $\alpha_1 \le (1-p)^{2r-1}$,

$$
f_2(\alpha_1) - \frac{r-1}{2} f_1(\alpha_1) \ge f_2((1-p)^{2r-1}) - \frac{r-1}{2} f_1((1-p)^{2r-1}) > 0. \qquad \square
$$

This concludes the analysis for Pick-r-Stars.

THEOREM 3.16. *Pick-r-Stars produces a single-batch policy with an expected value that is at least* $(r-1)/(r+1)$ *of the optimum.*

4. Approximating optimal k-batch policies.

Here we present an algorithm for the linear cost and time threshold (LT) model that approximates optimal k-batch policies with a constant ratio 1/5. Recall that our simplifying assumption here is that time durations are equal; consequently, optimal batched policies exist. The k-batch approximation algorithm, called Reverse-Greedy, is illustrated in Figure 4.1. The algorithm works by constructing an irreducible policy. It greedily constructs the policy batch by batch, starting from the last batch (rightmost) and going in reverse time. For each batch it invokes the single-batch algorithm Pick-a-Star, but with a modified profitability criterion that follows from equality (3.1) of Lemma 3.2 (see the comments following the lemma). Even though each source is profitable at the time it is added to a partially constructed batch, the completed batch may not be irreducible, i.e., some of the sources picked before the last source may become nonprofitable after the addition of the last source. Thus after each call to Pick-a-Star, the algorithm scans back over the newly created batch and drops any source that is nonprofitable. In this way, the final policy is surely irreducible. Clearly Reverse-Greedy can be implemented to run in time $O(kn^2)$.

The analysis of Reverse-Greedy makes use of Theorem 3.8. The difficulty here is that because the sources can be scheduled in different batches, some batches of an optimal k-batch policy could be arbitrarily better individually than their counterparts in APPR. To get around this, we relate an irreducible k-batch policy to its optimally serialized version. For any policy $\mathcal{P}$, let $\overline{\mathcal{P}}$ denote the optimal serial policy for the sources in $\mathcal{P}$. It is not hard to see that $V(\overline{\mathcal{P}}) \ge V(\mathcal{P})$. Note that a serial policy $\overline{\mathcal{P}}$ may violate the time threshold, however we use $V(\overline{\mathcal{P}})$ in the analysis as a means

```
1.  Sort the sources so that $c_1/p_1 \leq \cdots \leq c_n/p_n$.
2.  APPR $= \emptyset$.    (* APPR denotes the $k$-batch policy. *)
3.  For $i := k$ downto 1
4.    $S = \emptyset$.    (* $S$ is the best $i$th batch found so far. *)
5.    $Q = 1$.    (* $Q$ is the collective failure probability of $S$. *)
6.    For $j := 1$ to $n$, where $s_j \notin$ APPR
7.      $S_1 := \{s_j\}$.
8.      $Q_1 := 1 - p_j$.    (* $Q_1$ is the collective failure probability of $S_1$. *)

19. Output policy APPR.
```

FIG. 4.1. *The algorithm Reverse-Greedy.*

of bounding the value of an optimal scheduling of the sources in $\mathcal{P}$. First, let us characterize an optimal serial policy.

LEMMA 4.1. *For any set of sources, an optimal serial policy (including all sources in the set) sorts the sources in the nondecreasing order of their cost to success probability ratios.*

Proof. Consider any serial policy $\mathcal{P} = s_{i_1}, \ldots, s_{i_m}$. Then

$$V(\mathcal{P}) = p_{i_1} - c_{i_1} + (1 - p_{i_1})(p_{i_2} - c_{i_2}) + \cdots + \prod_{j=1}^{m-1}(1 - p_{i_j})(p_{i_m} - c_{i_m}).$$

Hence swapping source s_{i_j} and source $s_{i_{j+1}}$ would result in a net value of

$$\begin{aligned}&\prod_{l=1}^{j-1}(1 - p_{i_l})(p_{i_{j+1}} - c_{i_{j+1}} + (1 - p_{i_{j+1}})(p_{i_j} - c_{i_j}))\\ &- \prod_{l=1}^{j-1}(1 - p_{i_l})(p_{i_j} - c_{i_j} + (1 - p_{i_j})(p_{i_{j+1}} - c_{i_{j+1}}))\\ &\qquad = \prod_{l=1}^{j-1}(1 - p_{i_l})(p_{i_{j+1}}c_{i_j} - p_{i_j}c_{i_{j+1}}),\end{aligned}$$

which is positive if $c_{i_{j+1}}/p_{i_{j+1}} < c_{i_j}/p_{i_j}$. ∎

The following property of optimal serial policies is a side product of the above lemma and will be useful in the analysis.

COROLLARY 4.2. *Let S_1 and S_2 be two sets of sources and $S_1 \subseteq S_2$. An optimal serial policy for S_2 gives an expected value at least that of an optimal serial policy for S_1.*

Proof. Recall our basic assumption from section 3 that $p_i \geq c_i$ for all sources s_i. As a consequence an optimal serial policy for the sources in S_2 exists that includes all the sources in S_2. Starting from such an optimal serial policy for S_2, we can gradually swap the sources that are not in S_1 towards the end of the sequence and eventually remove them. By Lemma 4.1, no such swap or removal can increase the expected value. ▯

The following lemma, which is somewhat surprising, is a key to our analysis. It states that serializing an irreducible batched policy can at most triple the expected value.

LEMMA 4.3. *Let P denote the success probability of an irreducible batched policy $\mathcal{P}$. Then $V(\overline{\mathcal{P}}) \leq (2+P)V(\mathcal{P})$.*

Proof. The proof is by induction on the number of sources of the policy. Assume that the statement holds for any irreducible policy consisting of $n-1 \geq 1$ sources, and consider an irreducible policy $\mathcal{P}$ consisting of n sources. Let S denote the set of sources in the first (leftmost) batch and s_n denote a source in S. In order to maximize the difference between $V(\overline{\mathcal{P}})$ and $V(\mathcal{P})$ we assume that the cost-to-success-probability ratios of all the sources in S are at the maximum possible (without violating the irreducibility condition). We perturb the initial policy $\mathcal{P}$ and transform it into another irreducible policy $\mathcal{P}'$, by moving s_n to the left in the time-line so that it finishes before all the other sources. We increase the cost of source s_n and other sources in S by amounts to be described below. Note that policy $\mathcal{P}'$ will not be different from policy $\mathcal{P}$ if $S - \{s_n\} = \emptyset$. Due to the potential increase in costs in the transformation, we will see that $V(\mathcal{P}') \leq V(\mathcal{P})$ and $V(\overline{\mathcal{P}'}) \leq V(\overline{\mathcal{P}})$. We first show that

$$2\,(V(\mathcal{P}) - V(\mathcal{P}')) \geq V(\overline{\mathcal{P}}) - V(\overline{\mathcal{P}'}). \tag{4.1}$$

We complete the proof by showing, using the inductive hypothesis, that the statement of the lemma holds for policy $\mathcal{P}'$.

Let Q denote the collective failure probability of the sources in S and V_a denote the expected value of policy $\mathcal{P}$ without batch S. Let $S' = S - \{s_n\}$. Since the cost-to-success-probability ratios of sources in S are as high as possible, we have $c_i/p_i = Q/(1-p_i)(1-V_a)$ for $s_i \in S$ according to the definition of irreducibility. Let c'_n and c'_i be the costs of sources s_n and $s_i \in S'$ in policy $\mathcal{P}'$. Again, we set these costs to be as high as they can be: $c'_i = p_i(Q/(1-p_i)(1-p_n))(1-V_a) = c_i/(1-p_n)$ and $c'_n = p_n(Q/(1-p_n) + \sum_{s_i\in S'} c'_i - Q/(1-p_n)V_a)$. Therefore we have that $\forall s_i \in S', c'_i - c_i = c'_i - (1-p_n)c'_i = c'_i p_n$ and $c'_n - c_n = \sum_{s_i\in S'} p_n c'_i$. Thus the change in the cost of s_n is equal to the total change in the costs of the sources in S'.

We have $V(\mathcal{P}') = 1 - Q - c'_n - (1-p_n)\sum_{s_i\in S'} c'_i + QV_a$, and $V(\mathcal{P}) = 1 - Q - \sum_{s_i\in S} c_i + QV_a$. Thus $V(\mathcal{P}) - V(\mathcal{P}') = c'_n - c_n = p_n \sum_{s_i\in S'} c'_i$. In other words, in going from policy $\mathcal{P}'$ to policy $\mathcal{P}$, only the reduction in the cost of source s_n is felt in the increase of the expected value. Observe that this reduction is exactly half of the total change in all costs. Now it is easy to see that $2\,(V(\mathcal{P}) - V(\mathcal{P}')) \geq V(\overline{\mathcal{P}}) - V(\overline{\mathcal{P}'})$: In the transition from the optimal serial policy $\overline{\mathcal{P}'}$ to the optimal serial policy $\overline{\mathcal{P}}$, the reduction in the costs of both source s_n and the sources in S', which is twice the reduction in the cost of source s_n, is reflected in the increase of the expected value. However, $V(\overline{\mathcal{P}}) - V(\overline{\mathcal{P}'}) \leq 2p_n \sum_{s_i\in S'} c'_i$, since in a serial policy the effect of a cost reduction on each source is reduced due to the success probability of the sources queried earlier.

Next we show

$$V(\overline{\mathcal{P}'}) \leq (2+P)V(\mathcal{P}'). \tag{4.2}$$

Note that source s_n is the only scheduled source in the leftmost batch of policy $\mathcal{P}'$, and since its cost-to-success-probability ratio c_n/p_n is maximized, $c_n/p_n = 1 - V$, where V denotes the expected value of the policy $\mathcal{P}'$ excluding s_n. Again, since c_n/p_n is maximized, $V = V(\mathcal{P}')$, i.e., the presence of s_n in $\mathcal{P}'$ does not increase $V(\mathcal{P}')$ (see Lemma 3.2). Hence $c_n/p_n = 1 - V(\mathcal{P}')$. Consider the subpolicy A consisting of the sources in $\mathcal{P}'$ with cost-to-success-probability ratio less than $1 - V(\mathcal{P}')$, and let P_A denote its success probability. Let B denote the subpolicy consisting of the rest of the sources in $\mathcal{P}'$ with success probability P_B. The sources in B have higher cost-to-success-probability ratios than the sources in A; hence they are queried later than the sources in A in policy $\overline{\mathcal{P}'}$. Therefore we have $V(\overline{\mathcal{P}'}) = V(\overline{A}) + (1 - P_A)V(\overline{B})$. Since $\mathcal{P}'$ is irreducible, $V(A) \le V(\mathcal{P}')$, and because subpolicy A is irreducible and does not include s_n, we have $V(\overline{A}) \le (2 + P_A)V(A) \le (2 + P_A)V(\mathcal{P}')$ by induction. It is not hard to see that $V(\overline{B}) \le P_B V(\mathcal{P}')$: Let the sources in B be $s_1, \ldots, s_m$, and let α_i denote the cost-to-success-probability ratio of s_i, where $\alpha_1 \le \cdots \le \alpha_m$. Then

$$\begin{aligned} V(\overline{B}) &= p_1(1-\alpha_1) + (1-p_1)p_2(1-\alpha_2) + \cdots + \left(\prod_{i=1}^{m-1}(1-p_i)\right) p_m(1-\alpha_m) \\ &\le \left(p_1 + (1-p_1)p_2 + \cdots + \left(\prod_{i=1}^{m-1}(1-p_i)\right) p_m\right)(1-\alpha_1) \\ &\le P_B V(\mathcal{P}'). \end{aligned}$$

Therefore

$$\begin{aligned} V(\overline{\mathcal{P}'}) &= V(\overline{A}) + (1-P_A)V(\overline{B}) \\ &\le 2V(\mathcal{P}') + P_A V(\mathcal{P}') + (1-P_A)P_B V(\mathcal{P}') \\ &= 2V(\mathcal{P}') + (P_A + (1-P_A)P_B)V(\mathcal{P}') \\ &= (2+P)V(\mathcal{P}'). \end{aligned}$$

We complete the proof using inequalities (4.1) and (4.2):

$$V(\overline{\mathcal{P}}) \le 2(V(\mathcal{P}) - V(\mathcal{P}')) + V(\overline{\mathcal{P}'})) \le 2V(\mathcal{P}) - 2V(\mathcal{P}') + (2+P)V(\mathcal{P}')$$

or

$$V(\overline{\mathcal{P}}) \le 2V(\mathcal{P}) + PV(\mathcal{P}) = (2+P)V(\mathcal{P}). \qquad \square$$

A similar proof shows that Lemma 4.3 also holds for the general case of an irreducible schedule with sources that can have unequal durations. However the irreducibility criterion is slightly more complicated than what is derived from (3.2) for batched schedules, and unfortunately, unlike for the case for batched schedules, we don't know how to use that fact to derive an approximation algorithm for the general case. The interested reader is referred to [10] for a proof for the general case. Interestingly, serializing a single irreducible batch of sources can at most double the value (this result was used in [1]).

Now we analyze the performance of algorithm Reverse-Greedy. Just as in the case for single-batch policies, we will also use set operations on k-batch policies when there is no ambiguity. Denote the optimal policy as OPT, and partition OPT as

$$\begin{aligned} \mathrm{OPT}_1 &= \mathrm{APPR} \cap \mathrm{OPT}, \\ \mathrm{OPT}_2 &= \mathrm{OPT} - \mathrm{OPT}_1, \end{aligned}$$

where the sources in OPT_1 and OPT_2 are scheduled in the same batches as they are in OPT. By Lemma 3.1,

$$V(\mathrm{OPT}) \le V(\mathrm{OPT}_1) + V(\mathrm{OPT}_2).$$

We compare the performances of OPT_1 and OPT_2 with that of APPR separately.

LEMMA 4.4. *$V(\mathrm{OPT}_1) \le 3V(\mathrm{APPR})$.*

Proof. This follows immediately from Corollary 4.2 and Lemma 4.3. ∎

LEMMA 4.5. *$V(\mathrm{OPT}_2) \le 2V(\mathrm{APPR})$.*

Proof. For each $i = 1, \dots, k$, let $\mathrm{OPT}_2(i)$ and $\mathrm{APPR}(i)$ denote the subpolicies of OPT_2 and APPR consisting of the last $k-i+1$ batches. We prove inductively, starting from the last batch, that $V(\mathrm{OPT}_2(i)) \le 2V(\mathrm{APPR}(i))$. Without loss of generality, we may assume that $V(\mathrm{APPR}(i)) \le V(\mathrm{OPT}_2(i))$ for all i because otherwise we could always replace the last $k-i+1$ batches of OPT_2 with those of APPR and continue with the induction. This could only improve $V(\mathrm{OPT}_2)$.

The base of the induction is clearly true by Theorem 3.8. Note that making each batch irreducible can only increase the expected value of the batch. Suppose that the claim holds for $i+1 \le k$, and consider batch i. Let P_o, C_o be the collective success probability and cost of the sources in the ith batch of OPT_2 and P_a, C_a the corresponding quantities for APPR. By Lemma 3.2,

$$V(\mathrm{APPR}(i)) - V(\mathrm{APPR}(i+1)) = P_a(1 - V(\mathrm{APPR}(i+1))) - C_a,$$

$$V(\mathrm{OPT}_2(i)) - V(\mathrm{OPT}_2(i+1)) = P_o(1 - V(\mathrm{OPT}_2(i+1))) - C_o.$$

Taking the ratio and noting that $V(\mathrm{APPR}(i+1)) \le V(\mathrm{OPT}_2(i+1))$,

$$\begin{aligned}\frac{P_a(1 - V(\mathrm{APPR}(i+1))) - C_a}{P_o(1 - V(\mathrm{OPT}_2(i+1))) - C_o} &= \frac{1 - V(\mathrm{APPR}(i+1))}{1 - V(\mathrm{OPT}_2(i+1))}\left[\frac{P_a - \frac{C_a}{1-V(\mathrm{APPR}(i+1))}}{P_o - \frac{C_o}{1-V(\mathrm{OPT}_2(i+1))}}\right]\\ &\ge \frac{P_a - C_a/(1 - V(\mathrm{APPR}(i+1)))}{P_o - C_o/(1 - V(\mathrm{OPT}_2(i+1)))}\\ &\ge \frac{P_a - C_a/(1 - V(\mathrm{APPR}(i+1)))}{P_o - C_o/(1 - V(\mathrm{APPR}(i+1)))}.\end{aligned}$$

Let set S consist of all sources that do not appear in $\mathrm{APPR}(i+1)$. Clearly, S includes all sources in OPT_2 and thus all sources in the ith batch of OPT_2. Divide the cost of each source by $1 - V(\mathrm{APPR}(i+1))$. Then on input S, Pick-a-Star would return exactly the same set as the ith batch of APPR with expected value being $P_a - C_a/(1 - V(\mathrm{APPR}(i+1)))$. By Theorem 3.8, the value is at least half of the optimal expected value for set S which is in turn at least $P_o - C_o/(1-V(\mathrm{APPR}(i+1)))$. This means

$$2(V(\mathrm{APPR}(i)) - V(\mathrm{APPR}(i+1))) \ge V(\mathrm{OPT}_2(i)) - V(\mathrm{OPT}_2(i+1)),$$

and hence $2V(\mathrm{APPR}(i)) \ge V(\mathrm{OPT}_2(i))$. ∎

Lemmas 4.4 and 4.5 together give the following theorem.

THEOREM 4.6. *Algorithm Reverse-Greedy returns a k-batch policy with an expected value at least $1/5$ of the optimum.*

5. Approximation algorithms for the cost threshold models. We first present an FPTAS for model TL under a weak assumption: $p_i - d_i \geq 0$ for every source s_i (d_i is the time duration of s_i), i.e., every source considered is profitable by itself. The extension to model TT (with no restriction) is straightforward. Note that in model TT our goal is simply to maximize the overall probability of getting the information under the time and cost constraints.

The main idea is the rounding technique introduced in [6] for Knapsack. As mentioned before, in the cost threshold model TL, an optimal policy should be in fact a single-batch policy. Let $\mathcal{P} = \{s_{i_1}, \ldots, s_{i_m}\}$ be a single-batch policy, where $d_{i_1} \leq \cdots \leq d_{i_m}$. Then

$$V(\mathcal{P}) = 1 - \prod_{j=1}^{m}(1 - p_{i_j}) - \sum_{j=1}^{m}\prod_{l=1}^{j-1}(1 - p_{i_l})p_{i_j}d_{i_j} - \prod_{j=1}^{m}(1 - p_{i_j})d_{i_m}.$$

We cannot apply the rounding technique to the above objective function directly because it involves subtractions. We rewrite the expression as

$$\begin{aligned} V(\mathcal{P}) &= \sum_{j=1}^{m}\prod_{l=1}^{j-1}(1 - p_{i_l})p_{i_j}(1 - d_{i_j}) - \prod_{j=1}^{m}(1 - p_{i_j})d_{i_m} \\ &= \sum_{j=1}^{m-1}\prod_{l=1}^{j-1}(1 - p_{i_l})p_{i_j}(1 - d_{i_j}) + \prod_{j=1}^{m-1}(1 - p_{i_j})(p_{i_m} - d_{i_m}). \end{aligned} \tag{5.1}$$

Since $p_i - d_i \geq 0$ by our assumption, every term is nonnegative in (5.1), and we can apply rounding as follows.

Let $\epsilon > 0$ be any desired relative error. Sort the sources in the ascending order of their time durations. We will exhaustively consider every possible choice of s_{i_m}. For each $i \leq n$, consider only policies that includes the source s_i and possibly some others from $\{s_1, \ldots, s_{i-1}\}$, subject to the same cost threshold. Let $\mathrm{OPT}(i)$ denote an optimal such policy. For simplicity, assume that $|\mathrm{OPT}(i)| > 1$. We find a trivial lower bound for $V(\mathrm{OPT}(i))$:

$$V(\mathrm{OPT}(i)) \geq L_i = \max\left\{p_i - d_i, \quad \max_{\substack{j<i \\ c_j + c_i \leq \varsigma}} p_j(1 - d_j)\right\}.$$

Similar to [6], we formulate a new instance by rounding $p_i - d_i$ and each $p_j(1 - d_j)$ *down* to the nearest multiple of $\epsilon L_i/(2i)$. But here we also need round each $1 - p_j$ to the nearest power of $(1 - \epsilon/(2i))^{1/(i-1)}$. In other words, we round each $\log(1 - p_j)$ to the nearest multiple of $(\log(1 - \epsilon/(2i)))/(i - 1)$. We solve the new instance optimally. Let OPT_i denote an optimal policy for the new instance. It is sufficient to bound the difference between $V(\mathrm{OPT}(i))$ and $V(\mathrm{OPT}_i)$ and we do this by obtaining an upper bound between each term of $OPT(i)$ and the corresponding rounded value. Each term difference is upper bounded when the $p_i - d_i$ or $p_i(1 - d_i)$ part of a term is at its maximum L_i and the probability factors in the unrounded term are all 1 (otherwise they are factored out and reduce the difference). Thus we obtain a maximum difference of $L_i - L_i(1 - \frac{\epsilon}{2i})[(1 - \frac{\epsilon}{2i})^{\frac{1}{i-1}}]^{i-1}$ for every term and there can be at most i many:

$$V(\mathrm{OPT}(i)) - V(\mathrm{OPT}_i) \leq i\left(L_i - L_i\left(1 - \frac{\epsilon}{2i}\right)\left[\left(1 - \frac{\epsilon}{2i}\right)^{\frac{1}{i-1}}\right]^{i-1}\right)$$

$$\begin{aligned}&= iL_i\left(1-\left(1-\frac{\epsilon}{2i}\right)^2\right)\\&\le iL_i\left(1-\left(1-\frac{\epsilon}{i}\right)\right)\\&=\epsilon L_i\\&\le \epsilon V(\mathrm{OPT}(i)).\end{aligned}$$

Hence the new instance approximates the original problem with the desired ratio.

We can compute OPT_i for the new instance by dynamic programming in the space $\mathcal{S}_i$ of all possible values of $V(\mathrm{OPT}_i)$. Denote $Q_i = \prod_{j<i}(1-p_j)$. By the above rounding, the cardinality of $\mathcal{S}_i$ is upper bounded by

$$i\left(\frac{2i}{\epsilon}\right)\left(\frac{(i-1)\log Q_i}{\log(1-\epsilon/(2i))}\right) < i\left(\frac{2i}{\epsilon}\right)\left(\frac{2i^2\log Q_i}{-\epsilon}\right) = \frac{-4i^4\log Q_i}{\epsilon^2},$$

which is polynomial in the input size and $1/\epsilon$. In the above inequality, the factor $\frac{2i}{\epsilon}$ represents the number of different values that $p_i - d_i$ and $p_j(1-d_j)$ can have after being rounded to the nearest multiple of $\epsilon L_i/(2i)$, and the factor $\frac{(i-1)\log Q_i}{\log(1-\epsilon/(2i))}$ represents the number of different exponents that a product of the form $\prod_{l=1}^{j-1}(1-p_{i_l})$ can have after being rounded to the nearest power of $(1-\epsilon/(2i))^{1/(i-1)}$.

Rewrite the expression in equality (5.1) as a nested form:

$$p_{i_1}(1-d_{i_1}) + (1-p_{i_1})[p_{i_2}(1-d_{i_2}) + (1-p_{i_2})[\cdots + (1-p_{i_{m-1}})(p_{i_m} - d_{i_m})]].$$

The form easily suggests a backward inductive algorithm. The algorithm will cycle through the list $s_{i-1},\ldots,s_1$. For each $j = i,\ldots,1$ and each possible value $x \in \mathcal{S}_i$, it computes and records a policy of expected value x for the subset of sources $\{s_j,\ldots,s_i\}$ that contains the source s_i and costs the least. The above nested form allows the algorithm to find the cheapest policy of a specific expected value for subset $\{s_j,\ldots,s_i\}$ by expanding the cheapest policies of the same or lower expected values recorded before for subset $\{s_{j+1},\ldots,s_i\}$ to potentially include the source s_j. The running time is at most $O(i^2|\mathcal{S}_i|)$, which is polynomial in the input size and $1/\epsilon$.

THEOREM 5.1. *Assume that $p_i - d_i \ge 0$ for every source s_i. There is an FPTAS for the problem of computing optimal policies in model* TL.

COROLLARY 5.2. *There is an FPTAS for the problem of computing optimal policies in model* TT.

Proof. Recall that the objective function in this case is

$$V(\mathcal{P}) = 1 - \prod_{j=1}^{m}(1-p_{i_j}),$$

which involves only the success probabilities of the sources queried. Hence the above FPTAS works if we simply throw out all sources whose time duration exceeds the deadline. ◻

6. Concluding remarks. As charging for information on the Internet becomes more common, information-acquisition algorithms will have to weigh the benefits of acquiring information against the cost of doing so. Characteristics of these problems are (1) the fact that the information provided by a source cannot be fully predicted in all cases, so the benefit of asking for information can be uncertain, (2) the fact that there can be monetary and time costs associated with information requests, and (3) the fact that information providers can be accessed both serially and in parallel.

We have developed a model that takes into account these aspects of information scheduling and have established worst-case complexity and approximation results for a variety of objective functions: those in which the value is linear in the cost or time attributes and the consumer supplies a cost and/or time threshold for acquiring information. All of these models have plausible applications for information access on the World Wide Web.

Appendix A. Verifying the claims. We prove the claims made on the behavior of the various functions that came up in the main proofs.

Proof of Claim 3.5. We show that the function $P_1 - l(1-(1-P_1)^{1/l})\alpha_1$ is decreasing in P_1, where $1 - P_1 \geq \alpha_1$.

We take the derivative with respect to P_1 and get

$$1 - \alpha_1(1-P_1)^{\frac{1}{l}-1} = 1 - \frac{\alpha_1}{(1-P_1)^{\frac{l-1}{l}}}.$$

The ratio is increasing in P_1 as long as $(1-P_1)^{\frac{l-1}{l}} > \alpha_1$.

Proof of Claim 3.6. We show that the function $h(l, p_1) = l(1-(1-p_1)^{1/l})$ is nondecreasing in l.

Taking the derivative, we have

$$\frac{\partial h(l,p_1)}{\partial l} = 1 - (1-p_1)^{1/l} + \frac{\ln(1-p_1)(1-p_1)^{1/l}}{l}.$$

We observe that $\frac{\partial h(l,0)}{\partial l} = 1 - 1 + 0 = 0$ and

$$\begin{aligned}\frac{\partial h(l,p_1)}{\partial p_1 \partial l} &= 1/l(1-p_1)^{1/l-1} - \frac{(1-p_1)^{1/l}}{l(1-p_1)} - \frac{(1-p_1)^{1/l-1}\ln(1-p_1)}{l^2} \\ &= -\frac{(1-p_1)^{1/l-1}\ln(1-p_1)}{l^2} \geq 0.\end{aligned}$$

Therefore $\frac{\partial h(l,p_1)}{\partial l}$ is nonnegative for all $p_1 \in [0, 1.0]$. Whence $h(l,p_1)$ is nondecreasing in l.

Proof of Claim 3.7. We need show that the ratio $(\frac{1}{1-x^{m/(m-1)}})(\frac{1-x+x\ln x}{1-x})$ is decreasing in $x \in (0,1)$.

We take the derivative

$$\begin{aligned}&\left(\frac{\frac{m}{m-1}x^{\frac{1}{m-1}}}{(1-x^{\frac{m}{m-1}})^2}\right)\left(\frac{1-x+x\ln x}{1-x}\right) + \left(\frac{1}{1-x^{m/(m-1)}}\right)\left(\frac{(1-x)\ln x + 1 - x + x\ln x}{(1-x)^2}\right) \\ &\quad = \frac{1}{(1-x^{m/(m-1)})(1-x)}\left[\left(\frac{\frac{m}{m-1}x^{\frac{1}{m-1}}}{1-x^{\frac{m}{m-1}}}\right)(1-x+x\ln x) + \left(\frac{1-x+\ln x}{1-x}\right)\right].\end{aligned}$$

The factor $\frac{1}{(1-x^{m/(m-1)})(1-x)}$ is positive in the interval; hence it suffices to show that the term in the brackets is negative. Noting that $1 - x + x\ln x$ in the left summand is nonnegative (the derivative $\ln x$ is negative, and the function is zero at 1), and that in the right summand $1 - x + \ln x \leq 0$, we conclude that the left summand is nonnegative, while the right one is nonpositive. We will verify that

$$\frac{1}{1-x} \geq \frac{\frac{m}{m-1}x^{\frac{1}{m-1}}}{1-x^{\frac{m}{m-1}}}. \tag{A.1}$$

This eliminates the extra factors and makes it sufficient to show that $h_1(x) = (1 - x + x\ln x) + 1 - x + \ln x < 0$. We note that $h_1(x)$ is negative at x arbitrarily close to zero, and zero at $x = 1$, and its derivative $-1 + \ln x + 1/x = \frac{1-x+x\ln x}{x}$ is nonnegative in the interval.

Rearranging (A.1), we need to verify that

$$\frac{\frac{m}{m-1}x^{\frac{1}{m-1}}(1-x)}{1-x^{\frac{m}{m-1}}} \le 1.$$

The fraction is zero at $x = 0$ and, taking the limit as x approaches 1, we have

$$\lim_{x\to 1} \frac{\frac{m}{m-1}x^{\frac{1}{m-1}}(1-x)}{1-x^{\frac{m}{m-1}}} = \frac{\frac{m}{m-1}(\frac{1}{m-1} - \frac{m}{m-1})}{-\frac{m}{m-1}} = 1.$$

Finally, we can verify that the derivative is nonnegative in the region. We may ignore the factor $\frac{m}{m-1}$, and to simplify a little, we make the substitution $u = x^{\frac{1}{m-1}}$. Hence we want to show that the derivative of $h_2(u) = \frac{u(1-u^{m-1})}{1-u^m}$ is positive. Taking the derivative

$$h_2'(u) = \frac{(1 - mu^{m-1})(1-u^m) + mu^m(1-u^{m-1})}{(1-u^m)^2},$$

we will show that the numerator

$$1 - mu^{m-1} - u^m + mu^{2m-1} + mu^m - mu^{2m-1} = u^{m-1}((m-1)u - m) + 1$$

is positive. The function $h_3(u) = u^{m-1}((m-1)u - m) + 1$ is nonnegative on the interval since $h_3(0) = 1$ and $h_3(1) = 0$ and $h_3'(u) < 0$ on the interval:

$$\begin{aligned} h_3'(u) &= (m-1)u^{m-2}((m-1)u - m) + (m-1)u^{m-1} \\ &= (m-1)u^{m-2}((m-1)u - m + u) = (m-1)u^{m-2}(m(u-1)) < 0. \end{aligned}$$

Hence $h_2'(u) \ge 0$.

Proof of Claim 3.15. We need to show that the function

$$\begin{aligned} f_2(\alpha_1) - \frac{r-1}{2}f_1(\alpha_1) = {}& \frac{r(r-1)}{2}(1-p)^{r-2}p^2 + \alpha_1 \ln\left(\frac{\alpha_1}{(1-p)^r}\right) \\ &+ (1-p)^r - \alpha_1 - \frac{r-1}{2}\left(\alpha_1 p^2 - \alpha_1 p \ln\left(\frac{\alpha_1}{(1-p)^r}\right)\right) \end{aligned}$$

is decreasing in α_1 for $\alpha_1 \le (1-p)^{2r-1}$. Taking the partial derivative on $f_2(\alpha_1) - \frac{r-1}{2}f_1(\alpha_1)$ with respect to α_1,

$$\begin{aligned} &\frac{\partial\left[\frac{r(r-1)}{2}(1-p)^{r-2}p^2 + \alpha_1\ln\left(\frac{\alpha_1}{(1-p)^r}\right) + (1-p)^r - \alpha_1 - \frac{r-1}{2}\left(\alpha_1 p^2 - \alpha_1 p \ln\left(\frac{\alpha_1}{(1-p)^r}\right)\right)\right]}{\partial \alpha_1} \\ &= \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + 1 - 1 - \frac{r-1}{2}p^2 + \frac{(r-1)p}{2}\ln\left(\frac{\alpha_1}{(1-p)^r}\right) + \frac{(r-1)p}{2} \\ &< \ln\left(\frac{\alpha_1}{(1-p)^r}\right) + \frac{(r-1)p}{2} \end{aligned}$$

$$\begin{aligned}
&\leq (r-1)\ln(1-p) + \frac{(r-1)p}{2}\\
&< -(r-1)p + \frac{(r-1)p}{2}\\
&\leq 0.
\end{aligned}$$

Acknowledgments. Many thanks to Richard Anderson and Richard Karp for the discussions and their very valuable suggestions, and to the two anonymous referees for their careful reading and constructive criticism of the paper.

VIRTUAL PATH LAYOUTS IN ATM NETWORKS*

LADISLAV STACHO† AND IMRICH VRŤO†

Abstract. We study virtual path layouts in a very popular type of fast interconnection networks, namely asynchronous transfer mode (ATM) networks. One of the main problems in such networks is to construct path layouts that minimize the hop-number (i.e., the number of virtual paths between any two nodes) as a function of the edge congestion c (i.e., the number of virtual paths going through a link). In this paper we construct for any n vertex network H and any c a virtual path layout with hop-number $O(\frac{diam(H)\log\Delta}{\log c})$, where $diam(H)$ is the diameter of the network H and Δ is its maximum degree. Involving a general lower bound from [E. Kranakis, D. Krizanc, and A. Pelc, *Seventh IEEE Symposium on Parallel and Distributed Processing*, IEEE Computer Society, 1995, pp. 662–668], we see that these hop-numbers are optimal for bounded degree networks with the diameter $O(\log n)$ for any congestion c. In the case of unbounded degree networks (with the diameter $O(\log n)$) these hop-numbers are optimal for any $c \geq \Delta$. For instance, this gives optimal hop-numbers for hypercube related networks. Moreover, we improve known results for paths and meshes and prove optimal hop-numbers for hypercubes.

Key words. ATM network, congestion, hop-number, virtual paths layout

1. Introduction.

Broadband integrated services digital network (B-ISDN) is a new paradigm in digital communication which integrates previous distinct networks (telephone, cable television, computer) into a single digital network. The basic network transmission medium is a fiber-optic cable capable of transferring data at very high rates. The bottleneck caused by slow software-based switches is resolved by special purpose fast hardware. To utilize this, a new multiplexing and switching technology called ATM (asynchronous transfer mode) was proposed (see, e.g., [9]). Packet routing in ATM networks is based on relatively small fixed-size packets. Messages may be transmitted through arbitrarily long virtual paths. Packets are routed along these paths by maintaining a routing field whose subfields determine intermediate destinations of the packet, i.e., end-points of virtual paths on their way to the final destination. One of the main problems in such networks is to construct path layout that minimizes the hop-number (i.e., the number of virtual paths between any two nodes) as a function of the edge congestion c (i.e., the number of virtual paths going through a link).

In this paper we construct for any n vertex network H and any c a virtual path layout with the hop-number $O(\frac{diam(H)\log\Delta}{\log c})$, where $diam(H)$ is the diameter of the network H and Δ is its maximum degree. Involving a general lower bound from [6], we see that these hop-numbers are optimal for bounded degree networks with the diameter $O(\log n)$ for any congestion c. In the case of unbounded degree networks (with the diameter $O(\log n)$) these hop-numbers are optimal for any $c \geq \Delta$. For instance, this gives optimal hop-numbers for hypercube related networks. Moreover, we improve known results for paths and meshes of Kranakis, Krizanc, and Pelc [6].

Finally, we prove optimal hop-numbers for hypercubes.

1.1. Model, notation, and results. The basic model of ATM networks was introduced by Gerstel et al. in [1, 2, 4, 5] and further developed in [3, 6]. By a network we understand any graph $G = (V_G, E_G)$. By $diam(G)$ we denote the *diameter* of G. Similarly, by $d(x, y)$ we denote the distance of the vertices x and y in G. Let Δ denote the maximum degree of a graph. Let $G = (V_G, E_G)$ and $H = (V_H, E_H)$ be graphs such that $|V_G| \leq |V_H|$. An *embedding* of G in H is a pair of mappings (ϕ, ψ) satisfying

$$\phi : V_G \to V_H \quad \text{is an injection}, \quad \psi : E_G \to \{\text{ set of all paths in } H\ \},$$

such that if $uv \in E_G$, then $\psi(uv)$ is a path between $\phi(u)$ and $\phi(v)$. Define the *congestion of an edge* $e \in E_H$ as $cg_{(\phi,\psi)}(e) = |\{f \in E_G \ : \ e \in \psi(f)\}|$ and the *congestion* of G in H as $cg(G, H) = \min_{(\phi,\psi)} \max_{e\in E_H} \{cg_{(\phi,\psi)}(e)\}$. Note that if there is no confusion we will omit the subscript (ϕ, ψ) in $cg_{(\phi,\psi)}(e)$.

The paths $\{\psi(E_G)\}$ are called *virtual paths*. The virtual path problem can be mathematically defined as follows. Given a graph H and a positive number c, among all graphs G satisfying $|V_G| = |V_H|$ and $cg(G, H) \leq c$, find a graph G_0 of minimum diameter. The minimum diameter is called the *hop-number* and is denoted by $Hop_H(c)$.

Gerstel and Zaks [5] studied virtual path layouts for paths, cycles, and meshes. They assumed an additional requirement that virtual channels are the shortest paths in the networks. Kranakis, Krizanc, and Pelc [6] dropped the requirement and proved several optimal results on the hop-number of paths and meshes for small c. Namely, if P_n denotes an n-vertex path, then $Hop_{P_n}(2) = \sqrt{2n} + o(1)$, $Hop_{P_n}(c) = \Theta(n^{1/c})$, when c is a constant and $Hop_{P_n}(\log^2 n/\log\log n) = \Theta(\log n/\log\log n)$, and if M_n denotes an $n \times n$ mesh, then $Hop_{M_n}(c) = \Theta(\log n)$ for constant c.

We assume the same model as Kranakis, Krizanc, and Pelc [6]. Our main result says that for any $c \geq 1$ and any n vertex graph H of bounded degree and diameter $O(\log n)$, $Hop_H(c) = \Theta(\log n/\log c)$. Several standard networks belong to this class of graphs, e.g., mesh of trees, butterfly, cube-connected-cycles, binary de Bruijn, or shuffle-exchange graph. If $c \geq \Delta$, then we construct optimal virtual path layouts for some unbounded degree networks, e.g., star, pancake, and k-ary de Bruijn and Kautz graphs.

Further, we improve the results of Kranakis, Krizanc, and Pelc [6] in the following way:

(i) $Hop_{P_n}(c) = \Theta(\frac{\log n}{\log c})$, if $c \geq \log^{1+\varepsilon} n$, for any fixed $\varepsilon > 0$.

(ii) If H denotes two-dimensional $n\times n$ mesh, then $Hop_H(c) = \Theta(\frac{\log n}{\log c})$for $c \geq 2$.

Finally, we show that for the n-dimensional hypercube Q_n,

$$Hop_{Q_n}(c) = \begin{cases} \Theta\left(\frac{n}{\log n}\right) & \text{if } 2 \leq c \leq n, \\ \Theta\left(\frac{n}{\log c}\right) & \text{otherwise.} \end{cases}$$

2. General bounds. In this section we describe a general method for constructing virtual path layouts and then apply it to some standard networks. Since we deal only with asymptotic results, we can restrict ourselves to looking for the graph G_0 among trees.

PROPOSITION 2.1. *Let a graph G_0 minimize $diam(G)$ with respect to $cg(G, H) \leq c$. Then there exists a tree T with $diam(T) \leq 2diam(G_0)$ and $cg(T, H) \leq c$.*

Indeed, we can take T as a breadth first search spanning tree of H_0. We will often apply the following useful lemma from [10].

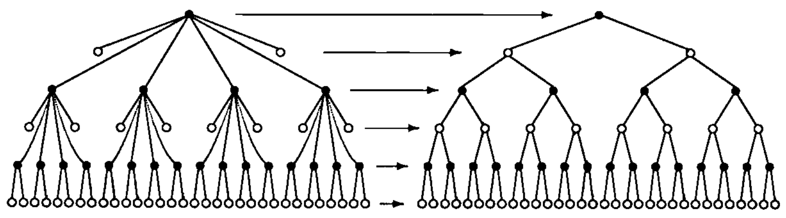

FIG. 1. *The embedding of $F(4;2,6)$ in $R(2,6)$.*

LEMMA 2.2. *Let G_1, G_2, and G_3 be graphs with $|V_{G_1}| \leq |V_{G_2}| \leq |V_{G_3}|$. Consider an embedding of G_1 into G_2 and an embedding of G_2 into G_3. Then $cg(G_1, G_3) \leq cg(G_1, G_2)cg(G_2, G_3)$.*

It is worth noting that an embedding of G_1 into G_2 followed by the embedding of G_2 into G_3 induces an embedding of G_1 into G_3. An image of an edge under this composed embedding is not necessarily a path but a walk in general. It is easy to transform the walk into a path by omitting multiple edges and vertices.

Throughout, we will use a general lower bound of Kranakis, Krizanc, and Pelc [6].

LEMMA 2.3. *For any n vertex graph H of maximum degree Δ and for any $c \geq 1$,*

$$Hop_H(c) \geq \frac{\log n}{\log(c\Delta)} - 1.$$

By $R(k, n)$ we denote the complete k-ary n-level tree. Note that by a k-ary 1-level and 0-ary k-level tree we mean a single vertex. We sometimes abbreviate this notation in the case of $R(2, n)$ to B_n (the complete binary tree) and $R(l, 2)$ to S_l (the star on $l + 1$ vertices).

Let T be a rooted tree. Let G be a rooted tree with $l \geq k$ leaves, where l and k are positive integers. By $G * kT$ we denote the graph constructed as follows: take k copies of T and identify the roots of the copies of T with k distinct leaves of G.

For $d, i, n \geq 1$, and $k = d^i$, define the tree $F(k; d, n)$ recursively as follows. If $i = 1$, set $F(k; d, n) = R(d, n)$. If $i \geq n$, set $F(k; d, n) = R(\frac{d^n-1}{d-1} - 1, 2)$. If $1 < i < n$, set $F(k; d, n) = R(\frac{d^{i+1}-1}{d-1} - 1, 2) * kF(k; d, n - i)$. Note that the number of vertices of $F(k; d, n)$ is $\frac{d^n-1}{d-1}$. A picture of $F(4; 2, 6)$ is depicted in Figure 1 (the left tree).

LEMMA 2.4. *For $d, i, n \geq 1$, and $k = d^i$, $diam(F(k; d, n)) = 2(a + \lceil\frac{r}{i}\rceil) = 2\lceil\frac{n-1}{i}\rceil$, where $n - 1 = ai + r$, $0 \leq r < i$.*

Proof. For $n = 1, 2$, the lemma is easy to observe. We assume that the lemma is true for all $l < n$ and we prove it for $l = n$. For $i = 1$, $diam(R(d, n)) = 2(n - 1)$, the lemma is true. Similarly, for $i \geq n$, $diam(R(\frac{d^n-1}{d-1} - 1, 2)) = 2$. Now, let $1 < i < n$. Hence $F(k; d, n) = R(\frac{d^{i+1}-1}{d-1} - 1, 2) * kF(k; d, n-i)$. Let $n-1 = ai+r$, $0 \leq r < i$. Since $n-i \geq 1$ and since $n-i = (a-1)i+r$, by induction, $diam(F(k; d, n-i)) = 2(a-1+\lceil\frac{r}{i}\rceil)$, and $diam(R(\frac{d^{i+1}-1}{d-1} - 1, 2)) = 2$. It follows from the construction of $F(k; d, n)$ that $diam(F(k; d, n)) = diam(F(k; d, n - i)) + 2 = 2(a + \lceil\frac{r}{i}\rceil) = 2\lceil\frac{n-1}{i}\rceil$. ◻

LEMMA 2.5. *For $d, i, n \geq 1$, and $k = d^i$, $cg(F(k; d, n), R(d, n)) \leq \frac{k-1}{d-1}$.*

Proof. We proceed by induction on n. For $n = 1, 2$, the result is easy to see. Assuming the result is true for $l \leq n - 1$, we prove it for $l = n$. For $i = 1$, the statement of the lemma is true (we take as the mapping (ϕ, ψ) the natural isomorphism $\phi : F(k; d, n) \to R(d, n)$, and ψ the induced mapping by ϕ). If $i \geq n$, let ϕ map the root of $R(\frac{d^n-1}{d-1} - 1, 2)$ on the root of $R(d, n)$ and other vertices, injectively in an arbitrary way, on the remaining vertices of $R(d,n)$. Further, let ψ map each edge e of $R(\frac{d^n-1}{d-1}-1,2)$ on the unique paths in $R(d,n)$ connecting the images of the end-vertices of e. It is a matter of routine to observe that the congestion of each edge of $R(d,n)$ induced by (ϕ,ψ) is at most $\frac{k-1}{d-1}$ (the maximum congestion is achieved on edges incident with the root of $R(d,n)$), thus $cg(R(\frac{d^n-1}{d-1}-1,2),R(d,n)) \le \frac{k-1}{d-1}$. Now, let $1<i<n$. By definition $F(k;d,n)=R(\frac{d^{i+1}-1}{d-1}-1,2)*kF(k;d,n-i)$. It holds that $R(d,n)=R(d,i+1)*kR(d,n-i)$. Using induction we can embed $kF(k;d,n-i)$ into $kR(d,n-i)$ (each $F(k;d,n-i)$ into some $R(d,n-i)$) with congestion $\le \frac{k-1}{d-1}$ and thus $cg(kF(k;d,n-i),kR(d,n-i)) \le \frac{k-1}{d-1}$. Similarly, we obtain $cg(R(\frac{d^{i+1}-1}{d-1}-1,2),R(d,i+1)) \le \frac{k-1}{d-1}$. Obviously, these two embeddings together induce an embedding (ϕ,ψ) of $F(k;d,n)$ into $R(d,n)$ with congestion at most $\frac{k-1}{d-1}$. ∎

Remark 2.1. The embedding (ϕ,ψ), constructed in the previous proof, has the property that for each vertex $v \in V_{F(k;d,n)}$ there is at most one neighbor $u \in V_{F(k;d,n)}$ such that the unique $\phi(v)-\phi(u)$ path in $R(d,n)$ contains a vertex x with $d(\phi(x),r) < d(\phi(v),r)$, where r is the root of $R(d,n)$. This can be observed in Figure 1, where the embedding of $F(4;2,6)$ in $R(2,6)$ is depicted.

LEMMA 2.6. *Let $\Delta \ge 3$, $i \ge 1$, and let T be a tree with maximum degree at most Δ. Then there exists a tree T' with $|V_T|=|V_{T'}|$, $diam(T') \le 2\lceil\frac{diam(T)}{i}\rceil$, and $cg(T',T) \le \frac{(\Delta-1)^i-1}{\Delta-2}$.*

Proof. Let v be a vertex of degree $\le \Delta-1$ in T (since T is a tree, such a vertex always exists). For each $x \in V_T$, $d(x,v) \le diam(T)$. It is easy to observe that T can be extended to the complete $(\Delta-1)$-ary tree $L=R(\Delta-1,diam(T)+1)$ by successively adding vertices of degree one. Let S be the set of all added vertices to T. Let us consider the graph $G=F((\Delta-1)^i;\Delta-1,diam(T)+1)$. By Lemma 2.4, $diam(G) \le 2\lceil\frac{diam(T)}{i}\rceil$. Moreover, by Lemma 2.5, there is an embedding (ϕ,ψ) of G in L with $cg_{(\phi,\psi)}(G,L) \le \frac{(\Delta-1)^i-1}{\Delta-2}$. Let T' be defined as $T'=G-\{x : \phi(x)\in S\}$. In what follows we show that T' is indeed the required tree.

Let ϕ' be the restricted mapping ϕ to the graph T'. Obviously, ϕ' is an injection. Since ϕ' is a surjection as well, $|V_{T'}|=|V_T|$. Since ψ maps each edge xy to the unique $\phi(x)-\phi(y)$ path in L and since L and T are trees, the restricted mapping ψ to the graph T', say ψ', is well defined.

Hence (ϕ',ψ') is an embedding of T' in T with $cg_{(\phi',\psi')}(T',T) \le cg_{(\phi,\psi)}(G,L) \le \frac{(\Delta-1)^i-1}{\Delta-2}$. Since G is a tree, to finish the proof it is sufficient to prove that T' is connected, since then $diam(T') \le diam(G) \le 2\lceil\frac{diam(T)}{i}\rceil$. Let x be the last vertex added to T in the construction of L. Since x is a leaf in L and by Remark 2.1, it follows that $\phi^{-1}(x)$ is a leaf in G as well. Thus after removing x and $\phi^{-1}(x)$, the resulting graphs will be connected. We can continue removing vertices from L and its preimages in G (in the opposite way they were added to T) to obtain T and T', respectively. Since in each step the deleted vertex is a leaf of a subgraph of L, by Remark 2.1, its preimage is also a leaf of a subgraph of G, and thus T' is connected. ∎

THEOREM 2.7. *For any graph H of maximum degree $\Delta \ge 3$ and any given $c \ge 1$,*

$$Hop_H(c) = O\left(\frac{diam(H)\log\Delta}{\log c}\right).$$

Proof. Let T be a breadth first search spanning tree of G. Then T has the maximum degree at most $\Delta \ge 3$ and $diam(T) \le 2diam(H)$. Find i such that $\frac{(\Delta-1)^i-1}{\Delta-2} \le$

$c < \frac{(\Delta-1)^{i+1}-1}{\Delta-2}$. Now, by Lemma 2.6, there is a tree T' with $cg(T',T) \leq \frac{(\Delta-1)^{i}-1}{\Delta-2}$. Clearly $cg(T',H) \leq \frac{(\Delta-1)^{i}-1}{\Delta-2} \leq c$. Similarly, by Lemma 2.6,

$$\begin{aligned} Hop_H(c) \leq diam(T') \leq 2\left\lceil \frac{diam(T)}{i} \right\rceil \leq 2\left\lceil \frac{2diam(H)\log(\Delta-1)}{\log((\Delta-2)c+1)-\log(\Delta-1)} \right\rceil \\ = O\left(\frac{diam(H)\log\Delta}{\log c}\right). \quad \square \end{aligned}$$

Theorem 2.7 together with Lemma 2.3 has two important consequences.

Corollary 2.8. *Let H be a graph of order n with $\Delta = O(1)$ and $diam(H) \leq O(\log n)$. Then $Hop_H(c) = \Theta(\frac{\log n}{\log c})$ for any c.*

Note that several standard networks belong to this class of graphs, e.g., mesh of trees, butterfly, cube-connected-cycles, and binary de Bruijn, or shuffle-exchange graph.

Corollary 2.9. *Let H be a graph of order n with maximum degree $\Delta \geq 3$ satisfying $diam(H)\log\Delta = O(\log n)$. Then $Hop_H(c) = \Theta(\frac{\log n}{\log c})$ for $c \geq \Delta$.*

If $c \geq \Delta$, then the above corollary gives optimal virtual path layouts for, e.g., star, pancake, and k-ary de Bruijn and Kautz graphs.

3. Paths and meshes.

Let P_n denote an n vertex path and $M_n = P_n \times P_n$ denote an $n \times n$ mesh. The next theorem improves virtual path layouts for paths and meshes of Kranakis, Krizanc, and Pelc [6].

Theorem 3.1. *Let $c \geq 1$. Then*

(i)

$$Hop_{P_n}(c) = \Theta\left(\frac{\log n}{\log c}\right) \text{ for } c \geq \log^{1+\varepsilon} n \quad \text{for any fixed } \varepsilon > 0,$$

(ii)

$$Hop_{M_n}(c) = \Theta\left(\frac{\log n}{\log c}\right) \quad \text{for } c \geq 2.$$

Proof. Both lower bounds easily follow by applying Lemma 2.3. Consider the upper bounds. To prove (i), first find m and $k = 2^i$ such that

$$2^m - 1 \leq n < 2^{m+1} - 1 \text{ and } (k-1)(m+2)/2 + 1 \leq c < (2k-1)(m+2)/2 + 1.$$

Setting $G_1 = F(k;2,m), G_2 = B_m$, and $G_3 = P_{2^m-1}$ in Lemma 2.2 and using a result of Lengauer (based on the orthogonal projection of B_m on a horizontal line) [8], $cg(B_m, P_{2^m-1}) \leq (m+2)/2$, and by Lemma 2.5 we get an embedding of $F(k;2,m)$ into P_{2^m-1} with

$$cg(F(k;2,m), P_{2^m-1}) \leq (k-1)(m+2)/2.$$

Now choose $n - 2^m + 1$ new vertices and join them to leaves of $F(k;2,m)$ (at most two per each leaf) in such a way that the resulting graph, say T, has $m+1$ levels. Note that this is always possible. Clearly, T has n vertices. It is easy to extend the above embedding of $F(k;2,m)$ into P_{2^m-1} to an embedding of T into P_n with

$$cg(T, P_n) \leq cg(F(k;2,m), P_{2^m-1}) + 1 \leq c.$$

Moreover, by Lemma 2.4,

$$Hop_{P_n}(c) \le diam(T) \le diam(F(k;2,m)) + 2 = 2\left\lceil \frac{m-1}{i} \right\rceil + 2 \le \frac{2m}{\log k} + 4$$
$$\le \frac{2\log(n+1)}{\log \frac{c}{2\log n}} + 4 \le \frac{2\log(n+1)}{\frac{\varepsilon}{1+\varepsilon}\log c - 1} + 4 = O\left(\frac{\log n}{\log c}\right)$$

for $c \ge \log^{1+\varepsilon} n$.

For (ii) assume first the case $n = 2^m, m \ge 1$. Find $k = 2^i$ such that

$$2(k-1) + 1 \le \frac{c}{4} < 2(2k-1) + 1.$$

Set $G_1 = F(k;2,2m), G_2 = B_{2m}$, and $G_3 = M_n$ in Lemma 2.2. Zienicke [11] showed that $cg(B_{2m}, M_n) = 2$. Now we add one new vertex and edge to $F(k;2,2m)$ resulting in a graph F on n vertices embeddable into M_n with $cg(F, M_n) \le 2(k-1)+1 \le c/4$. The diameter of F is increased by at most 1.

Second, consider an arbitrary n. Find m such that $2^m - 1 \le n < 2^{m+1} - 1$. Embed the graph F into the left lower submesh of M_n of size $2^m \times 2^m$. Similarly, embed the graph F into the other three "corner" submeshes of M_n. We get a virtual path layout for M_n with congestion at most $4cg(F, M_n) \le c$ and the hop-number

$$Hop_{M_n}(c) \le 2diam(F) \le 2(diam(F(k;2,2m)) + 1) \le 2\left\lceil \frac{2m-1}{i} \right\rceil + 2$$
$$\le 2\frac{2\log(n+1)}{\log(\frac{c+4}{16})} + 4 = O\left(\frac{\log n}{\log c}\right). \qquad \square$$

Note that $Hop_{P_n}(c)$ for nonconstant $c \le \log n$ remains an open problem.

4. Hypercubes. The main result of this section is an optimal virtual path layout for hypercubes. The n-dimensional hypercube, denoted by Q_n, is defined, by means of the Cartesian product of graphs, as $Q_0 = v$ (a single vertex) and $Q_n = Q_{n-1} \times P_2$. The edges of Q_n are divided into n groups in a natural way according to the dimensions they belong to.

Let us define the tree T_1 to be a single vertex. Now, for $n \ge 2$ let the tree $T_n = S_{2k-2} * kT_{n-i}$, where $k = 2^i \le n < 2^{i+1}$. Note that the number of vertices of T_n is $2^n - 1$.

LEMMA 4.1. *The diameter of T_n satisfies*

$$diam(T_n) < \frac{8n}{\lfloor \log n \rfloor} + 2\lfloor \log n \rfloor.$$

Proof. Let $depth(T_n)$ denote the depth of T_n. Then

$$depth(T_n) = depth(T_{n-i}) + 1,$$

where $i = \lfloor \log n \rfloor$. Solving this recurrence, we get

$$depth(T_n) \le \left\lceil \frac{n - 2^i + 1}{i} \right\rceil + \left\lceil \frac{2^i - 2^{i-1}}{i-1} \right\rceil + \cdots + \left\lceil \frac{2^2 - 2^1}{1} \right\rceil$$
$$< \sum_{j=1}^{i} \left\lceil \frac{2^j}{j} \right\rceil \le \sum_{j=1}^{i} \frac{2^j}{j} + i \le \frac{2^{i+2}}{i} + i \le \frac{4n}{\lfloor \log n \rfloor} + \lfloor \log n \rfloor,$$

where the estimation of the sum was done by a straightforward induction. Noting that $diam(T_n) \leq 2depth(T_n)$, we have the result. $\square$

Let G be a graph and let S (U) be a subset of E_G (V_G). We define the *graph induced by U under S* as the graph with the vertex set U and all edges $xy \in (U \times U) \cap S$.

Let S be the set of all edges in some $i \leq n$ dimensions of Q_n. Then the graph $Q_n - S$ consists of 2^i copies of Q_{n-i}, say $Q^1, Q^2, \ldots, Q^{2^i}$. Let v^1 be a vertex of Q^1. Let $v^l \in Q^l$, $2 \leq l \leq 2^i$, be the corresponding vertices to v^1, i.e., $v^l, 2 \leq l \leq i$, is the copy of v^1 chosen in the natural way. Then the graph induced by $\{v^1, v^2, \ldots, v^{2^i}\}$ under S is an i-dimensional hypercube, say $Q_i(v^1)$. Observe that the hypercubes $Q_i(x)$ for all $x \in Q^1$ are vertex disjoint. Moreover, the mapping $\xi : Q^1 \to Q^l$, $l = 2, \ldots, 2^i$, given by $\xi(x) = y$, where $y \in Q^l \cap Q_i(x)$, is the isomorphism induced by $Q_i(v^1)$.

LEMMA 4.2. *For all $n \geq 1$, $cg(T_n, Q_n) \leq 2$.*

Proof. In fact we prove, by induction on n, the following stronger statement. There exists an embedding (ϕ, ψ) of T_n into Q_n with $cg(e) \leq 2$, for all edges $e \in Q_n$, satisfying the following two additional conditions. Let r be the root of T_n and $v \in V_{Q_n} \setminus \phi[V_{T_n}]$.

(i) There exists a $\phi(r) - v$ path P such that each edge of P has congestion at most 1, and just one neighbor of v is on P.

(ii) For all neighbors x of v in Q_n, $cg(vx) = 0$.

Let us call the vertex v a *free vertex*, the path P a *free path*, and the embedding a *good embedding*. For $n = 1, 2, 3$ the statement is easy to observe. Thus we assume we have proved the statement for all integers up to $n - 1$ and we prove it for $n \geq 4$. By definition, $T_n = S_{2k-2} * kT_{n-i}$, where $k = 2^i \leq n < 2^{i+1}$. Let us delete all edges in some i dimensions of Q_n obtaining thereby k copies of Q_{n-i}, say $Q^1, \ldots, Q^k$ (see Figure 2).

For notational convenience let us denote some important vertices of T_n. By r we denote the root of T_n (this is also the root of S_{2k-2}). Further, by r^l we denote the leaf of S_{2k-2}, which is the root of $F^l = T_{n-i}$ $(l = 1, 2, \ldots, k)$. Note that r^l are the vertices at which the subtrees T_{n-i} are amalgamated with S_{2k-2} in T_n. Finally, by x^l $(l = 3, 4, \ldots, k)$ we denote the $k - 2$ remaining leaves of S_{2k-2}.

