To argue about the security of our IBE system, we define chosen ciphertext security for IBE. Our model gives the adversary more power than the standard model for chosen ciphertext security [37, 2]. First, we allow the attacker to attack an arbitrary public key ID of her choice. Second, while mounting a chosen ciphertext attack on ID, we allow the attacker to obtain from the PKG the private key for any public key of her choice, other than the private key for ID. This models an attacker who obtains a number of private keys corresponding to some identities of her choice and then tries to attack some other public key ID of her choice. Even with the help of such queries, the attacker should have negligible advantage in defeating the semantic security of the system.

The rest of the paper is organized as follows. Several applications of IBE are discussed in section 1.1. We then give precise definitions and security models in section 2. We describe bilinear maps with certain properties in section 3. Our IBE scheme is presented in section 4 using general bilinear maps. Then a concrete identity-based system from the Weil pairing is given in section 5. Some extensions and variations (efficiency improvements, distribution of the master-key) are considered in section 6. Our construction for ElGamal encryption with a global escrow key is described in section 7. Section 8 gives conclusions and some open problems. The appendices contain a more detailed discussion of the Weil pairing.

1.1. Applications for IBE. The original motivation for IBE is to help the deployment of a public key infrastructure. In this section, we show several other unrelated applications.

1.1.1. Revocation of public keys. Public key certificates contain a preset expiration date. In an IBE system, key expiration can be done by having Alice encrypt e-mail sent to Bob using the public key "`bob@company.com` $\|$ `current-year`." In doing so, Bob can use his private key during the current year only. Once a year, Bob needs to obtain a new private key from the PKG. Hence we get the effect of annual private key expiration. Note that unlike the existing public key infrastructure (PKI), Alice does not need to obtain a new certificate from Bob every time Bob refreshes his private key.

One could potentially make this approach more granular by encrypting e-mail for Bob using "bob@company.com ‖ current-date." This forces Bob to obtain a new private key every day. This might be possible in a corporate PKI, where the PKG is maintained by the corporation. With this approach, key revocation is very simple: when Bob leaves the company and his key needs to be revoked, the corporate PKG is instructed to stop issuing private keys for Bob's e-mail address. As a result, Bob can no longer read his email. The interesting property is that Alice does not need to communicate with any third party certificate directory to obtain Bob's daily public key. Hence IBE is a very efficient mechanism for implementing ephemeral public keys. Also note that this approach enables Alice to send messages into the future: Bob will only be able to decrypt the e-mail on the date specified by Alice (see [38, 12] for methods of sending messages into the future using a stronger security model).

Managing user credentials. A simple extension to the discussion above enables us to manage user credentials using the IBE system. Suppose Alice encrypts mail to Bob using the public key: "bob@company.com ‖ current-year ‖ clearance=secret." Then Bob will only be able to read the e-mail if on the specified date he has secret clearance. Consequently, it is easy to grant and revoke user credentials using the PKG.

1.1.2. Delegation of decryption keys. Another application for IBE systems is delegation of decryption capabilities. We give two example applications. In both applications, the user Bob plays the role of the PKG. Bob runs the Setup algorithm to generate his own IBE system parameters params and his own master-key. Here we view params as Bob's public key. Bob obtains a certificate from a CA for his public key params. When Alice wishes to send mail to Bob, she first obtains Bob's public key params from Bob's public key certificate. Note that Bob is the only one who knows his master-key, and hence there is no key escrow with this setup.

1. *Delegation to a laptop.* Suppose Alice encrypts mail to Bob using the current date as the IBE encryption key. (She uses Bob's params as the IBE system parameters.) Since Bob has the master-key, he can extract the private key corresponding to this IBE encryption key and then decrypt the message. Now, suppose Bob goes on a trip for seven days. Normally, Bob would put his private key on his laptop. If the laptop is stolen, the private key is compromised. When using the IBE system, Bob could simply install on his laptop the seven private keys corresponding to the seven days of the trip. If the laptop is stolen, only the private keys for those seven days are compromised. The master-key is unharmed. This is analogous to the delegation scenario for *signature schemes* considered by Goldreich, Pfitzmann, and Rivest [23].

2. *Delegation of duties.* Suppose Alice encrypts mail to Bob using the subject line as the IBE encryption key. Bob can decrypt mail using his master-key. Now, suppose Bob has several assistants each responsible for a different task (e.g., one is "purchasing," another is "human-resources," etc.). Bob gives one private key to each of his assistants corresponding to the assistant's responsibility. Each assistant can then decrypt messages whose subject line falls within its responsibilities, but it cannot decrypt messages intended for other assistants. Note that Alice obtains only a single public key from Bob (params), and she uses that public key to send mail with any subject line of her choice. The mail can be read only by the assistant responsible for that subject.

More generally, IBE can simplify security systems that manage a large number of public keys. Rather than storing a big database of public keys, the system can either derive these public keys from usernames or simply use the integers $1, \ldots, n$ as

distinct public keys.

2. Definitions. IBE. An IBE scheme $\mathcal{E}$ is specified by four randomized algorithms: Setup, Extract, Encrypt, and Decrypt.

Setup takes a security parameter k and returns params (system parameters) and master-key. The system parameters include a description of a finite message space $\mathcal{M}$ and a description of a finite ciphertext space $\mathcal{C}$. Intuitively, the system parameters will be publicly known, while the master-key will be known only to the "private key generator (PKG)."

Extract takes as input params, master-key, and an arbitrary $\mathsf{ID} \in \{0,1\}^*$ and returns a private key d. Here ID is an arbitrary string that will be used as a public key, and d is the corresponding private decryption key. The Extract algorithm extracts a private key from the given public key.

Encrypt takes as input params, ID, and $M \in \mathcal{M}$. It returns a ciphertext $C \in \mathcal{C}$.

Decrypt takes as input params, $C \in \mathcal{C}$, and a private key d. It returns $M \in \mathcal{M}$.

These algorithms must satisfy the standard consistency constraint; namely, when d is the private key generated by algorithm Extract when it is given ID as the public key, then

$$\forall M \in \mathcal{M} : \mathsf{Decrypt}(\mathsf{params}, C, d) = M, \quad \text{where} \quad C = \mathsf{Encrypt}(\mathsf{params}, \mathsf{ID}, M).$$

Chosen ciphertext security. Chosen ciphertext security (IND-CCA) is the standard acceptable notion of security for a public key encryption scheme [37, 2, 13]. Hence it is natural to require that an IBE scheme also satisfy this strong notion of security. However, the definition of chosen ciphertext security must be strengthened a bit. The reason is that when an adversary attacks a public key ID in an identity-based system, the adversary might already possess the private keys of users $\mathsf{ID}_1, \ldots, \mathsf{ID}_n$ of her choice. The system should remain secure under such an attack. Hence the definition of chosen ciphertext security must allow the adversary to obtain the private key associated with any identity ID_i of her choice (other than the public key ID being attacked). We refer to such queries as private key extraction queries. Another difference is that the adversary is challenged on a public key ID of her choice (as opposed to a random public key).

We say that an IBE scheme $\mathcal{E}$ is semantically secure against an adaptive chosen ciphertext attack (IND-ID-CCA) if no polynomially bounded adversary $\mathcal{A}$ has a nonnegligible advantage against the challenger in the following IND-ID-CCA game.

Setup. The challenger takes a security parameter k and runs the Setup algorithm. It gives the adversary the resulting system parameters params. It keeps the master-key to itself.

Phase 1. The adversary issues queries $q_1, \ldots, q_m$, where query q_i is one of the following:

- Extraction query $\langle \mathsf{ID}_i \rangle$. The challenger responds by running algorithm Extract to generate the private key d_i corresponding to the public key $\langle \mathsf{ID}_i \rangle$. It sends d_i to the adversary.
- Decryption query $\langle \mathsf{ID}_i, C_i \rangle$. The challenger responds by running algorithm Extract to generate the private key d_i corresponding to ID_i. It then runs algorithm Decrypt to decrypt the ciphertext C_i using the private key d_i. It sends the resulting plaintext to the adversary.

These queries may be asked adaptively; that is, each query q_i may depend on the replies to $q_1, \ldots, q_{i-1}$.

Challenge. Once the adversary decides that Phase 1 is over, it outputs two equal length plaintexts $M_0, M_1 \in \mathcal{M}$ and an identity ID on which it wishes to be challenged. The only constraint is that ID did not appear in any private key extraction query in Phase 1.

The challenger picks a random bit $b \in \{0,1\}$ and sets the challenge ciphertext to $C = \mathsf{Encrypt}(\mathsf{params}, \mathsf{ID}, M_b)$. It sends C as the challenge to the adversary.

Phase 2. The adversary issues more queries $q_{m+1}, \ldots, q_n$, where q_i is one of the following:

- Extraction query $\langle \mathsf{ID}_i \rangle$, where $\mathsf{ID}_i \neq \mathsf{ID}$. The challenger responds as in Phase 1.
- Decryption query $\langle \mathsf{ID}_i, C_i \rangle \neq \langle \mathsf{ID}, C \rangle$. The challenger responds as in Phase 1.

These queries may be asked adaptively as in Phase 1.

Guess. Finally, the adversary outputs a guess $b' \in \{0,1\}$. The adversary wins the game if $b = b'$.

We refer to such an adversary $\mathcal{A}$ as an IND-ID-CCA adversary. We define adversary $\mathcal{A}$'s advantage in attacking the scheme $\mathcal{E}$ as the following function of the security parameter k (recall that k is given as input to the challenger):

$$\mathrm{Adv}_{\mathcal{E},\mathcal{A}}(k) = \left| \Pr[b = b'] - \frac{1}{2} \right|.$$

The probability is over the random bits used by the challenger and the adversary.

Using the IND-ID-CCA game, we can define chosen ciphertext security for IBE schemes. As usual, we say that a function $g : \mathbb{R} \to \mathbb{R}$ is *negligible* if $g(k)$ is smaller than $1/f(k)$ for any polynomial f.

DEFINITION 2.1. *We say that the IBE system $\mathcal{E}$ is semantically secure against an adaptive chosen ciphertext attack if for any polynomial time* IND-ID-CCA *adversary $\mathcal{A}$ the function $Adv_{\mathcal{E},\mathcal{A}}(k)$ is negligible. As shorthand, we say that $\mathcal{E}$ is* IND-ID-CCA *secure.*

Note that the standard definition of chosen ciphertext security (IND-CCA) [37, 2] is the same as above except that there are no private key extraction queries and the adversary is challenged on a random public key (rather than a public key of her choice). Private key extraction queries are related to the definition of chosen ciphertext security in the multiuser settings [7]. After all, our definition involves multiple public keys belonging to multiple users. In [7], the authors show that that multiuser IND-CCA is reducible to single user IND-CCA using a standard hybrid argument. This does not hold in the identity-based settings, IND-ID-CCA, since the adversary gets to choose which public keys to corrupt during the attack. To emphasize the importance of private key extraction queries, we note that our IBE system can be easily modified (by removing one of the hash functions) into a system which has chosen ciphertext security when private extraction queries are disallowed. However, the scheme is completely insecure when extraction queries are allowed.

Semantically secure IBE. The proof of security for our IBE system makes use of a weaker notion of security known as semantic security (also known as semantic security against a chosen plaintext attack) [24, 2]. Semantic security is similar to chosen ciphertext security (IND-ID-CCA) except that the adversary is more limited; it cannot issue decryption queries. For a standard public key system (not an identity-based system), semantic security is defined using the following game: (1) the adversary is given a random public key generated by the challenger; (2) the adversary outputs

two equal-length messages M_0 and M_1 and receives the encryption of M_b from the challenger, where b is chosen at random in $\{0,1\}$; (3) the adversary outputs b' and wins the game if $b = b'$. The public key system is said to be semantically secure if no polynomial time adversary can win the game with a nonnegligible advantage. As shorthand, we say that a semantically secure public key system is IND-CPA secure. Semantic security captures our intuition that, given a ciphertext, the adversary learns nothing about the corresponding plaintext.

To define semantic security for identity-based systems (denoted IND-ID-CPA), we strengthen the standard definition by allowing the adversary to issue chosen private key extraction queries. Similarly, the adversary is challenged on a public key ID of her choice. We define semantic security for IBE schemes using an IND-ID-CPA game. The game is identical to the IND-ID-CCA game defined above except that the adversary cannot make any decryption queries. The adversary can only make private key extraction queries. We say that an IBE scheme $\mathcal{E}$ is semantically secure (IND-ID-CPA) if no polynomially bounded adversary $\mathcal{A}$ has a nonnegligible advantage against the challenger in the following IND-ID-CPA game.

Setup. The challenger takes a security parameter k and runs the Setup algorithm. It gives the adversary the resulting system parameters params. It keeps the master-key to itself.

Phase 1. The adversary issues private key extraction queries $\mathsf{ID}_1, \ldots, \mathsf{ID}_m$. The challenger responds by running algorithm Extract to generate the private key d_i corresponding to the public key ID_i. It sends d_i to the adversary. These queries may be asked adaptively.

Challenge. Once the adversary decides that Phase 1 is over, it outputs two equal-length plaintexts $M_0, M_1 \in \mathcal{M}$ and a public key ID on which it wishes to be challenged. The only constraint is that ID did not appear in any private key extraction query in Phase 1. The challenger picks a random bit $b \in \{0,1\}$ and sets $C = \mathsf{Encrypt}(\mathsf{params}, \mathsf{ID}, M_b)$. It sends C as the challenge to the adversary.

Phase 2. The adversary issues more extraction queries $\mathsf{ID}_{m+1}, \ldots, \mathsf{ID}_n$. The only constraint is that $\mathsf{ID}_i \neq \mathsf{ID}$. The challenger responds as in Phase 1.

Guess. Finally, the adversary outputs a guess $b' \in \{0,1\}$. The adversary wins the game if $b = b'$.

We refer to such an adversary $\mathcal{A}$ as an IND-ID-CPA adversary. As in the above, the advantage of an IND-ID-CPA adversary $\mathcal{A}$ against the scheme $\mathcal{E}$ is the following function of the security parameter k: $\mathrm{Adv}_{\mathcal{E},\mathcal{A}}(k) = \left|\Pr[b = b'] - \frac{1}{2}\right|$.

The probability is over the random bits used by the challenger and the adversary.

DEFINITION 2.2. *We say that the IBE system $\mathcal{E}$ is semantically secure if for any polynomial time* IND-ID-CPA *adversary $\mathcal{A}$ the function $Adv_{\mathcal{E},\mathcal{A}}(k)$ is negligible. As shorthand, we say that $\mathcal{E}$ is* IND-ID-CPA *secure.*

One-way IBE. One can define an even weaker notion of security called one-way encryption (OWE) [16]. Roughly speaking, a public key encryption scheme is a one-way encryption if, given the encryption of a random plaintext, the adversary cannot produce the plaintext in its entirety. One-way encryption is a weak notion of security since there is nothing preventing the adversary from, say, learning half the bits of the plaintext. Hence one-way encryption schemes do not generally provide secure encryption. In the random oracle model, one-way encryption schemes can be used for encrypting session-keys. (The session-key is taken to be the hash of the plaintext.) We note that one can extend the notion of one-way encryption to identity-based systems

by adding private key extraction queries to the definition. We do not give the full definition here since in this paper we use semantic security as the weakest notion of security. See [5] for the full definition of identity-based one-way encryption and its use as part of an alternative proof strategy for our main result.

Random oracle model. To analyze the security of certain natural cryptographic constructions, Bellare and Rogaway introduced an idealized security model called the random oracle model [3]. Roughly speaking, a random oracle is a function $H : X \to Y$ chosen uniformly at random from the set of all functions $\{h : X \to Y\}$. (We assume Y is a finite set.) An algorithm can query the random oracle at any point $x \in X$ and receive the value $H(x)$ in response. Random oracles are used to model cryptographic hash functions such as SHA-1. Note that security in the random oracle model does not imply security in the real world. Nevertheless, the random oracle model is a useful tool for validating natural cryptographic constructions. Security proofs in this model prove security against attackers that are confined to the random oracle world.

Notation. From here on we use $\mathbb{Z}_q$ to denote the group $\{0, \ldots, q-1\}$ under addition modulo q. For a group $\mathbb{G}$ of prime order, we use $\mathbb{G}^*$ to denote the set $\mathbb{G}^* = \mathbb{G} \setminus \{O\}$, where O is the identity element in the group $\mathbb{G}$. We use $\mathbb{Z}^+$ to denote the set of positive integers.

3. Bilinear maps and the bilinear Diffie–Hellman assumption. Let $\mathbb{G}_1$ and $\mathbb{G}_2$ be two groups of order q for some large prime q. Our IBE system makes use of a *bilinear* map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ between these two groups. The map must satisfy the following properties:

1. *Bilinear.* We say that a map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ is *bilinear* if $\hat{e}(aP, bQ) = \hat{e}(P, Q)^{ab}$ for all $P, Q \in \mathbb{G}_1$ and all $a, b \in \mathbb{Z}$.
2. *Nondegenerate.* The map does not send all pairs in $\mathbb{G}_1 \times \mathbb{G}_1$ to the identity in $\mathbb{G}_2$. Observe that since $\mathbb{G}_1, \mathbb{G}_2$ are groups of prime order, this implies that if P is a generator of $\mathbb{G}_1$, then $\hat{e}(P, P)$ is a generator of $\mathbb{G}_2$.
3. *Computable.* There is an efficient algorithm to compute $\hat{e}(P, Q)$ for any $P, Q \in \mathbb{G}_1$.

A bilinear map satisfying the three properties above is said to be an *admissible* bilinear map. In section 5, we give a concrete example of groups $\mathbb{G}_1, \mathbb{G}_2$ and an admissible bilinear map between them. The group $\mathbb{G}_1$ is a subgroup of the additive group of points of an elliptic curve $E/\mathbb{F}_p$. The group $\mathbb{G}_2$ is a subgroup of the multiplicative group of a finite field $\mathbb{F}^*_{p^2}$. Therefore, throughout the paper, we view $\mathbb{G}_1$ as an additive group and $\mathbb{G}_2$ as a multiplicative group. As we will see in section 5.1, the Weil pairing can be used to construct an admissible bilinear map between these two groups.

The existence of the bilinear map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ as above has two direct implications to these groups.

1. *The MOV reduction.* Menezes, Okamoto, and Vanstone [32] show that the discrete log problem in $\mathbb{G}_1$ is no harder than the discrete log problem in $\mathbb{G}_2$. To see this, let $P, Q \in \mathbb{G}_1$ be an instance of the discrete log problem in $\mathbb{G}_1$ where both P, Q have order q. We wish to find an $\alpha \in \mathbb{Z}_q$ such that $Q = \alpha P$. Let $g = \hat{e}(P, P)$ and $h = \hat{e}(Q, P)$. Then, by bilinearity of $\hat{e}$, we know that $h = g^\alpha$. By nondegeneracy of $\hat{e}$, both g, h have order q in $\mathbb{G}_2$. Hence we reduced the discrete log problem in $\mathbb{G}_1$ to a discrete log problem in $\mathbb{G}_2$. It follows that, for discrete log to be hard in $\mathbb{G}_1$, we must choose our security parameter so that discrete log is hard in $\mathbb{G}_2$ (see section 5).

2. *Decision Diffie–Hellman is easy.* The decision Diffie–Hellman problem (DDH) [4] in $\mathbb{G}_1$ is to distinguish between the distributions $\langle P, aP, bP, abP\rangle$ and $\langle P, aP, bP, cP\rangle$, where a, b, c are random in $\mathbb{Z}^*_q$ and P is random in $\mathbb{G}^*_1$. Joux and Nguyen [28] point

out that DDH in $\mathbb{G}_1$ is easy. To see this, observe that, given $P, aP, bP, cP \in \mathbb{G}_1^*$, we have

$$c = ab \bmod q \quad \Longleftrightarrow \quad \hat{e}(P, cP) = \hat{e}(aP, bP).$$

The computational Diffie–Hellman problem (CDH) in $\mathbb{G}_1$ can still be hard. (CDH in G_1 is to find abP given random $\langle P, aP, bP\rangle$.) Joux and Nguyen [28] give examples of mappings $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$, where CDH in $\mathbb{G}_1$ is believed to be hard even though DDH in $\mathbb{G}_1$ is easy.

3.1. The bilinear Diffie–Hellman assumption (BDH). Since the DDH in $\mathbb{G}_1$ is easy, we cannot use DDH to build cryptosystems in the group $\mathbb{G}_1$. Instead, the security of our IBE system is based on a variant of the CDH assumption called the bilinear Diffie–Hellman assumption (BDH).

BDH problem. Let $\mathbb{G}_1, \mathbb{G}_2$ be two groups of prime order q. Let $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ be an admissible bilinear map, and let P be a generator of $\mathbb{G}_1$. The BDH problem in $\langle \mathbb{G}_1, \mathbb{G}_2, \hat{e}\rangle$ is as follows: Given $\langle P, aP, bP, cP\rangle$ for some $a, b, c \in \mathbb{Z}_q^*$, compute $W = \hat{e}(P, P)^{abc} \in \mathbb{G}_2$. An algorithm $\mathcal{A}$ has advantage ϵ in solving BDH in $\langle \mathbb{G}_1, \mathbb{G}_2, \hat{e}\rangle$ if

$$\Pr\left[\mathcal{A}(P, aP, bP, cP) = \hat{e}(P, P)^{abc}\right] \geq \epsilon,$$

where the probability is over the random choice of a, b, c in $\mathbb{Z}_q^*$, the random choice of $P \in \mathbb{G}_1^*$, and the random bits of $\mathcal{A}$.

BDH parameter generator. We say that a randomized algorithm $\mathcal{G}$ is a *BDH parameter generator* if (1) $\mathcal{G}$ takes a security parameter $k \in \mathbb{Z}^+$, (2) $\mathcal{G}$ runs in polynomial time in k, and (3) $\mathcal{G}$ outputs a prime number q, the description of two groups $\mathbb{G}_1, \mathbb{G}_2$ of order q, and the description of an admissible bilinear map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$. We denote the output of $\mathcal{G}$ by $\mathcal{G}(1^k) = \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}\rangle$. The security parameter k is used to determine the size of q; for example, one could take q to be a random k-bit prime. For $i = 1, 2$, we assume that the description of the group $\mathbb{G}_i$ contains polynomial time (in k) algorithms for computing the group action in $\mathbb{G}_i$ and contains a generator of $\mathbb{G}_i$. The generator of $\mathbb{G}_i$ enables us to generate uniformly random elements in $\mathbb{G}_i$. Similarly, we assume that the description of $\hat{e}$ contains a polynomial time algorithm for computing $\hat{e}$. We give an example of a BDH parameter generator in section 5.1.

BDH assumption. Let $\mathcal{G}$ be a BDH parameter generator. We say that an algorithm $\mathcal{A}$ has advantage $\epsilon(k)$ in solving the BDH problem for $\mathcal{G}$ if, for sufficiently large k,

$$\mathrm{Adv}_{\mathcal{G},\mathcal{A}}(k) = \Pr\left[\mathcal{A}\begin{pmatrix} q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, \\ P, aP, bP, cP \end{pmatrix} = \hat{e}(P, P)^{abc} \;\middle|\; \begin{array}{l} \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}\rangle \leftarrow \mathcal{G}(1^k), \\ P \leftarrow \mathbb{G}_1^*,\ a, b, c \leftarrow \mathbb{Z}_q^* \end{array}\right] \geq \epsilon(k).$$

We say that $\mathcal{G}$ satisfies the BDH assumption if for any randomized polynomial time (in k) algorithm $\mathcal{A}$ and for any polynomial $f \in \mathbb{Z}[x]$ we have that $\mathrm{Adv}_{\mathcal{G},\mathcal{A}}(k) < 1/f(k)$ for sufficiently large k. When $\mathcal{G}$ satisfies the BDH assumption, we say that BDH is hard in groups generated by $\mathcal{G}$.

In section 5.1, we give some examples of BDH parameter generators that are believed to satisfy the BDH assumption. We note that Joux [26] (implicitly) used the BDH assumption to construct a one-round three party Diffie–Hellman protocol. The BDH assumption is also needed for constructions in [46, 40].

Hardness of BDH. It is interesting to study the relationship of the BDH problem to other hard problems used in cryptography. Currently, all we can say is that the

BDH problem in $\langle \mathbb{G}_1, \mathbb{G}_2, \hat{e} \rangle$ is no harder than the CDH problem in $\mathbb{G}_1$ or $\mathbb{G}_2$. In other words, an algorithm for CDH in $\mathbb{G}_1$ or $\mathbb{G}_2$ is sufficient for solving BDH in $\langle \mathbb{G}_1, \mathbb{G}_2, \hat{e} \rangle$. The converse is currently an open problem: is an algorithm for BDH sufficient for solving CDH in $\mathbb{G}_1$ or in $\mathbb{G}_2$? We refer to a recent survey by Joux [27] for a more detailed analysis of the relationship between BDH and other standard problems.

We note that in all our examples (in section 5.1) the isomorphisms from $\mathbb{G}_1$ to $\mathbb{G}_2$ induced by the bilinear map are believed to be one-way functions. More specifically, for a point $Q \in \mathbb{G}_1^*$ define the isomorphism $f_Q : \mathbb{G}_1 \to \mathbb{G}_2$ by $f_Q(P) = \hat{e}(P, Q)$. If any one of these isomorphisms turns out to be invertible, then BDH is easy in $\langle \mathbb{G}_1, \mathbb{G}_2, \hat{e} \rangle$. Fortunately, an efficient algorithm for inverting f_Q for some fixed Q would imply an efficient algorithm for deciding DDH in the group $\mathbb{G}_2$. In all our examples DDH is believed to be hard in the group $\mathbb{G}_2$. Hence, all the isomorphisms $f_Q : \mathbb{G}_1 \to \mathbb{G}_2$ induced by the bilinear map are believed to be one-way functions.

4. Our IBE scheme.

We describe our scheme in stages. First we give a basic IBE scheme which is not secure against an adaptive chosen ciphertext attack. The only reason for describing the basic scheme is to make the presentation easier to follow. Our full scheme, described in section 4.2, extends the basic scheme to get security against an adaptive chosen ciphertext attack (IND-ID-CCA) in the random oracle model. In section 4.3, we relax some of the requirements on the hash functions.

The presentation in this section uses an arbitrary BDH parameter generator $\mathcal{G}$ satisfying the BDH assumption. In section 5, we describe a concrete IBE system using the Weil pairing.

4.1. BasicIdent.

To explain the basic ideas underlying our IBE system, we describe the following simple scheme, called BasicIdent. We present the scheme by describing the four algorithms: Setup, Extract, Encrypt, Decrypt. We let k be the security parameter given to the setup algorithm. We let $\mathcal{G}$ be some BDH parameter generator.

Setup: Given a security parameter $k \in \mathbb{Z}^+$, the algorithm works as follows:

Step 1: Run $\mathcal{G}$ on input k to generate a prime q, two groups $\mathbb{G}_1, \mathbb{G}_2$ of order q, and an admissible bilinear map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$. Choose an arbitrary generator $P \in \mathbb{G}_1$.

Step 2: Pick a random $s \in \mathbb{Z}_q^*$, and set $P_{pub} = sP$.

Step 3: Choose a cryptographic hash function $H_1 : \{0,1\}^* \to \mathbb{G}_1^*$. Choose a cryptographic hash function $H_2 : \mathbb{G}_2 \to \{0,1\}^n$ for some n. The security analysis will view H_1, H_2 as random oracles.

The message space is $\mathcal{M} = \{0,1\}^n$. The ciphertext space is $\mathcal{C} = \mathbb{G}_1^* \times \{0,1\}^n$. The system parameters are $\mathsf{params} = \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, H_1, H_2 \rangle$. The master-key is $s \in \mathbb{Z}_q^*$.

Extract: For a given string $\mathsf{ID} \in \{0,1\}^*$ the algorithm does the following: (1) it computes $Q_{\mathsf{ID}} = H_1(\mathsf{ID}) \in \mathbb{G}_1^*$, and (2) it sets the private key d_{ID} to be $d_{\mathsf{ID}} = sQ_{\mathsf{ID}}$, where s is the master key.

Encrypt: To encrypt $M \in \mathcal{M}$ under the public key ID, do the following: (1) compute $Q_{\mathsf{ID}} = H_1(\mathsf{ID}) \in \mathbb{G}_1^*$, (2) choose a random $r \in \mathbb{Z}_q^*$, and (3) set the ciphertext to be

$$C = \langle rP,\ M \oplus H_2(g_{\mathsf{ID}}^r) \rangle, \quad \text{where} \quad g_{\mathsf{ID}} = \hat{e}(Q_{\mathsf{ID}}, P_{pub}) \in \mathbb{G}_2^*.$$

Decrypt: Let $C = \langle U, V\rangle \in \mathcal{C}$ be a ciphertext encrypted using the public key ID. To decrypt C using the private key $d_{\mathsf{ID}} \in \mathbb{G}_1^*$, compute

$$V \oplus H_2(\hat{e}(d_{\mathsf{ID}}, U)) = M.$$

This completes the description of BasicIdent. We first verify consistency. When everything is computed as above, we have the following:

1. During encryption, M is bitwise exclusive-ored with the hash of g_{ID}^r.
2. During decryption, V is bitwise exclusive-ored with the hash of $\hat{e}(d_{\mathsf{ID}}, U)$.

These masks used during encryption and decryption are the same since

$$\hat{e}(d_{\mathsf{ID}}, U) = \hat{e}(sQ_{\mathsf{ID}}, rP) = \hat{e}(Q_{\mathsf{ID}}, P)^{sr} = \hat{e}(Q_{\mathsf{ID}}, P_{pub})^r = g_{\mathsf{ID}}^r.$$

Thus applying decryption after encryption produces the original message M as required. Performance considerations of BasicIdent are discussed in section 5. Note that the value of g_{ID} in algorithm Encrypt is independent of the message to be encrypted. Hence there is no need to recompute g_{ID} on subsequent encryptions to the same public key ID.

Security. Next, we study the security of this basic scheme. The following theorem shows that BasicIdent is a semantically secure IBE scheme (IND-ID-CPA) assuming BDH is hard in groups generated by $\mathcal{G}$.

THEOREM 4.1. *Suppose the hash functions H_1, H_2 are random oracles. Then* BasicIdent *is a semantically secure IBE scheme* (IND-ID-CPA) *assuming BDH is hard in groups generated by $\mathcal{G}$. Concretely, suppose there is an* IND-ID-CPA *adversary $\mathcal{A}$ that has advantage $\epsilon(k)$ against the scheme* BasicIdent. *Suppose $\mathcal{A}$ makes at most $q_E > 0$ private key extraction queries and $q_{H_2} > 0$ hash queries to H_2. Then there is an algorithm $\mathcal{B}$ that solves BDH in groups generated by $\mathcal{G}$ with advantage at least*

$$Adv_{\mathcal{G},\mathcal{B}}(k) \geq \frac{2\epsilon(k)}{e(1+q_E)\cdot q_{H_2}}.$$

Here $e \approx 2.71$ is the base of the natural logarithm. The running time of $\mathcal{B}$ is $O(time(\mathcal{A}))$.

To prove the theorem, we first define a related public key encryption scheme (not an identity-based scheme) called BasicPub. BasicPub is described by three algorithms: keygen, encrypt, decrypt.

keygen: Given a security parameter $k \in \mathbb{Z}^+$, the algorithm works as follows:

Step 1: Run $\mathcal{G}$ on input k to generate two prime order groups $\mathbb{G}_1, \mathbb{G}_2$ and a bilinear map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$. Let q be the order of $\mathbb{G}_1, \mathbb{G}_2$. Choose an arbitrary generator $P \in \mathbb{G}_1$.

Step 2: Pick a random $s \in \mathbb{Z}_q^*$, and set $P_{pub} = sP$. Pick a random $Q_{\mathsf{ID}} \in \mathbb{G}_1^*$.

Step 3: Choose a cryptographic hash function $H_2 : \mathbb{G}_2 \to \{0,1\}^n$ for some n.

Step 4: The public key is $\langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, Q_{\mathsf{ID}}, H_2\rangle$. The private key is $d_{\mathsf{ID}} = sQ_{\mathsf{ID}} \in \mathbb{G}_1^*$.

encrypt: To encrypt $M \in \{0,1\}^n$, choose a random $r \in \mathbb{Z}_q^*$, and set the ciphertext to

$$C = \langle rP,\ \ M \oplus H_2(g^r)\rangle, \quad \text{where} \quad g = \hat{e}(Q_{\mathsf{ID}}, P_{pub}) \in \mathbb{G}_2^*.$$

decrypt: Let $C = \langle U, V\rangle$ be a ciphertext created using the BasicPub public key $\langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, Q_{\mathsf{ID}}, H_2\rangle$. To decrypt C using the private key $d_{\mathsf{ID}} \in \mathbb{G}_1^*$, compute

$$V \oplus H_2(\hat{e}(d_{\mathsf{ID}}, U)) = M.$$

This completes the description of BasicPub. We now prove Theorem 4.1 in two steps. We first show that an IND-ID-CPA attack on BasicIdent can be converted to an IND-CPA attack on BasicPub. This step shows that private key extraction queries do not help the adversary. We then show that BasicPub is IND-CPA secure if the BDH assumption holds.

LEMMA 4.2. *Let H_1 be a random oracle from $\{0,1\}^*$ to $\mathbb{G}_1^*$. Let $\mathcal{A}$ be an* IND-ID-CPA *adversary that has advantage $\epsilon(k)$ against* BasicIdent. *Suppose $\mathcal{A}$ makes at most $q_E > 0$ private key extraction queries. Then there is an* IND-CPA *adversary $\mathcal{B}$ that has advantage at least $\epsilon(k)/e(1+q_E)$ against* BasicPub. *Its running time is $O(time(\mathcal{A}))$.*

Proof. We show how to construct an IND-CPA adversary $\mathcal{B}$ that uses $\mathcal{A}$ to gain advantage $\epsilon/e(1+q_E)$ against BasicPub. The game between the challenger and the adversary $\mathcal{B}$ starts with the challenger first generating a random public key by running algorithm keygen of BasicPub. The result is a public key $K_{pub} = \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, Q_{\mathsf{ID}}, H_2\rangle$ and a private key $d_{\mathsf{ID}} = sQ_{\mathsf{ID}}$. Let q be the order of $\mathbb{G}_1, \mathbb{G}_2$. The challenger gives K_{pub} to algorithm $\mathcal{B}$. Algorithm $\mathcal{B}$ is supposed to output two messages M_0 and M_1 and expects to receive back the BasicPub encryption of M_b under K_{pub}, where $b \in \{0,1\}$. Then algorithm $\mathcal{B}$ outputs its guess $b' \in \{0,1\}$ for b.

Algorithm $\mathcal{B}$ works by interacting with $\mathcal{A}$ in an IND-ID-CPA game as follows ($\mathcal{B}$ simulates the challenger).

Setup. Algorithm $\mathcal{B}$ starts by giving algorithm $\mathcal{A}$ the BasicIdent system parameters $\langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, H_1, H_2\rangle$. Here $q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}$, n, P, P_{pub}, H_2 are taken from K_{pub}, and H_1 is a random oracle controlled by $\mathcal{B}$ as described below.

***H_1*-queries.** At any time algorithm $\mathcal{A}$ can query the random oracle H_1. To respond to these queries algorithm $\mathcal{B}$ maintains a list of tuples $\langle \mathsf{ID}_j, Q_j, b_j, c_j\rangle$ as explained below. We refer to this list as the H_1^{list}. The list is initially empty. When $\mathcal{A}$ queries the oracle H_1 at a point ID_i, algorithm $\mathcal{B}$ responds as follows:

1. If the query ID_i already appears on the H_1^{list} in a tuple $\langle \mathsf{ID}_i, Q_i, b_i, c_i\rangle$, then Algorithm $\mathcal{B}$ responds with $H_1(\mathsf{ID}_i) = Q_i \in \mathbb{G}_1^*$.
2. Otherwise, $\mathcal{B}$ generates a random $coin \in \{0,1\}$ so that $\Pr[coin = 0] = \delta$ for some δ that will be determined later.
3. Algorithm $\mathcal{B}$ picks a random $b \in \mathbb{Z}_q^*$.
   If $coin = 0$, compute $Q_i = bP \in \mathbb{G}_1^*$. If $coin = 1$, compute $Q_i = bQ_{\mathsf{ID}} \in \mathbb{G}_1^*$.
4. Algorithm $\mathcal{B}$ adds the tuple $\langle \mathsf{ID}_i, Q_i, b, coin\rangle$ to the H_1^{list} and responds to $\mathcal{A}$ with $H_1(\mathsf{ID}_i) = Q_i$.

Note that either way Q_i is uniform in $\mathbb{G}_1^*$ and is independent of $\mathcal{A}$'s current view as required.

Phase 1. Let ID_i be a private key extraction query issued by algorithm $\mathcal{A}$. Algorithm $\mathcal{B}$ responds to this query as follows:

1. Run the above algorithm for responding to H_1-queries to obtain a $Q_i \in \mathbb{G}_1^*$ such that $H_1(\mathsf{ID}_i) = Q_i$. Let $\langle \mathsf{ID}_i, Q_i, b_i, coin_i\rangle$ be the corresponding tuple on the H_1^{list}. If $coin_i = 1$, then $\mathcal{B}$ reports failure and terminates. The attack on BasicPub failed.
2. We know $coin_i = 0$ and hence $Q_i = b_iP$. Define $d_i = b_iP_{pub} \in \mathbb{G}_1^*$. Observe that $d_i = sQ_i$, and therefore d_i is the private key associated to the public key ID_i. Give d_i to algorithm $\mathcal{A}$.

Challenge. Once algorithm $\mathcal{A}$ decides that Phase 1 is over, it outputs a public key ID_{ch} and two messages M_0, M_1 on which it wishes to be challenged. Algorithm $\mathcal{B}$ responds as follows:

1. Algorithm $\mathcal{B}$ gives the challenger M_0, M_1 as the messages that it wishes to be challenged on. The challenger responds with a BasicPub ciphertext $C = \langle U, V\rangle$ such that C is the encryption of M_c for a random $c \in \{0,1\}$.
2. Next, $\mathcal{B}$ runs the algorithm for responding to H_1-queries to obtain a $Q \in \mathbb{G}_1^*$ such that $H_1(\mathsf{ID}_{ch}) = Q$. Let $\langle \mathsf{ID}_{ch}, Q, b, coin\rangle$ be the corresponding tuple on the H_1^{list}. If $coin = 0$, then $\mathcal{B}$ reports failure and terminates. The attack on BasicPub failed.
3. We know $coin = 1$, and therefore $Q = bQ_{\mathsf{ID}}$. Recall that when $C = \langle U, V\rangle$, we have $U \in \mathbb{G}_1^*$. Set $C' = \langle b^{-1}U,\ V\rangle$, where b^{-1} is the inverse of $b \bmod q$. Algorithm $\mathcal{B}$ responds to $\mathcal{A}$ with the challenge C'. Note that C' is a BasicIdent encryption of M_c under the public key ID_{ch} as required. To see this, first observe that, since $H_1(\mathsf{ID}_{ch}) = Q$, the private key corresponding to ID_{ch} is $d_{ch} = sQ$. Second, observe that

$$\hat{e}(b^{-1}U, d_{ch}) = \hat{e}(b^{-1}U, sQ) = \hat{e}(U, sb^{-1}Q) = \hat{e}(U, sQ_{\mathsf{ID}}) = \hat{e}(U, d_{\mathsf{ID}}).$$

   Hence the BasicIdent decryption of C' using d_{ch} is the same as the BasicPub decryption of C using d_{ID}.

Phase 2. Algorithm $\mathcal{B}$ responds to private key extraction queries in the same way it did in Phase 1.

Guess. Eventually algorithm $\mathcal{A}$ produces a guess c' for c. Algorithm $\mathcal{B}$ outputs c' as its guess for c.

Claim. If algorithm $\mathcal{B}$ does not abort during the simulation, then algorithm $\mathcal{A}$'s view is identical to its view in the real attack. Furthermore, if $\mathcal{B}$ does not abort, then $|\Pr[c = c'] - \frac{1}{2}| \geq \epsilon$. The probability is over the random bits used by $\mathcal{A}, \mathcal{B}$ and the challenger.

Proof of claim. The responses to H_1-queries are as in the real attack since each response is uniformly and independently distributed in $\mathbb{G}_1^*$. All responses to private key extraction queries are valid. Finally, the challenge ciphertext C' given to $\mathcal{A}$ is the BasicIdent encryption of M_c for some random $c \in \{0,1\}$. Therefore, by definition of algorithm $\mathcal{A}$, we have that $|\Pr[c = c'] - \frac{1}{2}| \geq \epsilon$. □

To complete the proof of Lemma 4.2, it remains to calculate the probability that algorithm $\mathcal{B}$ aborts during the simulation. Suppose $\mathcal{A}$ makes a total of q_E private key extraction queries. Then the probability that $\mathcal{B}$ does not abort in Phases 1 or 2 is δ^{q_E}. The probability that it does not abort during the challenge step is $1 - \delta$. Therefore, the probability that $\mathcal{B}$ does not abort during the simulation is $\delta^{q_E}(1 - \delta)$. This value is maximized at $\delta_{opt} = 1 - 1/(q_E + 1)$. Using δ_{opt}, the probability that $\mathcal{B}$ does not abort is at least $1/e(1 + q_E)$. This shows that $\mathcal{B}$'s advantage is at least $\epsilon/e(1 + q_E)$ as required. □

The analysis used in the proof of Lemma 4.2 uses a similar technique to Coron's analysis of the full domain hash signature scheme [9]. Next, we show that BasicPub is a semantically secure public key system if the BDH assumption holds.

LEMMA 4.3. *Let H_2 be a random oracle from $\mathbb{G}_2$ to $\{0,1\}^n$. Let $\mathcal{A}$ be an* IND-CPA *adversary that has advantage $\epsilon(k)$ against* BasicPub. *Suppose $\mathcal{A}$ makes a total of $q_{H_2} > 0$ queries to H_2. Then there is an algorithm $\mathcal{B}$ that solves the BDH problem for $\mathcal{G}$ with advantage at least $2\epsilon(k)/q_{H_2}$ and a running time $O(time(\mathcal{A}))$.*

Proof. Algorithm $\mathcal{B}$ is given as input the BDH parameters $\langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}\rangle$ produced by $\mathcal{G}$ and a random instance $\langle P, aP, bP, cP\rangle = \langle P, P_1, P_2, P_3\rangle$ of the BDH problem for these parameters; i.e., P is random in $\mathbb{G}_1^*$ and a, b, c are random in $\mathbb{Z}_q^*$, where q is

the order of $\mathbb{G}_1, \mathbb{G}_2$. Let $D = \hat{e}(P,P)^{abc} \in \mathbb{G}_2$ be the solution to this BDH problem. Algorithm $\mathcal{B}$ finds D by interacting with $\mathcal{A}$ as follows.

Setup. Algorithm $\mathcal{B}$ sets $P_{pub} = P_1$ and $Q_{\mathsf{ID}} = P_2$ and creates the BasicPub public key $K_{pub} = \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, Q_{\mathsf{ID}}, H_2 \rangle$. Here H_2 is a random oracle controlled by $\mathcal{B}$ as described below. Algorithm $\mathcal{B}$ gives $\mathcal{A}$ the BasicPub public key K_{pub}. Observe that the (unknown) private key associated to K_{pub} is $d_{\mathsf{ID}} = aQ_{\mathsf{ID}} = abP$.

***H_2*-queries.** At any time, algorithm $\mathcal{A}$ may issue queries to the random oracle H_2. To respond to these queries, $\mathcal{B}$ maintains a list of tuples called the H_2^{list}. Each entry in the list is a tuple of the form $\langle X_j, H_j \rangle$. Initially the list is empty. To respond to query X_i, algorithm $\mathcal{B}$ does the following:

1. If the query X_i already appears on the H_2^{list} in a tuple $\langle X_i, H_i \rangle$, then respond with $H_2(X_i) = H_i$.
2. Otherwise, $\mathcal{B}$ just picks a random string $H_i \in \{0,1\}^n$ and adds the tuple $\langle X_i, H_i \rangle$ to the H_2^{list}. It responds to $\mathcal{A}$ with $H_2(X_i) = H_i$.

Challenge. Algorithm $\mathcal{A}$ outputs two messages M_0, M_1 on which it wishes to be challenged. Algorithm $\mathcal{B}$ picks a random string $R \in \{0,1\}^n$ and defines C to be the ciphertext $C = \langle P_3, R \rangle$. Algorithm $\mathcal{B}$ gives C as the challenge to $\mathcal{A}$. Observe that, by definition, the decryption of C is $R \oplus H_2(\hat{e}(P_3, d_{\mathsf{ID}})) = R \oplus H_2(D)$.

Guess. Algorithm $\mathcal{A}$ outputs its guess $c' \in \{0,1\}$. At this point, $\mathcal{B}$ picks a random tuple $\langle X_j, H_j \rangle$ from the H_2^{list} and outputs X_j as the solution to the given instance of BDH.

Algorithm $\mathcal{B}$ is simulating a real attack environment for algorithm $\mathcal{A}$ (it simulates the challenger and the oracle for H_2). We show that algorithm $\mathcal{B}$ outputs the correct answer D with probability at least $2\epsilon/q_{H_2}$ as required. The proof is based on comparing $\mathcal{A}$'s behavior in the simulation to its behavior in a real IND-CPA attack game (against a real challenger and a real random oracle for H_2).

Let $\mathcal{H}$ be the event that algorithm $\mathcal{A}$ issues a query for $H_2(D)$ at some point during the simulation above. (This implies that at the end of the simulation D appears in some tuple on the H_2^{list}.) We show that $\Pr[\mathcal{H}] \geq 2\epsilon$. This will prove that algorithm $\mathcal{B}$ outputs D with probability at least $2\epsilon/q_{H_2}$. We also study event $\mathcal{H}$ in the real attack game, namely, the event that $\mathcal{A}$ issues a query for $H_2(D)$ when communicating with a real challenger and a real random oracle for H_2.

Claim 1. $\Pr[\mathcal{H}]$ in the simulation above is equal to $\Pr[\mathcal{H}]$ in the real attack.

Proof of claim. Let $\mathcal{H}_\ell$ be the event that $\mathcal{A}$ makes a query for $H_2(D)$ in one of its first ℓ queries to the H_2 oracle. We prove by induction on ℓ that $\Pr[\mathcal{H}_\ell]$ in the real attack is equal to $\Pr[\mathcal{H}_\ell]$ in the simulation for all $\ell \geq 0$. Clearly, $\Pr[\mathcal{H}_0] = 0$ in both the simulation and in the real attack. Now suppose that, for some $\ell > 0$, we have that $\Pr[\mathcal{H}_{\ell-1}]$ in the simulation is equal to $\Pr[\mathcal{H}_{\ell-1}]$ in the real attack. We show that the same holds for $\mathcal{H}_\ell$. We know that

$$\begin{aligned} \Pr[\mathcal{H}_\ell] &= \Pr[\mathcal{H}_\ell \mid \mathcal{H}_{\ell-1}] \Pr[\mathcal{H}_{\ell-1}] + \Pr[\mathcal{H}_\ell \mid \neg\mathcal{H}_{\ell-1}] \Pr[\neg\mathcal{H}_{\ell-1}] \\ &= \Pr[\mathcal{H}_{\ell-1}] + \Pr[\mathcal{H}_\ell \mid \neg\mathcal{H}_{\ell-1}] \Pr[\neg\mathcal{H}_{\ell-1}]. \end{aligned} \tag{4.1}$$

We argue that $\Pr[\mathcal{H}_\ell \mid \neg\mathcal{H}_{\ell-1}]$ in the simulation is equal to $\Pr[\mathcal{H}_\ell \mid \neg\mathcal{H}_{\ell-1}]$ in the real attack. To see this, observe that as long as $\mathcal{A}$ does not issue a query for $H_2(D)$, its view during the simulation is identical to its view in the real attack (against a real challenger and a real random oracle for H_2). Indeed, the public key and the challenge are distributed as in the real attack. Similarly, all responses to H_2-queries are uniform and independent in $\{0,1\}^n$. Therefore, $\Pr[\mathcal{H}_\ell \mid \neg\mathcal{H}_{\ell-1}]$ in the simulation is equal to

$\Pr[\mathcal{H}_\ell \mid \neg\mathcal{H}_{\ell-1}]$ in the real attack. It follows by (4.1) and the inductive hypothesis that $\Pr[\mathcal{H}_\ell]$ in the real attack is equal to $\Pr[\mathcal{H}_\ell]$ in the simulation. By induction on ℓ, we obtain that $\Pr[\mathcal{H}]$ in the real attack is equal to $\Pr[\mathcal{H}]$ in the simulation. □

Claim 2. In the real attack, we have $\Pr[\mathcal{H}] \geq 2\epsilon$.

Proof of claim. In the real attack, if $\mathcal{A}$ never issues a query for $H_2(D)$, then the decryption of C is independent of $\mathcal{A}$'s view (since $H_2(D)$ is independent of $\mathcal{A}$'s view). Therefore, in the real attack, $\Pr[c = c' \mid \neg\mathcal{H}] = 1/2$. By definition of $\mathcal{A}$, we know that in the real attack $|\Pr[c = c'] - 1/2| \geq \epsilon$. We show that these two facts imply that $\Pr[\mathcal{H}] \geq 2\epsilon$. To do so, we first derive simple upper and lower bounds on $\Pr[c = c']$:

$$\begin{aligned}\Pr[c = c'] &= \Pr[c = c' | \neg\mathcal{H}] \Pr[\neg\mathcal{H}] + \Pr[c = c' | \mathcal{H}] \Pr[\mathcal{H}] \\ &\leq \Pr[c = c' | \neg\mathcal{H}] \Pr[\neg\mathcal{H}] + \Pr[\mathcal{H}] = \frac{1}{2}\Pr[\neg\mathcal{H}] + \Pr[\mathcal{H}] = \frac{1}{2} + \frac{1}{2}\Pr[\mathcal{H}], \\ \Pr[c = c'] &\geq \Pr[c = c' | \neg\mathcal{H}] \Pr[\neg\mathcal{H}] = \frac{1}{2} - \frac{1}{2}\Pr[\mathcal{H}].\end{aligned}$$

It follows that $\epsilon \leq |\Pr[c = c'] - 1/2| \leq \frac{1}{2}\Pr[\mathcal{H}]$. Therefore, in the real attack, $\Pr[\mathcal{H}] \geq 2\epsilon$. □

To complete the proof of Lemma 4.3, observe that by Claims 1 and 2 we know that $\Pr[\mathcal{H}] \geq 2\epsilon$ in the simulation above. Hence, at the end of the simulation, D appears in some tuple on the H_2^{list} with probability at least 2ϵ. It follows that $\mathcal{B}$ produces the correct answer with probability at least $2\epsilon/q_{H_2}$ as required. □

We note that one can slightly vary the reduction in the proof above to obtain different bounds. For example, in the "Guess" step above, one can avoid having to pick a random element from the H_2^{list} by using the random self-reduction of the BDH problem. This requires running algorithm $\mathcal{A}$ multiple times (as in Theorem 7 of [42]). The success probability for solving the given BDH problem increases at the cost of also increasing the running time.

Proof of Theorem 4.1. The theorem follows from Lemmas 4.2 and 4.3. Composing both reductions shows that an IND-ID-CPA adversary on BasicIdent with advantage $\epsilon(k)$ gives a BDH algorithm for $\mathcal{G}$ with advantage at least $2\epsilon(k)/e(1 + q_E)q_{H_2}$, as required. □

4.2. IBE with chosen ciphertext security. We use a technique due to Fujisaki and Okamoto [16] to convert the BasicIdent scheme of the previous section into a chosen ciphertext secure IBE system (in the sense of section 2) in the random oracle model. Let $\mathcal{E}$ be a probabilistic public key encryption scheme. We denote by $\mathcal{E}_{pk}(M; r)$ the encryption of M using the random bits r under the public key pk. Fujisaki and Okamoto define the hybrid scheme $\mathcal{E}^{hy}$ as

$$\mathcal{E}^{hy}_{pk}(M) \;=\; \langle\, \mathcal{E}_{pk}(\sigma; H_3(\sigma, M)),\;\; H_4(\sigma) \oplus M \,\rangle.$$

Here σ is generated at random, and H_3, H_4 are cryptographic hash functions. Fujisaki and Okamoto show that if $\mathcal{E}$ is a one-way encryption scheme, then $\mathcal{E}^{hy}$ is a chosen ciphertext secure system (IND-CCA) in the random oracle model (assuming $\mathcal{E}_{pk}$ satisfies some natural constraints). We note that semantic security implies one-way encryption, and hence the Fujisaki–Okamoto result also applies if $\mathcal{E}$ is semantically secure (IND-CPA).

We apply the Fujisaki–Okamoto transformation to BasicIdent and show that the resulting IBE system is IND-ID-CCA secure. We obtain the following IBE scheme which we call FullIdent. Recall that n is the length of the message to be encrypted.

Setup. As in the BasicIdent scheme. In addition, we pick a hash function $H_3 : \{0,1\}^n \times \{0,1\}^n \to \mathbb{Z}_q^*$ and a hash function $H_4 : \{0,1\}^n \to \{0,1\}^n$.

Extract. As in the BasicIdent scheme.

Encrypt. To encrypt $M \in \{0,1\}^n$ under the public key ID, do the following: (1) compute $Q_{\mathsf{ID}} = H_1(\mathsf{ID}) \in \mathbb{G}_1^*$, (2) choose a random $\sigma \in \{0,1\}^n$, (3) set $r = H_3(\sigma, M)$, and (4) set the ciphertext to be

$$C = \langle rP,\ \sigma \oplus H_2(g_{\mathsf{ID}}^r),\ M \oplus H_4(\sigma)\rangle, \quad \text{where} \quad g_{\mathsf{ID}} = \hat{e}(Q_{\mathsf{ID}}, P_{pub}) \in \mathbb{G}_2.$$

Decrypt. Let $C = \langle U, V, W\rangle$ be a ciphertext encrypted using the public key ID. If $U \notin \mathbb{G}_1^*$, reject the ciphertext. To decrypt C using the private key $d_{\mathsf{ID}} \in \mathbb{G}_1^*$, do:

1. Compute $V \oplus H_2(\hat{e}(d_{\mathsf{ID}}, U)) = \sigma$.
2. Compute $W \oplus H_4(\sigma) = M$.
3. Set $r = H_3(\sigma, M)$. Test that $U = rP$. If not, reject the ciphertext.
4. Output M as the decryption of C.

This completes the description of FullIdent. Note that M is encrypted as $W = M \oplus H_4(\sigma)$. This can be replaced by $W = E_{H_4(\sigma)}(M)$, where E is a semantically secure symmetric encryption scheme (see [16]).

Security. The following theorem shows that FullIdent is a chosen ciphertext secure IBE (i.e., IND-ID-CCA), assuming BDH is hard in groups generated by $\mathcal{G}$.

THEOREM 4.4. *Let the hash functions H_1, H_2, H_3, H_4 be random oracles. Then* FullIdent *is a chosen ciphertext secure IBE* (IND-ID-CCA)*, assuming BDH is hard in groups generated by $\mathcal{G}$.*

Concretely, suppose there is an IND-ID-CCA *adversary $\mathcal{A}$ that has advantage $\epsilon(k)$ against the scheme* FullIdent *and $\mathcal{A}$ runs in time at most $t(k)$. Suppose $\mathcal{A}$ makes at most q_E extraction queries, at most q_D decryption queries, and at most $q_{H_2}, q_{H_3}, q_{H_4}$ queries to the hash functions H_2, H_3, H_4, respectively. Then there is a BDH algorithm $\mathcal{B}$ for $\mathcal{G}$ with running time $t_1(k)$, where*

$$Adv_{\mathcal{G},\mathcal{B}}(k) \geq 2FO_{adv}\left(\tfrac{\epsilon(k)}{e(1+q_E+q_D)},\ q_{H_4},\ q_{H_3},\ q_D\right)/q_{H_2},$$
$$t_1(k) \leq FO_{time}(t(k), q_{H_4}, q_{H_3}),$$

where the functions FO_{time} and FO_{adv} are as defined in Theorem 4.5.

The proof of Theorem 4.4 is based on the following result of Fujisaki and Okamoto (Theorem 14 in [16]). Let BasicPub^{hy} be the result of applying the Fujisaki–Okamoto transformation to BasicPub.

THEOREM 4.5 (Fujisaki–Okamoto). *Suppose $\mathcal{A}$ is an* IND-CCA *adversary that achieves advantage $\epsilon(k)$ when attacking* BasicPub^{hy}*. Suppose $\mathcal{A}$ has running time $t(k)$, makes at most q_D decryption queries, and makes at most q_{H_3}, q_{H_4} queries to the hash functions H_3, H_4, respectively. Then there is an* IND-CPA *adversary $\mathcal{B}$ against* BasicPub *with running time $t_1(k)$ and advantage $\epsilon_1(k)$, where*

$$\epsilon_1(k) \geq FO_{adv}(\epsilon(k), q_{H_4}, q_{H_3}, q_D) = \frac{1}{2(q_{H_4}+q_{H_3})}\left[(\epsilon(k)+1)(1-2/q)^{q_D} - 1\right],$$
$$t_1(k) \leq FO_{time}(t(k), q_{H_4}, q_{H_3}) = t(k) + O((q_{H_4}+q_{H_3})\cdot n).$$

Here q is the size of the groups $\mathbb{G}_1, \mathbb{G}_2$, and n is the length of σ.

In fact, Fujisaki and Okamoto prove a stronger result: Under the hypothesis of Theorem 4.5, BasicPub^{hy} would not even be a one-way encryption scheme. For our

purposes, the result in Theorem 4.5 is sufficient. To prove Theorem 4.4, we also need the following lemma to translate between an IND-ID-CCA chosen ciphertext attack on FullIdent and an IND-CCA chosen ciphertext attack on BasicPub^{hy}.

LEMMA 4.6. *Let $\mathcal{A}$ be an* IND-ID-CCA *adversary that has advantage $\epsilon(k)$ against* FullIdent. *Suppose $\mathcal{A}$ makes at most $q_E > 0$ private key extraction queries and at most q_D decryption queries. Then there is an* IND-CCA *adversary $\mathcal{B}$ that has advantage at least $\frac{\epsilon(k)}{e(1+q_E+q_D)}$ against* BasicPub^{hy}. *Its running time is $O(time(\mathcal{A}))$.*

Proof. We construct an IND-CCA adversary $\mathcal{B}$ that uses $\mathcal{A}$ to gain advantage $\epsilon/e(1 + q_E + q_D)$ against BasicPub^{hy}. The game between the challenger and the adversary $\mathcal{B}$ starts with the challenger first generating a random public key by running algorithm keygen of BasicPub^{hy}. The result is a public key

$$K_{pub} = \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, P_{pub}, Q_{\mathsf{ID}}, H_2, H_3, H_4 \rangle$$

and a private key $d_{\mathsf{ID}} = sQ_{\mathsf{ID}}$. The challenger gives K_{pub} to algorithm $\mathcal{B}$.

Algorithm $\mathcal{B}$ mounts an IND-CCA attack on the key K_{pub} using the help of algorithm $\mathcal{A}$. Algorithm $\mathcal{B}$ interacts with $\mathcal{A}$ as follows.

Setup. Same as in Lemma 4.2 (with H_3, H_4 included in the system parameters given to $\mathcal{A}$).

***H_1*-queries.** These queries are handled as in Lemma 4.2.

Phase 1. Private key queries. These are handled as in Lemma 4.2.

Phase 1. Decryption queries. Let $\langle \mathsf{ID}_i, C_i \rangle$ be a decryption query issued by algorithm $\mathcal{A}$. Let $C_i = \langle U_i, V_i, W_i \rangle$. Algorithm $\mathcal{B}$ responds to this query as follows:

1. Run the above algorithm for responding to H_1-queries to obtain a $Q_i \in \mathbb{G}_1^*$ such that $H_1(\mathsf{ID}_i) = Q_i$. Let $\langle \mathsf{ID}_i, Q_i, b_i, coin_i \rangle$ be the corresponding tuple on the H_1^{list}.
2. Suppose $coin_i = 0$. In this case, run the algorithm for responding to private key queries to obtain the private key for the public key ID_i. Then use the private key to respond to the decryption query.
3. Suppose $coin_i = 1$. Then $Q_i = b_i Q_{\mathsf{ID}}$.
   – Recall that $U_i \in \mathbb{G}_1$. Set $C_i' = \langle b_i U_i,\ V_i,\ W_i \rangle$. Let $d_i = sQ_i$ be the (unknown) FullIdent private key corresponding to ID_i. Then the FullIdent decryption of C_i using d_i is the same as the BasicPub^{hy} decryption of C_i' using d_{ID}. To see this, observe that

$$\hat{e}(b_i U_i, d_{\mathsf{ID}}) = \hat{e}(b_i U_i, sQ_{\mathsf{ID}}) = \hat{e}(U_i, sb_i Q_{\mathsf{ID}}) = \hat{e}(U_i, sQ_i) = \hat{e}(U_i, d_i).$$

   – Relay the decryption query $\langle C_i' \rangle$ to the challenger and relay the challenger's response back to $\mathcal{A}$.

Challenge. Once algorithm $\mathcal{A}$ decides that Phase 1 is over, it outputs a public key ID_{ch} and two messages M_0, M_1 on which it wishes to be challenged. Algorithm $\mathcal{B}$ responds as follows:

1. Algorithm $\mathcal{B}$ gives the challenger M_0, M_1 as the messages that it wishes to be challenged on. The challenger responds with a BasicPub^{hy} ciphertext $C = \langle U, V, W \rangle$ such that C is the encryption of M_c for a random $c \in \{0, 1\}$.
2. Next, $\mathcal{B}$ runs the algorithm for responding to H_1-queries to obtain a $Q \in \mathbb{G}_1^*$ such that $H_1(\mathsf{ID}_{ch}) = Q$. Let $\langle \mathsf{ID}_{ch}, Q, b, coin \rangle$ be the corresponding tuple on the H_1^{list}. If $coin = 0$, then $\mathcal{B}$ reports failure and terminates. The attack on BasicPub^{hy} failed.

3. We know $coin = 1$ and therefore $Q = bQ_{\mathsf{ID}}$. Recall that when $C = \langle U, V, W\rangle$, we have $U \in \mathbb{G}_1^*$. Set $C' = \langle b^{-1}U,\ V,\ W\rangle$, where b^{-1} is the inverse of b mod q. Algorithm $\mathcal{B}$ responds to $\mathcal{A}$ with the challenge C'. Note that, as in the proof of Lemma 4.2, C' is a FullIdent encryption of M_c under the public key ID_{ch} as required.

Phase 2. Private key queries. Algorithm $\mathcal{B}$ responds to private key extraction queries in the same way it did in Phase 1.

Phase 2. Decryption queries. Algorithm $\mathcal{B}$ responds to decryption queries in the same way it did in Phase 1. However, if the resulting decryption query relayed to the challenger is equal to the challenge ciphertext $C = \langle U, V, W\rangle$, then $\mathcal{B}$ reports failure and terminates. The attack on $\mathsf{BasicPub}^{hy}$ failed.

Guess. Eventually algorithm $\mathcal{A}$ produces a guess c' for c. Algorithm $\mathcal{B}$ outputs c' as its guess for c.

Claim. If algorithm $\mathcal{B}$ does not abort during the simulation, then algorithm $\mathcal{A}$'s view is identical to its view in the real attack. Furthermore, if $\mathcal{B}$ does not abort, then $|\Pr[c = c'] - \frac{1}{2}| \geq \epsilon$. The probability is over the random bits used by $\mathcal{A}, \mathcal{B}$ and the challenger.

Proof of claim. The responses to H_1-queries are as in the real attack since each response is uniformly and independently distributed in $\mathbb{G}_1^*$. All responses to private key extraction queries and decryption queries are valid. Finally, the challenge ciphertext C' given to $\mathcal{A}$ is the FullIdent encryption of M_c for some random $c \in \{0, 1\}$. Therefore, by definition of algorithm $\mathcal{A}$, we have that $|\Pr[c = c'] - \frac{1}{2}| \geq \epsilon$. □

It remains to bound the probability that algorithm $\mathcal{B}$ aborts during the simulation. The algorithm could abort for three reasons: (1) a bad private key query from $\mathcal{A}$ during Phase 1 or 2, (2) $\mathcal{A}$ chooses a bad ID_{ch} to be challenged on, or (3) a bad decryption query from $\mathcal{A}$ during phase 2. We define three corresponding events.

- $\mathcal{E}_1$ is the event that $\mathcal{A}$ issues a private key query during Phase 1 or 2 that causes algorithm $\mathcal{B}$ to abort.
- $\mathcal{E}_2$ is the event that $\mathcal{A}$ chooses a public key ID_{ch} to be challenged on that causes algorithm $\mathcal{B}$ to abort.
- $\mathcal{E}_3$ is the event that, during Phase 2 of the simulation, Algorithm $\mathcal{A}$ issues a decryption query $\langle \mathsf{ID}_i, C_i\rangle$ so that the decryption query that $\mathcal{B}$ would relay to the $\mathsf{BasicPub}^{hy}$ challenger is equal to C. Recall that $C = \langle U, V, W\rangle$ is the challenge ciphertext from the $\mathsf{BasicPub}^{hy}$ challenger.

Claim. $\Pr[\neg\mathcal{E}_1 \wedge \neg\mathcal{E}_2 \wedge \neg\mathcal{E}_3] \geq \delta^{q_E+q_D}(1-\delta)$.

Proof of claim. We prove the claim by induction on the maximum number of queries $q_E + q_D$ made by the adversary. Let $i = q_E + q_D$, and let $\mathcal{E}^{0\ldots i}$ be the event that $\mathcal{E}_1 \vee \mathcal{E}_3$ happens after $\mathcal{A}$ issues at most i queries. Similarly, let $\mathcal{E}^i$ be the event that $\mathcal{E}_1 \vee \mathcal{E}_3$ happens for the first time when $\mathcal{A}$ issues the ith query. We prove by induction on i that $\Pr[\neg\mathcal{E}^{0\ldots i} \mid \neg\mathcal{E}_2] \geq \delta^i$. The claim follows because $\Pr[\neg\mathcal{E}_1 \wedge \neg\mathcal{E}_2 \wedge \neg\mathcal{E}_3] = \Pr[\neg\mathcal{E}_1 \wedge \neg\mathcal{E}_3 \mid \neg\mathcal{E}_2]\Pr[\neg\mathcal{E}_2] \geq \Pr[\neg\mathcal{E}_1 \wedge \neg\mathcal{E}_3 \mid \neg\mathcal{E}_2](1-\delta)$.

For $i = 0$, the claim is trivial since by definition $\Pr[\neg\mathcal{E}^{0\ldots 0}] = 1$. Now, suppose the claim holds for $i - 1$. Then

$$\begin{aligned}\Pr[\neg\mathcal{E}^{0\ldots i} \mid \neg\mathcal{E}_2] &= \Pr[\neg\mathcal{E}^{0\ldots i} \mid \neg\mathcal{E}^{0\ldots i-1} \wedge \neg\mathcal{E}_2]\Pr[\neg\mathcal{E}^{0\ldots i-1} \mid \neg\mathcal{E}_2] \\ &= \Pr[\neg\mathcal{E}^{i} \mid \neg\mathcal{E}^{0\ldots i-1} \wedge \neg\mathcal{E}_2]\Pr[\neg\mathcal{E}^{0\ldots i-1} \mid \neg\mathcal{E}_2] \\ &\geq \Pr[\neg\mathcal{E}^{i} \mid \neg\mathcal{E}^{0\ldots i-1} \wedge \neg\mathcal{E}_2]\delta^{i-1}.\end{aligned}$$

Hence it suffices to bound $q_i = \Pr[\neg\mathcal{E}^i \mid \neg\mathcal{E}^{0\ldots i-1} \wedge \neg\mathcal{E}_2]$. In other words, we bound the probability that the ith query does not cause $\mathcal{E}^i$ to happen given that the first

$i-1$ queries did not and given that $\mathcal{E}_2$ does not occur. Consider the ith query issued by $\mathcal{A}$ during the simulation. The query is either a private key query for $\langle \mathsf{ID}_i \rangle$ or a decryption query for $\langle \mathsf{ID}_i, C_i \rangle$, where $C_i = \langle U_i, V_i, W_i \rangle$. If the query is a decryption query, we assume it takes place during Phase 2 since otherwise it has no effect on $\mathcal{E}_3$.

Let $H_1(\mathsf{ID}_i) = Q_i$, and let $\langle \mathsf{ID}_i, Q_i, b_i, coin_i \rangle$ be the corresponding tuple on the H_1^{list}. Recall that when $coin_i = 0$, the query cannot cause event $\mathcal{E}_1$ to happen. Similarly, when $coin_i = 0$, the query cannot cause event $\mathcal{E}_3$ to happen since in this case $\mathcal{B}$ does not relay a decryption query to the $\mathsf{BasicPub}^{hy}$ challenger. We use these facts to bound q_i. There are four cases to consider. In the first three cases, we assume ID_i is not equal to the public key ID_{ch} on which $\mathcal{A}$ is being challenged.

Case 1. The ith query is the first time $\mathcal{A}$ issues a query containing ID_i. In this case, $\Pr[coin_i = 0] = \delta$, and hence $q_i \geq \delta$.

Case 2. The public key ID_i appeared in a previous private key query. Since by assumption this earlier private key query did not cause $\mathcal{E}^{0\ldots i-1}$ to happen, we know that $coin_i = 0$. Hence we have $q_i = 1$.

Case 3. The public key ID_i appeared in a previous decryption query. Since by assumption this earlier decryption query did not cause event $\mathcal{E}^{0\ldots i-1}$ to happen, we have that either $coin_i = 0$ or $coin_i$ is independent of $\mathcal{A}$'s current view. Either way, we have that $q_i \geq \delta$.

Case 4. The public key ID_i is equal to the public key ID_{ch} on which $\mathcal{A}$ is being challenged. Then, by definition, the ith query cannot be a private key query. Therefore, it must be a decryption query $\langle \mathsf{ID}_i, C_i \rangle$. Furthermore, since $\mathcal{E}_2$ did not happen, we know that $coin_i = 1$, and hence $\mathcal{B}$ will relay a decryption query C_i' to the $\mathsf{BasicPub}^{hy}$ challenger. Let C' be the challenge ciphertext given to $\mathcal{A}$. By definition we know that $C_i \neq C'$. It follows that $C_i' \neq C$. Therefore, this query cannot cause event $\mathcal{E}_3$ to happen. Hence in this case $q_i = 1$.

To summarize, we see that whatever the ith query is, we have that $q_i \geq \delta$. Therefore, we have that $\Pr[\neg\mathcal{E}^{0\ldots i} \mid \neg\mathcal{E}_2] \geq \delta^i$ as required. The claim now follows by setting $i = q_E + q_D$. □

To conclude the proof of Lemma 4.6, it remains to optimize the choice of δ. Since $\Pr[\neg\mathcal{E}_1 \wedge \neg\mathcal{E}_2 \wedge \neg\mathcal{E}_3] \geq \delta^{q_E+q_D}(1-\delta)$, the success probability is maximized at $\delta_{opt} = 1 - 1/(q_E + q_D + 1)$. Using δ_{opt}, the probability that $\mathcal{B}$ does not abort is at least $\frac{1}{e(1+q_E+q_D)}$. This shows that $\mathcal{B}$'s advantage is at least $\epsilon/e(1 + q_E + q_D)$ as required. □

Proof of Theorem 4.4. By Lemma 4.6, an IND-ID-CCA adversary on FullIdent implies an IND-CCA adversary on $\mathsf{BasicPub}^{hy}$. By Theorem 4.5, an IND-CCA adversary on $\mathsf{BasicPub}^{hy}$ implies an IND-CPA adversary on BasicPub. By Lemma 4.3, an IND-CPA adversary on BasicPub implies an algorithm for BDH. Composing all these reductions gives the required bounds. □

4.3. Relaxing the hashing requirements. Recall that the IBE system of section 4.2 uses a hash function $H_1 : \{0,1\}^* \to \mathbb{G}_1^*$. The concrete IBE system presented in the next section uses $\mathbb{G}_1$ as a subgroup of the group of points on an elliptic curve. In practice, it is difficult to build hash functions that hash directly onto such groups. We therefore show how to relax the requirement of hashing directly onto $\mathbb{G}_1^*$. Rather than hash onto $\mathbb{G}_1^*$, we hash onto some set $A \subseteq \{0,1\}^*$ and then use a deterministic encoding function to map A onto $\mathbb{G}_1^*$.

Admissible encodings. Let $\mathbb{G}_1$ be a group, and let $A \in \{0,1\}^*$ be a finite set. We say that an encoding function $L : A \to \mathbb{G}_1^*$ is *admissible* if it satisfies the following

properties.

1. *Computable.* There is an efficient deterministic algorithm to compute $L(x)$ for any $x \in A$.
2. ℓ-*to*-1. For any $y \in \mathbb{G}_1^*$, the preimage of y under L has size exactly ℓ. In other words, $|L^{-1}(y)| = \ell$ for all $y \in \mathbb{G}_1^*$. Note that this implies that $|A| = \ell \cdot |\mathbb{G}_1^*|$.
3. *Samplable.* There is an efficient randomized algorithm $\mathcal{L}_S$ such that $\mathcal{L}_S(y)$ induces a uniform distribution on $L^{-1}(y)$ for any $y \in \mathbb{G}_1^*$. In other words, $\mathcal{L}_S(y)$ is a uniform random element in $L^{-1}(y)$.

We slightly modify FullIdent to obtain an IND-ID-CCA secure IBE system where H_1 is replaced by a hash function into some set A. Since the change is so minor, we refer to this new scheme as FullIdent'.

Setup. As in the FullIdent scheme. The only difference is that H_1 is replaced by a hash function $H_1' : \{0,1\}^* \to A$. The system parameters also include a description of an admissible encoding function $L : A \to \mathbb{G}_1^*$.

Extract, Encrypt. As in the FullIdent scheme. The only difference is that in Step 1 these algorithms compute $Q_{\mathsf{ID}} = L(H_1'(\mathsf{ID})) \in \mathbb{G}_1^*$.

Decrypt. As in the FullIdent scheme.

This completes the description of FullIdent'. The following theorem shows that FullIdent' is a chosen ciphertext secure IBE (i.e., IND-ID-CCA), assuming FullIdent is.

THEOREM 4.7. *Let $\mathcal{A}$ be an* IND-ID-CCA *adversary on* FullIdent' *that achieves advantage $\epsilon(k)$. Suppose $\mathcal{A}$ makes at most q_{H_1} queries to the hash function H_1'. Then there is an* IND-ID-CCA *adversary $\mathcal{B}$ on* FullIdent *that achieves the same advantage $\epsilon(k)$ and $time(\mathcal{B}) = time(\mathcal{A}) + q_{H_1} \cdot time(L_S)$*

Proof sketch. Algorithm $\mathcal{B}$ attacks FullIdent by running algorithm $\mathcal{A}$. It relays all decryption queries, extraction queries, and hash queries from $\mathcal{A}$ directly to the challenger and relays the challenger's response back to $\mathcal{A}$. It behaves differently only when $\mathcal{A}$ issues a hash query to H_1'. Recall that $\mathcal{B}$ has access only to a hash function $H_1 : \{0,1\}^* \to \mathbb{G}_1^*$. To respond to H_1' queries, algorithm $\mathcal{B}$ maintains a list of tuples $\langle \mathsf{ID}_j, y_j \rangle$ as explained below. We refer to this list as the $(H_1')^{list}$. The list is initially empty. When $\mathcal{A}$ queries the oracle H_1' at a point ID_i, algorithm $\mathcal{B}$ responds as follows.

1. If the query ID_i already appears on the $(H_1')^{list}$ in a tuple $\langle \mathsf{ID}_i, y_i \rangle$, then respond with $H_1'(\mathsf{ID}_i) = y_i \in A$.
2. Otherwise, $\mathcal{B}$ issues a query for $H_1(\mathsf{ID}_i)$, say, $H_1(\mathsf{ID}_i) = \alpha \in \mathbb{G}_1^*$.
3. $\mathcal{B}$ runs the sampling algorithm $\mathcal{L}_S(\alpha)$ to generate a random element $y \in L^{-1}(\alpha)$.
4. $\mathcal{B}$ adds the tuple $\langle \mathsf{ID}_i, y \rangle$ to the $(H_1')^{list}$ and responds to $\mathcal{A}$ with $H_1'(\mathsf{ID}_i) = y \in A$. Note that y is uniformly distributed in A as required since α is uniformly distributed in $\mathbb{G}_1^*$ and L is an ℓ-to-1 map.

Algorithm $\mathcal{B}$'s responses to all of $\mathcal{A}$'s queries, including H_1' queries, are identical to $\mathcal{A}$'s view in the real attack. Hence $\mathcal{B}$ will have the same advantage $\epsilon(k)$ in winning the game with the challenger. □

5. A concrete IBE system using the Weil pairing. In this section, we use FullIdent' to describe a concrete IBE system based on the Weil pairing. We first review some properties of the pairing (see the appendix for more details).

5.1. Properties of the Weil pairing. Let $p > 3$ be a prime satisfying $p = 2 \bmod 3$, and let q be some prime factor of $p+1$. Let E be the elliptic curve defined by the equation $y^2 = x^3 + 1$ over $\mathbb{F}_p$. We state a few elementary facts about this curve E (see [43] for more information). From here on, we let $E(\mathbb{F}_{p^r})$ denote the group of

points on E defined over $\mathbb{F}_{p^r}$.

Fact 1. Since $x^3 + 1$ is a permutation on $\mathbb{F}_p$, it follows that the group $E(\mathbb{F}_p)$ contains $p + 1$ points. We let O denote the point at infinity. Let $P \in E(\mathbb{F}_p)$ be a point of order q, and let $\mathbb{G}_1$ be the subgroup of points generated by P.

Fact 2. For any $y_0 \in \mathbb{F}_p$, there is a unique point (x_0, y_0) on $E(\mathbb{F}_p)$, namely, $x_0 = (y_0^2 - 1)^{1/3} \in \mathbb{F}_p$. Hence, if (x, y) is a random nonzero point on $E(\mathbb{F}_p)$, then y is uniform in $\mathbb{F}_p$. We use this property to build a simple admissible encoding function.

Fact 3. Let $1 \neq \zeta \in \mathbb{F}_{p^2}$ be a solution of $x^3 - 1 = 0 \bmod p$. Then the map $\phi(x, y) = (\zeta x, y)$ is an automorphism of the group of points on the curve E. Note that, for any point $Q = (x, y) \in E(\mathbb{F}_p)$, we have that $\phi(Q) \in E(\mathbb{F}_{p^2})$, but $\phi(Q) \notin E(\mathbb{F}_p)$. Hence $Q \in E(\mathbb{F}_p)$ is linearly independent of $\phi(Q) \in E(\mathbb{F}_{p^2})$.

Fact 4. Since the points $P \in \mathbb{G}_1$ and $\phi(P)$ are linearly independent, they generate a group isomorphic to $\mathbb{Z}_q \times \mathbb{Z}_q$. We denote this group of points by $E[q]$.

Let $\mathbb{G}_2$ be the subgroup of $\mathbb{F}_{p^2}^*$ of order q. The Weil pairing on the curve $E(\mathbb{F}_{p^2})$ is a mapping $e : E[q] \times E[q] \to \mathbb{G}_2$ defined in the appendix. For any $Q, R \in E(\mathbb{F}_p)$, the Weil pairing satisfies $e(Q, R) = 1$. In other words, the Weil pairing is degenerate on $E(\mathbb{F}_p)$ and hence degenerate on the group $\mathbb{G}_1$. To get a nondegenerate map, we define the modified Weil pairing $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ as follows:

$$\hat{e}(P, Q) = e(P, \phi(Q)).$$

The modified Weil pairing satisfies the following properties:

1. *Bilinear.* For all $P, Q \in \mathbb{G}_1$ and for all $a, b \in \mathbb{Z}$, we have $\hat{e}(aP, bQ) = \hat{e}(P, Q)^{ab}$.
2. *Nondegenerate.* If P is a generator of $\mathbb{G}_1$, then $\hat{e}(P, P) \in \mathbb{F}_{p^2}^*$ is a generator of $\mathbb{G}_2$.
3. *Computable.* Given $P, Q \in \mathbb{G}_1$, there is an efficient algorithm, due to Miller, to compute $\hat{e}(P, Q) \in \mathbb{G}_2$. This algorithm is described in the appendix. Its running time is comparable to exponentiation in $\mathbb{F}_p$.

Joux and Nguyen [28] point out that, although the CDH problem appears to be hard in the group $\mathbb{G}_1$, the DDH problem is easy in $\mathbb{G}_1$ (as discussed in section 3).

BDH parameter generator $\mathcal{G}_1$. Given a security parameter $2 < k \in \mathbb{Z}$, the BDH parameter generator picks a random k-bit prime q and finds the smallest prime p such that (1) $p = 2 \bmod 3$, (2) q divides $p + 1$, and (3) q^2 does not divide $p + 1$. We write $p = \ell q + 1$. The group $\mathbb{G}_1$ is the subgroup of order q of the group of points on the curve $y^2 = x^3 + 1$ over $\mathbb{F}_p$. The group $\mathbb{G}_2$ is the subgroup of order q of $\mathbb{F}_{p^2}^*$. The bilinear map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ is the modified Weil pairing defined above.

The BDH parameter generator $\mathcal{G}_1$ is believed to satisfy the BDH assumption asymptotically. However, there is still the question of what values of p and q can be used in practice to make the BDH problem sufficiently hard. At the very least, we must ensure that the discrete log problem in $\mathbb{G}_1$ is sufficiently hard. As pointed out in section 3, the discrete log problem in $\mathbb{G}_1$ is efficiently reducible to discrete log in $\mathbb{G}_2$ (see [32, 17]). Hence computing discrete log in $\mathbb{F}_{p^2}^*$ is sufficient for computing discrete log in $\mathbb{G}_1$. In practice, for proper security of discrete log in $\mathbb{F}_{p^2}^*$, one often uses primes p that are at least 512 bits long (so that the group size is at least 1024 bits long). Consequently, one should not use this BDH parameter generator with primes p that are less than 512 bits long.

5.2. An admissible encoding function: MapToPoint. Let $\mathbb{G}_1, \mathbb{G}_2$ be two groups generated by $\mathcal{G}_1$ as defined above. Recall that the IBE system of section 4.2 uses a hash function $H_1 : \{0,1\}^* \to \mathbb{G}_1^*$. By Theorem 4.7, it suffices to have a

hash function $H_1 : \{0,1\}^* \to A$ for some set A and an admissible encoding function $L : A \to \mathbb{G}_1^*$. In what follows, the set A will be $\mathbb{F}_p$, and the admissible encoding function L will be called MapToPoint.

Let p be a prime satisfying $p = 2 \bmod 3$ and $p = \ell q - 1$ for some prime $q > 3$. We require that q does not divide ℓ (i.e., that q^2 does not divide $p+1$). Let E be the elliptic curve $y^2 = x^3 + 1$ over $\mathbb{F}_p$. Let $\mathbb{G}_1$ be the subgroup of points on E of order q. Suppose we already have a hash function $H_1 : \{0,1\}^* \to \mathbb{F}_p$.

Algorithm MapToPoint works as follows on input $y_0 \in \mathbb{F}_p$:

1. Compute $x_0 = (y_0^2 - 1)^{1/3} = (y_0^2 - 1)^{(2p-1)/3} \in \mathbb{F}_p$.
2. Let $Q = (x_0, y_0) \in E(\mathbb{F}_p)$, and set $Q_{\mathsf{ID}} = \ell Q \in \mathbb{G}_1$.
3. Output $\mathsf{MapToPoint}(y_0) = Q_{\mathsf{ID}}$.

This completes the description of MapToPoint.

We note that there are $\ell - 1$ values of $y_0 \in \mathbb{F}_p$ for which $\ell Q = \ell(x_0, y_0) = O$. (These are the non-$O$ points of order dividing ℓ.) Let $B \subset \mathbb{F}_p$ be the set of these y_0. When $H_1(\mathsf{ID})$ is one of these $\ell - 1$ values, Q_{ID} is the identity element of $\mathbb{G}_1$. It is extremely unlikely for $H_1(\mathsf{ID})$ to hit one of these points—the probability is $1/q < 1/2^k$. Hence, for simplicity, we say that $H_1(\mathsf{ID})$ outputs elements only in $\mathbb{F}_p \setminus B$, i.e., $H_1 : \{0,1\}^* \to \mathbb{F}_p \setminus B$. Algorithm MapToPoint can be easily extended to handle the values $y_0 \in B$ by hashing ID multiple times using different hash functions.

LEMMA 5.1. *$\mathsf{MapToPoint} : \mathbb{F}_p \setminus B \to \mathbb{G}_1^*$ is an admissible encoding function.*

Proof. The map is clearly computable and is an ℓ-to-1 mapping. It remains to show that L is samplable. Let P be a generator of $E(\mathbb{F}_p)$. Given a $Q \in \mathbb{G}_1^*$, the sampling algorithm $\mathcal{L}_S$ does the following: (1) pick a random $b \in \{0, \ldots, \ell - 1\}$, (2) compute $Q' = \ell^{-1} \cdot Q + bqP = (x, y)$, and (3) output $\mathcal{L}_S(Q) = y \in \mathbb{F}_p$. Here ℓ^{-1} is the inverse of ℓ in $\mathbb{Z}_q^*$. This algorithm outputs a random element from the ℓ elements in $\mathsf{MapToPoint}^{-1}(Q)$ as required. ∎

5.3. A concrete IBE system. Using FullIdent' from section 4.3 with the BDH parameter generator $\mathcal{G}_1$ and the admissible encoding function MapToPoint, we obtain a concrete IBE system. Note that, in this system, H_1 is a hash function from $\{0,1\}^*$ to $\mathbb{F}_p$ (where p is the finite field output by $\mathcal{G}_1$). The security of the system follows directly from Theorems 4.4 and 4.7. We summarize this in the following corollary.

COROLLARY 5.2. *The IBE system* FullIdent' *using the BDH parameter generator $\mathcal{G}_1$ and the admissible encoding* MapToPoint *is a chosen ciphertext secure IBE (i.e.,* IND-ID-CCA *in the random oracle model) assuming $\mathcal{G}_1$ satisfies the BDH assumption.*

Performance. Algorithms Setup and Extract are very simple. At the heart of both algorithms is a standard multiplication on the curve $E(\mathbb{F}_p)$. Algorithm Encrypt requires that the encryptor compute the Weil pairing of Q_{ID} and P_{pub}. Note that this computation is independent of the message to be encrypted and hence can be done once and for all. Once g_{ID} is computed, the performance of the system is almost identical to standard ElGamal encryption. Decryption is a single Weil pairing computation. We note that the ciphertext length of BasicIdent using $\mathcal{G}_1$ is the same as in regular ElGamal encryption in $\mathbb{F}_p$.

6. Extensions and observations. We briefly describe a few extensions to the IBE scheme of the previous sections.

Tate pairing and other curves. Our IBE system works with any efficiently computable bilinear pairing $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ between two groups $\mathbb{G}_1, \mathbb{G}_2$ as long as the BDH assumption holds. Many different curves, or more generally Abelian varieties, are believed to give rise to such maps. For example, one could use the curve

$y^2 = x^3 + x$ over $\mathbb{F}_p$ with $p = 3 \bmod 4$ and its endomorphism $\phi : (x, y) \to (-x, iy)$, where $i^2 = -1$. As another example, Galbraith [18] suggests using supersingular elliptic curves over a field of small characteristic to reduce the ciphertext size in our system. More general Abelian varieties are proposed by Rubin and Silverberg [39]. We note that both encryption and decryption in FullIdent can be made faster by using the Tate pairing on elliptic curves rather than the Weil pairing [19, 1].

Asymmetric pairings. Our IBE system can use slightly more general bilinear maps, namely, maps of the form $\hat{e} : \mathbb{G}_0 \times \mathbb{G}_1 \to \mathbb{G}_2$, where $\mathbb{G}_0, \mathbb{G}_1, \mathbb{G}_2$ are three groups of prime order q. Using the notation of section 4.1, the only change to BasicIdent is that we take P and P_{pub} as elements in $\mathbb{G}_0$ and let H_1 be a hash function $H_1 : \{0,1\}^* \to \mathbb{G}_1^*$. Everything else remains the same. However, to make the proof of security go through (Lemma 4.2 in particular), we need a different complexity assumption which we call the co-BDH assumption: given random $P, aP, bP \in \mathbb{G}_0$ and $Q, aQ, cQ \in \mathbb{G}_1$, no polynomial time algorithm can compute $\hat{e}(P, Q)^{abc}$ with nonnegligible probability. If one is willing to accept this assumption, then we can avoid using supersingular curves and instead use elliptic curves over $\mathbb{F}_p$, $p > 3$, proposed by Miyaji, Nakabayashi, and Takano [35]. Curves $E/\mathbb{F}_p$ in this family are not supersingular and have the property that if q divides $|E(F_p)|$, then $E[q] \subseteq E(F_{p^6})$. (Recall that $E[q]$ is the group containing all points in E of order dividing q.) One way to use these curves is to set $\mathbb{G}_1$ to be a cyclic subgroup of $E(\mathbb{F}_p)$ of order q and $\mathbb{G}_0$ to be a different cyclic subgroup of $E(\mathbb{F}_{p^6})$ of the same order q. The standard Weil or Tate pairings on $\mathbb{G}_0 \times \mathbb{G}_1$ can be used as the bilinear map $\hat{e}$. Note that hashing public keys onto $\mathbb{G}_1 \subseteq E(\mathbb{F}_p)$ is easily done. Alternatively, to reduce the ciphertext size (which contains an element from $\mathbb{G}_0$), one could take $\mathbb{G}_0$ as a subgroup of order q of $E(\mathbb{F}_p)$ and $\mathbb{G}_1$ as a different subgroup of $E(\mathbb{F}_{p^6})$ of the same order. The question is how to hash public keys into $\mathbb{G}_1$. To do so, let $\mathrm{tr} : E(\mathbb{F}_{p^6}) \to E(\mathbb{F}_p)$ be the trace map on the curve, and define $\mathbb{G}_1$ to be the subgroup of $E[q]$ containing all points P whose trace is O, i.e., $\mathrm{tr}(P) = O$. Then, given a hash function $H : \{0,1\}^* \to E[q]$, we can hash a public key ID into $\mathbb{G}_1$ by computing $H_1(\mathsf{ID}) = 6H(\mathsf{ID}) - \mathrm{tr}(H(\mathsf{ID})) \in \mathbb{G}_1$. Finally, we note that by modifying the security proof appropriately, one can take $\mathbb{G}_1 = E[q]$ (a noncyclic group) and then avoid computing traces while hashing into $\mathbb{G}_1$ (see also [18]).

Distributed PKG. In the standard use of an IBE in an e-mail system, the master-key stored at the PKG must be protected in the same way that the private key of a CA is protected. One way of protecting this key is by distributing it among different sites using techniques of threshold cryptography [20]. Our IBE system supports this in a very efficient and robust way. Recall that the master-key is some $s \in \mathbb{Z}_q^*$. In order to generate a private key, the PKG computes $Q_{priv} = sQ_{\mathsf{ID}}$, where Q_{ID} is derived from the user's public key ID. This can easily be distributed in a t-out-of-n fashion by giving each of the n PKGs one share s_i of a Shamir secret sharing of $s \bmod q$. When generating a private key, each of the t chosen PKGs simply responds with $Q_{priv}^{(i)} = s_i Q_{\mathsf{ID}}$. The user can then construct Q_{priv} as $Q_{priv} = \sum \lambda_i Q_{priv}^{(i)}$, where the λ_i's are the appropriate Lagrange coefficients.

Furthermore, it is easy to make this scheme robust against dishonest PKGs using the fact that DDH is easy in $\mathbb{G}_1$. During the set-up phase, each of the n PKGs publishes $P_{pub}^{(i)} = s_i P$. During a key generation request, the user can verify that the response from the ith PKG is valid by testing that

$$\hat{e}(Q_{priv}^{(i)}, P) = \hat{e}(Q_{\mathsf{ID}}, P_{pub}^{(i)}).$$

Thus a misbehaving PKG will be caught immediately. There is no need for zero-

knowledge proofs as in regular robust threshold schemes [21]. The PKG's master-key can be generated in a distributed fashion using the techniques of [22].

Note that a distributed master-key also enables threshold decryption on a *per-message* basis, without any need to derive the corresponding decryption key. For example, threshold decryption of BasicIdent ciphertext (U, V) is straightforward if each PKG responds with $\hat{e}(s_i Q_{\mathsf{ID}}, U)$.

Working in subgroups. The performance of our IBE system (section 5) can be improved if we work in a small subgroup of the curve. For example, choose a 1024-bit prime $p = 2 \bmod 3$ with $p = aq - 1$ for some 160-bit prime q. The point P is then chosen to be a point of order q. Each public key ID is converted to a group point by hashing ID to a point Q on the curve and then multiplying the point by a. The system is secure if the BDH assumption holds in the group generated by P. The advantage is that the Weil computation is done on points of small order and hence is much faster.

IBE implies signatures. Moni Naor has observed that an IBE scheme can be immediately converted into a public key signature scheme. The reasoning is as follows. The private key for the signature scheme is the master key for the IBE scheme. The public key for the signature scheme is the global system parameters for the IBE scheme. The signature on a message M is the IBE decryption key for $\mathsf{ID} = M$. To verify a signature, choose a random message M', encrypt M' using the public key $\mathsf{ID} = M$, and then attempt to decrypt using the given signature on M as the decryption key. If the IBE scheme is IND-ID-CCA, then the signature scheme is existentially unforgeable against a chosen message attack. Note that, unlike most signature schemes, the signature verification algorithm here is randomized. This shows that secure IBE schemes incorporate both public key encryption and digital signatures. We note that the signature scheme derived from our IBE system has some interesting properties [6].

7. Escrow ElGamal encryption. In this section, we show that the Weil pairing enables us to add a global escrow capability to the ElGamal encryption system. A single escrow key enables the decryption of ciphertexts encrypted under any public key. Paillier and Yung have shown how to add a global escrow capability to the Paillier encryption system [36]. Our ElGamal escrow system works as follows.

Setup. Let $\mathcal{G}$ be some BDH parameter generator. Given a security parameter $k \in \mathbb{Z}^+$, the algorithm works as follows.

Step 1: Run $\mathcal{G}$ on input k to generate a prime q, two groups $\mathbb{G}_1, \mathbb{G}_2$ of order q, and an admissible bilinear map $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$. Let P be a generator of $\mathbb{G}_1$.

Step 2: Pick a random $s \in \mathbb{Z}_q^*$, and set $Q = sP$.

Step 3: Choose a cryptographic hash function $H : \mathbb{G}_2 \to \{0,1\}^n$.

The message space is $\mathcal{M} = \{0,1\}^n$. The ciphertext space is $\mathcal{C} = \mathbb{G}_1 \times \{0,1\}^n$. The system parameters are $\mathsf{params} = \langle q, \mathbb{G}_1, \mathbb{G}_2, \hat{e}, n, P, Q, H \rangle$. The escrow key is $s \in \mathbb{Z}_q^*$.

keygen. A user generates a public/private key pair for herself by picking a random $x \in \mathbb{Z}_q^*$ and computing $P_{pub} = xP \in \mathbb{G}_1$. Her private key is x, and her public key is P_{pub}.

Encrypt. To encrypt $M \in \{0,1\}^n$ under the public key P_{pub}, do the following: (1) pick a random $r \in \mathbb{Z}_q^*$, and (2) set the ciphertext to be

$$C = \langle rP,\ M \oplus H(g^r) \rangle, \quad \text{where} \quad g = \hat{e}(P_{pub}, Q) \in \mathbb{G}_2.$$

Decrypt. Let $C = \langle U, V \rangle$ be a ciphertext encrypted using P_{pub}. Then $U \in \mathbb{G}_1$. To decrypt C using the private key x, do:

$$V \oplus H(\hat{e}(U, xQ)) = M.$$

Escrow-decrypt. To decrypt $C = \langle U, V \rangle$ using the escrow key s, do:

$$V \oplus H(\hat{e}(U, sP_{pub})) = M.$$

A standard argument shows that assuming that BDH is hard for groups generated by $\mathcal{G}$ the system has semantic security in the random oracle model. (Recall that, since DDH is easy, we cannot prove semantic security based on DDH.) Yet the escrow agent can decrypt any ciphertext encrypted using any user's public key. The decryption capability of the escrow agent can be distributed using the PKG distribution techniques described in section 6.

Using a similar hardness assumption, Verheul [46] described an ElGamal encryption system with nonglobal escrow. Each user constructs a public key with two corresponding private keys and gives one of the private keys to the trusted third party. The trusted third party must maintain a database of all private keys given to it by the various users.

8. Summary and open problems. We defined chosen ciphertext security for identity-based systems and proposed a fully functional IBE system. The system has chosen ciphertext security in the random oracle model assuming BDH, a natural analogue of the CDH problem. The BDH assumption deserves further study considering the powerful cryptosystems derived from it. For example, it could be interesting to see whether the techniques of [30] can be used to prove that the BDH assumption is equivalent to the discrete log assumption on the curve for certain primes p.

Recently, Cocks [8] proposed another IBE system whose security is based on the difficulty of distinguishing quadratic residues from nonresidues in the ring $\mathbb{Z}/N\mathbb{Z}$, where N is an RSA modulus (i.e., a product of two large primes). Cocks' system is somewhat harder to use in practice than the IBE system in this paper. Cocks' system uses bit-by-bit encryption and consequently outputs long ciphertexts. Also, encryption/decryption is a bit slower than the system described in this paper. Nevertheless, it is encouraging to see that IBE systems can be built using very different complexity assumptions.

It is an open problem to build chosen ciphertext secure identity-based systems that are secure in the standard computation model (rather than the random oracle model). One might hope to use the techniques of Cramer–Shoup [10] to provide chosen ciphertext security based on DDH. Unfortunately, as mentioned in section 3, the DDH assumption is false in the group of points on the curve E. However, simple variants of DDH do seem to hold. In particular, the following two distributions appear to be computationally indistinguishable: $\langle P, aP, bP, cP, abcP \rangle$ and $\langle P, aP, bP, cP, rP \rangle$, where a, b, c, r are random in $\mathbb{Z}_q$. We refer to this assumption as BDDH. A chosen ciphertext secure identity-based system strictly based on BDDH would be a plausible analogue of the Cramer–Shoup system. Building a chosen ciphertext secure IBE (IND-ID-CCA) in the standard model is currently an open problem.

Appendix A. Definition of the Weil pairing. We define the Weil pairing and show how to efficiently compute it using an algorithm due to Miller [34]. To be concrete, we present the algorithm as it applies to supersingular elliptic curves defined

over a prime field $\mathbb{F}_p$ with $p > 3$. (The curve $y^2 = x^3 + 1$ over $\mathbb{F}_p$ with $p = 2 \bmod 3$ is an example of such a curve.) The definition and algorithm easily generalize to computing the Weil pairing over other elliptic curves. We state a few elementary facts about such curves [43].

Fact 1. A supersingular curve $E/\mathbb{F}_p$ (with $p > 3$) contains $p+1$ points in $\mathbb{F}_p$. We let O denote the point at infinity. The group of points over $\mathbb{F}_p$ forms a cyclic group of order $p+1$. Let $P \in E(\mathbb{F}_p)$ be a point order n, where n divides $p+1$.

Fact 2. The group of points $E(\mathbb{F}_{p^2})$ contains a point Q of order n which is linearly independent of the points in $E(\mathbb{F}_p)$. Hence $E(\mathbb{F}_{p^2})$ contains a subgroup which is isomorphic to the group $\mathbb{Z}_n^2$. The group is generated by $P \in E(\mathbb{F}_p)$ and $Q \in E(\mathbb{F}_{p^2})$. We denote this group by $E[n]$.

Throughout this section, we let $\mathbb{G}_2$ denote the subgroup of $\mathbb{F}_{p^2}^*$ of order n. We will be working with the Weil pairing e which maps pairs of points in $E[n]$ to $\mathbb{G}_2$, i.e., $e : E[n] \times E[n] \to \mathbb{G}_2$. To define the pairing, we review a few basic concepts (see [29, pp. 243–245]). In what follows, we let P and Q be arbitrary points in $E(\mathbb{F}_{p^2})$.

Divisors. A divisor is a formal sum of points on the curve $E(\mathbb{F}_{p^2})$. We write divisors as $\mathcal{A} = \sum_P a_p(P)$, where $a_P \in \mathbb{Z}$ and $P \in E(\mathbb{F}_{p^2})$. For example, $\mathcal{A} = 3(P_1) - 2(P_2) - (P_3)$ is a divisor. We will consider only divisors $\mathcal{A} = \sum_P a_p(P)$, where $\sum_P a_p = 0$.

Functions. Roughly speaking, a function f on the curve $E(\mathbb{F}_{p^2})$ can be viewed as a rational function $f(x, y) \in \mathbb{F}_{p^2}(x, y)$. For any point $P = (x, y) \in E(\mathbb{F}_{p^2})$, we define $f(P) = f(x, y)$.

Divisors of functions. Let f be a function on the curve $E(\mathbb{F}_{p^2})$. We define its divisor, denoted by (f), as $(f) = \sum_P \mathrm{ord}_P(f) \cdot (P)$. Here $\mathrm{ord}_P(f)$ is the order of the zero that f has at the point P. For example, let $ax + by + c = 0$ be the line passing through the points $P_1, P_2 \in E(\mathbb{F}_{p^2})$ with $P_1 \neq \pm P_2$. This line intersects the curve at a third point $P_3 \in E(\mathbb{F}_{p^2})$. Then the function $f(x, y) = ax + by + c$ has three zeroes P_1, P_2, P_3 and a pole of order 3 at infinity. The divisor of f is $(f) = (P_1) + (P_2) + (P_3) - 3(O)$.

Principal divisors. Let $\mathcal{A}$ be a divisor. If there exists a function f such that $(f) = \mathcal{A}$, then we say that $\mathcal{A}$ is a principal divisor. We know that a divisor $\mathcal{A} = \sum_P a_p(P)$ is principal if and only if $\sum_P a_p = 0$ and $\sum_P a_P P = O$. Note that the second summation is using the group action on the curve. Furthermore, given a principal divisor $\mathcal{A}$, there exists a *unique* function f (up to constant multiples) such that $(A) = (f)$.

Equivalence of divisors. We say that two divisors $\mathcal{A}, \mathcal{B}$ are equivalent if their difference $\mathcal{A} - \mathcal{B}$ is a principal divisor. We know that any divisor $\mathcal{A} = \sum_P a_p(P)$ (with $\sum_P a_P = 0$) is equivalent to a divisor of the form $\mathcal{A}' = (Q) - (O)$ for some $Q \in E$. Observe that $Q = \sum_P a_P P$.

Notation. Given a function f and a divisor $\mathcal{A} = \sum_P a_p(P)$, we define $f(\mathcal{A})$ as $f(\mathcal{A}) = \prod_P f(P)^{a_P}$. Note that, since $\sum_P a_P = 0$, we have that $f(\mathcal{A})$ remains unchanged if instead of f we use cf for any $c \in \mathbb{F}_{p^2}$.

We are now ready to define the Weil pairing of two points $P, Q \in E[n]$. Let $\mathcal{A}_P$ be some divisor equivalent to the divisor $(P) - (O)$. We know that $n\mathcal{A}_P$ is a principal divisor (it is equivalent to $n(P) - n(O)$ which is clearly a principal divisor). Hence there exists a function f_P such that $(f_P) = n\mathcal{A}_P$. Define $\mathcal{A}_Q$ and f_Q analogously. The Weil pairing of P and Q is defined as

$$e(P, Q) = \frac{f_P(\mathcal{A}_Q)}{f_Q(\mathcal{A}_P)}.$$

This ratio defines the Weil pairing of P and Q whenever it is well defined (no division by zero occurred). If this ratio is undefined, we use different divisors $\mathcal{A}_P, \mathcal{A}_Q$ to define $e(P,Q)$.

We briefly show that the Weil pairing is well defined. That is, the value of $e(P,Q)$ is independent of the choice of the divisor $\mathcal{A}_P$ as long as $\mathcal{A}_P$ is equivalent to $(P)-(O)$ and $\mathcal{A}_P$ leads to a well-defined value. The same holds for $\mathcal{A}_Q$. Let $\hat{\mathcal{A}}_P$ be a divisor equivalent to $\mathcal{A}_P$, and let $\hat{f}_P$ be a function so that $(\hat{f}_P) = n\hat{\mathcal{A}}_P$. Then $\hat{\mathcal{A}}_P = \mathcal{A}_P + (g)$ for some function g and $\hat{f}_P = f_P \cdot g^n$. We have that

$$\begin{aligned} e(P,Q) &= \frac{\hat{f}_P(\mathcal{A}_Q)}{f_Q(\hat{\mathcal{A}}_P)} = \frac{f_P(\mathcal{A}_Q)g(\mathcal{A}_Q)^n}{f_Q(\mathcal{A}_P)f_Q((g))} = \frac{f_P(\mathcal{A}_Q)}{f_Q(\mathcal{A}_P)} \cdot \frac{g(n\mathcal{A}_Q)}{f_Q((g))} \\ &= \frac{f_P(\mathcal{A}_Q)}{f_Q(\mathcal{A}_P)} \cdot \frac{g((f_Q))}{f_Q((g))} = \frac{f_P(\mathcal{A}_Q)}{f_Q(\mathcal{A}_P)}. \end{aligned}$$

The last equality follows from the following fact known as Weil reciprocity: for any two functions f, g, we have that $f((g)) = g((f))$. Hence the Weil pairing is well defined.

FACT A.1. *The Weil pairing has the following properties for points in $E[n]$:*

- *For all $P \in E[n]$, we have $e(P,P) = 1$.*
- *Bilinear: $e(P_1 + P_2, Q) = e(P_1, Q) \cdot e(P_2, Q)$ and $e(P, Q_1 + Q_2) = e(P, Q_1) \cdot e(P, Q_2)$.*
- *When $P, Q \in E[n]$ are collinear, $e(P,Q) = 1$. Similarly, $e(P,Q) = e(Q,P)^{-1}$.*
- *nth root: for all $P, Q \in E[n]$, we have $e(P,Q)^n = 1$, i.e., $e(P,Q) \in \mathbb{G}_2$.*
- *Nondegenerate in the following sense: if $P \in E[n]$ satisfies $e(P,Q) = 1$ for all $Q \in E[n]$, then $P = O$.*

As discussed in section 5, our concrete IBE scheme uses the modified Weil pairing $\hat{e}(P,Q) = e(P, \phi(Q))$, where ϕ is an automorphism on the group of points of E.

Tate pairing. The Tate pairing [17] is another bilinear pairing that has the required properties for our system. We slightly modify the original definition to fit our purpose. Define the Tate pairing of two points $P, Q \in E[n]$ as $T(P,Q) = f_P(\mathcal{A}_Q)^{|\mathbb{F}_{p^2}^*|/n}$, where f_P and $\mathcal{A}_Q$ are defined as above. This definition gives a computable bilinear pairing $T : E[n] \times E[n] \to \mathbb{G}_2$.

Appendix B. Computing the Weil pairing. Given two points $P, Q \in E[n]$, we show how to compute $e(P,Q) \in \mathbb{F}_{p^2}^*$ using $O(\log p)$ arithmetic operations in $\mathbb{F}_p$. We assume $P \neq Q$. We proceed as follows: pick two random points $R_1, R_2 \in E[n]$. Consider the divisors $\mathcal{A}_P = (P + R_1) - (R_1)$ and $\mathcal{A}_Q = (Q + R_2) - (R_2)$. These divisors are equivalent to $(P) - (O)$ and $(Q) - (O)$, respectively. Hence we can use $\mathcal{A}_P$ and $\mathcal{A}_Q$ to compute the Weil pairing as

$$e(P,Q) = \frac{f_P(\mathcal{A}_Q)}{f_Q(\mathcal{A}_P)} = \frac{f_P(Q + R_2) f_Q(R_1)}{f_P(R_2) f_Q(P + R_1)}.$$

This expression is well defined with very high probability over the choice of R_1, R_2. (The probability of failure is at most $O(\frac{\log p}{p})$.) In the rare event that a division by zero occurs during the computation of $e(P,Q)$, we simply pick new random points R_1, R_2 and repeat the process.

To evaluate $e(P,Q)$, it suffices to show how to evaluate the function f_P at $\mathcal{A}_Q$. Evaluating $f_Q(\mathcal{A}_P)$ is done analogously. We evaluate $f_P(\mathcal{A}_Q)$ using repeated doubling. For a positive integer b, define the divisor

$$\mathcal{A}_b = b(P + R_1) - b(R_1) - (bP) + (O).$$

It is a principal divisor, and therefore there exists a function f_b such that $(f_b) = \mathcal{A}_b$. Observe that $(f_P) = (f_n)$ and hence $f_P(\mathcal{A}_Q) = f_n(\mathcal{A}_Q)$. It suffices to show how to evaluate $f_n(\mathcal{A}_Q)$.

LEMMA B.1. *There is an algorithm $\mathcal{D}$ that given $f_b(\mathcal{A}_Q), f_c(\mathcal{A}_Q)$ and $bP, cP, (b+c)P$ for some $b, c > 0$ outputs $f_{b+c}(\mathcal{A}_Q)$. The algorithm uses only a (small) constant number of arithmetic operations in $\mathbb{F}_{p^2}$.*

Proof. We first define two auxiliary linear functions g_1, g_2:

1. Let $a_1x + b_1y + c_1 = 0$ be the line passing through the points bP and cP. (If $b = c$, then let $a_1x + b_1y + c_1 = 0$ be the line tangent to E at bP.) Define $g_1(x, y) = a_1x + b_1y + c_1$.
2. Let $x + c_2 = 0$ be the vertical line passing through the point $(b+c)P$. Define $g_2(x, y) = x + c_2$.

The divisors of these functions are

$$(g_1) = (bP) + (cP) + (-(b+c)P) - 3(O),$$
$$(g_2) = ((b+c)P) + (-(b+c)P) - 2(O).$$

By definition we have that

$$\mathcal{A}_b = b(P + R_1) - b(R_1) - (bP) + (O),$$
$$\mathcal{A}_c = c(P + R_1) - c(R_1) - (cP) + (O),$$
$$\mathcal{A}_{b+c} = (b+c)(P + R_1) - (b+c)(R_1) - ((b+c)P) + (O).$$

It now follows that $\mathcal{A}_{b+c} = \mathcal{A}_b + \mathcal{A}_c + (g_1) - (g_2)$. Hence

$$f_{b+c}(\mathcal{A}_Q) = f_b(\mathcal{A}_Q) \cdot f_c(\mathcal{A}_Q) \cdot \frac{g_1(\mathcal{A}_Q)}{g_2(\mathcal{A}_Q)}. \tag{B.1}$$

This shows that to evaluate $f_{b+c}(\mathcal{A}_Q)$ it suffices to evaluate $g_i(\mathcal{A}_Q)$ for all $i = 1, 2$ and plug the results into (B.1). Hence, given $f_b(\mathcal{A}_Q), f_c(\mathcal{A}_Q)$ and $bP, cP, (b+c)P$, one can compute $f_{b+c}(\mathcal{A}_Q)$ using a constant number of arithmetic operations. ∎

We let $\mathcal{D}\big(f_b(\mathcal{A}_Q), f_c(\mathcal{A}_Q), bP, cP, (b+c)P\big) = f_{b+c}(\mathcal{A}_Q)$ denote the output of Algorithm $\mathcal{D}$ defined in Lemma B.1. Then one can compute $f_P(\mathcal{A}_Q) = f_n(\mathcal{A}_Q)$ using the following standard repeated doubling procedure. Let $n = b_m b_{m-1} \dots b_1 b_0$ be the binary representation of n, i.e., $n = \sum_{i=0}^{m} b_i 2^i$.

Init: Set $Z = O$, $V = f_0(\mathcal{A}_Q) = 1$, and $k = 0$.

Iterate: For $i = m, m-1, \dots, 1, 0$ do:

1: If $b_i = 1$, then do: Set $V = \mathcal{D}(V, f_1(\mathcal{A}_Q), Z, P, Z + P)$, set $Z = Z + P$, and set $k = k + 1$.

2: If $i > 0$, set $V = \mathcal{D}(V, V, Z, Z, 2Z)$, set $Z = 2Z$, and set $k = 2k$.

3: Observe that at the end of each iteration we have $Z = kP$ and $V = f_k(\mathcal{A}_Q)$.

Output: After the last iteration, we have $k = n$, and therefore $V = f_n(\mathcal{A}_Q)$ as required.

To evaluate the Weil pairing $e(P, Q)$, we run the above algorithm once to compute $f_P(\mathcal{A}_Q)$ and once to compute $f_Q(\mathcal{A}_P)$. The Tate pairing is evaluated similarly. Note that the repeated squaring algorithm needs to evaluate $f_1(\mathcal{A}_Q)$. This is easily done since the function $f_1(x, y)$ (whose divisor is $(f_1) = (P + R_1) - (R_1) - (P) + (O)$) can be written out explicitly as follows.

1. Let $a_1x + b_1y + c_1 = 0$ be the line passing through the points P and R_1. Define the function $g_1(x, y) = a_1x + b_1y + c_1$.

2. Let $x + c_2 = 0$ be the vertical line passing through the point $P + R_1$. Define the function $g_2(x, y) = x + c_2$.
3. The function $f_1(x, y)$ is simply $f_1(x, y) = g_2(x, y)/g_1(x, y)$, which is easy to evaluate in $\mathbb{F}_{p^2}$.

Acknowledgments. The authors thank Moni Naor, Alice Silverberg, Ben Lynn, Steven Galbraith, Kenny Paterson, and Mike Scott for helpful discussions about this work.

3-DIMENSIONAL EUCLIDEAN VORONOI DIAGRAMS OF LINES WITH A FIXED NUMBER OF ORIENTATIONS*

VLADLEN KOLTUN† AND MICHA SHARIR‡

Abstract. We show that the combinatorial complexity of the Euclidean Voronoi diagram of n lines in $\mathbb{R}^3$ that have at most c distinct orientations is $O(c^3 n^{2+\varepsilon})$ for any $\varepsilon > 0$. This result is a step toward proving the long-standing conjecture that the Euclidean Voronoi diagram of lines in three dimensions has near-quadratic complexity. It provides the first natural instance in which this conjecture is shown to hold. In a broader context, our result adds a natural instance to the (rather small) pool of instances of general 3-dimensional Voronoi diagrams for which near-quadratic complexity bounds are known.

1. Introduction.

Background. The Voronoi diagram of a set Γ of disjoint objects ("sites") in some space under some metric is a subdivision of the space into cells, one cell per site, such that the cell associated with a site $O \in \Gamma$ comprises the points in space for which O is closer (under the given metric) than all other sites of Γ.

The study of Voronoi diagrams in the plane has been very extensive over the past 20 years, and the structure of such diagrams is by now thoroughly understood. The study has covered diagrams for many kinds of sites, and for many kinds of metrics or distance functions, and has also considered other variants of the problem, such as kth order diagrams, constrained Delaunay triangulations, and more. Surveys of the state of the art are given in Aurenhammer and Klein [4] and Fortune [10].

In contrast, Voronoi diagrams in three and higher dimensions have been much less studied, and many basic problems are still wide open. Most variants of planar Voronoi diagrams have linear complexity, which is usually a consequence of the planarity of the diagram. In three dimensions, a prevailing conjecture is that the complexity of Voronoi diagrams should be in general at most quadratic or near-quadratic in the number of sites. This is known to hold only for a very few special cases, including the cases of point sites under the Euclidean metric [16, 21], point sites under any "polyhedral" metric or distance function (i.e., distance functions induced by a convex polytope with $O(1)$ facets; see [5, 15, 24] for details), line sites under similar distance functions [6], and sphere sites under the Euclidean metric [3]. Only very recently,

the authors [17] have shown this to hold also in the case of arbitrary polyhedral sites under polyhedral distance functions.

In all the other, "open" cases, cubic or near-cubic upper bounds for the complexity of 3-dimensional Voronoi diagrams are known. They are a consequence of the representation of such diagrams as lower envelopes of trivariate functions, each measuring the distance from a point in $\mathbb{R}^3$ to one of the sites; see [8] for this representation and [23] for the bounds just stated. In contrast, only quadratic or near-quadratic lower bounds for the complexity of 3-dimensional diagrams are known [2, 6].

The case of the Euclidean metric appears to be harder than the case of polyhedral metrics (or distance functions), because the trivariate functions that measure distances are curved (except for the special case of point sites, where they can be transformed into linear functions), and the constraints that define the diagram are harder to analyze. The simplest open case of 3-dimensional Euclidean diagrams is that in which the sites are lines. This specific problem is listed as Problem 3 in the list of open problems in computational geometry, recently published by Mitchell and O'Rourke [19]. A recent result that lends credence to the conjecture that the complexity of such diagrams is near-quadratic is due to Agarwal and Sharir [1], who showed that the complexity of the union of n infinite congruent cylinders in 3-space is near-quadratic. The boundary of this union can be interpreted as a cross-section of the Euclidean Voronoi diagram of the axes of the cylinders, being the locus of all those points whose distance to the nearest axis has a fixed value (equal to the common radius of the cylinders). The complicated proof in [1] and the fact that the result applies merely to a single cross-section of the diagram suggest that the problem involving the whole Euclidean Voronoi diagram of lines might be particularly hard to tackle.

Our contribution. In this paper, we obtain the first result toward the described goal. We study the special case in which the sites are lines that have a fixed number c of distinct orientations (and the metric is Euclidean). Even this special case is quite nontrivial to analyze. We show that the complexity of the diagram is $O(c^3 n^{2+\varepsilon})$ for any $\varepsilon > 0$, where the constant of proportionality depends on ε. This implies, in particular, that when the number of distinct orientations in a collection of lines is constant (that is, $c = O(1)$), the complexity of its Euclidean Voronoi diagram is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$. This completely confirms the above-mentioned conjecture in this case.

The motivation underlying the study of Voronoi diagrams in computational geometry has always been algorithmic. They provide a natural data structure for handling a variety of applications, important both in theory and in practice, such as proximity (nearest neighbor) queries, high-clearance placements and motion planning problems, clustering and classification problems, and many more (see, among others, the survey by Aurenhammer and Klein [4] and the book by Okabe et al. [20] for a description of many of these applications).

There are several general techniques for computing Voronoi diagrams, such as randomized incremental construction or sweep-based methods, and many more ad hoc approaches. However, a precursory stage to the design of any algorithm for computing Voronoi diagrams is obtaining sharp bounds on their complexity. This will serve as a lower bound for the efficiency of any such algorithm and quite often can be used in the design of algorithms with roughly the same running time. Nevertheless, most of the algorithmic study of Voronoi diagrams has been confined to planar diagrams for the good reason that we are still lacking sharp general bounds for the complexity of generalized 3-dimensional diagrams.