Let v^1 be any vertex of Q^1. In what follows we describe for $l = 1, \ldots, k$ a good embedding of F^l into Q^l. By the induction hypothesis there is a good embedding

(ϕ_1, ψ_1) of F^1 into Q^1. Since Q^1 is vertex transitive, we may assume that v^1 is the free vertex in Q^1. Moreover, there is a free $\phi_1(r^1) - v^1$ path, say P^1. By v^l we denote the vertex corresponding to v^1 in Q^l. It follows from the symmetry of Q_{n-i} that there is a good embedding (ϕ_2, ψ_2) of F^2 into Q^2 (obtained from the embedding of F^1 into Q^1) for which $\phi_2(r^2) = v^2$ and the free vertex in Q^2, say v, is the vertex corresponding to $\phi_1(r^1)$. Furthermore, there is a $v^2 - v$ free path P^2 in Q^2. Finally, for $l = 3, \ldots, k$, by the existence of the isomorphism induced by $Q_i(v^1)$, there is a good embedding (ϕ_l, ψ_l) of F^l into Q^l for which $\phi_l(r^l)$ is the vertex corresponding to $\phi_1(r^1)$ and v^l is the free vertex in Q^l. By the same argument, there is a $v^l - \phi_l(r^l)$ free path P^l in Q^l, $l = 3, \ldots, k$.

Since $Q^1 \cup Q^2 \cup \cdots \cup Q^k$ is a factor of Q_n and since $F^1 \cup F^2 \cup \cdots \cup F^k \cong kT_{n-i}$, the embeddings (ϕ_l, ψ_l), $l = 1, \ldots, k$, together induce an embedding (ϕ, ψ) of kT_{n-i} into $Q_n \setminus \{v, v^1, v^3, v^4, \ldots, v^k\}$. To obtain the required embedding we put $\phi(r) = v^1$ and $\phi(x^l) = v^l$ for $l = 3, 4, \ldots, k$. Finally, we have to embed the edges of S_{2k-2}. Since all the vertices of S_{2k-2} are already embedded, it is enough to describe the paths $v^1 - \phi(r^l)$, $l = 1, 2, \ldots, k$, and the paths $v^1 - v^l$, $l = 3, 4, \ldots, k$.

The path $v^1 - \phi(r^1) = P^1$ and the path $v^1 - \phi(r^2) = v^1v^2$. We construct the remaining paths using neighbors of the vertex v^1 in Q^1. Since the degree of Q_n is $n \geq k$ and since P^1 is a free path, there are $k-2$ neighbors of v^1 which lie neither on P^1 nor on v^1v^2, say $c_3^1, c_4^1, \ldots, c_k^1$. For each vertex c_j^1, $j = 3, 4, \ldots, k$, there is the hypercube $Q_i(c_j^1)$. Let c_j^l be the corresponding vertex for c_j^1 in Q^l. Since the mapping on corresponding vertices is an isomorphism, the vertex c_j^l is adjacent to the vertex v^l. Since $Q_i(c_j^1)$ $(j = 3, 4, \ldots, k)$ is connected, there is a $c_j^1 - c_j^l$ path, say $P(c_j^1, c_j^l)$, in $Q_i(c_j^1)$. Note that all $P(c_j^1, c_j^l)$ for $j = 3, 4, \ldots, k$ are vertex disjoint. Now, we are able to describe all remaining paths. For $j = 3, 4, \ldots, k$, the path $v^1 - v^j = (v^1c_j^1) \circ P(c_j^1, c_j^j) \circ (c_j^jv^j)$, and the path $v^1 - \phi(r^j) = (v^1c_j^1) \circ P(c_j^1, c_j^j) \circ (c_j^jv^j) \circ P^j$, where $\circ$ is the concatenation operation.

The embedding is now completely defined. It is an easy but time-consuming exercise to observe that $cg(e) \leq 2$ for each edge $e \in Q_n$. If we define $P = (v^1v^2) \circ P^2$, then since P^2 is a free path, P is a $\phi(r) - v$ free path as well. Moreover, no edge incident with v is used in the embedding, thus $cg(vx) = 0$ for all neighbors x of v and the embedding (ϕ, ψ) is good. □

Theorem 4.3. *For the n-dimensional hypercube we have*

$$Hop_{Q_n}(c) = \begin{cases} \Theta\left(\frac{n}{\log n}\right) & \text{if } 2 \leq c \leq n, \\ \Theta\left(\frac{n}{\log c}\right) & \text{otherwise.} \end{cases}$$

Proof. The upper bound of the first case follows from Lemmas 4.1 and 4.2. The lower bound is implied by Lemma 2.3. The second case is proved in a similar way as the result for the mesh using the fact from [7] that the complete binary tree on $2^n - 1$ vertices can be embedded in the n-dimensional hypercube with congestion 1. □

In particular, the above result says that if the congestion c is smaller than the degree of the hypercube, then the hop-number does not depend on c. It is an interesting open question whether this holds for other important networks of unbounded degree like k-ary de Bruijn and star graph. Another open problem is to find an optimal virtual paths layout for the n-vertex path if c is nonconstant and less than or equal to $\log^{1+\varepsilon} n$ for $\varepsilon > 0$.

SELF-TESTING WITHOUT THE GENERATOR BOTTLENECK*

FUNDA ERGÜN†, S. RAVI KUMAR‡, AND D. SIVAKUMAR§

Abstract. Suppose P is a program designed to compute a function f defined on a group G. The task of self-testing P, that is, testing if P computes f correctly on most inputs, usually involves testing explicitly if P computes f correctly on *every* generator of G. In the case of multivariate functions, the number of generators, and hence the number of such tests, becomes prohibitively large. We refer to this problem as the *generator bottleneck*. We develop a technique that can be used to overcome the generator bottleneck for functions that have a certain nice structure, specifically if the relationship between the values of the function on the set of generators is easily checkable. Using our technique, we build the first efficient self-testers for many linear, multilinear, and some nonlinear functions. This includes the FFT, and various polynomial functions. All of the self-testers we present make only $O(1)$ calls to the program that is being tested. As a consequence of our techniques, we also obtain efficient program result-checkers for all these problems.

Key words. program correctness, self-testing, generator bottleneck

1. Introduction.

The notions of program result-checking, self-testing, and self-correcting as introduced in [4, 17, 5] are powerful tools for attacking the problem of program correctness. These methods offer both realistic and efficient tools for software verification. Various useful mathematical functions have been shown to have self-testers and self-correctors; some examples can be found in [5, 3, 17, 9, 14, 19, 1, 20, 22, 6]. The theoretical developments in this area are at the heart of the recent breakthrough results on probabilistically checkable proofs and the subsequent results that show nonapproximability of hard combinatorial problems.

Suppose we are given a program P designed to compute a function f. Informally, a *self-tester* for f distinguishes the case where P computes f correctly always from the case where P errs frequently. A *result-checker* for a function f takes as input a program P and an input q to P and outputs PASS when P correctly computes f always and outputs FAIL if $P(q) \neq f(q)$. Given a program P that computes f correctly on most inputs, a *self-corrector* for f is a program $P_{\rm sc}$ that uses P as an oracle and computes f correctly on every input with high probability.

1.1. Definitions and basics. Before we discuss our results, we present the basic definitions of testers, checkers, etc., and state some desirable properties of these programs. Let f be a function on a domain $\mathcal{D}$ and let P be a program that purports to compute f. The testers, correctors, and checkers we define are probabilistic programs that take P as an oracle, and in addition, take one or both of the following parameters as input: an *accuracy parameter* ϵ that specifies the conditions that P is expected to meet and a *confidence parameter* ρ that is an upper bound on the probability that the tester/corrector/checker fails to do its job. The following definitions formalize the notions of self-tester [5], self-corrector [5, 17], and result-checker [4].

Definition 1.1 (self-tester). *An* ϵ-self-tester *for f is a probabilistic oracle program T that, given $\rho > 0$, satisfies the following conditions*:

- $\Pr_{x\in\mathcal{D}}[P(x) = f(x)] = 1 \Rightarrow \Pr[T^P$ *outputs* PASS $] = 1$, *and*
- $\Pr_{x\in\mathcal{D}}[P(x) \neq f(x)] \geq \epsilon \Rightarrow \Pr[T^P$ *outputs* FAIL $] \geq 1-\rho$.

Definition 1.2 (self-corrector). *An* ϵ-self-corrector *for f is a probabilistic oracle program $P_{\rm sc}$ that, given any input y, and $\rho > 0$, satisfies the following condition*:

- $\Pr_{x\in\mathcal{D}}[P(x) = f(x)] \geq 1-\epsilon \Rightarrow \Pr[P_{\rm sc}(y) = f(y)] \geq 1-\rho$.

Definition 1.3 (result-checker). *A* checker *(or* result-checker*) for f is a probabilistic oracle program C that, given an input y and $\rho > 0$, satisfies the following conditions*:

- $\Pr_{x\in\mathcal{D}}[P(x) = f(x)] = 1 \Rightarrow C^P(y)$ *outputs* PASS, *and*
- $P(y) \neq f(y) \Rightarrow \Pr[C^P(y)$ *outputs* FAIL $] \geq 1-\rho$.

We now list three important properties that are required of self-testers, self-correctors, and result-checkers. For definiteness, we state these for the case of self-testers. First, the self-tester T should be computationally *different* from and more *efficient* than any program that computes f [4]. This restriction ensures that T does not implement the obvious algorithm to compute f (and hence could harbor the same set of bugs, or be computationally inefficient). Furthermore, this ensures that the running time of T is *asymptotically better than* the running time of the best *known* algorithm for f. The second important property required of T is that it should not require the knowledge of too many correct values of f. In particular, this rules out the possibility that T merely keeps a large table of the correct values of f for all inputs. The third important property required of a self-tester is *efficiency*: an efficient self-tester should only make $O(1/\epsilon, \lg(1/\rho))$ calls to P. For constant ϵ and ρ, an efficient self-tester makes only $O(1)$ calls to the program. (In the rest of the paper, we often write $O(1)$ as a shorthand for $O(1/\epsilon, \lg(1/\rho))$, particularly when discussing the dependence on other parameters of interest.)

The following well-known lemma summarizes some relationships between the notions of self-testers, self-correctors, and result-checkers. For the reader's convenience, we sketch the idea of the proof of this lemma, suppressing the details of the accuracy and confidence parameters.

Lemma 1.4 (see [5]). (a) *If f has a self-tester and a self-corrector that make $O(1)$ calls to the program, then f has a result-checker that makes $O(1)$ calls to the program.*

(b) *If f has a result-checker, then it has a self-tester.*

Proof (sketch). For part (a), suppose that f has a self-tester and a self-corrector. Given an input y and oracle access to a program P, first self-test P to ensure that it doesn't err too often. If the self-tester finds P to be too erroneous, output FAIL. Otherwise, compute $f(y)$ by using the self-corrector for $P_{\rm sc}$ and the program P, and output PASS iff $P(y) = P_{\rm sc}(y)$.

Clearly a perfect program always passes. Suppose $P(y) \neq f(y)$. Then one of the following two cases must occur. The program is too erroneous, in which case the self-tester, and hence the checker, outputs FAIL. The program is not too erroneous, in which case the self-corrector computes $f(y)$ correctly with high probability, so the checker detects that $P(y) \neq P_{\mathrm{sc}}(y)$ and outputs FAIL.

For part (b), suppose that f has a result-checker. By using the result-checker to test if $P(x) = f(x)$ for many randomly chosen inputs x, the fraction of inputs x for which $P(x) \neq f(x)$ can be estimated. Output PASS iff this fraction is less than ϵ. □

A useful tool in constructing self-correctors is the notion of *random self-reducibility*. The fine details of this notion are beyond the scope of this paper, and we refer the reader to the papers [3, 17] (see also the survey paper [11]). Informally, a function f is randomly self-reducible if evaluation of f on an input can be reduced efficiently to the evaluation of f on one or more random inputs. For a brief example, note that linear functions are randomly self-reducible: to compute $f(x)$, it suffices to pick a random r, compute $f(x+r)$ and $f(r)$, and finally obtain $f(x) = f(x+r) - f(r)$. All functions that we consider in this paper are efficiently randomly self-reducible; therefore, whenever required we will always assume that efficient self-correction is possible.

1.2. Building self-testers using properties.

The process of self-testing whether a program P computes a function f correctly on most inputs is usually a two-step strategy. It is necessary to first perform some tests to verify that P agrees on most inputs with a function g that belongs to a certain class $\mathcal{F}$ of functions that contains f. Some additional tests are then needed to verify that the function g is, in fact, the intended function f.

The standard way to test whether P agrees with some function in a class $\mathcal{F}$ of functions is based on the notion of a *robust property*. Informally, property $\mathcal{I}$ is said to be a robust characterization of a function family $\mathcal{F}$ if the following two conditions hold: (1) every $f \in \mathcal{F}$ satisfies $\mathcal{I}$, and (2) if P is a function (program) that satisfies $\mathcal{I}$ for most inputs, then P must agree with some $g \in \mathcal{F}$ on most inputs. For example, Blum, Luby, and Rubinfeld [5] establish that the property of linearity $f(x+y) = f(x) + f(y)$ serves as a robust property for the class of all linear functions, and use this to build self-testers for linear functions. This generic technique was first formalized in [20].

DEFINITION 1.5 (robust property). *A* property *is a predicate* $\mathcal{I}^f(\vec{x} = x_1, \ldots, x_k)$. *A property* $\mathcal{I}^f(\vec{x})$ *is* (ϵ, δ)-robust *for a class of functions* $\mathcal{F}$ *over a domain* $\mathcal{D}$ *if it satisfies the following conditions*:

- $(\forall f)\left[f \in \mathcal{F} \iff (\forall \vec{x} \in \mathcal{D}^k)[\mathcal{I}^f(\vec{x}) = \mathsf{TRUE}]\right]$.
- *If a function (program) P satisfies* $\Pr_{\vec{x} \in \mathcal{D}^k}[\mathcal{I}^P(\vec{x}) = \mathsf{TRUE}] \geq 1 - \epsilon$, *then there is a function g such that*
  - ◦ $(\forall \vec{x} \in \mathcal{D}^k)[\mathcal{I}^g(\vec{x}) = \mathsf{TRUE}]$, *and*
  - ◦ $\Pr_{x \in \mathcal{D}}[g(x) = P(x)] \geq 1 - \delta$,

that is, $(\exists g \in \mathcal{F})$ *such that P agrees with g on all but δ fraction of inputs.*

We now outline the process of building self-testers using robust properties (cf. [5]). Let $\mathcal{D}$ be a (finite) group with generators $e_1, \ldots, e_n$, and let $\mathcal{F}$ denote some class of functions from $\mathcal{D}$ into some range $\mathcal{R}$. Further assume that the functions in $\mathcal{F}$ possess the property of random self-reducibility and can hence be self-corrected efficiently. Suppose P is a program that purports to compute a specific function $f \in \mathcal{F}$. Let $\mathcal{I}^f(\vec{x})$ be a robust property that characterizes $\mathcal{F}$.

As mentioned earlier, the process of building self-testers is a two-step process. In the first step, we will ensure that that the program P agrees with some function

$g \in \mathcal{F}$ on most inputs. To do this, we use the fact that $\mathcal{I}^f$ is a robust property that characterizes $\mathcal{F}$. Specifically, the self-tester will estimate the fraction of k-tuples $\vec{x} \in \mathcal{D}^k$ for which $\mathcal{I}^f(\vec{x})$ holds. If this fraction is at least $1-\epsilon$, then by the robustness of $\mathcal{I}^f$, it follows that there is some $g \in \mathcal{F}$ that agrees with P on all but δ fraction of $\mathcal{D}$. The required estimation can be carried out by a random sampling of $\vec{x}$ and testing the property $\mathcal{I}^f$.

The next step is to verify that the function g is the same as the function f that P purports to compute. This is achieved by testing that $g(e_i) = f(e_i)$ for every *generator* of the group $\mathcal{D}$. If this is true, then by an easy induction it would follow that $g \equiv f$. An important point to be made here is that the self-tester has access only to P and not to g; the function g is only guaranteed to exist. Nevertheless, the required values of g may be obtained by using a self-corrected version P_{sc} of P. Another point worth mentioning is that to carry out this step, the self-tester needs to know the values of f on every generator of $\mathcal{D}$.

1.3. The generator bottleneck. An immediate application of the basic method outlined above to functions whose domains are vector spaces of large dimension suffers from a major efficiency drawback. For example, if the inputs to the function f are n-dimensional vectors (or $n \times n$ matrices), then the number of generators of the domain is n (resp., n^2). The straightforward approach of exhaustively testing if P_{sc} agrees with f on each generator makes n (resp., n^2) calls to P; furthermore, the self-tester built on this approach requires the knowledge of the correct value of f on n (resp., n^2) generators. When n is large, this makes the overhead in the self-testing process too high. This issue is called the *generator bottleneck* problem.

In this paper, we address the generator bottleneck problem and solve it for a fairly large class of functions that satisfy some nice structural properties. The self-testers that we build are not only useful in themselves, but are also useful in building efficient result-checkers, which are important for practical applications.

1.4. Our results. We present a fairly general method of overcoming the generator bottleneck and testing multivariate functions by making only $O(1)$ calls to the program being tested.

First we investigate the problem of *multivariate linear functions* (i.e., the functions f satisfying $f(\vec{x})+f(\vec{y}) = f(\vec{x}+\vec{y})$). We show a general technique that can be applied in a natural vector space setting. The main idea is to obtain an easy and uniform way of "generating" all generators from a single generator. Using this idea, we give a simple and powerful condition for a linear function f to be efficiently self-testable on a large vector space. We then apply this scheme to obtain very efficient self-testers for many functions. This includes polynomial differentiation (of arbitrary order), polynomial integration, polynomial "mod" function, etc. We also obtain the first efficient self-tester for Fourier transforms.

We then extend this method to the case of *multilinear functions* (i.e., functions f that are linear in each variable when the other variables are fixed). We build an efficient tester for polynomial multiplication as a consequence. Another application we give is for large finite fields: we show that multilinear functions over finite field extensions of dimension n can be efficiently self-tested with $O(1)$ calls, independent of the dimension n. We also provide a new efficient self-tester for matrix multiplication.

We next extend the result to some *nonlinear functions.* We give self-testers for exponentiation functions that avoid the generator bottleneck. For example, consider the function that computes the square of a polynomial over a finite field: $f(q) = q^2$. Here we do not have the linearity property that is crucial in the proof for the linear functions. Instead, we use the fact that the Lagrange interpolation identity (cf. Fact 4.1) for polynomials gives a robust characterization. We exhibit a self-tester for the function $f(q) = q^d$ that makes $O(d)$ calls to the program being tested. Extending the technique when f is a constant degree exponentiation to the case when f is a constant degree polynomial (e.g., $f(q) = q^d + q + 1$, where q is a polynomial over a finite field) is much harder. First we show a reduction from multiplication to the computation of low-degree polynomials. Using this reduction and the notion of a result-checker, we construct a self-tester for degree d polynomials over finite field extensions of dimension n that make $O(2^d)$ calls to the program being tested.

1.5. Related work. One method that has been used to get around the generator bottleneck has been to exploit the property of *downward self-reducibility* [5]. The self-testers that use this property, however, have to make $\Omega(\log n)$ calls to the program depending on the way the problem decomposes into smaller problems. For instance, a tester for the permanent function of $n \times n$ matrices makes $O(n)$ calls to the program, whereas a tester for polynomial multiplication that uses similar principles makes $O(\log n)$ calls. In [5] a bootstrap tester for polynomial multiplication that makes $O(\log n)$ calls to the program being tested is given. It is already known that matrix multiplication can be tested (without any calls to the program) using a result-checker due to Freivalds [13]. The idea of Freivalds' matrix multiplication checker can also be adapted to build testers for polynomial multiplication that make no calls to the program being tested. This approach, however, requires the underlying field to be large (have at least $(2+\gamma)n$ elements, where n is the degree of the polynomials being multiplied, and γ is a positive constant). Moreover, this scheme requires the tester to perform polynomial evaluations, whereas ours does not. For Fourier transforms, a different result-checker that uses preprocessing has been given independently in [6].

A useful fact. The following fact, a variant of the well-known Chernoff–Hoeffding bounds, is often very useful in obtaining error-bounds in sampling 0/1 random variables [15].

FACT 1.6. *Let $Y_1, Y_2, \ldots$ be independently and identically distributed 0/1 random variables with means μ. Let $\theta \leq 2$. If $N \geq (1/\mu)(4\ln(2/\rho)/\theta^2)$, then $\Pr[(1-\theta)\mu \leq \widetilde{Y} \leq (1+\theta)\mu] \geq 1 - \rho$, where $\widetilde{Y} = \sum_{i=1}^{N} Y_i/N$.*

Organization of the paper. Section 2 discusses the scheme for linear functions over vector spaces; section 3 extends the scheme for multilinear functions; section 4 outlines the approach for nonlinear functions.

2. Linear functions over vector spaces.

In this section, we address the problem of self-testing linear functions on a vector space without the generator bottleneck. We demonstrate a general technique to self-test without the generator bottleneck and provide several interesting applications of our technique.

Definitions. Let V be a vector space of finite dimension n over a field $\mathbb{K}$, and let f be a function from V into a ring R. We are interested in building a self-tester for the case where $f(\cdot)$ is a *linear* function, that is, $f(c\alpha + \beta) = cf(\alpha) + f(\beta)\ \forall\ \alpha, \beta \in V$ and $c \in \mathbb{K}$. For $1 \leq i \leq n$, let e_i denote the unit vector that has a 1 in the ith position and 0's in the other positions. The vectors $e_1, e_2, \ldots, e_n$ form a collection of basis vectors that span V. Viewed as an Abelian group under vector addition, V is generated by $e_1, \ldots, e_n$. We assume that the field $\mathbb{K}$ is finite, since it is not clear how to choose a random element from an infinite field.

The property of linearity $\mathcal{I}^f(\alpha, \beta) \equiv [f(\alpha + \beta) = f(\alpha) + f(\beta)]$ was shown to be robust in [5]. Using this and the generic construction of self-testers from robust properties, one obtains the following self-tester for the function f:

```
Property Test:
  Repeat $O(\frac{1}{\epsilon}\log\frac{1}{\rho})$ times
    Pick $\alpha, \beta \in_R V$
    Verify $P(\alpha+\beta) = P(\alpha) + P(\beta)$
    Reject if the test fails

Generator Tests:
  For $i = 1$ to $n$
    Verify $P_{\text{sc}}(e_i) = f(e_i)$
```

If P passes the `Property Test` then we are guaranteed the existence of a linear function g that is close to P. There are, however, two problems with the `Generator Tests`: one is that the self-tester is inefficient—if the inputs are vectors of size n, the self-tester makes $O(n)$ calls to the program, which is not desirable. Second, the self-tester needs to know the correct value of f on n different points, which is also undesirable. Our primary interest is to avoid this generator bottleneck and solve both of the problems mentioned. The key idea is to find an easy and uniform way that "converts" one generator into the next generator. We illustrate this idea through the following example.

Example. Let $\mathcal{P}_n$ denote the additive group of all degree n polynomials over a field $\mathbb{K}$. The elements $1, x, x^2, \ldots, x^n$ generate $\mathcal{P}_n$, and multiplying any generator x^k by x gives the next generator x^{k+1}. For a polynomial $q \in \mathcal{P}_n$ and a scalar $c \in \mathbb{K}$, let $E_c(q)$ denote the function that evaluates $q(c)$. Clearly E_c is linear and satisfies the simple relation $E_c(xq) = cE_c(q)$. Suppose P is a program that purports to compute E_c, and assume that P has passed `Property Test` given above. Then we know by robustness of linearity that there is a linear function g that agrees with P on most inputs. Note that g can be computed correctly with high probability via the self-corrector (which is easy to construct for linear functions [5]). Now, rather than verify that $g(x^k) = E_c(x^k)$ for all generators x^k of $\mathcal{P}_n$, we may instead verify that g satisfies the property $g(xq) = cg(q)$ everywhere. By an easy induction, this implies that g agrees with E_c at all the generators. By linearity of g, it follows that g agrees with E_c on all inputs.

We are now faced with the task of verifying $g(xq) = cg(q)\ \forall\ q \in \mathcal{P}_n$, which is too expensive to be tried explicitly and exhaustively. Instead, we prove that it suffices to check with $O(1)$ tests that $g(xq) = cg(q)$ almost every place that we look at. That is, pick many random $q \in \mathcal{P}_n$, ask the program P_{sc} to compute the values of $g(q)$ and $g(xq)$, and cross-check that $g(xq) = cg(q)$ holds. In other words, we prove that the property $\mathcal{J}^g(q) \equiv [g(xq) = cg(q)]$ is robust (in a restricted sense) under the assumption that g is linear. (In its most general interpretation, robustness guarantees the existence of h that satisfies $h(xq) = ch(q)\ \forall\ q \in \mathcal{P}_n$, and that agrees with g on a large fraction of inputs. We actually show that $h \equiv g$, hence the "restricted sense.") The self-tester needs to know the value of f on only one point, in contrast to n, as in the original approach of [5].

Generalization via the basis rotation function θ. We note that this idea has a natural generalization to vector spaces. Let θ denote the *basis rotation function*, i.e., the linear operator on a vector space V that "rotates" the coordinate axes that span V. θ, which can be viewed as a matrix, defines a one-to-one correspondence from the set of basis vectors to itself: for every i, $\theta(e_i) = e_{(i+1) \bmod n}$. The computational payoff is achieved when there is a simple relation between $f(\alpha)$ and $f(\theta(\alpha))$ for all vectors $\alpha \in V$. More specifically, we show that the generator bottleneck can be avoided if there is an easily computable function $h_{\theta,f}$ such that

$$f(\theta(\alpha)) = h_{\theta,f}(\alpha, f(\alpha)),$$

$\forall\ \alpha \in V$. (For instance, for polynomial evaluation E_c, $f(\theta(q)) = c \cdot f(q), \forall q \in \mathcal{P}_n$.) From here on, when obvious, we drop the suffix f and simply denote $h_{\theta,f}$ as h_θ. If the function f is linear, the linearity of θ implies that h_θ is linear in its second argument in the following sense: $h_\theta(\alpha+\beta, f(\alpha+\beta)) = h_\theta(\alpha, f(\alpha)) + h_\theta(\beta, f(\beta))$. What is more important is that h_θ be easy to compute, given just α and $f(\alpha)$. Using this scheme, we show that many natural functions f have a suitable candidate for h_θ. The `Generator Tests` of [5] can now be replaced by:

```
Basis Test:
  Verify $P_{\rm sc}(e_1) = f(e_1)$

Inductive Test:
  Repeat $O(\frac{1}{\epsilon}\log\frac{1}{\rho})$ times
    Pick $\alpha \in_R V$
    Verify $P_{\rm sc}(\theta(\alpha)) = h_\theta(\alpha, P_{\rm sc}(\alpha))$
    Reject if the test fails
```

The following theorem proves that this replacement is valid.

THEOREM 2.1. *Suppose f is a linear function from the vector space V into a ring R, and suppose P is a program for f.*

(a) *Let $\epsilon < 1/2$, and suppose P satisfies the following condition*:

(1) $\Pr_{\alpha,\beta\in V}[P(\alpha+\beta) \neq P(\alpha) + P(\beta)] \leq \epsilon$. *Then the function g defined by $g(\alpha) = \text{majority}_{\beta\in V}\{P(\alpha+\beta) - P(\beta)\}$ is a linear function on V, and g agrees with P on at least $1-2\epsilon$ fraction of the inputs.*

(b) *Furthermore, suppose $h_\theta(\alpha, f(\alpha)) = f(\theta(\alpha))$ and g satisfies the following conditions*:

(2) $g(e_1) = f(e_1)$.

(3) $\Pr_{\alpha\in V}[g(\theta(\alpha)) \neq h_\theta(\alpha, g(\alpha))] \leq \epsilon$, *where α is such that $\theta(\alpha)$ is defined. Then $g(\alpha) = f(\alpha)\ \forall\ \alpha \in V$.*

Remarks. The above theorem merely lists a set of properties. The fact that this set yields a self-tester is presented in Theorem 2.2. Note that hypotheses (1), (2), and (3) above are *conditions* on P and g, not *tests* performed by a self-tester.

Proof. The proof that the function g is linear and $P_{\rm sc}$ computes g (with high probability) is due to [5]. For the rest of this proof, we will assume that g is linear and that it satisfies conditions (2) and (3) above.

We first argue that it suffices to prove that if the conditions hold, then for every $\alpha \in V$, $g(\theta(\alpha)) = h_\theta(\alpha, g(\alpha))$. By condition (2), g agrees with f on the first basis vector. For $i > 1$, the basis vector e_i can be obtained by $\theta(e_{i-1})$. If g satisfies $g(\theta(\alpha)) = h_\theta(\alpha, g(\alpha))$ everywhere, it would follow that g computes f correctly on all the basis vectors. Finally, since g is linear, it computes f correctly on all of V, since the vectors in V are just linear combinations of the basis vectors.

Now we show that condition (3) implies that $\forall \alpha \in V$, $g(\theta(\alpha)) = h_\theta(\alpha, g(\alpha))$. Fix an arbitrary element $\alpha \in V$. We will show that the probability over a random $\beta \in V$

that $g(\theta(\alpha)) = h_\theta(\alpha, g(\alpha))$ is positive. Since the equality is independent of β and holds with nonzero probability, it must be true with probability 1. Now

$$\begin{aligned}\Pr_{\beta\in V}\big[g(\theta(\alpha)) &= g(\theta(\beta+\alpha-\beta))\\ &= g(\theta(\beta)+\theta(\alpha-\beta))\\ &= g(\theta(\beta))+g(\theta(\alpha-\beta))\\ &= h_\theta(\beta, g(\beta)) + h_\theta(\alpha-\beta, g(\alpha-\beta))\\ &= h_\theta(\beta+\alpha-\beta, g(\beta)+g(\alpha-\beta))\\ &= h_\theta(\alpha, g(\alpha))\big] \geq 1-2\epsilon > 0.\end{aligned}$$

The first equality in the above is just rewriting. The second equality follows from the linearity of θ. The third equality follows from the fact that g is linear. If the random variable β is distributed uniformly in V, the random variables β and $\alpha - \beta$ are distributed identically and uniformly in V. Therefore, by the assumption that g satisfies condition (3), the fourth equality fails with probability at most 2ϵ. The fifth equality uses the fact that h_θ is linear, and the last equality uses the fact that g is linear. □

The foregoing theorem shows that if P (and g) satisfy certain conditions, then g, which can be computed using P, is identically equal to the function f. The self-tester comprises the following tests: `Linearity Test`, `Basis Test`, and `Inductive Test`.

THEOREM 2.2. *For any $\rho < 1$ and $\epsilon < 1/2$, the above three tests compose a 2ϵ-self-tester for f. That is, if a program P computes f correctly on all inputs, then the self-tester outputs* PASS *with probability* 1, *and if P computes f incorrectly on more than 2ϵ fraction of the inputs, then the self-tester outputs* FAIL *with probability at least $1-\rho$.*

Proof. In performing the three tests, the self-tester is essentially estimating the probabilities listed in conditions (1), (2), and (3) of the hypothesis of Theorem 2.1. Note that condition (2) does not involve any probability; rather, the self-tester uses P_{sc} to compute $g(e_1)$. By choosing $O((1/\epsilon)\log(1/\rho))$ samples in `Linearity Test` and `Inductive Test` and by using the self-corrector with confidence parameter $\rho/3$ in `Basis Test` the self-tester ensures that its confidence in checking each condition is at least $1-(\rho/3)$.

Clearly if P always computes f correctly, the tester always outputs PASS. Conversely, suppose the tester outputs PASS. Then with probability $1-\rho$, the hypotheses of Theorem 2.1 are true. By the conclusion of Theorem 2.1, it follows that a function g that is identical to f exists, and that g equals P on at least $1-2\epsilon$ fraction of the inputs. □

2.1. Applications. We present some applications of Theorem 2.2. We remind the reader that a linear function f on a vector space V is efficiently self-testable without the generator bottleneck if there is a (linear) function h_θ that is easily computable and that satisfies $f(\theta(\alpha)) = h_\theta(\alpha, f(\alpha))\ \forall\ \alpha \in V$. In each of our applications f, we show that a suitable function $h = h_{\theta,f}$ exists that satisfies the above conditions. Recall the example of the polynomial evaluation function $E_c(q) = q(c)$, where the identity $E_c(xq) = cE_c(q)$ holds; in the applications below, we will establish only similar relationships. Also, for the sake of simplicity, we do not give all the technical parameters required; these can be computed by routine calculations following the proofs of the theorems in the last section.

Our applications concern linear functions of polynomials. We obtain self-testers for polynomial evaluation, Fourier transforms, polynomial differentiation, polynomial integration, and the *mod* function of polynomials. Moreover, the vector space setting lets us state some of these results in terms of the matrices that compute linear transforms of vector spaces.

Let $\mathcal{P}_n \subseteq \mathbb{K}[x]$ denote the group of polynomials in x of degree $\leq n$ over a field $\mathbb{K}$. The group $\mathcal{P}_n$ forms a vector space under usual polynomial addition and scalar multiplication by elements from $\mathbb{K}$. The polynomials $1, x, x^2, \ldots, x^n$ span $\mathcal{P}_n$, and a polynomial $q(x) = \sum_{i=0}^{n} q_i x^i$ has the vector representation $(q_n, q_{n-1}, \ldots, q_1, q_0)$. The basis rotation function θ in this case is just multiplication by x, thus $\theta(q) = xq$. Note that multiplying q by x results in a polynomial of degree $n+1$. To handle this minor detail, we will assume that the program works over the domain $\mathcal{P}_{n+1}$, and we conclude correctness over $\mathcal{P}_n$.

Polynomial evaluation. For any $c \in \mathbb{K}$, let $E_c(q)$ denote, as described before, the function that returns the value $q(c)$. This function is linear. Moreover, the relation between $E_c(xq)$ and $E_c(q)$ is simple and linear: $E_c(xq) = cE_c(q)$. To self-test a program P that claims to compute E_c, the `Inductive Test` is simply to choose many random q's, and verify that $P_{\text{sc}}(xq) = cP_{\text{sc}}(q)$ holds.

Vandermonde operators and the discrete Fourier transform. If $u_1, u_2, \ldots, u_{n+1}$ are $n+1$ distinct elements of $\mathbb{K}$, then one may wish to evaluate a polynomial $q \in \mathcal{P}_n$ simultaneously on all $n+1$ points. The ideas for E_c extend easily to this case, for $E_u(xq) = uE_u(q)$ for any $u \in \mathbb{K}$, and these relations hold simultaneously.

Let ω be a principal $(n+1)$-st root of unity in $\mathbb{K}$. The operation of converting a polynomial from its coefficient representation to pointwise evaluation at the powers of ω is known as the discrete Fourier transform (DFT). DFT has many fundamental applications that include fast multiplication of integers and polynomials. With our notation, the DFT of a polynomial $q \in \mathcal{P}_n$ is simply $F(q) = (E_{\omega^0}(q), E_{\omega^1}(q), \ldots, E_{\omega^n}(q))$. The DFT F is linear, and $F(xq) = (\omega^0 E_{\omega^0}(q), \ldots, \omega^n E_{\omega^n}(q))$. Notice that here the function h is really n coordinate functions h_{ω^i} for $0 \leq i \leq n$. The self-tester will simply choose q's randomly, request the program to compute $F(q)$ and $F(xq)$, and verify for each i, $0 \leq i \leq n$, that $(F(xq))[i] = \omega^i (F(q))[i]$ holds.

This suggests the following generalization (for the case of arbitrary vector spaces). Simultaneous evaluation of a polynomial at $d+1$ points $u_1, \ldots, u_{n+1}$ corresponds to multiplying the vector p by a Vandermonde matrix M, where $M_{ij} = u_i^{j-1}$. The ideas used to test simultaneous evaluation of polynomials and the DFT extend to give a self-tester for any linear transform that is represented by a Vandermonde matrix.

The matrix for the DFT can be written as a Vandermonde matrix F, where $F_{ij} = \omega^{ij}$. The inverse of the DFT, that is, converting a polynomial from pointwise representation to coefficient form, also has a Vandermonde matrix whose entries are given by $\widetilde{F}_{ij} = (1/\det F)\omega^{-ij}$. It follows that the inverse Fourier transform can be self-tested efficiently. Another point worth mentioning here is that in carrying out the `Inductive Test` the self-tester does not have to compute $\det F$. All it needs to do is verify that for many randomly chosen q's, the identity $(\widetilde{F}(xq))[i] = \omega^{-i}(\widetilde{F}(q))[i]$ holds.

Operators in elementary Jordan canonical form. A linear operator M is said to be in elementary Jordan canonical form if all the diagonal entries of M are c for some $c \in \mathbb{K}$, and all the elements to the left of the main diagonal (the first non principal diagonal in the lower triangle of M) are 1's. It is easy to verify that $M\theta = \theta M + M'$, where M' is a matrix that has a -1 in the top left corner and a 1 in the bottom right corner and zeroes elsewhere. Therefore, for every $v = (v_n, v_{n-1}, \ldots, v_2, v_1)^T$ in the vector space, $M(\theta(v)) = \theta(M(v)) + (-v_n, 0, \ldots, 0, v_1)^T$. This gives an easy way to implement the `Inductive Test` in the self-tester.

An attempt to extend this to matrices in Jordan canonical form, or even to diagonal matrices, seems not to work. If, however, a diagonal or shifted diagonal matrix has a special structure, then we can obtain self-testers that avoid the generator problem. For example, the matrix corresponding to the differentiation of polynomials has a special structure: it contains the entries $n, n-1, \ldots, 1$ on the diagonal above the main diagonal.

Differentiation and integration of polynomials. Differentiation of polynomials is a linear function $D : \mathcal{P}_n \to \mathcal{P}_{n-1}$. We have the explicit form for h: $D(xq) = q + xD(q)$. Integration of polynomials is a linear function $I : \mathcal{P}_n \to \mathcal{P}_{n+1}$. The explicit form for h is $I(xq) = xI(q) - I(I(q))$. Even though this does not readily fit into our framework (since it is not of the form $I(xq) = h(q, I(q))$), the proof of Theorem 2.1 can be easily modified to handle this case using the linearity of I. For completeness, we spell out the details for the robustness of the `Inductive Test`, which is the only change required.

LEMMA 2.3. *If $g : \mathcal{P}_n \to \mathcal{P}_{n+1}$ is a linear function that satisfies $\Pr_{q\in\mathcal{P}_n}[g(xq) \neq xg(q) - g(g(q))] = \epsilon < 1/2$, then $\Pr_{q\in\mathcal{P}_n}[g(xq) = xg(q) - g(g(q))] = 1$.*

Proof.

$$\begin{aligned}\Pr_{r\in\mathcal{P}_n}\big[g(xq) &= g(x(r+q-r))\\ &= g(xr + x(q-r))\\ &= g(xr) + g(x(q-r))\\ &= xg(r) - g(g(r)) + xg(q-r) - g(g(q-r))\\ &= x(g(r) + g(q-r)) - g(g(r) + g(q-r))\\ &= xg(q) - g(g(q))\big] \geq 1 - 2\epsilon > 0.\end{aligned}$$

Since the event $g(xq) = xg(q) - g(g(q))$ holds with positive probability and is independent of r, it holds with probability one. ☐

Thus we can avoid the generator bottleneck for these functions. This can be considered as a special case of the previous application.

Higher order differentiation of polynomials. Let D^k denote the kth differential operator. It is easy to write a recurrence-like identity for D^k in terms of $D^j, j < k$. This gives us a self-tester only in the library setting described in [5, 21], where one assumes that there are programs to compute all these differential operators. If we wish to self-test a program that only computes D^k and have no library of lower-order differentials, this assumption is not valid. To remedy this, we will use the following lemma, which is proved in the appendix.

LEMMA 2.4. *If q is a polynomial in x of degree $\geq k$, then*

$$\sum_{i=0}^{k} \binom{k}{i} (-x)^{k-i} D^k(x^i q) = k!q.$$

Using this identity, the self-tester can perform an `Inductive Test`. The robustness of the `Inductive Test` can be established as in the proof of Theorem 2.1. For completeness, we outline the key step here. Let c_i denote the coefficient of the term $D^k(x^i q)$ in the sum in Lemma 2.4. Thus $c_i = \binom{k}{i}(-x)^{k-i}$.

LEMMA 2.5. *If g is a linear function that satisfies* $\Pr_{q\in\mathcal{P}_n}[\sum_i c_i g(x^i q) \neq k!q] = \epsilon < 1/2$, *then* $\Pr_{q\in\mathcal{P}_n}[\sum_i c_i g(x^i q) = k!q] = 1$.

Proof.

$$\begin{aligned}\Pr_{r\in\mathcal{P}_n}\Big[\sum_i c_i g(x^i q) &= \sum_i c_i g(x^i(r+q-r)) \\ &= \sum_i c_i g(x^i r) + \sum_i c_i g(x^i(q-r)) \\ &= k!r + k!(q-r) \\ &= k!q\Big] \geq 1-2\epsilon > 0.\end{aligned}$$

Here the first equality is rewriting; the second equality holds with probability $1-2\epsilon$ by the assumption that $\Pr_q[\sum_i c_i g(x^i q) \neq k!q] = \epsilon$. Since the event $\sum_i c_i g(x^i q) = k!q$ holds with positive probability and is independent of r, it holds with probability one. ∎

Thus, testing if g satisfies this identity for most q suffices to ensure that g satisfies this identity everywhere. If g does satisfy this identity, then we know the following: if $g(q) = D^k(q), g(xq) = D^k(xq), g(x^2q) = D^k(x^2q), \ldots, g(x^{k-1}q) = D^k(x^{k-1}q)$, then $g(x^kq) = D^k(x^kq)$. To conclude that $g \equiv D^k$ by induction, we need to modify `Basis Test` to test k base cases: if $g(1) = D^k(1), g(x) = D^k(x), g(x^2) = D^k(x^2), \ldots, g(x^{k-1}) = D^k(x^{k-1})$, i.e., if $g(1) = g(x) = g(x^2) = \cdots = g(x^{k-1}) = 0$.

Mod function. Let $\alpha \in \mathbb{K}[x]$ be a monic irreducible polynomial. Let $M_\alpha(q)$ denote the mod function with respect to α, that is, $M_\alpha(q) = q \bmod \alpha$. This is a linear function when the addition is interpreted as mod α addition. Since α is monic, the degree of $M_\alpha(q)$ is always less than $\deg\alpha$. If $c \in \mathbb{K}$ is the coefficient of the highest degree term in $M_\alpha(q)$, we have

$$M_\alpha(xq) = \begin{cases} xM_\alpha(q) & \text{if } \deg xM_\alpha(q) < \deg\alpha, \\ xM_\alpha(q) - c\alpha & \text{if } \deg xM_\alpha(q) = \deg\alpha. \end{cases}$$

As before, in testing if a program P computes the function M_α, step (3) of the self-tester is to choose many q's at random, compute $P_{\mathrm{sc}}(q)$ and $P_{\mathrm{sc}}(xq)$, and verify that one of the identities $P_{\mathrm{sc}}(xq) = xP_{\mathrm{sc}}(q)$ or $P_{\mathrm{sc}}(xq) = xP_{\mathrm{sc}}(q) - cq$ holds (depending on the degree of q).

3. Multilinear functions.

In this section we extend the ideas in section 2 to multilinear functions. A k-variate function f is called *k-linear* if it is linear in each of its variables when the other variables are fixed, i.e., $f(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i + \beta_i, \alpha_{i+1}, \ldots, \alpha_k) = f(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i, \alpha_{i+1}, \ldots, \alpha_k) + f(\alpha_1, \ldots, \alpha_{i-1}, \beta_i, \alpha_{i+1}, \ldots, \alpha_k)$ $\forall\ i = 1, \ldots, k$.

Our main motivating example for a multilinear function is polynomial multiplication $f : \mathcal{P}_{n-1} \times \mathcal{P}_{n-1} \to \mathcal{P}_{2n-1}$, which is bilinear. Note that the domain of f is generated by n^2 generators of the form (x^i, x^j) for $0 \leq i, j \leq n$ (i.e., pairs of generators of $\mathcal{P}_{n-1}$). Now, suppose we wish to test P that purports to compute f. The naive approach would require doing the `Generator Tests` at these n^2 generators. This requires $O(n^2)$ calls to P, rendering the self-tester highly inefficient. Blum, Luby, and Rubinfeld [5] give a more efficient bootstrap self-tester that makes $O(\log^{O(k)} n)$ calls to P. It can be seen that for general k-linear functions, their method can be extended to yield a tester that makes $O(\log^{O(k)} n)$ calls to P. (In our context, it is allowable to think of k as a constant since changing k results in an entirely different function f.) We are interested in reducing the number of calls to P with respect to the problem size n for a specific function f. The complexity of the tester we present here is independent of n, and the self-tester is required to know the correct value of f at only one point. As in the previous section, our result applies to many general multilinear functions over large vector spaces.

As before, we define a set of properties depending on f, that, if satisfied by P, would necessarily imply that P must be the same as the particular multilinear function f. For simplicity, we present the following theorem for f that is bilinear. This is an analog of Theorem 2.1 for multilinear functions.

THEOREM 3.1. *Suppose f is a bilinear function from V^2 into a ring R, and suppose P is a program for f.*

(a) *Let $\epsilon < 1/4$, and suppose P satisfies the following condition*:

(1) $\Pr_{\alpha_1,\alpha_2,\beta_1,\beta_2 \in V}[P(\alpha_1+\beta_1,\alpha_2+\beta_2) \neq P(\alpha_1,\alpha_2)+P(\alpha_1,\beta_2)+P(\beta_1,\alpha_2)+P(\beta_1,\beta_2)] \leq \epsilon$.

Then the function g defined by $g(\alpha_1,\alpha_2) = \text{majority}_{\beta_1,\beta_2\in V}\{P(\alpha_1-\beta_1,\alpha_2-\beta_2)+P(\alpha_1-\beta_1,\beta_2)+P(\beta_1,\alpha_2-\beta_2)+P(\beta_1,\beta_2)\}$ is a bilinear function on V^2, and g agrees with P on at least $1-2\epsilon$ fraction of the inputs.

(b) *Furthermore, suppose g satisfies the following conditions*:

(2) $g(e_1,e_1) = f(e_1,e_1)$,

(3)

$$\Pr_{\alpha_1,\alpha_2\in V}[g(\theta(\alpha_1),\alpha_2) \neq h_\theta^{(1)}(\alpha_1, g(\alpha_1,\alpha_2))] \leq \epsilon,$$

$$\Pr_{\alpha_1,\alpha_2\in V}[g(\alpha_1,\theta(\alpha_2)) \neq h_\theta^{(2)}(\alpha_2, g(\alpha_1,\alpha_2))] \leq \epsilon.$$

Then $g(\alpha_1,\alpha_2) = f(\alpha_1,\alpha_2)\ \forall\ \alpha_1,\alpha_2 \in V$.

Proof. A simple extension of the proof in [5] shows that g is bilinear. (Better bounds on ϵ via a different test can be obtained by appealing to [2].) As in the proof of Theorem 2.1, it suffices to show that given the three conditions, a stronger version of condition (3) holds: $g(\theta(\alpha_1),\alpha_2) = h_\theta^{(1)}(\alpha_1, g(\alpha_1,\alpha_2))$ and $g(\alpha_1,\theta(\alpha_2)) = h_\theta^{(2)}(\alpha_2, g(\alpha_1,\alpha_2))$ for every $\alpha_1,\alpha_2 \in V$. With the addition of this last property, it can be shown that $g \equiv f$. Taking condition (2) that $g(e_1,e_1) = f(e_1,e_1)$ as the base case and inducting by obtaining (e_{i+1},e_i) and (e_i,e_{i+1}) from (e_i,e_i) via an application of θ to either generator $\forall\ 1 \leq i < n$, it can be shown that $g(e_i,e_j) = f(e_i,e_j)$ for any bases elements e_i, e_j of V. This, combined with the bilinearity property of g, implies the correctness of g on every input.

Now we proceed to show the required intermediate result that given conditions (1) and (2), g satisfies the stronger version of condition (3) that we require above:

$$\begin{aligned}
\Pr_{\beta_1,\beta_2\in V^2}\big[&g(\alpha_1,\theta(\alpha_2))\\
&= g(\beta_1+\alpha_1-\beta_1, \theta(\beta_2+\alpha_2-\beta_2))\\
&= g(\beta_1,\theta(\beta_2+\alpha_2-\beta_2)) + g(\alpha_1-\beta_1,\theta(\beta_2+\alpha_2-\beta_2))\\
&= g(\beta_1,\theta(\beta_2)) + g(\beta_1,\theta(\alpha_2-\beta_2)) + g(\alpha_1-\beta_1,\theta(\beta_2)) + g(\alpha_1-\beta_1,\theta(\alpha_2-\beta_2))\\
&= h_\theta^{(2)}(\beta_2, g(\beta_1,\beta_2)) + h_\theta^{(2)}(\alpha_2-\beta_2, g(\beta_1,\alpha_2-\beta_2))\\
&\quad + h_\theta^{(2)}(\beta_2, g(\alpha_1-\beta_1,\beta_2)) + h_\theta^{(2)}(\alpha_2-\beta_2, g(\alpha_1-\beta_1,\alpha_2-\beta_2))\\
&= h_\theta^{(2)}(\alpha_2, g(\beta_1,\alpha_2)) + h_\theta^{(2)}(\alpha_2, g(\alpha_1-\beta_1,\alpha_2))\\
&= h_\theta^{(2)}(\alpha_2, g(\alpha_1,\alpha_2))\big] \geq 1-4\epsilon > 0.
\end{aligned}$$

The first equality is a rewriting of terms. Multilinearity of g implies the second and third equalities. If the probability $\Pr[g(\alpha_1, \theta(\alpha_2)) \neq h_\theta^{(2)}(\alpha_2, g(\alpha_1, \alpha_2))] < \epsilon$, then the fourth equality fails with probability less than 4ϵ. The rest of the equality follows from the multilinearity of $h_\theta^{(2)}$ and g. If $\epsilon < 1/4$, this probability is nonzero. Since the first and last terms are independent of β_1, β_2, and are equal with nonzero probability, the result follows. A similar approach works for $h_\theta^{(1)}$ as well. ∎

```
Multilinearity Test:
  Repeat $O(\frac{1}{\epsilon}\log\frac{1}{\rho})$ times
    Pick $\alpha_1, \alpha_2, \beta_1, \beta_2 \in_R V$
    Verify $P(\alpha_1+\beta_1, \alpha_2+\beta_2) = P(\alpha_1, \alpha_2) + P(\beta_1, \alpha_2) +$
          $P(\alpha_1, \beta_2) + P(\beta_1, \beta_2)$
    Reject if the test fails

Basis Test:
  Verify $P_{\text{sc}}(e_1, e_1) = f(e_1, e_1)$

Inductive Test:
  Repeat $O(\frac{1}{\epsilon}\log\frac{1}{\rho})$ times
    Pick $\alpha_1, \alpha_2 \in_R V$
    Verify $P_{\text{sc}}(\theta(\alpha_1), \alpha_2) = h_\theta^{(1)}(\alpha_1, P_{\text{sc}}(\alpha_1, \alpha_2))$
    Verify $P_{\text{sc}}(\alpha_1, \theta(\alpha_2)) = h_\theta^{(2)}(\alpha_2, P_{\text{sc}}(\alpha_1, \alpha_2))$
    Reject if the test fails
```

Note that in the latter two tests we use a self-corrected version P_{sc} of P. The notion of self-correctors for multilinear functions over vector spaces is implied by random self-reducibility.

It is easy to see that Theorem 3.1 extends to an arbitrary k-linear function so long as $\epsilon < 1/2^k$. Thus, we obtain the following theorem whose proof mirrors that of Theorem 2.2.

THEOREM 3.2. *If f is a k-variate linear function, then for any $\rho < 1$ and $\epsilon < 1/2^k$, the above three tests comprise a $2^k\epsilon$-self-tester for f that succeeds with probability at least $1-\rho$.*

3.1. Applications. Let q_1, q_2 denote polynomials in x. The function $M(q_1, q_2)$ that multiplies two polynomials is symmetric and linear in each variable. Moreover, since $M(xq_1, q_2) = M(q_1, xq_2) = xM(q_1, q_2)$, polynomial multiplication has an efficient self-tester.

An interesting application of polynomial multiplication, together with the mod function described in section 2.1, is the following. It is well known that a degree n (finite) extension $\mathbb{K}$ of a finite field $\mathbb{F}$ is isomorphic to the field $\mathbb{F}[x]/(\alpha)$, where α is an irreducible polynomial of degree n over $\mathbb{F}$. Under this isomorphism, each element of $\mathbb{K}$ is viewed as a polynomial of degree $\leq n$ over $\mathbb{F}$; addition of two elements $q_1, q_2 \in \mathbb{K}$ is just their sum $q_1 + q_2$ as polynomials; and multiplication of $q_1, q_2 \in \mathbb{K}$ is given by $q_1 q_2 \bmod \alpha$. It follows that field arithmetic (addition and multiplication) in finite extensions of a finite field can be self-tested without the generator bottleneck, that is, the number of calls made to the program being tested is independent of the degree of the field extension.

3.2. Matrix multiplication. Let $\mathcal{M}_n$ denote the algebra of $n \times n$ matrices over $\mathbb{Z}_p$, and let $f : \mathcal{M}_n \times \mathcal{M}_n \to \mathcal{M}_n$ denote matrix multiplication. Matrix multiplication is a bilinear function; however, since it is a matrix operation rather than a vector operation, it requires a slightly different treatment from the general multilinear functions. $\mathcal{M}_n$, viewed as an additive group, has n^2 generators; one possible set of generators is $\{E_{i,j} \mid 1 \leq i, j \leq n\}$, where each generator $E_{i,j}$ is a matrix that has a 1 in position (i, j) and 0's elsewhere. We note that any generator $E_{i,j}$ can be converted into any other generator $E_{k,\ell}$ via a sequence of horizontal and vertical rotations obtained by multiplications by the special *permutation matrix* Π:

$$\Pi = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & 0 & 0 & \dots & 0 \end{bmatrix} \Rightarrow \; E_{i,j} = \Pi^{k-i} \cdot E_{k,\ell} \cdot \Pi^{\ell-j}.$$

The rotation operations correspond to the θ operator of the model for multilinear functions. There are, however, two different kinds of rotations—horizontal and vertical—due to the two-dimensional nature of the input, and the function h defining the behavior of the function with respect to these rotations is not always easily computable, short of actually performing a matrix multiplication. We therefore exploit some additional properties of the problem to come up with a set of conditions that are sufficient for P to be computing matrix multiplication f. Let $\mathcal{M}'_n$ denote the subgroup of $\mathcal{M}_n$ that contains only matrices with columns $2, \dots, n$ all-zero.

THEOREM 3.3. *Let P be a program for f and $\epsilon < 1/8$.*

(a) *Suppose P satisfies the following*:

(1) $\Pr_{X,Y,Z,W \in \mathcal{M}_n}[P(X+Z, Y+W) \neq P(X,Y)+P(X,W)+P(Z,Y)+P(Z,W)] \leq \epsilon$.

Then the function g defined by $g(X,Y) = \text{majority}_{Z,W \in \mathcal{M}_n}\{P(X-Z, Y-W)+P(X-Z, W)+P(Z, Y-W)+P(Z,W)\}$ is a bilinear function on $\mathcal{M}_n^2$, and g agrees with P on at least $1-2\epsilon$ fraction of the inputs.

(b) *Furthermore, suppose g satisfies the following conditions*:

(2) $\Pr_{X \in \mathcal{M}'_n, Y \in \mathcal{M}_n}[g(X,Y) \neq f(X,Y)] \leq \epsilon$,

(3) $\Pr_{X \in \mathcal{M}_n}[g(X,\Pi) \neq f(X,\Pi)] \leq \epsilon$ *and* $\Pr_{X \in \mathcal{M}_n}[g(\Pi, X) \neq f(\Pi, X)] \leq \epsilon$,

(4) $\Pr_{X,Y,Z \in \mathcal{M}_n}[g(X, g(Y,Z)) \neq g(g(X,Y),Z)] \leq \epsilon$.

Then $g(X,Y) = f(X,Y)\ \forall\ X, Y \in \mathcal{M}_n$.

To be able to prove this theorem, we first need to show that the conditions recounted have stronger implications than their statements. Then we will show that these strengthened versions of the conditions imply Theorem 3.3.

First, we show that condition (2) implies a stronger version of itself.

LEMMA 3.4. *If condition* (2) *in Theorem* 3.3 *holds, then $g(E_{i,1}, Y) = f(E_{i,1}, Y)$ $\forall\ Y \in \mathcal{M}_n$ and $1 \leq i \leq n$.*

Proof. We in fact show something stronger. We show that $g(X,Y) = f(X,Y)\ \forall\ X \in \mathcal{M}'_n$ and $Y \in \mathcal{M}_n$:

$$\begin{aligned}\Pr_{Z \in \mathcal{M}'_n, W \in \mathcal{M}_n}\big[g(X,Y) &= g(Z, Y-W) + g(X-Z, Y-W) + g(Z,W) + g(X-Z,W) \\ &= f(Z, Y-W) + f(X-Z, Y-W) + f(Z,W) + f(X-Z,W) \\ &= f(X,Y)\big] > 1-4\epsilon > 0.\end{aligned}$$

The second equality holds with probability $\geq 1-4\epsilon$ by condition (2). All the rest hold from linearity of g and f. The result follows since $\epsilon < 1/4$. The lemma follows since $E_{i,1} \in \mathcal{M}'_n$. ∎

An immediate adaptation of the proof of Lemma 3.4 can be used to extend condition (3) to hold for all inputs.

Next, we show that the linearity of g makes it possible to conclude from hypothesis (4) that g is associative.

LEMMA 3.5. *If condition* (4) *in Theorem* 3.3 *holds, then g is always associative.*

Proof.

$$\begin{aligned}
&\Pr_{X_1,Y_1,Z_1\in\mathcal{M}_n}\Big[g(g(X,Y),Z)\\
&= g(g(X_1,Y_1),Z_1) + g(g(X-X_1,Y_1),Z_1) + g(g(X_1,Y-Y_1),Z_1)\\
&\quad + g(g(X-X_1,Y-Y_1),Z_1) + g(g(X_1,Y_1),Z-Z_1) + g(g(X-X_1,Y_1),Z-Z_1)\\
&\quad + g(g(X_1,Y-Y_1),Z-Z_1) + g(g(X-X_1,Y-Y_1),Z-Z_1)\\
&= g(X_1,g(Y_1,Z_1)) + g(X-X_1,g(Y_1,Z_1)) + g(X_1,g(Y-Y_1,Z_1))\\
&\quad + g(X-X_1,g(Y-Y_1,Z_1)) + g(X_1,g(Y_1,Z-Z_1)) + g(X-X_1,g(Y_1,Z-Z_1))\\
&\quad + g(X_1,g(Y-Y_1,Z-Z_1)) + g(X-X_1,g(Y-Y_1,Z-Z_1))\\
&= g(X,g(Y,Z))\Big] \geq 1-8\epsilon > 0.
\end{aligned}$$

The first equality holds from the linearity of g after expanding X, Y, Z as $X_1 + (X - X_1), Y_1 + (Y - Y_1), Z_1 + (Z - Z_1)$, respectively. The second equality is true by the condition (4) with probability $\geq 1 - 8\epsilon$. The last equality is a recombination of terms using linearity. ∎

We now have the tools to prove Theorem 3.3.