The results presented in this paper are an attempt to remedy this situation. The special case we treat is important because it provides us with one more problem instance where near-quadratic bounds can be established. We hope that the method developed here will find applications in the analysis of other types of 3-dimensional Voronoi diagrams (see the remark at the end of section 3) and thereby lead us further toward the ultimate goal of establishing near-quadratic bounds for general 3-dimensional diagrams, following which near-quadratic algorithms for their construction will not be too difficult to design.

Moreover, the considered setting of lines with a fixed number of orientations is interesting in its own right. It is applicable, for example, to the problem of motion planning, or of finding largest free placements, of a ball amid a collection of "beams" or "pipes" in 3-space. It is a natural assumption that the beams have only a constant number of orientations. (Typical examples of this setting occur in architectural design.)

Organization. We first study, in section 2, the special case in which the lines have at most three distinct orientations. In this special case, we obtain the slightly improved bound $O(n\lambda_5(n))$, where $\lambda_5(n) = O(n \cdot \alpha(n)^{O(\alpha(n))})$ is the maximum length of Davenport–Schinzel sequences of order 5 on n symbols, and where $\alpha(n)$ is the extremely slowly growing inverse Ackermann function (see [23] for details). The case of four orientations is treated in section 3, and the simple extension to more than four orientations is described in section 4.

2. The case of two or three orientations. Let L be a set of n lines in 3-space which have up to three distinct orientations. Thus L can be written as $R \cup B \cup G$, where all the lines in R (called "red" lines) have the same orientation, and the same holds for the lines of B ("blue" lines) and those of G ("green" lines).

We adopt a limited general position assumption on L as follows. First, we assume that each of the collections R, B, and G is in general position in the sense that its intersection with any fixed generic plane is a collection of points in general position (that is, it does not contain collinear triples or cocircular quadruples of points or other degenerate configurations). We also assume that the three vectors that are parallel to the orientations of the collections R, B, and G do not lie in a common plane.

Before we proceed, we need to mention some basic properties of *bisectors* and *trisectors* of lines, which are, respectively, the loci of points equidistant from two and three lines. These geometric properties are reported here without proofs, which are given as an appendix below, in order to maintain the flow of exposition. The main conclusions from the analysis carried out in the appendix are as follows. A bisector of two lines is in general a hyperbolic paraboloid, which is a doubly ruled quadratic surface. (It degenerates to a plane when the two lines are parallel.) A trisector of three pairwise nonparallel lines is an algebraic curve of degree four and, if nonsingular, has exactly four components, all unbounded. If two of the three defining lines are parallel, the trisector becomes a planar conic section (of degree two, consisting of at most two unbounded components). If all three lines are parallel, the trisector is a line parallel to them. The fact that no component of any trisector is bounded will be significant in our analysis. In what follows, we will denote the bisector of two lines e, f by $H_{e,f}$, and the trisector of three lines e, f, g will be denoted by $\tau_{e,f,g}$.

Denote the Euclidean Voronoi diagram of L by $Vor(L)$. We begin by bounding the number of its vertices. Let v be such a vertex, incident to the cells of four lines $\ell_1, \ell_2, \ell_3, \ell_4$. At least two of them must be of the same color. Suppose first that three of them are of the same color, say, $\ell_1, \ell_2, \ell_3 \in R$. Project v and all the lines of R

onto a plane π orthogonal to these lines. Then each line of R projects to a point, and v projects onto a vertex v^* of the planar Voronoi diagram of the projected points within π. The number of such vertex projections v^* is thus at most $2n-4$. Moreover, the number of vertices v that can project onto the same point v^* is at most $2n$. This is because the radius r of the ball centered at v and touching ℓ_1, ℓ_2, ℓ_3 is equal to the radius of the disk within π centered at v^* and touching the point projections of these three lines. As we slide a ball of radius r while maintaining contact with ℓ_1, ℓ_2, ℓ_3, we reach at most $2n$ placements where it touches a fourth line. Each of these touching placements in which the ball is not crossed by any other line gives rise to a Voronoi vertex that projects onto v^*. This implies that the overall number of Voronoi vertices of the kind under consideration is at most $(2n-4) \cdot 2n = O(n^2)$.

Suppose then that exactly two of the four lines are of the same color, say, $\ell_1, \ell_2 \in R$, $\ell_3 \in B$, and $\ell_4 \in G$. If we project v and the lines of R onto the same plane π as above, we obtain that the projection of v lies on a Voronoi edge of the planar diagram of the point projections of the red lines. The number of such edges is $O(n)$.

Fix such an edge e, and consider the 2-dimensional slab Σ_e obtained by sweeping e in the direction of the red lines; by construction, $v \in \Sigma_e$. Moreover, Σ_e is the locus of all the centers of balls that touch ℓ_1 and ℓ_2 and no other red line. Let H_e denote the plane containing Σ_e, and let ℓ_0 be the line of intersection between H_e and the plane π_0 spanned by ℓ_1 and ℓ_2—this intersection is the midline of the 2-dimensional slab spanned by ℓ_1 and ℓ_2. Denote the two halfspaces bounded by π_0 as π_0^+ and π_0^-. See Figure 1.

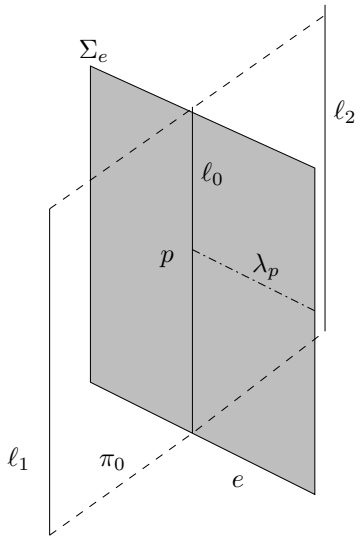

FIG. 1. *The bisector of ℓ_1 and ℓ_2.*

Fix a point $p \in \ell_0$, and consider the line λ_p that passes through p, lies in H_e, and is orthogonal to ℓ_0. Parametrize λ_p by a real parameter y, where $y = 0$ at p, $y > 0$ within π_0^+, and $y < 0$ within π_0^-. Move a point q along the entire λ_p in the direction of increasing y. The ball centered at q and touching ℓ_1, ℓ_2 has the property that its intersection with π_0^+ keeps expanding during the motion (i.e., any point of π_0^+ that the moving ball meets will remain inside the ball as its center keeps moving in the

above direction). Similarly, the portion of the moving ball within π_0^- keeps shrinking "into itself."

Let each line $\ell \in B \cup G$ define two rays $\ell^+ = \ell \cap \pi_0^+$, $\ell^- = \ell \cap \pi_0^-$. With each ray ℓ^+ (resp., ℓ^-), associate a function ψ_{ℓ^+} (resp., ψ_{ℓ^-}) on ℓ_0, where $\psi_{\ell^+}(p)$ (resp., $\psi_{\ell^-}(p)$) for $p \in \ell_0$ is the y-value of the center of the ball that touches ℓ_1, ℓ_2, and ℓ^+ (resp., ℓ^-), where the center lies on λ_p. The functions ψ_{ℓ^+}, ψ_{ℓ^-} are defined (and continuous) when ℓ does not intersect the disk centered at p, lying in π_0, and touching ℓ_1 and ℓ_2. Hence the (common) domain of definition of ψ_{ℓ^+} and ψ_{ℓ^-} is either the full line ℓ_0 if ℓ does not intersect the 2-dimensional slab spanned by ℓ_1 and ℓ_2 or the union of two rays along ℓ_0 otherwise.

Denote the collection of the functions ψ_{ℓ^+} (resp., ψ_{ℓ^-}) for $\ell \in B \cup G$ by Ψ^+ (resp., by Ψ^-). The preceding observations imply that any Voronoi vertex $v \in \Sigma_e$ under consideration (two of whose defining lines are in $B \cup G$) corresponds either to a vertex of the lower envelope of Ψ^+ or to a vertex of the upper envelope of Ψ^- or to an intersection point between the two envelopes.

It is easily seen that any pair of functions of the above kind intersect in at most four points. Indeed, any such intersection point w is equidistant from ℓ_1, ℓ_2, and from two other lines $\ell_3, \ell_4 \in B \cup G$. That is, we have

$$d^2(w, \ell_1) \left(= d^2(w, \ell_2)\right) = d^2(w, \ell_3) = d^2(w, \ell_4).$$

The squared distance of a point w from a line that passes through a point a and has unit direction u is

$$\|w - a\|^2 - ((w - a) \cdot u)^2,$$

which is a quadratic polynomial in the coordinates of w. Since w lies on the plane H_e, we obtain a system of two quadratic equations in two variables which has at most four solutions (see also the proof of Lemma 3.1 below).

It is shown, e.g., in [23, Lemma 1.8] that the complexity of the upper or lower envelope of continuous functions, so that each function is defined on a ray or on the whole real line, and so that each pair of them intersect in at most four points, is $O(\lambda_5(n)) = O(n \cdot \alpha(n)^{O(\alpha(n))})$ [23], where $\lambda_5(n)$ is the maximum length of Davenport–Schinzel sequences of order 5 on n symbols, and where $\alpha(n)$ is the extremely slowly growing inverse Ackermann function. As observed above, we can split each partially defined function in $\Psi^+ \cup \Psi^-$ into two functions, each defined over a ray. We thus conclude that the number of Voronoi vertices in (the relative interior of) Σ_e is $O(\lambda_5(n))$. Multiplying this bound by the number $O(n)$ of edges e and adding the preceding bound $O(n^2)$ on the number of vertices defined by three lines of the same color, we conclude that the number of vertices of the diagram $Vor(L)$ is $O(n\lambda_5(n))$.

We next bound the number of edges of $Vor(L)$. If an edge e is delimited by a Voronoi vertex v, we charge e to v. By the general position assumption, each v is charged at most four times, so the number of edges e of this kind is $O(n\lambda_5(n))$. Let e be a Voronoi edge that has no incident Voronoi vertex. As mentioned above, the analysis of trisectors implies that e is not bounded.

Fix two planes $\pi^{\pm}$: $z = \pm z_0$ such that each unbounded edge of $Vor(L)$ intersects at least one of them. (Assuming that the coordinate directions are generic, such planes exist.) It therefore suffices to bound the complexity of the cross-sections of $Vor(L)$ with the planes $\pi^{\pm}$. Consider, say, the plane π^+. The Voronoi cells in each of the monochromatic diagrams $Vor(R)$, $Vor(B)$, $Vor(G)$ are unbounded convex prisms, whose faces are all parallel to the orientation of the respective collection of lines, and

the overall complexity of each diagram is $O(n)$. Hence, the intersection of π^+ with each of these monochromatic diagrams is a planar convex subdivision of complexity $O(n)$. The overlay of these cross-sections is a planar convex subdivision of complexity $O(n^2)$. For each cell ξ of the overlay, there exist a fixed red line r, a fixed blue line b, and a fixed green line g, which are the nearest red, blue, and green lines to any point in ξ, respectively. It follows that the complexity of the overall diagram $Vor(L)$ within ξ is bounded by a constant, which implies that the complexity of the diagram within π^+ (and, symmetrically, within π^-) is $O(n^2)$.

This implies that the number of unbounded edges of $Vor(L)$ is $O(n^2)$. It is easily seen that the number of 2-faces of the diagram is proportional to the number of vertices plus the number of edges plus $O(n^2)$. Finally, the number of 3-cells is only n: Each line has a connected, star-shaped Voronoi cell [18]. Hence we obtain the following theorem, the main result of this section.

THEOREM 2.1. *The complexity of the Voronoi diagram of a set of n lines with at most three distinct orientations is $O(n\lambda_5(n)) = O(n^2 \cdot \alpha(n)^{O(\alpha(n))})$.*

3. The case of four orientations. We now assume that the given set L of lines is the union of four subsets, each consisting of lines at a fixed direction. We denote these subsets by R (consisting of "red" lines), B (consisting of "blue" lines), G (consisting of "green" lines), and Y (consisting of "yellow" lines). The proof of the following elementary geometric fact is provided for completeness.

LEMMA 3.1. *The maximum number of balls tangent to four given lines in 3-space, assuming general position, is 8.*

Proof. As already noted, the distance $d(\mathbf{x}, \ell)$ between a point $\mathbf{x} \in \mathbb{R}^3$ and a line ℓ, passing through a point a and having unit direction u, satisfies

$$d^2(\mathbf{x}, \ell) = \|\mathbf{x} - a\|^2 - ((\mathbf{x} - a) \cdot u)^2,$$

which is a quadratic function of $\mathbf{x}$. Given four lines $\ell_1, \ell_2, \ell_3, \ell_4$ in general position, the center $\mathbf{x}$ of a ball that is tangent to all four lines has to satisfy the equations

$$d^2(\mathbf{x}, \ell_1) = d^2(\mathbf{x}, \ell_2) = d^2(\mathbf{x}, \ell_3) = d^2(\mathbf{x}, \ell_4).$$

These are three quadratic equations, so, by Bezout's theorem [14], the number of solutions is at most $2^3 = 8$.

The number 8 can be attained: We first give a construction where the lines are not in general position. Take ℓ_1, ℓ_2, ℓ_3 to be any three nonconcurrent lines in the xy-plane. They determine four disks D_1, D_2, D_3, D_4 in that plane that are tangent to all three of them, as shown in Figure 2. Take ℓ_4 to be any line perpendicular to the xy-plane, meeting the plane at a point not lying in any of these disks. Fix a disk D_i, and let λ_i be the z-vertical line passing through the center of D_i; this is the locus of all centers of balls that touch ℓ_1, ℓ_2, ℓ_3 and meet the xy-plane at D_i. It is easily seen that there are exactly two points on λ_i, symmetric to each other with respect to the xy-plane, that are centers of balls that also touch ℓ_4. For any specific disc D_i, this yields two distinct balls that touch all four lines, giving us eight such balls overall. By slightly perturbing the lines, we can obtain a construction for lines in general position. This completes the proof of the lemma. □

Let $\ell_1, \ell_2, \ell_3, \ell_4$ be four given lines of different colors. Let $s \leq 8$ denote the number of balls tangent to all four of them, and let $c_1, \ldots, c_s$ denote the centers of these balls, sorted in increasing order of their x-coordinate. (The coordinate frame is assumed to be generic so that no two c_i's have the same x-coordinates.) Define the *index* $\mathrm{ind}(c_i)$ of c_i to be $\min\{i - 1, s - i\}$, so we have $0 \leq \mathrm{ind}(c_i) \leq 3$ for each i.

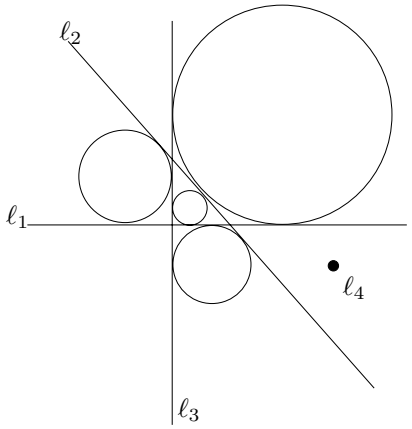

FIG. 2. *Four lines having eight Voronoi vertices.*

With each line $\ell \in L = R \cup B \cup G \cup Y$ we associate the squared distance function $f_\ell \colon \mathbb{R}^3 \mapsto \mathbb{R}$, given by $f_\ell(\mathbf{x}) = d^2(\mathbf{x}, \ell)$. Let $\mathcal{E}_\mathcal{F}$ denote the lower envelope of the set $\mathcal{F} = \mathcal{F}(L) = \{f_\ell \mid \ell \in L\}$. Clearly, the *minimization diagram* of $\mathcal{E}_\mathcal{F}$, namely, the projection of (the graph of) $\mathcal{E}_\mathcal{F}$ onto the xyz-space, is the Voronoi diagram $Vor(L)$ (see also [8]).

For each point $\mathbf{q} = (q_1, q_2, q_3, q_4) \in \mathbb{R}^4$, define its *$R$-level* (resp., *$B$-level*, *$G$-level*, *$Y$-level*) to be the number of lines $\ell \in R$ (resp., $\ell \in B$, $\ell \in G$, $\ell \in Y$) whose corresponding function graphs pass below $\mathbf{q}$; that is, $q_4 > f_\ell(q_1, q_2, q_3)$. The *combined level* of $\mathbf{q}$ is the sum of its red, blue, green, and yellow levels. We denote the graph of each $f_\ell \in \mathcal{F}$ by $\tilde{f}_\ell$. Denote by $\tilde{R}$ the collection of all graphs $\tilde{f}_\ell$ for $\ell \in R$, and define $\tilde{B}$, $\tilde{G}$, $\tilde{Y}$, and $\tilde{L}$ analogously. Let $\mathcal{A}(\tilde{L})$ denote the arrangement in $\mathbb{R}^4$ of the graphs $\tilde{f}_\ell$ of the functions in $\tilde{L}$. Clearly, for a vertex $\mathbf{q}$ of $\mathcal{A}(\tilde{L})$, $\mathbf{q}$ is a vertex of $\mathcal{E}_\mathcal{F}$ if and only if the combined level of $\mathbf{q}$ is 0.

Let $V_0^{(j)}(L)$ (resp., $V_{\leq k}^{(j)}(L)$) denote the number of "4-colored" vertices $\mathbf{q}$ of $\mathcal{A}(\tilde{L})$ (i.e., vertices incident to a red graph, a blue graph, a green graph, and a yellow graph) of index $\leq j$, whose combined level is 0 (resp., at most k). Put $V_0(L) = V_0^{(3)}(L)$ and $V_{\leq k}(L) = V_{\leq k}^{(3)}(L)$. We also put $V_0^{(j)}(n) = \max_L V_0^{(j)}(L)$, where the maximum is taken over all families L of n lines, each having one of the four given orientations; $V_{\leq k}^{(j)}(n)$ is defined analogously. Using the Clarkson–Shor bound on levels [7], we have

$$V_{\leq k}^{(j)}(n) = O\left(k^4 V_0^{(j)}\left(\frac{n}{k}\right)\right).$$

As mentioned in section 2 and proven in the appendix, every connected component of any trisector is unbounded. However, in the proof below, we will *not* make use of this property at all. This will be significant when we extend the analysis to more general setups—see a discussion at the end of this section.

3.1. Irregular vertices. Let v be a 4-colored vertex of the diagram, interpreted as a vertex of the lower envelope $\mathcal{E}_\mathcal{F}$, incident to four graphs $\tilde{f}_r$, $\tilde{f}_b$, $\tilde{f}_g$, $\tilde{f}_y$ for some $r \in R$, $b \in B$, $g \in G$, and $y \in Y$. The vertex v is incident to four edges of the envelope, which we denote mnemonically as rbg, rby, rgy, and bgy, where $rbg \subseteq \tau_{r,b,g}$ denotes the edge lying on the graphs $\tilde{f}_r$, $\tilde{f}_b$, $\tilde{f}_g$, and similarly for the three other edges. As noted in [22], at least one of these edges emanates from v in the positive x-direction,

and at least one edge emanates in the negative x-direction. We call v a *regular* vertex if exactly two of these edges emanate from v in the positive x-direction and exactly two emanate from v in the negative x-direction. Otherwise, we call v *irregular*.

LEMMA 3.2. *There are only $O(n\lambda_5(n))$ irregular vertices.*

Proof. Let v be an irregular vertex. If v is not 4-colored, then the claim follows from Theorem 2.1, so assume that v is 4-colored, and use the above notation to denote the surfaces and edges incident to v. Suppose, without loss of generality, that three of the incident edges emanate from v to the left, and assume that they are rbg, rby, and rgy. In this case (assuming general position), v is a locally x-maximal vertex of the Voronoi cell $V(r)$ of r. Clearly, each line has a single connected Voronoi cell. In fact, each cell, star-shaped with respect to its defining line, is also simply connected; see, e.g., [18].

As shown, e.g., in [12, Lemma 2.4], the number of locally x-extremal points of a simply connected 3-dimensional region K is proportional to 1 plus the number of *critical points* of ∂K (relative to the x-direction). These are points w for which the cross-section of the interior of K with the yz-parallel plane through w is disconnected near w but becomes connected (near w) when the plane slightly translates in some direction. Hence the number of irregular vertices of $Vor(L)$ is proportional to the number of critical points of cell boundaries plus $O(n)$.

Assuming general position, each critical point w of $\partial V(r)$ is incident to only three surfaces; it is typically a locally x-extremal point of a Voronoi edge of $V(r)$. Suppose, without loss of generality, that w is incident to $\tilde{f}_r, \tilde{f}_{b_1}, \tilde{f}_{g_1}$ for some $b_1 \in B$, $g_1 \in G$. Then w is a locally x-extremal point of (the relative interior of) a Voronoi edge (a portion of τ_{r,b_1,g_1}) of the 3-colored Voronoi diagram $Vor(R \cup B \cup G)$. By Theorem 2.1, the overall number of such features is $O(n\lambda_5(n))$, and this completes the proof of the lemma. □

3.2. The counting scheme. In light of Lemma 3.2, this section is devoted to bounding the number of regular vertices of $Vor(L)$. This number is estimated using a variation of the "counting scheme" technique, as introduced by Halperin and Sharir [11, 22] (see also [23]).

Let v be a 4-colored regular vertex, incident to $\tilde{f}_r, \tilde{f}_b, \tilde{f}_g, \tilde{f}_y$, using the notation introduced above. Let $0 \le j \le 3$ be the index of v. Without loss of generality, assume that there are exactly j vertices incident to $\tilde{f}_r, \tilde{f}_b, \tilde{f}_g, \tilde{f}_y$ to the *right* (that is, in the x-increasing direction) of v. By definition, v is incident to two edges of $\mathcal{E}_{\mathcal{F}}$ that emanate from it to the right, and to two edges that emanate from it to the left. Without loss of generality, assume that the edges emanating to the right are rbg and rby and the edges emanating to the left are rgy and bgy.

Consider the 2-dimensional bisector $H_{g,y}$. Denote by R_{gy} the set of trisectors $\tau_{g,y,r'}$ drawn as curves along $H_{g,y}$ for red lines $r' \in R$. Define in an analogous manner the sets B_{gy}, G_{gy}, and Y_{gy} (where the latter two sets exclude the ill-defined trisectors induced by g and y themselves). Let $\mathcal{A}_{gy}$ denote the 2-dimensional arrangement of the collection $R_{gy} \cup B_{gy} \cup G_{gy} \cup Y_{gy}$ of curves within $H_{g,y}$. It follows that there exists a face of $\mathcal{A}_{gy}$ that is also a 2-face of $\mathcal{E}_{\mathcal{F}}$ on $H_{g,y}$, such that v is a locally x-maximal vertex of that face.

Let $\gamma_r \in R_{gy}$ (resp., $\gamma_b \in B_{gy}$) denote the trisector $\tau_{r,g,y}$ (resp., $\tau_{b,g,y}$), regarded as a curve within $H_{g,y}$. If we follow γ_r from v to the right, we lie, locally near v, above $\mathcal{E}_{\mathcal{F}}$ (actually, above $\tilde{f}_b$), and similarly for γ_b (which lies locally above $\tilde{f}_r$). See Figure 3.

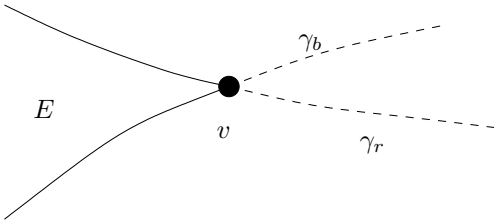

FIG. 3. *The vertex v on $H_{g,y}$—a view from the bottom (in $\mathbb{R}^4$).*

3.2.1. Initial counting stages and vertices of index 0 and 1.

LEMMA 3.3. *$V_0^{(0)}(n)$ and $V_0^{(1)}(n)$ are bounded by $O(n\lambda_5(n))$.*

Proof. Trace the curve γ_r from v to the right, and stop as soon as we reach one of the following *critical events* along γ_r:

(a) We reach another intersection of the four graphs $\tilde{f}_r, \tilde{f}_b, \tilde{f}_g, \tilde{f}_y$.
(b) We reach a 3-colored vertex.
(c) We reach $x = +\infty$.
(d) We reach a locally x-extremal point of the curve γ_r.

We refer to events of types (b)–(d) as *terminal events*.

Perform a similar tracing along γ_b. Suppose that at least one of the tracings, say, along γ_r, reaches a terminal event. The first such event either is a vertex of the 3-colored Voronoi diagram of $R \cup G \cup Y$ or can be charged to an edge of this diagram. By Theorem 2.1, the number of such events is thus $O(n\lambda_5(n))$, and each such event is uniquely counted by some vertex v. (This follows since between v and the terminal event we are always above $\mathcal{E}_{\mathcal{F}}$.) Hence the number of vertices v that fall in this case is $O(n\lambda_5(n))$. In particular, this bounds the number of vertices of index 0.

We may thus assume that the tracing of γ_r ends at a vertex u, and the tracing of γ_b ends at a vertex w, so that both u and w are incident to $\tilde{f}_r, \tilde{f}_b, \tilde{f}_g, \tilde{f}_y$ (see Figure 4). Moreover, the portion $\delta_r^{(1)}$ of γ_r between v and u and the portion $\delta_b^{(1)}$ of γ_b between v and w are both x-monotone, and neither of them contains a 3-colored vertex or another terminal event. In particular, u and w lie to the right of v, the red, green, and yellow levels of u are all 0, and the blue, green, and yellow levels of w are all 0.

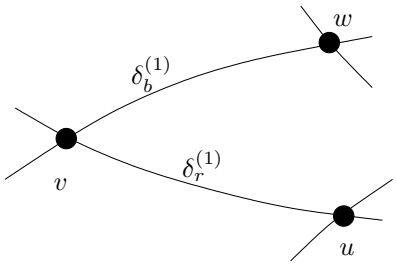

FIG. 4. *Tracing from v to the right.*

If $u = w$, then this is a vertex of the diagram (because all its colored levels are 0) of index at most $j - 1$ (because it lies to the right of v). The number of vertices v in this subcase is thus at most $V_0^{(j-1)}(n)$. In particular, this is easily seen to imply that

the number of vertices of index 1 is $O(n\lambda_5(n))$. We have thus shown the following:

$$V_0^{(0)}(n) = O(n\lambda_5(n)), \qquad V_0^{(1)}(n) = O(n\lambda_5(n)),$$

which completes the proof of the lemma. □

3.2.2. Subsequent counting stages and vertices of index 2. In what follows, we assume that $j = 2$ or 3. In light of the arguments made in the proof of Lemma 3.3, we may assume that $u \neq w$. Fix some threshold parameter k to be determined later.

LEMMA 3.4. *$V_0^{(2)}(n)$ is bounded by $O(k^3 n\lambda_5(n) + k^2 V_0(\frac{n}{5k}))$.*

Proof. Suppose that the blue (and thus the combined) level of u is at most $4k$. In this case, we charge v to u. The charging is unique, implying that the number of vertices v in this case is at most

$$V_{\leq 4k}^{(j-1)}(n) = O\left(k^4 V_0^{(j-1)}\left(\frac{n}{4k}\right)\right),$$

where, as already mentioned, we use the Clarkson–Shor bound on levels [7]. A similar charging is applied if the level of w is at most $4k$. Hence, in what follows, we may assume that $u \neq w$ and that both lie at combined level $> 4k$.

Let W denote the portion of $H_{g,y}$ consisting of all points that lie above the graphs of both f_r and f_b, and let W_0 be the connected component of W whose boundary contains v. The region W_0 is bounded, locally near v and to its right, by the two arcs $\delta_r^{(1)}$ and $\delta_b^{(1)}$, and v is a locally leftmost (x-minimal) vertex of W_0. Let $\delta_b^{(2)}$ (resp., $\delta_r^{(2)}$) denote the other edge of ∂W_0 incident to u (resp., to w). Both $\delta_r^{(1)}$ and $\delta_r^{(2)}$ are contained in the trisector $\tau_{r,g,y}$, although they do not have to lie on the same component of that curve. Similarly, $\delta_b^{(1)}$ and $\delta_b^{(2)}$ are contained in $\tau_{b,g,y}$. Without loss of generality, we assume that $\delta_r^{(1)}$ lies clockwise to $\delta_b^{(1)}$ (when viewed from above); see Figure 5 for an illustration of several possible shapes of W_0.

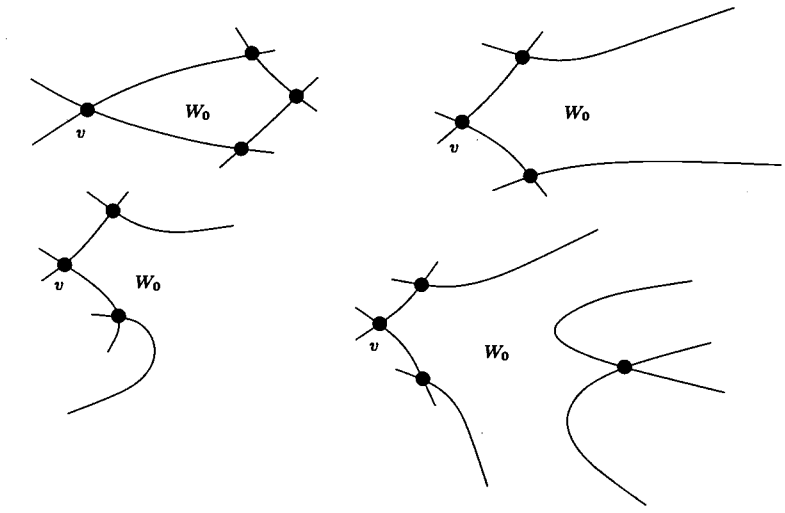

FIG. 5. *Several possible structures of the region W_0. In all cases, at most three vertices of W_0 lie to the right of v.*

Let ζ be a vertex of $\mathcal{A}_{gy}$ along $\delta_r^{(1)}$, incident to the graph of some other blue function f_β. (Recall that, by assumption, all vertices along $\delta_r^{(1)}$ are 4-colored.) Consider the trisector $\tau_{\beta,g,y}$ as a curve γ_β within $H_{g,y}$, and let δ_β denote the connected component of $\gamma_\beta \cap W_0$ incident to ζ. We say that δ_β is a *deep* arc if it contains at least k vertices of $\mathcal{A}_{gy}$. If δ_β is not deep and it contains a terminal event (namely, it contains a 3-colored vertex, or contains a locally x-extremal point, or reaches $x = \pm\infty$), we call it a *terminal* arc. Otherwise, we call it *shallow*. See Figure 6 for a special case of a shallow arc. Similar notation applies to red arcs that emanate from vertices of $\mathcal{A}_{gy}$ along $\delta_b^{(1)}$.

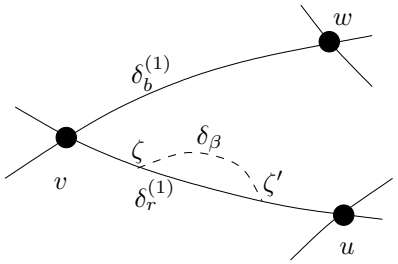

FIG. 6. *A shallow arc that lands back on* $\delta_r^{(1)}$.

Consider the first $4k$ vertices along $\delta_r^{(1)}$. (By assumption, $\delta_r^{(1)}$ must contain at least this many vertices.) If at least $2k$ of the corresponding arcs δ_β are deep, then collecting the first k vertices along each of these arcs yields a set of at least $2k^2$ vertices of $\mathcal{A}_{gy}$ within W_0, all lying at combined level at most $5k$. We claim that each of them is charged by vertices like v at most a constant number of times. Indeed, let η be such a vertex, lying on a deep blue arc δ_β. Note that the starting point ζ of δ_β is at red level 0, but all points in the relative interior of δ_β have strictly positive red levels. Hence we can trace δ_β back from η (there are two possible directions for this tracing) until we reach the first point ζ at red level 0. The point ζ must lie on $\delta_r^{(1)}$, and we can trace $\delta_r^{(1)}$ from ζ backward (to the left) until we reach v—the first vertex at combined level 0. Hence, using [7], as above, the number of vertices v in this subcase is at most

$$O\left(\frac{1}{k^2} V_{\le 5k}(n)\right) = O\left(k^2 V_0\left(\frac{n}{5k}\right)\right).$$

The same bound applies to the number of vertices v for which at least $2k$ of the first $4k$ vertices along $\delta_b^{(1)}$ are sources of deep red arcs.

Hence we may assume that, among the first $4k$ vertices along $\delta_r^{(1)}$, at least $2k$ are sources of shallow or terminal arcs, and similarly for $\delta_b^{(1)}$. If any of these arcs is terminal, we charge v to the corresponding terminal event along the arc. We note that such an event η lies at combined level at most $5k$. Hence η is or can be charged to a $(\le 5k)$-level feature of one of the 4-dimensional 3-colored arrangements $\mathcal{A}(\tilde{B} \cup \tilde{G} \cup \tilde{Y})$, $\mathcal{A}(\tilde{R} \cup \tilde{G} \cup \tilde{Y})$. Moreover, arguing as in the preceding paragraph, η is charged by vertices like v at most twice. By Theorem 2.1 and [7], the number of such events η, and thus also the number of vertices v that fall into this subcase, is at most

$$O\left(k^4 \cdot \frac{n}{5k} \lambda_5\left(\frac{n}{5k}\right)\right) = O(k^2 n \lambda_5(n)).$$

Hence we may assume that at least $2k$ of the first $4k$ vertices along $\delta_r^{(1)}$ are sources of shallow arcs, and none of these vertices are sources of terminal arcs. Moreover, the same property holds for $\delta_b^{(1)}$.

Suppose that one of these shallow arcs, δ_β, emanating from $\delta_r^{(1)}$, terminates also on $\delta_r^{(1)}$, as in Figure 6. By definition, δ_β does not encounter any blue graph $\tilde{f}_{\beta'}$ (for then δ_β would contain a 3-colored vertex and thus would be terminal). Hence the blue level of the terminal endpoint ζ' of δ_β is equal to the blue level of the starting point ζ, and all other levels of both endpoints are 0. In this case, we skip the portion of $\delta_r^{(1)}$ between ζ and ζ'. More precisely, we modify the tracing procedure used so far as follows: Trace $\delta_r^{(1)}$ to the right, starting from v, and attempt to collect either $2k$ deep arcs or a terminal arc or $2k$ shallow arcs that do not terminate on $\delta_r^{(1)}$. If during this tracing we reach a shallow arc δ_β that does terminate on $\delta_r^{(1)}$, we take a "shortcut" along δ_β and continue the tracing of $\delta_r^{(1)}$ from the other endpoint of δ_β. It is clear that this modified process must terminate successfully, or else we would reach the endpoint u of $\delta_r^{(1)}$, which then would lie at level $\leq 4k$, contrary to assumption. From now on, we apply a similarly modified tracing procedure to $\delta_b^{(1)}$ as well.

We thus reach the following situation. We have collected at least $2k$ shallow blue arcs that emanate from $\delta_r^{(1)}$ and terminate on other red edges of ∂W_0 and at least $2k$ shallow red arcs that emanate from $\delta_b^{(1)}$ and terminate on other blue edges of ∂W_0. The combined level of any point on any of these arcs is at most $5k$.

Suppose that one of the shallow blue arcs δ_β that emanates from $\delta_r^{(1)}$ terminates on a (red) edge $\delta_r^{(3)}$ of ∂W_0 that does not intersect $\tau_{b,g,y}$ at all. That is, $\delta_r^{(3)}$ is a full (bounded or unbounded) component of the trisector $\tau_{r,g,y}$, which lies fully above the graph of f_b, as in Figure 7. Let η be the "landing point" of δ_β on $\delta_r^{(3)}$. The combined level of η is at most $5k$. Trace $\delta_r^{(3)}$ from η to the right (i.e., in the positive x-direction) until we reach a terminal event η', to which we charge v. (Such an η' always exists: even if we do not encounter any finite event, we will reach $x = +\infty$, which is a terminal event, by definition.) Note that η' is or can be charged to a feature of the 4-dimensional arrangement $\mathcal{A}(\tilde{R} \cup \tilde{G} \cup \tilde{Y})$, whose combined level (in this 3-colored arrangement) is at most $5k$. Arguing as above, the number of such events is $O(k^2 n \lambda_5(n))$. Here we cannot claim that η' is uniquely charged by v, but we can still bound the number of times η' is charged, as follows.

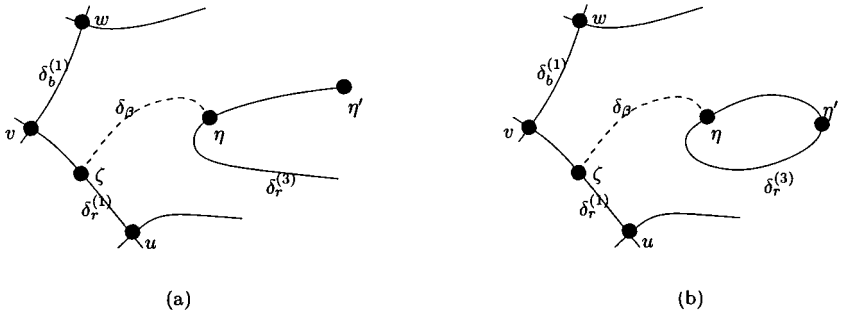

FIG. 7. *Charging v when a shallow arc lands on an edge of W_0 that does not meet other such edges.*

Trace $\delta_r^{(3)}$ back (in the negative x-direction) from η' (there may be two choices for r and for $\delta_r^{(3)}$ given a specific η', since η' may be a 3-colored vertex) until the first time we reach a point whose combined level (including the blue level) is at most $5k$. This backward tracing has to succeed: it will reach η or stop earlier. Then any charging vertex v must be a vertex incident to $\tilde{f}_r$, $\tilde{f}_g$, $\tilde{f}_y$, and to some $\tilde{f}_{b_1}$, from the at most $5k$ blue surfaces b_1 that lie below the stopping point. In other words, η' can be charged at most $O(k)$ times, implying that the number of vertices v that fall into this subcase is

$$O(k^3 n \lambda_5(n)). \tag{1}$$

A symmetric analysis applies if a shallow red arc lands on a blue edge of ∂W_0 which is a full component of $\tau_{b,g,y}$. Moreover, the analysis just given also holds if $\delta_r^{(3)}$ meets $\tilde{f}_b$ in only one of the two directions from η and extends to infinity in the other direction. It also holds if, in at least one of the two directions, we meet a terminal event before meeting $\tilde{f}_b$. And it also holds in the symmetric extended cases, in which the roles of the red and blue colors are interchanged.

The above analysis implies, in particular, that in what follows we may assume that none of the first $2k$ shallow arcs that emanate from $\delta_r^{(1)}$ and $\delta_b^{(1)}$ terminate on a bounded component of ∂W_0 that does not meet other components of ∂W_0. Note also that the analysis holds if $\delta_r^{(3)}$ is a bounded component of $\tau_{r,g,y}$ that lies fully to the right of v. Indeed, even if such a component does meet $\tilde{f}_b$, it must meet it at two points, both different from u, w and lying to the right of v, which is impossible.

Suppose now that one of the collected blue shallow arcs δ_β terminates on $\delta_r^{(2)}$, as in Figure 8. Each of the $\geq 2k$ red shallow arcs that we have collected along $\delta_b^{(1)}$ must cross δ_β. Indeed, none of these arcs terminate on $\delta_b^{(1)}$, by construction; they cannot terminate on $\delta_r^{(1)}$ or on $\delta_r^{(2)}$, for that would have made them terminal; and, as argued above, they also do not terminate on an isolated bounded component of ∂W_0. This, however, contradicts the shallowness of δ_β, since it cannot contain more than k crossings with other arcs. We have thus showed that none of the collected blue shallow arcs terminate on $\delta_r^{(2)}$. Symmetrically, it can be shown that none of the collected red shallow arcs terminate on $\delta_b^{(2)}$.

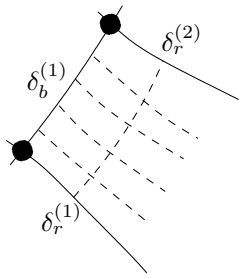

FIG. 8. *A shallow blue arc cannot "intercept," by terminating on $\delta_r^{(2)}$, the shallow red arcs emanating from $\delta_b^{(1)}$.*

The bounds accumulated so far account for all the vertices v with index at most 2. Specifically, we have

$$V_0^{(2)}(n) = O\left(k^3 n \lambda_5(n) + k^2 V_0\left(\frac{n}{5k}\right)\right),$$

thereby proving the lemma. □

3.2.3. Final counting stages and vertices of index 3.

LEMMA 3.5. *$V_0^{(3)}(n)$ is bounded by*

$$O\left(\left(k^2\ell^2+\ell^3\right)n\lambda_5(n)+V_0^{(2)}(n)+k^4V_0^{(2)}\left(\frac{n}{4k}\right)\right.$$

$$\left.+k^2V_0^{(3)}\left(\frac{n}{5k}\right)+\ell^4V_0^{(2)}\left(\frac{n}{5\ell}\right)+k^2\ell^2V_0^{(3)}\left(\frac{n}{6\ell}\right)\right).$$

Proof. From now on, we deal with vertices v of index 3. They are treated by considering a number of possible structures of the region W_0 as well as possible behavior patterns of arcs inside W_0 and bounding the maximal number of vertices v in each case. This will often be performed by charging v to certain features in W_0.

We already have sufficient machinery to dispose of vertices v for which $\delta_r^{(2)}$ and $\delta_b^{(2)}$ meet at a common endpoint, as in Figure 9. The preceding arguments allow us to assume that there are no shallow arcs that connect $\delta_r^{(1)}$ to $\delta_r^{(2)}$, or $\delta_b^{(1)}$ to $\delta_b^{(2)}$, and that there are no shallow arcs that land on any bounded component of W_0 within the quadrangle formed by $\delta_r^{(1)}$, $\delta_b^{(1)}$, $\delta_r^{(2)}$, and $\delta_b^{(2)}$. This means that, in this case, unless u and w have level $O(k)$, we can either collect a terminal arc or at least $2k$ deep arcs when sliding from v as above. In other words, we can charge v (almost uniquely) either to $\Theta(k^2)$ low-level vertices (at level $O(k)$) within W_0 or to a low-level terminal event within W_0 or to some other vertex of W_0 (that is, to u or to w) which lies at level at most $4k$ and has a smaller index. Arguing as above, the number of vertices v that fall into this case is

$$O\left(k^3n\lambda_5(n)+k^2V_0\left(\frac{n}{5k}\right)+k^4V_0^{(2)}\left(\frac{n}{4k}\right)\right).$$

We may thus assume that $\delta_r^{(2)}$ and $\delta_b^{(2)}$ do not meet.

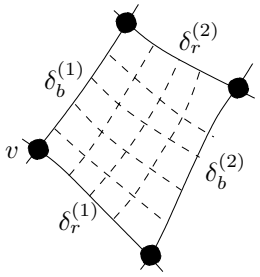

FIG. 9. *The case in which W_0 is a quadrangle.*

Suppose, without loss of generality, that the vertex u lies to the left of w. Then any shallow blue arc δ_β that emanates from $\delta_r^{(1)}$ must terminate at a point that lies to the right of v (regardless of whether it extends to the right or to the left); see Figure 10. This is due to the fact that these arcs are x-monotone. Let η be the terminal point of δ_β, and let $\delta_r^{(3)} \neq \delta_r^{(1)}, \delta_r^{(2)}$ denote the red edge of ∂W_0 that contains η. (The preceding analysis implies that we may assume that all shallow blue arcs that we have collected do land on a new red edge of ∂W_0.) Trace $\delta_r^{(3)}$ from η in the

increasing x-direction. (Note the two different situations that can arise, where we can turn from δ_β to the traced portion of $\delta_r^{(3)}$ either to the left or to the right.[1]) By the analysis just given, we may assume that this portion of $\delta_r^{(3)}$ terminates at a vertex t of W_0, incident to $\tilde{f}_r$, $\tilde{f}_b$, $\tilde{f}_g$, $\tilde{f}_y$, which lies to the right of v and is different from u, w. That is, t is the "missing" third sibling vertex of v that lies to the right of v. Moreover, the portion of $\delta_r^{(3)}$ between η and t contains no terminal event.

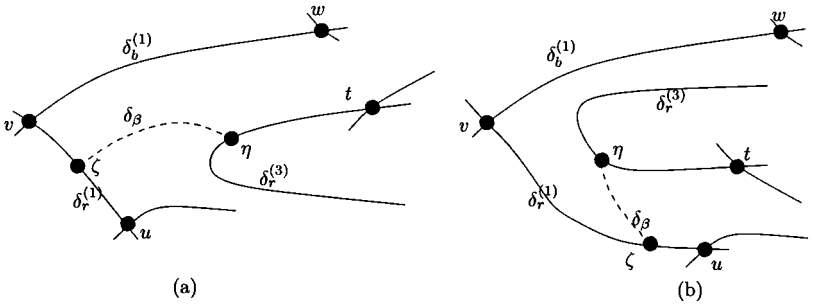

FIG. 10. *If u lies to the left of w, a shallow arc emanating from $\delta_r^{(1)}$ must terminate to the right of v. In* (a)*, we make a left turn from δ_β to $\delta_r^{(3)}$ at η, and in* (b)*, we make a right turn. In both cases, $\delta_r^{(3)}$ has to contain a vertex t of W_0 in the direction of our tracing.*

Suppose first that w lies to the left of t; see Figure 11. There must exist a red shallow arc δ_ρ that emanates from $\delta_b^{(1)}$ and does not cross δ_β (and it also cannot cross $\delta_r^{(1)}$, $\delta_r^{(2)}$, or $\delta_r^{(3)}$). Since δ_ρ is x-monotone, it must terminate at a point η' to the right of v, regardless of whether it extends to the right or to the left: the concatenation of $\delta_r^{(1)}$, δ_β, and $\delta_r^{(3)}$ up to t does not allow δ_ρ to reach points left of v because t lies to the right of w; see Figure 11. The point η' lies on some blue edge $\delta_b^{(3)} \neq \delta_b^{(1)}, \delta_b^{(2)}$. Tracing $\delta_b^{(3)}$ from η' in the positive x-direction, we may assume that it terminates at a vertex of W_0 (the case of a terminal event can be charged as above), which is necessarily t itself. Moreover, the portion of $\delta_b^{(3)}$ between η' and t contains no terminal event. We now note that the red and blue levels of t are both at most k since the red level of η and the blue level of η' are at most k and since there are no terminal events on $\delta_r^{(3)}$ between η and t and on $\delta_b^{(3)}$ between η' and t. Thus the combined level of t is $O(k)$. Since t is of index at most 1 (it lies to the right of w) and is uniquely charged by v, the number of vertices v in this subcase is $O(k^2 n \lambda_5(n))$.

Suppose then that w lies to the right of t. If any shallow red arc that emanates from $\delta_b^{(1)}$ and does not cross δ_β terminates to the right of v, we proceed as in the case, just treated, where t lies to the right of w. The only way in which this does not occur is when all these shallow red arcs emanate from $\delta_b^{(1)}$ in the negative x-direction, starting to the right of t and "bypassing" the concatenation of $\delta_r^{(1)}$, δ_β, and $\delta_r^{(3)}$ up to t. See Figure 12.

To handle this case, choose another threshold parameter $\ell \gg k$, to be determined later. If t lies at level at most $5k + 4\ell$, we charge v to t. We note, as above, that the

[1]Recall that, in the analysis of W_0, we refer to the view of this region from above (in the vertical direction of $\mathbb{R}^4$).

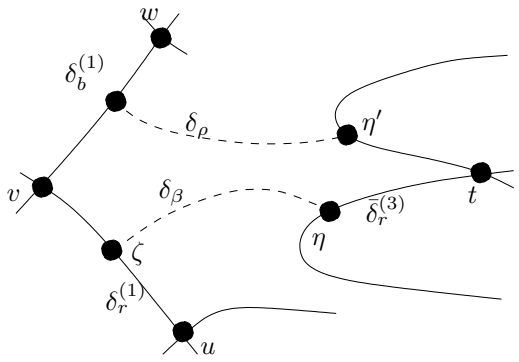

FIG. 11. *The case in which w lies to the left of t.*

charging is unique and use the fact that the index of t is at most 2 to conclude that the number of vertices v in this subcase is at most $V^{(2)}_{\leq 5k+4\ell}(n)$. Our choice of ℓ will ensure that $5k+4\ell \leq 5\ell$, so, using [7], the number of vertices v under consideration is

$$O\left(\ell^4 V_0^{(2)}\left(\frac{n}{5\ell}\right)\right).$$

Assume then that the level of t is $> 5k+4\ell$. Then the portion $\bar{\delta}_r^{(3)}$ of $\delta_r^{(3)}$ between η and t must contain at least 4ℓ (4-colored) vertices. We now apply a collection process for blue arcs that emanate from $\bar{\delta}_r^{(3)}$. The process is very similar to that applied to $\delta_r^{(1)}$ (and to $\delta_b^{(1)}$), except that we redefine the notions of being deep, terminal, or shallow in terms of the parameter ℓ rather than k. To distinguish between the old and new notions, we say that an arc is *ℓ-deep* (resp., *ℓ-shallow*) if it contains at least ℓ (resp., fewer than ℓ) vertices (and so that none of the first ℓ vertices is terminal). If one of the first ℓ vertices lying on an arc is terminal, the arc is said to be ℓ-terminal. The old notions are from now on designated, in complete analogy, as k-deep, k-shallow, and k-terminal.

The collection process on $\bar{\delta}_r^{(3)}$ is therefore as follows. Starting from η, we proceed along $\bar{\delta}_r^{(3)}$, taking shortcuts along ℓ-shallow arcs that land back on $\bar{\delta}_r^{(3)}$, and collect either 2ℓ ℓ-deep blue arcs or an ℓ-terminal blue arc or 2ℓ ℓ-shallow blue arcs that do not terminate on $\bar{\delta}_r^{(3)}$. The starting point of any collected arc is at blue level at most $4k+4\ell \leq 5\ell$ and at red level at most k.

A significant technical difference between the two collection processes is that, in the new process, we do not have the unique charging property that was utilized in the preceding analysis. Nevertheless, we do have a weaker property that we detail next.

Suppose that we have collected 2ℓ ℓ-deep blue arcs, as just described. See Figure 12. We thus obtain $\Theta(\ell^2)$ vertices along these arcs, all contained in W_0 and lying at combined level $4k+5\ell \leq 6\ell$. We claim that each such vertex q is collected in this fashion by at most $O(k^2)$ vertices v.

Consider such a vertex q, and attempt to trace back from q to determine the charging vertex v as follows. Proceed from q along the ℓ-deep blue arc $\delta_{\beta'}$ that contains q, until the first time we reach a vertex q' at red level $\leq k$. (This will happen either when we reach $\bar{\delta}_r^{(3)}$ or earlier.) The red surface incident to any charging vertex v must be one of the $\leq k$ red graphs that lie below q'. (Clearly, $\tilde{f}_r$ is one of these graphs.) Pick any of these graphs, $\tilde{f}_{r'}$, and continue to trace $\delta_{\beta'}$ backward until the

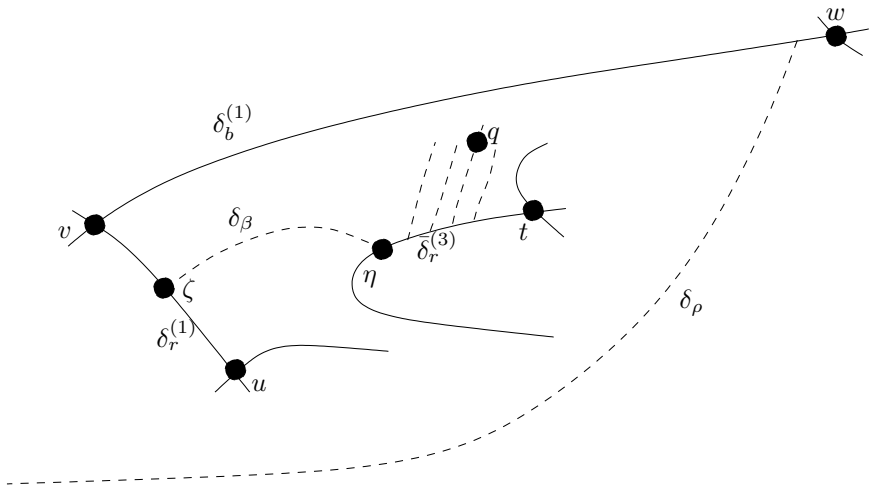

FIG. 12. *The case in which w lies to the right of t and at a high level. The figure depicts the subcase in which there are many deep blue arcs emanating from $\bar{\delta}_r^{(3)}$.*

first time it actually intersects $\tilde{f}_{r'}$. If the stopping point is at red level $> k$, then r' is a wrong guess. We thus keep picking candidate graphs in this fashion until, for one of them, $\tilde{f}_{r''}$, the backward tracing of $\delta_{\beta'}$ reaches $\tilde{f}_{r''}$ at red level $\leq k$. Once this situation is attained, we trace the red curve $\gamma_{r''}$ that we have hit, in the negative x-direction, until the first time we reach a point ν whose blue level is at most $4k$. (As above, if no such point exists, then r'' is a wrong guess, and we keep trying with different candidates $\tilde{f}_{r'''}$.) The blue arc incident to a charging vertex v that is incident to $\tilde{f}_{r''}$ must then correspond to one of the $\leq 4k$ blue graphs lying below ν. ($\tilde{f}_b$ is clearly one of them when $r'' = r$.) Now note that knowing which red and blue arcs are incident to v determines v uniquely. We have thus shown that there are only $O(k^2)$ possible vertices v that can charge q. Hence, using [7], the number of vertices v in this subcase is

$$O(k^2) \cdot O\left(\frac{1}{\ell^2} V_{\leq 6\ell}(n)\right) = O\left(k^2 \ell^2 V_0\left(\frac{n}{6\ell}\right)\right).$$

Similarly, if we collect an ℓ-terminal blue arc, the terminal event along it is charged by at most $O(k^2)$ vertices v, and there are $O(\ell^2 n \lambda_5(n))$ such events. The number of vertices v in this subcase is thus $O(k^2 \ell^2 n \lambda_5(n))$.

We are left to treat the case in which we have collected 2ℓ ℓ-shallow blue arcs. Note that their starting points on $\bar{\delta}_r^{(3)}$ are at combined level at most $5k + 4\ell \leq 5\ell$. Trace any such arc $\delta_{\beta'}$ to its end-point η', which lies on some red edge of ∂W_0, and at combined level $\leq 6\ell$. Several cases can arise, as depicted in Figure 13.

(a) $\eta' \in \delta_r^{(1)}$, and we make a *right* turn from δ_β to $\delta_r^{(3)}$ at η: See Figure 13(a). In this case, we trace $\delta_r^{(3)}$ from η to the left (in the negative x-direction). Since η lies to the left of w, it is easily seen that this tracing of $\delta_r^{(3)}$ must reach a local x-minimum that lies to the right of v. Such cases, however, were ruled out above, where the number of vertices v for which a terminal event on $\delta_r^{(3)}$ can be reached in this fashion was bounded by $O(k^3 n \lambda_5(n))$ in (1).

(a') $\eta' \in \delta_r^{(1)}$, and we make a *left* turn from δ_β to $\delta_r^{(3)}$ at η: See Figure 13(a'). This

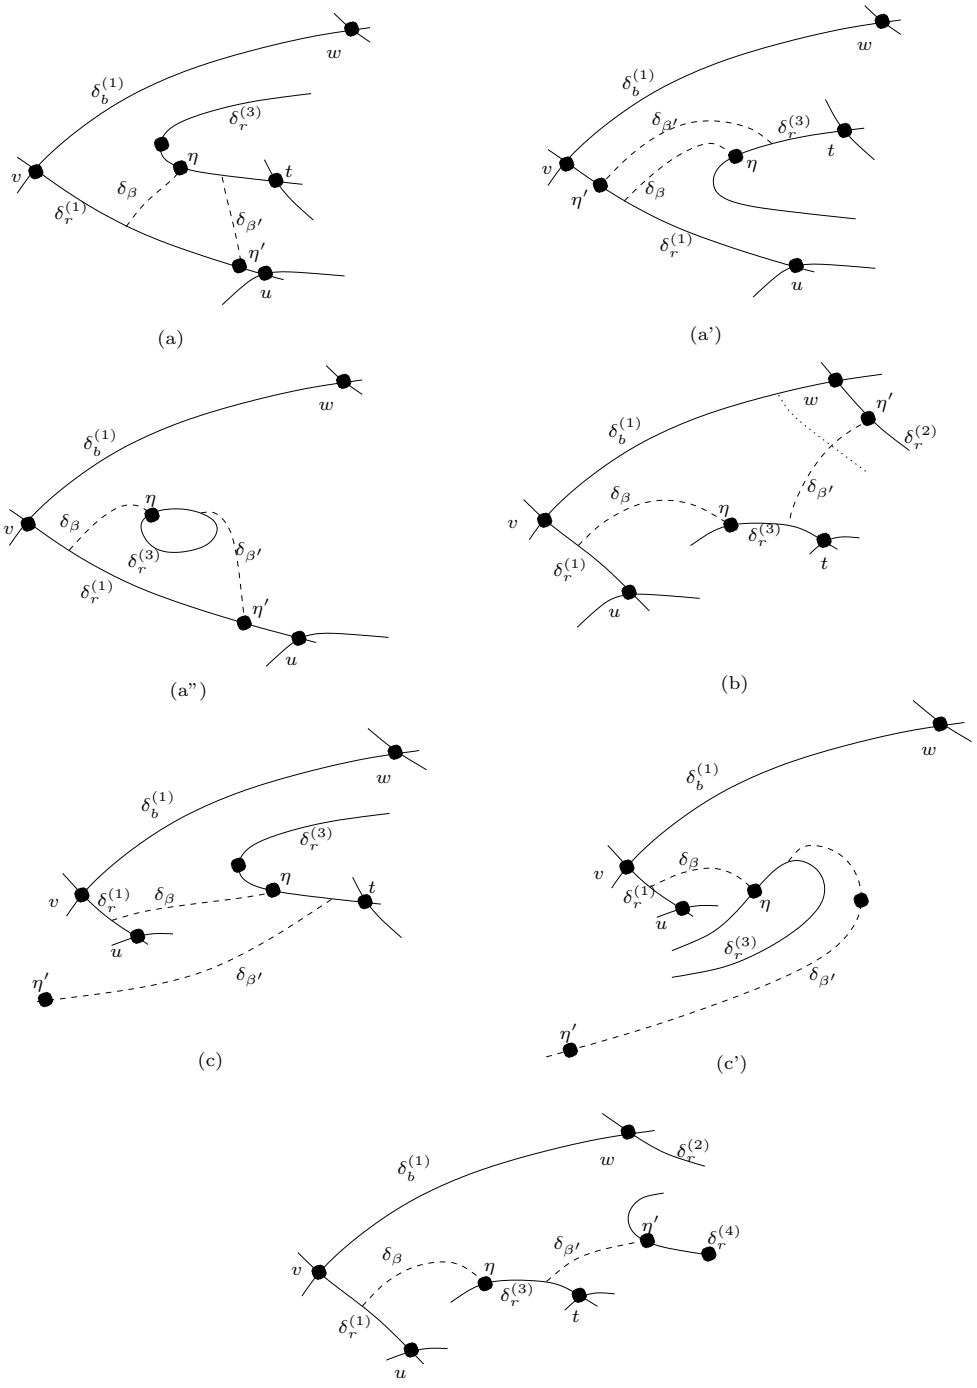

FIG. 13. *Various cases of ℓ-shallow blue arcs that emanate from $\bar{\delta}_r^{(3)}$.*

case can arise only when $\delta_{\beta'}$ lands back on $\delta_r^{(1)}$, between v and δ_β, as in Figure 13(a'). (Otherwise, the component of $\tau_{r,g,y}$ that contains $\delta_r^{(3)}$ would have been forced to be bounded: It has to be contained in the region bounded by δ_β, $\delta_{\beta'}$, $\delta_r^{(3)}$, and $\delta_r^{(1)}$; see Figure 13(a"). This possibility, however, has already been ruled out, as in case (a) above.) Observe that there are overall at most $4k$ arcs $\delta_{\beta'}$ that land back on $\delta_r^{(1)}$ in this fashion. Therefore, at least $2\ell - 4k$ of the ℓ-shallow arcs emanating from $\bar{\delta}_r^{(3)}$ do not belong to case (a').

(b) $\eta' \in \delta_r^{(2)}$: See Figure 13(b). This case can arise only when we make a left turn from δ_β to $\delta_r^{(3)}$ at η, or else $\delta_r^{(3)}$ would have to be a bounded component, as in case (a'). (The configuration would have looked like a "mirror image" of the one depicted in Figure 13(a").) Any red k-shallow arc that emanates from $\delta_b^{(1)}$ must then cross either δ_β or $\delta_{\beta'}$. At most k of these red arcs can cross δ_β, so at least k of them cross each ℓ-shallow arc $\delta_{\beta'}$ that falls into case (b). Since any of these k-shallow red arcs can cross only k blue arcs, it follows that at most k of the ℓ-shallow arcs emanating from $\bar{\delta}_r^{(3)}$ belong to case (b). Since only at most $4k$ arcs fall into case (a'), we conclude that one of the cases (a), (c), or (d) must arise for at least $2\ell - 5k > \ell$ arcs $\delta_{\beta'}$.

(c) η' lies to the left of v. This case cannot arise when we make a right turn from δ_β to $\delta_r^{(3)}$ at η (see Figure 13(c)), for then we could reach, in the opposite direction, a local x-extremum on $\delta_r^{(3)}$, as in case (a). However, if we make a left turn at η, as shown in Figure 13(c'), then $\delta_{\beta'}$ must leave $\delta_r^{(3)}$ in the positive x-direction, or else it would have been "trapped" between $\delta_b^{(1)}$ on one side and $\delta_r^{(1)}$, δ_β, and $\delta_r^{(3)}$ on the other side, which would make it impossible for $\delta_{\beta'}$ to reach to the left of v. Hence $\delta_{\beta'}$ must have a locally x-maximal point before it reaches η'; since this is a terminal event, this contradicts the shallowness of $\delta_{\beta'}$.

(d) η' lies to the right of v on a new edge $\delta_r^{(4)}$ of ∂W_0, different from $\delta_r^{(i)}$, for $i = 1, 2, 3$: See Figure 13(d). In this case, we trace $\delta_r^{(4)}$ from η' in the positive x-direction, and we will not reach any vertex of W_0. (We have already exhausted all such vertices to the right of v.) The tracing will thus reach a terminal event. Since η' lies at combined level at most $5k + 5\ell \leq 6\ell$, this also bounds the 3-colored level of the terminal event. Hence, arguing as above, the number of such events is $O(\ell^2 n \lambda_5(n))$, and each of them is charged by only $O(\ell)$ vertices v. To see the latter claim, we spell out, for the sake of completeness, a modified version of a previous argument.

Trace $\delta_r^{(4)}$ back (in either direction, if more than one direction is applicable, as there may be two choices for r and for $\delta_r^{(4)}$) from the terminal event until the first time we reach a point whose combined level (including the blue level) is at most 6ℓ. (This will be either at η' or earlier.) Then any charging vertex v is a vertex incident to $\tilde{f}_r$, $\tilde{f}_g$, $\tilde{f}_y$, and to some $\tilde{f}_b$ from the at most 6ℓ blue surfaces that lie below the stopping point. In other words, the terminal event can be charged by at most $O(\ell)$ vertices v, implying that the number of vertices v that fall into this final subcase is $O(\ell^3 n \lambda_5(n))$.

This completes the consideration of all possible situations that arise with vertices v of index at most 3. Collecting all of the bounds obtained during the analysis of such vertices leads to the following equation:

$$V_0^{(3)}(n) = O\left(\left(k^2\ell^2 + \ell^3\right) n\lambda_5(n) V_0^{(2)}(n) + k^4 V_0^{(2)}\left(\frac{n}{4k}\right) \right.$$
$$\left. + k^2 V_0^{(3)}\left(\frac{n}{5k}\right) + \ell^4 V_0^{(2)}\left(\frac{n}{5\ell}\right) + k^2\ell^2 V_0^{(3)}\left(\frac{n}{6\ell}\right)\right),$$

which proves the lemma. □

3.3. Putting it all together. Recall that in section 3.2 we handled only regular vertices v. To complete the counting, we have to add the number of irregular vertices to each of the above bounds on the quantities $V_0^{(j)}(n)$. Since there are only $O(n\lambda_5(n))$ irregular vertices, this does not affect any of these asymptotic estimates. Thus, collecting the bounds obtained in Lemmas 3.3–3.5, we obtain the following recurrence relations:

$$V_0^{(0)}(n) = O(n\lambda_5(n)),$$

$$V_0^{(1)}(n) = O(n\lambda_5(n)),$$

$$V_0^{(2)}(n) = O\left(k^3 n\lambda_5(n) + k^2 V_0^{(3)}\left(\frac{n}{5k}\right)\right),$$

$$V_0^{(3)}(n) = O\left(\left(k^2\ell^2 + \ell^3\right) n\lambda_5(n) + V_0^{(2)}(n) + k^4 V_0^{(2)}\left(\frac{n}{4k}\right)\right.$$

$$\left. + k^2 V_0^{(3)}\left(\frac{n}{5k}\right) + \ell^4 V_0^{(2)}\left(\frac{n}{5\ell}\right) + k^2\ell^2 V_0^{(3)}\left(\frac{n}{6\ell}\right)\right).$$

We choose different values of k in the recurrences for $V_0^{(2)}$ and for $V_0^{(3)}$ and denote them by k_2 and k_3, respectively. These values, together with ℓ, are chosen to be sufficiently large constants satisfying $\ell = k_3^{1/(c\varepsilon)}$ and $k_2 = \ell^{1/(c\varepsilon)}$ for an arbitrarily small but prescribed positive constant ε and for some fixed small positive fraction c. (Note that this choice of parameters satisfies $\ell \gg k_3$, which was needed in our analysis.) We also require that k_3^{ε} be sufficiently large. The recurrence for $V_0^{(3)}$ then becomes

$$\begin{aligned}
V_0^{(3)}(n) &= O\left(\left(k_2^{c\varepsilon(2+2c\varepsilon)} + k_2^{3c\varepsilon}\right) n\lambda_5(n) + V_0^{(2)}(n) + k_2^{4c^2\varepsilon^2} V_0^{(2)}\left(\frac{n}{4k_2^{c^2\varepsilon^2}}\right)\right.\\
&\qquad \left. + k_2^{2c^2\varepsilon^2} V_0^{(3)}\left(\frac{n}{5k_2^{c^2\varepsilon^2}}\right) + k_2^{4c\varepsilon} V_0^{(2)}\left(\frac{n}{5k_2^{c\varepsilon}}\right) + k_2^{2c\varepsilon+2c^2\varepsilon^2} V_0^{(3)}\left(\frac{n}{6k_2^{c\varepsilon}}\right)\right)\\
&= O\left(k_2^{3+2c\varepsilon} n\lambda_5(n) + k_2^2 V_0^{(3)}\left(\frac{n}{5k_2}\right) + k_2^{2+4c^2\varepsilon^2} V_0^{(3)}\left(\frac{n}{20k_2^{1+c^2\varepsilon^2}}\right)\right.\\
&\qquad + k_2^{2c^2\varepsilon^2} V_0^{(3)}\left(\frac{n}{5k_2^{c^2\varepsilon^2}}\right) + k_2^{2+4c\varepsilon} V_0^{(3)}\left(\frac{n}{25k_2^{1+c\varepsilon}}\right)\\
&\qquad \left. + k_2^{2c\varepsilon(1+c\varepsilon)} V_0^{(3)}\left(\frac{n}{6k_2^{c\varepsilon}}\right)\right).
\end{aligned}$$

As in other works where similar recurrences have been derived (see, e.g., [23]), it is easy to show, using induction on n, that, with an appropriate choice of c and k_2 (where the choice of k_2 depends on ε but the choice of c does not), the solution of this recurrence is

$$V_0(n) = V_0^{(3)}(n) = O(n^{2+\varepsilon})$$

for any ε, where the constant of proportionality depends on ε. We have thus shown the following.

THEOREM 3.6. *The complexity of the Euclidean Voronoi diagram of a set of n lines in $\mathbb{R}^3$ with four distinct orientations is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$.*

Remark 1. Inspecting the proof of Theorem 3.6, we see that it is fairly general and does not explicitly use the fact that the sites are lines. It can thus be extended to the case of the Voronoi diagram of any reasonable collection of sites (of constant description complexity), which is the union of four subfamilies, under any reasonable metric in $\mathbb{R}^3$, provided that (i) we have a near-quadratic bound for the complexity of the diagram of any three of the given families and (ii) any four sites determine at most eight Voronoi vertices. We strongly suspect that the requirement (ii) can be dropped. This would require us to handle vertices v that have index $x \geq 4$, which in turn would have made the preceding analysis more complicated, mainly by having to use additional thresholds for shallowness (like the k and ℓ that we used). Still, it seems plausible that the analysis could go through.

4. More than four orientations. The case of an arbitrary number c of orientations is easy to handle by noting that any vertex v of the full Voronoi diagram $Vor(L)$ is also a vertex of the diagram of the set of all lines whose orientations are equal to the (at most) four orientations of the lines that are (equally) nearest to v. Let $u_1, \ldots, u_c$ denote the given orientations. Let L_j, for $j = 1, \ldots, c$, denote the set of lines in L at orientation u_j, and put $n_j = |L_j|$. Then $\sum_{j=1}^{c} n_j = n$. Suppose, without loss of generality, that $n_1 \leq n_2 \leq \cdots \leq n_c$. The number of vertices of $Vor(L)$ is at most $\sum_{i<j<k<l} V_{ijkl}$, where V_{ijkl} is the number of vertices of $Vor(L_i \cup L_j \cup L_k \cup L_l)$. By Theorem 3.6, $V_{ijkl} = O((n_i + n_j + n_k + n_l)^{2+\varepsilon}) = O(n_l^{2+\varepsilon})$. Hence the complexity of $Vor(L)$ is at most $O(\sum_{i<j<k<l} n_l^{2+\varepsilon}) = O(\sum_{l=4}^{c} l^3 n_l^{2+\varepsilon})$. As is easily verified, the maximum value of this latter sum is $O(c^3 n^{2+\varepsilon})$. We thus obtain the following theorem, the main result of the paper.

THEOREM 4.1. *The combinatorial complexity of the Euclidean Voronoi diagram of n lines in three dimensions, where the lines have $1 \leq c \leq n$ distinct orientations, is $O(c^3 n^{2+\varepsilon})$ for any $\varepsilon > 0$.*

COROLLARY 4.2. *The combinatorial complexity of the Euclidean Voronoi diagram of n lines in $\mathbb{R}^3$ that have a constant number of distinct orientations is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$.*

Remark 2. As shown in [22], the complexity of the diagram in the general case, without any restrictions on the orientations of the lines (that is, when $c = n$), is $O(n^{3+\varepsilon})$. This leads us to conjecture that the bound in Theorem 4.1 can be improved to at least $O(cn^{2+\varepsilon})$ for any $\varepsilon > 0$. The latter bound is consistent with the result of [22] (when $c = O(n)$) and with Corollary 4.2 (when $c = O(1)$) and might be easier to obtain than a near-quadratic bound like $O(n^{2+\varepsilon})$ for any $1 \leq c \leq n$. (Nevertheless, in line with the general conjecture concerning 3-dimensional Voronoi diagrams, we conjecture that the latter bound does indeed hold independently of c.)

Appendix. In this appendix, we provide a study of the geometric structure of *bisectors* and *trisectors*, which are, respectively, the loci of points equidistant from two and three lines. This analysis is useful in its own right, but most of the details are not needed for the main result of this paper.

We begin with the analysis of bisectors, which have also been studied, e.g., in [9]. Consider the bisector H_{ℓ_1,ℓ_2} between two lines ℓ_1, ℓ_2 at different orientations. Without loss of generality, by translating, rotating, and scaling 3-space, we may as-

sume that ℓ_1 and ℓ_2 are both horizontal, and ℓ_1 (resp., ℓ_2) passes through $(0,0,1)$ (resp., $(0,0,-1)$) and forms a horizontal angle of α (resp., $-\alpha$) with the positive x-direction for $\alpha \in (-\pi/2, \pi/2]$.

The squared distance of a point (x,y,z) from ℓ_1 is

$$d^2((x,y,z),\ell_1) = x^2 + y^2 + (z-1)^2 - (x\cos\alpha + y\sin\alpha)^2,$$

and the squared distance of (x,y,z) from ℓ_2 is

$$d^2((x,y,z),\ell_2) = x^2 + y^2 + (z+1)^2 - (x\cos\alpha - y\sin\alpha)^2.$$

Hence the equation of H_{ℓ_1,ℓ_2} is

$$x^2 + y^2 + (z-1)^2 - (x\cos\alpha + y\sin\alpha)^2 = x^2 + y^2 + (z+1)^2 - (x\cos\alpha - y\sin\alpha)^2,$$

or

$$z = -xy\sin\alpha\cos\alpha.$$

This is the equation of a hyperbolic paraboloid. It has two sets of generating lines, one set consisting of lines parallel to the xz-plane and the other consisting of lines parallel to the yz-plane. Specifically, lines in the first family have the following form, parametrized over $t \in \mathbb{R}$:

$$\lambda_t : \qquad y = -\frac{t}{\sin\alpha\cos\alpha}, \qquad z = tx.$$

Similarly, lines in the second family have the form, parametrized over $s \in \mathbb{R}$,

$$\bar{\lambda}_s : \qquad x = -\frac{s}{\sin\alpha\cos\alpha}, \qquad z = sy.$$

We can project H_{ℓ_1,ℓ_2} onto the xy-plane π_0 bijectively and note that the generating lines project to lines parallel to the axes.

Fix a line λ_t of the first family, having parameter t. Let ℓ_3 be a differently oriented line passing through some point $\mathbf{a} = (a_1, a_2, a_3)$ and having direction $\mathbf{u} = (u_1, u_2, u_3)$, which is a unit vector along ℓ_3 and is common to all input lines of a fixed color. By our general position assumption, we may assume that $u_3 \neq 0$, i.e., that the direction $\mathbf{u}$ is not coplanar with the directions of l_1 and l_2. Without loss of generality, we assume that $\mathbf{a}\cdot\mathbf{u} = 0$. The distance between a point $\mathbf{w} = \mathbf{w}(x)$ on λ_t, parametrized as $(x, -t/(\sin\alpha\cos\alpha), tx)$, and ℓ_3 is

$$d^2(\mathbf{w},\ell_3) = \|\mathbf{w}-\mathbf{a}\|^2 - ((\mathbf{w}-\mathbf{a})\cdot\mathbf{u})^2 = \|\mathbf{w}-\mathbf{a}\|^2 - (\mathbf{w}\cdot\mathbf{u})^2$$

$$= (x-a_1)^2 + \left(\frac{t}{\sin\alpha\cos\alpha} + a_2\right)^2 + (tx-a_3)^2 - \left(xu_1 - \frac{tu_2}{\sin\alpha\cos\alpha} + txu_3\right)^2.$$

Consider the function

$$F(x) = d^2(\mathbf{w}(x),\ell_3) - d^2(\mathbf{w}(x),\ell_1)$$

$$= (x-a_1)^2 + \left(\frac{t}{\sin\alpha\cos\alpha} + a_2\right)^2 + (tx-a_3)^2 - \left(xu_1 - \frac{tu_2}{\sin\alpha\cos\alpha} + txu_3\right)^2$$

$$- x^2 - \frac{t^2}{\sin^2\alpha\cos^2\alpha} - (tx-1)^2 + \left(x\cos\alpha - \frac{t}{\cos\alpha}\right)^2.$$

Note that $F(x)$ is positive (resp., zero, negative) if the ball centered at $\mathbf{w}(x)$ and touching ℓ_1 and ℓ_2 is disjoint from (resp., touches, intersects) ℓ_3. Hence the locus of the roots of $F(x)$, as we trace them by varying t from $-\infty$ to $+\infty$, is the *trisector* $\tau_{\ell_1,\ell_2,\ell_3}$—the locus of all centers of balls that touch ℓ_1, ℓ_2, ℓ_3 simultaneously.

The function $F(x)$ is quadratic (for any fixed t), and its global behavior along λ_t depends largely on the sign of the coefficient of x^2, which is

$$A(t) = 1 + t^2 - (u_1 + tu_3)^2 - 1 - t^2 + \cos^2\alpha = \cos^2\alpha - (u_1 + tu_3)^2.$$

Hence, if $A(t) > 0$, then $F(x)$ is convex and is positive at $x = \pm\infty$, meaning that at the extremities of λ_t the ball touching ℓ_1, ℓ_2 is disjoint from ℓ_3 (we are in the *free region* associated with ℓ_3), whereas if $A(t) < 0$, then $F(x)$ is concave, and at the extremities of λ_t we are in the *intersection region* of ℓ_3.

In other words, assuming, as above, that $u_3 \neq 0$, and, for specificity, that $u_3 > 0$, we have that $A(t) < 0$ if and only if $|u_1 + tu_3| > \cos\alpha$ or

$$t > \frac{-u_1 + \cos\alpha}{u_3} \quad \text{or} \quad t < \frac{-u_1 - \cos\alpha}{u_3}.$$

The corresponding critical y-values are

$$y_T = \frac{u_1 + \cos\alpha}{u_3 \sin\alpha\cos\alpha} \quad \text{and} \quad y_B = \frac{u_1 - \cos\alpha}{u_3 \sin\alpha\cos\alpha},$$

and we denote the corresponding horizontal *critical lines* by $\lambda^{(T)}$ and $\lambda^{(B)}$, respectively. (Note that the critical lines depend *only* on the orientation $\mathbf{u}$ of l_3.)

We next apply a symmetric analysis to lines in the other family. We obtain that the critical x-values where the corresponding quadratic function changes from being convex to being concave are

$$x_R = \frac{u_2 + \sin\alpha}{u_3 \sin\alpha\cos\alpha} \quad \text{and} \quad x_L = \frac{u_2 - \sin\alpha}{u_3 \sin\alpha\cos\alpha};$$

the corresponding vertical critical lines are denoted by $\bar{\lambda}^{(R)}$ and $\bar{\lambda}^{(L)}$.

We next claim that, for $|t|$ sufficiently large, the line λ_t intersects the trisector in exactly two points. For this, we need to show that the discriminant of the quadratic equation $F(x)$ becomes positive as $|t|$ tends to ∞.

Write $F(x)$ as $A(t)x^2 + 2B(t)x + C(t)$, where

$$\begin{aligned} A(t) &= \cos^2\alpha - (u_1 + tu_3)^2, \\ B(t) &= -a_1 - a_3 t + \tfrac{u_2 t(u_1 + tu_3)}{\sin\alpha\cos\alpha}, \\ C(t) &= a_1^2 + \left(\tfrac{t}{\sin\alpha\cos\alpha} + a_2\right)^2 + a_3^2 - \tfrac{t^2 u_2^2}{\sin^2\alpha\cos^2\alpha} - \tfrac{t^2}{\sin^2\alpha\cos^2\alpha} - 1 + \tfrac{t^2}{\cos^2\alpha}. \end{aligned}$$

As $|t|$ tends to ∞, the sign of the discriminant $\Delta(t)$ depends only on the coefficients of t^2 in these three expressions. That is, the limit of Δ/t^4 is

$$\lim_{|t|\to\infty} \frac{B^2(t) - A(t)C(t)}{t^4} = \lim_{|t|\to\infty} \left[\left(\frac{B(t)}{t^2}\right)^2 - \frac{A(t)}{t^2} \cdot \frac{C(t)}{t^2} \right]$$

$$= \frac{u_2^2 u_3^2}{\sin^2\alpha\cos^2\alpha} + u_3^2 \cdot \left(\frac{1}{\cos^2\alpha} - \frac{u_2^2}{\sin^2\alpha\cos^2\alpha} \right) = \frac{u_3^2}{\cos^2\alpha} > 0.$$

That is, for large values of $|t|$, the trisector $\tau_{\ell_1,\ell_2,\ell_3}$ meets λ_t at two points $w_1(t)$, $w_2(t)$. The asymptotic values of these roots are

$$\lim_{|t|\to\infty} w_{1,2}(t) = \lim_{|t|\to\infty} \frac{-B(t) \pm \sqrt{\Delta(t)}}{A(t)} = \lim_{|t|\to\infty} \frac{-B(t)/t^2 \pm \sqrt{\Delta(t)/t^4}}{A(t)/t^2}$$

$$= \frac{-\frac{u_2 u_3}{\sin\alpha\cos\alpha} \pm \frac{u_3}{\cos\alpha}}{-u_3^2} = \frac{u_2 \pm \sin\alpha}{u_3 \sin\alpha\cos\alpha}.$$

That is, $w_1(t)$ and $w_2(t)$ tend to x_L and x_R, respectively.

Symmetrically, there always exist two intersection points of $\tau_{\ell_1,\ell_2,\ell_3}$ with the lines $\bar{\lambda}_s$, as $|s|$ tends to ∞, and their limits are at the ordinates y_B and y_T.

We have thus shown that any sufficiently large circle intersects the trisector at eight points. We denote the points "at infinity" that lie on the vertical critical lines $\bar{\lambda}^{(L)}$, $\bar{\lambda}^{(R)}$ as $v_{LB}, v_{LT}, v_{RB}, v_{RT}$, where v_{LB} (resp., v_{LT}) is the bottom (resp., top) end of $\bar{\lambda}^{(L)}$, and similarly for the other two points. The points at infinity on the horizontal lines are denoted, in a similar manner, as $h_{LB}, h_{LT}, h_{RB}, h_{RT}$. See Figure 14(a) for an illustration.

Assuming that the trisector is nonsingular, it has exactly four unbounded components, each connecting two of these points at infinity. We next proceed to classify the structure of these components.

The function $F(x)$ becomes linear along each of the horizontal critical lines $\lambda^{(T)}$, $\lambda^{(B)}$, and thus each of these two critical lines is intersected by the trisector exactly once; symmetrically, this also holds for $\bar{\lambda}^{(L)}$, $\bar{\lambda}^{(R)}$. Number the eight points at infinity in a cyclic order. Then it is clear that each odd-numbered point must be connected to an even-numbered point, since the components of the trisector are disjoint. Hence, v_{LT} can be connected to h_{LT}, v_{LB}, h_{RB}, or to v_{RT}, and similarly for the other points at infinity.

Consider the second case, in which v_{LT} is connected to v_{LB} via one component γ_1 of the trisector. This component crosses the two critical horizontal lines $\lambda^{(B)}$, $\lambda^{(T)}$ (each exactly once). In this case, no other component of the trisector can intersect any of these lines, so each of the remaining three components is fully contained in one of the three horizontal slabs delimited by $\lambda^{(B)}$ and $\lambda^{(T)}$, and each of these slabs contains exactly one such component. It then follows that these components must connect h_{LT} to h_{LB}, v_{RT} to h_{RT}, and v_{RB} to h_{RB}. Moreover, γ_1 must cross $\bar{\lambda}^{(L)}$ (exactly once), and one of the two components on the right must cross $\bar{\lambda}^{(R)}$ (exactly once). Hence the trisector has a shape similar to that shown in Figure 14(b).

Consider next the third case, in which v_{LT} is connected to h_{RB} via one component γ_1 of the trisector. Another component, γ_2, must connect v_{RT} to h_{RT}. We have two subcases.

In the first subcase, h_{LT} is connected to v_{RB}, and h_{LB} is connected to v_{LB}. In this case, none of the components can cross any of its asymptotes. See Figure 14(a).

In the second subcase, h_{LT} is connected to h_{LB}, and v_{LB} is connected to v_{RB}. In this case, we must allow each of the lines $\lambda^{(B)}$, $\bar{\lambda}^{(L)}$ to be crossed (once) by some component. See Figure 14(c). This figure depicts one of several possible subcases, depending on which component crosses which critical line. In Figure 14(c) the component connecting v_{LT} to h_{RB} crosses all four critical lines, but it might also be possible for this component to cross only $\lambda^{(T)}$ and $\bar{\lambda}^{(R)}$ or to cross just one more critical line and let the left and/or bottom components cross the other one or two critical lines (in a manner similar to that of the top-right component in Figure 14(b)).

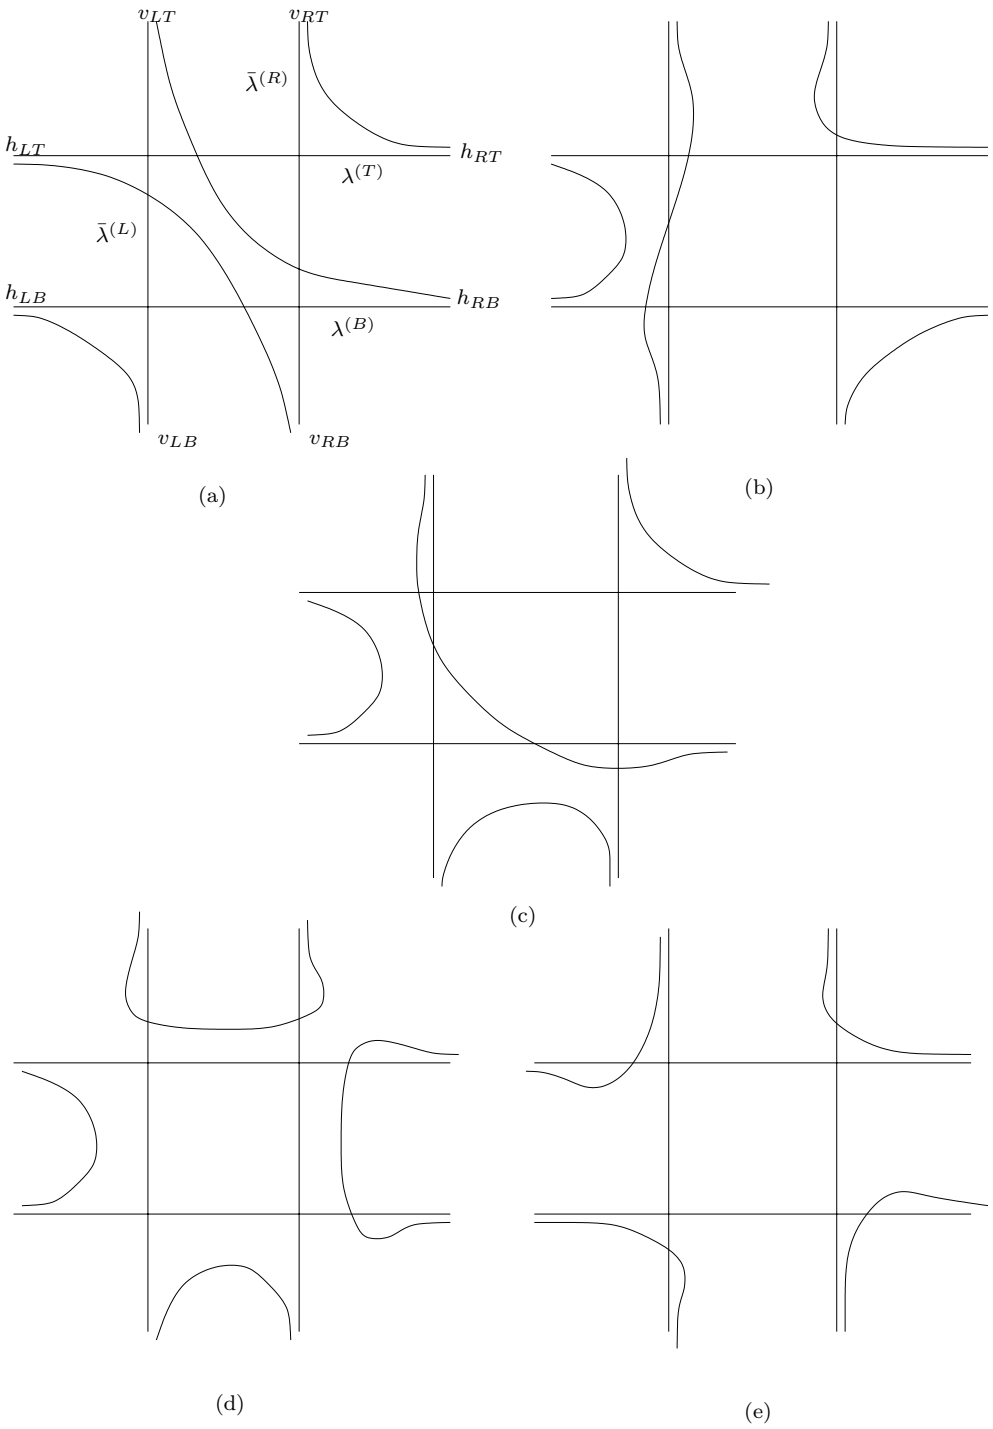

FIG. 14. *The various possible structures of a trisector.*

If none of the above cases occur, including their various symmetric variants, then each end of each critical line must be connected to one of its two neighbors in the above cyclic order. Only two cases are possible.

In the first subcase, h_{LT} is connected to h_{LB}, v_{LB} is connected to v_{RB}, h_{RT} is connected to h_{RB}, and v_{LT} is connected to v_{RT}. As above, we must let some of these components cross some of their asymptotes to ensure that each of the four critical lines is crossed once by the trisector. See Figure 14(d), which, as above, depicts just one of several possible subcases.

In the second subcase, h_{LT} is connected to v_{LT}, h_{LB} is connected to v_{LB}, h_{RT} is connected to v_{RT}, and h_{RB} is connected to v_{RB}. Again, we must let some of these components cross some of their asymptotes. One of several possible such configurations is shown in Figure 14(e).

We also note that each trisector is an algebraic curve of degree 4. By Harnack's theorem [13], the number of components of a real nonsingular algebraic plane curve of degree d is at most $(d-1)(d-2)/2+1$. Hence the number of components of each trisector is at most $3 \cdot 2/2 + 1 = 4$. Since it has exactly four unbounded components, we conclude that these are *all* the components of the trisector. In particular, no component of any trisector is bounded. This completes the classification of the trisectors.

Remark 3. We conjecture that, up to symmetry, only trisectors of the kind shown in Figure 14(b) are possible. A program that we have written to explore the structure of trisectors has revealed only trisectors of this kind, after several tens of thousands of tests with randomly generated lines.

Acknowledgments. We are grateful to Mark de Berg, who raised the possibility of improving the bound $O(c^4 n^{2+\varepsilon})$, which appeared in preliminary versions of this paper, to the bound $O(c^3 n^{2+\varepsilon})$ that is currently proved in section 4. We are also grateful to Emo Welzl and the European Graduate Program on Combinatorics, Geometry and Computation for hosting us at ETH Zürich, where the work on this paper was initiated.

SETTING PARAMETERS BY EXAMPLE*

DAVID EPPSTEIN†

Abstract. We introduce a class of "inverse parametric optimization" problems, in which one is given both a parametric optimization problem and a desired optimal solution; the task is to determine parameter values that lead to the given solution. We describe algorithms for solving such problems for minimum spanning trees, shortest paths, and other "optimal subgraph" problems and discuss applications in multicast routing, vehicle path planning, resource allocation, and board game programming.

Key words. inverse optimization, parametric search, shortest paths, minimum spanning tree, vehicle routing, adaptive user interfaces, alpha-beta search, evaluation function, randomized algorithms, ellipsoid method

1. Introduction.

Many cars now come equipped with route planning software that suggests a path from the current location to a desired destination. Similar services are also available on the Internet (e.g., from http://maps.yahoo.com/). But although these routes may be found by computing shortest paths in a graph representing the local road system, the "distance" may be a weighted sum of several values other than actual mileage: expected travel time, scenic value, number of turns, tolls, etc. [23]. Different drivers may have different preferences among these values, and they may not be able to clearly articulate these preferences. Can we automatically infer the appropriate weights to use in the sum by observing the routes actually chosen by a driver?

More abstractly, we define an *inverse parametric optimization* problem as follows: we are given as input both a *parametric optimization* problem (that is, a combinatorial optimization problem such as shortest paths, but with the element weights being linear combinations of certain parameters rather than fixed numbers) and a desired optimal solution for the problem.[1] Our task is to determine parameter values such that the given solution is optimal for those values.

Along with the path planning problem described above, one can find many other applications in which one must tune the parameters to an optimization problem:

- In many online services such as web page hosting, data is sent in a star topology from a central server to each user. But in multicast routing of video and other high-bandwidth information, network resources are conserved by sending the data along the edges of a tree, in which some users receive copies of the data from other users rather than from the central server. Natural measures of the quality of each edge in this routing tree include the edge's bandwidth, congestion, delay, packet loss, and possibly monetary charges for

[1]One could more generally allow as input a set of problem-solution pairs, but for most of the problems we consider, any such set can be represented equally well by a single larger problem.

use of that link. Since one can find minimum spanning trees efficiently in the distributed setting [14], it is natural to try to model this routing problem using minimum spanning trees. Given one or more networks with these parameters, and examples of desired routing trees, how can we set the weights of each quality measure so that the desired trees are the minimum spanning trees of their networks?

- Bipartite matching, or the *assignment problem*, is a common formalism for grouping indivisible resources with resource consumers. For instance, the first example given for matching by Ahuja, Magnanti, and Orlin [2] is to assign recently hired workers to jobs, using weights based on such values as aptitude test scores and college grades. One might set the weight of an edge from worker i to job j to be $a_i \cdot p_j$, where a_i is the (known) set of aptitudes of the worker, and p_j is the (unknown) set of parameters describing the combination of aptitudes best fitting the job. Again, it is natural to ask for a way to automatically set the parameters of each job based on experience assigning previously hired workers to those jobs.
- Many board games, such as chess, checkers, or Othello, can be played well by programs based on relatively simple alpha-beta searching algorithms. However, these programs use relatively complex evaluation functions in which the evaluation of a given position can be the sum of hundreds or thousands of terms. Some of these terms may represent the gross material balance of a game (e.g., in chess, one usually normalizes the score so that a pawn is worth 1 point, while a knight may be worth 2.5–3 points) while others represent more subtle features of piece placement, king safety, advanced pawns, etc. The weight of each of these terms may be individually adjusted in order to improve the quality of play. Although there have been some preliminary experiments in using evolutionary learning techniques to tune these weights [25], they are currently usually set by hand. The true test of a game program is in actual play, but programs are also often tuned by using *test suites*, large collections of positions for which the correct move is known. If we are given a test suite, can we automatically set evaluation weights in such a way that a shallow alpha-beta search can find each correct move?

1.1. New results. We show the following theoretical results. For the inverse parametric minimum spanning tree problem, in the case that the number of parameters is a fixed constant, we provide a randomized algorithm with linear expected running time, and a deterministic algorithm with worst-case running time $O(m \log^2 n)$. For the minimum spanning tree, shortest path, matching, and other "optimal subgraph" problems for which the optimization problem can be solved in polynomial time, we show that the inverse optimization problem can also be solved in polynomial time by means of the ellipsoid method from linear programming, even when the number of parameters is large.

In addition, we discuss the problem of setting weights for game evaluation and describe how to solve it within the same inverse parametric optimization framework.

In cases where the initial problem is infeasible (there is no parameter setting for which the desired solution is optimal), our techniques provide a witness for infeasibility: a small number of alternative solutions, one of which must be better than the given solution for any parameter setting. One can then examine these solutions to determine whether the initial solution is suboptimal or whether additional parameters should be added to better model the users' utility functions.

1.2. Relation to previous work. Although there has been considerable work on parametric versions of optimization problems such as minimum spanning trees [1] and shortest paths [26], we are not aware of any prior work in inverting such problems to produce parameter values that match given solutions. One could compute the set of solutions available over the range of parameter values and compare these solutions to the given one, but the number of different solutions would typically grow exponentially with the number of parameters.

The inverse parametric optimization problems considered here are most closely related to *parametric search*, which describes a general class of problems in which one sets the parameters of a parametric problem in order to optimize some criterion. However, in most applications of parametric search, the criterion being optimized is a numeric function of the solution (e.g., the ratio between two linear weights) rather than the solution structure itself. Megiddo [20] describes a very general technique for solving parametric search problems in which one simulates the steps of an optimization algorithm, at each conditional step using the algorithm itself as an oracle to determine which conditional branch to take. However, this technique does not seem to apply to our problems, because the given optimal structure (e.g., a single shortest path) does not give enough information to deduce the conditional branches followed by a shortest path algorithm.

The vehicle routing problem discussed in the introduction was introduced by Rogers and Langley [23]. However, they used a weaker model of optimization (a hill-climbing procedure) and a stronger model of user interaction requiring the user to specify preferences in a sequence of choices between pairs of routes.

The inverse parametric optimization problems we study are also related to previous work on "inverse optimization" problems, in which one is given an optimization problem with a solution and must find new weights for the problem that make the given solution optimal [3, 4, 5, 24, 27, 28]. However, work on these problems has not focused on the parametric aspects of such optimization, which can be interpreted in this framework as requiring the edge weights to be in a linear subspace rather than being unrestricted, and has instead looked at finding a set of weights that is as close as possible to some given set.

2. Minimum spanning trees. In this section, we consider the *inverse parametric minimum spanning tree problem*, in which we are given a fixed tree T in a network in which the weight of each edge e is a linear function $w(e) = \mathbf{c}_e \cdot \mathbf{p}$ (where $\mathbf{p}$ represents the unknown vector of parameter settings and $\mathbf{c}_e$ represents the known value of edge e according to each parameter). Our task is to find a value of $\mathbf{p}$ such that T is the unique minimum spanning tree for the weights $w(e)$.

If we fix a given spanning tree T in a network, a pair of edges (e, f) is defined to be a *swap* if $T \cup \{f\} \setminus \{e\}$ is also a spanning tree; that is, if e is an edge in T, f is not an edge in T, and e belongs to the cycle induced in T by f. T is the unique minimum spanning tree if and only if for every swap (e, f), the weight of f is greater than the weight of e.

Thus we can solve the inverse parametric minimum spanning tree problem as a linear program, in which we have one variable per parameter, an additional variable δ measuring the amount by which the inequality $w(f) > w(e)$ holds, and one constraint $(\mathbf{c}_f - \mathbf{c}_e) \cdot \mathbf{p} \geq \delta$ per swap. To avoid multiple equally good spanning trees we use the maximization of δ as our objective function, and to avoid unboundedness we can add constraints such as $-\mathbf{1} \leq \mathbf{p} \leq \mathbf{1}$. We call these additional constraints *parameter constraints* since they do not depend on the input network.

If the number of variables is a fixed constant, a linear program may be solved in time linear in the number of constraints [21]; however, here the number of constraints may be $\Theta(mn)$. We show how to improve this by a randomized algorithm which takes linear time and by a deterministic algorithm which takes time $O(m \log^2 n)$.

2.1. Randomized spanning tree algorithm. In the conference version of this paper, we described a linear time algorithm for the inverse parametric minimum spanning tree problem, using ideas of Clarkson [9] to bound the sizes of the remaining subproblems after two levels of random sampling. Here we replace this technique by a simpler method of Chan [8].

LEMMA 1 (Chan [8]). *Let P be a class of problems with real-valued solutions such that any instance of size n can be divided in time $T(n)$ into a constant number of subproblems of size αn, $\alpha < 1$, so that the solution of the original instance is the minimum of the subproblem solutions. Further suppose that for any instance of size n and subproblem solution v we can decide whether the solution of another subproblem has a value less than v, in time $T(n)$, and that $T(n) = \Omega(n^\epsilon)$ for some $\epsilon > 0$. Then we can solve any problem in P in time $O(T(n))$.*

Given an instance (G, T) of the inverse parametric spanning tree problem, and given a subset S of the edges, define an instance (G_S, T_S) by contracting all edges in $E(T) \cap S$ and deleting from G all edges in $(E(G) \setminus E(T)) \cap S$. The contraction of T is a tree with edges in $E(T) \setminus S$, and the contraction and deletion of edges in G forms a graph with edges in $E(G) \setminus S$. It is not hard to see that a pair (e, f) forms a swap in (G_S, T_S) if and only if (e, f) is a swap in (G, T) and neither e nor f belongs to S.

THEOREM 2. *We can solve the inverse parametric minimum spanning tree problem for any constant number of parameters in randomized linear expected time.*

Proof. Let the number of parameters be d; then the linear programming formulation of the problem has dimension $d+1$, and its solution is the minimum value of δ determined by some $(d+1)$-tuple of swaps. Partition the edges of G into $2d+3$ equal-cardinality subsets S_i; then at least one of the sets S_i is disjoint from the $2d+2$ swap edges that determine the problem's solution. Therefore, the solution to the problem is the minimum of the solutions to the $2d+3$ subproblems (G_{S_i}, T_{S_i}), each of which has size (number of edges) $(2d+2)/(2d+3)$ times the size of the original instance.

If v is the solution to one of the subproblems, let $\mathbf{p}$ denote the parameter vector associated with v. To test whether another subproblem (G_{S_i}, T_{S_i}) has a smaller solution than v, we use a linear time minimum spanning tree verification algorithm [10, 18] to check whether T_{S_i} is a minimum spanning tree of G_{S_i} for parameter setting $\mathbf{p}$. If not, some linear programming constraint is violated by the solution $\mathbf{p}$ and the subproblem solution is smaller than v.

The time to partition the problem into subproblems and to test subproblem solutions is linear, so by Chan's lemma, the overall time to solve the inverse parametric minimum spanning tree problem is also linear. □

2.2. Deterministic spanning tree algorithm. To solve the inverse parametric minimum spanning tree problem deterministically, we use a different sampling technique of Clarkson [9] and derandomize it using methods very similar to those of an approximate set cover algorithm of Brönnimann and Goodrich [7].

We begin by applying the *multilevel restricted partition* technique of Frederickson [12, 13] to the given tree T.

By introducing dummy edges, we can assume without loss of generality that T is binary and that the root t of T has indegree one. These dummy edges will only

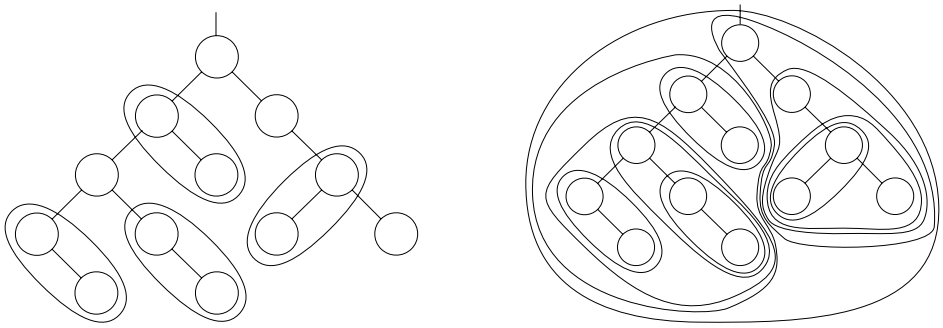

FIG. 1. (a) *Restricted partition of order* 2*;* (b) *multilevel partition.*

be used to form the partition and will not take part in the eventual optimization procedure.

DEFINITION 1. *A restricted partition of order z with respect to a rooted binary tree T is a partition of the vertices of V such that*

1. *each set in the partition contains at most z vertices;*
2. *each set in the partition induces a connected subtree of T;*
3. *for each set S in the partition, if S contains more than one vertex, then there are at most two tree edges having one endpoint in S;*
4. *no two sets can be combined and still satisfy the other conditions.*

Such a partition (for $z = 2$) is depicted in Figure 1(a). In general such a partition can easily be found in linear time by merging sets until we get stuck. Alternatively, by working bottom up we can find an optimal partition in linear time. We will defer until later choosing a value for z; for now we leave it as a free parameter.

LEMMA 3 (Frederickson [13]). *Any order-z partition of a binary tree T has $O(n/z)$ sets in the partition. For $z = 2$ we can find a partition with at most $5n/6$ sets.*

Contracting each set in a restricted partition again gives a binary tree. We form a *multilevel partition* [13] by recursively partitioning this contracted binary tree (Figure 1(b)).

We now use these partitions to construct a set Π of paths in T. For any set S in the multilevel partition, define an *internal edge* of S to be an edge of T that has both endpoints in S, but at most one endpoint in any set in a lower level of the partition, and define an *external edge* of S to be an edge of T that has exactly one endpoint in S. Define a *terminal* of S to be an endpoint of an internal or external edge of S. We form Π by including all paths in T between pairs (u, v), where u and v are both terminals of the same set.

LEMMA 4. *The set of paths Π defined above has the following properties:*

- *There are $O(nz)$ paths in Π.*
- *Each edge in T belongs to $O(z^2 \log_z n)$ paths of Π.*
- *Any path in T can be decomposed into the disjoint union of $O(\log_z n)$ paths of Π.*

Proof. The first property follows immediately from Lemma 3, since each set of the partition contributes $O(z^2)$ paths, there are $O(n/z)$ sets at the bottom level of the partition, and the number of sets decreases at least geometrically at each level. Similarly, the second property follows, since an edge can belong to $O(z^2)$ paths per level and there are $O(\log_z n)$ levels.

Finally, to prove the third property, let p be an arbitrary path in T. We describe a procedure for decomposing p into few paths $\pi_i \in \Pi$. More generally, suppose we have a path p contained in a set S at some level of a multilevel decomposition (note that the whole tree is the set at the highest level of the partition). Then S can be decomposed into at most z sets at the next level of the partition; p has endpoints in at most two of these sets and may pass completely through some other sets. Therefore, p can be decomposed into the union of two smaller paths in the sets containing its endpoints, together with a single path π_i connecting those two sets. By repeating this decomposition recursively at each level of the tree, we obtain a decomposition into at most two paths per level, or $O(\log_z n)$ paths overall. □

We now describe how to use this path decomposition in our inverse optimization problem. For each path $\pi_i \in \Pi$, let A_i denote the set of edges in T belonging to π_i. Let B_i denote the set of nontree edges (u, v) such that π_i is included in the decomposition of the path in T from u to v. The total size of all the sets A_i is $O(nz^2 \log_z n)$ by the second property of Lemma 4, and the total size of all the sets B_i is $O(m \log_z n)$ by the third property of the same lemma. It is not difficult to explicitly construct all sets A_i and B_i in time linear in their total size.

A pair (e, f) is a swap if and only if there is some e for which $e \in A_i$ and $f \in B_i$. With this decomposition, the inverse parametric minimum spanning tree problem becomes equivalent to asking for a parameter $\mathbf{p}$ such that for each i, the weight of every member of A_i is less than the weight of every member of B_i.

For a single value of i, one could solve such a problem by a $(d+1)$-dimensional linear program in which we augment the parameters by an additional variable that is constrained to be greater than each $e \in A_i$ and less than each $f \in B_i$; however, adding a separate variable for each i would make the dimension nonconstant.

Instead, we use a standard derandomization technique from computational geometry, *ϵ-nets*. If we graph the weight of each edge in a d-dimensional space (where again d is one more than the number of parameters), letting the $d-1$ parameter values be independent variables and the weight be the dependent variable, the result is a hyperplane. Suppose that these edges are also given costs, independent of their weights. For any set S of these hyperplanes and any $\epsilon > 0$, define an ϵ-net for vertical line segments to be a subset S' with the following property: if any vertical line segment V intersects a subset of the hyperplanes having cost at least ϵ times the total cost of all hyperplanes, then the same segment must intersect at least one hyperplane in S'. Figure 2 shows an example in which $\epsilon = 1/2$ and all costs are equal. If $1/\epsilon = O(1)$, an ϵ-net of size $O(1)$ can be found in time linear in $|S|$ [6].

Our algorithm can then be described as follows. We will use $\epsilon = 1/4d$.

1. Construct a multilevel partition.
2. Find the set of paths Π connecting terminals of the sets of the partition.
3. Find the sets A_i by listing the edges in each path $\pi \in \Pi$.
4. Find the sets B_i by decomposing the paths in T connecting the endpoints of each nontree edge.
5. Assign unit cost to each edge in the graph.
6. Repeat until terminated:
   (a) Construct ϵ-nets A'_i and B'_i for each A_i and B_i.
   (b) Let S be the set of swaps involving only ϵ-net members. Find the optimal solution $(\mathbf{p}, \delta)$ for the constraints from S together with the parameter constraints.
   (c) Find the maximum weight a_i of an edge in each A_i and the minimum

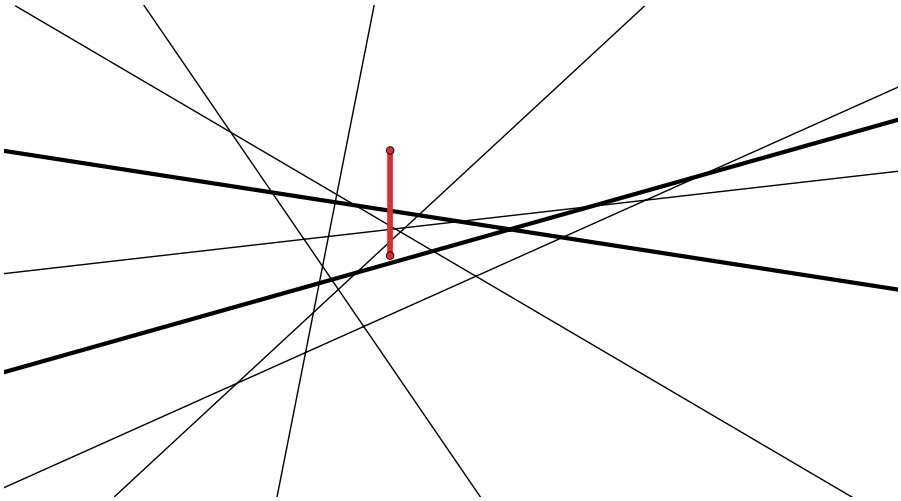

FIG. 2. *Example ϵ-net for $\epsilon = 1/2$: every vertical line segment that crosses $\geq n/2$ lines in the overall arrangement also crosses at least one of the two heavy lines.*

weight b_i of an edge in each B_i, where weights are measured according to $\mathbf{p}$. If $a_i \leq b_i - \delta$ for each i, terminate the algorithm.

(d) Find the maximum weight a'_i of an edge in each A'_i and the minimum weight b'_i of an edge in each B'_i. Double the cost of each edge in A_i with $w(e) > a'_i$, and each edge in B_i with $w(e) < b'_i$.

As in previous work on derandomized iterated reweighting schemes [7], each iteration increases the total cost of all the sets A_i (and similarly B_i) by a factor of at most $1 + \epsilon = 1 + 1/4d$, but at least one edge from the optimal base has its cost increase, so the cost of the optimal base increases on average by a factor of at least $2^{1/2d} \approx 1 + \ln(2)/2d \approx 1/2.88d$ per iteration. Since the base's cost increases at a rate faster than the total cost, it can only continue to do so for $O(d \log n)$ iterations before it overtakes the total cost—an impossibility. So at some point within those $O(d \log n)$ iterations the algorithm must terminate the loop.

THEOREM 5. *We can solve the inverse parametric minimum spanning tree problem for any constant number of parameters in worst-case time $O(m \log n \log_{m/n} n)$.*

Proof. We use the algorithm described above, setting $z = \max(2, \sqrt{m/n})$. Therefore, the total size of the sets A_i and B_i (and the total time to find these sets and to perform each iteration) is $O(m \log_{m/n} n)$. Since d is constant, there are $O(\log n)$ iterations, and the total time is $O(m \log n \log_{m/n} n)$. □

3. Other optimal subgraph problems. We now describe a method for solving inverse parametric optimization on a more general class of *optimal subgraph problems*, in which we are given a graph with parametric edge weights and must find the minimum weight *suitable subgraph*, where suitability is defined according to the particular problem. The minimum spanning tree problem considered earlier has this form, with the suitable subgraphs simply being trees. The shortest path and minimum weight matching problems also have this form. In order to solve these problems, we resort to the ellipsoid method from linear programming. This has the disadvantage of being not strongly polynomial nor very practical, but its advantages are in its extreme generality—not only can we handle any optimal subgraph problem for which the op-

timization version is polynomial, but (unlike our minimum spanning tree algorithms) we are not limited to a fixed number of parameters.

A good introduction to the ellipsoid method and its applications in combinatorial optimization can be found in the book by Grötschel, Lovász, and Schrijver [15].

LEMMA 6 (Grötschel, Lovász, and Schrijver [15, p. 158]). *For any polyhedron P defined by a strong separation oracle, and for any rational linear objective function f, one can find the point in P maximizing f in time polynomial in the dimension of P and in the maximum encoding length of the linear inequalities defining P.*

The *strong separation oracle* required by this result is a routine that takes as input a d-dimensional point and either determines that the point is in P or returns a closed halfspace containing P and not containing the test point. One slight technical difficulty with this approach is that it requires the polyhedron to be closed (else one could not separate it from a point on one of its boundary facets), while our problems are defined by strict inequalities forming open halfspaces. To solve this problem, as in the inverse spanning tree problem, we introduce an additional parameter δ measuring the separation of the desired optimal subgraph from other subgraphs and attempt to maximize δ.

THEOREM 7. *Let (G, X) be an inverse parametric optimization problem in which G is a graph with parametric edge weights and X is the given solution for an optimal subgraph problem, and in which there exists a polynomial time algorithm that determines whether X is the unique optimal subgraph and, if not, finds a different optimal subgraph Y. Then we can solve the inverse parametric optimization problem for (G, X) in time polynomial in the number of parameters, in the size of the graph, and in the maximum encoding length of the linear functions defining the edge weights of G.*

Proof. We define a polyhedron P by linear inequalities $w(X) \le w(Y) - \delta$, where w denotes the weight of a subgraph for the given point $\mathbf{p}$, Y can be any suitable subgraph, and δ is an additional parameter. To avoid problems with unboundedness, we can also introduce additional normalizing inequalities $-\mathbf{1} \le \mathbf{p} \le \mathbf{1}$. Clearly, there exists a point $(\mathbf{p}, \delta)$ with $\delta > 0$ in P if and only if $\mathbf{p}$ gives a feasible solution to the inverse parametric optimization problem.

Although there can be exponentially many inequalities, we can easily define an oracle that either terminates the entire algorithm successfully or acts as a strong separation oracle: to test a point $(\mathbf{p}, \delta)$, simply compute the optimal subgraph Y for the weights defined by $\mathbf{p}$. If $X = Y$, we have solved the problem. If $w(X) \le w(Y) - \delta$, the point is feasible. Otherwise, return the halfspace $w(X) \le w(Y) - \delta$.

Therefore, we can apply the ellipsoid method to find the point maximizing δ on P. If the method returns a point with $\delta > 0$ or terminates early with $X = Y$, we must have solved the problem; otherwise the problem must be infeasible. □

COROLLARY 8. *We can solve the inverse parametric minimum spanning tree, shortest path, or matching problems in time polynomial in the size of the given graph and in the encoding length of its parametric weight functions.*

As a variant of this result, by using an algorithm for finding the *second* best subgraph, we can test whether a given solution $(\mathbf{p}, \delta)$ is feasible even when the optimal subgraph for $\mathbf{p}$ is the desired subgraph by testing whether its weight is separated by at least δ from the next best subgraph for $\mathbf{p}$. Thus, we can complete the ellipsoid method without early termination and find a parameter value for which X is optimally separated from other subgraphs. Efficient second-best algorithms are known for minimum spanning trees [10, 17, 18], shortest paths [16], and matching [22]; in

general the second-best subgraph is the best subgraph within all graphs formed by deleting one edge of X from G.

4. Game tree search. As described in the introduction, we would like to be able to tune the weights of a game program's evaluation function so that a shallow search (to some fixed depth D) makes the correct move for each position in a given test suite. However, because of the possibility of making the right move for the wrong reasons, this problem seems highly nonlinear. Instead, we now sketch how to use the ellipsoid method to search for an evaluation function that not only makes all the right moves but also correctly orders certain pairs of positions found in its searches.

Define an *unavoidable set* of positions for a given player and depth D to be a set of positions, each of which occurs D half-moves from the present situation, such that, no matter what the opponent does, the given player can force the game to reach some position in the set. For any given position p_i, one can prove that one particular move μ is best (from the point of view of a depth D search) by exhibiting a pair (A_i, B_i) where A_i is an unavoidable set for the first player after move μ, B_i is an unavoidable set for the second player after all other moves, and the evaluation of all positions in A is better than the evaluation of any position in B. Minimax or alpha-beta search can be interpreted as finding both of these sets.

Our separation oracle runs a depth-D search on each test position until one is found at which the wrong move is made. We then construct A_i and B_i for that one position, using a deep search, and look for $a \in A_i$ and $b \in B_i$ that have evaluations in the wrong order. The oracle returns a constraint that the evaluation of a should be greater than the evaluation of b.

The result of applying the ellipsoid method with this separation oracle is either an evaluation function that makes the correct move (with a depth D search) in each test position or a determination that it is impossible to correctly order all (a, b) pairs found by the oracle.

5. Conclusions. We have discussed several problems of inverse parametric optimization, provided general solutions to a wide class of optimal subgraph problems based on the ellipsoid method, and provided faster combinatorial algorithms for the inverse parametric minimum spanning tree problem.

One difficulty with our approach comes from infeasible inputs: what if there is no linear combination of parameters that leads to the desired solution? Rogers and Langley [23] observe a similar phenomenon in their vehicle routing experiments and suggest searching for additional parameters to use. This search may be aided by the fact that infeasible linear programs can be witnessed by a small number of mutually inconsistent constraints: in the path planning problem, we can find $d+1$ paths, one of which must be better than the given path for any combination of known parameters. Studying these paths may reveal the nature of the missing parameters. Alternatively, a search for a linear programming solution with few violated constraints [19] may provide a parameter setting for which the user's chosen solution is near-optimal.

A natural direction for future research is in dealing with nonlinearity. Problems in which the solution weight includes low-degree combinations of element weights (as are used in game programming to represent interactions between positional features) may be dealt with by including additional parameters for each such combination. But what about problems in which the element weights are nonlinear combinations of the parameters? For instance, if the parameters are coordinates of points, any problem involving comparisons of distances will involve quadratic functions of those coordinates. The question of finding coordinates such that a given tree is the Euclidean

minimum spanning tree of the points is known to be NP-hard [11], but if the points' coordinates depend only on a constant number of parameters, one can solve the problem in polynomial time. Can the exponent of this polynomial be made independent of the number of parameters?

It may be possible to extend our spanning tree methods to other matroids. For example, transversal matroids provide a formulation of bipartite matching in which the weights are on the vertices of one side of the bipartition rather than the edges. Can we solve inverse parametric transversal matroid optimization efficiently? Are there natural applications of this or other matroidal problems?

Another open question concerns the existence of combinatorial algorithms for the inverse parametric shortest path problem. It is unlikely that a strongly polynomial algorithm exists without restricting the dimension: one can encode any linear programming feasibility problem as an inverse parametric shortest path (or other optimal subgraph) problem by using a parallel pair of edges for each constraint. But is there a strongly polynomial algorithm for inverse parametric shortest paths when the number of parameters is small?