Proof. The bilinearity of g follows from the proof of Theorem 3.1.

From Lemmas 3.4 and 3.5, we have that condition (2) can be extended such that $g(E_{i,1}, X) = f(E_{i,1}, X)\ \forall\ 1 \leq i \leq n$ and $X \in \mathcal{M}_n$, and conditions (3) and (4) on g hold for all inputs.

To show that these properties are sufficient to identify g as matrix multiplication, note that from the multilinearity of g, we can write

$$g(X,Y) = g\left(\sum_{1\leq i,j\leq n} x_{i,j}\cdot E_{i,j},\ \sum_{1\leq k,\ell\leq n} y_{k,\ell}\cdot E_{k,\ell}\right) = \sum_{1\leq i,j,k,\ell\leq n} x_{i,j}\cdot y_{k,\ell}\cdot g(E_{i,j},E_{k,\ell}).$$

If $g(E_{i,j}, E_{k,\ell}) = f(E_{i,j}, E_{k,\ell})\ \forall\ i, j, k, \ell$, then multilinearity implies that g is the same as f. Now, using our assumptions, we proceed to show the former holds:

$$\begin{aligned}
g(E_{i,j},E_{k,\ell}) &= g(f(E_{i,1},\Pi^{j-1}), f(\Pi^{k-1},E_{1,\ell}))\\
&= g(g(E_{i,1},\Pi^{j-1}), g(\Pi^{k-1},E_{1,\ell}))\\
&= g(E_{i,1}, g(\Pi^{j+k-2}), E_{1,\ell})\\
&= g(E_{i,1}, E_{k+j-2,\ell})\\
&= f(E_{i,1}, E_{k+j-2,\ell})\\
&= f(E_{i,j}, E_{k,\ell}).
\end{aligned}$$

The first equality is just a rewriting of the two generators in terms of other generators. The second one follows from the strengthening of condition (3) that g computes f whenever one of its arguments is equal to a power of Π. The third one follows from the associativity of g, and the fourth one holds because g is the same as f when the first input is a power of Π and by rewriting $E_{k+j-2,\ell}$. The fifth equality is true because g

computes f correctly when its first argument is $E_{i,1}$ (as the consequence of condition (2), see Lemma 3.4). The last one is a rewriting of the previous equality, using the associativity of multiplication. Therefore, g is the same function as f. □

We now present the test for associativity:

```
Associativity Test:
  Repeat $O(\frac{1}{\epsilon}\log\frac{1}{\rho})$ times
    Pick $X, Y, Z \in_R \mathcal{M}_n$
    Verify $P_{\rm sc}(X, P_{\rm sc}(Y, Z)) = P_{\rm sc}(P_{\rm sc}(X, Y), Z)$
    Reject if the test fails
```

A self-tester can be built by testing conditions (1), (2), (3), and (4), which correspond to the `Property Test`, the `Basis Test`, the `Inductive Test`, and the `Associativity Test`, respectively. Note that testing conditions (2) and (3) involve knowing the value of f at random inputs. These inputs, however, come from a restricted subspace which makes it possible to compute f both easily and efficiently. The following theorem is immediate.

THEOREM 3.6. *For any $\rho < 1$ and $\epsilon < 1/8$, there is an ϵ-self-tester for matrix multiplication that succeeds with probability at least $1 - \rho$.*

4. Nonlinear functions.

In this section, we consider nonlinear functions. Specifically, we deal with exponentiation and constant degree polynomials in the ring of polynomials over the finite fields $\mathbb{Z}_p$. It is obvious that exponentiation and constant degree polynomials are clearly defined over this ring.

4.1. Constant degree exponentiation.

We first consider the function $f(q) = q^d$ for some d (that is, raising a polynomial to the dth power). Suppose a program P claims to perform this exponentiation for all degree n polynomials $q \in \mathcal{P}_n \subseteq \mathbb{K}[x]$. Using the low-degree test of Rubinfeld and Sudan [20] (see also [14]) we can first test if the function computed by P is close to some degree d polynomial g. As before, using the self-corrected version $P_{\rm sc}$ of P, we can also verify that $g(e_1) = f(e_1)$.

The induction identity $f(xq) = x^d f(q)$ also applies, and one can test whether P satisfies this property on most inputs. Now it remains to show that this implies $g(xq) = x^d g(q)\ \forall\ q \in \mathcal{P}_n$. We follow a strategy similar to the case of linear functions, this time using the Lagrange interpolation formula as the robust property that identifies a degree d polynomial. We note that this idea is similar to the use of the interpolation formula by Gemmell et al. [14], which extends the [5] result from linear functions to low-degree polynomials. Before proceeding with the proof, we state the following fact concerning the Lagrange interpolation identity.

FACT 4.1. *Let g be a degree d polynomial. For any $q \in \mathcal{P}_n$, if $q_1, q_2, \ldots, q_{d+1}$ are distinct elements of $\mathcal{P}_n$,*

$$g(q) = \sum_{i=1}^{d+1} g(q_i) \prod_{j\neq i} \frac{q - q_j}{q_i - q_j} \qquad \textit{and} \qquad g(xq) = \sum_{i=1}^{d+1} g(xq_i) \prod_{j\neq i} \frac{q - q_j}{q_i - q_j}.$$

The self-tester for $f(q) = q^d$ comprises the following tests:

```
Degree Test:
  Verify $P$ is close to a degree $d$ polynomial $g$ (low-degree test)
  Reject if the test fails

Basis Test:
  Verify $P_{\rm sc}(e_1) = f(e_1)$

Inductive Test:
  Repeat $O(\frac{1}{\epsilon}\log\frac{1}{\rho})$ times
    Pick $\alpha \in_R V$
    Verify $P_{\rm sc}(\theta(\alpha)) = x^d P_{\rm sc}(\alpha)$
    Reject if the test fails
```

Let β denote the probability that the $d+1$ random choices from the domain produce distinct elements. We will assume that the domain is large enough so that β is close to 1.

Assume that P passes the `Degree Test` and $P_{\rm sc}$ passes the `Basis Test`, that is, P agrees with some degree-d polynomial g on most inputs. We note that the low-degree of test of [20] makes $O((1/\epsilon)\log(1/\rho))$ calls to render a decision with confidence $1-(\rho/3)$. Furthermore, $P_{\rm sc}$ also requires only $O((1/\epsilon)\log(1/\rho))$ calls to compute g correctly with probability $1-(\rho/3)$. Below we sketch the proof that if $\epsilon < \beta/(d+1)$ and $P_{\rm sc}$ passes the `Inductive Test`, then g satisfies $g(xq) = x^d g(q)$ everywhere. Note that $(1/\epsilon) = \Theta(d)$, so the time taken by the tester is only $\Theta(d)$ (when ρ is a constant).

$$\begin{aligned}\Pr_{q_1,\dots,q_{d+1}}[g(xq) &= \sum_{i=1}^{d+1} a_i g(xq_i)\\ &= \sum_{i=1}^{d+1} a_i x^d g(q_i)\\ &= x^d \sum_{i=1}^{d+1} a_i g(q_i)\\ &= x^d g(q)] \geq \beta - (d+1)\epsilon > 0.\end{aligned}$$

Here $a_i = \prod_{j\neq i}(q-q_j)/(q_i-q_j)$. The first equality is Fact 4.1, and applies since g has been verified to be a degree d polynomial. Since the q_i's are uniformly and identically distributed, by `Inductive Test` the second equality fails with probability $< (d+1)\epsilon$. The third equality is just rewriting, and the fourth equality is due to Fact 4.1 (the interpolation identity), which can be applied so long as the q_i's are distinct, an event that occurs with probability β. Since the equality $g(xq) = x^d g(q)$ holds independent of q_i's, if $\epsilon < \beta/(d+1)$, it holds with probability 1.

THEOREM 4.2. *The function $f(q) = q^d$ (where $q \in \mathcal{P}_n$) has an $O(1/d)$-self-tester that makes $O(d)$ queries.*

4.2. Constant degree polynomials. Next we consider extending the result of section 4.1 to arbitrary degree-d polynomials $f : \mathcal{P}_n \to \mathcal{P}_{nd}$. Clearly the low-degree test and the basis test work as before. The interpolation identity is also valid. The missing ingredient is the availability of an identity like "$f(xq) = x^d f(q)$," which, as we have shown above, is a robust property that can be efficiently tested. We show how to get around this difficulty; this idea is based on a suggestion by R. Rubinfeld [18].

Suppose $f : \mathcal{P}_n \to \mathcal{P}_{nd}$ is a degree-d polynomial (e.g., $f(q) = q^2 + q + 1$), and suppose a program P purports to compute f. Our strategy is to design a self-corrector R for P and to then estimate the fraction of inputs q such that $P(q) \neq R(q)$. The difficulty in implementing this idea by directly using the random self-reducibility of f is that the usefulness of the self-corrector (to compute f correctly on every input) depends critically on our ability to certify that P is correct on most inputs. Since checking whether P is correct on most inputs is precisely the task of self-testing, we seem to be going in cycles.

To circumvent this problem, we will design an intermediate multiplication program Q that uses P as an oracle. To design the program Q, we prove the following technical lemma that helps us express d-ary multiplication in terms of f—that is, we establish a reduction from the multilinear function $\prod_{i=1}^{d} q_i$ to the nonlinear function f. This reduction is a generalization to degree d of the elementary polarization identity $xy = ((x+y)^2 - (x-y)^2)/4$, but slightly stronger in that it works for arbitrary polynomials of degree d, not just degree-d exponentiation.

LEMMA 4.3. *For $x \in \{0,1\}^d$, let x_i denote the ith bit of x. For any polynomial $G(q) = \sum_i p_i q^i$ of degree d,*

$$\sum_{x \in \{0,1\}^d} \left(\prod_{i=1}^{d} (-1)^{x_i} \right) G\left(\sum_{i=1}^{d} (-1)^{x_i} q_i \right) = p_d 2^d d! \prod_{i=1}^{d} q_i.$$

Using the reduction given by Lemma 4.3, we will show how to construct an ϵ-self-tester T for f (for $\epsilon = \Theta(2^{-d})$), following the outline sketched.

(1) First we build a program Q that performs c-ary multiplication for any $c \leq d$ (if $c < d$, we can simply multiply by extra 1's). The program Q is then self-tested efficiently (without the generator bottleneck) by using a $(1/2^{d+1})$-self-tester for the d-variate multilinear multiplication function from section 3. The number of queries made to P in this process is $O(1)$, where the constant depends on d (the degree of f) but not on n (the dimensionality of the domain of f). Thus, if Q passes this self-testing step, then it computes multiplication correctly on all but $1/2^{d+1}$ fraction of the inputs. If Q fails the self-testing process, the self-tester T rejects.

(2) Next we build a reliable program Q_{sc} that self-corrects Q using the random self-reducibility of the multilinear multiplication function. That is, Q_{sc} can be used to compute c-ary multiplication (for any $c \leq d$) correctly for every input with probability at least $1 - \rho$ for any constant $\rho > 0$. In particular, by making $O(2^d \log d)$ calls to Q (and, hence, $O(2^{2d} \log d)$ calls to P), Q_{sc} can be used to compute multiplication correctly for every input with probability at least $1 - (1/10d)$.

(3) Next, we use Q_{sc} to build the program R that computes $f(q)$ in a straightforward way by using Q_{sc} to compute the d required multiplications. If Q_{sc} computes multiplication correctly with probability $1 - (1/10d)$, then R computes f correctly for any input with probability at least 0.9.

(4) Finally, T randomly picks $N = O((1/\epsilon)\log(1/\rho))$ many samples q and checks if $P(q) = R(q)$, and outputs PASS iff $P(q) = R(q)$ for all the chosen values of q.

It is easy to see that if P computes f correctly on all inputs, the self-tester T will output PASS with probability one. For the converse, suppose that $\delta =_{\mathrm{def}} \Pr_q[P(q) \neq f(q)] > \epsilon$, and yet T outputs PASS. We will upper bound the probability of this event by ρ.

Since Q passes the self-testing step (step (1)), it computes multiplication correctly on all but $1/2^{d+1}$ fraction of the inputs, and therefore, the use of the self-corrector

$Q_{\rm sc}$ as described in step (2) is justified. This, in turn, implies the guarantee made of R in step (3): for every input q, $R(q) = f(q)$ with probability at least 0.9. In step (4), the probability that $P(q) \neq R(q)$ for a single random q is at least $(0.9)\delta$. The probability that $P(q) = R(q)$ for every random input q chosen in step (4) is therefore at most $(1-(0.9)\delta)^N = (1-(0.9)\delta)^{O((1/\epsilon)\log(1/\rho))} < (1-(0.9)\delta)^{O((1/\delta)\log(1/\rho))} < \rho$. Thus the probability that T outputs PASS, given that $\Pr_q[P(q) \neq f(q)] > \epsilon$, is at most ρ. The following theorem is proven, modulo the proof of Lemma 4.3.

THEOREM 4.4. *The function $f(q)$, where f is a polynomial in $q \in \mathcal{P}_n$ of degree d, has an $O(1/2^d)$-self-tester that makes $O(2^d)$ queries.*

Even though our self-tester makes $O(2^d)$ queries to test degree-d exponentiation, the number of queries is independent of n, the dimensionality of the domain. Thus, our self-tester is attractive if n is large and d is small. In particular, in conjunction with the testers for finite field arithmetic described in section 3.1, the self-testers described here help us to efficiently self-test constant degree polynomials on finite field extensions of large dimension.

It remains to prove Lemma 4.3. This lemma is a direct corollary of the following lemma, which illustrates a method to express d-ary multiplication in terms of f. The proof of the next lemma is given in the Appendix.

LEMMA 4.5. *Let $p_1, \ldots, p_d$ be distinct variables. For $x \in \{0,1\}^d$, let x_i denote the ith bit of x. Then*

$$\sum_{x\in\{0,1\}^d} \left(\prod_{i=1}^{d} (-1)^{x_i}\right) \left(\sum_i (-1)^{x_i} p_i\right)^c = \begin{cases} 0 & \text{if } c < d, \\ 2^d d! \prod_{i=1}^d p_i & \text{if } c = d. \end{cases}$$

Appendix. Proof of Lemmas 2.4 and 4.5.

LEMMA 2.4. *If q is a polynomial in x of degree $\geq k$, then*

$$\sum_{i=0}^{k} \binom{k}{i} (-x)^{k-i} D^k(x^i q) = k!q.$$

Proof. The proof is by induction on k. The base case $(k=0)$ is obviously true. Let $k > 0$. We have $\mathcal{S}_k = \sum_{i=0}^{k+1} \binom{k+1}{i} (-x)^{k+1-i} D^{k+1}(x^i q)$. Since $D^{k+1}(x^i q) = D^k(ix^{i-1}q + x^i D(q))$ and since differentiation is linear, we have

$$\mathcal{S}_k = \left[\sum_{i=0}^{k+1} \binom{k+1}{i} (-x)^{k+1-i} D^k(ix^{i-1}q)\right] + \left[\sum_{i=0}^{k+1} \binom{k+1}{i} (-x)^{k+1-i} D^k(x^i D(q))\right].$$

Since the first term $(i=0)$ in the first sum vanishes, and since $i\binom{k+1}{i} = (k+1)\binom{k}{i-1}$, the first sum evaluates to $(k+1)\sum_{i=1}^{k+1} \binom{k}{i-1} (-x)^{k+1-i} D^k(x^{i-1}q)$, which equals $(k+1)!q$ by the inductive hypothesis. Hence it suffices to show that the second sum evaluates to 0. This summation can be written as $\sum_{i=0}^{k} \binom{k+1}{i} (-x)^{k+1-i} D^k(x^i D(q))$ $+D^k(x^{k+1}D(q))$. By Pascal's identity, this sum can be split into the terms $\sum_{i=0}^{k} \binom{k}{i-1} (-x)^{k+1-i} D^k(x^i D(q))$, $\sum_{i=0}^{k} \binom{k}{i} (-x)^{k+1-i} D^k(x^i D(q))$, and $D^k(x^k \cdot x D(q))$. The second term can be seen to be $(-x)k!D(q)$ using the induction hypothesis. The first and third terms can be combined to obtain $k!(xD(q))$, again using the induction hypothesis. Thus, the entire expression equals $(-x)k!D(q) + k!(xD(q)) = 0$. ∎

LEMMA 4.5. *Let $p_1, \dots, p_d$ be distinct variables. For $x \in \{0,1\}^d$, let x_i denote the ith bit of x. Then*

$$\sum_{x\in\{0,1\}^d}\left(\prod_{i=1}^d(-1)^{x_i}\right)\left(\sum_i(-1)^{x_i}p_i\right)^c = \begin{cases} 0 & \text{if } c<d,\\ 2^d d!\prod_{i=1}^d p_i & \text{if } c=d.\end{cases}$$

Proof. The proof uses the Fourier transform on the Boolean cube $\{0,1\}^d$ (using the standard isomorphism between $\{0,1\}^d$ and $\mathbb{Z}_2^d$). Let $\mathcal{F}$ denote the space of functions from $\mathbb{Z}_2^d$ into $\mathbb{C}$. $\mathcal{F}$ is a (finite) vector space of functions of dimension 2^d. Define the inner product between functions $f, g \in \mathcal{F}$ by $\langle f,g\rangle = 2^{-d}\sum_x f(x)g(x)$. For $\alpha \in \mathbb{Z}_2^d$, define the function $\chi_\alpha : \mathbb{Z}_2^d \to \mathbb{C}$ by $\chi_\alpha(x) = \prod_{i=1}^d(-1)^{x_i\alpha_i}$, where x_i and α_i denote the ith bits, respectively, of x and α. It is easy to check that $\chi_\alpha(x)\chi_\alpha(y) = \chi_\alpha(x+y)$, whence every χ_α is a character of $\mathbb{Z}_2^d$. Furthermore, it is easy to check that $\langle\chi_\alpha,\chi_\beta\rangle$ equals 0 if $\alpha \neq \beta$, and equals 1 if $\alpha = \beta$. Therefore, the characters χ_α form an orthonormal basis of $\mathcal{F}$, and every function $f : \mathbb{Z}_2^d \to \mathbb{C}$ has a unique expansion in this basis as $f = \sum_\alpha \widehat{f}_\alpha\chi_\alpha$. This is called the Fourier transform of f, and the coefficients $\widehat{f}_\alpha$ are called the Fourier coefficients of f; by the orthonormality of the basis, $\widehat{f}_\alpha = \langle\chi_\alpha, f\rangle$. An easy property of the Fourier transform is that for $\alpha \neq 0^d$, $\sum_x \chi_\alpha(x) = 0$ (in fact, this is true for any nontrivial character of any group).

For the proof of the lemma, we note that it suffices to prove the lemma for all complex numbers p_i. Fix a list of complex numbers $p_1, \dots, p_d$, and define the function $f : \mathbb{Z}_2^d \to \mathbb{C}$ by $f(x) = \left(\sum_i(-1)^{x_i}p_i\right)^c$. Then the left-hand side of the statement of the lemma is just $2^d\widehat{f}_\alpha$, where $\alpha = 1^d$. Thus,

$$\begin{aligned}
&\sum_{x\in\mathbb{Z}_2^d}\left(\prod_{i=1}^d(-1)^{x_i}\right)\left(\sum_i(-1)^{x_i}p_i\right)^c\\
&= 2^d\widehat{f}_\alpha\\
&= \sum_x \chi_\alpha(x)f(x)\\
&= \sum_x \chi_\alpha(x) \sum_{\substack{n_1+\cdots+n_d=c\\0\le n_1,\dots,n_d\le c}} \binom{c}{n_1,\dots,n_d}\prod_{i=1}^d(-1)^{x_in_i}p_i^{n_i}\\
&= \sum_{\substack{n_1+\cdots+n_d=c\\0\le n_1,\dots,n_d\le c}} \binom{c}{n_1,\dots,n_d}\prod_{i=1}^d p_i^{n_i}\sum_x\prod_{i=1}^d \chi_\alpha(x)\chi_\beta(x), \qquad \text{where } \beta_i = n_i \bmod 2\\
&= \sum_{\substack{n_1+\cdots+n_d=c\\0\le n_1,\dots,n_d\le c}} \binom{c}{n_1,\dots,n_d}\prod_{i=1}^d p_i^{n_i}\sum_x\prod_{i=1}^d \chi_{\alpha+\beta}(x).
\end{aligned}$$

The innermost sum is zero if $\alpha+\beta \neq 0^d$, i.e., if $\alpha \neq \beta$, and equals 2^d otherwise. Thus $\beta_i = \alpha_i = 1$ for every i, that is, $n_i \equiv 1 (\text{mod } 2)$ for every i. If $c < d$, this is impossible, since $\sum_i n_i = c$. If $c = d$, then the only way this can happen is if $n_i = 1\ \forall\ i$; otherwise, for some i, $n_i > 1$, and since $\sum_i n_i = d$, some $n_i = 0$. When $n_i = 1\ \forall\ i$, it is easy to see that we have $2^d\widehat{f}_\alpha = 2^d d!\prod_{i=1}^d p_i$. $\square$

Acknowledgments. We are very grateful to Ronitt Rubinfeld for her valuable suggestions and guidance. We thank Manuel Blum and Mandar Mitra for useful discussions. We thank Dexter Kozen for his comments. We are grateful to the two anonymous referees for valuable comments that resulted in many improvements to our exposition. The idea of describing the proof of Lemma 4.5 using Fourier transforms also comes from one of the referees.

SAFE CONSTRAINT QUERIES*

MICHAEL BENEDIKT† AND LEONID LIBKIN‡

Abstract. We extend some of the classical characterization theorems of relational database theory—particularly those related to query safety—to the context where database elements come with fixed interpreted structure and where formulae over elements of that structure can be used in queries. We show that the addition of common interpreted functions, such as real addition and multiplication, to the relational calculus preserves important *characterization theorems* of the relational calculus and also preserves certain *combinatorial properties* of queries. Our main result of the first kind is that there is a syntactic characterization of the collection of safe queries over the relational calculus supplemented by a wide class of interpreted functions—a class that includes addition, multiplication, and exponentiation—and that this characterization gives us an interpreted analog of the concept of range-restricted query from the uninterpreted setting. Furthermore, our range-restricted queries are particularly intuitive for the relational calculus with real arithmetic and give a natural syntax for safe queries in the presence of polynomial functions. We use these characterizations to show that safety is decidable for Boolean combinations of conjunctive queries for a large class of interpreted structures. We show a dichotomy theorem that sets a polynomial bound on the growth of the output of a query that might refer to addition, multiplication, and exponentiation.

We apply the above results for finite databases to get results on constraint databases representing potentially infinite objects. We start by getting syntactic characterizations of the queries on constraint databases that preserve geometric conditions in the constraint data model. We consider classes of convex polytopes, polyhedra, and compact semilinear sets, the latter corresponding to many spatial applications. We show how to give an effective syntax to safe queries and prove that for conjunctive queries the preservation properties are decidable.

1. Introduction.

The power of classical query languages is linked to the fact that these queries express a restricted class of declarative programs. The class of semantic objects expressible through queries in the relational calculus, for example, is limited in a number of helpful ways: each such query is polynomial-time computable, each is local, and each has well-defined asymptotics. Although relational calculus queries may not return finite results, a natural subclass of the relational calculus does, namely, the class of *range-restricted queries*. This class gives guarantees of finite output and is complete in this respect: it captures all relational calculus queries whose outputs are always finite, the *safe* queries [1, 21, 39].

The relational theory on which these results are based deals only with *pure* relational queries, that is, those containing no interpreted predicates. Practical query languages, in contrast, contain interpreted functions such as $+$ and $*$. The resulting queries, then, make use of the domain semantics, rather than being independent of them, as pure relational queries are. For example, if the underlying

structure is the field of real numbers $\langle \mathbb{R}, +, *, 0, 1, < \rangle$, the extension of relational calculus is achieved by using polynomial (in)equalities. For example, the query $\varphi(x, y) \equiv \exists z. R(x, z) \wedge R(z, y) \wedge x^2 + y^2 = z$ defines a subset of the self-join with the condition that in joinable tuples (x, z) and (z, y), z must be the sum of squares of x and y. A natural question, then, is what sort of restrictions still apply to queries given with interpreted structure.

Clearly, many standard results fail in the presence of interpreted structure; for example, queries may no longer express only local properties of inputs. Complexity bounds are often dependent on fragile properties of both the functions present and the encodings of the structures in some computational model. In contrast, we show here that certain kinds of *structural* properties of relational calculus queries remain when a reasonable interpreted structure is present. These include the classical equivalence of safe and range-restricted queries, decidability of safety for restricted classes of queries, as well as *combinatorial* properties of the queries, for example, restrictions on the growth rate of the result sets. A primary example of well-behaved combinatorics of these structures is a *growth dichotomy theorem*, which says that the output of a query is either polynomial in the database or infinite. We show that the well-behavedness of a structure, together with the decidability of its first-order theory, has *algorithmic* consequences; for example, the set of range-restricted formulae can be effectively computed.

A problem related to safety is that of *state-safety*, studied in [3]: for a query *and* a database, determine if the output is finite. Unlike the safety problem, which is undecidable (cf. [1]), the state-safety problem is decidable for some domains, for example, natural numbers with the order relation; see [3, 5]. However, there are interpreted structures (even having a decidable first-order theory) for which this problem is undecidable [36]. Moreover, [36] established that for the same interpreted structure, no recursive set of queries captures the class of safe queries; that is, it is impossible to have an analog of the concept of range-restriction. In contrast, we show that for many well-behaved structures, state-safety is decidable. Furthermore, safety over all states is decidable for restricted classes of queries (namely, Boolean combinations of conjunctive queries).

The above results are for the standard relational calculus with interpreted functions on finite structures; we then apply these results to get structural restrictions on the behavior of queries in other models, particularly the constraint database model introduced by Kanellakis, Kuper, and Revesz [20]. This model is motivated by new applications involving spatial and temporal data, which require storing and querying infinite collections. The constraint model generalizes the relational model by means of "generalized relations." These are possibly infinite sets defined by quantifier-free first-order formulae in the language of some underlying infinite structure $\mathcal{M} = \langle \mathcal{U}, \Omega \rangle$. Here $\mathcal{U}$ is a set (assumed to be infinite), and Ω is a signature that consists of a number of interpreted functions and predicates over $\mathcal{U}$. For example, in spatial applications, $\mathcal{M}$ is usually the real field $\langle \mathbb{R}, +, *, 0, 1, < \rangle$, and generalized relations describe sets in $\mathbb{R}^n$.

A database given by a quantifier-free formula $\alpha(x_1, \ldots, x_n)$ in the language of Ω defines a (possibly infinite) subset of $\mathcal{U}^n$ given by $D_\alpha = \{\vec{a} \in \mathcal{U}^n \mid \mathcal{M} \models \alpha(\vec{a})\}$. Such databases are called *finitely representable* [16], as the formula α provides a finitary means for representing an infinite set. For example, if $\alpha(x, y) \equiv (x^2 + y^2 \leq 1)$, then D_α is the circle of radius 1 with the center in $(0, 0)$.

Relational calculus can be straightforwardly extended to this model by incorporating atomic formulas which are Ω-constraints, that is, atomic Ω-formulae. For example, $\varphi(x, y) \equiv (D(x, y) \wedge y = x^2)$ is a first-order query which, on D_α defined above, returns the intersection of the circle with the graph of the function $y = x^2$.

One of the reasons why the constraint model can be used in spatial applications is that such queries admit a form of safety: the closed form evaluation over structures $\langle \mathbb{R}, +, -, 0, 1, < \rangle$ (linear constraints) and $\langle \mathbb{R}, +, *, 0, 1, < \rangle$ (polynomial constraints), most often used to represent spatial data. This sort of closure is a reformulation of the fact that the two structures above admit *effective quantifier-elimination* (QE). To evaluate a query, one can replace each occurrence of a database symbol D by its representation as a collection of constraints, apply the QE procedure to the resulting formula, and obtain a quantifier-free formula giving a finite representation of the output. There has been work in extending these closure properties to other classes of constraint databases and other logics, and this work indicates that the existence of closure properties is often problematic. For example, for integer gap-order constraints $x <_n y$ (meaning $x < y + n$), restrictions guaranteeing safety were studied in [32] for relational calculus and stratified datalog, and the inherent incompleteness of those restrictions was later shown in [38]. However, in this paper we do obtain new positive results on closure properties for constraint queries—albeit of a different nature than [32] and [38]—and we do so in domains that are quite relevant to spatial applications.

For those domains, we consider the preservation of restricted geometric classes of databases within powerful constraint query languages. In particular, we consider the behavior of queries with polynomial functions over *linear* constraint databases. Linear constraints are used to represent spatial data in many applications; see [13, 17, 29] and references therein. Linear constraints have several advantages over polynomial ones: the QE procedure is less costly, and numerous algorithms have been developed to deal with figures represented by linear constraints; cf. [26]. At the same time, the extension of relational calculus with linear constraints has severely limited power as a query language; see [2, 29]. Thus, it appears to be natural to use a more powerful language, such as relational calculus with polynomial constraints, to query databases represented by linear constraints [43].

As soon as the class of constraints used in queries is more general than the class used to define databases, we encounter the safety/closure property again: the output of a query using polynomial constraints may fail to be definable with linear constraints alone! More generally, if spatial databases are required to have certain geometric properties, then the safety problem is whether those geometric properties are preserved by a given query language.

When the underlying query language is relational calculus with polynomial constraints, there is a recursively enumerable class of programs that express exactly those queries that preserve the property of being definable with linear constraints; this follows from the decidability of the latter property, shown in [13]. Corresponding to our results in the first part of the paper, we are interested in getting explicit and natural complete languages for preserving linear constraints, and also natural effective syntax for other geometric properties. We give a general schema for coming up with such languages. As applications, we consider the properties of being a convex polytope, a convex polyhedron, and a compact semilinear set. For those classes, we provide an effective syntax for polynomial constraint queries preserving the properties. We also show that for unions of conjunctive queries (CQs) with polynomial constraints, it is decidable whether the properties of being a convex polytope or a compact semilinear set are preserved. By applying the growth bounds for the relational calculus with interpreted functions, we find restrictions of the growth in the number of vertices of polytopes and use them to show that certain kinds of triangulations cannot be done even with very powerful constraints.

Organization. In section 2, we present the notation. Sections 3, 4, 5, and 6 all deal primarily with the standard relational calculus with interpreted functions (although generalizations to the "natural semantics" hold, and are given here, as well). Section 3 shows that the underlying interpreted structure one uses does matter: we define the concept of a *safe translation* of queries and show that some structures admit it and some don't. It follows that for many common structures the state-safety problem is decidable.

In section 4, we define the concept of range-restriction and show that the classes of safe and range-restricted queries coincide over well-behaved structures. The general concept of range-restriction is based on the notion of algebraic formulae in the underlying model. We show that for polynomial functions, these range-restricted formulae have a particularly nice characterization, namely, as queries that are bounded by roots of polynomials with coefficients from the database. We then show that for underlying structures admitting QE, it is possible to construct, effectively, a range-restricted query that coincides with a given query Q on all databases for which Q is safe.

In section 5 we show that over well-behaved structures, it is decidable whether a Boolean combination of CQs is safe.

Section 6 establishes the dichotomy result: for every query Q over a well-behaved structure, one can find a polynomial p such that the size of $Q(D)$ is either infinite or at most the value of p on the size of D. We also prove a stronger trichotomy theorem for monotone queries.

Section 7 deals with finitely representable databases. We first introduce a general schema for transferring results about query safety to the finitely representable setting. We then apply this to show bounds on the growth of vertices of polytopes in safe constraint queries, and give effective syntax for queries preserving geometric properties, such as the classes of convex polytopes, polyhedra, and compact semi-linear sets (the latter only in the two-dimensional case). We also show that it is decidable whether unions of CQs with polynomial constraints preserve the first and the third properties. Concluding remarks are given in section 8.

An extended abstract of this paper appeared in [9].

2. Notation.

The notation we use is fairly standard in the literature on constraint databases; cf. [6, 8, 7, 28, 29]. We study databases over infinite structures. Let $\mathcal{M} = \langle \mathcal{U}, \Omega \rangle$ be an infinite structure, where $\mathcal{U}$ is an infinite set, called a carrier (in the database literature it is often called a domain), and Ω is a set of interpreted functions, constants, and predicates. For example, for the real field $\langle \mathbb{R}, +, *, 0, 1, < \rangle$, the carrier is $\mathbb{R}$ (the set of real numbers), and the signature consists of the functions $+$ and $*$, constants 0 and 1, and predicate $<$.

A (relational) *database schema SC* is a nonempty collection of relation names $\{S_1, \ldots, S_l\}$ with associated arities $p_1, \ldots, p_l > 0$. Given $\mathcal{M}$, an *instance* of *SC* over $\mathcal{M}$ is a family of finite sets, $\{R_1, \ldots, R_l\}$, where $R_i \subset \mathcal{U}^{p_i}$. That is, each schema symbol S_i of arity p_i is interpreted as a finite p_i-ary relation over $\mathcal{U}$. Given an instance D, $adom(D)$ denotes its *active domain*, that is, the set of all elements that occur in the relations in D. We normally assume $adom(D) \neq \emptyset$. Although often convenient in simplifying notation, this restriction is by no means necessary, as all results straightforwardly extend to empty databases.

As our basic query language, we consider relational calculus, or *first-order logic*, FO, over the underlying models and the database schema. In what follows, $L(SC, \Omega)$ stands for the language that contains all symbols of SC and Ω; by $\mathrm{FO}(SC, \Omega)$ we mean the class of all first-order formulae built up from the atomic SC and Ω-formulae by using Boolean connectives $\vee, \wedge, \neg$ and quantifiers $\forall, \exists$ and $\forall x \in adom, \exists x \in adom$. When Ω is $(+, -, 0, 1, <)$ or $(+, *, 0, 1, <)$ or $(+, *, e^x, 0, 1, <)$, we use the standard abbreviations $\mathrm{FO}+\textsc{Lin}$, $\mathrm{FO}+\textsc{Poly}$, and $\mathrm{FO}+\textsc{Exp}$, often omitting the schema when it is understood. Regardless of whether we are in the "classical" setting, where these queries are applied to finite databases, or in the constraint query setting discussed later in the paper, we will refer to the syntactic query languages as *relational calculus with* Ω *constraints*.

The semantics is as follows. For a structure $\mathcal{M}$ and an SC-instance D, the notion of $(\mathcal{M}, D) \models \varphi$ is defined in a standard way for $\mathrm{FO}(SC, \Omega)$ formulae, where $\exists x \in adom$ is the *active-domain* quantification. That is, $(\mathcal{M}, D) \models \exists x\ \varphi(x, \cdot)$ if for some $a \in \mathcal{U}$ we have $(\mathcal{M}, D) \models \varphi(a, \cdot)$, and $(\mathcal{M}, D) \models \exists x \in adom\ \varphi(x, \cdot)$ if for some $a \in adom(D)$ we have $(\mathcal{M}, D) \models \varphi(a, \cdot)$. If $\mathcal{M}$ is understood, we write $D \models \varphi$. The output of a query $\varphi(x_1, \ldots, x_n)$ on D is $\{\vec{a} = (a_1, \ldots, a_n) \in \mathcal{U}^n \mid D \models \varphi(\vec{a})\}$, and it is denoted by $\varphi[D]$. For example, $\varphi(x, y) \equiv (S(x, y) \wedge y = x * x)$ is an $\mathrm{FO}+\textsc{Poly}$ query over the schema that contains one binary relation S, and $\varphi[D]$ is the set of pairs in (x, y) in D where $y = x^2$.

We now, following [21, 22], say that an $\mathrm{FO}(SC, \Omega)$ query $\varphi(\vec{x})$ is *safe* for an SC-database D if it has finitely many satisfiers for D; that is, $\varphi[D]$ is finite. A query is safe if it is safe for all databases.

As we explained before, we need to distinguish a class of well-behaved models. Following [6, 7, 8], we use *o-minimality* [30, 42] and QE [11] for this purpose. We say that $\mathcal{M}$ is o-minimal if every definable set is a finite union of points and open intervals $\{x \mid a < x < b\}$, $\{x \mid x < a\}$, and $\{x \mid x > a\}$ (we assume that $<$ is in Ω). Definable sets are those of the form $\{x \mid \mathcal{M} \models \varphi(x)\}$, where φ is a first-order formula in the language of $\mathcal{M}$, possibly supplemented with symbols for constants from $\mathcal{M}$. We say that $\mathcal{M}$ admits QE if, for every formula $\varphi(\vec{x})$, there is an equivalent quantifier-free formula $\psi(\vec{x})$ such that $\mathcal{M} \models \forall \vec{x}. \varphi(\vec{x}) \leftrightarrow \psi(\vec{x})$. Below we list the most important examples, which correspond to classes of interpreted structures and constraints often used in applications.

Linear Constraints: $\langle \mathbb{R}, +, -, 0, 1, < \rangle$ is o-minimal and has QE, and its first-order theory is decidable; cf. [11].

Polynomial Constraints: The real field $\langle \mathbb{R}, +, *, 0, 1, < \rangle$ is o-minimal and has QE, and its first-order theory is decidable. This follows from Tarski's theorem; cf. [11, 42].

Exponential Constraints: $\langle \mathbb{R}, +, *, e^x, 0, 1, < \rangle$ is o-minimal [48] but does not have QE [41].

An example of a structure that is not o-minimal is $\langle \mathbb{N}, +, < \rangle$, as the formula $\exists y (x = y + y)$ defines the set of even numbers. Table 2.1 provides examples of some often-encountered structures and their standing with respect to o-minimality and QE.

We will need the following result about o-minimal structures, which will be used numerous times in proofs.

Fact 2.1 (uniform bounds; see [30]). *If $\mathcal{M}$ is o-minimal and $\varphi(x, \vec{y})$ is a first-order formula in the language of $\mathcal{M}$, possibly supplemented with symbols for constants from $\mathcal{M}$, then there is an integer K such that, for each vector $\vec{a}$ from $\mathcal{M}$, the set $\{x \mid \mathcal{M} \models \varphi(x, \vec{a})\}$ is composed of fewer than K intervals.*

If only quantifiers $\forall x \in adom$ and $\exists x \in adom$ are used in a query, it is called an

TABLE 2.1
Examples of structures.

Structure	o-minimal	Has QE
$\langle \mathbb{R}, < \rangle$	Y	Y
$\langle \mathbb{R}, +, -, 0, 1, < \rangle$	Y	Y
$\langle \mathbb{R}, +, *, 0, 1, < \rangle$	Y	Y
$\langle \mathbb{R}, +, *, e^x \rangle$	Y	N
$\langle \mathbb{Q}, < \rangle$	Y	Y
$\langle \mathbb{Q}, +, *, 0, 1, < \rangle$	N	N
$\langle \mathbb{N}, < \rangle$	Y	N
$\langle \mathbb{N}, +, 0, 1, \{\equiv_k\}_{k>1}, < \rangle$	N	Y
$\langle \mathbb{N}, +, *, 0, 1, < \rangle$	N	N

active-semantics query. This is the usual semantics for databases, and it will be the one used in most of the results in this paper. If quantification over the entire infinite universe is allowed, we speak of a *natural-semantics* query. Active-semantics queries admit the standard bottom-up evaluation, while for natural-semantics it is not clear a priori if they can be evaluated at all. However, in many cases one can restrict one's attention to active-semantics queries. The following result was first shown for the pure case (no interpreted structure) in [18] and for linear constraints [28], and then for a large class of structures as follows.

FACT 2.2 (natural-active collapse; see [7, 8]). *If $\mathcal{M}$ is o-minimal and has QE and φ is an arbitrary* $\mathrm{FO}(SC, \Omega)$ *query, then there exists an equivalent* $\mathrm{FO}(SC, \Omega)$ *active-semantics query φ_{act}. Moreover, if the first-order theory of $\mathcal{M}$ is decidable and QE is effective, then the translation $\varphi \to \varphi_{\text{act}}$ is effective.*

We now define the classes of CQs, unions of conjunctive queries (UCQs), and Boolean combinations of conjunctive queries (BCCQs) in the interpreted setting. CQs are built up from atomic *SC* formulae and *arbitrary* Ω-formulae by using $\wedge$ and quantifiers $\exists x$ and $\exists x \in$ *adom*. Note that we can always assume that parameters of each *SC* relation are variables, as Ω-terms can be eliminated by using existential (active-domain) quantifiers. It is easy to see that each CQ can be represented in the form

$$\varphi(\vec{z}) \;\equiv\; \exists \vec{x} \exists \vec{y} \in adom\; S_1(\vec{u}_1) \wedge \ldots \wedge S_k(\vec{u}_k) \wedge \gamma(\vec{x}, \vec{y}, \vec{z}),$$

where S_is are schema relations (not necessarily distinct), $\vec{u}_i$ is a vector of variables from $\vec{x}, \vec{y}, \vec{z}$ of appropriate arity, and γ is an Ω-formula. If $\Omega = \emptyset$ and $\vec{x} = \emptyset$, this is the usual notion of CQs. If γ is quantifier-free, this is the notion of CQs used in [19].

We define UCQs to be built up from atomic *SC* formulae and *arbitrary* Ω-formulae by using $\wedge$, $\vee$, and quantifiers $\exists x$ and $\exists x \in$ *adom*. Again, it is easy to see that those are precisely the queries of the form $\varphi_1 \vee \ldots \vee \varphi_k$, where each φ_i is a CQ. Finally, BCCQs are arbitrary Boolean combinations of CQs.

Although we could define active-domain versions of CQs, the results we state here (e.g., decidability of safety) for the more general classes above will automatically imply the corresponding results for the more restricted class of active-domain conjunctive queries.

For background on finitely representable databases, see the beginning of section 7.

3. Safe translations. The main goal of this section is to show that what kind of interpreted structure one uses does matter when one studies query safety. As a by-product, we show that the state-safety problem is decidable over certain structures.

We study *safe translations*, that is, translations from arbitrary queries into safe ones that do not change the result of a query if it is finite.

Definition 3.1. *We say that there is a safe translation of (active-semantics) first-order queries over $\mathcal{M}$ if there is a function $\varphi \to \varphi_{\text{safe}}$ on (active-semantics) formulae such that for every φ,*

(1) *φ_{safe} is safe, and*

(2) *if φ is safe for D, then $\varphi[D] = \varphi_{\text{safe}}[D]$.*

A translation is canonical if $\varphi_{\text{safe}}[D] = \emptyset$ whenever φ is not safe on D. A translation is recursive if the function $\varphi \to \varphi_{\text{safe}}$ is recursive.

It is known that there are domains over which safe translations do not exist; see [36]. The result of [36] uses quantification over the entire universe in an essential way. Here we restrict our attention to active-domain quantification. The following generalizes our result from [8].

Proposition 3.2. *Let $\mathcal{M}$ be o-minimal, be based on a dense order, admit effective QE, and have a decidable theory. Then there exists a recursive canonical safe translation of active-semantics formulae over $\mathcal{M}$.*

Proof. Given an active-semantics formula φ, let $\alpha(x)$ be a formula defining the active domain of the output of φ. Let Ψ be an active-semantics sentence equivalent to

$$\neg\exists x_1, x_2\ ((x_1 < x_2) \wedge (\forall x\ x_1 < x < x_2 \to \alpha(x)))$$

(it exists by Fact 2.2). We then define φ_{safe} as $\varphi \wedge \Psi$. The proposition then follows from the following claim: $D \models \Psi$ iff $\varphi[D]$ is finite.

First, assume that $D \models \neg\Psi$; then clearly $\varphi[D]$ is infinite because $<$ is dense. Suppose $D \models \Psi$. We then look at all occurrences of SC predicates in α and replace each of them with a disjunction of tuples. This results in $\alpha'(x)$ in the language of Ω and constants for elements of $\mathcal{U}$; further, $D \models \alpha(a)$ iff $\mathcal{M} \models \alpha'(a)$. Let Ψ' be obtained from Ψ by substituting α' for α. We then have $\mathcal{M} \models \Psi'$. Since $\alpha'(\mathcal{M}) = \{a \mid \mathcal{M} \models \alpha'(a)\}$ is a finite union of points and intervals, and since $\mathcal{M} \models \Psi'$, it follows that no nondegenerate interval is in $\alpha'(\mathcal{M})$. Thus, from o-minimality, we get that $\alpha'(\mathcal{M})$ is a finite union of points. Hence, $\{a \mid D \models \alpha(a)\}$ is finite, thus showing finiteness of $\varphi[D]$. ◻

Examples of structures satisfying the conditions of Proposition 3.2 are $\langle \mathbb{R}, +, -, 0, 1, <\rangle$ and $\langle \mathbb{R}, +, *, 0, 1, <\rangle$. An immediate corollary to the proposition above is the following.

Corollary 3.3. *Let $\mathcal{M}$ be as in Proposition* 3.2. Then the state-safety problem over $\mathcal{M}$ is decidable. That is, given a first-order query φ, and a database D, it is decidable whether $\varphi[D]$ is finite. ◻

Proof. We showed that the active-semantics sentence Ψ tests whether $\varphi[D]$ is finite. ◻

We next show that safe translations (recursive or not!) need not exist even when one restricts one's attention to active-semantics queries and all predicates in the signature Ω are computable.

Proposition 3.4. *There is a structure $\mathcal{M} = \langle \mathbb{N}, P\rangle$, where P is a computable predicate, such that there is no safe translation of active-semantics first-order queries over $\mathcal{M}$.*

Proof. Let P be a ternary predicate defined as $P(i, j, k)$ iff the ith Turing machine on the input j makes at least k moves (assuming some standard encoding of machines and inputs). Consider the schema that consists of a single binary relation U. Assume to the contrary that there is a safe translation over $\mathcal{M}$. Let

$\varphi(k) \equiv \exists i, j \in \mathit{adom}\ U(i,j) \wedge P(i,j,k)$, and let $\psi(k)$ be φ_{safe}. Note that ψ is an active-domain formula in the language of U and P. We now show how to use ψ to decide the halting problem.

Suppose we are given the ith machine M_i and the input j. We assume without loss of generality that M_i makes at least one move on j. Define D that consists of a single pair (i,j). Since we know that ψ is safe, we then compute the minimum number l such that $D \not\models \psi(l)$. It is computable since (a) it exists, and (b) for each k, it is decidable whether $D \models \psi(k)$.

Assume that $D \models \varphi(l)$. Then M_i does not halt on j. Indeed, if M_i halts, then $\varphi[D]$ is finite, and hence $\varphi[D] = \psi[D]$, but we have $l \in \varphi[D] - \psi[D]$. Assume that $D \not\models \varphi(l)$. Then M_i makes $k < l$ moves on j, and thus halts. Hence, $D \models \varphi(l)$ iff M_i halts on j. Since it is decidable whether $D \models \varphi(l)$, we get a contradiction. ∎

In the remainder of the paper, we concentrate on *well-behaved* structures, typically o-minimal ones. For computability, we often impose QE and decidability of first-order theory.

4. Range-restriction and safety. Let us informally describe the concept of range-restriction for databases over interpreted structures. It can be seen as a generalization to arbitrary structures of the idea of finiteness dependencies [31]. Consider a query $\varphi(x)$ over a database which is a finite set S of real numbers:

$$\varphi(x,y) \ \equiv\ \exists z\ [S(z) \wedge (x > y) \wedge (x > 0) \wedge (x * x = z) \wedge (y + y = z)].$$

This query defines a set of pairs of reals. Clearly, it is safe, as the size of its output is at most twice the size of the input. Moreover, and this is the key observation, from the query φ and any database S, one can compute an upper bound on the output $\varphi[S]$: indeed, every element in $\mathit{adom}(\varphi[S])$ is either $\sqrt{a}$ or $\frac{a}{2}$ for some element $a \in S$. Equivalently, in this upper bound every element is a solution to either $x^2 = a$ or $2x = a$ when a ranges over S. That is, in this example, an upper bound on the result of a safe query can be found as the set of roots of polynomials with coefficients coming from the active domain of the database and a finite set of constants.

This is essentially the idea of range-restriction: we find, for a safe query, a set of formulae defining an upper bound on the output. A similar approach was used in [14], although the focus of [14] is different: it does not consider how the underlying structure affects safety, but instead gives a syntactically restricted class of queries with interpreted functions that can be translated into algebra expressions, along the lines of [46]. In contrast, we are interested in how the underlying structure interacts with queries. For example, we show that not only does a set of range-restriction formulae exist for any query over a well-behaved structure, but also, under additional conditions, it can be found effectively. The result that we prove is actually a bit stronger, as it shows that the upper bound works not only for safe queries, but for arbitrary queries, provided they are safe on a given database.

The first difficulty we encounter is finding an analog of the set of roots of polynomials, when we deal with arbitrary structures (e.g., $\langle \mathbb{R}, +, *, e^x \rangle$). The solution to this is provided by the model-theoretic notion of *algebraic* formulae, reviewed in section 4.1. The range-restriction theorem is proved in section 4.2. Then, in section 4.3, we give two examples: the pure case, where our main result trivially translates into a classical relational theory result, and a much less trivial FO + POLY case, where we confirm the original intuition that the upper bound is a set of roots of polynomials. We finish the section by giving a couple of extensions of the main result.

4.1. Algebraic formulae over o-minimal structures. In this subsection, we study formulae over $\mathcal{M}$, that is, first-order formulae in the language $L(\Omega)$. We shall consider formulae $\varphi(\vec{x};\vec{y})$ with distinguished parameter variables $\vec{y}$; we use ";" to separate those variables. Assume that $\vec{x}$ is of length n and $\vec{y}$ is of length m. Such a formula (in the language of Ω and constants for elements of $\mathcal{U}$) is called *algebraic* if for each $\vec{b}$ in $\mathcal{U}^m$ there are only finitely many satisfiers of $\varphi(\vec{x},\vec{b})$; that is, the set $\{\vec{a} \in \mathcal{U}^n \mid \mathcal{M} \models \varphi(\vec{a};\vec{b})\}$ is finite. A collection of formulae is algebraic if each of its elements is algebraic.

For example, the formula $\varphi(x;y) \equiv (x^2 = y)$ is algebraic over $\langle \mathbb{R},+,*,0,1,<\rangle$. It can easily be seen that if $\varphi_1(\vec{x};\vec{y})$ and $\varphi_2(\vec{x};\vec{y})$ are algebraic, then so are $\varphi_1 \wedge \varphi_2$, $\varphi_1 \vee \varphi_2$, and $\exists x \varphi_1$, where x is one of the variables in $\vec{x}$; however, algebraic formulae are not closed under negation.

Let us list some simple properties of algebraic formulae over o-minimal structures.

LEMMA 4.1. *Let $\mathcal{M} = \langle \mathcal{U},\Omega\rangle$ be o-minimal and based on a dense order, and let $\gamma(\vec{x};\vec{y})$ be algebraic. Then*

- *There exists a number K such that for any $\vec{b} \in \mathcal{U}^m$, the set $\{\vec{a} \in \mathcal{U}^n \mid \mathcal{M} \models \gamma(\vec{a};\vec{b})\}$ has fewer than K elements.*
- *There is a recursively enumerable collection of algebraic formulae $\{\chi_i(\vec{x};\vec{y})\}$ such that every algebraic formula $\gamma(\vec{x};\vec{y})$ is equivalent to one of the χ_i.*[1] *If $\mathcal{M}$ is decidable, then the collection of algebraic formulae is recursive.*

Proof. For the first item, consider all formulae $\gamma_i(x_i;\vec{y}) \equiv \exists \vec{x}^{(i)}\ \gamma(\vec{x};\vec{y})$, where $\vec{x}^{(i)}$ contains all components of $\vec{x}$ except x_i. By Fact 2.1, there is an integer K_i such that for each $\vec{b}$, $\{a \mid \mathcal{M} \models \gamma_i(a;\vec{b})\}$ is composed of fewer than K_i intervals. Since γ is algebraic and $<$ is dense, it means that $\{a \mid \mathcal{M} \models \gamma_i(a;\vec{b})\}$ has fewer than K_i elements. Hence, there are at most $K = \prod_{i=1}^n K_i$ vectors $\vec{a}$ such that $\mathcal{M} \models \gamma(\vec{a};\vec{b})$.

For the second item, for each $\gamma(\vec{x};\vec{y})$, let $\chi_\gamma^k(\vec{x})$ be a first-order formula

$$\forall \vec{y} \neg \exists \vec{x}_1 \ldots \exists \vec{x}_k . \bigwedge_{i=1}^{k} \gamma(\vec{x}_i;\vec{y}) \wedge \bigwedge_{i\neq j} (\vec{x}_i \neq \vec{x}_j),$$

saying that there are fewer than k vectors $\vec{x}$ that satisfy $\gamma(\vec{x};\vec{y})$ for all $\vec{y}$. Consider the recursively enumerable collection of formulae of the form $\gamma(\vec{x};\vec{y}) \wedge \chi_\gamma^k(\vec{x})$, where γ ranges over $\mathrm{FO}(\Omega)$ and k ranges over $\mathbb{N}$. It follows from the first item that it enumerates all algebraic formulae. If $\mathcal{M}$ is decidable, it is also decidable whether $\gamma(\vec{x};\vec{y})$ is algebraic. Indeed, the latter happens iff $\gamma^*(x;\vec{y}) = \bigvee_i \gamma_i(x;\vec{y})$ is algebraic (see the proof of the first item), which in turn happens iff there is no open interval contained in $\{a \mid \mathcal{M} \models \gamma^*(a;\vec{b})\}$ for any $\vec{b}$. The latter can be formulated as a first-order sentence $\forall \vec{y} \neg \exists u, v \forall z.(u < z < v \rightarrow \gamma^*(z;\vec{y}))$. $\square$

While we do get an enumeration of algebraic formulae from Lemma 4.1, we need one more representation for algebraic formulae as a tool in proofs. This representation is provided below. We first treat the one-variable case, that is, formulae $\varphi(x;\vec{y})$.

Let $\Xi = \{\xi_1(x;\vec{y}),\ldots,\xi_k(x;\vec{y})\}$ be a collection of formulae. Let

$$\mathrm{same}_\Xi(x,x';\vec{y}) \quad\equiv\quad \bigwedge_{i=1}^{k} (\xi_i(x;\vec{y}) \leftrightarrow \xi_i(x';\vec{y})).$$

[1]Provided that Ω is a recursive set.

Now define

$$\beta_\Xi(x;\vec{y}) \ \equiv\ \forall x', x''.x' < x < x'' \to (\exists z.x' \le z \le x'' \wedge \neg\mathrm{same}_\Xi(x,z;\vec{y})).$$

This provides the desired syntactic characterization.

PROPOSITION 4.2. *Let $\mathcal{M}$ be an o-minimal structure based on a dense order. Then a formula $\varphi(x;\vec{y})$ is algebraic (over $\mathcal{M}$) iff there exists a collection of formulae Ξ such that φ is equivalent to β_Ξ. A formula $\varphi(\vec{x};\vec{y})$ is algebraic iff there exists a collection of formulae Ξ in variables $(x;\vec{y})$ and a formula $\psi(\vec{x};\vec{y})$ such that φ is equivalent to $\beta_\Xi(x_1;\vec{y}) \wedge \ldots \wedge \beta_\Xi(x_n;\vec{y}) \wedge \psi(\vec{x};\vec{y})$.*

Proof. Prove the one-variable case first.

Let Ξ be a collection of formulae and assume that β_Ξ is not algebraic. That is, for some $\vec{b}$ over $\mathcal{U}$, $\beta_\Xi(\mathcal{M};\vec{b}) = \{a \mid \mathcal{M} \models \beta_\Xi(a;\vec{b})\}$ is infinite. Since $\mathcal{M}$ is o-minimal, $\beta_\Xi(\mathcal{M};\vec{b})$ is a finite union of points and intervals. Since $<$ is dense, it means that there exist $a_0 < b_0 \in \mathcal{U}$ such that $[a_0,b_0] \subseteq \beta_\Xi(\mathcal{M};\vec{b})$. We now consider the formulae $\xi'_i(x) = \xi_i(x;\vec{b})$ for all $\xi_i \in \Xi$. Since both $\xi'_i(\mathcal{M}) = \xi_i(\mathcal{M};\vec{b})$ and $\neg\xi'_i(\mathcal{M}) = \neg\xi_i(\mathcal{M};\vec{b})$ are finite unions of intervals and $<$ is dense, for every nondegenerate interval J, it is the case that either $J \cap \xi'_i(\mathcal{M})$ or $J \cap \neg\xi'_i(\mathcal{M})$ contains an infinite (closed) interval. Using this, we construct a sequence of intervals as follows: $I_0 = [a_0,b_0]$, $I_1 \subseteq I_0$ is an interval that is contained either in $I_0 \cap \xi'_1(\mathcal{M})$ or in $I_0 \cap \neg\xi'_1(\mathcal{M})$. At the jth step, $I_j \subseteq I_{j-1}$ is an interval that is contained either in $I_{j-1} \cap \xi'_j(\mathcal{M})$ or in $I_{j-1} \cap \neg\xi'_j(\mathcal{M})$. Let $I = I_k$. Then, for any $c, d \in I$, $\mathcal{M} \models \xi_i(c,\vec{b}) \leftrightarrow \xi_i(d;\vec{b})$.

Since $I = [a',b'] \subseteq [a_0,b_0]$ and $\mathcal{M} \models \beta_\Xi(c;\vec{b})$ for all $c \in I$, we obtain that, for every $c \in (a',b')$, there exists $d \in [a',b']$ such that $\mathcal{M} \models \neg\mathrm{same}_\Xi(c,d;\vec{b})$. That is, for some $\xi_i \in \Xi$, $\mathcal{M} \models \neg(\xi_i(c;\vec{b}) \leftrightarrow \xi_i(d;\vec{b}))$, which is impossible by construction of I. This proves that β_Ξ is algebraic.

For the converse, we let Ξ consist of just φ for any $\varphi(x;\vec{y})$. That is, $\beta_\Xi(x;\vec{y})$ is

$$\forall x', x''.x' < x < x'' \to (\exists z.x' \le z \le x'' \wedge \neg(\varphi(x;\vec{y}) \leftrightarrow \varphi(z;\vec{y}))).$$

We claim that φ and β_Ξ are equivalent if φ is algebraic. Fix any $\vec{b}$ of the same length as $\vec{y}$, and assume that $\varphi(a;\vec{b})$ holds. If $\beta_\Xi(a;\vec{b})$ does not hold, then there exist $a' < a < a''$ such that for every $c \in [a',a'']$, $\varphi(c;\vec{b}) \leftrightarrow \varphi(a;\vec{b})$ holds; thus, $\varphi(c;\vec{b})$ holds for infinitely many c, contradicting algebraicity of φ. Hence, $\beta_\Xi(a;\vec{b})$ holds. Conversely, assume that $\beta_\Xi(a;\vec{b})$ holds. If $\varphi(a;\vec{b})$ does not hold, then there is an interval containing a on which $\varphi(\cdot;\vec{b})$ does not hold. Indeed, $\neg\varphi(\mathcal{M};\vec{b})$ is a finite union of intervals whose complement is a finite set of points, so the above observation follows from the density. We now pick $a' < a''$ such that $\varphi(\cdot;\vec{b})$ does not hold on $[a',a'']$. Since $\beta_\Xi(a;\vec{b})$ holds, we find $c \in [a',a'']$ such that $\neg(\varphi(a;\vec{b}) \leftrightarrow \varphi(c;\vec{b}))$ holds; that is, $\varphi(c;\vec{b})$ holds for $c \in [a',a'']$, which is impossible. Thus, we conclude that $\varphi(a;\vec{b})$ holds, proving that for any $\vec{b}$, $\forall x.\ (\varphi(x;\vec{b}) \leftrightarrow \beta_\Xi(x;\vec{b}))$. This finishes the one-variable case.