AN APPROXIMATION ALGORITHM FOR MINIMUM CONVEX COVER WITH LOGARITHMIC PERFORMANCE GUARANTEE*

STEPHAN J. EIDENBENZ† AND PETER WIDMAYER‡

Abstract. The problem MINIMUM CONVEX COVER of covering a given polygon with a minimum number of (possibly overlapping) convex polygons is known to be *NP*-hard, even for polygons without holes [J. C. Culberson and R. A. Reckhow, *J. Algorithms,* 17 (1994), pp. 2–44]. We propose a polynomial-time approximation algorithm for this problem for polygons with or without holes that achieves an approximation ratio of $O(\log n)$, where n is the number of vertices in the input polygon. To obtain this result, we first show that an optimum solution of a restricted version of this problem, where the vertices of the convex polygons may lie only on a certain grid, contains at most three times as many convex polygons as the optimum solution of the unrestricted problem. As a second step, we use dynamic programming to obtain a convex polygon which is maximum with respect to the number of "basic triangles" that are not yet covered by another convex polygon. We obtain a solution that is at most a logarithmic factor off the optimum by iteratively applying our dynamic programming algorithm. Furthermore, we show that MINIMUM CONVEX COVER is *APX*-hard; i.e., there exists a constant $\delta > 0$ such that no polynomial-time algorithm can achieve an approximation ratio of $1+\delta$. We obtain this result by analyzing and slightly modifying an already existing reduction [J. C. Culberson and R. A. Reckhow, *J. Algorithms,* 17 (1994), pp. 2–44].

1. Introduction and problem definition.

The problem MINIMUM CONVEX COVER is the problem of covering a given polygon T with a minimum number of (possibly overlapping) convex polygons that lie in T. This problem belongs to the family of classic art gallery problems; it is known to be *NP*-hard for input polygons with holes [17] and without holes [4]. The study of approximations for hard art gallery problems has rarely led to good algorithms or good lower bounds; we discuss a few exceptions below. In this paper, we propose the first nontrivial approximation algorithm for MINIMUM CONVEX COVER. Our algorithm works for polygons with and without holes. It relies on a strong relationship between the continuous original problem version and a particular discrete version in which all relevant points are restricted to lie on a kind of grid that we call a quasi grid. The quasi grid is the set of intersection points of

all lines connecting two vertices of the input polygon. In the RESTRICTED MINIMUM CONVEX COVER problem, the vertices of the convex polygons that cover the input polygon may lie only on this quasi grid. We prove that an optimum solution of the RESTRICTED MINIMUM CONVEX COVER problem needs at most three times the number of convex polygons that the MINIMUM CONVEX COVER solution needs. To find an approximate solution for the RESTRICTED MINIMUM CONVEX COVER problem, we propose a greedy approach: we compute one convex polygon of the solution after the other, and we pick as the next convex polygon one that covers a maximum number of triangles defined on an even finer quasi grid, where these triangles are not yet covered by previously chosen convex polygons. We propose an algorithm for finding such a maximum convex polygon by means of dynamic programming. To obtain an upper bound on the quality of the solution, we interpret our covering problem on triangles as a special case of the general MINIMUM SET COVER problem that gives as input a base set of elements and a collection of subsets of the base set and that asks for a smallest number of subsets in the collection whose union contains all elements of the base set. In our special case, each triangle is an element, and each possible convex polygon is a possible subset in the collection, but not all of these subsets are represented explicitly. (There could be an exponential number of subsets.) This construction translates the logarithmic quality of the approximation from MINIMUM SET COVER to MINIMUM CONVEX COVER [13].

On the negative side, we show that MINIMUM CONVEX COVER is *APX*-hard; i.e., there exists a constant $\delta > 0$ such that no polynomial-time algorithm can achieve an approximation ratio of $1 + \delta$ (see [3] for an introduction to the class *APX*). This inapproximability result is based on a problem transformation shown by Culberson and Reckhow [4]; we modify this transformation and show that it is gap-preserving (as defined by Arora and Lund [1]).

The related problem of partitioning a given polygon into a minimum number of nonoverlapping convex polygons is polynomially solvable for input polygons without holes [2]. It is *NP*-hard for input polygons with holes [15] and can be approximated with an approximation ratio of 4 [12]; it remains *NP*-hard even if the convex partition must be created by cuts from a given family of (at least three) directions [16]. Other related results for art gallery problems include approximation algorithms with logarithmic approximation ratios for MINIMUM VERTEX GUARD and MINIMUM EDGE GUARD [10], as well as for the problem of covering a polygon with rectangles in any orientation [11]. Furthermore, logarithmic inapproximability results are known for MINIMUM POINT/VERTEX/EDGE GUARD for polygons with holes, and *APX*-hardness results are known for the same problems for polygons without holes [6]. The related problem RECTANGLE COVER of covering a given orthogonal polygon with a minimum number of rectangles can be approximated with a constant ratio for polygons without holes [9] and with an approximation ratio of $O(\sqrt{\log n})$ for polygons with holes [14]. For additional results, see the surveys on art galleries [18, 19]. The general idea of using dynamic programming to find maximum convex structures has been used before to solve the problem of finding a maximum (with respect to the number of vertices) empty convex polygon, given a set of vertices in the plane [5]. An $O(\log n)$ approximation algorithm for the problem of covering a polygon with rectangles in any orientation [11] relies on an approach similar to ours that consists of making the problem discrete and then transforming it to a MINIMUM SET COVER instance.

In section 2, we define the quasi grid and its refinement into triangles. Section 3

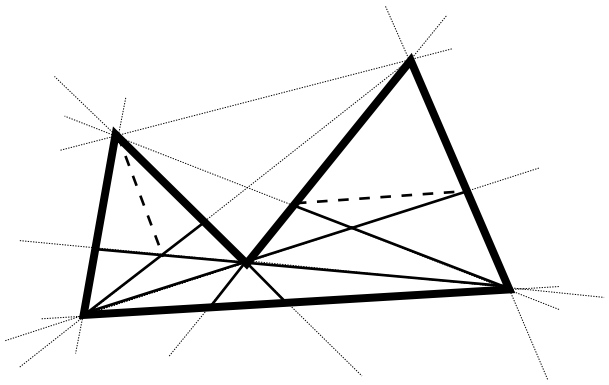

FIG. 1. *Construction of first-order basic triangles.*

contains the proof of the linear relationship between the sizes of the optimum solutions of the unrestricted and restricted convex cover problems. We propose a dynamic programming algorithm to find a maximum convex polygon in section 4 before showing how to iteratively apply this algorithm to find a convex cover in section 5. In section 6, we present the proof of the *APX*-hardness of MINIMUM CONVEX COVER. Concluding thoughts are in section 7.

2. From the continuous to the discrete. We consider simple input polygons with and without holes, where a polygon T is given as an ordered list of vertices in the plane. If T contains holes, each hole is also given as an ordered list of vertices. Let V_T denote the set of vertices (including the vertices of holes, if any) of a given polygon T. While in the general MINIMUM CONVEX COVER problem the vertices of the convex polygons that cover the input polygon can be positioned anywhere in the interior or on the boundary of the input polygon, we restrict their positions in an intermediate step: they may be positioned only on a quasi grid in the RESTRICTED MINIMUM CONVEX COVER problem.

In order to define the RESTRICTED MINIMUM CONVEX COVER problem more precisely, we partition the interior of a polygon T into *convex components* (as proposed in [10] for a different purpose) by drawing a line through each pair of vertices of T. We then triangulate each convex component arbitrarily. We call the triangles thus obtained *first-order basic triangles*. Figure 1 shows an example of the first-order basic triangles of a polygon (thick solid lines) with an arbitrary triangulation (fine solid lines and dashed lines). If a polygon T consists of n vertices, drawing a line through each pair of vertices of T will yield less than $\binom{n}{2} \cdot \binom{n}{2} \in O(n^4)$ intersection points. Let V_T^1 be the set of these intersection points that lie in T (in the interior or on the boundary). Note that $V_T \subseteq V_T^1$. The first-order basic triangles are a triangulation of V_T^1 inside T; therefore, the number of first-order basic triangles is also $O(n^4)$. The RESTRICTED MINIMUM CONVEX COVER problem asks for a minimum number of convex polygons, with vertices restricted to V_T^1, that together cover the input polygon T. We call V_T^1 a quasi grid that is imposed on T. For solving the RESTRICTED MINIMUM CONVEX COVER problem, we make use of a finer quasi grid: simply partition T by drawing lines through each pair of points from V_T^1. This yields again convex components, and we triangulate them again arbitrarily. This higher resolution partition yields $O(n^{16})$ intersection points, which define the set V_T^2. We call the resulting triangles *second-order basic triangles*. Obviously, there are $O(n^{16})$ second-order basic triangles. Note

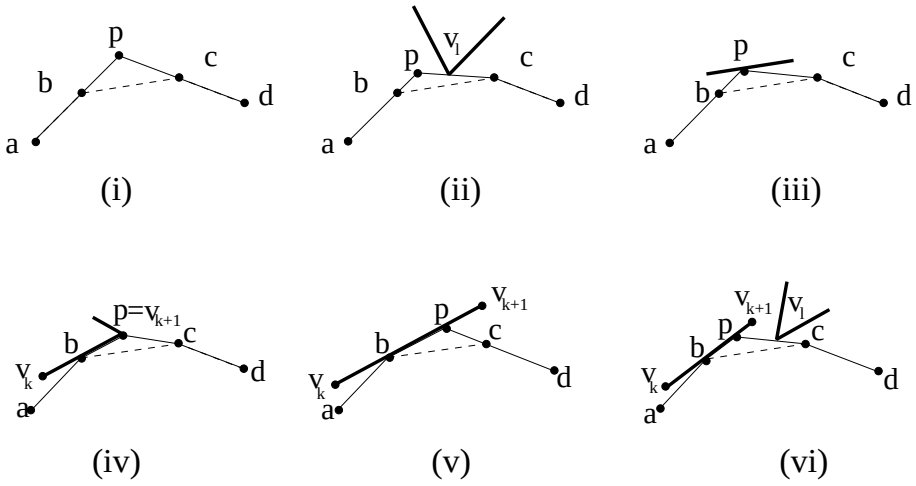

FIG. 2. *Expansion of edge (b,c).*

that $V_T \subseteq V_T^1 \subseteq V_T^2$.

3. The optimum solution of MINIMUM CONVEX COVER vs. the optimum solution of RESTRICTED MINIMUM CONVEX COVER. The quasi grids V_T^1 and V_T^2 serve the purpose of making a convex cover computationally efficient while at the same time guaranteeing that the cover on the discrete quasi grid is not much worse than the desired cover in continuous space. The following theorem proves the latter.

THEOREM 1. *Let T be an arbitrary simple input polygon with n vertices. Let OPT denote the size of an optimum solution of* MINIMUM CONVEX COVER *with input polygon T, and let OPT' denote the size of an optimum solution of* RESTRICTED MINIMUM CONVEX COVER *with input polygon T. Then*

$$OPT' \leq 3 \cdot OPT.$$

Proof. We proceed as follows: we show how to *expand* a given arbitrary convex polygon $C \subseteq T$ to another convex polygon $C' \subseteq T$ with $C \subseteq C'$ by iteratively expanding edges. We then replace the vertices in C' by vertices from V_T^1, which results in a (possibly) nonconvex polygon $C'' \subseteq T$ with $C' \subseteq C''$. Finally, we describe how to obtain three convex polygons C_1'', C_2'', C_3'' with $C'' = C_1'' \cup C_2'' \cup C_3''$ that contain only vertices from V_T^1. This will complete the proof, since each convex polygon from an optimum solution of MINIMUM CONVEX COVER can be replaced by at most three convex polygons that are in a solution of RESTRICTED MINIMUM CONVEX COVER. Following this outline, let us present the proof details.

Expanding edges. Let C be an arbitrary convex polygon inside polygon T. Let the vertices of C be given in clockwise order. We obtain a series of convex polygons $C^1, C^2, \ldots, C'$ with $C = C^0 \subseteq C^1 \subseteq C^2 \subseteq \cdots \subseteq C'$, where C^{i+1} is obtained from C^i as follows (see Figure 2).

Let a, b, c, d be consecutive vertices (in clockwise order) in the convex polygon C^i that lies inside polygon T. For ease of description, we assume that C^i does not contain vertices that are collinear with its two neighboring vertices, except when such a vertex happens to be a vertex from V_T; moreover, any vertex from V_T that lies on the boundary of C^i is also a vertex of C^i, even if it has collinear neighbors in C^i.

Let vertices $b, c \notin V_T$, with b and c not on the same edge of T. Then the edge (b, c) is called *expandable*. If there exists no expandable edge in C^i, then $C' = C^i$, which means that we have found the end of the series of convex polygons. If (b, c) is an expandable edge, we *expand* the edge from vertex b to vertex c as follows:

- If b does not lie on the boundary of T, then we let a point p start at b and move along the halfline through a and b away from a and b until either one of the following two events happens: p lies on the line through c and d, or the triangle p, c, b touches the boundary of T. Fix p as soon as the first of these events happens. Figure 2 shows a list of all possible cases, where the edges from polygon T are drawn as thick edges: point p lies on the intersection point of the lines from a through b and from c through d as in case (i), or there is a vertex v_l on the line segment from p to c as in case (ii), or p lies on an edge of T as in case (iii).
- If b lies on the boundary of T, i.e., on some edge of T, say, from v_k to v_{k+1} (in clockwise order), then let p move from b as before, except that the move is now along the halfline from v_k through b away from v_k and b up until at most v_{k+1} (instead of the ray from a through b). Figure 2 shows a list of all possible cases: point p lies either at vertex v_{k+1} as in case (iv) or on the intersection point of the lines from b to v_{k+1} and from d through c as in case (v), or there is a vertex v_l on the line segment from p to c as in case (vi).

A new convex polygon C_p^i is obtained by simply adding point p as a vertex in the ordered set of vertices of C^i between the two vertices b and c; if—as in cases (ii) and (vi)—a vertex from V_T lies on the boundary of C_p^i, it is also added as a vertex (despite the fact that it may have two collinear neighbors). In contrast, all vertices in C_p^i that have collinear neighbors and that are not vertices in V_T are eliminated.

An edge from two consecutive vertices b and c with $b, c \notin V_T$ can always be expanded in such a way that the triangle b, p, c that is added to the convex polygon is nondegenerate, i.e., has nonzero area, unless b and c both lie on the same edge of polygon T. This follows from the cases (i)–(vi) of Figure 2.

Let $C^{i+1} = C_p^i$ if either a new vertex of V_T has been added to C_p^i in the expansion of the edge, which is true in cases (ii), (iv), and (vi), or the number of vertices of C_p^i that are not vertices from V_T has decreased, which is true in case (i). If p is as in case (iii), we expand the edge (p, c), which will result in case (iv), (v), or (vi). Note that in cases (iv) and (vi), we have found C^{i+1}. If p is as in case (v), we expand the edge (p, d), which will result in case (iv), (v), or (vi). If it is case (v) again, we repeat the procedure by expanding the edge from p and the successor (clockwise) of d. This needs to be done at most as many times as there are vertices in C^i, since the procedure eliminates a vertex from C^i in each iteration and will stop before it tries to expand an edge ending at vertex a as the resulting polygon would not be convex. Therefore, we obtain C^{i+1} from C^i in a finite number of steps.

Let τ_i denote the number of vertices in C^i that are also vertices in T, and let $\hat{\tau}_i$ be the number of vertices in C^i that are not vertices in T. Note that $\phi(i) = \hat{\tau}_i - 2\tau_i + 2n$ is a function that bounds the number of remaining iteration steps that are needed to reach C'; it strictly decreases with every increase in i and cannot become negative as $\hat{\tau}_i$ and τ_i are both nonnegative numbers by definition and $n \geq \tau_i$. The existence of such a bounding function, which is often called a variant function, implies the finiteness of the series $C^1, C^2, \ldots, C'$ of convex polygons.

By definition, there are no expandable edges left in C'. Call a vertex of C' a T-vertex if it is a vertex in T. From the definition of expandable edges, it is clear that

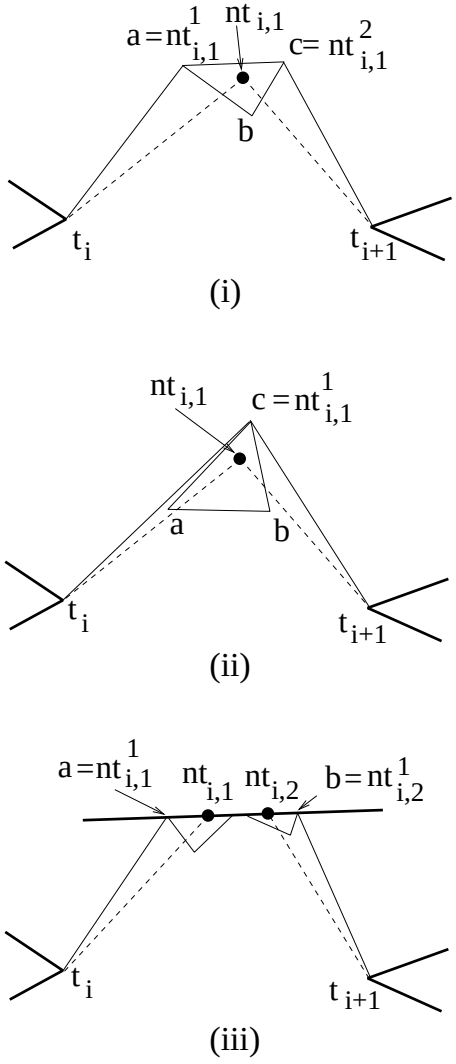

FIG. 3. *Replacing non-T-vertices.*

there can be at most two non-T-vertices between any two consecutive T-vertices in C', and if there are two non-T-vertices between two consecutive T-vertices, they must both lie on the same edge in T. (Otherwise, the edge between two non-T-vertices would be expandable, which contradicts the definition of C'.)

Replacing vertices. Let the T-vertices in C' be $t_1, \ldots, t_l$ in clockwise order, and let the non-T-vertices between t_i and t_{i+1} be $nt_{i,1}$ and $nt_{i,2}$ if they exist. We will replace each non-T-vertex $nt_{i,j}$ in C' by one or two vertices $nt^1_{i,j}$ and $nt^2_{i,j}$ that are both elements of the quasi grid V^1_T. This will transform the convex polygon C' into a not necessarily convex polygon C''. (We will show later how C'' can be covered by at most three convex polygons C''_1, C''_2, C''_3.) The details are as follows: let a, b, c be the first-order basic triangle in which non-T-vertex $nt_{i,j}$ lies, as illustrated in Figure 3. Points a, b, c are all visible from both vertices t_i and t_{i+1}. To see this, assume by contradiction that the view from, say, t_i to a is blocked by an edge e of T. Since $nt_{i,j}$

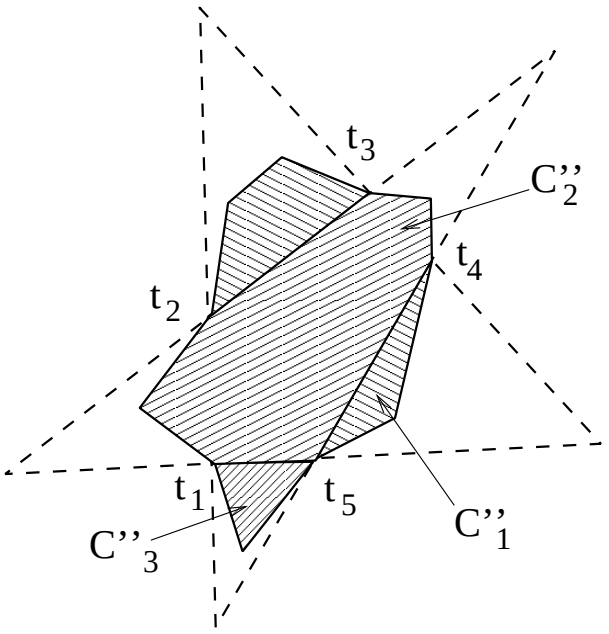

FIG. 4. *Covering C'' with three convex polygons.*

must see t_i, the edge e must contain a vertex e' in the triangle $t_i, a, nt_{i,j}$, but then a cannot be a vertex of the first-order basic triangle in which $nt_{i,j}$ lies, since the line from vertex t_i through vertex e' would cut through the first-order basic triangle—an impossibility.

Assume that only one non-T-vertex $nt_{i,1}$ exists between t_i and t_{i+1}. If the triangle t_i, t_{i+1}, a completely contains the triangle $t_i, nt_{i,1}, t_{i+1}$, then we let $nt^1_{i,1} = a$, and likewise for b and c (see Figure 3 (ii)). Otherwise, we let $(nt^1_{i,1}, nt^2_{i,1})$ be $(a, b), (a, c)$, or (b, c), as in Figure 3 (i), such that the polygon $t_i, nt^1_{i,1}, nt^2_{i,1}, t_{i+1}$ is convex and completely contains the triangle $t_i, nt_{i,1}, t_{i+1}$. This is always possible by the definition of points a, b, c.

Assume that two non-T-vertices $nt_{i,1}$ and $nt_{i,2}$ exist between t_i and t_{i+1}. From the definition of C', we know that $nt_{i,1}$ and $nt_{i,2}$ must lie on the same edge e of T. Therefore, the basic triangle in which $nt_{i,1}$ lies must contain a vertex a either at $nt_{i,1}$ or preceding $nt_{i,1}$ on edge e along T in clockwise order. Let $nt^1_{i,1} = a$. The basic triangle in which $nt_{i,2}$ lies must contain a vertex b either at $nt_{i,2}$ or succeeding $nt_{i,2}$ on edge e. Let $nt^1_{i,2} = b$. (See Figure 3 (iii).) Note that the convex polygon $t_i, nt^1_{i,1}, nt^1_{i,2}, t_{i+1}$ completely contains the polygon $t_i, nt_{i,1}, nt_{i,2}, t_{i+1}$.

After applying this change to all non-T-vertices in C', we obtain a (possibly) nonconvex polygon C''.

Covering with three convex polygons. We will now show how to cover C'' with at most three convex polygons. First, assume that C'' contains an odd number f of T-vertices. We let C''_1 be the polygon defined by vertices $t_i, nt^k_{i,j}$, and t_{i+1} for all j, k and for all odd i, but $i \neq f$. By construction, C''_1 is convex. To see this, assume C''_1 is not convex; it would then have to have at least one vertex whose inner angle is larger than π, which cannot happen at non-T-vertices in C''_1 by construction. The inner angles at a T-vertex t_{i-1} for i odd cannot be larger than π either, because

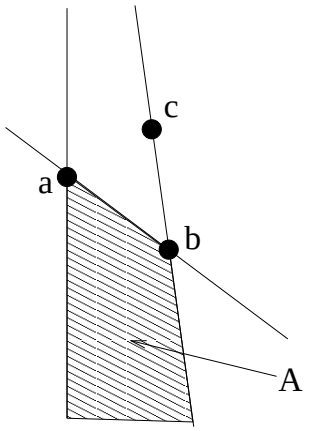

FIG. 5. *Dynamic programming.*

polygon C_1'' lies entirely to the right of the line going from t_{i-1} through t_i. Let C_2'' be the polygon defined by vertices $t_i, nt_{i,j}^k$, and t_{i+1} for all j, k and for all even i. Finally, let C_3'' be the polygon defined by vertices $t_f, nt_{f,j}^k$, and t_1 for all j, k. Using similar arguments as for C_1'', polygons C_2'' and C_3'' are convex as well. Figure 4 shows an example. Obviously, C_1'', C_2'', and C_3'' together cover all of C''. Second, assume that C'' contains an even number of T-vertices, and cover it with only two convex polygons using the same concept. This completes the proof. □

4. Finding maximum convex polygons. Assume that each second-order basic triangle from a polygon T is assigned a weight value of either 1 or 0. In this section, we present an algorithm using dynamic programming that computes a convex polygon M in a polygon T that contains a maximum number of second-order basic triangles with weight 1 and that has vertices only from V_T^1. For simplicity, we call such a polygon a *maximum convex polygon*. The weight of a polygon M is defined as the sum of the weights of the second-order basic triangles in the polygon and is denoted by $|M|$. We will later use the algorithm described below to iteratively compute a maximum convex polygon with respect to the triangles that are not yet covered, to eventually obtain a convex cover for T.

Let $a, b, c \in V_T^1$. Let $P_{a,b,c}$ denote the maximum convex polygon that

- contains only vertices from V_T^1,
- contains vertices a, b, c in counterclockwise order,
- has a as its left-most vertex,[1]
- contains additional vertices only between vertices a and b, and
- is completely contained in T.

Given three vertices $a, b, c \in V_T^1$, let A be the (possibly infinite) area of points that are

- to the right of vertex a,
- to the left of the line oriented from b through a, and
- to the left of the line oriented from b through c.

[1] If polygon $P_{a,b,c}$ has several left-most vertices, vertex a is one of them.

1.	Initialize table $S(a,b,c)$ with zeros	
2.	FORALL $a \in V_T^1$ DO	$O(n^{28})$
3.	Choose a helper point a' with the same x-coordinate and an arbitrary but smaller y-coordinate than a	
4.	Order all vertices $b \in V_T^1$ to the right of a according to the angle formed by b, a, a'; let the resulting ordered set be B	$O(n^4 \log n)$
5.	$B' := \emptyset$	
6.	WHILE $B \neq \emptyset$ DO	$O(n^{24})$
7.	Let b be the smallest element in B; $B := B - \{b\}$; $B' := B' \cup \{b\}$	
8.	FORALL $c \in V_T^1 \backslash B'$ to the right of a DO	$O(n^{20})$
9.	Compute $\lvert\Delta a, b, c\rvert$	$O(n^{16})$
10.	Define area A with respect to vertices a, b, c according to Lemma 2	
11.	FORALL $d \in (V_T^1 \cap A)$ DO	$O(n^4)$
12.	Look up $\lvert P_{a,d,b}\rvert$ and store maximizing d in $d_{\max}$	
13.	END	
14.	$\lvert P_{a,b,c}\rvert := \lvert\Delta a, b, c\rvert + \lvert P_{a,d_{\max},b}\rvert$	
15.	Store $\lvert P_{a,b,c}\rvert$ in table S	
16.	END	
17.	END	
18.	END	
19.	Find maximum entry in table S	

FIG. 6. *Algorithm for computing a maximum weight convex polygon.*

For an illustration, see Figure 5. Let

$$P'_{a,b,c} = \max_{d \in V_T^1 \cap A} P_{a,d,b} \cup \Delta a, b, c,$$

where $\Delta a, b, c$ is the triangle a, b, c and max is defined as follows (to simplify notation):

$$\max\{P_1, P_2\} = \begin{cases} P_1 & \text{if } |P_1| \geq |P_2|, \\ P_2 & \text{otherwise.} \end{cases}$$

LEMMA 2. *$P_{a,b,c} = P'_{a,b,c}$ if the triangle a, b, c is completely contained in the polygon T.*

Proof. Consider $P_{a,b,c}$, which is maximum by definition. $P_{a,b,c}$ must contain additional vertices between a and b. (Otherwise, the lemma is trivially true.) Let d' be the predecessor of b in the counterclockwise order of $P_{a,b,c}$. Vertex d' must lie in A as defined above. Now consider $P'' = P_{a,b,c} - \Delta a, b, c$. From the definition of A it is clear that P'' can contain only vertices that lie in A. Now $P_{a,d',b}$ is maximum by definition, and it is considered when computing $P'_{a,b,c}$. □

Let M be a maximum convex polygon for a polygon T with weights assigned to the second-order basic triangles. Let a be the left-most vertex of M, let c be the predecessor of a in M in counterclockwise order, and let b be the predecessor of c. Then $|P_{a,b,c}| = |M|$ by definition. We will use Lemma 2 to construct an algorithm, which takes as input a polygon T and an assignment of weight 0 or 1 to each second-order basic triangle of T and computes the maximum convex polygon. An overview of the algorithm is given in Figure 6.

In more detail, we start by initializing a table $S(a, b, c)$, where the entry at position a, b, c denotes the weight $|P_{a,b,c}|$, in line 1 of Figure 6. In a first loop, we fix vertex $a \in V_T^1$ in line 2, let a' be a helper point with the same x-coordinate and an arbitrary but smaller y-coordinate than a, and order all vertices $b \in V_T^1$ to the right of a according to the angle formed by b, a, a'. We call the resulting ordered set B and let B' be the empty set. In a second loop, starting at line 6, we iteratively take the smallest element b from B, remove it from B, and add it to set B'; then for every $c \in V_T^1 \backslash B'$ to the right of a (see line 8), we compute weight $|\Delta a, b, c|$ of the triangle a, b, c and compute $P_{a,b,c}$ according to Lemma 2 in line 11 (i.e., look up the values of $P_{a,d,b}$ for all $d \in V_T^1 \cap A$ and take the maximum; all these values were computed in earlier iterations). We then compute weight $|P_{a,b,c}|$ by adding $|\Delta a, b, c|$ to $|P_{a,d,b}|$, where d is the maximizing argument, and store the value in table S. Note that the computation of $P_{a,b,c}$ according to Lemma 2 is always possible, since all possible vertices d in $P_{a,d,b}$ lie to the left of the line from b to a (see also definition of area A), have therefore smaller angles d, a, a' than b, a, a', and have therefore already been computed. The algorithm is executed for every $a \in V_T^1$, and—by using standard bookkeeping techniques (not explicitly given in the pseudocode of Figure 6)—the maximum convex polygon found is returned.

The cumulative running times of the loops and the running times of some crucial individual lines of the algorithm are given in Figure 6, resulting in an overall running time of $O(n^{28})$. To see this, we first look at the loop from line 8 to line 16: each iteration of this loop takes time $O(n^{16})$, which is the running time of computing the weight of a triangle a, b, c (see line 9) as we have to add the weights of almost all second-order basic triangles; the $O(n^4)$ running time of the inner loop (lines 11 to 13) is dominated by the $O(n^{16})$ running time of line 9. Since there are $O(n^4)$ iterations of the loop from line 8 to line 16, we get a running time of $O(n^{20})$ for this loop. The loop from lines 6 to 17 consists of a total of $O(n^4)$ iterations of the $O(n^{20})$ loop from lines 8 to 16, thus resulting in a cumulative running time of $O(n^{24})$. Finally, the loop from lines 2 to 18 has $O(n^4)$ iterations of the $O(n^{24})$ loop from lines 6 to 17; the $O(n^4 \log n)$ time required for sorting in line 4 is dominated by the $O(n^{24})$ time for the loop. Thus the overall running time is $O(n^{28})$. Memory requirements are $O(n^{12})$ as we need to allocate table S.

5. An approximation algorithm for Minimum Convex Cover. Given a polygon T, we obtain a convex cover by iteratively applying the algorithm for computing a maximum convex polygon from section 4. It works as follows for an input polygon T:

1. Let all second-order basic triangles have weight 1. Let $S = \emptyset$.
2. Find the maximum convex polygon M of polygon T using the algorithm from section 4, and add M to the solution S. Decrease the weight of all second-order basic triangles that are contained in M to 0.[2]
3. Repeat step 2 until there are no second-order basic triangles with weight 1 left. Return S.

To obtain a performance guarantee for this algorithm, consider the Minimum Set Cover instance I, which has all second-order basic triangles as elements and where the second-order basic triangles with weight 1 of each convex polygon in T, which contains only vertices from V_T^1, form a set in I. The greedy heuristic for Minimum

[2]Note that by the definition of second-order basic triangles, a second-order basic triangle either is completely contained in M or is completely outside M.

SET COVER achieves an approximation ratio of $1 + \ln n'$, where n' is the number of elements in I [13], and it works in exactly the same way as our algorithm. However, we do not have to (and could not afford to) compute all the sets of the MINIMUM SET COVER instance I (which would be a number exponential in n'); it suffices to always compute a set, which contains a maximum number of elements not yet covered by the solution thus far. This is achieved by reducing the weights of the second-order basic triangles already in the solution to 0; i.e., a convex polygon with maximum weight is such a set.

Note that $n' = O(n^{16})$ since the number of triangles in a triangulation is proportional to the number of points in V_T^2 that induce the triangulation. Therefore, our algorithm achieves an approximation ratio of $O(\log n)$ for RESTRICTED MINIMUM CONVEX COVER on input polygon T. Because of Theorem 1, we know that the solution found for RESTRICTED MINIMUM CONVEX COVER is also a solution for the unrestricted MINIMUM CONVEX COVER that is at most a factor of $O(\log n)$ off the optimum solution.

As for the running time of this algorithm, observe that the algorithm adds to the solution in each round a convex polygon with nonzero weight. An optimum solution would consist of at most $O(n)$ convex polygons, since a triangulation of the vertices of the input polygon yields a trivial solution with $O(n)$ convex polygons that are triangles in this case. Since our algorithm finds a solution that is at most a factor $O(\log n)$ off the optimum solution and since it adds a convex polygon to the solution in each round, there can be at most $O(n \log n)$ rounds before the algorithm finishes. As each round takes time $O(n^{28})$, the total running time is $O(n^{29} \log n)$. This completes the proof of our first main theorem:

THEOREM 3. MINIMUM CONVEX COVER *for input polygons with or without holes can be approximated by a polynomial-time algorithm with an approximation ratio of* $O(\log n)$*, where* n *is the number of polygon vertices.*

6. *APX*-hardness of MINIMUM CONVEX COVER. The upper bound of $O(\log n)$ on the approximation ratio for MINIMUM CONVEX COVER may not be tight: we will now prove that there is a constant lower bound on the approximation ratio, and hence a gap remains. More precisely, we prove MINIMUM CONVEX COVER to be *APX*-hard. Our proof of the *APX*-hardness of MINIMUM CONVEX COVER for input polygons with or without holes uses a construction similar to the one that is used to prove the *NP*-hardness of this problem for input polygons without holes[4].[3] However, we reduce the problem MAXIMUM 5-OCCURRENCE-3-SAT rather than SATISFIABILITY (SAT) (as done in the original reduction [4]) to MINIMUM CONVEX COVER, and we design the reduction to be gap-preserving [1]. MAXIMUM 5-OCCURRENCE-3-SAT is the variant of SAT in which each variable may appear at most five times in clauses and each clause contains at most three literals. MAXIMUM 5-OCCURRENCE-3-SAT is *APX*-complete [1].

The reduction is constructed as follows: for a given instance I of MAXIMUM 5-OCCURRENCE-3-SAT with n variables $x_1, \ldots, x_n$ and m clauses $c_1, \ldots, c_m$, we construct an instance I' of MINIMUM CONVEX COVER. To stick to the notation of [4], let $l_i \leq 5$ denote the number of literals of variable x_i in the clauses, and let $l = \sum_{i=1}^{n} l_i$ be the total number of literals.

For each literal in I, we construct a literal pattern, which we call a "beam ma-

[3] *APX*-hardness for MINIMUM CONVEX COVER for input polygons without holes implies *APX*-hardness for the same problem for input polygons with holes.

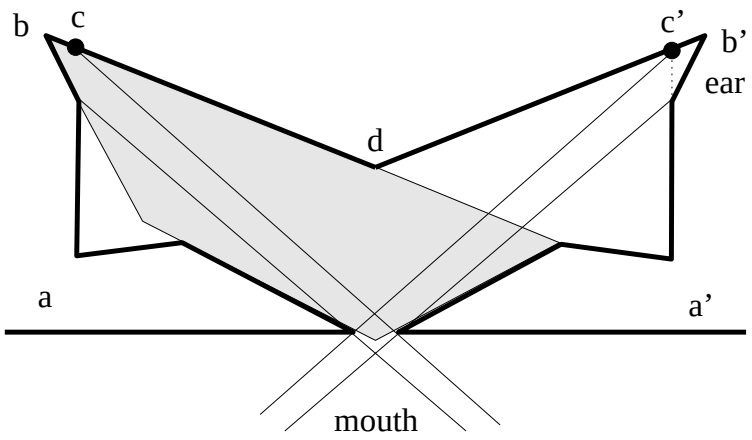

FIG. 7. *The beam machine.*

chine," as illustrated in Figure 7. A beam machine allows us to send a beam, i.e., a slim convex polygon in one of two possible directions out of the beam machine toward a structure that represents a clause. The beam machines of all literals of a variable are then combined into a variable structure, as illustrated in Figure 8. All these variable structures are then arranged in a half-circle such that the beams emitted from the beam machines reach the appropriate clause checkers, which are simple dents. An overview of the whole structure is given in an example in Figure 9. After this overview, let us give a more detailed description.

The beam machine that is constructed for each literal is shown in Figure 7. Since no two of the four vertices a, a', b, and b' see each other, at least four convex polygons are needed to cover the beam machine. Two of these are the maximal convex polygons a, c, d and a', c', d. The remaining areas around the mouth and the ear (the triangle) at b or b' can be covered by a large convex polygon shown in light gray in Figure 7. Finally, a fourth convex polygon is needed to cover the other ear (at b' in Figure 7). This polygon, which we call a beam, is very slim and can be extended indefinitely beyond the mouth outside the beam machine. The large light gray convex polygon thus acts as a switch: depending on whether we let it cover the ear at b or b', we can turn on the indefinite beam polygon at the other ear. However, we cannot turn on both beams and still use only four polygons to cover the beam machine. Note that we can "focus" and "aim" the beam by slightly bending the whole beam machine or by making the ears smaller.

The variable structure is illustrated in Figure 8. Its basic shape is butterfly-like. The beam machines for each occurrence of the variable in a literal in a clause are set on top of the butterfly with the positive literals on the right wing and the negative literals on the left wing of the butterfly. For each literal, we have a dent on the bottom line of the wing. If we cover each dent of the left or right wing with a maximal convex polygon, i.e., with a polygon that covers the whole dent and then extends canonically, then we have covered almost all of the left or right wing except for the area around the mouth of the variable structure and except for a small triangular region for each literal that lies between two dents. These triangles are called beam locks. We can cover the beam locks either by beams emanating from the beam machines or by a single large convex polygon which also covers the region around the mouth of the variable structure. Such a polygon is drawn in light gray in Figure 8. In a similar

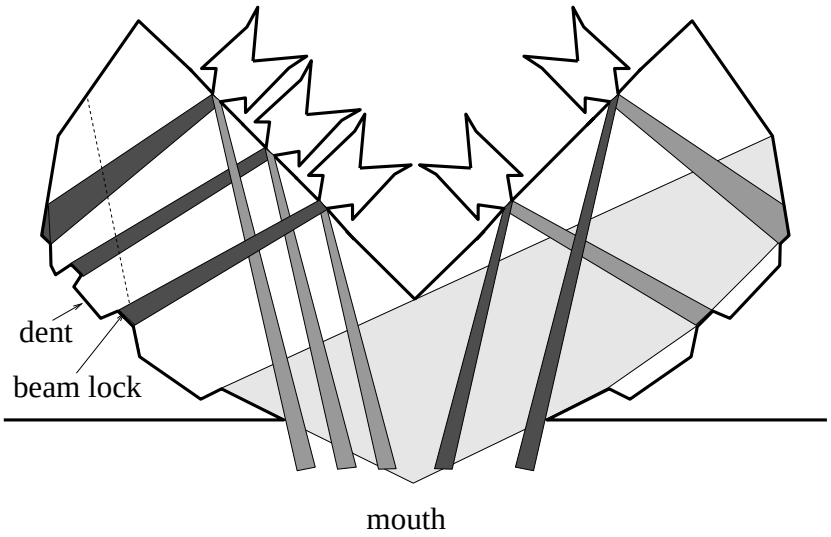

FIG. 8. *The variable structure.*

way as in the beam machine, this large convex polygon acts as a switch: in order to cover the whole variable structure with a minimum number of convex polygons, we can have the beam locks of only one wing covered with such a single polygon; the beam locks of the other wing must be covered by the beams of the beam machines. In Figure 8, beams that are turned on are drawn in dark gray, while beams that are turned off are medium gray. Thus, in Figure 8, all beam machines of positive literals are turned off, and all beam machines of negative literals are turned on and can shine infinitely far beyond the mouth of the variable structure.[4]

We need four convex polygons to cover each beam machine; thus we need $4l_i$ convex polygons to cover the beam machines in the variable structure for variable x_i. For each literal, we need an additional polygon to cover the dent, and we need one additional large switcher polygon to cover the mouth and the beam locks of either the positive or negative literals. Thus a minimum number of $5l_i + 1$ convex polygons are required to cover the variable structure of variable x_i. Note that if the beams of only one negative and one positive literal that are both aimed toward and beyond the mouth of the variable structure are turned on, then $5l_i + 2$ convex polygons are needed to cover the variable structure. On the other hand, if the beams of all (positive and negative) literals that cover the beam locks are turned on, there are still $5l_i + 1$ convex polygons needed to cover the variable structure, since we also need to cover the area around the mouth.

We arrange all variable structures in a half-circle-like shape above a base line, which contains triangular dents that represent the clauses, as illustrated in Figure 9. This is done in such a way that a beam emanating from a beam machine of a literal that appears in a clause reaches the corresponding dent (the clause checker) that represents that clause and thus covers it. Note that we can arrange the variable structures in such a way that they cannot interfere with each other; i.e., no convex polygon can cover any beam locks or areas around the mouth of two different variable structures. We can achieve this by making the angles at the mouth of each variable

[4]The beam machines have not been drawn exactly to scale in Figure 8.

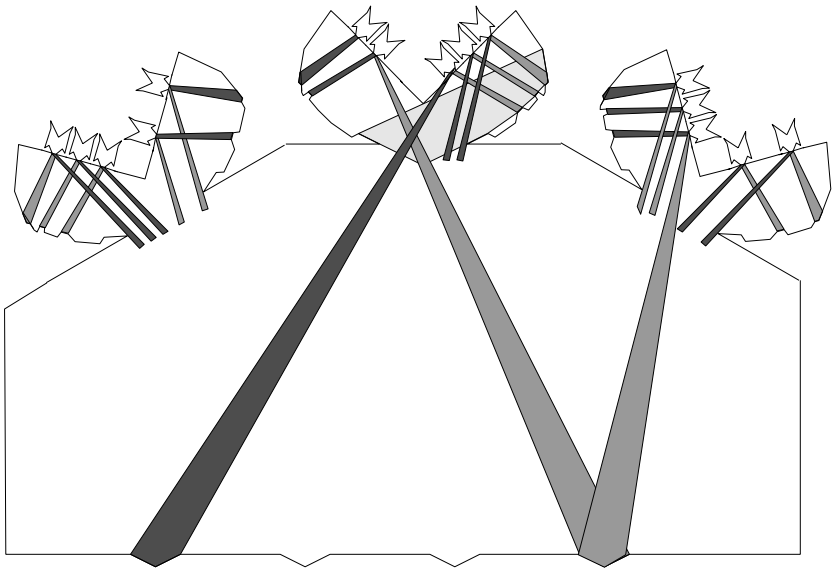

FIG. 9. *Overview of the construction.*

structure very small.

THEOREM 4. *Let I be an instance of* MAXIMUM 5-OCCURRENCE-3-SAT *consisting of n variables and m clauses with a total of l literals, and let I' be the corresponding instance of* MINIMUM CONVEX COVER. *Let OPT be the maximum number of satisfied clauses of I by any assignment of the variables. Let OPT' be the minimum number of convex polygons needed to cover the polygon of I', and let $\epsilon > 0$ be constant. Then*

$$OPT = m \Longrightarrow OPT' = 5l + n + 1,$$
$$OPT < (1 - 15\epsilon)m \Longrightarrow OPT' > 5l + n + 1 + \epsilon n.$$

Proof. The first implication is trivial: if we have a variable assignment that satisfies all variables, we turn on the beams that are aimed toward the clause checkers of all beam machines that represent literals that are satisfied by the assignment. We turn on the beams that are aimed toward the beam locks for all other beam machines. Thus we need $5l_i + 1$ convex polygons to cover the variable structure x_i. If we sum this up over all n variables, we obtain $5l + n$ convex polygons. We need one additional polygon to cover the space between the base line and the variable structures.

Since each clause is satisfied, we must have for each clause checker at least one beam turned on that covers it. Thus the convex polygons as just described cover all of I'.

We prove the second implication by proving its contraposition, i.e., $OPT' \leq 5l + n + 1 + \epsilon n \Longrightarrow OPT \geq (1 - 15\epsilon)m$. To this end, we show how to transform the convex polygons of any solution S' of the MINIMUM CONVEX COVER instance I' in such a way that their total number does not increase and in such a way that a truth assignment of the variables satisfying the desired number of clauses can be "inferred" from the convex polygons.

Suppose we are given a solution S' of the CONVEX COVER instance with $|S'| \leq 5l + n + 1 + \epsilon n$.

By construction, the variable generator for variable x_i must be covered by at least $5l_i+1$ convex polygons. Moreover, by construction, there is no convex polygon, which simultaneously covers a part of a beam lock in any variable generator and a part of a clause checker. There is not even a convex polygon which covers a part of a beam lock and touches the horizontal line, on which the clause checkers lie. Similarly, note that there is no convex polygon which can simultaneously cover a part of an ear of a beam machine and a part of any clause checker, except for the clause checker associated with the beam machine.

Proceed in the following order:

1. Determine which convex polygon in S' covers the midpoint on the line segment between the clause checkers of clause c_1 and c_2. Transform this polygon in such a way that it covers all of the area between the clause checkers and the variable generators. Note that no convex polygon that covers this midpoint can also cover any beam lock, ear of a beam machine, or clause checker. Therefore, we have a feasible solution after this step.
2. For each clause checker, proceed as follows: for each convex polygon in S' that covers part of the clause checker and that is not a regular beam which leads to a beam machine associated with the clause checker, turn the polygon into a beam to any of the associated beam machines.
3. If there exists a convex polygon in S' that covers parts of the interior of at least two different variable structures, then choose any variable structure in which it lies, and cut off all other parts. This operation results in a feasible solution since, by construction, such a polygon cannot cover the beam locks or the area around the mouths of two different variable structures.
4. For each variable structure, proceed as follows:
   - If the variable structure for x_i is covered by $5l_i+2$ or more convex polygons, then rearrange the convex polygons in such a way that all beams that point to clause checkers are turned on for positive and negative literals. By construction, this is always possible with $5l_i + 2$ convex polygons.
   - If the variable structure for x_i is covered by $5l_i + 1$ convex polygons and one beam from a beam machine for literal x_i ($\neg x_i$) that is aimed at its associated clause checker is turned on, then rearrange all convex polygons in the variable generator in such a way that all beams from beam machines for literal x_i ($\neg x_i$) that are aimed at the associated clause checkers are turned on.

The convex cover obtained this way is still a feasible solution. After this transformation, we have for each variable structure x_i one of the following cases:

- for all negative and positive literals, the beams that are aimed toward the clause checkers are turned on;
- only for all positive or negative literals, the beams that are aimed toward the clause checkers are turned on;
- for negative and positive literals, the beams that are aimed toward the beam locks are turned on.

We set the truth values for the variables as follows: if all beams of literal x_i ($\neg x_i$) that are aimed at clause checkers and no beams of literal $\neg x_i$ (x_i) that are aimed at clause checkers are turned on, then let the variable x_i have truth value TRUE (FALSE). If either all or no beams (of both literals x_i and $\neg x_i$) that are aimed at clause checkers are turned on, then let variable x_i be TRUE.

By construction, every solution of I' must consist of at least $5l + n + 1$ convex polygons. If we transform a solution of I' with $5l + n + 1 + \epsilon n$ convex polygons as indicated above, we get at most ϵn variable structures in which the beams of all literals (positive and negative) that are aimed at the clause checkers are turned on. By assigning all these variables the value TRUE, we falsify at most five clauses for each variable, since each variable appears at most five times as a literal.

Therefore, we get a solution of I with at least $m - 5\epsilon n$ clauses satisfied. Since $3m \geq n$, the solution has at least $m(1 - 15\epsilon)$ satisfied clauses. □

In the so-called promise problem [1] of MAXIMUM 5-OCCURRENCE-3-SAT as described above, we are promised that either all clauses are satisfiable or at most a fraction of $1 - 15\epsilon$ of the clauses is satisfiable, and we are to find out which of the two possibilities is true. This problem is *NP*-hard for sufficiently small values of $\epsilon > 0$ (see [1]). Therefore, Theorem 4 implies that the promise problem for MINIMUM CONVEX COVER, where we are promised that the minimum solution contains either $5l + n + 1$ convex polygons or at least $5l + n + 1 + \epsilon n$ convex polygons, is *NP*-hard as well for sufficiently small values of $\epsilon > 0$. Therefore, MINIMUM CONVEX COVER cannot be approximated with a ratio of $\frac{5l+n+1+\epsilon n}{5l+n+1} \geq 1 + \frac{\epsilon n}{25n+n+1} \geq 1 + \frac{\epsilon}{27}$, where we have used that $l \leq 5n$ and $n \geq 1$. This establishes the following theorem.

THEOREM 5. MINIMUM CONVEX COVER *on input polygons with or without holes is APX-hard.*

7. Conclusion. We have proposed a polynomial-time approximation algorithm for MINIMUM CONVEX COVER that achieves an approximation ratio that is logarithmic in the number of vertices of the input polygon. This has been achieved by showing that there is a discretized version of the problem using no more than three times the number of cover polygons. The discretization may be a first step toward answering the long-standing open question of whether the decision version of the MINIMUM CONVEX COVER problem is in *NP* [18]: we know now that there always exists an optimum solution such that the convex polygons in such an optimum solution contain only a polynomial number of vertices and that a considerable fraction of these vertices are actually vertices from the input polygon; however, all other vertices of the convex polygons could still need a superpolynomial number of bits for their coordinates to be expressed. Apart from the discretization, our algorithm applies a MINIMUM SET COVER approximation algorithm to a MINIMUM SET COVER instance with an exponential number of sets that are represented only implicitly, through the geometry. We propose an algorithm that picks the best of the implicitly represented sets with a dynamic programming approach and hence runs in polynomial time. This technique may prove to be of interest for other problems as well. Moreover, by showing *APX*-hardness, we have eliminated the possibility of the existence of a polynomial-time approximation scheme for this problem. However, polynomial-time algorithms could still achieve constant approximation ratios. Whether our algorithm is the best asymptotically possible is therefore an open problem. Furthermore, our algorithm has a rather excessive running time of $O(n^{29} \log n)$, and it is by no means clear how this can be improved substantially.

Acknowledgments. We would like to thank anonymous referees for numerous valuable comments that greatly improved this paper; in particular, we thank the referees for pointing us to [11] and [16] and for providing the running time analysis in section 5 that reduces the overall running time of our algorithm from $O(n^{44})$, which we had in earlier versions of this paper, to $O(n^{29} \log n)$.

PARALLEL PROCESSOR SCHEDULING WITH LIMITED NUMBER OF PREEMPTIONS*

OLIVER BRAUN† AND GÜNTER SCHMIDT†

Abstract. In this paper, we compare the makespan of preemptive and i-preemptive schedules where only a limited number i of preemptions is allowed. The problem is to schedule n independent jobs on m identical processors that operate in parallel. The objective is to minimize the makespan, i.e., the completion time of the last job that finishes. We show that the ratio of the optimal i-preemptive schedule length $C_{max}^{ip^*}$ versus the optimal preemptive schedule length $C_{max}^{p^*}$ is bounded from above by $C_{max}^{ip^*} \leq (2 - 2/(m/(i+1)+1))C_{max}^{p^*}$. Furthermore, we show that the ratio of the length C_{max}^{LPT} of a nonpreemptive schedule following the *longest processing time (LPT)* rule versus the optimal preemptive schedule length $C_{max}^{p^*}$ is bounded from above by exactly the same bound when $i = 0$.

Key words. parallel processor scheduling, preemptive scheduling, nonpreemptive scheduling, i-preemptive scheduling, longest processing time rule, schedule length, worst-case analysis

1. Introduction.

In this paper, we compare the makespan of preemptive, i-preemptive, and LPT schedules for the problem in which a set of n independent jobs has to be scheduled on m identical processors that operate in parallel. The objective is to minimize the makespan, i.e., the maximum completion time of any job. Using the notation by Braun [2], we mean by an i-preemptive schedule that the maximum number of preemptions is bounded from above by a nonnegative integer number i. A preemptive schedule is allowed to interrupt a job and later resume its execution without any loss of time. Also, the minimum time slice for preempting a job may be arbitrarily small. In nonpreemptive schedules, a job is started and executed to completion without any interruption. It is easy to construct an optimal preemptive schedule with McNaughton's *wrap around* rule [9], whereas it is an NP-hard problem to construct an optimal nonpreemptive schedule. The *longest processing time (LPT)* rule, which orders the jobs in nondecreasing order of their processing times, is a $(4/3 - 1/3m)$-approximation algorithm for the nonpreemptive case [6]. Preemptive, nonpreemptive, and LPT schedules are commonly studied in the literature. An analysis of the complexity of these problems, along with several of their variants and special cases, can be found, e.g., in [1], [5], [3], and [10].

It is easy to see that an optimal preemptive schedule is never longer than an optimal nonpreemptive one. The time savings of a preemptive schedule are bought at the costs of moving a job off a processor before it is finished and at the costs of saving information about the job while it is waiting to be resumed. The costs of preempting a job may be neglected in a computer environment. Here, the costs of preempting the execution of a job in the main memory and transferring it to and from the virtual memory, such as mass storage devices, may be ignored. Generally, however, there arise costs with job preemptions such as inventory and transportation

costs. A small number of preemptions, in general, has advantages such as lower work-in-process inventories, reduced material handling costs, fewer tooling changes, quality improvements, and simplified production planning of materials and labor.

We investigate the following question: How much more effective (with respect to the objective of minimizing the makespan) can optimal preemptive scheduling be compared to optimal i-preemptive scheduling? More precisely, over all instances I, what is the least upper bound on $C_{max}^{ip^*}(I)/C_{max}^{p^*}(I)$, where $C_{max}^{ip^*}$ and $C_{max}^{p^*}$ denote an optimal i-preemptive and an optimal preemptive makespan, respectively? For a job system with arbitrary precedence constraints, Liu conjectured in [8] that the ratio of the optimal nonpreemptive makespan versus the optimal preemptive makespan is bounded above by $2 - 2/(m+1)$. His upper bound proof was found to be incorrect. Coffman and Garey [4] proved Liu's conjecture for a system with arbitrary precedence constraints and two processors. Hong and Leung [7] showed the correctness of the bound for unit execution time (UET) and also for tree-structured job systems. Their proof for tree-structured job systems is also valid for independent jobs.

The paper is organized as follows. In section 2, we show that the ratio of the optimal i-preemptive makespan $C_{max}^{ip^*}$ versus the optimal preemptive makespan $C_{max}^{p^*}$ is bounded from above by $C_{max}^{ip^*} \leq (2 - 2/(m/(i+1)+1))C_{max}^{p^*}$ for $0 \leq i \leq m-1$. It follows from [9] that no more than $m-1$ preemptions are necessary to construct a schedule which is optimal concerning the makespan. Then we show that the ratio of the makespan C_{max}^{LPT} of a nonpreemptive schedule following the LPT rule versus the optimal preemptive makespan $C_{max}^{p^*}$ is bounded from above by $C_{max}^{LPT} \leq (2m/(m+1))C_{max}^{p^*}$. For each of the two bounds, we give an example which shows the tightness of the bounds. Concluding remarks are given in section 3.

2. Worst-case analysis. The scheduling problem under consideration is as follows. There are n jobs $J_1, \ldots, J_n$ with processing times $p_1, \ldots, p_n$ that have to be scheduled on m identical parallel processors $P_1, \ldots, P_m$ so as to minimize the makespan C_{max}. C_{max} is the maximum of all finish times $C_j, j = 1, \ldots, n$, of all jobs. Each processor may work only on one job at a time, and each job may be processed by only one machine at a time. $C_{max}^{p^*}$ is the makespan (schedule length) of an optimal preemptive schedule, $C_{max}^{ip^*}$ is the makespan of an optimal i-preemptive schedule, and C_{max}^{LPT} is the makespan of a schedule constructed with the LPT rule. The LPT rule works in the following way: First, sort the jobs in a list in order of nonincreasing processing times. Then assign the first unscheduled job in the list to any one of the least loaded processors. An optimal i-preemptive schedule S allows at most i preemptions. We assume that preemptions are allowed only on the i processors $P_2, \ldots, P_{i+1}$. With $p_{max} = \max_{j=1,\ldots,n} p_j$ we denote the maximum processing time of a job, and with $\sum p_j = \sum_{j=1}^{n} p_j$ we denote the sum of all processing times.

McNaughton [9] has given a lower bound for the makespan of preemptive schedules:

$$C_{max}^{p^*} = \max\left\{ \frac{\sum p_j}{m} \ , \ p_{max} \right\}. \tag{2.1}$$

The *wrap around* rule of McNaughton constructs optimal schedules with at most $m-1$ preemptions. If at least $m-1$ preemptions are allowed, then one always can construct an optimal schedule with McNaughton's algorithm. Therefore, we have to investigate for i-preemptive scheduling only the case when $0 \leq i \leq m-1$.

Let J_k be a job with processing time p_k and completion time $C_k = C_{max}^{ip^*}$. We assume without loss of generality that job J_k is processed on processor P_{i+1} or on

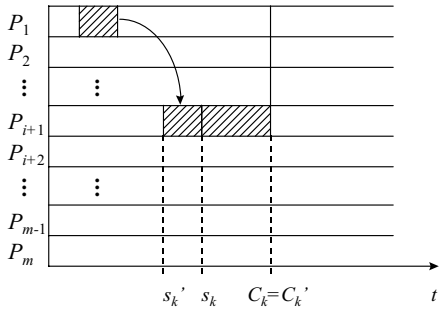

FIG. 2.1. *Lemma* 2.1.

processor P_{i+2}. The structure of the proof is as follows. If $p_k \geq \sum p_j/m$, we have $C_{max}^{ip^*} = C_{max}^{p^*}$, as by (2.1) a preemptive schedule cannot be shorter than p_k. So we assume that $p_k < \sum p_j/m$. In Lemma 2.1, we show that in an optimal i-preemptive schedule S, there always exists a job J_k with processing time p_k and completion time $C_k = C_{max}^{ip^*}$ which is not interrupted. Note that preemptions are allowed only on the i processors $P_2, \ldots, P_{i+1}$. In Lemma 2.2, we prove that the start time of J_k is not larger than $(\sum p_j - (i+1)p_k)/m$. In Lemmas 2.3 and 2.4, we show that in the case when $p_k \leq (m/(m+i+1))C_{max}^{p^*}$ and $p_k > (m/(m+i+1))C_{max}^{p^*}$, the inequality $C_{max}^{ip^*} \leq (2 - 2/(m/(i+1)+1))C_{max}^{p^*}$ is fulfilled. Next we prove the lemmas.

LEMMA 2.1. *Let J_k be a job with processing time $p_k < \sum p_j/m$ and completion time $C_k = C_{max}^{ip^*}$. In an optimal i-preemptive schedule S, J_k is not preempted.*

Proof. This proof is by contradiction. Note that a job is preempted one time at most and that the first scheduled part of job J_k must be scheduled on one of the first $i+1$ processors, because only on these processors are preemptions allowed. If in schedule S job J_k would be preempted, it would be possible to construct a new schedule S' with the same makespan and with J_k not preempted as follows. Without loss of generality, let P_1 be the processor where J_k is preempted in schedule S, and let P_{i+1} be the processor where the processing of J_k is finished. If we move the part of job J_k that is scheduled on processor P_1 immediately before the start time s_k of J_k on processor P_{i+1} and schedule the load of $P_1, \ldots, P_{i+1}$ with McNaughton's rule, we obtain a new schedule S' with the following properties (see Figure 2.1).

1. The finish times of processors $P_{i+2}, \ldots, P_m$ remain unchanged.
2. The total capacity to be scheduled on processors $P_1, \ldots, P_{i+1}$ remains unchanged in schedule S'. As it is allowed to schedule this capacity with McNaughton's rule, and as there is no job J_j with $p_j = C_{max}^{ip^*}$, the finish times of processors $P_2, \ldots, P_{i+1}$ in schedule S' are not larger than C_k of schedule S.

Thus schedule S' has the same makespan as schedule S, and J_k is not preempted. □

LEMMA 2.2. *Let J_k be a job with processing time $p_k < \sum p_j/m$ and completion time $C_k = C_{max}^{ip^*}$. For $0 \leq i \leq m-1$, the maximum number of allowed preemptions, the start time s_k of J_k in an optimal i-preemptive schedule S is not larger than $(\sum p_j - (i+1)p_k)/m$.*

Proof. In Lemma 2.1, it has been shown that in an optimal i-preemptive schedule S, job J_k with $C_k = C_{max}^{ip^*}$ is not preempted. Note that only on the i processors $P_2, \ldots, P_{i+1}$ are preemptions allowed. Thus we distinguish two cases.

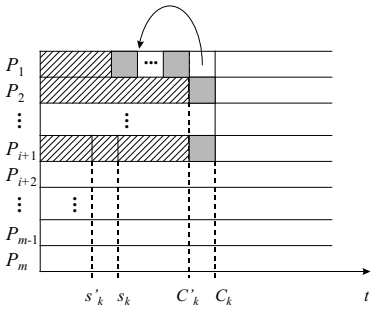

FIG. 2.2. *Lemma* 2.2, *Case* 1a.

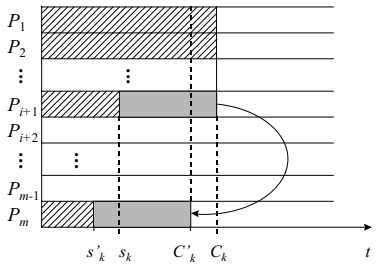

FIG. 2.3. *Lemma* 2.2, *Case* 1b.

Case 1. In an optimal i-preemptive schedule S, J_k is processed on one of the first $i+1$ processors (without loss of generality on P_{i+1}).

Note that we are allowed to schedule the load on the first $i+1$ processors with McNaughton's *wrap around* rule and that there is no job J_j with $p_j = C_{max}^{ip^*}$. In an optimal i-preemptive schedule S, the load on the first $i+1$ processors is at least $(i+1)C_k$. If not, one could construct a new schedule S' with a smaller makespan as follows. Without loss of generality, let P_1 be a processor with load less than C_k. By scheduling the load on the first $i+1$ processors with McNaughton's rule, we would get a new schedule S' with the following properties (see Figure 2.2).

1. The total capacity to be scheduled on processors $P_1, \ldots, P_{i+1}$ remains unchanged in schedule S'. As we are allowed to schedule this capacity with McNaughton's rule, and as there is no job J_j with $p_j = C_{max}^{ip^*}$, the finish times of processors $P_1, \ldots, P_{i+1}$ in schedule S' are less than C_k of schedule S, and the number of preemptions is still at most i.
2. The finish times of processors $P_{i+2}, \ldots, P_m$ remain unchanged.

Thus schedule S' would have a smaller makespan than schedule S, and we have proved that the load on the first $i+1$ processors is at least $(i+1)C_k$.

Next, we show that the last $m-(i+1)$ processors have a load of at least $(m-(i+1))s_k$. If not, one could construct a new schedule S' with smaller makespan as follows. Without loss of generality, let P_m be a processor with load less than s_k. If we would move job J_k to processor P_m, we would obtain a new schedule S' with the following properties (see Figure 2.3).

1. The total capacity to be scheduled on processors $P_1, \ldots, P_{i+1}$ reduces by p_k in schedule S'. As we are allowed to schedule this capacity with McNaughton's *wrap around* rule, and as there is no job J_j with $p_j = C_{max}^{ip^*}$, the finish times of processors $P_1, \ldots, P_{i+1}$ in schedule S' are less than C_k of schedule S, and the number of preemptions is still at most i.
2. The finish times of processors $P_{i+2}, \ldots, P_{m-1}$ remain unchanged.
3. As the finish time on P_m was less than s_k (in schedule S), the finish time on P_m in schedule S' is less than C_k of schedule S.

Thus schedule S' would have a smaller makespan than schedule S, and we have proved that the load on the last $m-(i+1)$ processors is $(m-(i+1))s_k$.

In total, we have

$$\sum p_j \geq (i+1)C_k \quad + \quad (m-(i+1))s_k = (i+1)p_k + ms_k$$

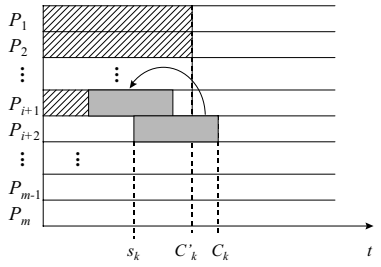

FIG. 2.4. *Lemma* 2.2, *Case* 2a.

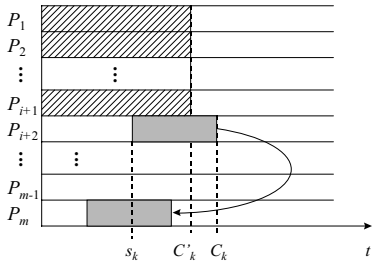

FIG. 2.5. *Lemma* 2.2, *Case* 2b.

or, equivalently,

$$s_k \leq \frac{\sum p_j - (i+1)p_k}{m}.$$

Case 2. In an optimal i-preemptive schedule S, J_k is processed on one of the last $m-(i+1)$ processors (without loss of generality on P_{i+2}).

The first $i+1$ processors have a load of at least $(i+1)C_k - p_k$. If not, we could generate a new schedule S' with a smaller makespan than S as follows. We are allowed to schedule the load on the first $i+1$ processors with McNaughton's rule, and there is no job J_j with processing time $p_j = C^{ip^*}_{max}$. Thus, in schedule S, there must be a processor (without loss of generality P_{i+1}) with load less than $C_k - p_k = s_k$. If we move job J_k to processor P_{i+1}, we would obtain a new schedule S' with the following properties (see Figure 2.4).

1. The finish times of processors $P_1, \ldots, P_i$ remain unchanged.
2. As the finish time on P_{i+1} was less than s_k (in schedule S), the finish time on P_{i+1} in schedule S' is less than C_k of schedule S.
3. The finish time of processor P_{i+2} reduces by p_k.
4. The finish times of processors $P_{i+3}, \ldots, P_m$ remain unchanged.

Thus schedule S' would have a smaller makespan than schedule S, and we have proved that the load on the first $i+1$ processors is at least $(i+1)C_k - p_k$.

Next we prove that the last $m-(i+1)$ processors have a load of at least $(m-(i+1))s_k + p_k$. If not, we could generate a new schedule S' with a smaller makespan than S as follows. Without loss of generality, let P_m be a processor with load less than s_k. If we would move job J_k to processor P_m, we would obtain a new schedule S' with the following properties (see Figure 2.5).

1. The finish times of processors $P_1, \ldots, P_{i+1}$ remain unchanged.
2. The finish time of processor P_{i+2} reduces by p_k.
3. The finish times of processors $P_{i+3}, \ldots, P_{m-1}$ remain unchanged.
4. As the finish time on P_m was less than s_k (in schedule S), the finish time on P_m in schedule S' is less than C_k of schedule S.

Thus schedule S' would have a smaller makespan than schedule S, and we have proved that the load on the last $m-(i+1)$ processors is $(m-(i+1))s_k + p_k$.

In total, we have

$$\begin{aligned}\sum p_j &\geq (i+1)C_k - p_k \quad + \quad (m-(i+1))s_k + p_k \\ &= (i+1)(s_k+p_k) - p_k \quad + \quad (m-(i+1))s_k + p_k = (i+1)p_k + ms_k\end{aligned}$$

or, equivalently,

$$s_k \leq \frac{\sum p_j - (i+1)p_k}{m}. \qquad \square$$

LEMMA 2.3. *Let S be an optimal i-preemptive schedule with makespan $C_{max}^{ip^*}$. Let J_k be a job with $C_k = C_{max}^{ip^*}$, $p_k < \sum p_j/m$, and*

$$p_k \leq C_{max}^{p^*} \left(\frac{m}{m+i+1} \right). \tag{2.2}$$

For $0 \leq i \leq m-1$, the maximum number of allowed preemptions, we have, for all instances of the problem $P \mid i - pmtn \mid C_{max}$,

$$C_{max}^{ip^*} \leq \left(2 - \frac{2}{\left(\frac{m}{i+1}\right)+1} \right) C_{max}^{p^*}.$$

Proof. From Lemma 2.2 we know that job J_k is not preempted. Thus we have for the schedule length of the optimal i-preemptive schedule

$$C_{max}^{ip^*} = s_k + p_k.$$

With the help of Lemma 2.2, we have

$$C_{max}^{ip^*} \leq \frac{\sum p_j - (i+1)p_k}{m} + p_k = \frac{\sum p_j}{m} + \frac{m-(i+1)}{m} p_k.$$

McNaughton's bound (2.1) and assumption (2.2) lead to

$$C_{max}^{ip^*} \leq C_{max}^{p^*} + \frac{m-(i+1)}{m} \frac{m}{m+(i+1)} C_{max}^{p^*} = \left(2 - \frac{2}{(\frac{m}{i+1})+1} \right) C_{max}^{p^*}. \qquad \square$$

LEMMA 2.4. *Let S be an optimal i-preemptive schedule with makespan $C_{max}^{ip^*}$. Let J_k be a job with $C_k = C_{max}^{ip^*}$, $p_k < \sum p_j/m$, and*

$$p_k > C_{max}^{p^*} \left(\frac{m}{m+i+1} \right). \tag{2.3}$$

For $0 \leq i \leq m-1$, the maximum number of allowed preemptions, we have, for all instances of the problem $P \mid i - pmtn \mid C_{max}$,

$$C_{max}^{ip^*} \leq \left(2 - \frac{2}{\left(\frac{m}{i+1}\right)+1} \right) C_{max}^{p^*}.$$

Proof. This proof is by contradiction. We assume that there is an optimal i-preemptive schedule S with $C_{max}^{ip^*} > (2-2/(m/(i+1)+1))C_{max}^{p^*}$. In this case, there is always a processor with a load of at most $(m/(m+i+1))C_{max}^{p^*}$, as we can see as follows. If there would not exist a processor with a load of maximum $(m/(m+i+1))C_{max}^{p^*}$,

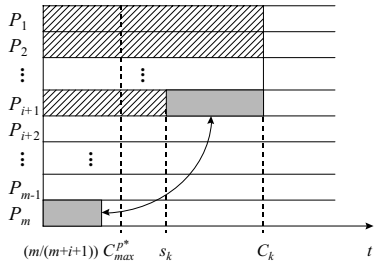

FIG. 2.6. *Lemma* 2.4, *Case* 1.

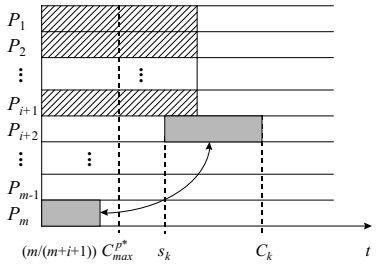

FIG. 2.7. *Lemma* 2.4, *Case* 2.

we would have

$$\begin{aligned}\sum p_j &> (i+1)C^{ip^*}_{max} \quad + \quad (m-(i+1))\left(\frac{m}{m+i+1}\right)C^{p^*}_{max} \\ &> (i+1)\left(2-\frac{2}{\left(\frac{m}{i+1}\right)+1}\right)C^{p^*}_{max} \quad + \quad (m-(i+1))\left(\frac{m}{m+i+1}\right)C^{p^*}_{max} \\ &= mC^{p^*}_{max}\ .\end{aligned}$$

This would be a contradiction to McNaughton's bound (2.1). Thus there is a processor with a load of at most $m/(m+i+1)C^{p^*}_{max}$. Without loss of generality, we assume that this processor is P_m with finish time F_m.

Case 1. In an optimal i-preemptive schedule S, J_k is processed on one of the first $i+1$ processors (without loss of generality on P_{i+1}). In this case, one could construct a new schedule S' with smaller makespan as follows. If we would switch job J_k with the jobs processed on processor P_m, we would obtain a new schedule S' with the following properties (see Figure 2.6).

1. Because of (2.3), we know that $p_k > (m/(m+i+1))C^{p^*}_{max}$. By switching all the jobs scheduled on P_m with J_k, the total capacity to be scheduled on processors $P_1, \ldots, P_{i+1}$ reduces by $p_k - F_m$ in schedule S'. As we are allowed to schedule the remaining capacity with McNaughton's *wrap around* rule, and as there is no job J_j with $p_j = C^{ip^*}_{max}$, the finish times of processors $P_1, \ldots, P_{i+1}$ in schedule S' are less than C_k of schedule S.
2. The finish times of processors $P_{i+2}, \ldots, P_{m-1}$ remain unchanged.
3. As the finish time F_m on P_m was less than p_k (in schedule S), and as J_k was not the only job scheduled on P_{i+1} (in schedule S), the finish time on P_m in schedule S' is less than C_k of schedule S.

Thus the makespan generated by S' is smaller than the makespan generated by S, which leads to a contradiction to the assumption of the optimality of S.

Case 2. In an optimal i-preemptive schedule S, J_k is processed on one of the last $m-(i+1)$ processors (without loss of generality on P_{i+2}). In this case, one could construct a new schedule S' with smaller makespan as follows. If we switch job J_k with the jobs processed on processor P_m, we obtain a new schedule S' with the following properties (see Figure 2.7).

1. The finish times of processors $P_1, \ldots, P_{i+1}$ remain unchanged.
2. Because of (2.3), we know that $p_k > (m/(m+i+1))C^{p^*}_{max}$. As the finish time F_m on P_m was less than p_k (in schedule S), the finish time on P_{i+2} in schedule S' is less than C_k of schedule S.

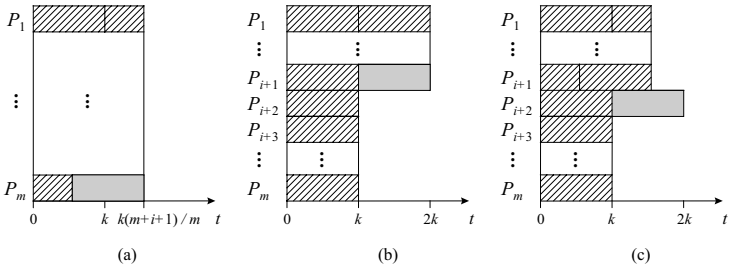

FIG. 2.8. *Optimal preemptive and i-preemptive schedules.*

3. The finish times of processors $P_{i+3}, \ldots, P_{m-1}$ remain unchanged.
4. As J_k was not the only job to be scheduled on P_{i+1} in schedule S, the finish time on P_m in schedule S' is less than C_k of schedule S.

Thus the makespan generated by S' is smaller than the makespan generated by S, which leads to a contradiction to the assumption of the optimality of S. □

THEOREM 2.5. *Let S be an optimal i-preemptive schedule with makespan $C_{max}^{ip^*}$. For $0 \leq i \leq m-1$, the maximum number of allowed preemptions, we have, for all instances of the problem $P \mid i - pmtn \mid C_{max}$,*

$$C_{max}^{ip^*} \leq \left(2 - \frac{2}{\left(\frac{m}{i+1}\right)+1}\right) C_{max}^{p^*} .$$

Proof. The proof is by Lemmas 2.3 and 2.4. □

To show the tightness of the bound $C_{max}^{ip^*} \leq (2 - 2/(m/(i+1)+1))C_{max}^{p^*}$, we consider the following problem instance: n jobs are to be scheduled on m processors with $n = m+i+1$ and $p_j = k, j = 1, \ldots, n$. The optimal i-preemptive schedule always has length $2k$, whereas the optimal preemptive schedule length is $k(m+i+1)/m$ (see Figure 2.8).

Job J_k with $C_k = C_{max}^{ip^*}$ is marked grey. In figure (a), the jobs are scheduled with McNaughton's rule. In figure (b), job J_k is scheduled on the first $i+1$ processors which allow preemptions (without loss of generality on P_{i+1}). In figure (c), job J_k is scheduled on the last $m-(i+1)$ processors which forbid preemptions (without loss of generality on P_{i+2}). In both cases (b) and (c), there must exist a processor that schedules two jobs without preemption.

We have

$$\frac{C_{max}^{ip^*}}{C_{max}^{p^*}} = \frac{2k}{k(m+i+1)/m} = \left(2 - \frac{2}{\left(\frac{m}{i+1}\right)+1}\right).$$

In the following, we show that the relation between a schedule constructed with the *LPT* rule and an optimal preemptive schedule is bounded from above by $2 - 2/(m+1)$.

THEOREM 2.6. *For schedules generated with the LPT rule, we have, for all instances,*

$$C_{max}^{LPT} \leq \left(2 - \frac{2}{m+1}\right) C_{max}^{p^*}.$$

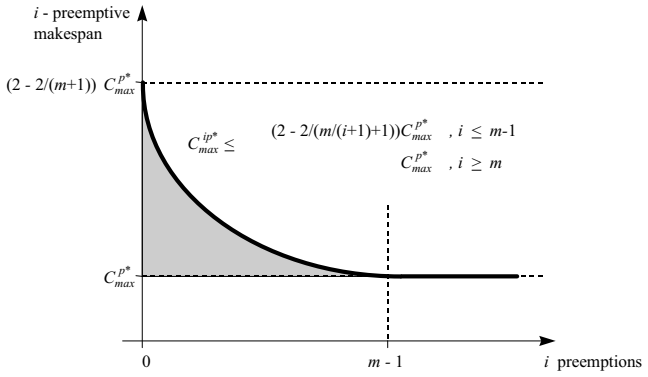

FIG. 3.1. *i-preemptive makespan (worst-case).*

Proof. Let J_k be the job that determines the schedule length of the LPT schedule. If $p_k \leq (m/(m+1))C_{max}^{p^*}$, we have

$$C_{max}^{LPT} = s_k + p_k \leq \frac{\sum p_j - p_k}{m} + p_k = \frac{\sum p_j}{m} + \left(1 - \frac{1}{m}\right) p_k$$
$$\leq C_{max}^{p^*} + \left(1 - \frac{1}{m}\right) C_{max}^{p^*} \left(\frac{m}{m+1}\right) = \left(2 - \frac{2}{m+1}\right) C_{max}^{p^*} .$$

If $p_k > (m/(m+1))C_{max}^{p^*}$, we have

$$p_k > C_{max}^{p^*} \left(\frac{m}{m+1}\right) \geq \left(\frac{\sum p_j}{m}\right) \left(\frac{m}{m+1}\right) = \frac{\sum p_j}{m+1}$$
$$\Longrightarrow p_k > \frac{\sum p_j, j \neq k}{m} \quad \geq \quad s_k$$
$$\Longrightarrow s_k < p_k.$$

s_k is only less than p_k if $s_k = 0$. (Note that the schedule is generated with the LPT rule.) Thus we have $C_{max}^{LPT} = C_{max}^{p^*}$ if $p_k > (m/(m+1))C_{max}^{p^*}$. □

For $i = 0$, this bound is also met by schedules generated by the LPT rule.

3. Summary. We compared the length of preemptive and i-preemptive schedules for the problem in which a set of n independent jobs has to be scheduled on m identical processors that operate in parallel. The objective is to minimize the makespan. We showed that the ratio of the optimal i-preemptive schedule length $C_{max}^{ip^*}$ (with a limited number $0 \leq i \leq m-1$ of preemptions) versus the optimal preemptive schedule length $C_{max}^{p^*}$ is bounded from above by $C_{max}^{ip^*} \leq (2 - 2/(m/(i+1)+1))C_{max}^{p^*}$. The grey region in Figure 3.1 displays all possible makespans as a function of the number i of maximum allowed preemptions.

Furthermore, we showed that the ratio of the length C_{max}^{LPT} of a nonpreemptive schedule generated by the LPT rule versus the optimal preemptive schedule length $C_{max}^{p^*}$ is bounded from above by exactly the same bound if $i = 0$. We gave an example which shows the tightness of the bounds.

Further research is needed to investigate the trade-off between the objectives of minimizing the makespan (time objective) and minimizing the number of preemptions (cost objective), i.e., to find a minimal length schedule for a given i. Clearly, if

$i \geq m-1$, one can generate an optimal schedule with the algorithm of McNaughton. For any value between 0 and $m-2$, however, the problem of finding a minimal length schedule is NP-hard.

The same problem arises if we try to find a schedule with a makespan not greater than $C_{max}^{allowed}$ and with a minimal number of preemptions. Clearly, if $C_{max}^{allowed} < C_{max}^{p^*}$, then there is no feasible schedule, and if $C_{max}^{allowed} \geq 2 - (2/(m+1))C_{max}^{p^*}$, then any LPT schedule meets this bound by generating no preemptions. For any value between these two values, however, the problem of minimizing the number of preemptions is NP-hard.

NONDETERMINISTIC QUANTUM QUERY AND COMMUNICATION COMPLEXITIES*

RONALD DE WOLF†

Abstract. We study nondeterministic quantum algorithms for Boolean functions f. Such algorithms have positive acceptance probability on input x iff $f(x) = 1$. In the setting of query complexity, we show that the nondeterministic quantum complexity of a Boolean function is equal to its "nondeterministic polynomial" degree. We also prove a quantum-vs.-classical gap of 1 vs. n for nondeterministic query complexity for a total function. In the setting of communication complexity, we show that the nondeterministic quantum complexity of a two-party function is equal to the logarithm of the rank of a nondeterministic version of the communication matrix. This implies that the quantum communication complexities of the equality and disjointness functions are $n + 1$ if we do not allow any error probability. We also exhibit a total function in which the nondeterministic quantum communication complexity is exponentially smaller than its classical counterpart.

Key words. quantum computing, query complexity, communication complexity, nondeterminism

1. Introduction.

1.1. Motivation. In classical computing, *nondeterministic* computation has a prominent place in many different models and for many good reasons. For example, in Turing machine complexity, the study of nondeterminism leads naturally to the class of NP-complete problems, which contains some of the most important and practically relevant computer science problems—as well as some of the hardest theoretical open questions. In fields like query complexity and communication complexity, there is a tight relation between deterministic complexity and nondeterministic complexity, but it is often much easier to analyze upper and lower bounds for the latter than for the former.

Suppose we want to compute a Boolean function f in some algorithmic setting, such as that of Turing machines, decision trees, or communication protocols. Consider the following two ways of viewing a nondeterministic algorithm. The first and most common way is to think of it as a "certificate verifier": a deterministic algorithm A that receives, apart from the input x, a "certificate" y whose validity it needs to verify. For all inputs x, if $f(x) = 1$, then there is a certificate y such that $A(x, y) = 1$; if $f(x) = 0$, then $A(x, y) = 0$ for all y. Second, we may view A as a *randomized* algorithm whose acceptance probability is positive if $f(x) = 1$ and whose acceptance probability is zero if $f(x) = 0$. It is easy to see that these two views are equivalent in the classical case. To turn an algorithm A of the first kind into one of the second kind, we can just guess a certificate y at random and output $A(x, y)$. This will have positive acceptance probability iff $f(x) = 1$. For the other direction, we can consider

the sequence of coin flips used by an algorithm of the second kind as a certificate. Clearly, there will be a certificate leading to output 1 iff $f(x) = 1$, which gives us an algorithm of the first kind.

Both views may be generalized to the quantum case, yielding *three* potential definitions of nondeterministic quantum algorithms, possibly nonequivalent. The quantum algorithm may be required to output the right answer $f(x)$ when given an appropriate certificate, which we can take to be either quantum or classical. Or, third, the quantum algorithm may be required to have positive acceptance probability iff $f(x) = 1$. An example is given by two alternative definitions of quantum nondeterminism in the case of quantum Turing machine complexity. Kitaev defines the class "bounded-error quantum-NP" (BNQP) as the set of languages accepted by polynomial-time bounded-error quantum algorithms that are given a polynomial-size quantum certificate (e.g., [32, 31] and [30, Chapter 14]). On the other hand, Adleman, Demarrais, and Huang [2] and Fenner et al. [24] define quantum-NP as the set of languages L for which there is a polynomial-time quantum algorithm whose acceptance probability is positive iff $x \in L$. This quantum class was shown to be equal to the classical counting class co-$\mathrm{C_{=}P}$ [24, 52] using tools from Fortnow and Rogers [25].

In this paper, we adopt the latter view: a nondeterministic quantum algorithm for f is defined to be a quantum algorithm that outputs 1 with positive probability if $f(x) = 1$ and that always outputs 0 if $f(x) = 0$. This definition contrasts with the more traditional view of classical determinism as "certificate verification." The motivation for our choice of definition of quantum nondeterminism is twofold. First, in the appendix, we show that this definition is strictly more powerful than the other two possible definitions in the sense of being able to simulate the other definitions efficiently, while the reverse is not true. Second, it turns out that this definition lends itself to very crisp results. Rather than in the quantum Turing machine setting of Kitaev, Adleman, etc., we study the complexity of nondeterministic algorithms in the query complexity and communication complexity settings. Our main results are exact characterizations of these nondeterministic quantum complexities in algebraic terms and large gaps between quantum and classical complexities in both settings. Our algebraic characterizations can be extended to nontotal functions in the obvious way, but we will stick to total functions in our presentation.

1.2. Query complexity. We first consider the model of query complexity, also known as decision tree complexity or black box complexity. Here the goal is to compute some function $f : \{0,1\}^n \to \{0,1\}$, making as few queries to input bits as possible. Most existing quantum algorithms can naturally be expressed in this model and achieve provable speed-ups over the best classical algorithms. Examples can be found, e.g., in [22, 48, 26, 12, 13, 14] and also include the order-finding problem on which Shor's celebrated factoring algorithm is based [47].

Let $D(f)$ and $Q_E(f)$ denote the query complexities of optimal deterministic and quantum algorithms that compute f exactly. Let $deg(f)$ denote the minimal degree among all multilinear polynomials that represent f. (A polynomial p represents f if $f(x) = p(x)$ for all $x \in \{0,1\}^n$.) The following relations are known. The first inequality is due to Beals et al. [6], the second inequality is obvious, and the last is due to Nisan and Smolensky—unpublished, but described in the survey paper [20].

$$\frac{deg(f)}{2} \leq Q_E(f) \leq D(f) \leq O(deg(f)^4).$$

Thus $deg(f)$, $Q_E(f)$, and $D(f)$ are polynomially related for all total f. (The situation

is very different for partial f [22, 48, 47, 7].) Nisan and Szegedy [42] exhibit a function with a large gap between $D(f) = n$ and $deg(f) = n^{0.6\cdots}$, but no function is known where $Q_E(f)$ is significantly larger than $deg(f)$, and it may in fact be true that $Q_E(f)$ and $deg(f)$ are linearly related. In section 2, we show that the *nondeterministic* versions of $Q_E(f)$ and $deg(f)$ are in fact *equal*:

$$NQ(f) = ndeg(f).$$

Here $NQ(f)$ denotes the query complexity of an optimal nondeterministic quantum algorithm for f, which has nonzero acceptance probability iff $f(x) = 1$. The nondeterministic degree $ndeg(f)$ is the minimal degree of a so-called *nondeterministic* polynomial for f, which is required to be nonzero iff $f(x) = 1$. A note on terminology: the name "nondeterministic polynomial" is based only on analogy with the acceptance probability of a nondeterministic algorithm. This name is less than ideal, since such polynomials have little to do with the traditional view of nondeterminism as certificate verification. Nevertheless, we use this name because any alternatives that we could think of were worse (too verbose or confusing).

Apart from the algebraic characterization of the nondeterministic quantum query complexity $NQ(f)$, we also show that $NQ(f)$ may be much smaller than its classical analogue $N(f)$: we exhibit an f where $NQ(f) = 1$ and $N(f) = n$, which is the biggest possible gap allowed by this model. Accordingly, while the case of exact (or, for that matter, bounded-error) computation allows at most polynomial quantum-classical query complexity gaps for total functions, the nondeterministic case allows *unbounded* gaps.

1.3. Communication complexity. In the case of communication complexity, the goal is for two distributed parties, Alice and Bob, to compute some function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. Alice receives an $x \in \{0,1\}^n$, and Bob receives a $y \in \{0,1\}^n$, and they want to compute $f(x,y)$, exchanging as few bits of communication as possible. This model was introduced by Yao [53] and is fairly well understood for the case in which Alice and Bob are classical players exchanging classical bits [36]. Much less is known about *quantum* communication complexity, where Alice and Bob have a quantum computer and can exchange qubits. This was first studied by Yao [54], and it was shown later that quantum communication complexity can be significantly smaller than classical communication complexity [21, 17, 5, 44, 16].

Let $Dcc(f)$ and $Qcc_E(f)$ denote the communication required for optimal deterministic classical and exact quantum protocols for computing f, respectively.[1] Here we assume Alice and Bob do not share any randomness or prior entanglement. Let $rank(f)$ be the rank of the $2^n \times 2^n$ communication matrix M_f, which is defined by $M_f(x,y) = f(x,y)$. The following relations are known:

$$\frac{\log rank(f)}{2} \leq Qcc_E(f) \leq Dcc(f).$$

The first inequality follows from work of Kremer [35] and Yao [54], as first noted by Buhrman, Cleve, and Wigderson [17]. (In [19] it is shown that this lower bound also holds if the quantum protocol can make use of unlimited prior entanglement between Alice and Bob.) It is an open question whether $Dcc(f)$ can in turn be upper bounded

[1] The notation $D(f)$ is used for deterministic complexity in decision tree complexity as well as in communication complexity. To avoid confusion, we will consistently add "cc" to indicate communication complexity.

by some polynomial in $\log rank(f)$. The conjecture that it can is known as the *log-rank conjecture*. If this conjecture holds, then $Dcc(f)$ and $Qcc_E(f)$ are polynomially related for all total f (which may well be true). It is known that $\log rank(f)$ and $Dcc(f)$ are not linearly related [43]. In section 3, we show that the *nondeterministic* version of $\log rank(f)$ in fact fully determines the nondeterministic version of $Qcc_E(f)$:

$$NQcc(f) = \lceil \log nrank(f) \rceil + 1.$$

Here $nrank(f)$ denotes the minimal rank of a matrix whose (x, y)-entry is nonzero iff $f(x, y) = 1$. Thus we can characterize the nondeterministic quantum communication complexity fully by the logarithm of the rank of its nondeterministic matrix. As far as we know, only two other log-rank-style characterizations of certain variants of communication complexity are known: the communication complexity of quantum sampling due to Ambainis et al. [5] and the so-called modular communication complexity due to Meinel and Waack [38].

Equality and disjointness both have nondeterministic rank 2^n, so their nondeterministic complexities are maximal: $NQcc(\text{EQ}) = NQcc(\text{DISJ}) = n+1$. Since $NQcc(f)$ lower bounds $Qcc_E(f)$, we also obtain optimal bounds for the exact quantum communication complexity of equality and disjointness. In particular, for the equality function, we get $Qcc_E(\text{EQ}) = n + 1$, which answers a question posed by Gilles Brassard in a personal communication [10]. Surprisingly, no proof of this fact seems to be known that avoids our detour via nondeterministic computation. Thus our methods also give new lower bounds for regular quantum communication complexity.

Finally, analogous to the query complexity case, we also show an exponential gap between quantum and classical nondeterministic communication complexity: we exhibit an f where $NQcc(f) \leq \log(n + 1) + 1$ and $Ncc(f) \in \Omega(n)$. Massar et al. [37] earlier found another gap that is unbounded, yet in some sense smaller: $NQcc(\text{NE}) = 2$ versus $Ncc(\text{NE}) = \log n + 1$, where NE is the nonequality function.

2. Nondeterministic quantum query complexity.

2.1. Functions and polynomials. For $x \in \{0, 1\}^n$, we use $|x|$ for the Hamming weight (number of 1's) of x, and x_i for its ith bit, $i \in [n] = \{1, \ldots, n\}$. We use $\vec{0}$ for a string of n zeros. If $B \subseteq [n]$ is a set of (indices of) variables, then x^B denotes the input obtained from x by complementing all variables in B. If $x, y \in \{0, 1\}^n$, then $x \wedge y$ denotes the n-bit string obtained by bitwise ANDing x and y. Let $f : \{0, 1\}^n \to \{0, 1\}$ be a total Boolean function. For example, $\text{OR}(x) = 1$ iff $|x| \geq 1$, $\text{AND}(x) = 1$ iff $|x| = n$, $\text{PARITY}(x) = 1$ iff $|x|$ is odd. We use $\overline{f}$ for the function $1 - f$.

For $b \in \{0, 1\}$, a *b-certificate* for f is an assignment $C : S \to \{0, 1\}$ to some set S of variables, such that $f(x) = b$ whenever x is consistent with C. The *size* of C is $|S|$. The *certificate complexity* $C_x(f)$ of f on input x is the minimal size of an $f(x)$-certificate that is consistent with x. We define the 1-certificate complexity of f as $C^{(1)}(f) = \max_{x:f(x)=1} C_x(f)$. We define $C^{(0)}(f)$ similarly. For example, $C^{(1)}(\text{OR}) = 1$ and $C^{(0)}(\text{OR}) = n$, but $C^{(1)}(\overline{\text{OR}}) = n$ and $C^{(0)}(\overline{\text{OR}}) = 1$.

An n-variate *multilinear polynomial* is a function $p : \mathbb{C}^n \to \mathbb{C}$ that can be written

$$p(x) = \sum_{S \subseteq [n]} a_S X_S.$$

Here S ranges over all sets of indices of variables, a_S is a complex number, and the monomial X_S is the product $\Pi_{i \in S} x_i$ of all variables in S. The *degree* $deg(p)$

of p is the degree of a largest monomial with nonzero coefficient. It is well known that every total Boolean f has a unique polynomial p such that $p(x) = f(x)$ for all $x \in \{0,1\}^n$. Let $deg(f)$ be the degree of this polynomial, which is at most n. For example, $\mathrm{OR}(x_1, x_2) = x_1 + x_2 - x_1x_2$, which has degree 2. Every multilinear polynomial $p = \sum_S a_S X_S$ can also be written out uniquely in the so-called *Fourier basis*:

$$p(x) = \sum_S c_S(-1)^{x \cdot S}.$$

Again S ranges over all sets of indices of variables (we often identify a set S with its characteristic n-bit vector), c_S is a complex number, and $x \cdot S$ denotes the inner product of the n-bit strings x and S, or, equivalently, $x \cdot S = |x \wedge S| = \sum_{i \in S} x_i$. It is easy to see that $deg(p) = \max\{|S| \mid c_S \neq 0\}$. For example, $\mathrm{OR}(x_1, x_2) = \frac{3}{4} - \frac{1}{4}(-1)^{x_1} - \frac{1}{4}(-1)^{x_2} - \frac{1}{4}(-1)^{x_1+x_2}$ in the Fourier basis. We refer to [8, 42, 20] for more details about polynomial representations of Boolean functions.

We introduce the notion of a *nondeterministic polynomial* for f. This is a polynomial p such that $p(x) \neq 0$ iff $f(x) = 1$. Let the *nondeterministic degree* of f, denoted $ndeg(f)$, be the minimum degree among all nondeterministic polynomials p for f. For example, $p(x) = \sum_{i=1}^n x_i$ is a nondeterministic polynomial for OR; hence $ndeg(\mathrm{OR}) = 1$.

We mention some upper and lower bounds for $ndeg(f)$. Let f be a nonconstant symmetric function (i.e., $f(x)$ depends only on $|x|$). Suppose f achieves value 0 on the z Hamming weights, $k_1, \ldots, k_z$. Since $|x| = \sum_i x_i$, it is easy to see that $(|x|-k_1)(|x|-k_2)\cdots(|x|-k_z)$ is a nondeterministic polynomial for f; hence $ndeg(f) \leq z$. This upper bound is tight for AND (see below) but not for PARITY. For example, $p(x_1, x_2) = x_1 - x_2$ is a degree-1 nondeterministic polynomial for PARITY on two variables: it assumes value 0 on x-weights 0 and 2 and ± 1 on weight 1. By squaring $p(x)$ and then using standard symmetrization techniques (as used, for instance, in [39, 42, 6]), we can also show the general lower bound $ndeg(f) \geq z/2$ for symmetric f. Furthermore, it is easy to show that $ndeg(f) \leq C^{(1)}(f)$ for every f. (Take a polynomial that is the "sum" over all 1-certificates for f.)

Finally, we mention a general lower bound on $ndeg(f)$. Let $\Pr[p \neq 0] = |\{x \in \{0,1\}^n \mid p(x) \neq 0\}|/2^n$ denote the probability that a random Boolean input x makes a function p nonzero. A lemma of Schwartz [46] (see also [42, section 2.2]) states that if p is a nonconstant multilinear polynomial of degree d, then $\Pr[p \neq 0] \geq 2^{-d}$, and hence $d \geq \log(1/\Pr[p \neq 0])$. Since a nondeterministic polynomial p for f is nonzero iff $f(x) = 1$, it follows that

$$ndeg(f) \geq \log(1/\Pr[f \neq 0]) = \log(1/\Pr[f = 1]).$$

Accordingly, functions with a very small fraction of 1-inputs will have high nondeterministic degree. For instance, $\Pr[\mathrm{AND} = 1] = 2^{-n}$, so $ndeg(\mathrm{AND}) = n$.

2.2. Quantum computing. We assume familiarity with classical computation and briefly sketch the setting of quantum computation (see, e.g., [40] for more details). An *m-qubit state* is a linear combination of all classical m-bit states

$$|\phi\rangle = \sum_{i \in \{0,1\}^m} \alpha_i |i\rangle,$$

where $|i\rangle$ denotes the basis state i (a classical m-bit string) and α_i is a complex number that is called the *amplitude* of $|i\rangle$. We require $\sum_i |\alpha_i|^2 = 1$. Viewing $|\phi\rangle$ as

a 2^m-dimensional column vector, we use $\langle\phi|$ for the row vector that is the conjugate transpose of $|\phi\rangle$. Note that the inner product $\langle i||j\rangle = \langle i|j\rangle$ is 1 if $i = j$ and 0 if $i \neq j$. When we observe $|\phi\rangle$, we will see $|i\rangle$ with probability $|\langle i|\phi\rangle|^2 = |\alpha_i|^2$, and the state will collapse to the observed $|i\rangle$. A quantum operation which is not an observation corresponds to a unitary (i.e., norm-preserving) transformation U on the 2^m-dimensional vector of amplitudes.

2.3. Query complexity. Suppose we want to compute some function $f : \{0,1\}^n \to \{0,1\}$. For input $x \in \{0,1\}^n$, a *query* corresponds to the unitary transformation O that maps $|i,b,z\rangle \to |i,b \oplus x_i,z\rangle$. Here $i \in [n]$ and $b \in \{0,1\}$; the z-part corresponds to the workspace, which is not affected by the query. We assume that the input can be accessed only via such queries. A T-query quantum algorithm has the form $A = U_T O U_{T-1} \cdots O U_1 O U_0$, where the U_k are fixed unitary transformations, independent of the input x. This A depends on x via the T applications of O. We sometimes write A_x to emphasize this. The algorithm starts in initial state $|\vec{0}\rangle$, and its *output* is the bit obtained from observing the leftmost qubit of the final superposition $A|\vec{0}\rangle$. The *acceptance probability* of A (on input x) is its probability of outputting 1 (on x).

We will consider classical and quantum algorithms and will count only the number of queries these algorithms make on a worst-case input. Let $D(f)$ and $Q_E(f)$ be the query complexities of optimal deterministic classical and exact quantum algorithms for computing f, respectively. $D(f)$ is also known as the decision tree complexity of f. Similarly we can define $R_2(f)$ and $Q_2(f)$ to be the query complexity of f for bounded-error classical and quantum algorithms, respectively. Quantum query complexity and its relation to classical complexity has been well studied in recent years; see, for example, [6, 4, 20].

We define a *nondeterministic algorithm* for f to be an algorithm that has positive acceptance probability on input x iff $f(x) = 1$. Let $N(f)$ and $NQ(f)$ be the query complexities of optimal nondeterministic classical and quantum algorithms for f, respectively. It is easy to show that the 1-certificate complexity fully characterizes the classical nondeterministic complexity of f.

PROPOSITION 2.1. $N(f) = C^{(1)}(f)$.

Proof. A classical algorithm that guesses a 1-certificate, queries its variables, and outputs 1 iff the certificate holds is a nondeterministic algorithm for f. Hence $N(f) \leq C^{(1)}(f)$.

A nondeterministic algorithm for f can only output 1 if the outcomes of the queries that it has made force the function to 1. Hence, if x is an input where all 1-certificates have size at least $C^{(1)}(f)$, then the algorithm will have to query at least $C^{(1)}(f)$ variables before it can output 1 (which it must do on some runs). Hence $N(f) \geq C^{(1)}(f)$. □

2.4. Algebraic characterization. Here we show that $NQ(f)$ is equal to $ndeg(f)$, using the following result from [6].

LEMMA 2.2 (see [6]). *The amplitudes of the basis states in the final superposition of a T-query quantum algorithm can be written as multilinear complex-valued polynomials of degree $\leq T$ in the n x_i-variables. Therefore, the acceptance probability of the algorithm (which is the sum of squares of some of those amplitudes) can be written as an n-variate multilinear polynomial $P(x)$ of degree $\leq 2T$.*

Note that the acceptance probability of a nondeterministic quantum algorithm is actually a nondeterministic polynomial for f, since it is positive iff $f(x) = 1$. By Lemma 2.2, this polynomial will have degree at most twice the number of queries

of the algorithm, which immediately implies $ndeg(f)/2 \leq NQ(f)$. Below we will show how we can get rid of the factor $1/2$ in this lower bound, improving it to $ndeg(f) \leq NQcc(f)$. We show that this lower bound is in fact optimal by deriving a nondeterministic algorithm from a nondeterministic polynomial. This derivation uses a trick similar to the one used in [24] to show that co-C$_=$P $\subseteq$ quantum-NP.

THEOREM 2.3. *$NQ(f) = ndeg(f)$.*

Proof. Upper bound. Let $p(x)$ be a nondeterministic polynomial for f of degree $d = ndeg(f)$. Recall that $x \cdot S$ denotes $|x \wedge S|$, identifying $S \subseteq [n]$ with its characteristic n-bit vector. We write p in the Fourier basis:

$$p(x) = \sum_S c_S (-1)^{x \cdot S}.$$

Since $deg(p) = \max\{|S| \mid c_S \neq 0\}$, we have that $c_S \neq 0$ only if $|S| \leq d$.

We can construct a unitary transformation F that uses d queries to x and maps $|S\rangle \rightarrow (-1)^{x \cdot S}|S\rangle$ whenever $|S| \leq d$. Informally, this transformation does a controlled parity-computation: it computes $|x \cdot S| \pmod 2$ using $|S|/2$ queries [6, 23], then adds a phase "-1" if that answer is 1, and then reverses the computation to clean up the workspace and the answer at the cost of another $|S|/2$ queries. (If $|S|$ is odd, then one variable is treated separately, still using $|S|$ queries in total.)

Now consider the following quantum algorithm:

1. Start with $c \sum_S c_S |S\rangle$ (an n-qubit state, where $c = 1/\sqrt{\sum_S |c_S|^2}$ is a normalizing constant).
2. Apply F to the state.
3. Apply a Hadamard transform H to each qubit.
4. Measure the final state, and output 1 if the outcome is the all-zero state $|\vec{0}\rangle$, and output 0 otherwise.

The state after step 2 is $c \sum_S c_S (-1)^{x \cdot S} |S\rangle$. Note that the sum of the amplitudes in this state is $c \cdot p(x)$, which is nonzero iff $f(x) = 1$. The Hadamard transform in step 3 gives us this sum as amplitude of the $|\vec{0}\rangle$-state, with a normalizing factor of $1/\sqrt{2^n}$. Accordingly, the probability of observing $|\vec{0}\rangle$ at the end is

$$\begin{aligned} P(x) &= \left| \langle \vec{0} | H^{\otimes n} F c \sum_S c_S |S\rangle \right|^2 \\ &= \frac{c^2}{2^n} \left| \sum_{S'} \langle S' | \sum_S c_S (-1)^{x \cdot S} |S\rangle \right|^2 \\ &= \frac{c^2}{2^n} \left| \sum_S c_S (-1)^{x \cdot S} \right|^2 \\ &= \frac{c^2 p(x)^2}{2^n}. \end{aligned}$$

Since $p(x)$ is nonzero iff $f(x) = 1$, $P(x)$ will be positive iff $f(x) = 1$. Hence we have a nondeterministic quantum algorithm for f with $d = ndeg(f)$ queries.

Lower bound. Let $T = NQ(f)$, and consider a T-query nondeterministic quantum algorithm for f. By Lemma 2.2, the amplitudes α_i in the final state,

$$|\phi^x\rangle = \sum_i \alpha_i(x) |i\rangle,$$

on input x are n-variate polynomials of x of degree $\leq T$. We use the probabilistic method [3] to show that some linear combination of these polynomials is a nondeterministic polynomial for f, thus avoiding losing the factor $1/2$ mentioned after Lemma 2.2.

Let S be the set of basis states having a 1 as leftmost bit (observing such a state will lead the algorithm to output 1). Since the algorithm is nondeterministic, we have the following properties:

If $f(x) = 0$, then $\alpha_i(x) = 0$ for all $i \in S$.

If $f(x) = 1$, then $\alpha_i(x) \neq 0$ for at least one $i \in S$.

Let I be an arbitrary set of more than 2^n numbers. For each $i \in S$, pick a coefficient c_i uniformly at random from I, and define $p(x) = \sum_{i \in S} c_i \alpha_i(x)$. By the first property, we have $p(x) = 0$ whenever $f(x) = 0$. Now consider an x for which $f(x) = 1$, and let $k \in S$ satisfy $a = \alpha_k(x) \neq 0$. Such a k must exist by the second property. We want to show that the event $p(x) = 0$ happens only with very small probability (probability taken over the random choices of the c_i). In order to do this, we fix the random choices c_i for all $i \neq k$ and view $p(x) = ac_k + b$ as a linear function in the only not-yet-chosen coefficient c_k. Since $a \neq 0$, at most one out of $|I| > 2^n$ many possible choices of c_k can make $p(x) = 0$, so

$$\Pr[p(x) = 0] < 2^{-n}.$$

However, then, by the union bound we have

$$\Pr\left[\text{there is an } x \in f^{-1}(1) \text{ for which } p(x) = 0\right] \leq \sum_{x \in f^{-1}(1)} \Pr[p(x) = 0] < 2^n \cdot 2^{-n} = 1.$$

This probability is strictly less than 1, which shows that there exists a way of setting the coefficients c_i that satisfies $p(x) \neq 0$ for all $x \in f^{-1}(1)$, thus making p a nondeterministic polynomial for f. Since p is a sum of polynomials of degree $\leq T$, it follows that $ndeg(f) \leq deg(p) \leq T = NQ(f)$. □

2.5. Quantum-classical separation. What is the biggest possible gap between quantum and classical nondeterministic query complexity? Consider the total Boolean function $f : \{0,1\}^n \to \{0,1\}$ defined by

$$f(x) = 1 \text{ iff } |x| \neq 1.$$

It is easy to see that $N(f) = C^{(1)}(f) = C^{(0)}(f) = n$. On the other hand, the following is a degree-1 nondeterministic polynomial for f:

$$p(x) = \left(\sum_{i=1}^{n} x_i\right) - 1 = \frac{n}{2} - 1 - \frac{1}{2}\sum_{i=1}^{n}(-1)^{x_i}. \tag{2.1}$$

Thus we have that $NQ(f) = ndeg(f) = 1$. Explicitly, the 1-query algorithm that we get from the proof is as follows:

1. Start with $c\,((n/2-1)|\vec{0}\rangle - (1/2)\sum_i |e_i\rangle)$, where $c = 1/\sqrt{n^2/4 - 3n/4 + 1}$ and $|e_i\rangle$ has a 1 only at the ith bit.
2. Using one query, we can map $|e_i\rangle \to (-1)^{x_i}|e_i\rangle$.
3. Applying a Hadamard transform turns the amplitude of $|\vec{0}\rangle$ into $\alpha_{\vec{0}} = \frac{c}{\sqrt{2^n}}\,((n/2-1) - \sum_i (-1)^{x_i}/2) = cp(x)/\sqrt{2^n}$.

4. Hence the probability of observing $|\vec{0}\rangle$ at the end is $\alpha_{\vec{0}}^2 = c^2 p(x)^2/2^n$.

For the complement of f, we can easily show $NQ(\overline{f}) = ndeg(\overline{f}) \geq n-1$ (the "-1" is tight for $n=2$; witness $p(x) = x_1 - x_2$). In sum, we have the following theorem.

THEOREM 2.4. *For the above f, we have $NQ(f) = 1$, $NQ(\overline{f}) \geq n-1$, and $N(f) = N(\overline{f}) = n$.*

2.6. Relation to some other complexity measures. Many relations are known between all sorts of complexity measures of Boolean functions, such as polynomial degree, certificate complexity, various classical and quantum decision tree complexities, etc. A survey may be found in [20]. In this subsection, we will similarly embed $ndeg(f)$ $(= NQ(f))$ in this web of relations and give upper bounds on $D(f)$ in terms of $ndeg(f)$, $C(f)$, and the *block sensitivity* $bs(f)$, which is defined as follows. A set of (indices of) variables $B \subseteq [n]$ is called a *sensitive block* for f on input x if $f(x) \neq f(x^B)$; B is *minimal* if no $B' \subset B$ is sensitive. The block sensitivity $bs_x(f)$ is the maximal number of disjoint minimal sensitive blocks in x, and $bs^{(b)}(f) = \max_{x \in f^{-1}(b)} bs_x(f)$.

LEMMA 2.5. *If $f(x) = 0$ and B is a minimal sensitive block for f on x, then $|B| \leq ndeg(f)$.*

Proof. Assume without loss of generality that $x = \vec{0}$. Because B is minimal, for every proper subset B' of B, we have $f(x) = f(x^{B'}) = 0$, but on the other hand $f(x^B) = 1$. Accordingly, if we fix all variables outside of B to zero, then we obtain the AND-function of $|B|$ variables, which requires nondeterministic degree $|B|$. Hence $|B| \leq ndeg(f)$. □

LEMMA 2.6. $C^{(0)}(f) \leq bs^{(0)}(f) ndeg(f)$.

Proof. Consider any input x. As Nisan [41] proved, the union of a maximal set of sensitive blocks forms a certificate for that input (for otherwise there would be one more sensitive block). If $f(x) = 0$, then there can be at most $bs^{(0)}(f)$ disjoint sensitive blocks, and by the previous lemma each block contains at most $ndeg(f)$ variables. Hence each 0-input contains a certificate of at most $bs^{(0)}(f) ndeg(f)$ variables. □

The following theorem improves upon an argument of Nisan and Smolensky, described in [20].

THEOREM 2.7. $D(f) \leq C^{(0)}(f) ndeg(f)$.

Proof. Let p be a nondeterministic polynomial for f of degree $d = ndeg(f)$. Note that if we take a 0-certificate $C : S \to \{0,1\}$ and fix the S-variables accordingly, then p must reduce to the constant-0 polynomial. This implies that S intersects all degree-d monomials of p, because a nonintersected degree-d monomial would still be present in the reduced polynomial, which would then not be constant-0. Thus taking a minimal 0-certificate and querying its variables reduces the degree of p by at least 1. Repeating this at most $ndeg(f)$ times, we reduce p to a constant polynomial and know $f(x)$. This algorithm takes at most $C^{(0)}(f) ndeg(f)$ queries. □

Combining this with the fact that $bs^{(0)}(f) \leq 6Q_2(f)^2$ [6], we obtain the following.

COROLLARY 2.8. $D(f) \leq bs^{(0)}(f) ndeg(f)^2 \leq 6\, Q_2(f)^2 NQ(f)^2$.

This corollary has the somewhat paradoxical consequence that if the nondeterministic complexity $NQ(f)$ is small, then the bounded-error complexity $Q_2(f)$ must be large (i.e., close to $D(f)$). For instance, if $NQ(f) = O(1)$, then $Q_2(f) = \Omega(\sqrt{D(f)})$. We hope that this result will help tighten the relation $D(f) = O(Q_2(f)^6)$ that was proved in [6].

3. Nondeterministic quantum communication complexity.

3.1. Communication complexity. In the standard version of communication complexity, two parties (Alice and Bob) want to compute some function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. For example, $\mathrm{EQ}(x,y) = 1$ iff $x = y$, $\mathrm{NE}(x,y) = 1$ iff $x \neq y$, and $\mathrm{DISJ}(x,y) = 1$ iff $|x \wedge y| = 0$. A *rectangle* is a subset $R = S \times T$ of the domain of f. R is a 1-*rectangle* (for f) if $f(x,y) = 1$ for all $(x,y) \in R$. A 1-*cover* for f is a set of 1-rectangles whose union contains all 1-inputs of f. $Cov^1(f)$ denotes the minimal size (i.e., minimal number of rectangles) of a 1-cover for f. Similarly, we define 0-rectangles, 0-covers, and $Cov^0(f)$.

The *communication matrix* M_f of f is the $2^n \times 2^n$ Boolean matrix whose (x,y)-entry is $f(x,y)$, and *rank*(f) denotes the rank of M_f over the field of complex numbers. A $2^n \times 2^n$ matrix M is called a *nondeterministic communication matrix* for f if it has the property that $M(x,y) \neq 0$ iff $f(x,y) = 1$. Thus M is any matrix obtainable by replacing 1-entries in M_f by nonzero complex numbers. Let the *nondeterministic rank* of f, denoted *nrank*(f), be the minimum rank (over the complex field) among all nondeterministic matrices M for f.[2]

We consider classical and quantum communication protocols and count only the amount of communication (bits or qubits) that these protocols make on a worst-case input. For classical communication protocols, we refer to [36]. Here we briefly define quantum communication protocols, referring to the surveys [49, 15, 33, 11, 51] for more details. The space in which the quantum protocol works consists of three parts: Alice's part, the communication channel, and Bob's part. (We do not write the dimensions of these spaces explicitly.) Initially these three parts contain only 0-qubits,

$$|0\rangle|0\rangle|0\rangle.$$

We assume Alice starts the protocol. She applies a unitary transformation $U_1^A(x)$ to her private space and part of the channel. This corresponds to her initial computation and her first message. The length of this message is the number of channel qubits on which $U_1^A(x)$ acts. The total state is now

$$(U_1^A(x) \otimes I^B)|0\rangle|0\rangle|0\rangle,$$

where $\otimes$ denotes tensor product, and I^B denotes the identity transformation on Bob's part. Then Bob applies a unitary transformation $U_2^B(y) = V_2^B(y)S_2^B$ to his part and the channel. First, the operation S_2^B "reads" Alice's message by swapping the contents of the channel with some fresh $|0\rangle$-qubits in Bob's private space. After this, the unitary $V_2^B(y)$ is applied to Bob's private space and part of the channel. This corresponds to Bob's private computation and his putting a message to Alice on the channel. The length of this new message is the number of channel-qubits on which

[2] This definition looks somewhat similar to the definition of the *Colin de Verdiére parameter* $\mu(G)$ of an undirected graph G [27]. For $G = (V,E)$ with $|V| = n$, $\mu(G)$ is defined to be the maximal corank ($= n - rank$) among all real symmetric $n \times n$ matrices M having the following three properties: (1) $M_{ij} < 0$ if $(i,j) \in E$ and $M_{ij} = 0$ if $i \neq j$ and $(i,j) \notin E$; (2) M has exactly one negative eigenvalue of multiplicity 1; (3) there is no real symmetric matrix $X \neq 0$ such that $MX = 0$ and $X_{ij} = 0$ whenever $i = j$ or $M_{ij} \neq 0$. Such a matrix M is a nondeterministic matrix for the communication complexity problem $f : [n] \times [n] \to \{0,1\}$ defined by $f(i,j) = 1$ iff $(i,j) \in E$, with the promise that the inputs i and j are distinct. However, the Colin de Verdière requirement appears to be more stringent, since it constrains the nondeterministic matrix further by properties (2) and (3).

$V_2^B(y)$ acts. This process goes back and forth for some k messages, so the final state of the protocol on input (x,y) will be (in case Alice goes last as well)

$$(U_k^A(x)\otimes I^B)(I^A\otimes U_{k-1}^B(y))\cdots(I^A\otimes U_2^B(y))(U_1^A(x)\otimes I^B)|0\rangle|0\rangle|0\rangle.$$

The total *cost* of the protocol is the total length of all messages sent, on a worst-case input (x,y). For technical convenience, we assume that at the end of the protocol the output bit is the first qubit on the channel. Thus the acceptance probability $P(x,y)$ of the protocol is the probability that a measurement of the final state gives a "1" in the first channel-qubit. Note that we do not allow intermediate measurements during the protocol. This is without loss of generality; it is well known that such measurements can be postponed until the end of the protocol at no extra communication cost.

Let $Dcc(f)$ and $Qcc_E(f)$ be the communication complexities of optimal deterministic classical and quantum protocols for computing f, respectively. A *nondeterministic protocol* for f is a protocol that has positive acceptance probability on input (x,y) iff $f(x,y)=1$. Let $Ncc(f)$ and $NQcc(f)$ be the communication complexities of optimal nondeterministic classical and quantum protocols for f, respectively. Our $Ncc(f)$ is called $N^1(f)$ in [36].

It is not hard to show that $Ncc(f)=\lceil\log Cov^1(f)\rceil+1$, where the "+1" is due to the fact that we want Alice and Bob both to know the output at the end of the protocol.

3.2. Algebraic characterization. Here we characterize $NQcc(f)$ in terms of $nrank(f)$. We use the following lemma. It was stated without proof by Yao [54] and in more detail by Kremer [35] and is key to many of the earlier lower bounds on quantum communication complexity as well as to ours. It is easily proven by induction on ℓ.

LEMMA 3.1 (see Yao [54] and Kremer [35]). *The final state of an ℓ-qubit protocol on input (x,y) can be written as*

$$\sum_{i\in\{0,1\}^\ell}|A_i(x)\rangle|i_\ell\rangle|B_i(y)\rangle,$$

where the $A_i(x),B_i(y)$ are vectors (of norm ≤ 1), and i_ℓ denotes the last bit of the ℓ-bit string i (the output bit).

The acceptance probability $P(x,y)$ of the protocol is the squared norm of the part of the final state that has $i_\ell=1$. Letting a_{ij} be the 2^n-dimensional complex column vector with the inner products $\langle A_i(x)|A_j(x)\rangle$ as entries and b_{ij} the 2^n-dimensional column vector with entries $\langle B_i(y)|B_j(y)\rangle$, we can write P (viewed as a $2^n\times 2^n$ matrix) as the sum $\sum_{i,j:i_\ell=j_\ell=1}a_{ij}b_{ij}^T$ of $2^{2\ell-2}$ matrices, each of rank at most 1, so the rank of P is at most $2^{2\ell-2}$. For example, for exact protocols this gives immediately that $\ell\ge\frac{1}{2}\log rank(f)+1$, and for nondeterministic protocols $\ell\ge\frac{1}{2}\log nrank(f)+1$.

Below we show how we can get rid of the factor $\frac{1}{2}$ in the nondeterministic case and show that the lower bound of $\log nrank(f)+1$ is actually optimal. The lower bound part of the proof relies on the following technical lemma.

LEMMA 3.2. *If there exist two families of vectors $\{A_1(x),\ldots,A_m(x)\}\subseteq\mathbb{C}^d$ and $\{B_1(y),\ldots,B_m(y)\}\subseteq\mathbb{C}^d$ such that, for all $x\in\{0,1\}^n$ and $y\in\{0,1\}^n$, we have*

$$\sum_{i=1}^m A_i(x)\otimes B_i(y)=0 \text{ iff } f(x,y)=0,$$

then $nrank(f)\le m$.

Proof. Assume there exist two such families of vectors. Let $A_i(x)_j$ denote the jth entry of vector $A_i(x)$, and similarly let $B_i(y)_k$ denote the kth entry of vector $B_i(y)$. We use pairs $(j,k) \in \{1,\ldots,d\}^2$ to index entries of vectors in the d^2-dimensional tensor space. Note that

if $f(x,y)=0$, then $\sum_{i=1}^m A_i(x)_j B_i(y)_k = 0$ for all (j,k), and
if $f(x,y)=1$, then $\sum_{i=1}^m A_i(x)_j B_i(y)_k \neq 0$ for some (j,k).

As a first step, we want to replace the vectors $A_i(x)$ and $B_i(y)$ by numbers $a_i(x)$ and $b_i(y)$ that have similar properties. We use the probabilistic method to show that this can be done.

Let I be an arbitrary set of 2^{2n+1} numbers. Choose coefficients $\alpha_1,\ldots,\alpha_d$ and $\beta_1,\ldots,\beta_d$, each coefficient picked uniformly at random from I. For every x define $a_i(x) = \sum_{j=1}^d \alpha_j A_i(x)_j$, and for every y define $b_i(y) = \sum_{k=1}^d \beta_k B_i(y)_k$. Consider the number

$$v(x,y) = \sum_{i=1}^m a_i(x)b_i(y) = \sum_{j,k=1}^d \alpha_j\beta_k \left(\sum_{i=1}^m A_i(x)_j B_i(y)_k\right).$$

If $f(x,y)=0$, then $v(x,y)=0$ for all choices of the α_j,β_k.

Now consider some (x,y) with $f(x,y)=1$. There is a pair (j',k') for which $\sum_{i=1}^m A_i(x)_{j'} B_i(y)_{k'} \neq 0$. We want to prove that $v(x,y)=0$ happens only with very small probability. In order to do this, fix the random choices of all α_j, $j \neq j'$, and β_k, $k \neq k'$, and view $v(x,y)$ as a function of the two remaining not-yet-chosen coefficients $\alpha = \alpha_{j'}$ and $\beta = \beta_{k'}$,

$$v(x,y) = c_0\alpha\beta + c_1\alpha + c_2\beta + c_3.$$

Here we know that $c_0 = \sum_{i=1}^m A_i(x)_{j'} B_i(y)_{k'} \neq 0$. There is at most one value of α for which $c_0\alpha + c_2 = 0$. All other values of α turn $v(x,y)$ into a linear equation in β, so for those α there is at most one choice of β that gives $v(x,y)=0$. Hence out of the $(2^{2n+1})^2$ different ways of choosing (α,β), at most $2^{2n+1} + (2^{2n+1}-1)\cdot 1 < 2^{2n+2}$ choices give $v(x,y)=0$. Therefore,

$$\Pr[v(x,y)=0] < \frac{2^{2n+2}}{(2^{2n+1})^2} = 2^{-2n}.$$

Using the union bound, we now have

$$\Pr\left[\text{there is an } (x,y)\in f^{-1}(1) \text{ for which } v(x,y)=0\right] \leq \sum_{(x,y)\in f^{-1}(1)} \Pr[v(x,y)=0] < 2^{2n}\cdot 2^{-2n} = 1.$$

This probability is strictly less than 1, so there exist sets $\{a_1(x),\ldots,a_m(x)\}$ and $\{b_1(y),\ldots,b_m(y)\}$ that make $v(x,y)\neq 0$ for every $(x,y)\in f^{-1}(1)$. We thus have that

$$\sum_{i=1}^m a_i(x)b_i(y) = 0 \text{ iff } f(x,y)=0.$$

View the a_i and b_i as 2^n-dimensional vectors, let A be the $2^n \times m$ matrix having the a_i as columns, and let B be the $m \times 2^n$ matrix having the b_i as rows. Then $(AB)_{xy} = \sum_{i=1}^m a_i(x)b_i(y)$, which is 0 iff $f(x,y)=0$. Thus AB is a nondeterministic matrix for f, and $nrank(f) \leq rank(AB) \leq rank(A) \leq m$. ∎

Lemma 3.2 allows us to prove the following tight characterization.

THEOREM 3.3. $NQcc(f) = \lceil \log nrank(f) \rceil + 1$.

Proof. Upper bound. Let $r = nrank(f)$, and let M be a rank-r nondeterministic matrix for f. Let $M^T = U\Sigma V$ be the singular value decomposition of the transpose of M [28], so U and V are unitary, and Σ is a diagonal matrix whose first r diagonal entries are positive real numbers and whose other diagonal entries are 0. Below we describe a one-round nondeterministic protocol for f, using $\lceil \log r \rceil + 1$ qubits.

First, Alice prepares the state $|\phi_x\rangle = c_x \Sigma V |x\rangle$, where $c_x > 0$ is a normalizing real number that depends on x. Because only the first r diagonal entries of Σ are nonzero, only the first r amplitudes of $|\phi_x\rangle$ are nonzero, so $|\phi_x\rangle$ can be compressed into $\lceil \log r \rceil$ qubits. Alice sends these qubits to Bob. Bob then applies U to $|\phi_x\rangle$ and measures the resulting state. If he observes $|y\rangle$, then he puts 1 on the channel, and otherwise he puts 0 there. The acceptance probability of this protocol is

$$P(x,y) = |\langle y|U|\phi_x\rangle|^2 = c_x^2 |\langle y|U\Sigma V|x\rangle|^2 = c_x^2 |M_{yx}^T|^2 = c_x^2 |M_{xy}|^2.$$

Since M_{xy} is nonzero iff $f(x,y) = 1$, $P(x,y)$ will be positive iff $f(x,y) = 1$. Thus we have a nondeterministic quantum protocol for f with $\lceil \log r \rceil + 1$ qubits of communication.

Lower bound. Consider a nondeterministic ℓ-qubit protocol for f. By Lemma 3.1, its final state on input (x,y) can be written as

$$\sum_{i \in \{0,1\}^\ell} |A_i(x)\rangle |i_\ell\rangle |B_i(y)\rangle.$$

Without loss of generality, we assume the vectors $A_i(x)$ and $B_i(y)$ all have the same dimension d. Let $S = \{i \in \{0,1\}^\ell \mid i_\ell = 1\}$, and consider the part of the state that corresponds to output 1 (we drop the $i_\ell = 1$ and the $|\cdot\rangle$-notation here),

$$\phi(x,y) = \sum_{i \in S} A_i(x) \otimes B_i(y).$$

Because the protocol has acceptance probability 0 iff $f(x,y) = 0$, this vector $\phi(x,y)$ will be the zero vector iff $f(x,y) = 0$. The previous lemma gives $nrank(f) \leq |S| = 2^{\ell-1}$; hence $\log(nrank(f)) + 1 \leq NQcc(f)$. □

Note that any nondeterministic matrix for the equality function has nonzeros on its diagonal and zeros off-diagonal and hence has full rank. Thus we obtain $NQcc(\mathrm{EQ}) = n + 1$. Similarly, a nondeterministic matrix for disjointness has full rank, because reversing the ordering of the columns in M_f gives an upper triangular matrix with nonzero elements on the diagonal. This gives tight bounds for the nondeterministic as well as for the exact setting, neither of which was known prior to this work.

COROLLARY 3.4. $Qcc_E(\mathrm{EQ}) = NQcc(\mathrm{EQ}) = n+1$ *and* $Qcc_E(\mathrm{DISJ}) = NQcc(\mathrm{DISJ}) = n + 1$.

3.3. Quantum-classical separation. To repeat, classically we have $Ncc(f) = \lceil \log Cov^1(f) \rceil + 1$, and quantumly we have $NQcc(f) = \lceil \log nrank(f) \rceil + 1$. We now give a total function f with an exponential gap between $Ncc(f)$ and $NQcc(f)$. For $n > 1$, define f by

$$f(x,y) = 1 \text{ iff } |x \wedge y| \neq 1.$$

We first show that the quantum complexity $NQcc(f)$ is low.

THEOREM 3.5. *For the above f, we have $NQcc(f) \leq \lceil \log(n+1) \rceil + 1$.*

Proof. By Theorem 3.3, it suffices to prove $nrank(f) \leq n+1$. We will derive a low-rank nondeterministic matrix from the polynomial p of (2.1), using a technique from [43]. Let M_i be the matrix defined by $M_i(x,y) = 1$ if $x_i = y_i = 1$ and by $M_i(x,y) = 0$ otherwise. Notice that M_i has rank 1. Define a $2^n \times 2^n$ matrix M by

$$M(x,y) = \left(\sum_{i=1}^{n} M_i(x,y) \right) - 1.$$

Note that $M(x,y) = p(x \wedge y)$. Since p is a nondeterministic polynomial for the function which is 1 iff its input does not have weight 1, it can be seen that M is a nondeterministic matrix for f. Because M is the sum of $n+1$ rank-1 matrices, M itself has rank at most $n+1$. □

Now we show that the classical $Ncc(f)$ is high (both for f and its complement).

THEOREM 3.6. *For the above f, we have $Ncc(f) \in \Omega(n)$ and $Ncc(\overline{f}) \geq n-1$.*

Proof. Let $R_1, \ldots, R_k$ be a minimal 1-cover for f. We use the following result from [36, Example 3.22 and section 4.6], which is essentially due to Razborov [45].

> There exist sets $A, B \subseteq \{0,1\}^n \times \{0,1\}^n$ and a probability distribution $\mu : \{0,1\}^n \times \{0,1\}^n \to [0,1]$ such that all $(x,y) \in A$ have $|x \wedge y| = 0$, all $(x,y) \in B$ have $|x \wedge y| = 1$, $\mu(A) = 3/4$, and there are $\alpha, \delta > 0$ (independent of n) such that for all rectangles R, $\mu(R \cap B) \geq \alpha \cdot \mu(R \cap A) - 2^{-\delta n}$.

Since the R_i are 1-rectangles, they cannot contain elements from B. Hence $\mu(R_i \cap B) = 0$ and $\mu(R_i \cap A) \leq 2^{-\delta n}/\alpha$. However, since all elements of A are covered by the R_i, we have

$$\frac{3}{4} = \mu(A) = \mu\left(\bigcup_{i=1}^{k} (R_i \cap A) \right) \leq \sum_{i=1}^{k} \mu(R_i \cap A) \leq k \cdot \frac{2^{-\delta n}}{\alpha}.$$

Therefore, $Ncc(f) = \lceil \log k \rceil + 1 \geq \delta n + \log(3\alpha/4)$.

For the lower bound on $Ncc(\overline{f})$, consider the set $S = \{(x,y) \mid x_1 = y_1 = 1, x_i = \overline{y_i} \text{ for } i > 1\}$. This S contains 2^{n-1} elements, all of which are 1-inputs for $\overline{f}$. Note that if (x,y) and (x',y') are two elements from S, then $|x \wedge y'| > 1$ or $|x' \wedge y| > 1$, so a 1-rectangle for $\overline{f}$ can contain at most one element of S. This shows that a minimal 1-cover for $\overline{f}$ requires at least 2^{n-1} rectangles and $Ncc(\overline{f}) \geq n-1$. □

Another quantum-classical separation was obtained earlier by Massar et al. [37]. We include it for the sake of completeness. It shows that the nondeterministic complexity of the *non*equality problem is extremely low, in sharp contrast to the equality problem itself.

THEOREM 3.7 (see [37]). *For the nonequality problem on n bits, $NQcc(\mathrm{NE}) = 2$ versus $Ncc(\mathrm{NE}) = \log n + 1$.*

Proof. $Ncc(\mathrm{NE}) = \log n + 1$ is well known (see [36, Example 2.5]). Below we give the protocol for NE from [37].

Viewing her input x as a number $\in [0, 2^n - 1]$, Alice rotates a $|0\rangle$-qubit over an angle $x\pi/2^n$, obtaining a qubit $\cos(x\pi/2^n)|0\rangle + \sin(x\pi/2^n)|1\rangle$ which she sends to Bob. Bob rotates the qubit back over an angle $y\pi/2^n$, obtaining $\cos((x-y)\pi/2^n)|0\rangle + \sin((x-y)\pi/2^n)|1\rangle$. Bob now measures the qubit and sends back the observed bit. If $x = y$, then $\sin((x-y)\pi/2^n) = 0$, so Bob will always send 0. If $x \neq y$, then $\sin((x-y)\pi/2^n) \neq 0$, so Bob will send 1 with positive probability. □

In another direction, Klauck [34] showed that $NQcc(f)$ is in general incomparable to bounded-error quantum communication complexity: the latter may be exponentially larger or smaller, depending on f.

4. Future work. One of the main reasons for the usefulness of nondeterministic query and communication complexities in the classical case is the tight relation of these complexities with deterministic complexity.

In the query complexity (decision tree) setting, we have the well-known bound

$$\max\{N(f), N(\overline{f})\} \leq D(f) \leq N(f)N(\overline{f}).$$

We conjecture that something similar holds in the quantum case:

$$\max\left\{NQ(f), NQ(\overline{f})\right\} \leq Q_E(f) \leq D(f) \stackrel{?}{\leq} O(NQ(f)NQ(\overline{f})).$$

The ?-part is open and ties in with tightly embedding $NQ(f)$ and $ndeg(f)$ into the web of known relations between various complexity measures (section 2.6). This conjecture implies, for instance, $D(f) \in O(deg(f)^2)$, which would be close to optimal [42]. Similarly, it would imply $D(f) \in O(Q_0(f)^2)$, which would be close to optimal as well [18]. In both cases, the currently best relation has a fourth power instead of a square.

Similarly, for communication complexity, the following is known [36, section 2.11]:

$$\max\{Ncc(f), Ncc(\overline{f})\} \leq Dcc(f) \leq O(Ncc(f)Ncc(\overline{f})).$$

An analogous result might be true in the quantum setting, but we have been unable to prove it. So far, the best result in this direction is Klauck's observation that $Dcc(f) = O(Ncc(f)NQcc(\overline{f}))$ [33, Theorem 1].

Appendix. Comparison with alternative definitions. As mentioned in the introduction, three different definitions of nondeterministic quantum complexity are possible. We may consider the complexity of quantum algorithms that

1. output 1 iff given an appropriate *classical* certificate (and such certificates must exist iff $f(x) = 1$),
2. output 1 iff given an appropriate *quantum* certificate (and such certificates must exist iff $f(x) = 1$), or
3. output 1 with positive probability iff $f(x) = 1$.

The third definition is the one we adopted for this paper. Clearly definition 2 is at least as strong as definition 1 in the sense that the complexity of a function according to definition 2 will be less than or equal to the complexity according to definition 1. In fact, in the setting of query complexity, these two definitions are equivalent, because without loss of generality the certificate can be taken to be the purported input. See Aaronson [1] for some recent results about "quantum certificate (query) complexity."

Here we show that definition 3 is at least as strong as definition 2. We give the proof for the query complexity setting, but the same proof can be modified to work for communication complexity and other nonuniform settings as well. We then give an example in which the query complexity according to definition 3 is much less than according to definition 2. This shows that our $NQ(f)$ is in fact the most powerful definition of nondeterministic quantum query complexity.

We formalize definition 2 as follows. A *T-query quantum verifier* for f is a T-query quantum algorithm V together with a set $\mathcal{C}$ of m-qubit states, such that for all $x \in \{0,1\}^n$ we have (1) if $f(x) = 1$, then there is a $|\phi_x\rangle \in \mathcal{C}$ such that $V_x|\phi_x\rangle$ has

acceptance probability 1; and (2) if $f(x) = 0$, then $V_x|\phi\rangle$ has acceptance probability 0 for every $|\phi\rangle \in \mathcal{C}$. Informally, the set $\mathcal{C}$ contains all possible certificates: (1) for every 1-input, there is a verifiable 1-certificate in $\mathcal{C}$; and (2) for 0-inputs, there are not any. We do not put any constraints on $\mathcal{C}$. However, note that the definition implies that if $f(x) = 0$ for some x, then $\mathcal{C}$ cannot contain *all* m-qubit states; otherwise, $|\phi_x\rangle = V_x^{-1}|1\vec{0}\rangle$ would be a 1-certificate in $\mathcal{C}$ even for x with $f(x) = 0$.

We now prove that a T-query quantum verifier can be turned into a T-query nondeterministic quantum algorithm according to our third definition. This shows that the third definition is at least as powerful as the second. In fact, this even holds if we replace the acceptance probability 1 in clause (1) of the definition of a quantum verifier by just positive acceptance probability—in this case, both definitions are equivalent.

THEOREM A.1. *If there is a T-query quantum verifier V for f, then $NQ(f) \leq T$.*

Proof. The verifier V and the associated set $\mathcal{C}$ satisfy the following:

1. If $f(x) = 1$, then there is a $|\phi_x\rangle \in \mathcal{C}$ such that $V_x|\phi_x\rangle$ has acceptance probability 1.
2. If $f(x) = 0$, then $V_x|\phi\rangle$ has acceptance probability 0 for all $|\phi\rangle \in \mathcal{C}$.

Let $X_1 = \{z \mid f(z) = 1\}$. For each $z \in X_1$, choose one specific 1-certificate $|\phi_z\rangle \in \mathcal{C}$. Now let us consider some input x and see what happens if we run $V_x \otimes I$ (where I is the $2^n \times 2^n$ identity operation) on the $m + n$-qubit state

$$|\phi\rangle = \frac{1}{\sqrt{|X_1|}} \sum_{z \in X_1} |\phi_z\rangle|z\rangle.$$

V_x acts on only the first m qubits of $|\phi\rangle$; the $|z\rangle$-part remains unaffected. Therefore, running $V_x \otimes I$ on $|\phi\rangle$ gives the same acceptance probabilities as when we first randomly choose some $z \in X_1$ and then apply V_x to $|\phi_z\rangle$. In the case when $f(x) = 0$, this $V_x|\phi_z\rangle$ will have acceptance probability 0, so $(V_x \otimes I)|\phi\rangle$ will have acceptance probability 0 as well. In the case when the input x is such that $f(x) = 1$, the specific certificate $|\phi_z\rangle$ that we chose for this x will satisfy that $V_x|\phi_x\rangle$ has acceptance probability 1. However, then $(V_x \otimes I)|\phi\rangle$ has acceptance probability at least $1/|X_1| > 0$. Accordingly, $(V_x \otimes I)|\phi\rangle$ has positive acceptance probability iff $f(x) = 1$. By prefixing $V_x \otimes I$ with a unitary transformation that maps $|\vec{0}\rangle$ (of $m + n$ qubits) to $|\phi\rangle$, we have constructed a nondeterministic quantum algorithm for f with T queries. □

The above proof shows that our definition of $NQ(f)$ is at least as strong as the certificate-verifier definition. Could it be that both definitions are in fact equivalent (i.e., yield the same complexity)? The function we used in section 2.5 shows that this is not the case. Consider again

$$f(x) = 1 \text{ iff } |x| \neq 1.$$

It satisfies $NQ(f) = 1$. On the other hand, if we take a T-query verifier for f and fix the certificate for the all-0 input, we obtain a T-query algorithm that always outputs 1 on the all-0 input and that outputs 0 on all inputs of Hamming weight 1. The quantum search lower bounds [9, 6] immediately imply $T = \Omega(\sqrt{n})$. This shows that our definition of $NQ(f)$ is strictly more powerful than the certificate-verifying one.

Acknowledgments. Many thanks to Peter Høyer for stimulating discussions and for his permission to include the nondeterministic parts of our joint paper [29] in this paper. I also thank Scott Aaronson, Harry Buhrman, Richard Cleve, Wim

van Dam, Lance Fortnow, Hartmut Klauck, Peter Shor, and John Watrous for various helpful discussions, comments, and pointers to the literature. Thanks to the anonymous referees for suggesting some improvements.

SEMI-ONLINE MAINTENANCE OF GEOMETRIC OPTIMA AND MEASURES*

TIMOTHY M. CHAN†

Abstract. We give the first nontrivial worst-case results for dynamic versions of various basic geometric optimization and measure problems under the semi-online model, where during the insertion of an object we are told when the object is to be deleted. Problems that we can solve with sublinear update time include the Hausdorff distance of two point sets, discrete 1-center, largest empty circle, convex hull volume in three dimensions, volume of the union of axis-parallel cubes, and minimum enclosing rectangle. The decision versions of the Hausdorff distance and discrete 1-center problems can be solved fully dynamically. Some applications are mentioned.

Key words. computational geometry, dynamic data structures

1. Introduction.

Problems in computational geometry that admit simple and efficient static solutions can often be significantly harder to solve in the *dynamic* setting, when data are inserted and deleted and answers have to be updated quickly. For example, the *width* of a planar n-point set is an easy-to-state quantity and can be computed by a "textbook" $O(n \log n)$ algorithm, but a data structure that can maintain the width under arbitrary point updates in a manner faster than recomputing from scratch had eluded researchers for years and was found only recently [8]. In this paper, we look at more standard geometric optimization and measure problems, study their worst-case complexities in the dynamic setting, and try to gain a better understanding into generally what types of problems admit nontrivial dynamization results.

The importance of dynamic computational geometry was realized long ago [10], and while there have been many fundamental results in the area, our current knowledge is still limited. Dynamic data structures for all kinds of problems reducible to range searching [1], including linear/convex programming, are known. A class of *decomposable* query problems [5] has been recognized as easy, for which simple general tricks are known. A useful technique has been devised to deal with problems of the form, "Which pair of objects minimizes a function?" [14]. Yet, simple nonconvex minimization problems, like the width or smallest enclosing rectangle, or max-min problems, like the Hausdorff distance (see below), defy solutions by all these methodologies.

Over a decade ago, Dobkin and Suri [11] introduced the *semi-online* model as a restricted form of dynamic computation. The model assumes that when an object is inserted, we are given the time at which the object is to be deleted. The model simultaneously generalizes the *incremental* case (when there are no deletions) and the *off-line* case (when the entire insertion/deletion sequence is known in advance).

TABLE 1.1
Summary of results.

Semi-online update time		
Hausdorff distance (2-d)	$\widetilde{O}(n^{5/6})$	(Corollary 3.2)
Discrete 1-center (2-d)	$\widetilde{O}(n^{5/6})$	(Corollary 3.2)
Largest empty circle	$\widetilde{O}(n^{7/8})$	(Corollary 5.2)
Volume of 3-d convex hull	$\widetilde{O}(n^{7/8})$	(Corollary 5.3)
Volume of union of unit cubes	$\widetilde{O}(n^{1/2})$	(Theorem 6.1)
Minimum-perimeter/area rectangle	$\widetilde{O}(n^{1/2})$ / $\widetilde{O}(n^{5/6})$	(Corollary 7.2/7.3)
Fully dynamic update time (amortized)		
Hausdorff distance decision (2-d)	$\widetilde{O}(n^{1/2})$	(Corollary 4.2)
Discrete 1-center decision (2-d)	$\widetilde{O}(n^{1/2})$	(Corollary 4.2)
Largest discrete empty circle	$\widetilde{O}(1)$	(Corollary 4.4)

Considering the apparent difficulty in obtaining worst-case results under the original fully dynamic model, such a restriction is generally a reasonable starting point for research; it lets us obtain semi-dynamic algorithms that are provably efficient and still practically relevant. We adopt the semi-online model in this paper and initiate the study of problems of a broader scope and higher complexity than those originally considered by Dobkin and Suri themselves. (As we now know, most of the problems they considered can be solved fully dynamically by the techniques mentioned, notably Eppstein's work [14].)

Table 1.1 gives a list of problems familiar to computational geometers and the results obtained in this paper. Background to many of the problems can be found in texts such as [27]. Statically, each problem can be solved in $O(n \log n)$ time, by construction of a planar convex hull, three-dimensional convex hull (in particular, planar Voronoi diagram), or three-dimensional union of cubes. Dynamically, however, one can see plenty of challenges—we are unaware of nontrivial worst-case results for any of these problems, even in the incremental case!

Specifically, the first problem is to determine the Hausdorff distance $\max_{q \in Q} \min_{p \in P} d(p, q)$ for two given sets P and Q of n points in the plane, subject to semi-online updates to both P and Q, where $d(\cdot, \cdot)$ is the Euclidean metric; the Hausdorff distance is commonly used as a measure of resemblance between two images. Given planar point set P, the discrete 1-center problem asks for the smallest circle, centered at a point of P, that encloses P; this is a popular variant of the standard 1-center problem that cannot be solved by convex programming (in fact, Dobkin and Suri [11] raised this as an open question for semi-online algorithms). In contrast, the largest empty circle problem, another example in facility location, seeks the largest circle whose interior avoids P, with center inside a given region, say, a triangle Δ (note that there are different versions of the center constraint in the literature). The next two are measure problems in three dimensions and ask for the volume of the convex hull of n points and of the union of a set of n congruent axis-parallel cubes. The last (related to the width problem) is to find the smallest rectangle, in terms of perimeter or area, that encloses a planar point set; this "bounding box" is allowed to have arbitrary orientation. All these problems have practical applications. We obtain a sublinear semi-online algorithm for each, using $\widetilde{O}(n)$ space. (Throughout the paper, the $\widetilde{O}$ notation hides factors that are $o(n^{\varepsilon})$ for any fixed $\varepsilon > 0$.)

Along the way, we notice a few easier variants that admit sublinear fully dynamic

algorithms. These variants include the decision versions of the Hausdorff distance and discrete 1-center problems (decide whether the Hausdorff distance is less than a given value r, and decide whether there exists a circle of radius r, centered at a point of P, that encloses P), as well as the discrete version of the largest empty circle problem (find the largest circle, centered at a point of P, whose interior avoids P except the center).

Our semi-online algorithms all begin with a very simple strategy that was used recently by the author to tackle the width problem [8] and is outlined in the next section (Lemma 2.1). As one might guess, data structures for range searching [1] are exploited to obtain the sublinear time bounds, but in nontrivial (and at times, creative) ways. Most of our results are therefore theoretical. It is assumed that the input is in general position, without loss of generality, by known perturbation schemes.

We mention some "applications" in section 8, including improved time bounds for Klee's measure problem [26] in the case of four-dimensional unit hypercubes, and for the minimum-diameter spanning tree problem, which are of independent interest.

2. The strategy for semi-online dynamization. The most common dynamization strategy [5, 24, 25] is based on decomposing a set of objects into subsets, solving the problem on each subset, and combining the answers. An update affects only a small number of subsets and thus can be efficiently handled. Unfortunately, this simple approach is not viable for any of our problems, because they are not directly "decomposable"—there is no effective way to combine the answers when the set is arbitrarily decomposed into a large number of subsets.

Fortunately, another very simple (but lesser known) approach works for us, using a weaker form of decomposability based on dividing the given set into *two* subsets, one of which is kept small, as explained in the lemma below. The strategy was most recently used by the author [8] (building on a previous work by Eppstein [16]) to obtain a fully dynamic algorithm for planar width with $\widetilde{O}(n^{1/2})$ amortized time, by a variant of the lemma that handles arbitrary deletions (with $\alpha = \beta = 1$). A similar idea was also used in one example from Dobkin and Suri's paper [11].

LEMMA 2.1. *Consider a problem* Π *with the following property, where* $\alpha \geq 1$ *and* $0 < \beta \leq 1$ *are constants: we can preprocess a set* S *of* n *objects into a data structure in* $\widetilde{O}(n)$ *time and space such that, given any additional set* S' *of* b *objects, we can solve* Π *on the set* $S \cup S'$ (block query) *in* $\widetilde{O}(b^\alpha n^{1-\beta})$ *time. Then we can solve* Π *on a set of* n *objects under semi-online updates in* $\widetilde{O}(n^{1-\beta/(1+\alpha)})$ *time per update, using* $\widetilde{O}(n)$ *space.*

Proof. We store most of the objects in a static set S, preprocessed in the given data structure, and put the rest in an auxiliary list S'. Insertions and deletions are done directly to S', but after every b updates, we reset S' to hold the objects with the b smallest deletion times and S to hold all other objects (this ensures that any object to be deleted in the next round of b updates is indeed in S', not S). The data structure for S has to be rebuilt, in $\widetilde{O}(n)$ time, for every b updates. At any time, S' has $O(b)$ size, so the solution can be computed by a block query in $\widetilde{O}(b^\alpha n^{1-\beta})$ time. The total time for n updates is therefore

$$\widetilde{O}((n/b) \cdot n \,+\, n \cdot (b^\alpha n^{1-\beta})) \;=\; \widetilde{O}(n^{2-\beta/(1+\alpha)}) \tag{2.1}$$

if we set the parameter $b \approx n^{\beta/(1+\alpha)}$. This proves an amortized time bound of $\widetilde{O}(n^{1-\beta/(1+\alpha)})$.

If the application insists on a *worst-case* time bound, a well-known modification (e.g., see [24, 25]) is required: spread the work of rebuilding the data structure for S evenly over the next $b/2$ updates. The data structure for S is available for the jth update whenever $j \bmod b \geq b/2$. A similar "shifted" version of S and S' can deal with the other case $j \bmod b < b/2$. □

All our efforts are now directed to demonstrating that our problems obey the requirement of the lemma. This task isn't necessarily straightforward, as we will see when we examine each problem in detail.

On one occasion (in a higher-dimensional application), we find the following modification of the lemma useful.

LEMMA 2.2. *Lemma* 2.1 *still holds if we are unable to preprocess S from scratch in $\widetilde{O}(n)$ time but can create a copy of the data structure for $S \cup S'$* (block insertion)*, given the data structure for S, within $\widetilde{O}(n + b^{\alpha} n^{1-\beta})$ time.*

Proof. This is similar to the previous proof, except that we will use multiple levels of decomposition (increasing space by a logarithmic factor). Specifically, let $\ell = \lceil \log_2(n/b) \rceil$. For each $i = 1, \ldots, \ell$, we maintain a partition of the objects into a set S_i, stored in a data structure, and an auxiliary list S'_i: insertions and deletions are done directly to S'_i, but after every $n/2^{i+1}$ updates, we reset S'_i to hold all objects with the $n/2^i$ smallest deletion times and S_i to the complement of S'_i. The size of S'_i is always $O(n/2^i)$.

After every $n/2^{i+1}$ updates, we need to rebuild the data structure for S_i. We know that $S_{i-1} \subseteq S_i$ (because at any time, S'_{i-1} must contain all objects with the $n/2^i$ smallest deletion times). Thus, a data structure for S_i can be created by copying the structure for S_{i-1} and inserting $S'_{i-1} \setminus S'_i$ in $O(\frac{n}{2^i b})$ blocks. The total number of block insertions over n updates is therefore $O(\sum_{i=1}^{\ell} 2^{i+1} \cdot \frac{n}{2^i b}) = \widetilde{O}(n/b)$. At any time, the solution can be computed by a block query to the data structure for S_ℓ, so we again arrive at the same expression (2.1).

If the application insists on a worst-case time bound, we can again spread the construction of the data structures over time, and for each i, maintain two shifted versions of S_i and S'_i to ensure that one of them is available at any given time. We omit the standard details. □

3. Optimizing over discrete points on a polytope. We consider first the problem of maintaining the Hausdorff distance $\max_{q \in Q} \min_{p \in P} d(p, q)$ dynamically. The difficulty here is the apparent necessity to know the nearest neighbor of *each* point $q \in Q$ to the point set P (unlike in the bichromatic closest pair problem studied by Eppstein [14] of the min-min type). As points are inserted to P, a large number of these nearest neighbors could change. The idea is that with Lemma 2.1 (and Lemma 2.2), we do not need to maintain the newest version of these nearest neighbors after every single update but only after a block of updates.

The method involves multilevel range searching tools. Although the description assumes familiarity with these tools, it is conceptually not complicated.

The method is quite general: we can combine the nearest neighbor distances by operators other than the maximum, and we can solve the problem in any fixed dimension. For this reason, we state a more general problem. Let d be a constant. Given a set H of hyperplanes in $\mathbb{R}^d$, define a mapping $\lambda_H : \mathbb{R}^{d-1} \to \mathbb{R}^d$ as follows: $\lambda_H(q)$ is the point obtained by lifting q vertically onto the lower envelope of H (in other words, the lowest intersection of H with the vertical line at q). Given a set of points $Q \subset \mathbb{R}^{d-1}$, we wish to maintain implicitly the set of points $\lambda_H(Q) = \{\lambda_H(q) \mid q \in Q\}$ (all lying on a polytope's boundary, as the title of this section suggests); actually,

we want the output to be $\square\lambda_H(Q)$ for some *decomposable* operator $\square$, satisfying the requirement that for any disjoint pair of sets S_1 and S_2, $\square S_1$ and $\square S_2$ can be combined to form $\square(S_1 \cup S_2)$ in constant time.

THEOREM 3.1. *Suppose that we can preprocess an n-point set $Q \subset \mathbb{R}^{d-1}$ in $\widetilde{O}(n)$ time so that $\square\lambda_h(Q)$ for any hyperplane h in $\mathbb{R}^d$ can be computed in $\widetilde{O}(n^{1-\gamma})$ time, with $\gamma \geq 1/d$. Then we can maintain $\square\lambda_H(Q)$ for a set Q of at most n points in $\mathbb{R}^{d-1}$ and a set H of at most n hyperplanes in $\mathbb{R}^d$ in $\widetilde{O}(n^{1-\frac{1}{d(\lfloor d/2\rfloor+1)}})$ time per semi-online update to Q and H.*

Proof. We show how to store Q and H so that $\square\lambda_{H\cup H'}(Q \cup Q')$ can be computed efficiently given small additional blocks Q' and H'.

Preprocess the hyperplanes H in $\widetilde{O}(n)$ time to support vertical ray shooting queries in $\widetilde{O}(n^{1-1/\lfloor d/2\rfloor})$ time [1]. For each $q \in Q$, compute $\lambda_H(q)$; for $d \leq 3$, this step takes $O(n \log n)$ time. In $\widetilde{O}(n)$ time, preprocess $\lambda_H(Q)$ for simplex range searching [1, 23] to form canonical subsets $\{Q_i\}_i$ of total size $\widetilde{O}(n)$ such that, given any query simplex $\Delta \subset \mathbb{R}^d$, we can retrieve all points $q \in Q$ with $\lambda_H(q) \in \Delta$ as a union of disjoint canonical subsets $\{Q_i\}_{i\in I}$ in $\widetilde{O}(n^{1-1/d})$ time, with $\sum_{i\in I} |Q_i|^{1-1/d} = \widetilde{O}(n^{1-1/d})$. Precompute $\square\lambda_H(Q_i)$ for every canonical subset Q_i. In addition, preprocess each Q_i as specified so that given any hyperplane h, $\square\lambda_h(Q_i)$ can be found in $\widetilde{O}(n^{1-\gamma})$ time; the total preprocessing time is $\widetilde{O}(n)$.

Given query sets Q' and H' of size b, construct the lower envelope of H' in $\widetilde{O}(b^{\lfloor d/2\rfloor})$ time and triangulate it into $\widetilde{O}(b^{\lfloor d/2\rfloor})$ $(d-1)$-simplices. Take each such simplex Δ, defined by hyperplane $h' \in H'$, say.

- Consider the points $q \in Q$ such that $\lambda_H(q)$ lies directly below Δ. By simplex range searching, these points can be partitioned into canonical subsets $\{Q_i\}_{i\in I}$. Take each Q_i. All points $q \in Q_i$ have $\lambda_{H\cup H'}(q) = \lambda_H(q)$; so combine the current answer with $\square\lambda_H(Q_i)$. The time required is $\widetilde{O}(n^{1-1/d})$.
- Consider the points $q \in Q$ such that $\lambda_H(q)$ lies directly above Δ. Again these points can be partitioned into canonical subsets $\{Q_i\}_{i\in I}$. Take each such Q_i. All points $q \in Q_i$ have $\lambda_{H\cup H'}(q) = \lambda_{h'}(q)$; so combine the current answer with $\square\lambda_{h'}(Q_i)$. The time required is $\widetilde{O}(\sum_{i\in I} |Q_i|^{1-\gamma}) = \widetilde{O}(n^{1-1/d})$.

Applying this process to all simplices requires $\widetilde{O}(b^{\lfloor d/2\rfloor} n^{1-1/d})$ time overall. The current answer is $\square\lambda_{H\cup H'}(Q)$. To get $\square\lambda_{H\cup H'}(Q \cup Q')$, compute $\lambda_{H\cup H'}(q')$ for each $q' \in Q'$ by vertical ray shooting on H and on H', in $\widetilde{O}(bn^{1-1/\lfloor d/2\rfloor})$ total time, and combine the current answer with $\square\lambda_{H\cup H'}(Q')$.

For $d \leq 3$, the preprocessing time is $\widetilde{O}(n)$, so Lemma 2.1 is applicable, with $\alpha = \lfloor d/2\rfloor$ and $\beta = 1/d$. For $d \geq 4$, we cannot afford to recompute $\lambda_H(Q)$ from scratch, so Lemma 2.2 is required: to build a new data structure for $Q \cup Q'$ and $H \cup H'$, compute $\lambda_{H\cup H'}(q)$ from $\lambda_H(q)$ for every $q \in Q$, by vertical ray shooting on H', in total time $\widetilde{O}(b^{\lfloor d/2\rfloor} + n)$; in addition, compute $\lambda_{H\cup H'}(q')$ for every $q' \in Q'$ in total time $\widetilde{O}(bn^{1-1/\lfloor d/2\rfloor})$; now, the rest of the new data structure can be built from scratch in $\widetilde{O}(n)$ time. ∎

Note that we have used simplex range searching only for point sets *in convex position*. If it is possible to improve the range searching results under this special case (for example, it is not difficult in two dimensions), the bound in the theorem would be improved as well.

The Hausdorff distance is just a special case of the above problem in one dimension higher by a standard transformation. The discrete 1-center problem can similarly be

solved, as it asks for a similar quantity $\min_{q\in P}\max_{p\in P} d(p,q)$. In a forthcoming application, we encounter an additively weighted variant that seeks $\max_{q\in Q}\min_{p\in P}[d(p,q)+w_q]$ or $\min_{q\in P}\max_{p\in P}[d(p,q)+w_q]$, given weights w_q; this variant can be solved similarly as well.

COROLLARY 3.2. *In $\mathbb{R}^d$, we can maintain the Hausdorff distance of two sets of at most n points and the discrete 1-center of a set of n points (possibly with additive weights) in $\widetilde{O}(n^{1-\frac{1}{(d+1)(\lceil d/2\rceil+1)}})$ time per semi-online update.*

Proof. For the unweighted Hausdorff distance problem, transform each point $p=(a_1,\ldots,a_d)$ in P to a $(d+1)$-dimensional hyperplane h in H with equation $\{(x_1,\ldots,x_{d+1}) \mid x_{d+1}=a_1^2+\cdots+a_d^2-2a_1x_1-\cdots-2a_dx_d\}$. The points in $\lambda_H(Q)$ correspond to the nearest neighbors of the points in Q to set P. The operator $\square$ takes the maximum of $x_{d+1}+x_1^2+\cdots+x_d^2$ (the actual nearest neighbor distance squared) over the points. The requirement in the theorem (finding $\square\lambda_h(Q)$ for a given hyperplane h) translates to finding the largest distance of Q to a given point p, which can be done by farthest neighbor queries with $\gamma=1/\lceil d/2\rceil$ [1].

In the weighted case, the operator $\square$ should instead return the maximum of $\sqrt{x_{d+1}+x_1^2+\cdots+x_d^2}+w$, where w is the weight of the point $q=(x_1,\ldots,x_d)$. The requirement translates to finding weighted farthest neighbors: more precisely, given query point $(a_1,\ldots,a_d)$, find the maximum of

$$\sqrt{a_1^2+\cdots+a_d^2-2a_1x_1-\cdots-2a_dx_d+x_1^2+\cdots+x_d^2}+w$$

over a set of $O(n)$ tuples $(x_1,\ldots,x_d,w)$. We can compare this maximum with any value b by halfspace range search in $d+2$ dimensions: given $(a_1,\ldots,a_d,b)$, find a tuple that satisfies $w\ge b$ or $[a_1^2+\cdots+a_d^2-b^2]-2a_1x_1-\cdots-2a_dx_d+2bw+[x_1^2+\cdots+x_d^2-w^2]\ge 0$. This gives a data structure with $\gamma=1/(\lfloor d/2\rfloor+1)$ for the decision query problem and, by parametric or randomized search, for the maximization query problem as well [1]. ∎

By linearization or the use of lower envelopes of surfaces and semi-algebraic range searching [1], sublinear results can also be obtained for other metric $d(\cdot,\cdot)$ with constant description complexity. For Hausdorff distances under the L_∞ metric, much simplification is possible, since orthogonal range searching [1, 27] replaces simplex/halfspace range searching, and an L_∞-Voronoi diagram [6] replaces the lower envelope; the time bound reduces to $O(n^{1-\frac{1}{\lceil d/2\rceil+1}}\operatorname{polylog} n)$.

4. Some easier variants. Next, we give faster algorithms for the *decision* versions of the Hausdorff distance and discrete 1-center problem. The algorithms are in fact fully dynamic and are obtained by directly modifying known range searching structures (more specifically, by augmenting a standard partition tree to store two extra numbers at each node). The idea is actually to generalize the problem of *testing* whether each point is above the lower envelope, to *counting* the number of hyperplanes below each point.

To state the generalized problem, define the mapping $c_H:\mathbb{R}^d\to\mathbb{N}$, where $c_H(q)$ is the number of hyperplanes of H that lie below q. Implicitly, we wish to maintain the multiset of numbers $c_H(Q)=\{c_H(q) \mid q\in Q\}$ for a given set of points $Q\subset\mathbb{R}^d$; more precisely, we want to output $\square c_H(Q)$, where the operator $\square$ is assumed to be decomposable and furthermore satisfy the property that for any set S of numbers and a number j, $\square(S+j)$ can be computed from $\square S$ in constant time (where $S+j=\{i+j \mid i\in S\}$).

THEOREM 4.1. *We can maintain $\Box c_H(Q)$ for a set Q of at most n points and a set H of at most n hyperplanes in $\mathbb{R}^d$ in $\widetilde{O}(n^{1-1/d})$ amortized time per update to Q and H fully dynamically, using $O(n)$ space.*

Proof. Assume that the size of H is m instead. Store the dual points of H in a dynamic data structure to support simplex range counting queries in $\widetilde{O}(m^{1-1/d})$ time and updates in $\widetilde{O}(1)$ amortized time [1]. The notation H_Δ denotes the subset of all hyperplanes of H crossing a given simplex Δ.

Matoušek's partition theorem [1, 21] asserts that any set Q of n points can be partitioned into $O(r)$ subsets $\{Q_i\}_i$, each of size at most n/r and enclosed in a simplex Δ_i, with the property that every hyperplane crosses $O(r^{1-1/d})$ of these simplices. We choose r to be a constant here; the construction time is then linear. Assuming that Q itself is enclosed in a simplex Δ, we can ensure that the Δ_i's are all inside Δ (by intersecting with Δ and retriangulating).

Let c_{Δ_i} be the number of hyperplanes in H_Δ that lie completely below Δ_i. Note that the duals of all hyperplanes intersecting Δ and below Δ_i form cells in a hyperplane arrangement of constant size. Therefore, we can compute c_{Δ_i} by a constant number of simplex range counting queries in $\widetilde{O}(m^{1-1/d})$ time.

Our data structure for (Q, Δ) consists of recursively constructed structures for $\{(Q_i, \Delta_i)\}_i$, together with the numbers $\{c_{\Delta_i}\}_i$ and the answer $\Box c_{H_\Delta}(Q)$.

Knowing the subanswers $\Box c_{H_{\Delta_i}}(Q_i)$, we can compute the answer $\Box c_{H_\Delta}(Q)$ as follows. Take each Q_i. All points $q \in Q_i$ have $c_{H_\Delta}(q) = c_{H_{\Delta_i}}(q) + c_{\Delta_i}$; so combine the current answer with $\Box(c_{H_{\Delta_i}}(Q_i) + c_{\Delta_i})$. Repeating for all Q_i's yields the desired answer in constant ($O(r)$) time. By evaluating answers bottom-up, we can thus preprocess our data structure in time $\widetilde{O}(nm^{1-1/d})$.

To insert a hyperplane h to H_Δ, we can first increment the count c_{Δ_i} for each simplex Δ_i completely above h, then recursively insert h to H_{Δ_i} for each simplex Δ_i crossed by h, and finally recompute the answer $\Box c_{H_\Delta}(Q)$ from the subanswers $\Box c_{H_{\Delta_i}}(Q_i)$ in the manner described above. To delete h from H_Δ, we proceed similarly, decrementing the counts c_{Δ_i} instead. The recurrence for the insertion/deletion time is $t(n) = O(r^{1-1/d})t(n/r) + O(r)$, which solves to $t(n) = O(n^{1-1/d+\varepsilon})$ for an arbitrarily small $\varepsilon > 0$ if r is made arbitrarily large.

To delete a point q from Q, we recursively delete q from the subset Q_i that contains it, and then recompute the answer $\Box c_{H_\Delta}(Q)$ from the subanswers as above. The required time is only $O(\log n)$.

Initially Δ can be set to $\mathbb{R}^d$. We have thus obtained a data structure that maintains the value $\Box c_H(Q)$, supports updates to H in $\widetilde{O}(n^{1-1/d})$ time, can be preprocessed for any given Q in $T(n) = \widetilde{O}(nm^{1-1/d})$ time, and supports deletions from Q in $D(n) = O(\log n)$ time.

It remains to handle insertions to Q. For this, we apply a well-known general technique of Bentley and Saxe [5, 24, 25], which decomposes Q into logarithmically many deletion-only subsets (recall that the operator $\Box$ is decomposable) and transforms any data structure with preprocessing time $T(n)$ and deletion time $D(n)$ into a data structure that handles arbitrary updates to Q in amortized time $O((T(n)/n)\log n + D(n)) = \widetilde{O}(m^{1-1/d})$. As can be verified, this transformation preserves our ability to perform insertions and deletions to H, with the update time for H increased by a logarithmic factor, which is still $\widetilde{O}(n^{1-1/d})$. ∎

COROLLARY 4.2. *Given at most n points and at most n balls in $\mathbb{R}^d$, we can determine the ball that contains the least/most points in $\widetilde{O}(n^{1-\frac{1}{d+1}})$ amortized time fully dynamically. In $\mathbb{R}^d$, we can compare the Hausdorff distance of two sets of at*

most n points or the discrete 1-center radius of a set of n points with a fixed value r in $\widetilde{O}(n^{1-1/d})$ amortized time fully dynamically.

Proof. Transform each point to a $(d+1)$-dimensional hyperplane as in the proof of Corollary 4.2, transform each ball with center $(x_1, \ldots, x_d)$ and radius r to a $(d+1)$-dimensional point $(x_1, \ldots, x_d, r^2 - x_1^2 - \cdots - x_d^2)$, and take $\square$ to mean maximum/minimum. The second statement follows from the first: the slight improvement in the time bound is due to the fact that the balls have equal radius; here, the lifted points in Q lie on a common d-dimensional surface in $\mathbb{R}^{d+1}$, and the duals of the hyperplanes in H also lie on a common d-dimensional surface, so Agarwal and Matoušek's improved partition theorem [2] is applicable. □

Returning to the exact Hausdorff distance problem, we quickly mention a straightforward but fast algorithm for the special case when we expect only a small number of nearest neighbors to change in an update. This result is not surprising, but it makes us appreciate our earlier worst-case algorithms better. Still, the special-case algorithm would be interesting in applications where the update sequence is "random" (e.g., see [15]). The subsequent corollary mentions one particular consequence involving the *all-nearest-neighbors graph*, which connects each point $p \in P$ to its nearest neighbor in $P \setminus p$.

THEOREM 4.3. *We can maintain $\lambda_H(Q)$ for a set Q of at most n points in $\mathbb{R}^{d-1}$ and a set H of at most n hyperplanes in $\mathbb{R}^d$ in $\widetilde{O}(kn^{1-\frac{2}{\lfloor d/2 \rfloor + 1}})$ amortized time fully dynamically, with $\widetilde{O}(n^{2-\frac{2}{\lfloor d/2 \rfloor + 1}})$ space, where k is the number of changes to $\lambda_H(Q)$.*

Proof. Store H in a dynamic data structure for vertical ray shooting with $\widetilde{O}(n^{1-\frac{2}{\lfloor d/2 \rfloor + 1}})$ query and amortized update time [1]. Store $\lambda_H(Q)$ in a dynamic data structure for halfspace range reporting with $\widetilde{O}(n^{1-\frac{2}{\lfloor d/2 \rfloor + 1}} + A)$ query time (A is the answer size) and $\widetilde{O}(n^{1-\frac{2}{\lfloor d/2 \rfloor + 1}})$ amortized update time [1, 3]. The point set $\lambda_H(Q)$ itself can be maintained as follows: when a point q is inserted/deleted, simply insert/delete $\lambda_H(q)$, computable by vertical ray shooting; when a hyperplane h is inserted to H, find all k points q with $\lambda_H(q)$ above h by a halfspace range reporting query and reset each such $\lambda_H(q)$ to $\lambda_h(q)$; when h is deleted, retrieve all k points q with $\lambda_H(q)$ set to $\lambda_h(q)$ and recompute each such $\lambda_H(q)$ by vertical ray shooting. □

COROLLARY 4.4. *In $\mathbb{R}^d$, we can maintain the nearest neighbor of each point in one set of at most n points to another set of at most n points in $\widetilde{O}(kn^{1-\frac{2}{\lceil d/2 \rceil + 1}})$ amortized time fully dynamically, where k is the number of changes to the nearest neighbors. We can maintain the all-nearest-neighbors graph of an n-point set in $\widetilde{O}(n^{1-\frac{2}{\lceil d/2 \rceil + 1}})$ amortized time. We can maintain the largest discrete empty ball in the same time.*

Proof. The first statement is immediate by the standard transformation. The second statement can be obtained by a monochromatic variant of the algorithm, with the following well-known observation [28]: the degree of the all-nearest-neighbors graph is bounded by a constant, and thus the number of changes to the graph is $k = O(1)$ for every update. The largest distance in this graph is the radius of the largest discrete empty ball. □

The maintenance of the all-nearest-neighbors graph was raised by several researchers in connection with dynamic closest pairs [28], but considering that a dynamic all-nearest-neighbors algorithm can indirectly be used to answer nearest neighbor queries (by repeatedly inserting and then deleting the query point), the above bound is probably close to optimal.

The usual tricks could perhaps make the amortized bounds worst-case.

5. Optimizing over vertices of a 3-polytope. To solve problems like the largest empty circle (the original continuous version), we need to optimize a function over *all* points on a lower envelope rather than just a discrete set of points. Dynamization appears even harder. We may infer from the application that the optimum must be located at a vertex of the polytope (since we are actually maximizing a convex function), but the polytope, and thus its set of vertices, can change drastically in the worst case as hyperplanes are inserted and deleted. (Minimizing a convex function over a polytope is of course convex programming, but maximizing a convex function seems to require examining every vertex.)

We cannot afford to maintain the polytope explicitly after every update, so the idea is again to invoke Lemma 2.1 and use only a static structure, periodically rebuilt after a block of updates. The structure this time is more involved, as it needs to support queries on not just a set of points but a set of facial features (such as line segments) that come from the polytope.

This approach of implicitly maintaining a polytope again works in any fixed dimension in theory, but we will focus on problems involving three-dimensional polytopes that have efficient static solutions. (When the dimension exceeds 3, the number of vertices may be $\Omega(n^2)$ or bigger.)

The setup is as before and assumes a decomposable operator $\square$. Given a set H of planes in $\mathbb{R}^3$, let V_H denote the set of vertices of the lower envelope of H. The objective is to maintain $\square V_H$.

THEOREM 5.1. *Suppose that we can preprocess a set E of n pairs of planes in $\mathbb{R}^3$ in $\widetilde{O}(n)$ time so that $\square\{h_1 \cap h_2 \cap h \mid (h_1, h_2) \in E\}$ for any plane h can be computed in $\widetilde{O}(n^{1-\gamma})$ time, with $\gamma \geq 1/4$. Then we can maintain $\square V_H$ for a set H of n planes in $\mathbb{R}^3$ in $\widetilde{O}(n^{7/8})$ time per semi-online update.*

Proof. We show how to store a static set H so that $\square V_{H \cup H'}$ can be computed quickly given a block H' of b planes.

First construct the three-dimensional lower envelope of H in $O(n \log n)$ time [27] and preprocess it to support membership and ray shooting queries in $O(\log n)$ time [1]. In $\widetilde{O}(n)$ time, preprocess its $O(n)$ vertices V_H for three-dimensional simplex range searching [1] so that given any tetrahedron Δ, we can compute $\square(V_H \cap \Delta)$ in $\widetilde{O}(n^{2/3})$ time. Next, in $\widetilde{O}(n)$ time, preprocess the $O(n)$ edges E_H of the lower envelope for triangle-intersection queries so as to form canonical subsets $\{E_i\}_i$ of total size $\widetilde{O}(n)$ such that, given any triangle Δ, we can retrieve all edges (line segments) intersecting Δ as a union of disjoint canonical subsets $\{E_i\}_{i \in I}$ in $\widetilde{O}(n^{3/4})$ time, with $\sum_{i \in I} |E_i|^{3/4} = \widetilde{O}(n^{3/4})$—this involves multilevel range/intersection searching tools [1] (specifically, semi-algebraic range searching [2] in Plücker space; e.g., see [17, proof of Theorem 3.1], which examined a similar subproblem of quadrilaterial-intersection queries for rays). For yet another level, preprocess each canonical subset E_i as specified so that given any plane h intersecting every edge of E_i, $\square\{e \cap h \mid e \in E_i\}$ can be computed in $\widetilde{O}(n^{1-\gamma})$ time.

Given query set H', construct the lower envelope of H' (with vertex set $V_{H'}$ and edge set $E_{H'}$) and triangulate it into $O(b)$ triangles. Take each triangle Δ defined by plane $h' \in H'$, say.

- Vertices of V_H that lie directly below Δ are also vertices of $V_{H \cup H'}$, so combine the current answer with $\square\{v \in V_H \mid v \text{ directly below } \Delta\}$ by simplex range searching in $\widetilde{O}(n^{2/3})$ time.
- Consider the edges of E_H that intersect Δ. These edges can be partitioned

into canonical subsets $\{E_i\}_{i\in I}$. Take each such E_i. The intersection of the edges of E_i with h' are all vertices of $V_{H\cup H'}$, so combine the current answer with $\square\{e \cap h' \mid e \in E_i\}$. The time required is $\widetilde{O}(\sum_{i\in I} |E_i|^{1-\gamma}) = \widetilde{O}(n^{3/4})$.

Applying this process to all triangles requires $\widetilde{O}(bn^{3/4})$ time overall. So far, all vertices of $V_{H\cup H'}$ that are either vertices of V_H or intersections of edges of E_H with planes of H' have been accounted for. We can also take each edge $e' \in E_{H'}$, determine the at most two vertices of the intersection with the lower envelope of H, by ray shooting, and combine the answer with these vertices. We can further take each vertex of $V_{H'}$ that lies below the lower envelope of H and combine the answer with such vertices. The additional time is $O(b \log n)$, and the end result is $\square V_{H\cup H'}$.

The conclusion now follows from Lemma 2.1 with $\alpha = 1$ and $\beta = 1/4$. ∎

COROLLARY 5.2. *We can maintain the largest empty circle of an n-point set in $\mathbb{R}^2$, with center restricted inside any given triangle Δ, in $\widetilde{O}(n^{7/8})$ time per semi-online update.*

Proof. Apply the same transformation as in the proof of Corollary 4.2 to obtain n planes in $\mathbb{R}^3$. Add three nearly vertical planes along the edges of Δ (to ensure that the n planes cannot be seen from below when outside Δ). The largest empty circle must be centered at a vertex of the lower envelope of these $n + 3$ planes H (usually a Voronoi vertex, except in boundary cases). The optimal radius is then $\square V_H$, with the same operator $\square$ to maximize $x_3 + x_1^2 + x_2^2$. The requirement in the theorem (finding $\square\{h_1 \cap h_2 \cap h \mid (h_1, h_2) \in E\}$) seeks, for a given query plane h, the maximum of $O(n)$ functions in terms of h, parametrizable in 2 variables (since our planes are defined as liftings of points in $\mathbb{R}^2$). These nasty-looking bivariate functions nonetheless have constant description complexity, and by known semi-algebraic range searching and vertical ray shooting techniques in three dimensions [1, 2], we can achieve $\gamma = 1/3$. ∎

COROLLARY 5.3. *We can maintain the volume of the convex hull of an n-point set in $\mathbb{R}^3$ in $\widetilde{O}(n^{7/8})$ time per semi-online update.*

Proof. Apply duality to transform each given point p to a plane p^* so that facets of the upper hull of the points correspond to vertices of the lower envelope of the planes. For a vertex v defined by planes p_1^*, p_2^*, and p_3^*, we associate with it the volume of the tetrahedron $op_1p_2p_3$ for some fixed point o sufficiently far below the convex hull. The operator $\square$ just sums the volumes associated with the vertices of the given set. Applying a similar process to the lower hull and taking the difference yields the volume of the convex hull.

The theorem requires the sum of the volumes of op_1p_2p over n given pairs (p_1, p_2) and a query point p. By inspecting the proof of the theorem, we can ensure that the generated pairs (p_1, p_2) are consistently oriented with respect to the query point p. The volume of op_1p_2p is then a linear function in p (defined by a standard determinant), so the sum is also a linear function in p. By precomputing the coefficients in linear time, we can answer the volume-sum query in constant time for any given p, so $\gamma = 1$. ∎

One can imagine more applications of Theorem 5.1: for example, counting the number of vertices of a convex hull in $\mathbb{R}^3$, or determining the smallest/largest-area Delaunay triangle in $\mathbb{R}^2$. (The surface area of the convex hull, though, behaves differently, as we have to sum square roots.)

6. Measuring a union of unit cubes. We can apply the same approach to implicitly maintain structures other than a 3-polytope. To illustrate the idea on a simple example, we now explore the union of n unit axis-parallel cubes in three dimensions,

a structure also known to have linear complexity [6]. $O(\sqrt{n}\log n)$ dynamic algorithms for measuring the union of squares (in fact, arbitrary axis-parallel rectangles) were previously known by simple variants of the k-d tree (see [26]).

THEOREM 6.1. *We can maintain the volume of the union of a collection C of n unit axis-parallel cubes in $\mathbb{R}^3$ in $\widetilde{O}(\sqrt{n})$ time per semi-online update.*

Proof. We show how to store C so that the volume of $\bigcup(C \cup C')$ can be computed quickly given an additional set C' of b unit cubes.

First compute $\bigcup C$ and decompose this three-dimensional region into a collection S of $O(n)$ disjoint boxes (boxes here are axis-parallel); this computation can be done in $O(n \log n)$ time, as shown in [9]. Preprocess S in $\widetilde{O}(n)$ time so that given any query box $q \subset \mathbb{R}^3$, we can determine the sum of the volumes of $\sigma \cap q$ over all $\sigma \in S$ in $\widetilde{O}(1)$ time; in a moment, we will see exactly how this can be accomplished by orthogonal range searching.

Given query set C', compute $\bigcup C'$ and decompose the complement of the region into a collection S' of $O(b)$ disjoint boxes. Take each box $\sigma' \in S'$. Perform the above query to find the total volume of $\sigma \cap \sigma'$ over all $\sigma \in S$ in $\widetilde{O}(1)$ time. Summing over all $\sigma' \in S'$ yields the total volume of $\bigcup C$ outside $\bigcup C'$. Adding the volume of $\bigcup C'$ itself yields the final answer. The overall time is $\widetilde{O}(b)$, so we can apply Lemma 2.1 with $\alpha = \beta = 1$.

It remains to describe how to sum volumes of $\sigma \cap q$ over all $\sigma \in S$ for a given query box q. Lift each box $\sigma \in \mathbb{R}^3$ to a point $\sigma^* \in \mathbb{R}^6$ by taking the six coordinates of the box. By orthogonal range searching [1, 27], we can retrieve all boxes in S whose liftings lie in one of the 2^6 quadrants at q^* as a union of $\widetilde{O}(1)$ canonical subsets in $\widetilde{O}(1)$ time, after $\widetilde{O}(n)$-time preprocessing into canonical subsets of $\widetilde{O}(n)$ total size. Now, boxes σ inside each such quadrant intersect q (if at all) in a consistent "pattern" so that the volume of $\sigma \cap q$ can be characterized by a polynomial function (degree 3 at most) on the coordinates of q. By precomputing the (constant number of) coefficients of the sum of these polynomial functions in linear time for each canonical subset, we can therefore compute the sum of the volume of $\sigma \cap q$ over all σ^* inside a quadrant at q^* in $\widetilde{O}(1)$ time for any given q. Summing over all quadrants answers the query. ∎

The running time above is actually $O(\sqrt{n}\,\mathrm{polylog}\, n)$. With more effort, we should be able to maintain the surface area of the union of n unit axis-parallel cubes in $\mathbb{R}^3$ or the area/perimeter of a union of n homothets of a constant-size convex polygon in $\mathbb{R}^2$ (the latter union also has linear complexity).

7. Optimizing with multiple convex polygons. We started with optimization problems dealing with the interaction of points and a polytope. We will close with a more complicated form of optimization, but in the two-dimensional plane, dealing with interaction between two or more convex polygons. The planar width problem is perhaps the simplest in this category and was addressed in a previous paper [8]. Its relative, the minimum enclosing rectangle problem, is the main subject of this section; unlike in [8], we are not able to obtain a fully dynamic algorithm because of the added complications.

We first state the abstract problem. Given a set of lines H, let V_H be as before (the set of vertices of the lower envelope), but abusing notation slightly, let λ_H be instead a mapping from $\mathbb{R}^2$ to $\mathbb{R}^2$: $\lambda_H(q)$ is the point lying on the lower envelope of H and the vertical line at q. Let s be a constant. Below, $\langle \lambda_{H_1}, \ldots, \lambda_{H_s} \rangle(Q)$ denotes the set of tuples of points $\{\langle \lambda_{H_1}(q), \ldots, \lambda_{H_s}(q) \rangle \mid q \in Q\}$. The objective is to maintain $\square\langle \lambda_{H_1}, \ldots, \lambda_{H_s} \rangle(V_{H_1} \cup \cdots \cup V_{H_s})$ for s sets of lines $H_1, \ldots, H_s$ and some decomposable

operator $\square$.

Notation. Given a proper subset of indices $J \subset \{1, \ldots, s\}$, the *$J$-selector* refers to the following operator $\otimes$: $\langle p_1, \ldots, p_s\rangle \otimes \langle q_1, \ldots, q_s\rangle = \langle r_1, \ldots, r_s\rangle$, where $r_j = p_j$ if $j \in J$, and $r_j = q_j$ if $j \notin J$. There are a constant number $(2^s - 1)$ of such selectors.

THEOREM 7.1. *Suppose that we can preprocess a set $S \subset (\mathbb{R}^2)^s$ of n tuples (each consisting of s points on a common vertical line) in $\widetilde{O}(n)$ time so that given any s lines $h_1, \ldots, h_s$ and selector $\otimes$, $\square\{\langle \lambda_{h_1}(p_1), \ldots, \lambda_{h_s}(p_1)\rangle \otimes \langle p_1, \ldots, p_s\rangle \mid \langle p_1, \ldots, p_s\rangle \in P\}$ can be computed in $\widetilde{O}(n^{1-\gamma})$ time. Then we can maintain $\square\langle \lambda_{H_1}, \ldots, \lambda_{H_s}\rangle(V_{H_1} \cup \cdots \cup V_{H_s})$ for given sets $H_1, \ldots, H_s$ of at most n lines in $\mathbb{R}^2$ in $\widetilde{O}(n^{1-\gamma/2})$ time per semi-online update to $H_1, \ldots, H_s$.*

Proof. We show how to store $H_1, \ldots, H_s$ so that $\square\langle \lambda_{H_1 \cup H'_1}, \ldots, \lambda_{H_s \cup H'_s}\rangle(V_{H_1 \cup H'_1} \cup \cdots \cup V_{H_s \cup H'_s})$ can be computed efficiently given additional blocks $H'_1, \ldots, H'_s$ of size b.

Compute the lower envelope of each H_j (a convex polygon) in $O(n \log n)$ time. For each $v \in V_{H_1} \cup \cdots \cup V_{H_s}$, find $\lambda_{H_j}(v)$ by binary search. Using a binary tree construction, we can form canonical subsets $\{V_i\}_i$ of total size $O(n \log n)$ such that for any j, we can retrieve all points $v \in V_{H_j}$ inside a vertical slab as a union of $O(\log n)$ disjoint canonical subsets. For each canonical subset V_i, preprocess the tuples $\{\langle \lambda_{H_1}(v), \ldots, \lambda_{H_s}(v)\rangle \mid v \in V_i\}$ in the specified data structure.

Given query sets $H'_1, \ldots, H'_s$, construct the lower envelope of each H'_j in $O(b \log b)$ time. Draw vertical lines at the vertices of these s envelopes. In addition, intersect each edge of these envelopes with each of the lower envelopes of $H_1, \ldots, H_s$, by binary search [27] in total $O(b \log n)$ time. Draw vertical lines at these intersections. As a result, the plane is divided into $O(b)$ vertical slabs. Take each vertical open slab σ. Within σ, the lower envelope of $H_j \cup H'_j$ coincides with either the lower envelope of H_j or a single line $h'_j \in H'_j$. So, $V_{H_j \cup H'_j} \cap \sigma$ is either $V_{H_j} \cap \sigma$ or $\emptyset$. Assume the former.

Partition the point set $V_{H_j} \cap \sigma$ into $O(\log n)$ canonical subsets. Take each canonical subset V_i. Now, $\lambda_{H_k \cup H'_k}(V_i)$ is either $\lambda_{H_k}(V_i)$ or $\lambda_{h'_k}(V_i)$ for each k. Thus, $\square\langle \lambda_{H_1 \cup H'_1}, \ldots, \lambda_{H_s \cup H'_s}\rangle(V_i)$ is merely $\square\{\langle \lambda_{h'_1}(v), \ldots, \lambda_{h'_s}(v)\rangle \otimes \langle \lambda_{H_1}(v), \ldots, \lambda_{H_s}(v)\rangle \mid v \in V_i\}$ for some selector $\otimes$, and so can be computed in $\widetilde{O}(n^{1-\gamma})$ time per canonical subset V_i.

We conclude that $\square\langle \lambda_{H_1 \cup H'_1}, \ldots, \lambda_{H_s \cup H'_s}\rangle((V_{H_1 \cup H'_1} \cup \cdots \cup V_{H_s \cup H'_s}) \cap \sigma)$ can be computed in $\widetilde{O}(n^{1-\gamma})$ time. Repeating this process over all slabs requires $\widetilde{O}(bn^{1-\gamma})$ time overall. In addition, each of the $O(b)$ vertical lines drawn may pass through a vertex v_0 of $V_{H_1 \cup H'_1} \cup \cdots \cup V_{H_s \cup H'_s}$. If so, compute $\langle \lambda_{H_1 \cup H'_1}(v_0), \ldots, \lambda_{H_s \cup H'_s}(v_0)\rangle$ by binary searches on the lower envelopes of H_j and H'_j and combine with the answer. The additional time is $O(b \log n)$, and the end result is $\square\langle \lambda_{H_1 \cup H'_1}, \ldots, \lambda_{H_s \cup H'_s}\rangle(V_{H_1 \cup H'_1} \cup \cdots \cup V_{H_s \cup H'_s})$.

The conclusion now follows from Lemma 2.1 with $\alpha = 1$ and $\beta = \gamma$. ∎

COROLLARY 7.2. *We can maintain the minimum-perimeter rectangle enclosing an n-point set $P \subset \mathbb{R}^2$ in $\widetilde{O}(n^{1/2})$ time per semi-online update.*

Proof. We represent the rectangle using five parameters $\xi, \eta_1, \ldots, \eta_4$:

$$\{(x, y) \mid \ -\eta_1 \le \xi x + y \le \eta_2, \ \ -\eta_3 \le x - \xi y \le \eta_4\}.$$

The perimeter is $2(\eta_1 + \cdots + \eta_4)/\sqrt{1 + \xi^2}$.

So, transform each point $(a, b) \in P$ to the following four lines: $\{(\xi, \eta_1) \mid \eta_1 = -\xi a - b\}$ in H_1, $\{(\xi, \eta_2) \mid \eta_2 = \xi a + b\}$ in H_2, $\{(\xi, \eta_3) \mid \eta_3 = -a + \xi b\}$ in H_3, and $\{(\xi, \eta_4) \mid \eta_4 = a - \xi b\}$ in H_4. Define the operator $\square$ to minimize $(\eta_1 + \cdots + \eta_4)/\sqrt{1 + \xi^2}$ over all tuples $\langle(\xi, \eta_1), \ldots, (\xi, \eta_4)\rangle$ of the given set. Our problem is equivalent to

determining $\Box\langle\lambda_{H_1},\ldots,\lambda_{H_4}\rangle(\mathbb{R}^2)$. Since one of four sides of the optimal rectangle must be defined by a convex hull edge of the original points (see the appendix), our problem reduces to finding $\Box\langle\lambda_{H_1},\ldots,\lambda_{H_4}\rangle(V_{H_1}\cup\cdots\cup V_{H_4})$, so Theorem 7.1 is applicable with $s=4$.

Now, given the selector's index set $J\subset\{1,\ldots,4\}$, the theorem requires a data structure to store a set S of n tuples so that given query lines $\{(x,y)\mid y=s_jx+t_j\}$ $(j=1,\ldots,4)$, we can find the tuple $\langle(\xi,\eta_1),\ldots,(\xi,\eta_4)\rangle\in S$ that maximizes

$$\frac{\sum_{j\in J}(s_j\xi+t_j)+\sum_{j\notin J}\eta_j}{\sqrt{1+\xi^2}} = \frac{\xi}{\sqrt{1+\xi^2}}\sum_{j\in J}s_j+\frac{1}{\sqrt{1+\xi^2}}\sum_{j\in J}t_j+\frac{\sum_{j\notin J}\eta_j}{\sqrt{1+\xi^2}}.$$

By storing the plane

$$\left\{(X,Y,Z)\mid Z=\frac{\xi}{\sqrt{1+\xi^2}}X+\frac{1}{\sqrt{1+\xi^2}}Y+\frac{\sum_{j\notin J}\eta_j}{\sqrt{1+\xi^2}}\right\}$$

associated with each tuple for vertical ray shooting in three dimensions [1, 27] (by constructing a three-dimensional convex hull and performing two-dimensional point location), we can achieve $\gamma=1$. □

COROLLARY 7.3. *We can maintain the minimum-area rectangle enclosing an n-point set $P\subset\mathbb{R}^2$ in $\widetilde{O}(n^{5/6})$ time per semi-online update.*

Proof. Proceed as in the previous proof, but with a different objective to minimize $(\eta_1+\eta_2)(\eta_3+\eta_4)/(1+\xi^2)$.

The data structuring requirement is now more complex. Again we want to preprocess n tuples of the form $\langle(\xi,\eta_1),\ldots,(\xi,\eta_4)\rangle$. Let $\{(x,y)\mid y=s_jx+t_j\}$ $(j=1,\ldots,4)$ be the query lines. We consider the following cases of selectors only, as all other cases are symmetric or trivial.

- $J=\{1\}$. We want to minimize

$$\frac{(s_1\xi+t_1+\eta_2)(\eta_3+\eta_4)}{1+\xi^2} = \frac{\xi(\eta_3+\eta_4)}{1+\xi^2}s_1+\frac{\eta_3+\eta_4}{1+\xi^2}t_1+\frac{\eta_2(\eta_3+\eta_4)}{1+\xi^2}.$$

  By storing the plane $\{(X,Y,Z)\mid Z=\frac{\xi(\eta_3+\eta_4)}{1+\xi^2}X+\frac{\eta_3+\eta_4}{1+\xi^2}Y+\frac{\eta_2(\eta_3+\eta_4)}{1+\xi^2}\}$ associated with each tuple for three-dimensional vertical ray shooting as before, we can handle this type of query in $\widetilde{O}(1)$ time.
- $J=\{1,2\}$. We want to minimize

$$\frac{(s_1\xi+t_1+s_2\xi+t_2)(\eta_3+\eta_4)}{1+\xi^2} = \frac{\xi(\eta_3+\eta_4)}{1+\xi^2}[s_1+s_2]+\frac{\eta_3+\eta_4}{1+\xi^2}[t_1+t_2].$$

  This case reduces to two-dimensional vertical ray shooting.
- $J=\{1,3\}$. This is the most involved case and we will use linearization here [1]. We want to minimize

$$\begin{aligned}&\frac{(s_1\xi+t_1+\eta_2)(s_3\xi+t_3+\eta_4)}{1+\xi^2}\\ &\quad=s_1s_3+\frac{1}{1+\xi^2}[t_1t_3-s_1s_3]+\frac{\xi}{1+\xi^2}[s_1t_3+s_3t_1]\\ &\qquad+\frac{\xi\eta_4}{1+\xi^2}s_1+\frac{\eta_4}{1+\xi^2}t_1+\frac{\xi\eta_2}{1+\xi^2}s_3+\frac{\eta_2}{1+\xi^2}t_3+\frac{\eta_2\eta_4}{1+\xi^2}.\end{aligned}$$

By storing the hyperplane $\{(X_1, \ldots, X_7) \mid X_7 = \frac{1}{1+\xi^2}X_1 + \frac{\xi}{1+\xi^2}X_2 + \frac{\xi\eta_4}{1+\xi^2}X_3 + \frac{\eta_4}{1+\xi^2}X_4 + \frac{\xi\eta_2}{1+\xi^2}X_5 + \frac{\eta_2}{1+\xi^2}X_6 + \frac{\eta_2\eta_4}{1+\xi^2}\}$ associated with each tuple for seven-dimensional vertical ray shooting, we can handle this type of queries in $\widetilde{O}(n^{2/3})$ time with $\widetilde{O}(n)$ preprocessing [1, 22].

- $J = \{1, 2, 3\}$. This is similar to the previous case. We want to minimize

$$\begin{aligned}\frac{(s_1\xi + t_1 + s_2\xi + t_2)(s_3\xi + t_3 + \eta_4)}{1+\xi^2} &= (s_1 + s_2)s_3 + \frac{1}{1+\xi^2}[(t_1 + t_2)t_3 - (s_1 + s_2)s_3] \\ &\quad + \frac{\xi}{1+\xi^2}[(s_1 + s_2)t_3 + s_3(t_1 + t_2)] + \frac{\xi\eta_4}{1+\xi^2}[s_1 + s_2] + \frac{\eta_4}{1+\xi^2}[t_1 + t_2].\end{aligned}$$

Again we can use vertical ray shooting, this time in four dimensions. Thus, we can achieve $\gamma = 1/3$. □

The running time for Corollary 7.2 is actually $O(\sqrt{n}\,\mathrm{polylog}\, n)$ (only elementary tools are used). We will leave the reader with the question of whether the same approach works for similar problems like the minimum enclosing equilateral triangle (or convex polygon of a fixed angle sequence).

8. Some consequences. Faster dynamic data structures can generally lead to faster implementations of static algorithms. We briefly indicate a few sample applications of our results to illustrate their importance.

The generalized discrete 2*-center problem.* Given an n-point set $P \subset \mathbb{R}^2$, we want to find two points $p_1, p_2 \in P$ to minimize $f(r_1, r_2)$ such that every point $q \in P$ is within radius r_1 of p_1 *or* within radius r_2 of p_2. Here, $f(\cdot, \cdot)$ is some constant-time computable function that is monotone increasing in both arguments. Agarwal, Sharir, and Welzl [4] studied the most basic version with $f(r_1, r_2) = \max\{r_1, r_2\}$ and gave an $\widetilde{O}(n^{4/3})$ algorithm, but other functions, such as $f(r_1, r_2) = r_1 + r_2$, are reasonable in some situations. (See [13] for results on the generalized version of the original 2-center problem, where p_1 and p_2 can be arbitrary points in $\mathbb{R}^2$.)

An exhaustive algorithm may try each point $p_1 \in P$, shrink a ball B centered at p_1 with a decreasing radius r_1, and compute $r_2 = \min_{q\in P} \max_{p\in P\setminus B} d(p, q)$. We need to try n possible radii r_1 for each of the n choices for p_1, and if we compute r_2 from scratch in $O(n \log n)$ time via the farthest-point Voronoi diagram each time, the total running time would be $O(n^3 \log n)$. By applying the method of Corollary 3.2 and noting that $P \setminus B$ is subjected to insertions only as B shrinks (the insertion sequence is actually off-line), we immediately obtain an improved time bound of $\widetilde{O}(n^{3-1/6})$. In any constant dimension d, the bound is $\widetilde{O}(n^{3-\frac{1}{(d+1)(\lceil d/2\rceil+1)}})$.

The minimum-diameter spanning tree. An interesting application of the generalized discrete 2-center problem was considered by Ho et al. [20]: given an n-point set $P \subset \mathbb{R}^d$, find a spanning tree that minimizes its *diameter* (i.e., the maximum distance over all pairs of points, where the "distance" between p and q refers to the sum of the edge lengths, measured in the Euclidean metric, along the path connecting p and q in the tree). As Ho et al. showed, the resulting tree turns out to have very low *link diameter* (every pair of points is connected by a path with at most three edges), and consequently, the problem reduces to an additively weighted version of the discrete 2-center problem, where the objective is to minimize $r_1 + r_2 + d(p_1, p_2)$.

We can use the same exhaustive-search algorithm, except that while considering a center candidate p_1, we assign each point $q \in P \setminus B$ an additive weight of $w_q =$

$d(p_1, q)$ and maintain $\min_{q \in P} \max_{p \in P \setminus B}[d(p, q) + w_q]$ instead (using the method of Corollary 3.2). This results in the first subcubic time bound ($\widetilde{O}(n^{3-\frac{1}{(d+1)(\lceil d/2 \rceil + 1)}})$) for the problem.

Greedy disk cover. Consider the following (NP-hard) geometric version of the set cover problem: given n points and n balls in $\mathbb{R}^d$, find the smallest number of balls that together cover all the points. Although various approximation algorithms have been proposed (e.g., see [7]), the most well known is perhaps the greedy algorithm (which has a logarithmic approximation factor): choose the ball that covers the most points, remove the ball and all points inside it, and repeat. The naive implementation would require $O(n)$ time per iteration, for a total time of $O(n^2)$. By applying the fully dynamic Corollary 4.2, we can reduce the running time of the greedy algorithm to $O(n^{2-\frac{1}{d+1}})$. For unit balls, the time reduces to $O(n^{2-1/d})$.

Klee's measure problem for unit hypercubes. Klee's measure problem in $\mathbb{R}^d$ seeks the volume of n axis-parallel boxes. The fastest algorithm known is due to Overmars and Yap from 1991 [26] and runs in $O(n^{d/2} \log n)$ time. The algorithm basically exploits an orthogonal binary space partition of the $(d-2)$-faces of the boxes, and because such partitions have a worst-case lower bound of size $\Theta(n^{d/2})$ [12], improvement appears difficult in general.

Better bounds for the special case of unit hypercubes are possible, however (e.g., see [18]), because the union of unit hypercubes has size $O(n^{\lfloor d/2 \rfloor})$ only [6]. For example, for $d = 3$, we can afford to construct the union explicitly [9] and therefore find the volume in $O(n \log n)$ time. In higher dimensions, assuming that there is an algorithm $\mathcal{A}_d$ to construct the union and decompose the interior/exterior into disjoint boxes in $\widetilde{O}(n^{\lfloor d/2 \rfloor})$ time (for $d > 3$, we are unable to find an explicit reference to such an algorithm), we can solve Klee's problem for unit hypercubes in $\widetilde{O}(n^{\lfloor d/2 \rfloor})$ time—an improvement over Overmars and Yap's bound for odd dimensions d.

An interesting question involves the case of unit hypercubes in *even* dimensions $d > 2$. By a standard space sweep, the four-dimensional Klee's problem reduces to the off-line maintenance of the volume of a dynamic three-dimensional union and, by Theorem 6.1, can therefore be solved in $\widetilde{O}(n^{3/2})$ time. This is surprising considering that the union itself may have quadratic size in $\mathbb{R}^4$. A similar approach works for higher even dimensions and yields a time bound of $\widetilde{O}(n^{\lceil d/2 \rceil - 1 + \frac{1}{\lceil d/2 \rceil}})$, assuming the existence of algorithm $\mathcal{A}_{d-1}$ (the simple calculations are left for the interested readers to verify).

Hypercubes of possibly different sizes can have unions of complexity $\Theta(n^{\lceil d/2 \rceil})$ [6]. Assuming the existence of an algorithm to construct and decompose the union in near-optimal time, we can also obtain a similar algorithm, in this case with running time $\widetilde{O}(n^{\lfloor d/2 \rfloor + \frac{1}{\lfloor d/2 \rfloor + 1}})$, which is an improvement in odd dimensions $d \geq 5$.

Of course, a solution for hypercubes implies a solution for *fat* axis-parallel boxes, where the edge lengths of a box differ by at most a constant factor. (Unlike Overmars and Yap's method, though, our method does not solve the related problem of computing the *depth* in an arrangement of boxes [18].)

9. Conclusion. We have shown that a number of basic geometric problems have nontrivial (*sublinear*) dynamization results under the *semi-online* model. More important than the specific results themselves, however, are our general strategies for attacking different categories of problems; these strategies can serve as helpful design models to tackle further problems in dynamic computational geometry.

Of course, the ultimate wish is to have *fully* dynamic, *polylogarithmic* algorithms,

but at present this appears to be beyond our grasp for any of the problems discussed here. We hope that our results will inspire more work in this challenging area.

Appendix. It is a well-known fact [19] that the minimum-area rectangle enclosing a set of planar points has one side touching an edge of the convex hull, but since we are unable to find a reference stating the analogous fact for the minimum-perimeter rectangle, we include a quick proof:

Parametrize the rectangle differently in terms of variables $\xi, \eta, \omega_1, \omega_2, \zeta$:

$$\{(x, y) \mid \ \omega_1 \le \xi x + \eta y \le \omega_1 + \zeta, \quad \omega_2 \le \eta x - \xi y \le \omega_2 + (1 - \zeta)\}.$$

The perimeter is $2/\sqrt{\xi^2 + \eta^2}$. The problem is to maximize $\xi^2 + \eta^2$ subject to the constraints that the n given points lie in the rectangle—these constraints are linear in $\xi, \eta, \omega_1, \omega_2, \zeta$. To finish, observe that the maximum of a convex function over a polytope must be located at a vertex, here defined by five five-dimensional bounding hyperplanes, two of which are associated with a common side of the rectangle. □

Acknowledgment. I thank Der-Tsai Lee for (accidentally) mentioning the minimum-diameter spanning tree application to me.

IMPROVED BOUNDS FOR THE ONLINE SCHEDULING PROBLEM*

JOHN F. RUDIN III† AND R. CHANDRASEKARAN†

Abstract. The problem considered here is the same as the one discussed in [G. Galambos and G. J. Woeginger, eds., *SIAM J. Comput.,* 22 (1993), pp. 349–355]. It is an m-machine online scheduling problem in which we wish to minimize the competitive ratio for the makespan objective. In this paper, we show that $\sqrt{3}$ is a lower bound on this competitive ratio for $m = 4$. In particular, we show how to force a lower bound of $\sqrt{3} - \epsilon$ for any positive ϵ. This reduces the gap between the performance of known algorithms [S. Albers, in *Proceedings of the* 29*th Annual ACM Symposium on Theory of Computing,* ACM, New York, 1997, pp. 130–139] and the lower bound. The method used introduces an approach to building the task master's strategy.

1. Introduction.

We have m identical machines and a sequence of jobs to be processed on any one of these machines. Preemption is not allowed. We wish to minimize makespan. This is an online scenario: there are two players—a scheduler and a task master. The task master releases information on jobs (such as processing time) sequentially; the scheduler must schedule each job on a machine without knowing the future job information. These decisions are irrevocable. However, he knows the processing time of the current job before it is scheduled. At any time, the task master may stop issuing any further job. At this time, we calculate the ratio of the length of the schedule to the optimal offline schedule (which knows all of the data up front). The scheduler wants to minimize this ratio (known as *the competitive ratio*), and the task master attempts to make the scheduler look bad and therefore maximizes this ratio.

History. The problem of finding the optimal solution has been solved for two and three machines. In [8], Graham demonstrated that the greedy algorithm, now called list scheduling, had a competitive ratio of $2 - \frac{1}{m}$. The list scheduling algorithm always puts a new job on the machine with the lowest current load. This is an optimal algorithm for two or three machines, as was shown in [5]. For four or more machines, better algorithms have been found.

In 1989, Faigle, Kern, and Turan [5] showed a lower bound of $\frac{1+\sqrt{2}}{2} (\approx 1.7071)$ for all $m \geq 4$. For more than three machines, neither the best scheduling algorithm nor the competitive ratio is known. An upper bound that improved on Graham's greedy algorithm for four or more machines was discovered by Galambos and Woeginger [7] in 1993. Their algorithm had a competitive ratio of $2 - \frac{1}{m} - \epsilon(m)$ for some positive $\epsilon(m)$ (which tends to zero as $m \to \infty$). Bartal, Fiat, Karloff, and Vohra [2] provided an algorithm that was 1.978 competitive for all values of m. That bound was improved upon by Karger, Phillips, and Torng [10] with an algorithm for $m \geq 8$ that guarantees a competitive ratio of at most 1.945. This is a generalization of the earlier algorithm. In 1994 , Bartal, Karloff, and Rabani [3] improved the lower bound to 1.837 for

TABLE 1.1

m	LB	UB
2	$\frac{3}{2}$	$\frac{3}{2}$
3	$\frac{5}{3}$	$\frac{5}{3}$
4	1.7310	1.7333
5	1.7462	1.7708
6	1.7730	1.8
7	1.7910	1.8229
∞	1.8520	1.9230

$m \geq 3454$. Albers [1] produced an algorithm which is 1.923 competitive. She also improved the lower bound to 1.852 for m a multiple of 40.

Table 1.1 shows the best currently known bounds, as given in Fiat and Woeginger [6]. Many of these bounds were taken from Chen, van Vliet, and Woeginger [4].

Our primary result in this paper is to show a task master strategy that forces a minimum ratio of $\sqrt{3} - \epsilon$ for any positive ϵ for four machines. By using this method we can also improve the lower bounds in general for $m \geq 4$, and this is taken up in a forthcoming paper.

2. General method. The method presented in this paper will improve the lower bounds by presenting sequences of jobs for a given competitive ratio $(1 + V)$ and m, such that the scheduler is forced to schedule in a specific manner. Specifically, successive *layers* of jobs will be produced, each containing m jobs, as shown in Figure 2.1. The layers are constructed such that if the scheduler puts any two of the jobs in the same layer on the same machine, that machine will instantly have a makespan greater than or equal to the current divisor (a lower bound on the offline schedule length) times the competitive ratio. Therefore, regardless of the scheduling algorithm, at the end of a series of layers, we know that one of the following conditions holds:

- each machine has one job from each layer, or
- the competitive ratio of $1 + V$ or more has already been achieved.

Such a sequence guarantees that at the end of each layer, every machine has a minimum load equal to the sum of the smallest job in each layer, or the target competitive ratio has already been achieved.

The *current layer* of jobs will be designated the *A-layer* and will be $A_1, A_2, \ldots, A_m$. The layer before it will be $B_1, B_2, \ldots, B_m$, and the layer before that will be $C_1, C_2, \ldots, C_m$. After the first job in a layer is determined, no job in that layer will ever be any smaller; that is, $A_1 \leq A_i$ for all i.

We define S as the lowest possible machine load, assuming that each machine has one job from each layer. The total S depends on the number of layers that have been scheduled, so we define

$$S_B = B_1 + C_1 + \cdots,$$
$$S_A = A_1 + B_1 + C_1 + \cdots. = A_1 + S_B = A_1 + B_1 + S_C,$$

etc.

Therefore, when an entire layer has been scheduled by any scheduling algorithm, either a competitive ratio greater or equal to $(1 + V)$ will have already been achieved or every machine will have a load of at least S. For the remainder of this paper, it will

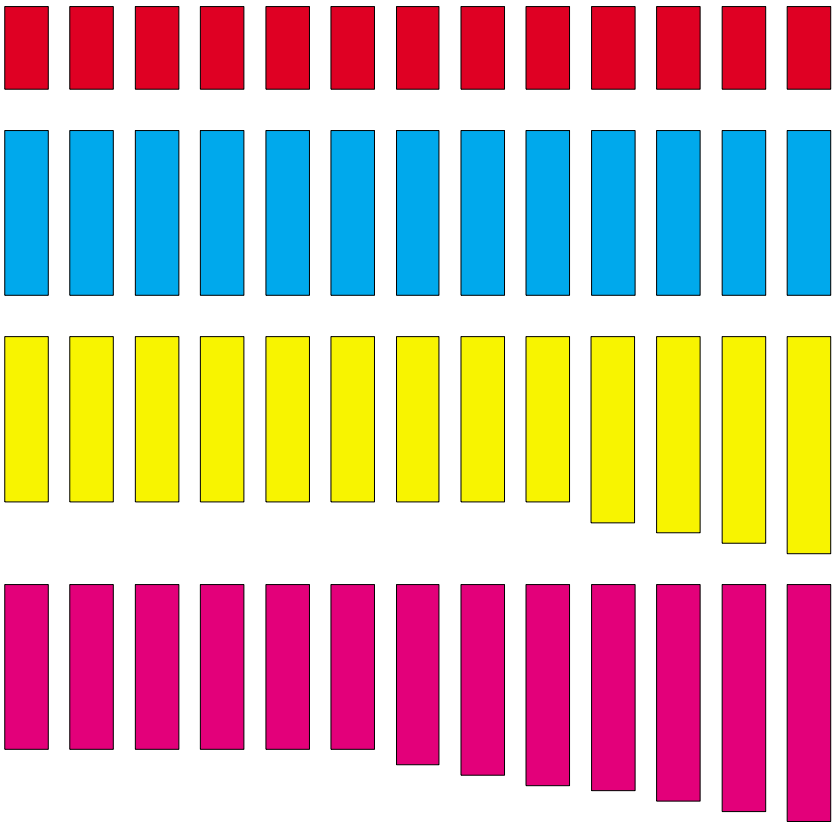

FIG. 2.1. *Typical sequence of jobs in the layering method.*

be assumed that the scheduler avoids the target competitive ratio as long as possible, and so it is assumed that at the end of each row, every machine has been given one job from each layer.

We also define the ratios

$$R_A = \frac{A_1}{S_A}, \quad R_B = \frac{B_1}{S_B},$$

etc.

The goal of the process is to produce a sequence of layers, each one reducing R, until $R = \frac{1}{2V}$. If $R = \frac{1}{2V}$, then, since $R_A = \frac{A_1}{S_A}$, we have

$$S_A = 2A_1V.$$

It is also necessary that all current jobs fit on an offline schedule on $m-1$ machines with loads no greater than $2A_1$. *This condition must be checked separately.* Then a final job of $2A_1$ is offered. No matter which machine it is scheduled on, that machine

will have a load of at least

$$2A_1 + S_A = 2A_1(1 + V).$$

Since the offline schedule for all jobs on m machines is $2A_1$, this will immediately force a competitive ratio of $1 + V$.

There will be two types of layers, each of m jobs, that we might use:

1. m jobs of equal size, i.e., $A_1 = A_2 = \cdots = A_i = \cdots = A_m$;
2. m jobs satisfying the relation $A_m \leq A_1 + 2C_1$; the offline makespan when A_m is being scheduled is exactly $A_1 + B_1 + 2C_1$.

In all cases, $A_1 \leq A_i$ for all i. They will be identically equal to A_1 as long as possible, becoming larger only when a larger value is needed to force the scheduler to schedule them on separate machines. The smallest load possible for a machine that already has a job from this layer is S_A. Therefore, A_i will be chosen so that a machine with load $S_A + A_i$ would force a competitive ratio of $1 + V$. For this reason, A_i will be $(1 + V)D_i - S_A$, where D_i is the divisor when A_i is to be scheduled. Since D_i is nondecreasing, it follows that $A_i \leq A_{i+1}$.

Consider the final situation, in which the next job of size J must force a competitive ratio of at least $1 + V$. We may assume, without loss of generality, that the divisor is 1 by scaling all jobs equally. Let S_A be the smallest total workload on any machine. Then the following statements are true:

1. $J \leq 1$ (no job can be greater than the divisor).
2. $S_A + J \geq 1 + V$.
3. Therefore, $S_A \geq V$.

The layering construction method presented assumes that a layer has just been completed as well as the fact that $J = 1$. Since the $m + 1$ jobs $A_1, \ldots, A_m$ plus J must all be scheduled on m machines with makespan less than or equal to 1, at least one of those jobs must be less than or equal to $\frac{1}{2}$. The smallest of these is A_1, so we assume that $A_1 = \frac{1}{2}$.

Therefore, for the final layer, the ratio $R_A = \frac{A_1}{S_A} \leq \frac{1}{2V}$. Achieving this ratio is a primary goal of the layering method.

2.1. Type-1 layers. Type-1 layers are layers of m identical jobs, that is, $A_1 = A_i$ for all i; and the scheduler is required to put each job of the layer on a separate machine, or he will immediately have caused the competitive ratio $1+V$ to have been reached. Let S_B be the smallest machine load prior to the placing of A_1. Then, by construction,

$$S_B = B_1 + C_1 + \cdots,$$
$$S_A = S_B + A_1.$$

Let $R = \frac{A}{S_A}$. Then, for a type-1 layer to force each A-job onto a distinct machine, we must have

$$A + S_A \geq (1 + V)D.$$

Since every machine has a load of at least S_A, it follows that $D \geq S_A$, with equality holding only if all previous layers are also type-1 layers. Therefore, A_1 must be chosen such that

$$A_1 + S_A \geq (1 + V)D \geq (1 + V)S_A.$$

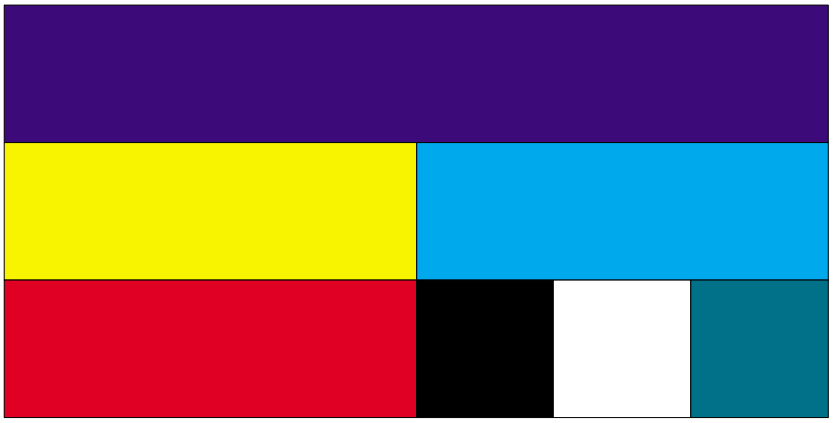

FIG. 2.2.

Hence

$$A_1 \geq VS_A,$$

and, therefore,

$$R = \frac{A_1}{S_A} \geq V.$$

By the previous result, R must be reduced to $\frac{1}{2V}$ by the end of the process. Therefore, type-1 layers can only achieve the desired competitive ratio if

$$V \leq R \leq \frac{1}{2V}.$$

This implies that $V^2 \leq \frac{1}{2}$, and hence $1 + V \leq 1 + \frac{1}{\sqrt{2}} \cong 1.7071$.

Using type-1 layers alone, Faigle, Kern, and Turan demonstrated that $\frac{3}{2}$ was the highest possible forced competitive ratio with two machines, and $\frac{5}{3}$ was the highest possible with three machines [5].

With two machines, a single layer of two jobs of size 1 is offered, followed by a job of size 2. The first two jobs are forced on separate machines to avoid the competitive ratio of 2, and then the final job forces a competitive ratio of $\frac{3}{2}$.

For three machines, two layers are needed. A layer of size $B = 1$ is followed by a layer of size $A = 3$, which must be scheduled on separate machines to avoid a competitive ratio of $\frac{7}{4}$. Since all jobs in type-1 layers are identical, no subscript is needed to distinguish them. At that point, every machine has a load of 4. When a final job of $2A$ is sent, then the machine it is scheduled on must have a makespan of 10. The offline schedule has makespan 6, as shown in Figure 2.2.

Therefore, a competitive ratio of $\frac{5}{3}$ is forced.

Since Graham's list scheduling algorithm can never be forced above $2 - \frac{1}{m}$, this is the highest that can be forced for $m = 2, 3$.

In 1989, Faigle, Kern, and Turan [5] showed a lower bound of $1 + \frac{\sqrt{2}}{2} (\cong 1.7071)$ for all $m \geq 4$. They used two type-1 layers. The first layer is $\frac{\sqrt{2}}{2} - \frac{1}{2} (\cong 0.2071)$. The

second layer is $\frac{1}{2}$; if two of these jobs are scheduled on the same machine, the ratio is

$$\frac{(\frac{\sqrt{2}}{2}+\frac{1}{2})}{\frac{\sqrt{2}}{2}} = 1+\frac{\sqrt{2}}{2}.$$

A final job of size 1 completes the sequence. As shown above, this is the highest that can be achieved with type-1 layers alone. To force higher ratios, we need type-2 layers.

2.2. Type-2 layers. A type-2 layer is a layer of m jobs, satisfying the relation

$$A_m \le A_1 + 2C_1,$$

and the divisor when A_m is being scheduled is exactly $A_1 + B_1 + 2C_1$. At the end of a layer, there are m A-layer jobs, each greater than or equal to A_1. It follows that if the ideal makespan is to be less than $2A_1$, then each of the m A-level jobs must be scheduled on different machines, so each machine contains at least A_1, from an A-level job, and unless it was a type-1 layer, one of the machines received $A_m > A_1$. Then, either one of the machines has two B-level jobs, or each machine has one of them. Therefore, the makespan is at least $\min[A_1 + 2B_1, A_m + B_1]$. Therefore, if

$$A_m \ge A_1 + B_1,$$

then the divisor is at least $A_1 + 2B_1$. For the divisor to go below this bound, each A-level job must be on a separate machine, and each B-level job must be as well. Therefore, to reduce the divisor further, we must enforce $A_m < A_1 + B_1$. By the same reasoning as before, if

$$A_m \ge A_1 + C_1,$$

then the competitive makespan is at least $A_1 + B_1 + 2C_1$. Type-2 layers are designed to force this competitive ratio. A type-2 layer is created by keeping the competitive divisor less than or equal to $A_1 + B_1 + 2C_1$ during the offering of the layer. This is always less than $A_1 + 2B_1$ or $2A_1$.

Since there are m separate jobs of size A_1 or greater, this bound requires m A-level jobs to be on the m machines for the competitive schedule. Since there are also m separate jobs of size B_1 or greater, these jobs must also each be on separate machines for the competitive schedule. Therefore, the machine with job $A_m (= A_1 + 2C_1)$ and some B-level job has a makespan of at least $A_1 + B_1 + 2C_1$. It is therefore sufficient to show a competitive schedule with makespan $A_1 + B_1 + 2C_1$ to prove that is the competitive divisor.

Example 1. As an example, consider the following series of jobs for $m = 4$ and $V = \frac{19}{11} = 1.727272$:

1	1	1	1
3	3	3	3
16	16	16	16
44	44	44	50
88			

The first three layers are type-1. They must be assigned across all four machines to avoid a competitive ratio of $\frac{7}{4}$. Therefore, at the end of the third row, each machine has a makespan of 20. As the first three numbers in the fourth layer are being assigned, the competitive divisor can be no more than 60, as shown by the following offline schedule: $[44, 16]; [44, 16]; [44, 16]; [16, 3, 3, 3, 3, 1, 1, 1, 1]$. It follows that the scheduler cannot allow any machine to exceed $60(\frac{19}{11})(= 103.636)$. *Note that the argument does not require proof that* 60 *is the length of the ideal schedule—merely that it is an upper bound on the length.*

Since each machine already has a load of 20, the scheduler cannot put any two of the 44-jobs on the same machine, which would give a makespan of 108.

When the job of length 50 is added, the makespan of the ideal schedule cannot be less than $A_1+B_1+2C_1(= 44+16+6 = 66)$, as shown above. The following schedule shows that this makespan is possible: $[50, 16]; [44, 16, 3, 3]; [44, 16, 3, 3]; [44, 16, 1, 1, 1, 1]$. Therefore adding the 50-job to a machine that has a 44-job already (and hence a makespan of 64) will give a makespan of 114 and a competitive ratio of $\frac{114}{66}(= 1.727272)$. If the scheduler avoids this by placing it on the fourth machine, then each machine has a load of at least 64, so the final job forces a makespan of $64+88(= 152)$. The competitive divisor is 88, as shown:$[88]; [44, 44]; [50, 16, 16, 3, 1, 1]; [44, 16, 16, 3, 3, 3, 1, 1]$. Therefore, a competitive ratio greater or equal to $\frac{152}{88}(= 1.727272)$ is forced against any scheduling algorithm.

Assume S_A, R, and A_1 as before. To create a type-2 layer, first a B_1 is selected, and all of the B_i jobs will be identical. B_1 must be chosen such that all B_i jobs must be forced onto separate machines to avoid an immediate ratio of $1 + V$. Since the C-row has already been scheduled across all m machines, we have already calculated a divisor D_C such that all jobs through row C can fit on m machines with makespan on any machine less than or equal to D_C. Therefore, the divisor

$$D_B = D_C + B_1.$$

Then B_1 must be sufficiently large that

$$2B_1 + S_C \geq (1 + V)D_B = (1 + V)(D_C + B_1).$$

Hence

$$(1 - V)B_1 \geq (1 + V)D_C - S_C,$$

and so

$$B_1 \geq \frac{(1 + V)D_C - S_C}{(1 - V)}.$$

B_1 is chosen to make the equality true. A_1 must be chosen so that

$$A_m + S_A \geq (1 + V)(A_1 + B_1 + 2C_1).$$

In a type-2 layer,

$$A_1 + 2C_1 \geq A_m,$$

and the divisor when A_m is added is $A_1 + B_1 + 2C_1$. Also,

$$S_A = A_1 + B_1 + S_C.$$

Therefore,

$$A_m + S_A \geq (1 + V)(A_1 + B_1 + 2C_1),$$

and hence

$$2A_1 + 2C_1 + B_1 + S_C \geq A_m + S_A \geq (1 + V)(A_1 + B_1 + 2C_1),$$

from which it follows that

$$(1 - V)A_1 \geq VB_1 + 2VC_1 - S_C$$

and

$$A_1 \geq \frac{(VB_1 + 2VC_1 - S_C)}{1 - V}.$$

A_1 is chosen to make the equality true in the above relation. Note that, in the first step above, this forces

$$A_m = A_1 + 2C_1.$$

Later, this restriction will be relaxed in some cases. However, this restriction gives us the smallest possible A_1, and so the smallest possible R_A, and the largest possible V. At each step, the ratio R_A is reduced. The reduction occurs asymptotically. The limit has no simple closed-form result, but experiment shows that, for V less than or equal to 0.73742, the limit can be reached so that a final type-2 layer can force the competitive ratio of $1 + V$.

More formally, consider the asymptotic behavior of the sequence. The highest possible V for which a solution can be reached is one for which the ratio of $\frac{S_A}{2A_1}$, or $\frac{1}{2R}$, approaches V, as the number of layers increases without bound. This can be found by assuming that

$$\frac{S_A}{2A_1} = V$$

and that the layers are identical in form. (Of course, this condition can never be reached in practice. However, an infinite series of type-2 layers will approach it asymptotically.) Therefore, we assume a steady state, at the end of the C-layer, with $C = \frac{1}{2}$ and $S_C = V$. By construction,

$$\begin{aligned} B_1 &= \frac{(1 + V)D_C - S_C}{1 - V} \\ &= \frac{(1 + V)D_C - V}{1 - V}, \end{aligned}$$

and

$$A_1 = \frac{VB_1 + 2VC_1 - S_C}{1 - V}$$
$$= \frac{VB_1}{1 - V}.$$

By the hypothesis that the asymptotic conditions have been reached, we can assume that

$$D_C = D_A \frac{C_1}{A_1} = (A_1 + B_1 + 2C_1)\frac{1}{2A_1}$$
$$= \frac{A_1 + B_1 + 1}{2A_1}.$$

Finally, we have the relation that

$$\frac{R_A}{S_A} = \frac{1}{2V}$$

or

$$2VA_1 = S_A = A_1 + B_1 + S_C$$
$$= A_1 + B_1 + V.$$

Therefore, we have four equations in the variables A_1, B_1, D_C, and V. The solution was found numerically and is

$$A_1 \cong 6.20899278265808,$$
$$B_1 \cong 2.21087597923733,$$
$$D_C \cong 0.758566573648259,$$
$$V \cong 0.737421563000747.$$

This is the highest value for V that we can achieve with type-1 and type-2 layers. The existing literature shows that, for two and three machines, type-2 layers are *not* needed to achieve optimal values of V. However, for four machines, we need type-2 layers, and these are sufficient to prove the results of this paper. We take up the case of more layers in a forthcoming paper.

3. Four machines. Here we use type-1 and type-2 layers, and they are interspersed. Alternate layers are of each type.

We will prove the following result.

THEOREM 3.1. *For any $\epsilon > 0$, there exists a finite series of jobs that can force any scheduler to a ratio of $\sqrt{3} - \epsilon$ when $m = 4$.*

A construction method will be presented, creating a sequence of jobs for $1 + V = \sqrt{3} - \epsilon$. It will be shown that the sequence terminates, and jobs in each layer (each layer contains four jobs) must be scheduled on the four different machines to avoid a ratio greater than or equal to $1 + V$. After all these layers of jobs are scheduled, a final job will force a ratio of at least $1 + V$.

Note. The type-1 layers are designated by B_i and the type-2 layers by A. These alternate. The sets of jobs are shown below.

B_n	B_n	B_n	B_n
A_n	A_n	A_n	A_n
B_{n-1}	B_{n-1}	B_{n-1}	B_{n-1}
A_{n-1}	A_{n-1}	A_{n-1}	$A_{n-1}+2A_n$
B_{n-2}	B_{n-2}	B_{n-2}	B_{n-2}
A_{n-2}	A_{n-2}	A_{n-2}	$A_{n-2}+2A_{n-1}$
.	.	.	.
.	.	.	.
B_i	B_i	B_i	B_i
A_i	A_i	A_i	A_i+2A_{i+1}
.	.	.	.
.	.	.	.
.	.	.	.
.	.	.	.
B_0	B_0	B_0	B_0
A_0	A_0	A_0	A_0+2A_1
$2A_0$			

S_i and R_i have the usual definition of S_A and R_A for the layer that begins with A_i. Since type-2 layers are being used, each B-row will have four identical jobs, and each A-row will have three identical jobs A_i and one job of size $A_i + 2A_{i+1}$.

3.1. Construction. If $1+V \le 1+\frac{\sqrt{2}}{2}$, then a simple solution using type-1 layers [5] is already known. For $1+\frac{\sqrt{2}}{2} < 1+V < \sqrt{3}$, the form of the sequence of jobs will be as shown in the table above.

We also define

$$S_i = \sum_{j=i}^{n} (A_j + B_j)$$

and

$$R_i = \frac{A_i}{S_i}.$$

Thus S_i is the minimum load on a machine when the jobs n through i have been loaded, as long as no two jobs (of four jobs) from any layer are scheduled on the same machine. Also let

$$V = \sqrt{3} - 1 - \epsilon,$$
$$M = \frac{3V-2}{2}.$$

To begin, define S_0 to be an arbitrary number. Then

$$A_0 = \frac{S_0}{2V},$$
$$R_0 = \frac{A_0}{S_0} = \frac{1}{2V},$$

$$\begin{aligned} B_0 &= S_0 - A_0 - MA_0, \\ S_i &= MA_{i-1}, \qquad i \geq 1, \\ Ai &= \frac{A_{i-1} - 2B_{i-1}}{4}, \qquad i \geq 1, \\ R_i &= \max\left[1, \frac{A_i}{S_i}\right], \qquad i \geq 1. \end{aligned}$$

If $R_i < V$, then

$$\begin{aligned} B_i &= S_i - A_i - MA_i \\ &= S_i - A_i - S_{i+1}, \end{aligned}$$

and we go to index $(i+1)$. If $V \leq R_i \leq 1$, then

$$B_i = S_i - A_i,$$

and the sequence terminates. If $R_i = 1$, then $B_i = 0$, and we redefine $A_i = S_i$, and the sequence terminates. The terminating i becomes n. Note that, by definition of B_n,

$$S_n = A_n + B_n.$$

Also, by definition of B_i,

$$S_i = A_i + B_i + S_{i+1}.$$

Therefore, by induction,

$$S_i = \sum_{j=i}^{n} (A_j + B_j).$$

This represents the smallest possible load on the smallest machine after the jobs n through i have been scheduled if each set of four jobs in a layer has been split among all four machines.

Claim. The procedure described above terminates in finite time for $(1+V) < \sqrt{3}$ and produces a sequence of jobs that will force a ratio of at least $(1+V)$.

LEMMA 3.2. *The procedure described above terminates in finite time for* $(1+V) < \sqrt{3}$.

Proof. Let $(1+V) = \sqrt{3} - \epsilon$. Then $V = \sqrt{3} - 1 - \epsilon$. Since $(1+V) > 1 + \frac{\sqrt{2}}{2}$, we know that

$$\begin{aligned} \epsilon &= \sqrt{3} - (1+V) \\ &< \sqrt{3} - \left(1 + \frac{\sqrt{2}}{2}\right) \\ &< 1.73206 - 1.70710 \\ &= 0.02496 \\ &< \frac{1}{40}. \end{aligned}$$

For $1 \leq i < n$, we have

$$\begin{aligned} R_{i+1} &= \frac{A_{i+1}}{S_{i+1}} \\ &= \frac{\frac{1}{4}A_i - \frac{1}{2}B_i}{MA_i} \\ &= \frac{1}{4M}\frac{A_i - 2(S_i - A_i - S_{i+1})}{A_i} \\ &= \frac{1}{4M}\frac{A_i(1 - (\frac{2}{R_i}) + 2 + 2M)}{A_i} \\ &= \frac{3 + 2M - (\frac{2}{R_i})}{4M} \\ &= \frac{3}{4M} + \frac{1}{2} - \frac{1}{2MR_i}. \end{aligned}$$

We define

$$\delta_i = R_i - R_{i-1},$$

and, therefore,

$$R_i = R_0 + \sum_{j=1}^{i} \delta_j.$$

Recalling that

$$R_0 = \frac{1}{2V},$$

we get

$$\begin{aligned} \delta_1 &= \frac{3}{4M} + \frac{1}{2} - \frac{1}{2MR_0} - \frac{1}{2V} \\ &= \frac{3V + 2MV - 4V^2 - 2M}{4MV} \\ &= \frac{3V + (3V-2)V - 4V^2 - (3V-2)}{4MV} \\ &= \frac{2 - 2V - V^2}{4MV}. \end{aligned}$$

Substituting

$$V = \sqrt{3} - 1 - \epsilon,$$

we get

$$\begin{aligned} \delta_1 &= \frac{2 - 2(\sqrt{3} - 1 - \epsilon) - (\sqrt{3} - 1 - \epsilon)^2}{4MV} \\ &= \frac{2\sqrt{3}\epsilon - \epsilon^2}{4MV} \\ &= \frac{2\sqrt{3}\epsilon - \epsilon^2}{(6V-4)V} \end{aligned}$$

$$
\begin{aligned}
&> \frac{2\sqrt{3}\epsilon - \epsilon^2}{(6\sqrt{3}-10)(\sqrt{3}-1)} \\
&> \frac{2\sqrt{3}\epsilon - \frac{\epsilon}{40}}{28-16\sqrt{3}} \\
&= \frac{(7+4\sqrt{3})(2\sqrt{3}-\frac{1}{40})\epsilon}{(7+4\sqrt{3})(28-16\sqrt{3})} \\
&> \frac{(14\sqrt{3}+24-\frac{7}{40}-\frac{\sqrt{3}}{10})\epsilon}{196-192} \\
&> \left(6+\frac{7}{2}\sqrt{3}-\frac{7}{160}-\frac{\sqrt{3}}{40}\right)\epsilon \\
&> (6+6.062-0.0438-0.0434)\epsilon \\
&> 11\epsilon > 0.
\end{aligned}
$$

Therefore,

$$\delta_1 = R_1 - R_0 > 0,$$

and so $R_1 > R_0$.

For $i \geq 2$,

$$
\begin{aligned}
\delta_i &= \frac{3}{4M} + \frac{1}{2} - \frac{1}{2MR_{i-1}} - \frac{3}{4M} - \frac{1}{2} + \frac{1}{2MR_{i-2}} \\
&= \frac{R_{i-1} - R_{i-2}}{2MR_{i-1}R_{i-2}} \\
&= \frac{\delta_{i-1}}{2MR_{i-1}R_{i-2}}.
\end{aligned}
$$

Since $\delta_1 > 0$, by induction it follows that $\delta_i > 0$, and hence $R_i - R_{i-1} > 0$. Now, if $R_j \geq V$, the sequence stops at j. Otherwise,

$$
\begin{aligned}
\delta_i &= \frac{\delta_{i-1}}{2MR_{i-1}R_{i-2}} \\
&> \frac{\delta_{i-1}}{(3V-2)V^2} \\
&= \frac{\delta_{i-1}}{(3(\sqrt{3}-1)-2)(\sqrt{3}-1)^2} \\
&= \frac{\delta_{i-1}}{(3\sqrt{3}-5)(4-2\sqrt{3})} \\
&= \frac{\delta_{i-1}}{22\sqrt{3}-38} \\
&> 9.5\delta_{i-1} \\
&> (9.5)^{i-1}\delta_1.
\end{aligned}
$$

Therefore,

$$\begin{aligned} R_i &= R_0 + \sum_{j=1}^{i} \delta_j \\ &> R_0 + \delta_1 \sum_{j=1}^{i} (9.5)^{j-1} \\ &= R_0 + \delta_1 \frac{(9.5)^i - 1}{9.5 - 1} \\ &> R_0 + \frac{11\epsilon}{8.5}[(9.5)^i - 1]. \end{aligned}$$

Therefore, R_i increases at an exponential rate, and the sequence will terminate in no more than $c(-\log_{9.5} \epsilon)$ steps, creating a sequence of no more than $[8+c(-8\log_{9.5} \epsilon)]$ jobs for some fixed positive constant c. This proves the lemma.

Remark 1. Note that if $1 + V > \sqrt{3}$ (and therefore ϵ is negative), we have

$$\begin{aligned} \delta_1 &= \frac{2 - 2(\sqrt{3} - 1 - \epsilon) - (\sqrt{3} - 1 - \epsilon)^2}{4MV} \\ &= \frac{2\epsilon\sqrt{3} - \epsilon^2}{4MV} < 0. \end{aligned}$$

Also,

$$\delta_i < (9.5)\delta_{i-1},$$

and so R_i does not increase with i. Hence the method does not terminate for $1+V > \sqrt{3}$. For $1 + V = \sqrt{3}$ (which implies that $\epsilon = 0$), $\delta_i = \delta_1 = 0$, and the method does not terminate. Therefore, this method cannot be used for $1 + V \geq \sqrt{3}$.

LEMMA 3.3. *The jobs from steps n through i can be sorted into four sets totaling no more than $\frac{3}{2}A_i$ and into three sets of no more than $2A_i$.*

Proof. The proof is by induction, beginning with $i = n$. With $i = n$, there are eight jobs

B_n	B_n	B_n	B_n
A_n	A_n	A_n	A_n

with $A_n \geq VS_n$ and $B_n \leq (1 - V)S_n$. Since $V \geq \frac{2}{3}$, $B_n \leq \frac{1}{2}A_n$, and hence

$$A_n + B_n \leq \frac{3}{2}A_n.$$

There are obviously four such sets. Also,

$$A_n + B_n + B_n \leq A_n + A_n.$$

Therefore, the three sets $\{A_n, A_n\}$,$\{A_n, B_n, B_n\}$,$\{A_n, B_n, B_n\}$ satisfy the first condition. Therefore, the lemma is true for $i = n$.

Now, assume that it is true for the jobs in sets n through i. Then those jobs can be collected into three sets that total to a number less than or equal to $2A_i$. These three sets, which are interchangeable for purposes of this proof, can be labeled X_{3i}.

Similarly, we have four sets X_{4i}, each of which total to a number less than or equal to $\frac{3}{2}A_i$.

Now, consider the three sets $\{A_{i-1}, A_{i-1}\}$,$\{A_{i-1}, B_{i-1}, B_{i-1}, X_{3i}, X_{3i}\}$, and $\{A_{i-1}+2A_i, B_{i-1}, B_{i-1}, X_{3i}\}$.

The total of the jobs in the first set is $2A_{i-1}$. Since the total in X_{3i} is less than or equal to $2A_i$, by the induction hypothesis, the second set's total is less than or equal to the third set's total. Therefore, we need only consider the third set. Please note that since

$$A_i = \frac{(A_{i-1} - 2B_i)}{4},$$

by construction, we have

$$A_{i-1} = 2B_{i-1} + 4A_i.$$

The total load of the third machine is

$$\begin{aligned} A_{i-1} + 2A_i + B_{i-1} + B_{i-1} + X_{3i} &\\ &\leq A_{i-1} + 2B_{i-1} + 4A_i \\ &\leq \ A_{i-1} + A_{i-1}. \end{aligned}$$

Therefore, all three machines have loads that are less than or equal to $2A_{i-1}$.

Now consider the four sets $\{A_{i-1}, B_{i-1}, X_{3i}\}$,$\{A_{i-1}, B_{i-1}, X_{3i}\}$,$\{A_{i-1}, B_{i-1}, X_{3i}\}$, and $\{A_{i-1} + 2A_i, B_{i-1}\}$.

Since the total load in set X_{3i} is less than or equal to $2A_i$, each set has a total load less than or equal to

$$\begin{aligned} A_{i-1} + B_{i-1} + 2A_i &\\ &= A_{i-1} + \frac{1}{2}A_{i-1} = \frac{3}{2}A_{i-1}. \end{aligned}$$

So Lemma 3.3 is true for $i-1$. Therefore, by induction, it is true for all $0 \leq i \leq n$.