For the multivariable case, we note that algebraicity of β_Ξ implies that $\varphi'(\vec{x};\vec{y}) = \beta_\Xi(x_1;\vec{y}) \wedge \ldots \wedge \beta_\Xi(x_n;\vec{y}) \wedge \psi(\vec{x};\vec{y})$ is algebraic. Conversely, let $\varphi(\vec{x};\vec{y})$ be algebraic. Consider

$$\varphi_i(x_i;\vec{y}) = \exists x_1 \ldots \exists x_{i-1} \exists x_{i+1} \ldots \exists x_n.\varphi(x_1,\ldots,x_i,\ldots,x_n;\vec{y}).$$

Let $\chi(x;\vec{y})$ be $\varphi_1(x;\vec{y}) \vee \ldots \vee \varphi_n(x;\vec{y})$. Obviously each φ_i is algebraic, and thus $\chi(x;\vec{y})$ is algebraic. Hence, $\chi(x;\vec{y})$ is equivalent to $\beta_\Xi(x;\vec{y})$ for some finite collection

Ξ of formulae in $(x;\vec{y})$. Note that if $\varphi(\vec{a};\vec{b})$ holds and a_i is the ith component of $\vec{a}$, then $\chi(a_i;\vec{b})$ holds and thus $\beta_\Xi(a_i;\vec{b})$ holds. This shows that φ is equivalent to $\beta_\Xi(x_1;\vec{y}) \wedge \ldots \wedge \beta_\Xi(x_n;\vec{y}) \wedge \varphi(\vec{x};\vec{y})$, thus completing the proof. ◻

Corollary 4.3. *If $\mathcal{M}$ is an o-minimal structure based on a dense order, and $\varphi(\vec{x};\vec{y})$ is algebraic over $\mathcal{M}$, then φ is algebraic over any $\mathcal{M}'$ elementary equivalent to $\mathcal{M}$.* ◻

Proof. There exists a collection of formulae Ξ such that $\mathcal{M} \models \forall\vec{x}\forall\vec{y}.\varphi(\vec{x};\vec{y}) \leftrightarrow (\varphi(\vec{x};\vec{y}) \wedge \bigwedge_i \beta_\Xi(x_i;\vec{y}))$. Hence the same sentence is true in $\mathcal{M}'$. Since $\mathcal{M}'$ is also o-minimal and based on a dense order, we get from Proposition 4.2 that φ is algebraic in $\mathcal{M}'$, too. ◻

4.2. Main theorem. We start with a few definitions. For an $L(\Omega)$-formula $\gamma(\vec{x};\vec{y})$ and database D, let

$$\gamma(D) \;=\; \{\vec{a} \mid \exists\vec{b} \in adom(D)^m \text{ such that } D \models \gamma(\vec{a};\vec{b})\}.$$

If Γ is a collection of formulae in $\vec{x};\vec{y}$, define

$$\Gamma(D) = \bigcup_{\gamma\in\Gamma} \gamma(D).$$

Note that if Γ is algebraic and finite, then $\Gamma(D)$ is finite.

Definition 4.4 (range-restriction). *Let $\mathcal{M}$ be an interpreted structure. A* range-restricted query *over $\mathcal{M}$ and a database schema SC is a pair $Q = (\Gamma, \varphi(\vec{x}))$, where Γ is a finite collection $\{\gamma_1(\vec{x};\vec{y}), \ldots, \gamma_m(\vec{x};\vec{y})\}$ of algebraic $L(\Omega)$-formulae, and $\varphi(\vec{x})$ is an $L(SC, \Omega)$ query.*

The semantics of Q is as follows:

$$Q[D] \quad = \quad \{\vec{a} \in \Gamma(D) \mid D \models \varphi(\vec{a})\}.$$

That is, Γ provides an upper bound on the output of a query; within this bound, a usual first-order query is evaluated. For example, let $\varphi(x)$ be the FO + Poly query $S(x) \vee (x > 5)$. Clearly, it is not safe. Now let $\gamma(x;y) \equiv (x * x = y)$ and $Q = (\{\gamma\}, \varphi)$. Then, for any database S (which is a finite set of the reals), $Q[S]$ is the set of those elements a such that $a^2 \in S$ and either $a \in S$ or $a > 5$. Clearly, this is a finite set.

Observation. Every range-restricted query is safe.

We call a range-restricted query (Γ, φ) *active semantics* if φ is an active-semantics formula. Note that Γ does not mention the database. It turns out that range-restricted active queries characterize all the safe active-semantics queries in the following sense.

Theorem 4.5. *Let $\mathcal{M}$ be any o-minimal structure based on a dense linear order. Then there is a function* Make_Safe *that takes as input an active-domain formula $\varphi(\vec{x})$ and outputs a range-restricted active query $Q = (\Gamma, \psi)$ with the property that* Make_Safe(φ) *is equivalent to φ on all databases D for which φ is safe. Furthermore, if $\mathcal{M}$ has effective QE, then* Make_Safe *is recursive.*

Proof. We deal with the one-variable case first. Let

$$\varphi(z) \;\equiv\; Q_1 w_1 \in adom \ldots Q_1 w_l \in adom.\alpha(z, \vec{w}),$$

where each Q_i is $\exists$ or $\forall$ and $\alpha(z,\vec{w})$ is quantifier-free, and all atomic subformulae $R(\cdots)$ contain only variables, excluding z. Any formula can be transformed into such by adding existential quantifiers; cf. [6, 8]. Let $\Xi = \{\xi_i(z,\vec{w}) \mid i = 1, \ldots, k\}$ be the collection of all Ω-atomic subformulae of α. We may assume without loss of generality that the length of $\vec{w}$ is nonzero, and that Ξ is nonempty. (If this is not true for φ, take $\varphi \wedge \forall w \in adom(w = w)$ and transform it to the above form.)

Define $\text{same}_\Xi(a, b, \vec{w})$, as before, to be $\bigwedge_{i=1}^{k}(\xi_i(a, \vec{w}) \leftrightarrow \xi_i(b, \vec{w}))$, and define $\gamma(x; \vec{w})$ to be $\beta_\Xi(x; \vec{w})$; that is, $\gamma(x, \vec{w}) \equiv \forall x', x''. x' < x < x'' \to \exists y.(x' \leq y \leq x'' \wedge \neg\text{same}_\Xi(x, y, \vec{w}))$. Now Γ consists just of γ, with $\vec{w}$ being distinguished parameters. We let Make_Safe(φ) output $(\{\gamma\}, \varphi)$.

Since γ is algebraic by Proposition 4.2, we must show that $\{a \mid D \models \varphi(a)\} = \{a \in \Gamma(D) \mid D \models \varphi(a)\}$ for every nonempty database for which φ is safe.

Assume otherwise; that is, for some nonempty D for which φ is safe, we have $D \models \varphi(a)$ but $a \notin \Gamma(D)$. Let $\vec{c}_1, \dots, \vec{c}_M$ be an enumeration of all vectors of the length of $\vec{w}$ of elements of the active domain. Note that $M > 0$. Since $a \notin \Gamma(D)$, we have that for each $i = 1, \dots, M$, there exist a_i', a_i'' such that $a_i' < a < a_i''$ and $\mathcal{M} \models \text{same}_\Xi(a, c, \vec{c}_i)$ for all $c \in [a_i', a_i'']$.

Let $b' = \max\{a_i'\}, b'' = \max\{a_i''\}$. We have $b' < a < b''$, and for each $\vec{c}$ (of length of $\vec{w}$) over the active domain, we have $\xi_i(a; \vec{c}) \leftrightarrow \xi_i(c, \vec{c})$ for every $c \in [b', b'']$. From this, by a simple induction on the structure of the formula (using the fact that z does not appear in any atomic formula $R(\cdots)$), we obtain that $D \models \alpha(a, \vec{c}) \leftrightarrow \alpha(c, \vec{c})$ for every $\vec{c}$ over $adom(D)$ and every $c \in [b', b'']$, and thus $D \models \varphi(a) \leftrightarrow \varphi(c)$, which implies that φ is not safe for D. This contradiction proves correctness of Make_Safe for the one-variable case.

This completes the proof for the one-variable case. We handle the multivariable case by reducing to the one-variable case.

Let $\mathcal{M}' = \langle \mathcal{U}, \Omega' \rangle$ be a definable extension of $\mathcal{M}$ that has QE. Note that $\mathcal{M}'$ is o-minimal. Let $\varphi(z_1, \dots, z_n)$ be given and define

$$\varphi_i(z_i) \quad \equiv \quad \exists z_1 \dots \exists z_{i-1} \exists z_{i+1} \dots \exists z_n . \varphi(z_1, \dots, z_{i-1}, z_i, z_{i+1}, \dots, z_n).$$

By [7, 8], there is an $L(SC, \Omega')$ *active* formula $\psi_i(z_i)$ such that $D \models \forall z. \psi_i(z) \leftrightarrow \varphi_i(z)$ for all D. Let $(\{\gamma_i(z_i, \vec{w}_i)\}, \psi_i(z_i))$ be the output of Make_Safe on ψ_i. Since $\mathcal{M}'$ is a definable extension, we can assume without loss that γ_i is an Ω-formula.

We now define

$$\gamma(\vec{z}; \vec{w}_1, \dots, \vec{w}_n) \quad \equiv \quad \gamma_1(z_1; \vec{w}_1) \wedge \dots \wedge \gamma_n(z_n; \vec{w}_n),$$

where each $\vec{w}_i$ is of the same length as the vector of distinguished parameters in the formulae γ_i. Finally, Make_Safe(φ) outputs $(\{\gamma\}, \varphi)$. To see that it works, first notice that algebraicity of all γ_i's implies algebraicity of γ. Now assume that $D \models \varphi(\vec{a})$ where $\vec{a} = (a_1, \dots, a_n)$. Then $D \models \varphi_i(a_i)$, and thus for some vector $\vec{c}_i$ of elements of the active domain, we have that $\gamma_i(a_i, \vec{c}_i)$ holds. Thus, if $\vec{c}$ is the concatenation of all $\vec{c}_i$s, then $\gamma(\vec{a}, \vec{c})$ holds, showing that $\vec{a} \in \Gamma(D)$, where $\Gamma = \{\gamma\}$. This completes the proof of the multivariable case.

We finally notice that Make_Safe for one-variable formulae is recursive, no matter what $\mathcal{M}$ is. For the multivariable case, to make it recursive, we need a procedure for converting natural-quantification formulae into active-quantification formulae. Such a procedure exists by Fact 2.2. $\square$

COROLLARY 4.6 (range-restricted = safe). *For any o-minimal structure based on a dense order, the class of safe active-semantics queries is the same as the class of range-restricted queries.* $\square$

Combining this with the natural-active collapse (Fact 2.2), we obtain the following corollary.

Corollary 4.7. *Let $\mathcal{M}$ be any o-minimal structure based on a dense linear order that admits QE. Then there is a function* Make_Safe *(recursive if so is QE and $\mathcal{M}$ is decidable) that takes as input a natural-semantics formula $\varphi(\vec{x})$, and outputs a range-restricted active query $Q = (\Gamma, \psi)$ with the property that* Make_Safe(φ) *is equivalent to φ on all databases D for which φ is safe. In particular, over $\mathcal{M}$, the classes of safe natural-semantics queries and range-restricted queries coincide.* $\square$

Corollary 4.8. *For any o-minimal structure based on a dense order (decidable or not), the collection of safe queries is recursively enumerable.* $\square$

We finish this section with a proposition that follows from the special form of formulae in Γ, as established in the proof of Theorem 4.5.

Proposition 4.9. *Let $\mathcal{M}$ be o-minimal and based on a dense order. Let $\varphi(\vec{x})$ be a first-order query. Then there exists a set Γ of algebraic formulae $\gamma(x; \vec{y})$ (that can be effectively constructed if $\mathcal{M}$ has effective QE and is decidable) such that, for any database D, if $\varphi[D]$ is finite, then $adom(\varphi[D]) \subseteq \Gamma(D)$.*

Proof. Assume φ is active-semantics. Then the proof follows the proof of Theorem 4.5, but at the end we replace $\gamma(x_1, \ldots, x_n; \vec{y})$ by

$$\gamma'(x; \vec{y}) \;=\; \bigvee_{i=1}^{n} \exists x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n \; \gamma(x_1, \ldots, x_{i-1}, x, x_{i+1}, \ldots, x_n; \vec{y})$$

to get a bound on the active domain, and output $(\{\gamma'\}, \varphi)$.

For an arbitrary φ, let $\mathcal{M}'$ be a definitional expansion of $\mathcal{M}$ that has QE (such an expansion always exists; cf. [11]). Since $\mathcal{M}$ and $\mathcal{M}'$ are elementary equivalent, $\mathcal{M}'$ is o-minimal [30] and the order is dense. Thus, there exists an active-semantics FO$(\mathcal{M}', SC)$ query $\psi(\vec{x})$ that is equivalent to φ (see Fact 2.2), and, by the above, we have a formula γ_0 in the language of $\mathcal{M}'$ such that $adom(\varphi[D]) = adom(\psi[D]) \subseteq \gamma_0(D)$. Now obtain an $L(\Omega)$ formula γ from γ_0 by replacing each new predicate symbol from $\mathcal{M}'$ by its definition by an $L(\Omega)$ formula. Then $\gamma(D) = \gamma_0(D)$, which proves the proposition. $\square$

4.3. Examples.

Below we give two examples. We consider the pure case, where Theorem 4.5 translates into a well-known result, and we also consider the case of polynomial constraints and show a more explicit form of range-restriction.

The pure case. We assume that we have the pure relational calculus; that is, our underlying structure is $\mathcal{M}^{\emptyset} = \langle \mathcal{U}, \emptyset \rangle$. The reason we can apply Theorem 4.5 is that we can extend $\mathcal{M}$ to $\mathcal{M}^{<} = \langle \mathcal{U}, < \rangle$ by adding a dense order without endpoints on $\mathcal{U}$; although it is never mentioned in queries, $\mathcal{M}^{<}$ is o-minimal (and has QE), and hence the results are applicable. Next, we need the following lemma.

Lemma 4.10. *Let $\gamma(x; \vec{y})$ be algebraic over $\mathcal{M}^{<}$. If $\mathcal{M}^{<} \models \gamma(a; \vec{b})$, then a coincides with one of $\vec{b}$'s components.*

Proof. Assume not and fix a counterexample $a, \vec{b}$ and let B be the set of components of $\vec{b}$ together with $-\infty, \infty$. Let b', b'' in B be such that $b' < a < b''$ and (b', b'') contains no other member of B. Since $\mathcal{M}^{<}$ has QE, γ is equivalent to a quantifier-free formula. For any $a' \in (b', b'')$, $(a, \vec{b})$ and $(a', \vec{b})$ satisfy the same atomic $<$-formulae, and hence $\mathcal{M}^{<} \models \gamma(a, \vec{b}) \leftrightarrow \gamma(a', \vec{b})$, which contradicts algebraicity. $\square$

This immediately implies that for an algebraic Γ and a database D, $\Gamma(D)$ is either empty (if Γ contains no formulae) or $\Gamma(D) = adom(D)$. Thus, the classes of safe pure relational calculus queries and relational calculus queries whose output is restricted to the active domain coincide. Of course, this is a standard result in database theory, proved here in a rather unusual way.

The real field: $\mathrm{FO} + \textsc{Poly}$. Can we find a more concrete representation of range-restricted queries over the real field? Intuitively, it should be sufficient to look for roots of polynomials $p(x, \vec{a})$, where $\vec{a}$ ranges over tuples of elements of the active domain, as was suggested by the example in the beginning of the section. However, even quantifier-free algebraic formulae do not give us this representation directly. Nevertheless, the following can be shown.

Let $p(x, \vec{y})$ be a multivariate polynomial over the real field. Define $\mathit{Root}(p, \vec{a})$ as $\emptyset$ if $p(x, \vec{a})$ is identically zero, and the set of roots of $p(x, \vec{a})$ otherwise. Given a collection P of polynomials $\{p_1(x, \vec{y}), \ldots, p_m(x, \vec{y})\}$ and a database D, let

$$P(D) \; = \bigcup_{i=1}^{m} \; \bigcup_{\vec{a} \subseteq \mathit{adom}(D)} \mathit{Root}(p_i, \vec{a}),$$

where $\vec{a}$ ranges over tuples of elements of $\mathit{adom}(D)$, of the same length as $\vec{y}$.

DEFINITION 4.11. *A query in polynomial range-restricted form is a pair (P, φ), where P is a finite collection of multivariate polynomials and $\varphi(x_1, \ldots, x_n)$ is a* $\mathrm{FO} + \textsc{Poly}$ *query. The semantics is defined as $(P, \varphi)[D] = \varphi[D] \cap P(D)^n$.*

PROPOSITION 4.12. *The class of safe* $\mathrm{FO} + \textsc{Poly}$ *queries (arbitrary or active-semantics) coincides with the class of queries in polynomial range-restricted form. Moreover, for every* $\mathrm{FO}{+}\textsc{Poly}$ *query φ, a collection of polynomials P can be effectively found such that φ and (P, φ) are equivalent on all databases on which φ is safe.*

Proof. Given a query $\varphi(\vec{x})$, find effectively a collection of algebraic formulae $\Gamma = \{\gamma_j(x; \vec{y})\}$ such that for any D for which φ is safe, $\mathit{adom}(\varphi[D]) \subseteq \Gamma(D)$. For each $\vec{a}$ and each $\gamma \in \Gamma$, the set $\gamma[\vec{a}] = \{c \mid \gamma(c; \vec{a})\}$ is finite, and by o-minimality there is a uniform bound M such that $\mathit{card}(\gamma[\vec{a}]) < M$ for all $\vec{a}$ and $\gamma \in \Gamma$.

Now let $\gamma_j^i(x; \vec{y})$, $i < M$, be defined as follows: $\mathcal{M} \models \gamma_j^i(c; \vec{a})$ if either (1) $\gamma_j[\vec{a}]$ has at least i elements, and c is the ith element in the order $<$, or (2) $\gamma_j[\vec{a}]$ is nonempty, has fewer than i elements, and c is the largest element of $\gamma_j[\vec{a}]$, or (3) $\gamma_j[\vec{a}]$ is empty, and $c = 0$. Note that $\gamma_j^i(x; \vec{y})$'s are indeed $L(+, *, 0, 1, <)$ formulae. It is easy to see that each $\gamma_j^i(x; \vec{y})$ defines a function $f_{ij} : \mathbb{R}^m \to \mathbb{R}$, where m is the length of $\vec{y}$, by $f_{ij}(\vec{a}) = c$ iff c is the unique element such that $\gamma_j^i(c; \vec{a})$ holds. Furthermore, this function is semialgebraic and the following property holds: if φ is safe for D, then $\mathit{adom}(\varphi[D])$ is contained in $\bigcup_{i,j} \bigcup_{\vec{a}} f_{ij}(\vec{a})$, where $\vec{a}$ ranges over $\mathit{adom}(D)$.

It follows from [23] that each $f_{ij}(\vec{y})$ is algebraic; that is, there exists a polynomial $p_{ij}(x, \vec{y})$ such that $p_{ij}(x, \vec{y}) = 0$ iff $x = f_{ij}(\vec{y})$. It is easy to see that for $P = \{p_{ij} \mid i < M, \gamma_j \in \Gamma\}$, $\Gamma(D) \subseteq P(D)$ and $P(D)$ is always finite. To complete the proof, we must show effectiveness. We can effectively construct Γ, and thus find M (by writing formulae saying that each $\gamma(x; \vec{y})$ has fewer than M satisfiers for each $\vec{y}$, and checking if it is true by applying QE; since it is true for some M, the process terminates). Hence, we can effectively construct γ_j^i's, and the procedure for finding p_{ij}'s is effective (although not stated in [23], it follows from the analysis of the proof there). ☐

4.4. Extensions. Suppose we are given two elementary equivalent structures $\mathcal{M}$ and $\mathcal{M}'$, for example, $\langle \mathbb{R}, +, < \rangle$ and $\langle \mathbb{Q}, +, < \rangle$. Assuming $\mathcal{M}$ is o-minimal based on a dense order, so is $\mathcal{M}'$, and thus the characterization of a safe query applies to $\mathcal{M}'$ as well. However, we would like to know more. Suppose φ is safe over $\mathcal{M}$. Is the same φ safe over $\mathcal{M}'$? The positive answer is provided for o-minimal structures.

PROPOSITION 4.13. *If $\mathcal{M}$ is an o-minimal structure based on a dense order, and φ is a safe active-semantics query, then φ is safe in any structure elementary* *equivalent to $\mathcal{M}$.*

Proof. Let $\varphi(\vec{z})$ be safe, and let $(\{\gamma(\vec{z};\vec{w})\},\varphi)$ be the output of Make_Safe (we just saw that it always can be made to have this form). Since φ is safe, we obtain that for every database D over $\mathcal{M}$ and for every $\vec{a}$ of the same length as $\vec{z}$ of elements of $\mathcal{M}$, $D \models \varphi(\vec{a}) \rightarrow \exists \vec{w} \in adom.\gamma(\vec{a};\vec{w})$. Now putting $\neg\varphi$ in prenex form, where only quantified variables appear inside the schema predicates (which can always be done), we have

$$D \models \exists \vec{w} \in adom.Q_1 y_1 \dots Q_n y_n.(\alpha(\vec{a},\vec{y}) \vee \gamma(\vec{a};\vec{w})),$$

where all quantification $Q_i y_i$ is active and α is the quantifier-free part of $\neg\varphi$. We now claim that the same is true in $\mathcal{M}'$ for every D over $\mathcal{M}'$ and every $\vec{a}$ of elements of $\mathcal{M}'$, as long as $\mathcal{M}'$ is elementary equivalent to $\mathcal{M}$. Note that this would imply that $D \models \varphi(\vec{a}) \rightarrow \exists \vec{w} \in adom.\gamma(\vec{a};\vec{w})$ holds in $\mathcal{M}'$ as well.

To prove this claim, assume to the contrary that this fails for some D and $\vec{a}$ over $\mathcal{M}'$. Let $\{b_1,\dots,b_m\}$ be $adom(D)$. We now define a sequence of formulae as follows: $\chi_n(\vec{a},\vec{b},\vec{w},y_1,\dots,y_{n-1}) = \bigvee_{i=1}^{m} \alpha(\vec{a},y_1,\dots,y_{n-1},b_i) \vee \gamma(\vec{a};\vec{w})$ if Q_n is $\exists$; if Q_n is $\forall$, we change $\bigvee$ to $\bigwedge$. Similarly, $\chi_j(\vec{a},\vec{b},\vec{w},y_1,\dots,y_{j-1}) = \bigvee_{i=1}^{m} \chi_{j+1}(\vec{a},\vec{b},\vec{w},y_1,\dots,y_{j-1},b_i)$ if Q_j is $\exists$; otherwise change $\bigvee$ to $\bigwedge$. Next, define $\chi'(\vec{a},\vec{b})$ as $\bigvee_{\vec{w}\in B} \chi_1(\vec{a},\vec{b},\vec{w})$, where B is the collection of all vectors from $\{b_1,\dots,b_m\}$ of the same length as $\vec{w}$. Notice that the only occurrence of the schema predicates is of the form $R(\cdot)$, where we list some b_i's as parameters. We finally replace those by *true* or *false*, depending on whether a particular tuple is in the database D. This results in a formula $\chi(\vec{a},\vec{b})$ that does not mention the schema predicates and has the property that $\mathcal{M}' \models \chi(\vec{a},\vec{b})$ iff $\exists \vec{w} \in adom.Q_1 y_1 \dots Q_n y_n.(\alpha(\vec{a},\vec{y}) \vee \gamma(\vec{a};\vec{w}))$ holds for $\vec{a}$ and the given D with the active domain $\{b_1,\dots,b_m\}$. Now the assumption gives us that $\mathcal{M}' \models \exists \vec{a}\exists \vec{b}.(\neg\chi(\vec{a},\vec{b}) \wedge \bigwedge_{i\neq j} \neg(b_i = b_j))$, thereby showing that the same sentence is true in $\mathcal{M}$. Then, by picking $\vec{a}$ and $\vec{b}$ in $\mathcal{M}$ that witness the failure of χ and defining a database D' on $\vec{b}$ in the same way as D was defined, we see, by an argument similar to the one above, that $D' \models \neg\chi'(\vec{a},\vec{b})$ and thus $\exists \vec{w} \in adom.Q_1 y_1 \dots Q_n y_n.(\alpha(\vec{a},\vec{y}) \vee \gamma(\vec{a};\vec{w}))$ fails in D', which is impossible. This finishes the proof of the claim.

Thus, $D \models \varphi(\vec{a}) \rightarrow \exists \vec{w} \in adom.\gamma(\vec{a};\vec{w})$ holds in $\mathcal{M}'$, and all we need to show to prove safety of φ is that γ is algebraic in $\mathcal{M}'$. From Proposition 4.2 we know that $\forall \vec{z}\forall \vec{w}.\gamma(\vec{z};\vec{w}) \leftrightarrow (\bigwedge_i \beta_\Xi(z_i;\vec{w}) \wedge \gamma(\vec{z};\vec{w}))$ holds in $\mathcal{M}$ for an appropriately chosen Ξ, and thus in $\mathcal{M}'$. Since both o-minimality and density are preserved under elementary equivalence, we get that β_Ξ is algebraic in $\mathcal{M}'$, and hence γ is algebraic in $\mathcal{M}'$, too. $\square$

5. Deciding safety of conjunctive queries and relatives. Safety of arbitrary calculus queries is undecidable even in the pure case [47], and of course it remains undecidable when interpreted functions are present. The main goal of this section is to show that safety is *decidable* for Boolean combinations of conjunctive queries in the presence of an interpreted structure such as $\langle \mathbb{R},+,*,0,1,<\rangle$. In particular, safety of FO + Poly and FO + Lin conjunctive queries is decidable.

Recall that we are using CQ, UCQ, and BCCQ for conjunctive, unions of conjunctive, and Boolean combinations of conjunctive queries (see section 2 for their definition in the presence of an interpreted structure). CQs, having dominated early research in relational theory because of their nice properties, resurfaced recently in a number of new applications; cf. [24, 19, 40]. Our proof will be by reduction to the containment problem, which is decidable for UCQs over certain structures. (Of course, *without* an interpreted structure, this is well known [35], as is the decidability of safety for BCCQs; cf. [1].) Note that CQs and UCQs are monotone (that is, $D \subseteq D'$ implies $\varphi[D] \subseteq \varphi[D']$). Since there are nonmonotone BCCQs, the class of UCQs is strictly contained in the class of BCCQs.

The main result is Theorem 5.1.

THEOREM 5.1. *Let $\mathcal{M}$ be o-minimal, based on a dense order, and decidable, and let it admit effective QE. Then it is decidable if a given BCCQ $\varphi(\vec{x})$ over $\mathcal{M}$ is safe.*

The proof is contained in the following two lemmas, which are of independent interest, and will be used later in section 7. Recall that by containment $\varphi \subseteq \psi$ we mean $\varphi[D] \subseteq \psi[D]$ for any D.

LEMMA 5.2. *Let $\mathcal{M}$ be o-minimal and based on a dense order, and $\varphi(\vec{x})$ be a first-order query. Then there exists an active-semantics CQ $\psi(\vec{x})$ such that φ is safe iff $\varphi \subseteq \psi$.*

Proof. The proof follows from Proposition 4.9: take $\Gamma = \{\gamma_1(x;\vec{y}), \ldots, \gamma_k(x;\vec{y})\}$ given by the proposition; let $\gamma = \bigvee_i \gamma_i$ and let $\psi(x_1, \ldots, x_n)$ be

$$\exists \vec{y}_1 \in adom \ldots \exists \vec{y}_n \in adom\ \gamma(x_1; \vec{y}_1) \wedge \ldots \wedge \gamma(x_n; \vec{y}_n).$$

If $\varphi \subseteq \psi$, then φ is safe since all γ_i's are algebraic. If φ is safe, then $adom(\varphi[D]) \subseteq \Gamma(D)$ for every D, which implies $\varphi \subseteq \psi$. ∎

LEMMA 5.3. *Let $\mathcal{M}$ be as in Theorem* 5.1. *Then containment of a BCCQ in a UCQ is decidable; that is, for a BCCQ $\varphi(\vec{x})$ and a UCQ $\psi(\vec{x})$ it is decidable if $\varphi \subseteq \psi$. This continues to hold if both φ and ψ are active-semantics queries.*

Proof. We start with the following claim.

CLAIM 5.4. *Given φ and ψ, one can effectively find a number k such that $\varphi \subseteq \psi$ iff for every database D with at most k tuples, $\varphi[D] \subseteq \psi[D]$.*

This clearly implies the result, as the latter condition can be expressed as an $L(\Omega)$ sentence. For example, if the schema contains one relational symbol S, this sentence is $\forall \vec{x}_1 \ldots \vec{x}_k \forall \vec{x}.\ \varphi(\vec{x})[\{\vec{x}_i\}/D] \rightarrow \psi(\vec{x})[\{\vec{x}_i\}/D]$, where $\varphi(\vec{x})[\{\vec{x}_i\}/D]$ is obtained from $\varphi(\vec{x})$ by replacing each occurrence of $S(\vec{z})$ by $\bigvee_i(\vec{z} = \vec{x}_i)$, and similarly for an arbitrary schema. The decidability of $\mathcal{M}$ now implies the lemma.

The proof of the claim proceeds similarly to [19]. Note that every BCCQ α can be represented as $\bigvee_{i=1}^{n}(\chi_i(\vec{x}) \wedge \neg\xi_i(\vec{x}))$, where each χ_i is a CQ and each ξ_i is a UCQ; this follows if one writes α as a disjunctive normal form (DNF). We take k to be the maximum length of χ_i (measured as the sum of the number of atomic formulae and the number of quantified variables).

Assume that $\varphi[D] \not\subseteq \psi[D]$ for some D; that is, we have $\vec{a} \in \varphi[D] \not\subseteq \psi[D]$. Assume that $D \models \chi_i(\vec{a}) \wedge \neg\xi_i(\vec{a})$ and let $\chi_i(\vec{x}) = \exists \vec{y} \exists \vec{z} \in adom\ \bigwedge_{j=1}^{l} \alpha_j(\vec{x}, \vec{y}, \vec{z})$. Then, for some $\vec{b}$ over $\mathcal{U}$ and $\vec{c}$ over $adom(D)$, we get $D \models \bigwedge_{j=1}^{l} \alpha_j(\vec{a}, \vec{b}, \vec{c})$. Consider those α_j's which are SC-formulae. For each such α_j, which is of the form $R(\cdots)$ where $R \in SC$, there is a tuple in D that satisfies it. Select one such tuple for each SC-atomic α_j, and let D' be D restricted to those tuples. Choose a set of at most $length(\vec{c})$ tuples in D containing all the components of $\vec{c}$, and add it to D'. Let the resulting database be D''. Clearly, it has at most k tuples.

Note that $D'' \models \bigwedge_{j=1}^{l} \alpha_j(\vec{a}, \vec{b}, \vec{c})$, and thus $D'' \models \chi_i(\vec{a})$ since $\vec{c} \subseteq adom(D'')$. On the other hand, $D'' \models \neg\xi_i(\vec{a})$ by monotonicity of ξ_i. Thus, we get that $\vec{a} \in \varphi[D''] - \psi[D'']$, where D'' has at most k tuples. This implies that each counterexample to containment is witnessed by a $\leq k$-element database, and finishes the proof Lemma 5.3. ∎

To complete the proof of Theorem 5.1, note that under the assumption on $\mathcal{M}$, the

CQ ψ such that $\varphi \subseteq \psi$ is equivalent to the safety of φ can be constructed effectively; this follows from the procedure for constructing Γ given in Proposition 4.9. The theorem now follows from Lemma 5.3. ∎

COROLLARY 5.5. *It is decidable whether any Boolean combination of* FO + LIN *or* FO + POLY *conjunctive queries is safe.* ∎

Note, however, that safety of CQs is not decidable over every structure. For example, for $\langle \mathbb{N}, +, *, 0, 1, < \rangle$, decidability of CQ safety would imply decidability of checking whether a Diophantine equation has finitely many solutions, which is known to be undecidable [12].

6. Dichotomy theorem and outputs of queries. The main result of this section is a simple but powerful combinatorial structure theorem, saying that over a well-behaved structure, outputs of safe queries cannot grow arbitrarily large in terms of the size of the input. In fact, we prove a *dichotomy* result: either a query φ is not safe on D, or $\varphi[D]$ is at most polynomial in the size of D, where the bounding polynomial depends only on φ. This result shows tame behavior of relational calculus queries over some important interpreted structures, in particular those giving rise to linear, polynomial, and exponential constraints. It can be used to show negative results, that is, new expressivity bounds, as well as positive results: the dichotomy theorem is a key ingredient in the decidability results of the next section.

We use the notation $\mathsf{size}(D)$ for the size of a database, measured here as the number of tuples. It can equivalently be measured as the cardinality of the active domain, or the number of tuples multiplied by their arity, and all the results will hold.

THEOREM 6.1 (dichotomy theorem). *Let $\mathcal{M}$ be o-minimal and based on a dense order. Let $\varphi(\vec{x})$ be a first-order query. Then there exists a polynomial $p_\varphi : \mathbb{R} \to \mathbb{R}$ such that, for any database D, either $\varphi[D]$ is infinite or $\mathsf{size}(\varphi[D]) \le p_\varphi(\mathsf{size}(D))$.*

Proof. Consider Γ given by Proposition 4.9. Since each $\gamma \in \Gamma$ is algebraic, there exists, by Lemma 4.1, a number c_γ such that $card(\{x \mid \gamma(x;\vec{y})\}) < c_\gamma$ for every $\vec{y}$. Thus, if $adom(\varphi[D])$ is finite, then its cardinality is at most

$$\sum_{\gamma\in\Gamma} c_\gamma \cdot n^{m_\gamma},$$

where m_γ is the number of $\vec{y}$ variables in γ and n is the size of the active domain of D. This is clearly bounded by $card(\Gamma) \cdot C_\Gamma \cdot n^{M_\Gamma}$, where $C_\Gamma = \max c_\gamma$ and $M_\Gamma = \max m_\gamma$.

Now notice that for every schema SC, there exist constants $c_0, d_0, c_1 > 0$ such that $c_1 \cdot card(adom(D)) \le \mathsf{size}(D) \le c_0 \cdot card(adom(D))^{d_0}$ for every D. Hence, for appropriately chosen $c_0, d_0 > 0$, we obtain that if $\varphi[D]$ is finite, then

$$\mathsf{size}(\varphi[D]) \le c_0 \cdot card(adom(\varphi[D]))^{d_0} \le c_0 \cdot (card(\Gamma) \cdot C_\Gamma \cdot n^{M_\Gamma})^{d_0} \le cn^d,$$

where $n = card(adom(D))$ and c, d are constants that depend only on φ. Hence, for some $c_1 > 0$ that depends on the schema only, we have $\mathsf{size}(\varphi[D]) \le c \cdot (\frac{n}{c_1})^d$, which proves the theorem. ∎

Are the assumptions on a structure important for the dichotomy result? That is, can we find structures over which it fails? The following is a simple counterexample to the dichotomy theorem: Let $\mathcal{M} = \langle \mathbb{N}, < \rangle$. Let $\varphi(x)$ be the following active-semantics query: $\exists y \in adom. x < y$. Clearly, $\varphi(x)$ is safe, but $\mathsf{size}(\varphi[D])$ can be arbitrarily large even for a database whose active domain consists of just one element.

The dichotomy theorem can also be stated in terms of a function measuring the growth of the output size. Formally, given a query φ, define $growth_\varphi : \mathbb{N} \to \mathbb{N} \cup \{\infty\}$

as

$$growth_\varphi(n) = \max\{\mathsf{size}(\varphi[D]) \mid \mathsf{size}(D) = n\}.$$

COROLLARY 6.2. *Let $\varphi(\vec{x})$ be an* FO + LIN, *or* FO + POLY, *or* FO + EXP *query. Then there exists a polynomial p_φ such that, for every $n \in \mathbb{N}$, either $growth_\varphi(n) = \infty$ or $growth_\varphi(n) \leq p_\varphi(n)$.* □

Note that for the query $\varphi(x)$ over $\langle \mathbb{N}, < \rangle$, which we used as a counterexample to the dichotomy theorem, $growth_\varphi(n) = \infty$ for all $n > 0$. Thus, we have a question whether Corollary 6.2 fails over some structures. The following proposition provides an example.

PROPOSITION 6.3. *Let $\mathcal{M} = \langle \mathbb{N}, +, <, 1 \rangle$. Then there exists an active-semantics first-order query $\varphi(x)$ over $\mathcal{M}$ such that $growth_\varphi(n) = 2^n$ for every $n > 0$.*

Proof. Let SC consist of one unary relation S. We show that there exists an FO$(\mathcal{M}, SC)$ sentence Ψ such that $S \models \Psi$ iff S is of the form $S_n = \{2^i \mid 1 \leq i \leq n\}$. This is done by letting Ψ be

$$\begin{array}{ll} & (\exists x \in adom. x = 1 + 1 \wedge S(x)) \\ \wedge & (\forall x \in adom. x = 1 + 1 \vee x > 1 + 1) \\ \wedge & (\forall x \in adom. x = 1 + 1 \vee \exists y \in adom. y + y = x) \\ \wedge & (\forall x \in adom. (\forall y \in adom. y < x \vee y = x) \vee (\exists y \in adom. y = x + x)). \end{array}$$

Now define $\varphi(x)$ as $\Psi \wedge \neg(x < 1) \wedge (\exists y \in adom. x < y \vee x = y)$. Then, for S not of the form S_n, we have $\varphi[S] = \emptyset$, and $\varphi[S_n] = \{1, 2, 3, \ldots, 2^n\}$. Since $card(S_n) = n$, this implies $growth_\varphi(n) = 2^n$ for $n > 0$. □

The dichotomy theorem gives easy expressivity bounds based on the growth of the output size, in fact, sometimes somewhat surprising ones: even if we use exponentiation, we still cannot express any queries with superpolynomial growth. For example, consider the following query Q: given a binary relation S containing $n+1$ distinct points $x_0, x_1, \ldots, x_n$ on a plane, return the vertices of the projection of an n-dimensional cube $[0,1]^n$, where the edges along the axes are projected onto $\vec{x_0 x_1}, \ldots, \vec{x_0 x_n}$. It is easy to see that for each fixed n, this query is expressible in FO + POLY. As a consequence of the dichotomy theorem, we conclude that Q cannot be expressed uniformly for all n even as an FO + EXP query.

For monotone queries, we can do better. We prove a trichotomy theorem that provides us with a lower bound as well. Recall that monotone queries are those for which $D_1 \subseteq D_2$ implies $\varphi[D_1] \subseteq \varphi[D_2]$. For example, any union of CQs is monotone.

THEOREM 6.4. *Let $\mathcal{M}$ be o-minimal based on a dense order. Then, for each monotone query $\varphi(\vec{x})$, there exist two polynomials p^1_φ and p^2_φ such that either $growth_\varphi$ is bounded by a constant or, for every n, either $p^1_\varphi(n) \leq growth_\varphi(n) \leq p^2_\varphi(n)$ or $growth_\varphi(n) = \infty$.*

Proof. In view of the previous theorem, it remains to show that if $growth_\varphi$ is not bounded by a constant, then it is bounded below by a polynomial. Assuming $growth_\varphi$ is not bounded by a constant, we get a family of databases $\{D_i\}_{i \in \mathbb{N}}$ such that $\mathsf{size}(\varphi[D_i]) > i$ for all i. Because of monotonicity, we can ensure, by adding elements to D_i, that $\mathsf{size}(D_i) \geq i$.

In the proof of Lemma 5.3 we showed that there exists a constant k that depends on φ only, such that $\vec{a} \in \varphi[D]$ iff there is a $D' \subseteq D$ with at most k tuples such that $\vec{a} \in \varphi[D']$. Thus, there is a $D'_i \subseteq D_i$ with at most $k(i+1)$ tuples such that $\mathsf{size}(\varphi[D'_i]) > i$.

Now, for a given n, let i be the maximal such that $k(i+1) \leq n$. Consider D'_i and extend it to contain exactly n tuples. For the resulting D''_i, we have $\mathsf{size}(\varphi[D'_i]) > i$ by monotonicity; hence $growth_\varphi(n) > i$. Since $n \leq k(i+1)$, we get from this that $growth_\varphi(n) \geq \frac{n}{k} - 1$, which completes the proof. □

It also follows from the proof that the lower polynomial bound does not require o-minimality. This gives us some new expressivity bounds. It is possible to find first-order queries with $growth_\varphi = O(f(n))$ for many nonpolynomial functions f. For example, consider a schema consisting of one unary relation X and one binary relation E, and a sentence Ψ saying that E codes the powerset of X; that is, the family of sets $X_a = \{y \mid E(y,a)\}$ is exactly the family of all nonempty subsets of X, when a ranges over the second projection of E. Such a sentence Ψ can be defined in first-order logic; cf. [1]. We now let $\varphi(x) \equiv X(x) \wedge \Psi$; it then follows that $growth_\varphi = O(\log n)$. Similarly, one can find queries with $growth_\varphi = O(\sqrt[k]{n})$ for any constant k. The trichotomy theorem says that such queries cannot be defined as monotone queries (e.g., unions of CQs) over *any* interpreted structure.

7. Preserving geometric properties of constraint databases. In this section, we switch from the finite world to the infinite; that is, we deal with constraint databases that represent potentially infinite objects. The notion of safety over constraint databases is different: we are interested in identifying languages that guarantee *preservation of certain geometric properties.*

To give a very simple example, assume that spatial objects stored in a database are convex polytopes in $\mathbb{R}^n$. A simple query, "return the convex hull of all the vertices x with $\| x \| < 1$" does always return a convex polytope. This query must be written in a rather expressive language: it can be expressed in FO + Poly but not FO + Lin [43]. Now, our question is, Can we ensure in some way that a class of FO + Poly programs preserves a given property, like being a convex polytope? That is, can we find an effective syntax for the class of queries that preserve certain geometric properties?

For FO + Poly and the class of databases definable with linear constraints (semilinear databases), [13] gave a solution, based on deciding semilinearity by an FO + Poly query. The resulting language is not quite natural, and [13] posed a problem of finding natural languages that capture queries with certain preservation properties. Our first goal here is to present a general scheme, different from the decidability approach, for enumerating such queries in FO($\mathcal{M}$). Here $\mathcal{M}$ is some structure on the reals, not necessarily $\langle \mathbb{R}, +, *, 0, 1, < \rangle$. The approach is based on reduction to the finite case and using our results about finite query safety. A similar approach was used in [37], where a coding was applied to reduce certain questions about ordered constraint databases to ones about finite databases.

As it often happens, the general case is solved rather easily, and gives us a pleasant characterization of queries preserving geometric properties, but working out the details of important motivating examples is a painful process. We do so for three properties: a convex polytope, a convex polyhedron, and a compact semilinear set in $\mathbb{R}^2$ (the latter are perhaps the most often-encountered class of constraint databases).

We then use our characterizations together with the dichotomy theorem of the previous section to show a somewhat surprising result that for unions of conjunctive FO + Poly queries, it is *decidable* whether they preserve convex polytopes or compact semilinear sets in $\mathbb{R}^2$.

To define a general framework for talking about queries that preserve geometric properties, we recall some basic definitions on constraint (or finitely representable) databases. As before, we have a language of some underlying structure $\mathcal{M}$ and a schema SC, but now m-relations in SC are given by quantifier-free formulae[2] $\alpha(x_1, \ldots, x_m)$ in $L(\Omega)$. If $\mathcal{M}$ is $\langle \mathbb{R}, +, -, 0, 1, < \rangle$, then sets so defined are called *semi-linear*; for $\langle \mathbb{R}, +, *, 0, 1, < \rangle$ they are called *semialgebraic*; cf. [42]. The query languages for constraint databases are the same as those we considered for finite ones: $\mathrm{FO}(SC, \Omega)$.

If $\mathcal{M} = \langle \mathcal{U}, \Omega \rangle$ is an infinite structure, let $\mathsf{Obj}(\Omega)$ be the class of finitely representable databases over $\mathcal{M}$; that is, $\mathsf{Obj}(\Omega) = \bigcup_{n<\omega} \mathsf{Obj}_n(\Omega)$ and $\mathsf{Obj}_n(\Omega)$ is the collection of subsets of $\mathcal{U}^n$ of the form $\{(x_1, \ldots, x_n) \mid \mathcal{M} \models \alpha(x_1, \ldots, x_n)\}$, where α is a quantifier-free first-order formula in $L(\Omega)$. We use SAlg_n for semialgebraic sets.

Let S be an m-ary relational symbol, and let $\psi(y_1, \ldots, y_n)$ be a first-order formula in the language of S and Ω. Then this query defines a map from $\mathsf{Obj}_m(\Omega)$ to $\mathsf{Obj}_n(\Omega)$ as follows: for any $X \in \mathsf{Obj}_m(\Omega)$, $\psi[X] = \{\vec{y} \mid (\mathcal{M}, X) \models \psi(\vec{y})\}$. Clearly $\psi[X] \in \mathsf{Obj}(\Omega)$ if $\mathcal{M}$ has QE.

Let $\mathcal{C}$ be a class of objects in $\mathsf{Obj}(\Omega)$. We say that a first-order query ψ *preserves* $\mathcal{C}$ if for any $X \in \mathcal{C}$, $\psi[X] \in \mathcal{C}$. For example, $\mathcal{C}$ can be the class of convex polytopes in SAlg.

Thus, the safety question for constraint databases is the following. Is there an effective syntax for the class of $\mathcal{C}$-preserving queries? Below, we show an approach to solution, based on the characterization theorems for the finite case.

DEFINITION 7.1. *The class $\mathcal{C}$ has a canonical representation in $\mathsf{Obj}(\Omega)$ if there is a recursive injective function $g : \mathbb{N} \to \mathbb{N}$ with computable inverse, and for each n, two functions, $code_n : 2^{\mathcal{U}^n} \to 2^{\mathcal{U}^m}$ and $decode_n : 2^{\mathcal{U}^m} \to 2^{\mathcal{U}^n}$, where $m = g(n)$, such that*

(1) *$decode_n \circ code_n(x) = x$ if $x \in \mathsf{Obj}_n(\Omega)$;*

(2) *$\mid code_n(x) \mid < \omega$ if $x \in \mathcal{C}$; $decode_n(x) \in \mathcal{C}$ if x is finite;*

(3) *$code_n$ is $\mathrm{FO}(\Omega)$-definable on $\mathsf{Obj}_n(\Omega)$;*

(4) *$decode_n$ is $\mathrm{FO}(\Omega)$-definable on finite sets.*

Intuitively, the canonical representation is a finite representation of $\mathcal{C}$ within $\mathsf{Obj}(\Omega)$ that can be defined in first-order logic over $\mathcal{M}$. For example, an approach to obtaining a canonical representation of convex polytopes would be to compute their vertices. This suffices to reconstruct the polytope, and the vertices can be defined by a first-order formula. The actual representation (Proposition 7.3) is indeed based on computing the vertices.

Next, we show that canonical representations solve the safety problem. We always assume that the set Ω is recursive.

THEOREM 7.2. *Let $\mathcal{M} = \langle \mathcal{U}, \Omega \rangle$ be o-minimal, based on a dense order, and decidable, and let it have effective QE. Suppose $\mathcal{C}$ is a class that has a canonical representation in $\mathsf{Obj}(\Omega)$. Then there is an effective syntax for $\mathcal{C}$-preserving $\mathrm{FO}(\Omega)$ queries; that is, there exists a recursively enumerable set of $\mathcal{C}$-preserving $\mathrm{FO}(\Omega)$ queries such that every $\mathcal{C}$-preserving $\mathrm{FO}(\Omega)$ query is equivalent to a query in this set.*

Proof. Consider an enumeration of all safe $\mathrm{FO}(\Omega)$ queries $\langle \varphi_i \rangle$ (from Corollary 4.8, we know that it exists). Let φ use the extra relation symbol of arity m and assume that n is such that $g(n) = m$; given the assumptions, we can compute that. Let φ_i have l parameters, and again let k be such that $g(k) = l$. If n and k are found for a given φ_i, we let ψ be

$$decode_k \circ \varphi_i \circ code_n.$$

This produces the required enumeration. So we have to check that every query above

[2]Without loss of generality, we do not assume relational attributes, as in [13, 27] and some other papers. They do not affect our results but would make notation heavier.

preserves $\mathcal{C}$, and for every $\mathcal{C}$ preserving ψ, we can get φ such that $decode \circ \varphi \circ code$ coincides with ψ. The first one is clear: if we have $X \in \mathcal{C}$, then $code_n(X)$ is finite, hence $\varphi_i[code_n(X)]$ is finite too, and applying $decode_k$, we get an object in $\mathcal{C}$.

For the converse, suppose we have a $\mathcal{C}$-preserving query $\psi : \mathsf{Obj}_n(\Omega) \to \mathsf{Obj}_k(\Omega)$. Define α as follows: $\alpha = code_k \circ \psi \circ decode_n$. That is, α is a query $\mathsf{Obj}_m(\Omega) \to \mathsf{Obj}_l(\Omega)$. Given this, notice that

$$decode_k \circ \alpha \circ code_n = decode_k \circ code_k \circ \psi \circ decode_n \circ code_n = \psi$$

on $\mathsf{Obj}_n(\Omega)$. Thus, it remains to show that α is safe, i.e., preserves finiteness. Let X be a finite set in $\mathcal{U}^m$. Then $decode_n(X) \in \mathcal{C}$, $decode_n(X) \subset \mathcal{U}^n$. Since ψ is $\mathcal{C}$-preserving, we get that $Y = \psi[decode_n(X)] \in \mathsf{Obj}_k(\Omega)$ is in $\mathcal{C}$, too, and thus $code_k(Y)$ is finite. This proves finiteness of α and concludes the proof of the theorem. ◻

We now turn to examples in the case when $\Omega = (+, *, 0, 1, <)$; that is, we are looking for canonical representations in SAlg. Let $\mathcal{CPH}$ be the class of convex polyhedra (intersections of a finite number of closed halfspaces) and $\mathcal{CPT}$ be the class of convex polytopes (bounded polyhedra). For the basic facts on convex sets that will be used in the proofs of the propositions below, see [33].

PROPOSITION 7.3. *The class $\mathcal{CPT}$ has canonical representation in* SAlg.

Proof. Given a convex polytope X in $\mathbb{R}^n$, its vertices can be found as $V(X) = \{\vec{x} \in \mathbb{R}^n \mid \vec{x} \in X, \vec{x} \notin \mathrm{conv}(X - \vec{x})\}$. Thus, vertices of convex polytopes are definable in FO$(+, *, 0, 1, <)$, because the convex hull of a finite set of points is definable, and, in view of Carathéodory's theorem, we have

$$V(X) = \{\vec{x} \in \mathbb{R}^n \mid \vec{x} \in X, \forall \vec{x}_1, \ldots, \vec{x}_{n+1} \in X - \vec{x}.\ \vec{x} \notin \mathrm{conv}(\{\vec{x}_1, \ldots, \vec{x}_{n+1}\})\}.$$

We now define $code_n$. To simplify the notation, we let it produce a pair of n-ary relations, but it can be straightforwardly coded by one relation. If $X = \mathrm{conv}(V(X))$, then $code_n(X) = (V(X), \emptyset)$; otherwise, $code_n(X) = (\mathbb{R}^n, X)$. The function $decode_n : 2^{\mathbb{R}^n} \times 2^{\mathbb{R}^n} \to 2^{\mathbb{R}^n}$ is defined as follows:

$$decode_n(Y, Z) = \begin{cases} \bigcup_{(\vec{y}_1, \ldots, \vec{y}_{n+1}) \in Y} \quad \mathrm{conv}(\{\vec{y}_1, \ldots, \vec{y}_{n+1}\}) & \text{if } Y \neq \mathbb{R}^n, \\ \hfill Z & \text{otherwise.} \end{cases}$$

Clearly, $decode_n \circ code_n$ is the identity function for any (semialgebraic) set; these functions are also first-order definable. If X is a polytope, $V(X)$ is finite, and by Carathéodory's theorem each point of X is contained in the convex hull of at most $n + 1$ vertices of X. Hence, $card(code_n(X)) \leq card(V(X))^{n+1} < \omega$. If (Y, Z) is finite, then $decode_n(Y)$ is $\mathrm{conv}(Y)$ and thus a convex polytope. This proves the proposition. ◻

PROPOSITION 7.4. *The class $\mathcal{CPH}$ has canonical representation in* SAlg.

Proof. We first give a brief sketch of the coding scheme. We start by recalling a few basic facts about convex polyhedra (see [15, 33]). Let X be a convex polyhedron in $\mathbb{R}^n$. Then $X = L + (X \cap L^{\perp})$, where L is its lineality space, defined as $\{\vec{y} \mid \vec{y} = \vec{0} \text{ or } \forall \vec{x} \in X \forall \lambda.\ \vec{y} + \lambda \cdot \vec{x} \in X\}$ (it is a subspace of $\mathbb{R}^n$) and $L^{\perp}$ is the orthogonal subspace $\{\vec{y} \mid \forall \vec{x} \in L.\ \langle \vec{x}, \vec{y} \rangle = 0\}$. We shall use X_0 for $X \cap L^{\perp}$ in this proof. It is known that X_0 is a convex polyhedron of lineality zero; that is, it contains no line. By $A + B$ we mean $\{\vec{a} + \vec{b} \mid \vec{a} \in A, \vec{b} \in B\}$. Note the difference between the translate $X - \vec{x} = \{\vec{y} - \vec{x} \mid \vec{y} \in X\}$ and the set-theoretic difference $X - x$; we use $\vec{x}$ to distinguish between them.

For X_0, define its vertices as $x \in X_0$ such that $x \notin \mathrm{conv}(X_0 - x)$. A direction is given by a vector $\vec{y}$ and corresponds to the equivalence class of rays which are translates of each other. Note that each direction can be canonically represented by $\vec{y}$ such that $\parallel \vec{y} \parallel = 1$. A direction $\vec{y}$ is an extreme direction of X_0 if for some vertex $\vec{x}$, the ray through $\vec{x}$ in the direction of $\vec{y}$, $l(\vec{x}, \vec{y}) = \{\vec{x} + \lambda \cdot \vec{y} \mid \lambda \geq 0\}$, is a face of X_0. Since X_0 is polyhedral of lineality zero, the set of vertices and extreme directions is finite. By (generalized) Carathéodory's theorem [15, 33], every point $\vec{z}$ of X_0 is a combination of at most $n+1$ vertices and extreme directions,

$$\lambda_1 \vec{x}_1 + \cdots + \lambda_k \vec{x}_k + \mu_1 \vec{y}_1 + \cdots + \mu_m \vec{y}_m,$$

where $\lambda_i, \mu_j \geq 0, \lambda_1 + \cdots + \lambda_k = 1, k + m \leq n + 1$.

This suggests the following coding scheme. As before, for simplicity of exposition, we assume several coding relations, but they can be combined into one easily. We also do not spell out every first-order formula, but the reader should be convinced from the mathematical definitions that all the concepts we use are first-order definable over the real field. We use relations $LINEAL_k$; each such relation contains a canonical representation (roughly, an orthogonal basis) of the lineality space of X, provided its dimension is k. That is, at most one of these relations actually contains some information. We then have the relations *Vert* and *ExtDir* for storing vertices and extreme directions of X_0. Finally, we have a relation *Points* that contains points that do not belong to $L + X_0$ (recall that the coding scheme applies to any semialgebraic set, so there could be such points, and we need to record them for the *decode* function).

Thus, to code (an arbitrary semialgebraic) set X, we first note that its lineality space $L(X) = \{\vec{y} \mid \forall \vec{x} \in X.\ \vec{x} + \vec{y} \in X\}$ and its orthogonal $L(X)^{\perp} = \{\vec{y} \mid \forall \vec{x} \in L(X).\ \langle \vec{x}, \vec{y} \rangle = 0\}$ are definable in FO + Poly (note that one can define the inner product in FO + Poly). Furthermore, for each $k \leq n$, there exists an FO + Poly sentence dim_k expressing the fact that $L(X)$ is a subspace of $\mathbb{R}^n$ and its dimension is k. This is true because in FO + Poly we can test linear independence; thus, we can check if there exists a system of k linearly independent vectors in L such that every vector in L is a linear combination of them.

Next, we show how to compute $LINEAL_k$ and *VertDir*. We first sketch the coding scheme for $LINEAL_k$. The set $L(X)$ is (FO + Poly)-definable. Assume that it is a k-dimensional linear space (which is tested by $\dim_k$). Let Δ_n be some canonically chosen n-dimensional simplex of diameter 1 such that the origin has barycentric coordinates $(\frac{1}{n}, \ldots, \frac{1}{n})$. Consider the intersection of $L(X)$ with one-dimensional faces of Δ_n (unless $L(X)$ is a line, in which case we consider its intersection with two-dimensional faces of Δ_n). If the intersection is a point, we record that point; if it contains the whole face, we record both endpoints of the face. From the selected points, find a linearly independent subsystem (note that it can be done canonically, for example, by listing the vertices and one-dimensional faces of Δ_n in some order). It then serves as a basis of $L(X)$, which we use to code $L(X)$. Note that $L(X)$ can be reconstructed in FO + Poly from its basis.

Now that we have a representation for the lineal space of X, and a first-order formula defining $L^{\perp}$, we have an FO + Poly formula defining X_0. Using it, we can compute vertices

$$V(X_0) = \{x \in X_0 \mid \neg \exists x_1, \ldots, x_{n+1} \in X_0 - x.\ x \in \mathrm{conv}(\{x_1, \ldots, x_{n+1}\})\}.$$

Clearly, this is a first-order definition. Next, we find the set

$$E(X_0) = \{\vec{y} \mid \langle \vec{y}, \vec{y} \rangle = 1 \text{ and } \exists \vec{x} \in V(X_0).\ l(\vec{x}, \vec{y}) \text{ is a face}\}.$$

A subset Y of X_0 is a face if every closed line segment in X_0 with a relative interior point in Y has both endpoints in Y. Clearly, this is first-order definable, and thus $E(X_0)$, the set of extreme directions of X_0, is first-order definable.

Given two sets V and E in $\mathbb{R}^n$, by $\text{conv}(V, E)$ we denote their convex hull, that is, the set of elements of $\mathbb{R}^n$ definable as $\sum_{i=1}^{k} \lambda_i \cdot \vec{x}_i + \sum_{j=1}^{m} \mu_j \cdot \vec{y}_j$, where $\vec{x}_i \in V$, $\vec{y}_j \in E$, $\sum_{i=1}^{k} \lambda_i = 1$, $\lambda_i, \mu_j \geq 0$, and $k + m \leq n + 1$. Again, this can be done in $\text{FO} + \text{POLY}$.

We now describe code_n. For a semialgebraic set X, it produces a tuple of relations

$$(\mathit{LINEAL}_0, \ldots, \mathit{LINEAL}_n, \mathit{Vert}, \mathit{ExtDir}, \mathit{Point})$$

as follows. It first determines, by computing $L(X)$, $L(X)^{\perp}$, $V(X_0)$, and $E(X_0)$ if it is the case that $L(X)$ is a linear subspace of $\mathbb{R}^n$ and

$$X \;=\; L(X) + \text{conv}(V(X_0), E(X_0)).$$

If this is the case, then LINEAL_k, *Vert*, and *ExtDir* are produced as before, and *Point* is empty. Otherwise, *Point* coincides with X, and all other sets in the coding are taken to be $\mathbb{R}^n$. From the description above it follows that code_n is $(\text{FO} + \text{POLY})$-definable.

To compute decode_n, we first check if the first $n+2$ relations in the code coincide with $\mathbb{R}^n$, and, if this is the case, output the last relation in the code. Otherwise, we use the nonempty LINEAL_k with least k to compute a linear subspace L of $\mathbb{R}^n$ generated by the vectors in LINEAL_k (if all LINEAL_k are empty, we let this subspace be $\{\vec{0}\}$). Next, compute $Y = \text{conv}(\mathit{Vert}, \mathit{ExtDir})$. Note that both are $(\text{FO} + \text{POLY})$-definable. Finally, return $L + Y \cap L^{\perp}$; this is $(\text{FO} + \text{POLY})$-definable also.

We now sketch the proof that this coding scheme satisfies the conditions of the definition of canonical representation. Both *code* and *decode* are $(\text{FO} + \text{POLY})$-definable. If $X \in \mathcal{CPH}$, then $L(X)$ is a linear space, X_0 has finitely many vertices and extreme directions, and $X = L + X_0$ implies that *Point* is empty, thus showing that *code* produces a finite set. Assume that *decode* is given a finite input Y. Then none of the first $n + 2$ relations is $\mathbb{R}^n$, and thus the output of *decode* is the sum of a vector space and a convex hull of a finite set of vertices and directions, and thus a convex polyhedron. To show that $\mathit{decode} \circ \mathit{code}(X) = X$ for any semialgebraic X, consider two cases. If $X = L(X) + \text{conv}(V(X_0), E(X_0))$, then *Point* is empty, and *Vert* and *ExtDir* record all vertices and extreme directions of X_0, and one of LINEAL_k codes the lineality space. Thus, *decode* applied to $\mathit{code}(X)$ will return $L + X_0 = X$. If $X \neq L(X) + \text{conv}(V(X_0), E(X_0))$, then all relations but *Point* coincide with $\mathbb{R}^n$, and *Point* contains X, and thus *decode* returns X. This completes the proof. $\square$

Let $\mathsf{SLinComp}$ be the class of *compact* (closed and bounded) semi-linear sets. We resolve this case for dimension 2.

PROPOSITION 7.5. *The class* $\mathsf{SLinComp}_2$ *has canonical representation in* SAlg_2.

Proof (sketch). An object in $\mathsf{SLinComp}_2$ is a finite union of convex polytopes in $\mathbb{R}^2$—this easily follows from cell decomposition. Any such object X admits a triangulation that does not introduce new vertices [26]. Thus, the idea of the coding is to find the set $V(X)$ of vertices and use as the code triples of vertices (not necessarily distinct) $(\vec{x}, \vec{y}, \vec{z})$ with $\text{conv}(\{\vec{x}, \vec{y}, \vec{z}\}) \subseteq X$. More precisely, a triple $(\vec{x}, \vec{y}, \vec{z})$ belongs to $\mathit{code}(X)$ if either $\vec{x}, \vec{y}, \vec{z} \in V(X)$ and $\text{conv}(\{\vec{x}, \vec{y}, \vec{z}\}) \subseteq X$, or $\vec{x} = \vec{y} = \vec{z}$ and there is no triple of elements of $V(X)$ whose convex hull is contained in X and contains $\vec{x}$. Thus, $\mathit{code}(X) \subseteq \mathbb{R}^6$. For *decode*, we use

$$\mathit{decode}(Y) = \bigcup_{(\vec{x}, \vec{y}, \vec{z}) \in Y} \text{conv}(\{\vec{x}, \vec{y}, \vec{z}\}).$$

Clearly, *decode* $\circ$ *code* is the identity, *decode* is first-order definable, and *decode*(Y) is compact and semilinear when Y is finite. Thus, it remains to show that $V(X)$ is finite and (FO + POLY)-definable. The former is well known (see [25]). For the first-order definition of $V(X)$ we use the following result from [25, 10]. Let X be a finite union of polyhedra (in $\mathbb{R}^n$) and let $B_\epsilon(\vec{x})$ be the ball of radius ϵ around $\vec{x}$. Then for each $\vec{x}$, there exists $\delta > 0$ such that for any $0 < \epsilon_1, \epsilon_2 < \delta$, we have

$$\vec{x} + \bigcup_{\lambda>0} \lambda \cdot [(X \cap B_{\epsilon_1}(\vec{x})) - \vec{x}] \quad = \quad \vec{x} + \bigcup_{\lambda>0} \lambda \cdot [(X \cap B_{\epsilon_2}(\vec{x})) - \vec{x}].$$

We denote this set by $X(\vec{x})$. Define the equivalence relation $\equiv_X$ by $\vec{y} \equiv_X \vec{z}$ if $X(\vec{y}) = X(\vec{z})$. Then the vertices of X are precisely the one-element equivalence classes of $\equiv_X$. It is routine to verify that the above can be translated into an (FO + POLY) definition of vertices. This completes the proof. $\square$

Note that the coding scheme used in the proof of Proposition 7.5 *cannot* be used in higher dimensions. We used the fact there is a triangulation of a two-dimensional polygon that does not introduce new vertices. However, in the three-dimensional case, there exist (nonconvex) polygons for which such a triangulation is impossible; cf. [34]. In fact, [34] shows that the problem of deciding if a three-dimensional polygon admits such a triangulation is NP-complete.

Summing up, we have the following theorem.

THEOREM 7.6. *There exists a recursively enumerable class of* FO + POLY *queries that captures the class of* $\mathcal{CPT}$- *(*$\mathcal{CPH}$- *and* $\mathsf{SLinComp}_2$-*, respectively) preserving queries.* $\square$

The coding technique given here gives more information, however, as shown in the next section.

7.1. Decidability results and geometric bounds.

While the classes of FO + POLY queries preserving certain properties have been shown to be recursively enumerable, in general, testing nontrivial preservation properties for arbitrary first-order queries is undecidable. For example, it is shown in [44] that it is undecidable whether an FO + POLY-query preserves semilinearity. Here, we show that for a restricted class of FO + POLY queries, unions of CQs, preserving two of the properties considered here is decidable. The proofs are based on the representation theorems of this section and the dichotomy theorem of the previous section. We first give the following bound on the behavior of conjunctive queries on convex polytopes.

LEMMA 7.7. *Let* $\varphi(x_1, \ldots, x_n)$ *be a union of* FO + POLY *CQs that mentions one* m*-ary relational symbol* S*. Then one can effectively find two numbers,* k *and* l*, such that* φ *is* $\mathcal{CPT}$*-preserving iff for every convex polytope* D *in* $\mathbb{R}^m$ *with at most* k *vertices, the output* $\varphi[D]$ *is a convex polytope with at most* l *vertices in* $\mathbb{R}^n$.

Proof. We can assume without loss of generality that $\varphi(\vec{x})$ is of the form

$$\bigvee_j \exists \vec{z} \bigwedge_i \alpha_{ij}(\vec{x}, \vec{z}),$$

where each α_{ij} is either $S(\cdots)$ or an $L(+, *, 0, 1, <)$ formula. Let k_0 be the maximal number of S-atomic formulae in a disjunct of φ. Then the argument made in the proof of Lemma 5.3 shows that for each $\vec{a} \in \varphi[D]$, there exists a subset of $D' \subseteq D$ with at most k_0 points such that $\vec{a} \in \varphi[D']$.

Now assume that D is a convex polytope in $\mathbb{R}^m$ and $V(D)$ is the set of its vertices. Then each element of D belongs to conv(V'), where V' is a subset of V of cardinality at most $m+1$. Now let $k' = k_0(m+1)$. Then it follows from monotonicity that for every $\vec{a} \in \varphi[D]$, there is a subset of $V' \subseteq V(D)$ of cardinality at most k such that $a \in \varphi[\text{conv}(V')]$; in particular,

$$\varphi[D] = \bigcup_{V' \subseteq V(D), card(V') \leq k'} \varphi[\text{conv}(V')].$$

We now set $k = 2k'$.

Next, consider the following FO + Poly query φ', which uses one m-ary relational symbol R. First, φ' constructs the convex hull of points in $\mathbb{R}^m$ which are in R. Then it applies φ to the result, to get a set Y. Finally, it returns $V(Y)$, that is, the set $\{y \in Y \mid y \notin \text{conv}(Y - y)\}$. Clearly, φ' is expressible in FO + Poly. From the dichotomy theorem, we know that there is a polynomial p with the following property: if R is finite and contains i points, then either $\varphi'[R]$ is infinite or it contains at most $p(i)$ points. We now let $l = \max\{p(i) \mid i = 1, \ldots, k\}$. Note that both k and l can be effectively calculated for a given φ.

It remains to show that if φ has the property that it sends a convex polytope with $\leq k$ vertices in $\mathbb{R}^m$ into a convex polytope with $\leq l$ vertices in $\mathbb{R}^n$, then it is $\mathcal{CPT}$-preserving. First, assume that D is a convex polytope with $\leq k$ vertices in $\mathbb{R}^m$. Assume $\varphi[D]$ is a convex polytope. If we apply φ' to a relation storing vertices of D, then the result is a finite set of vertices of $\varphi[D]$. Hence, by the dichotomy theorem, it has at most l vertices. That is, it now suffices to show that if φ has the property that it sends a convex polytope with $\leq k$ vertices in $\mathbb{R}^m$ into a convex polytope, then it is $\mathcal{CPT}$-preserving.

Let D be a convex polytope. We know that $\varphi[D] = \bigcup_{V'} \varphi[\text{conv}(V')]$, where V' ranges over subsets of $V(D)$ that have at most $k' \leq k$ elements. Thus, each $\varphi[\text{conv}(V')]$ is a convex polytope. Assume that $\varphi[D]$ is not convex. Then we can find two sets of vertices V_1, V_2, having at most k' elements each, and two points $\vec{a} \in \varphi[\text{conv}(V_1)]$, $\vec{b} \in \varphi[\text{conv}(V_2)]$, and $\vec{c}$ between $\vec{a}$ and $\vec{b}$ such that $\vec{c} \notin \varphi[D]$. Let $V_0 = V_1 \cup V_2$. Then, by monotonicity of φ, $\vec{a}, \vec{b} \in \varphi[\text{conv}(V_0)]$. By the assumption, $\varphi[\text{conv}(V_0)]$ is convex (since $card(V_0) \leq k$) and thus $\vec{c} \in \varphi[D]$. Hence, we showed that $\varphi[D]$ is convex. Since it is convex and a finite union of convex polytopes, it is a convex polytope itself. This completes the proof of Lemma 7.7. ∎

We now prove a similar bound for compact semilinear sets in $\mathbb{R}^2$. When we speak of a triangle, we mean convex hulls of three points in $\mathbb{R}^2$. In particular, a degenerate triangle can be a segment or a point. We now prove the following.

Lemma 7.8. *Let $\varphi(x, y)$ be a union of conjunctive* FO + Poly *queries that mentions one binary relational symbol S. Then one can effectively find two numbers, k and l, such that φ is $\mathsf{SLinComp}_2$-preserving iff for every set $D \subseteq \mathbb{R}^2$ which is a union of at most k triangles in $\mathbb{R}^2$, it is the case that $\varphi[D]$ is a union of at most l triangles in $\mathbb{R}^2$.*

Proof. Assume, as in the proof of Lemma 7.7, that $\varphi(\vec{x})$ is of the form

$$\bigvee_j \exists \vec{z} \bigwedge_i \alpha_{ij}(\vec{x}, \vec{z}),$$

where each α_{ij} is either $S(\cdots)$ or a $L(+, *, 0, 1, <)$ formula, and let k be the maximal number of S-atomic formulae in a disjunct of φ. Then, by the same argument as in the proof of Lemma 7.7, we obtain that if $\vec{x} \in \varphi[D]$, then there exist k points $\vec{z}_1, \ldots, \vec{z}_k$ in D such that $\vec{x} \in \varphi[\{\vec{z}_1, \ldots, \vec{z}_k\}]$. Assume that D is compact and semilinear; since

$D \subseteq \mathbb{R}^2$, it can be triangulated using only vertices of D. Let $V(D)$ be the set of vertices of D, which can be computed by an $\mathrm{FO}+\textsc{Poly}$ query, as shown in the proof of Proposition 7.5. Since every point of D is in the convex hull of a triangle whose vertices come from $V(D)$, we obtain, by monotonicity of φ, that if $\vec{x} \in \varphi[D]$, then there exists a set V' of triples of elements from $V(D)$ such that $\mathit{card}(V') \leq k$ and

$$\vec{x} \quad \in \quad \varphi\left[\bigcup_{(\vec{u},\vec{v},\vec{w})\in V'} \mathrm{conv}(\{\vec{u},\vec{v},\vec{w}\})\right].$$

Next, consider the following $\mathrm{FO}+\textsc{Poly}$ query ψ on finite databases. It uses one 6-ary schema relation R, which can be thought of as storing triples $(\vec{u},\vec{v},\vec{w})$ of points in $\mathbb{R}^2$. First, ψ computes

$$P(R) \;=\; \bigcup_{(\vec{u},\vec{v},\vec{w})\in R} \mathrm{conv}(\{\vec{u},\vec{v},\vec{w}\}),$$

which is a compact semilinear set, and then it computes the set $V(P(R))$ of vertices of $P(R)$, using the technique of [25], that we exploited in the proof of Proposition 7.5: for each $\vec{x}$, the set $P(R)(\vec{x}) = \vec{x}+[(P(R)\cap B_\epsilon(\vec{x}))-\vec{x}]$ does not depend on a particular value ϵ below some threshold δ. We then define vertices as those $\vec{x}$ for which there is no $\vec{x}_0 \neq \vec{x}$ with $P(R)(\vec{x}) = P(R)(\vec{x}_0)$. Thus, the query computing $V(P(R))$ is definable in $\mathrm{FO}+\textsc{Poly}$, and by the dichotomy theorem, there is a polynomial p such that, for each R, either $V(P(R))$ is infinite or it has at most $p(n)$ vertices, where n is the number of tuples in R. We now let l be $\max\{p(i) \mid i = 1,\ldots,k\}$.

To show that these k and l witness the conclusion of the lemma, assume that φ is $\mathsf{SLinComp}_2$-preserving. Then the output of every φ on every union of k triangles is a compact semilinear set. From the construction above, it follows that such an output can have no more than l vertices. Conversely, assume that the output of every union of k or fewer triangles is a union of l or fewer triangles. Since $\varphi[D]$ is the union of $\varphi[\bigcup_{(\vec{u},\vec{v},\vec{w})\in V} \mathrm{conv}(\{\vec{u},\vec{v},\vec{w}\})]$, where V ranges over k-element sets of triples of vertices of D, we obtain that $\varphi[D]$ is a union of a finite number of triangles, and thus compact and semilinear. This concludes the proof of the lemma. $\square$

The promised decidability results now follow from the bounds established in the lemmas above.

Theorem 7.9. *The following two properties of unions of conjunctive* $\mathrm{FO}+\textsc{Poly}$ *queries are decidable:*

(1) *being $\mathcal{CPT}$-preserving;*

(2) *being $\mathsf{SLinComp}_2$-preserving.*

Proof of (1). Note that for each i, there is an $\mathrm{FO}+\textsc{Poly}$ query ψ_i for each i that tests if a set D is a convex polytope with at most i vertices: it checks that the set of vertices $V(D) = \{x \in D \mid x \notin \mathrm{conv}(D-x)\}$ has at most i elements, and that $D = \mathrm{conv}(V(D))$. In order to check if a UCQ φ in $\mathrm{FO}+\textsc{Poly}$ is $\mathcal{CPT}$-preserving, one applies Lemma 7.7 to compute the numbers k and l, and then writes a sentence saying that for every $\leq k$-element set V in $\mathbb{R}^m$, applying φ to $\mathrm{conv}(V)$ yields a polytope with at most l vertices. Since conv and ψ_l are definable, this property can be expressed as an $\mathrm{FO}(+,*,0,1,<)$ sentence and thus it is decidable if it is true. Hence, the property of being $\mathcal{CPT}$-preserving is decidable.

Proof of (2). As in the proof of (1), we notice that the condition of Lemma 7.8

can be written as a first-order $L(+,*,0,1,<)$ sentence equivalent to

$$\forall\{\vec{x}_i^j\}_{i=1,\ldots,k}^{j=1,2,3}\ \exists\{\vec{y}_s^p\}_{s=1,\ldots,l}^{p=1,2,3}\ \forall\vec{x}.\ \left(\vec{x}\in\bigcup_{s=1}^{l}\operatorname{conv}(\{\vec{y}_s^p \mid p=1,2,3\})\right)\leftrightarrow\varphi'(\vec{x}),$$

where φ' is obtained from φ by replacing each occurrence of $S(u,v)$ with a formula expressing the fact that $(u,v)\in\bigcup_{i=1}^{k}\operatorname{conv}(\{\vec{x}_i^j \mid j=1,2,3\})$. Since the convex hull of a finite number of points is (FO + Poly)-definable, the condition of the lemma is indeed definable by an $L(+,*,0,1,<)$ sentence, and thus its validity is decidable. Hence, it is decidable if a union of conjunctive FO + Poly queries is $\mathsf{SLinComp}_2$-preserving. ∎

7.2. New expressivity bounds. We can also obtain new expressivity bounds by combining the dichotomy theorem with the idea of canonical representation. First, as an immediate consequence of the technique of Proposition 7.3, Lemma 7.7, and the dichotomy theorem, we obtain the following.

Corollary 7.10. *Let $\varphi(\vec{x})$ be an* FO + Poly *or* FO + Exp *$\mathcal{CPT}$-preserving query. Then there exists a polynomial p_φ such that, whenever D is a convex polytope with n vertices, $\varphi[D]$ has at most $p_\varphi(n)$ vertices.* ∎

From the proof of Lemma 7.8, one can extract the following, by applying the dichotomy theorem to a query that works on representations of compact semilinear sets in $\mathbb{R}^2$ as finite unions of triangles.

Corollary 7.11. *Let $\varphi(x,y)$ be an* FO + Poly *query that is* $\mathsf{SLinComp}_2$*-preserving. Then there exists a polynomial p_φ such that, whenever D is a compact semilinear set with n vertices, $\varphi[D]$ has at most $p_\varphi(n)$ vertices.* ∎

Consider the following problem: given a polyhedron P and $\epsilon > 0$, find a triangulation of P of mesh $< \epsilon$, that is, a triangulation such that the diameter of each simplex (triangle in dimension 2) is less than ϵ. It is a well-known result that each polyhedron admits such a triangulation [4]. The output of such a query can be structured in several ways, for example, by storing the information about the face structure of the triangulation. We impose only one requirement: that the vertices of the triangulation be computable.

Proposition 7.12. *There is no* FO + Exp *query that finds a triangulation of a given polygon with a given mesh. This continues to hold if we restrict to convex polytopes on a plane.*

Proof. Suppose such a query exists; now consider a new query that does the following. Its input is one binary relation containing a set X of points $\vec{x}_1,\ldots,\vec{x}_n$ on the real plane, and one unary relation containing a single real number $\epsilon > 0$. First, in FO + Poly, construct $\operatorname{conv}(X)$, and then find vertices of a triangulation with mesh $< \epsilon$. This is clearly a safe query, so by the dichotomy theorem, there exists a polynomial p such that the number of vertices of the triangulation is at most $m = p(n+1)$ ($n+1$ is the size of the input). Let d be the maximal distance between the points $\vec{x}_i, \vec{x}_j$ (and thus the diameter of $\operatorname{conv}(X)$). Since the segment $[\vec{x}_i, \vec{x}_j]$ with $d(\vec{x}_i, \vec{x}_j) = d$ must be covered by the simplexes of the triangulation, it is possible to find a number ϵ such that it cannot be covered by fewer than $m+1$ triangles of diameter ϵ, and hence the number of points in the triangulation is $> m$. This contradiction proves the proposition. ∎

8. Conclusion and future work. Let us summarize the main themes of the paper.

- The relational calculus with interpreted functions is a nontrivial and interesting extension of the relational calculus. Many useful properties of the relational calculus remain in place in the presence of built-in functions, but many don't. Identifying the analogs to classical results in the interpreted setting can be tricky; proving them is not necessarily a piece of cake either.
- What sort of interpreted structure one adds matters.
- By combining results on the relational calculus with interpreted functions with some simple canonical representations of constraint databases, one can get interesting bounds on the behavior of constraint queries.

We now discuss extensions of each of these themes to other settings. In the first part of the paper, we identified some helpful properties of the relational calculus that remain in the presence of well-behaved built-in functions, with the real arithmetic functions being our prototypical example. Looking at structures such as real arithmetic or rational addition was quite helpful in discovering these results, but these characterization theorems are by no means limited to functions on real or even rational domains. Results in this paper and in [8] indicate that the safety and bound results fail badly for full integer arithmetic. However, we are currently working on extensions of these results to well-behaved structures over the integers, such as linear integer constraints. Although the growth dichotomy and range-restriction theorems as stated here fail for integer linear constraints, modifications of the characterization results still hold. In addition, several of their algorithmic consequences, such as the decidability results for conjunctive queries, are still valid in the integer case.

In this paper we focused mainly on the relational calculus. Many of the proofs here, such as the results on range-restriction and safety, generalize straightforwardly to higher order logics (fixpoint, second-order). Still, the safety question for many higher order logics, particularly fixpoint logic in its many variations, is quite intricate, and we lack a full picture of what interpreted structures and recursion constructs permit a well-behaved theory of query safety.

Our emphasis here was showing that a wide class of interpreted functions satisfying some weak structural assumptions all exhibit certain kinds of tame behavior. In contrast, papers such as [19] give more detailed algorithmic analyses for specific structures. It still remains to give a complexity-theoretic analysis of both the safe translation problem and the query safety problem for conjunctive queries in the case of polynomial and linear constraints. A related interesting question is the complexity of deciding preservation properties for conjunctive queries over finitely representable databases.

We are working on several kinds of extensions of the growth bound theorems of section 6. Some of our current work is on broadening the class of models these results apply to, and some of it concerns getting more precise bounds on the behavior of the growth function. It is fairly clear why these bounds have never been stated for the pure case: they are completely obvious for any pure query language. However, the pure case does put some strong limits on what sort of more precise information one can obtain on the behavior of the growth function. For example, results in the pure first-order case show that the function $f(n)$ giving the minimum nonzero size of output over models of size n can be sublogarithmic. Well-known results on the spectrum problem give restrictions on the structure of the set $\{n : \mathit{growth}_\varphi(n) = k\}$ for k equal to any constant or ∞. One can, however, give theorems relating the behavior of the growth function of a polynomial constraint query to that of a pure first-order query. We are also working on characterizations of the classes of interpreted structures for which the growth bound dichotomy theorem holds, and on characterizations of structures for which the growth function is bounded not by a polynomial, but by other definable functions of the input size (e.g., exponential).

The second part of the paper deals with applying our results on finite databases to finitely representable ones, with the main technique coming via canonical codes. The main point of our codings was to facilitate this transfer of results. We are working on refining the results here to get natural canonical codings for larger geometric classes, and on studying these codes in themselves. The codings given here often capture a significant model-theoretic observation about the geometric class (e.g., the codings based on Carathéodory's theorem and its generalizations show that membership is determined by a bounded number of elements, and that these elements are definable from the database); they also give quite a bit of intuition on how queries that preserve these classes behave. We think this approach is quite a promising one for arriving at useful languages for queries that preserve geometric structure. In fact, very recently, a syntactically defined subquery language of $\mathrm{FO} + \mathrm{POLY}$ for manipulating semilinear databases was given in [45]. Their approach was to combine Theorems 4.5 and 7.2 with the coding technique of [13] to find a canonical coding for semi-linear sets. Further study of canonical codes may also shed light on decidability of preservation properties for special classes of queries.

Acknowledgments. We thank Ken Clarkson, Steve Fortune, and Jianwen Su for helpful discussions and anonymous referees for numerous comments and suggestions.

ON BROADCAST DISK PAGING*

SANJEEV KHANNA† AND VINCENZO LIBERATORE‡

Abstract. *Broadcast disks* are an emerging paradigm for massive data dissemination. In a broadcast disk, data is divided into n equal-sized pages, and pages are broadcast in a round-robin fashion by a server. Broadcast disks are effective because many clients can simultaneously retrieve any transmitted data. Paging is used by the clients to improve performance, much as in virtual memory systems. However, paging on broadcast disks differs from virtual memory paging in at least two fundamental aspects:

- A page fault in the broadcast disk model has a variable cost that depends on the requested page as well as the current state of the broadcast.
- Prefetching is both natural and a provably essential mechanism for achieving significantly better competitive ratios in broadcast disk paging.

In this paper, we design a deterministic algorithm that uses prefetching to achieve an $O(n \log k)$ competitive ratio for the broadcast disk paging problem, where k denotes the size of the client's cache. We also show a matching lower bound of $\Omega(n \log k)$ that applies even when the adversary is not allowed to use prefetching. In contrast, we show that when prefetching is not allowed, no deterministic online algorithm can achieve a competitive ratio better than $\Omega(nk)$. Moreover, we show a lower bound of $\Omega(n \log k)$ on the competitive ratio achievable by any nonprefetching randomized algorithm against an oblivious adversary. These lower bounds are trivially matched from above by known results about deterministic and randomized marking algorithms for paging. An interpretation of our results is that in the broadcast disk paging, prefetching is a perfect substitute for randomization.

1. Introduction.

In traditional client-server architectures, such as the World Wide Web, data transfers are initiated by clients that request information from servers. Such an architecture is said to be a "pull" system because clients pull data from the servers. An emerging alternative to pull systems is the "push" technology. In a push system, the server repeatedly broadcasts data to clients; thus the server now "pushes" information toward the clients.

Broadcast disks are a widely used type of push technology. In broadcast disks, data are divided into pages of equal sizes, and pages are broadcast in a round-robin fashion. The name "broadcast disk" derives from the broadcast program being a circular repetition of pages.

1.1. A widespread application.

Broadcast disks have been deployed since the early 80's by most national television companies in western Europe. Broadcast disk

technology has since attained nationwide diffusion and reaches most households. It provides a continuous information source and has deeply influenced the lifestyle of the countries where it is operational [10, 17]. Broadcast disks have been used in high throughput multiprocessor database systems over high bandwidth networks [6] and wireless communication [11]. An interested reader is referred to the survey lecture by Franklin and Zdonik [9] that reports results and research directions in the field of broadcast disks. The client storage resources have been recently integrated in the broadcast disk approach [1, 2]. The client decides which pages to keep in its local cache and which pages to evict. If the client finds a requested page in its local cache, then the page request can be satisfied at no cost. However, if the client does not have the requested page, it will have to wait for that page to be broadcast again by the server. The client's objective is to minimize the completion time needed to satisfy a sequence of page requests. The resulting paging system has some affinity to the traditional virtual memory systems [4]. We refer to it as *broadcast disk paging (BDP)*. The objective of this paper is to study paging algorithms for BDP in the framework of competitive analysis (see [5, 12, 18], for instance).

1.2. Theoretical significance. BDP is not reducible to traditional online paging and poses several unexplored theoretical problems. It differs from traditional paging in at least two main ways:

- The cost of faulting on any page changes dynamically with time in the case of BDP.
- Prefetching dramatically improves the competitive ratio of online algorithms for BDP and brings in the same advantage as randomization.

We elaborate these two points next. In traditional paging models, either the cost of a page fault is uniform [4] or depends only on the faulting page [15]. In contrast, the cost of a fault in BDP is the time spent waiting for the requested page to be transmitted. It depends on the time step reached during the transmission schedule and could range from 1 (the desired page is currently being broadcast) to n (the desired page was broadcast just before), where n is the total number of pages in the server broadcast. As a result, the design and analysis of BDP algorithms involve techniques and ideas that are often significantly different from those for traditional paging. Moreover, the final behavior of the BDP problem is very different from virtual memory paging as illustrated by the following elementary example. Suppose that the server broadcasts n pages and that the client has a local cache of size k. We show that, when $n = k + 1$, there is a 1-competitive deterministic BDP online algorithm. Briefly, the 1-competitive algorithm keeps in the cache all pages except the one that is about to be broadcast. Such an algorithm pays a constant cost per fault, and after at most n faults it will have in the cache exactly the same pages as the adversary. Hence, the algorithm cost is only an additive factor away from the optimum. This is to be contrasted with virtual memory paging where the adversary can force a worst-case competitive ratio of k.

BDP also differs from the traditional paging in the role played by *prefetching*. Prefetching is essentially ruled out from traditional paging without loss of generality [15]. In this paper, we will show that in BDP prefetching is critical to dramatically improve the competitive ratio of online algorithms. In fact, we will show that prefetching is an exact substitute for randomization in BDP. The importance of prefetching can be intuitively explained as follows. Prefetching makes it possible for a client to reload a page recently evicted and, in some sense, allows the client to dynamically revise its eviction decisions.

1.3. New results. In the absence of any prefetching, the conventional caching analysis can be extended to show that any marking algorithm is $O(nk)$-competitive. But things are far from clear when either the adversary or the online algorithm is allowed to prefetch arbitrary subsets of pages. Our main result is that there exists a deterministic online algorithm that uses prefetching and is $O(n \log k)$-competitive. Our algorithm uses the history of the request sequence and prefetching to develop a strategy that dynamically rectifies any potential eviction mistake. We also show that no deterministic online algorithm can achieve a competitive ratio better than $\Omega(n \log k)$. Therefore, our algorithm is optimal up to a constant factor. In contrast, we prove that in the absence of prefetching, no deterministic algorithm can achieve a competitive ratio better than $\Omega(nk)$, and that even with the use of randomization, there is a lower bound of $\Omega(n \log k)$ against oblivious adversaries. The corresponding randomized upper bound is $O(n \log k)$.

Finally, we extend all our results to a more general model, called the *delay model*, where at any step, the adversary generates either a page request or a delay request. The delay requests capture the fact that a client may use the pages in its cache for variable amounts of time, before ever requesting an outside page. The difficulty is that the adversary may introduce delays to disrupt the current state of the online algorithm. But we show that all of our results hold unchanged in the general model.

1.4. Paging and scheduling. In traditional paging, the cost of a page fault depends on the cache configuration. In BDP, the cost depends on a dynamic state that is not confined only to the contents of the local cache but reflects the configuration of other areas of the system. Specifically, the BDP cost is affected by the time reached along the broadcast schedule. In fact, BDP is only one of many problems where there is a strong interaction between caching and schedules. For example, paging can be integrated with prefetching strategies and yields a problem where performance depends on cache contents as well as on the current disk state [7]. We suspect that the results in this paper might shed light also on other online problems where caching is interrelated with scheduling problems.

1.5. Organization. In section 2, we formalize our problem, define our notation, and establish some basic properties of BDP that are useful to our study. In section 3, we study a simple special case of BDP that highlights an important difference between BDP and virtual memory paging. We next study deterministic as well as randomized BDP algorithms that do not use prefetching in section 4. In section 5, we establish our main results, namely, an $O(n \log k)$-competitive deterministic algorithm and an $\Omega(n \log k)$ lower bound on the deterministic competitive ratio for BDP with prefetching. In section 6, we examine the general delay model. We conclude the paper in section 7.

2. Preliminaries.

In this section, we formally describe various aspects of BDP and establish our notation. In a broadcast disk, a server broadcasts a set $P = \{0, 1, \ldots, n-1\}$ of pages over a network in a round-robin fashion. The pages are received by the clients in the same order as they are transmitted by the server. Each client operates in perfect isolation from other clients and thus the performance of a client is independent of the behavior of other clients. A client can cache at most k pages. We will typically assume that $a \leq k \leq bn$ for some positive integer a and a positive real constant $b < 1$. The assumption reflects the fact that paging is usually done only if there is enough space in the local cache for at least a small number of pages and that the local cache size is typically much smaller than n. Applications

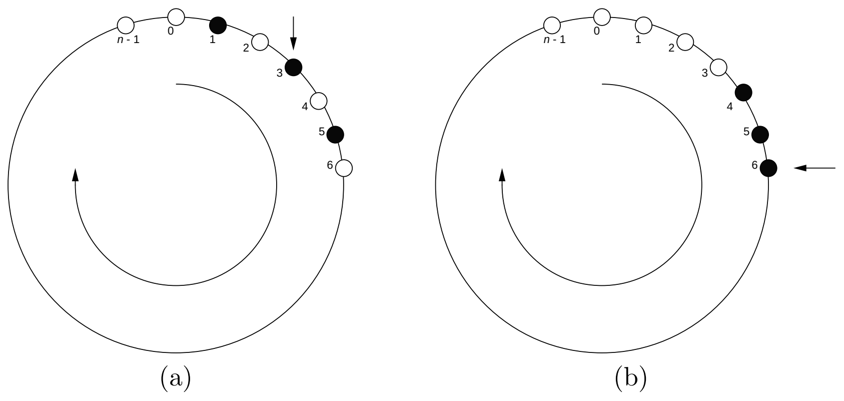

FIG. 2.1. *Examples of client configurations. Black circles represent cached pages and the outer arrow the algorithm position.*

running on the clients generate a sequence σ of page requests. We next define the notion of configuration of a paging algorithm and describe the sequence of actions taken by a client to service a sequence σ of page requests.

2.1. Configuration of an algorithm. The *configuration* of a BDP algorithm G is the contents of its cache along with the step reached along the transmission schedule. Formally, a configuration is a pair $(M, i) \in 2^P \times P$, where

- M is a subset of P of size at most k that is present in G's local cache,
- the index i is the last page that was broadcast and received by the client.

If G's configuration is (M, i), we will say that G is *positioned* over page i or that G's *position* is i. If $M = \{p_1, p_2, \ldots, p_h\}$, then we will denote the memory configuration (M, p_h) as $\{p_1, p_2, \ldots, \triangleright(p_h)\}$.

Example. Figure 2.1(a) represents a broadcast cycle and a configuration (M, i) with $M = \{1, 3, 5\}$ and $i = 3$. The inner arrow represents the order in which pages are broadcast. The outer arrow gives the position of G, that is, the last page that was received by the client. Black circles represent pages in M (contents of G's cache), and white circles represent pages that are not in M.

Let (M, i) be G's configuration. Then, the next page that G will receive is page $i' = (i + 1) \bmod n$. As soon as G has received i', it has the option of loading it into the cache. Thus G's new configuration is of the form (M', i'), where $M' \subseteq M \cup \{i'\}$. Notice that if the cache was full ($|M| = k$) and $i' \in M' - M$, then there must be a page $p \in M - M'$ that is evicted from the cache to make room for i'.

2.2. Page requests. The sequence of page requests generated by a client is denoted by $\sigma = \langle \sigma_1, \sigma_2, \ldots, \sigma_m \rangle \in P^m$. For notational convenience, let $\sigma_0 = k - 1$. The client services a request $\sigma_j \in \sigma$ in an online fashion by repeatedly performing the following sequence of actions: the client receives the next page i from the broadcast and decides whether to cache it or not. This procedure terminates only when the requested page σ_j is in the cache.

Remark. Notice that the client *can* stop the loop iteration when σ_j is in the cache, but it *does not have* to stop the loop the first time σ_j is in the cache. If the client finds it advantageous to keep listening to the broadcast after σ_j is received, it can do so. On the other hand, if σ_j is already in the cache immediately before the jth request is issued, then the client does not have to execute any loop iteration at all. We will prove in Proposition 2.7 that, without loss of generality, clients will stop as soon as σ_j is in the cache.

The cost of a client is the total number of pages it has received from the broadcast, or equivalently, the number of broadcast slots to which the client has listened.

Example. Assume the same set-up as in Figure 2.1(a) and suppose that a request for page 6 is issued. Since page 6 is not in the client's cache, the client listens to the broadcast. Since the client is positioned over page 3, the next page on the broadcast is page 4. The client receives it and decides whether to cache it or not. If it does, it will have to choose a page in $\{1, 3, 5\}$ to evict. In either case, page 6 is not in the cache, so the client keeps listening to the broadcast. Then, page 5 is broadcast. Again, the client can choose whether to cache page 5 or not and continues listening to the broadcast again. Finally, page 6 is broadcast. The client can choose to cache page 6. If it does, it can also choose whether it will keep listening to the broadcast for page 7 or whether it will remain positioned over page 6 and process the next request in σ. Figure 2.1(b) gives an example when pages 4, 5, and 6 have all been cached and the client has stopped immediately after loading page 6. The total cost incurred is three.

Remark. We remark that, according to the previous definition, only the number of received pages contributes to the cost. The definition above entails that when a requested page is in the cache and the client chooses not to move, the cost for that request is zero. In section 6, we will consider a more complex cost model where local computation could cause delays and force the client to skip items in the broadcast. However, for the time being, we will not charge for page requests directly satisfied in the cache.

Paging over a broadcast disk extends the virtual memory, except that now paging is from the network rather than from a physical disk. Clearly, as in virtual memory paging, a page replacement algorithm affects the performance of the system. Virtual memory paging and BDP differ on the following essential point: paging replacement algorithms aim at minimizing the number of page faults (since each fault costs the same), whereas BDP replacement algorithms aim at minimizing the total time spent waiting for pages to arrive from the network.

In what follows, we assume that G is a broadcast disk page replacement algorithm. We will say that G *prefetches* a page p if G loads p even though p is not the currently requested page. In BDP, some pages can be prefetched at no additional cost.

Example. In the example above, page 6 was requested, and page 4 and page 5 were loaded even though they were not requested. Hence page 4 and page 5 were prefetched. Moreover, the client cost is three, independent of whether pages 4 and 5 are prefetched.

We introduce the following notation. The memory configuration reached by G before the jth request will be denoted as $\mathcal{M}(G, j)$ or simply as $\mathcal{M}(G)$ when the time index is clear from the context. Note that the index i in (M, i), and the index j in $\mathcal{M}(G, j) = (M, i)$, denote different quantities. We will assume without loss of generality that the initial configuration of any algorithm G is $\mathcal{M}(G, 1) = \{0, 1, \ldots, \triangleright(k-1)\}$. If $\mathcal{M}(G) = (M, p)$, then we will write $q \in \mathcal{M}(G)$ if and only if $q \in M$. If the jth request $\sigma_j \notin \mathcal{M}(G, j)$, then we will say that G *misses* or *faults* on page σ_j. If $\mathcal{M}(G, j) \neq \mathcal{M}(G, j+1)$, we will say that G *moves* at step j. The algorithm G moves either when it changes cache contents or when it changes position. The cost of G on σ will be denoted as $c(G, \sigma)$ or simply as $c(G)$.

Example. In the example above, G misses and moves from page 3 to page 6. Eventually, G is positioned over page 6.

If $p \in P$ is a page and i a nonnegative integer, then we will write $p + i$ instead of

$(p+i)$ mod n when no confusion can arise. If $p, r \in P$ are pages then we will write $p - r$ instead of $(p-r)$ mod n when no confusion can arise. Such notation is useful for calculating costs and movements: if G moves from p to q, then its cost is $q - p$, and it is positioned over $q = p + (q - p)$.

2.3. Rotations, transit, and ubiquity. We next define two concepts that we use frequently in our analysis.

Definition 2.1. *The algorithm G executes at least i* rotations *during σ if $c(G, \sigma) \geq i \cdot n$.*

Definition 2.2. *The algorithm G is said to* transit over *page p at step j if it moves from a page $p - h$ to a page $p + l$ ($h > 0, l \geq 0$) at step j.*

Another notion is that of *ubiquitous adversary.* An adversary is said to be ubiquitous if it pays only a unit cost per fault. Since a fault forces any algorithm to receive at least one page, the ubiquitous adversary is at least as strong as an ordinary adversary. We will use the ubiquitous adversary to extend competitiveness results to the delay model. Henceforth, we will assume that the adversary is not ubiquitous unless stated otherwise. A property of the ubiquitous adversary is that it will never prefetch a page [15]. Actually, we could assume without loss of generality that the ubiquitous adversary serves a request sequence in accordance with Belady's algorithm [4], but we will not use this fact.

2.4. Lazy algorithms and hard sequences. We will now define the notions of *lazy algorithms* and *hard sequences* for BDP, compare our definitions with the analogous ones that are given in the context of virtual memory paging, and show that we can assume without loss of generality that algorithms are lazy and sequences hard. First, we define lazy algorithms.

Definition 2.3. *A paging algorithm G is* lazy for virtual memory paging *if G never prefetches a page.*

It can be shown that any algorithm for virtual memory paging can be transformed into a lazy algorithm without any degradation in performance [15]. The definition of lazy algorithms in BDP is as follows.

Definition 2.4. *A paging algorithm G is* lazy for BDP *(or simply* lazy*) if, when G is positioned on page r and faults on page p, its cost is exactly $p - r$.*

In other words, a lazy algorithm stops listening to the broadcast as soon as it receives the faulting page. According to Definition 2.4, a lazy algorithm can prefetch pages as long as those pages are loaded while waiting for the faulting page to be broadcast. Then, a lazy algorithm is not necessarily lazy for virtual memory paging, but a lazy algorithm for virtual memory paging is also lazy for BDP.

Definition 2.5. *A request sequence σ is* hard *for G if G faults on every request in σ.*

The definition above coincides with the one used in virtual memory paging and in BDP. We now claim in the spirit of [15] that it is enough to compare lazy online algorithms to adversaries running lazy algorithms on hard sequences.

Lemma 2.6. *For any (online) algorithm G, there is an (online) algorithm G' that satisfies $c(G') = c(G)$ and that has the property that, when G' faults on page σ_j, it always loads σ_j the first time G' transits over σ_j.*

Proof. The proof is by induction on the length of σ. Suppose that G satisfies the property before request σ_j, but it violates it on σ_j. The first time G transits over σ_j, it does not load it. Therefore, G will transit over σ_j a second time. Hence, G transits over every page in P after it has transited over σ_j for the first time. The algorithm G' will exactly follow G until page σ_j is received for the first time. Then, G' loads

σ_j and evicts a page p. Afterwards, G' emulates G until either G evicts p, in which case G' evicts σ_j, or G receives p. Notice that G receives p before it receives σ_j for the second time. At that point, G' evicts σ_j and reloads p. Now, the configurations of the two algorithms are identical, and the cost of G' is exactly equal to the cost of G. Finally, we notice that G' does not require any knowledge of the future beyond G's. $\square$

PROPOSITION 2.7. *For any (online) algorithm G, there is an (online) algorithm G' that is lazy and that satisfies $c(G') \leq c(G)$.*

Proof. The proof is by induction on the length of σ. Suppose that G is lazy before request σ_j, but it violates that condition on request σ_j. We can assume without loss of generality that G loads σ_j the first time it transits over it. Afterwards, G will receive an additional set Q of pages. The algorithm G' stops immediately after receiving σ_j. If $j = m$, then G' will not perform any further action and $c(G') < c(G)$. Otherwise, G' services σ_{j+1} by first receiving all pages in Q and then by emulating G on σ_{j+1}. Therefore, $\mathcal{M}(G, j+2) = \mathcal{M}(G', j+2)$ and $c(G') \leq c(G)$. Finally, we notice that G' does not require any knowledge of the future beyond G's. $\square$

PROPOSITION 2.8. *If G is an algorithm that does not move for requests that do not cause a fault, that does not base its eviction decision on nonfaulting requests, and that is c-competitive on all of its hard sequences, then G is c-competitive.*

Proof. Let σ be a sequence of request. Define σ' to be the associated hard sequence, that is, the subsequence of σ consisting of all requests where G faults. Then, $c(G,\sigma) = c(G,\sigma')$. Let H be the optimum algorithm. Then, $c(H,\sigma') \leq c(H,\sigma)$. It follows that, for some constant b,

$$c(G,\sigma) = c(G,\sigma') \leq c \cdot c(H,\sigma') + b \leq c \cdot c(H,\sigma) + b. \qquad \square$$

If G is a lazy algorithm and σ is hard, then G is positioned on σ_{j-1} before the jth request.

3. BDP and virtual memory paging: The case $n = k + 1$. In this section, we will analyze the simple case $n = k + 1$ to highlight a fundamental difference between traditional paging and BDP. In traditional paging, the adversary can force a worst-case sequence when $n = k + 1$. In contrast, we show the following result.

PROPOSITION 3.1. *There is a 1-competitive deterministic online algorithm for BDP when $n = k + 1$.*

Proof. Let G be the algorithm that on a faulting request σ_j maintains $\mathcal{M}(G, j+1) = \{\triangleright(\sigma_j)\} \cup \{i \in P : i \neq \sigma_j + 1\}$. In other words, $\sigma_j + 1$ is the only page missing from G's fast memory. When G faults on σ_j, it evicts $\sigma_j + 1$ and loads σ_j. So, G pays a unit cost whenever it faults. Suppose without loss of generality that σ is hard for G, and thus $c(G,\sigma) = m$. In fact, $\sigma_j = k + j$ by induction on j.

Assume without loss of generality that the adversary follows a lazy algorithm H. Suppose that H faults on $\sigma_{j_1}, \sigma_{j_2}, \ldots, \sigma_{j_h}$. The cost of H on σ is then

$$c(H,\sigma) = \sum_{l=1}^{h} (\sigma_{j_l} - \sigma_{j_{l-1}}) = \sum_{l=1}^{h} (k + j_l - k - j_{l-1}) = \sum_{l=1}^{h} (j_l - j_{l-1}) = j_h - 1.$$

Notice that any subsequence of at most n consecutive requests in σ consists of distinct pages. Also, H does not fault on σ_j when $j > j_h$, and so $|\{\sigma_{j_h+1}, \ldots, \sigma_m\}| \leq k-1 < n$, which implies that $\sigma_{j_h+1}, \ldots, \sigma_m$ are all distinct and $m - j_h \leq k - 1$. Therefore, $c(G,\sigma) - c(H,\sigma) = m - (j_h - 1) \leq k$, and the claim is proven. $\square$

The case $n = k + 1$ sets up the general framework for finding lower bounds on the competitive ratio of traditional paging algorithms. Clearly, the general paradigm does not work for BDP. Instead, we will show that all lower bounds can be ultimately traced back to the notion of algorithm in transit, as defined in the previous section.

4. BDP algorithms without prefetching. In this section, we will examine the competitive ratio of online algorithms that do not allow prefetching. In terms of Definition 2.3, such algorithms are lazy for virtual memory paging.

If G is a lazy algorithm for virtual memory paging, it induces an algorithm for BDP that is lazy and whose memory contents after σ_j are exactly the same as G's. For simplicity, we will denote both the virtual memory paging algorithm and its BDP counterpart with the same symbol. A strongly competitive deterministic paging algorithm never incurs more than k times the optimum number of page faults. Since its BDP counterpart is lazy, it follows that a page fault costs at most $n - 1$; the last page that was broadcasted and received must be in the algorithm's cache. Thus, any strongly competitive paging algorithm, e.g., the marking algorithm [13], is trivially $(k(n-1))$-competitive for broadcast disk paging even against a ubiquitous adversary. In fact, we can show a slightly better competitive ratio.

THEOREM 4.1. *Let G be a lazy α-competitive deterministic algorithm for paging. Then, the competitive ratio of G for BDP is $(\alpha - 1)n + 1$.*

Proof. We will assume without loss of generality that the sequence σ is hard for G and that the adversary uses a lazy algorithm H. First, we notice that the cost of H is at least equal to the number of page faults. Indeed, every time H brings a new page into fast memory, H has to transit over that page, paying a unit cost.

Let r_j be the page where the adversary is positioned before the jth request, and define the potential function as $\Phi(j) = r_j - \sigma_{j-1}$. Let $a_j = (\sigma_j - \sigma_{j-1}) + \Phi(j+1) - \Phi(j)$ be the amortized cost of G to serve request σ_j. Notice that if $r_{j+1} = r_j$, then $a_j = (\sigma_j - \sigma_{j-1}) + (r_j - \sigma_j) - (r_j - \sigma_{j-1}) \le n$. If $\sigma_j \notin \mathcal{M}(H, j)$, then $\Phi(j+1) = 0$ and $a_j = \sigma_j - \sigma_{j-1} + \Phi(j+1) - \Phi(j) = (\sigma_j - r_j) + (r_j - \sigma_{j-1}) - (r_j - \sigma_{j-1})$, which is the real cost of the optimum on that request. Let l be the number of times that the optimum algorithm faults. Then $|\sigma| \le \alpha l + b$ for some constant b. Moreover, $l \le c(H, \sigma)$. The resulting cost of G is $c(G, \sigma) = (|\sigma| - l)n + c(H, \sigma) \le ((\alpha - 1)l + b)n + c(H, \sigma) \le (n(\alpha - 1) + 1)c(H, \sigma) + bn$, which proves the theorem. □

COROLLARY 4.2. *The marking algorithm is $((k-1)n + 1)$-competitive.*

We next establish an essentially matching lower bound.

THEOREM 4.3. *No deterministic online algorithm without prefetching can have a competitive ratio better than $\Omega(nk)$ for $2 \le k \le n - 2$ and any fixed $b < 1$, even if the adversary is not allowed to do prefetching.*

Proof. Let G be an online algorithm without prefetching and H be the algorithm used by the adversary. The adversary proceeds in phases. We will maintain that, at the beginning of a phase, $\mathcal{M}(G)$ contains the same pages as $\mathcal{M}(H)$, and that H is positioned on a page q such that $q + 1, q + 2 \notin \mathcal{M}(H)$. Define the set $W = \mathcal{M}(H) \cup \{q + 1, q + 2\}$ and call W the *working set* of the current phase. The gist of the proof is as follows. Notice that $|W| = k + 2$, and so there are always two pages in the working set W that are not in G's fast memory. The adversary will request those pages, and consequently G will fault at every step. Furthermore, we will use the notion of transit to show that G pays $\Omega(n)$ on every two faults. The adversary will generate $\Omega(k)$ requests in the phase and itself serves them at a cost of two. We now detail the argument.

The adversary starts the phase by requesting page $q + 1$ followed by page $q + 2$.

Thus, both G and H are now positioned at $q+2$. The rest of the phase is divided into segments. We will let r be the page where G is positioned at the beginning of a current segment. For example, in the first segment, $r = q+2$. Let α and β be the two pages that are in the working set W but not in G's fast memory at the beginning of a segment. Assume without loss of generality that $\beta - r > \alpha - r$. Then, the adversary requests β followed by α, and the segment is over. The algorithm G faults on the request for β and transits over α while waiting for β to be transmitted; but it does not load α because it is not allowed to prefetch. Therefore, G faults also on the request for α. On the whole, G transits over α at least twice during the segment, and so it executes at least one rotation per segment. We will now describe how many segments are generated. The adversary counts the number of distinct pages that made G fault during all the segments generated so far. The adversary generates segments until G has faulted on a set F of at least $k-2$ distinct pages. Notice that F is contained in the working set. Moreover, during each segment, G faults on at most two new pages, so that $|F| \in \{k-2, k-1\}$. Hence, at least $\lceil (k-2)/2 \rceil$ segments are generated. We will now specify how H serves the requests in the phase. The algorithm H faults on $q+1$ and $q+2$. At this point, its fast memory contains all the pages of $F \cup \{q+2\}$, plus another arbitrary page from W if $|F \cup \{q+2\}| < k$. Notice that H does not prefetch any page and that H does not fault during any segment. If G and H's fast memory configurations still differ after all segments have been generated, the adversary keeps requesting pages in H's memory that are missing from G's memory, until the two memories coincide in their contents. Notice that if the two memories never coincide, then this step will continue indefinitely, and G is not competitive. Henceforth, assume that G's and H's memory contents will eventually be the same. At this point, the phase is over. The cost of G in the phase is at least the cost in the segment, and so hence at least $n(k-2)/2$. The cost of H in the entire phase is 2—due only to the initial faults on $q+1$ and $q+2$.

The adversary issues $(n-k)/2$ request phases paying only a cost of 2 per phase. Then the adversary pays a cost of k and returns to the starting configuration $\{0, 1, \ldots, \triangleright(k-1)\}$. It then keeps requesting pages $0, 1, \ldots, k-1$ until the fast memory configurations of G and H coincide. Therefore, the cost of the adversary on $(n-k)/2$ phases is n, while the cost of G is at least $((n-k)/2)(n(k-2)/2)$, and the result follows. $\square$

The construction above extends to a lower bound for randomized algorithms against an adaptive online adversary.

THEOREM 4.4. *No randomized online algorithm without prefetching can have a competitive ratio better than $\Omega(nk)$ against an adaptive online adversary for $3 \le k \le bn$ and any fixed $b < 1$, even if the adversary is not allowed to do prefetching.*

Proof. The initial setup of the proof is the same as that of Theorem 4.3. The main difference between the proofs of Theorem 4.3 and Theorem 4.4 is that, at the beginning of a phase, the adversary does not know the set F of pages that make G fault. We overcome the difficulty by letting the adversary guess F and showing that the expected number of segments is $\Omega(k)$.

The adversary proceeds in phases. Assume that j is the step of the first phase request, so that $\mathcal{M}(H, j)$ and $\mathcal{M}(G, j)$ denote the configurations of H and G immediately before the current phase begins. We will maintain that $\mathcal{M}(G, j)$ contains the same pages as $\mathcal{M}(H, j)$, and that H is positioned on a page q such that $q+1, q+2 \notin \mathcal{M}(H)$. Define the set $W = \mathcal{M}(H, j) \cup \{q+1, q+2\}$ and call W the working set of the current phase. The adversary starts the phase by requesting $q+1$

followed by $q+2$. Thus, both G and H are now positioned on $q+2$. The algorithm H makes room for $q+1$ and $q+2$ by evicting two random pages r_1 and r_2 from $\mathcal{M}(H,j)$, so that now H's configuration is $\mathcal{M}(H) = (\mathcal{M}(H)-\{r_1,r_2\})\cup\{q+1,\triangleright(q+2)\}$. Notice that $r_1, r_2 \in \mathcal{M}(H,j)$ implies $\{r_1,r_2\}\cap\{q+1,q+2\}=\emptyset$, a fact that we use later on.

The rest of the phase is divided into segments. A segment is defined exactly as in the proof of Theorem 4.3 and consists of two page requests that force G to execute one rotation. Both segment requests cause a fault for G but no fault for H. Therefore, the adversary generates segments while $|\mathcal{M}(H)-\mathcal{M}(G)|\geq 2$. Notice that the adversary is adaptive, and so it can determine if $|\mathcal{M}(H)-\mathcal{M}(G)|\geq 2$, which pages to request in each segment, and in which order. However, the adversary cannot determine at the beginning of a phase the set F of pages that will make G fault. It remains to estimate the expected number of segments. At all steps, G keeps all the pages in the working set W except two. Let α and β be the two pages that are in the working set but not in G's fast memory immediately after the ith segment has been serviced. Notice that the adversary generates an $(i+1)$st segment only if $|\mathcal{M}(H)-\mathcal{M}(G)|\geq 2$, or, equivalently, only if $\{\alpha,\beta\}\cap\{r_1,r_2\}=\emptyset$. Therefore, G should choose α and β so that $\{\alpha,\beta\}\cap\{r_1,r_2\}\neq\emptyset$. In other words, G should choose the missing pages α and β in order to guess H's missing pages r_1 and r_2. Since $\{r_1,r_2\}\cap\{q+1,q+2\}=\emptyset$, we assume without loss of generality that G always keeps $q+1$ and $q+2$ in fast memory, and so $\{\alpha,\beta\}\cap\{q+1,q+2\}=\emptyset$. We will now estimate the expected number of segments by means of the following simple random experiment. We will have a bin that contains k balls—a white ball for each page in $\mathcal{M}(H,j)-\{r_1,r_2\}$ and a black ball each for r_1 and r_2. In each segment, G extracts two balls α and β from the bin. If both α and β are white, then G gets another round; otherwise, either α or β are black and the experiment stops. The number of segments ℓ is exactly the number of rounds needed to extract a black ball. Clearly, ℓ is minimum if no ball is ever replaced in the bin. Elementary combinatorics now yields $E[\ell]=\Theta(k)$. As an aside, we observe that the case when balls are not replaced in the bin corresponds to the case when G keeps in fast memory a different subset of the working set in different segments.

After the last segment, $|\mathcal{M}(H)-\mathcal{M}(G)|\leq 1$. If $|\mathcal{M}(H)-\mathcal{M}(G)|=0$, then $\mathcal{M}(G)$ contains the same pages as $\mathcal{M}(H)$, and another phase starts. If $|\mathcal{M}(H)-\mathcal{M}(G)|=1$, then the adversary keeps requesting pages in $\mathcal{M}(H)-\mathcal{M}(G)$ until $\mathcal{M}(G)$ contains the same pages as $\mathcal{M}(H)$. Again, the adversary is adaptive and knows if $\mathcal{M}(G)$ coincides with $\mathcal{M}(H)$. There are two cases, depending on whether this step ends or not. The expected cost of G conditioned to the event that $\mathcal{M}(G)$ never coincides with $\mathcal{M}(H)$ is infinite, and so G is not competitive. The expected cost of G conditioned to the event that $\mathcal{M}(G)$ eventually coincides with $\mathcal{M}(H)$ is nonnegative. We will assume from now on that indeed G's memory will eventually coincide with H's. After $\mathcal{M}(G)$ and $\mathcal{M}(H)$ contain the same pages, a new phase starts. The expected cost of G in a phase is at least equal to the expected cost in the segments, and so it is at least $nE[\ell]=\Omega(nk)$. Meanwhile, the cost of H in the entire phase is due only to the initial faults on $q+1$ and $q+2$, and so it is 2. The adversary issues $(n-k)/2$ request phases paying only a cost of two per phase. Then the adversary pays a cost of k and returns to the starting configuration $\{0,1,\ldots,\triangleright(k-1)\}$. It will then keep requesting pages $0,1,\ldots,k-1$ until the fast memory configurations of G and H coincide. Therefore, the cost of the adversary on $(n-k)/2$ phases is n, while the expected cost of G is $\Omega(nk(n-k))$, and the result follows. $\square$

We next establish an $\Omega(n\log k)$ lower bound on the competitive ratio of randomized online algorithms without prefetching against an oblivious adversary. We start with the following simple proposition.