LEMMA 3.4. *The jobs $\{B_i, B_i, B_i, B_i\}$ must each be scheduled on a separate machine to prevent having a ratio $1+V$ or more. Furthermore, the four A-level jobs must each be scheduled on a separate machine to prevent having a ratio $1+V$ or more.*

Proof. Clearly it is true for B_n, since that situation is simply scheduling four identical jobs. If two of them are scheduled on one machine, the ratio is $2 > 1+V$. Since

$$R_n = \frac{A_n}{S_n} \geq V,$$

we have $A_n \geq VS_n$. Scheduling two jobs of size A_n on one machine gives a load of

$$\begin{aligned} (B_n + A_n) + A_n &\geq S_n + VS_n \\ &= (1+V)S_n. \end{aligned}$$

The divisor is S_n, so this forces a ratio greater than or equal to $1+V$. Therefore, the lemma is true for n. Assume that it is true for the jobs in sets n through i. Then all jobs in sets n through i must be scheduled evenly. In this case, the smallest

possible load on any machine is S_i. If two jobs of size B_{i-1} are scheduled on one machine, its load is greater than or equal to

$$\begin{aligned} S_i + 2B_{i-1} &= S_i + A_{i-1} - 4A_i \\ &= MA_{i-1} + A_{i-1} - 4A_i \\ &= \frac{M+1}{M} S_i - 4A_i \\ &= \frac{M+1}{MR_i} A_i - 4A_i \\ &= \frac{M+1-4MR_i}{MR_i} A_i. \end{aligned}$$

By Lemma 3.3, the divisor must be less than or equal to

$$\begin{aligned} B_{i-1} + X_{4i} &\leq \frac{1}{2} A_{i-1} - 2A_i + \frac{3}{2} A_i \\ &= \frac{1}{2}(A_{i-1} - A_i) \\ &= \frac{1}{2}\left(\frac{S_i}{M} - A_i\right) \\ &= \frac{1}{2}\left(\frac{A_i}{R_i M} - A_i\right) \\ &= \frac{1-R_iM}{2R_iM} A_i. \end{aligned}$$

Therefore, the ratio must be greater than or equal to

$$\begin{aligned} &\frac{2(M+1-4R_iM)}{1-R_iM} \\ &= \frac{2M+2-8R_iM}{1-R_iM} \\ &= 2 + \frac{2M-6R_iM}{1-R_iM}. \end{aligned}$$

Since $M \cong 0.09807 < 0.1$ and $R_i < V < \sqrt{3} - 1 < 0.733$ for $i < n$,

$$\begin{aligned} &2 + \frac{2M-6R_iM}{1-R_iM} \\ &= 2 - \frac{M(6R_i-2)}{1-R_iM} \\ &> 2 - \frac{0.1(4.398-2)}{0.9267} \\ &= 2 - 0.258 \\ &= 1.742 > (1+V). \end{aligned}$$

Therefore, two B_i cannot be scheduled on the same machine without exceeding the competitive ratio $1+V$. So if the lemma is true for n through i, then it is true for B_i.

The jobs $\{A_{i-1}, A_{i-1}, A_{i-1}, A_{i-1} + 2A_i\}$ must each be scheduled on separate machines to prevent having a ratio of $1+V$ or more.

As the fourth job is scheduled, any attempt to put it on the same machine as one of the other three will result in a machine whose load is at least

$$N_{i-1} = S_i + B_{i-1} + 2A_{i-1} + 2A_i = MA_{i-1} + 2A_{i-1} + \frac{1}{2}A_{i-1}$$
$$= A_{i-1}\left(M + \frac{5}{2}\right).$$

By Lemma 3.3, the denominator is no more than

$$D_{i-1} = \frac{3}{2}A_{i-1}.$$

So the ratio is at least

$$\frac{2M+5}{3} = \frac{3V-2+5}{3}$$
$$= \frac{3V+3}{3}$$
$$= 1+V.$$

As the second and third jobs are scheduled, any attempt to put two jobs on the same machine will result in a machine load of at least

$$S_i + B_{i-1} + 2A_{i-1} = A_{i-1}\left(M + \frac{5}{2} - 2\frac{A_i}{A_{i-1}}\right) = N_{i-1} - 2\frac{A_i}{A_{i-1}}.$$

The denominator is

$$A_{i-1} + B_{i-1} = D_{i-1} - 2\frac{A_i}{A_{i-1}}.$$

Therefore, this ratio is greater than $\frac{N_{i-1}}{D_{i-1}}$, previously shown to be greater than or equal to $1+V$. Therefore, by induction, Lemma 3.4 is true.

LEMMA 3.5. *The final job of $2A_0$ will force a ratio of at least $1+V$.*

Proof. By the previous lemma, if a scheduler schedules any two jobs from the same layer on one machine, it immediately forces a ratio greater than $1+V$. Therefore, the scheduler is forced to put one from each layer on each of the four machines. So the smallest possible load on any machine is the sum of the smallest load in each layer. This sum is S_0. By construction,

$$S_0 = 2A_0V.$$

Therefore, the numerator when a job of $2A_0$ is added will be at least

$$2A_0V + 2A_0 = (1+V)2A_0.$$

By Lemma 3.3, the denominator can be no more than $2A_0$. Therefore, the ratio is at least $1+V$. Therefore, this finite sequence forces a ratio of

$$1+V = \sqrt{3} - 1 - \epsilon$$

against any scheduler strategy.

Example 2. Let $\epsilon = 10^{-8}$. Then $1+V = 1.732050798$, $M = .098076196$, and the sequence in Table 3.1 is generated.

TABLE 3.1
Sequence of variables to generate layers for $1 + V = \sqrt{3} - 10^{-8}$.

1,830,126,994	1,830,126,994	1,830,126,994	1,830,126,994
5,000,000,000	5,000,000,000	5,000,000,000	5,669,873,006
10,000,000,000			

Since $R_7 > V$, the sequence terminates at $n = 7$. Therefore, the series of jobs in Table 3.2 guarantees a ratio greater than or equal to $\sqrt{3} - 10^{-8}$, against any scheduler strategy.

In a forthcoming paper, we discuss how this approach can lead to better lower bounds for a larger number of machines.

NEW LOWER BOUND TECHNIQUES FOR DYNAMIC PARTIAL SUMS AND RELATED PROBLEMS*

THORE HUSFELDT† AND THEIS RAUHE‡

Abstract. We study the complexity of the dynamic partial sum problem in the cell-probe model. We give the model access to nondeterministic queries and prove that the problem remains hard. We give the model access to the right answer ± 1 as an oracle and prove that the problem remains hard. This suggests which kind of information is hard to maintain.

From these results, we derive a number of lower bounds for dynamic algorithms and data structures: We prove lower bounds for dynamic algorithms for existential range queries, reachability in directed graphs, planarity testing, planar point location, incremental parsing, and fundamental data structure problems like maintaining the majority of the prefixes of a string of bits. We prove a lower bound for reachability in grid graphs in terms of the graph's width. We characterize the complexity of maintaining the value of any symmetric function on the prefixes of a bit string.

Key words. cell-probe model, partial sum, dynamic algorithm, data structure

1. Introduction.

The partial sum problem is to maintain n bits $x_1, \ldots, x_n \in \{0, 1\}$ that are subject to updates

$$\textit{update}(i)\text{: change } x_i \text{ to } 1 - x_i$$

and compute queries about the partial sums $x_1 + \cdots + x_i$.

It is easy to construct data structures that provide either very fast updates (by computing the answer from scratch after each query) or very fast queries (by recomputing all partial sums after each update). However, in many partial sum problems—and in many dynamic problems in general—we cannot have both. This trade-off between *update time* and *query time* was established by Fredman and Saks [15], who showed that, with the parity query

$$\textit{parity}(i)\text{: return } x_1 + \cdots + x_i \mod 2,$$

the partial sum problem requires time $\Omega(\log n / \log\log n)$ per operation on the unit-cost RAM with logarithmic cell size. In other words, even the least significant bits of the partial sums are hard to maintain.

The motivation for the present paper is that the hardness of the problem depends on the following query: If the parity query is replaced by

$$\textit{or}(i)\text{: return "yes" iff } x_1 + \cdots + x_i \geq 1 \text{ (equivalently, return } x_1 \vee \cdots \vee x_i),$$

then a Van Emde Boas tree provides an implementation in time $O(\log \log n)$ per operation, which is exponentially faster.

We show which queries are hard in this sense.

General partial sum queries. Consider two other natural partial sum queries:

$$\begin{aligned} &\textit{majority}(i)\text{: return 1 iff } x_1 + \cdots + x_i \geq \lceil \tfrac{1}{2} i \rceil, \\ &\textit{equality}(i)\text{: return 1 iff } x_1 + \cdots + x_i = \lceil \tfrac{1}{2} i \rceil. \end{aligned}$$

We can formulate these problems as database queries like "Did as many male as female guests arrive before noon?" or "Are more French than English talks scheduled between Tuesday and Friday?" Similarly, these problems can be viewed as natural *range query* problems in computational geometry.

Proposition 3 of the present paper shows that both problems require time $\Omega(\log n / \log \log n)$ per operation, just as parity. We then extend our analysis of the majority problem to the class of *threshold* functions and characterize the complexity of the resulting partial sum problem in terms of the size of the threshold in Proposition 4. This connects the majority problem, where the threshold is $\frac{1}{2}i$, and the *or* problem above, where the threshold is 1. Finally, we generalize this to the entire class of *symmetric* functions in Proposition 11.

Intriguingly, the resulting bounds closely resemble the corresponding results from Boolean circuit complexity, where these problems have been studied intensively, hinting at a connection between the dynamic and parallel realms.

Main contribution. Our main technical and conceptual contributions are lower bounds for partial sum problems in very strong models of computation. All our other results follow from these bounds.

The idea is to provide the query algorithm with well-defined parts of the answer for free without reducing the problem's complexity. We phrase the results for the *signed partial sum problem*. The problem is to maintain a string $x \in \{-1, 0, +1\}^n$ under the following operations:

$$\begin{aligned} &\textit{update}(i, a)\text{: change } x_i \text{ to } a \in \{-1, 0, +1\}, \\ &\textit{query}(i)\text{: return } x_1 + \cdots + x_i \mod 2. \end{aligned}$$

We prove two theorems about this problem.

Theorem 1 shows that, even in models with *nondeterministic* queries (defined and discussed in section 2), the partial sum problem requires time $\Omega(\log n / \log \log n)$ per operation. It is known that this is also the deterministic complexity of the problem [9, 15], so nondeterminism does not help.

Theorem 3 studies the same problem in a *promise* setting, where the (deterministic) query algorithm receives an almost correct answer for free. The updates are as before, and the query is

$$\textit{parity}(i, s)\text{: return } x_1 + \cdots + x_i \mod 2 \text{ provided that } \left| s - \sum_{j=1}^{i} x_j \right| \leq 1$$

(otherwise, the behavior of the query algorithm is undefined).

We show that this problem still requires $\Omega(\log n / \log \log n)$ per operation.

Lower bounds for dynamic algorithms. We present some applications to dynamic algorithms and data structure problems other than partial sums. Because Theorems 1 and 3 hold in very strong models of computation, we can construct powerful reductions.

We can show that the existential problem for orthogonal range queries in the plane requires time $\Omega(\log^{1/2} n)$ per operation (Proposition 2). We also present bounds for planar point location in monotone subdivisions [5, 26], reachability in upward planar digraphs [28], and incremental parsing of balanced parentheses [11]. We show that these problems require time $\Omega(\log n/\log\log n)$ per operation (Propositions 5–8). It is known [10, 14, 17, 23] that this is also a lower bound for reachability in grid graphs. However, grid graphs of constant width allow a reachability algorithm in time $O(\log\log n)$ per operation [4], an exponential improvement. We prove a lower bound that is parameterized by the width w of the graph: Proposition 10 states that dynamic reachability for grid graphs of width $w = O(\log n/\log\log n)$ requires time $\Omega(w)$ per operation, bridging the gap between the two results.

Apart from the bound for the existential range query problem, for which the authors recently proved a stronger bound using a different technique [3], all these bounds are new and the best known.

Related work. Fredman introduced the partial sum problem as a "toy problem which is both tractable and surprisingly interesting" [13], and it has been the focal point of many investigations of dynamic complexity in a variety of models [15, 31]. We reason within the cell-probe model of Fredman [12] and Yao [30] with some extensions to cope with our stronger modes of computation. The model can be viewed as a nonuniform version of the random access computer with arbitrary register instructions. Lower bounds are especially valid on RAMs with unit-cost instructions and logarithmic cell size. The success of this model is partly due to the validity of these bounds in light of schemes like hashing, indirect addressing, bucketing, pointer manipulation, or recent algorithms that exploit the parallelism inherent in unit-cost instructions. For these reasons, the cell-probe model has arguably become the model of choice for lower bounds for dynamic computation.

Theorems 1 and 3 are proved by extending the chronogram method, which was introduced by Fredman and Saks [15] and got its name in [7].

The prefix parity problem was solved in [15], but no nontrivial lower bounds for the majority or equality problems follow from that. The results from [6, 21, 22, 29] can be seen to imply $\Omega(\log\log n/\log\log\log n)$ lower bounds using an entirely different technique based on Ajtai's result [2]; and [19] reports $\Omega((\log n/\log\log n)^{1/2})$ for equality and $\Omega(\log n/(\log\log n)^2)$ for the majority.

2. Nondeterminism in dynamic algorithms.

2.1. Example: Range queries. We can illustrate our concept of nondeterministic queries using the *existential range query* problem. The object is to maintain a set $S \subseteq \{1,\dots,n\}^2$ of points in the plane under the following operations:

update(x): add $x \in \{1,\dots,n\}^2$ to S, or remove it if it is already there,

exists(y): return "yes" iff S contains a point x in the rectangle defined by the origin and y, i.e., such that $x_1 \le y_1$ and $x_2 \le y_2$.

With *nondeterministic* queries, the problem is very easy: guess a point and verify that it is in $S \cap R$. This shows that positive instances of this problem have short,

maintainable witnesses—the points themselves. On the other hand, it is known that, for deterministic computation, this problem requires time $\Omega(\log n/\log\log n)$ [3]; we prove a somewhat weaker bound in Proposition 2. Thus the hardness of this problem lies in maintaining precisely the kind of information that nondeterminism provides for free.

However, this is not true for all problems; we shall show that queries about the *size* $|R \cap S|$ remain hard even with nondeterminism. Thus we see that the hardness of the two problems, both of which have the same deterministic complexity, hinges on information of a fundamentally different kind.

Another example from computational geometry is *dynamic convex hull*, the problem of maintaining the convex hull of a set of points S, where points are inserted and removed. The query operation asks whether the query point q lies inside or outside the convex hull of S. Again, we can solve this problem with a trivial update algorithm that simply stores S in a large table. (In the cell-probe model, we do not worry about memory space; otherwise, we can use standard dictionaries.) The nondeterministic query guesses three points from S and verifies that the query point lies in the triangle spanned by these points—a well known result in plane geometry asserts that this is necessary and sufficient.

Thus we have identified a class of dynamic problems, namely, those with fast nondeterministic queries. Problems in this class have positive instances with short witnesses, and these witnesses can be maintained by an efficient data structure. This encompasses the class of problems where the outcome of each query depends on only a small number of updates. Contrast this with the problems identified in [15], where each update affects only a small number of queries, e.g., dictionary problems.

2.2. A model for nondeterministic query algorithms. We introduce a model for nondeterministic query algorithms for dynamic *decision* problems, where the query returns 0 or 1. We allow query algorithms to nondeterministically load a value into a memory cell. The semantics are as usual: The value returned by a nondeterministic query is 1 unless all nondeterministic choices return 0. For example, the following program solves in constant time the existential range query problem, storing all points from S in a two-dimensional array M:

update(x_1, x_2):
  $M[x_1, x_2] := 1 - M[x_1, x_2]$,

exists(y_1, y_2):
  guess $x_1 \le y_1$ and $x_2 \le y_2$
  return $M[x_1, x_2]$.

We should mention that we have not defined the *side-effects* of a nondeterministic query algorithm, i.e., the effect of its assignments to memory. This can be done in a number of ways; for example, we might say that if there are computations (i.e., sequences of nondeterministic choices) that result in "1," the algorithm will execute one of these computations; otherwise, it will execute a computation leading to "0." Our lower bound is immune to precisely how these effects are defined, since the hard operation sequence constructed in the proof needs only a single query, which happens at the very end.

2.3. Signed partial sum. The *signed partial sum* problem is to maintain a string of letters $x \in \{-1, 0, +1\}^n$, initially 0^n, under updates that change the letters

of x and queries about the parity of the prefix sums of x:

$$\begin{aligned} &\textit{update}(i,a)\text{: change } x_i \text{ to } a \in \{-1,0,+1\},\\ &\textit{query}(i)\text{: return } x_1 + \cdots + x_i \mod 2. \end{aligned}$$

The data structure of Dietz [9] solves this problem deterministically in time $O(\log n/\log\log n)$ per operation with logarithmic cell size. The next theorem states that nondeterministic queries can do no better. We state this theorem as a trade-off between update and query time.

THEOREM 1. *Every nondeterministic algorithm for the signed partial sum problem with cell size b, update time t_u, and query time t_q must satisfy*

$$t_q = \Omega\left(\frac{\log n}{\log(bt_u \log n)}\right). \tag{1}$$

Also, the lower bound holds even if the algorithm requires

$$0 \le x_1 + \cdots + x_i \le \left\lceil \frac{\log n}{\log(bt_u \log n)} \right\rceil \tag{2}$$

for all i after each update.

The proof is given in the next section.

Note that the query cannot distinguish $+1$ from -1 (since $1 = -1 \mod 2$), so a data structure for the signed partial sum problem structure can treat -1 as $+1$. The reason for introducing -1 in the problem is the balancing condition (2), which continues previous work [19] on extending the chronogram method.

In section 5.2, we state a further generalization of Theorem 1, relating the terms in (1) and (2).

2.4. Lower bound for existential range queries. We give a lower bound of size $\Omega(\log^{1/2} n)$ for the existential range query problem; we consider cell size $b = \log n$ for concreteness. The value of this result lies in its simplicity; it provides a good illustration of how to apply Theorem 1. Using a different technique [3], the authors with Alstrup have since established $\Omega(\log n/\log(bt_u))$, which is optimal. However, before the present paper, no lower bound better than $\Omega(\log\log n/\log\log\log n)$ was known for this problem (which is rather central—see the discussion by Agarwal [1]), so the result provides an exponential yet, by now, outdated improvement.

Following [3], we start with the *existential marked ancestor problem*. Consider a full rooted tree with nodes V, number of leaves n, height h, and arity d, where

$$h = \log^{1/2} n, \quad d = 2^h. \tag{3}$$

Let $\pi(v)$ denote the nodes on the path from v to the root (including v). The problem is to maintain a subset of *marked* nodes $M \subseteq V$ under the following operations:

mark(v): insert $v \in V$ in M,

unmark(v): remove $v \in V$ from M,

exists(v): return "yes" iff any of v's ancestors are marked, i.e., if $\pi(v) \cap M \neq \emptyset$.

The *counting marked ancestors* problem supports the same updates, and the query is

parity(v): return $|M \cap \pi(v)| \mod 2$, the parity of the number of marked ancestors of v.

The parity prefix sum problem is a special case of this problem, where the tree is a path. We begin by showing that the problem is hard also for d-ary trees, where $d = \log^{1/2} n$.

LEMMA 1. *Every nondeterministic algorithm for counting marked ancestors in trees with update time t_u requires query time*

$$t_q = \Omega\left(\frac{\log n}{\log^{1/2} n + \log(t_u \log n)}\right).$$

Proof. Let x be a length n instance to the signed partial sum problem. We assume that $\log^{1/2} n$ is an integer. Consider a data structure for the counting marked ancestor problem for a tree T with parameters as in (3), and update and query time t_u and t_q. The ith leaf v_i of T corresponds to x_i. We will maintain that the parity of the number of marked ancestors to v_i is the parity of the ith prefix sum in x, i.e.,

$$|\pi(v_i) \cap M| = x_1 + \cdots + x_i \pmod 2.$$

Thus the time for a partial sum query is the same as the time for a marked ancestor query, t_q. To maintain the invariant whenever x_i is changed (and thus the parity of all prefix sums $\geq i$ are changed), we change the marking of the root of a number of disjoint subtrees in T, whose leaves correspond to $x_i, \ldots, x_n$. These roots are the right siblings of $\pi(v_{i-1})$, so there are at most dh updates. Thus the update time is at most $t_u dh = O(2^{\log^{1/2} n} t_u \log^{1/2} n)$. Now Theorem 1 implies the bound on the query time. □

The proof of the next proposition contains the crucial application of nondeterminism to transform a counting problem into an existential one.

PROPOSITION 1. *Existential Marked Ancestor requires time $\Omega(\log^{1/2} n)$ per operation.*

Proof. Consider an algorithm for the existential problem with update time t_u and query time t_q, and let T be an instance of the counting marked ancestor problem. Construct 2^h new instances T_w indexed by bit strings $w \in \{0,1\}^h$. We maintain that the markings in the first instance $T_{00\ldots0}$ are the same as in T. In general, the ith bit of w is cleared iff the markings in T_w on level i are the same as in T. More precisely, if v is a node on level i, we have

$$(v \text{ marked in } T_w) = w_i \oplus (v \text{ marked in } T),$$

where $\oplus$ denotes exclusive or. The crucial observation is the following: Let v be a leaf. Then w is the characteristic vector of $\pi(v) \cap M$ iff the path $\pi(v)$ in T_w is unmarked.

Whenever a node in T is marked or unmarked, we must update all 2^h instances, so the update time is $2^h t_u$. For a query, we guess the characteristic vector of $\pi(v) \cap M$ and verify that $\pi(v)$ is unmarked in T_w. This takes time $t_q + O(1)$. We finish the proof by applying the above lemma. □

Finally, we present the application to range queries.

PROPOSITION 2. *Existential Range Query requires time $\Omega(\log^{1/2} n)$ per operation.*

Proof. Embed the tree from the marked ancestor problem in the first quadrant of the plane, with the root in the origin and the nodes at depth i spread out evenly on the diagonal $y = -x + d^h - d^{h-i}$. The query rectangle has its upper-right corner in the queried node. □

2.5. Discussion. Analyzing the above proof, we see that the algorithm used in the reduction actually solves the complement of the problem; we use it to verify $\pi(v) \cap M = \emptyset$. Thus the proof also yields a bound on the nondeterministic complexity of the *emptiness* problem (to return "yes" iff the query rectangle is empty). In other words, there is no short, maintainable witness to the absence of points in the plane.

In contrast, the emptiness problem in one dimension does admit a fast nondeterministic algorithm, since we can maintain a doubly linked list of the inserted points, and the query can guess both the immediate predecessor and immediate successor of a query interval and verify that they are neighbors in S. Using a Van Emde Boas tree, this can be implemented in time $O(\log \log n)$ per update and constant query time.

3. Proof of Theorem 1. We consider a specific sequence of operations that consists of a number of updates followed by a single query. The update sequence is chosen at random from a set U defined in section 3.5.

3.1. Model of computation. The computational model is an extension of the cell-probe model [12, 30]; since there is only a single query in the hard sequence of operations constructed in our proof, which happens at the very end of the sequence, we can model query algorithms by nondeterministic decision trees.

More precisely, a *cell-probe* algorithm consists of a family of trees, one for each operation, and a memory $M \in \{0, \dots, 2^b - 1\}^*$. We refer to the elements of M as *cells*, each of which can store a b-bit number. To each update we associate a decision-assignment tree as in [15]. There are two types of nodes: *Read* nodes are 2^b-ary and labeled by a memory address, and computation proceeds to the child identified at that address; *write* nodes are unary and labeled by a memory address and a b-bit value, with the obvious semantics.

To each query we associate a nondeterministic decision tree of arity 2^b whose internal nodes are labeled by a memory address or by "$\exists$." The leaves are labeled 0 or 1 to represent the possible answers to the query. We define the value $qM \in \{0, 1\}$ computed by a query tree q on memory M to be 1 if there exists a path from the root to a leaf with label 1. A witness of such an accepting computation is the description of the choices for the $\exists$ nodes. We let q_i denote the query tree corresponding to $query(i)$. The query time t_q is the height of the largest query tree, and the update time t_u is the height of the largest update tree. We account only for memory reads and writes and for nondeterministic choices; all other computation is for free.

3.2. Updates and epochs. Each update sequence in U is described by a binary string $u \in \{0, 1\}^*$. Each bit represents an update $update(j, a)$. The parameters for these updates will be specified in section 3.5. The update sequences $u \in U$ are split into d substrings each corresponding to an *epoch*. It turns out to be convenient that time flows backward, so epoch 1 corresponds to the end of u. In general, the update string is an element in $U = U_d U_{d-1} \cdots U_1$, where $U_t = \{0, 1\}^{e(t)}$ and where $e(t)$ is the length of epoch t such that $e(t) + \cdots + e(1) = \lfloor n^{t/d}/d \rfloor$. The length of the entire update sequence is $\lfloor n/d \rfloor$. The size of d and hence the growth rate of $e(t)$ are given by

$$d = \left\lceil \frac{\log n}{\log(b t_u \log n)} \right\rceil. \tag{4}$$

The goal is to establish that $t_q \in \Omega(d)$.

3.3. Time stamps and nondeterminism. To each cell we associate a time stamp when it is written. A cell receives time stamp t if some update during epoch t writes to it, and none of the subsequent updates during epochs $t-1$ to 1 write to it.

For an update sequence $u \in U$, let M^u denote the memory resulting from these updates (recall that updates are restricted to perform deterministically), starting with some arbitrary initial contents corresponding to the initial instance 0^n.

For index i and update string u, let $T(i,u)$ denote the set of time stamps that are found on every accepting computation path of q_i on M^u. If there are no accepting computations, the set is empty. More formally, let w denote a witness for a computation path of q_i on M^u, and let $A(i,u)$ denote the set of witnesses that leads to accepting computations of q_i on M^u. Let for a moment $T(i,u,w)$ denote the set of time stamps encountered by the computation of q_i on M^u that is witnessed by w. Then $T(i,u) = \bigcap \{\, T(i,u,w) \mid w \in A(i,u) \,\}$ if $A(i,u) \neq \emptyset$, and $T(i,u) = \emptyset$ otherwise.

The simple lemma below is the tool to identify a read of a cell with time stamp t by nondeterministic queries.

LEMMA 2. *If M^u and M^v differ only on cells with time stamp t, then $q_i M^u \neq q_i M^v$ implies $t \in T(i,u) \cup T(i,v)$.*

Proof. Suppose, on the contrary, that $q_i M^u \neq q_i M^v$ and $t \notin T(i,u) \cup T(i,v)$. Assume without loss of generality that $q_i M^u = 1$ and $q_i M^v = 0$. Since $t \notin T(i,u)$ and $q_i M^u = 1$, there is an accepting computation path that avoids cells with time stamp t. However, this computation might as well be executed on M^v, by the premise. Hence q_i has an accepting computation on M^v as well, contradicting $q_i M^v = 0$. □

3.4. Lower bound on query time. The update sequences are chosen such that, even if two sequences differ only in a single epoch, they still result in very different instances. To each update sequence $u \in U$ we associate the query vector $q^u = (q_1 M^u, q_2 M^u, \ldots, q_n M^u) \in \{0,1\}^n$. Update sequences that differ only in epoch t are called *t-different*.

LEMMA 3. *No Hamming ball of diameter $\frac{1}{8}n$ can contain more than $|U_t|^{9/10}$ query vectors from t-different update sequences for large n.*

The difficult part is constructing a set of update sequences for which the statement is true, which we present in section 3.5. The proof itself is as in [15] and is provided in section 3.5 for completeness.

Write $U_{>t}$ for $U_d \cdots U_{t+1}$, the set of update sequences prior to epoch t, and write $U_{<t}$ for $U_{t-1} \cdots U_1$, the set of update sequences in epoch t to epoch 1. Assume for the rest of this section that $t_{\mathrm{q}} = \mathrm{O}(\log n)$; else there is nothing to prove. The worst-case query time t_{q} is at least the average of $|T(i,u)|$ over choices of $i \in \{1,\ldots,n\}$ and $u \in U$, so

$$|U| n t_{\mathrm{q}} \geq \sum_{u \in U} \sum_{i=1}^{n} |T(i,u)| = \sum_{t=1}^{d} \sum_{u \in U_{>t}} \sum_{w \in U_{<t}} \sum_{v \in U_t} \sum_{i=1}^{n} \big(t \in T(i,uvw)\big).$$

The next lemma tells us how many $v \in U_t$ fail to make the last sum exceed $\frac{1}{16}n$.

LEMMA 4. *Fix any epoch $1 \leq t \leq d$ and past and future updates $x \in U_{<t}$, $y \in U_{>t}$. For large n, at least half of the update sequences $u \in xU_t y$ satisfy $\big|\{\, 1 \leq i \leq n \mid t \in T(i,u) \,\}\big| \geq \frac{1}{16}n$ if $t_{\mathrm{q}} = \mathrm{O}(\log n)$.*

Proof. Consider the set $V \subseteq xU_t y$ of updates after which fewer than $\frac{1}{16}n$ queries encounter time stamp t; i.e., xuy for $u \in U_t$ is in V if

$$\big|\{\, 1 \leq i \leq n \mid t \in T(i,xuy) \,\}\big| < \tfrac{1}{16}n.$$

We will bound the size of V below $\frac{1}{2}|U_t|$.

To this end, partition V into equivalence classes such that u and v are in the same class iff M^u and M^v agree on all cells except maybe those with time stamp t. We first bound the number of such classes. Since all cells with time stamp greater than t have identical content (they depend only on the common prefix x), we need only to analyze the amount of information distributed among cells with time stamps $t-1$ to 1. The number of cells written during the last $t-1$ epochs is at most $r = t_{\mathrm{u}} \cdot (e(t-1) + \cdots + e(1))$. Note that at most $n2^{t_{\mathrm{q}} b}$ different cells appear in the entire forest of query trees. The number of different ways we can choose such r cells and fix their content to some value in $\{0, \ldots, 2^b - 1\}$ is bounded by

$$(n2^{t_{\mathrm{q}} b} \cdot 2^b)^r \leq |U_t|^{o(1)}, \tag{5}$$

where the inequality uses (4). That is, $|U_t|^{o(1)}$ bounds the number of equivalence classes of V.

It remains to bound the size of each class. Consider two query vectors q^u and q^v for u and v in the same equivalence class. Then

$$|q^u - q^v| \leq \tfrac{1}{8}n \tag{6}$$

because $\frac{15}{16}n$ entries of each vector depend only on cells with time stamps other than t. On these cells, the memories are indistinguishable and therefore yield the same result by Lemma 2. By (6), all vectors from the same class end up in a Hamming ball of diameter $\frac{1}{8}n$, so Lemma 3 tells us that there can be only $|U_t|^{\frac{9}{10}}$ of them. We conclude that the size of V is bounded by $|U_t|^{\frac{9}{10}} \cdot |U_t|^{o(1)}$, which is less than $\frac{1}{2}|U_t|$ for large n. □

By this lemma we obtain for large n

$$|U| n t_{\mathrm{q}} \geq \sum_{t=1}^{d} |U_{>t}| \cdot |U_{<t}| \cdot \tfrac{1}{16}n \cdot \tfrac{1}{2}|U_t| = \tfrac{1}{32}nd|U|$$

and hence $t_{\mathrm{q}} \geq \frac{1}{32}d$ as desired.

3.5. Update scheme. The technical part that remains is to exhibit a set of update sequences U satisfying Lemma 3. There are a number of ways to do this; the following construction is one which simultaneously anticipates our needs in section 6 and satisfies the balancing condition (2).

To alleviate notation, we assume that n/d is an integer. Consider the updates in epoch t, and index them as $u_1 \cdots u_{e(t)} \in U_t$. If $u_i = 0$, then nothing happens in the ith update. Else it performs $\mathit{update}(j, a)$, where the update position j is given below. The new value is $a = (-1)^r$, where $r = 1 + u_1 + \cdots + u_i \mod 2$, so the nonzero updates in u alternate between -1 and $+1$, starting with $+1$. The position of the affected letter is defined as follows. Write x as a table of dimension $d \times n/d$ like this:

$$\begin{bmatrix} x_1 & x_{d+1} & & x_{n-d+1} \\ \vdots & \vdots & \cdots & \vdots \\ x_d & x_{2d} & & x_n \end{bmatrix}.$$

All updates in epoch t will affect only the letters in row t. The updates of an epoch are spread out evenly from left to right across that row, so the distance between two

of them is

$$\left\lfloor \frac{n/d}{e(t)} \right\rfloor. \tag{7}$$

In summary, the ith update in epoch t affects the letter in row t and the column given by $(i-1)\cdot\lfloor (n/d)/e(t)\rfloor + 1$.

This update scheme satisfies the statement in Lemma 3.

Proof of Lemma 3. Let xU_ty be any set of t-different update sequences. Pick any $u \in U_t$, and consider any Hamming ball of diameter $\frac{1}{8}n$ that contains query vector q^{xuy}. We will bound the number of $v \in U^t$ with query vector q^{xuy} ending up in that Hamming ball.

Let $w \in U_t$ record the difference between u and v; i.e., the ith letter of w is 1 iff u and v differ on the ith letter. Now let w' denote the string of prefix sum parities of w, i.e.,

$$w'_i = w_1 + \cdots + w_i \mod 2, \quad 1 \le i \le e(t).$$

It is easy to see that w' records the difference between the query vectors resulting from u and v. Indeed, each 1 in w' yields an interval of indices where the vectors differ, and the length of this interval is d times the distance given by (7). In other words, each 1 in w' contributes as many points to the Hamming distance between the resulting query vectors. So, if we let $|w'|_1$ denote the number of 1's in w', the Hamming distance between two query vectors is at least

$$|w'|_1 \cdot d \cdot \left\lfloor \frac{n/d}{e(t)} \right\rfloor \ge \tfrac{1}{2}|w'|_1 \cdot \frac{n}{e(t)}, \tag{8}$$

where we have used that $\lfloor a \rfloor \ge \frac{1}{2}a$ for $a \ge 1$.

By the triangle inequality, the maximum Hamming distance between two query vectors in the same ball is $\frac{1}{8}n$. This bounds the number of 1's in w' to $\frac{1}{4}e(t)$ for large n. Hence the number of choices for w' is bounded by

$$\sum_{i=0}^{\frac{1}{4}e(t)} \binom{e(t)}{i} < 2^{\frac{9}{10}e(t)} \tag{9}$$

for large n. This also bounds the number choices of $v \in U_t$ since there is a one-to-one correspondence between v and w'. ∎

The prefix sums of instances resulting from our scheme are small: Let x denote an instance resulting from our scheme from the initial instance 0^n. Let x^t denote the string resulting from only the updates in epoch t, and write x as $x^1 + \cdots + x^d$; this works because no two epochs write in the same positions. Then

$$\sum_{j=1}^{i} x_j = \sum_{j=1}^{i}\sum_{t=1}^{d} x_j^t = \sum_{t=1}^{d}\sum_{j=1}^{i} x_j^t \in \{0, \ldots, d\}$$

because the prefix sum of every x^t is 0 or 1 by construction. It can be checked that the balancing bound (2) holds at all times.

Another important feature of this update scheme, which we will use to prove Theorem 3, is that, if x and y result from t-different updates, then $x^r = y^r$ for $r \ne t$

and hence

$$\left| \sum_{j=1}^{i} x_j - \sum_{j=1}^{i} y_j \right| \le 1 \tag{10}$$

for all i.

4. Partial sum queries. The next result shows that the majority and equality problems defined in the introduction are just as hard as the parity query from [15]. The proof is a simple application of Theorem 1.

PROPOSITION 3. *The prefix equality and prefix majority problems satisfy*

$$t_{\mathrm{q}} = \Omega\left(\frac{\log n}{\log(t_{\mathrm{u}} b \log n)} \right).$$

Proof. We first give the proof for prefix equality. Let $d = \lceil \log n / \log(b t_{\mathrm{u}} \log n) \rceil$.

An instance $x \in \{-1, 0, +1\}^n$ of signed partial sum is encoded as the binary string x' by

$$-1 \mapsto 00, \quad 0 \mapsto 01, \quad +1 \mapsto 11.$$

We maintain $d+1$ strings $y^{(0)}, \dots, y^{(d)}$ as

$$y^{(t)} = (00)^t (01)^{d-t} x'.$$

Let $t_{\mathrm{u}} = t_{\mathrm{u}}(n)$ denote the update time of our prefix equality algorithm. Whenever x is changed, we make at most $2d+2$ updates in the strings $y^{(t)}$; so the update time is $(2d+2) \cdot t_{\mathrm{u}}(n + 2d + 2)$.

Index the strings $y^{(t)}$ from $-2d$ to $2n-1$. We then have

$$\sum_{j=-2d}^{2i-1} y_j^{(t)} = d - t + i + \sum_{j=1}^{i} x_j, \qquad 0 \le t \le d, \quad 1 \le i \le n. \tag{11}$$

Hence, in order to find the ith prefix sum of x, our algorithm can nondeterministically guess the sum $s \in \{0, \dots, d\}$; we can assume from the balancing condition (2) in Theorem 1 that the sum is in that set and verify $y_{-2d}^{(s)} + \cdots + y_{2i-1}^{(s)} = d + i$, which is the case iff *equality*$(2d+2i)$ on $y^{(s)}$ returns 1. The conclusion is by Theorem 1.

The same bound must hold for the majority problem since we can write

$$\begin{aligned} x_1 + \cdots + x_i = \left\lceil \tfrac{1}{2} i \right\rceil \text{ iff } & x_1 + \cdots + x_i \\ & \ge \left\lceil \tfrac{1}{2} i \right\rceil \wedge \bar{x}_1 + \cdots + \bar{x}_i \ge \left\lceil \tfrac{1}{2} i \right\rceil, \end{aligned}$$

where $\bar{x}_i = 1 - x_i$, and these negated values are easily maintained. □

To study this kind of problem in a general, let the *threshold* ϑ be an integer function such that $\vartheta(i) \in \{0, \dots, \lceil \frac{1}{2} i \rceil\}$. The query in the *prefix threshold problem for* ϑ is

threshold(i): return "yes" iff $x_1 + \cdots + x_i \ge \vartheta(i)$.

Prefix majority is the special case $\vartheta(i) = \lceil \frac{1}{2} i \rceil$; prefix-or is $\vartheta(i) = 1$. Now, for our lower bound, our assumption on ϑ is that there are integers $p(1) < p(2) < \cdots < p(i) < \cdots$ such that $\vartheta(p(i)) = i$. We call such functions *nice* for lack of a better word. It is

reasonable to assume that ϑ is monotonically increasing; the niceness assumption also prevents it from skipping points.

PROPOSITION 4. *Let $t_u = t_u(n)$ and $t_q = t_q(n)$ denote the update and query time of any cell size b implementation of the prefix threshold problem for a nice threshold ϑ. Then $t_q = \Omega(\log \vartheta / \log(t_u b \log \vartheta))$.*

Proof. The proof is not difficult but is tedious. The idea is to stretch an instance for a threshold problem, padding it with sufficiently many 0's or 1's to turn it into a majority problem.

Let ϑ be a nice function, and let $p(1), \ldots, p(n)$ be such that $\vartheta(p(i)) = i$. Assume we have an algorithm for the prefix problem for ϑ with the parameters given in the statement of the theorem. We will construct an algorithm for the majority with instance $x \in \{0,1\}^n$. Construct a bit string y as

$$y = 0 \cdots 0 x_1 x_1 0 \cdots 0 x_2 x_2 0 \cdots 0 x_n x_n,$$

where the letters of x are at positions $p(1)-1, p(1), p(2)-1, p(2), \ldots, p(n)-1, p(n)$; denote the length of y by $m = p(n)$.

The string y can be maintained in time $2t_u(m)$ for each update of x. For the query, note that $2x_1 + \cdots + 2x_i = y_1 + \cdots + y_{p(i)}$, so

$$x_1 + \cdots + x_i \geq \left\lceil \tfrac{1}{2} i \right\rceil \quad \text{iff} \quad y_1 + \cdots + y_{p(i)} \geq i = \vartheta(p(i)),$$

so the majority function (left-hand side) can be expressed in terms of the threshold function ϑ (right-hand side). Hence the query time is $t_q(m)$. However, from the bound on the complexity of the majority function, we know that

$$t_q(m) = \Omega\left(\frac{\log n}{\log(t_u(m) b(m) \log n)} \right).$$

The stated bound follows by substituting $\vartheta(m)$ for n. □

To gauge the strength of this result, we mention that the problem can be solved on the unit-cost RAM with logarithmic cell size in time $O((\log \vartheta / \log\log n) + \log\log n)$ per update (if $\vartheta(1), \ldots, \vartheta(n)$ can be computed in the preprocessing stage of the algorithm). The left term in the expression stems from a search tree, and the right term stems from a priority queue, which vanishes for cell size $b = \Omega(\log^2 n)$; details are omitted. A comparison with Proposition 4 shows that the lower bound is tight for logarithmic cell size and $\vartheta = \Omega(\log^{\log\log n} n)$. For smaller thresholds, the bounds leave a gap of size $O(\log\log n)$.

We consider a more general class of query functions in section 6.2.

5. Applications to dynamic algorithms. Theorem 1 suggests a new approach for proving lower bounds for dynamic algorithms by employing nondeterminism in the reduction from signed partial sum. We demonstrate this with a number of examples in this section. The results are presented for cell size $b = \log n$ for concreteness. Some of the reductions extend previous work of the authors with Søren Skyum [19].

5.1. Nested brackets. Consider the problem of maintaining a nested structure, i.e., a string x with round and square brackets under the following operations:

change(i, a): change x_i to a, where a is a round or square opening or a closing bracket or whitespace.

balance: return "yes" iff the brackets in x are properly nested.

This problem was studied in [11], where an algorithm with polylogarithmic update time is presented.

PROPOSITION 5. *Maintaining a string of nested brackets requires time* $\Omega(\log n/\log\log n)$ *per operation.*

Proof. Consider a deterministic algorithm for this problem, and consider an instance $x \in \{0,-1,+1\}^n$ to signed partial sum. Let b_i be an encoding of x_i given by

$$+1 \mapsto))\sqcup, \quad 0 \mapsto)\sqcup\sqcup, \quad -1 \mapsto \sqcup\sqcup\sqcup,$$

where "$\sqcup$" stands for space. Let c be the string "$\sqcup($" consisting of a single space and an opening bracket. We maintain a balanced string of brackets uvw, where $u = c^{2n}$, $v = b_1 b_2 \dots b_n$, and $w =)^{n-s}\sqcup^s$, where $s = x_1 + \cdots + x_n$. It is easy to see that uvw balances and can be maintained by a constant number of updates per update in x. For any prefix size i, this construction enables efficient verification of a nondeterministic guess g of the prefix sum $x_1 + \cdots + x_i$: Place a closing square bracket on the last $\sqcup$ of b_i and an opening square bracket on the $\sqcup$ of the first c of suffix c^{i+g} of u. This modification keeps uvw balanced iff g is the right guess of prefix sum $x_1 + \cdots + x_i$. The conclusion is by Theorem 1. □

5.2. Dynamic graph algorithms. Our techniques improve the lower bounds of a number of well-studied graph problems considered in [19].

Tamassia and Preparata [28] present an algorithm for the class of *upward planar source-sink graphs* that runs in time $O(\log n)$ per operation. These digraphs have a planar embedding where all edges point upward (meaning that their projection on some fixed direction is positive) and where exactly one node has indegree 0 (the source) and exactly one node has outdegree 0 (the sink). The updates are

insert(u,v): insert an edge from u to v,
delete(u,v): delete the edge from u to v if it exists,
reachable(u,v): return "yes" iff there is a path from u to v.

The updates have to preserve the topology of the graph, including the embedding.

PROPOSITION 6. *Dynamic reachability in upward planar source-sink graphs requires time* $\Omega(\log n/\log\log n)$ *per operation.*

Planarity testing is to maintain a planar graph where the query asks whether a new edge violates the planarity of the graph. Italiano, Poutré, and Rauch [20] present an efficient algorithm for a version of this problem, and a strong lower bound is exhibited by Fredman and Henzinger [14]. Our lower bound also holds for *upward* planarity testing, where the topology is further restricted to upward planar graphs. The updates insert and delete edges as above, and the query is as follows:

planar(u,v): return "yes" iff the graph remains upward planar after insertion of edge (u,v).

This problem was studied by Tamassia [27], who found an $O(\log n)$ upper bound.

PROPOSITION 7. *Upward planarity testing requires time* $\Omega(\log n/\log\log n)$ *per operation.*

A classical problem in computational geometry is *planar point location*: given a subdivision of the plane, i.e., a partition into polygonal regions induced by the straight-line embedding of a planar graph, determine the region of query point $q \in \mathbf{R}^2$.

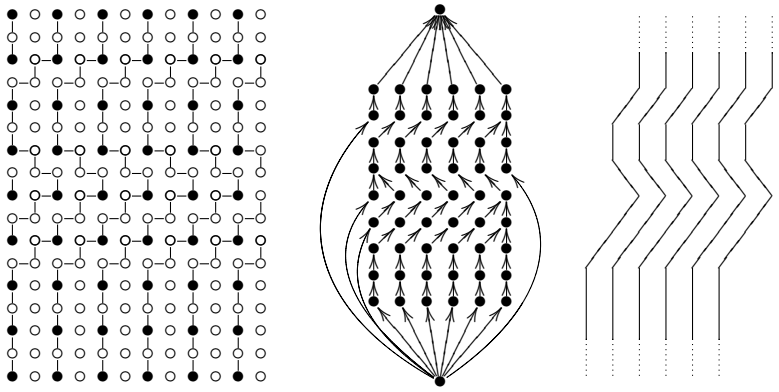

FIG. 1. *Planar graphs corresponding to* $x = (0, 0, +1, +1, -1, 0, +1, 0)$. *Left: Grid graph. Even grid points are marked* •*; odd grid points are marked* ○. *Middle: Upward planar source-sink graph. Right: Monotone planar subdivision.*

An important restriction of the problem considers only *monotone* subdivisions, where the subdivision consists of polygons that are monotone (so no horizontal line crosses any polygon more than twice). In the dynamic version of this problem, updates manipulate the geometry of the subdivision. Preparata and Tamassia [26] give an algorithm that runs in time $O(\log^2 n)$ per operation; this was improved to query time $O(\log n)$ by Baumgarten, Jung, and Mehlhorn [5]. The lower bound for this problem in [19] applies only to algorithms returning the name of the region containing the queried point. The techniques of the present paper extend this bound to work for simpler decision queries like

query(x): return "yes" iff x is in the same polygon as the origin.

PROPOSITION 8. *Planar point location requires time* $\Omega(\log n / \log\log n)$ *per operation, even in monotone subdivisions.*

Traditionally, lower bounds in computational geometry are proved in an algebraic, comparison-based model (see [25] for a textbook account) that is broken by standard RAM operations like indirect addressing, bucketing, hashing, etc. Cell-probe lower bounds for that field are lacking.

To explain our reduction, we turn to the conceptually very simple class of *grid graphs*. The vertices of a grid graph of width w and height h are integer points (i, j) in the plane for $1 \le i \le w$ and $1 \le j \le h$. All edges have length 1 and are parallel to the axes. The dynamic reachability problem for these graphs is the following:

flip(x, y): add an edge between $x \in [w] \times [h]$ and $y \in [w] \times [h]$ or remove it if it exists,

reachable(x, y): return "yes" iff there is a path from x to y.

There are several well-known constructions that prove a lower bound for this problem [10, 14, 17, 23], but our proof translates to the other problems in Propositions 6–8. The details in these constructions are omitted; Figure 1 illustrates the structures arising in the reductions.

PROPOSITION 9. *Dynamic reachability in grid graphs requires time* $\Omega(\log n/\log\log n)$ *per operation.*

Proof. From an instance $x \in \{0, \pm 1\}^n$ to signed partial sum, we build a grid graph on the points $\{0, \dots, 2w\} \times \{0, \dots, 2n\}$, where $w = \lceil \log n / \log\log n \rceil$. We will exploit the balancing constraint (2) of Theorem 1 to keep the instance within this width.

For every i and j, consider any point with even coordinates $(2i, 2j-2)$, drawn as $\bullet$ in Figure 1, and connect it to one of the three even grid points above it using  ,  , or  , depending on whether $x_j = +1$, 0, or -1, respectively. The idea is that the path from $(0, 0)$ mimics the prefix sums of x in that it passes through $(2s, 2j)$ iff $x_1 + \cdots + x_j$ equals s. Hence a guess of the sum can be verified by a single reachability query in the graph.

It remains to note that the graph can be maintained efficiently. Any changed letter in x incurs $O(w)$ edges to be inserted or deleted. So, if the update time of the graph algorithm is polylogarithmic, then the graph can be maintained in polylogarithmic time. The bound follows from Theorem 1. □

The width of the hard graph above is logarithmic in the height, while the graphs constructed in [10, 14, 17, 23] are square. Hence narrow grid graphs are as hard as square ones. However, this is not true for *very* narrow graphs: It is known that the reachability problem for grid graphs of *constant* width can be solved in time $O(\log\log n)$ by [4], an exponential improvement. This leaves open the question of what happens for graphs of sublogarithmic width. To answer this, we introduce a subtler statement of Theorem 1.

THEOREM 2. *Let* $d = O(\log n / \log(bt_u \log n))$ *be an integer function. Every nondeterministic algorithm for signed partial sum with cell size* b*, update time* t_u*, and query time* t_q *must satisfy* $t_q = \Omega(d)$*. The lower bound holds even if the algorithm requires* $0 \le x_1 + \cdots + x_i \le d$ *for all* i *after each update.*

This result implies a lower bound for grid graphs that smoothly connects the two extremes between linear and constant width. A similar parameterization can be done for all our problems.

PROPOSITION 10. *For every* $w = O(\log n / \log\log n)$*, dynamic reachability in grid graphs of width* w *requires time* $\Omega(w)$ *per operation.*

6. Refinement. We now take a somewhat subtler approach to our basic question than we take in section 2. Instead of nondeterminism, we study the performance of query algorithms in a *promise* setting. We assume that the query algorithm for signed partial sum receives a value s that is promised to be *close to* (but not known to be equal to) the right sum and then decides between right and wrong values.

The *partial sum refinement* problem can be phrased as follows: Maintain a string $x \in \{0, \pm 1\}^n$, initially 0^n, under the following operations:

update(i, a): change x_i to $a \in \{-1, 0, +1\}$,

parity(i, s): return $x_1 + \cdots + x_i \mod 2$ provided that $|s - \sum_{j=1}^{i} x_j| \le 1$ (for other values of s, the behavior of the query algorithm is undefined).

The problem gets its name from the following alternative definition, where the query operation is replaced by

refine(i, s): return 1 if $s = \sum_{j=1}^{i} x_j$ and 0 if $s \ne \sum_{j=1}^{i} x_j$, provided that $|s - \sum_{j=1}^{i} x_j| \le 1$. (For other values of s, the behavior of the query algorithm is undefined.)

The two problems are computationally equivalent.

THEOREM 3. *Let d be an integer function such that $d = \mathrm{O}(\log n/\log(t_{\mathrm{u}} b \log n))$. Every algorithm for partial sum refinement with cell size b, update time t_{u}, and query time t_{q} must satisfy $t_{\mathrm{q}} = \Omega(d)$. Moreover, this is true even for algorithms that require $0 \le x_1 + \cdots + x_i \le d$ for all i after each update.*

6.1. Proof of Theorem 3. Most of the technical work for this result was already done in section 3.5, where we found that the instances resulting from two t-different updates have close prefix sums (10).

The query trees in our computational model are now deterministic decision trees as in [15]. However, there are more of them: we associate a tree q_i^s to each query *parity*(i, s), yielding $n(2n+1)$ trees. (We could reduce this number to $n(d+1)$ by the balancing constraint, but that does not improve the bounds.)

For update string u, we write q_i^u for the query tree q_i^s corresponding to the "right guess" $s = x_1 + \cdots + x_i$, where x is the instance resulting from updates u. The *query vector* is $(q_1^u M, \ldots, q_n^u M)$, i.e., the responses yielded by guessing right every time. We let $T(i, u)$ denote the time stamps encountered by q_i^u on M^u and compare this with the construction in section 3.3.

The next lemma corresponds to Lemma 2 and shows that our update scheme constructs different instances whose prefix sums are so close that the query trees cannot use the (almost correct) value given to them.

LEMMA 5. *For t-different update sequence $u, v \in U_t$, if M^u and M^v differ only on cells with time stamp t, then, for all i,*

$$q_i^u M^u \neq q_i^v M^v \quad \textit{implies } t \in T(i,u) \cup T(i,v).$$

Proof. Assume, to the contrary, for some such t, u, v, and i, that $t \notin T(i, v)$ and $q_i^u M^u \neq q_i^v M^v$. Let x and y denote the input instances resulting from u and v, respectively. Let s denote $\sum_{j=1}^{i} x_j$. By (10) and without loss of generality, $\sum_{j=1}^{i} y_j = s+1$. By correctness, $q_i^s M^u = q_i^{s+1} M^u$. Since the computation path for $q_i^{s+1} M^v$ does not encounter time stamp t, this computation might as well be executed on M^u with the same result; i.e., $q_i^{s+1} M^u = q_i^{s+1} M^v = q_i^s M^u = q_i^u M^u$. However, this contradicts our assumption $q_i^u M^u \neq q_i^v M^v = q_i^{s+1} M^v$. □

The rest of the proof can be reused almost ad verbatim.

6.2. The partial sum problem for symmetric functions. Theorem 3 acts as an important ingredient in characterizing the dynamic complexity of all the *symmetric functions*, generalizing the results for the threshold functions of the last section. A Boolean function is *symmetric* if it depends only on the number of 1's in the input $x = (x_1, \ldots, x_n)$. The symmetric functions include some of the most well-studied functions in complexity theory like parity, majority, and the threshold functions.

In general, we can describe every symmetric function f in n variables by its *spectrum*, a string in $\{0,1\}^{n+1}$ whose ith letter is the value of f on inputs where exactly i variables are 1. The *boundary* of a spectrum s is the smallest value ϑ such that $s_{\lfloor \vartheta \rfloor} = s_{\lfloor \vartheta \rfloor + 1} = \cdots = s_{\lfloor n - \vartheta \rfloor}$. For instance, the boundary of the parity or majority functions is $\frac{1}{2}n$, and for the threshold functions with threshold ϑ, the boundary is $\min(\vartheta, n - \vartheta)$.

Let $\langle f_n \rangle = (f_1, \ldots, f_n)$ be a sequence of symmetric Boolean functions where the ith function f_i takes i variables. The *dynamic prefix problem for* $\langle f_n \rangle$ is to maintain

a bit string $x \in \{0,1\}^n$ under the following operations:

$$\begin{aligned} &\textit{update}(i)\text{: change } x_i \text{ to } \neg x_i,\\ &\textit{query}(i)\text{: return } f_i(x_1,\ldots,x_i). \end{aligned}$$

For example, taking f_i to be the parity function on i variables, we have the prefix parity problem of [15], and taking f_i to be the threshold function for $\vartheta(i)$, we have the problem from Proposition 4.

PROPOSITION 11. *Let ϑ be a nice function, and let $\langle f_n\rangle$ be a sequence of symmetric functions where $f_i\colon \{0,1\}^i \to \{0,1\}$ has boundary $\vartheta(i)$. Let t_{u} and t_{q} denote the update and query time of any cell size b implementation of the dynamic prefix problem for $\langle f_n\rangle$. Then $t_{\mathrm{q}} = \Omega(\log\vartheta/\log(t_{\mathrm{u}} b \log\vartheta))$.*

Proof. First assume that f_i's boundary is in the middle, i.e., $\vartheta(i) = \frac{1}{2}i$. Let $x \in \{+1,0,-1\}^n$ denote an instance to prefix refinement, and define d and maintain $d+1$ strings as in the proof for Proposition 3. Using the data structure for $\langle f_n\rangle$, we perform *refine*(i,g) as follows. Let s be the spectrum for f_{2i+2d}. Since its boundary is in the middle, it is the case that

$$s_{d+i-1}s_{d+i}s_{d+i+1} \in \{001, 010, 011, 100, 101, 110\}.$$

We consider only the case 001 above—the other cases are treated similarly. Recall that we can assume $x_1 + \cdots + x_i \in \{g-1, g, g+1\}$. Let r_{-1}, r_0, and r_{+1} denote the answer of *query*$(2d+2i)$ on $y^{(g-1)}$, $y^{(g)}$, and $y^{(g+1)}$, respectively. By (11) in the proof of Proposition 3, if $g = x_1 + \cdots + x_i$, then $r_{-1}r_0r_{+1} = s_{d+i-1}s_{d+i}s_{d+i+1} = 001$. If instead $g-1$ is the correct sum, then $r_{-1}r_0 = 01$, and finally if $g+1$ is the correct sum, then $r_0r_{+1} = 00$. Hence these three cases for g can be distinguished by the above three queries, and they hence determine the correct answer for *refine*(i,g). The bound then follows from Theorem 3.

The rest of the proof is a padding argument that "stretches" the above to work for smaller ϑ similarly to the proof of Proposition 3. We omit the details. □

Intriguingly, the bound in the proposition is precisely the same bound as for the size-depth trade-off for Boolean circuits for these functions [16, 8, 24].

Acknowledgments. The authors thank Arne Anderson, Gerth Stølting Brodal, Faith Fich, Peter Bro Miltersen, and Sven Skyum for valuable comments about various aspects of this work.

THE RECONSTRUCTION OF DOUBLED GENOMES*

NADIA EL-MABROUK† AND DAVID SANKOFF‡

Abstract. The genome can be modeled as a set of strings (chromosomes) of distinguished elements called genes. Genome duplication is an important source of new gene functions and novel physiological pathways. Originally (ancestrally), a duplicated genome contains two identical copies of each chromosome, but through the genomic rearrangement mutational processes of reciprocal translocation (prefix and/or suffix exchanges between chromosomes) and substring reversals, this simple doubled structure is disrupted. At the time of observation, each of the chromosomes resulting from the accumulation of rearrangements can be decomposed into a succession of conserved segments, such that each segment appears exactly twice in the genome. We present exact algorithms for reconstructing the ancestral doubled genome in linear time, minimizing the number of rearrangement mutations required to derive the observed order of genes along the present-day chromosomes. Somewhat different techniques are required for a translocations-only model, a translocations/reversals model, both of these in the multichromosomal context (eukaryotic nuclear genomes), and a reversals-only model for single chromosome prokaryotic and organellar genomes. We apply these methods to the yeast genome, which is thought to have doubled, and to the liverwort mitochondrial genome, whose duplicate genes are unlikely to have arisen by genome doubling.

Key words. genome duplication, genome rearrangement, signed genes, reversal, translocation, Hannenhalli–Pevzner graph, exact polynomial algorithms

1. Introduction.

In almost all the genomes which have been studied, there are some genes that are present in two or more copies. These copies may be identical or may have some differences, and they may be adjacent on a single chromosome or dispersed on different chromosomes throughout the genome. There are a number of different ways in which duplicate genes can arise; perhaps the most spectacular mechanism is the simultaneous doubling of the entire genome. Normally a lethal accident of meiosis or other reproductive step, if genome doubling can be resolved in the organism and eventually fixed as a normalized diploid state in a population, simultaneous doubling constitutes a duplication of the entire genetic complement. It transcends other mechanisms for gene duplication in that not only is one copy of each gene free to evolve its own function (or to lose function, becoming a pseudogene and mutating randomly, eventually beyond recognition), but it can evolve in concert with any subset of the thousands of other extra gene copies (cf. [14] for accounts of gene family coevolution). Whole new physiological pathways may emerge, involving novel functions for many of these genes. Genome duplication is thus a likely source of rapid and far-reaching evolutionary progress. Its rarity does not detract from its

importance.

For some genomes, recent polyploidy is easily detected due to the presence of a complete set of duplicated chromosomes. However, in most cases, all we can observe are duplicated chromosomal segments scattered throughout the genome.

Evidence for the effects of genome duplication has shown up across the eukaryote spectrum. More than two hundred million years ago, the vertebrate genome may have undergone two duplications [4, 20, 31], though at least one of these remains controversial [38, 21, 25, 8, 13]. Although numerous reversals and reciprocal translocations have subsequently occurred, the number of such chromosome rearrangements has been sufficiently modest that hundreds of conserved paralogous segments can be detected in the human genome since the ancient duplications; similar observations hold for the mouse genome [28, 29] and for less intensively mapped vertebrate genomes. More recent genome duplications are known to have occurred in some vertebrate lines, such as the frogs [40], the salmoniform fish [31], and the zebrafish [33].

Another example is given by the comparison of chromatin-eliminating Ascaridae with other nematodes. This comparison suggests that somatic cells of these worms have discarded a good proportion of the genes present in germ cells, possibly because these are redundant duplicates arising through genomic doubling some 200 million years ago [27].

Genome duplication is particularly prevalent in plants. Comparison of the well-studied rice [1], oats (wild and domestic), corn [1, 15], and wheat [26] genomes indicate several occurrences in the cereal lineage. Soybeans [36], Arabidopsis [24, 3], rapeseed [34], and other cultivars have genome duplications in their ancestry. Paterson et al. have presented convincing evidence that one or more genome duplications also occurred much earlier in plant evolution [32].

Following the complete sequencing of all Saccharomyces cerevisiae chromosomes, the prevalence of gene duplication has led to the hypothesis that this yeast genome is also the product of an ancient doubling [35, 39].

What of bacteria and other prokaryotes? In 1985, Herdman [19], observing that bacterial genome sizes clustered around multiples of 0.8Mb (i.e., 1.6Mb, 3.2Mb, etc.), suggested that the larger ones are the product of ancient duplications. The gene order of modern-day bacteria is not strong evidence for or against such duplication. There are often pairs of regions which are similar in gene content and order, but these are too rare and scattered to be convincing proof of a genome-wide duplication. If this event did occur, it has since been almost totally obscured by loss or divergence (in sequence and function) of one or both of the copies of most gene pairs, by lateral transfer of genes among related and unrelated organisms and by extensive rearrangement of the gene order. Nevertheless, prokaryotic genome duplication remains a possibility and often crops up in the literature, e.g., [23]. In contrast to plants, fungi, animals, and other eukaryotes which have a multiple-chromosome genome in their nucleii, prokaryotes tend to have a single, often circular, chromosome, so that translocation is not a possibility. They do not have meiosis, so genome duplication cannot arise as a result of a defect in this mechanism. It could, however, result from a fusion of two sister genomes. Reversal of long or short chromosomal segments is often cited as one of the predominant mechanisms for gene order rearrangement in unichromosomal genomes.

The prevalence and evolutionary importance of genome duplication, together with the fragmented nature of its present-day remnants, usually greatly obscured by subsequent developments at the sequence and chromosomal levels, lead to the question addressed in this paper: How can we reconstruct some or most of the original gene order at the time of genome duplication, based on traces conserved in the ordering

of those duplicate genes still identifiable? Solving this would allow us key insights into the mechanisms and consequences of this dramatic evolutionary event. A similar question can also be considered in the case of duplication of fragments of chromosomes [9].

Originally a duplicated genome contains two identical copies of each chromosome, but through intrachromosomal movements and reciprocal translocations, this simple doubled structure is disrupted. The problem considered here is therefore as follows: given a present-day genome modeled by a set of strings (chromosomes) of distinguished elements (genes), each gene appearing exactly twice in the genome, how to recover an ancestral duplicated genome by performing a minimal number of reversals and/or reciprocal translocations? We assume that a sign + or − is associated to each gene, representing its transcriptional orientation. Our method makes use of a formula of Hannenhalli and Pevzner (HP) for the classical problem of signed genome rearrangement.

In a series of papers published in 1995, HP solved the problems of calculating the minimum number of rearrangements necessary to transform one signed genome G into another signed genome H, with rearrangement models based on

- reversals only [17],
- translocations only [16], and
- both reversals and translocations [18].

Though the minimizing formulae and their derivations are different in each case, the frameworks for the three models are similar. They are based on a graph called the *breakpoint graph*, in which each vertex is incident to one black and one gray edge, black edges corresponding to genome G, and gray edges to genome H. This graph decomposes naturally into a set of color-alternating cycles. The number of cycles is the dominant term in the minimizing formulae. The other terms depend on overlap relationships among these cycles, and on their clustering into "good" and "bad" components.

The 1995 papers also presented exact polynomial algorithms for actually constructing a series of rearrangements satisfying the minimality criterion. Subsequently, many alternate versions have been proposed to make various parts of the algorithms more efficient [22, 6, 5, 37]. However, our results on duplicated genomes do not depend on these algorithms. After deriving an ancestral genome by our new methods, an efficient version of the HP algorithm can simply be applied to the present-day genome to convert it to the ancestral genome we obtain.

Our approach in this paper is, given a present-day genome G, to estimate its ancestral polyploid genome by one whose comparison with G minimizes the HP formulae. As the ancestral genome H is unknown, we can start only with the *partial graph* of black edges, and we must complete this graph with an optimal set of gray edges. Though the three evolutionary models described above have different aspects related to the particular kind of genome (multichromosomal or circular) and operation (translocations and/or reversals) considered, the key concepts are the same for the three models.

The first step of the general method is to complete the graph with "valid" gray edges, i.e., gray edges representing a duplicated genome, so as to maximize the number of cycles of the resulting graph. The key idea is to subdivide the graph into a set of disjoint subgraphs, called *natural and supernatural graphs*, that can be solved independently. This is detailed in section 5. These graphs first provide an upper bound for the number of cycles. This bound is presented in section 6. Section 7 then describes a linear algorithm, called *dedouble*, for constructing a completed graph, where

the number of cycles actually attains the upper bound. The main characteristic of *dedouble* is that any gray edge constructed links two vertices of the same supernatural graph. The second step of the general method consists in modifying *dedouble* in order to minimize the number of bad components. Though the concept of bad components is different for each of the three models, they are all related to the notion of *subpermutations* (SPs). Section 8 describes the general approach and the major modification to algorithm *dedouble*. Sections 9, 10, and 11 are then dedicated to the models with translocations only, translocations and reversals, and reversals only, respectively. Developments specific to each model are detailed in these sections. Finally, section 12 gives an application of our algorithm to the multichromosomal yeast genome, and section 13 gives another application to a circular mitochondrial genome.

We begin by formalizing the problem in the next section. We then introduce the HP graph and formulae in section 3 and introduce our notation and main definitions in section 4.

2. Formalizing the problem. We consider three models: translocations-only, both translocations and reversals, and reversals-only. The first two pertain to the multichromosomal context (eukaryotic nuclear genomes), while the third is relevant to single chromosome prokaryotic and organellar genomes.

A *string* is a sequence of signed (+ or −) terms (*genes*) from a set $\mathcal{B}$. A *multichromosomal genome* is a collection of at least two nonnull strings (*chromosomes*). For a string $X = x_1 x_2 \cdots x_r$, denote by $-X$ the *reverse* string $-x_r\ -x_{r-1} \cdots -\ x_1$.

In the models with translocations, a *rearranged duplicated genome* G is a multichromosomal genome containing an even number of chromosomes, such that each gene in $\mathcal{B}$ is present exactly twice, i.e., once in each of two different chromosomes, or twice in a single chromosome.

Example 1. Let $\mathcal{B} = \{a, b, c, d, e, f, g, h\}$ be a set of 8 genes, and let G be a genome consisting of four chromosomes:

$$1\text{: } +a\ +b\ -c\ +b\ -d; \quad 2\text{: } -c\ -a\ +f;$$
$$3\text{: } -e\ +g\ -f\ -d; \quad 4\text{: } +h\ +e\ -g\ +h.$$

G is a rearranged duplicated genome. Each gene appears exactly twice in the set of chromosomes; e.g., gene b appears twice in chromosome 1. Signs represent gene orientation.

A circular chromosome is a string $x_1 x_2 \cdots x_r$, where x_1 is considered to follow x_r. As most single chromosome genomes contain a circular chromosome, in this paper only these circular genomes are considered. However, the application of all the results to genomes with single noncircular chromosomes is straightforward.

In the reversals-only model, a rearranged duplicated genome consists of a single circular genome G containing each gene in $\mathcal{B}$ exactly twice.

Example 2. Let $G = +a\ +b\ -c\ +b\ -d\ -e\ +a\ +c\ -d\ -e$. G is a rearranged duplicated genome on the set of genes $\mathcal{B} = \{a, b, c, d, e\}$. That G is a circular genome means that vertex $+a$ is considered to follow vertex $-e$.

The problem is to calculate the minimum number of rearrangement operations required to transform a given rearranged duplicated genome G into some *perfect duplicated genome* H (or simply *duplicated genome*) to be found. We call this problem the *genome halving problem*. In the case of a multichromosomal genome, H consists of chromosomes $C_1, \ldots, C_{2N}$, where for each $i \in \{1, \ldots, 2N\}$, we have $C_i = C_j$ for exactly one $j \in \{1, \ldots, 2N\} \backslash \{i\}$. In the case of a circular genome, H is of the form $C\ C$ or $C\ -C$, where C is a string containing exactly one occurrence of each gene of $\mathcal{B}$.

Each of the three models permits a different combination of the rearrangement operations reversal and translocation. A *reversal* transforms some proper substring of a genome into its reverse. Let X_1, X_2, Y_1, and Y_2 be nonnull strings. A *reciprocal translocation* between two chromosomes $X = X_1X_2$ and $Y = Y_1Y_2$ is of the form $X_1X_2, Y_1Y_2 \longrightarrow X_1Y_2, Y_1X_2$ (prefix-prefix) or of the form $X_1X_2, Y_1Y_2 \longrightarrow X_1 - Y_1, -Y_2X_2$ (prefix-suffix) (see Figure 2.1).

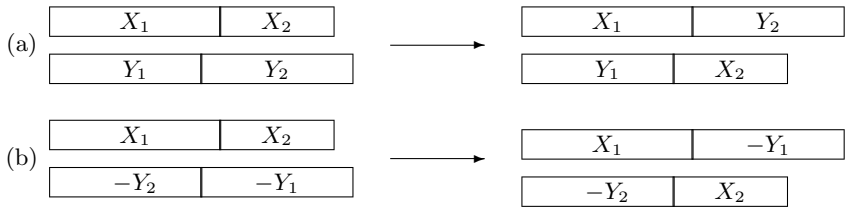

FIG. 2.1. *Reciprocal translocation between two chromosomes X_1X_2 and Y_1Y_2.* (a) *Prefix-prefix translocation.* (b) *Prefix-suffix translocation.*

3. The HP theory. Given two genomes H_1 and H_2 containing the same gene set $\mathcal{B}$, where each gene appears exactly once in each genome, the *genome rearrangement problem* is to find the minimum number of rearrangement operations necessary to transform H_1 into H_2 (or H_2 into H_1). HP designed polynomial algorithms for the reversals-only version of the problem (in the case of single chromosome genomes) [17], the translocations-only version [16], and the version with both reversals and translocations [18] (the latter two for multichromosomal genomes).

The algorithms all depend on a bicolored graph $\mathcal{G}_{12}$ constructed from H_1 and H_2. The details of this construction vary from model to model, due to the different ways chromosomal endpoints must be handled, but the general character of the graph is the same and may be summarized as follows.

Graph $\mathcal{G}_{12}$. If gene x of H_1 has positive sign, replace it by the pair x^tx^h, and if it is negative, replace it by x^hx^t. Then the vertices of $\mathcal{G}_{12}$ are just the x^t and the x^h for all x in $\mathcal{B}$. Any two vertices which are adjacent in some chromosome in H_1, other than x^t and x^h deriving from the same x, are connected by a black edge (thick lines in figures), and any two adjacent in H_2 are connected by a gray edge (thin lines). In the case of a single chromosome, the black edges may be displayed linearly according to the order of the genes in the chromosome (Figure 3.1). For a genome containing N chromosomes, N such linear orders are required (Figure 3.2), and the genes at either end of the chromosome must be treated somewhat differently.

Now, each vertex is incident to exactly one black and one gray edge so that there is a unique decomposition of $\mathcal{G}_{12}$ into c_{12} disjoint cycles of alternating edge colors. By the *size of a cycle* we mean the number of black edges it contains. Note that $c_{21} = c_{12} = c$ is maximized when $H_1 = H_2$, in which case each cycle has one black edge and one gray edge.

A rearrangement operation ρ, either a reversal or a translocation, is determined by the two points where it "cuts" the current genome which correspond to two black edges e and f. We say that ρ *is determined by the two black edges* e and f. Rearrangement operations may change the number of cycles of the graph so that minimizing the number of operations can be seen in terms of increasing the number of cycles as fast as possible. Let $\Delta(c)$ be the difference between the number of cycles before and after applying the rearrangement operation ρ. HP showed that $\Delta(c)$ may take on values

1, 0, or −1, in which cases they are called *ρ proper*, *improper*, or *bad*, respectively. Roughly speaking, an operation determined by two black edges in two different cycles will be bad, while one acting on two black edges within the same cycle may be proper or improper, depending on the type of cycle and the type of edges considered.

Key to the HP approach are the graph components. Two cycles, say, Cycles 1 and 2, all of whose black edges are related by the same linear order (i.e., are on the same line), and containing gray edges that "cross," e.g., gene i linked to gene j by a black edge (i.e., in H_1) in Cycle 1, gene k linked to gene t by a black edge in Cycle 2, but ordered i, k, j, t in H_2, are connected. A *component* of $\mathcal{G}_{12}$ is a maximal set of crossing cycles, excluding the case of a cycle of size 1 (see Figures 3.1 and 3.2). A component is termed *good* if it can be transformed to a set of cycles of size 1 by a series of proper operations, and *bad* otherwise. Bad components are called *subpermutations* in the translocations-only model, *hurdles* in the reversals-only model, and *knots* in the combined model. More details on bad components and how to solve them will be given in the sections dedicated to each of the three evolutionary models.

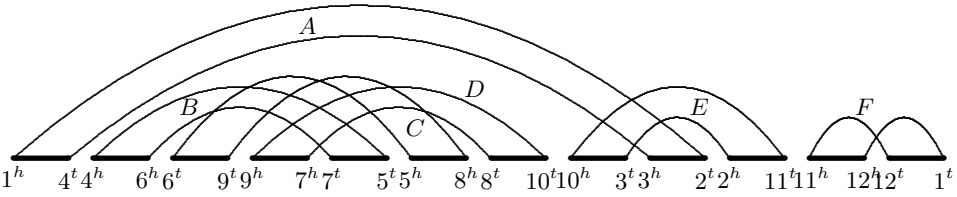

FIG. 3.1. *Graph $\mathcal{G}_{12}$ corresponding to circular genomes (i.e., the first gene is adjacent to the last gene) $H_1 = +1\,+4\,-6\,+9\,-7\,+5\,-8\,+10\,+3\,+2\,+11\,-12$ (black edges) and $H_2 = +1\,+2\,+3\cdots+12$ (gray edges). A, B, C, D, E, and F are the six cycles of $\mathcal{G}_{12}$. $\{A, E\}$, $\{B, C, D\}$, and $\{F\}$ are the three components of $\mathcal{G}_{12}$.*

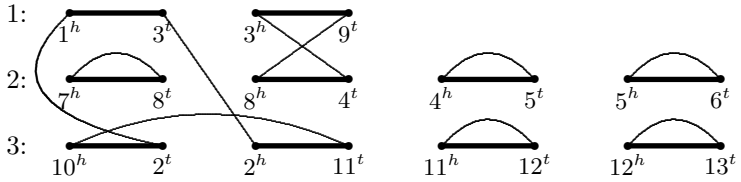

FIG. 3.2. *Graph $\mathcal{G}_{12}$ corresponding to genomes H_1, H_2, both with three chromosomes, where $H_1 = \{1 : 1\ 3\ 9\ ;\ 2 : 7\ 8\ 4\ 5\ 6\ ;\ 3 : 10\ 2\ 11\ 12\ 13\}$ and $H_2 = \{1 : 1\ 2\ 3\ 4\ 5\ 6\ ;\ 2 : 7\ 8\ 9\ ;\ 3 : 10\ 11\ 12\ 13\}$. All genes are signed "+." The edges, which are on the same horizontal row of the graph, correspond to a chromosome of H_1. There are seven cycles. As no cycle of size > 1 is contained on one row, $\mathcal{G}_{12}$ does not contain any component. Both genomes have the same set of endpoints, so we can omit the extremal vertices (x^t for initial genes and x^h for terminal genes) as discussed in section 4.*

The HP formulae for all three models may be summarized as follows:

$$\textbf{HP1}: \quad RO(H_1, H_2) = b(\mathcal{G}_{12}) - c(\mathcal{G}_{12}) + m(\mathcal{G}_{12}) + f(\mathcal{G}_{12}),$$

where $RO(G, H)$ is the minimum number of rearrangement operations (reversals and/or translocations), $b(\mathcal{G}_{12})$ is the number of black edges, $c(\mathcal{G}_{12})$ is the number of cycles, $m(\mathcal{G}_{12})$ is the number of bad components of $\mathcal{G}_{12}$, and $f(\mathcal{G}_{12})$ is a correction of size 0, 1, or 2 depending on the set of bad components.

Generally speaking, bad components are rare, so the number of cycles of $\mathcal{G}_{12}$ is the dominant parameter in the **HP1** formula if $b(\mathcal{G}_{12})$ is considered as a constant. In

other words, the more cycles there are, the fewer reversals we need to transform H_1 into H_2.

4. Preliminaries. To make use of the HP graph structure for our genome halving problem, we first introduce, arbitrarily, a distinction within each pair of identical genes in the rearranged duplicated genome G, labeling one occurrence x_1 and the other x_2 for each x in $\mathcal{B}$.

In the case of linear chromosomes (noncircular), the HP method requires that the two genomes being compared share the same set of chromosomal endpoints. To ensure this constraint for linear multichromosomal genomes, we add a new initial term O_{i1} and a new final term O_{i2} to each chromosome C_i. This also ensures that all translocations, including those which reduce (by *fusion*, e.g., null X_1Y_2, Figure 2.1) or augment (by *fission*, e.g., null X_1X_2, Figure 2.1) the number of chromosomes in the genome, can be treated as reciprocal translocations. This also allows us to consider genomes with an odd number $2N-1$ of chromosomes by adding a dummy chromosome consisting of just one initial and one final O, to obtain $2N$ chromosomes.

In each chromosome, each x_j (except the O_{ij}) is replaced by x_j^t and x_j^h as in the HP construction. Define

$$O = \{O_{i1}, O_{i2}\}_{i=1,\cdots,2N},\ V = \{x_j^s\}_{\substack{x\in\mathcal{B}\\ j=1,2}}^{s\in\{h,t\}},\ \mathbf{V} = O \cup V.$$

In the case of a circular genome, endpoints are irrelevant, and thus the set O is empty, and $\mathbf{V} = V$. We use the notation $\overline{1} = 2$, $\overline{2} = 1$, $\widetilde{t} = h$, $\widetilde{h} = t$. For $u = x_j^s \in V$, its *counterpart*, denoted $\overline{u}$, is $x_{\overline{j}}^s$ (the corresponding vertex in the paralogous gene), and its *obverse*, denoted $\widetilde{u}$, is $x_j^{\widetilde{s}}$ (the vertex corresponding to the other "end" of the gene). Note that $\overline{\overline{u}} = \widetilde{\widetilde{u}} = u$.

The *partial graph* $\mathcal{G}(\mathbf{V}, A)$ associated with G has the edge set A of black edges linking adjacent terms (other than the obverse) in G. The partial graph associated with the genome G of Example 1 is shown in Figure 4.1. To differentiate the two occurrences of each gene x, one is subscripted "1," and its counterpart is "2."

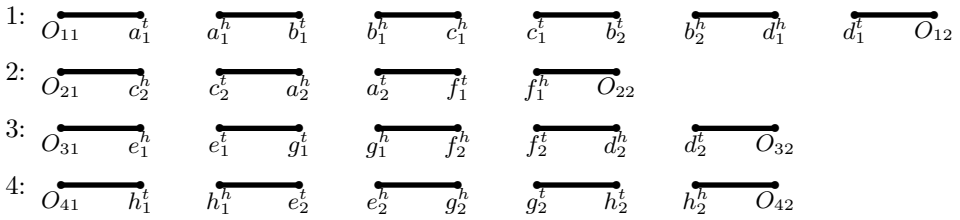

FIG. 4.1. *The partial graph* $\mathcal{G}(\mathbf{V}, A)$ *corresponding to Example* 1.

We are required to add to this partial graph a set Γ of gray edges so that every vertex in $\mathbf{V}$ is incident to exactly one black edge and one gray edge and so that the resulting genome is a perfectly duplicated one. A set Γ of gray edges giving rise to a duplicated genome is said to be *valid*. In the case of a multichromosomal genome, a chromosome of a perfectly duplicated genome should begin and end with two elements of O. The graph $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ obtained by adding a valid set Γ of gray edges is called a *completed graph* of $\mathcal{G}(\mathbf{V}, A)$. Lemmas 4.1 and 4.2 give the constraints that Γ should satisfy to be valid in the cases of multichromosomal and circular genomes, respectively.

LEMMA 4.1. *For multichromosomal genomes,* Γ *is valid if and only if the following conditions are satisfied:*

1. Γ *contains no edge of form* $(x, \overline{x})$ *for any* $x \in V$.
2. *Suppose* $(x, y) \in \Gamma$ *and* $y \in V$. *If* $x \in V$, *then* $(\overline{x}, \overline{y})$ *is also in* Γ. *Otherwise* $(x \in O)$, $\overline{y}$ *is also linked by a gray edge to an element of* O.
3. *The resulting genome does not contain any circular chromosome.*

Proof. Clearly, a duplicated genome must satisfy all three conditions. Suppose now that Γ is a set of gray edges so that every vertex of $\mathbf{V}$ is incident to exactly one gray edge, and Γ satisfies the three conditions. Then, from condition 3, as no circular fragment is present, and as the only "genes" with only one end are the elements of O, each chromosome of the resulting genome H has its two endpoints in O. From condition 1, the two copies of the same gene cannot be adjacent in H, and from condition 2, if two genes are adjacent in H, then their homologs are also adjacent in H in the same order. This ensures that each permutation (string) is present exactly twice in H. Therefore, H is a perfectly duplicated genome. ∎

LEMMA 4.2. *For circular genomes,* Γ *is valid if and only if the following conditions are satisfied:*

1. Γ *contains exactly zero or two edges of form* $(x, \overline{x})$.
2. *If* $(x, y) \in \Gamma$, *then* $(\overline{x}, \overline{y}) \in \Gamma$.
3. *The resulting genome consists of a single circular chromosome.*

Proof. The proof follows from the definition of a circular duplicated genome. ∎

To find a duplicated genome that gives rise to the minimal number of rearrangement operations, we have to construct a valid set of gray edges that minimizes the formula **HP1** (section 3). The key idea is to decompose the partial graph into a set of subgraphs that can be completed independently. We describe such a decomposition in the next section.

5. Decomposition into subgraphs. We define the set $\mathcal{NG}$ of *natural graphs* of $\mathcal{G}(\mathbf{V}, A)$ as follows.

DEFINITION 5.1. *Let* $e = (x, y) \in A$. *Define* A_e *recursively by* $(x, y) \in A_e$, *and if* $(x, y) \in A_e$, *then both the edge of* A *adjacent to* $\overline{x}$ *and the edge of* A *adjacent to* $\overline{y}$ *are also in* A_e.

Let $\mathbf{V}_e$ *be the subset of* $\mathbf{V}$ *made up of vertices incident to the edges in* A_e. *Then* $\mathcal{G}_e(\mathbf{V}_e, A_e)$ *is the* natural graph *(of* size $|A_e|$*) of* $\mathcal{G}(\mathbf{V}, A)$ *generated by* e. *Note that if* $f \in A_e$, *then* $A_f = A_e$.

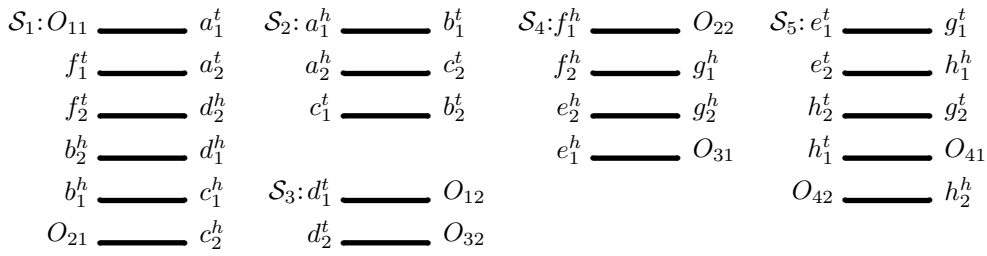

FIG. 5.1. *The natural graphs of the partial graph* $\mathcal{G}(\mathbf{V}, A)$ *of Figure* 4.1.

As an illustration, the decomposition of the partial graph of Figure 4.1 into natural graphs is given in Figure 5.1.

Let $\mathcal{G}_\alpha$ be a subgraph of $\mathcal{G}(\mathbf{V}, A)$. $\mathcal{G}_\alpha$ represents a set of fragments of the chromosomes of G. The subgraph $\mathcal{G}_\alpha$ is said to be *completable* if we can find a set of gray

edges linking the vertices of $\mathcal{G}_\alpha$ that gives rise to a set of fragments of a potential duplicated genome. Not every natural subgraph is completable. In the case of multichromosomal genomes, we proved in [10] that a natural graph is completable if and only if it is of even size or it contains vertices in O. Similarly, for circular genomes, all natural graphs of even size are completable. Moreover, as we can have at most two gray edges of form $(u, \overline{u})$, then at most two natural graphs of odd size are completable.

The underlying idea of the subdivision and amalgamating procedure is to form completable graphs. First, $\mathcal{NG}$ is subdivided into the following subsets:

- $\mathcal{NE}$ is the subset of $\mathcal{NG}$ containing the natural graphs of even size.
- $\mathcal{NO}$ is the subset of $\mathcal{NG}$ containing the natural graphs of odd size. We further subdivide $\mathcal{NO}$ into $\mathcal{NO}_+$ and $\mathcal{NO}_-$ according to whether the natural graphs include vertices in O or not. Note that $\mathcal{NO}_+$ may contain a natural graph formed by a single edge linking two vertices in O.

The set A contains $2(|\mathcal{B}| + N)$ edges in the case of multichromosomal genomes, and $2|\mathcal{B}|$ edges in the case of circular genomes. Moreover, the graphs of $\mathcal{NE}$ contain an even number of edges. Therefore, $\mathcal{NO}$ must also contain an even number of edges and thus an even number of graphs. We can then pair off all the graphs in $\mathcal{NO}$ as follows:

- Arbitrarily choose pairs of graphs in $\mathcal{NO}_+$ to amalgamate. The set of larger graphs thus formed is denoted $\mathcal{SO}_+$.
- Arbitrarily choose pairs of the remaining graphs in $\mathcal{NO}$ to amalgamate. This includes graphs in $\mathcal{NO}_-$ plus, if applicable, the remaining one in $\mathcal{NO}_+$. The set of graphs thus formed is denoted $\mathcal{SO}$.

We denote $\mathcal{SE} = \mathcal{NE} \cup \mathcal{SO}_+$, and we call the graphs of $\mathcal{SN} = \mathcal{SE} \cup \mathcal{SO}$ *supernatural*.

In the example of Figure 5.1, $\mathcal{NE} = \{\mathcal{S}_1,\ \mathcal{S}_3,\ \mathcal{S}_4\}$, $\mathcal{NO}_- = \{\mathcal{S}_2\}$, and $\mathcal{NO}_+ = \{\mathcal{S}_5\}$. Moreover, $\mathcal{SE} = \mathcal{NE}$, and if $\mathcal{S}_{25}$ is the supernatural graph obtained by amalgamating $\mathcal{S}_2$ and $\mathcal{S}_5$, then $\mathcal{SO} = \{\mathcal{S}_{25}\}$. The set $\{\mathcal{S}_1, \mathcal{S}_{25}, \mathcal{S}_3, \mathcal{S}_4\}$ is a decomposition of $\mathcal{G}(\mathbf{V}, A)$ into supernatural graphs.

Note that for circular genomes, $\mathcal{NO}_+$ is empty, and thus $\mathcal{NO}$ graphs are arbitrarily amalgamated. In that case, $\mathcal{SO}_+$ is empty and $\mathcal{SE} = \mathcal{NE}$.

Notation 1. In a supernatural graph $\mathcal{G}_\alpha(\mathbf{V}_\alpha, A_\alpha)$ of $\mathcal{NE} \cup \mathcal{SO}$, if a vertex $u \in \mathbf{V}_\alpha \cap O$ exists, then we denote by $\overline{u}$ the (only) other vertex in $\mathbf{V}_\alpha \cap O$. For example, in Figure 5.1, $\overline{0_{11}} = 0_{21}$, and $\overline{0_{41}} = 0_{42}$.

In a supernatural graph $\mathcal{G}_\alpha(\mathbf{V}_\alpha, A_\alpha)$ of $\mathcal{SO}_+$ made up of two natural graphs $\mathcal{G}_1(\mathbf{V}_1, A_1)$ and $\mathcal{G}_2(\mathbf{V}_2, A_2)$ of $\mathcal{NO}_+$, if $u \in \mathbf{V}_1 \cap O$, then we arbitrarily choose one of the two vertices of $\mathbf{V}_2 \cap O$ to be $\overline{u}$.

5.1. Ordering the edges of the natural subgraphs. To simplify the ensuing development, we use a particular representation of each supernatural graph $\mathcal{G}_\alpha(\mathbf{V}_\alpha, A_\alpha)$ of size $2n$, where $n > 1$. Relabeling the vertices in $\mathbf{V}_\alpha$ allows us to define a *suitable order* for the edges in A_α (cf. Figure 5.2).

1. If $\mathcal{G}_\alpha \in \mathcal{CE}$, $A_\alpha = \{e_1, e'_1, \ldots, e_n, e'_n\}$ such that the following hold:
   - $e_1 = (a_1, b_1)$; $e'_1 = (\overline{a_1}, b_2)$.
   - For each i, $1 < i < n$, $e_i = (a_i, \overline{b_{i-1}})$ and $e'_i = (\overline{a_i}, b_{i+1})$.
   - $e_n = (a_n, \overline{b_{n-1}})$; $e'_n = (\overline{a_n}, \overline{b_n})$.
2. If $\mathcal{G}_\alpha \in \mathcal{SO}$, let $\mathcal{G}_1(A_1)$ and $\mathcal{G}_2(A_2)$ be its two component natural subgraphs, where $A_\alpha = A_1 \cup A_2$. Then $A_1 = \{e_1, e'_1, \ldots, e_{n_1-1}, e'_{n_1-1}, e_{n_1}\}$, where e_i and e'_i are defined as above except that $e_{n_1} = (\overline{b_{n_1}}, \overline{b_{n_1-1}})$. Similarly, $A_2 = \{e_{n_1+1}, e'_{n_1+1}, \ldots, e_{n-1}, e'_{n-1}, e_n\}$ with $e_n = (\overline{b_n}, \overline{b_{n-1}})$.

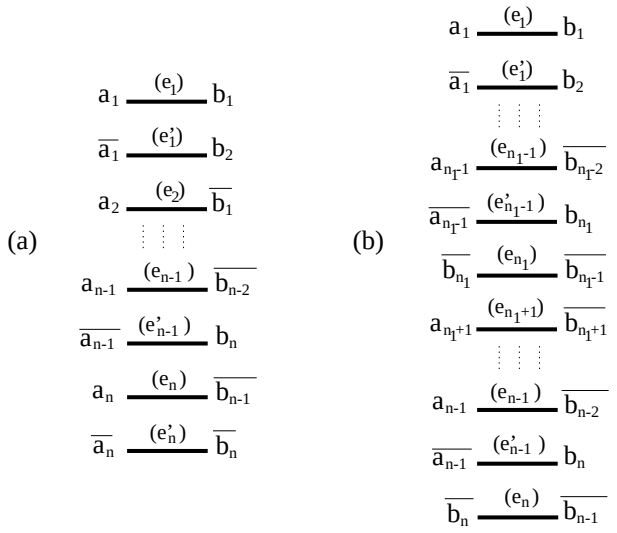

FIG. 5.2. *A suitable order for the edges of supernatural graphs.* (a) *A supernatural graph in* $\mathcal{SE}$. (b) *A supernatural graph in* $\mathcal{SO}$.

For an illustration, consider the supernatural graphs $\{\mathcal{S}_1, \mathcal{S}_{25}, \mathcal{S}_3, \mathcal{S}_4\}$ of our running example. By means of a relabeling of the vertices (a vertex x_1 could be relabeled as x_2, or vice-versa), one possible suitable order for the edges of the graphs is considered in Figure 7.5.

In the ensuing discussion, we start with any decomposition of $\mathcal{G}(\mathbf{V}, A)$ into a set $\mathcal{SN}$ of supernatural graphs in the suitable order.

As the dominant parameter in the **HP1** formula is the number of cycles, we begin by considering a set of valid gray edges maximizing the number of cycles of a completed graph. In the next section, we provide an upper bound on the number of cycles, and in section 7, we describe an algorithm for constructing a completed graph that allows us to reach this bound.

6. Upper bound on the number of cycles. We need a preliminary definition.

DEFINITION 6.1. *Let* $\mathcal{G}_\alpha(\mathbf{V}_\alpha, A_\alpha)$ *be a supernatural graph of size* $2n$. *Consider the ordering of* A_α *described in the last section. Then* $V_l = \bigcup_{1 \le i \le n} \{a_i, \overline{a_i}\}$ *is the set of* left vertices *of* $\mathbf{V}_\alpha$, *and* $V_r = \bigcup_{1 \le i \le n} \{b_i, \overline{b_i}\}$ *is the set of* right vertices *of* $\mathbf{V}_\alpha$.

Note that from the definition, a natural subgraph of $\mathcal{SO}$ has four more right vertices than left vertices.

The set $\mathbf{V}$ is partitioned into subsets of left and right vertices: x is a left vertex in $\mathbf{V}$ if it is a left vertex of a graph of $\mathcal{SN}$. Otherwise, it is a right vertex.

Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be a completed graph of $\mathcal{G}(\mathbf{V}, A)$, and let C be a particular cycle of size r of the graph with vertex set $\mathbf{V}_C$ and black and gray edge sets A_C and Γ_C, respectively. We define the *signature* S_C of C to be the subset of $\mathbf{V}_C$ derived as follows: For every left vertex x in $\mathbf{V}_C$, if $\overline{x}$ is not already in S_C, then add x to S_C.

Let $\mathcal{S}$ be the set of signatures of all the cycles of $\mathcal{G}_\Gamma$. Define the *signature graph* with the set of nodes $\mathcal{S}$ and the set of edges E as follows: for all $S_1, S_2 \in \mathcal{S}$, S_1 and S_2 are linked by an edge in E if and only if there is a vertex x such that $x \in S_1$ and $\overline{x} \in S_2$.

In Figure 6.1, a completed graph is given on the left. It represents a completed

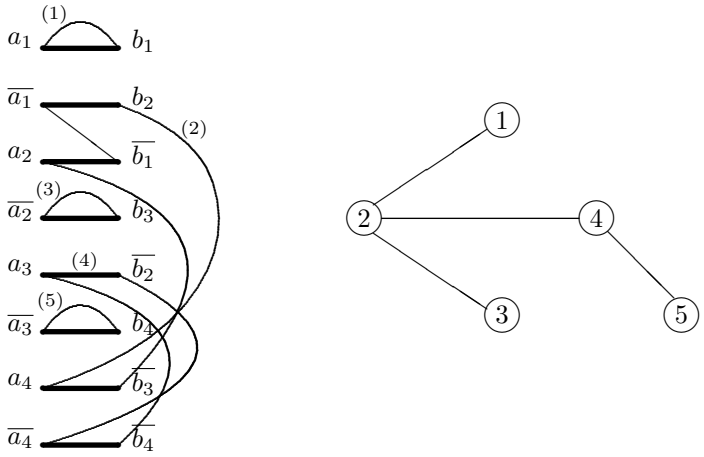

FIG. 6.1. *Example of a signature graph.*

supernatural graph of $\mathcal{SE}$. The completed graph is made up of five cycles, whose signatures are as follows:

$$1.\ \{a_1\};\quad 2.\ \{\overline{a_1}, a_2, a_4\};\quad 3.\ \{\overline{a_2}\};\quad 4.\ \{a_3, \overline{a_4}\};\quad 5.\ \{\overline{a_3}\}.$$

The graph on the right of Figure 6.1 is the signature graph derived from the graph on the left.

LEMMA 6.2. *In the case of multichromosomal genomes, the signature graph of any completed supernatural graph is connected.*

Proof. The proof is deduced from the fact that $\mathcal{SN}$ is a set of smallest completable graphs: for any supernatural graph $\mathcal{G}_\alpha$, there does not exist any subgraph of $\mathcal{G}_\alpha$ that is also completable. □

For a node S_C of $\mathcal{S}$, denote by $t(S_C)$ the number of vertices in S_C and by $\delta(S_C)$ the number of outgoing edges.

LEMMA 6.3. *For a multichromosomal genome, let $\mathcal{G}_e(\mathbf{V}_e, A_e)$ be a supernatural graph of size $2n$, where $n > 0$. Let $\mathcal{G}_e(\mathbf{V}_e, A_e, \Gamma_e)$ be a completed graph, and let c_e be its number of cycles. If $\mathcal{G}_e \in \mathcal{SE}$, then $c_e \leq n+1$. Otherwise ($\mathcal{G}_e \in \mathcal{SO}$), $c_e \leq n$.*

Proof. Let $\mathcal{S}$ be the set of vertices and E the set of edges of the signature graph of $\mathcal{G}_e(\mathbf{V}_e, A_e, \Gamma_e)$. Then $c_e = |\mathcal{S}|$.

For every $S_C \in \mathcal{S}$, $\delta(S_C) \leq t(S_C)$. Now $\sum_{S_C \in \mathcal{S}} t(S_C) \leq 2n$ so that

$$|E| = \frac{1}{2} \sum_{S_C \in \mathcal{S}} \delta(S_C) \leq \frac{1}{2} \sum_{S_C \in \mathcal{S}} t(S_C) \leq n.$$

From Lemma 6.2, a signature graph is connected so that $|\mathcal{S}| \leq |E| + 1 \leq n + 1$.

For the case $\mathcal{G}_e(\mathbf{V}_e, A_e) \in \mathcal{SO}$, $\sum_{S_c \in \mathcal{S}} t(S_C) \leq 2n - 2$. By the same argument as above,

$$|\mathcal{S}| \leq |E| + 1 = \frac{1}{2} \sum_{S_C \in \mathcal{S}} \delta(S_C) + 1 \leq \frac{1}{2} \sum_{S_C \in \mathcal{S}} t(S_C) + 1 \leq n. \qquad \square$$

Results are slightly different for circular genomes.

LEMMA 6.4. *In the case of circular genomes, the signature graph of any completed supernatural graph of $\mathcal{SE}$ is connected. On the other hand, at most one completed*

supernatural graph of $\mathcal{SO}$ has a signature graph with two connected components. The signature graph corresponding to any other graph of $\mathcal{SO}$ is connected.

Proof. In the case of circular genomes, at most two natural graphs among all natural graphs of odd size are completable. This follows from the fact that a circular genome contains at most two adjacencies of form $(x, \overline{x})$. Therefore, as a supernatural graph of $\mathcal{SO}$ is obtained by concatenating two natural graphs of odd size, at most one completable supernatural graph of $\mathcal{SO}$ has a signature graph with two connected components. Any other graph of $\mathcal{SN}$ cannot be subdivided into smallest completable graphs and thus have signature graphs reduced to one connected component. ∎

LEMMA 6.5. *For a circular genome, let $\mathcal{G}_e(\mathbf{V}_e, A_e, \Gamma_e)$ be a completed supernatural graph of size $2n$, and let c_e be its number of cycles. If $\mathcal{G}_e \in \mathcal{SE}$, then $c_e \leq n+1$. Moreover, there is at most one supernatural graph $\mathcal{G}_e$ of $\mathcal{SO}$ such that $c_e = n+1$. For all the other supernatural graphs of $\mathcal{SO}$, $c_e \leq n$.*

Proof. The proof is similar to that of Lemma 6.3 but uses the result of Lemma 6.4. ∎

Notation 2. We denote by $\boldsymbol{\gamma(G)}$ the number of "good" supernatural graphs:

- In the case of a multichromosomal genome G, $\gamma(G) = |\mathcal{SE}|$.
- In the case of a circular genome G, if $\mathcal{SO}$ is empty, then $\gamma(G) = |\mathcal{SE}|$; otherwise, $\gamma(G) = |\mathcal{SE}| + 1$.

THEOREM 6.6. *Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be a completed graph of $\mathcal{G}(\mathbf{V}, A)$, and let $c(\mathcal{G}_\Gamma)$ be its number of cycles. Then*

$$c(\mathcal{G}_\Gamma) \leq \frac{|A|}{2} + \gamma(G).$$

Proof. If any cycle C of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ is "good," i.e., such that all black edges of C belong to the same supernatural graph of $\mathcal{SG}$, then, according to Lemmas 6.3 and 6.5, $c(\mathcal{G}_\Gamma) \leq \frac{|A|}{2} + \gamma(G)$.

Suppose now that there exist "bad cycles" in $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$, i.e., cycles containing black edges of different supernatural graphs. Let c_b be the number of bad cycles, and let c_g be the number of good cycles of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. Then $c(\mathcal{G}_\Gamma) = c_b + c_g$.

Let $\mathcal{G}_p(\mathbf{V}_p, A_p)$ be a supernatural graph, and let $\mathcal{C}_p$ be the set of cycles of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ containing at least one edge in A_p. Let c_{g_p} be the number of good cycles and c_{b_p} the number of bad cycles of $\mathcal{C}_p$. Denote by $\{x_i, 1 \leq i \leq |\mathbf{V}_p|\}$ the set of vertices of $\mathbf{V}_p$.

Suppose that C is a bad cycle of $\mathcal{C}_p$ of size > 1. Denote $C = x_1x_2 - -x_3x_4 - - x_5x_6, \ldots$, where x_i's are the vertices in $\mathbf{V}_p$ and "$--$" denote paths in the cycle that do not contain any vertex in $\mathbf{V}_p$. Some of these paths can be empty.

We modify the bad cycles of $\mathcal{C}_p$ by the following procedure:

1. For any bad cycle $C = x_1x_2 - -x_3x_4 - -x_5x_6 \cdots$ and any x_i with an even i, do
2. If $x_{i+1} \neq \overline{x_i}$, do
3. Remove the gray edges adjacent to x_i, x_{i+1}, $\overline{x_i}$, $\overline{x_{i+1}}$;
4. Construct the gray edges (x_i, x_{i+1}) and $(\overline{x_i}, \overline{x_{i+1}})$;
5. Else, there is another path of form $x_j - -\overline{x_j}$ (i.e., $x_{j+1} = \overline{x_j}$) either in C, or in another cycle of $\mathcal{C}_p$;
6. Choose such a path, if possible in C, otherwise in another bad cycle, else, in a good cycle;
7. Remove the gray edges adjacent to x_i, x_{i+1}, x_j, and x_{j+1};
8. Construct the gray edges (x_i, x_j), (x_{i+1}, y_{j+1}), $(\overline{x_i}, \overline{x_j})$, and $(\overline{x_{i+1}}, \overline{x_{j+1}})$;
9. End of If
10. End of For

The procedure constructs a completed graph $\mathcal{G}_p(\mathbf{V}_p, A_p, \Gamma_p)$. Let c_p be the number of cycles of $\mathcal{G}_p(\mathbf{V}_p, A_p, \Gamma_p)$. As the only way to decrease the number of cycles is to amalgamate pairs of bad cycles or to amalgamate at most once a bad cycle with a good one (lines 5 to 8 of the procedure), we have $c_p \geq c_{g_p} + c_{b_p} - \lceil \frac{c_{b_p}}{2} \rceil \geq c_{g_p} + \lfloor \frac{c_{b_p}}{2} \rfloor$. Let $c_{max,p}$ be the maximal number of cycles of a completed graph of $\mathcal{G}_p(\mathbf{V}_p, A_p)$. Then $c_{g_p} + \lfloor \frac{c_{b_p}}{2} \rfloor \leq c_{max,p}$.

Let now c_{max} be the maximal number of cycles of a completed graph of $\mathcal{G}(\mathbf{V}, A)$, and let c_d be the total number of bad cycles of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. Then (1) $c_g + c_d \leq c_{max} + \lfloor \frac{c_d}{2} \rfloor \Longrightarrow c_g + \lceil \frac{c_d}{2} \rceil \leq c_{max}$.

On the other hand, as any bad cycle of a supernatural graph (a cycle containing at least one edge in the supernatural graph) corresponds to a bad cycle of another supernatural graph, the total number of cycles of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ is (2) $c(\mathcal{G}_\Gamma) = c_g + c_b \leq c_g + \lceil \frac{c_d}{2} \rceil$. We deduce from inequalities (1) and (2) that $c(\mathcal{G}_\Gamma) \leq c_{max} \leq \frac{|A|}{2} + \gamma(G)$. □

7. Maximizing the number of cycles. Based on the decomposition of $\mathcal{G}(\mathbf{V}, A)$ into supernatural graphs, can we construct a completed graph $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ having $c(\mathcal{G}_\Gamma) = \gamma(G) + \frac{|A|}{2}$ cycles? By Theorem 6.6, this would necessarily be a *maximal completed graph*, that is, a completed graph with a maximal number of cycles. In this section, we focus on multichromosomal genomes. Modifications that have to be introduced in the case of circular genomes are presented in section 11.

We will use the following notation: for any set U of natural graphs, we denote by $\mathbf{V}_U$ the set of vertices of all natural graphs of U and by A_U the set of all black edges of U. For example, $\mathbf{V}_{\mathcal{SE}}$ will be the set of vertices of $\mathcal{SE}$.

We require a preliminary definition. A *fragment* of a genome is just a linear substring of G. For example, $F_1 = +g_1\ -f_2\ -d_2$ and $F_2 = 0_{11}\ +a_1\ +b_1$ are two fragments of the genome represented by the partial graph of Figure 4.1. A fragment has two *endpoints*, unless it is restricted to one element of O. In the example given here, the two endpoints of F_1 are g_1^t and d_2^t, and the two endpoints of F_2 are 0_{11} and b_1^h. We call a fragment that has its two endpoints in V a $\mathcal{B}$-fragment.

Suppose that we have reached a certain step s in the construction, that Γ_s is the set of gray edges already constructed, and that $\mathcal{G}(\Gamma_s)$ is the "partially completed" graph obtained at this step. Suppose also that the natural graph being considered at this step is $\mathcal{G}_\alpha$, that the set of gray edges linking vertices of $\mathcal{G}_\alpha$ already constructed is $\Gamma_{s,\alpha}$, and that $\mathcal{G}_\alpha(\Gamma_{s,\alpha})$ is the obtained "partially completed" natural graph. A vertex of V is said to be *unlinked* if it is not yet linked by a gray edge at the current step of the algorithm.

We denote by $\mathcal{F}$ the fragments set resulting from Γ_s. At the outset, $\mathcal{F}$ is made up of the *unitary fragments*, which include not only $x^t x^h$ for all $x \in \mathcal{B}$ (the *$\mathcal{B}$-unitary fragments*) but also the $2N$ elements of O (the *O-unitary fragments*). As the construction proceeds, whenever a gray edge (x, y) is created, the fragment containing x and the one containing y are joined together.

DEFINITION 7.1. *Let $\mathcal{V}_s$ be a subset of the set of unlinked vertices at step s of the algorithm. The* border *of $\mathcal{V}_s$ is the set of all vertices x of $\mathcal{V}_s$ such that $x \in O$, or x is an endpoint of a $\mathcal{B}$-fragment $F \in \mathcal{F}$, and the second endpoint of F is not in $\mathcal{V}_s$.*

The graph $\mathcal{G}(\Gamma_s)$ is *bad* if there exists a subset U of $\mathcal{SN}$ such that the border of $\mathbf{V}_{s,U}$ is empty, where $\mathbf{V}_{s,U}$ is the set of unlinked vertices of $\mathbf{V}_U$ at step s. Otherwise, $\mathcal{G}(\Gamma_s)$ is a *good graph*. For an example, see Figure 7.1.

LEMMA 7.2. *Any set of gray edges linking the remaining unlinked vertices of a bad graph creates at least one circular fragment.*

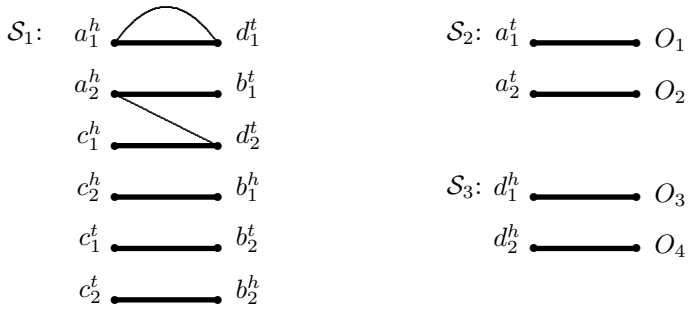

FIG. 7.1. *The partial graph corresponding to the genome with the two chromosomes:* $O_1 + a_1 + d_1\ O_3$; $O_2 + a_2 + b_1 - c_2 - b_2 + c_1 + d_2\ O_4$. *If we construct the two gray edges* $(a_1^h, d_1^t), (a_2^h, d_2^t)$, *the graph becomes bad, as the border of the supernatural graph* $\mathcal{S}_1$ *becomes empty.*

Proof. Suppose that U is a subset of $\mathcal{SN}$ such that the border of $\mathbf{V}_{s,U}$ is empty. Then there is a set $\mathcal{F}_d$ of fragments such that the set of endpoints of $\mathcal{F}_d$ is exactly $\mathbf{V}_{s,U}$. Then, by linking the vertices of $V_{s,U}$ by gray edges, all we can do is close all the fragments of $\mathcal{F}_d$, that is, create at least one circular fragment. □

The above lemma implies that we have to be careful during the execution of the algorithm so as not to end up with a bad graph. Now suppose that $\mathcal{G}(\Gamma_s)$ is a good graph. Let $x, y, \overline{x}, \overline{y}$ be four unlinked vertices of $\mathcal{G}_\alpha(\Gamma_{s,\alpha})$. The pair of "potential" gray edges $\{(x, y), (\overline{x}, \overline{y})\}$ will be termed *impossible* if, when constructed, it creates either a circular fragment or a bad graph and *possible* otherwise. It is easy to see that a pair of edges $\{(x, y), (\overline{x}, \overline{y})\}$ creates a circular fragment if and only if one of the following properties is satisfied (see Figure 7.2).

Property I. The vertices $\{x, y\}$ are the endpoints of a $\mathcal{B}$-fragment of $\mathcal{F}$.

Property II. The pairs of vertices $\{x, \overline{y}\}, \{\overline{x}, y\}$ are the endpoints of two $\mathcal{B}$-fragments of $\mathcal{F}$.

FIG. 7.2. *The left (resp., right) figure represents Property* I *(resp., Property* II*). Bold lines represent fragments, and thin lines represent the "potential" gray edges* $(x, y), (\overline{x}, \overline{y})$. *In any of these cases, the resulting fragment is circular.*

Now, let us consider a third property of a pair $\{(x, y), (\overline{x}, \overline{y})\}$ of potential gray edges.

Property III. x, y are two endpoints of two different fragments F_1, F_2 of $\mathcal{F}$, and neither one of the two other endpoints of F_1, F_2, if any, is in $\mathcal{G}_\alpha$.

LEMMA 7.3. *Suppose that* $\mathcal{G}(\Gamma_s)$ *is good. Suppose that, at step* $s+1$, *we construct the two gray edges* $(x, y), (\overline{x}, \overline{y})$. *If these gray edges do not satisfy Property* III, *then* $\mathcal{G}(\Gamma_{s+1})$ *is good.*

Proof. Let F_1, F_2 be the two fragments such that x is an endpoint of F_1 and y is an endpoint of F_2. Suppose that x, y do not satisfy Property III. Let U be any subset of $\mathcal{SN}$.

- Suppose F_1, F_2 have four endpoints, and all of these endpoints are in $\mathcal{G}_\alpha$. Then it is easy to see that linking F_1 to F_2 does not modify either the border

corresponding to $\mathcal{G}_\alpha$ or that corresponding to U. Thus the state of $\mathcal{G}_\alpha$ (good or bad) could not have changed between steps s and $s+1$.

- Suppose that F_1, F_2 have at least three endpoints, and three such endpoints are in $\mathcal{G}_\alpha$. The subgraph U is bad if and only if $\mathbf{V}_{U,s+1}$ contains the fourth endpoint of F_1, F_2 not in $\mathcal{G}_\alpha$ and the border of $\mathbf{V}_{U,s+1}$ is empty. However, in that case, U would also have been bad at step s, which is a contradiction. ∎

For example, in Figure 7.1, the two gray edges $(a_2^h, b_1^t), (a_1^h, b_2^t)$ do not satisfy Property III, as the second endpoint of the fragment containing b_1^t is b_1^h, and b_1^h is in $\mathcal{S}_1$. Therefore, constructing these gray edges does not create a bad graph.

COROLLARY 7.4. *If a pair of potential gray edges* $\{(x,y),(\overline{x},\overline{y})\}$ *of a good graph does not satisfy any of the Properties* I, II, *and* III, *then it is a possible pair of gray edges.*

Let x be an unlinked vertex of $\mathcal{G}_\alpha$. Then x is one of the two endpoints of a path (made up of a succession of black and gray edges) completely contained in $\mathcal{G}_\alpha$. We denote by x^c the second endpoint of this path. We say that a gray edge *closes the path* if and only if it links x to x^c.

Algorithm *dedouble* described in Figure 7.3 completes each supernatural graph of $\mathcal{SN}$, one after the other, in a specific order. The notation and edge order are those described in section 5.1.

LEMMA 7.5. *At each step, algorithm* dedouble *constructs possible pairs of gray edges.*

Proof. Supernatural graphs of $\mathcal{SE}$, *with* $n = 1$. At the beginning of the algorithm, the gray edges $(a_1, b_1), (\overline{a_1}, \overline{b_1})$ of $\mathcal{SE}$ are clearly possible, as they form fragments of the original genome G (Figure 7.4.(a)).

Suppose that we have reached a certain step in the construction and that the current supernatural graph of $\mathcal{SO}$ has the four vertices $b_1, b_2, \overline{b_1}, \overline{b_2}$ (Figure 7.4.(b)).

Suppose b_1, b_2 do not satisfy Property I, that is, they are the two endpoints of a fragment $F = b_1 \cdots b_2$. F cannot be a fragment of G, as in that case G would contain a circular fragment. Thus F should contain an adjacency (b_i, b_j) constructed from a supernatural subgraph of $\mathcal{SO}$, which means that $(a_i, \overline{a_i})$ and $(a_j, \overline{a_j})$ are two adjacencies in G. Then, if $F = b_1 \cdots a_i a_j \cdots b_2$, it is easy to see that G should contain two fragments of form $b_1 \cdots b_i \overline{b_i} \cdots \overline{b_1}$ and $b_2 \cdots b_j \overline{b_j} \cdots \overline{b_2}$. But since $(b_1, \overline{b_1}), (b_2, \overline{b_2})$ are two adjacencies in G (from the fact that the four vertices belong to a graph in $\mathcal{SO}$), this implies that G contains two circular fragments, which is impossible. Therefore, (b_1, b_2) (or, similarly, $(\overline{b_1}, \overline{b_2})$) does not create a circular fragment. We can prove in a similar way that $(b_1, b_2), (\overline{b_1}, \overline{b_2})$ do not satisfy Property II.

Suppose now that (b_1, b_2) creates a bad graph. Then there exists a subset U of $\mathcal{SN}$ such that the border of $\mathbf{V}_{U,s}$ is $B(U,s) = \{b_1, b_2, \overline{b_1}, \overline{b_2}\}$. This implies that the vertices of $\mathbf{V}_{U,s}$ belong to two fragments of G with the four endpoints $\{b_1, b_2, \overline{b_1}, \overline{b_2}\}$. This is also impossible as the two edges $(b_1, b_2), (\overline{b_1}, \overline{b_2})$ would give rise to a circular fragment in G.

Therefore, at the end of step 1 of the algorithm, the partial graph obtained is a good graph.

Supernatural graphs of $\mathcal{SE}$, *with* $n > 1$. Suppose that we have reached a good graph $\mathcal{G}(\Gamma_s)$ with a certain number of completed supernatural graphs. Suppose that $\mathcal{G}_\alpha$ is the supernatural graph currently being completed and that the current vertices to be considered are $a_i, \overline{a_i}$. Suppose first that $i \leq n-2$. It is easy to see, from the construction, that $a_i^c \neq \overline{a_i}^c$ and thus the two pairs of gray edges $p_{i,1}$ and $p_{i,2}$ are different.

Algorithm dedouble:

Subgraphs in $\mathcal{SE}$, $n = 1$

1. Construct the gray edges $\{(a_1, b_1), (\overline{a_1}, \overline{b_1})\}$ (cf. Figure 7.4.(a));

Subgraphs in $\mathcal{SO}$, $n = 1$

2. Construct the gray edges $\{(b_1, b_2), (\overline{b_1}, \overline{b_2})\}$ (cf. Figure 7.4.(b));

Subgraphs in $\mathcal{SE}$, $n > 1$

3. **For** $i = 1$ to $n - 2$ **Do**
4. Set $c = a_i^c$ and $d = \overline{a_i}^c$;
5. **If** $p_{i,1} = \{(a_i, c), (\overline{a_i}, \overline{c})\}$ does not satisfy Properties I, II, and, III, **Then**
6. Construct the gray edges of $p_{i,1}$;
7. **Else**
8. Construct the gray edges of $p_{i,2} = \{(\overline{a_i}, d), (a_i, \overline{d})\}$;
9. **End of if**
10. **End for**
11. Set $c = a_{n-1}^c$ and $d = \overline{a_{n-1}}^c$ (cf. Figure 7.4.(c));
12. **If** $p_{n-1,1} = \{(a_{n-1}, c), (\overline{a_{n-1}}, \overline{c})\}$ and $p_{n,1} = \{(a_n, d), (\overline{a_n}, \overline{d})\}$ do not
13. satisfy any of the Properties I, II, and III, **Then**
14. Construct the gray edges of $p_{n-1,1}, p_{n,1}$;
15. **Else**
16. Construct the gray edges of $p_{n-1,2} = \{(\overline{a_{n-1}}, d), (a_{n-1}, \overline{d})\}$ and
17. $p_{n,2} = \{(a_n, \overline{c}), (\overline{a_n}, c)\}$;
18. **End of if**

Subgraph $\mathcal{G}_\alpha$ in $\mathcal{SO}$, $n > 1$

Let $\mathcal{G}_1, \mathcal{G}_2$ be the two natural graphs amalgamated to form $\mathcal{G}_\alpha$, and $n_1 > 1$;

19. **For** $i = 1$ to $n_1 - 2$ **Do**
20. Construct gray edges as in the previous case;
21. **End of for**
22. **For** $i = n_1 + 1$ to $n - 1$ **Do**
23. Construct gray edges as in the previous case;
24. **End of for**
25. Set $c = a_{n_1-1}^c, d = \overline{a_{n_1-1}}^c$ (cf. Figure 7.4.(d));
26. Let $e, \overline{e}$ be the only unlinked vertices in $\mathcal{G}_2$;
27. **If** $p_{n-1,1} = \{(a_{n_1-1}, c), (\overline{a_{n-1}}, \overline{c})\}$ and $p_{n,1} = \{(e, d), (\overline{e}, \overline{d})\}$ do not
28. satisfy any of the Properties I, II, and III, **Then**
29. Construct the gray edges of $p_{n-1,1}, p_{n,1}$;
30. **Else**
31. Construct the gray edges of $p_{n-1,2} = \{(\overline{a_{n_1-1}}, d), (a_{n_1-1}, \overline{d})\}$ and
32. $p_{n,2} = \{(c, e), (\overline{c}, \overline{e})\}$;
33. **End of if**

FIG. 7.3. *Algorithm for constructing a maximal completed graph.*

Suppose now that $p_{i,1}$ is impossible. We want to prove that $p_{i,2}$ is possible. Suppose $p_{i,1}$ satisfies Property I. That means that a_i and c are the endpoints of the same fragment F. Therefore, a_i and $\overline{d}$ cannot be the endpoints of the same fragment, which means that $p_{i,1}$ does not satisfy Property I. The vertices a_i and d are not the endpoints of the same fragment either, which means that $p_{i,2}$ does not satisfy

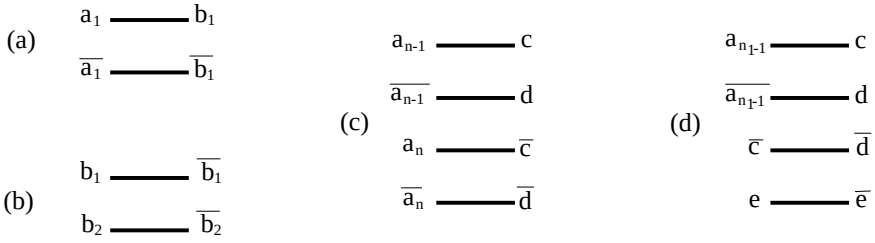

FIG. 7.4. *Different situations considered by* dedouble. (a) *A supernatural graph of* $\mathcal{SE}$*, with* $n = 1$. (b) *A supernatural graph of* $\mathcal{SO}$*, with* $n = 1$. (c) *The last step for a supernatural graph of* $\mathcal{SE}$*; corresponds to lines* 10 *to* 15 *of the algorithm.* (d) *The last step for a supernatural graph of* $\mathcal{SO}$*; corresponds to lines* 23 *to* 29 *of the algorithm. In* (c) *and* (d)*, edges represent paths that can contain more than one edge.*

Property II. Now, since a_i and $\overline{d}$ are two endpoints of two fragments, one of them, which is F having both endpoints in $\mathcal{G}_\alpha$, $p_{i,2}$, does not satisfy Property III either.

We prove similarly that, if $p_{i,1}$ satisfies Property II, then $p_{i,1}$ cannot satisfy any of the three properties.

Suppose now that $p_{i,1}$ creates a bad graph. That means that there exists a subset U of $\mathcal{E}$ such that the border of $V_{U,s}$ is $B(U,s) = \{a_i, \overline{a_i}, c, \overline{c}\}$; then a_i and c should belong to two different fragments with the two other endpoints not in $\mathcal{G}_\alpha$. Then clearly $p_{i,2}$ cannot satisfy Property I or Property II. Suppose that it satisfies Property III. That means that there exists a subset U' of $\mathcal{E}$ such that the border of $V_{U',s}$ is $B(U',s) = \{a_i, \overline{a_i}, d, \overline{d}\}$. Therefore, the border of $U \cup U'$ is restricted to $\{a_i, \overline{a_i}\}$ and is of size 2. The other vertices of $U \cup U'$ cannot be in O (as, otherwise, these vertices would have been part of the border), and if u is in $U \cup U'$, then $\overline{u}, u^s, \overline{u}^s$ are also in $U \cup U'$. Therefore, the number of vertices of $U \cup U'$ is $4m + 2$ for some m. However, this is impossible as the number of vertices of $U \cup U'$ remaining unlinked should be divisible by 4.

To finish the proof, we have to show that, if $p_{n-1,1}$ and $p_{n,1}$ are impossible, then $p_{n-1,2}$ and $p_{n,2}$ are possible (Figure 7.4(c)).

Suppose (a_{n-1}, c) (and $(\overline{a_{n-1}}, \overline{c})$) satisfies Property I, that is, a_{n-1} and c are the endpoints of a fragment F. Then clearly neither $(\overline{a_{n-1}}, d)$ nor $(\overline{a_n}, c)$ satisfies Property I or Property II. Suppose $(\overline{a_{n-1}}, d), (\overline{a_n}, c)$ give rise to one circular fragment. This is possible if a_{n-1}, c and $\overline{a_n}, d$ are the endpoints of two fragments. However, in that case, the supernatural graph $\mathcal{G}_\alpha$ would have had an empty border just before the current step, and the graph would have been a bad graph. However, this contradicts the recurrence hypothesis. Suppose finally that $p_{n-1,2}$ and $p_{n,2}$ create a bad graph. Then there exists a subset U of $\mathcal{SN}$ such that the border of U is in $\{a_{n-1}, \overline{a_{n-1}}, a_n, \overline{a_n}, c, \overline{c}, d, \overline{d}\}$. However, just before this step, $U \cup \{\mathcal{G}_\alpha\}$ would have been a bad graph, which contradicts the recurrence hypothesis.

The remaining cases are treated in a similar way, and we prove with similar arguments that, in any of these cases, $p_{n-1,2}, p_{n,2}$ are possible.

Supernatural graphs of $\mathcal{SO}$ *with* $n > 1$. The construction method for $1 \leq i \leq n_1 - 2$ and $n_1 + 1 \leq i \leq n - 1$ is identical to that in a supernatural subgraph of $\mathcal{SE}$ for $1 \leq i \leq n - 2$. Therefore, the same proof as before holds in that case. Finally, we should prove that, if $p_{n-1,1}$ and $p_{n,1}$ are impossible, then $p_{n-1,2}$ and $p_{n,2}$ are possible. To do so, arguments similar to those for a supernatural subgraph of $\mathcal{SE}$ are used to treat each case. □

Example 3. Consider the genome G of Example 1 and the decomposition of its

partial graph into the supernatural graphs $\{\mathcal{S}_1, \mathcal{S}_{25}, \mathcal{S}_3, \mathcal{S}_4\}$. Figure 7.5 depicts the completed graph produced by *dedouble*.

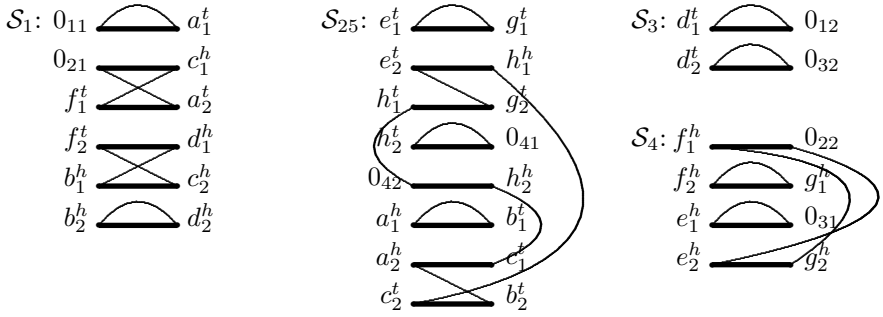

FIG. 7.5. *The completed graph* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *constructed by* dedouble.

The number of cycles in the completed graph is $c(\mathcal{G}) = 13$. As $\gamma(G) = 3$ and $|A| = 20$, according to Theorem 6.6, it is a maximal completed graph.

The corresponding duplicated genome H is made up of the four chromosomes

1. $O_{11} + a_1 + b_1 - d_1\ O_{12}$;
2. $O_{21} + a_2 + b_2 - d_2\ O_{32}$;
3. $O_{42} + h_1 + c_2 + f_2 - g_1 + e_1\ O_{31}$;
4. $O_{41} + h_2 + c_1 + f_1 - g_2 + e_2\ O_{22}$.

THEOREM 7.6. *Algorithm* dedouble *constructs a maximal completed graph* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$*, containing* $c(G) = \frac{|A|}{2} + \gamma(G)$ *cycles.*

Proof. To prove this result, it is sufficient to prove that, for every supernatural graph $\mathcal{G}_\alpha$ with $2n$ black edges, if $\mathcal{G}_\alpha \in \mathcal{SE}$, then the number of cycles in the completed graph obtained by *dedouble* is $c(\mathcal{G}_\alpha) = n+1$, and if $\mathcal{G}_\alpha \in \mathcal{SO}$, this number is $c(\mathcal{G}_\alpha) = n$.

Let $\mathcal{G}_\alpha$ be a supernatural graph of $\mathcal{SE}$. For each i, $1 \leq i \leq n-2$, the algorithm constructs either (a_i, a_i^c) or $(\overline{a_i}, \overline{a_i}^c)$. Thus, at each step of the construction, at least one path is closed to form a cycle. Finally, it is easy to see, from Figure 7.4(c), that instructions 11–16 close three more cycles. Therefore, in total, at least $n+1$ cycles are formed in $\mathcal{G}_\alpha$. According to Lemma 6.3, the maximal number of cycles of a completed graph of $\mathcal{SE}$ is $n+1$. Therefore, $c(\mathcal{G}_\alpha) = n+1$.

Similarly, for a supernatural graph $\mathcal{G}_\alpha$ of $\mathcal{SO}$ with $2n$ black edges, steps 17–22 of the algorithm close at least $n-2$ cycles. Then it is easy to see, from Figure 7.4(d), that instructions 24–29 close two more cycles. Therefore, as n is the maximal number of cycles of a completed graph of $\mathcal{SO}$ (Lemma 6.3), $c(\mathcal{G}_\alpha) = n$. ∎

The following theorem is a direct consequence of Theorems 6.6 and 7.6.

THEOREM 7.7. *The number of cycles of a maximal completed graph of* $\mathcal{G}(\mathbf{V}, A)$ *is*

$$c(G) = \frac{|A|}{2} + \gamma(G).$$

Complexity. At each step, algorithm *dedouble* considers at most four black edges of the graph and constructs two gray edges with four vertices of the considered black edges. Choosing the right vertices to connect requires checking Properties I, II, and III for at most two pairs of gray edges. This is clearly done in constant time. Thus each step of the algorithm takes constant time. As each step constructs two gray edges, the graph is completed in $\frac{|A|}{2}$ steps. Therefore, the time complexity of algorithm *dedouble* is $O(|A|)$.

8. Bad components. We turn now our attention to minimizing the number of bad components of a completed graph. Even if the concept of bad components is different for each of the three models considered in this paper (translocations-only, reversals-only, or both reversals and translocations), it is always related to the notion of "subpermutation" introduced by Hannenhalli [16] and summarized below.

Given two genomes H_1 and H_2 containing the same gene set, where each gene appears exactly once in each genome, a subpermutation of H_1 (or, similarly, of the breakpoint graph $\mathcal{G}_{12}$ associated with H_1 and H_2) is a subsequence $S = u_1u_2, \cdots u_{p-1}u_p$ of a chromosome X of H_1 such that there is a permutation P and a subsequence $T = P(S) = u_1v_2 \cdots v_{p-1}u_p$ of a chromosome Y of H_2, with $v_2 \neq u_2$ and $v_{p-1} \neq u_{p-1}$. A *minimal SP* (minSP) is an SP not containing any other SP, and a *maximal SP* (maxSP) is an SP not included in any other SP.

We call *the interval of a component* C the interval $I = [u_l, u_r]$, where u_l and u_r are the endpoints of C. The interval I is such that no gray edge links a vertex of I to a vertex outside of I, and at least one cycle of I is of size greater than 1. A *minimal component* is a component whose interval contains no other component. There is a bijection between the SPs of $\mathcal{G}_{12}$ and the components of $\mathcal{G}_{12}$. More precisely, let S be an SP, let $\Pi = \{\pi_1, \ldots, \pi_p\}$ be the set of components containing the vertices of S, and for any i, let $\mathbf{V_i}$ be the set of vertices of π_i. Then the following hold:

- S_i is an SP contained in S (inner SP of S, possibly S itself) if and only if S_i corresponds to an interval of a component π_i of Π. We call this component the *component of the SP* S_i.
- S_i is a minimal inner SP of S if and only if S_i corresponds to an interval of a minimal component of Π.

Example 4. Consider the following two circular genomes and the corresponding breakpoint graph (Figure 8.1):

$$G = +a_1\ +b_1\ +c_1\ +d_1\ +e_1\ +d_2\ -f_1\ -e_2\ -f_2\ +a_2\ -b_2\ +c_2,$$
$$H = +a_1\ +b_1\ +c_1\ +d_1\ +e_1\ +f_2\ -f_1\ -e_2\ -d_2\ -c_2\ -b_2\ -a_2.$$

Each of the three components of this graph is made up of a single cycle.

$\mathcal{C}_1$ is the component of the SP $S_1 = +e_1\ +d_2\ -f_1\ -e_2\ -f_2\ +a_2\ -b_2\ +c_2\ +a_1$.

$\mathcal{C}_2$ is the component of the SP $S_2 = +d_2\ -f_1\ -e_2\ -f_2$.

$\mathcal{C}_3$ is the component of the SP $S_3 = +a_2\ -b_2\ +c_2$.

The only two minSPs are S_2 and S_3.

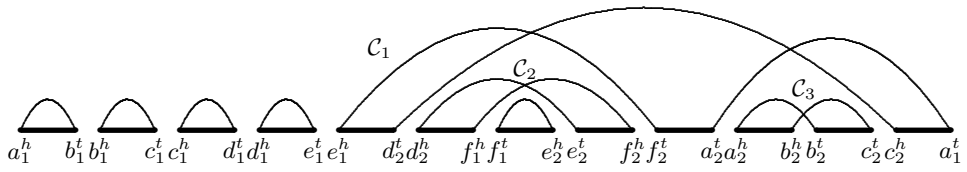

FIG. 8.1. *Breakpoint graph corresponding to genomes G and H.*

For the problem of rearrangement by translocations [16], all minSPs are bad components of an HP graph. More precisely, if $s(\mathcal{G}_{12})$ is the number of minSPs of $\mathcal{G}_{12}$, then, in formulae **HP1** (section 3), $m(\mathcal{G}_{12}) = s(\mathcal{G}_{12})$. For the problem of rearrangement by reversals, or by reversals and translocations, certain SPs can still be solved by proper operations, while others, the "bad components," require bad operations to be solved. The *hurdles* in the case of reversals [17] and the *knots* in the

case of reversals and translocations [18] are the bad (intrachromosomal) minSPs and maxSPs.

Returning to our genome halving problem, we want to determine the minimal number of such (bad) SPs in a completed graph of $\mathcal{G}(\mathbf{V}, A)$. In the case of circular genomes, we need to distinguish between SPs that do not contain both x and $\overline{x}$ for the same vertex x, which we call *normal*, and those that do, the *special* ones. As duplicated multichromosomal genomes cannot have both x and $\overline{x}$ on one chromosome, all SPs are normal for multichromosomal genomes. In the rest of the paper, if not specified, an SP will designate a normal one.

DEFINITION 8.1. *Let $S = x_1 x_2 \cdots x_{n-1} x_n$ be a subsequence of a chromosome of G. S is a* local SP *of G if S is a* real local SP *or a* potential local SP*, namely:*

- *S is a real local SP of G if $\{x_1, \ldots, x_n\} \cap O = \emptyset$ and there exists another subsequence of a chromosome of G of form $\overline{S} = \overline{x_1} P(\overline{x_2}, \ldots, \overline{x_{n-1}})\overline{x_n}$, where P is a permutation other than the identity.*
- *S is a potential local SP if either* i. *$\{x_1, x_n\} \subset O$, and there exists a chromosome of G containing a subsequence $\overline{S} = O_1 P(\overline{x_2}, \ldots, \overline{x_{n-1}})O_2$, where P is a permutation other than the identity and $\{O_1, O_2\} \in O$, or* ii. *$x_1 \in O$, and there exists a chromosome containing a subsequence $\overline{S} = O_1 P(\overline{x_2}, \ldots, \overline{x_{n-1}})x_n$, where P is a permutation other than the identity and $O_1 \in O$. An analogous condition holds for x_n.*

We call $\overline{S}$ the complementary sequence *of S. We say that a local SP (real or potential) S is* minimal *if it does not contain any subsequence corresponding to another local SP.*

For circular genomes, as the notion of endpoints is irrelevant, potential SPs do not exist and all local SPs are real ones.

Example 5. Let $G = +a_1\ +b_1\ +c_1\ +d_1\ +e_1\ -d_2\ +b_1\ +c_1\ -a_2\ +e_2$. The subsequence $S = +a_1 +b_1 +c_1 +d_1$ is a local SP of G. In the genome G of Example 4, the subsequence $+a_1 +b_1 +c_1$ is a local SP of G.

8.1. Correcting the completed graph obtained by algorithm *dedouble*. In this section, we describe a modification of algorithm *dedouble* that will be used to produce an optimal completed graph (i.e., a completed graph giving rise to a duplicated genome minimizing the rearrangement distance to G).

Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be a maximal completed graph produced by *dedouble*, and let $S = x_1 \cdots x_n$ be an SP of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. The following procedure applies to the SP S.

Procedure spoil-SP(S):

Remove all the edges of Γ adjacent to the vertices of $\{x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}\}$;
Construct the edges (x_k, x_{k+1}) and $(\overline{x_k}, \overline{x_{k+1}})$ for all k, $1 \leq k < n$.

Consider the maximal completed graph $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ produced by *dedouble*. Let $\mathcal{S}$ be the set of SPs in $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ that do not correspond to local SPs of G. Correcting $\mathcal{G}_\Gamma$ consists in applying *spoil-SP* to each $S \in \mathcal{S}$.

Complexity. To correct the completed graph $\mathcal{G}$ produced by *dedouble*, we have to consider all the SPs of $\mathcal{G}$. This problem is equivalent to that of decomposing a breakpoint graph into its components. As shown in [22], this can be done in time $O(|A|)$. Then, verifying if an SP is a local SP of G and applying procedure *spoil-SP* takes time linear in the number of edges of the considered SP. Therefore, the total time needed to correct the graph is linear in the number of black edges $|A|$ of the graph. As algorithm *dedouble* has also been shown to be linear in $|A|$, the complexity of the whole algorithm (*dedouble* and graph correction) is $O(|A|)$.

8.2. Genome with no local SP. In this section, we show that for a genome with no local SP, the corrected graph is optimal.

LEMMA 8.2. *Suppose that the completed graph* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *produced by* dedouble *contains an SP* S*. If* S *is not a local SP of* G*, then* spoil-SP*(*S*)* *gives rise to a completed graph* $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ *containing at least the same number of cycles as* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *and one less SP.*

Proof. Let $\mathcal{C}$ be the set of cycles of $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ containing at least one vertex in $V(x, \overline{x}) = \{x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}\}$, $\mathcal{C}(x)$ the subset of $\mathcal{C}$ containing cycles with at least one vertex in $V(x) = \{x_1, \ldots, x_n\}$, and $\mathcal{C}(\overline{x})$ the subset of $\mathcal{C}$ containing cycles with at least one vertex in $V(\overline{x}) = \{\overline{x_1}, \ldots, \overline{x_n}\}$. Let $c = |\mathcal{C}|$, $c(x) = |\mathcal{C}(x)|$, and $c(\overline{x}) = |\mathcal{C}(\overline{x})|$. As S is an SP, $\mathcal{C}(x) \cap \mathcal{C}(\overline{x}) = \emptyset$.

Let $\mathcal{CP}$ be the set of cycles pairs (C_k, C_l) of $\mathcal{C}(x)$ such that $C_k \neq C_l$, and there is a vertex x_k in C_k and a vertex x_l in C_l such that $\overline{x_k}$ and $\overline{x_l}$ belong to the same cycle in $\mathcal{C}(\overline{x})$. Let $\pi = |\mathcal{CP}|$.

There are at most $\frac{n}{2} - \pi$ cycles in $\mathcal{C}(\overline{x})$, so $c \leq c(x) + \frac{n}{2} - \pi$.

Let $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ be the graph obtained after applying procedure *spoil-SP*$(x_1, \ldots, x_n)$, and let $\mathcal{C}'$, $\mathcal{C}'(x)$ and $\mathcal{C}'(\overline{x})$ be the sets defined respectively as $\mathcal{C}$, $\mathcal{C}(x)$ and $\mathcal{C}(\overline{x})$ but for $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma')$. Let $c' = |\mathcal{C}'|$, $c'(x) = |\mathcal{C}'(x)|$, and $c'(\overline{x}) = |\mathcal{C}'(\overline{x})|$. As only size 1 cycles are formed with $V(x)$ vertices, $c'(x) = \frac{n}{2}$.

Let $C_1, \ldots, C_m$ be the cycles of size > 1 of $\mathcal{C}(x)$ for all r, $1 \leq r \leq m$, $|C_r| = p_r$, and let $\{x_{r_1}, \ldots, x_{r_{q_r}}\}$ be the vertices of $V(x)$ contained in C_r. Suppose we transform C_1 into $\frac{p_1}{2}$ size 1 cycles. The vertices $\{\overline{x_{1_1}}, \ldots, \overline{x_{1_{q_1}}}\}$ belong to at least one cycle. Then transform C_2 into $\frac{n}{2}$ size 1 cycles. If $(C_1, C_2) \in \mathcal{CP}$, then the vertices $\{\overline{x_{1_1}}, \ldots, \overline{x_{1_{q_1}}}, \overline{x_{2_1}}, \ldots, \overline{x_{2_{q_2}}}\}$ belong to at least 2 cycles; otherwise, they belong to at least 1 cycle.

By continuing this reasoning until C_m, we show that $c'(\overline{x}) \geq c(x) - \pi$. Thus $c' \geq \frac{n}{2} + c(x) - \pi$, and so $c \leq c'$. The completed graph $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ is then also maximal but no longer contains the SP $x_1 \cdots x_n$.

Suppose that the procedure *spoil-SP*$(x_1 \cdots x_n)$ creates an SP that was not in $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. Since the only modified edges are those linking vertices of $V(x, \overline{x})$, this new SP has to be formed by vertices in $V(\overline{x})$. Thus $x_1 \cdots x_n$ is necessarily a local SP of G. □

As a corollary to Lemma 8.2 we have the following.

COROLLARY 8.3. *For a genome* G *with no local SP, the corrected graph produced by* dedouble *is maximal and contains no SP.*

Then, from the formula **HP1** (section 3) and from the fact that, for all three rearrangement models considered, a bad component is attached to an SP of the graph (section 8), if G is a genome with no local SP, then the corrected graph produced by *dedouble* is optimal (i.e., gives rise to a duplicated genome minimizing the rearrangement distance to G).

In the remainder of this paper, it will be implicit that the correction of the graph, as described in the previous section, is incorporated at the end of algorithm *dedouble*. We turn next to the case in which G contains local SPs.

8.3. General formula for the rearrangement distance. The next lemma shows that any maximal completed graph should contain at least as many SPs as the number of real local SPs of G.

LEMMA 8.4. *Suppose that* G *contains a real local SP* $S = x_1 \cdots x_n$*. Suppose that the completed graph* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *contains no SP made up of the vertices* $\{x_1, \ldots, x_n\}$.

If c_{max} is the maximal number of cycles of a completed graph of $\mathcal{G}(\mathbf{V}, A)$ and $c(\mathcal{G}_\Gamma)$ is the number of cycles of $\mathcal{G}_\Gamma$, then $c(\mathcal{G}_\Gamma) \leq c_{max} - 2$.

Proof. Let $X_S = \{x_1, \ldots, x_n\}$ be the vertices of a subsequence $S = x_1 \cdots x_n$ of a certain chromosome of G, and let $\overline{X_S} = \{\overline{x_1}, \ldots, \overline{x_n}\}$ be the vertices of the complementary sequence $\overline{S}$ contained in a chromosome of G (another one or the same).

Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be a maximal completed graph. Suppose that some vertices in X_S are linked by gray edges to vertices outside X_S. Let X be this set of vertices. Vertices in X are of two types: those linked to vertices in $\overline{X}$ and those linked to vertices outside $X \cup \overline{X}$. Denote $X_1 = \{x_{k_1}, \ldots, x_{k_l}\}$ as the set of l vertices of the first type, $X_2 = \{x_{p_1}, \ldots, x_{p_m}\}$ as the set of m vertices of the second type, and $Y = \{y_1, \ldots, y_m\} \subset \mathbf{V} \setminus X \cup \overline{X}$ as the vertices adjacent to them.

As all X vertices are adjacent to each other by black edges, a cycle containing a vertex in $X \cup Y$ contains at least two vertices of this set. Thus at most $\frac{l+m}{2}$ cycles contain a vertex in $X \cup Y$. Similarly, at most $\frac{m}{2}$ cycles contain a vertex in $\overline{X_2} \cup \overline{Y}$. Moreover, a cycle containing a vertex in $\overline{X_1}$ should contain a vertex in X_1. Therefore, the number of cycles containing a vertex in $X \cup Y \cup \overline{XY}$ is at most $\frac{l+m}{2} + \frac{m}{2} = m + \frac{l}{2}$.

Now, let $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ be the completed graph obtained from $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ by the following procedure:

For all $x \in X$ do
- Remove gray edges adjacent to x and $\overline{x}$;
- Construct the gray edge (x, x'), where x' is the vertex in X linked to x by a black edge;
- Construct the gray edge $(\overline{x}, \overline{x'})$;

For all $y \in Y$ do
- Construct the gray edge (y, y'), where y' is the vertex in $\mathbf{V} \setminus X$ linked to y by a black edge;
- Construct the gray edge $(\overline{y}, \overline{y'})$.

Then exactly $\frac{l+m}{2}$ cycles have vertices in X and they are all of size 1, and exactly $\frac{m}{2}$ cycles have vertices in Y and they are also of size 1. Moreover, there is no cycle containing at the same time a vertex in $\overline{X}$ and another one in $\overline{Y}$, and there are at least two cycles with a vertex in $\overline{X}$ or a vertex in $\overline{Y}$. Therefore, the number of cycles containing vertices in $X \cup Y \cup \overline{XY}$ is at least $\frac{l+m}{2} + \frac{m}{2} + 2 = m + \frac{l}{2} + 2$. As the above procedure does not modify the other cycles, $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ has at least two more cycles than $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$, which is a contradiction with the fact that $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ is a maximal completed graph. □

Remark 1. Let S be a local SP of G and $\overline{S}$ the complementary sequence of S. We can suppose, without loss of generality, that *dedouble* constructs only cycles of size 1 with vertices of $\overline{S}$ and that the SPs of the final completed graph are formed by the vertices of S. (We can always modify the resulting completed graph so that it satisfies these properties.)

For multichromosomal genomes, potential SPs give rise to additional problems. The goal is to minimize the number of such potential SPs that become SPs of the final completed graph. For circular genomes, all local SPs are real ones. However, in that case, one additional problem is due to special SPs.

Let $RO(G)$ be the minimal number of rearrangement operations required to transform G into a duplicated genome. Though $RO(G)$ is different depending on the model

considered (reversals, translocations, reversals and translocations), we will prove in the coming sections that all results can be summarized by the following formula:

$$RO(G) = \frac{|A|}{2} - \gamma(G) + m(G) + \phi(G),$$

where $m(G)$ is the number of bad real local SPs of G and $\phi(G)$ is a correction depending on bad potential local SPs (for multichromosomal genomes) and special SPs (for circular genomes).

Moreover, we will show that, with an appropriate construction of natural graphs, and with other minor corrections in the case of sorting by translocations and reversals, the completed graph produced by algorithm *dedouble* gives rise to the rearrangement distance.

9. Genome halving with translocations only. For two multichromosomal genomes H_1 and H_2, if $\mathcal{G}_{12}$ is the breakpoint graph associated to H_1 and H_2, the minimal number $T(H_1, H_2)$ of translocations required to transform H_1 to H_2 is given by the formulae proved in [16]:

$$\textbf{HP2}: \quad T(H_1, H_2) = b(\mathcal{G}_{12}) - c(\mathcal{G}_{12}) + s(\mathcal{G}_{12}) + f(\mathcal{G}_{12}),$$

where $s(\mathcal{G}_{12})$ is the number of minSPs of H_1. In other words, in the formula **HP1**, we have $m(\mathcal{G}_{12}) = s(\mathcal{G}_{12})$.

The value of the parameter $f(\mathcal{G}_{12})$ depends on a characteristic of the breakpoint graph, defined in [16]. The graph $\mathcal{G}_{12}$ has an *even-isolation* if the next three conditions are satisfied:

1. All minSPs of $\mathcal{G}_{12}$ are on a single chromosome of H_1.
2. $s(\mathcal{G}_{12})$ is even.
3. All minSPs are contained within a single SP.

If $\mathcal{G}_{12}$ has an even-isolation, then $f(\mathcal{G}_{12}) = 2$; if $\mathcal{G}_{12}$ has an odd number of minSPs, then $f(\mathcal{G}_{12}) = 1$; otherwise, $f(\mathcal{G}_{12}) = 0$ [16].

Returning to our problem of genome halving, denote by $\mathbf{T}(\mathbf{G})$ the minimal number of translocations required to transform G into a perfectly duplicated genome. In section 7, we described an algorithm for constructing a maximal completed graph in the case of multichromosomal genomes. We also proved, in section 8, that the minimal number of SPs of a completed graph can be deduced from the local (real or potential) SPs of G. The following corollary is a direct consequence of these results (Theorem 7.7, Corollary 8.3, and formula **HP2**).

COROLLARY 9.1. *If G does not contain any local SP, then* $T(G) = |A| - c(G) = \frac{|A|}{2} - \gamma(G)$.

Moreover, in section 8, we treated the case of real SPs. It remains now to consider potential local SPs.

Let S be a potential SP with two ends O_1, O_1' in O, and let O_2, O_2' be the two ends of $\overline{S}$. S becomes a real SP if and only if $\overline{O_2} = O_1$ and $\overline{O_2'} = O_1'$. Similarly, let S be a potential SP with only one end O_1 in O, and let O_2 be the vertex of $\overline{S}$ in O. S becomes a real SP if and only if $\overline{O_2} = O_1$. The problem is to avoid such situations.

According to formula **HP2**, we need only to minimize the number of minSPs of a completed graph (instead of SPs). Therefore, we consider only potential local minSPs. In the ensuing discussion, we just call them potential SPs.

Remark 2. Let S be a potential SP and $V(S, \overline{S})$ the set of vertices of S and $\overline{S}$ excluding those in O. The number of natural graphs containing vertices both in

$V(S, \overline{S})$ and O is exactly two if S has both its ends in O, and one if S has only one end in O. We call these graphs the *graphs associated to* S.

We distinguish between two kinds of potential SPs.

DEFINITION 9.2. *A potential SP is* even *(PES) if its associated graphs (one or two) are in* $\mathcal{NE}$*, i.e., are of even size. Otherwise, the potential SP is* odd *(POS). A POS necessarily has both its ends in* O *and thus two associated graphs in* $\mathcal{NO}_+$.

Notation 3. We denote $\mathcal{PES}$ the set of all PES, and $e = |\mathcal{PES}|$. For i, $1 \leq i \leq e$, P_i is the set of (one or two) graphs associated to the ith PES for an arbitrary ordering of the PESs.

We denote $\mathcal{POS}$ the set of all POS, and $o = |\mathcal{POS}|$. For every i, $1 \leq i \leq o$, denote by $Q_i = (A_i, A'_i)$ the pair of graphs associated to the ith POS for an arbitrary ordering of the POSs.

In section 5, we arbitrarily amalgamated pairs of natural graphs of odd size to form supernatural graphs. To avoid transforming a POS into an SP, we introduce a more deterministic way to amalgamate graphs of $\mathcal{POS}$. If $|\mathcal{POS}| > 1$, we proceed as follows:

Procedure amalgamating POS. For every i, $1 \leq i \leq o$, amalgamate each graph of the pair Q_i with a graph of a pair Q_j, where $j \neq i$.

Similar constraints are required in amalgamating PESs to avoid transforming them into SPs. If $|\mathcal{PES}| > 1$, we proceed as follows:

Procedure amalgamating PES. For every i, $1 \leq i \leq e$, amalgamate each graph of P_i with a graph in P_j, where $j \neq i$. Moreover, if $\mathcal{PES}$ has at least one P_i with two graphs and if a last nonamalgamated graph G_P remains, then G_P should belong to a P_i of size 2. Suppose G_1 and G_2 are amalgamated, O_1 and O'_1 are the two vertices of $G_1 \cap O$, and O_2 and O'_2 are the two vertices of $G_2 \cap O$. Then set $\overline{O_1} = O_2$ and $\overline{O'_1} = O'_2$.

Note that, in the case of the PESs, we amalgamate even size (completable) natural graphs. The consequence is that *dedouble*, applied to such supernatural graphs, generates a completed graph that is no longer maximal. This gives rise to additional difficulties.

After amalgamating the graphs of $\mathcal{PES} \cup \mathcal{POS}$ by the procedures described above, there remain some nonamalgamated graphs. This gives rise to eight possible configurations. For some of them, additional graphs are amalgamated.

C1. There remain no nonamalgamated graphs.

C2. There remains one Q_i in $\mathcal{POS}$. This happens when $\mathcal{POS}$ contains a single POS.

C3. There remains one P_i of two graphs in $\mathcal{PES}$. This happens when $\mathcal{PES}$ contains a single PES.

C4. There remains one graph in $\mathcal{PES}$, and it belongs to a P_i of size 2.

C5. There remains one graph in $\mathcal{PES}$, and it belongs to a P_i of size 1. This happens when all P_is are of size 1 and e is even.

C6. There remains one $Q_i = (G_1, G_2)$ in $\mathcal{POS}$ and one G_3 in $\mathcal{PES}$ belonging to a P_i of size 1. Then we amalgamate the three graphs G_1, G_2, and G_3 if that does not create an even-isolation. If O_1 and O'_1 are the vertices of $G_1 \cap O$, O_2 and O'_2 are the vertices of $G_2 \cap O$, and O_3 and O'_3 are the vertices of $G_3 \cap O$, then we set $\overline{O_1} = O_3$, $\overline{O'_1} = O'_2$, and $\overline{O_2} = O'_3$.

C6' will denote the configuration that would give rise to an even-isolation. In this case, the graphs are not amalgamated.

C7. There remains one Q_i in $\mathcal{POS}$ and one graph in $\mathcal{PES}$ belonging to a P_i of size 2.

C8. There remains one $Q_i = (G_1, G_2)$ in $\mathcal{POS}$ and one $P_i = (G_3, G_4)$ in $\mathcal{PES}$. Then we amalgamate G_1 and G_2 and one of the two graphs of P_i if that does not create an even-isolation. Counterpart elements are set similarly to C6. C8' will denote the configuration that would give rise to an even-isolation. In that case, the graphs are not amalgamated.

A local SP that is either real or potential, but not solved by the amalgamating procedure described above, is called a *final SP*.

In the remainder of this section, $\mathcal{SG}$ will designate the set of completable graphs obtained by the procedure described above for the graphs in $\mathcal{POS} \cup \mathcal{PES}$, and by the usual way (section 5) for the other natural graphs.

Notation 4. Consider the following parameters:

- $\mathbf{s}(\mathbf{G})$ is the number of real minSPs of G;
- $\mathbf{sp}(\mathbf{G})$ is the number of graphs obtained by amalgamating $\mathcal{PES}$ graphs;
- $\psi(\mathbf{G}) = 1$ if configuration C6 or C8 is encountered, and $\psi(\mathbf{G}) = 0$ otherwise;
- $\mathbf{sr}(\mathbf{G}) = 0$ if one of the configurations C1, C4, C6, or C8 is encountered; $sr(G) = 1$ for C2, C3, C5, or C7; $sr(G) = 2$ for C6' or C8'. $sr(G)$ is the number of potential SPs that become final SPs.
- $\mathbf{f}(\mathbf{G}) = 2$ if the set of final SPs represents an even-isolation; $f(G) = 1$ if the number of final SPs is odd; $f(G) = 0$ otherwise.

Recall that $c(G)$ is the number of cycles of a maximal completed graph of $\mathcal{G}(\mathbf{V}, A)$ (Theorem 7.6).

THEOREM 9.3. *Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be the completed graph produced by* dedouble. *Let H be the resulting duplicated genome. Then $c(\mathcal{G}_\Gamma) = c(G) - sp(G) - \psi(G)$, $s(\mathcal{G}_\Gamma) = s(G) + sr(G)$, and*

$$T(G, H) = |A| - c(G) + sp(G) + \psi(G) + s(G) + sr(G) + f(G).$$

The minimal number of translocations required to transform G into a duplicated genome is $T(G) = T(G, H)$.

Proof. According to Corollary 8.3 and Lemma 8.4, if G does not contain any PESs, then *dedouble* produces a maximal completed graph $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ with $c(G)$ cycles.

Suppose now that G contains local SPs. Let $\mathcal{G}_3$ be a graph of $\mathcal{SG}$ obtained by amalgamating two natural graphs of $\mathcal{PES}$: $\mathcal{G}_1$ of size n_1 and $\mathcal{G}_2$ of size n_2. Given that this graph has as many left edges as right edges, a proof similar to that of Lemma 6.3 shows that the maximal number of cycles of a completed graph of $\mathcal{G}_3$ is $\frac{n_1+n_2}{2} + 1$, and *dedouble* produces such a maximal completed graph. If we apply *dedouble* to each of the two graphs $\mathcal{G}_1$ and $\mathcal{G}_2$, we obtain two completed graphs with a total of $\frac{n_1}{2} + 1 + \frac{n_2}{2} + 1$ cycles, that is, one more cycle than for $\mathcal{G}_3$. Thus, if we apply *dedouble* to the graphs of $\mathcal{SG}$ obtained by amalgamating graphs in $\mathcal{PES}$, we obtain $sp(G)$ fewer cycles than if we apply the algorithm to each graph of $\mathcal{PES}$. Moreover, one fewer cycle is also obtained by amalgamating one graph pair of $\mathcal{POS}$ and one graph of $\mathcal{PES}$. As these are the only modifications to the original procedure of graph amalgamating that changes the number of cycles, $c(\mathcal{G}_\Gamma) = c(G) - sp(G) - \psi(G)$.

Moreover, also according to Corollary 8.3 and Lemma 8.4, if G does not contain any PESs, then *dedouble* produces a maximal completed graph $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ with $s(\mathcal{G}_\Gamma)$ SPs corresponding to the $s(G)$ local SPs of G and to the only existing POS, if

any. Moreover, the $sr(G)$ potential SPs not amalgamated are the only potential SPs that become real SPs. Therefore, $s(\mathcal{G}) = s(G) - sr(G)$.

We deduce that

$$T(G,H) = |A| - c(\mathcal{G}_\Gamma) + s(\mathcal{G}_\Gamma) + f(\mathcal{G}_\Gamma) = |A| - c(G) + sp(G) + \psi(G) + s(G) + sr(G) + f(G).$$

Suppose $T(G,H) > T(G)$. Then there is a completed graph $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ containing $c(\mathcal{G}_{\Gamma'})$ cycles, $s(\mathcal{G}_{\Gamma'})$ SPs, and a value of $f(\mathcal{G}_{\Gamma'})$ such that (1) $c(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_{\Gamma'}) - f(\mathcal{G}_{\Gamma'}) > c(\mathcal{G}_\Gamma) - s(\mathcal{G}_\Gamma) - f(\mathcal{G}_\Gamma)$, i.e., $c(\mathcal{G}_{\Gamma'}) - c(\mathcal{G}_\Gamma) > (s(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_\Gamma)) + (f(\mathcal{G}_{\Gamma'}) - f(\mathcal{G}_\Gamma))$.

First, suppose that $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ contains p fewer SPs than $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. Suppose first that $p = 1$ and that this SP is a real local SP of G. Then, by Lemma 8.4, $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ is a completed graph that is not maximal and contains at most $c(\mathcal{G}_\Gamma) - 2$ cycles. More generally, a construction that removes p real local SPs of G gives rise to a completed graph with at most $c - 2p$ cycles. Suppose now that $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ has one less SP than $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$, but this SP is not a real local SP of G. That means that it corresponds to a potential SP transformed into a final SP. This occurs in configurations C2, C3, C5, C6', C7, and C8. In all cases, it is easy to show that at least two cycles would necessarily be removed if we remove such an SP. Therefore, (2) $c(\mathcal{G}_{\Gamma'}) \leq c(\mathcal{G}_\Gamma) - 2(s(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_{\Gamma'}))$.

We deduce from (1) and (2) that $s(\mathcal{G}_\Gamma) - s(\mathcal{G}_{\Gamma'}) < f(\mathcal{G}_\Gamma) - f(\mathcal{G}_{\Gamma'})$.

As $s(\mathcal{G}_\Gamma) - s(\mathcal{G}_{\Gamma'}) \geq 0$ and $f(\mathcal{G}_\Gamma) - f(\mathcal{G}_{\Gamma'}) \leq 2$, we should have $s(\mathcal{G}_\Gamma) - s(\mathcal{G}_{\Gamma'}) = 1$ and $f(\mathcal{G}_\Gamma) - f(\mathcal{G}_{\Gamma'}) = 2$. We can see, from the definition of f, that this configuration is impossible.

Suppose now that $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ contains p more SPs than $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. If these SPs that are in $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ but not in $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ do not correspond to potential local SPs of G, then, from Lemma 8.2 and the fact that $f(\mathcal{G}_\Gamma) \leq 2$, the value of $-c(\mathcal{G}_\Gamma) + s(\mathcal{G}_\Gamma + f(\mathcal{G}_\Gamma)$ is not changed if we remove these SPs. Thus these SPs correspond necessarily to potential local SPs that are transformed into final SPs in $\mathcal{G}_{\Gamma'}(\mathbf{V}, A, \Gamma')$ but not in $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$. Necessarily, $p \geq 2$.

Suppose first $p = 2$. If these two SPs correspond to

- two POS, then amalgamating these two SPs gives rise to two fewer SPs and to the same number of cycles,
- two PES, then amalgamating these two SPs gives rise to two fewer SPs and one less cycle,
- one POS and one PES, then amalgamating these SPs gives rise to two fewer SPs and one less cycle.

More generally, a graph containing $2p$ more SPs contains at most p more cycles than $\mathcal{G}(\mathbf{V}, A, \Gamma)$. Therefore, (3) $c(\mathcal{G}_{\Gamma'}) - c(\mathcal{G}_\Gamma) \leq \frac{s(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_\Gamma)}{2}$.

We deduce from (1) and (3) that $s(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_\Gamma) < 2(f(\mathcal{G}_\Gamma) - f(\mathcal{G}_{\Gamma'}))$.

As $s(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_\Gamma) \geq 2$ and $f(\mathcal{G}_\Gamma) - f(\mathcal{G}_{\Gamma'}) \leq 2$, $s(\mathcal{G}_{\Gamma'}) - s(\mathcal{G}_\Gamma) = 2$ and $f(\mathcal{G}_\Gamma) - f(\mathcal{G}_{\Gamma'}) = 2$. That means that amalgamating the two potential SPs gives rise to an even-isolation, which is in contradiction with the properties of the amalgamating procedure. □

10. Genome halving with translocations and reversals.

10.1. The HP method. Given two genomes H_1 and H_2 with the same number of chromosomes, HP [18] determined the minimal number of reversals and translocations $RT(H_1, H_2)$ required to transform H_1 into H_2. Formula **HP1** (section 3) is a general description of the result. A more precise description requires a deeper consideration of the problem.

We will only sketch the HP procedure, which is rather complex. The first step in the comparison of two multichromosomal genomes through translocations and reversals is to reduce it to a problem of comparing two single chromosome genomes through reversals only. These latter genomes are constructed essentially by concatenating the individual chromosomes in the original genomes end-to-end in an arbitrary order. Additional dummy genes, called *caps*, must be appropriately inserted at the ends of the original chromosomes of both genomes. A translocation in an original genome becomes a reversal in the new one.

More precisely, let $H = C_1, \ldots, C_N$ be a genome of N chromosomes written in a particular order. An H *concatenate* is a genome $\tilde{H}$ with a single chromosome: $\tilde{H} = (s_1 C_1) \cdots (s_N C_N)$, where each s_i, $1 \leq i \leq N$, is in $\{-1, 1\}$. The *identity concatenate* of H is the H concatenate satisfying $s = (s_1, \ldots, s_N) = (1, \ldots, 1)$.

Let $O = \{O_0, \ldots, O_{2N-1}\}$ be a set of caps and $\hat{H}_1$ the genome obtained by adding one cap at each end of each chromosome of H_1. Any sequence of reversals/translocations transforming H_1 into H_2 induces a sequence of reversals transforming $\hat{H}_1$ into a genome $\hat{H}_2$, where $\hat{H}_2$ is a particular capping of H_2. We can prove that $RT(H_1, H_2) = \min_{\hat{H}_2 \in \hat{\mathcal{H}}} RT(\hat{H}_1, \hat{H}_2)$, where $\hat{\mathcal{H}}$ is the set of all possible cappings of H_2.

Let $\tilde{H}_1$ be the identity concatenate of $\hat{H}_1$. Let $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ be the graph defined as follows: $V = \{x^{s \in \{t,h\}},\ x \in \mathcal{B}\}$ and $\mathbf{V} = V \cup O$; A is the set of black edges connecting adjacent vertices in H_1 other than (x^t, x^h) for the same x; Γ_s is the set of gray edges connecting adjacent vertices in H_2. Denote by V_e the set of vertices of V located at the ends of H_2 chromosomes. Note that vertices of $V_e \cup O$ are not connected by gray edges in $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$. $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is called the *semicompleted graph* associated to H_1 and H_2. It is a collection of cycles and paths. Paths are of three kinds: those ending with a vertex in O and another in V, called *good paths*, those ending with two vertices in O, called *bad paths*, and those ending with two vertices in V. Denote, respectively, $\mathcal{OV}$, $\mathcal{OO}$, and $\mathcal{VV}$ as these three path sets. We have $|\mathcal{OO}| = |\mathcal{VV}|$.

A gray edge in a cycle or a path of size > 1 is *oriented* if it links the vertices at the left ends of two black edges or at the right ends of two black edges, while an *unoriented gray edge* links two different sides of two black edges. A cycle or a path is *good* if it contains at least one oriented gray edge, and *bad* otherwise. A component is *good* if it has at least one good cycle or path and thus at least one oriented gray edge, and *bad* otherwise.

HP showed that a good component can be *solved*, i.e., transformed to a set of cycles (and paths) of size 1, by a series of proper reversals (reversals increasing the number of cycles; see section 3). However, bad components often require bad reversals. The set of bad components is subdivided into subsets, depending on the difficulty of solving them (i.e., transforming them into good components). This subdivision is explained below.

An edge of Γ_s is *intrachromosomal* if it connects two vertices both belonging to the same chromosome of H_1 and *interchromosomal* otherwise. A component of $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is intrachromosomal if it contains only intrachromosomal edges, and interchromosomal otherwise. We say that the component U *separates* two components U' and U'' if any edge we tried to draw from a vertex of U' to one of U'' would cut a gray edge of U. A *knot* is an intrachromosomal bad component which does not separate any pair of bad components. Now, a *real knot* is a knot that contains only cycles (no paths), and a *semiknot* is a knot containing at least one path in $\mathcal{OV}$ and no path in $\mathcal{OO} \cup \mathcal{VV}$.

The underlying idea is that a bad component U that separates two bad components U' and U'' is automatically solved by solving U' and U'' and thus may just as well be considered to be a good one. On the other hand, a real knot requires bad reversals to be solved, while a semiknot can be transformed into a good component if paths are closed appropriately.

HP proved that the problem of sorting by reversals/translocations is reduced to a problem of finding an appropriate capping of H_2, that is, finding appropriate connections between vertices of V_e and vertices of O. Finally, they proved that the minimal number of reversals/translocations required to transform H_1 into H_2 is

$$\textbf{HP3}: \quad RT(H_1,H_2) = b(\mathcal{G}_s) - cp(\mathcal{G}_s) + bp(\mathcal{G}_s) + rr(\mathcal{G}_s) + \left\lceil \frac{s(\mathcal{G}_s) - gr(\mathcal{G}_s) + fr(\mathcal{G}_s)}{2} \right\rceil,$$

where $b(\mathcal{G}_s) = |A|$; $cp(\mathcal{G}_s)$ is the number of cycles and paths of $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$; $bp(\mathcal{G}_s)$ is the number of bad paths; $rr(\mathcal{G}_s)$ is the number of real knots obtained after closing paths of $\mathcal{OV}$ that are not included in semiknots; $s(\mathcal{G}_s)$ is the number of semiknots; and $gr(\mathcal{G}_s)$ and $fr(\mathcal{G}_s)$ take values 0 or 1, depending on the set of real knots and semiknots.

Returning to the problem of genome halving, we represent the genome G as H_1, i.e., by adding caps at the ends of the chromosomes, and by concatenating the resulting chromosomes. The partial graph $\mathcal{G}(\mathbf{V}, A)$ associated to G is thus represented on a single line instead of $2N$ lines. Algorithm *dedouble* can be applied to such a partial graph as well. The goal is to construct a semicompleted graph $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ that minimizes formula **HP3**. We first construct a *maximal semicompleted graph* that maximizes $cp(\mathcal{G}_s) - bp(\mathcal{G}_s)$.

10.2. Constructing a maximal semicompleted graph. Denote by $c(G)$ the number of cycles of a maximal completed graph of $\mathcal{G}(\mathbf{V}, A)$ obtained by *dedouble*. For any semicompleted graph $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$, denote by $c(\mathcal{G}_s)$ its number of cycles and by $p(\mathcal{G}_s)$ its total number of paths. Denote also $cc(\mathcal{G}_s) = cp(\mathcal{G}_s) - bp(\mathcal{G}_s)$.

LEMMA 10.1. *Let $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ be a maximal semicompleted graph of $\mathcal{G}(\mathbf{V}, A)$. Then $cc(\mathcal{G}_s) \leq c(G)$.*

Proof. As mentioned above, we have $|\mathcal{OO}| = |\mathcal{VV}|$. Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be the graph obtained by closing good paths and by constructing cycles with remaining paths, each of these paths obtained by connecting a path of $\mathcal{OO}$ with a path of $\mathcal{VV}$. Such a graph is clearly a completed graph of $\mathcal{G}(\mathbf{V}, A)$ with $c(\mathcal{G}_s) - p(\mathcal{G}_s)$ cycles. As $c(G)$ is the number of cycles of a maximal completed graph, we have $c(\mathcal{G}_s) - p(\mathcal{G}_s) \leq c(G)$. ∎

We now construct a semicompleted graph $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ satisfying $cc(\mathcal{G}_s) = c(G)$. From Lemma 10.1, this graph must be maximal.

THEOREM 10.2. *Let $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ be the maximal completed graph obtained by applying* dedouble *to $\mathcal{G}(\mathbf{V}, A)$. Let Γ_s be the set of gray edges obtained from Γ by removing all edges adjacent to at least one vertex in O, and consider the semicompleted graph $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$. Then $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is a maximal semicompleted graph of $\mathcal{G}(\mathbf{V}, A)$. Moreover, $cp(\Gamma_s) = c(G)$.*

Proof. According to the construction of natural and supernatural graphs, each supernatural graph contains 0, 2, or 4 vertices in O. Moreover, it is easy to see that each cycle of a maximal completed graph contains at most two vertices in O as if this is not satisfied, then the cycle could be subdivided into at least two cycles, and thus the completed graph could not be maximal.

Let $\mathcal{G}'(\mathbf{V}', A')$ be a supernatural graph. Let $\mathcal{G}_{\Gamma'}(\mathbf{V}', A', \Gamma')$ be this supernatural graph completed by *dedouble*, and let $\mathcal{G}'_s(\mathbf{V}', A', \Gamma'_s)$ be the semicompleted supernat-

ural graph obtained by removing from Γ' edges with at least one end in O. Let $c(\Gamma')$ be the number of cycles of $\mathcal{G}_{\Gamma'}(\mathbf{V}', A', \Gamma')$.

- Suppose that $\mathbf{V}'$ does not contain any vertex in O. In this case, no edge is removed from Γ' to form $\mathcal{G}'_s(\mathbf{V}', A', \Gamma'_s)$, and thus $c(\mathcal{G}'_s) - p(\mathcal{G}'_s) = c(\Gamma')$.
- Suppose that $\mathbf{V}'$ contains two vertices in O. Suppose that these two vertices are in two different cycles of $\mathcal{G}_{\Gamma'}(\mathbf{V}', A', \Gamma')$. Then removing the two gray edges connecting these two vertices transforms the two corresponding cycles into two good paths. Thus $c(\mathcal{G}'_s) - p(\mathcal{G}'_s) = c(\Gamma')$.
  Suppose now that both vertices are in the same cycle. Then removing the two gray edges connecting these two vertices transforms the cycle into two paths, and at most one of them is bad. (In this case, the second path is in $\mathcal{VV}$.) Thus $c(\mathcal{G}'_s) - p(\mathcal{G}'_s) \geq (c(\Gamma') - 1) + 2 - 1 = c(\Gamma')$.
- Suppose that $\mathbf{V}'$ contains four vertices in O. If these vertices are in four or three different cycles, then we prove by an argument similar to the previous case that $c(\mathcal{G}'_s) - p(\mathcal{G}'_s) \geq c(\Gamma')$.
  Otherwise, if these vertices are in two cycles, then each of these cycles contains two of the four vertices. In that case, removing the four gray edges adjacent to these four vertices transforms the two cycles into four paths, and at most two of them are bad. Thus $c(\mathcal{G}'_s) - p(\mathcal{G}'_s) \geq (c(\Gamma') - 2) + 4 - 2 = c(\Gamma')$.

In all cases, $c(\mathcal{G}'_s) - p(\mathcal{G}'_s) \geq c(\Gamma')$. We deduce that $c(\mathcal{G}_s) - p(\mathcal{G}_s) \geq c(G)$. As $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ is a maximal completed graph, from Lemma 10.1, $c(\mathcal{G}_s) - p(\mathcal{G}_s) = c(G)$ and $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is a maximal semicompleted graph. □

We call *semidedouble* the algorithm obtained by incorporating, at the end of *dedouble*, the procedure that removes the gray edges adjacent to at least one vertex of O. From Theorem 10.2, *semidedouble* constructs a maximal semicompleted graph.

Remark 3. Let C be a cycle of a completed graph $\mathcal{G}(\mathbf{V}, A, \Gamma)$ containing two vertices O_1 and O_2 in O. Let C_1 and C_2 be the two paths obtained by removing the two gray edges adjacent to O_1 and O_2. Then one of the following situations is satisfied: 1. C_1 and C_2 are two paths in $\mathcal{OV}$; or 2. C_1 is a bad path (in $\mathcal{OO}$) and C_2 is in $\mathcal{VV}$.

The first situation occurs when O_1 and O_2 are separated by an odd number of vertices in C (to the right or to the left), and the second situation occurs when O_1 and O_2 are separated by an even number of vertices.

10.3. Knots. We now turn our attention to minimizing, in formula **HP3**, the expression $rr(\mathcal{G}_s) + \lceil \frac{s(\mathcal{G}_s) - gr(\mathcal{G}_s) + fr(\mathcal{G}_s)}{2} \rceil$. Denote by $RT(G)$ the minimal number of reversals/translocations required to transform G into a duplicated genome. We deduce the following corollary from Theorem 7.7, Corollary 8.3, and formula **HP3**.

COROLLARY 10.3. *If G does not contain any local SP, then $RT(G) = T(G) = |A| - c(G) = \frac{|A|}{2} - \gamma(G)$.*

Suppose now that G contains local SPs. Let S be a local SP, and let $\Pi = \{\pi_1, \ldots, \pi_p\}$ be the set of components of the maximal semicompleted graph obtained by *semidedouble*, containing the vertices of S. In order to consider the components which may form knots, we introduce another definition. Let $\mathcal{U} = \{u_1, \ldots, u_p\}$ be a subset of $\mathcal{B}$, and $\overline{\mathcal{U}} = \{\overline{u_1}, \ldots, \overline{u_p}\}$. We say that $\mathcal{U}$ is *unoriented* if genes u_i and $\overline{u_i}$ have either the same sign in G or opposite signs for all i. Otherwise, $\mathcal{U}$ is *oriented*. Let $\pi_i \in \Pi$, and let $\mathbf{V_i}$ be its vertex set. $\mathbf{V_i}$ is oriented if and only if the set of genes corresponding to the vertices in $\mathbf{V_i}$ is oriented.

LEMMA 10.4. *π_i is a good component if and only if $\mathbf{V_i}$ is oriented.*

Proof. π_i is good if and only if π_i contains at least one cycle with at least one

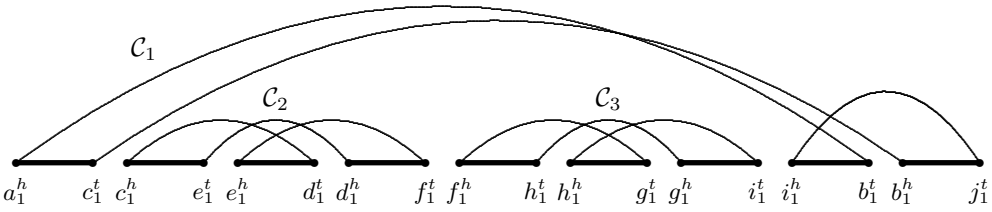

FIG. 10.1. *Inner SPs corresponding to* S_1.

oriented gray edge. Suppose that $\mathbf{V_i}$ is unoriented. We can suppose, without loss of generality, that all corresponding genes are signed +. All $\mathcal{C}$ cycles of π_i are such that left vertices are of form x^h and right edges are of form x^t (Definition 6.1). Moreover, there is no supernatural graph of $\mathcal{SO}$ obtained by amalgamating natural graphs containing vertices in $\mathbf{V_i}$. Therefore, a gray edge necessarily connects a left vertex to a right one in $\mathcal{C}$ cycles, and thus a vertex of form x^h to one of form x^t. From the definition of gray edge orientation, all gray edges of π_i are unoriented, and thus π_i is bad.

Conversely, if $\mathbf{V_i}$ is oriented, then we can assume, without loss of generality, that there exist two genes a and b such that a and b are adjacent and are both signed positively in S, but a and b do not have the same sign in $\overline{S}$. Algorithm *dedouble* constructs the gray edges (a^h, b^t) and $(\overline{a}^h, \overline{b}^t)$. As a and b do not have the same sign in $\overline{S}$, $\overline{a}^h$ and $\overline{b}^t$ are either both left ends or both right ends of black edges. Therefore, the gray edge $(\overline{a}^h, \overline{b}^t)$ is oriented. □

We say that a *real local SP is oriented* if the set of vertices in its component is oriented and is unoriented otherwise. Knots produced by *semidedouble* then correspond to the real minimal unoriented SPs, which we call *real minimal SPs*, and to at most one other SP, the maximal one, defined as follows.

DEFINITION 10.5. *Let* $S = x_1 \cdots x_n$ *be a local SP. The* outer SP *of* S *is the largest SP* S_e *contained in* S *satisfying the following three conditions:*

1. *The component* π_e *of* S_e *is bad;*
2. S_e *is not minimal, and the interval of* S_e *contains all the real minimal SPs of* S*;*
3. S_e *does not separate two real minimal SPs.*

A local SP S *is* maximal *if all the real minimal SPs of* G *are inner SPs of* S *and if there exists an outer SP of* S.

Example 6. Suppose that the genome G contains the local SP $S_1 = a_1\ c_1\ e_1\ d_1\ f_1\ h_1\ g_1\ i_1\ b_1\ j_1$, with complement $\overline{S_1} = a_2\ b_2\ c_2\ d_2\ e_2\ f_2\ g_2\ h_2\ i_2\ j_2$. The components of S_1 and the inner SPs of S_1 are depicted in Figure 10.1. The two components $\mathcal{C}_2$ and $\mathcal{C}_3$ correspond to components of the two minimal SPs of S. $\mathcal{C}_1$ is the component of S_1. It is bad and does not separate two minimal SPs. S_1 is thus an outer SP.

A *bad real SP* is a real SP which is either minimal or maximal. We denote by $\mathbf{brs}(\mathbf{G})$ the number of bad SPs of G.

As for semiknots, they are associated to potential SPs. To minimize them, we must minimize the number of potential SPs that become bad SPs of the final graph.

We already saw in section 9 how to solve POSs, provided that at least two of them exist. We can therefore assume that at most one POS exists. Suppose that one such POS S exists. In that case, we amalgamate the two odd size natural graphs G_1 and G_2 associated to S. Suppose that $G_1 = O_1 x_1 \cdots x_n O_1'$ and $G_2 = O_2 y_1 \cdots s\overline{x_1} \cdots y_n O_2'$,

where s is the sign of $\overline{x_1}$. If $s = +$, then we set $\overline{O_1} = O_2'$ and $\overline{O_1'} = O_2$. Otherwise ($s = -$), we set $\overline{O_1} = O_2$ and $\overline{O_1'} = O_2'$. With this construction, we ensure that the set of vertices $\{O_1^h, x_1, \ldots, x_n, O_1^{'t}\}$ is oriented.

Consider now the PESs. For every graph associated to a PES and containing two vertices O_1 and O_2 of O, *semidedouble* sets $\overline{O_1} = O_2$. We say that a PES S is unoriented if the set of vertices of S is unoriented and oriented otherwise. As oriented PESs do not give rise to any problem, we consider only, in the ensuing discussion, an unoriented PES S. S is a *minimal PES* if S is minimal. Moreover, an *outer PES* of S is defined in a similar way as for a real SP (Definition 10.5) by replacing "real minimal SPs" by "real minimal SPs and minimal PESs." We similarly define a *maximal PES* and a *bad PES*.

We denote by *BPES* a bad PES, b is the number of BPESs, and $\mathcal{BPES} = \{P_1, \ldots, P_b\}$ with, for every i, P_i as the set of graphs associated to the BPES i.

To minimize the number of semiknots, graphs of *BPES* are amalgamated with procedure *amalgamating-PES* described in section 9. Three configurations can arise after applying the procedure:

R1. There remains no nonamalgamated graph.
R2. There remains only one nonamalgamated graph, and it belongs to a P_i of size 2.
R3. There remains one $P_i \in \mathcal{BPES}$ with one or two nonamalgamated graphs. This happens if only one BPES exists or if b is odd and $\mathcal{BPES}$ contains only sets of size 1.

In the remainder of this section, $\mathcal{SG}$ is the set of completable graphs obtained by amalgamating the two graphs of a POS, if any, as described above, by using procedure *amalgamating-PES* for the graphs of $\mathcal{BPES}$, and by the usual way for the other natural graphs.

LEMMA 10.6. *Let $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ be the semicompleted graph obtained by* semidedouble. *Then $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is a maximal semicompleted graph.*

Proof. Suppose that G does not contain any BPESs. The amalgamating procedure is then identical to that of section 5. Thus, from Theorem 10.2, *dedouble* constructs a maximal completed graph.

Suppose now that G contains BPESs. The only graphs of $\mathcal{SG}$ not corresponding to those of section 5 are those obtained by amalgamating graphs of $\mathcal{BPES}$. Let $\mathcal{G}_3(\mathbf{V}_3, A_3)$ be a graph of size n_3 obtained by amalgamating the two graphs $\mathcal{G}_1 = (\mathbf{V}_1, A_1)$ of size n_1 and $\mathcal{G}_2 = (\mathbf{V}_2, A_2)$ of size n_2 of $\mathcal{BPES}$. By arguments similar to those used in the proof of Theorem 9.3, we can see that *dedouble* gives rise to one less cycle when it is applied to a set of graphs containing $\mathcal{G}_3$, instead of a set of graphs containing the two supernatural graphs $\mathcal{G}_1$ and $\mathcal{G}_2$. More precisely, let c_{max} be the maximal number of cycles containing edges of $A_1 \cup A_2$ obtained when the two graphs $\mathcal{G}_1$, $\mathcal{G}_2$ are considered and c the number of cycles containing edges of A_3 obtained when $\mathcal{G}_3$ is considered. Then $c = c_{max} - 1$.

Let Γ_3' be the set of gray edges linking the vertices of $\mathbf{V}_3$ in a completed graph obtained by applying *dedouble* to a set of graphs containing $\mathcal{G}_3(\mathbf{V}_3, A_3)$. $\mathbf{V}_3$ has four vertices in O, denoted by the set O'. *Dedouble* constructs two cycles of size 1, each containing one of the vertices of O', and one cycle C of size > 1 containing the two remaining vertices of O'. Let $\mathcal{G}_{3,s}(\mathbf{V}_3, A_3, \Gamma_3)$ be the semicompleted graph of $\mathcal{G}_3(\mathbf{V}_3, A_3)$ obtained by *semidedouble*, that is, by removing from Γ_3' the edges adjacent to vertices of O. From Remark 3, vertices of O are either all left vertices or all right vertices. Therefore, removing from Γ_3' the edges adjacent to the vertices of O

transforms C into two good paths. The number of bad paths of $\mathcal{G}_{3,s}$ is then $bp_3 = 0$. Moreover, $cc(\mathcal{G}_{3,s}) = c_{max}$.

We deduce that $cc(\mathcal{G}_s) = c(G)$. $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is thus a maximal semicompleted graph. □

A local SP that is either real or a BPES not solved by the procedure *amalgamating-PES* is called a *final SP*.

Notation 5. Consider the following parameters:

- $\mathbf{s(G)}$ is the number of BPESs that become semiknots. $s(G) = 0$ if configurations R1, R2 are encountered, and $s(G) = 1$ otherwise.
- $\mathbf{brs(G)}$ is the number of bad real SPs of G.
- $\mathbf{fr(G)}$ and $\mathbf{gr(G)}$ are defined like $fr(\mathcal{G}_s)$ and $gr(\mathcal{G}_s)$ [18]. They depend on the set of real knots and semiknots determined by the set of final SPs of G.

We require one more lemma.

LEMMA 10.7. *Suppose that G contains an unoriented local SP S. Let π be the component of S. Then any maximal completed graph must contain an unoriented component made up of the vertices of π.*

Proof. Suppose that G contains an unoriented real SP S. From Lemma 8.4, any maximal completed graph $\mathcal{G}(\mathbf{V}, A, \Gamma)$ contains an SP formed by S vertices. As S does not contain any vertex in O, any maximal semicompleted graph also contains an SP formed by S vertices. On the other hand, all supernatural graphs containing vertices of $S \cup \overline{S}$ are in $\mathcal{SE}$, and the corresponding completed supernatural graphs (in a maximal completed graph) give rise to at least one component. We want to show that each of these components contains exclusively unoriented gray edges.

As S is unoriented, we can assume that all genes corresponding to S vertices are signed positively and that all left vertices of S are of form x^h and all right vertices of form x^t. Let $\mathcal{G}_{sn}(\mathbf{V_{sn}}, A_{sn})$ be a supernatural graph containing vertices of S. Suppose that the corresponding completed supernatural graph $\mathcal{G}_{sn}(\mathbf{V_{sn}}, A_{sn}, \Gamma_{sn})$ contains an oriented edge. Such an edge necessarily links two left vertices or two right vertices. Arguments similar to those used in the proof of Lemma 6.3 show that $\mathcal{G}_{sn}(\mathbf{V_{sn}}, A_{sn}, \Gamma_{sn})$ contains at least one cycle less than a completed supernatural graph corresponding to a maximal completed graph. □

THEOREM 10.8. *Let $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ be the semicompleted graph produced by* semidouble. *Let H be the resulting duplicated genome. Then $cp(\mathcal{G}_s) - bp(\mathcal{G}_s) = c(G) = \frac{1}{2}|A| + \gamma(G)$, $rr(\mathcal{G}_s) = brs(G)$, $s(\mathcal{G}_s) = s(G)$, $fr(\mathcal{G}_s) = fr(G)$, $gr(\mathcal{G}_s) = gr(G)$, and*

$$RT(G,H) = \frac{1}{2}|A| - \gamma(G) + brs(G) + \left\lceil \frac{s(G) - gr(G) + fr(G)}{2} \right\rceil.$$

Moreover, $RT(G,H) = RT(G)$.

Proof. To simplify the notation, denote by cc, cp, bp, rr, s, gr, and fr the parameters corresponding to the graph $\mathcal{G}_s$.

From Lemma 10.6, $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$ is a maximal semicompleted graph, and $cp - bp = c(G)$. Now, we know that real knots correspond to bad real SPs, plus at most one maximal SP. Thus $rr = brs(G)$. As for semiknots, they correspond to bad components containing at least one good path and for which the corresponding interval does not contain any path in $\mathcal{OO} \cup \mathcal{VV}$. As POSs do not give rise to bad components, the only remaining nonamalgamated PES, if any, is the only SP giving rise to a bad component with vertices in O. As these vertices (in O) are either all left vertices or all right vertices, from Remark 3, removing gray edges adjacent to these vertices gives rise to only good cycles. One semiknot is then due to this nonamalgamated PES. Therefore, $s = s(G)$. We deduce

$$RT(G,H) = |A| - cp + bp + rr + \left\lceil \frac{s - gr + fr}{2} \right\rceil$$
$$= \frac{1}{2}|A| - \gamma(G) + brs(G) + \left\lceil \frac{s(G) - gr(G) + fr(G)}{2} \right\rceil.$$

Suppose $RT(G,H) > RT(G)$. This means that there exists a completed graph $\mathcal{G}_{s'}(\mathbf{V}, A, \Gamma'_s)$ with parameters cc', cp', bp', rr', s', gr', and fr' such that $cp' - bp' - rr' - \left\lceil \frac{s'-gr'+fr'}{2} \right\rceil > cp - bp - rr - \left\lceil \frac{s-gr+fr}{2} \right\rceil$, i.e.,

$$(1) \qquad cc' - cc > (rr' - rr) + \left(\left\lceil \frac{s' - gr' + fr'}{2} \right\rceil - \left\lceil \frac{s - gr + fr}{2} \right\rceil \right).$$

Suppose first that the completed graph $\mathcal{G}_{s'}(\mathbf{V}, A, \Gamma'_s)$ contains x fewer real knots than $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$. Suppose first that $x = 1$ and that it corresponds to a bad real SP. Then, from Lemma 10.7, $\mathcal{G}_{s'}(\mathbf{V}, A, \Gamma'_s)$ is a completed graph that is not maximal. More generally, a construction that removes x bad real SPs gives rise to a completed graph for which $cp' \leq c(G) - x$.

Suppose now that $\mathcal{G}_{s'}(\mathbf{V}, A, \Gamma'_s)$ contains one less semiknot than $\mathcal{G}_s(\mathbf{V}, A, \Gamma_s)$. This can occur in situations R2 or R3. However, removing such a semiknot, for example by constructing a good component, would also remove at least two cycles. Therefore,

$$(2) \qquad cp' - cp \leq (rr' - rr) + (s' - s).$$

We deduce from the above observations that

$$(\mathrm{I}) \qquad \left\lceil \frac{s' - gr' + fr'}{2} \right\rceil - \left\lceil \frac{s - gr + fr}{2} \right\rceil < s' - s.$$

Two possible situations occur:

1. $s' - gr' + fr'$ is even and $s - gr + fr$ is odd. In that case, inequality (I) induces $(s - s') < (-gr + fr) - (-gr' + fr') + 1$.
   But $s - s' \geq 0$ and $(-gr + fr) - (-gr' + fr') \leq 1$. This is due to the fact that if $fr = 1$, then $gr = 1$. (The same holds for fr' and gr'.)
   There are three possible cases: (a) $s - s' = 0$ and $(-gr + fr) - (-gr' + fr') = 0$; (b) $s - s' = 0$ and $(-gr + fr) - (-gr' + fr') = 1$; (c) $s - s' = 0$ and $(-gr + fr) - (-gr' + fr') = 1$.
   Cases (a) and (b) contradict the fact that $s' - gr' + fr'$ and $s - gr + fr$ are not both even or both odd.
2. All other situations for $s' - gr' + fr'$ and $s - gr + fr$ (other than $s' - gr' + fr'$ even and $s - gr + fr$ odd). In that case, inequality (I) induces $(s - s') < (-gr + fr) - (-gr' + fr')$. As $s - s' \geq 0$ and $(-gr + fr) - (-gr' + fr') \leq 1$, we should have $s - s' = 0$ and $(-gr + fr) - (-gr' + fr') = 1$.

Thus the only situation remaining is $s = s'$ and $(-gr + fr) = (-gr' + fr') + 1$. However, from the definitions of gr, fr, gr', and fr', this situation is impossible.

On the other hand, as the amalgamating procedure of $\mathcal{BPES}$ graphs preserves a maximal completed graph, a completed graph that contained more real knots or semiknots than $\mathcal{G}_s$ would not satisfy inequality (I). □

11. Genome halving with reversals.

11.1. The HP result. The problem of reconstructing a duplicated circular genome by reversals is a special case of the problem of reconstructing a duplicated multichromosomal genome by reversals and translocations. As the notion of endpoints is irrelevant for circular genomes, the distinction between a semicompleted graph and a completed graph is absent in this case. Let $\mathcal{G}(\mathbf{V}, A, \Gamma)$ be the completed graph obtained by *dedouble*. This graph can be decomposed into a set of alternating cycles (no paths). We define good and bad components in a similar way as for multichromosomal genomes (section 10), but by considering only cycles (no paths). Moreover, the concept of knots is here replaced by the concept of *hurdles*. Note that the concepts of "real hurdles" and "semihurdles" are irrelevant.

Let H_1 and H_2 be two single chromosome genomes, and let $\mathcal{G}_{12}$ be the breakpoint graph associated to H_1 and H_2. HP proved [17] that the minimal number of reversals required to transform H_1 to H_2 is

$$\textbf{HP4}: \quad R(H_1, H_2) = b(\mathcal{G}_{12}) - c(\mathcal{G}_{12}) + h(\mathcal{G}_{12}) + f(\mathcal{G}_{12}),$$

where $h(\mathcal{G}_{12})$ is the number of hurdles of $\mathcal{G}_{12}$ and $f(\mathcal{G}_{12})$ is a correction of size 0 or 1. In other words, in formula **HP1** (section 3), $m(\mathcal{G}_{12}) = h(\mathcal{G}_{12})$.

11.2. Maximizing the number of cycles. We denote by $R(G)$ the minimum number of reversals necessary to transform G into a duplicated genome. Denote by $c(G)$ the number of cycles of a maximal completed graph of $\mathcal{G}(\mathbf{V}, A)$. Theorem 6.6 gives an upper bound for $c(G)$. We would like to construct a completed graph with a number of cycles equal to this upper bound. This completed graph would then be maximal.

The method is almost identical to that described in section 7 for multichromosomal genomes. In particular, if we set $O = \emptyset$, then all the definitions and notation introduced in section 7 are valid for the circular genome case.

During the construction of gray edges, we still have to be careful not to create a circular fragment as long as unlinked vertices remain in the partially completed graph. In other words, the last step of the algorithm is the only one "closing" a fragment, eventually by constructing two gray edges of form $(x, \overline{x})$. Therefore, at each step except the last one (when there remain just four gray edges to be constructed to complete the graph), we have to construct possible pairs of gray edges, that is, pairs of gray edges that do not satisfy Properties I, II, and III (section 7).

In the case of circular genomes, if $\mathcal{SO}$ is not empty, then the set of "good" supernatural graphs, that is, the supernatural graphs of size $2n$ that can be completed by forming $n + 1$ cycles, contains one supernatural graph of $\mathcal{SO}$ (Lemma 6.5 and Theorem 6.6). However, constructing $n + 1$ cycles on a supernatural graph of $\mathcal{SO}$ creates a circular fragment. Therefore, to be able to construct a maximal number of cycles, we have to be careful to end up with a supernatural graph of $\mathcal{SO}$, if any.

The algorithm used in this case is also *dedouble*, with the slight difference described above. This algorithm constructs a maximal completed graph, that is, a completed graph with $c(\mathcal{G}_\Gamma) = \gamma + \frac{|A|}{2}$ cycles.

Example 7. Consider the genome $G = +a\ +b\ -c\ +b\ -d\ -e\ +a\ +c\ -d\ -e$. The decomposition of the partial graph into supernatural graphs is shown in Figure 11.1. We have $|A| = 10, \gamma = 3$, and thus $c = \gamma + \frac{A}{2} = 8$. Figure 11.1 depicts the completed graph produced by *dedouble*. The corresponding circular duplicated genome is

$$H = +c_1\ -b_1\ -a_1\ +e_2\ +d_2\ -d_1\ -e_1\ +a_2\ +b_2\ -c_2.$$

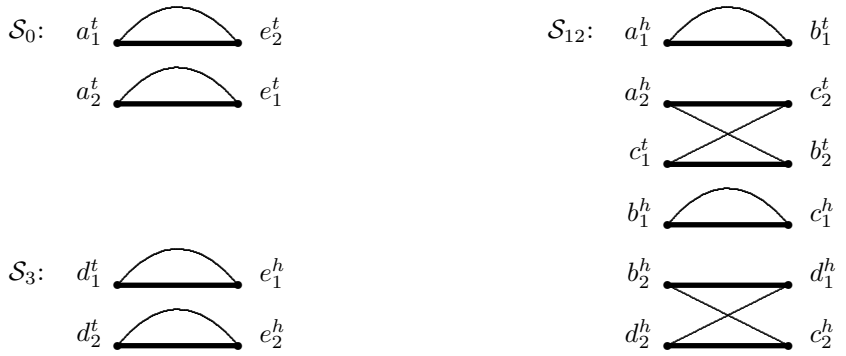

FIG. 11.1. *Completed graph* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *constructed by* dedouble.

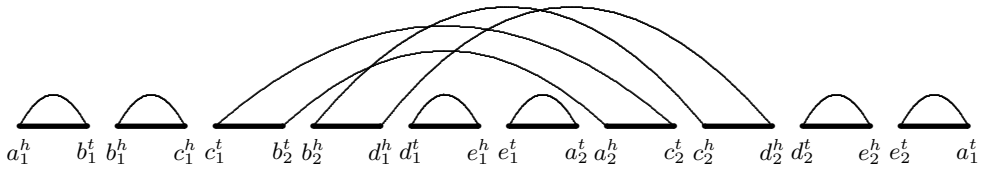

FIG. 11.2. *The completed graph constructed by* dedouble *for the genome* G *of Example* 7.

11.3. Hurdles. We now evaluate the number of hurdles contained in the maximal completed graph obtained by *dedouble*.

For circular genomes, the notion of a potential local SP is irrelevant, and only real local SPs remain. We saw, in section 8, how to modify *dedouble* so that, applied to a genome that does not contain any local SP, it gives rise to a completed graph containing no real SP.

The concepts of maximal, minimal, and bad SPs are defined as in section 10.3. Let $\mathbf{brs}(\mathbf{G})$ be the number of bad (real) SPs of G. Then, from Lemma 8.4 and Theorem 7.6, the completed graph $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ produced by *dedouble* contains exactly $brs(G)$ hurdles corresponding to these bad SPs. In addition, there may be at most two more special hurdles due to the special SPs defined in section 8.

Consider the parameter $f(G)$ which is 1 if the hurdles determined by the bad SPs of G form a fortress [17] and 0 otherwise. The next theorem is proved by arguments similar to those used for Theorem 10.8.

THEOREM 11.1. *Let* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *be the completed graph produced by* dedouble*, and let* H *be the resulting duplicated genome. Then*

$$\frac{|A|}{2} - \gamma(G) + brs(G) + f(G) \leq R(G, H) \leq \frac{|A|}{2} - \gamma(G) + brs(G) + f(G) + 2.$$

In addition,

$$\frac{|A|}{2} - \gamma(G) + brs(G) + f(G) \leq R(G) \leq \frac{|A|}{2} - \gamma(G) + brs(G) + f(G) + 2.$$

After Theorem 11.1, we have the following corollary.

COROLLARY 11.2. *Let* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *be the completed graph of* $\mathcal{G}(\mathbf{V}, A)$ *produced by* dedouble-circular. *If* $\mathcal{G}_\Gamma(\mathbf{V}, A, \Gamma)$ *does not contain any special hurdle, then*

$$R(G) = \frac{|A|}{2} - \gamma(G) + brs(G) + f(G).$$

Example 8. Consider genome G of Example 7 and the corresponding completed graph of Figure 7.5. Figure 11.2 gives a planar representation of this graph.

The number of cycles of this graph is $c(G) = 8$, $|A| = 10$, $brs(G) = 0$, and $f(G) = 0$. It does not contain any hurdles. Thus the minimum number of reversals necessary to transform genome G into a duplicated genome is $R(G) = 10-8+0+0 = 2$.

12. Analyzing the yeast genome. Wolfe and Shields [39] proposed that yeast is a degenerate tetraploid resulting from a genome duplication 10^8 years ago. They identified 55 duplicated regions, representing 50% of the genome.

12.1. Sorting by translocations. Applying our algorithm to the yeast genome data of Table 12.1, we obtain the perfect duplicated genome G_d represented in Table 12.2. The number of cycles of the corresponding completed graph $\mathcal{G}(V, A, \Gamma)$ is $c = 81$. Since G does not contain any local SPs, we can deduce that the minimal number of translocations required to transform G into G_d is

$$t = 2|\mathcal{B}| + |\mathcal{O}| - 2N - c = 142 - 16 - 81 = 45.$$

12.2. Sorting by reversals and translocations. As the yeast genome does not contain any real or potential local SPs, our method for sorting by reversals and translocations does not involve any reversals, so 45 translocations are still required.

13. An application on a circular genome. The mitochondrial genome of the liverwort plant *Marchantia polymorpha* is rather unusual in that many of its genes are manifested in two or three copies [30]. It is very unlikely that these arose from genome doubling, since this would not account for the numerous triplicates, nor is it consistent with comparative data on mitochondrial genomes. Nevertheless, it provides a convenient small example to test our method. A somewhat artificial map was extracted from the Genbank entry, deleting all singleton genes and one gene from each triplet. (The two genes furthest apart were saved from each triplet.) This led to a "rearranged duplicated genome" with 25 pairs of genes. A single supernatural graph in $\mathcal{SE}$ emerged from the analysis. This produced a minimum of 25 inversions, which is what one would expect from a random distribution of the duplicate genes on the genome. Any trace of genome duplication, were this even biologically plausible, has been obscured.

14. Conclusions. Calculating the HP formula for the edit distance between two genomes requires a rather intricate evaluation of the bicolored graph, including up to seven different structural parameters. In minimizing these formulae over the set of all (diploid) genomes, it is somewhat surprising that we can reconstruct an optimal ancestral genome exactly in all cases except the simplest reversals-only model. In the latter case, the uncertainty is not a deficiency of the algorithm but is due to ambiguity in how the doubled genome is constructed.

This work completes the major part of the program we undertook in [11]. In that article, we proposed a suite of "genome halving" problems and offered an algorithm for one of them in which a diploid genome is considered to be a set of genes partitioned among a number of subsets called chromosomes. The only operation is translocation considered as an exchange of subsets between two chromosomes. For the reconstruction problem in that context, in all likelihood NP-hard, we offered an effective heuristic which functions well on trial data. The present work shows that by adding gene order and transcription direction (strandedness, sign, polarity) to chromosome structure and adding the reversal operation, exact linear algorithms are possible. (Gene order alone, without transcription direction, would likely not suffice to permit polynomial-time exact algorithms; cf. [7].)

An additional level of structure to increase the realism of the model would be to incorporate a *centromere* on each chromosome. The centromere can occur anywhere in the linear order of genes, the centromeres are structurally indistinguishable from each other (for our purposes), and there is normally exactly one centromere per chromosome. This condition excludes some translocations, namely, those which result in one chromosome with two centromeres and one with none. The algorithms we have developed for the reconstruction of doubled genomes are not easily adaptable in this context. It should be noted that the condition on single centromeres is occasionally violated in nature, as, for example, with fissions and fusions, so that ideally the model should be complicated to allow for centromere creation and disappearance. As a final note, this work, together with [12] on hybridization and [9] on segment duplication, represents the use of computational biology techniques first developed for comparative genomics, as tools for the internal reconstruction of the evolutionary history of a single genome.

EXPECTED-CASE COMPLEXITY OF APPROXIMATE NEAREST NEIGHBOR SEARCHING*

SUNIL ARYA† AND HO-YAM ADDY FU†

Abstract. Most research in algorithms for geometric query problems has focused on their worst-case performance. However, when information on the query distribution is available, the alternative paradigm of designing and analyzing algorithms from the perspective of expected-case performance appears more attractive. We study the approximate nearest neighbor problem from this perspective.

As a first step in this direction, we assume that the query points are sampled uniformly from a hypercube that encloses all the data points; however, we make no assumption on the distribution of the data points. We show that with a simple partition tree, called the sliding-midpoint tree, it is possible to achieve linear space and logarithmic query time in the expected case; in contrast, the data structures known to achieve linear space and logarithmic query time in the worst case are complex, and algorithms on them run more slowly in practice. Moreover, we prove that the sliding-midpoint tree achieves optimal expected query time in a certain class of algorithms.

Key words. nearest neighbor searching, approximation, expected-case analysis, priority search, sliding-midpoint tree

1. Introduction.

The main focus in the design of data structures and algorithms for geometric query problems has been to obtain optimal worst-case query time. However, in many applications, the average time for answering a query is more important than the worst-case time. Thus, when we have information on the query distribution, we believe it is prudent to incorporate it in the algorithm design with a view to minimize the *expected* query time and to provide simpler data structures. We study the approximate nearest neighbor problem from this novel perspective.

Nearest neighbor searching is a fundamental problem in computational geometry with applications in numerous areas such as pattern recognition [11], data compression [17], information retrieval [10], and multimedia databases [15]. Since the problem is very difficult to solve exactly in high dimensions, researchers have investigated the *approximate* nearest neighbor problem. Consider a set S of n data points in R^d and a query point $q \in R^d$. Given an error bound $\epsilon > 0$, we say that a point $p \in S$ is a $(1+\epsilon)$-*approximate nearest neighbor* of q if $dist(p,q) \leq (1+\epsilon)dist(p^*,q)$, where p^* is the true nearest neighbor of q. This problem has been extensively studied from the worst-case perspective [2, 3, 5, 6, 7, 8, 9, 12, 18, 19, 21].

For our expected-case study, we consider that the set S of n data points is contained within the unit hypercube $U = [0,1]^d$ and assume that the query points are sampled from the uniform distribution in U. Note that we make no assumption on the distribution of the data points. While the assumption of uniformly distributed query points is admittedly simplistic, we think it is a natural first step toward the design of algorithms for more general query distributions. We investigate a general approach for

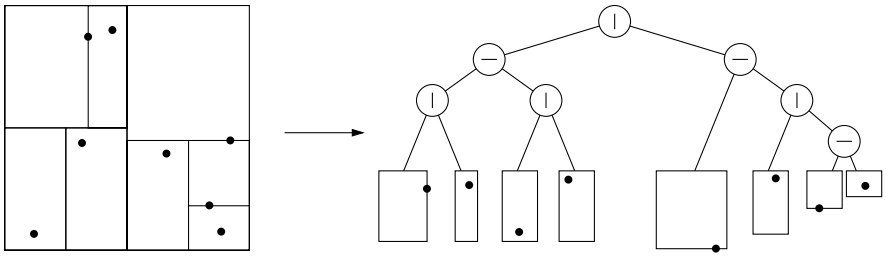

FIG. 1. *Sliding-midpoint tree.*

finding the approximate nearest neighbor devised by Arya et al. [4, 6], called *priority search*. This approach can be used in conjunction with any partition tree for S and is based on efficiently enumerating the leaves of the tree in order of increasing distance from the query point until a certain termination condition is satisfied. (Section 3 describes this method and presents its important features.) In this study, we consider the question of how to construct the partition tree so as to minimize the expected query time.

Our main results are for a partition tree based on a very simple splitting method called the *sliding-midpoint method*, introduced by Mount and Arya [24]. As in the standard kd-tree [16], cells are recursively subdivided using hyperplanes that are orthogonal to the coordinate-axes. More precisely, we first place a hyperplane orthogonal to the longest side of the cell and at its middle. We let this hyperplane be the splitting plane if there are data points located on both sides; otherwise, we slide the hyperplane toward the side that contains all the data points until it just touches a point. The point that touches the splitting plane is assigned to the side that is originally empty. (See Figure 1.) The space used by this tree is $O(n)$ (since no empty cells are created), and it can be easily constructed in $O(n \log n)$ time using well-known techniques [6]. Although its worst-case query time can be as bad as $\Omega(n)$, Maneewongvatana and Mount [22] have studied it empirically and observed that it performs well in practice. We present two results pertaining to its expected query time that provide some theoretical justification for its good practical performance.

First, we prove that the expected query time for this tree is $O((1/\epsilon)^d \log n)$, irrespective of the distribution of data points. We note that Arya et al. [6] and, more recently, Duncan, Goodrich, and Kobourov [12] have proposed partition trees for which priority search achieves logarithmic worst-case query time. However, they both use considerably more complex ways of subdividing a cell. (In addition to axis-orthogonal splits, Arya et al. allow a *shrink* operation, which can generate a cell that is the set-theoretic difference of two rectangles. Duncan, Goodrich, and Kobourov restrict themselves to splits with a hyperplane; however, the hyperplane is not necessarily axis-orthogonal.) Although both these partition trees provide optimal worst-case query time, the features introduced to ensure this property hurt their practical performance.

Our second result, which is of greater significance, shows that the sliding-midpoint tree is, in fact, optimal in a certain sense. Consider the class of algorithms obtained by running priority search on partition trees, where the splits are made by hyperplanes at arbitrary orientations (that is, not necessarily axis-orthogonal). We prove that, for any given data distribution, priority search on the sliding-midpoint tree achieves the minimum expected query time (up to a constant factor depending on d and ϵ)

over all such algorithms. Our proof also implies that priority search on the sliding-midpoint tree attains lower expected query time compared to any algorithm that can be modeled as an algebraic decision tree using linear tests (that is, involving the evaluation of a polynomial of degree one).

The paper is organized as follows. In section 2, we describe our notation. Section 3 reviews the priority search approach for finding the approximate nearest neighbor. Section 4 presents a general framework for the expected-case analysis of partition trees. In section 5, we give a simple proof that the expected query time using the sliding-midpoint tree is $O(\log n)$, and, in section 6, we establish the optimality of this tree. Finally, we present our experimental results in section 7.

2. Conventions. Let U denote the unit hypercube $[0,1]^d$ in d dimensions. We assume that the set S of n data points has been scaled and translated to lie within U. To avoid confusion, we always use *data point* to refer to a point in the data set S, and we use *point* to refer to any point in space. We assume that the dimension d and the error bound ϵ are fixed constants, independent of the number of data points.

We will assume that distances are measured in the Euclidean metric (although our results can be easily generalized to any Minkowski metric). We define the distance between a point p and a region z to be the minimum distance between p and any point in z.

Throughout, the word *rectangle* will denote a d-dimensional axis-parallel hyper-rectangle. We define the *size* of a rectangle to be the length of its longest side. For any region z, we let v_z denote its volume (area in two dimensions and length in one dimension). If z is the set-theoretic difference of two rectangles, one enclosed within the other, we denote the *outer rectangle* and *inner rectangle* by z_O and z_I, respectively, and we define its *size* to be the size of its outer rectangle.

The data structures we consider are based on partition trees that represent a hierarchical decomposition of U. We recall some basic facts about partition trees. Each node of the partition tree is associated with a region of space, called a *cell*, and the set of data points that lie in this cell. The cell associated with any node is partitioned into disjoint cells and associated with the children of the node. We assume that the cell associated with the root of the partition tree is the unit hypercube U. The leaves of the tree contain at most a constant number of data points, called the *bucket size* (henceforth assumed to be ≤ 1 for simplicity).

Given a partition tree T, let $\mathcal{I}_T, \mathcal{L}_T$, and $\mathcal{N}_T$ denote the set of its internal nodes, leaf nodes, and all nodes, respectively. We let $\mathcal{Z}_T$ denote the subdivision of U induced by the leaf nodes of T. Let x be a node in T. We let C_x denote the cell associated with x and v_x denote the volume of C_x. If C_x is a rectangle or the difference of two rectangles, we use s_x to denote the size of C_x. We will often use R_x in place of C_x if C_x is a rectangle. Finally, we use ℓ_x to denote the level of x, that is, the length of the path from the root to x. Note that the root is at level 0.

3. Background. We briefly review some features of the priority search approach for approximate nearest neighbor searching, proposed by Arya and Mount [4] and Arya et al. [6].

3.1. Query algorithm. The algorithm is based on visiting leaf cells in order of increasing distance from the query point q. For each leaf cell visited, the algorithm computes the distance between q and the data point stored with the leaf and updates p, the closest neighbor to q found so far, and r_p, the distance to it. The algorithm terminates when the distance between q and the leaf cell exceeds $r_p/(1+\epsilon)$, returning

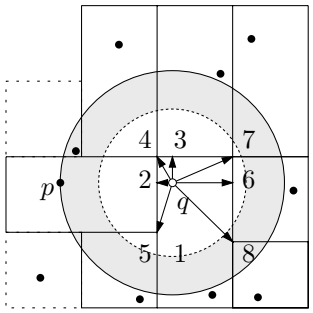

FIG. 2. *Algorithm overview.*

p as the answer. For example, in Figure 2, the leaf cells have been labeled in order of increasing distance from the query point q. The algorithm terminates on visiting cell 8, since its distance from the query point exceeds $r_p/(1+\epsilon)$ (the radius of the dotted circle shown).

To see that the algorithm works correctly for any partition tree, let B denote the ball of radius $r_p/(1+\epsilon)$ centered at q. Since the algorithm has already seen all leaf cells overlapping B, it is clear that B contains no data point. Thus point p is a $(1+\epsilon)$-approximate nearest neighbor of q.

It remains to describe the method used to enumerate the leaf cells in order of increasing distance from the query point. The algorithm maintains a priority queue of nodes, where the priority of a node is inversely related to the distance between the query point and the corresponding cell. Initially, the root of the tree is inserted into the queue. Then the following procedure is repeatedly carried out. First, the node with the highest priority is extracted from the queue, that is, the node closest to the query point. Then the algorithm descends the subtree associated with this node until reaching the leaf closest to the query point. For each internal node visited, the distance between the query point and the children of the node is computed. The algorithm descends to the child that is closer to the query point, while the other child is inserted into the queue. When the algorithm reaches the leaf, it processes the data point associated with it. The correctness of the algorithm is based on the invariant that the set of leaves descended from the nodes in the priority queue is disjoint and their union is the set of all unvisited leaves.

While priority search can be applied on any partition tree, it is especially efficient on trees that use only axis-orthogonal splits. The reason is that, for each internal node visited, the algorithm needs to compute the distance between the query point and the children of the node. If we do not restrict ourselves to axis-orthogonal splits, this computation can take time proportional to the complexity of the cell. In contrast, for a node that is partitioned by an axis-orthogonal hyperplane, this computation can be done in $O(1)$ time *independent* of dimension d, using a technique called *incremental distance computation*. From a practical perspective, the difference is significant especially in high dimensions. Intuitively, this technique works because the cells for the children differ from the parent's cell in only one of the d dimensions. For details, we refer the reader to Arya and Mount [4].

3.2. Query time. The analysis of the query time given in [6] employs the following two lemmas, which will also be useful for us. Lemma 3.1 says that all the leaf cells visited, except possibly the last one, are large relative to their distance from the

query point. Lemma 3.2 relates the query time to the number of internal nodes and leaf nodes visited. Their proofs follow from the discussion in [6]; we repeat them here for the sake of completeness.

LEMMA 3.1 (see [6]). *Consider a partition tree T built using axis-orthogonal splits, such that each leaf cell contains a data point. Suppose that we run priority search on T with query point q and error bound ϵ. Then the size of any leaf cell x that does not cause the algorithm to terminate is at least $r\epsilon/\sqrt{d}$, where r is the distance from q to x.*

Proof. Suppose that the size of x is less than $r\epsilon/\sqrt{d}$. Clearly, the diameter of x is then less than $r\epsilon$, and so it contains a data point at distance less than $r(1+\epsilon)$ from q. This implies that x must satisfy the termination condition, which is a contradiction. □

LEMMA 3.2 (see [4, 6]). *Consider a partition tree T built using axis-orthogonal splits. Suppose that we run priority search on T with query point q and error bound ϵ. Let I and L be the number of internal nodes and leaf nodes, respectively, visited by the algorithm. Then the query time is $O(I + Ld + L\log I)$, where the constant factor in the O-notation is independent of d and ϵ.*

Proof. On visiting an internal node, the algorithm first updates the distance to its two children; since the children are created by an axis-orthogonal split, this can be done in $O(1)$ time using incremental distance computation. Then it inserts the farther child into the priority queue; using Fibonacci heaps, the amortized time for each insertion is $O(1)$. Finally, it descends to the closer child, which takes $O(1)$ time.

On visiting a leaf node, it computes the distance between q and the data point stored with the leaf, which takes $O(d)$ time. It then extracts the closest node from the queue. Since each internal node visited inserts one child into the queue, the size of the queue is at most I. Thus it takes $O(\log I)$ time to extract the closest node. The total query time is therefore $O(I + L(d + \log I)) = O(I + Ld + L\log I)$. □

4. Expected-case analysis: General framework. In this section, we set up the basic framework for analyzing the expected query time of priority search on a partition tree. For the sake of simplicity, we assume that the partition tree is built using axis-orthogonal splitting planes. Before presenting the analysis, we first need to make a small but important modification to priority search.

4.1. Modified priority search. We give some intuition for why this modification is needed. Recall from section 3 that priority search is given a chance to terminate the search only at leaf nodes. Further, it follows from Lemma 3.1 that it visits at most one leaf cell of size less than $r\epsilon/\sqrt{d}$, where r is the distance from the query point to the leaf cell. However, while descending the tree to this small leaf cell, the algorithm may visit a large number of small internal nodes. This is undesirable as it increases the query time and prevents us from proving good bounds on the expected query time. Thus the idea of the modification is to allow the search to be terminated at internal nodes as well to ensure that at most one node (leaf or internal) of size less than $r\epsilon/\sqrt{d}$ is visited.

The details of the modification are as follows. With each internal node x, we store its size s_x and a pointer to any data point p_x inside R_x. (Asymptotically, this does not increase the space or preprocessing requirements.) The search algorithm works in exactly the same way if a leaf node is visited. If an internal node x is visited, then let r denote its distance from the query point q. If $s_x \geq r\epsilon/\sqrt{d}$, the algorithm works just as before. However, if $s_x < r\epsilon/\sqrt{d}$, the algorithm computes the distance from q to the associated data point p_x, updates the closest point seen so far, and terminates.

It is easy to see that the modified algorithm remains correct. Obviously, if the algorithm terminates at a leaf node, then it behaves exactly as the unmodified algorithm and is therefore correct. If it terminates at an internal node x at a distance r from q, then the diameter of R_x is at most $r\epsilon$, and so the associated data point p_x is at a distance at most $r(1+\epsilon)$ from q. Note that the algorithm has already seen any data point that lies in the ball of radius r centered at q. Clearly, if this ball contains no data point, then p_x is a $(1+\epsilon)$-approximate nearest neighbor. Otherwise, the algorithm returns the nearest neighbor of q. In either case, the algorithm returns the correct answer.

For the rest of this paper, we shall assume that priority search has been modified as indicated above. Note that Lemmas 3.1 and 3.2 continue to hold after this modification.

4.2. Upper bound on expected number of nodes visited. Recall that S is a set of n data points in U and the query point is sampled from the uniform distribution in U. In Lemma 4.1, we establish upper bounds on the expected number of internal nodes and leaf nodes visited by priority search, which depend only on the sizes of the rectangles associated with the nodes of the partition tree. Together with Lemma 3.2, these upper bounds facilitate the expected-case analysis of partition trees formed by different splitting methods. In sections 5 and 6, we will apply them to the sliding-midpoint tree.

LEMMA 4.1. *Let d and ϵ be any fixed constants. Let S be a set of n data points in U. Let T be a partition tree for S built using axis-orthogonal splits, such that each leaf cell contains a data point. Assume that the query point is sampled from the uniform distribution in U. Then the expected number of internal nodes and leaf nodes visited by priority search is at most $1+(1+2\sqrt{d}/\epsilon)^d \sum_{x\in\mathcal{I}_T} s_x^d$ and $1+(1+2\sqrt{d}/\epsilon)^d \sum_{x\in\mathcal{L}_T} s_x^d$, respectively.*

Proof. We will prove only the bound on the expected number of internal nodes visited, since the proof for leaf nodes is similar. Let q be a query point. Let x be any node visited that does not cause the algorithm to terminate, and let r be the distance between q and R_x. We claim that $s_x \geq r\epsilon/\sqrt{d}$. If x is an internal node, this follows in view of the modifications made to priority search, and if x is a leaf node, this follows from Lemma 3.1. Thus $r \leq s_x\sqrt{d}/\epsilon$. That is, if a node x is visited and does not cause the algorithm to terminate, then the query point q must be at a distance at most $s_x\sqrt{d}/\epsilon$ from R_x.

With each internal node x, associate a random variable V_x that takes the value 1 if node x is visited and does not cause the algorithm to terminate; otherwise, it takes the value 0. Let I denote the number of internal nodes visited by priority search. Clearly $I \leq 1+\sum_{x\in\mathcal{I}_T} V_x$. Here we have added 1 to take into account the last internal node visited, which may have caused the algorithm to terminate. By linearity of expectation,

$$E[I] \leq 1 + \sum_{x\in\mathcal{I}_T} E[V_x]. \tag{1}$$

Note that $E[V_x]$ equals the probability that V_x is 1. We compute an upper bound on this probability. From our earlier observation, it follows that if node x is visited and does not cause the algorithm to terminate, then q lies inside the hypercube of size $(1+2\sqrt{d}/\epsilon)s_x$, whose center coincides with the center of R_x. Since q is sampled from the uniform distribution in U, the volume of this hypercube, $(1+2\sqrt{d}/\epsilon)^d s_x^d$, is

an upper bound on the desired probability and hence on $E[V_x]$. Using this bound in (1) completes the proof. □

5. Logarithmic bound on expected query time of sliding-midpoint tree. By Lemma 4.1, the expected query time of priority search on a partition tree T is related to the quantities $\sum_{x\in\mathcal{I}_T} s_x^d$ and $\sum_{x\in\mathcal{L}_T} s_x^d$. The following lemma obtains upper bounds on these two quantities for the sliding-midpoint tree.

LEMMA 5.1. *Let S be a set of n data points in U. Let T be the partition tree for S built using the sliding-midpoint method. Then the following are true:* (i) $\sum_{x\in\mathcal{I}_T} s_x^d = O(\log n)$, *and* (ii) $\sum_{x\in\mathcal{L}_T} s_x^d = O(1)$. *The constant factors in the O-notation depend on d.*

Proof. Recall that the sliding-midpoint method partitions a cell into two subcells by a hyperplane orthogonal to its longest side and its middle. If there are data points in both subcells, it does nothing else. Otherwise, if there are no data points in one subcell, it slides the splitting plane until it just passes through a data point; the larger child becomes a leaf, and the smaller child becomes an internal node. It follows that the size of an internal node decreases by a factor of at least 2 as we descend d levels in the tree.

For $i \geq 1$, define *block* i to consist of levels $(i-1)d$ to $id-1$. Let $\mathcal{I}_i$ denote the set of internal nodes in block i. By the above observation, the size of an internal node in block i is at most $1/2^{i-1}$. Since the number of internal nodes in block i is at most $2^{(i-1)d}(2^d-1)$,

$$\sum_{x\in\mathcal{I}_i} s_x^d \leq \left(\frac{1}{2^{i-1}}\right)^d 2^{(i-1)d}(2^d-1) = 2^d - 1.$$

Let $\mathcal{I}'$ be the set of internal nodes in blocks numbered from 1 to $\lceil \log n/d \rceil$, and let $\mathcal{I}''$ be the remainder of the internal nodes. We will show that $\sum_{x\in\mathcal{I}'} s_x^d = O(\log n)$ and $\sum_{x\in\mathcal{I}''} s_x^d = O(1)$, which will prove (i).

Since $\mathcal{I}'$ consists of $\lceil \log n/d \rceil$ blocks,

$$\sum_{x\in\mathcal{I}'} s_x^d \leq \left\lceil \frac{\log n}{d} \right\rceil (2^d - 1) = O(\log n).$$

It remains to show that $\sum_{x\in\mathcal{I}''} s_x^d = O(1)$. Since each internal node has at least two data points, the number of internal nodes at any level is at most $\lceil n/2 \rceil \leq n$. Thus the number of internal nodes in a block is at most nd, which implies that

$$\sum_{x\in\mathcal{I}_i} s_x^d \leq nd \left(\frac{1}{2^{i-1}}\right)^d.$$

Therefore,

$$\sum_{x\in\mathcal{I}''} s_x^d \leq \sum_{i>\left\lceil \frac{\log n}{d} \right\rceil} \frac{nd}{2^{(i-1)d}} \leq nd \left(\frac{1/n}{1-1/2^d}\right) \leq 2d = O(1).$$

This completes the proof of (i).

Next we prove (ii). Recall that for any node x in the tree, R_x is the associated rectangle, defined by the splitting planes used in the construction of the tree. Now we associate a new rectangle R'_x with node x using the following simple procedure.

The root is associated with the unit hypercube U. Inductively, assume that R'_x is the rectangle associated with node x. If x is an internal node, then split any of the longest sides of R'_x at its middle, and associate the two resulting rectangles with the children of node x.

For each node x, let s'_x denote the longest side of the rectangle R'_x. Since the procedure splits the longest side of the rectangle each time, s'_x decreases by a factor of 2 as we descend d levels in the tree. Thus for any internal node x, $s_x \leq s'_x$, and for any leaf node x, $s_x \leq 2s'_x$, which implies that

$$\sum_{x \in \mathcal{L}_T} s_x^d \leq 2^d \sum_{x \in \mathcal{L}_T} (s'_x)^d. \tag{2}$$

Further, since the rectangles R'_x have an aspect ratio bounded by 2,

$$\sum_{x \in \mathcal{L}_T} (s'_x)^d \leq 2^{d-1} \sum_{x \in \mathcal{L}_T} v'_x, \tag{3}$$

where v'_x denotes the volume of rectangle R'_x. Also, $\sum_{x \in \mathcal{L}_T} v'_x = 1$, since the rectangles R'_x associated with the leaves form a subdivision of U. Combining this with (2) and (3), we get $\sum_{x \in \mathcal{L}_T} s_x^d = O(1)$. □

Using the upper bounds obtained in Lemma 5.1, it is easy to bound the expected query time.

THEOREM 5.2. *Let S be any set of n data points in $U = [0,1]^d$. Given any ϵ, assuming that the query point is sampled from the uniform distribution in U, the expected query time of priority search on the sliding-midpoint tree is $O((1/\epsilon)^d \log n)$. The constant factor in the O-notation depends on d.*

Proof. By Lemma 3.2, the query time is $O(I + Ld + L \log I)$, where I and L are the number of internal and leaf nodes visited, respectively. For fixed d, the expected query time is given by $O(E[I] + E[L \log I])$. Since $I \leq n$, the expected query time can be written as $O(E[I] + (\log n)E[L])$. By Lemmas 4.1 and 5.1, $E[I] = O((1/\epsilon)^d \log n)$ and $E[L] = O((1/\epsilon)^d)$. Thus the expected query time is $O((1/\epsilon)^d \log n)$. □

6. Optimality of sliding-midpoint tree. If the data points are uniformly distributed, then $\Omega(\log n)$ is a lower bound on the expected query time in the decision tree model. Thus it follows from Theorem 5.2 that the sliding-midpoint tree achieves optimal expected query time for uniformly distributed data points (ignoring constant factors depending on d and ϵ). The question naturally arises whether the sliding-midpoint tree achieves optimal performance for other data distributions as well. We prove that this is indeed the case under reasonable assumptions.

Let $\mathcal{T}_S$ denote the class of partition trees for S formed by splits using arbitrarily oriented hyperplanes (that is, *binary space partition trees*) such that each leaf cell contains at most one data point. We have the following result.

THEOREM 6.1. *Let d and ϵ be any fixed constants. There exists a constant c depending on d and ϵ such that the following is true. Let S be any set of n data points in $U = [0,1]^d$, and let T be any partition tree in $\mathcal{T}_S$. Assuming that the query point is sampled from the uniform distribution in U, the expected query time of priority search on the sliding-midpoint tree is no more than c times the expected query time of priority search on T.*

Let $\mathcal{Z}$ denote any set of regions inside U. (Note that the regions need not form a subdivision of U, nor are they necessarily disjoint.) We define the *entropy* of $\mathcal{Z}$ to be $\sum_{z \in \mathcal{Z}} v_z \log(1/v_z)$. The entropy of a subdivision of U is defined to be the entropy of the set of regions that form the subdivision.

We give a brief overview of the proof. Let S be a set of n data points in U. Let $\mathcal{D}$ denote any set of cells in U that satisfy the following properties for some constants c_a and c_n, depending on dimension.

A.1. *Difference of two rectangles:* A cell is the set-theoretic difference of two rectangles, one enclosed within the other. Note that the inner rectangle need not be present.

A.2. *Bounded aspect ratio:* The outer rectangle and inner rectangle (if present) have an aspect ratio (ratio of longest to shortest side) of at most c_a.

A.3. *Stickiness:* If the cell has an inner rectangle, then for each dimension, the separation between the corresponding faces of the inner and outer rectangles is either 0 or at least the length of the inner rectangle along that dimension.

A.4. *Existence of a close data point:* There is a data point whose distance from any point inside the outer rectangle of the cell is at most $c_n s$, where s is the size of the cell (that is, the length of the longest side of its outer rectangle).

A.5. *Disjointedness:* Given any two cells in $\mathcal{D}$, either the outer rectangles of the two cells are disjoint or the outer rectangle of one cell is contained within the inner rectangle of the other.

The basic idea of the proof is to show that the entropy of any such set of cells is a lower bound on the expected query time of priority search on any partition tree. For the upper bound, we will determine a set $\mathcal{D}$ of cells in U satisfying properties A.1–A.5 such that the expected query time of priority search on the sliding-midpoint tree is no more than the entropy of $\mathcal{D}$ (ignoring constant additive and multiplicative factors depending on d and ϵ).

6.1. Lower bound. The main result of this subsection is the following lemma.

LEMMA 6.2. *Let d and ϵ be any fixed constants. Let S be any set of n data points in U, and let T be any partition tree in $\mathcal{T}_S$. Let $\mathcal{D}$ be any set of cells in U satisfying properties* A.1–A.5. *Assuming that the query point is sampled from the uniform distribution in U, the expected query time of priority search on T is $\Omega(entropy(\mathcal{D}) + 1)$. The constant factor in the Ω-notation depends on d.*

Briefly, the proof works as follows. Let T be any partition tree in $\mathcal{T}_S$. Recall that $\mathcal{Z}_T$ denotes the subdivision of U induced by the leaf nodes of T. Since each internal node of T splits the associated region into two parts by a hyperplane, it follows that the cells in $\mathcal{Z}_T$ are convex polytopes. Further, each cell in $\mathcal{Z}_T$ either is empty or contains one data point. Let $\mathcal{Z}'_T$ denote the subdivision formed by splitting each nonempty cell in $\mathcal{Z}_T$ into two parts by passing a hyperplane through the data point inside it. The cells in $\mathcal{Z}'_T$ are convex polytopes in U and satisfy the following properties for constant c_v, depending on dimension (property B.1 is obvious; property B.2 is proved in Lemma 6.3).

B.1. *Empty interior:* A cell contains no data point in its interior.

B.2. *Proportionality of swept volume to radius:* Let z denote the cell, $\ominus$ denote the Minkowski difference operator, and B_r denote a ball of radius r. For any $r \geq 0$, the volume of $z - (z \ominus B_r)$ (that is, the set of points inside z within distance r of the boundary of z) is at most $c_v r$.

Let $\mathcal{D}$ be any set of cells in U satisfying properties A.1–A.5, and let $\mathcal{Z}$ be any subdivision of U into cells satisfying properties B.1–B.2. Lemmas 6.4, 6.5, and 6.6 form the cornerstone of the lower bound argument and show that the entropy of $\mathcal{D}$ is $O(entropy(\mathcal{Z})+1)$. Since $\mathcal{Z}'_T$ satisfies properties B.1–B.2, it follows that the entropy of $\mathcal{D}$ is $O(entropy(\mathcal{Z}'_T)+1)$. It is easy to show that $entropy(\mathcal{Z}'_T) \leq entropy(\mathcal{Z}_T)+1$. Thus $entropy(\mathcal{D}) = O(entropy(\mathcal{Z}_T)+1)$, as shown in Lemma 6.7. Finally, Lemma 6.8 proves

that the expected query time of priority search on T is $\Omega(\mathit{entropy}(\mathcal{Z}_T)+1)$. Together these imply that the expected query time of priority search on T is $\Omega(\mathit{entropy}(\mathcal{D})+1)$.

We start by proving that any convex polytope in U satisfies property B.2 (for constant $c_v = 2d$).

LEMMA 6.3. *Let z be a convex polytope contained within U. For any $r \geq 0$, the volume of $z - (z \ominus B_r)$ is at most $2dr$.*

Proof. Let $y = z - (z \ominus B_r)$. By definition, y is the set of points inside z at distance at most r from the boundary of z. For $d = 1$, z is a line segment, and it is obvious that the volume of y is at most $2r$.

Let $d > 1$. For each facet of z, construct a prism with this facet as base, directed inward into z, and with height r. It is easy to see that any point in y must lie in one of these prisms. Thus the volume of y is no more than the sum of the volume of all the prisms, which is clearly $a_z r$, where a_z is the surface area (perimeter, in two dimensions) of z. Since $z \subseteq U$, a_z is no more than the surface area of U, which is $2d$. (Here we have employed the following fact: if A and B are two closed, bounded, and convex subsets of R^d and $A \subseteq B$, then the surface area of A is no more than the surface area of B. See [13] for a proof.) Thus the volume of y is at most $2dr$. □

Now we are ready to present the key lemma for the lower bound argument. In view of the applications of the lemma to other problems (such as planar point location [1]), we prove a stronger version than is strictly needed here.

LEMMA 6.4. *Let d be any fixed constant. Let $\mathcal{Z}$ be any set of disjoint cells in U satisfying property* B.2 *(for constant c_v), and let $\mathcal{D}$ be any set of cells in U satisfying properties* A.1, A.2 *(for constant c_a),* A.3, *and* A.5. *Assume further that there exists a constant c_n such that, for any cell $u \in \mathcal{D}$ and $z \in \mathcal{Z}$, if $u_O \subseteq z$, then the distance to any point in u_O from the boundary of z is at most $c_n s_u$. Define a* fragment *to be a connected component in the intersection of a cell in $\mathcal{Z}$ with a cell in $\mathcal{D}$. Let $\mathcal{F}$ be the set of all fragments. Then*

$$\mathit{entropy}(\mathcal{F}) \leq d \cdot \mathit{entropy}(\mathcal{Z}) + O\left(\sum_{z \in \mathcal{Z}} v_z\right),$$

where the constant factor in the O-notation depends on d.

Proof. For any cell $z \in \mathcal{Z}$, let $\mathcal{F}_z \subseteq \mathcal{F}$ denote the set of fragments that are contained within z. We will show that $\mathit{entropy}(\mathcal{F}_z) \leq dv_z \log(1/v_z) + O(v_z)$. Since $\mathit{entropy}(\mathcal{F}) = \sum_{z \in \mathcal{Z}} \mathit{entropy}(\mathcal{F}_z)$, the lemma will then follow by summing over all $z \in \mathcal{Z}$.

Let z be any cell in $\mathcal{Z}$. We start by partitioning z into an infinite set of regions, denoted $z_i, i \geq 1$, as follows. Let $r_c = v_z/c_v$. Define z'_i to be the region consisting of points inside z at a distance of at least $r_c/2^i$ from the boundary of z. Clearly $z'_i \subseteq z'_{i+1}$ for $i \geq 1$. By property B.2 and the definition of r_c, it follows that the volume of z'_i is at least $v_z(1 - 1/2^i)$. The volume of z'_1 is thus at least $v_z/2$; we define z_1 to be any region of volume $v_z/2$ inside z'_1. Next observe that the volume of z'_2 is at least $3v_z/4$, and so the volume of $z'_2 - z_1$ is at least $v_z/4$; we define z_2 to be any region of volume $v_z/4$ inside z'_2 that is disjoint from z_1. Continuing in this way, we define $z_i, i \geq 1$, to be any region of volume $v_z/2^i$ inside z'_i that is disjoint from all of the regions $z_1, z_2, \ldots, z_{i-1}$. It is clear that the regions $z_i, i \geq 1$, form an infinite partition of z and satisfy the following two conditions: $v_{z_i} = v_z/2^i$ and $z_i \subseteq z'_i$.