LEMMA 4.5. *Let G be a deterministic lazy algorithm, $\sigma = (\langle \sigma_1, \sigma_2, \ldots \sigma_l \rangle)^h$ for some $l \leq k$. If $\{\sigma_1, \sigma_2, \ldots, \sigma_l\} - \mathcal{M}(G, lh) \neq \emptyset$, then $c(G, \sigma) \geq h - 1$ for all configurations $\mathcal{M}(G, 1)$.*

Proof. The proof is by induction on c. The claim clearly is true for $c = 1$. Let $\Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_l\}$ and $\sigma' = \langle \sigma_1, \sigma_2, \ldots, \sigma_l \rangle$. Suppose that $\Sigma - \mathcal{M}(G, l(h)) \neq \emptyset$. Since G is lazy, $\mathcal{M}(G)$ will remain unchanged as soon as $\Sigma \subseteq \mathcal{M}(G)$. Then, $\Sigma - \mathcal{M}(G, l(h-1)) \neq \emptyset$, and by induction hypothesis $c(G, (\sigma')^{h-1}) \geq h-2$. Moreover, G faults at least once during the last repetition of σ', and the lemma follows. ◻

THEOREM 4.6. *No randomized online algorithm without prefetching can have a competitive ratio better than $\Omega(n \log k)$ for $3 \leq k \leq bn$ and any fixed $b < 1$, even if the adversary is not allowed to do prefetching.*

By the minimax theorem [5], it will be enough to show that there is a probability distribution $\mathcal{P}$ over sequences of page requests such that for any lazy deterministic algorithm G, $E_{\mathcal{P}}\{c(G, \sigma)\} \geq c \cdot c(H, \sigma)$ where $c = \Omega(n \log k)$ and H is an optimal offline strategy.

Proof. The main difference between the proofs of Theorem 4.4 and Theorem 4.6 is that the adversary cannot foresee what pages α and β are in the working set but not in G's fast memory. We sidestep the difficulty by showing that with some probability the adversary is still able to force G to execute one rotation.

The request sequence. The page request sequence σ is of the form $\sigma = (\Gamma_1 \ldots \Gamma_{(n-k)/2} \Gamma_0)^l$, where l is a positive integer, $\Gamma_0 = \langle 0, 1, \ldots, k-1 \rangle$, and Γ_i $(1 \leq i \leq (n-k)/2)$ will be defined later. Roughly speaking, the subsequences Γ_i for $i \geq 1$ are the analogues of phases in the previous proofs, and Γ_0 corresponds to the final coordination step that brings about the initial configuration $\{0, 1, \ldots, \triangleright(k-1)\}$. We will now describe the phase Γ_i, a few quantities determined by the Γ_i's, and the value of these quantities at the beginning of Γ_i. A phase Γ_i depends on the set S_{i-1}, which is defined recursively: let $S_0 = \{0, 1, \ldots, k-1\}$, and S_i contains all the pages requested during the phase Γ_i. Throughout we will maintain the following properties:

- $|S_i| = k$ for $1 \leq i \leq (n-k)/2$.
- H holds S_{i-1} in fast memory immediately before the start of phase Γ_i.
- The pages $q_i + 1, q_i + 2 \notin S_{i-1}$, where $q_i = k - 1 + 2i$. In other words, we maintain that $q_i + 1$ and $q_i + 2$ are not in H's fast memory immediately before phase Γ_i starts. For example, k and $k+1$ are not in H's fast memory immediately before Γ_1.

Define the working set in phase Γ_i to be the set $W_i = S_{i-1} \cup \{q_i + 1, q_i + 2\}$. Let $\gamma_1, \gamma_2, \ldots, \gamma_k$ be a random k-permutation of the working set W_i; define $S_i = \{\gamma_1, \gamma_2, \ldots, \gamma_k\}$. The basic plan of the adversary is to request the pages in S_i in the given order $\gamma_1, \gamma_2, \ldots, \gamma_k$. However, the adversary will also request a sequence of other pages between the first request for a page γ_j and the first request for page γ_{j+1}, $1 \leq j \leq (k-1)$, in order to force G's memory configuration. Specifically, $\Gamma_i = \rho_0 \langle \gamma_1 \rangle \rho_1 \langle \gamma_2 \rangle \rho_2 \ldots \langle \gamma_k \rangle$, where

- ρ_0 is a repetition for $c+1$ times of S_{i-1}, and
- $\rho_j = (\langle \gamma_1, \gamma_2, \ldots, \gamma_j \rangle)^{c+1}$, where $1 \leq j \leq k$.

We will now turn to estimate the expected cost of G during Γ_i conditioned to the event that either (i) a page in S_{i-1} is not in G's cache immediately before the first request to γ_1, or (ii) one of the $\gamma_1, \ldots, \gamma_{j-1}$ is not in G's cache immediately before the first request to γ_j $(2 \leq j \leq k)$. Suppose that there is a page in S_{i-1} missing from G's cache immediately before the request to γ_1. By the previous lemma, G pays at least $c = \Omega(n \log k)$ on ρ_0. Analogously, suppose that there is one of $\gamma_1, \ldots, \gamma_{j-1}$

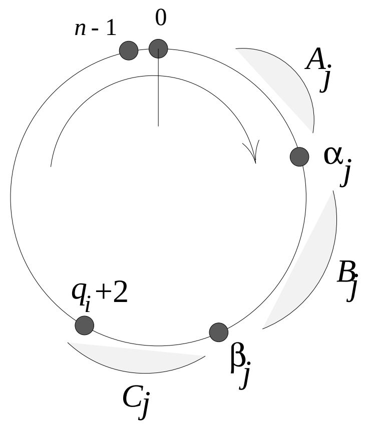

FIG. 4.1. *Lower bound for randomized algorithms without prefetching.*

missing from G's cache immediately before the request to γ_j $(1 \leq j \leq k)$. By the previous lemma, G pays at least $c = \Omega(n \log k)$ on ρ_{j-1}. Therefore, $\Omega(n \log k)$ bounds G's expected cost conditioned to the event that either (i) or (ii) occurred. It remains to show that G's expected cost is $\Omega(n \log k)$ even when neither (i) nor (ii) occurred. We will condition the rest of the analysis to such event, and so we will assume that G has $\gamma_1, \ldots, \gamma_{j-1}$ in fast memory before the request for γ_j where $j = 2, \ldots, k$, and G has all the elements in S_{i-1} before γ_1.

Costs of G and H. The adversary's algorithm H keeps S_i in fast memory throughout Γ_i. Therefore, H pays a cost of at most n on the sequence $\Gamma_1 \ldots \Gamma_{(n-k)/2}\Gamma_0$, exactly as in the previous proofs. We will now show that the expected cost of G on Γ_i $(1 \leq i \leq (n-k)/2)$ is $\Omega(n \log k)$. Let

$$t_j = \begin{cases} 1 & \text{if } G \text{ transits over page 0 while serving } \gamma_j, \\ 0 & \text{otherwise.} \end{cases}$$

The quantity t_j will be referred to as the *transit cost* of G for γ_j. Define $t = \sum_{j=1}^{k} t_j$ to be the transit cost of G in the phase Γ_i. Observe that G executes at least $t-1$ rotations during Γ_i, and so G's cost during Γ_i is at least $n(t-1)$. Hence, it is enough to show that $t = \Omega(\log k)$.

Before estimating t, we will make some definitions and observations. Let Y_{ij} be the set of pages in W_i that have not been requested prior to the first request for γ_j, that is, $Y_{ij} = W_i - \{\gamma_1, \ldots, \gamma_{j-1}\}$, $j = 1, \ldots, k$. Then by assumptions (i) and (ii) above, there are at least two pages in Y_{ij} that are missing from G's fast memory before γ_j is requested. Let $\alpha_j, \beta_j \in Y_{ij}$ be two such pages and assume without loss of generality that $\alpha_j < \beta_j$, as depicted in Figure 4.1. Notice that if G does not fault on γ_j, then G does not move and $\alpha_{j+1} = \alpha_j$ and $\beta_{j+1} = \beta_j$. Let r_j be the position taken by G before the request for γ_j. It can be seen that $r_j \in W_i$ by induction on j. Moreover, G is lazy and so $r_j \neq \alpha_j, \beta_j$. As depicted in Figure 4.1, let

- $A_j = \{p \in W_i : p < \alpha_j\}$,
- $B_j = \{p \in W_i : \alpha_j < p < \beta_j\}$, and
- $C_j = \{p \in W_i : \beta_j < p\}$.

Notice that $r_j \in A_j \cup B_j \cup C_j$.

We now turn to estimate the transit cost t_j. Define the potential of G immediately before γ_j as

$$\Phi(j) = \begin{cases} \frac{1}{2} & \text{if } r_j \in B_j \cup C_j, \\ 0 & \text{otherwise} \end{cases}$$

and the amortized transit cost of G as $t_j + \Phi(j+1) - \Phi(j)$. We will show that the expected amortized transit cost of G during Γ_i is $\Omega(\log k)$. Since the real transit cost of G is equal to the amortized transit cost minus $O(1)$, we obtain that the real transit cost of G during Γ_i is $t = \Omega(\log k)$. Putting together, it will then follow that the actual cost of G during Γ_i is $\Omega(n \log k)$.

If $r_j \in A_j$ and $\beta_j = \gamma_j$, then the potential increases by $1/2$. Moreover, $\beta_j = \gamma_j$ with probability $1/|Y_{ij}| = 1/(k+3-j)$, so that G's expected amortized transit cost when $r_j \in A_j$ is at least $(1/2)/(k+3-j)$. If $r_j \in B_j \cup C_j$ and $\alpha_j = \gamma_j$, then G pays a real transit cost at least equal to 1, and the potential drops by no more than $1/2$. Moreover, $\alpha_j = \gamma_j$ with probability $1/|Y_{ij}| = 1/(k+3-j)$, so that G's expected amortized transit cost when $r_j \in B_j \cup C_j$ is at least $(1/2)/(k+3-j)$. The expected amortized transit cost of G during Γ_i is at least

$$\sum_{j=1}^{k} \left(\frac{1}{2} \frac{1}{k+3-j} \right) = \frac{1}{2} \sum_{j=3}^{k+2} \frac{1}{j} = \Omega(\log k).$$

Consequently, $t = \Omega(\log k)$, and the actual cost of G during Γ_i is $\Omega(n \log k)$.

Finally, we recall that on $\Gamma_1 \Gamma_2 \ldots \Gamma_{(n-k)/2} \Gamma_0$, the cost of H is n, and the cost of G is $\Omega(n^2 \log k)$, which proves the theorem. □

Conversely, the competitive randomized algorithms in [3, 8, 16] immediately imply an $O(n \log k)$-competitive randomized algorithm for BDP even against a ubiquitous adversary.

5. BDP algorithms with prefetching.

In this section, we will establish our main theorems. We will first show a lower bound of $\Omega(n \log k)$ on the competitive ratio of any deterministic online algorithm that uses prefetching, even when compared to an adversary that does not do any prefetching. We will then present a deterministic online algorithm that achieves a competitive ratio of $O(n \log k)$ and therefore is optimal up to a constant factor.

5.1. A lower bound.

We first prove the lower bound.

THEOREM 5.1. *No deterministic algorithm for BDP can achieve a competitive ratio better than $\Omega(n \log k)$ when $3 \le k \le bn$ for any fixed $b < 1$ even if the adversary is not allowed to do prefetching.*

Proof. The main difference between the present proof and that of Theorem 4.3 is that G might reload α when it faults on β, and so the online algorithm cannot be made to execute one rotation every other request. In fact, we will typically need several requests to have the online algorithm complete a rotation. The basic plan of the adversary is as follows: repeatedly request a page that is not in the online algorithm G's fast memory and is farthest from the page where G is positioned. We will assume without loss of generality that G is lazy. Let H be the algorithm that the adversary uses to satisfy the request sequence.

The request sequence. The adversary proceeds in phases. We will maintain that, at the beginning of a phase, G and H hold the same set of pages W in fast memory and that H is positioned on a page q such that $q+1, q+2 \notin W$. In this proof, the set W will take the function that the working set had in the previous proofs, namely, we will extract requests from W in order to make G fault. The adversary starts the phase by requesting page $q+1$ followed by page $q+2$. We will maintain that there are always at least two pages in W that G does not have. The adversary will request one of those pages, and if r is the page where G is currently positioned, the adversary will issue a request for the missing page α that maximizes the quantity $\alpha - r$. However, the adversary will also insert other page requests to force G's fast memory configuration. On the whole, the phase has the form $\langle q+1, q+2\rangle \rho_1 \langle \gamma_1 \rangle \rho_2 \langle \gamma_2 \rangle \dots \rho_{k-2} \langle \gamma_{k-2} \rangle$, where

- γ_j is the page in W that is not in G's fast memory, and that is farthest from the current position r of G, $1 \le j \le k-2$,
- ρ_j denotes the sequence of requests $\rho_j = (\langle q+1, q+2, \gamma_1, \dots, \gamma_{j-1}\rangle)^{c+1}$, where $c = \Omega(n \log k)$ and $1 \le j \le k-2$.

Suppose that G and H do not have the same set of pages in fast memory after the request for γ_{k-2}. In that case, the adversary keeps requesting a page that H has, but G does not. Eventually, G and H will have the same set of pages in fast memory, or else G is not competitive, and another phase starts.

Costs of G and H in each phase. Let $R_j = \{q+1, q+2, \gamma_1, \dots, \gamma_{j-1}\}$ denote the set of pages requested in the sequence ρ_j. Notice that R_j is precisely the set of pages requested since the beginning of the phase until the request γ_j, and that $R_j \subset R_{j+1}$. The algorithm H keeps R_{k-1} throughout the phase and pays a cost of two. We can assume the following about the behavior of the algorithm G by Lemma 4.5: (i) G has R_j in its fast memory before the request for γ_j, and (ii) G does not move at all during the ρ_j's, but that it moves only to service the requests for the γ_j's. Thus from here on we can simply assume that a phase merely consists of the sequence of requests $\langle q+1, q+2, \gamma_1, \gamma_2, \dots, \gamma_{k-2}\rangle$. By this assumption, γ_{j+1} is the page in W that is not in G's fast memory and that maximizes $\gamma_{j+1} - \gamma_j$.

We will now show that the cost of G is $\Omega(n \log k)$ on the sequence $\Gamma = \langle q+1, q+2, \gamma_1, \gamma_2, \dots, \gamma_{k-2}\rangle$. To estimate G's cost, we will divide a phase into subphases with the property that G executes one rotation per subphase. Then, it will be enough to count the number of subphases. Specifically, we define subsequences $Z_1, Z_2, \dots, Z_t$ such that

- $Z_1 Z_2 \dots Z_t = \Gamma$, and
- $Z_1 Z_2 \dots Z_i$ is the smallest prefix of Γ on which G completes i rotations ($1 \le i < t$).

Since G executes at least $t-1$ rotations in the phase, it suffices to show that $t = \Omega(\log k)$. The idea is to show that $|Z_i|$ decreases as i increases, and then it will follow that t is large. Let x_i denote the number of pages in W that have not been requested prior to the start of the subsequence Z_i. Then we claim that $|Z_i| \le \lceil (x_i+1)/2 \rceil$. This easily follows from the observations that at each step G has at least 2 pages missing from the set W and we always request the missing page that is farthest. Thus G must complete a rotation after $\lceil (x_i+1)/2 \rceil$ requests.

Observe that $x_1 = k$ and that upon termination, $x_{t+1} = 2$, and so $2 \le x_i \le k$ for all $i = 1, 2, \dots, t+1$. Furthermore, $x_{i+1} = x_i - |Z_i| \ge \lfloor (x_i - 1)/2 \rfloor \ge (x_i/2) - 1$. It is then straightforward to see that $t = \Omega(\log k)$. The cost of G during a phase is thus at least $nt = \Omega(n \log k)$.

Putting it all together. Observe that the adversary can issue $(n-k)/2$ consecutive phases. Then, it will reload $\{0, 1, \dots, \triangleright(k-1)\}$ and another sequence of $(n-k)/2$ phases starts. The total cost of the adversary in such a sequence of phases is n while the total cost of G is $\Omega(n^2 \log k)$, and the result follows. $\square$

5.2. An upper bound: The gray algorithm. We will now design a paging algorithm $\mathcal{G}$, referred to as the *gray algorithm*, that is $O(n \log k)$-competitive. The gray algorithm uses a set of three marks {black, gray, white} and maintains a mark for each page in P. Notice that $\mathcal{G}$'s marking policy is somewhat different from that of the marking algorithm [13] that uses only two marks and marks only the pages in fast memory. We define b_j to be the number of black pages immediately before the jth request. The gray algorithm $\mathcal{G}$ works as follows:

- Initially, $\mathcal{G}$ marks the pages $\{0, 1, \dots, k-1\}$ black and all other pages white.
- $\mathcal{G}$ ignores all requests that do not cause a fault. Henceforth, assume that σ is hard for $\mathcal{G}$.
- $\mathcal{G}$ works in phases:
  - A new phase is started when $b_j = k$.
  - At the beginning of a phase, $\mathcal{G}$ marks all gray pages white and all black pages gray.
- When $\mathcal{G}$ faults on σ_j, $\mathcal{G}$ loads σ_j and marks it black.
- Before the jth request, $\mathcal{G}$ keeps in its fast memory
  - the b_j black pages, plus
  - the set of $q_j = k - b_j$ gray pages $\gamma_1, \gamma_2, \dots, \gamma_{q_j}$ that have the q_j smallest values of $\sigma_{j-1} - \gamma_i$ $(i = 1, 2, \dots, q_j)$. In other words, the gray pages $\gamma_1, \gamma_2, \dots, \gamma_{q_j}$ are the q_j gray pages that are most expensive to reload from σ_{j-1}.

We have stated the gray algorithm by assuming that a mark is associated with all n pages. In fact, $\mathcal{G}$ needs only to keep track of the black and gray pages, and a straightforward induction shows that, at any step, there are at most $2k$ gray and black pages.

It is not obvious that the gray algorithm could be implemented to maintain the prescribed set of gray pages without paying a large overhead. The following lemma shows that $\mathcal{G}$ is lazy.

LEMMA 5.2. *The gray algorithm $\mathcal{G}$ is lazy.*

Proof. Let σ be a hard sequence for $\mathcal{G}$. Suppose that $p \in \mathcal{M}(\mathcal{G}, j+1) - \mathcal{M}(\mathcal{G}, j)$ and $p \neq \sigma_{j+1}$. First, we show that p is gray at both step j and $j+1$. Since $p \notin \mathcal{M}(\mathcal{G}, j)$, p is not black at step j, and since $p \neq \sigma_{j+1}$, p is not black at step $j+1$. Since $p \in \mathcal{M}(G, j+1)$, p is not white at step $j+1$, and so it is not white at step j. It follows that p is gray at both steps. If p is in the interval from σ_j to σ_{j+1}, then it can be prefetched at no cost while $\mathcal{G}$ moves from σ_j to σ_{j+1}. We now show that no page that lies in the interval from σ_{j+1} to σ_j is prefetched by $\mathcal{G}$. Suppose, by contradiction, that such a page p is prefetched. First, we observe that σ_{j+1} does not start a new phase. Indeed, if σ_{j+1} started a new phase, then $\mathcal{M}(\mathcal{G}, j)$ is exactly the set of gray pages immediately before step $j+1$. However, p is gray and $p \notin \mathcal{M}(\mathcal{G}, j)$. We conclude that σ_{j+1} did not start a new phase. Therefore, $b_{j+1} = b_j + 1$ and so $q_{j+1} = q_j - 1$. Let ζ_j be the number of gray pages remaining after the jth request and notice that $\zeta_{j+1} \geq \zeta_j - 1$. Since $p \in \mathcal{M}(\mathcal{G}, j+1)$, p has one of the q_{j+1} largest values of $p - \sigma_{j+1}$ among all ζ_{j+1} pages that are gray at step $j+1$. Therefore, there are at least $\zeta_{j+1} - q_{j+1} \geq \zeta_j - q_j$ gray pages between σ_{j+1} and p. Since $p \notin \mathcal{M}(\mathcal{G}, j)$, p does not have one of the q_j largest values of $p - \sigma_j$ among all ζ_j gray pages at step j. Therefore, there are at most $\zeta = \zeta_j - q_j - 1$ gray pages between σ_j and p at step j. Since the number of gray pages never increases during a phase, there are at most ζ gray pages between σ_j and p at step $j+1$. However, $p - \sigma_{j+1} < p - \sigma_j$, which is to say that the interval from σ_{j+1} to p is contained in the interval from σ_j to p. Hence, there are at most $\zeta < \zeta_{j+1} - q_{j+1}$ gray pages between σ_{j+1} and p. Thus, we reach a contradiction and the lemma is proven. $\square$

Remark. The gray algorithm is similar to a marking algorithm once we identify black pages with the marked pages and white pages with the unmarked pages. However, the gray algorithm differs from the marking algorithm in one important respect: an evicted page might be prefetched and reloaded later on in the phase, without being requested again. By Lemma 5.2, the prefetch operation is executed at no cost. Thus, the gray algorithm adjusts the eviction pattern dynamically according to the requests in a phase. We would like to point out here that an analysis of the standard marking algorithm explicitly uses three marks and marks all n pages [3].

THEOREM 5.3. *The gray algorithm $\mathcal{G}$ is $O(n \log k)$-competitive even against a ubiquitous adversary.*

In the rest of the section, we will prove Theorem 5.3. Let H be the adversary's algorithm and assume without loss of generality that H is lazy. We will assume without loss of generality that the request sequence σ is hard for $\mathcal{G}$. No page is requested more than once in a phase and there are exactly k requests in a phase. Since all black pages are in $\mathcal{G}$'s fast memory, all requests are for gray and white pages. Correspondingly, we will say that a request is gray (white) if the requested page is gray (white) immediately before it is requested. The first request of a phase is white because all gray pages are in $\mathcal{G}$'s fast memory at the beginning of the phase.

The proof is structured as follows.

- We begin by defining the notion of a *segment*; segments allow us to give a lower bound on the cost of H.
- We proceed to examine $\mathcal{G}$'s cost on gray requests in a given segment, and show that it is at most $O(wn \log k)$, where w is the total number of white requests in the segment.
- Finally, we use a potential function argument to show that the amortized cost of $\mathcal{G}$ is no more than $O(n \log k)$ times the cost of H.

5.3. Segments.

We now define the notion of segments. Segments start from the second request of a phase and end with the first request of the next phase.

DEFINITION 5.4. *A* segment *is a subsequence of the form*

$$\langle \sigma_{ik+2}, \sigma_{ik+3}, \ldots, \sigma_{(i+1)k+1} \rangle$$

for some $i \geq 0$.

The notion of segment will be central to the rest of the proof because segments allow us to compute algorithm cost. We will estimate the cost of $\mathcal{G}$ and H on each segment and prove that the cost of $\mathcal{G}$ in a segment is no more than $O(n \log k)$ the cost of H in the same segment.

From now on, we will fix our attention on the first segment for simplicity of notation and without loss of generality. The first segment consists of the request sequence $\langle \sigma_2, \sigma_3, \ldots, \sigma_{k+1} \rangle$. Recall that σ_{k+1} is a white request.

5.4. Cost of *H*.

We turn now to examine the cost of H in a segment. Define w^N to be the number of white pages that are requested in the segment and that cause H to fault. Clearly, the cost of H is at least w^N. Suppose that on a white request for a page p, H already has p in its fast memory. Then the ratio of the actual costs of $\mathcal{G}$ and H for the request to p is infinity. This scenario thus requires a careful analysis as we describe below.

DEFINITION 5.5. *A page p is* hidden *at step j if p is white before the jth request and $p \in \mathcal{M}(H, j)$.*

Broadly speaking, our objective is to show that H also implicitly pays a cost on the hidden white pages. We will prove that the cost of H on the segment is at least D, where D is the number of hidden pages at step $k+1$.

LEMMA 5.6. *If a page p is hidden at step $k+1$, then p has not been requested in the segment.*

Proof. If $p \in \{\sigma_2, \dots, \sigma_k\}$, then p is black after step k and becomes gray before step $k+1$. Therefore, p is not white at step $k+1$ and so p is not hidden at step $k+1$. ∎

Let p be a hidden page at step $k+1$. Notice that $p \in \mathcal{M}(H, k+1)$, p was not requested in the segment, and H has not prefetched p. We conclude that p has been in $\mathcal{M}(H)$ throughout the segment.

LEMMA 5.7. *The cost of H in a segment is at least D.*

Proof. The proof is reminiscent of those in [12, 13, 18]. Clearly, $\sigma_1 \in \mathcal{M}(H, 2)$. Moreover, the previous lemma implies that all D pages hidden at step $k+1$ are in $\mathcal{M}(H, 2)$. Within a segment, the requests $\sigma_2, \dots, \sigma_k$ are for pages that are not hidden at step $k+1$ and that are not σ_1. At most $k-D-1$ of those $k-1$ pages are in $\mathcal{M}(H, 2)$, and so the cost of H is at least $k-1-(k-D-1) = D$. ∎

On the whole, the cost of H in the segment is at least $\max\{w^N, D\} \geq (w^N + D)/2$.

5.5. Potential function. Let us turn now to evaluate the cost of $\mathcal{G}$ in the same segment. Let $\gamma = 3(n-1) + n \ln k$. We will denote by D_j the number of hidden pages at step j, and so $D = D_{k+1}$. Define the potential function at step j to be

$$\Phi(j) = (3(n-1) + n \ln k) D_j = \gamma D_j.$$

Clearly, $\Phi(j) \geq 0$ for all j's. We will analyze the amortized cost of $\mathcal{G}$ by considering the following cases:

- In the first case, $\mathcal{G}$ does not pay any real cost, but the potential might increase as a consequence of an increase of the number D_j of hidden pages.
- In the next two cases, $\mathcal{G}$ indeed pays a real cost.
  - We will examine the cost of $\mathcal{G}$ on gray requests, and finally
  - we will examine the cost of $\mathcal{G}$ on white requests.

5.6. Potential increase. First, we show that the potential increases only at the end of a phase. We will need the following lemma.

LEMMA 5.8. *If a page p is hidden at step j ($2 \leq j \leq k$), then p was hidden at step 2.*

Proof. It is enough to show that if a page p is hidden at step j $(2 < j \leq k+1)$, then p was hidden at step $j-1$. Suppose to the contrary that p is hidden at step j, but not at step $j-1$. Then, either p is not white at step $j-1$ or $p \notin \mathcal{M}(H, j-1)$. However, $j \leq k$, so that no gray page has turned white. Hence, it must be the case that $p \notin \mathcal{M}(H, j-1)$. Since H does not prefetch, $p = \sigma_{j-1}$, and so p is black at step j, which is a contradiction, and the lemma is proven. ∎

Lemma 5.8 implies that $D_{j-1} \geq D_j$ for $j = 2, \dots, k$. It follows that the potential increase increases only at the end of a phase when some gray pages become hidden white pages. The potential increase is γD.

5.7. Gray requests. We now evaluate $\mathcal{G}$'s cost on the gray requests. Define a *gray block* as a maximal sequence of gray requests followed by a white request. The segment can be partitioned into a sequence of gray blocks that alternate with white requests. Notice that there are at most w gray blocks in a phase, where w was defined as the number of white requests in the segment. Actually, the first phase request and the last segment request are both white, so that w is also the number of white requests in the phase. We will argue that the cost incurred by $\mathcal{G}$ during the gray blocks does not exceed $w(2(n-1) + n \ln k)$.

Consider a gray block $B_i = \langle \sigma_j, \sigma_{j+1}, \ldots, \sigma_{j+q} \rangle$. Since σ_{k+1} is a white request, $j + q \leq k$. $\mathcal{G}$'s cost for σ_j is at most $n - 1$. We now estimate $\mathcal{G}$'s cost in the rest of the block. In what follows, we denote

- by α_l, the number of gray pages that are missing from $\mathcal{G}$'s fast memory before the lth request ($j \leq l \leq j + q$),
- by β_l, the number of pages that are gray at the lth request ($j \leq l \leq j + q$),
- by g_l, the number of gray pages requested from the beginning of the phase up to step $l - 1$ inclusive,
- by w_l, the number of white pages requested from the beginning of the phase up to step $l - 1$ inclusive, and
- by $b_l = w_l + g_l$, the number of black pages before the lth request.

The notation β_l is related to that in Lemma 5.2 by $\beta_l = \zeta_{l-1}$. Notice that $\beta_l = k - g_l$ and that $\alpha_l = \beta_l - q_l = k - g_l - (k - b_l) = g_l + w_l - g_l = w_l = w_j$ is a constant throughout the current gray block. Moreover, $\alpha_l \leq w_{k+1}$. Observe that w_{k+1} is the number of white requests in $\langle \sigma_1, \sigma_2, \ldots, \sigma_k \rangle$, w is the number of white requests in $\langle \sigma_2, \ldots, \sigma_k, \sigma_{k+1} \rangle$, and both σ_1 and σ_{k+1} are white requests. Therefore, $w_{k+1} = w$ and $\alpha_l \leq w$.

$\mathcal{M}(\mathcal{G}, l)$ contains all but at most w gray pages, and the missing gray pages are the closest to its current position σ_{l-1}. Thus, once $\mathcal{G}$ is positioned at σ_{l-1}, no more than w gray pages lie in the closed interval between σ_{l-1} and σ_l ($l = j + 1, \ldots, j + q$). Hence, if $\mathcal{G}$ starts from σ_j and moves for more than n units, then there are at most $\beta_j - \left\lceil \frac{\beta_j + 1}{w} \right\rceil \leq \beta_j \left(1 - \frac{1}{w}\right)$ pages that are still gray. Hence, if during the block B_i, $\mathcal{G}$ pays $r_i n + a$, for some $a < n$, then $\beta_{j+q+1} \leq (1 - 1/w)^{r_i} \beta_j$. On the other hand, since $\beta_2 = k$, if $\sum r_i > w \ln k$, no gray pages could be remaining since

$$\left(1 - \frac{1}{w}\right)^{\sum r_i} k < \left(\frac{1}{e}\right)^{\ln k} k = 1.$$

We conclude that $\sum r_i \leq w \ln k$. Notice that the quantity a contributes for at most $n - 1$ per gray block to the cost on gray requests. Recall that σ_j contributed for another $n - 1$ term per gray block. Since there are at most w gray blocks, the cost paid during all gray blocks is at most $2w(n - 1) + n \sum r_i \leq w(2(n - 1) + n \ln k)$.

5.8. White requests.

Henceforth, we will assume that $\mathcal{G}$ processes gray requests for free, but each white request is charged $2(n - 1) + n \ln k$. Such a charge is in addition to the cost required to process the white request itself. Notice that on any white request, $\mathcal{G}$ pays a real cost of at most $n - 1$, is charged $2(n - 1) + n \ln k$ for gray requests, and so $\mathcal{G}$'s amortized cost is $3(n - 1) + n \ln k = \gamma$ plus any increase of the potential function. Suppose that σ_j is a white request that causes H to fault. The potential does not increase, and $\mathcal{G}$'s amortized cost is γ. Suppose now that σ_j is a white request that does not cause H to fault. Then, p is hidden, the potential decreases by γ, and $\mathcal{G}$'s amortized cost is naught. Finally, G pays a cost of γD at the end of the phase. On the whole, $\mathcal{G}$'s cost in the segment is $w^N \gamma + D\gamma$, which is no more than $2\gamma = O(n \log k)$ times the actual cost of H in the segment, and the proof is complete.

6. Delay model.

We will now describe the delay model for BDP. In the delay model, the adversary has the power of issuing requests of two types: page requests, like in the ordinary BDP, and delays, where one delay request forces any algorithm to listen to one more page. Hence, if the algorithm G is positioned over page i before a delay request, G will be positioned over $i+1$ after the delay request. The algorithm G is free to decide whether page $i+1$ should be cached or not. Let G be an algorithm for BDP. The algorithm G can be turned into a BDP algorithm G^D in the delay model as follows. On a page request, G^D behaves exactly as the algorithm G would on that request. However, when G^D receives a delay request, it executes at most one full rotation after serving the delay request and returns to the configuration that it had before the delay.

Proposition 6.1. *If G is c-competitive for BDP against a ubiquitous adversary for some $c = \Omega(n)$, then G^D is $O(c)$-competitive in the delay model.*

Proof. Let σ^D be a request sequence consisting of page requests and delays, σ the request sequence where all delays have been removed, and d the number of delay requests in σ^D. Let f be the minimum number of faults on σ and H be the adversary algorithm. Observe that $c(H,\sigma^D) \geq f + d$. Then, $c(G^D,\sigma^D) = c(G,\sigma) + nd \leq cf + nd + b \leq O(c)(f+d) + b \leq O(c)c(H,\sigma^D) + b$ for some constant b. It is then proved that G is $O(c)$-competitive. □

An immediate corollary of the above proposition is as follows.

Corollary 6.2. *There is an $O(n \log k)$-competitive randomized algorithm for the delay model with no prefetching and an $O(n \log k)$ deterministic algorithm for the delay model with prefetching.*

Proof. The first result follows from the $O(\log k)$-competitive lazy randomized algorithm for virtual memory paging [3, 8, 16], whereas the second result follows from the fact that the gray algorithm is $O(n \log k)$-competitive against an ubiquitous adversary. □

7. Concluding remarks. We studied deterministic as well as randomized algorithms for broadcast disk paging. An interesting question not resolved by our work is that of the competitive ratio of randomized prefetching algorithms. A lower bound of $\Omega(n)$ is easy to show. It is conceivable that a simultaneous use of randomization and prefetching yields an algorithm that is $o(n \log k)$-competitive.

Recently, the second author performed an empirical evaluation of the gray algorithm on both synthetic and Web traces and found that the gray algorithm always and consistently outperformed the least recently used (LRU) algorithm [14].

Acknowledgments. We thank Martin Farach-Colton for many discussions, Uli Kremer and Stefan Langerman for telling us about the German and Belgian videotext systems, and two anonymous referees for helping us to improve the presentation of this paper.

CONTENTION RESOLUTION IN HASHING BASED SHARED MEMORY SIMULATIONS[*]

ARTUR CZUMAJ[†], FRIEDHELM MEYER AUF DER HEIDE[†], AND VOLKER STEMANN[‡]

Abstract. In this paper we study the problem of simulating shared memory on the distributed memory machine (DMM). Our approach uses multiple copies of shared memory cells, distributed among the memory modules of the DMM via universal hashing. The main aim is to design strategies that resolve contention at the memory modules. Extending results and methods from random graphs and very fast randomized algorithms, we present new simulation techniques that enable us to improve the previously best results exponentially. In particular, we show that an n-processor CRCW PRAM can be simulated by an n-processor DMM with delay $\mathcal{O}(\log\log\log n \log^* n)$, with high probability.

Next we describe a general technique that can be used to turn these simulations into time-processor optimal ones, in the case of EREW PRAMs to be simulated. We obtain a time-processor optimal simulation of an $(n \log\log\log n \log^* n)$-processor EREW PRAM on an n-processor DMM with delay $\mathcal{O}(\log\log\log n \log^* n)$, with high probability. When an $(n \log\log\log n \log^* n)$-processor CRCW PRAM is simulated, the delay is only by a $\log^* n$ factor larger.

We further demonstrate that the simulations presented can not be significantly improved using our techniques. We show an $\Omega(\log\log\log n / \log\log\log\log n)$ lower bound on the expected delay for a class of PRAM simulations, called topological simulations, that covers all previously known simulations as well as the simulations presented in the paper.

1. Introduction.

Parallel machines that communicate via a shared memory (*parallel random access machines, PRAMs*) are the most commonly used theoretical machine model for describing parallel algorithms (see, e.g., [16, 18, 28]). A PRAM consists of p processors $P_0, \ldots, P_{p-1}$, each having local memory, and a shared memory with cells $U = \{0, \ldots, m-1\}$. The processors work synchronously and have random access to the shared memory cells, each of which can store an integer. In this paper we deal only with *exclusive read exclusive write (EREW)* PRAMs and (ARBITRARY) *concurrent read concurrent write (CRCW)* PRAMs. On the EREW PRAM no pair of processors can simultaneously write to or read from the same memory location. On the (ARBITRARY) CRCW PRAM concurrent reading is allowed and, if several processors want to write to the same memory cell simultaneously, an arbitrary one of them succeeds. The PRAM is relatively comfortable to program, because the programmer does not have to allocate storage within a distributed memory or specify interprocessor communication. On the other hand, shared memory machines are very

unrealistic from the technological point of view, because on large machines a parallel shared memory access can only be realized at the cost of a significant time delay.

A more realistic theoretical model is the *distributed memory machine (DMM)*, in which the memory is divided into a limited number of memory modules, one module per processor. A DMM has n processors $Q_0, \dots, Q_{n-1}$ which are connected by an interconnection network with a distributed memory consisting of n memory modules $M_0, \dots, M_{n-1}$. In this paper we study DMMs with the *complete interconnection network* between processors and modules (cf. [7]). The computation of our DMM is synchronized. In a step each processor either performs a local computation or issues a read or write request for a memory cell x to the module holding x. Each module answers incoming requests. In this paper we shall focus on the DMM in which the modules obey the ARBITRARY conflict resolution rule: If more than one request is directed to a module, it serves an arbitrary one of them and ignores the others. However, the answer to the successful request is available to all processors accessing the module. It is easy to observe that an n-processor DMM can be simulated with constant delay on an n-processor ARBITRARY CRCW PRAM with $\Theta(n)$ shared memory cells and vice versa. Motivated by optical crossbar technology, there is another conflict resolution rule considered in the literature, the c-COLLISION rule. In this model a module can only answer if it gets at most c requests; otherwise a collision symbol is sent to all processors that wanted to access the module.

No matter which conflict resolution rule is used for a DMM, a module can respond to at most a constant number of accesses at a time. Thus DMMs exhibit the phenomenon of *memory contention*, in which an access request is delayed because of concurrent requests to the same module.

In an effort to understand the effects of memory contention on the performance of parallel computers, several authors have investigated the simulation of shared memory machines on DMMs. Often the authors assumed that processors and modules are connected by a bounded degree network (e.g., by a mesh, a butterfly, or an expander), and packet routing is used to access the modules [17, 20, 21, 27, 31]. In this paper we consider DMMs with a complete interconnection between processors and modules, i.e., we focus on the issue of resolving memory contention.

All of our algorithms are randomized, and the time bounds hold *with high probability* (*w.h.p.*), i.e., with probability at least $1 - n^{-\alpha}$ for arbitrary constant $\alpha > 1$; the choice of α will affect the respective running times by at most a constant factor. We focus on simulations that minimize the *delay*, i.e., the time needed to simulate a parallel memory access of a PRAM on a DMM. Furthermore, we are interested in optimal simulations. We say a simulation of a p-processor PRAM on an n-processor DMM is *time-processor optimal* if the delay is $\mathcal{O}(\lceil p/n \rceil)$.

The most efficient simulations of shared memory are based on the idea of hashing, i.e., of distributing the shared memory cells of the PRAM (almost) randomly among the memory modules of the DMM. Mehlhorn and Vishkin [24] design a simple simulation of an n-processor EREW PRAM by an n-processor DMM with expected delay $\mathcal{O}(\log n / \log\log n)$, by storing each cell of the PRAM in a module that is determined by a single hash function. One can easily show that this result cannot be improved when each cell of the PRAM is represented only by one copy. Dietzfelbinger and Meyer auf der Heide [7] extend this result to the CRCW PRAM model and show that one step of an n-processor CRCW PRAM can be simulated by an n-processor DMM with expected delay $\mathcal{O}(\log n / \log\log n)$. Karp, Luby, and Meyer auf der Heide [19] break the $\log n / \log\log n$ bound by applying the idea of redundant storage representation, that is, by storing in the DMM more than one copy of each memory cell of the PRAM. In order to distribute some number of copies of each memory cell, randomly and independently chosen hash functions are used. Karp, Luby, and Meyer auf der Heide obtain a simulation of an n-processor CRCW PRAM on an n-processor DMM with delay $\mathcal{O}(\log\log n)$. They present how to get time-processor optimal simulations. These authors show that any simulation of one step of an n-processor EREW PRAM on an n-processor DMM with delay τ that uses only a constant number of hash functions can be turned into a time-processor optimal simulation with delay $\mathcal{O}(\tau \log^* n)$. In the case of CRCW PRAMs, the simulation is close to optimal: One step of an $(\tau \cdot n)$-processor CRCW PRAM can be simulated on an n-processor DMM with delay $\mathcal{O}(\tau \log^* n)$. Using the majority technique due to Upfal and Wigderson [32], Dietzfelbinger and Meyer auf der Heide [8] extend the $\mathcal{O}(\log\log n)$-delay simulation of Karp, Luby, and Meyer auf der Heide [19] to a much simpler schedule for an $\mathcal{O}(\log\log n)$-time simulation on the weaker c-COLLISION DMM, for some constant $c > 2$. Goldberg, Matias, and Rao [12] show that one can perform a time-processor optimal simulation with delay $\mathcal{O}(\log\log n)$, even on a 1-collision model (called also *optical communication parallel computer*, OCPC). Meyer auf der Heide, Scheideler, and Stemann [25] extend the algorithm from [8] and present a simulation on a DMM (with the ARBITRARY write conflict resolution rule) achieving delay $\mathcal{O}(\log\log n/\log\log\log n)$. This is the first simulation that beats the $\log\log n$ bound, however, it can not be turned into a time-processor optimal one because it uses nonconstant storage redundancy, that is, each memory cell of the PRAM has a nonconstant number of copies in the memory modules of the DMM. The techniques used in these papers do not seem to yield simulations with smaller delay. In particular, MacKenzie, Plaxton, and Rajaraman [22] and, independently, Meyer auf der Heide, Scheideler, and Stemann [25] show lower bounds for classes of algorithms that capture all these algorithms.

In this paper we design new shared memory simulations that improve all previously known results by an exponential decrease of the delay. The core of our simulations is a new analysis of a special sparse almost random graph, the access graph, which represents requests of the PRAM processors and an efficient use of log-star-time randomized algorithms, which leads to fast techniques for exploring neighborhoods of nodes in such sparse random graphs. The key steps of our simulations are partitioning techniques that make it possible to decompose every connected component of a random sparse graph into small pieces. Using different, more and more sophisticated partitioning techniques, we design simulations of one step of n-processor EREW PRAMs on n-processor DMMs with delay $\mathcal{O}(\log\log n/\log\log\log n)$, $\mathcal{O}(\sqrt{\log\log n}\log^* n)$, and finally $\mathcal{O}(\log\log\log n \log^* n)$, refining the simulation techniques step by step. Finally we transform all these bounds into simulations of one step of n-processor CRCW PRAMs on n-processor DMMs without asymptotic time loss.

Next we present a general technique that can be used to transform any simulation of an n-processor EREW PRAM on an n-processor DMM with delay $\tau \geq \log^* n$ that uses a constant number of hash functions into a time-processor optimal simulation. Our transformation relies on a new routing problem, called *all-but-linear routing*, which is a relaxed version of the $k - k$ relation routing problem. Using the ideas for $k - k$ relation routing developed for the OCPC model [1, 11], we show how to solve all-but-linear routing with random or almost random requests optimally for any $k = \Omega(\log^* n)$.

Finally we pinpoint the limit of our techniques. We analyze a *topological game* in graphs that is the essential part of the most efficient previously known simulations

[8, 12, 19, 22, 25], as well as the simulations presented in this paper. We show that a randomized topological game requires $\Omega(\log\log\log n/\log\log\log\log n)$ expected delay. This indicates that the techniques presented in the paper cannot lead to significantly better simulations than the ones presented in this paper.

Organization of the paper. We begin in section 2 with outlining techniques used by our simulations. Section 3 provides some basic tools. In section 4 we define the access graph and the access game and prove some properties about the distribution of sizes of connected components in a random graph that are essential for our proofs of the running time of the simulations. Section 5 contains the first simulation of an EREW PRAM, which has delay $\mathcal{O}(\log\log n/\log\log\log n)$, w.h.p. In section 6 we present two simulations of an EREW PRAM, one with delay $\mathcal{O}(\sqrt{\log\log n}\log^* n)$ and another with delay $\mathcal{O}(\log\log\log n\log^* n)$, w.h.p. Section 7 describes a transformation that turns EREW PRAM simulations into CRCW PRAM simulations. Section 8 analyzes the all-but-linear routing problem which is used in section 9 to get time-processor optimal simulations. In section 10 we present the lower bound for the topological game.

2. Outline of techniques.

We start with the simulation of an n-processor EREW PRAM on an n-processor DMM. Our shared memory simulations are based on *redundant storage representation*; that is, we assume that the shared memory cells of the PRAM are distributed among the modules of the DMM using some number a of hash functions $h_1,\dots,h_a : U \to \{0,\dots,n-1\}$, so that copies of cell $u \in U$ are stored in the modules $M_{h_1(u)},\dots,M_{h_a(u)}$. All such simulations assume that $h_1,\dots,h_a$ are randomly chosen from a *high performance universal class* of hash functions as presented, e.g., by Siegel [29] or Karp, Luby, and Meyer auf der Heide [19]. A function randomly chosen from such a class of hash functions behaves almost like a random function but can be stored using little ($\mathcal{O}(\sqrt{n})$) space and can be evaluated in constant time. Actually, any $(2,\log^2 n)$-universal class of hash functions (cf. [6]) would be sufficient for our purposes. Upfal and Wigderson [32] observe how to use redundant storage representation in order to speed up shared memory simulations. They introduce the majority technique which utilizes the observation that accessing more than half of the a copies of a requested shared memory cell is sufficient for reading as well as for writing: If processor P wants to write to cell u, it updates more than half of the copies of u and adds a time-stamp indicating the PRAM time. If processor P wants to read cell u it reads at least half of the copies of u and takes the copy with the latest time-stamp.

Let us refer to the task of accessing b out of the a copies of each of the n requested shared memory cells as the *"b out of a" task.* A method for performing a "b out of a" task is called a *protocol.* For the analysis it is more convenient to consider a "1 out of c" task. It is possible to reduce a "b out of a" task to $\binom{a}{b-1}$ "1 out of $a-b+1$" tasks, each with a different subset of $a-b+1$ hash functions. For constant a this yields only a constant factor in the delay. In this paper we present shared memory simulations based on executing the "2 out of 3" task. In fact, because of the reasons mentioned above, we only analyze protocols for the "1 out of 2" task. From now on we will assume that each memory cell u of the PRAM is stored in the modules $M_{h_1(u)}$ and $M_{h_2(u)}$.

Our protocols for the "1 out of 2" task are based on the model introduced by Karp, Luby, and Meyer auf der Heide [19]. Let ε be a constant, $0 < \varepsilon < 1$, that will be specified later. Consider a batch of εn requests, for which the "1 out of 2" task has to be executed. For such a batch, we define the labeled *access graph H* as follows. Its nodes correspond to the n modules of the DMM, and for each key u from the batch, H contains an edge labeled u between $M_{h_1(u)}$ and $M_{h_2(u)}$. Now a protocol for the "1 out of 2" task can be viewed as an *access game* on H. The access game is performed in rounds, and in each round each node of H (i.e., each module in the DMM) can remove one of its incident edges (i.e., one of the access requests directed to the module is processed). The access game is finished when all the edges have been removed from the graph.

2.1. Fast protocols for the "1 out of 2" task. The simple protocol for the "1 out of 2" task, as in [8, 12, 19, 25], corresponds to the access game in which, in each round, each node of H removes an arbitrary incident edge, i.e., processes one arbitrary request directed to it. MacKenzie, Plaxton, and Rajaraman [22] and Meyer auf der Heide, Scheideler, and Stemann [25] prove the tight lower bound of $\Omega(\log\log n)$ for the time needed by this protocol.

For the analysis of the access game or the protocol for the "1 out of 2" task, respectively, we also follow the idea of Karp, Luby, and Meyer auf der Heide [19], who analyze the structure of the access graph H. As h_1 and h_2 are almost random (i.e. randomly chosen from a high performance universal class), H is almost a random graph with n nodes and εn edges. In analogy to results on truly random graphs, these authors [19] show that H consists of connected components of size $\mathcal{O}(\log n)$, w.h.p., each of which is a tree with a constant number of additional edges, w.h.p. One can show (compare also [19]) that this property of H implies the existence of a schedule that works in constant time. The previously best algorithm to find this schedule takes $\mathcal{O}(\log\log n)$ time and yields the simulation from [8]. In contrast to formerly analyzed protocols for the access game, the heart of our simulations lies in finding fast protocols to execute the access game on H. In order to make the description of our protocols more intuitive, we assume that also the *module* may take part in the computation. Clearly this assumption is not critical, because we could let this work be carried out by the corresponding processor. Thus we assign the processors of the DMM both to the nodes and to the edges of H and allow the nodes (the modules) to decide which edges (if any) are to be removed. However, the knowledge about H is distributed among the processors at the beginning of the simulation, so that each processor knows just one edge. The only way the nodes may decide which edge to remove is to analyze their neighborhoods in H. There are two issues we have to deal with. First, each node has to explore its neighborhood quickly, and second, we have to find a rule to guide the nodes in their decision on which edge to remove on the basis of the structure of their neighborhood.

Exploring the neighborhood seems to be a complicated task. Even computing the degree of a node of H is complicated, because the edges in H are given in an arbitrary order and we do not have the adjacency list at hand. We show how each node v may explore certain properties of its k*-neighborhood*, i.e., the subgraph of H induced by the nodes at distance at most k from v, in time close to $\mathcal{O}(\log k)$. To succeed in this, we present a new precise analysis of the structure of H and apply extremely fast algorithms. We use probabilistic tools like the method of bounded differences [23] and a generalization of the Markov inequality to show that, w.h.p., for all i, the number of connected components of H of size at least i is bounded by $n/2^{bi}$ for some constant b.

Based on log-star techniques as developed in [3, 10, 14], we show how to use the structural properties of H mentioned above to compute certain properties of the k-neighborhood of all nodes of H in time $\mathcal{O}(\log k \log^* n)$. We then present a sequence of more and more involved protocols that use such information to design fast access protocols.

We can extend all our results to the simulation of the CRCW PRAM. It is well known that by applying integer sorting to the memory requests issued in one step of the CRCW PRAM, one can reduce the simulation of one step of the CRCW PRAM to that of one step of the EREW PRAM. We observe that instead of integer sorting one can use an algorithm for *strong semisorting* [3], which can be solved on the DMM much faster than sorting. This allows us to turn any simulation of one step of an n-processor EREW PRAM by an n-processor DMM with delay $\tau \geq \log^* n$ into a simulation of one step of an n-processor CRCW PRAM on an n-processor DMM with delay $\mathcal{O}(\tau)$.

2.2. Time-processor optimal simulations. We present a general method for making simulations based on hashing multiple copies of the PRAM memory cells time-processor optimal. Consider a simulation of one step of an n-processor EREW PRAM on an n-processor DMM with delay not exceeding τ, w.h.p., that works by solving the "b out of a" task with $b > a/2$ (cf. the discussion in section 2). Further, suppose that it solves the "b out of a" task by running $\binom{a}{b-1}$ "1 out of $a - b + 1$" tasks. We show that if a and b are constants, then the simulation can be made time-processor optimal with delay $\mathcal{O}(\tau)$ for $\tau \geq \log^* n$. This improves upon the $\mathcal{O}(\tau \log^* n)$ delay achieved in [19].

If we want to simulate one step of an $(n \cdot \tau)$-processor EREW PRAM on an n-processor DMM, each processor of the DMM simulates τ processors of the EREW PRAM. Hence, each processor of the DMM has a list of τ memory requests. We use $a + 2$ hash functions and perform the simulation by solving the "$b + 1$ out of $a + 2$" task. By our discussion in section 2, one can solve the task by performing a "1 out of $a - b + 2$" task for each subset of size $a - b + 2$ of the $a + 2$ hash functions. Therefore we focus on solving the "1 out of $a - b + 2$" task. Thus let us suppose that we have $a - b + 2$ hash functions. Our protocol consists of two phases. In the first phase, all but $\mathcal{O}(n)$ requests are satisfied in time $\mathcal{O}(\tau)$, using only one of the hash functions. We achieve this goal by analyzing a new routing problem, called all-but-linear routing. In the second phase we first evenly redistribute the remaining requests among the DMM processors such that each processor only gets a constant number of requests. Then we use the other $a - b + 1$ hash functions and perform a protocol for the "1 out of $a - b + 1$" task to satisfy the remaining requests. Since each processor has a constant number of requests to be sent, we may use the solution for the "1 out of $a - b + 1$" task to perform this step in time $\mathcal{O}(\tau)$, w.h.p.

2.3. Lower bound for topological simulations. Our solutions for the access game, as well as all previously known solutions to the "1 out of 2" task, are special cases of a *topological game* on the access graph. In this game, in order to remove all the edges from the graph, each node first analyzes its neighborhood and then removes its incident edges in a way depending on the topology of the neighborhood. We prove an $\Omega(\log \log \log n / \log \log \log \log n)$ lower bound for the topological game, which indicates that our $\mathcal{O}(\log \log \log n \log^* n)$-delay PRAM simulation is almost optimal in the class of algorithms based on the topological game.

3. Preliminaries. This section describes basic techniques used in the paper. All our simulations are based on universal hashing, i.e., the shared memory cells are distributed among the memory modules using three or more hash functions, randomly drawn from a universal class of hash functions. The analysis of the simulations requires high performance universal classes; i.e., if a function is chosen at random from the class, then its behavior will be close to that obtained by choosing a function at random from the class of all functions.

Since our simulations have $o(\log\log n)$ delay, we cannot afford to use deterministic and exact solutions for fundamental parallel problems, like sorting or prefix sums computation. Therefore, we use instead relaxed counterparts of these problems that can be solved by $\mathcal{O}(\log^* n)$-time randomized algorithms.

Section 3.1 briefly introduces the concept of hashing and universal hashing, section 3.2 states two tail estimates for dependent random variables, and section 3.3 presents results about fast randomized algorithms used in the paper.

3.1. Universal hashing. Our simulations require that the shared memory U of the PRAM is distributed among the memory modules of the DMM. For this we use hash functions that have properties similar to random functions. We use notation from Dietzfelbinger et al. [6], generalizing notions from Carter and Wegman [5].

For an integer k, define $[k] = \{0, \dots, k-1\}$. Let $U = [m]$, where $m > n$.

DEFINITION 1 (see [6]). *A family $\mathcal{H}_{m,n}$ of hash functions mapping U into $[n]$ is (μ, k)-universal, if for each $u_1 < \cdots < u_k \in U$, $l_1, \dots, l_k \in [n]$, and the hash function h drawn with uniform probability from $\mathcal{H}_{m,n}$, we have*

$$\Pr(h(u_1) = l_1, \dots, h(u_k) = l_k) \le \frac{\mu}{n^k} \ .$$

Such classes have been called sometimes μ strongly k universal or $((k)_\mu)$-independent. Notice that if $\mathcal{H}_{m,n}$ is (μ, k)-universal, then it is also (ν, j)-universal for all $\nu \ge \mu$ and $j \le k$.

For our purposes we require a $(2, \log^2 n)$-universal class of hash functions $\mathcal{H}_{m,n}$, such that a random $h \in \mathcal{H}_{m,n}$ can be constructed quickly, stored using little space ($\mathcal{O}(\sqrt{n})$ suffices), and evaluated in constant time. For example, we can use an $(1, n^\varepsilon)$-universal class of hash functions (where ε is a small positive constant) described by Siegel [29] for the case $n = m$, with the extension to $(2, n^\varepsilon)$-universal class for arbitrarily large $m > n$ from [19]. For a detailed description of this class see [19].

3.2. Tail estimates. In this paper we mainly deal with dependent random variables. To bound the deviation of the sum of dependent random variables from the expected value, we use two different tail estimates. The first one is also called the *method of bounded differences*, given in this form by McDiarmid [23].

LEMMA 3.1 (the method of bounded differences). *Let $x_1, \dots, x_n$ be independent random variables, where x_i takes values from a finite set A_i, for $i = 1, \dots, n$. Suppose that the function $f : \Pi_{i=1}^n A_i \to \mathbb{R}$ satisfies $|f(\bar{x}) - f(\bar{x}')| \le c_i$ whenever the vectors $\bar{x}$ and $\bar{x}'$ differ only in the ith coordinate. Let Y be the random variable $f(x_1, \dots, x_n)$. Then, for any $t > 0$,*

$$\Pr(Y \ge E(Y) + t) \le \exp\left(\frac{-2t^2}{\sum_{i=1}^n c_i^2}\right) \ .$$

Another tail estimate is a well-known generalization of the Markov inequality.

LEMMA 3.2 (the kth moment inequality). *Let Y be a random variable and $s > 0$. Then, for each $\alpha > 0$,*

$$\Pr(|Y| \ge \alpha) \le \frac{E(|Y|^s)}{\alpha^s} \ .$$

3.3. Log-star algorithms. In this section we outline main algorithmic tools used by our algorithms. Some of them are subsumed by others. Nevertheless, we state all of them to make it easier to refer to specific tasks. If an array of size $2 \cdot n$ contains at least n objects, we will call the array *padded-consecutive.*

DEFINITION 2. *The* strong semisorting *problem is the following: Given n integers $x_1, x_2, \ldots, x_n$, $x_i \in [n]$, store them in a padded-consecutive array, such that all variables with the same value occur in a padded-consecutive subarray.*

DEFINITION 3. *The* all nearest one *problem is the following: Given n bits $x_1, x_2, \ldots, x_n$, find for each bit x_i the nearest* 1*'s both to its left and to its right.*

DEFINITION 4. *The* approximate prefix sums *problem is the following: Given a sequence of nonnegative integers, $x_1, \ldots, x_n$, find a sequence $y_0 = 0$, $y_1, \ldots, y_n$, such that for $i \in [n]$, $y_i - y_{i-1} \geq x_i$, and*

$$\frac{1}{2}\sum_{j=1}^{i} x_j \leq y_i \leq 2\sum_{j=1}^{i} x_j.$$

The following lemma is a combination of several results.

LEMMA 3.3. *The following problems can be solved on the n-processor DMM in $\mathcal{O}(\log^* n)$-time with exponentially high probability, i.e., with probability $1 - 2^{-n^{\varepsilon}}$ for a constant $\varepsilon > 0$:*

(1) *strong semisorting,*

(2) *all nearest one, and*

(3) *approximate prefix sums.*

Proof. First, since an n-processor DMM can be simulated with a constant delay on an n-processor CRCW PRAM with $\Theta(n)$ shared memory, it is enough to prove the lemma for the n-processor CRCW PRAM that uses only $\mathcal{O}(n)$ space.

(1) Bast and Hagerup [3] show how to solve strong semisorting in $\mathcal{O}(\log^* n)$-time with the desired probability on a CRCW PRAM, provided the input is from $[n]$. For a general input, $\mathcal{O}(\log^* n)$-time perfect hashing [2, 10] reduces the problem to the solution of Bast and Hagerup. (See also [14, p. 275].)

(2) The all nearest one problem can be solved in $\mathcal{O}(\alpha(n)) = \mathcal{O}(\log^* n)$ time deterministically on a CRCW PRAM by an algorithm due to Ragde [26], and Berkman and Vishkin [4].

(3) Approximate prefix sums can be solved within the desired bound using an algorithm of Goodrich, Matias, and Vishkin [13]. □

4. The access graph. In this section we show how PRAM simulation can be modeled as the access game on the access graph. We also discuss basic properties of the access graph.

4.1. Definition and properties of the access graph. We start with the simulation of an EREW PRAM. The memory of the PRAM is hashed using three hash functions h_1, h_2, and h_3. That means each memory cell $u \in U$ of the PRAM is stored in the modules $M_{h_1(u)}, M_{h_2(u)}$, and $M_{h_3(u)}$ of the DMM. We call the representations of u in the $M_{h_i(u)}$'s the *copies* of u. We assume that all the hash functions used are drawn uniformly at random from a $(2, \log^2 n)$-universal class of hash functions $\mathcal{H}_{m,n}$ (see section 3.1). As mentioned in section 2, it is enough to analyze only protocols for the "1 out of 2" task, and therefore in our description we will use only two hash functions h_1 and h_2.

For technical reasons, we do not perform all n accesses to the shared memory simultaneously but split the requests into batches of size $n/2^{2c+6}$ for some constant $c \geq 1$ to be specified later. Since we only have a constant number of batches, this will slow down our algorithm only by a constant factor.

Let S denote such a batch. Let $G = ([n], E)$ be the labeled directed graph defined by two hash functions h_1, h_2 from $\mathcal{H}_{m,n}$ and the set of requests S. G has an edge $(h_1(u), h_2(u))$ labeled u for each $u \in S$. Note that parallel edges and self-loops are allowed in G, however all labels are distinct.

DEFINITION 5. *The* access graph H *is the labeled graph obtained from* G *by removing all directions from the edges. It consists of* n *nodes and* $n/2^{2c+6}$ *edges for some constant* $c \geq 1$.

The algorithms we present rely on the properties of the access graph. The following lemma is an extension of a result of Karp, Luby, and Meyer auf der Heide [19]. Define the size of a connected component C, denoted by $|C|$, to be the number of nodes it contains.

LEMMA 4.1. *For arbitrary positive constants* l *and* c *and for sufficiently large* n

(a) $\Pr$*(*H *has a connected component of size at least* $\frac{l}{c}\log n$*)* $\leq n^{-l}$*, and*

(b) *there is a constant* $w \geq 1$ *such that*

$$\Pr(H \textit{ has a connected component } C \textit{ with at least } |C| + w - 1 \textit{ edges}) \leq n^{-l}.$$

Proof. For the proof of the lemma it suffices that h_1 and h_2 are chosen uniformly at random from any $(2, \log^2 n)$-universal class of hash functions. The proof of the lemma relies on the following claim.

CLAIM 4.2. *Let* $k \geq 2, w \geq 0, k + w - 1 \leq \log^2 n$*. The probability that there is a connected subgraph* $G' \subseteq G$ *such that* G' *contains* k *vertices and at least* $k + w - 1$ *edges is at most*

$$n^{-w+1}k^{w-2}2^{-2c(k+w-1)} \quad .$$

Proof. Let $\mathcal{G}_{k,w}$ be the set of all directed connected graphs on node set $[n]$ with k vertices and $k + w - 1$ edges labeled by elements of S. Since any connected subgraph $G' \subseteq G$ with k vertices and at least $k + w - 1$ edges must contain a subgraph from $\mathcal{G}_{k,w}$, it is sufficient to show that G contains a subgraph from $\mathcal{G}_{k,w}$ with probability at most $n^{-w+1}k^{w-2}2^{-2c(k+w-1)}$.

An element of $\mathcal{G}_{k,w}$ can be generated by first choosing k vertices, then taking an undirected tree on these vertices and orienting the tree edges, then adding further w directed edges on the vertices of the tree, and finally assigning the labels to the chosen $k + w - 1$ edges. Therefore,[1]

$$\begin{aligned} |\mathcal{G}_{k,w}| &\leq \binom{n}{k} k^{k-2} 2^{k-1} k^{2w} 2^w \left(\frac{n}{2^{2c+6}}\right)^{k+w-1} \\ &\leq n^{2k+w-1} k^{2w-2} \left(\frac{e^2}{2^{2c+6}}\right)^{k+w-1} \quad . \end{aligned}$$

For fixed $G' \in \mathcal{G}_{k,w}$ and randomly chosen h_1 and h_2, G' is a subgraph of G only if the directions and labels with respect to h_1 and h_2 coincide with G'. Since $k +$

[1]Throughout the paper the inequalities $k^k/k! < e^k$ and $(k/l)^l \leq \binom{k}{l} \leq (ek/l)^l$ will be used without further comment.

$w-1 \le \log^2 n$ and h_1, h_2 are independently chosen from a $(2, \log^2 n)$-universal class, the probability that G' is a subgraph of G is at most $\left(2/n^{k+w-1}\right)^2$. Therefore, the probability that there is some $G' \in \mathcal{G}_{k,w}$ that appears as a subgraph of G is at most

$$n^{-w+1}k^{2w-2}\left(\frac{4e^2}{2^{2c+6}}\right)^{k+w-1} \le n^{-w+1}k^{2w-2}2^{-2c(k+w-1)} \ . \qquad \square$$

To prove part (a) of the lemma we use Claim 4.2 with $w=0$ and $k=\frac{l}{c}\log n$. This yields an upper bound on the probability of the existence of a connected component of size at least $k=\frac{l}{c}\log n$.

To prove part (b) notice first that from part (a) we obtain that H has a connected component of size at least $\frac{l}{2c}\log n$ with probability at most $n^{-l/2}$. Observe also that for any constant s, H contains a vertex with at least s self-loops with probability at most n^{1-s}. Hence we may use Claim 4.2 to obtain the upper bound for the probability that H has a connected component C with at least $|C|+w-1$ edges:

$$\begin{aligned} n^{-l/2}+n^{1-w}+\sum_{k=2}^{\frac{l}{2c}\log n} n^{-w+1}k^{w-2}2^{-2c(k+w-1)} &\le n^{-l/2}+n^{1-w}+\sum_{k=2}^{\frac{l}{2c}\log n}(k/n)^{w-1} \\ &\le n^{-l/2}+n^{1-w}+n^{2-w} \ . \end{aligned}$$

Thus if we set $w=\lceil 2+l/2\rceil$, then the probability is at most n^{-l}. $\square$

LEMMA 4.3. *Let l, b, and c be any positive constants with $c-1\ge b>2$, $l>2$, and let $1<k\le\frac{1}{2b}\log n$. Then, for n large enough,*

$$\Pr\left(H \textit{ has at least } \frac{n}{2^{bk}} \textit{ connected components of size at least } k\right) \le n^{-(l-1)} \ .$$

Proof. We first consider connected components of H of size exactly k, and then we extend our analysis to connected components of size at least k.

Let $\mathcal{W}_k$ be the set of all subsets of size k of the set of n nodes. With each $W\in\mathcal{W}_k$ we associate a binary random variable $\mathcal{I}_W$, such that $\mathcal{I}_W=1$ if the nodes from the set W form a connected component in H. Otherwise $\mathcal{I}_W=0$.

We want to bound the random variable

$$X_{(k)}=\sum_{W\in\mathcal{W}_k}\mathcal{I}_W,$$

which is the number of connected components of size k. As the random variables $\mathcal{I}_{W_1}$ and $\mathcal{I}_{W_2}$ are not independent for $W_1, W_2\in\mathcal{W}_k$, we use Lemma 3.2 to bound $X_{(k)}$. We compute the sth moment of $X_{(k)}$ with the following formula:

$$E(X_{(k)}^s)=E\left[\left(\sum_{W\in\mathcal{W}_k}\mathcal{I}_W\right)^s\right]=\sum_{(W_1,\ldots,W_s)\in(\mathcal{W}_k)^s}E(\mathcal{I}_{W_1}\mathcal{I}_{W_2}\cdots\mathcal{I}_{W_s}) \ .$$

Consider a fixed tuple $(W_1,\ldots,W_s)$. If there exists a pair of sets $W_i, W_j\in\{W_1,\ldots,W_s\}$ that are not disjoint and not equal, i.e., $W_i\ne W_j$ and $W_i\cap W_j\ne\emptyset$, then $E(\mathcal{I}_{W_1}\mathcal{I}_{W_2}\cdots\mathcal{I}_{W_s})=0$. This follows from the definition of the binary random variables because the two sets cannot both form a connected component of size exactly k. Hence, we only have to deal with the case that z sets, $1\le z\le s$, are disjoint and the other $s-z$ sets are equal to one of them. If we fix z, there are $\binom{s}{z}$ ways to choose the z sets that are disjoint and at most z^{s-z} ways to assign the remaining sets to one of them. Hence we can bound the sth moment in the following way:

$$E(X^s_{(k)}) \le \sum_{z=1}^{s} \binom{s}{z} z^{s-z} \sum_{\substack{(W_1,\ldots,W_z)\in(\mathcal{W}_k)^z \\ W_1,\ldots,W_z \text{ disjoint}}} E(\mathcal{I}_{W_1}\mathcal{I}_{W_2}\cdots\mathcal{I}_{W_z}) \ .$$

Fix z disjoint sets $W_1,\ldots,W_z$ and assume that $s(k-1) \le \log^2 n$. For every i, $1 \le i \le z$, let $\mathcal{T}_i$ be the set of all directed spanning trees on nodes of W_i with edges labeled by the elements of S. Notice that

$$E(\mathcal{I}_{W_1}\mathcal{I}_{W_2}\cdots\mathcal{I}_{W_z}) \le \sum_{T_1\in\mathcal{T}_1,\ldots,T_z\in\mathcal{T}_z} \Pr(\text{each of } T_1,\ldots,T_z \text{ is a subgraph of } H) \ .$$

Using arguments similar to those used in the proof of Claim 4.2, and by observing that the endpoints of the edges are chosen by hash functions from a $(2,\log^2 n)$-universal class, we obtain

$$E(\mathcal{I}_{W_1}\mathcal{I}_{W_2}\cdots\mathcal{I}_{W_z}) \le \left(k^{k-2}\cdot 2^{k-1}\cdot\left(\frac{n}{2^{2c+6}}\right)^{k-1}\right)^z \cdot \left(\frac{2}{n^{k-1}}\right)^{2z} \ .$$

Now we can bound $E(X^s_{(k)})$:

$$\begin{aligned}
E(X^s_{(k)}) &\le \sum_{z=1}^{s}\binom{s}{z} z^{s-z}\binom{n}{k,k,\ldots,k,(n-zk)} k^{z(k-2)}\left(\frac{n}{2^{2c+5}}\right)^{z(k-1)}\left(\frac{4}{n^2}\right)^{z(k-1)} \\
&\le \sum_{z=1}^{s}\left(\frac{se}{z}\right)^z z^{s-z}\left(\frac{ne}{k}\right)^{zk} k^{z(k-2)}\left(\frac{1}{n2^{2c+3}}\right)^{z(k-1)} \\
&\le \sum_{z=1}^{s}\left(\frac{s}{z}\right)^z z^{s-z} n^z\left(\frac{e}{k^2}\cdot\frac{e^k}{2^{(2c+3)(k-1)}}\right)^z \\
&\le \sum_{z=1}^{s}\left(\frac{sn}{z^2 2^{ck}}\right)^z z^s \ .
\end{aligned}$$

Finally, Lemma 3.2 implies

$$\begin{aligned}
\Pr\left(X_{(k)} \ge \frac{n}{2^{bk+1}}\right) &\le \frac{E(X^s_{(k)})}{\left(\frac{n}{2^{bk+1}}\right)^s} \\
&\le \sum_{z=1}^{s}\left(\frac{sn}{z^2 2^{ck}}\right)^z\cdot\left(\frac{z2^{bk+1}}{n}\right)^s \\
&= 2^s\cdot\sum_{z=1}^{s}\left(\frac{s}{z2^{(c-b)k}}\right)^z\cdot\left(\frac{z2^{bk}}{n}\right)^{s-z} \\
&\le 2^s\cdot\sum_{z=1}^{s}\left(\frac{s}{z2^k}\right)^z\cdot\left(\frac{z}{\sqrt{n}}\right)^{s-z} \\
&= 2^s\cdot\sum_{z=1}^{s}\left(\frac{s\sqrt{n}}{z^2 2^k}\right)^z\cdot\left(\frac{z}{\sqrt{n}}\right)^{s} \\
&\le 2^s\cdot s\cdot\left(\frac{1}{2}\right)^{ks} .
\end{aligned}$$

In the fourth inequality we need $c \geq b+1$ and $k \leq \frac{1}{2b}\log n$. By setting $s = (l+2)\log n/(k-1)$ we obtain

$$\Pr\left(X_{(k)} \geq \frac{n}{2^{bk+1}}\right) \leq n^{-(l+1)} \ .$$

Now we extend our analysis to connected components of size at least k. For this we have only to observe

$$\Pr\left(\sum_{t \geq k} X_{(t)} \geq \frac{n}{2^{bk}}\right) \leq \Pr\left(\sum_{t\geq k} X_{(t)} \geq \sum_{t=k}^{n} \frac{n}{2^{bt+1}}\right)$$
$$\leq \sum_{t \geq k} \Pr\left(X_{(t)} \geq \frac{n}{2^{bt+1}}\right) \leq n^{-l} \ . \qquad \square$$

Lemma 4.1 and Lemma 4.3 are the basis of the proof of the following lemma which is essential for the analysis of our simulations.

LEMMA 4.4. *Let H be the access graph with n nodes and $\frac{n}{2^{2c+6}}$ edges for some constant $c \geq 1$ defined as in Lemma 4.3. For all constants β and l such that $c \geq 2l(\beta+2)$, with probability at least $1 - 2(\frac{1}{n})^{l-1}$,*

$$\sum_{\substack{\text{connected components } C \\ |C|>1}} |C| \cdot 2^{|C|\,\beta} \leq n \ .$$

Proof. Let $b = \beta + 2$. We split the sum into two parts:

$$\sum_{1<|C|\leq \frac{1}{2b}\log n} |C| \cdot 2^{|C|\,\beta} + \sum_{\frac{1}{2b}\log n < |C|} |C| \cdot 2^{|C|\,\beta} \ .$$

Observe that because $c \geq 2bl$, we get $\frac{1}{2b}\log n \geq \frac{l}{c}\log n$. Therefore, the right-hand part is zero w.h.p. by part (a) of Lemma 4.1. Hence, by Lemma 4.3, with probability at least $1 - 2\left(\frac{1}{n}\right)^{l-1}$, the above sum is bounded by

$$\sum_{k=2}^{\frac{1}{2b}\log n} \frac{n}{2^{bk}} k 2^{\beta k} \leq n \sum_{k=2}^{\frac{1}{2b}\log n} \left(\frac{1}{2^{b-\beta-1}}\right)^{k} \leq n \ .$$

The last inequality holds as $b = \beta + 2$. $\square$

4.2. The access game. In the following we view a PRAM simulation, or more precisely a protocol for the "1 out of 2" task, as the following process on the access graph H, which we call the *access game* on H. Each processor that wants to access a shared memory cell $u \in U$ asks in each step either $M_{h_1(u)}$ or $M_{h_2(u)}$. Consequently, if a module M_j answers the request for cell u, then the edge labeled u is removed from H. That is, every node in H removes one incident edge (if any). The simulation ends when all the edges from H are removed.

Note that initially all the processors are assigned to the edges in H and that the nodes in H do not know the adjacent edges. We want to view the simulation from the point of view of the nodes; i.e., a node removes an incident edge. For this we assign to each node a processor that computes which of the incoming edges will be removed. Then it sends a message to the processor assigned to this edge to send a request to the respective module.

Remark 1. Lemma 4.1 immediately implies the $\mathcal{O}(\log\log n)$ implementation of the "1 out of 2" task due to Karp, Luby, and Meyer auf de Heide [19]. In each round, each module removes an arbitrary incident edge. Lemma 4.1 ensures that the connected components have at most $\mathcal{O}(\log n)$ edges. Thus, because in each round the number of edges in each connected component is at least halved, $\mathcal{O}(\log\log n)$ rounds suffice to remove all edges.

5. A simulation with delay $O(\log\log n/\log\log\log n)$.

Throughout this section, H will denote the access graph, which is assumed to satisfy the conditions of Lemma 4.4. After the comments in section 4.2, the main challenge is how to remove the edges from the access graph. The first result is a randomized simulation of one step of an EREW PRAM with delay $\mathcal{O}(\log\log n/\log\log\log n)$, w.h.p. Its basic routine works with two hash functions and solves the "1 out of 2" task. The high level description of the protocol in terms of the processors and the modules is as follows. In each step, each module chooses among its incoming requests the one with the highest contention, i.e., for which the memory module storing the other copy gets most requests. For implementing the access protocol we use log-star techniques described in section 3.3 to get an $\mathcal{O}(\log^* n)$-time preprocessing algorithm for computing the number of requests directed to each module.

5.1. The neighbor-data-structure.

We introduce a data structure called *neighbor-data-structure*. The neighbor-data-structure supports the following two operations on the access graph: (i) remove a set of edges and (ii) assign to each nonisolated node its neighbor with the maximum degree.

The preprocessing phase generates an array A of length $4n$. It contains, for each node v, a subarray A_v of length $\tilde{d}(v)$, $d(v) \le \tilde{d}(v) \le 2d(v)$. A_v contains the $d(v)$ edges incident to v and gaps in the remaining positions. Further, an array B of length n contains a pointer to the leftmost cell of A_v for each node v. In addition, the preprocessing phase assigns $\tilde{d}(v)2^{\tilde{d}(v)}$ processors to each nonisolated node v. By Lemma 4.4, at most n processors are needed for this assignment.

For a subgraph H' of H, the neighbor-data-structure is derived from the one for H by simply removing the missing edges from the subarrays A_v. The assignment of processors and the lengths of the A_v's remain unchanged.

NDS PREPROCESSING.

- *Represent each (undirected) edge (i,j) by two ordered pairs $[i,j]$ and $[j,i]$.*
- *Perform strong semisorting with respect to the first coordinate.*
- *Compute for each node v the size $\tilde{d}(v)$ of the subarray A_v containing all edges adjacent to v.*
- *Allocate $\tilde{d}(v)\,2^{\tilde{d}(v)}$ processors to each node v.*

After strong semisorting, the second step of the preprocessing, all edges (the corresponding ordered pairs) adjacent to a node v of degree $d(v)$ appear in a subarray A_v of size $\tilde{d}(v) = \mathcal{O}(d(v))$. The algorithm for the all nearest one problem can be used to find the first and the last edge of each node and therefore to compute the size $\tilde{d}(v)$ of the subarray A_v. The following lemma bounds the time needed for the preprocessing.

LEMMA 5.1. NDS PREPROCESSING *builds up the neighbor-data-structure and can be performed in $\mathcal{O}(\log^* n)$ time on an n-processor DMM, w.h.p.*

Proof. The time bound follows from Lemma 3.3. Note that $d(v) \le \tilde{d}(v) \le 2d(v)$. Hence, by Lemma 4.4, the total size of the neighbor-data-structure is n. In addition, since the degree of v is bounded by the size of its connected component, w.h.p., the total number of allocated processors to each connected component is at most $2\,|C|^2\,2^{2\,|C|}$. Therefore, Lemma 4.4 ensures that we allocate only a linear number of processors, w.h.p. ∎

The following lemma shows how to dynamically manipulate the neighbor-data-structure.

LEMMA 5.2. *Once the neighbor-data-structure is built, one can update the neighbor-data-structure after deletion of any set of edges in constant time on an n-processor DMM.*

Proof. Since each edge e knows its positions in the arrays A_v, one can remove any edge by changing the corresponding positions into gaps. ∎

The next lemma describes the functionality of the neighbor-data-structure.

LEMMA 5.3. *Given the neighbor-data-structure for some subgraph of H, on an n-processor DMM, it is possible in constant time to assign to each nonisolated node a neighbor of maximum degree.*

Proof. Let us look at the array A_v as an array containing marked objects (corresponding to edges adjacent to v) and unmarked objects (corresponding to gaps). To compute the degree of v it is sufficient to compute the number of marked objects in A_v. Since there are only $2^{\tilde{d}(v)}$ combinations of marked and unmarked objects in A_v, one can compute this number in constant time, using $\tilde{d}(v)$ processors for each combination. Note that this amount of processors is available for each node because we allocated an exponential number of processors to each node. Now each node v can get the degrees of all its neighbors in constant time with $\tilde{d}(v)$ processors. To find a node with the maximum degree one can use the standard maximum finding algorithm that runs (deterministically) in constant time with $(\tilde{d}(v))^2$ processors [16, p. 72]. ∎

5.2. Schedule and analysis of the simulation. In section 4 we have shown that if every node always removes an arbitrary adjacent edge, then a simulation with delay $\Theta(\log\log n)$ results. We want to describe a more efficient protocol, SIMULATION 1, using the neighbor-data-structure.

SIMULATION 1.

```
• NDS PREPROCESSING: Build up the neighbor-data-structure.
• Repeat until no more edges are left:
    – In parallel, each node removes the edge
      pointing to a neighbor with highest degree.
    – Update the neighbor-data-structure.
```

We bound the number of iterations of the algorithm.

LEMMA 5.4. SIMULATION 1 *is finished after $\mathcal{O}(\frac{\log\log n}{\log\log\log n})$ iterations, w.h.p.*

Proof. We say an access graph H *survives* k iterations of SIMULATION 1, if at least one edge is left after performing k iterations. We want to construct structures that are embeddable in the access graph H, if it survives k iterations of SIMULATION 1. Let $k \geq 1$. A *k-fork* consists of k different nodes (called *leaves*) connected to one node (called the *center*) that is connected to another node called the *parent node* of the k-fork. A *k-witness* is defined recursively as follows. A 1-witness is a path of length 5 (i.e., with 6 nodes); the two nodes of degree one are the *leaves*. For $k > 1$, a k-witness is a $(k-1)$-witness each leaf of which is a parent node of a different k-fork. All leaves of the k-forks are called the leaves of the k-witness. Note that a k-witness has $2k!$ leaves. An example of a 4-witness is given in Figure 1. The proof of the lemma is based on the following claim.

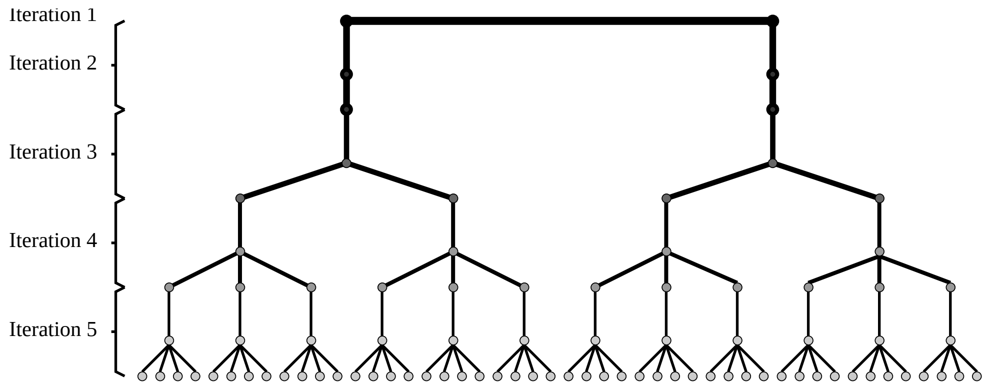

FIG. 1. *A 4-witness.*

CLAIM 5.5. *If H survives k iterations of* SIMULATION 1*, then there is an embedding of a k-witness W in H that maps edges that have a node in common to different edges of H.*

Proof. The proof of the claim is by induction on k. If H survives one iteration, then a path of length 5 must be embeddable in H. Assume now that the claim holds for k and let H survive $k+1$ iterations.

Perform the first iteration on the graph H. A subgraph $\tilde{H} \subseteq H$ which survives k iterations will be left. From the induction hypothesis, we know that a k-witness $\tilde{W}$ can be embedded in $\tilde{H}$ in the way described in the claim. For this structure to survive the last iteration we extend it to a witness-structure W that must be embeddable in H. Since in the first iteration no edge from $\tilde{H}$ has been removed, each node from $\tilde{H}$ must have removed an incident edge in $H - \tilde{H}$. As $\tilde{W}$ is a k-witness, it consists of a $(k-1)$-witness each leaf of which is a parent node of a k-fork. Because each center of a k-fork removes an edge from $H - \tilde{H}$ that points to a neighbor with the maximum degree, its degree in H is at least $k+2$. Thus every leaf v in $\tilde{W}$ must have a neighbor u (different than the center) of degree at least $k+2$. Hence v must be the parent node of a $(k+1)$-fork that consists of v, u and $k+1$ neighbors of u other than v and the center of the k-fork. This defines the required embedding of W in H. ◻

Assume that SIMULATION 1 needs more than k iterations on the graph H. Then by Claim 5.5 a k-witness W is embedded in a connected component C of H.

By Lemma 4.1, $|C| = \mathcal{O}(\log n)$, and C consists of a tree and a constant number ζ of additional edges, w.h.p. In the worst case, at each node of C, at most ζ edges from W can be embedded into these ζ edges of C. Therefore, there must exist a $(k-\zeta)$-witness $\tilde{W}$ that can be embedded one-to-one in C. As $|\tilde{W}| \geq 2(k-\zeta)!$, by the definition of a $(k-\zeta)$-witness, the embedding of W in C as described in Claim 5.5 uses $\Omega((k-\zeta)!)$ nodes of C. Since $|C| = \mathcal{O}(\log n)$, we can embed only a k-witness W for $k = \mathcal{O}(\frac{\log\log n}{\log\log\log n})$. ◻

This lemma together with Lemmas 5.1, 5.2, and 5.3 implies the following theorem.

THEOREM 5.6. *One can simulate one step of an n-processor EREW PRAM on an n-processor DMM with delay $\mathcal{O}(\log\log n/\log\log\log n)$, w.h.p.*

6. Faster simulations. In this section we extend the ideas from the previous section. We present an algorithm that not only computes information on the 2-neighborhood (degrees of neighbors) but explores a larger neighborhood of each node. Then, a second algorithm is presented that removes all edges from the access graph in constant time, assuming each node knows its whole connected component. As a first consequence we give a simple protocol that significantly improves the delay of the simulations presented before. Finally, we present the $\mathcal{O}(\log\log\log n \log^* n)$ delay simulation.

6.1. The path-access-structure. In this subsection we develop some algorithmic utilities for almost random graphs, especially methods for exploring a large neighborhood of a node, which is essential for our algorithms. Throughout this section, H will denote the access graph which fulfills the conditions of Lemma 4.4. The *k-neighborhood* of a node v is the subgraph of H containing the nodes and the edges that are reachable from v by a path of length at most k.

Our simulations use a data structure, called *path-access-structure* (PAS), that allows fast access to all simple paths of length at most k in H. We prove a simple lemma to bound the total length of all simple paths in H.

LEMMA 6.1. *Let C be a connected component that is a tree with a constant number ζ of additional edges and v be a node in C. Then the total number of simple paths starting at v is $\mathcal{O}(|C|)$.*

Proof. The total number of simple paths that do not use the additional edges is $|C|$. The other simple paths can use each additional edge only once. Therefore, the number of simple paths using additional edges can be bounded by $\zeta!2^{\zeta+1}|C| = \mathcal{O}(|C|)$. ∎

Note that, by Lemma 4.1, each connected component C of H has the properties stated in Lemma 6.1, w.h.p. As each simple path in C has length at most $|C|$, we can bound the total length of all simple paths in C by $\mathcal{O}(|C|^3)$, w.h.p. Hence, by the statement made in Lemma 4.4 about the distribution of the sizes of these components, the total length of all the simple paths is $\mathcal{O}(n)$, w.h.p.

The *path-access-structure for (simple paths of length at most) k* is a data structure that supports the following operations on H: (i) remove a set of edges, (ii) assign to each nonisolated node v the node with minimum identifier in the k-neighborhood of v, (iii) assign to each nonisolated node in H an incident edge that begins a simple path of length at least k (if there exists such an edge), and (iv) for all edges e and indices r, $1 \le r \le k$, give the number of simple paths of length exactly r that start with edge e.

Now we describe the implementation details of the path-access-structure for k. We store the simple paths of length at most k in an array S of length $\mathcal{O}(n)$, which consists of padded-consecutive subarrays S_v, one for each node v of H. Each S_v contains a representation of all paths starting in v, each one in consecutive cells. In order to access the paths we build up an array P which consists of padded-consecutive subarrays P_v, one for each node v of H. P_v contains a pointer to the header of each path starting at node v together with the length of this path.

We first give a high level description of how to apply the doubling technique to build up the path-access-structure for simple paths of length at most k.

PAS PREPROCESSING.

```
All nodes are active.
Initialize all the $P_v$ and $S_v$ as empty.
For $r = 0$ to $\log k$ perform the following iteration for all active nodes $v$ in parallel:
    • Using $P_v$, compute an approximate (within a factor of 2) number $\tilde{\delta}_r(v)$ of
      simple paths of length at most $2^r$ starting at $v$.
    • Using $S_v$, compute an approximate (within a factor of 2) total length $\tilde{\gamma}_r(v)$
      of all simple paths starting at $v$.
```

- *Update the sizes of S_v and P_v using $\tilde{\delta}_r$ and $\tilde{\gamma}_r$.*
- *Using the doubling technique, find all simple paths of length l, $2^r < l \leq 2^{r+1}$, starting at v and store them in S_v and P_v.*
- *Inactivate all nodes that are not beginnings of a simple path of length 2^{r+1}.*

LEMMA 6.2. *In time $\mathcal{O}(\log k \log^* n)$, with linear total work, the path-access-structure for all simple paths in H of length at most k can be built on an n-processor DMM, w.h.p., using the procedure* PAS PREPROCESSING.

Proof. The algorithm is based on the standard doubling technique (see, e.g., [16]). We perform $\log k + 1$ iterations and ensure the following invariant after r iterations, $0 \leq r \leq \log k$: Each node v has already found all simple paths of length at most 2^r that start at v, stored them in a padded-consecutive subarray S_v and stored the pointers to each path together with its length in a padded-consecutive subarray P_v. If a given node has already found all its simple paths, then it is *inactive*. Otherwise it is *active*. Note that in each iteration of the algorithm only active nodes participate.

When $r = 0$, then all the paths of length 1 are exactly the edges incident to v. Thus, this 0th iteration of PAS PREPROCESSING is covered by the construction of the neighbor-data-structure. The NDS PREPROCESSING and Lemma 5.1 can be used to build up the neighbor-data-structure. Within $\mathcal{O}(\log^* n)$ time and linear work, one can move all the edges incident to v to a padded-consecutive subarray at the beginning of A_v, w.h.p. (compare section 3.3). This creates the adjacency list of v. Thus, we can create the arrays S_v and P_v. Additionally, we inactivate all isolated nodes.

We perform the $(r+1)$st iteration, for $r \geq 0$, using the doubling technique. Let v be any active node and C_v be its connected component. Note that since v is active, we have $|C_v| \geq 2^r$. First, v computes how many simple paths of length at most 2^r start at v. Because it is hard to compute this value exactly, each node v computes a value $\tilde{\delta}_r(v)$ which is not smaller and at most 2 times larger than the number of paths that start at v. Since the subarray P_v containing the pointers to all simple paths starting at v is padded-consecutive, simply finding the first and the last such paths makes it possible to compute $\tilde{\delta}_r(v)$ after performing the algorithm for the all nearest one problem. Now we compute an approximation $\tilde{\gamma}_r(v)$ of the total length of all simple paths stored at S_v. Since the lengths of all such paths are stored at P_v, we compute $\tilde{\gamma}_r(v)$ using the approximate prefix sums algorithm for all v. The difference between the last cumulative path-lengths in two consecutive subarrays P_v and $P_{v'}$ gives us $\tilde{\gamma}_r(v)$.

Let (x, y) be the last edge of any simple path p of length 2^r which starts at v. To find all paths of length l, $2^r < l \leq 2^{r+1}$, starting with p, we must combine p with all paths of length at most 2^r starting at y. Then we remove the anomalies, i.e., the paths that create cycles.

Observe that, using the values $\tilde{\delta}_r(y)$ and $\tilde{\gamma}_r(y)$, we know how big the new arrays P_v and S_v have to be (for each path p, P_v has to be extended by $\tilde{\delta}_r(y)$ and S_v by $2^r \cdot \tilde{\delta}_r(y) + \tilde{\gamma}_r(y)$). This space allocation can be done using global approximate prefix sums. Observe that $\tilde{\delta}_r(v) = \mathcal{O}(|C_v|)$ and $\tilde{\gamma}_r(v) = \mathcal{O}(|C_v| \cdot 2^r) = \mathcal{O}(|C_v|^2)$, w.h.p., using Lemma 6.1. Hence the size of the new P_v is $\mathcal{O}(|C_v|^2)$, and the size of the new S_v is $\mathcal{O}(|C_v|^3)$, w.h.p.

It is easy to compute the length of each newly created path to maintain P_v. To update S_v we have only to copy the old paths from S_v and concatenate the paths from v to y with simple paths from y. Hence these operations can be performed in constant time with total work proportional to the sizes of the new P_v and S_v. This means that the total work for all nodes is $\sum_{|C| \geq 2^r} \mathcal{O}(|C|^4)$, and the total running time in each iteration is $\mathcal{O}(\log^* n)$, since it is dominated by the cost of computing $\tilde{\gamma}_r(v)$, $\tilde{\delta}_r(y)$ and of allocating the subarrays P_v and S_v.

Finally, we have to remove those obtained paths that are not simple. We identify each path in S_v with the position of the first node. Then we perform strong semisorting within all arrays S_v with respect to the pairs [path, a node on the path]. Now, if there is more than one pair $[p, y]$, which can be verified by applying the all nearest one algorithm, then the path p is not simple and we eliminate it. Strong semisorting within all arrays P_v can be used to remove nonsimple paths from these arrays. Using the lengths of the paths in the P_v's, approximate prefix sums makes it possible to remove all nonsimple paths in the arrays S_v. Hence we can maintain the P_v's and S_v's to be padded-consecutive. Now we inactivate a node v if the new P_v contains no path of length 2^{r+1}.

The running time of iteration r is $\mathcal{O}(\log^* n)$ with $\mathcal{O}(\sum_{|C|\geq 2^r} |C|^4)$ total work. Therefore, the total work of the algorithm is

$$\mathcal{O}\left(\sum_{r=0}^{\log k} \sum_{|C|\geq 2^r} |C|^4\right) = \mathcal{O}\left(\sum_{C} |C|^4 \log |C|\right),$$

and by Lemma 4.4, this is $\mathcal{O}(n)$. ∎

Now we show how to maintain the path-access-structure dynamically, that is, when we allow removing edges from the graph. The proof of the following lemma is in the spirit of the proof of Lemma 6.2.

LEMMA 6.3. *Assume that the path-access-structure has already been built. Then, after removing some edges from the graph, it can be updated in time $\mathcal{O}(\log^* n)$ on an n-processor DMM, w.h.p.*

Proof. First we perform the preprocessing step and run strong semisorting on all arrays S_v with respect to the names of the edges. (Of course, it causes no problem to find and look at the edges instead of the nodes.) The result is an array $\mathcal{R}$ of linear size, such that for each edge e in a padded-consecutive subarray of $\mathcal{R}$ all the occurrences on all simple paths together with the pointers to these paths in P_v's are stored.

Now, when an edge e is removed, we can easily remove from the arrays P_v and S_v all simple paths on which e occurs. To remove all the edges, one needs constant time and work proportional to the size of $\mathcal{R}$. If one requires that all the subarrays P_v and S_v still have to be padded-consecutive, then additional $\mathcal{O}(\log^* n)$ time is needed. ∎

LEMMA 6.4. *Assume that the path-access-structure for k has been built. Then, to each nonisolated node one can assign the node with the minimum identifier in its k-neighborhood in $\mathcal{O}(\log^* n)$ time on an n-processor DMM.*

Proof. All simple paths that start at v and are of length at most k are stored in a padded-consecutive subarray S_v. Thus, this subarray contains exactly the nodes from the k-neighborhood of v. Now each node v can find the node w with the minimal identifier in its k-neighborhood in $\mathcal{O}(\log^* n)$ time. Each node v has $|S_v| = \mathcal{O}(|C_v|^2)$ candidates, where C_v denotes the connected component v belongs to, and using $|S_v|^2 = \mathcal{O}(|C_v|^4)$ processors it can find the node with minimum identifier in constant time [16, p. 72]. $\mathcal{O}(\log^* n)$ time is needed for assigning processors to the nodes by using approximate prefix sums. ∎

LEMMA 6.5. *Assume that the path-access-structure for k is given. One can assign to each node its incident edge that begins a simple path of length at least k in constant time on an n-processor DMM.*

Proof. For each node v the array P_v immediately gives such an edge. ◻

The next lemma shows how to use the path-access-structure for k to count the number of all simple paths of length at most k.

LEMMA 6.6. *Suppose that the path-access-structure for k is given. Then, for all edges e and integers r, $1 \leq r \leq k$, the number of simple paths of length exactly r that start with edge e can be computed in $\mathcal{O}(\log^* n)$ on an n-processor DMM, w.h.p.*

Proof. For each simple path in all S_v's we consider the pairs [starting edge of the path, length of the path]. We perform strong semisorting with respect to these keys. In this way, all the simple paths (in fact their representatives) that start with the same edge e and are of the same length r are stored in a padded-consecutive subarray, which we call $X_{e,r}$. If $y_{e,r}$ denotes the number of such paths, then $y_{e,r} \leq |X_{e,r}| \leq 2y_{e,r}$. We allocate $|X_{e,r}| \cdot 2^{|X_{e,r}|}$ processors to the pair $[e, r]$ and compute $y_{e,r}$ in the same way as in the proof of Lemma 5.1 in constant time. Now we have to show that we use only n processors. Let C_e be the connected component e belongs to. By Lemma 4.1, $y_{e,r} = \alpha|C_v|$ and each connected component C has at most $\beta|C|$ edges, for some constants α and β. Hence

$$\sum_{e\in E}\sum_{r=0}^{k}|X_{e,r}|\cdot 2^{|X_{e,r}|} \leq \sum_{C}\sum_{e\in C}|C|\cdot(2y_{e,r})2^{2y_{e,r}} \leq \sum_{|C|>1} 2\alpha\beta|C|^3 2^{2\alpha|C|} \leq \sum_{|C|>1}|C|2^{b|C|}$$

for some constant b. Lemma 4.4 ensures that this is bounded by n. ◻

A *k-branch* of a node v in the access graph H is the set of all different simple paths of length at most k that start with the same edge incident to v. Clearly, for every node v the number of its k-branches equals its degree. Define LEVEL(r) of a k-branch of a node v to be the set of all simple paths of length r, $0 < r \leq k$, of this k-branch. The *weight* of a k-branch of a node v is the bit-vector $\overline{w} = (w_1, \dots, w_k)$, where w_r is 1 if and only if the number of simple paths in LEVEL(r) of the branch is at least 2^{r-1}. We order the weights with respect to the lexicographical ordering. Informally, a k-branch is lexicographically larger than another k-branch, if it is more similar to a complete binary tree with respect to the number of nodes in each level.

LEMMA 6.7. *Suppose that the path-access-structure for k is given. Then one can assign to each node in H an incident edge that begins a k-branch with maximum weight in $\mathcal{O}(\log^* n)$ time on an n-processor DMM.*

Proof. Using Lemma 6.6, each node can get the weights of all incident k-branches in $\mathcal{O}(\log^* n)$ time. Let C_v denote the connected component containing node v. Each node has $\mathcal{O}(|C_v|)$ k-branches, each of depth $\mathcal{O}(|C_v|)$. Hence it can find a k-branch with the maximum weight in constant time using $|C_v|^4$ processors using the standard algorithm (see, e.g., [16, p. 72]). Hence all nodes together can find the required k-branches in constant time on a p-processor DMM with $p = \sum_v |C_v|^4 = \sum_{|C|>1} |C|^5$. By Lemma 4.4, $p \leq n$. ◻

6.2. Cleaning up connected components.

The $\mathcal{O}(\log\log n/\log\log\log n)$-time simulation from section 5 is based on very local information. Each node looks only at its neighbors in the access graph and, based on their degrees, chooses one incident edge. The main idea leading to improvements of that result is to analyze the access graph in a nonlocal way and to try to use information on as many nodes and edges as possible.

The notion of the k-neighborhood plays the crucial role. Instead of looking only at the neighbors, now each node v will base the decision which incident edge to remove on the structure of its k-neighborhood. We will explore the k-neighborhood of each node in H. As we have seen in Lemma 6.2, essentially all information on the k-neighborhood can be computed in time $\mathcal{O}(\log k \log^* n)$. In this subsection we will describe a process that removes all edges from a connected component with diameter δ in time $\mathcal{O}(\log \delta \log^* n)$.

Cleaning up Connected Components.

```
• PAS Preprocessing: Build up the path-access-structure.
• Perform for each node in parallel:
    – Each node $v$ obtains the node $w$ with the minimal identifier in its component.
    – If $v \neq w$, then $v$ finds all nodes $u_1, u_2, \ldots, u_r$, such that $(v, u_i)$ is the
      first edge of a simple path from $v$ to $w$.
    – $v$ removes the edges $(v, u_i)$, $1 \leq i \leq r$.
```

The access protocols described in previous papers (e.g., in [19], see also Remark 1 in section 4.2) show how to remove all edges of a connected component C of H in time $\mathcal{O}(\log(|C|))$. The following lemma proves that Cleaning up Connected Components achieves time $\mathcal{O}(\log(\text{diameter of } C))$. Note that this does not give fast simulations on its own, because H has a connected component of diameter $\Omega(\log n / \log \log n)$, with constant probability (see Lemma 10.2).

Lemma 6.8. *Let δ be the maximum diameter of the connected components of H. Then* Cleaning up Connected Components *removes all edges in H in time $\mathcal{O}(\log \delta \log^* n)$, w.h.p.*

Proof. As it is shown in Lemma 6.2, one can build up the path-access-structure for δ in time $\mathcal{O}(\log \delta \log^* n)$ on an n-processor DMM. Because for each node its δ-neighborhood is equal to its connected component, Lemma 6.4 allows us to find the nodes w in Cleaning up Connected Components in $\mathcal{O}(\log^* n)$ time.

By Lemma 4.1 we have $r = \mathcal{O}(1)$, w.h.p. Now we may use the array S from the path-access-structure to find for each node v the nodes $u_1, \ldots, u_r$ in $\mathcal{O}(1)$ time. Notice also that each edge e of H must be of the form (v, u_i) for some v and i. Therefore, at the end of the algorithm all the edges are removed. Since $r = \mathcal{O}(1)$ w.h.p., the last step of the algorithm takes $\mathcal{O}(1)$ time, w.h.p. ∎

6.3. An $O(\sqrt{\log\log n}\log^* n)$-delay simulation. The $\mathcal{O}(\sqrt{\log\log n}\log^* n)$ simulation consists of three phases and may be described on a high level in the following way. Let $k = 2^{\sqrt{\log\log n}}$.

Simulation 2.

```
• PAS Preprocessing: Build up the path-access-structure for $k$.
• Repeat $2 \cdot \log\log n / \log k$ times:
    – Each node removes an incident edge which is the beginning of a simple
      path of length at least $k$, if there exists such an edge.
    – Update the path-access-structure.
• Cleaning up connected components.
```

Since the clean-up phase removes all edges from H, the correctness of the algorithm is obvious. We show that after performing the loop in the second phase of Simulation 2, we have partitioned H so that the diameter of each connected component is at most $2k$. Therefore, the clean-up phase can be performed in time $\mathcal{O}(\log k \log^* n)$ on an n-processor DMM, w.h.p., as shown in Lemma 6.8.

We say that a connected component C of H *survives* t iterations of Simulation 2 if at least one edge of C is not removed at the end of the tth iteration in the second phase. The idea of the proof is to bound the size of C.

LEMMA 6.9. *After the second phase of* SIMULATION 2*, the diameter of each connected component is at most* $2k$*, w.h.p.*

Proof. Consider a connected component C of H that survives t iterations and any maximal connected subgraph C_t of C of size larger than 1 that is left after t iterations. Define inductively a sequence $C_t, C_{t-1}, \dots, C_0$ such that for every i, $0 \le i < t$, C_i is a maximal connected subgraph of C that survives the ith iteration and contains C_{i+1}.

If the diameter of C_t is greater than $2k$, then every node v on C_t is the beginning of a simple path of length k. Hence, according to the elimination rule of the first phase of SIMULATION 2, every node has removed in this iteration an incident edge not belonging to C_t which was the beginning of a simple path of length at least k. (Note that if the diameter of C_t is greater than $2k$, then this also holds for C_{t-i}, $1 \le i \le t$.)

The $|C_t| \cdot k$ edges of these paths are edges of the access graph H. Since each path is simple, edges of one path are embedded injectively. From Lemma 4.1 we know that each connected component C consists of $|C| + \mathcal{O}(1)$ edges. Hence, it has only a constant number ζ of cycles. If we embed edges of two of these paths to the same edge in H, then the sum of the two paths contains a cycle in H. Therefore, at least $|C_t| - \zeta$ of these simple paths of length k are disjoint from each other in the embedding, that is, C_{t-1} has $k \cdot (|C_t| - \zeta) \ge \frac{k}{2} \cdot |C_t|$ edges.

This recursion shows: if a connected component C survives t iterations in the second phase of SIMULATION 2, and if a connected part of C left at the end of the tth iteration has diameter greater than $2k$, then C must be of size $\Omega(k^t/2^t)$. Now assume that this is the case for $t = 2 \cdot \log\log n / \log k$. Then C must be of size $\Omega(\log^2 n)$, which contradicts Lemma 4.1. ∎

From Lemmas 6.2, 6.3, and 6.5, it follows that it is possible for each node to analyze in the first phase its k-neighborhood in time $\mathcal{O}(\log k \log^* n)$ and each iteration in the second phase can be executed in time $\mathcal{O}(\log^* n)$, w.h.p. Therefore, if we set $k = 2^{\sqrt{\log\log n}}$ and apply the majority technique we obtain the following theorem.

THEOREM 6.10. *One can simulate one step of an n-processor EREW PRAM on an n-processor DMM with $\mathcal{O}(\sqrt{\log\log n}\log^* n)$ delay, w.h.p.*

6.4. An $O(\log\log\log n \log^* n)$-delay simulation. In this subsection we describe a simulation of an n-processor EREW-PRAM on an n-processor DMM that improves all previously known simulations exponentially. Essentially, we show how to partition each connected component using information about the $(\log\log n)$-neighborhood so that the diameter of the largest connected component is $\mathcal{O}((\log\log n)^2)$. Then we can apply the CLEANING UP CONNECTED COMPONENTS procedure to remove the remaining edges in H. To achieve an improvement compared to SIMULATION 2, we use the knowledge about the k-neighborhood in a more efficient way.

SIMULATION 3.
- PAS PREPROCESSING*: Build up the path-access-structure.*
- *Each node v removes the incident edge which is the beginning of a k-branch with maximal weight.*
- CLEANING UP CONNECTED COMPONENTS.

Lemmas 6.2 and 6.7 make sure that the first two phases of SIMULATION 3 can be performed in time $\mathcal{O}(\log k \log^* n)$, w.h.p. Now we prove that at the beginning of the clean-up phase the maximum diameter of each connected component in H is at most $\mathcal{O}(k^2)$, w.h.p., for $k \ge \log\log n$.

LEMMA 6.11. *Let $k \ge \log\log n$, and ζ denote the number of cycles in the access graph H. After the second phase of* SIMULATION 3*, w.h.p., H does not contain any simple path of length more than $(\zeta + 1) \cdot (2k + 1)^2$.*

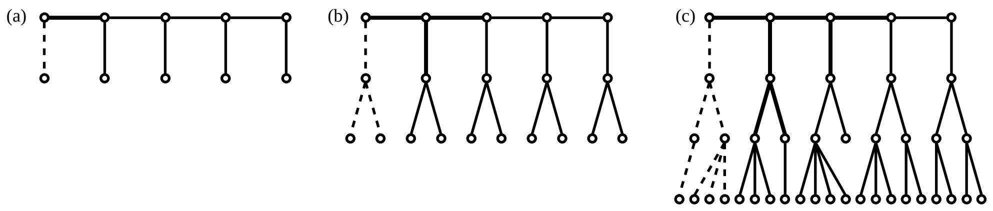

FIG. 2. (a) *the path $\tilde{p}$ with the edges that are removed by the nodes of $\tilde{p}$;* (b) *the path $\tilde{p}$ with the edges required by the elimination rule on* LEVEL(2)*;* (c) *the path $\tilde{p}$ with the edges required by the elimination rule on* LEVEL(3)*.*

Proof. Assume, to the contrary, that at the beginning of the clean-up phase a simple path p of length $(\zeta+1)\cdot(2k+1)^2$ survives. Let us call a branch that starts with an edge from p the *path-branch*, and let us call any k-branch chosen in the second phase of SIMULATION 3 by a node from p the *side-branch* of this node. Since no edge of the path p has been removed in the first step, for each node of p, the side-branch differs from the path-branch. Lemma 4.1 ensures that $\zeta = \mathcal{O}(1)$. Hence there exists a subpath $\tilde{p} = (v_0, v_1, \dots, v_{2k})$ of p, such that all vertices of the side-branches of nodes from $\tilde{p}$ are not contained in any cycle of length smaller than $2k$.

If the weight of a k-branch satisfies $w_1 = w_2 = \cdots = w_r = 1$, then we call it *$r$-complete*. We show that for each node from $\tilde{p}$ the side-branch must be r-complete; for all nodes v_i, $0 \le i \le 2k-r$, the right path-branch (starting from the edge (v_i, v_{i+1})) is r-complete; and for all nodes v_i, $r \le i \le 2k$, the left path-branch (starting from the edge (v_i, v_{i-1})) is also r-complete.

We prove the desired properties by induction on the levels (defined in section 6.1). For an example see Figure 2.

LEVEL(1). Because no edge of a simple path $\tilde{p}$ of length $2k$ was removed in the first step of the algorithm, each node from $\tilde{p}$ had to remove an incident edge not belonging to $\tilde{p}$. Therefore for each node from $\tilde{p}$ the side-branch is 1-complete. Similarly, since for each node from $\tilde{p}$ each path-branch has $w_1 = 1$, for each node v_i, $0 \le i \le 2k-1$, the right path-branch is 1-complete, and for each node v_i, $1 \le i \le 2k$, the left path-branch is 1-complete.

LEVEL(r). Now assume that $r > 1$ and for each node of $\tilde{p}$ the side-branch and the respective path-branches are $(r-1)$-complete. Consider a node v_i, $0 \le i \le 2k-r$, and the edge (v_i, v_{i+1}). Since the side-branch and the right path-branch of v_{i+1} are both $(r-1)$-complete and disjoint and have no cycle of length smaller than or equal to k, the right path-branch of v_i also must be r-complete. The nodes v_i, $r \le i \le 2k$, can be treated in a similar way.

This implies that we need a connected structure containing at least $2k\cdot 2^{k-1}$ nodes in H for a simple path of length $(\zeta+1)\cdot(2k+1)^2$ to survive the second phase of SIMULATION 3. For $k \ge \log\log n$ this contradicts Lemma 4.1. ☐

This yields the following result.

THEOREM 6.12. *One can simulate one step of an n-processor EREW PRAM on an n-processor DMM in $\mathcal{O}(\log\log\log n \log^* n)$ time, w.h.p.*

7. Reduction from CRCW PRAM to EREW PRAM.

In this section we show how to reduce the problem of simulating a CRCW PRAM on a DMM to the simulation of an EREW PRAM. It is standard to build simulations of CRCW PRAMs by combining sorting with simulations for EREW PRAMs. However, since we are interested in very fast simulations for which sorting is too slow, our reduction is based on strong semisorting. Suppose that processor P_i of the CRCW PRAM wants to access memory cell $u_i \in U$, for $1 \le i \le n$. In order to reduce the problem to the EREW PRAM we have to show how to deal with duplicate requests to the same memory cell. We consider only reading accesses; writing accesses can be performed similarly.

We first perform strong semisorting on pairs $(u_1, 1), \ldots, (u_n, n)$ with respect to the first coordinate. This results in the addresses with the same value being stored in a padded-consecutive subsequence of the output sequence. Using the algorithm for the all nearest one problem each u_i can test whether it is the first element in the padded-consecutive subsequence or not. If so, we call u_i a *leader*. Notice that if u_i is not a leader, then the solution to the all nearest one problem provides the pointer to its leader. Now we perform an EREW simulation on the DMM with requests only from leaders. Afterwards all leaders have accessed their cell u_i and can broadcast the value to the duplicates in constant time.

LEMMA 7.1. *If one step of an n-processor EREW PRAM can be simulated on an n-processor DMM with delay t, w.h.p., then one step of an n-processor CRCW PRAM can be simulated on an n-processor DMM with delay $\mathcal{O}(t + \log^* n)$, w.h.p.*

Coupled with Theorem 6.12, this yields the following theorem.

THEOREM 7.2. *One step of an n-processor CRCW PRAM can be simulated on an n-processor DMM with $\mathcal{O}(\log^* n \log\log\log n)$ delay, w.h.p.*

8. All-but-linear routing.

In this section we analyze a relaxed version of the routing problem, the *all-but-linear routing* problem. Unlike in the general routing problem, we do not require that all messages are delivered to their destinations, but we have to route a large fraction of the messages. The motivation for our study is the problem of transforming simulations of n-processor PRAMs by n-processor DMMs into time-processor optimal simulations. As we will show in section 9, a fast solution for all-but-linear routing can be directly applied to obtain efficient time-processor optimal PRAM simulations.

DEFINITION 6. *In the* all-but-linear routing *problem on an n-processor DMM each processor Q_i has k keys $u_{i,1}, u_{i,2}, \ldots, u_{i,k}$, each to be sent to a destination from $M_0, \ldots, M_{n-1}$. The task is to deliver all but $\mathcal{O}(n)$ of the $n \cdot k$ keys.*

In our application we will need the destinations of the keys to be chosen almost randomly. The actual input for the PRAM simulation consists of *kn distinct* integers $x_{1,1}, \ldots, x_{n,k}$ from $[m]$, and we let $u_{i,j} = h(x_{i,j})$, for $i \in [n], j \in [k]$, where h is chosen uniformly at random from a $(2, \log^2 n)$-universal class $\mathcal{H}_{m,n}$ of hash functions (see section 3.1). We call such an instance of all-but-linear routing *quasi-random*. In fact, we could give a simpler solution if h were a truly random function (see [30]).

Our main result in this section is the following theorem.

THEOREM 8.1. *The quasi-random all-but-linear routing problem can be solved in time $\mathcal{O}(k + \log^* n)$, w.h.p., for $k \le \sqrt[4]{\log n}$.*

Our solution for quasi-random all-but-linear routing is based on an algorithm for the $k - k$ relation routing problem by Goldberg et al. [11].

DEFINITION 7. *In the $k - k$ relation routing problem, each processor wants to send at most k messages to other processors which are assumed to be distinct. The destinations can be arbitrary except that each processor is the destination of at most k messages.*

8.1. Reduction to $k - k$ relation routing.

We will reduce quasi-random all-but-linear routing to $k-k$ relation routing by achieving the following two goals. First, we will ensure that each processor has only keys with distinct destinations. Second, we will restrict the problem to processors that are destinations of $\mathcal{O}(k)$ messages.

The first problem can be solved using an element distinctness algorithm for each processor. That is, each processor Q_i sequentially runs through its keys $u_{i,1}, \ldots, u_{i,k}$ and finds all duplicate destinations. This can be done by using, for example, bucket sorting, in $\mathcal{O}(k)$ time and with $\mathcal{O}(n)$ space for each processor. Let us call a processor *bad* if it has keys that have the same destination.

LEMMA 8.2. *If $k = \mathcal{O}(\sqrt[4]{\log n})$, then $\mathcal{O}(\log^2 n)$ processors are bad, w.h.p.*

Proof. Let X_i, $i = 1, \ldots, n$, denote the binary random variable indicating if processor P_i is bad or not. Processor P_i is bad with probability at most $\binom{k}{2}\frac{2}{n} \le \frac{k^2}{n}$, that is, $P(X_i = 1) \le k^2/n$. Let $X = \sum X_i$. Since the keys have destinations chosen by a function h taken at random from a $(2, \log^2 n)$-universal class of hash functions, the choices of any $ek^2 \log n$ processors are almost independent (cf. Definition 1). In particular, we can give the following bound for $X = \sum_{i=1}^{n} X_i$:

$$\Pr(X \ge ek^2 \log n) \le \binom{n}{ek^2 \log n} 2 \left(\frac{k^2}{n}\right)^{ek^2 \log n} \le 2 \left(\frac{1}{\log n}\right)^{ek^2 \log n} \le \frac{1}{n^{\log \log n}}. \qquad \square$$

Hence, for all-but-linear routing, we can leave all keys of bad processors unprocessed, subsuming them in the $\mathcal{O}(n)$ remaining keys. To reduce the remaining all-but-linear routing to $k - k$ relation routing, we need the following lemma that bounds the number of keys that have their destination at modules with load at least $\Omega(k)$.

LEMMA 8.3. *Let h be chosen uniformly at random from a $(2, \log^2 n)$-universal class of hash functions with range $[n]$, and $1 \le k \le \frac{\log n}{\log \log n}$. If $n \cdot k$ keys are distributed among n locations using h, then at most $\frac{n}{2^k}$ keys are in locations with load at least $8k$, w.h.p.*

Proof. Denote the nk keys by $b_0, \ldots, b_{nk-1}$. A location is *heavy* if its load is at least $8k$. We associate with each key b_i a binary random variable $\mathcal{E}_i$ with $\mathcal{E}_i = 1$ if b_i is in a heavy location; otherwise $\mathcal{E}_i = 0$.

We want to bound the random variable $X = \sum_{i=0}^{kn-1} \mathcal{E}_i$. Again we use the kth moment inequality (Lemma 3.2) and therefore compute $E(X^s)$ for $s = \Theta(\log n)$.

$$E(X^s) = \sum_{(j_1,\ldots,j_s)\in[kn]^s} E(\mathcal{E}_{j_1} \cdots \mathcal{E}_{j_s}) = \sum_{z=1}^{s} \sum_{\substack{(j_1,\ldots,j_s)\in[kn]^s \\ z \text{ of the } j_i \text{ are different}}} E(\mathcal{E}_{j_1} \cdots \mathcal{E}_{j_s}) \ .$$

First we bound each term $E(\mathcal{E}_{j_1} \cdots \mathcal{E}_{j_s})$. Fix keys $(j_1, \ldots, j_s) \in [kn]^s$ such that z of the j_i are different. $E(\mathcal{E}_{j_1} \cdots \mathcal{E}_{j_s})$ is equal to the probability that each of the z keys has its destination in a heavy location. This probability is bounded by the sum over all possible locations of the z keys of the probabilities that the z keys have destinations in given locations and that the locations are heavy. Since h is chosen from a $(2, \log^2 n)$-universal class of hash functions and $z < \log^2 n$, the probability that the z keys have destinations in given r locations, $1 \le r \le z$, is bounded by $r^z \cdot 2/n^z$. For $r \le z/8k$, we trivially estimate the probability that r locations are heavy by 1. If $z/8k < r \le z$, then we observe that in order to r locations be heavy there must be other $8kr - z$ keys with destinations in the r locations. Therefore in that case we bound the probability that the r locations are heavy by $\binom{nk}{8kr-z} \cdot 2 \cdot (r/n)^{8kr-z}$.