Define a *subfragment* to be the intersection of a fragment in $\mathcal{F}_z$ with a region $z_i, i \geq 1$. Let $\mathcal{G}_z$ denote the set of all subfragments. Since each fragment $y \in \mathcal{F}_z$ is

partitioned into subfragments $y \cap z_i, i \geq 1$, it is easy to see that

$$entropy(\mathcal{F}_z) \leq entropy(\mathcal{G}_z). \tag{4}$$

Let $\mathcal{G}_{z_i}$ denote the set of subfragments that lie inside z_i. Clearly

$$entropy(\mathcal{G}_z) = \sum_{i \geq 1} entropy(\mathcal{G}_{z_i}). \tag{5}$$

Next we compute an upper bound on $entropy(\mathcal{G}_{z_i})$; the desired bound on $entropy(\mathcal{F}_z)$ will follow using (4) and (5). Obviously $entropy(\mathcal{G}_{z_i}) \leq entropy(\mathcal{G}_{z_i} \cup \{x\})$, where $x = z_i - \bigcup \mathcal{G}_{z_i}$ (that is, the region remaining in z_i after removing all the subfragments in $\mathcal{G}_{z_i}$). Let m_i be the number of subfragments in $\mathcal{G}_{z_i}$. It follows from basic calculus that $entropy(\mathcal{G}_{z_i} \cup \{x\})$ can be no more than the entropy of the set of regions formed by splitting z_i into $m_i + 1$ parts of equal volume. Thus

$$entropy(\mathcal{G}_{z_i}) \leq v_{z_i} \log \frac{m_i + 1}{v_{z_i}}. \tag{6}$$

We will show that $m_i \leq c \cdot 2^{id}/v_z^{d-1}$, where c is a constant that depends on dimension d. Assuming this fact for now and recalling that $v_{z_i} = v_z/2^i$, we get

$$entropy(\mathcal{G}_{z_i}) \leq \frac{v_z}{2^i} \log \frac{c2^{id}/v_z^{d-1} + 1}{v_z/2^i} \leq \frac{v_z}{2^i} \log \frac{(c+1)2^{id}/v_z^{d-1}}{v_z/2^i}.$$

Letting $c' = c + 1$ and simplifying, we get

$$entropy(\mathcal{G}_{z_i}) \leq \left(dv_z \log \frac{1}{v_z} + v_z \log c' \right) \frac{1}{2^i} + (d+1) v_z \frac{i}{2^i}.$$

Using (5), we obtain

$$entropy(\mathcal{G}_z) \leq dv_z \log \frac{1}{v_z} + v_z(\log c' + 2(d+1)) = dv_z \log \frac{1}{v_z} + O(v_z),$$

where the constant factor in the O-notation depends on d. By (4), $entropy(\mathcal{F}_z) \leq dv_z \log(1/v_z) + O(v_z)$, which is the desired claim.

It remains to show that $m_i \leq c \cdot 2^{id}/v_z^{d-1}$. Recall that m_i is the number of fragments that overlap z_i. Since $z_i \subseteq z_i'$, it follows that m_i is no more than the number of fragments that overlap z_i'. Let $\mathcal{F}_{z_i'}$ denote the set of fragments that overlap z_i'. For convenience, set $r_i = r_c/2^i$ and $c_n' = \max(c_n, \sqrt{d})$. Below we describe a set of disjoint hypercubes $\mathcal{H}$ and give a 1-1 mapping from $\mathcal{H}$ to $\mathcal{F}_{z_i'}$ such that at least a fraction $(1/2d)$ of the fragments in $\mathcal{F}_{z_i'}$ lie in the image of this mapping. (We will use H_y to denote the hypercube, if any, that maps to fragment y and say that H_y is *associated* with y.) Further, each hypercube in $\mathcal{H}$ is contained within z and has size $r_i/(c_n' c_a)$. A simple packing argument then implies that

$$|\mathcal{H}| \leq \frac{v_z}{(r_i/(c_n' c_a))^d}.$$

Substituting $r_i = r_c/2^i$ and $r_c = v_z/c_v$, we get

$$|\mathcal{H}| \leq \frac{(c_n' c_a c_v)^d 2^{id}}{v_z^{d-1}}.$$

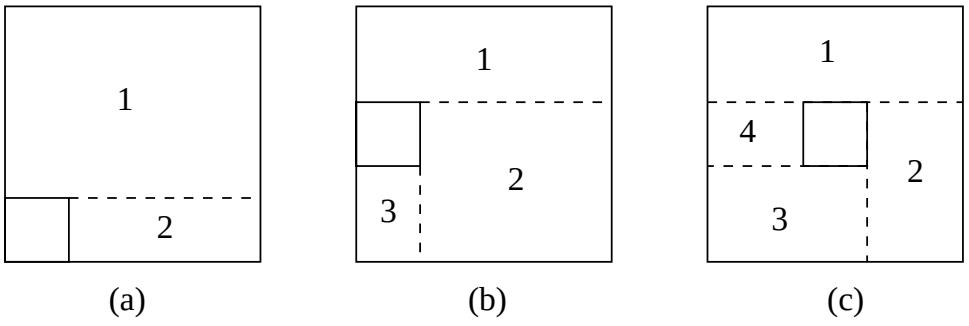

FIG. 3. *Partitioning a cell into rectangles.*

The number of fragments in $\mathcal{F}_{z'_i}$ is at most $2d$ times this quantity. We thus obtain the desired bound $m_i \leq c \cdot 2^{id}/v_z^{d-1}$, where $c = 2d(c'_n c_a c_v)^d$.

Let $u \in \mathcal{D}$ be any cell that contains a fragment of $\mathcal{F}_{z'_i}$. Clearly u overlaps z'_i. We claim that the size of u is at least r_i/c'_n. If u_O overlaps the boundary of z, then the diameter of u_O must exceed r_i, and so s_u is at least $r_i/\sqrt{d}$. Otherwise, u_O is contained within z, and, by the statement of the lemma, the distance to any point in u_O from the boundary of z is at most $c_n s_u$. Since u_O overlaps z'_i, it contains a point at a distance of at least r_i from the boundary of z; thus $c_n s_u \geq r_i$, which implies that $s_u \geq r_i/c_n$. Combining the two cases, we get $s_u \geq r_i/c'_n$, where $c'_n = \max(c_n, \sqrt{d})$. We will make use of this fact in our proof.

We now describe how to associate hypercubes with fragments in $\mathcal{F}_{z'_i}$; later we will show that the resulting set of hypercubes $\mathcal{H}$ satisfies all the properties mentioned earlier. For each fragment $y \in \mathcal{F}_{z'_i}$, choose a point p_y in $y \cap z'_i$. (We call such a point a *fragment representative point*.) Let $u \in \mathcal{D}$ be any cell that overlaps z'_i. We consider three cases: (i) u has no inner rectangle, (ii) u has an inner rectangle of size at least r_i/c'_n, and (iii) u has an inner rectangle of size less than r_i/c'_n.

If u has no inner rectangle, then, with each fragment $y \in \mathcal{F}_{z'_i}$ such that $y \subseteq u$, associate a hypercube H_y of size $r_i/(c'_n c_a)$ that overlaps p_y and is contained within u. Note there exists such a hypercube since, as shown above, $s_u \geq r_i/c'_n$ and, by property A.2 (bounded aspect ratio), the length of each side of u is at least $r_i/(c'_n c_a)$.

In the second case, u has an inner rectangle of size at least r_i/c'_n. Observe that u can be partitioned into t rectangles, where $1 \leq t \leq 2d$ is the number of sides of the inner rectangle that do not touch the corresponding side of the outer rectangle. (This can be done by successively passing hyperplanes that touch a side of the inner rectangle. For example, Figures 3(a), (b), and (c) show how a cell in two dimensions is partitioned into 2, 3, and 4 rectangles, respectively.) Note that by properties A.2 (bounded aspect ratio) and A.3 (stickiness), each side of these t rectangles is of length at least $r_i/(c'_n c_a)$. Of these t rectangles, let R denote the rectangle that has the maximum number of fragment representative points corresponding to the fragments in $\mathcal{F}_{z'_i}$. With each fragment $y \in \mathcal{F}_{z'_i}$ such that $p_y \in R$, associate a hypercube H_y of size $r_i/(c'_n c_a)$ that overlaps p_y and is contained within R. With the remaining fragments in u (that is, fragments whose corresponding representative point lies in $u - R$), we associate no hypercube.

In the third case, u has an inner rectangle of size less than r_i/c'_n. As in the second case, we partition u into t rectangles, $1 \leq t \leq 2d$, and determine the rectangle R among them that has the maximum number of fragment representative points

corresponding to the fragments in $\mathcal{F}_{z_i'}$. With each fragment $y \in \mathcal{F}_{z_i'}$ such that $p_y \in R$, associate a hypercube H_y of size $r_i/(c_n' c_a)$ that overlaps p_y and is contained within the outer rectangle of u. Such a hypercube exists because, as shown above, $s_u \geq r_i/c_n'$. With the remaining fragments in u, we associate no hypercube. (Note that, unlike the second case, the sides of R may have length less than $r_i/(c_n' c_a)$, and the hypercube H_y may overlap the inner rectangle of u.)

It remains to argue that the resulting set of hypercubes $\mathcal{H}$ has the desired properties. Let y denote a fragment in $\mathcal{F}_{z_i'}$. By construction, the size of H_y (if defined) is $r_i/(c_n' c_a)$. Second, since H_y overlaps p_y and p_y is at distance at least r_i from the boundary of z, it follows that H_y is contained within z. Third, for any cell u that overlaps z_i', it is clear that we associate a hypercube with at least a fraction $1/(2d)$ of the fragments of $\mathcal{F}_{z_i'}$ contained in u. It follows that a hypercube is associated with at least a fraction $1/(2d)$ of the fragments in $\mathcal{F}_{z_i'}$.

The only thing left to show is that the hypercubes are all disjoint. Let $y_1, y_2 \in \mathcal{F}_{z_i'}$ be any two distinct fragments that each have a hypercube associated with them. Let $u_1, u_2 \in \mathcal{D}$ be the cells containing y_1, y_2, respectively. There are four different cases: (i) $u_{1O} \cap u_{2O} = \emptyset$, (ii) $u_{2O} \subseteq u_{1I}$, (iii) $u_{1O} \subseteq u_{2I}$, and (iv) $u_1 = u_2$. (Note that, in case (iv), y_1 and y_2 are contained in the same cell.)

By our construction, $H_{y_1} \subseteq u_{1O}$ and $H_{y_2} \subseteq u_{2O}$. It follows that in case (i), H_{y_1} and H_{y_2} must be disjoint. In case (ii), recall that a cell containing a fragment of $\mathcal{F}_{z_i'}$ must have size at least r_i/c_n'. Thus u_2 has size at least r_i/c_n', and hence u_{1I} has size at least r_i/c_n'. By our construction, this implies that $H_{y_1} \subseteq u_1$. Since $H_{y_2} \subseteq u_{2O}$, it follows that H_{y_1} and H_{y_2} are disjoint. Case (iii) is similar to the second case. In case (iv), observe that the line segment joining p_{y_1} and p_{y_2} lies entirely within cell u_1. (This is obvious if u_1 has no inner rectangle; if u_1 has an inner rectangle, this follows from the fact that we partition u_1 into rectangles and associate hypercubes with fragment representative points lying in only one of these rectangles.) Since y_1 and y_2 are distinct fragments created by the intersection of z with u_1, the boundary of z must intersect this line segment. Since the distance of both p_{y_1} and p_{y_2} from the boundary of z is at least r_i, the distance between p_{y_1} and p_{y_2} must be at least $2r_i$. Since H_{y_1} and H_{y_2} overlap p_{y_1} and p_{y_2}, respectively, and each has size $r_i/(c_n' c_a)$, it is easy to verify that H_{y_1} and H_{y_2} are disjoint. This completes the proof of the lemma. □

LEMMA 6.5. *Let d be any fixed constant. Let $\mathcal{Z}$ and $\mathcal{D}$ be sets of cells satisfying all the conditions given in the statement of Lemma* 6.4. *Further, let $\mathcal{F}$ be as defined in the statement of Lemma* 6.4. *Assuming that $\mathcal{Z}$ is a subdivision of U,*

$$\mathit{entropy}(\mathcal{D}) \leq \mathit{entropy}(\mathcal{F}) \leq d \cdot \mathit{entropy}(\mathcal{Z}) + O(1),$$

where the constant factor in the O-notation depends on d.

Proof. Clearly, the set of fragments in $\mathcal{F}$ form a refinement of the set of cells in $\mathcal{D}$. Thus $\mathit{entropy}(\mathcal{D}) \leq \mathit{entropy}(\mathcal{F})$. Using Lemma 6.4 and the fact that $\sum_{z \in \mathcal{Z}} v_z = 1$, we get $\mathit{entropy}(\mathcal{F}) \leq d \cdot \mathit{entropy}(\mathcal{Z}) + O(1)$, which completes the proof. □

LEMMA 6.6. *Let d be any fixed constant. Let S be any set of n data points in U. Let $\mathcal{Z}$ be a subdivision of U whose cells satisfy properties* B.1–B.2, *and let $\mathcal{D}$ be a set of cells in U satisfying properties* A.1–A.5. *Then*

$$\mathit{entropy}(\mathcal{D}) = O(\mathit{entropy}(\mathcal{Z}) + 1),$$

where the constant factor in the O-notation depends on d.

Proof. Let u be a cell in $\mathcal{D}$ whose outer rectangle is contained within some cell $z \in \mathcal{Z}$. We claim that the distance to any point p in u_O from the boundary of z is at most $c_n s_u$. This follows from the facts that the distance between p and the nearest data point is at most $c_n s_u$ (property A.4) and z contains no data point in its interior (property B.1). Thus $\mathcal{D}$ and $\mathcal{Z}$ satisfy the conditions of Lemma 6.5, which implies the desired claim. □

LEMMA 6.7. *Let d be any fixed constant. Let S be any set of n data points in U, and let T be any partition tree in $\mathcal{T}_S$. Then entropy$(\mathcal{D}) = O($entropy$(\mathcal{Z}_T) + 1)$, where $\mathcal{D}$ is any set of cells in U satisfying properties* A.1–A.5. *The constant factor in the O-notation depends on d.*

Proof. Refine the subdivision $\mathcal{Z}_T$ by splitting each nonempty cell of $\mathcal{Z}_T$ into two parts by passing any hyperplane through the data point inside the cell. Let $\mathcal{Z}'_T$ be the new subdivision. It is easy to see that *entropy*$(\mathcal{Z}'_T)$ can be no more than the entropy of the set of regions formed by splitting each cell of $\mathcal{Z}_T$ into two parts of equal volume. Thus

$$\text{(7)}\quad \textit{entropy}(\mathcal{Z}'_T) \le \sum_{z \in \mathcal{Z}_T} 2\frac{v_z}{2} \log \frac{1}{v_z/2} = \sum_{z \in \mathcal{Z}_T} \left(v_z \log \frac{1}{v_z} + v_z \right) = \textit{entropy}(\mathcal{Z}_T) + 1,$$

where we have used the fact that $\sum_{z \in \mathcal{Z}_T} v_z = 1$.

Clearly, $\mathcal{Z}'_T$ is a subdivision of U into cells satisfying property B.1 (empty interior). Also, since the cells in $\mathcal{Z}'_T$ are convex polytopes contained within U, by Lemma 6.3, they satisfy property B.2 (proportionality of swept volume to radius). Thus $\mathcal{D}$ and $\mathcal{Z}'_T$ satisfy the conditions of Lemma 6.6, which implies that

$$\text{(8)}\qquad \textit{entropy}(\mathcal{D}) = O(\textit{entropy}(\mathcal{Z}'_T) + 1).$$

The lemma now follows from (7) and (8). □

LEMMA 6.8. *Let d and ϵ be any fixed constants. Let S be any set of n data points in U, and let T be any partition tree in $\mathcal{T}_S$. Assuming that the query point is sampled from the uniform distribution in U, the expected query time of priority search on T is $\Omega($entropy$(\mathcal{Z}_T) + 1)$.*

Proof. Recall that the algorithm starts by descending from the root of the tree T to the leaf that contains the query point. Thus the expected number of nodes visited by the algorithm to locate the leaf cell containing the query point is $\sum_{z \in \mathcal{Z}_T} v_z(\ell_z + 1)$. Note that this is the weighted external path length [20] of the tree, where the weight of a leaf is the volume of the associated cell. A fundamental information theoretic result due to Shannon [20, 25] implies that the weighted external path length of any binary tree with these weights is at least $\sum_{z \in \mathcal{Z}_T} v_z \log(1/v_z)$. Thus *entropy*$(\mathcal{Z}_T)$ is a lower bound on the expected number of nodes visited. Noting that the algorithm must visit at least one node, the lemma follows. □

Finally, Lemmas 6.7 and 6.8 together imply Lemma 6.2.

6.2. Upper bound. In this subsection, we compute an upper bound on the expected query time of priority search on the sliding-midpoint tree. We will prove that the expected query time is $O($*entropy*$(\mathcal{D}) + 1)$, where $\mathcal{D}$ is some set of cells in U satisfying properties A.1–A.5. In view of Lemma 6.2, this would imply the optimality of the sliding-midpoint tree in the sense of Theorem 6.1.

Our approach for obtaining $\mathcal{D}$ is as follows. In Lemma 6.9, we show that, for any sliding-midpoint tree T, there exists a closely related partition tree T' whose leaves satisfy properties A.1–A.5 and whose internal nodes satisfy properties A.1–A.4. In addition, T' possesses the following property, which is important for our analysis.

A.6. *Geometric decrease in volume:* The volume of the cells associated with the nodes decreases by at least a constant factor every $O(1)$ levels of descent in the tree. This property implies that if the volume of a leaf is v, then its level is $O(\log(1/v) + 1)$.

We define $\mathcal{D}$ to be the set of cells corresponding to the leaves of T'. In Lemmas 6.10, 6.11, 6.12, and 6.13, by exploiting properties of T and T', we give a simple analysis proving that the expected query time of priority search on T is $O(\mathit{entropy}(\mathcal{D}) + 1)$.

LEMMA 6.9. *Let S be a set of n data points in U. Let T be the sliding-midpoint tree for S. Then there exists a partition tree T' such that the following hold:*

(1) *The cells associated with the nodes (internal and leaf) of tree T' satisfy properties* A.1–A.4 *and* A.6. *Also, the set of cells associated with the leaves of T' satisfy property* A.5.

(2) *There exists a* 1-1 *mapping f from the nodes of T to the nodes of T' such that for any node x of T, $s_x/2 \le s_{f(x)} \le 8s_x$.*

Proof. We will construct the partition tree T' and the mapping f incrementally in $n-1$ steps. To this end, we label the internal nodes of T from 1 to $n-1$ such that the label assigned to any child is greater than the label assigned to its parent. Clearly, there exists such a labeling. (For example, label the internal nodes in a breadth-first manner.) Let T_i denote the subtree of T consisting of the root and the nodes whose parents have label $\le i$.

Let T'_i denote the tree constructed after i steps. In addition to this tree, we also maintain a 1-1 mapping f from the nodes of T_i to the nodes of T'_i. We will prove by induction that the following invariant holds at each step of the construction. (For convenience, we denote the cell associated with a node u by R_u if it is a rectangle and by C_u if it is the difference of two rectangles.)

(1) T'_i is a partition tree, and f is a 1-1 mapping from the nodes of T_i to the nodes of T'_i.

(2) Properties A.1–A.4 and A.6 hold for the cells associated with the nodes (internal and leaf) in T'_i.

(3) Property A.5 holds for the set of cells associated with the leaves of T'_i.

(4) Let x be any internal node in T that is present in T_i. Let $y = f(x)$. Then
   (a) the cell associated with node y is a rectangle (denoted R_y) and $R_x \subseteq R_y$,
   (b) each side of R_y has length $\ge s_x/2$ and $\le 4s_x$, and
   (c) if x is a leaf in T_i, then y is a leaf in T'_i.

(5) Let x be any leaf in T that is present in T_i. Let $y = f(x)$. Then $s_x/2 \le s_y \le 8s_x$.

It is clear that the lemma will then follow from the fact that the invariant holds for the final tree $T' = T'_{n-1}$.

Initially, T'_0 consists of just the root node, which is associated with U. Further, the root of T is mapped by f to the root of T'_0. It is easy to see that the invariant holds for $i = 0$. We now describe the ith step of the construction. Let x denote the internal node of T labelled i. Observe that our method of labeling implies that x is a leaf in T_{i-1}. Thus, by (4(c)) of the invariant, the corresponding node $y = f(x)$ must be a leaf in T'_{i-1}. Let x_1 and x_2 denote the two children of x. In the ith step, we *attach* a subtree consisting of a constant number of nodes to node y and map x_1 and x_2 by function f to two leaf nodes in this subtree. For the other nodes in T_i, the mapping f remains unchanged. (Note that they are all present in T_{i-1}.)

Now we give the details. Let the longest side of R_x that is split to form R_{x_1} and R_{x_2} be aligned along the kth coordinate axis, and let P denote the hyperplane

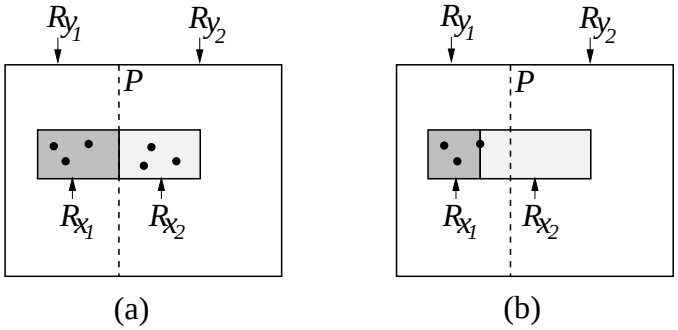

FIG. 4. *Proof of Lemma* 6.9.

orthogonal to it and passing through the center of R_x. We consider two cases.

Case 1. P is the splitting plane associated with node x. (See Figure 4(a).)

This implies that P splits R_x into R_{x_1} and R_{x_2} and there is a data point in each of these two rectangles. We modify T'_{i-1} in two substeps and show that the invariant holds after the second substep.

Substep 1. By (4(a)) of the invariant, the cell associated with y is a rectangle R_y, and $R_x \subseteq R_y$. We create two children y_1 and y_2 for node y. We then split R_y into two rectangles by hyperplane P and associate these rectangles with y_1 and y_2 such that R_{y_1} and R_{x_1} are both on the same side of P, and R_{y_2} and R_{x_2} are both on the other side of P. Henceforth, in our discussion of Case 1, we focus only on nodes x_1 and y_1 since nodes x_2 and y_2, respectively, play a symmetrical role.

We show that properties A.1–A.4 hold for R_{y_1}. First, observe that since R_{y_1} is a rectangle, it trivially satisfies properties A.1 (difference of two rectangles) and A.3 (stickiness). Second, since $R_{x_1} \subseteq R_{y_1}$ and there is a data point in R_{x_1}, it is clear that R_{y_1} satisfies property A.4 (existence of a close data point).

Third, we claim that each side of R_{y_1} has length $\geq s_x/2$ and $\leq 4s_x$. Note that this would imply that R_{y_1} satisfies property A.2 (bounded aspect ratio). From (4(b)) of the invariant, each side of R_y has length $\geq s_x/2$ and $\leq 4s_x$. Since R_{y_1} is formed from R_y by splitting side k (that is, the side aligned along the kth coordinate axis), the claim is obviously true for all sides of R_{y_1} other than side k. Further, the length of side k of R_{y_1} must be $\leq 4s_x$ since it must be smaller than the corresponding side of R_y. It remains to show that the length of side k of R_{y_1} is $\geq s_x/2$. Recall that $R_{x_1} \subseteq R_{y_1}$. Also, side k of R_{x_1} has length $s_x/2$ since P splits R_x at the middle of side k, which is one of the longest sides of R_x. Thus the length of side k of R_{y_1} is $\geq s_x/2$.

Next we claim that the volume of R_{y_1} is at most 7/8th the volume of R_y. As we will see, substep 2 creates either zero or two children for y_1; thus the volume of the nodes decreases by at least a factor of 8/7 after every two levels of descent in T'_i, which implies that T'_i satisfies property A.6 at the end of substep 2. To see the claim, observe that the ratio of the volume of R_{y_2} to the volume of R_y is the same as the ratio of the length of side k of R_{y_2} to the length of side k of R_y. Since the length of any side of R_{y_2} is $\geq s_x/2$, and the length of any side of R_y is $\leq 4s_x$, this ratio is at least 1/8. Thus the volume of R_{y_1} is at most 7/8th the volume of R_y.

Substep 2. Let $B_1 \subseteq R_{y_1}$ denote a rectangle formed by expanding each side of R_{x_1} that is smaller than $s_{x_1}/2$ to $s_{x_1}/2$. Note that it is possible to do the expansion such that B_1 lies inside R_{y_1}, since $R_{x_1} \subseteq R_{y_1}$ and, as shown in the discussion of substep 1, each side of R_{y_1} is of length $\geq s_x/2 \geq s_{x_1}/2$. Clearly, each side of B_1 has length

$\geq s_{x_1}/2$ and $\leq s_{x_1}$.

Next, if rectangle B_1 has a side that violates the stickiness property with respect to the corresponding side of R_{y_1}, expand it until it touches the side of R_{y_1}. Continue this process until all sides of the resulting rectangle (call it B_2) satisfy the stickiness property. It is easy to see that this can increase the length of a side of B_1 by a factor of at most 4 (since its length can increase by a factor of at most 2 in each of two expansions). Thus the length of each side of B_2 is $\geq s_{x_1}/2$ and $\leq 4s_{x_1}$.

If $B_2 = R_{y_1}$, then set $f(x_1) = y_1$. Otherwise, create two children y_{11} and y_{12} for node y_1, associate rectangle B_2 with y_{11} and $R_{y_1} - B_2$ with y_{12}, and set $f(x_1) = y_{11}$. Note that y_{12} will be a leaf in the final tree T'.

We now show that the invariant holds. We have already seen that T'_i satisfies property A.6, and properties A.1–A.4 hold for the node y_1 added in substep 1. We next show that properties A.1–A.4 hold for the children (if any) added to y_1.

If $f(x_1) = y_1$, then no children are added, and there is nothing to show. Otherwise, nodes y_{11} and y_{12} are made children of y_1. Recall that $R_{y_{11}} = B_2$ and $C_{y_{12}} = R_{y_1} - B_2$, and the length of each side of B_2 is $\geq s_{x_1}/2$ and $\leq 4s_{x_1}$. It follows that $R_{y_{11}}$ and $C_{y_{12}}$ satisfy properties A.1 (difference of two rectangles) and A.2 (bounded aspect ratio). Since B_2 is a rectangle, it satisfies property A.3 (stickiness). By construction of B_2, it is clear that $C_{y_{12}}$ also satisfies stickiness. Since B_2 has a data point inside it, it follows that B_2 and $C_{y_{12}}$ both satisfy property A.4 (existence of a close data point).

Next we show that (4(a)–(c)) of the invariant hold if x_1 is an internal node of T, and (5) of the invariant holds if x_1 is a leaf node. To prove (4(a)), note that by construction $R_{f(x_1)}$ is the rectangle B_2, and $R_{x_1} \subseteq B_2$ (since B_2 is formed by expanding R_{x_1}). Recall that each side of B_2 is of length $\geq s_{x_1}/2$ and $\leq 4s_{x_1}$, which implies (4(b)) and (5). Since $f(x_1)$ is a leaf in the tree T'_i, it follows that (4(c)) holds.

Finally, it is clear from our construction that T'_i is a partition tree whose leaves satisfy property A.5, and f is a 1-1 mapping from the nodes of T_i to the nodes of T'_i ((1) and (3) of the invariant).

Case 2. P is not the splitting plane associated with node x. (See Figure 4(b).)

This implies that all the data points in R_x are on the same side of P, and the splitting plane for x is obtained by sliding P along dimension k until it just passes through a data point. Without loss of generality, suppose that R_{x_1} is smaller than R_{x_2}, as shown in Figure 4(b). (The other case can be handled similarly.) Note that x_2 is a leaf containing exactly one data point.

As in Case 1, the cell associated with node y is a rectangle R_y and $R_x \subseteq R_y$. We modify T'_{i-1} in two substeps. In substep 1, we create two children y_1 and y_2 for node y. We then split R_y into two rectangles by hyperplane P; the rectangle that is on the same side of P as R_{x_1} is associated with y_1, and the other rectangle is associated with y_2. Next we set $f(x_2) = y_2$. Note that y_2 will be a leaf in the final tree T'.

The description of substep 2 is identical to Case 1, and so we omit it. Note that we need only to process nodes x_1 and y_1 in substep 2 (since x_2 is already mapped by f in substep 1).

We now show that the invariant holds. The argument is similar to that for Case 1, with two differences: (1) in showing that there is a data point close to R_{y_2} (property A.4), and (2) in showing that the size of R_{y_2} is $\geq s_{x_2}/2$ and $\leq 8s_{x_2}$ ((5) of the invariant).

Arguing as in Case 1, we can show that the length of each side of R_{y_2} is $\geq s_x/2$ and $\leq 4s_x$. Further, since R_x contains a data point (call it p), and $R_x \subseteq R_y$, the

distance between any point in R_y and p is no more than the diameter of R_y; by (4(b)) of the invariant, this is $\leq 4\sqrt{d}s_x$. Since $R_{y_2} \subseteq R_y$, this bound also applies to the distance between any point in R_{y_2} and p. It follows that R_{y_2} satisfies property A.4. Finally, to show the desired lower and upper bound on the size of R_{y_2}, note that R_{x_2} is the larger of the two children formed by applying the sliding-midpoint method to R_x. Thus $s_x \geq s_{x_2} \geq s_x/2$, which implies that the length of each side of R_{y_2} is $\geq s_{x_2}/2$ and $\leq 8s_{x_2}$. This completes the proof. □

The following lemma proved in [23] gives a bound on the number of leaf cells visited by priority search that holds irrespective of the data distribution and the location of the query point.

LEMMA 6.10 (see [23]). *The number of leaf cells of the sliding-midpoint tree visited by priority search in the worst case is* $O((1+1/\epsilon)^d)$. *The constant factor in the O-notation depends on d.*

Let T denote the sliding-midpoint tree, and let T' denote the tree corresponding to it, given in the statement of Lemma 6.9.

LEMMA 6.11. *The expected query time of priority search on the sliding-midpoint tree* T *is* $O(\sum_{x\in\mathcal{N}_{T'}} s_x^d)$. *The constant factor in the O-notation depends on d and* ϵ.

Proof. By Lemma 3.2, the query time is $O(I + Ld + L\log I)$, where I and L are the number of internal and leaf nodes visited, respectively. Thus, for fixed d, the expected query time is $O(E[I] + E[L\log I])$. By Lemma 6.10, L is bounded by a constant. Hence the expected query time is $O(E[I]+E[\log I]) = O(E[I])$. Lemma 4.1 implies that $E[I] = O(\sum_{x\in\mathcal{N}_T} s_x^d)$. By Lemma 6.9, there is a 1-1 function f that maps each node in T to a node in T', whose size is the same to within a constant factor. The lemma now follows. □

LEMMA 6.12. *Let* $\tilde{T}$ *be any partition tree in which the cells associated with the leaf and internal nodes of the tree satisfy properties* A.1–A.3 *and* A.6. *Let* $\mathcal{Z}_{\tilde{T}}$ *denote the subdivision of U induced by the leaf nodes of* $\tilde{T}$. *Then* $\sum_{x\in\mathcal{N}_{\tilde{T}}} s_x^d = O(entropy(\mathcal{Z}_{\tilde{T}}) + 1)$, *where the constant factor in the O-notation depends on d.*

Proof. Since the cells associated with the nodes of the tree satisfy property A.2 (bounded aspect ratio) and property A.3 (stickiness), it follows that $\sum_{x\in\mathcal{N}_{\tilde{T}}} s_x^d = O(\sum_{x\in\mathcal{N}_{\tilde{T}}} v_x)$. Since the volume of a node x is the sum of the volume of all the leaf nodes descended from it, we can write $\sum_{x\in\mathcal{N}_{\tilde{T}}} v_x = \sum_{x\in\mathcal{L}_{\tilde{T}}} v_x(\ell_x + 1)$, where ℓ_x denotes the level of leaf x. Further, by property A.6, $\ell_x = O(\log(1/v_x) + 1)$. Thus $\sum_{x\in\mathcal{N}_{\tilde{T}}} s_x^d = O(\sum_{x\in\mathcal{L}_{\tilde{T}}} v_x(\log(1/v_x) + 1)) = O(entropy(\mathcal{Z}_{\tilde{T}}) + 1)$. □

By Lemma 6.9, T' satisfies the conditions of Lemma 6.12, and thus $\sum_{x\in\mathcal{N}_{T'}} s_x^d = O(entropy(\mathcal{Z}_{T'}) + 1)$. Setting $\mathcal{D} = \mathcal{Z}_{T'}$ and applying Lemmas 6.9 and 6.11, we obtain the desired upper bound on the expected query time.

LEMMA 6.13. *The expected query time of priority search on the sliding-midpoint tree is* $O(entropy(\mathcal{D}) + 1)$, *where* $\mathcal{D}$ *is some set of cells in U satisfying properties* A.1–A.5. *The constant factor in the O-notation depends on d and* ϵ.

Finally, combining this lemma with the lower bound given in Lemma 6.2 establishes Theorem 6.1.

Remark. It is easy to see that our proof of Theorem 6.1 also implies the following: Let S be any set of n data points in U, and let A be any algorithm for finding the approximate nearest neighbor that can be modeled as an algebraic decision tree T using linear tests. Then the expected query time of priority search on the sliding-midpoint tree is no more than a constant (depending on d and ϵ) times the expected query time of A.

We mention only two key observations. First, the leaf nodes of T induce a subdivision $\mathcal{Z}_T$ of U into convex cells, such that each cell has at most one data point (since the same data point must be the approximate nearest neighbor, no matter where the query point lies in the cell). Second, the weighted path length of T, where the volume of a leaf is its weight, is a lower bound on the expected query time of A. Thus, as in section 6.1, we can prove that the expected query time of A is $\Omega(\mathit{entropy}(\mathcal{D}) + 1)$, where $\mathcal{D}$ is any set of cells in U satisfying properties A.1–A.5. The claim now follows in light of Lemma 6.13.

7. Experimental results. We ran experiments to compare the performance of the sliding-midpoint tree with the *standard kd-tree*, a partition tree devised by Friedman, Bentley, and Finkel [16] which is often used in nearest neighbor searching (both exact and approximate). The standard kd-tree recursively splits the data set into two sets of equal size by a hyperplane orthogonal to the dimension in which the points have maximum *spread* (difference of maximum and minimum coordinate). Friedman, Bentley, and Finkel showed that this tree can be used to answer nearest neighbor queries in $O(\log n)$ expected time, assuming that both data and query points are sampled from a distribution of bounded density.

We start by listing the point distributions used for generating the data sets [6, 24]. The clustered segments distribution was used to model data sets that exhibit clustering in low dimensional subspaces. The correlated Gaussian and correlated Laplacian point distributions were chosen to model data from speech processing applications. These two distributions were formed by grouping the output of autoregressive sources into vectors of length d. An autoregressive source uses the following recurrence to generate successive outputs:

$$X_n = \rho X_{n-1} + W_n,$$

where W_n is a sequence of zero mean independent, identically distributed random variables. The correlation coefficient ρ was taken as 0.9 for our experiments. Each point was generated by selecting its first coordinate from the corresponding uncorrelated distribution (either Gaussian or Laplacian), and then the remaining coordinates were generated by the equation above. See Farvardin and Modestino [14] for more information.

Uniform. Each coordinate was chosen uniformly from the interval $[0, 1]$.

Clustered segments. Eight axis-parallel line segments were sampled from a hypercube as follows. For each line segment a random coordinate axis x_k was selected, and a point p was sampled uniformly from the hypercube. The line segment is the intersection of the hypercube with the line parallel to x_k, passing through p. An equal number of points were generated uniformly along the length of each line segment and a Gaussian error with standard deviation of 0.001 was added.

Gaussian. Each coordinate was chosen from the Gaussian distribution with zero mean and unit variance.

Laplace. Each coordinate was chosen from the Laplacian distribution with zero mean and unit variance.

Correlated Gaussian. W_n was chosen so that the marginal density of X_n is normal with variance unity.

Correlated Laplacian. W_n was chosen so that the marginal density of X_n is Laplacian with variance unity.

We generated data points in dimension 16 from these distributions and in each case generated query points uniformly from a hypercube enclosing 90% of the data

points (to reduce the effect of outliers). Throughout, we used a bucket size (the maximum number of data points inside a leaf cell) of one for the partition trees.

For each experiment, we fixed ϵ and measured a number of statistics, averaging over 200 query points. The statistics included the average number of nodes visited, the average number of floating point operations (that is, any arithmetic operation involving point coordinates or distances), and the average CPU time. We present plots showing the number of floating point operations, which agrees well with the CPU times and provides a reasonable machine-independent measure of the query time.

The results for the uniform, clustered segments, correlated Gaussian, and correlated Laplacian distributions are shown in Figures 5 and 6. Figure 5 shows the average number of floating point operations as a function of n when ϵ is 2. Figure 6 shows the average number of floating point operations as a function of ϵ when n is $128,000$. We used a large value of ϵ in some of our experiments because we observed that the actual relative error committed by the algorithm is typically smaller by factors between 10 and 100.

We can make the following observations from the plots.

- The key observation is that for the clustered and the two correlated distri-

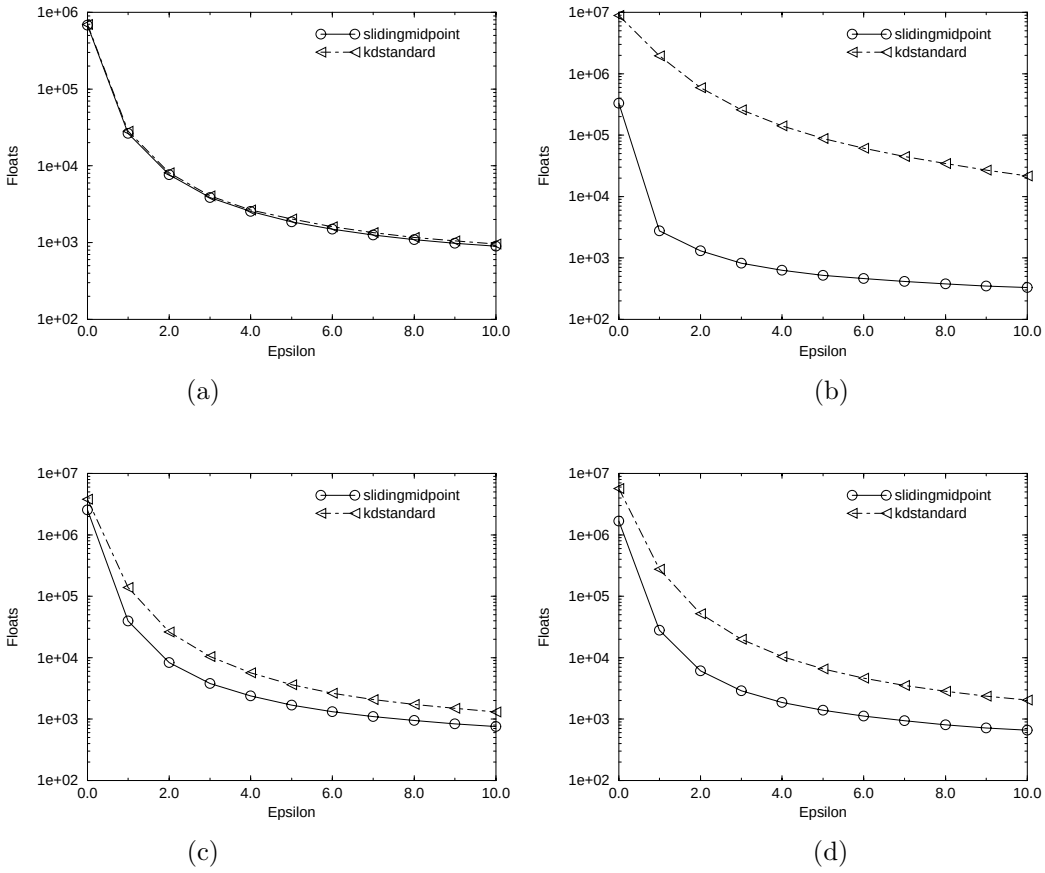

FIG. 6. *Average number of floating point operations for the* (a) *uniform,* (b) *clustered segments,* (c) *correlated Gaussian, and* (d) *correlated Laplacian distributions versus* ϵ. *Here* $n = 128,000$.

butions, the sliding-midpoint tree offers significant speed-up, sometimes by factors of over 10, compared to the standard kd-tree. Moreover, the speed-up increases with n.

- For the uniform distribution, both trees yield very similar query times.
- For the clustered segments distribution, the expected query time for the sliding-midpoint tree appears to be independent of the number of data points. (This is not hard to explain using Lemma 4.1.)
- As ϵ increases from 0 to 2, the query times of both the trees decrease significantly, usually by factors between 10 and 100.

Because of its design, the sliding-midpoint tree does a better job than the standard kd-tree of zooming toward the region where the data points are more densely clustered. This is the reason why it enjoys a considerable advantage for clustered data sets.

8. Conclusion. We have studied the approximate nearest neighbor problem from the perspective of expected-case performance. Our analysis assumes that the query points are sampled uniformly from a hypercube enclosing all the data points but makes no assumption on the distribution of data points. We have shown that the sliding-midpoint tree achieves linear space and logarithmic expected query time. We have also shown that this tree attains optimal expected query time (ignoring constant

factors) for any set of data points in a certain class of algorithms. The data structure is simple and easy to implement, and our empirical studies indicate that it performs well in practice.

There are several interesting open problems. The main limitation of our work is that it is restricted to the case of uniform query distribution. It would be interesting to develop an algorithm that achieves optimal expected query time for nonuniform query distributions. Another problem concerns strengthening the optimality claim for the sliding-midpoint tree. We proved that the sliding-midpoint tree achieves expected query time no more than a constant times that of any algorithm that can be modeled as an algebraic decision tree using linear tests. Does this optimality claim hold even if we allow polynomials of higher degree?

THE ONLINE MEDIAN PROBLEM*

RAMGOPAL R. METTU† AND C. GREG PLAXTON‡

Abstract. We introduce a natural variant of the (metric uncapacitated) k-median problem that we call the online median problem. Whereas the k-median problem involves optimizing the simultaneous placement of k facilities, the online median problem imposes the following additional constraints: the facilities are placed one at a time, a facility cannot be moved once it is placed, and the total number of facilities to be placed, k, is not known in advance. The objective of an online median algorithm is to minimize the competitive ratio, that is, the worst-case ratio of the cost of an online placement to that of an optimal offline placement. Our main result is a constant-competitive algorithm for the online median problem running in time that is linear in the input size. In addition, we present a related, though substantially simpler, constant-factor approximation algorithm for the (metric uncapacitated) facility location problem that runs in time linear in the input size. The latter algorithm is similar in spirit to the recent primal-dual-based facility location algorithm of Jain and Vazirani, but our approach is more elementary and yields an improved running time. While our primary focus is on problems which ask us to minimize the weighted average service distance to facilities, we also show that our results can be generalized to hold, to within constant factors, for more general objective functions. For example, we show that all of our approximation results hold, to within constant factors, for the k-means objective function.

1. Introduction.

Suppose we wish to open a new chain of stores in a city with n neighborhoods and that we have a good estimate of the demand for our product in each neighborhood. In determining where to locate the stores, our high-level strategy is to minimize the *service cost* associated with our configuration of stores, which we define as the demand-weighted average distance from a customer to the nearest store. Our business plan is to start with one store and then to gradually add new stores as allowed by our profits. (Remark: We will never move a previously established store.) Thus our configuration of stores may change over time, and hence the ratio between the service cost of our configuration and that of an optimal same-size configuration may also change. The goal of the *online median problem* is to choose a site for each new store so that the maximum value of this ratio is minimized. An online median algorithm that guarantees a ratio of at most r is said to achieve a *competitive ratio* of r, or to be *r-competitive*.

The variant of this problem, in which the total number of stores to be built, k, is known in advance, corresponds to the classic *k-median problem*. The k-median problem is known to be $\mathcal{NP}$-hard and has been studied extensively over several decades (see, e.g., [25] for many pointers to the literature). Charikar et al. presented the

first polynomial-time constant-factor approximation algorithm for the k-median problem [5]; subsequently, improved time bounds and approximation factors have been obtained by Charikar and Guha [4], Jain and Vazirani [17], and Arya et al. [2].

Note that the online median problem can be viewed as the offline problem of determining a permutation of the n neighborhoods (specifying the order in which to build our stores) that minimizes the maximum ratio between the service cost of any prefix of the permutation and that of an optimal same-size configuration. We adopt this view throughout the remainder of the paper. Given the existence of constant-factor approximation algorithms for the k-median problem, it is natural to ask whether there is a constant-competitive algorithm for the online median problem. In other words, can we (efficiently) find a permutation of the n neighborhoods such that the service cost of any prefix of the permutation is at most a constant times that of an optimal same-size configuration? Note that, given an arbitrary problem instance, it is not clear a priori that such a permutation even exists.

In this paper, we affirm the existence of such a permutation and give a deterministic constant-competitive algorithm for the online median problem. Furthermore, the running time of our algorithm is $O(n^2 + \ell n)$ (where ℓ is the number of bits required to represent each distance), which is linear in the size of the input. While the main contribution of this paper is to identify and solve the online median problem, it worth noting that the k-median problem is a special case of the online median problem. Hence our linear-time online median algorithm is also the first deterministic constant-factor approximation algorithm for the k-median problem running in time that is linear in the size of the input. (The best previous running time of $O((n^2 \log n)(\ell + \log n))$ is given in [17].)

An obvious approach to the online median problem is to iteratively choose the point that minimizes the objective function. Greedy strategies of this kind are commonly applied in the design of online algorithms [3, 15]. It turns out, however, that for the online median problem, the simple strategy suggested above has an unbounded competitive ratio. We show that a modification of this strategy that we call *hierarchically greedy* can be used to obtain a constant-competitive algorithm for the online median problem that has a running time that is linear in the size of the input. We develop this strategy by first considering a simple greedy algorithm for facility location.

1.1. Problem definitions. Fix a set of points U, a distance function $d : U \times U \to \mathbb{R}$, and nonnegative functions $f, w : U \to \mathbb{R}$. We assume throughout that d is a metric, that is, d is nonnegative and symmetric and satisfies the triangle inequality, and $d(x, y) = 0$ iff $x = y$. For the online median problem, it will prove useful to consider a slightly more general class of distance functions in which the triangle inequality is relaxed to the following "λ-approximate" triangle inequality, where $\lambda \geq 1$: For any sequence of points $\langle x_0, \ldots, x_m \rangle$, $d(x_0, x_m) \leq \lambda \cdot \sum_{0 \leq i < m} d(x_i, x_{i+1})$. We refer to such a distance function as a λ-*approximate metric*. (Remark: The inequality associated with a λ-approximate metric is referred to as the "λ-polygonal inequality" in [9].) We let $n = |U|$, and we define a subset of U to be a *configuration* iff it is nonempty. For any point x and configuration X, we define $d(x, X)$ as $\min_{y \in X} d(x, y)$.

We consider three computational problems: k-median, online median, and facility location. For the k-median and online median problems, the *cost* of a configuration, which we denote as $cost(X)$, is defined to be $\sum_{x \in U} d(x, X) \cdot w(x)$. The input to the k-median problem is (U, d), w, and an integer k, $0 < k \leq n$. The output is a minimum-cost configuration of size k. The input to the online median problem is

(U, d) and w. The output is a total order on U. We define the competitive ratio of such an ordering as the maximum over all k, $0 < k \leq n$, of the ratio of the cost of the configuration given by the first k points in the ordering to that of an optimal k-median configuration. We define the *competitive ratio* of an online median algorithm as the supremum, over all possible choices of the input instance (U, d) and w, of the competitive ratio of the ordering produced by the algorithm.

For the facility location problem, the *cost* of a configuration, denoted $cost(X)$, is defined as the sum of $\sum_{x \in X} f(x)$ and $\sum_{x \in U} d(x, X) \cdot w(x)$. The input to the facility location problem is (U, d), f, and w. The output is a minimum-cost configuration.

1.2. Previous work. There has been much prior work on the facility location and k-median problems. In this paper, we focus on the metric versions of these problems; for recent work and pointers to the literature on the general (nonmetric) facility location and k-median problems, see [28]. The first constant-factor approximation algorithm for facility location is due to Shmoys, Tardos, and Aardal [26] and is based on rounding the (fractional) solution to a linear program (LP). Chudak [6] gives an LP-based $(1 + 2/e)$-approximation algorithm for facility location. This was the best constant factor known until the work of Charikar and Guha [4], which establishes a slightly lower approximation ratio of 1.728. Jain, Mahdian, and Saberi [16] give a simple greedy algorithm for the facility location that has an approximation ratio of 1.61. To our knowledge, the best approximation ratio for facility location is currently 1.52, due to Mahdian, Ye, and Zhang [23]. Guha and Khuller [12] provide the best lower bound known of 1.463 on the approximation ratio for the facility location problem.

The first constant-factor approximation for the k-median problem was recently given by Charikar et al. [5] and is also LP-based. That work follows a sequence of bicriteria results utilizing LP-based techniques [21, 22]. (These bicriteria results produce a configuration of size $O(k)$ with cost at most a constant factor times that of an optimal configuration of size k.) Jain and Vazirani [17] give the first nearly linear-time (in the input size) combinatorial algorithms for the facility location and k-median problems, achieving approximation ratios of 3 and 6, respectively. While the latter algorithms are combinatorial, the primal-dual approach used in their analysis is based on LP theory. (See [11] for an excellent introduction to the primal-dual method.) To our knowledge, the best approximation ratio for the k-median problem is $3 + \varepsilon$, due to Arya et al. [2]. Jain, Mahdian, and Saberi [16] provide the best lower bound known of $1 + 2/e$ on the approximation ratio for the k-median problem.

Strategies based on local search and greedy techniques for facility location and the k-median problem have previously been studied. The work of Korupolu, Plaxton, and Rajaraman shows that a simple local search heuristic proposed by Kuehn and Hamburger [20] yields both a constant-factor approximation for the facility location problem and a bicriteria approximation for the k-median problem [18]. To obtain their approximation result, Arya et al. [2] analyze a similar local search heuristic with a generalized local search step. Guha and Khuller [12] show that greedy improvement can be used as a postprocessing step to improve the approximation guarantee of certain facility location algorithms. Charikar and Guha [4] achieve an approximation ratio of 1.728 for facility location by combining a local search heuristic with the best LP-based algorithm known. Charikar and Guha also give a 4-approximation for the k-median problem by building on the techniques of Jain and Vazirani [17].

1.3. Contributions. Algorithms for problems in discrete location theory arise in many practical applications; see [7, 25], for example, for numerous pointers to the literature. Given that many of these problems are $\mathcal{NP}$-hard, it is desirable to

develop fast approximation algorithms. As mentioned above, it is not uncommon for approximation algorithms to be based on a greedy approach. In this paper, we show that greedy strategies yield a fast constant-factor approximation algorithm for the facility location problem and a fast constant-competitive algorithm for the online median problem.

We give an algorithm for the facility location problem that achieves an approximation ratio of 3 and runs in $O(n^2)$ time (i.e., time linear in the size of the input). The main idea of the algorithm is to compute and use the "value" of balls about every point in the metric space. In retrospect, the idea of value is implicit in the work of Jain and Vazirani [17]. We make this idea explicit and use the values of balls to make greedy choices. Additionally, our algorithm is faster than the Jain-Vazirani algorithm by a logarithmic factor.

While a simple greedy algorithm yields a constant-factor approximation bound for the facility location problem, it appears that a more sophisticated approach is needed to obtain a constant-factor approximation guarantee for the k-median problem, let alone a constant-competitiveness result for the online median problem. For example, in section 3, we show that perhaps the most natural greedy approach to the k-median (resp., online median) problem leads to an unbounded approximation (resp., competitive) ratio.

Our main result is a constant-competitive algorithm for the online median problem that runs in time linear in the size of the input. We achieve this result using a "hierarchically greedy" approach. The basic idea behind this approach is as follows: Rather than selecting the next point in the ordering based on a single greedy criterion, we greedily choose a region (the set of points lying within some ball) and then recursively select a point within that region. Thus the choice of point is influenced by a sequence of greedy criteria addressing successively finer levels of granularity.

Finally, we show that our analysis holds for more general classes of distance functions. We study two classes of "approximate" metrics for which the triangle inequality holds only to within a constant factor. We define and study *λ-approximate metrics* and *weakly λ-approximate metrics*. We show that our analysis holds to within constant factors given either of these two classes of distance functions. First, we show that λ-approximate distance functions facilitate an implementation of our online median algorithm running in time linear in the input size. We then show that weakly λ-approximate distance functions allow us to apply our techniques to objective functions other than the k-median objective. For example, we show that the approximation bounds for both of our algorithms hold to within constant factors for the well-known k-means objective function [8].

1.4. Outline. The rest of this paper is organized as follows. In section 2, we present our facility location algorithm and prove that it achieves an approximation ratio of 3. In section 3, we present our online median algorithm and prove that it is constant-competitive. Then, in section 4, we consider a weaker form of the triangle inequality in which we assume that the triangle inequality holds only to within a constant factor and show that our approximation bounds still hold (to within constant factors). Section 5 offers some concluding remarks.

2. Facility location. The following definitions are used throughout the present section as well as section 3.

(i) For any nonnegative integer m, let $[m]$ denote the set $\{i \mid 0 \leq i < m\}$.

(ii) A *ball* A is a pair (x, r), where the *center* x of A, denoted *center*(A), belongs to U, and the *radius* r of A, denoted *radius*(A), is a nonnegative real.

(iii) Given a ball $A = (x, r)$, we let *Points*(A) denote the set $\{y \in U \mid d(x, y) \leq r\}$. However, for the sake of brevity, we tend to write A instead of *Points*(A). For example, we write "$x \in A$" and "$A \cup B$" instead of "$x \in$ *Points*(A)" and "*Points*$(A) \cup$ *Points*(B)," respectively.

(iv) The *value* of a ball $A = (x, r)$, denoted *value*(A), is $\sum_{y \in A}(r - d(x, y)) \cdot w(y)$.

(v) For any ball $A = (x, r)$ and any nonnegative real c, we define cA as the ball (x, cr).

2.1. Algorithm. In the first step of the following algorithm, we assume that there is at least one point x such that $w(x) > 0$. (The problem is trivial otherwise.) The output of the algorithm is the configuration Z_n, which we also refer to as Z. (Remark: The indexing of the sets Z_i has been introduced solely to facilitate the analysis.)

1. For each point x, determine a ball $A_x = (x, r_x)$ such that *value*$(A_x) = f(x)$.
2. Determine a bijection $\varphi : [n] \to U$ such that $r_{\varphi(i-1)} \leq r_{\varphi(i)}$, $0 < i < n$.
3. Let $B_i = (x_i, r_i)$ denote the ball $A_{\varphi(i)}$, $0 \leq i < n$. Let $Z_0 = \emptyset$.
4. For $i = 0$ to $n - 1$: If $Z_i \cap 2B_i = \emptyset$, then let $Z_{i+1} = Z_i \cup \{x_i\}$; otherwise, let $Z_{i+1} = Z_i$.

We now sketch a simple $O(n^2)$-time implementation of the above algorithm. For each point x, the associated radius r_x can be computed in $O(n)$ time. (This is essentially a weighted selection problem.) Thus the first step requires $O(n^2)$ time. The second step involves sorting n values and can be accomplished in $O(n \log n)$ time. The running time for the third step is negligible. Each iteration of the fourth step can be easily implemented in $O(n)$ time; thus the time complexity of the fourth step is $O(n^2)$.

2.2. Approximation ratio. In this section, we establish the following theorem.

THEOREM 2.1. *For any configuration X, cost$(Z) \leq 3 \cdot$ cost(X).*

Proof. The proof is immediate from Lemmas 2.4 and 2.8 below. □

LEMMA 2.2. *For any point x_i, there exists a point x_j in Z such that $j \leq i$ and $d(x_i, x_j) \leq 2r_i$.*

Proof. If there is no such point x_j with $j < i$, then $Z_i \cap 2B_i$ is empty, and so x_i belongs to Z. □

LEMMA 2.3. *Let x_i and x_j be distinct points in Z. Then $d(x_i, x_j) > 2 \cdot \max\{r_i, r_j\}$.*

Proof. Assume without loss of generality that $j < i$. Thus $r_i \geq r_j$. Furthermore, $d(x_i, x_j) > 2r_i$ since x_j belongs to Z_i and $Z_i \cap 2B_i$ is empty. □

For any point x and any configuration X, let

$$\mathit{charge}(x, X) = d(x, X) + \sum_{x_i \in X} \max\{0, r_i - d(x_i, x)\}.$$

LEMMA 2.4. *For any configuration X, $\sum_{x \in U}$ charge$(x, X) \cdot w(x) =$ cost(X).*

Proof. Note that

$$\begin{aligned}\sum_{x \in U} \mathit{charge}(x, X) \cdot w(x) &= \sum_{x_i \in X} \sum_{x \in B_i} (r_i - d(x_i, x)) \cdot w(x) + \sum_{x \in U} d(x, X) \cdot w(x) \\ &= \sum_{x_i \in X} \mathit{value}(B_i) + \sum_{x \in U} d(x, X) \cdot w(x),\end{aligned}$$

which is equal to *cost*(X) since *value*$(B_i) = f(x_i)$. □

LEMMA 2.5. *Let x be a point, let X be a configuration, and let x_i belong to X. If $d(x, x_i) = d(x, X)$, then charge$(x, X) \geq \max\{r_i, d(x, x_i)\}$.*

Proof. If x does not belong to B_i, then $charge(x, X) \geq d(x, x_i) > r_i$. Otherwise, $charge(x, X) \geq d(x, x_i) + (r_i - d(x, x_i)) = r_i \geq d(x, x_i)$. □

LEMMA 2.6. *Let x be a point, and let x_i belong to Z. If x belongs to B_i, then $charge(x, Z) \leq r_i$.*

Proof. By Lemma 2.3, there is no point x_j in Z such that $i \neq j$ and x belongs to B_j. The claim now follows from the definition of $charge(x, Z)$, since $d(x, Z) \leq d(x, x_i)$. □

LEMMA 2.7. *Let x be a point, and let x_i belong to Z. If x does not belong to B_i, then $charge(x, Z) \leq d(x, x_i)$.*

Proof. The claim is immediate unless there is a point x_j in Z such that x belongs to B_j. If such a point x_j exists, then Lemmas 2.3 and 2.6 imply $d(x_i, x_j) > 2 \cdot \max\{r_i, r_j\}$ and $charge(x, Z) \leq r_j$, respectively. The claim now follows since $d(x, x_i) \geq d(x_i, x_j) - d(x, x_j) > 2r_j - r_j = r_j$. □

LEMMA 2.8. *For any point x and configuration X, $charge(x, Z) \leq 3 \cdot charge(x, X)$.*

Proof. Let x_i be some point in X such that $d(x, x_i) = d(x, X)$. By Lemma 2.2, there exists a point x_j in Z such that $j \leq i$ and $d(x_i, x_j) \leq 2r_i$.

If x belongs to B_j, then $charge(x, Z) \leq r_j$ by Lemma 2.6. The claim follows since $j \leq i$ implies $r_j \leq r_i$ and Lemma 2.5 implies $charge(x, X) \geq r_i$.

If x does not belong to B_j, then $charge(x, Z) \leq d(x, x_j)$ by Lemma 2.7. Thus $charge(x, Z) \leq d(x, x_i) + d(x_i, x_j) \leq d(x, x_i) + 2r_i$. The claim now follows by Lemma 2.5, since the ratio of $d(x, x_i) + 2r_i$ to $\max\{r_i, d(x, x_i)\}$ is at most 3. □

3. Online median placement. In the previous section, we found that a simple greedy algorithm yields interesting results for the facility location problem. The most obvious greedy algorithm for the online median problem is to select as the next point in the ordering the one that minimizes the objective function. Unfortunately, this algorithm gives an unbounded competitive (resp., approximation) ratio for the online median (resp., k-median) problem. To see this, consider an instance consisting of $n > 3$ points, one "red" and the rest "blue," such that the following conditions are satisfied: the red point has weight 0; each blue point has weight 1; the distance from the red point to any blue point is 1, and the distance between any pair of distinct blue points is 2. The aforementioned greedy algorithm chooses the red point first in the ordering, since that gives a cost of $n - 1$, while choosing any other point gives a cost of $2n - 4$. Consequently, the ratio for a configuration of size $n - 1$ is unbounded since the greedy cost is 1 and the optimal cost is 0. (This example also shows that no online median algorithm can achieve a competitive ratio below $2 - \frac{2}{n-1}$.)

We show that a more careful choice of the point, which we call hierarchically greedy, works well. Let Δ (resp., δ) denote the largest (resp., smallest) distance between two distinct points in the metric space. We define a certain ball about each point and select a ball A of maximum value. However, rather than simply choosing the center of ball A as the next point in the ordering, we apply the approach recursively to select a point within a region defined by A. At each successive level of recursion, we consider geometrically smaller balls about the remaining candidate points. Within $O(\log \frac{\Delta}{\delta})$ levels of recursion, we arrive at a ball containing a single point, and we return this point as the next one in the ordering. Note that whereas the greedy algorithm discussed in the previous paragraph makes a single greedy choice to select a point, the hierarchically greedy algorithm makes $O(\log \frac{\Delta}{\delta})$ greedy choices per point.

Throughout this section, let λ, α, β, and γ denote real numbers satisfying the following inequalities:

$$\lambda \geq 1, \tag{1}$$

$$\alpha > 1 + \lambda, \tag{2}$$

$$\beta \geq \frac{\lambda(\alpha - 1)}{\alpha - 1 - \lambda}, \tag{3}$$

$$\gamma \geq \left(\frac{\alpha^2 \beta + \alpha\beta}{\alpha - 1} + \alpha \right) \lambda. \tag{4}$$

The online median algorithm of section 3.1 below makes use of the following additional definitions.

(i) A *child* of a ball (x, r) is any ball $(y, \frac{r}{\alpha})$, where $d(x, y) \leq \beta r$.

(ii) For any point x and configuration X, let $\mathit{isolated}(x, X)$ denote the ball $(x, d(x, X)/\gamma)$. We let $\mathit{isolated}(x, \emptyset)$ denote the ball $(x, \max_{y \in U} d(x, y))$.

(iii) For any nonempty sequence ϱ, we let $\mathit{head}(\varrho)$ (resp., $\mathit{tail}(\varrho)$) denote the first (resp., last) element of ϱ.

3.1. Algorithm. Let $Z_0 = \emptyset$. For $i = 0$ to $n - 1$, execute the following steps:

1. Let σ_i denote the singleton sequence $\langle A \rangle$, where A is a maximum value ball in $\{\mathit{isolated}(x, Z_i) \mid x \in U \setminus Z_i\}$.

2. While the ball $\mathit{tail}(\sigma_i)$ has more than one child, append a maximum value child of $\mathit{tail}(\sigma_i)$ to σ_i.

3. Let $Z_{i+1} = Z_i \cup \{\mathit{center}(\mathit{tail}(\sigma_i))\}$.

The output of the online median algorithm is a collection of point sets Z_i such that $|Z_i| = i$, $0 \leq i \leq n$, and $Z_i \subseteq Z_{i+1}$, $0 \leq i < n$. Note that it is sufficient for an implementation of the algorithm to maintain the ball $\mathit{tail}(\sigma_i)$ as opposed to the entire sequence σ_i. The sequence σ_i has been introduced in order to facilitate the analysis.

We discuss two implementations of the online median algorithm in section 3.4. The first implementation has a running time that is slightly superlinear in the input size. The second implementation has a running time that is linear in the input size but assumes a (linear) preprocessing phase in which all distances are rounded down to the nearest integral power of λ. (Note that for the preprocessing phase to be well defined, we require $\lambda > 1$.) If the input distance function is a metric, it is straightforward to see that such rounding produces a λ-approximate metric.

3.2. Competitive ratio. Before proceeding with the analysis, we introduce a number of additional definitions.

(i) Let z_i denote the unique point in $Z_{i+1} \setminus Z_i$, $0 \leq i < n$.

(ii) For any configuration X and set of points Y, let $\mathit{cost}(X, Y) = \sum_{y \in Y} d(y, X) \cdot w(y)$.

(iii) For any configuration X, we partition U into $|X|$ sets $\{\mathit{cell}(x, X) \mid x \in X\}$ as follows: For each point y in U, we choose a point x in X such that $d(y, X) = d(y, x)$ and add y to $\mathit{cell}(x, X)$.

(iv) For any configuration X, point x in X, and set of points Y, we define $\mathit{in}(x, X, Y)$ as $\mathit{cell}(x, X) \cap \mathit{isolated}(x, Y)$ and $\mathit{out}(x, X, Y)$ as $\mathit{cell}(x, X) \setminus \mathit{in}(x, X, Y)$.

(v) For any configuration X and set of points Y, we let $\mathit{in}(X, Y)$ denote the set $\cup_{x \in X} \mathit{in}(x, X, Y)$ and $\mathit{out}(X, Y)$ denote $U \setminus \mathit{in}(X, Y)$.

Note that the $|X|$ sets $\mathit{cell}(x, X)$, $x \in X$, partition U by assigning each point in U to its closest point in X, breaking ties arbitrarily. The sets $\mathit{in}(x, X, Y)$ and $\mathit{out}(x, X, Y)$ partition the set $\mathit{cell}(x, X)$ into two disjoint sets. In our arguments, we will consider the sets $\mathit{in}(x, X, Z_{|X|})$ and $\mathit{out}(x, X, Z_{|X|})$ for $x \in X$, where X is an arbitrary configuration.

We note that the set $\mathit{out}(x, X, Z_{|X|})$ corresponds to the points in $\mathit{cell}(x, X)$ that are "outside" the ball $\mathit{isolated}(x, Z_{|X|})$. That is, if $\mathit{isolated}(x, Z_{|X|})$ has radius r,

then by the definition of $isolated(x, Z_{|X|})$, the points contained in $out(x, X, Z_{|X|})$ are exactly the points in $cell(x, X)$ that have distance greater than r to x but distance at most γr to some point in $Z_{|X|}$. Thus we can view the points in $out(x, X, Z_{|X|})$ as the points that are "close" to $Z_{|X|}$ and "far" from X. For any point y in $out(X, Z_{|X|})$, it is relatively straightforward (see Lemma 3.2) to show that $d(y, Z_{|X|})$ (i.e., the distance to the configuration $Z_{|X|}$ computed by our online median algorithm) is within a constant factor of $d(y, X)$.

We devote considerably more effort to showing that the cost incurred by $Z_{|X|}$ to serve the set $in(x, X, Z_{|X|})$ is within a constant factor of optimal. The set $in(x, X, Z_{|X|})$ corresponds to the points in $cell(x, X)$ that are contained in the ball $isolated(x, Z_{|X|})$. Suppose that $isolated(x, Z_{|X|})$ has radius r. By the definition of $isolated(x, Z_{|X|})$, the points contained in $in(x, X, Z_{|X|})$ are exactly the points in $cell(x, X)$ that are in the ball (x, r) but have distance strictly greater than γr to any point in $Z_{|X|}$. Thus the points in $in(x, X, Z_{|X|})$ are those points in $cell(x, X)$ that are "close" to X and "far" from $Z_{|X|}$. Accounting for the cost incurred by $Z_{|X|}$ for the points $in(X, Z_{|X|})$ will comprise the majority of the proofs in this subsection and the following subsection.

We now present our main result, Theorem 3.1. In order to minimize the competitive ratio of $2\lambda(\gamma + 1)$ implied by the theorem, we set λ to 1, set α to $2 + \sqrt{3}$, and set β and γ to the right-hand sides of (3) and (4), respectively. We thereby establish a competitive ratio of below 29.86 for the online median problem. In section 3.4, we describe an implementation of the online median algorithm for which the parameter λ is required to be strictly greater than 1. The degradation in the competitive ratio that results by setting λ greater than 1 can be made arbitrarily small by choosing λ sufficiently close to 1.

THEOREM 3.1. *For any configuration X, $cost(Z_{|X|}) \leq 2\lambda(\gamma + 1) \cdot cost(X)$.*

Proof. Let $Y = in(X, Z_{|X|})$, and let $Y' = out(X, Z_{|X|}) = U \setminus Y$. Note that $cost(X) = cost(X, Y) + cost(X, Y')$ and $cost(Z_{|X|}) = cost(Z_{|X|}, Y) + cost(Z_{|X|}, Y')$. Thus the theorem follows immediately from Lemmas 3.3, 3.5, and 3.6 below. ∎

LEMMA 3.2. *For any configuration X, and points x in X and y in $out(x, X, Z_{|X|})$, $d(y, Z_{|X|}) \leq \lambda(\gamma + 1) \cdot d(y, X)$.*

Proof. Let $isolated(x, Z_{|X|}) = (x, r)$. Note that $d(x, y) > r$. Also, by the definition of $isolated(x, Z_{|X|})$, there is a point z in $Z_{|X|}$ such that $d(x, z) = \gamma r$. Hence $d(y, z) \leq \lambda[d(x, y) + d(x, z)] = \lambda[d(x, y) + \gamma r] < \lambda[d(x, y) + \gamma \cdot d(x, y)] = \lambda(\gamma + 1) \cdot d(x, y) = \lambda(\gamma+1) \cdot d(y, X)$, where the last step follows since y is in $cell(x, X)$. The claim follows since $d(y, z) \geq d(y, Z_{|X|})$. ∎

LEMMA 3.3. *For any configuration X, $cost(Z_{|X|}, out(X, Z_{|X|}))$ is at most $\lambda(\gamma + 1) \cdot cost(X, out(X, Z_{|X|}))$.*

Proof. Summing the inequality of Lemma 3.2 over all y in $out(x, X, Z_{|X|})$, we obtain

$$cost(Z_{|X|}, out(x, X, Z_{|X|})) \leq \lambda(\gamma + 1) \cdot cost(X, out(x, X, Z_{|X|})).$$

The claim now follows by summing the above inequality over all x in X. ∎

LEMMA 3.4. *For any configuration X and point x in X, $cost(Z_{|X|}, in(x, X, Z_{|X|}))$ is at most $\lambda(\gamma + 1)[cost(X, in(x, X, Z_{|X|})) + value(isolated(x, Z_{|X|}))]$.*

Proof. Assume that $isolated(x, Z_{|X|}) = (x, r)$. Note that $d(x, y) = \gamma r$ for some y in $Z_{|X|}$. Thus, for any z in $isolated(x, Z_{|X|})$, $d(y, z) \leq \lambda[d(y, x) + d(x, z)] \leq \lambda(\gamma + 1)r$, where the last step follows from our bound on $d(x, y)$ and the definition of $isolated(x, Z_{|X|})$. It follows that $cost(Z_{|X|}, in(x, X, Z_{|X|}))$ is at most $\lambda(\gamma + 1)$

times

$$\sum_{z \in in(x,X,Z_{|X|})} r \cdot w(z) \leq \sum_{z \in in(x,X,Z_{|X|})} d(x,z) \cdot w(z) + \sum_{z \in isolated(x,Z_{|X|})} (r - d(x,z)) \cdot w(z)$$
$$= cost(X, in(x, X, Z_{|X|})) + value(isolated(x, Z_{|X|})). \qquad \square$$

LEMMA 3.5. *For any configuration X and point x in X, $cost(Z_{|X|}, in(X, Z_{|X|}))$ is at most $\lambda(\gamma+1)[cost(X, in(X, Z_{|X|})) + \sum_{x \in X} value(isolated(x, Z_{|X|}))]$.*

Proof. The claim follows by summing the inequality of Lemma 3.4 over all x in X. $\square$

Our main technical lemma is stated below. The proof is given in the next subsection.

LEMMA 3.6. *For any configuration X,*

$$\sum_{x \in X} value(isolated(x, Z_{|X|})) \leq cost(X).$$

3.3. Proof of Lemma 3.6. In this section, we establish our main technical lemma, Lemma 3.6. Informally, Lemma 3.6 yields an upper bound on the value of certain balls containing points "far" from $Z_{|X|}$, where X is an arbitrary configuration. The upper bound we obtain states that the value associated with these points is at most $cost(X)$. Thus, in combination with Lemmas 3.3 and 3.5, we can conclude that $cost(Z_{|X|})$ is $O(cost(X))$. To prove Lemma 3.6, we argue that for each ball $isolated(x, Z_{|X|})$, it is possible to identify a ball with commensurately high value that does not contain a point from X. More precisely, we construct a matching between the points in $Z_{|X|}$ and X and show that for each point x in $X \setminus Z_{|X|}$ we can identify a ball A_x appearing in some sequence $\sigma_i < |X|$ such that $value(A_x) \geq isolated(x, Z_{|X|})$, $cost(X, A_x) \geq value(A_x)$, and all such balls A_x are disjoint. Intuitively, we will identify these balls by making use of the greedy manner in which our online median algorithm constructs the sequences of balls σ_i, $0 \leq i < |X|$.

LEMMA 3.7. *Let $A = (x, r)$ belong to σ_i. Then $d(x, Z_i) \geq \gamma r$.*

Proof. Let z be a point in Z_i such that $d(x,z) = d(x, Z_i)$. If $A = head(\sigma_i)$, then $A = isolated(x, Z_i)$, and the result is immediate. Otherwise, let $B = (y, s)$ denote the predecessor of A in σ_i, and assume inductively that $d(y, Z_i) \geq \gamma s$. Note that $d(x,y) \leq \beta s$ and $s = \alpha r$. Thus $d(x, Z_i) = d(x,z) \geq d(y,z)/\lambda - d(x,y) \geq (\gamma/\lambda - \beta)\alpha r \geq \gamma r$, where the last step follows from (4). $\square$

LEMMA 3.8. *Let $A = (x, r)$ belong to σ_i, and let $B = (y, s)$ belong to σ_j. If $i < j$ and $d(x,y) \leq r + s$, then the following claims hold:* (i) *$radius(head(\sigma_j)) \leq \frac{r}{\alpha}$;* (ii) *$A \neq tail(\sigma_i)$;* (iii) *the successor of A in σ_i (call it C) satisfies $value(C) \geq value(head(\sigma_j))$.*

Proof. Let $head(\sigma_j) = (y', s')$. For part (i), we begin by deriving upper and lower bounds on $d(y', z_i)$. For a lower bound on $d(y', z_i)$, note that $d(y', z_i) \geq d(y', Z_j)$ (since $i < j$) and $d(y', Z_j) \geq \gamma s'$ by Lemma 3.7. To derive an upper bound on $d(y', z_i)$, we first let P denote the prefix of sequence σ_j ending with ball B, and we let S denote the suffix of sequence σ_i beginning with ball A. We then apply the λ-approximate triangle inequality to the sequence of points $\langle y', \ldots, y, x, \ldots, z_i \rangle$, where the prefix $\langle y', \ldots, y \rangle$ corresponds to the centers of the balls in P and the suffix $\langle x, \ldots, z_i \rangle$ corresponds to the centers of the balls in S. By repeated application of the definition of a child, and using the given upper bound on $d(x,y)$, we obtain

$$d(y', z_i) \leq \lambda \left[\beta \left(s' + \frac{s'}{\alpha} + \cdots + \alpha s \right) + s + r + \beta \left(r + \frac{r}{\alpha} + \cdots \right) \right]$$

$$\leq \left[\frac{\alpha\beta}{\alpha-1}\cdot(r+s')+r\right]\lambda.$$

Combining the bounds on $d(y', z_i)$ and applying (4), we obtain

$$\left(\frac{\alpha^2\beta+\alpha\beta}{\alpha-1}+\alpha\right)\lambda s' \leq \left[\frac{\alpha\beta}{\alpha-1}\cdot(r+s')+r\right]\lambda.$$

Multiplying through by $(\alpha-1)/\lambda$ and rearranging, we get $r \geq \frac{\alpha^2\beta+\alpha^2-\alpha}{\alpha\beta+\alpha-1}\cdot s' = \alpha s'$, establishing the claim.

For part (ii), note that $d(x,y) \leq r + \frac{r}{\alpha} < \beta r$ by part (i) and (3). Thus A has at least two children; the claim follows.

For part (iii), we obtain an upper bound on $d(x, y')$ by applying the λ-approximate triangle inequality to the sequence of points $\langle y', \ldots, y, x\rangle$, where the prefix $\langle y', \ldots, y\rangle$ corresponds to the centers of the balls in P (as defined in part (i) above). By repeated application of the definition of a child and by the given upper bound on $d(x,y)$, we observe that

$$d(x,y') \leq \lambda\left[r+s+\left(\alpha s+\alpha^2 s+\cdots+s'\right)\beta\right].$$

Then, by using (2) and (3) and part (i), we observe that

$$\begin{aligned}\lambda\left[r+s+\left(\alpha s+\alpha^2 s+\cdots+s'\right)\beta\right] &\leq \lambda r+\frac{\alpha\beta\lambda}{\alpha-1}\cdot s'\\ &\leq \lambda r+\frac{\alpha\beta\lambda}{\alpha-1}\cdot\frac{r}{\alpha}\\ &\leq \left(\frac{\beta}{\alpha-1}+1\right)\lambda r.\end{aligned}$$

Observe that $(\frac{\beta}{\alpha-1}+1)\lambda r$ is at most βr by (3). It then follows that $head(\sigma_j)$ is contained in a child of A. Thus $value(C) \geq value(head(\sigma_j))$. □

For ease of notation, throughout the remainder of this section, we fix a configuration X, and let k denote $|X|$. We now describe a *pruning procedure* that we use for the purpose of analyzing our online median algorithm. The pruning procedure takes as input the k sequences σ_i, $0 \leq i < k$, and produces as output k sequences τ_i, $0 \leq i < k$. The sequence τ_i is initialized to σ_i, $0 \leq i < k$. The (nondeterministic) pruning procedure then performs a number of iterations. In a general iteration, the pruning procedure checks whether there exist two balls $A = (x, r)$ and $B = (y, s)$ in distinct sequences τ_i and τ_j, respectively, such that $i < j$ and $d(x,y) \leq r + s$. If not, the pruning procedure terminates. If so, the sequence τ_i is redefined as the proper suffix of (the current) τ_i beginning at the successor of A. Note that part (ii) of Lemma 3.8 ensures that the pruning procedure is well defined. Furthermore, the procedure is guaranteed to terminate since each iteration reduces the length of some sequence τ_i.

LEMMA 3.9. *Let $A = (x, r)$ belong to τ_i, and let $B = (y, s)$ belong to τ_j. If $i < j$, then $d(x,y) > r + s$.*

Proof. The proof is immediate from the definition of the pruning procedure. □

LEMMA 3.10. *Each sequence τ_i is nonempty.*

Proof. The proof is immediate from part (ii) of Lemma 3.8 and the definition of the pruning procedure. □

LEMMA 3.11. *Let x be a point, and assume that $0 \leq i < j \leq n$. Then*

$$value(isolated(x, Z_i)) \geq value(isolated(x, Z_j)).$$

Proof. Since $Z_i \subseteq Z_j$, $radius(isolated(x, Z_i)) \geq radius(isolated(x, Z_j))$. The claim follows. ∎

LEMMA 3.12. *Let x be a point, and assume that $0 \leq i < k$. Then*

$$value(head(\sigma_i)) \geq value(isolated(x, Z_k)).$$

Proof. If x belongs to Z_i, then $radius(isolated(x, Z_i)) = 0$. It follows that $value(isolated(x, Z_i)) = 0$, and there is nothing to prove. Otherwise, $value(head(\sigma_i)) \geq value(isolated(x, Z_i))$ by the definition of the online median algorithm, and the claim follows by Lemma 3.11. ∎

LEMMA 3.13. *Let x be a point, and assume that $0 \leq i < k$. Then*

$$value(head(\tau_i)) \geq value(isolated(x, Z_k)).$$

Proof. We prove that the claim holds before and after each iteration of the pruning procedure. Initially, $\tau_i = \sigma_i$, and the claim holds by Lemma 3.12. If the claim holds before an iteration of the pruning procedure, then it holds after the iteration by part (iii) of Lemma 3.8. ∎

A ball $A = (x, r)$ is defined to be *covered* iff $d(x, X) < r$. A ball is *uncovered* iff it is not covered.

LEMMA 3.14. *For any uncovered ball $A = (x, r)$, $cost(X, A) \geq value(A)$.*

Proof. Note that $cost(X, A) \geq \sum_{y \in A} d(y, X) \cdot w(y) \geq \sum_{y \in A} (r - d(y, x)) \cdot w(y) = value(A)$. ∎

Let I denote the set of all indices i in $[k]$ such that some ball in τ_i is covered. We now construct a matching between the sets $[k]$ and X as follows. First, for each i in I, we match i with a point x in X that belongs to the last covered ball in the sequence τ_i. (Note that such a point x is guaranteed to exist by the definition of I. Furthermore, Lemma 3.9 ensures that we do not match the same point with more than one index.) Second, for each i in $[k] \setminus I$ in turn, we match i with an arbitrary unmatched point x in X.

We now construct a function φ mapping each point x in X to an uncovered ball. For each x in X that is matched with an index i in $[k] \setminus I$, we set $\varphi(x)$ to $head(\tau_i)$. For each x in X that is matched with an index i in I, we set $\varphi(x)$ to the successor of the last covered ball in τ_i unless $tail(\tau_i)$ is covered, in which case we set $\varphi(x)$ to the ball $(x, 0)$.

LEMMA 3.15. *For any pair of distinct points x and y in X, $\varphi(x) \cap \varphi(y) = \emptyset$.*

Proof. The proof is immediate from Lemma 3.9 and the fact that the ball $(x, 0)$ is contained in $tail(\tau_i)$. ∎

LEMMA 3.16. *For any point x in X, $value(\varphi(x)) \geq value(isolated(x, Z_k))$.*

Proof. If x is matched with an index i in $[k] \setminus I$, the claim follows by Lemma 3.13. If x is matched with an index i in I, we consider two cases. If $tail(\tau_i)$ is covered, then $x = z_i$ since $tail(\tau_i)$ has exactly one child. The claim follows since $\varphi(x) = isolated(x, Z_k) = (x, 0)$. If $tail(\tau_i)$ is uncovered, then the predecessor of $\varphi(x)$ in τ_i (call it $A = (y, r)$) exists and contains x. It follows that $value(\varphi(x)) \geq value(B)$, where $B = (x, r/\alpha)$ is the child of A centered at x. Let $C = (x, s)$ denote the ball $isolated(x, Z_k)$. Below we complete the proof of the claim by showing that $r/\alpha \geq s$, which implies that $B \supseteq C$ and hence $value(B) \geq value(C)$.

It remains to prove that $r/\alpha \geq s$ in the final case considered above. We prove the claim by deriving upper and lower bounds on $d(x, z_i)$. Let S be the suffix of the sequence τ_i beginning with the ball A. For the upper bound, we apply the triangle inequality to the sequence of points $\langle x, y, \ldots, z_i \rangle$, where the suffix $\langle y, \ldots, z_i \rangle$ consists of the centers of the balls in S. We then obtain that

$$\begin{aligned} d(x, z_i) &\leq \lambda \left(r + \beta \left(r + \frac{r}{\alpha} + \cdots \right) \right) \\ &\leq \left(1 + \frac{\alpha\beta}{\alpha - 1} \right) \lambda r, \end{aligned}$$

which is less than $\gamma r/\alpha$ by (4). The desired inequality follows since $d(x, z_i) \geq \gamma s$ by the definition of C. □

Lemmas 3.14, 3.15, and 3.16 together yield a proof of Lemma 3.6.

3.4. Time complexity. In this section, we describe two implementations of the online median algorithm given in section 3.1. Throughout this section, let ℓ denote the quantity $\log \frac{\Delta}{\delta}$. The first implementation runs in $O((n+\ell) \cdot n \log n)$ time. The second implementation runs in $O(n^2 + \ell n)$ time and assumes an $O(n^2)$-time preprocessing phase in which all distances are rounded down to the nearest integral power of λ. To analyze the running time of the implementations given below, we make use of the following lemma.

LEMMA 3.17. *Let $A = (x, r)$ be a child of a ball B in sequence σ_i, and let $A' = (x, r')$ be a child of a ball B' in sequence σ_j. If $i < j$, then $r \geq (\alpha + 1 + \frac{1}{\beta})r'$.*

Proof. We first obtain an upper bound on $d(x, z_i)$ by applying the λ-approximate triangle inequality to a sequence of points consisting of the centers of the balls in the suffix of σ_i beginning with ball A. Thus $d(x, z_i) \leq \lambda\beta\,(r + r/\alpha + \cdots) \leq \lambda\alpha\beta r/(\alpha - 1)$. By Lemma 3.7 and since $j > i$, we get that $\gamma r' \leq d(x, Z_j) \leq d(x, z_i)$. Combining these inequalities and using (4), we obtain

$$\begin{aligned} r &\geq \frac{(\alpha - 1)\gamma}{\lambda\alpha\beta} \cdot r' \\ &\geq \frac{\alpha - 1}{\alpha\beta} \cdot \left(\frac{\alpha^2\beta + \alpha\beta}{\alpha - 1} + \alpha \right) \lambda \cdot r' \\ &= \left(\alpha + 1 + \frac{1}{\beta} \right) r'. \qquad \square \end{aligned}$$

In the first implementation, for each point x in U, we sort the remaining points by their distance from x. The total sorting time is $O(n^2 \log n)$. Using these sorted arrays, we can compute the value of any given ball in $O(\log n)$ time. We also maintain the distance from x to the nearest point in Z_i. Note that $d(x, Z_{i+1})$ can be determined in constant time given $d(x, Z_i)$ and z_i. The total time to maintain such distances is thus $O(n^2)$. It follows that the first step of each iteration can be implemented in $O(n)$ time. The total time for the second step is $O(\log n)$ times the sum over all balls A appearing in some sequence σ_i, $0 \leq i < n$, of the number of children of A. By Lemma 3.17, it is straightforward to see that the latter sum is $O(\ell n)$, and thus the total time for the second step is $O(\ell n \log n)$. The running time of the third step is negligible. Thus the running time of the first implementation is $O((n + \ell) \cdot n \log n)$, as claimed above.

For the second implementation, note that after the preprocessing phase, there are $O(\ell)$ distinct distances. Thus, for each point x, $O(n+\ell)$ time is sufficient to construct

an $O(\ell)$-sized table that can be used to compute the value of any ball (x, r) in $O(1)$ time. It follows that the total time for the second step can be improved to $O(\ell n)$. The running time of the second implementation is therefore $O(n^2 + \ell n)$, which is linear in the size of the input (in bits).

4. Weakly λ-approximate metrics. The analysis in section 3 of this paper assumes that the (nonnegative, symmetric) distance function d approximately satisfies the triangle inequality. Recall that we defined a "λ-approximate" triangle inequality for $\lambda \geq 1$ as follows: For any sequence of points $x_0, \ldots, x_m$ in U, $d(x_0, x_m) \leq \lambda \cdot \sum_{0 \leq i < m} d(x_i, x_{i+1})$. We refer to such a distance function as a *λ-approximate metric*.

In this section, we show that the analysis in both sections 2 and 3 holds to within constant factors for an even weaker form of the triangle inequality. We say that a distance function d satisfies a "weakly λ-approximate" triangle inequality if, for any x, y, and z, $d(x, z) \leq \lambda(d(x, y) + d(y, z))$. We note that this inequality has been studied previously and is also referred to as the relaxed triangle inequality [10], the parameterized triangle inequality [1], and the λ-triangle inequality [9]. We will say that a distance function satisfying this inequality is a *weakly λ-approximate metric*. We will make use of such distance functions to extend our results to other objective functions. For example, the well-known k-means heuristic [8] has a sum of squared distances in its objective function. It is straightforward to show that squaring the distances in a metric yields a weakly 2-approximate metric. Thus the results in this section show that our analysis also holds, to within constant factors, with respect to the k-means objective function. (Remark: More generally, it is not hard to show that raising the distances in a metric to any constant power yields a weakly $O(1)$-approximate metric.)

Lemmas 4.1 and 4.2 establish that the approximation results in this paper hold, up to constant factors, even for weakly λ-approximate metrics. Recall that, in sections 2 and 3, we make use of the triangle inequality and the λ-approximate triangle inequality on sequences of points to derive upper bounds on the distances between pairs of points. In most cases, we consider constant-length sequences of points to derive our upper bounds. In such cases, Lemma 4.1 shows that a weakly λ-approximate metric is sufficient to guarantee that our upper bounds hold to within constant factors. Unfortunately, Lemma 4.1 alone is not sufficient to generalize our upper bounds based on nonconstant-length sequences of points, which arise in Lemmas 3.8, 3.16, and 3.17. For these cases, we require Lemma 4.2. Lemmas 4.1 and 4.2 together show that the upper bounds derived in Lemmas 3.8, 3.16, and 3.17 still hold up to constant factors given only a weakly λ-approximate triangle inequality.

LEMMA 4.1. *Let d be a weakly λ-approximate metric, and let $x_0, x_1, \ldots, x_m$ be points with $m \geq 1$. Then $d(x_0, x_m) \leq \lambda^{\lceil \log_2 m \rceil} \cdot \sum_{0 \leq i < m} d(x_i, x_{i+1})$.*

Proof. We will prove the lemma by induction. The base case, $m = 1$, is trivial. For the induction step, assume that for any sequence of points $y_0, \ldots, y_i$, $1 \leq i < m$, $d(y_0, y_i) \leq \lambda^{\lceil \log_2 i \rceil} \sum_{0 \leq j < i} d(y_j, y_{j+1})$. Then

$$
\begin{aligned}
d(x_0, x_m) &\leq \lambda \left(d(x_0, x_{\lceil \frac{m}{2} \rceil}) + d(x_{\lceil \frac{m}{2} \rceil}, x_m) \right) \\
&\leq \lambda \left(\lambda^{\lceil \log_2 \lceil \frac{m}{2} \rceil \rceil} \left(\sum_{0 \leq j < \lceil \frac{m}{2} \rceil} d(x_j, x_{j+1}) \right) + \lambda^{\lceil \log_2 \lfloor \frac{m}{2} \rfloor \rceil} \sum_{\lceil \frac{m}{2} \rceil \leq j < m} d(x_j, x_{j+1}) \right) \\
&\leq \lambda \cdot \lambda^{\lceil \log_2 m \rceil - 1} \sum_{0 \leq j < m} d(x_j, x_{j+1})
\end{aligned}
$$

$$= \lambda^{\lceil \log_2 m \rceil} \sum_{0 \le j < m} d(x_j, x_{j+1}).$$

The first step follows from the weakly λ-approximate triangle inequality. The second step follows by applying the induction hypothesis twice. (Note that $m \ge 2$ implies that $0 < \lceil \frac{m}{2} \rceil < m$, so the induction hypothesis is applicable.) The last step follows from the fact that $\lceil \log_2 \lceil \frac{m}{2} \rceil \rceil = \lceil \log_2 m \rceil - 1$. □

If λ and m are constant, then Lemma 4.1 implies that $d(x_0, x_m)$ is

$$\Theta\left(\sum_{0 \le i < m} d(x_i, x_{i+1}) \right).$$

Thus Lemma 4.1 is sufficient to show that the upper bounds derived in section 2 using the triangle inequality hold to within a constant factor given only a weakly λ-approximate metric. Similarly, the upper bounds derived in section 3 using the λ-approximate triangle inequality on constant-length sequences of points also hold to within constant factors given only a weakly λ-approximate metric. However, in Lemmas 3.8, 3.16, and 3.17, we derive upper bounds on distances by applying the λ-approximate triangle inequality to nonconstant-length sequences of points that appear in the sequences σ_i associated with our online median algorithm. In these cases, the nonconstant-length sequences of points we consider have the property that they are composed of a constant number of contiguous subsequences in which distances between successive points are either geometrically increasing or geometrically decreasing. Lemma 4.2 shows that the upper bounds derived using these sequences hold to within a constant factor assuming only a weakly λ-approximate metric.

LEMMA 4.2. *Let d be a weakly λ-approximate metric, and let $x_0, x_1, \ldots, x_m$ be points such that for $1 \le i \le m$, $d(x_i, x_{i+1}) \le d(x_{i-1}, x_i)/\xi$ for a positive real $\xi > \lambda$. Then $d(x_0, x_m) \le \frac{\lambda\xi}{\xi - \lambda} d(x_0, x_1)$.*

Proof. We first prove by induction that $d(x_0, x_m) \le \sum_{0 \le i < m} \lambda^{i+1} d(x_i, x_{i+1})$. For the base case, take $m = 1$. Then $d(x_0, x_1) \le \lambda d(x_0, x_1)$ since $\lambda \ge 1$. For the induction step, assume that for any sequence of points $y_0, \ldots, y_i$, $1 \le i < m$, $d(y_0, y_i) \le \sum_{0 \le j < i} \lambda^{j+1} d(y_j, y_{j+1})$. Observe that

$$\begin{aligned} d(x_0, x_m) &\le \lambda \left(d(x_0, x_1) + d(x_1, x_m) \right) \\ &\le \lambda d(x_0, x_1) + \lambda \left(\sum_{1 \le i < m} \lambda^i d(x_i, x_{i+1}) \right) \\ &\le \sum_{0 \le i < m} \lambda^{i+1} d(x_i, x_{i+1}), \end{aligned}$$

where the first step follows from the weakly λ-approximate triangle inequality and the second step follows from the induction hypothesis. Then

$$\begin{aligned} d(x_0, x_m) &\le \sum_{0 \le i < m} \lambda^{i+1} d(x_i, x_{i+1}) \\ &\le \sum_{0 \le i < m} \frac{\lambda^{i+1}}{\xi^i} d(x_0, x_1) \\ &\le \frac{\xi\lambda}{\xi - \lambda} d(x_0, x_1), \end{aligned}$$

where the second step follows from the assumption that $d(x_i, x_{i+1}) \leq d(x_{i-1}, x_i)/\xi$ for $0 \leq i < m$ and the third step follows from the assumption that $\xi > \lambda$. □

As stated above, Lemma 4.2 is needed in addition to Lemma 4.1 to show that the upper bounds derived in Lemmas 3.8, 3.16, and 3.17 hold to within a constant factor given only a weakly λ-approximate metric. We now explain how Lemmas 4.1 and 4.2 may be used to show that the upper bound obtained in part (i) of Lemma 3.8 holds to within a constant factor given a weakly λ-approximate metric. Recall that in part (i) of Lemma 3.8, we derive an upper bound on the distance $d(y', z_i)$. For the argument, we apply the λ-approximate triangle inequality to the sequence of points $\langle y', \ldots, y, x, \ldots, z_i \rangle$ and show that $d(y', z_i)$ is within a constant factor of the sum of the distances between successive points in this sequence. The prefix $\langle y', \ldots, y \rangle$ of this sequence appears in the sequence of balls σ_j associated with our online median algorithm. By the definition of our online median algorithm, the distances between successive points in $\langle y', \ldots, y \rangle$ decrease by a factor of β. Since β and λ are constants, and since $\beta > \lambda$, we can apply Lemma 4.2 with $\xi = \beta$ to conclude that $d(y', y)$ is within a constant factor of the sum of distances between successive points in $\langle y', \ldots, y \rangle$ given only a weakly λ-approximate metric. By a similar application of Lemma 4.2 to $d(x, z_i)$ with $\langle x, \ldots, z_i \rangle$ as the sequence of points, we can conclude that $d(x, z_i)$ is within a constant factor of the sum of distances between successive points in $\langle x, \ldots, z_i \rangle$ given only a weakly λ-approximate metric. With upper bounds on $d(y', y)$ and $d(x, z_i)$, we can then apply Lemma 4.1 to the constant-length sequence $\langle y', y, x, z_i \rangle$ to conclude that, given only a weakly λ-approximate metric, $d(y', z_i)$ is within a constant factor of the sum of distances between successive points in the sequence $\langle y', \ldots, y, x, \ldots, z_i \rangle$. Using Lemmas 4.1 and 4.2 in this manner, the bounds derived in part (iii) of Lemma 3.8 and in Lemmas 3.16 and 3.17 can also be shown to hold to within constant factors given only a weakly λ-approximate metric.

5. Concluding remarks. We plan to investigate whether the ideas presented in this paper can be applied to other problems. Korupolu, Plaxton, and Rajaraman [19] give an algorithm and an efficient distributed implementation for hierarchical cooperative caching in which the distance function is an ultrametric. We would like to see if the hierarchical greedy strategy can be used or extended to solve the cooperative caching problem in an arbitrary metric space. It would also be interesting to see if the hierarchical greedy strategy admits an efficient distributed implementation for this problem.

This paper has focused on the development of fast deterministic algorithms for the facility location problem and the online median problem. It is worth noting that there have been a number of recent results that make use of randomization to obtain fast algorithms for the k-median problem. The first such result was due to Indyk [14]; for the uniform-demand k-median problem, he gives a bicriteria approximation algorithm that uses random sampling and a black-box k-median algorithm. His algorithm has a constant probability of success and runs in $\tilde{O}(nk^3)$ time. (The $\tilde{O}$-tilde notation omits polylogarithmic factors in n and k.) Assuming the existence of an $\tilde{O}(n^2)$-time bicriteria k-median algorithm, this time bound can be reduced to $\tilde{O}(nk)$. Subsequently, Guha et al. obtained an $\tilde{O}(nk)$-time constant-factor approximation algorithm for the k-median problem in the data stream model of computation [13]. More recently, Thorup [27] has obtained a randomized constant-factor approximation algorithm for the k-median problem in a graph setting. For this problem, the interpoint distances are given by a graph on m edges rather than being fully specified in the input. That is, to obtain the distance between two points x and y, we must compute the shortest path

between x and y. Thorup gives an $\tilde{O}(m)$ constant-factor approximation algorithm for this problem. His algorithm implies an $\tilde{O}(nk)$-time algorithm for the version of the k-median problem defined in section 1.

Recently, we have obtained a randomized constant-factor approximation algorithm for the k-median problem that runs in $O(n(k + \log n) + k^2 \log^2 n)$ time under the standard assumption that the point weights and interpoint distances are polynomially bounded [24]. Thus, for k such that $\log n \leq k \leq n/\log^2 n$, our algorithm runs in $O(nk)$ time. Our algorithm succeeds *with high probability*, that is, for any positive constant ξ, we can adjust constant factors in the definition of the algorithm to achieve a failure probability less than $n^{-\xi}$. We also establish a matching $\Omega(nk)$ lower bound on the running time of any randomized constant-factor approximation algorithm for the k-median problem that has even a nonnegligible success probability (e.g., at least $\frac{1}{100}$).

Acknowledgments. The authors would like to thank the anonymous referees for making many helpful comments on the presentation.

A FASTER SCALING ALGORITHM FOR MINIMIZING SUBMODULAR FUNCTIONS*

SATORU IWATA†

Abstract. Combinatorial strongly polynomial algorithms for minimizing submodular functions have been developed by Iwata, Fleischer, and Fujishige (IFF) and by Schrijver. The IFF algorithm employs a scaling scheme for submodular functions, whereas Schrijver's algorithm achieves strongly polynomial bound with the aid of distance labeling. Subsequently, Fleischer and Iwata have described a push/relabel version of Schrijver's algorithm to improve its time complexity. This paper combines the scaling scheme with the push/relabel framework to yield a faster combinatorial algorithm for submodular function minimization. The resulting algorithm improves over the previously best known bound by essentially a linear factor in the size of the underlying ground set.

1. Introduction.

Let V be a finite nonempty set of cardinality n. A set function f on V is *submodular* if it satisfies

$$f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y) \qquad \forall X, Y \subseteq V.$$

Submodular functions are discrete analogues of convex functions [14]. Examples of submodular functions include cut capacity functions, matroid rank functions, and entropy functions.

The first polynomial-time algorithm for submodular function minimization is due to Grötschel, Lovász, and Schrijver [9]. A strongly polynomial algorithm has also been described by Grötschel, Lovász, and Schrijver [10]. These algorithms rely on the ellipsoid method, which is not efficient in practice.

Recently, combinatorial strongly polynomial algorithms have been developed by Iwata, Fleischer, and Fujishige (IFF) [13] and by Schrijver [16]. Both of these algorithms build on works of Cunningham [2, 3]. The IFF algorithm employs a scaling scheme developed in capacity scaling algorithms for the submodular flow problem [7, 11]. In contrast, Schrijver [16] directly achieves a strongly polynomial bound by introducing a novel subroutine in the framework of lexicographic augmentation. Subsequently, Fleischer and Iwata [5, 6] have described a push/relabel algorithm using Schrijver's subroutine to improve the running time bound. In this paper, we combine the scaling scheme with the push/relabel technique to yield a faster combinatorial algorithm.

Let γ denote the time required for computing the function value of f and M denote the maximum absolute value of f. The IFF scaling algorithm minimizes an integral submodular function in $O(n^5\gamma \log M)$ time. The strongly polynomial version

runs in $O(n^7\gamma \log n)$ time, whereas an improved variant of Schrijver's algorithm runs in $O(n^7\gamma + n^8)$ time [6].

The time complexity of our new scaling algorithm is $O((n^4\gamma + n^5)\log M)$. Since the function evaluation oracle has to identify an arbitrary subset of V as its argument, it is natural to assume γ is at least linear in n. With this assumption, the new algorithm is faster than the IFF algorithm by a factor of n. The strongly polynomial version of the new scaling algorithm runs in $O((n^6\gamma + n^7)\log n)$ time. This is an improvement over the previous best bound by essentially a linear factor in n.

These combinatorial algorithms perform multiplications and divisions, although the problem of submodular function minimization does not involve those operations. Schrijver [16] asks if one can minimize submodular functions in strongly polynomial time using only additions, subtractions, comparisons, and oracle calls for the function values. Such an algorithm is called "fully combinatorial." A very recent paper [12] settles this problem by developing a fully combinatorial variant of the IFF algorithm. Similarly, we can implement the strongly polynomial version of our scaling algorithm in a fully combinatorial manner. The resulting algorithm runs in $O(n^8\gamma \log^2 n)$ time, improving the previous $O(n^9\gamma \log^2 n)$ bound by a factor of n.

This paper is organized as follows. Section 2 provides preliminaries on submodular functions. In section 3, we describe the new scaling algorithm. Section 4 is devoted to its complexity analysis. Finally, in section 5, we discuss its extensions as well as a fully combinatorial implementation.

2. Preliminary. This section provides preliminaries on submodular functions. See [8, 14] for more details and general background.

For a vector $x \in \mathbf{R}^V$ and a subset $Y \subseteq V$, we denote $x(Y) = \sum_{u\in Y} x(u)$. We also denote x^- the vector in $\mathbf{R}^V$ with $x^-(u) = \min\{x(u), 0\}$. For each $u \in V$, let χ_u denote the vector in $\mathbf{R}^V$ with $\chi_u(u) = 1$ and $\chi_u(v) = 0$ for $v \in V\backslash\{u\}$.

For a submodular function $f : 2^V \to \mathbf{R}$ with $f(\emptyset) = 0$, we consider the *base polyhedron*

$$\mathrm{B}(f) = \{x \mid x \in \mathbf{R}^V,\ x(V) = f(V),\ \forall Y \subseteq V : x(Y) \leq f(Y)\}.$$

A vector in $\mathrm{B}(f)$ is called a *base*. In particular, an extreme point of $\mathrm{B}(f)$ is called an *extreme base*. An extreme base can be computed by the greedy algorithm of Edmonds [4] and Shapley [17] as follows.

Let $L = (v_1, \ldots, v_n)$ be a linear ordering of V. For any $v_j \in V$, we denote $L(v_j) = \{v_1, \ldots, v_j\}$. The greedy algorithm with respect to L generates an extreme base $y \in \mathrm{B}(f)$ by

$$y(u) := f(L(u)) - f(L(u)\backslash\{u\}). \tag{2.1}$$

Conversely, any extreme base can be obtained in this way with an appropriate linear ordering.

LEMMA 2.1. *Let Q and R be disjoint subsets of V such that $Q \cup R$ forms an interval in L. Let L' be the linear ordering obtained from L by moving Q to the place immediately after R without changing the orderings in Q and in R. Then the extreme base y' generated by L' satisfies $y'(q) \leq y(q)$ for $q \in Q$ and $y'(r) \geq y(r)$ for $r \in R$.*

Proof. For any $q \in Q$, we have $L'(q) \supseteq L(q)$. Therefore, the submodularity of f implies $y'(q) = f(L'(q)) - f(L'(q)\backslash\{q\}) \leq f(L(q)) - f(L(q)\backslash\{q\}) = y(q)$. Similarly, $L'(r) \subseteq L(r)$ holds for $r \in R$. Then it follows from the submodularity of f that $y'(r) = f(L'(r)) - f(L'(r)\backslash\{r\}) \geq f(L(r)) - f(L(r)\backslash\{r\}) = y(r)$. ∎

For any base $x \in \mathrm{B}(f)$ and any subset $Y \subseteq V$, we have $x^-(V) \leq x(Y) \leq f(Y)$. The following theorem shows that these inequalities are in fact tight for appropriately chosen x and Y.

THEOREM 2.2. *For a submodular function $f : 2^V \to \mathbf{R}$, we have*

$$\max\{x^-(V) \mid x \in \mathrm{B}(f)\} = \min\{f(Y) \mid Y \subseteq V\}.$$

Moreover, if f is integer-valued, then the maximizer x can be chosen from among integral bases. □

This theorem is immediate from the vector reduction theorem on polymatroids due to Edmonds [4]. It has motivated combinatorial algorithms for minimizing submodular functions.

3. A scaling algorithm. This section presents a new scaling algorithm for minimizing an integral submodular function $f : 2^V \to \mathbf{Z}$.

The algorithm consists of scaling phases with a scale parameter $\delta \geq 0$. It keeps a set of linear orderings $\{L_i \mid i \in I\}$ of the vertices in V. We denote $v \preceq_i u$ if v precedes u in L_i or $v = u$. Each linear ordering L_i generates an extreme base $y_i \in \mathrm{B}(f)$ by the greedy algorithm. The algorithm also keeps a base $x \in \mathrm{B}(f)$ as a convex combination $x = \sum_{i \in I} \lambda_i y_i$ of the extreme bases. Initially, $I = \{0\}$ with an arbitrary linear ordering L_0 and $\lambda_0 = 1$.

Furthermore, the algorithm works with a flow in the complete directed graph on the vertex set V. The flow is represented as a skew-symmetric function $\varphi : V \times V \to \mathbf{R}$. Each arc capacity is equal to δ. Namely, $\varphi(u, v) + \varphi(v, u) = 0$ and $-\delta \leq \varphi(u, v) \leq \delta$ hold for any pair of vertices $u, v \in V$. The boundary $\partial\varphi$ is defined by $\partial\varphi(u) = \sum_{v \in V} \varphi(u, v)$ for $u \in V$. Initially, $\varphi(u, v) = 0$ for any $u, v \in V$.

Each scaling phase aims at increasing $z^-(V)$ for $z = x + \partial\varphi$. Given a flow φ, the procedure constructs an auxiliary directed graph $G_\varphi = (V, A_\varphi)$ with arc set $A_\varphi = \{(u, v) \mid u \neq v,\ \varphi(u, v) \leq 0\}$. Let $S = \{v \mid z(v) \leq -\delta\}$ and $T = \{v \mid z(v) \geq \delta\}$. A directed path in G_φ from S to T is called an *augmenting path*.

Each scaling phase also keeps a valid labeling d. A labeling $d : V \to \mathbf{Z}$ is *valid* if $d(u) = 0$ for $u \in S$ and $v \preceq_i u$ implies $d(v) \leq d(u) + 1$. A valid labeling $d(v)$ serves as a lower bound on the number of arcs from S to v in the directed graph $G_I = (V, A_I)$ with the arc set $A_I = \{(u, v) \mid \exists i \in I,\ v \preceq_i u\}$.

If there is an augmenting path P, the algorithm augments the flow φ along P by $\varphi(u, v) := \varphi(u, v) + \delta$ and $\varphi(v, u) := \varphi(v, u) - \delta$ for each arc (u, v) in P. This procedure is referred to as $\mathsf{Augment}(\varphi, P)$. As a result of $\mathsf{Augment}(\varphi, P)$, the initial vertex s of P may get rid of S and no new vertex joins S. Thus $\mathsf{Augment}(\varphi, P)$ does not violate the validity of d.

Let W be the set of vertices reachable from S in G_φ, and let Z be the set of vertices that attains the minimum labeling in $V \backslash W$. A pair (u, v) of $u \in W$ and $v \in Z$ is called *active* for $i \in I$ if v is the first vertex of Z in L_i and u is the last vertex in L_i with $v \preceq_i u$ and $d(v) = d(u) + 1$. A triple (i, u, v) is also called *active* if (u, v) is active for $i \in I$. The procedure $\mathsf{Multiple\text{-}Exchange}(i, u, v)$ is applicable to an active triple (i, u, v).

For an active triple (i, u, v), the set of vertices from v to u in L_i is called an *active interval*. The active interval is divided into Q and R by $Q = \{w \mid w \in W,\ v \prec_i w \preceq_i u\}$ and $R = \{w \mid w \in V \backslash W,\ v \preceq_i w \prec_i u\}$.

The procedure $\mathsf{Multiple\text{-}Exchange}(i, u, v)$ moves the vertices in R to the place immediately after u in L_i, without changing the ordering in Q and in R. Then it computes an extreme base y_i generated by the new L_i. By Lemma 2.1, this results

in $y_i(q) \geq y_i^\circ(q)$ for $q \in Q$ and $y_i(r) \leq y_i^\circ(r)$ for $r \in R$, where y_i° denotes the previous y_i.

Consider a complete bipartite graph with the vertex sets Q and R. The algorithm finds a flow $\xi : Q \times R \to \mathbf{R}_+$ such that $\sum_{r \in R} \xi(q,r) = y_i(q) - y_i^\circ(q)$ for each $q \in Q$ and $\sum_{q \in Q} \xi(q,r) = y_i^\circ(r) - y_i(r)$ for each $r \in R$. Such a flow can be obtained easily by the so-called northwest corner rule. Then the procedure computes $\alpha = \min\{\lambda_i, \delta/\beta\}$ with $\beta = \max\{\xi(q,r) \mid q \in Q,\, r \in R\}$ and moves x by $x := x + \alpha(y_i - y_i^\circ)$. In order to keep z invariant, the procedure adjusts the flow φ by $\varphi(q,r) := \varphi(q,r) - \alpha\xi(q,r)$ and $\varphi(r,q) := \varphi(r,q) + \alpha\xi(q,r)$ for every $(q,r) \in Q \times R$. The resulting φ satisfies the capacity constraints due to the choice of α, and the vertices in W remain reachable from S in G_φ.

If $\alpha = \lambda_i$, Multiple-Exchange(i,u,v) is called *saturating*. Otherwise, it is called *nonsaturating*. In a nonsaturating Multiple-Exchange(i,u,v), a new index k is added to I. The associated linear ordering L_k is the previous L_i. The coefficient λ_k is determined by $\lambda_k := \lambda_i - \alpha$, and then λ_i is replaced by $\lambda_i := \alpha$. Thus the algorithm continues to keep x as a convex combination $x = \sum_{i \in I} \lambda_i y_i$.

Suppose the labeling d is valid before the algorithm applies Multiple-Exchange to an active triple (i,u,v). For any vertex w in the active interval, $d(v) \leq d(w) + 1$ and $d(w) \leq d(u)+1$ hold. These inequalities and $d(v) = d(u)+1$ imply $d(v) \leq d(w) \leq d(u)$. Note that $d(v) \leq d(r)$ holds for any $r \in R \subseteq V \backslash W$. Hence we have $d(r) = d(v)$ for any $r \in R$. If Multiple-Exchange(i,u,v) adds a new arc (s,t) to A_I, then $s \in Q$ and $t \in R$. Therefore, we have $d(t) = d(v) \leq d(s) + 1$. Thus Multiple-Exchange$(i,u,v)$ does not violate the validity of d.

Let h denote the number of vertices in the active interval. The number of function evaluations required for computing the new extreme base y_i by the greedy algorithm is at most h. The northwest corner rule can be implemented to run in $\mathrm{O}(h)$ time, and the number of arcs (q,r) with $\xi(q,r) > 0$ is at most $h - 1$. Thus the total time complexity of Multiple-Exchange(i,u,v) is $\mathrm{O}(h\gamma)$.

If there is no active triple, the algorithm applies Relabel to each $v \in Z$. The procedure Relabel(v) increments $d(v)$ by one. Then the labeling d remains valid.

The number of extreme bases in the expression of x increases by one as a result of nonsaturating Multiple-Exchange. In order to reduce the complexity, the algorithm occasionally applies a procedure Reduce(x,I) that computes an expression of x as a convex combination of affinely independent extreme bases chosen from the currently used ones. This computation takes $\mathrm{O}(n^2|I|)$ time with the aid of Gaussian elimination.

We are now ready to describe the new scaling algorithm.

Step 0: Let L_0 be an arbitrary linear ordering. Compute an extreme base y_0 by the greedy algorithm with respect to L_0. Put $x := y_0$, $\lambda_0 := 1$, $I := \{0\}$, and $\delta := |x^-(V)|/n^2$.

Step 1: Put $d(v) := 0$ for $v \in V$, and $\varphi(u,v) := 0$ for $u, v \in V$.

Step 2: Put $S := \{v \mid z(v) \leq -\delta\}$ and $T := \{v \mid z(v) \geq \delta\}$, where $z = x + \partial\varphi$. Let W be the set of vertices reachable from S in G_φ.

Step 3: If there is an augmenting path P, then do the following.

(3-1) Apply Augment(φ, P).

(3-2) Apply Reduce(x,I).

(3-3) Go to Step 2.

Step 4: Compute $\ell := \min\{d(v) \mid v \in V \backslash W\}$ and put $Z := \{v \mid v \in V \backslash W,\, d(v) = \ell\}$. If $\ell < n$, then do the following.

(4-1) If there is an active triple (i,u,v), then apply Multiple-Exchange(i,u,v).

(4-2) Otherwise, apply Relabel(v) for each $v \in Z$.

(4-3) Go to Step 2.

Step 5: Determine the set X of vertices reachable from S in G_I. If $\delta \geq 1/n^2$, then apply Reduce(x, I), $\delta := \delta/2$, and go to Step 1.

We now show that the last set X obtained by the scaling algorithm is a minimizer of f.

LEMMA 3.1. *At the end of each scaling phase,* $z^-(V) \geq f(X) - n(n+1)\delta/2$.

Proof. At the end of each scaling phase, $d(v) = n$ for every $v \in V \backslash W$. Since $d(v)$ is a lower bound on the number of arcs from S to v in G_I, this means there is no directed path from S to $V \backslash W$ in G_I. Thus we have $X \subseteq W \subseteq V \backslash T$, which implies $z(v) \leq \delta$ for $v \in X$. It follows from $S \subseteq X$ that $z(v) \geq -\delta$ for $v \in V \backslash X$. Since there is no arc in G_I emanating from X, we have $y_i(X) = f(X)$ for each $i \in I$, and hence $x(X) = \sum_{i \in I} \lambda_i y_i(X) = f(X)$. We also have $\partial\varphi(X) \geq -\delta\,|X| \cdot |V \backslash X| \geq -n(n-1)\delta/2$. Therefore, we have $z^-(V) = z^-(X) + z^-(V \backslash X) \geq z(X) - \delta|X| - \delta|V \backslash X| = x(X) + \partial\varphi(X) - n\delta \geq f(X) - n(n+1)\delta/2$. □

LEMMA 3.2. *At the end of each scaling phase,* $x^-(V) \geq f(X) - n^2\delta$.

Proof. The set $Y = \{v \mid x(v) < 0\}$ satisfies $x^-(V) = x(Y) = z(Y) - \partial\varphi(Y) \geq z^-(V) - \partial\varphi(Y)$. Note that $\partial\varphi(Y) \leq \delta\,|Y| \cdot |V \backslash Y| \leq n(n-1)\delta/2$. Therefore, we have $x^-(V) \geq z^-(V) - n(n-1)\delta/2$, which together with Lemma 3.1 implies $x^-(V) \geq f(X) - n^2\delta$. □

THEOREM 3.3. *At the end of the last scaling phase,* X *is a minimizer of* f.

Proof. Since $\delta < 1/n^2$ in the last scaling phase, Lemma 3.2 implies $x^-(V) > f(X) - 1$. Then it follows from the integrality of f that $f(X) \leq f(Y)$ holds for any $Y \subseteq V$. □

4. Complexity. This section is devoted to complexity analysis of the new scaling algorithm.

LEMMA 4.1. *Each scaling phase performs* Augment $O(n^2)$ *times.*

Proof. At the beginning of each scaling phase, the set X obtained in the previous scaling phase satisfies $z^-(V) \geq f(X) - 2n^2\delta$ by Lemma 3.2. For the first scaling phase, we have the same inequality by taking $X = \emptyset$. Note that $z^-(V) \leq z(X) \leq f(X) + n(n-1)\delta/2$ throughout the algorithm. Thus each scaling phase increases $z^-(V)$ by at most $3n^2\delta$. Since each augmentation increases $z^-(V)$ by δ, each scaling phase performs at most $3n^2$ augmentations. □

LEMMA 4.2. *Each scaling phase performs* Relabel $O(n^2)$ *times.*

Proof. Each application of Relabel(v) increases $d(v)$ by one. Since Relabel(v) is applied only if $d(v) < n$, Relabel(v) is applied at most n times for each $v \in V$ in a scaling phase. Thus the total number of relabels in a scaling phase is at most n^2. □

LEMMA 4.3. *The number of indices in* I *is at most* $2n$.

Proof. A new index is added as a result of nonsaturating Multiple-Exchange. In a nonsaturating Multiple-Exchange(i, u, v), the arc (q, r) that determines β satisfies $\varphi(q, r) \leq 0$ after the update of φ, and the vertex r in R becomes reachable from S in G_φ. This means the set W is enlarged. Thus there are at most n applications of nonsaturating Multiple-Exchange between augmentations. Hence the number of indices added between augmentations is at most n. After each augmentation, the number of indices is reduced to at most n. Therefore, $|I| \leq 2n$ holds throughout the algorithm. □

In order to analyze the number of function evaluations in each scaling phase, we now introduce the notion of reordering phase. A *reordering phase* consists of consecutive applications of Multiple-Exchange between those of Relabel or Reduce. By Lemmas 4.1 and 4.2, each scaling phase performs $O(n^2)$ reordering phases.

LEMMA 4.4. *There are* $O(n^2)$ *function evaluations in each reordering phase.*

Proof. The number of function evaluations in Multiple-Exchange(i, u, v) is at most the number of vertices in the active interval for (i, u, v). In order to bound the total number of function evaluations in a reordering phase, suppose the procedure Multiple-Exchange(i, u, v) marks each pair (i, w) for w in the active interval. We now intend to claim that any pair (i, w) of $i \in I$ and $w \in V$ is marked at most once in a reordering phase.

In a reordering phase, the algorithm does not change the labeling d nor does it delete a vertex from W. Hence the minimum value of d in $V\backslash W$ is nondecreasing. After execution of Multiple-Exchange(i, u, v), there will not be an active pair for i until the minimum value of d in $V\backslash W$ becomes larger. Let Multiple-Exchange(i, s, t) be the next application of Multiple-Exchange to the same index $i \in I$. Then we have $d(t) > d(v) = d(u) + 1$, which implies $v \prec_i u \prec_i t \prec_i s$ in the linear ordering L_i before Multiple-Exchange(i, u, v). Thus a pair (i, w) marked in Multiple-Exchange(i, u, v) will not be marked again in the reordering phase.