Hence, we obtain

$$\begin{aligned} E(\mathcal{E}_{j_1}\cdots\mathcal{E}_{j_s}) &\le \sum_{1\le r\le \frac{z}{8k}} \binom{n}{r} 2\left(\frac{r}{n}\right)^z + \sum_{\frac{z}{8k}<r\le z} \binom{n}{r} 2\left(\frac{r}{n}\right)^z \binom{nk}{8kr-z} 2\left(\frac{r}{n}\right)^{8kr-z} \\ &\le 2\sum_{r\le\frac{z}{8k}} \left(\frac{ne}{r}\right)^r \left(\frac{r}{n}\right)^z + 4\sum_{\frac{z}{8k}<r\le z} \left(\frac{ne}{r}\right)^r \left(\frac{r}{n}\right)^z \left(\frac{nker}{(8kr-z)n}\right)^{8kr-z} \\ &\le 4\left(\frac{8ekn}{z}\right)^{\frac{z}{8k}} \left(\frac{z}{8kn}\right)^z + 8\left(\frac{en}{z}\right)^z \left(\frac{z}{n}\right)^z \left(\frac{kez}{(8k-1)z}\right)^{(8k-1)z} \\ &\le 4\left(\frac{z}{\sqrt{n}}\right)^z + \left(\frac{1}{2}\right)^{8(k-1)z} \\ &\le 5\left(\frac{1}{2}\right)^{8(k-1)z} . \end{aligned}$$

The third inequality holds for $k = \mathcal{O}(\log n/\log\log n)$ and $z = o(n)$, which holds as $z \le s = \Theta(\log n)$. In this case it is easily seen that the terms in each sum at least double when r increases. Hence we can bound each sum by two times the largest term. Now we can bound $E(X^s)$:

$$\begin{aligned} E(X^s) &\le \sum_{z=1}^{s} \sum_{\substack{(j_1,\dots,j_s)\in[kn]^s \\ z \text{ of the } j_i \text{ are different}}} 5\left(\frac{1}{2}\right)^{8(k-1)z} \\ &\le \sum_{z=1}^{s} \binom{s}{z} (kn)^z z^{s-z} 5\left(\frac{1}{2}\right)^{8(k-1)z} \\ &\le 5\sum_{z=1}^{s} z^s \left(\frac{sekn}{z^2 2^{8(k-1)}}\right)^z \\ &\le 10 s^s \left(\frac{ekn}{s 2^{8(k-1)}}\right)^s \\ &\le \left(\frac{n}{2^{2k}}\right)^s . \end{aligned}$$

Again, each term of the sum in the third line at least doubles for large enough n if z increases. Hence, we have bounded the sum by two times the largest term.

As the $\mathcal{E}_i$ and therefore also X are nonnegative random variables, we finally get

$$\Pr(X \ge \alpha) \le \frac{E(X^s)}{\alpha^s} \le \left(\frac{n}{2^{2k}\alpha}\right)^s .$$

For $\alpha = \frac{n}{2^k}$ we get

$$\Pr\left(X \ge \frac{n}{2^k}\right) \le \left(\frac{1}{2^k}\right)^s .$$

For any positive l, if $s \ge l \log n$, then this probability is bounded by n^{-l}. ☐

8.2. $k-k$ relation routing. It remains to show that we can perform the $k-k$ relation routing in time $\mathcal{O}(k)$. As was observed by Anderson and Miller [1], one can solve the off-line version of the problem in k steps. However, we are interested in this problem when each processor has only the information about the messages it has to send, and it can learn about the messages of the other processors only by sending and receiving messages.

It is easy to see that any $k-k$ relation routing can be performed in time k^2 on a DMM, but our aim is to do this faster. Anderson and Miller [1] considered the $k-k$ relation routing problem on a model equivalent to a 1-collision DMM and showed how to solve $\log n - \log n$ relation routing in $\mathcal{O}(\log n)$ expected time. Valiant [33] considered the more general problem. He described a $\Theta(\log n + k)$ expected time algorithm on the same model. This result was improved by Goldberg et al. [11], to an algorithm for the $k-k$ relation routing problem running in $\mathcal{O}(\log\log n + k)$ time, w.h.p. We describe a faster algorithm on an DMM.

THEOREM 8.4. *The $k-k$ relation routing problem can be solved on an n-processor DMM in $\mathcal{O}(\min\{\log^* n + k, k^2\})$ communication steps for any $k \le n^{1/11}$.*

The proof of this theorem uses known methods and techniques from [1, 11]. In fact it is very similar in spirit to the results presented there. Nevertheless we present the full proof in order to make our description of the all-but-linear routing algorithm self-contained.

To prove the theorem we first describe the randomized routing protocol. It consists of $\mathcal{O}(\log k)$ rounds. In round i the problem of a $k/2^{i-1} - k/2^{i-1}$ relation routing will be reduced to a $k/2^i - k/2^i$ relation routing problem. After the last round all but n/k of the $n \cdot k$ keys will be delivered. Then we redistribute the remaining keys among the processors and deliver them in $\mathcal{O}(k)$ steps, w.h.p.

Before presenting more details we introduce some notation. We call a processor *overloaded* at the beginning of round i if the number of keys it has not already delivered is greater than $k/2^{i-1}$. Similarly we call a module *overloaded* at the beginning of phase i if the number of keys that it still has to receive is greater than $k/2^{i-1}$. A module or a processor, respectively, becomes overloaded in round i if it was not overloaded at the beginning of round i but it is at the beginning of round $i+1$. The idea of the algorithm is that in each round only nonoverloaded processors *participate*, i.e., only those keys participate that are not sent by an overloaded processor. Additionally we consider only keys sent to a nonoverloaded module. The main problem is to bound the number of overloaded processors and modules and hence the number of keys that are left after the $\log k$ rounds. Let c be a positive constant, $c \ge 80$.

$k-k$ RELATION ROUTING.

```
(1) For $1 \le i \le \log(\frac{k}{5\log k}) + 1$, perform the following round $i$:
    Only processors that have fewer than $k/2^{i-1}$ keys left to send participate.
      • Repeat $c \cdot k/2^i$ times:
        Each participating processor chooses a random number $r$ from $[\frac{k}{2^{i-1}}]$ and
        tries to send the $r$th undelivered message, if it exists.
(2) All processors that have fewer than $5\log k/2$ nondelivered keys send the keys
    one by one, each key $5\log k/2$ times.
(3) Redistribute evenly the remaining keys using approximate parallel prefix sums
    applied to the numbers of nondelivered keys belonging to each processor.
(4) Deliver the remaining keys.
```

The proof of the theorem is based on the following lemma which bounds the number of keys not participating.

LEMMA 8.5. *Let $k \le n^{1/11}$, and let i be an arbitrary round in the first step of the $k-k$ relation routing algorithm above. Then at most n/k^4 modules and at most n/k^4 processors become overloaded in round i, w.h.p.*

Proof. Consider an arbitrary round i of the algorithm, $1 \leq i \leq (\frac{k}{5\log k}) + 1$. Let x_j denote the sequence of integers randomly chosen by processor P_j during round i.

We first prove that the number of overloaded modules at the beginning of round $i+1$ can be bounded by n/k^4, w.h.p. Let Y_M be the number of modules that become overloaded during round i. Let M be a module that is not overloaded at the beginning of round i, and let m_j denote the number of participating keys that are destined for M at the jth step of round i. Notice that M cannot become overloaded in round i if m_j is less than $k/2^i$. Therefore, in that case, the probability that M does not receive a message in the jth step is

$$\left(1 - \frac{1}{k/2^{i-1}}\right)^{m_j} \leq \left(1 - \frac{1}{k/2^{i-1}}\right)^{k/2^i} \leq e^{-1/2} \ .$$

Observe now that if M is overloaded at the end of round i, then in at least $ck/2^i - k/2^i$ steps of this round no message is received by M. Therefore, we can bound the probability that M is overloaded at the end of round i by

$$\binom{c \cdot k/2^i}{k/2^i} \cdot (e^{-1/2})^{c\cdot k/2^i - k/2^i} \leq (ec)^{k/2^i} \cdot (e^{-1/2})^{(c-1)\cdot k/2^i} = \left(c \cdot e^{3/2 - c/2}\right)^{k/2^i} \ .$$

Since we have assumed that $i \leq \log(\frac{k}{5\log k}) + 1$ and $c \geq 80$, we may bound the probability by $1/2k^4$. This immediately implies that $E(Y_M)$, the expected number of modules that become overloaded in round i, is at most $n/2k^4$. Now we apply the method of bounded differences (Lemma 3.1) to bound the probability that $Y_M \geq n/k^4$. For this we view Y_M as the image of a function f_M:

$$Y_M = f_M(\{x_j | P_j \text{ is participating at the beginning of round } i\}) \ .$$

Observe that any change of the choice of P_j in a single step from key α to β may change only the load of the two modules being destinations of α and β. Since all choices of P_j are independent, a change of the value of x_j for any j may change the number of modules overloaded in round i by at most $2ck/2^i \leq ck$. Hence we apply Lemma 3.1 to get

$$\Pr(Y_M \geq n/k^4) \leq \Pr(Y_M \geq n/2k^4 + E(Y_M)) \leq \exp\left(-\frac{2(n/k^4)}{n(ck)^2}\right) = \exp\left(-\frac{2n}{c^2k^{10}}\right).$$

This probability is exponentially small for $k \leq n^{1/11}$.

Now we want to show that, w.h.p., at most n/k^4 processors become overloaded during round i. Let Y_P be the number of processors that become overloaded during round i. Let P be any participating processor in round i and let p_j denote the number of keys that P still has to send in the jth step of round i.

Let $d_{l,j}$ denote the number of participating keys in the jth step that have the same destination as the lth key that P has to send. We consider only those P that do not send to overloaded modules. Therefore each $d_{l,j}$ is less than or equal to $k/2^{i-1}$. Note that P cannot become overloaded in round i if p_j is ever less than $k/2^i$. Thus we consider only the case $p_j \geq k/2^i$ for all j. In that case the probability that P sends a key successfully in the jth step is at least

$$\sum_{l=1}^{p_j} 2^{i-1}/k \cdot \left(1 - 2^{i-1}/k\right)^{d_{l,j}-1} \geq \sum_{l=1}^{p_j} 2^{i-1}/k \cdot \left(1 - 2^{i-1}/k\right)^{k/2^{i-1}} \geq 1/2e^2 \ .$$

Therefore, using arguments similar to those above, we obtain that the probability that P stops participating in round i is at most

$$\binom{ck/2^i}{k/2^i} \cdot (1-1/2e^2)^{(c-1)k/2^i} \leq \left(e \cdot c \cdot (1-1/2e^2)^{c-1}\right)^{k/2^i} .$$

Since $i \leq \log(\frac{k}{5\log k}) + 1$ and we set $c \geq 80$, this probability is bounded by $1/2k^4$. As in the proof of the first part, we can conclude that the expected number of processors that become overloaded during round i is at most $\frac{n}{2k^4}$. One can verify that if the value of x_j changes for any j, then Y_P changes by at most ck. Therefore, by the method of bounded differences (Lemma 3.1), the probability that Y_P is greater than n/k^4 is at most

$$\Pr\left(Y_P \geq \frac{n}{k^4}\right) \leq \Pr\left(Y_P \geq \frac{n}{2k^4} + E(Y_P)\right) \leq \exp\left(-\frac{2(n/k^4)^2}{n \cdot (ck)^2}\right) = \exp\left(-\frac{2n}{c^2k^{10}}\right) .$$

This probability is exponentially small for $k \leq n^{1/11}$. □

Now we proceed with the proof of Theorem 8.4.

Proof of Theorem 8.4. After the first step of $k-k$ RELATION ROUTING a key may be left if either its processor has fewer than $5\log k/2$ nondelivered keys, or its processor is overloaded in some round and stops participating, or the module where the key should be sent is overloaded in some round. If the key is in the processor with fewer than $5\log k/2$ nondelivered keys, then after sending it $5\log k/2$ times in the second step either it will be delivered to the destination, or there are more than $5\log k/2$ keys sending to the destination module. The latter means that the module is overloaded at some round in the first step. Therefore, after the second step, we are left only with such keys for which either the processor to which they belong or the corresponding destination module is overloaded at some round in the first step. Because an overloaded processor affects at most k keys and an overloaded module affects at most k^2 keys, the number of keys that are left at the end of the $\log k$ rounds can be bounded using Lemma 8.5 by

$$\log k\left(k^2\frac{n}{k^4} + k\frac{n}{k^4}\right) \leq \frac{n}{k} .$$

Using approximate parallel prefix computation (Lemma 3.3) applied to the number of nondelivered keys belonging to each processor, we can redistribute the n/k remaining keys among the modules in $\mathcal{O}(\log^* n)$ time, such that each processor gets at most a constant number, w.h.p. Finally, each processor can now deliver its keys in $\mathcal{O}(k)$ steps.

Hence, altogether we need $\mathcal{O}(\log^2 k + k + \log^* n)$ time. □

At the beginning of $k-k$ relation routing a module is called *overloaded* if it gets $\omega(k)$ requests.

Lemma 8.3 bounds the number of keys affected by the modules getting $\omega(k)$ requests by $kn/2^k$. These keys and the keys from the bad processors have to be added to the other keys that will not be processed during the $\mathcal{O}(\log k)$ rounds of $k-k$ relation routing. Therefore, the total number of keys not processed during the $\mathcal{O}(\log k)$ rounds of $k-k$ relation routing remains linear. This finishes the description of quasi-random all-but-linear routing and completes the proof of Theorem 8.1.

9. Time-processor optimal EREW PRAM simulations. In this section we want to present time-processor optimal simulations of EREW PRAMs on DMMs, that is, simulations of $(n \cdot t)$-processor EREW PRAMs on n-processor DMMs with delay not exceeding $\mathcal{O}(t)$, w.h.p. For this we first consider the problem of accessing 1 out of c copies of the $(n \cdot t)$ requested distinct memory cells on an n-processor DMM. The copies are distributed using c independently and randomly chosen functions from a $(2, \log^2 n)$-universal class of hash functions. We show that such a problem can be reduced in time $\mathcal{O}(t + \log^* n)$, w.h.p., to a constant number of independent "1 out of $c - 1$" tasks, provided that $t \leq \sqrt[4]{\log n}$. Next we apply this reduction to obtain our time-processor optimal simulations of an $(n \cdot t)$-processor EREW PRAM on an n-processor DMM.

Let us consider the problem of accessing 1 out of the c copies of the $(n \cdot t)$ requested distinct memory cells, where the copies are distributed using independent hash functions $h_1, \ldots, h_c$. We assume that each processor of the DMM has a list of t keys (memory requests). We consider only the situation where $t \leq \sqrt[4]{\log n}$. We first use all-but-linear routing to satisfy all but $\mathcal{O}(n)$ of the access requests, by accessing the copies of the keys stored in memory modules given by h_1. Theorem 8.1 ensures that this phase can be performed in time $\mathcal{O}(t + \log^* n)$, w.h.p. Next, the remaining $\mathcal{O}(n)$ access requests are redistributed evenly among the processors of the DMM such that each processor gets $\mathcal{O}(1)$ of them. For that we use approximate prefix sums with respect to the number of nondelivered keys of each processor and then accordingly redistribute the keys. By Lemma 3.3, approximate prefix sums require $\mathcal{O}(\log^* n)$ time, w.h.p. Given computed approximate prefix sums, the distribution phase can be done in time $\mathcal{O}(t)$. Let us observe that, since the hash functions $h_2, h_3, \ldots, h_c$ are independent of h_1, the remaining $\mathcal{O}(n)$ requests are independent of $h_2, h_3, \ldots, h_c$. Therefore, we can use them as the input for a constant number of "1 out of $c - 1$" tasks on the basis of hash functions $h_2, h_3, \ldots, h_c$. Thus the above algorithm reduces the initial problem to a constant number of "1 out of $c-1$" tasks in time $\mathcal{O}(t+\log^* n)$, w.h.p.

By our discussion in section 2, a simulation of one step of an $(n \cdot t)$-processor EREW PRAM on an n-processor DMM can be reduced to solving independently $\binom{a}{b-1}$ times (for $b > a/2$) the problem of accessing 1 out of the $a - b + 1$ copies of the $(n \cdot t)$ requested distinct memory cells. Therefore, the algorithm above implies the following theorem.

THEOREM 9.1. *If one can execute a "1 out of $a - b$" task ($b > a/2$) in time bounded by $t \leq \sqrt[4]{\log n}$, w.h.p., then one step of an $(n \cdot t)$-processor EREW PRAM can be simulated on an n-processor DMM with delay $\mathcal{O}(\binom{a}{b-1} \cdot (t + \log^* n))$, w.h.p.*

Hence we can combine Theorem 9.1 with the algorithm for the "1 out of 2" task described in section 6.4 to obtain the following theorem.

THEOREM 9.2. *One step of an $(n \log\log\log n \log^* n)$-processor EREW PRAM can be simulated on an n-processor DMM with delay $\mathcal{O}(\log\log\log n \log^* n)$, w.h.p.*

We finally note that Karp, Luby, and Meyer auf de Heide [19] gave a slightly weaker theorem than Theorem 9.1 for CRCW PRAM simulations. We may apply it to get the following.

THEOREM 9.3. *One step of an $(n \log\log\log n \log^* n)$-processor CRCW PRAM can be simulated on an n-processor DMM with delay $\mathcal{O}(\log\log\log n (\log^* n)^2)$, w.h.p.*

10. A lower bound for the topological game. In this section we pinpoint the limits of our approach based on the "1 out of 2" task. We show that all previously known solutions based on the "1 out of 2" task as well as our algorithms are special cases of a game on the access graph, called the *topological game*. Then we prove a lower bound for the topological game.

All simulations based on the “1 out of 2” task, or equivalently on the analysis of the access game, have the following common scheme. In each step i each node v of H either analyzes its $k_{v,i}$-neighborhood or, on the basis of the structure of its $k_{v,i}$-neighborhood, decides which edge to remove, where $k_{v,i}$ is some integer. We can describe this scheme in a slightly more general way. Let k be the maximum of $k_{v,i}$ taken over all nodes v of H and all steps i of the algorithm. In the first superstep each node finds and analyzes its k-neighborhood. Then, in the remaining rounds it decides which edge to remove on the basis of the current k-neighborhood. Here we assume that each node will get the information on all removed edges in its k-neighborhood for free. It is easy to see that this extension makes the algorithm at least as powerful as the original one.

Let H be the access graph as defined in section 4 with n nodes and n/c edges, for $c < \log\log n$. Further assume that H is composed using two independent random hash functions. We define the *topological game* on the access graph H as follows. k is a parameter for the game.

Topological Game.

(1) Each node of H finds and analyzes its k-neighborhood; we charge for this $\log k$ steps.
(2) Repeat the following round until all the edges are removed:
    (a) Each node of degree one removes all edges in its k-neighborhood.
    (b) Each other node removes one incident edge. The choice of this edge solely depends on the topology of the current topology of its k-neighborhood.

We stress here the following features of this scheme.

Explanation and discussion of step 10. Let us observe that in all previous simulations [8, 12, 19, 22, 25] only a 1-neighborhood was analyzed. On the other hand, we notice that the time needed for computing any information about the k-neighborhood of a node v that involves the knowledge on any node that is in distance k from v seems to require $\Omega(\log k)$ steps. We remark that our data structures presented in section 6 allow each processor to obtain useful information about its k-neighborhood in $\mathcal{O}(\log k \cdot \log^* n)$ time, w.h.p.

Explanation and discussion of step 0a. This step is motivated by the fact that using a slight modification of the algorithm Cleaning Up Connected Components, each node that is close to the border of its connected component (that is, a node whose k-neighborhood contains a simple path of length less than k that cannot be extended by any edge to a simple path) can be removed in constant time using only the information about the k-neighborhood.

Explanation and discussion of step 0b. Here we make a key assumption concerning the topological game. A node bases its decision of which edge to choose on the topologies of the $(k-1)$-neighborhoods of its (direct) neighbors. The names of the nodes and the labels of the edges are not allowed to be used. In particular, in the case of all $(k-1)$-neighborhoods being disjoint and isomorphic, the node can only choose a random incident edge to remove. We further assume that removing further edges during the game does not increase the number of rounds required. All strategies known so far fit into this model. Especially, no simulation strategy is known that takes advantage of using the labels of nodes and edges to break ties, i.e., to choose among neighbors with disjoint isomorphic $(k-1)$-neighborhoods. On the other hand, it is challenging to find simulations that take advantage of using the labels, or to extend our lower bound.

The main idea of the lower bound for the topological game is to focus only on fully symmetric structures in H. We show that there exists a node that has a (topologically) symmetric k-neighborhood, possibly after removing some edges, and does not contain nodes of degree one in its k-neighborhood. Then we assume that it randomly makes the decision which outgoing edge to remove. We show that, after performing these random decisions, a smaller symmetric subgraph will be left in the next round, with sufficiently high probability. The bound for decreasing the size of the symmetric subgraph will yield the lower bound.

For $0 \le i < \frac{\log\log\log n}{8\log\log\log\log n}$, define the values of δ_i and d_i as follows:

$$\delta_i = \frac{\log\log n}{(\log\log\log n)^{4(i+1)}} \quad \text{and} \quad d_i = \frac{\log\log n}{(\log\log\log n)^{4(i+1)-2}} \ .$$

We will use the following inequalities for values δ_i and d_i.

LEMMA 10.1. *For every $1 \le k \le \sqrt{\log\log n}$, $0 \le i < \frac{\log\log\log n}{8\log\log\log\log n} - 1$, and sufficiently large n the following inequalities hold:*

(i) $2e^{-\frac{2\cdot\delta_i^{d_i}}{2^{2(\delta_i-\delta_{i+1})}}} \le \frac{1}{\log n}$ *and*

(ii) $\frac{3\cdot\delta_i^{d_i}}{2^{\delta_i-\delta_{i+1}-1}} \le \delta_i^{d_i-d_{i+1}-2k}$.

Proof.

(i) It is enough to show that

$$d_i\log\delta_i - 2\delta_i + 2\delta_{i+1} \ge \log\ln(2\log n).$$

If we substitute the terms that define δ_i and d_i on the left-hand side and use the assumption about the range of i, we get the following inequality:

$$\begin{aligned}
&\frac{\log\log n}{(\log\log\log n)^{4(i+1)-2}}(\log\log\log n - 4(i+1)\log\log\log\log n)\\
&-2\left(\frac{\log\log n}{(\log\log\log n)^{4(i+1)}} + \frac{\log\log n}{(\log\log\log n)^{4(i+2)}}\right)\\
&\ge \frac{\log\log n}{(\log\log\log n)^{4(i+1)-2}}\\
&\ge \sqrt{\log\log n}\,(\log\log\log n)^2\\
&\ge \log\ln(2\log n).
\end{aligned}$$

(ii) It is enough to show that

$$\delta_i - \delta_{i+1} - 3 - d_{i+1}\log\delta_i - 2k\log\delta_i \ge 0.$$

It is easily checked that $2k \le d_{i+1}$ for all i in the indicated range. This yields the following inequalities if we substitute the terms that define δ_i and d_i on the left-hand side and use the assumption about the range of i and k:

$$\begin{aligned}
&\delta_i - \delta_{i+1} - 3 - d_{i+1}\log\delta_i - 2k\log\delta_i\\
&\ge \delta_i - \delta_{i+1} - 3 - 2d_{i+1}\log\delta_i\\
&= \frac{\log\log n}{(\log\log\log n)^{4(i+1)}} - \frac{\log\log n}{(\log\log\log n)^{4(i+2)}} - 3\\
&\quad -2\frac{\log\log n}{(\log\log\log n)^{4(i+2)-2}}\log\left(\frac{\log\log n}{(\log\log\log n)^{4(i+1)}}\right)
\end{aligned}$$

$$\geq \frac{\log\log n}{2(\log\log\log n)^{4(i+1)}} - 3 - 2\frac{\log\log n}{(\log\log\log n)^{4(i+2)-3}}$$
$$\geq \frac{\log\log n}{4(\log\log\log n)^{4(i+1)}} \geq 0 \ . \qquad \square$$

DEFINITION 8. *A (δ_i, d_i)-tree is an undirected, unlabeled, and acyclic connected graph that contains a vertex r of degree δ_i such that all vertices in distance (exactly) d_i from r are of degree 1 and all other vertices are of degree δ_i.*

Fix an algorithm A that performs the topological game. We say a labeled directed graph A contains a copy of an unlabeled undirected graph B if, after removal of the labels and the edge orientation in A, the obtained graph contains a subgraph isomorphic to B. We want to maintain the condition that the access graph remaining after performing i rounds of the algorithm contains a copy of a (δ_i, d_i)-tree with sufficiently high probability. The proof of this invariant is done by induction, which is based on the following two lemmas.

LEMMA 10.2. *Let G be the directed access graph with n labeled nodes and n/c labeled edges (cf. section 4.1). Let $c < \log\log n$, and let $\mathfrak{T}_q$ be a fixed unlabeled and undirected tree with q nodes. For $q \leq \frac{\log n}{10\log\log n}$ and sufficiently large n, the probability that G contains a copy of $\mathfrak{T}_q$ is at least $1/2$.*

The proof of the lemma is in the spirit of the proof of a similar lemma for balanced graphs due to Erdős and Rényi [9].

Proof. Since the lemma trivially holds for $q = 1$, we assume that $q \geq 2$. Let $\mathcal{T}_q^{(n)}$ be the set of all subgraphs of the complete directed graph on n nodes and n/c edges labeled by the elements of S (cf. section 4.1) that, after removal of the labels and the edge orientations, are isomorphic to $\mathfrak{T}_q$. With each $T \in \mathcal{T}_q^{(n)}$ we associate a binary random variable $\mathcal{E}(T)$, such that $\mathcal{E}(T) = 1$ or $\mathcal{E}(T) = 0$ according to whether T is a subgraph of G or not. Our aim is to bound the probability that $\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T) = 0$. We estimate that probability by using Chebyshev's inequality. For that purpose we now provide bounds for the expectation and the variance of the random variable $\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)$.

First consider the expected value $E(\sum \mathcal{E}(T))$. The probability that a fixed tree with $q-1$ edges is a subgraph of G is $(1/n^2)^{q-1}$. In order to obtain a lower bound on the number of trees in $\mathcal{T}_q^{(n)}$ we observe that we may obtain a subset of $\mathcal{T}_q^{(n)}$ by selecting trees with given q nodes and given labels assigned to the edges of the tree. Hence we obtain the following formula:

$$E\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right) = \sum_{T\in\mathcal{T}_q^{(n)}} E(\mathcal{E}(T))$$
$$= |\mathcal{T}_q^{(n)}| \cdot \left(\frac{1}{n^2}\right)^{q-1} \tag{1}$$
$$\geq \binom{n}{q} \frac{\left(\frac{n}{c}\right)!}{\left(\frac{n}{c} - (q-1)\right)!} \left(\frac{1}{n^2}\right)^{q-1}$$
$$\geq \left(\frac{n}{q}\right)^q \left(\frac{n}{2c}\right)^{q-1} n^{-2(q-1)}$$
$$\geq \frac{n}{(2cq)^q} \ . \tag{2}$$

Let T_1 and T_2 be two elements from $\mathcal{T}_q^{(n)}$. If T_1 and T_2 have no edges in common, then

$$E(\mathcal{E}(T_1)\mathcal{E}(T_2)) = \left(\frac{1}{n^2}\right)^{2(q-1)} .$$

Therefore

$$\begin{aligned} E\left(\sum_{\substack{T_1,T_2\in\mathcal{T}_q^{(n)}\\ T_1,T_2\\ \text{edge-disjoint}}} \mathcal{E}(T_1)\mathcal{E}(T_2)\right) &= |\{T_1,T_2\in\mathcal{T}_q^{(n)} : T_1,T_2\,\text{edge disjoint}\}|\cdot\left(\frac{1}{n^2}\right)^{2(q-1)} \\ &\le (|\mathcal{T}_q^{(n)}|)^2\cdot\left(\frac{1}{n^2}\right)^{2(q-1)} \\ &\overset{(1)}{\le} \left(E\left(\sum_{T\in\mathcal{T}_q^{(n)}}\mathcal{E}(T)\right)\right)^2 . \end{aligned} \tag{3}$$

If T_1 and T_2 have exactly r edges in common ($1 \le r \le q-1$), then we get

$$E(\mathcal{E}(T_1)\mathcal{E}(T_2)) = \left(\frac{1}{n^2}\right)^{2(q-1)-r} .$$

Because T_1 and T_2 are trees, they have at least $r+1$ nodes in common. Hence, we can give an upper bound for the number of such pairs T_1, T_2 of subgraphs:

$$\begin{aligned} &(2^q\cdot q^{q-2})^2\sum_{j=r+1}^{q}\binom{n}{q}\binom{q}{j}\binom{n-q}{q-j}\left(\frac{n}{c}\right)^{2(q-1)-r} \\ &\le q^{4q-4}\sum_{j=r+1}^{q}\frac{n!}{q!(n-q)!}\frac{q!}{j!(q-j)!}\frac{(n-q)!}{(q-j)!(n-2q+j)!}\left(\frac{n}{c}\right)^{2(q-1)-r} \\ &\le q^{4q-4}\sum_{j=r+1}^{q}\frac{n^{2q-j+2(q-1)-r}}{j!((q-j)!)^2c^{2(q-1)-r}} \\ &\le q^{4q-4}qn^{4q-2r-3} . \end{aligned}$$

Hence we obtain

$$E\left(\sum_{\substack{T_1,T_2\in\mathcal{T}_q^{(n)}\\ T_1,T_2\\ \text{not edge-disjoint}}} \mathcal{E}(T_1)\mathcal{E}(T_2)\right) \le \sum_{r=1}^{q-1} q^{4q-3}n^{4q-2r-3}\left(\frac{1}{n^2}\right)^{2(q-1)-r} \le nq^{4q-2} . \tag{4}$$

Now we may bound $E((\sum_{T\in\mathcal{T}_q^{(n)}}\mathcal{E}(T))^2)$:

$$E\left(\left(\sum_{T\in\mathcal{T}_q^{(n)}}\mathcal{E}(T)\right)^2\right)$$

$$= E\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right) + E\left(\sum_{\substack{T_1,T_2\in\mathcal{T}_q^{(n)}\\ T_1,T_2\\ \text{edge-disjoint}}} \mathcal{E}(T_1)\mathcal{E}(T_2)\right)$$

$$+ E\left(\sum_{\substack{T_1,T_2\in\mathcal{T}_q^{(n)}\\ T_1,T_2\\ \text{not edge-disjoint}}} \mathcal{E}(T_1)\mathcal{E}(T_2)\right)$$

$$\overset{(3)(4)}{\le} E\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right) + \left(E\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right)\right)^2 + nq^{4q-2} \ . \tag{5}$$

Finally we provide an upper bound for the variance:

$$\operatorname{Var}\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right) = E\left(\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right)^2\right) - \left(E\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right)\right)^2$$

$$\overset{(5)}{\le} E\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T)\right) + nq^{4q-2} \ . \tag{6}$$

Using the Chebyshev inequality we can bound the probability that no $T \in \mathcal{T}_q^{(n)}$ is a subgraph of G:

$$\begin{aligned}
\Pr\left(\sum_{T\in\mathcal{T}_q^{(n)}} \mathcal{E}(T) = 0\right) &\le \frac{\operatorname{Var}\left(\sum \mathcal{E}(T)\right)}{\left(E\left(\sum \mathcal{E}(T)\right)\right)^2} \\
&\overset{(6)}{\le} \frac{\sum E(\mathcal{E}(T)) + nq^{4q-2}}{\left(E\left(\sum \mathcal{E}(T)\right)\right)^2} \\
&\overset{(2)}{\le} \frac{(2cq)^q}{n} + \frac{nq^{4q-2}(2cq)^{2q}}{n^2} \\
&= \frac{(2cq)^q + (2c)^{2q}q^{6q-2}}{n} \\
&\le \frac{q^{10q}}{n} \qquad \text{for} \quad c \le q \\
&\le \frac{1}{2} \qquad \text{for} \quad q \le \frac{\log n}{10\log\log n} \ .
\end{aligned}$$

Therefore, the probability that G contains a copy of $\mathfrak{T}_q$ is at least $1/2$ for $q \le \frac{\log n}{10\log\log n}$. ◻

LEMMA 10.3. *Consider a (δ_i, d_i)-tree for $0 \le i < \frac{\log\log\log n}{8\log\log\log\log n}$, and let $k \le \sqrt{\log\log n}$. If every node randomly removes an incident edge, then, with probability at least $1 - 1/\log n$, at most $\delta_i^{d_i - d_{i+1} - 2k}$ of the nodes have degree smaller than δ_{i+1}.*

Proof. Consider a fixed node v with degree δ_i. Each edge incident to v will be removed by an incident node with the same probability $1/\delta_i$. Define for $1 \le j \le \delta_i$ the binary random variable X_j which is one if and only if the jth incident edge of v will be removed by an incident node. We know that $\Pr(X_j = 1) = 1/\delta_i$. Let $X = \sum X_j$. Note that $E(X) = 1$. We want to bound the deviation from the expected value. Because the decisions of the adjacent nodes are independent, we can use the Chernoff bound [15]:

$$\Pr(X \ge \alpha) = \Pr(X \ge \alpha E(X)) \le \frac{1}{2^\alpha} \text{ for } \alpha \ge 5 \enspace .$$

In particular, this implies that

$$\Pr(\text{a node has degree smaller than } \delta_{i+1}) \le \left(\frac{1}{2}\right)^{\delta_i - \delta_{i+1} - 1} \enspace .$$

Let x_l, $1 \le l \le \frac{\delta_i^{d_i+1}-1}{d_i-1}$, be the sequence of independent random decisions made by the $\frac{\delta_i^{d_i+1}-1}{d_i-1}$ nodes of the (δ_i, d_i)-tree. The random variable

$$Y = f\left(\left\{x_l : 1 \le l \le \frac{\delta_i^{d_i+1}-1}{d_i-1}\right\}\right)$$

denotes the number of nodes that have degree smaller than δ_{i+1}. If we change the value of one x_l, Y can be changed by at most two. The expected number of nodes having degree less than δ_{i+1} can be bounded by

$$\frac{\frac{\delta_i^{d_i+1}-1}{d_i-1}}{2^{\delta_i-\delta_{i+1}-1}} \le 2\frac{\delta_i^{d_i}}{2^{\delta_i-\delta_{i+1}-1}} \enspace .$$

Using the method of bounded differences (Lemma 3.1), we get

$$\begin{aligned}\Pr\left(Y \ge 3\frac{\delta_i^{d_i}}{2^{\delta_i-\delta_{i+1}-1}}\right) &\le \Pr\left(Y \ge E(Y) + \frac{\delta_i^{d_i}}{2^{\delta_i-\delta_{i+1}-1}}\right) \\ &\le 2e^{-2\frac{\left(\delta_i^{d_i}\right)^2}{2^{2(\delta_i-\delta_{i+1}-1)}}\cdot\frac{d_i-1}{4\left(\delta_i^{d_i+1}-1\right)}} \\ &\le 2e^{-\frac{\delta_i^{d_i}}{2^{2(\delta_i-\delta_{i+1})}}} \enspace .\end{aligned}$$

Substituting the values of δ_i and d_i into this formula and using Lemma 10.1 we get that for $k \le \sqrt{\log\log n}$ the number of nodes with small degree can be bounded by $\delta_i^{d_i-d_{i+1}-2k}$ with probability at least $1 - 1/\log n$. ◻

Using these two lemmas we can show the following.

LEMMA 10.4. *After performing i rounds of the algorithm A, a (δ_i, d_i)-tree is a subgraph of the remaining access graph with probability at least $(1 - 1/\log n)^i$ for $1 \le i < \frac{\log\log\log n}{8\log\log\log\log n}$ and $k \le \sqrt{\log\log n}$.*

Proof. The proof is done by induction on i. For $i = 0$ we use Lemma 10.2. Assume that the lemma holds for some i, where $i < \frac{\log\log\log n}{8\log\log\log\log n}$. From the induction hypothesis we know that a (δ_i, d_i)-tree is a subgraph of the access graph at the beginning of round $i+1$. We consider only the edges from this tree and remove all other edges. Because of the definition of the topological game, we remove all nodes that are within distance at most k from a leaf of the tree. Each decision based on the topology of the k-neighborhood made by the remaining nodes is random and is independent of decisions of other nodes.

Hence, using Lemma 10.3, at most $\delta_i^{d_i - d_{i+1} - 2k}$ nodes have degree smaller than δ_{i+1}, and a (δ_i, d_i)-tree is a subgraph of the remaining graph. □

The invariant of Lemma 10.4 holds for k small enough in every round i, $1 \le i < \frac{\log\log\log n}{8\log\log\log\log n}$, even if we start only with $\frac{n}{\log\log\log n}$ edges. This implies the following theorem.

THEOREM 10.5. *The expected number of rounds in any topological game until all edges of the access graph H will be removed is* $\Omega(\frac{\log\log\log n}{\log\log\log\log n})$.

Proof. After $\frac{\log\log\log n}{8\ \log\log\log\log n}$ rounds it is only possible to pick a k-neighborhood for

$$k \le 2^{\frac{\log\log\log n}{8\ \log\log\log\log n}} \le \sqrt{\log\log n}\ .$$

Therefore, when we use Lemma 10.4, after $i \le \frac{\log\log\log n}{8\log\log\log\log n}$ rounds some edges will be left. The probability for this event can be bounded by

$$\left(1 - \frac{1}{\log n}\right)^{\frac{\log\log\log n}{8\log\log\log\log n}} \ge 1/e\ . \qquad □$$

ALL-PAIRS ALMOST SHORTEST PATHS*

DORIT DOR†, SHAY HALPERIN†, AND URI ZWICK†

Abstract. Let $G = (V, E)$ be an unweighted undirected graph on n vertices. A simple argument shows that computing all distances in G with an additive one-sided error of at most 1 is as hard as Boolean matrix multiplication. Building on recent work of Aingworth et al. [*SIAM J. Comput.*, 28 (1999), pp. 1167–1181], we describe an $\tilde{O}(\min\{n^{3/2}m^{1/2}, n^{7/3}\})$-time algorithm $\mathbf{APASP}_2$ for computing all distances in G with an additive one-sided error of at most 2. Algorithm $\mathbf{APASP}_2$ is simple, easy to implement, and faster than the fastest known matrix-multiplication algorithm. Furthermore, for every even $k > 2$, we describe an $\tilde{O}(\min\{n^{2-2/(k+2)}m^{2/(k+2)}, n^{2+2/(3k-2)}\})$-time algorithm $\mathbf{APASP}_k$ for computing all distances in G with an additive one-sided error of at most k. We also give an $\tilde{O}(n^2)$-time algorithm $\mathbf{APASP}_\infty$ for producing stretch 3 estimated distances in an unweighted and undirected graph on n vertices. No constant stretch factor was previously achieved in $\tilde{O}(n^2)$ time.

We say that a weighted graph $F = (V, E')$ *k-emulates* an unweighted graph $G = (V, E)$ if for every $u, v \in V$ we have $\delta_G(u, v) \le \delta_F(u, v) \le \delta_G(u, v) + k$. We show that every unweighted graph on n vertices has a 2-emulator with $\tilde{O}(n^{3/2})$ edges and a 4-emulator with $\tilde{O}(n^{4/3})$ edges. These results are asymptotically tight.

Finally, we show that any *weighted* undirected graph on n vertices has a 3-spanner with $\tilde{O}(n^{3/2})$ edges and that such a 3-spanner can be built in $\tilde{O}(mn^{1/2})$ time. We also describe an $\tilde{O}(n(m^{2/3}+n))$-time algorithm for estimating all distances in a *weighted* undirected graph on n vertices with a stretch factor of at most 3.

1. Introduction.

The all-pairs shortest paths (APSP) problem is one of the most fundamental algorithmic graph problems. The complexity of the fastest known algorithm for solving the problem for weighted directed graphs is $O(mn + n^2 \log n)$, where n and m are the number of vertices and edges in the graph (Johnson [22]; see also [14]). Algorithms for the APSP problem which work on directed graphs with nonnegative edge weights and whose running times are $O(m^*n + n^2 \log n)$, where m^* is the number of edges participating in shortest paths, were obtained by Karger, Koller, and Phillips [23] and by McGeoch [26]. Karger, Koller, and Phillips [23] also obtain an $\Omega(mn)$ lower bound on any *path comparison*-based algorithm for the APSP problem. Takaoka [29], slightly improving a result of Fredman [17], obtained an algorithm for the APSP problem whose running time is $O(n^3((\log\log n)/\log n)^{1/2})$. These algorithms work again on directed graphs with nonnegative edge weights.

The special case of the APSP problem in which the input graph is unweighted is closely related to matrix multiplication. It is fairly easy to see that solving the APSP problem exactly, even on unweighted graphs, is at least as hard as Boolean matrix multiplication. Recent work by Alon, Galil, and Margalit [3], Alon and Naor [4], Galil and Margalit [19], [20], [21], and Seidel [28] have shown that if matrix multiplication can be performed in $O(M(n))$ time, then the APSP problem for unweighted directed

graphs can be solved in $\tilde{O}(\sqrt{n^3 M(n)})$ time and the APSP problem for unweighted undirected graphs can be solved in $\tilde{O}(M(n))$ time ($\tilde{O}(f)$ means $O(f \operatorname{polylog} n)$). The $\tilde{O}(\sqrt{n^3 M(n)})$ bound for directed graphs was very recently improved by Zwick [33]. The current best upper bound on matrix multiplication is $M(n) = O(n^{2.376})$ (Coppersmith and Winograd [13]).

While the above results are extremely interesting from the theoretical point of view, they are of little use in practice because the fast matrix multiplication algorithms are better than the naive $O(n^3)$-time algorithm only for very large values of n. There is interest therefore in obtaining fast algorithms for the APSP problem that do *not* use fast matrix multiplication. The current best *combinatorial* algorithm for the unweighted APSP problem is an $O(n^3/\log n)$-time algorithm obtained by Feder and Motwani [16] (see also [8]). This offers only a marginal improvement over the naive $O(n^3)$-time algorithm.

Because an algorithm for the APSP problem would yield an algorithm with a similar time bound for Boolean matrix multiplication, obtaining a combinatorial $O(n^{3-\epsilon})$-time algorithm for the APSP problem would be a major breakthrough. Here we obtain such combinatorial algorithms for the all-pairs *almost* shortest paths (APASP) problem.

Awerbuch et al. [7] and Cohen [11] considered the problem of finding stretch t all-pairs paths, where t is some fixed constant and a path is of stretch t if its length is at most t times the distance between its endpoints. Cohen [11], improving the results of Awerbuch et al. [7], obtains, for example, an $\tilde{O}(n^{5/2})$-time algorithm for finding stretch $4+\epsilon$ paths and distances in weighted undirected graphs for any $\epsilon > 0$ (all weights from now on are assumed to be positive). She also exhibits a trade-off between the running time of the algorithm and the obtained stretch factor. For any even t, stretch $t+\epsilon$ paths between all pairs of vertices can be found in $\tilde{O}(n^{2+2/t})$ time. The works of Awerbuch et al. [7] and Cohen [11] are based on the construction of sparse spanners (Awerbuch [6], Peleg and Schäffer [27]). A t-spanner of a graph $G = (V, E)$ is a subgraph $G' = (V, E')$ of G such that for every $u, v \in V$ we have $\delta_{G'}(u,v) \le t \cdot \delta_G(u,v)$, where $\delta_G(u,v)$ is the distance between the vertices u and v in the (possibly weighted) graph G.

A different approach altogether was employed recently by Aingworth et al. [2]. They describe a simple and elegant $\tilde{O}(n^{5/2})$-time algorithm for finding all distances in unweighted and undirected graphs with an *additive* one-sided error of at most 2. They also make the very important observation that the small distances, and not the long distances, are the hardest to approximate. Based on the ideas of Aingworth et al. [2], James B. Orlin (unpublished) obtained an $\tilde{O}(n^{7/3})$-time algorithm for finding all distances with an additive one-sided error of at most 4.

In this work we improve and extend the result of Aingworth et al. [2], and of Orlin, and obtain an $\tilde{O}(\min\{n^{3/2}m^{1/2}, n^{7/3}\})$-time algorithm, called $\mathbf{APASP}_2$, for finding all distances in unweighted and undirected graphs with an additive one-sided error of at most 2. Algorithm $\mathbf{APASP}_2$ is just the first in a sequence of algorithms $\mathbf{APASP}_k$ for even $k \ge 2$ that exhibit a trade-off between running time and accuracy. For any even $k > 2$, algorithm $\mathbf{APASP}_k$ runs in $\tilde{O}(\min\{n^{2-\frac{2}{k+2}} m^{\frac{2}{k+2}}, n^{2+\frac{2}{3k-2}}\})$ time and has a one-sided error of at most k. Algorithm $\mathbf{APASP}_4$, for example, runs in $\tilde{O}(n^{5/3}m^{1/3}, n^{11/5})$ time. All algorithms described in this paper can be easily adapted to find almost shortest paths whose lengths are equal to the estimated distances.

In addition, we show that for any $k \ge 2$, the stretch of the estimates produced by algorithm $\mathbf{APASP}_k$ is at most 3. As k increases, the running time of algorithm

$\mathbf{APASP}_k$ decreases. For $k = \Theta(\log n)$, the running time becomes $\tilde{O}(n^2)$. We let $\mathbf{APASP}_\infty$ be the algorithm $\mathbf{APASP}_k$ with $k = 2\lfloor \log n \rfloor$. Algorithm $\mathbf{APASP}_\infty$ produces stretch 3 distances in unweighted undirected graphs in $\tilde{O}(n^2)$ time. As mentioned, no fixed stretch factor was previously achieved in $\tilde{O}(n^2)$ time.

The errors in the estimated distances produced by $\mathbf{APASP}_k$ are *one sided*. If $\delta(u,v)$ denotes the distance between two vertices u and v in $G = (V,E)$ and $\hat{\delta}(u,v)$ denotes the estimated distance between u and v produced by the algorithm, then for every $u,v \in V$ we have $\delta(u,v) \le \hat{\delta}(u,v) \le \delta(u,v) + k$. The fact that $\delta(u,v) \le \hat{\delta}(u,v)$ follows immediately from the fact that each estimated distance $\hat{\delta}(u,v)$ is the length of a path from u to v in the graph. Note that by subtracting $\lfloor k/2 \rfloor$ from all the estimated distances produced by $\mathbf{APASP}_k$ we can obtain estimates $\tilde{\delta}(u,v)$ satisfying $|\delta(u,v) - \tilde{\delta}(u,v)| \le \lceil k/2 \rceil$ for every $u,v \in V$.

We next introduce the notion of *emulators*. We say that a weighted graph $F = (V,E')$ *k-emulates* an unweighted graph $G = (V,E)$ if for every $u,v \in V$ we have $\delta_G(u,v) \le \delta_F(u,v) \le \delta_G(u,v)+k$. Emulators may be seen as the additive counterparts of spanners. We show that any graph on n vertices has a 2-emulator with $\tilde{O}(n^{3/2})$ edges and a 4-emulator with $\tilde{O}(n^{4/3})$ edges. These can be constructed in $\tilde{O}(n^{5/2})$ and in $\tilde{O}(n^{7/3})$ time, respectively. We are not able to obtain sparser emulators. We are able, however, to construct 6-emulators of size $\tilde{O}(n^{4/3})$ in $\tilde{O}(n^2)$ time. The bounds on the number of edges in 2-emulators and 4-emulators are asymptotically tight. For any $\epsilon > 0$, there are graphs on n vertices that cannot be 2-emulated by graphs with $n^{3/2-\epsilon}$ edges, and there are graphs on n vertices that cannot be 4-emulated by graphs with $n^{4/3-\epsilon}$ edges.

We are also able to obtain some results for *weighted* undirected graphs. We show that any weighted graph on n vertices has a 3-spanner with $\tilde{O}(n^{3/2})$ edges and that such a 3-spanner can be found in $\tilde{O}(mn^{1/2})$ time. Finally, we describe an $\tilde{O}(n(m^{2/3}+n))$-time algorithm for finding stretch 3 distances in a weighted undirected graph on n vertices. Extended and improved results for weighted graphs, including an $\tilde{O}(n^2)$-time algorithm for finding stretch 3 distances and an $\tilde{O}(n^{3/2}m^{1/2})$-time algorithm for finding stretch 2 distances, appear in Cohen and Zwick [12].

2. Preliminaries.

The work of Aingworth et al. [2] is based on the following simple observation: there is a small set of vertices that dominates all the high-degree vertices of a graph. A set of vertices D is said to *dominate* a set U if every vertex in U has a neighbor in D. This observation is also central to our work.

Aingworth et al. [2] show that there is always a set of size $O(n \log n/s)$ that dominates all the vertices of degree at least s in a graph on n vertices and that such a set can be found deterministically in $O(m + ns)$ time, where m is the number of edges in the graph. Here, we show that such a set can be found deterministically in $O(m+n)$ time.

LEMMA 2.1. *Let $G = (V,E)$ be an undirected graph with n vertices and m edges. Let $1 \le s \le n$. A set D of size $O((n \log n)/s)$ that dominates all the vertices of degree at least s in the graph can be found deterministically in $O(m+n)$ time.*

Proof. Before describing a deterministic algorithm we note that picking each vertex of V independently at random with probability $(c \log n)/s$, for some large enough $c > 0$, yields a desired dominating set of size $O((n \log n)/s)$ with high probability.

The deterministic algorithm uses the greedy heuristic. Start with an empty set D. At each stage, add to D a vertex of V that dominates the largest number of vertices of degree at least s that are not already dominated by vertices of D. Lovász [25] and Chvátal [9] show that the greedy heuristic produces a dominating set whose size

```
Algorithm decompose$(G, \langle s_1, s_2, \ldots, s_{k-1}\rangle)$:

input:  (i) An undirected graph $G = (V, E)$.
        (ii) A decreasing sequence $s_1, s_2, \ldots, s_{k-1}$ of degree thresholds.

output: (i) A sequence $E_1, E_2, \ldots, E_k, E^*$ of edge sets.
        (ii) A sequence $D_1, D_2, \ldots, D_k$ of vertex sets.

For $i \leftarrow 2$ to $k$ do $E_i \leftarrow \{e = (u, v) \in E \mid \deg(u) \le s_{i-1}$ or $\deg(v) \le s_{i-1}\}$
For $i \leftarrow 1$ to $k-1$ do $(D_i, E_i^*) \leftarrow$ dominate$(G, s_i)$
$E_1 \leftarrow E$ ; $D_k \leftarrow V$ ; $E^* \leftarrow \bigcup_{1 \le i < k} E_i^*$
```

FIG. 1. *A decomposition algorithm.*

is at most $\ln n$ times the size of the smallest fractional dominating set. A fractional dominating set of size n/s is easily obtained by giving each vertex of the graph a weight of $1/s$. The size of the dominating set produced by the greedy heuristic is therefore at most $(n \ln n)/s$, as required.

It is easy to see that the greedy heuristic can be implemented in $O(m + n)$ time. For each vertex v of G we maintain a linked list of the edges that connect v to vertices of G of degree at least s (in the original graph) that are not yet dominated by the vertices of D. We use a simple array of length n to implement a priority queue that holds the vertices of G. The key of each vertex is the length of its linked list. When a vertex is added to D, we have to update the lists and the keys of some of the vertices in the graph. If a vertex u now becomes dominated, then we have to update the lists and the keys of all its neighbors in G. This takes, however, only $O(\deg(u))$ time, where $\deg(u)$ is the degree of u in G. The total running time is therefore $O(m + n)$. ☐

In what follows we use an algorithm, called **dominate**(G, s), that receives an undirected graph $G = (V, E)$ and a *degree threshold* s. The algorithm outputs a pair (D, E^*), where D is a set of size $O((n \log n)/s)$ that dominates the set of vertices of degree at least s in G. The set $E^* \subseteq E$ is a set of edges of G of size $O(n)$ such that for every vertex $u \in V$ with degree at least s, there is an edge $(u, w) \in E^*$ such that $w \in D$. Once a dominating set D is obtained, the set E^* can be easily obtained by including in it a single edge for each vertex of the graph of degree at least s.

Almost all the algorithms presented in this paper use the decomposition algorithm given in Figure 1. The input to the algorithm is an undirected graph $G = (V, E)$ and a decreasing sequence $s_1 > s_2 > \cdots > s_{k-1}$ of degree thresholds.

Algorithm **decompose** produces a decreasing sequence of edge sets $E_1 \supseteq E_2 \supseteq \cdots \supseteq E_k$, where $E_1 = E$ and E_i for $1 < i \le k$ includes the edges that touch vertices of degree at most s_{i-1}. As the number of vertices of degree at most s_{i-1} is at most n, and as each such vertex contributes at most s_{i-1} edges to E_i, the number of edges in E_i for $1 < i \le k$ is at most ns_{i-1}. Throughout the paper, we let $\deg(v)$ denote the degree of a vertex v.

Algorithm **decompose** also produces a set of dominating sets $D_1, D_2, \ldots, D_k$ and an edge set E^*. The set D_i for $1 \le i < k$ dominates all the vertices in G of degree greater than s_i. In what follows we denote the set of vertices of degree greater than s_i by V_i. The set D_k is simply V, the set of all vertices of the graph. The set

$E^* \subseteq E$ is a set of edges of the graph such that if $u \in V_i$, i.e., if $\deg(u) > s_i$, then there exists a vertex $w \in D_i$ such that $(u, w) \in E^*$. The size of E^* is at most kn. As the running time of **dominate** is $O(m + n)$, the running time of **decompose** is clearly $O(k(m + n))$.

Another ingredient used by our algorithm is the classical Dijkstra's algorithm.

LEMMA 2.2 (Dijkstra's algorithm). *Let $G = (V, E)$ be a weighted directed graph with n vertices and m edges. Let $s \in V$. Dijkstra's algorithm runs in $O(m + n \log n)$ time and finds distances and a tree of shortest paths from s to all the vertices of V. Furthermore, if the weights of the edges are nonnegative integers, then the distances from s to all the vertices that are at distance at most m from s can be found in $O(m + n)$ time.*

Dijkstra's algorithm appeared originally in [15], though the running time of the version described there is $O(n^2)$. For a more modern description of Dijkstra's algorithm see [14]. The running time of $O(m + n \log n)$ is obtained by using *Fibonacci heaps* [18]. If all the weights in the graph G are nonnegative integers and only the distances that are most m are to be computed, then a simple array of length m can be used as a priority queue, resulting in an $O(m + n)$ running time. Thorup [30] showed recently, using more sophisticated techniques, that Dijkstra's algorithm can be implemented to run in $O(m + n)$ time even if the distances of the vertices from s are not bounded, provided that bit operations on the weights are allowed. Our algorithms do not rely on his results.

In all the algorithms described in this paper, except those of section 7, we start with an *unweighted* undirected graph $G = (V, E)$. We then build many auxiliary *weighted* graphs and run Dijkstra's algorithm on each one of them. The weights of the edges in these auxiliary graphs will always be integers in the range $\{1, 2, \ldots, n-1\}$. As we will only be interested in distances that are at most $n - 1$ we can, if we want to, use the simple $O(m + n)$-time implementation of Dijkstra's algorithm. Using the $O(m + n \log n)$-time implementation of Dijkstra's algorithm will not result in a loss of efficiency, however, as all our algorithms are faster than the exact $O(mn)$-time algorithm that simply runs breadth-first search (BFS) from each vertex only when $m \geq n \log n$.

As mentioned above, we can easily solve the APSP problem in unweighted graphs in $O(mn)$ time. Our goal in this paper is to reduce the running time of APSP algorithms to as close to $\tilde{O}(n^2)$ as possible. To achieve this goal we are willing to settle for *almost* shortest paths instead of genuine shortest paths.

Our algorithms involve many runs of Dijkstra's algorithm. Most of these runs are performed, however, on graphs with substantially fewer edges than in the original input graph. It is interesting to note that we use Dijkstra's algorithm, which works on *weighted* graphs, even though the problem that we are trying to solve is unweighted. A typical step in our algorithms is to choose a vertex $u \in V$, choose a set of edges F, and then run Dijkstra's algorithm from u on the graph $H = (V, F)$. The set of edges F is *not* necessarily a subset of the edge set E of the input graph. Furthermore, the set F *varies* from step to step. The weight of an edge $(u, v) \in F$ is taken to be the current best upper bound on the distance between u and v in the input graph G. Bounds obtained in a run of Dijkstra's algorithm are used, therefore, in some of the subsequent runs.

In our algorithms, we use a *symmetric* $n \times n$ matrix, denoted $\{\hat{\delta}(u, v)\}_{u,v}$, to hold the current best upper bounds on distances between all pairs of vertices in the input graph $G = (V, E)$. Initially $\hat{\delta}(u, v) = 1$ if $(u, v) \in E$ and $\hat{\delta}(u, v) = +\infty$ otherwise. (If we assume that the input graph G is connected, we can replace each $+\infty$ by $n-1$.) By **dijkstra**$((V,F),\hat{\delta},u)$ we denote an invocation of Dijkstra's algorithm from the vertex u on the graph (V,F), where the weight of an edge $(u,v)\in F$ is taken to be $\hat{\delta}(u,v)$. As we are interested only in distances that are at most $n-1$, the running time of such a call to Dijkstra's algorithm is $O(|F|+n)$. The edges of F are considered to be *undirected*. As mentioned, an edge of F is not necessarily an edge of E. If $(u,v)\in F$ is an edge of the original graph, then its weight is 1, otherwise, its weight is greater than 1. A call to **dijkstra**$((V,F),\hat{\delta},u)$ updates the row and the column belonging to u in the matrix $\hat{\delta}$ with the distances found during this run if they are smaller than the previous estimates. Note that the matrix $\{\hat{\delta}(u,v)\}_{u,v}$ serves as both input and output of **dijkstra**.

If the graph (V,F) is a subgraph of the input graph $G=(V,E)$, then a call to **dijkstra**$((V,F),\hat{\delta},u)$ amounts to running a BFS on (V,F) from u. When we want to stress this fact, we denote such a call by **bfs**$((V,F),\hat{\delta},u)$. In such a call, the matrix $\{\hat{\delta}(u,v)\}_{u,v}$ is only used for output because the weight of each edge in the input graph is assumed to be 1.

It should be clear from the above discussion that at any time during the run of our algorithms and for any $u,v\in V$ we have $\delta(u,v)\le\hat{\delta}(u,v)$, where $\delta(u,v)$ is the distance between u and v in the input graph G.

In the next section we describe a sequence of algorithms $\mathbf{apasp}_k$ for $k\ge 2$. Algorithm $\mathbf{apasp}_k$ runs in $\tilde{O}(n^{2-1/k}m^{1/k})$ time and produces estimates with surplus $2(k-1)$. In section 4 we describe a sequence of algorithms $\overline{\mathbf{apasp}}_k$ for $k\ge 2$. Algorithm $\overline{\mathbf{apasp}}_k$ runs in $\tilde{O}(n^{2+1/k})$ time and produces estimates with surplus $2(\lfloor k/3\rfloor+1)$. Algorithm $\mathbf{APASP}_k$, mentioned in the abstract and in the introduction, is a combination of a suitable algorithm from the sequence $\mathbf{apasp}_k$ with a suitable algorithm from the sequence $\overline{\mathbf{apasp}}_k$, as explained after the proof of Theorem 4.2 in section 4.

3. Algorithm $\mathbf{apasp}_k$.

Aingworth et al. [2] obtained an $\tilde{O}(n^{5/2})$-time algorithm for approximating all distances in an undirected and unweighted graph with a one-sided additive error of at most 2. We describe a family of algorithms $\mathbf{apasp}_k$, where $k\ge 2$ is an integer. Algorithm $\mathbf{apasp}_k$ runs in $\tilde{O}(n^{2-1/k}m^{1/k})$ time and produces estimated distances with an additive error of at most $2(k-1)$. Note that for $k=2$, we get a running time of $\tilde{O}(n^{3/2}m^{1/2})$ and an additive error of at most 2. At the other extreme, if we take $k=\lceil\log n\rceil$, we get a running time of $\tilde{O}(n^2)$ and an additive error of $O(\log n)$.