Since $|I| \leq 2n$ by Lemma 4.3, there are at most $2n^2$ possible marks without duplications. Therefore, the total number of function evaluations in a reordering phase is $O(n^2)$. □

In order to find an active triple efficiently in Step (4-1), we keep track of possible candidates of active triples. For each $i \in I$ and $\ell = 1, \ldots, n-1$, let $u_{i\ell}$ denote the last vertex u in L_i such that $u \in W$ and $d(u) = \ell - 1$. Similarly, $v_{i\ell}$ denotes the first vertex v in L_i such that $v \in V\backslash W$ and $d(v) = \ell$. Then $(i, u_{i\ell}, v_{i\ell})$ is an active triple if $\ell = \min\{d(v) \mid v \in V\backslash W\}$ and $v_{i\ell} \prec u_{i\ell}$. At the beginning of each reordering phase, we scan the linear orderings to find all those candidates in $O(n^2)$ time.

In the rest of the reordering phase, we update the candidates whenever a new vertex is added to W. Let w be the vertex that is added to W. For each $i \in I$, if $u_{i\ell} \preceq w$ with $d(w) = \ell - 1$, then we replace $u_{i\ell}$ by w. If $w = v_{i\ell}$, then we find the new $v_{i\ell}$ by scanning L_i. Thus it takes $O(n^2)$ time to update the candidates when a new vertex is added to W. Since at most n vertices are added to W, each reordering phase requires $O(n^3)$ fundamental operations.

THEOREM 4.5. *The algorithm performs* $O(n^4 \log M)$ *function evaluations and* $O(n^5 \log M)$ *arithmetic computations.*

Proof. Consider the set $U = \{u \mid x(u) > 0\}$ for the initial base $x \in B(f)$. Then we have $x^-(V) = x(V) - x(U) \geq f(V) - f(U) \geq -2M$. Therefore, the initial value of δ satisfies $\delta \leq 2M/n^2$. Each scaling phase cuts the value of δ in half, and the algorithm terminates when $\delta < 1/n^2$. Thus the algorithm consists of $O(\log M)$ scaling phases.

Since each scaling phase performs $O(n^2)$ reordering phases, Lemma 4.4 implies that the number of function evaluations in a scaling phase is $O(n^4)$. In addition, each reordering phase requires $O(n^3)$ steps to keep track of active triples. By Lemma 4.1, each scaling phase performs $O(n^2)$ calls of Reduce, which requires $O(n^3)$ arithmetic computations. Thus each scaling phase consists of $O(n^4)$ function evaluations and $O(n^5)$ arithmetic computations. Therefore, the total running time bound is $O((n^4\gamma + n^5) \log M)$. □

5. Discussions. A family $\mathcal{D} \subseteq 2^V$ is called a distributive lattice (or a ring family) if $X \cap Y \in \mathcal{D}$ and $X \cup Y \in \mathcal{D}$ for any pair of $X, Y \in \mathcal{D}$. A compact representation of $\mathcal{D}$ is given by a directed graph as follows. Let $D = (V, F)$ be a directed graph with the arc set F. A subset $Y \subseteq V$ is called an ideal of D if no arc enters Y in D. Then the set of ideals of D forms a distributive lattice. Conversely, any distributive lattice $\mathcal{D} \subseteq 2^V$ with $\emptyset, V \in \mathcal{D}$ can be represented in this way due to

Birkhoff's representation theorem [1, Theorem 2.5]. Moreover, contracting strongly connected components of D to single vertices, we may assume that the directed graph D is acyclic.

For minimizing a submodular function f on $\mathcal{D}$, we apply the scaling algorithm with a minor modification. The modified version uses the directed graph $G_\varphi = (V, A_\varphi \cup F)$ instead of $G_\varphi = (V, A_\varphi)$. The initial linear ordering L_0 must be consistent with D; i.e., $v \preceq_i u$ if $(u, v) \in F$. Then all the linear orderings that appear in the algorithm will be consistent with D. This ensures that the set X obtained at the end of each scaling phase belongs to $\mathcal{D}$. Thus the modification of our scaling algorithm finds a minimizer of f in $\mathcal{D}$.

Iwata, Fleischer, and Fujishige [13] also describe a strongly polynomial algorithm that repeatedly applies their scaling algorithm with $O(\log n)$ scaling phases. The number of iterations is $O(n^2)$. Replacing the scaling algorithm by the new one, we obtain an improved strongly polynomial algorithm that runs in $O((n^6\gamma + n^7)\log n)$ time.

A very recent paper [12] has shown that the strongly polynomial IFF algorithm can be implemented by using only additions, subtractions, comparisons, and oracle calls for function values. Similarly, the new strongly polynomial scaling algorithm can be made fully combinatorial as follows.

The first step towards a fully combinatorial implementation is to neglect Reduce. This causes growth of the number of extreme bases for convex combination. However, the number is still bounded by a polynomial in n. Since the number of indices added between augmentations is at most n, each scaling phase yields $O(n^3)$ new extreme bases. Hence the number of extreme bases through the $O(\log n)$ scaling phases is $O(n^3 \log n)$.

The next step is to choose an appropriate step length in Multiple-Exchange so that the coefficients should be rational numbers with a common denominator bounded by a polynomial in n. Let θ denote the value of δ in the first scaling phase. Then $\kappa = \theta/\delta$ is an integer. For each $i \in I$, we keep $\lambda_i = \mu_i/\kappa$ with an integer μ_i. We then modify the definition of saturating Multiple-Exchange. Multiple-Exchange(i, u, v) is now called saturating if $\lambda_i \xi(q, r) \le \varphi(q, r)$ for every $(q, r) \in Q \times R$. Otherwise, it is called nonsaturating. In nonsaturating Multiple-Exchange(i, u, v), let ν be the minimum integer such that $\nu\xi(q, r) > \varphi(q, r)\kappa$ for some $(q, r) \in Q \times R$. Such an integer ν can be computed by binary search. Then the new coefficients λ_k and λ_i are determined by $\mu_k := \mu_i - \nu$ and $\mu_i := \nu$. Thus the coefficients are rational numbers whose common denominator is κ, which is bounded by a polynomial in n through the $O(\log n)$ scaling phases. Then it is easy to implement this algorithm using only additions, subtractions, comparisons, and oracle calls for the function values.

Finally, we discuss time complexity of the resulting fully combinatorial algorithm. The algorithm performs $O(n^2)$ iterations of $O(\log n)$ scaling phases. Since it keeps $O(n^3 \log n)$ extreme bases, each scaling phase requires $O(n^6 \log n)$ oracle calls for function evaluations and $O(n^7 \log n)$ fundamental operations. Therefore, the total running time is $O((n^8\gamma + n^9)\log^2 n)$. This improves the previous $O(n^9\gamma \log^2 n)$ bound in [12] by essentially a linear factor in n.

In order to reduce this time complexity, McCormick [15] suggests a more efficient implementation for finding active triples. For each $i \in I$ and $\ell = 1, \ldots, n$, let $\sigma_{i\ell}$ denote the last vertex s in L_i with $d(s) = \ell - 1$. Similarly, $\tau_{i\ell}$ denotes the first vertex t in L_i with $d(t) = \ell$. Then there is an active triple (i, u, v) with $d(v) = \ell$ only if $\tau_{i\ell} \prec_i \sigma_{i\ell}$. At the beginning of each reordering phase we scan the linear orderings to

find all $\sigma_{i\ell}$ and $\tau_{i\ell}$ in $O(n|I|)$ time. Note that within the reordering phase, $\sigma_{i\ell}$ and $\tau_{i\ell}$ are invariant until the algorithm performs Multiple-Exchange(i, u, v) with $d(v) = \ell$. Once such a Multiple-Exchange is applied, there will be no active triples for the same i and ℓ in the rest of the reordering phase.

For a pair of i and ℓ with $\tau_{i\ell} \prec \sigma_{i\ell}$, we may restrict the search for active triples to the interval between $\tau_{i\ell}$ and $\sigma_{i\ell}$ in L_i. Since these intervals are disjoint, the total number of fundamental operations required for finding active triples is $O(n|I|)$ in each reordering phase. This reduces the number of fundamental operations in a scaling phase to $O(n^6 \log n)$. Thus the resulting fully combinatorial algorithm runs in $O(n^8 \gamma \log^2 n)$ time.

Acknowledgments. The author is grateful to Lisa Fleischer, Satoru Fujishige, Yasuko Matsui, Tom McCormick, and Kazuo Murota for stimulating conversations and helpful comments on the manuscript. The idea of Multiple-Exchange was originally suggested by Satoru Fujishige as heuristics to improve the practical performance of the IFF algorithm. Lisa Fleischer kindly pointed out an error in an earlier version of this paper, and Tom McCormick generously allowed me to include his idea for implementing the algorithm that leads to the bound of the fully combinatorial version. Finally, the author wishes to thank two anonymous referees for many helpful suggestions to improve the presentation of this paper.

THE PARTITION TECHNIQUE FOR OVERLAYS OF ENVELOPES*

VLADLEN KOLTUN† AND MICHA SHARIR‡

Abstract. We obtain a near-tight bound of $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$ on the complexity of the overlay of the minimization diagrams of two collections of surfaces in four dimensions. This settles a long-standing problem in the theory of arrangements, most recently cited by Agarwal and Sharir [in *Handbook of Computational Geometry*, North–Holland, Amsterdam, 2000, pp. 49–119, Open Problem 2], and substantially improves and simplifies a result previously published by the authors [in *Proceedings of the* 13*th ACM–SIAM Symposium on Discrete Algorithms*, ACM, New York, SIAM, Philadelphia, 2002, pp. 810–819].

Our bound is obtained by introducing a new approach to the analysis of combinatorial structures arising in geometric arrangements of surfaces. This approach, which we call the "partition technique," is based on k-fold divide and conquer, in which a given collection $\mathcal{F}$ of n surfaces is partitioned into k subcollections $\mathcal{F}_i$ of n/k surfaces each, and the complexity of the relevant combinatorial structure in $\mathcal{F}$ is recursively related to the complexities of the corresponding structures in each of the $\mathcal{F}_i$'s. We introduce this approach by applying it first to obtain a new *simple* proof for the known near-quadratic bound on the complexity of an overlay of two minimization diagrams of collections of surfaces in $\mathbb{R}^3$, thereby simplifying the previously available proof [P. K. Agarwal, O. Schwarzkopf, and M. Sharir, *Discrete Comput. Geom.*, 15 (1996), pp. 1–13].

The main new bound on overlays has numerous algorithmic and combinatorial applications, some of which are presented in this paper.

1. Introduction.

In this paper, we obtain combinatorial bounds on overlays of minimization diagrams by introducing a new approach to the analysis of combinatorial structures in arrangements of surfaces. Let us start with the basic definitions. (For a thorough treatment of the topic we are about to briefly introduce, the reader is referred to [21, Chapter 7].)

Let $\mathcal{F}$ be a family of n d-variate (not necessarily continuous or totally defined) functions of *constant description complexity*; that is, the graph of each function is a semialgebraic set in $\mathbb{R}^{d+1}$ defined by a constant number of polynomial equalities and inequalities of constant maximum degree. The lower envelope $E_{\mathcal{F}}$ of $\mathcal{F}$ is the pointwise minimum of the functions of $\mathcal{F}$:

$$E_{\mathcal{F}}(\mathbf{x}) = \min_{f \in \mathcal{F}} f(\mathbf{x}) \qquad \text{for } \mathbf{x} \in \mathbb{R}^d.$$

$E_{\mathcal{F}}$ is itself a d-variate function whose graph is a semialgebraic set in $\mathbb{R}^{d+1}$. The projection onto d-space of this graph is called the *minimization diagram* of $\mathcal{F}$ and is denoted by $M_{\mathcal{F}}$. This is a subdivision of $\mathbb{R}^d$ into maximal connected relatively open cells of dimensions that range between 0 and d so that, for each cell τ, a fixed subset of $\mathcal{F}$ attains $E_{\mathcal{F}}$ over all points $\mathbf{x} \in \tau$ (and no other function attains the envelope over any point in τ). The complexity of $M_{\mathcal{F}}$ (and of $E_{\mathcal{F}}$) is the number of cells (of all dimensions) of $M_{\mathcal{F}}$.

It has been shown by Halperin and Sharir [12, 20] that the complexity of $M_{\mathcal{F}}$ (and of $E_{\mathcal{F}}$) is $O(n^{d+\varepsilon})$ for any $\varepsilon > 0$, where the constant of proportionality depends on ε, d, and the maximum degree of the polynomials defining the functions of $\mathcal{F}$. A (slightly) super-$\Omega(n^d)$ lower bound is known, so the bound of [12, 20] is almost tight in the worst case. Its proof is fairly involved and is based on a counting (or charging) scheme, where vertices of the envelope are charged to sets of "nearby" vertices of the arrangement $\mathcal{A}(\mathcal{F})$ of the function graphs.

This technique and various refinements and extensions thereof have been successful in bounding the complexity of lower envelopes and of several related structures, such as a single cell in a d-dimensional arrangement [6, 13]. However, the technique has had only partial success in analyzing the *overlay* of minimization diagrams. The overlay of two (or several) minimization diagrams of d-variate functions, as above, is the superposition of these diagrams in $\mathbb{R}^d$; specifically, it is the arrangement in d-space of the union of the curves or surfaces (of various dimensions) that constitute the individual diagrams. The *complexity* of the overlay is the complexity of this arrangement, namely, the number of its cells of all possible dimensions. The overlay of minimization diagrams became an important concept in the theory of arrangements after it was demonstrated that a successful analysis of the complexity of the overlay can lead to simple divide and conquer algorithms for the computation of lower envelopes and related structures [11]. Moreover, overlays arise naturally in many applications, as will be described below in more detail.

For $d = 1$ (the case of univariate functions), each minimization diagram is simply a partition of the x-axis into a finite number of intervals; if each pair of functions intersects in at most s points, then the size of the minimization diagram of n functions is known to be at most $\lambda_s(n)$ for totally defined continuous functions or $\lambda_{s+2}(n)$ for partially defined continuous functions, where $\lambda_s(n)$ is the maximum length of (n, s)-Davenport–Schinzel sequences [21], which is near-linear in n for any fixed s. The overlay of two (or more) minimization diagrams is simply the partition obtained by merging the breakpoints of the diagrams into a single sequence. The complexity of the overlay is thus proportional to the sum of the complexities of the individual diagrams; in particular, it is near-linear in the number of functions.

For $d = 2$, it was shown by Agarwal, Schwarzkopf, and Sharir [2] that the overlay of two minimization diagrams, each defined for some set of n bivariate functions of constant description complexity, is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$. That is, the asymptotic bounds on the complexity of the overlay and on the complexity of a single diagram are the same, which is somewhat counterintuitive. The proof uses a refined and more involved variant of the counting scheme mentioned above.

The prevailing conjecture is that the complexity of the overlay of two minimization diagrams of d-variate functions of constant description complexity is $O(n^{d+\varepsilon})$ for any $\varepsilon > 0$ (the same asymptotic bound as that for the complexity of a single envelope). This has been an open problem for all $d \geq 3$. Recently [18], the authors have made a small step toward establishing the conjecture for $d = 3$, obtaining bounds of the form

$O(n^{4-\frac{1}{s}+\varepsilon})$, where s is a constant integer parameter that depends on the shape and the (constant) maximum degree of the given functions. The proof in [18] is based on the counting scheme and is highly complicated.

In this paper, we settle the conjecture affirmatively for $d = 3$ and prove the following theorem.

THEOREM 1.1. (a) *The complexity of the overlay of two minimization diagrams of a total of n trivariate functions of constant description complexity is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

(b) *The complexity of the overlay of $k \geq 3$ minimization diagrams, each of n/k trivariate functions of constant description complexity, is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

This is achieved by introducing the *partition technique*, a new approach to this problem, which we hope will also prove useful in the analysis of the complexity of other substructures in arrangements. The technique is based on *k-fold divide and conquer*, in which each of the given collections is partitioned into k subcollections of n/k functions each, where k is some parameter, and the complexity of the entire overlay is expressed in terms of the complexities of various "suboverlays" and related substructures. The analysis exploits and extends ideas used by Har-Peled [14, 15] for the analysis of the complexity of substructures in the overlay of planar arrangements.

We introduce our approach by presenting a new *simple* proof for the complexity of the overlay of the minimization diagrams of two collections of bivariate functions. This compares favorably with the previously available proof [2].

So far, the partition technique faces technical difficulties when applied to the analysis of other structures (like vertical decompositions) or to overlays in higher dimensions. Nevertheless, we feel hopeful that it will develop further, becoming able to tackle these problems and to find many additional applications.

Our result has several applications, which we enumerate in section 5 (some of which were already noted in our previous work [18]). It can be used to obtain an improved near-cubic bound, which is nearly tight in the worst case, on the complexity of the region enclosed between two envelopes in four dimensions. Another application is an improved near-cubic bound on the complexity of the space of all hyperplane transversals of a collection of simply shaped convex sets in 4-space, and on the complexity of the space of all line transversals of a similar collection of convex sets in 3-space. Using these bounds, one can adapt randomized incremental techniques, proposed in [1, 5], to construct the boundary of these transversal spaces in expected near-cubic time. We also obtain an improved near-cubic bound on the number of geometric permutations in a collection of disjoint convex bodies in $\mathbb{R}^3$. Our new bound can also be used to obtain a near-cubic bound on the complexity of the union of certain families of fat convex objects of nearly equal size in 4-space.

Parts of our analysis are of independent interest, and we adapt one to show that the complexity of the lower envelope of an arrangement of n totally defined semialgebraic surfaces of constant description complexity in $\mathbb{R}^3$, that does not contain any vertices, is $O(n^{1+\varepsilon})$ for any $\varepsilon > 0$.

The rest of the paper is organized as follows. We begin by introducing the partition technique. It is introduced by example, in section 2, where it is used to rederive the known near-quadratic bound for the complexity of the overlay of the minimization diagrams of two collections of bivariate functions. In section 3, we provide a useful technical tool needed for applying the partition technique in three dimensions. Finally, we use the partition technique to prove a near-cubic bound on the complexity of the overlay of minimization diagrams of trivariate functions in section 4. Several

applications of this new bound are described in section 5.

2. The overlay of bivariate minimization diagrams. We start by introducing the partition technique. This introduction is done by example, on the analysis of overlays of minimization diagrams of two collections of bivariate functions.

Let $\mathcal{F}$ and $\mathcal{G}$ be two collections, each consisting of n bivariate functions of constant description complexity. We prove that the complexity of the overlay of the minimization diagrams $M_{\mathcal{F}}$ of $\mathcal{F}$ and $M_{\mathcal{G}}$ of $\mathcal{G}$ is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$. Denote the overlay by $Q(\mathcal{F}, \mathcal{G})$, and define the *bichromatic complexity* $C(\mathcal{F}, \mathcal{G})$ of the overlay to be the number of intersections between edges of $M_{\mathcal{F}}$ and edges of $M_{\mathcal{G}}$. Clearly, since each overlay is a planar map, the actual complexity of $Q(\mathcal{F}, \mathcal{G})$ is proportional to $C(\mathcal{F}, \mathcal{G}) + |M_{\mathcal{F}}| + |M_{\mathcal{G}}|$, where $|M_{\mathcal{F}}|$ (resp., $|M_{\mathcal{G}}|$) is the complexity of the minimization diagram $M_{\mathcal{F}}$ (resp., of $M_{\mathcal{G}}$).

Throughout what follows, we will assume that all the functions in $\mathcal{F}$ and $\mathcal{G}$ are continuous and totally defined. This involves no real loss of generality, because one can always partition each function graph in $\mathcal{F}$ and $\mathcal{G}$ into a constant number of continuous patches, which can then be extended to be totally defined without decreasing the complexity of the overlay. Indeed, a continuous partially defined function graph can be extended to be totally defined by means of near-vertical semi-infinite walls attached to its boundary. Formally, we replace each graph by the boundary of its Minkowski sum with a steeply sloped vertical cone; it is easy to see that, if the slope of the cone is large enough, this can only increase the complexity of the overlay. This extension can be analogously performed for collections $\mathcal{F}$ and $\mathcal{G}$ of functions in any dimension.

Partition $\mathcal{G}$ into k groups, $\mathcal{G}_1, \ldots, \mathcal{G}_k$, each of n/k functions, for some threshold parameter k that we will determine later. Fix an edge e of $M_{\mathcal{F}}$, and consider the vertical 2-dimensional *wall* $V^{(e)}$ erected over e; this is the union of all z-parallel lines that pass through points of e. Restrict the functions of $\mathcal{G}$ over e to obtain a collection $\mathcal{G}^{(e)}$ of univariate functions of constant description complexity. It is partitioned in an obvious way into k subcollections $\mathcal{G}_1^{(e)}, \ldots, \mathcal{G}_k^{(e)}$.

We shall now see that the complexity of the lower envelope of $\mathcal{G}^{(e)}$ is roughly proportional to the sum of the complexities of the lower envelopes of all the subsets $\mathcal{G}_i^{(e)}$, disregarding a small additive term and a near-constant multiplicative factor.

Let s denote the (constant) maximum number of intersections of the xy-projections of an intersection curve of two function graphs in $\mathcal{F}$ and of an intersection curve of two function graphs in $\mathcal{G}$. In particular, the number of intersections between any pair of (graphs of) functions in $\mathcal{G}^{(e)}$ is at most s.

Note that the lower envelope $E_{\mathcal{G}^{(e)}}$ of $\mathcal{G}^{(e)}$ is the lower envelope of the lower envelopes $E_{\mathcal{G}_i^{(e)}}$ of the subcollections $\mathcal{G}_i^{(e)}$ for $i = 1, \ldots, k$. Define the complexity $|E^{(e)}|$ of a univariate envelope $E^{(e)}$ over a connected arc e to be the number of vertices (breakpoints) of $E^{(e)}$ over points in the relative interior of e. Using an easy modification of an observation due to Har-Peled [14, 15], the complexity of $E_{\mathcal{G}^{(e)}}$ is

$$|E_{\mathcal{G}^{(e)}}| = O\left(\frac{\lambda_s(k)}{k} \sum_{i=1}^{k} \left(1 + |E_{\mathcal{G}_i^{(e)}}|\right)\right). \tag{2.1}$$

Indeed, Har-Peled's proof merges the breakpoints of the $E_{\mathcal{G}_i^{(e)}}$'s into a single sequence and partitions this sequence into blocks of k breakpoints each. Within each block, at most $2k$ functions can appear on the merged envelope, and they contribute at most $O(\lambda_s(k))$ breakpoints to $E_{\mathcal{G}^{(e)}}$. If an envelope $E_{\mathcal{G}_i^{(e)}}$ does not have any breakpoint

over (the relative interior of) e, we still need to consider the single function that it contributes to the overall envelope. The term 1, added to each term $|E_{\mathcal{G}_i^{(e)}}|$ in the above bound, takes care of these extreme cases.

Putting $\beta_s(k) = \lambda_s(k)/k$ and summing these bounds over all edges e of $M_{\mathcal{F}}$, we obtain that the bichromatic complexity $C(\mathcal{F}, \mathcal{G})$ of the overlay of $M_{\mathcal{F}}$ and $M_{\mathcal{G}}$ satisfies

$$C(\mathcal{F}, \mathcal{G}) = O\left(|M_{\mathcal{F}}|\lambda_s(k) + \beta_s(k)\sum_{i=1}^{k} C(\mathcal{F}, \mathcal{G}_i)\right). \tag{2.2}$$

Informally, we have just shown that, ignoring an additive term dominated by $|M_{\mathcal{F}}|$ and a negligible multiplicative factor of $\beta_s(k)$, the complexity of the overlay of $M_{\mathcal{F}}$ with $M_{\mathcal{G}}$ is roughly proportional to the sum of the complexities of the overlays of $M_{\mathcal{F}}$ with all the minimization diagrams $M_{\mathcal{G}_i}$. This is the essence of the partition technique for overlays, and it allows us to easily finish off the analysis as follows.

We reverse the roles of $\mathcal{F}$ and $\mathcal{G}$, as follows. Fix a subset $\mathcal{G}_i$, and consider an edge e' of $M_{\mathcal{G}_i}$. Partition $\mathcal{F}$ into k groups, $\mathcal{F}_1, \ldots, \mathcal{F}_k$, each of n/k functions, and consider the vertical 2-dimensional wall $V^{(e')}$ erected over e'. Restrict the functions of $\mathcal{F}$ over e' to obtain a collection $\mathcal{F}^{(e')}$ of univariate functions of constant description complexity, which is partitioned in an obvious way into $\mathcal{F}_1^{(e')}, \ldots, \mathcal{F}_k^{(e')}$.

As above, the lower envelope of the individual lower envelopes $E_{\mathcal{F}_j^{(e')}}$ over e' is the lower envelope $E_{\mathcal{F}^{(e')}}$. Using once again the technique of Har-Peled [14, 15], the complexity of $E_{\mathcal{F}^{(e')}}$ is

$$|E_{\mathcal{F}^{(e')}}| = O\left(\beta_s(k)\sum_{j=1}^{k}\left(1 + |E_{\mathcal{F}_j^{(e')}}|\right)\right).$$

Summing these bounds over all edges e' of $M_{\mathcal{G}_i}$, we obtain that the bichromatic complexity $C(\mathcal{F}, \mathcal{G}_i)$ of the overlay of $M_{\mathcal{F}}$ and $M_{\mathcal{G}_i}$ satisfies

$$C(\mathcal{F}, \mathcal{G}_i) = O\left(|M_{\mathcal{G}_i}|\lambda_s(k) + \beta_s(k)\sum_{j=1}^{k} C(\mathcal{F}_j, \mathcal{G}_i)\right).$$

This is essentially the same equation as (2.2), with $\mathcal{G}_i$ in the role of $\mathcal{F}$ and $\mathcal{F}$ in the role of $\mathcal{G}$, and it was obtained using an identical mechanism. If we now simply substitute this equation into (2.2), we obtain

$$C(\mathcal{F}, \mathcal{G}) = O\left(|M_{\mathcal{F}}|\lambda_s(k) + \beta_s(k)\sum_{i=1}^{k}\left(|M_{\mathcal{G}_i}|\lambda_s(k) + \beta_s(k)\sum_{j=1}^{k} C\left(\mathcal{F}_j, \mathcal{G}_i\right)\right)\right). \tag{2.3}$$

Let $C(n)$ denote the maximum complexity of the overlay of the minimization diagrams of two collections of n bivariate functions, each of the same constant description complexity,[1] and recall that the complexity of a lower envelope of n bivariate functions of constant description complexity is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$ [12, 20]. This simplifies (2.3) into the recurrence

$$C(n) = O\left(n^{2+\varepsilon}\lambda_s(k) + k^2\beta_s^2(k)C\left(\frac{n}{k}\right)\right),$$

[1]Having a fixed constant description complexity means that a function graph is defined by a fixed maximum number of polynomials of a fixed maximum degree.

the solution of which is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$ (see [13, 20, 21] for demonstrations of solutions of similar recurrence relations, which are obtained by choosing a suitable parameter k as a function of ε). We have thus shown the following theorem.

THEOREM 2.1. *The complexity of the overlay of the minimization diagrams of two collections of n bivariate functions of constant description complexity is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$, where the constant of proportionality depends on ε.*

3. The partition technique in three dimensions. In this section, we take a crucial preparatory step toward a bound on the complexity of overlays of collections of trivariate functions. The partition technique, as exposed in the previous section, calls for relating the complexity of the minimization diagram of a collection $\mathcal{F} = \bigcup_{i=1}^{k} \mathcal{F}_i$ of functions to the sum of the complexities of the minimization diagrams of all the subcollections $\mathcal{F}_i$. This is precisely what was established in (2.1), in the case of univariate functions, where it was essentially shown that

$$|M_{\mathcal{F}}| = O\left(\beta_s(k) \sum_{i=1}^{k} \bigl(1 + |M_{\mathcal{F}_i}|\bigr)\right)$$

when $\mathcal{F}$ is a collection of univariate functions.

Utilizing the partition technique in three dimensions requires a parallel relation to be established for the case of bivariate functions. Such a relation, which we believe to be of independent interest, is proved below. Although it is sufficient for our purposes, it is not as intuitive as its counterpart in the univariate case.

THEOREM 3.1. *Let $\mathcal{F}_1, \ldots, \mathcal{F}_k$ be k sets of bivariate functions of constant description complexity, and put $\mathcal{F} = \bigcup_{i=1}^{k} \mathcal{F}_i$. Then*

$$|M_{\mathcal{F}}| = O\left(k^{2+\varepsilon} + k^{1+\varepsilon} \sum_{i=1}^{k} |M_{\mathcal{F}_i}| + k^{\varepsilon} \sum_{i=1}^{k} \sum_{j=i+1}^{k} C(\mathcal{F}_i, \mathcal{F}_j)\right)$$

for any $\varepsilon > 0$, where $C(\mathcal{F}_i, \mathcal{F}_j)$ is, as above, the bichromatic complexity of the overlay $Q(\mathcal{F}_i, \mathcal{F}_j)$.

Proof. $E_{\mathcal{F}}$ is the lower envelope of $E_{\mathcal{F}_1}, \ldots, E_{\mathcal{F}_k}$. Take, as above, the minimization diagrams $M_{\mathcal{F}_1}, \ldots, M_{\mathcal{F}_k}$, and overlay them to obtain a planar subdivision, which is the arrangement of the edges of these individual minimization diagrams. We may, of course, interpret this overlay as the combination of the overlays of pairs of these minimization diagrams. (For example, each vertex of the overlay, which is not a vertex of one of the diagrams $\mathcal{M}_{\mathcal{F}_i}$, is also a vertex of one of these pairwise overlays.) However, in order to derive the relation asserted in the theorem, we treat the overlay in a more "economical" manner, which can be regarded as a 2-dimensional extension of the technique of Har-Peled [14, 15].

Specifically, let N_i denote the number of edges of $M_{\mathcal{F}_i}$ for $i = 1, \ldots, k$. Clearly, $N_i = O(|M_{\mathcal{F}_i}|)$. Put $N = \sum_{i=1}^{k} N_i$, and let V denote the number of crossings between these N arcs. Note that, by definition,

$$V = \sum_{i=1}^{k} \sum_{j=i+1}^{k} C(\mathcal{F}_i, \mathcal{F}_j).$$

It is therefore sufficient to show that

$$|M_{\mathcal{F}}| = O\left(k^{2+\varepsilon} + k^{1+\varepsilon} N + k^{\varepsilon} V\right)$$

for any $\varepsilon > 0$, and we establish this bound as follows.

Put $r = \lceil N/k \rceil$, and construct a $(1/r)$-cutting Ξ of the arrangement of the above N edges. This is a decomposition of the plane into cells, each of constant description complexity, such that each cell is crossed by at most N/r arcs of the arrangement. The size of a cutting is said to be its number of cells. As shown, e.g., by de Berg and Schwarzkopf [9], there exists a cutting Ξ of size

$$O\left(r + \frac{Vr^2}{N^2}\right) = O\left(1 + \frac{N}{k} + \frac{V}{k^2}\right).$$

Let τ be a cell of Ξ. It is crossed by at most $N/r \leq k$ edges. Let m_i denote the number of edges of $M_{\mathcal{F}_i}$ that cross τ; we have $\sum_{i=1}^{k} m_i \leq k$. It is easily seen that the number of functions of $\mathcal{F}_i$ that can attain $E_{\mathcal{F}_i}$ over τ is at most $m_i + 1$. Indeed, construct a spanning tree T of the adjacency graph of the faces of $M_{\mathcal{F}_i} \cap \tau$. ($T$ exists since the adjacency graph is clearly connected.) Each edge of T corresponds to an edge of $M_{\mathcal{F}_i}$ that crosses τ, so T has at most m_i edges and thus at most $m_i + 1$ nodes, corresponding to at most $m_i + 1$ faces of $M_{\mathcal{F}_i}$ that cross τ; this is easily seen to imply the claim.

We have thus shown that the number of functions that can attain $E_{\mathcal{F}}$ over τ is at most $\sum_{i=1}^{k}(m_i + 1) \leq 2k$. The complexity of $E_{\mathcal{F}}$ over τ is thus $O(k^{2+\varepsilon})$ for any $\varepsilon > 0$ [12, 20]. Summing this bound over all cells τ of Ξ, the overall complexity of $E_{\mathcal{F}}$ is

$$O(k^{2+\varepsilon}|\Xi|) = O\left(k^{2+\varepsilon} \cdot \left(1 + \frac{N}{k} + \frac{V}{k^2}\right)\right) = O(k^{2+\varepsilon} + k^{1+\varepsilon}N + k^{\varepsilon}V)$$

for any $\varepsilon > 0$, as asserted. □

Remark 1. An obvious open problem is to extend Theorem 3.1 to the case of trivariate functions. Here we have a collection of 2-dimensional surface patches in $\mathbb{R}^3$, which are the faces of the individual minimization diagrams, and we want to construct a $(1/r)$-cutting for this collection. The crucial ingredient in the preceding proof is a sharp bound for the size of such a cutting, which becomes a considerably harder task in the trivariate case. Specifically, the only known general-purpose method for constructing cuttings of curved surfaces in three (and higher) dimensions uses the *vertical decomposition* of a sample Σ of the given surfaces (see [21]). The size of such a vertical decomposition depends on the number of *visibility events* in Σ, which are triples of the form (e, e', s), where each of e, e' is an intersection curve of two surfaces in Σ or a boundary edge or the silhouette of a single surface, and s is a vertical segment that connects a point on e to a point on e' and does not meet any other surface of Σ. Obtaining sharp bounds on the number of visibility events in a sample of faces of the k given minimization diagrams appears to be a fairly involved problem, which makes an extension of Theorem 3.1 to the trivariate case a difficult task.

4. The overlay of trivariate minimization diagrams. Armed with the extension given in Theorem 3.1, we apply the partition technique to prove the main result of the paper, which yields a near-cubic bound for the complexity of overlays of minimization diagrams of trivariate functions. The general approach is the same as the one demonstrated in the proof of Theorem 2.1, but the technical details are unfortunately more complicated.

4.1. Preliminaries. Let $\mathcal{F}$ and $\mathcal{G}$ be two collections, each consisting of n totally defined trivariate functions of constant description complexity. Consider the overlay

$Q(\mathcal{F},\mathcal{G})$ of the minimization diagrams $M_{\mathcal{F}}$ (of $\mathcal{F}$) and $M_{\mathcal{G}}$ (of $\mathcal{G}$). The combinatorial complexity of $Q(\mathcal{F},\mathcal{G})$ counts the number of cells of all dimensions in the overlay.

Each vertex (0-dimensional cell) of $Q(\mathcal{F},\mathcal{G})$ is a vertex either of $M_{\mathcal{F}}$ or of $M_{\mathcal{G}}$, or a crossing between an edge of one diagram and a 2-face of the other. Denote by $C_{32}(\mathcal{F},\mathcal{G})$ the number of crossings between edges of $M_{\mathcal{F}}$ and 2-faces of $M_{\mathcal{G}}$ (the subscripts 3 and 2 indicate that we consider interactions between features of $M_{\mathcal{F}}$ defined by three functions and features of $M_{\mathcal{G}}$ defined by two functions). Our analysis will concentrate on $C_{32}(\mathcal{F},\mathcal{G})$, and the complementary count $C_{23}(\mathcal{F},\mathcal{G})$ of the number of crossings between 2-faces of $M_{\mathcal{F}}$ and edges of $M_{\mathcal{G}}$ will be handled in a fully symmetric manner. Vertices counted in $C_{32}(\mathcal{F},\mathcal{G})$ will sometimes be referred to as $(3,2)$-vertices, and vertices in $C_{23}(\mathcal{F},\mathcal{G})$ can similarly be called $(2,3)$-vertices.

Each edge (1-dimensional cell) of $Q(\mathcal{F},\mathcal{G})$ is (a portion of) an edge either of $M_{\mathcal{F}}$ or of $M_{\mathcal{G}}$, or a maximal connected portion of an intersection curve between a 2-face of $M_{\mathcal{F}}$ and a 2-face of $M_{\mathcal{G}}$, which does not meet any other 2-face of either diagram. Any edge of the latter kind that has an endpoint can be charged to that endpoint, which is a vertex of the overlay. Under an appropriate general position assumption, each vertex is charged in this manner only $O(1)$ times, so we will not have to be concerned explicitly with such edges. Any other edge is either unbounded or a closed bounded connected curve without a vertex. An unbounded edge e, formed by the intersection of two 2-faces φ_1 of $M_{\mathcal{F}}$ and φ_2 of $M_{\mathcal{G}}$, can be charged to a crossing between φ_1 and φ_2 at infinity (or, alternatively, at some sufficiently large sphere or cube, enclosing all bounded features of $Q(\mathcal{F},\mathcal{G})$). The number of such crossings is equal to the complexity of the overlay of $M_{\mathcal{F}}$ and $M_{\mathcal{G}}$ at infinity, which is the overlay of two minimization diagrams of *bivariate* functions of constant description complexity, and its complexity, denoted as $C_\infty(\mathcal{F},\mathcal{G})$, is $O(n^{2+\varepsilon})$ for any $\varepsilon > 0$ (see [2] and the analysis in section 2).

We are thus left with edges of Q that are closed and bounded connected components of "bichromatic" intersection curves. Computing the number of such edges turns out to be the most involved part of our analysis. We denote their number by $C_{22}(\mathcal{F},\mathcal{G})$.

There is no need to consider separately 2-faces of $Q(\mathcal{F},\mathcal{G})$. Any 2-face φ of $Q(\mathcal{F},\mathcal{G})$ can be charged to a bounding edge, except for those 2-faces that have no boundary. The number of 2-faces of this latter kind is only $O(n^2)$, as is easily seen.

Levels. We can extend the above definitions as follows. The *level* of a point $\mathbf{x}$ in the arrangement $\mathcal{A}(\mathcal{F})$ of $\mathcal{F}$ is the number of graphs of functions in $\mathcal{F}$ that lie vertically below $\mathbf{x}$, and similarly for $\mathcal{A}(\mathcal{G})$. Consider a projection of an a-level edge (resp., 2-face) of $\mathcal{A}(\mathcal{F})$, and a projection of a b-level 2-face (resp., edge) of $\mathcal{A}(\mathcal{G})$. A crossing between these two projections is said to be an (a,b)-*level overlay vertex* (note, though, that these vertices do not show up at all in the actual overlay unless $a = b = 0$). The number of such vertices is denoted by $C_{32}^{(a,b)}(\mathcal{F},\mathcal{G})$ (resp., $C_{23}^{(a,b)}(\mathcal{F},\mathcal{G})$). Denote by $C_{32}^{(\le k)}(\mathcal{F},\mathcal{G})$ (resp., $C_{23}^{(\le k)}(\mathcal{F},\mathcal{G})$) the number of all such vertices for which $a + b \le k$. $C_{22}^{(\le k)}(\mathcal{F},\mathcal{G})$ is defined analogously. (Note that, since our functions are totally defined and since we count here curves that have no vertex, the level of a curve is well defined and is the same for all points on the curve.) Obviously, $C_{32}(\mathcal{F},\mathcal{G}) = C_{32}^{(0,0)}(\mathcal{F},\mathcal{G})$, and the same is true for $C_{23}(\mathcal{F},\mathcal{G})$ and $C_{22}(\mathcal{F},\mathcal{G})$.

Denote by $C_{32}^{(\le k)}(n)$ the maximum value of $C_{32}^{(\le k)}(\mathcal{F},\mathcal{G})$ over all collections $\mathcal{F},\mathcal{G}$, each consisting of n trivariate functions of the same constant description complexity. The quantities $C_{23}^{(\le k)}(n)$, $C_{22}^{(\le k)}(n)$ are defined analogously. For the case $k = 0$, where features of the actual overlay are counted, we use the notation $C_{32}(n)$, $C_{23}(n)$, and

$C_{22}(n)$, respectively. Since $\mathcal{F}$ and $\mathcal{G}$ are assumed to belong to the same general class of functions, we have $C_{32}(n) = C_{23}(n)$ and $C_{32}^{(\leq k)}(n) = C_{23}^{(\leq k)}(n)$, so we will address only the quantities $C_{32}(n)$ and $C_{32}^{(\leq k)}(n)$, and not their symmetric counterparts, in what follows.

We can estimate $C_{32}^{(\leq k)}(n)$ in terms of $C_{32}(n)$. Since every crossing counted in $C_{32}^{(\leq k)}(\mathcal{F}, \mathcal{G})$ is defined by five surfaces, the standard random sampling argument of Clarkson and Shor [8] implies

$$C_{32}^{(\leq k)}(n) = O\left(k^5 C_{32}\left(\frac{n}{k}\right)\right). \tag{4.1}$$

Similarly, we get for overlay edges (each defined by four surfaces) that

$$C_{22}^{(\leq k)}(n) = O\left(k^4 C_{22}\left(\frac{n}{k}\right)\right). \tag{4.2}$$

Remark 2. A more general problem involving overlays of trivariate functions is that of the overlay of *three* or more minimization diagrams, rather than just two. The reason is that overlays of three minimization diagrams contain a new kind of features: vertices formed by the intersection of three 2-faces, one from each diagram. Overlays of two diagrams are special in that they do not give rise to such vertices. Nevertheless, as will be shown below, our analysis will lead us straight into the consideration of such triple overlays. As a byproduct, we will also obtain near-cubic bounds on their complexity.

4.2. Overlay vertices (counting $C_{32}(n)$). As in section 2, we apply a 2-stage analysis. We fix a parameter k, and, in the first stage, we partition $\mathcal{G}$ into k subgroups $\mathcal{G}_1, \ldots, \mathcal{G}_k$, each consisting of n/k functions.

Fix an edge e of $M_{\mathcal{F}}$, and erect a 2-dimensional wall $V^{(e)}$ over e consisting of all x_4-parallel lines that pass through e. Restrict the functions of $\mathcal{G}$ over e to obtain a collection $\mathcal{G}^{(e)}$ of univariate functions of constant description complexity, which is partitioned in an obvious way into k subcollections $\mathcal{G}_1^{(e)}, \ldots, \mathcal{G}_k^{(e)}$.

Let s denote the maximum number of intersections between the xy-projections of an intersection curve of three function graphs in $\mathcal{F}$, and of an intersection 2-surface of two function graphs in $\mathcal{G}$. Since $\mathcal{F}$ and $\mathcal{G}$ are assumed to belong to the same general class of functions, we may assume that s also bounds the number of intersections between the xy-projections of any intersection curve of three function graphs in $\mathcal{G}$, and of an intersection 2-surface of two function graphs in $\mathcal{F}$.

Consider the lower envelopes $E_{\mathcal{G}_i^{(e)}}$ of $\mathcal{G}_i^{(e)}$ for $i = 1, \ldots, k$. Note that the lower envelope of the $E_{\mathcal{G}_i^{(e)}}$'s is the restriction $E_{\mathcal{G}^{(e)}}$ of the lower envelope $E_{\mathcal{G}}$ over e and that the number of breakpoints of $E_{\mathcal{G}^{(e)}}$ is the number of crossings between e and the 2-faces of $M_{\mathcal{G}}$ (and similarly for each $E_{\mathcal{G}_i^{(e)}}$). Hence, applying the analysis of section 2, the complexity of $E_{\mathcal{G}^{(e)}}$ is

$$|E_{\mathcal{G}^{(e)}}| = O\left(\beta_s(k) \sum_{i=1}^{k} \left(1 + |E_{\mathcal{G}_i^{(e)}}|\right)\right).$$

Summing this bound over all edges e of $M_{\mathcal{F}}$, we obtain the recurrence

$$C_{32}(\mathcal{F}, \mathcal{G}) = O\left(|M_{\mathcal{F}}|\lambda_s(k) + \beta_s(k) \sum_{i=1}^{k} C_{32}(\mathcal{F}, \mathcal{G}_i)\right). \tag{4.3}$$

In the (considerably more involved) second stage, we partition $\mathcal{F}$ into k groups $\mathcal{F}_1, \ldots, \mathcal{F}_k$, each consisting of n/k functions. Fix a subset $\mathcal{G}_b$ and a 2-face φ of $M_{\mathcal{G}_b}$. Let $V^{(\varphi)}$ denote the 3-dimensional wall erected over φ. (It is the union of all x_4-parallel lines passing through points of φ.) Restrict the functions of $\mathcal{F}$ over φ to obtain a collection $\mathcal{F}^{(\varphi)}$ of bivariate functions of constant description complexity, which is partitioned in an obvious way into $\mathcal{F}_1^{(\varphi)}, \ldots, \mathcal{F}_k^{(\varphi)}$.

Note that the number of crossings between edges of $M_{\mathcal{F}}$ and φ is equal to the number of vertices of the lower envelope $E_{\mathcal{F}^{(\varphi)}}$ (over the relative interior of φ). Using Theorem 3.1, we can estimate $|E_{\mathcal{F}^{(\varphi)}}|$ or, rather, $|M_{\mathcal{F}^{(\varphi)}}|$ as follows:

$$|M_{\mathcal{F}^{(\varphi)}}| = O\left(k^{2+\varepsilon} + k^{1+\varepsilon}\sum_{i=1}^{k}|M_{\mathcal{F}_i^{(\varphi)}}| + k^{\varepsilon}\sum_{i=1}^{k}\sum_{j=i+1}^{k} C\left(\mathcal{F}_i^{(\varphi)}, \mathcal{F}_j^{(\varphi)}\right)\right).$$

We sum this bound over all 2-faces φ of $M_{\mathcal{G}_b}$ to obtain an upper bound for $C_{32}(\mathcal{F}, \mathcal{G}_b)$. The terms $k^{2+\varepsilon}$ add up to $O(k^{2+\varepsilon}|M_{\mathcal{G}_b}|)$. The sum $\sum_{\varphi}|M_{\mathcal{F}_i^{(\varphi)}}|$ for any fixed i is equal, by definition, to

$$O\left(C_{32}(\mathcal{F}_i, \mathcal{G}_b) + C_{23}(\mathcal{F}_i, \mathcal{G}_b) + C_{22}(\mathcal{F}_i, \mathcal{G}_b) + C_{\infty}(\mathcal{F}_i, \mathcal{G}_b)\right).$$

Indeed, vertices of $M_{\mathcal{F}_i^{(\varphi)}}$ that lie in the relative interior of φ are counted in $C_{32}(\mathcal{F}_i, \mathcal{G}_b)$. Closed and bounded connected edges of $M_{\mathcal{F}_i^{(\varphi)}}$ that have no vertex and are fully contained in the relative interior of φ are counted in $C_{22}(\mathcal{F}_i, \mathcal{G}_b)$. Edges with no vertex that reach the boundary of φ induce, at their boundary crossings, $(2,3)$-vertices and are thus counted in $C_{23}(\mathcal{F}_i, \mathcal{G}_b)$. Edges that reach infinity (which can happen when φ is unbounded) are counted in $C_{\infty}(\mathcal{F}_i, \mathcal{G}_b)$. Finally, edges with a vertex can be charged to that vertex.

The sum $\sum_{\varphi} C(\mathcal{F}_i^{(\varphi)}, \mathcal{F}_j^{(\varphi)})$ for any fixed i, j is equal to the number of vertices of the *triple overlay* of $M_{\mathcal{F}_i}$, $M_{\mathcal{F}_j}$, and $M_{\mathcal{G}_b}$, which are intersections of three 2-faces, one of each diagram; we refer to such vertices as *trichromatic*. We denote this triple overlay by $Q^*(\mathcal{F}_i, \mathcal{F}_j, \mathcal{G}_b)$ and denote by $C_{222}(\mathcal{F}_i, \mathcal{F}_j, \mathcal{G}_b)$ the number of trichromatic vertices of the overlay. We define the notation $C_{222}^{(\le k)}(\mathcal{F}_i, \mathcal{F}_j, \mathcal{G}_b)$, $C_{222}^{(\le k)}(n)$, and $C_{222}(n)$ in complete analogy with the definition of the similar quantities given above.

Note that we started our analysis by considering the overlay $Q(\mathcal{F}, \mathcal{G})$ of only two minimization diagrams, and there we needed only to consider "bichromatic" vertices, formed by the intersection of edges of one diagram with the 2-faces of the other. As mentioned in the remark above, when we overlay three or more diagrams, we also encounter trichromatic vertices, formed by the intersection of three 2-faces, one of each diagram.

Combining the analysis just given with (4.3) and using the fact that $|M_{\mathcal{F}}| = O(n^{3+\varepsilon})$ for any $\varepsilon > 0$ [20], we obtain, for any $\varepsilon > 0$,

$$\begin{aligned} C_{32}(n) &= O\left(\lambda_s(k)n^{3+\varepsilon} + \beta_s(k)\sum_{b=1}^{k}\left[k^{2+\varepsilon}|M_{\mathcal{G}_b}|\right.\right. \\ &\qquad \left.\left. + k^{1+\varepsilon}\sum_{i=1}^{k}\left(C_{32}\left(\frac{n}{k}\right) + C_{22}\left(\frac{n}{k}\right) + \left(\frac{n}{k}\right)^{2+\varepsilon}\right) + k^{\varepsilon}\sum_{i=1}^{k}\sum_{j=i+1}^{k} C_{222}\left(\frac{n}{k}\right)\right]\right) \\ &= O\left(\lambda_s(k)n^{3+\varepsilon} + k^{3+\varepsilon}C_{32}\left(\frac{n}{k}\right) + k^{3+\varepsilon}C_{22}\left(\frac{n}{k}\right) + k^{3+\varepsilon}C_{222}\left(\frac{n}{k}\right)\right). \end{aligned} \tag{4.4}$$

Note that the final value of ε in this relation has to be taken slightly larger than the one we started with to accommodate the extra factor $\beta_s(n)$. However, the recurrence still holds for any arbitrarily small $\varepsilon > 0$.

4.3. Trichromatic vertices (counting $C_{222}(n)$). Let $\mathcal{F}, \mathcal{G}, \mathcal{H}$ be three collections, each consisting of n trivariate functions of constant description complexity, as above. We want to estimate the number $C_{222}(\mathcal{F}, \mathcal{G}, \mathcal{H})$ of triple intersections of 2-faces in the triple overlay $Q^*(\mathcal{F}, \mathcal{G}, \mathcal{H})$ of $M_{\mathcal{F}}, M_{\mathcal{G}}, M_{\mathcal{H}}$. Here we use a 3-stage analysis based on a variant of the analysis of the overlay of bivariate functions given in section 2. Interestingly, this part of our analysis of overlays of trivariate minimization diagrams is the simplest. Informally, this is because, in each of the three stages below, we have to consider only overlays of univariate functions, as in section 2.

We fix a parameter k and partition $\mathcal{H}$ into k groups $\mathcal{H}_1, \ldots, \mathcal{H}_k$ of n/k functions each. Fix a 2-face φ_1 of $M_{\mathcal{F}}$ and a 2-face φ_2 of $M_{\mathcal{G}}$, and let e be a connected component of the intersection curve $\varphi_1 \cap \varphi_2$ in $\mathbb{R}^3$. Note that the number of such edges e that have at least one endpoint is proportional to $C_{32}(\mathcal{F}, \mathcal{G}) + C_{23}(\mathcal{F}, \mathcal{G})$, because each endpoint of e is a crossing between an edge of one diagram and a 2-face of the other. Any other edge is either unbounded or a closed and bounded Jordan curve, and the number of such edges, as analyzed above, is $O(n^{2+\varepsilon} + C_{22}(n))$. Thus the number of edges e under consideration is $O(n^{2+\varepsilon} + C_{32}(n) + C_{22}(n))$.

Restrict the functions in $\mathcal{H}$ to the vertical wall $V^{(e)}$, as defined above, to obtain a collection $\mathcal{H}^{(e)}$ of univariate functions of constant description complexity, which is partitioned in an obvious way into k subcollections $\mathcal{H}_1^{(e)}, \ldots, \mathcal{H}_k^{(e)}$. As above, we have

$$|M_{\mathcal{H}^{(e)}}| = O\left(\beta_s(k) \sum_{i=1}^{k} \left(1 + |M_{\mathcal{H}_i^{(e)}}|\right)\right),$$

and, summing this bound over all such edges e, we obtain, by definition,

$$C_{222}(\mathcal{F}, \mathcal{G}, \mathcal{H}) = O\left(\left(n^{2+\varepsilon} + C_{22}(n) + C_{32}(n)\right) \lambda_s(k) + \beta_s(k) \sum_{i=1}^{k} C_{222}(\mathcal{F}, \mathcal{G}, \mathcal{H}_i)\right).$$

We repeat the same counting stage twice more. In the second stage, we fix $\mathcal{F}$ and one subcollection $\mathcal{H}_c$, partition $\mathcal{G}$ into k subgroups $\mathcal{G}_1, \ldots, \mathcal{G}_k$, and conclude, as above, that

$$C_{222}(\mathcal{F}, \mathcal{G}, \mathcal{H}_c) = O\left(\left(n^{2+\varepsilon} + C_{22}(n) + C_{32}(n)\right) \lambda_s(k) + \beta_s(k) \sum_{j=1}^{k} C_{222}(\mathcal{F}, \mathcal{G}_j, \mathcal{H}_c)\right).$$

(Note that the "overhead" term depends on $C_{22}(\mathcal{F}, \mathcal{H}_c) + C_{32}(\mathcal{F}, \mathcal{H}_c) + C_{23}(\mathcal{F}, \mathcal{H}_c) + C_{\infty}(\mathcal{F}, \mathcal{H}_c)$, which still involves $\Theta(n)$ functions in $\mathcal{F}$.)

Similarly, in the third stage, we fix two subsets $\mathcal{G}_b$ and $\mathcal{H}_c$, partition $\mathcal{F}$ into k subgroups $\mathcal{F}_1, \ldots, \mathcal{F}_k$, and obtain

$$C_{222}(\mathcal{F}, \mathcal{G}_b, \mathcal{H}_c) = O\left(\left(\left(\frac{n}{k}\right)^{2+\varepsilon} + C_{22}\left(\frac{n}{k}\right) + C_{32}\left(\frac{n}{k}\right)\right) \lambda_s(k) + \beta_s(k) \sum_{\ell=1}^{k} C_{222}\left(\mathcal{F}_\ell, \mathcal{G}_b, \mathcal{H}_c\right)\right).$$

Substituting these estimates into one another, we obtain

$$\begin{aligned} C_{222}(n) = O\Bigg(& \left(n^{2+\varepsilon} + C_{22}(n) + C_{32}(n)\right)\lambda_s(k) \\ & + \lambda_s(k)\Bigg[\left(n^{2+\varepsilon} + C_{22}(n) + C_{32}(n)\right)\lambda_s(k) \\ & + \lambda_s(k)\left[\left(\left(\frac{n}{k}\right)^{2+\varepsilon} + C_{22}\left(\frac{n}{k}\right) + C_{32}\left(\frac{n}{k}\right)\right)\lambda_s(k) + \lambda_s(k) C_{222}\left(\frac{n}{k}\right)\right]\Bigg]\Bigg) \end{aligned}$$

or

$$\begin{aligned} & C_{222}(n) \\ & = O\left(\lambda_s^2(k)\left[n^{2+\varepsilon} + C_{22}(n) + C_{32}(n)\right] + \lambda_s^3(k)\left[C_{22}\left(\frac{n}{k}\right) + C_{32}\left(\frac{n}{k}\right) + C_{222}\left(\frac{n}{k}\right)\right]\right). \end{aligned} \tag{4.5}$$

4.4. Overlay edges (counting $C_{22}(n)$). In this section, we analyze the quantity $C_{22}(\mathcal{F}, \mathcal{G})$, which is the number of "bichromatic" overlay edges that are closed bounded Jordan curves, each formed as a connected component of an intersection of a face of $M_{\mathcal{F}}$ and a face of $M_{\mathcal{G}}$, which are not adjacent to any overlay vertex. Overlay edges are structurally quite different from overlay vertices. To bound their number, we do not use the partition technique but employ the well-known technique of counting schemes introduced by Halperin and Sharir [12, 20] (see also [21]) and already mentioned in the introduction. This part of the analysis is essentially identical to the corresponding part in the precursor paper [18].

Our counting scheme for $C_{22}(\mathcal{F}, \mathcal{G})$ is another novel technical feature of this paper, and no similar scheme that charges curves rather than vertices has been employed in previous works involving substructures in arrangements. In this counting scheme, we partition the set of overlay edges into a small number of groups, according to the *index* of the edge (a notion to be defined shortly, and quite different from the standard notion of indices, as used in the analysis of substructures in arrangements [21]). We establish a separate recurrence relation for the number of edges in each group. These recurrences will depend on each other as well as on $C_{32}(n)$.

Fix some threshold parameter k. Consider the (at most a constant number of) connected components of a bichromatic overlay intersection curve defined by a fixed quadruple of surfaces $f_1, f_2 \in \mathcal{F}$, $g_1, g_2 \in \mathcal{G}$. Suppose one of these components contains a point at level at most k and either is incident to an $(\leq k)$-level overlay vertex or extends to infinity. The discussion in section 4.1 easily implies that the number of such overlay edges (that is, edges counted in $C_{22}(n)$ for which a sibling component of the same intersection curve satisfies the above properties) is, for any $\varepsilon > 0$,

$$O\left(k^5 C_{32}\left(\frac{n}{k}\right) + k^2 n^{2+\varepsilon}\right). \tag{4.6}$$

In the remainder of this section, we treat bichromatic overlay edges defined by some quadruple f_1, f_2, g_1, g_2 such that all $(\leq k)$-level edges defined by f_1, f_2, g_1, g_2 are closed and bounded Jordan curves that are not incident to any vertex. (The level of such a curve is well defined: all points on the curve have the same level, assuming, as above, that the functions in $\mathcal{F}$ and $\mathcal{G}$ are totally defined.) We fix a 2-face φ that belongs to $E_{\mathcal{G}}$ and is a connected portion of the intersection of the graphs of two functions $g_1, g_2 \in \mathcal{G}$, and we consider the vertical 3-dimensional wall $V^{(\varphi)}$ erected over φ, as in the previous sections. Let $\mathcal{F}^{(\varphi)}$ be the cross-section of $\mathcal{F}$ within $V^{(\varphi)}$,

and let f_φ be the cross-section of the graph of a function f within $V^{(\varphi)}$ for each $f \in \mathcal{F}$. $\mathcal{A}(\mathcal{F}^{(\varphi)})$ can be regarded as an arrangement of xy-monotone 2-dimensional surfaces in $\mathbb{R}^3$.

Let $\Gamma(\mathcal{F}^{(\varphi)})$ denote the set of edges, for which the following holds. Each edge c of $\Gamma(\mathcal{F}^{(\varphi)})$ is a 0-level edge that lies completely in the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ and is a connected component of an intersection curve $f_1 \cap f_2$ for some $f_1, f_2 \in \mathcal{F}^{(\varphi)}$ such that all the connected components (including c) of this intersection that lie at level at most k of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ are closed and bounded Jordan curves and are not incident to any vertex. Note that any bichromatic overlay edge of the kind we are after corresponds to a curve in $\Gamma(\mathcal{F}^{(\varphi)})$ for some 2-face φ of $E_\mathcal{G}$.

Define $S(\mathcal{F}, \mathcal{G}) \equiv \sum_\varphi |\Gamma(\mathcal{F}^{(\varphi)})|$ and $S(n) \equiv \max S(\mathcal{F}, \mathcal{G})$, where the maximum is taken over all sets $\mathcal{F}$ and $\mathcal{G}$ of size n as above. The above analysis implies, for any $\varepsilon > 0$,

$$C_{22}(n) = O\left(S(n) + k^5 C_{32}\left(\frac{n}{k}\right) + k^2 n^{2+\varepsilon}\right). \tag{4.7}$$

We next define the notion of *index* that we attach to intersection curves. For readers who have encountered previous similar-purpose definitions [20], we remark that our definition is conceptually different in that it is not "local," meaning that the index given to a specific intersection curve is defined with respect to the whole arrangement $\mathcal{A}(\mathcal{F}^{(\varphi)})$ and may change as the set $\mathcal{F}^{(\varphi)}$ decreases.

Specifically, consider the intersection $f_1 \cap f_2$ for any $f_1, f_2 \in \mathcal{F}^{(\varphi)}$. Consider all the connected components of this intersection that are edges of $\Gamma(\mathcal{F}^{(\varphi)})$, and let j be their number. We set the index of the curve $f_1 \cap f_2$ to j. We will say that j is also the index of all the edges of $\Gamma(\mathcal{F}^{(\varphi)})$ that are connected components of $f_1 \cap f_2$.

Let q be the maximum possible number of connected components of an intersection $f_1 \cap f_2$ as above. By the constant description complexity and the general position assumptions, q is constant. Clearly, j varies between 1 and q. The case $j = 0$ means that either no component of $f_1 \cap f_2$ shows up on the envelope or some such components do show up, but there exists a component at level at most k that has a vertex or reaches infinity. We will not be concerned with edges of index 0, because either we do not have to count them at all, or else we can bound their number using (4.6).

Let $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ denote the subset of $\Gamma(\mathcal{F}^{(\varphi)})$ that contains edges with index at least j. Define $S^{(j)}(\mathcal{F}, \mathcal{G}) \equiv \sum_\varphi |\Gamma^{(j)}(\mathcal{F}^{(\varphi)})|$ and $S^{(j)}(n) \equiv \max S^{(j)}(\mathcal{F}, \mathcal{G})$, where the maximum is taken over all sets $\mathcal{F}$ and $\mathcal{G}$ of size n as above. Since the maximal index of an edge is q, we have $S^{(q+1)}(n) = 0$. We also have, by definition, $S(n) = S^{(1)}(n)$.

We note that the index of $f_1 \cap f_2$ depends on the current set $\mathcal{F}$. When $\mathcal{F}$ is replaced by a smaller sample, as happens, for example, when applying the Clarkson–Shor bound, the index may increase, because either (i) more components of $f_1 \cap f_2$ appear on the envelope, or (ii) all vertices of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ that lie on components of $f_1 \cap f_2$ at level at most k disappear, since all the third surfaces incident to these vertices have been removed from $\mathcal{F}$. (Note that the level of a curve can only decrease when functions are removed from $\mathcal{F}$.) In this latter case, the index jumps from 0 (no component of $f_1 \cap f_2$, even those on the envelope, qualified to belong to $\Gamma(\mathcal{F}^{(\varphi)})$ before $\mathcal{F}$ was reduced) to some j equal to the number of components that lie on the envelope after the reduction.

The index of $f_1 \cap f_2$ can decrease in only one way, as follows. There may exist an intersection curve $f_1 \cap f_2$ that had a positive index, but, after $\mathcal{F}$ has been reduced, new components of $f_1 \cap f_2$ reach the $(\leq k)$-level of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ and do contain vertices or do reach infinity. The index of $f_1 \cap f_2$ then drops to 0. However, the number of

such curves in the reduced arrangement can be estimated using the bound in (4.6) (applied to the reduced arrangement). To conclude, with the exception of these drops to zero, the index of a curve can only increase when the size of $\mathcal{F}$ is reduced.

The counting scheme below bounds $S^{(j)}(n)$ for all $1 \leq j \leq q$. It proceeds by distinguishing between five possible scenarios (Cases 1–5) and treating each in turn.

Case 1: $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ *is small.* Suppose first that at most $(q+1)k+2 = O(k)$ surfaces of $\mathcal{F}$ attain the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$. In this case, we use the naive bound $|\Gamma^{(j)}(\mathcal{F}^{(\varphi)})| = O(k^2)$. Since there are $O(n^{3+\varepsilon})$ possible faces φ, the maximum number of edges of this kind that are counted in $S^{(j)}(n)$ is $O(k^2 n^{3+\varepsilon})$ (for all j). In what follows, we consider only faces φ such that more than $(q+1)k+2$ surfaces of $\mathcal{F}$ attain the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$.

Case 2: *There is a "shallow" connected component of the same intersection curve.* Consider any pair of surfaces $P, Q \in \mathcal{F}$ such that there is a connected component c of the intersection $P_\varphi \cap Q_\varphi$ that is an edge of $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$. The component c is, by definition, also an edge of $\Gamma(\mathcal{F}^{(\varphi)})$, which implies that all the connected components of $P_\varphi \cap Q_\varphi$ that lie at level at most k of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ are closed and bounded Jordan curves and are not incident to a vertex. Also, since the index of $P_\varphi \cap Q_\varphi$ is at least j, the number of connected components of $P_\varphi \cap Q_\varphi$ that lie on the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ is at least j. Suppose there is a connected component c' defined by $P_\varphi \cap Q_\varphi$ whose level is between 1 and k. (As noted, the level of a curve that satisfies the above properties is well defined.) In this case, we charge all edges of $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ defined by $P_\varphi \cap Q_\varphi$ to c'. It is easy to see that each such edge c' is charged in this fashion at most a constant number of times (that is, at most $q-1$ times).

Let $\Gamma(c')$ be the set of the (at most k) surfaces of $\mathcal{F}^{(\varphi)}$ that lie below c'. Set $\tilde{\mathcal{F}}^{(\varphi)} \equiv \mathcal{F}^{(\varphi)} \setminus \Gamma(c')$, and consider the arrangement $\mathcal{A}(\tilde{\mathcal{F}}^{(\varphi)})$. Clearly, c' lies on its lower envelope. Moreover, there are at least $j+1$ connected components of the intersection $P_\varphi \cap Q_\varphi$ that lie on this lower envelope. Thus the index of c' is now at least $j+1$, and c' belongs to $\Gamma^{(j+1)}(\tilde{\mathcal{F}}^{(\varphi)})$. More accurately, c' belongs to $\Gamma^{(j+1)}(\tilde{\mathcal{F}}^{(\varphi)})$ unless a new component of $P_\varphi \cap Q_\varphi$, that either reaches infinity or contains a vertex of $\mathcal{A}(\tilde{\mathcal{F}}^{(\varphi)})$, has "descended" to the first k levels in $\mathcal{A}(\tilde{\mathcal{F}}^{(\varphi)})$, thereby dropping the index of c' to 0. (Note that this analysis also applies to any subset $\mathcal{F}' \subseteq \tilde{\mathcal{F}}^{(\varphi)}$.) A standard random sampling argument, such as the ones used in section 4.1, now implies, in combination with (4.6), that the maximum number of edges of this kind that are counted in $S^{(j)}(\mathcal{F}, \mathcal{G})$ is

$$O\left(k^4 S^{(j+1)}\left(\frac{n}{k}\right) + k^4\left[k^5 C_{32}\left(\frac{n}{k^2}\right) + n^{2+\varepsilon}\right]\right) = O\left(k^4 S^{(j+1)}\left(\frac{n}{k}\right) + k^9 C_{32}\left(\frac{n}{k^2}\right) + k^4 n^{2+\varepsilon}\right).$$

In what follows, we assume that there is no connected component c' as above.

Case 3: *There is a "shallow" vertex.* Since Case 1 is ruled out, there are at least $(q+1)k$ surfaces, other than P_φ, Q_φ, that attain the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ over φ. Consider all the connected components (edges) of $P_\varphi \cap Q_\varphi$ that lie in the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$. These edges partition both P_φ and Q_φ into at most $(q+1)$ pairs of relatively open regions, where each pair consists of two regions, one on P_φ and one on Q_φ, that have a common boundary (over the relative interior of φ) and a common projection onto φ. One of these projections, denoted by Δ_0, has to contain at least k subregions where k other distinct surfaces attain the envelope. Each of these surfaces, T_φ, lies strictly above $P_\varphi \cap Q_\varphi$ over all points of $\partial\Delta_0$ defined by $P_\varphi \cap Q_\varphi$. Hence T_φ intersects both P_φ and Q_φ over Δ_0, and the projection of each component

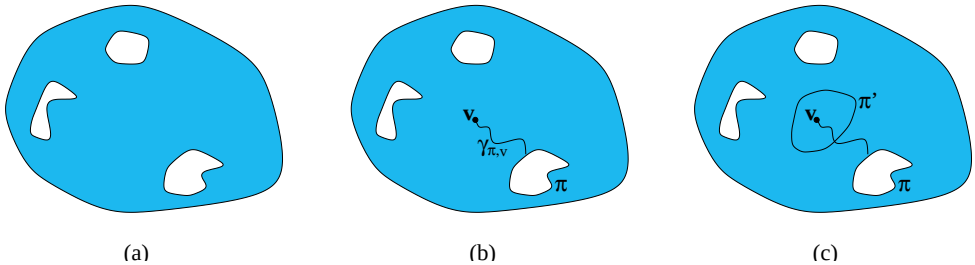

FIG. 4.1. *The region* Δ *(shaded) is illustrated in* (a). (b) *shows a point* v *that is charged by an edge* π*, together with the connecting arc* $\gamma_{\pi,v}$*. The interior of the arc* $\gamma_{\pi,v}$ *lies fully within* Δ *and thus cannot intersect any connected component of* $P_\varphi \cap Q_\varphi$ *that lies on the lower envelope.* (c) *depicts the edge* π'*, whose assumed existence leads to the contradiction in the proof of Lemma* 4.1.

of either intersection onto φ is not incident to those boundary components of Δ_0 that are defined by $P_\varphi \cap Q_\varphi$. (We emphasize that the region Δ_0 is *fixed* in all the remaining charging steps during the present case and in Cases 4 and 5 below.)

Consider an arbitrary edge π (defined by $P_\varphi \cap Q_\varphi$) whose projection onto φ lies on the boundary of Δ_0, and assume, without loss of generality, that P_φ lies below Q_φ when approaching (the projection of) π from within Δ_0. Let Δ denote the portion of Q_φ (the surface that is higher near π) that projects onto Δ_0 (see Figure 4.1(a)), and let C be the set of edges (each being a connected component of $O_\varphi \cap Q_\varphi$ for some $O_\varphi \in \mathcal{F}^{(\varphi)}$) contained in Δ. By what we have just argued, $|C| \geq k$.

Suppose that there is at least one vertex v on Q_φ within Δ that lies at level at most k, such that v can be connected to a point on π by an arc $\gamma_{\pi,v}$ (of some finite though not necessarily constant description complexity) that lies on Q_φ within Δ, and is at level ($\leq k$) for all points in its relative interior. In this case, we charge all the edges of $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ defined by $P_\varphi \cap Q_\varphi$ to an arbitrary such vertex (see Figure 4.1(b)). Note that each such vertex corresponds to a $(\leq k, 0)$-level overlay vertex.

Similarly, suppose there is at least one edge that passes above/below the boundary of φ at level $\leq k$, while lying on Q_φ within Δ, at a certain point v, such that v can be connected to π by an arc $\gamma_{\pi,v}$ as above. By construction, this implies that part of $\partial\Delta$ is covertical with the boundary of φ, and this is the part of $\partial\Delta$ that contains v. (In general, notice that Δ is always bounded by φ in the sense that the projection Δ_0 of Δ is contained in φ. In the case under consideration, Δ_0 touches the boundary of φ, and thus part of $\partial\Delta_0$ lies on $\partial\varphi$.) In this case, we charge all the edges in $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ defined by $P_\varphi \cap Q_\varphi$ to an arbitrary such point v, as above, noting that each such point again corresponds to a $(\leq k, 0)$-level overlay vertex. (Note that, in the preceding case, the charged vertex was a $(3, 2)$-vertex, whereas now it is a $(2, 3)$-vertex.)

An observation that will prove useful in the proof of the following lemma is that an arc $\gamma_{\pi,v}$ cannot cross any connected component of $P_\varphi \cap Q_\varphi$ that lies in the lower envelope of $\mathcal{A}(\mathcal{F}^{(\varphi)})$, since the interior of $\gamma_{\pi,v}$ is required to lie inside the region Δ.

LEMMA 4.1. *Each point* v *is charged by at most* qk *distinct edges of* $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ *as prescribed in Case* 3.

Proof. The proof is visualized in Figure 4.1. Suppose a point v that lies on Q_φ is charged by an edge π. By construction, π is a connected component of an intersection of Q_φ with another surface P_φ. The crucial observation is that P_φ has to lie below v. Indeed, suppose P_φ lies above v. By construction, there exists an arc $\gamma_{\pi,v}$ that connects v to a point on π and lies fully within level $\leq k$ in its interior. Also by

construction, P_φ lies below Q_φ when we approach π on $\gamma_{\pi,v}$, and our assumption states that P_φ lies above Q_φ when we approach v on $\gamma_{\pi,v}$. Thus P_φ has to intersect the interior of $\gamma_{\pi,v}$, which implies the existence of an edge π' defined by $P_\varphi \cap Q_\varphi$, distinct from π, within level $\leq k$. As observed just before the statement of the lemma, $\gamma_{\pi,v}$ cannot intersect π' at level 0. Thus the level of π' is between 1 and k. Such a situation, however, has been ruled out in Case 2, leading us to a contradiction.

We have thus shown that v can only be charged by connected components of intersections of Q_φ with surfaces that lie below v. Since at most k surfaces lie below v and each defines at most q such connected components (edges) along Q_φ, v is charged by at most qk distinct edges that lie on Q_φ. Since v lies on at most three surfaces of $\mathcal{F}^{(\varphi)}$, it can be charged by at most $3qk$ edges overall. □

Combined with (4.1) and with the fact that q is a constant, Lemma 4.1 implies that the maximum number of edges of this kind that are counted in $S^{(j)}(\mathcal{F}, \mathcal{G})$ is $O(kC_{32}^{(\leq k)}(n)) = O(k^6 C_{32}(n/k))$. In what follows, we assume that there is no vertex v as above (for the specific region Δ which we now keep fixed).

Case 4: *There is a "shallow" edge that reaches infinity.* We continue to use the setup introduced in Case 3 and suppose that there is an edge c of C that lies at level at most k and is not a closed and bounded Jordan curve, and c can be reached from π along an arc $\gamma_{\pi,c}$, as above, that stays at level $\leq k$. (Since we assume that the scenario treated in Case 3 does not hold, this can only occur if Δ is unbounded, c has no vertices, and c reaches infinity. This, in turn, can only happen when φ is unbounded.) In this case, we charge all the edges of $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ defined by $P_\varphi \cap Q_\varphi$ to the edge c. Arguing as above, we can show that the overall number of such edges is $O(k^2 n^{2+\varepsilon})$. The proof of Lemma 4.1 can easily be modified to show that each edge is charged at most $2qk$ times in this fashion. (In the modified proof, we use the fact that the set of surfaces that lie below a point on c is the same for all points of c.) Thus the maximum number of edges of this kind that are counted in $S^{(j)}(\mathcal{F}, \mathcal{G})$ is $O(k^3 n^{2+\varepsilon})$. In what follows, we assume that there is no edge $c \in C$ as above (for our fixed Δ).

Case 5. In this final case, we distinguish between two subcases. In both, we charge one edge π of $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ defined by $P_\varphi \cap Q_\varphi$ (out of the at most q such edges), which bounds the region Δ under consideration, to k edges $c \in C$ that lie at level $\leq k$ and can be reached from π along an $(\leq k)$-level arc $\gamma_{\pi,c}$, as above.

Subcase 5.A: *There is a point on* Δ *that lies at level* $> k$. We can connect this point to a point on one of the boundary arcs π of Δ, defined by $P_\varphi \cap Q_\varphi$, by an arc (of some finite though not necessarily constant description complexity) that lies on Q_φ within Δ, in its interior. Since one endpoint of this arc lies at level $> k$ and the other lies on the lower envelope, the arc intersects at least k distinct edges of C. Moreover, the first k distinct edges encountered when walking along the arc away from π lie at level $\leq k$ since π lies on the lower envelope. We charge π to these first k edges of C.

Subcase 5.B: Δ *lies entirely at level* $\leq k$. We charge π to k arbitrary edges of C.

We emphasize that in both subcases there exists an arc $\gamma_{\pi,c}$ for each edge c charged by π that connects a point on c to a point on π and lies on Q_φ within Δ, and its interior lies fully at level $\leq k$. In Subcase 5.A, $\gamma_{\pi,c}$ is the appropriate prefix of the arc used to identify the k edges that are charged, while in Subcase 5.B, $\gamma_{\pi,c}$ exists since Δ lies entirely at level $\leq k$ and is connected. Therefore, since Cases 1–4 are assumed not to occur, it follows that each of these edges c is a closed bounded Jordan curve not incident to any vertex. Indeed, had vertices incident to c existed, one of them would lie at level $\leq k$ and could be connected to a point on π as prescribed in Case 3. We have assumed, however, that there are no such vertices. The exclusion of Case

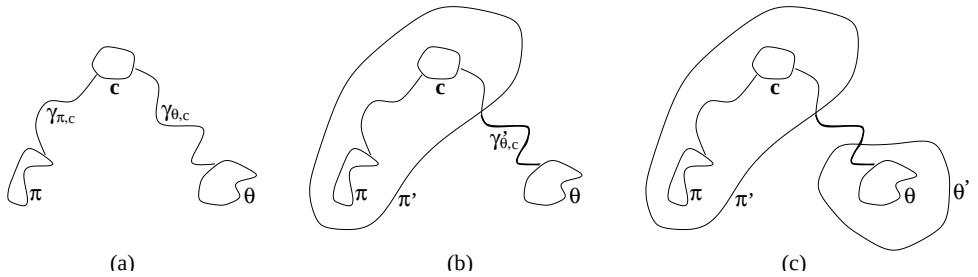

FIG. 4.2. *A schematic visualization of the proof of Lemma* 4.2. *The general setup is introduced in* (a)*;* (b) *illustrates the edge* π' *and the arc* $\gamma'_{\theta,c}$ *(with the latter thickened), and* (c) *illustrates the edge* θ'.

4 similarly implies that c is a closed bounded Jordan curve. (Note that there may nevertheless exist edges $c \in C$ at level $\leq k$ that contain a vertex or are unbounded but are *unreachable* from π along a low-level arc $\gamma_{\pi,c}$, as above.)

Let c be an edge of C that is charged in the above fashion. Lemma 4.2 below states that c is charged at most twice. Let $\Gamma(c)$ be the set of the (at most k) surfaces of $\mathcal{F}^{(\varphi)}$ that lie below c, and set $\tilde{\mathcal{F}}^{(\varphi)} \equiv \mathcal{F}^{(\varphi)} \setminus \Gamma(c)$. Since we assume that none of the scenarios treated in Cases 1–4 holds, it is easy to see that c is an edge of $\Gamma(\tilde{\mathcal{F}}^{(\varphi)})$, unless there exists a component c' "sibling" to c that meets the first k levels of $\mathcal{A}(\tilde{\mathcal{F}}^{(\varphi)})$ and either reaches infinity or contains a vertex of $\mathcal{A}(\tilde{\mathcal{F}}^{(\varphi)})$; the component c' has either descended to the first k levels in $\mathcal{A}(\tilde{\mathcal{F}}^{(\varphi)})$, thereby dropping the index of c to 0, or has already existed within the first k levels of $\mathcal{A}(\mathcal{F}^{(\varphi)})$ but was "hidden" from the charging curve π, as described in the preceding paragraph. (These properties also hold for any subset of $\tilde{\mathcal{F}}^{(\varphi)}$.) As in Case 2, a standard random sampling argument, such as the ones used in section 4.1, now implies, in combination with (4.6), that the maximum number of edges of this kind that are counted in $S^{(j)}(\mathcal{F}, \mathcal{G})$ is

$$\frac{q}{k} \cdot O\left(k^4 S\left(\frac{n}{k}\right) + k^4\left[k^5 C_{32}\left(\frac{n}{k^2}\right) + n^{2+\varepsilon}\right]\right) = O\left(k^3 S\left(\frac{n}{k}\right) + k^8 C_{32}\left(\frac{n}{k^2}\right) + k^3 n^{2+\varepsilon}\right).$$

We now give the lemma, referred to in the beginning of the paragraph, that ensures that each edge $c \in C$ is charged in the above fashion at most twice.

LEMMA 4.2. *Each curve is charged by at most two distinct edges of* $\Gamma^{(j)}(\mathcal{F}^{(\varphi)})$ *as prescribed in Case* 5.

Proof. By construction, an edge $c \subseteq Q_\varphi \cap O_\varphi$ can only be charged by edges that lie either on Q_φ or on O_φ. Assume, for the sake of contradiction, that c is charged by two edges, $\pi \subseteq Q_\varphi \cap P_\varphi$ and $\theta \subseteq Q_\varphi \cap T_\varphi$, for some $P_\varphi, T_\varphi \in \mathcal{F}^{(\varphi)}$ (see Figure 4.2). Notice that the level of c is at most k and that c can be connected to π and θ by arcs $\gamma_{\pi,c}$ and $\gamma_{\theta,c}$, respectively, as described above (see Figure 4.2(a) for an illustration). As argued above, this implies that c is a closed bounded Jordan curve that is incident to no vertex.

We can assume, without loss of generality, that θ and c lie on the same side of the closed curve π. The arguments in the proof of Lemma 4.1 imply that P_φ has to lie completely below c. Consider the arc $\gamma_{\theta,c}$ connecting a point on c to a point on θ, as above. P_φ lies below Q_φ when we approach c on $\gamma_{\theta,c}$, but since θ lies on the lower envelope, P_φ lies above Q_φ when we approach θ on $\gamma_{\theta,c}$. Thus P_φ has to intersect the

relative interior of $\gamma_{\theta,c}$, which implies the existence of a closed curve π' defined by $P_\varphi \cap Q_\varphi$, within level $\leq k$ such that θ and c lie on different sides of π'. π' is therefore distinct from π. If its level is between 1 and k, we reach a contradiction since such situations have been ruled out in Case 2. π' therefore lies on the lower envelope.

Consider the part $\gamma'_{\theta,c}$ of $\gamma_{\theta,c}$ that lies between (the last intersection of $\gamma_{\theta,c}$ with) π' and θ (as shown in Figure 4.2(b)). By construction, T_φ lies below Q_φ when we approach θ on $\gamma'_{\theta,c}$, but since π' lies on the lower envelope, T_φ lies above Q_φ when we approach π' on $\gamma'_{\theta,c}$. Thus T_φ has to intersect the relative interior of $\gamma'_{\theta,c}$, which implies the existence of a closed curve θ' defined by $T_\varphi \cap Q_\varphi$, distinct from θ, within level $\leq k$ (as illustrated in Figure 4.2(c)). As observed just before Lemma 4.1, $\gamma_{\theta,c}$ cannot intersect θ' at level 0. Thus the level of θ' is between 1 and k. Such a situation has however been ruled out in Case 2, leading to a contradiction.

We have shown that c can be charged by a connected component of an intersection of Q_φ with only one other surface. A symmetric statement holds for O_φ. $c \subseteq Q_\varphi \cap O_\varphi$ can thus be charged at most twice. □

We can now write the following relations for all $1 \leq j \leq q$. (Note that for $j = q$ the second term on the right side is not present.)

$$S^{(j)}(n) = O\left[k^3 S\left(\frac{n}{k}\right) + k^4 S^{(j+1)}\left(\frac{n}{k}\right) + k^6 C_{32}\left(\frac{n}{k}\right) + k^9 C_{32}\left(\frac{n}{k^2}\right) + k^4 n^{3+\varepsilon}\right]. \tag{4.8}$$

4.5. Putting it all together. We claim that the system of interdependent recurrences derived in this section, given in (4.4), (4.5), (4.7), (4.8), solves to

$$C_{32}(n) = O(n^{3+\varepsilon}), \qquad C_{22}(n) = O(n^{3+\varepsilon}), \qquad C_{222}(n) = O(n^{3+\varepsilon})$$

for any $\varepsilon > 0$. This is shown by induction, as in [20], choosing a different value of k for each recurrence. In more detail, we order the functions appearing in the recurrences as $(C_{22}, S^{(1)}, S^{(2)}, \ldots, S^{(q)}, C_{222}, C_{32})$ and denote this, for uniformity, as $(F_1, F_2, \ldots, F_{q+3})$. Each recurrence is roughly of the form

$$F_i(n) = O\left(k_i^{\beta_1} F_{j_1}\left(\frac{n}{k_i^{\alpha_1}}\right)\right) + O\left(k_i^{\beta_2} F_{j_2}\left(\frac{n}{k_i^{\alpha_2}}\right)\right) + \cdots + O\left(k_i^{\beta_r} F_{j_r}\left(\frac{n}{k_i^{\alpha_r}}\right)\right) + O\left(f_i(n)\right).$$

We represent this system by a directed graph G on the indices $\{1, 2, \ldots, q+3\}$, whose directed edges are $(i, j_1), \ldots, (i, j_r)$ for all i. We call an edge (i, j) a *forward* (resp., *backward*) edge if $j > i$ (resp., $j \leq i$). Let γ be the maximum of the ratios β_t/α_t taken over all corresponding edges (i, j_t) that are *backward* edges, and assume also that $f_i(n) = O(n^{\gamma+\varepsilon})$ for each i and for any $\varepsilon > 0$. Then one can show that the solution of this system is $F_i(n) = O(n^{\gamma+\varepsilon})$ for any $\varepsilon > 0$ and for all i. Informally, larger exponent ratios in terms that relate F_i to a function F_j with a *larger* index do not affect the overall bound because (almost all of) their effect can be suppressed by the choice of appropriate values for the k_i's, which decrease exponentially with i.

Since in our case, under the order given above, $\gamma = 3$, we obtain the bound asserted above.[2] This completes the proof of Theorem 1.1.

[2]Technically, γ is not quite 3 because of the factors $\beta_s(k)$ and k^ε that are also present in our recurrences. However, any $\gamma > 3$ can be used as a bound for the exponent of the solution, so $O(n^{3+\varepsilon})$ is a solution of the system.

5. Applications. Our bound on the complexity of overlays in $\mathbb{R}^4$ has many applications. We mention several of the more obvious ones. All the results listed below improve significantly upon the best previously known ones. Their proofs crucially rely on Theorem 1.1. Some of the more standard details in the proofs are omitted.

The region "sandwiched" between two envelopes. Let $\mathcal{F}$ and $\mathcal{G}$ be two families of n trivariate functions of constant description complexity, as above. Let $\Sigma_{\mathcal{F},\mathcal{G}}$ denote the *sandwich region* consisting of all points that lie above the upper envelope $E_{\mathcal{G}}$ of $\mathcal{G}$ and below the lower envelope $E_{\mathcal{F}}$ of $\mathcal{F}$. That is, $\Sigma_{\mathcal{F},\mathcal{G}}$ is the set of all quadruples (x_1, x_2, x_3, x_4), such that $g(x_1, x_2, x_3, x_4) \leq x_4 \leq f(x_1, x_2, x_3, x_4)$ for each $f \in \mathcal{F}$, $g \in \mathcal{G}$.

THEOREM 5.1. *The combinatorial complexity of the sandwich region $\Sigma_{\mathcal{F},\mathcal{G}}$ is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

Proof. Consider, for example, the number of vertices of $\Sigma_{\mathcal{F},\mathcal{G}}$. Any such vertex is (i) a vertex of $E_{\mathcal{F}}$ or of $E_{\mathcal{G}}$ (there are $O(n^{3+\varepsilon})$ such vertices for any $\varepsilon > 0$), (ii) an intersection between an edge e of $E_{\mathcal{F}}$ and a facet φ of $E_{\mathcal{G}}$, (iii) an intersection between an edge e of $E_{\mathcal{G}}$ and a facet φ of $E_{\mathcal{F}}$, or (iv) an intersection between a 2-face f of $E_{\mathcal{F}}$ and a 2-face g of $E_{\mathcal{G}}$. Consider the overlay $Q(\mathcal{F}, \mathcal{G})$ of the minimization diagram $M_{\mathcal{F}}$ of $\mathcal{F}$ and the *maximization diagram* $M_{\mathcal{G}}$ of $\mathcal{G}$ (defined in complete analogy to the definition of minimization diagrams). In cases (ii) and (iii), the projections of e and of φ in $Q(\mathcal{F}, \mathcal{G})$ have a nonempty intersection. That is, there exists a connected portion of e that appears as a feature of $Q(\mathcal{F}, \mathcal{G})$, and the cells of $Q(\mathcal{F}, \mathcal{G})$ that it bounds are portions of the projection of φ. Similarly, in case (iv), the projections of f and of g intersect in a curve that is a feature (or a union of features) of $Q(\mathcal{F}, \mathcal{G})$. We can thus charge vertices of $\Sigma_{\mathcal{F},\mathcal{G}}$ to features of $Q(\mathcal{F}, \mathcal{G})$ in a unique manner, which clearly implies the claim. □

Note that the bound in Theorem 5.1 is nearly tight in the worst case. As a matter of fact, the proof of Theorem 5.1 implies the following stronger result; we refer the reader to [7, 17] for details concerning vertical decompositions in four dimensions.

COROLLARY 5.2. *The combinatorial complexity of the first stage of the vertical decomposition of the sandwich region $\Sigma_{\mathcal{F},\mathcal{G}}$ is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

This corollary still leaves open the question of whether the complexity of the entire vertical decomposition of $\Sigma_{\mathcal{F},\mathcal{G}}$ is near-cubic or at least subquartic. This problem is still open even when one collection is empty, i.e., the problem concerning the vertical decomposition of the region below the lower envelope of a collection of trivariate functions.

The space of hyperplane transversals in 4-space. Let $\mathcal{C}$ be a collection of n convex sets in $\mathbb{R}^4$, each being semialgebraic of constant description complexity. Let $T_3(\mathcal{C})$ denote the space of all hyperplane transversals of $\mathcal{C}$, i.e., the set of all hyperplanes that intersect every member of $\mathcal{C}$. Using a standard duality transformation [10], we map hyperplanes to points and points to hyperplanes so that the incidence and the above/below relationships between points and hyperplanes are preserved. (This transformation excludes hyperplanes parallel to the x_4-axis, which can be handled separately in a much simpler manner.) Then each $c \in \mathcal{C}$ is mapped into two totally defined trivariate functions f_c^+, f_c^- such that a hyperplane $x_4 = h_1x_1+h_2x_2+h_3x_3+h_4$ intersects c if and only if $f_c^-(h_1, h_2, h_3) \leq h_4 \leq f_c^+(h_1, h_2, h_3)$. See [2] for more details. Hence $T_3(\mathcal{C})$ is the region sandwiched between the upper envelope of $\{f_c^- | c \in \mathcal{C}\}$ and the lower envelope of $\{f_c^+ | c \in \mathcal{C}\}$. Using Theorem 5.1, we thus obtain the following result.

THEOREM 5.3. *The combinatorial complexity of the space $T_3(\mathcal{C})$ of all hyperplane*

transversals of a set $\mathcal{C}$ of n convex sets of constant description complexity in $\mathbb{R}^4$ is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.

Remark 3. Note that each vertex of $T_3(\mathcal{C})$ is dual to a hyperplane transversal that is tangent to four members of $\mathcal{C}$. Similar geometric interpretations hold for other features of $\partial T_3(\mathcal{C})$.

The space of line transversals in 3*-space.* Let $\mathcal{C}$ be a collection of n convex sets in $\mathbb{R}^3$, each being semialgebraic of constant description complexity. Let $T_1(\mathcal{C})$ denote the space of all line transversals of $\mathcal{C}$. We can map each line l in $\mathbb{R}^3$, given by the equations $y = a_1x + a_2$, $z = a_3x + a_4$, to the point $l^* = (a_1, a_2, a_3, a_4) \in \mathbb{R}^4$. (This excludes lines parallel to the yz-plane, which can be handled separately in a much simpler manner.) As above (see [2] for details), each $c \in \mathcal{C}$ is mapped to a pair of partially defined trivariate functions f_c^+, f_c^- such that f_c^+ and f_c^- have the same domain of definition, and a line l, with $l^* = (a_1, a_2, a_3, a_4)$, is a transversal of c if and only if the functions f_c^+, f_c^- are defined at (a_1, a_2, a_3) and $f_c^-(a_1, a_2, a_3) \le a_4 \le f_c^+(a_1, a_2, a_3)$. Hence this problem too reduces to a sandwich region in four dimensions, and Theorem 5.1 implies the following result.

THEOREM 5.4. *The combinatorial complexity of the space $T_1(\mathcal{C})$ of all line transversals of a set $\mathcal{C}$ of n convex sets of constant description complexity in $\mathbb{R}^3$ is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

Remark 4. As above, vertices of $T_1(\mathcal{C})$ are dual to lines that are tangent to four members of $\mathcal{C}$.

This implies the following corollary concerning the number of *geometric permutations*. Such a permutation is the order in which a collection of disjoint convex bodies can be stabbed by a line transversal.

COROLLARY 5.5. *The number of geometric permutations in a collection $\mathcal{C}$ of n pairwise disjoint convex sets of constant description complexity in $\mathbb{R}^3$ is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

This improves the general known upper bound of $O(n^4)$ [22] (for the special case of sets with constant description complexity) but is not known to be tight, since the only known lower bound is $\Omega(n^2)$ [16].

Efficient construction of transversal spaces. Theorems 5.3 and 5.4 do not address the problem of efficient construction of the respective spaces $T_3(\mathcal{C})$, $T_1(\mathcal{C})$. We next show that the boundaries of these spaces can be constructed efficiently in time $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$. To avoid (the routine though somewhat technical) details involving the representation of the combinatorial structure of the boundary as a 3-dimensional cell complex, we restrict the algorithm to produce, for every pair $c_1, c_2 \in \mathcal{C}$, just the portion of $\partial T_3(\mathcal{C})$ (or $\partial T_1(\mathcal{C})$) that consists of all the points representing hyperplanes (or lines) that are tangent to c_1, c_2 and intersect all the other sets in $\mathcal{C}$. The representation of such a portion, which consists of some faces of a 2-dimensional arrangement (see below), is easy to define and compute. Our construction technique follows the approach used in [1, 5] and is easy to adapt to constructing a complete representation of $\partial T_3(\mathcal{C})$ (or $\partial T_1(\mathcal{C})$).

In more detail, let us consider the case of $T_3(\mathcal{C})$. Fix a pair of sets $c_1, c_2 \in \mathcal{C}$, and consider any pair of functions from $\{f_{c_1}^+, f_{c_1}^-\} \times \{f_{c_2}^+, f_{c_2}^-\}$, say, $f_{c_1}^+, f_{c_2}^+$. The intersection of their graphs is a 2-dimensional surface φ. For each $c \in \mathcal{C}^* \equiv \mathcal{C} \setminus \{c_1, c_2\}$, let

$$K_c = \{h \in \varphi \mid f_c^-(h_1, h_2, h_3) \le h_4 \le f_c^+(h_1, h_2, h_3)\}.$$

We need to construct $\bigcap_{c \in \mathcal{C}^*} K_c$. We do it using the randomized incremental technique of [1, 5]. That is, we insert the sets K_c for $c \in \mathcal{C}^*$ in some random order and update

the intersection after the insertion of each new set. We omit further details, which can be easily adapted from the algorithms just cited. The analysis given in [5], combined with Theorem 5.3, can easily be adjusted to the case at hand, implying that the overall expected running time of this algorithm, when applied to all pairs $c_1, c_2 \in \mathcal{C}$, is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$. Applying a fully analogous procedure for the case of line transversals in 3-space, we obtain the following theorem.

THEOREM 5.6. (a) *The boundary of the space of hyperplane transversals $T_3(\mathcal{C})$ in four dimensions, as defined above, can be computed in $O(n^{3+\varepsilon})$ randomized expected time for any $\varepsilon > 0$.*

(b) *The boundary of the space of line transversals $T_1(\mathcal{C})$ in three dimensions, as defined above, can be computed in $O(n^{3+\varepsilon})$ randomized expected time for any $\varepsilon > 0$.*

Union of objects in 4-space. Let $\mathcal{C}$ be a collection of n convex sets in $\mathbb{R}^4$, each being semialgebraic of constant description complexity, such that (i) the mean curvature [19] of any $c \in \mathcal{C}$ is at most some constant κ, and (ii) for any pair of sets $c_1, c_2 \in \mathcal{C}$, the ratio between their diameters is at most some constant α. (We refer to such sets as being of "nearly equal size.")

Let $\mathcal{U}$ denote the union of $\mathcal{C}$. The combinatorial complexity of $\mathcal{U}$ is the number of faces of all dimensions of the arrangement of the boundaries ∂c of the sets $c \in \mathcal{C}$, which appear on $\partial\mathcal{U}$.

THEOREM 5.7. *The combinatorial complexity of the union $\mathcal{U}$ of n convex sets of constant description complexity in $\mathbb{R}^4$ that satisfy properties* (i) *and* (ii) *is $O(n^{3+\varepsilon})$ for any $\varepsilon > 0$.*

Proof. We may assume that the diameter of any $c \in \mathcal{C}$ is between 1 and α. This, plus the bounded mean curvature assumption, implies the following two properties. Let G be an infinite axis-parallel grid in $\mathbb{R}^4$, where each cell of G is a hypercube of side length b for some sufficiently small constant $b < 1$. Then (a) each $c \in \mathcal{C}$ intersects only $O(1)$ cells of G; (b) let c be a set in $\mathcal{C}$ such that ∂c intersects a cell τ of G. Let $\Delta(c, \tau)$ denote the set of all directions d, such that $\partial c \cap \tau$ is monotone orthogonally to d. That is, $\partial c \cap \tau$ can be regarded as the graph of a (partially defined) function, where the dependent variable is in direction d. (Clearly, $\Delta(c, \tau)$ is centrally symmetric: $d \in \Delta(c, \tau) \Leftrightarrow -d \in \Delta(c, \tau)$.) Then the measure of $\Delta(c, \tau)$ is at least $7/8$ of the measure of the entire sphere of directions (provided b is sufficiently small).

This is easy to establish, and a similar analysis in three dimensions is provided in [4]. To verify property (b), note that the bounded mean curvature assumption implies that for any pair of points $x, y \in \partial c$ on a surface $c \in \mathcal{C}$

$$d_S(N_c(x), N_c(y)) \leq \kappa' \|x - y\|,$$

where κ' is a constant dependent on κ, $N_c(x)$ denotes the direction of the outward normal to ∂c at x, and d_S is the geodesic distance along the unit sphere of directions $\mathbb{S}^3$. Choose b sufficiently small so that $2\kappa' b < \delta$, where the value of δ will be determined shortly. Fix some $x_0 \in \partial c \cap \tau$. Let d be any direction forming an angle θ with $N_c(x_0)$. Suppose that there exists a line λ parallel to d that intersects $\partial c \cap \tau$ at two points u, v. Then $N_c(u) \cdot d$ and $N_c(v) \cdot d$ have different signs so that, say, $N_c(u) \cdot d < 0$. Assuming θ to be smaller than $\pi/2 - \delta$, it follows that $d_S(N_c(x_0), N_c(u)) \geq \pi/2 - \theta > \delta$. On the other hand, the bounded mean curvature assumption implies that $d_S(N_c(x_0), N_c(u)) \leq \kappa' \|u - x_0\| \leq 2\kappa' b \leq \delta$, which is a contradiction. This implies that the set of directions d that satisfy the property in (b) contains the two spherical caps centered at $\pm N_c(x_0)$ and having geodesic radius $\pi/2 - \delta$. Choosing δ (and b) sufficiently small, the validity of property (b) follows.

Property (b) implies that there exists a set Δ of $O(1)$ directions such that, for any quadruple $c_1, c_2, c_3, c_4 \in \mathcal{C}$ whose boundaries all cross a cell τ, we have $\Delta \cap \bigcap_{i=1}^{4} \Delta(c_i, \tau) \neq \emptyset$.

Now, fix a cell τ. If τ is fully contained in some set $c \in \mathcal{C}$, then we ignore τ; it contributes nothing to $\partial\mathcal{U}$. Otherwise, we consider the set $\mathcal{C}_\tau = \{c \in \mathcal{C} \mid \partial c \cap \tau \neq \emptyset\}$ and further partition it into the subsets $\mathcal{C}^+_{\tau,d}$, $\mathcal{C}^-_{\tau,d}$ for $d \in \Delta$, where $\mathcal{C}^+_{\tau,d}$ (resp., $\mathcal{C}^-_{\tau,d}$) consists of all sets $c \in \mathcal{C}_\tau$ for which $d \in \Delta(c, \tau)$ and such that, if we move slightly from any point on $\partial c \cap \tau$ in the direction $+d$ (resp., $-d$), we enter c. (A set c may belong to more than one of these subcollections.)

The preceding discussion implies the following property: (b') let $v \in \tau$ be a vertex of $\mathcal{U}$, incident to the boundaries of four sets $c_1, c_2, c_3, c_4 \in \mathcal{C}$. Then there exists a direction $d \in \Delta$ such that $c_1, c_2, c_3, c_4 \in \mathcal{C}^+_{\tau,d} \cup \mathcal{C}^-_{\tau,d}$.

Property (b') implies that the number of vertices of $\partial\mathcal{U} \cap \tau$ can be upper bounded by the sum, over $d \in \Delta$, of the number of vertices of the sandwich region between the upper envelope of the boundaries of the sets in $\mathcal{C}^+_{\tau,d}$ and the lower envelope of the boundaries of the sets in $\mathcal{C}^-_{\tau,d}$, where both boundaries are clipped to within τ. Using Theorem 5.1 plus the facts that $|\Delta| = O(1)$ and $\sum_\tau |\mathcal{C}_\tau| = O(n)$ (which follows from property (a)), the bound on the complexity of $\mathcal{U}$ follows. □

Arrangements with no vertices. The analysis in section 4.4, which uses a quite nonstandard counting scheme, is of interest on its own and can be adapted to other settings. In particular, it can be easily adjusted to show the following.

THEOREM 5.8. *The complexity of the lower envelope of an arrangement of n totally defined semialgebraic surfaces of constant description complexity in $\mathbb{R}^3$, that does not contain any vertices, is $O(n^{1+\varepsilon})$ for any $\varepsilon > 0$.*

Note that if the surfaces are not totally defined, the complexity of the lower envelope may still be quadratic. An easy lower bound construction is provided by a family of $n/2$ nearly x-parallel lines and another family of $n/2$ nearly y-parallel lines that together make up a grid-structure when viewed from below.

6. Conclusion. We have obtained several results concerning overlays of minimization diagrams using a novel approach. We feel that this approach might find applications for related problems like the analysis of vertical decompositions of arrangements [17]. Although the partition technique seems quite general, our initial steps in applying it in more general contexts have encountered some technical difficulties, which we hope to be able to resolve in the future. We also hope to be able to apply the technique to settle the conjecture concerning the complexity of overlays of minimization diagrams in all dimensions.

In general, it would be interesting to analyze the partition technique from a more "philosophical" point of view and to understand, in particular, the underlying reason for why it was so successful in the analysis of overlays, where the technique of counting schemes has provided only partial results but does not seem to be easily applicable to the related problem of the analysis of single cells, where a near-optimal solution using counting schemes exists [6]. The two techniques seem to be related, at least in the fact that the final recurrences that are derived by both techniques have very similar structures. This is apparent, for instance, in the case of overlays for bivariate functions, in which both techniques provide the same near-optimal solution. The difference, in this case at least, is that the way to obtain these recurrences via the partition technique is arguably much simpler.

Acknowledgments. Part of the work on this paper was carried out while the authors were visiting ETH Zürich, hosted by the European Graduate Program on Combinatorics, Geometry and Computation. The authors are grateful to the program, and, in particular, to Emo Welzl, for the hospitality. Emo Welzl also contributed valuable ideas through helpful discussions.

COMPUTING PHYLOGENETIC ROOTS WITH BOUNDED DEGREES AND ERRORS*

ZHI-ZHONG CHEN†, TAO JIANG‡, AND GUOHUI LIN§

Abstract. Given a set of species and their similarity data, an important problem in evolutionary biology is how to reconstruct a phylogeny (also called evolutionary tree) so that species are close in the phylogeny if and only if they have high similarity. Assume that the similarity data are represented as a graph $G = (V, E)$, where each vertex represents a species and two vertices are adjacent if they represent species of high similarity. The phylogeny reconstruction problem can then be abstracted as the problem of finding a (phylogenetic) tree T from the given graph G such that (1) T has no degree-2 internal nodes, (2) the external nodes (i.e., leaves) of T are exactly the elements of V, and (3) $(u, v) \in E$ if and only if $d_T(u, v) \leq k$ for some fixed threshold k, where $d_T(u, v)$ denotes the distance between u and v in tree T. This is called the *phylogenetic kth root problem* (PRk), and such a tree T, if it exists, is called a *phylogenetic kth root* of graph G. The computational complexity of PRk is open, except for $k \leq 4$. In this paper, we investigate PRk under a natural restriction that the maximum degree of the phylogenetic root is bounded from above by a constant. Our main contribution is a linear-time algorithm that determines if G has such a phylogenetic kth root, and if so, demonstrates one. On the other hand, because in practice the collected similarity data are usually not perfect and may contain errors, we propose to study a generalized version of PRk where the output phylogeny is required only to be an *approximate* root of the input graph. We show that this and other related problems are computationally intractable.

1. Introduction.

The reconstruction of evolutionary history for a set of species from quantitative biological data has long been a popular problem in computational biology. This evolutionary history is typically modeled by an evolutionary tree, or *phylogeny*. A phylogeny is a tree where the leaves are labeled by species and each internal node represents a speciation event whereby an ancestral species gives rise to two or more child species. Both rooted and unrooted trees have been used to describe phylogenies in the literature, although they are practically equivalent. In this paper, we will consider only unrooted phylogenies for the convenience of presentation.[1] The internal nodes of a phylogeny have degrees (in the sense of unrooted trees, i.e.,

[1]But some of our hardness proofs will also use rooted trees as intermediate data structures in the construction.

the number of incident edges) at least 3. Proximity within a phylogeny in general corresponds to similarity in evolutionary characteristics.

Many phylogenetic reconstruction algorithms have been proposed and studied in the literature [12]. In this paper we investigate the computational feasibility of a graph-theoretic approach for reconstructing phylogenies from similarity data. Specifically, interspecies similarity is represented by a graph where the vertices are the species and the adjacency relation represents evidence of evolutionary similarity. A phylogeny is then reconstructed from the graph such that the leaves of the phylogeny are labeled by vertices of the graph (i.e., species) and for any two vertices of the graph, they are adjacent in the graph if and only if their corresponding leaves in the phylogeny are connected by a path of length at most k, where k is a predetermined proximity threshold. To be clear, vertices in the graph are called *vertices* while those in the phylogeny are called *nodes*. Recall that the length of the (unique) path connecting two nodes u and v in phylogeny T is the number of edges on the path, which is denoted by $d_T(u, v)$. This approach gives rise to the following algorithmic problem [8].

PHYLOGENETIC kTH ROOT PROBLEM (PRk). *Given a graph $G = (V, E)$, find a phylogeny T with leaves labeled by the elements of V such that for each pair of vertices $u, v \in V$, $(u, v) \in E$ if and only if $d_T(u, v) \leq k$.*

Such a phylogeny T (if it exists) is called a *phylogenetic kth root*, or a *kth root phylogeny*, of graph G. Graph G is called the *kth phylogenetic power* of T. For convenience, we denote the kth phylogenetic power of any phylogeny T as T^k. That is, $T^k = \{(u, v) \mid u \text{ and } v \text{ are leaves of } T \text{ and } d_T(u, v) \leq k\}$. Thus, PR$k$ asks for a phylogeny T such that $G = T^k$.

1.1. Connection to graph and tree roots, and previous results. Phylogenetic power might be thought of as a *Steiner* extension of the standard notion of *graph power*. A graph G is the *kth power* of a graph H (or equivalently, H is a *kth root* of G) if vertices u and v are adjacent in G if and only if the length of the shortest path from u to v in H is at most k. An important special case of graph power/root problems is the following.

TREE kTH ROOT PROBLEM (TRk). *Given a graph $G = (V, E)$, find a tree $T = (V, E_T)$ such that $(u, v) \in E$ if and only if $d_T(u, v) \leq k$.*

If T exists, then it is called a *tree kth root*, or a *kth root tree*, of graph G. Note that in the phylogenetic root problem the leaves of T correspond to the vertices of G, while in the tree root problem the nodes of T correspond to the vertices of G.

The special case TR2 is also known as the *tree square root problem* [9]. Correspondingly, we call PR2 the *phylogenetic square root problem*. There is abundant literature on graph root and power (see [2, section 10.6] for an overview) but few results on phylogenetic/tree roots/powers. It is NP-complete to recognize a graph power [10]; nonetheless, it is possible to determine if a graph has a kth root tree, for any fixed k, in $O(n^3)$ time, where n is the number of vertices in the input graph [5]. In particular, determining if a graph has a tree square root can be done in $O(n + e)$ time [9], where e is the number of edges in the input graph. Recently, Nishimura, Ragde, and Thilikos [11] presented an $O(n^3)$-time algorithm for a variant of PRk for $k \leq 4$, where internal nodes of the output phylogeny are allowed to have degree 2. More recently, Lin, Kearney, and Jiang [8] introduced a novel notion of *critical clique* and obtained an $O(n + e)$-time algorithm for PRk for $k \leq 4$. Unfortunately, both algorithms cannot be generalized to $k \geq 5$.

1.2. Our contribution. In the practice of phylogeny reconstruction, most phylogenies considered are trees of degree 3 [12] because speciation events are usually

bifurcating events in the evolutionary process. In such *fully resolved* phylogenetic trees, each internal node has three neighbors and represents a speciation event in which some ancestral species splits into two child species. Nodes of degrees higher than 3 are introduced only when the input biological (similarity) data is not sufficient to separate individual speciation events, and hence several such events may be collapsed into a nonbifurcating (super) speciation event in the reconstructed phylogeny. Hence in this paper, we consider a restricted version of PRk where the output phylogeny is assumed to have degree at most Δ for some fixed constant $\Delta \geq 3$. For simplicity, we call it the *degree-*Δ PRk and denote it in short as ΔPRk. Since in the practice of computational biology the species under consideration are more or less related, we are mostly interested in connected graphs. The main contribution of this paper is a linear-time algorithm that determines, for any input connected graph G and constant $\Delta \geq 3$, if G has a kth root phylogeny with degree at most Δ, and if so, demonstrates one such phylogeny. The basic construction in our algorithm is a nontrivial application of bounded-width tree-decomposition of certain chordal graphs [2].

Notice that the input graph in PRk is derived from some similarity data, which is usually inexact in practice and may have erroneous (spurious or missing) edges. Such errors may result in graphs that have no phylogenetic roots. Hence, it is natural to consider a more relaxed problem where we look for phylogenetic trees whose powers are *close* to the input graphs. The precise formulation is as follows.

CLOSEST PHYLOGENETIC kTH ROOT PROBLEM (CPRk). *Given a graph* $G = (V, E)$ *and a nonnegative integer* ℓ*, find a phylogeny* T *with leaves labeled by* V *such that* G *and* T^k *differ by at most* ℓ *edges. That is,*

$$\left|E(G) \oplus E(T^k)\right| = \left|\left(E(G) - E(T^k)\right) \cup \left(E(T^k) - E(G)\right)\right| \leq \ell.$$

A phylogeny T which minimizes the above edge discrepancy is called a *closest* k*th root phylogeny* of graph G.

The *closest tree* k*th root problem* (CTRk) is defined analogously. Notice that CTR1 is trivially solved by finding a spanning tree of the input graph. Kearney and Corneil [5] proved that CTRk is NP-complete when $k \geq 3$. The computational complexity for CTR2 had been open for a while and was recently shown to be intractable by Jiang, Lin, and Xu [4]. In this paper, we will show that CPRk is NP-complete for any $k \geq 2$. Another closely related problem, the *Steiner* k*th root problem* (where $k \geq 1$), is also studied.

We introduce some notation and definitions, as well as some existing related results, in the next section. Our main result on bounded-degree PRk is presented in section 3. The hardness of closest phylogenetic root and Steiner root problems is discussed in section 4. We close the paper with some open problems in section 5.

2. Preliminaries. We employ standard terminologies in graph theory. In particular, the subgraph of a graph G induced by a vertex set U of G is denoted by $G[U]$, the degree of a vertex v in G is denoted by $deg_G(v)$, and the maximum size of a clique in G is denoted by $\omega(G)$. First, it is obvious that if a graph has a kth root phylogeny, then it must be *chordal*; that is, it contains no induced subgraph which is a cycle of size greater than 3 [2].

DEFINITION 2.1. *A* tree-decomposition *of a graph* $G = (V, E)$ *is a pair* $\mathcal{D} = (\mathcal{T}, \mathcal{B})$ *consisting of a tree* $\mathcal{T} = (U, F)$ *and a collection* $\mathcal{B} = \{B_\alpha \mid B_\alpha \subseteq V, \alpha \in U\}$ *of* sets *(called* bags*) for which*

- $\bigcup_{\alpha \in U} B_\alpha = V$;

- *for each edge* $(v_1, v_2) \in E$*, there is a node* $\alpha \in U$ *such that* $\{v_1, v_2\} \subseteq B_\alpha$*; and*
- *if* $\alpha_2 \in U$ *is on the path connecting* α_1 *and* α_3 *in* $\mathcal{T}$*, then* $B_{\alpha_1} \cap B_{\alpha_3} \subseteq B_{\alpha_2}$.

The treewidth *associated with this tree-decomposition* $\mathcal{D} = (\mathcal{T}, \mathcal{B})$ *is* $tw(G, \mathcal{D}) = \max_{\alpha \in U} |B_\alpha| - 1$.

The treewidth *of graph* G*, denoted by* $tw(G)$*, is the minimum* $tw(G, \mathcal{D})$ *taken over all tree-decompositions* $\mathcal{D}$ *of* G.

A clique-tree-decomposition *of* G *is a tree-decomposition* $(\mathcal{T}, \mathcal{B})$ *of* G *such that each bag in* $\mathcal{B}$ *is a maximal clique of* G.

LEMMA 2.2 (see [6]). *Every chordal graph has a clique-tree-decomposition, and it can be computed in linear time.*

From the proof of Lemma 2.2 given in [6], it is not difficult to see that a clique-tree-decomposition $\mathcal{D} = (\mathcal{T}, \mathcal{B})$ of a given chordal graph G can be computed in linear time if $\omega(G) = O(1)$. We can further modify $\mathcal{D}$ so that $deg_{\mathcal{T}}(\alpha) \leq 3$ for each node α of $\mathcal{T}$ [1]. This modification takes linear time too if $\omega(G) = O(1)$.

Hereafter, a tree-decomposition of a chordal graph G always means a clique-tree-decomposition $\mathcal{D} = (\mathcal{T}, \mathcal{B})$ of G such that $deg_{\mathcal{T}}(\alpha) \leq 3$ for all nodes α of $\mathcal{T}$. Furthermore, in what follows, we abuse the notation to use $\mathcal{D}$ to denote the tree $\mathcal{T}$ in it (since we will use T to denote the kth root phylogeny of graph G) and denote the bag associated with a node α of $\mathcal{D}$ by B_α.

3. Algorithm for bounded-degree PR*k*. This section presents a linear-time algorithm for solving 3PRk. The adaptation to ΔPRk where $\Delta \geq 4$ is straightforward and hence omitted here.

We assume that the input graph $G = (V, E)$ is connected. We further assume that G is not complete but is chordal; otherwise the problem is trivially solved in linear time. Since every vertex $v \in V$ appears as an external node (i.e., leaf) in the kth root phylogeny, the maximum size $\omega(G)$ of a clique in G can be bounded from above by a constant $f(k)$, where

$$f(k) = \begin{cases} 3 \cdot 2^{\frac{k}{2}-1} & \text{if } k \text{ is even,} \\ 2^{\frac{k+1}{2}} - 1 & \text{if } k \text{ is odd.} \end{cases}$$

The first step of the algorithm consists of constructing a clique-tree-decomposition $\mathcal{D}$ of G in linear time, as given in Lemma 2.2. Then the kth root phylogeny is computed by a dynamic programming algorithm applied on a rooted version of the decomposition $\mathcal{D}$. The dynamic programming starts at the leaves of $\mathcal{D}$ and proceeds upwards. After processing the root, the algorithm will construct a kth root phylogeny of G if there is any. The processing of a node α of $\mathcal{D}$ can be sketched as follows. Let U_α be the union of the bags associated with α and its descendants in $\mathcal{D}$. While processing α, the algorithm computes a set of trees T such that (1) T may possibly be a subtree of a kth root phylogeny of G, (2) all vertices of U_α are leaves of T, and (3) each leaf of T not contained in U_α is not labeled. The unlabeled leaves of T serve as ports from which we can expand T so that it may eventually become a kth root phylogeny of G. The crucial point we will observe is that we need only those ports that are at distance at most k apart from vertices of B_α in T. This point implies that the number of necessary ports depends only on k and hence is a constant. The details of the dynamic programming algorithm are developed in the next two subsections.

One more notation is in order. For two adjacent nodes α and β of $\mathcal{D}$, let $U(\alpha, \beta) = \bigcup_\gamma B_\gamma$, where γ ranges over all nodes of $\mathcal{D}$ with $d_{\mathcal{D}}(\gamma, \alpha) < d_{\mathcal{D}}(\gamma, \beta)$. In other words,

if we root $\mathcal{D}$ at node β, then $U(\alpha, \beta)$ is the union of the bags associated with α and its descendants in $\mathcal{D}$. A useful property of $\mathcal{D}$ is that for every internal node β and every two neighbors α_1 and α_2 of β in $\mathcal{D}$, G has no edge between any vertex of $U(\alpha_1, \beta) - B_\beta$ and any vertex of $U(\alpha_2, \beta) - B_\beta$.

3.1. Ideas behind the dynamic programming algorithm. Note that since $\Delta = 3$, every internal node in a kth root phylogeny T of G has degree exactly 3.

DEFINITION 3.1. *Let U be a set of vertices of G. A* relaxed phylogeny *for U is a tree R satisfying the following conditions:*

- *The degree of each internal node in R is* 3.
- *Each vertex of U is a leaf in R and appears in R only once. For convenience, we call the leaves of R that are also vertices of U* final leaves *of R, and we call the rest of the leaves of R* temporary leaves *of R.*
- *For every two vertices u and v of U, u and v are adjacent in G if and only if $d_R(u, v) \leq k$.*
- *Each temporary leaf v of R is assigned a pair (γ, t), where γ is a node of $\mathcal{D}$ and $0 \leq t \leq k$. We call γ the* color *of v and call t the* threshold *of v. For convenience, we denote the color of a temporary leaf v of R by $c_R(v)$, and denote the threshold of v by $t_R(v)$.*

Intuitively speaking, the temporary leaves of R serve as ports from which we can expand R so that it may eventually become a kth root phylogeny of G.

Recall that our algorithm processes the nodes of $\mathcal{D}$ one by one. While processing a node α of $\mathcal{D}$, the algorithm finds out all relaxed phylogenies for B_α that are subtrees of kth root phylogenies of graph G. The following lemma shows that such relaxed phylogenies for B_α have certain useful properties.

LEMMA 3.2. *Let T be a kth root phylogeny of G. Let α be a node of $\mathcal{D}$. Root T at an arbitrary leaf that is in B_α. Define a* pure *node to be a node w of T such that α has a neighbor γ in $\mathcal{D}$ such that all leaf descendants of w in T are in $U(\gamma, \alpha) - B_\alpha$. Define a* critical *node to be a pure node of T whose parent is not pure. Let R be the relaxed phylogeny for B_α obtained from T by performing the following steps of operations:*

1. *For every critical node w of T, perform the following:*
   (a) *Compute the minimum distance from w to a leaf descendant of w in T; let i_w denote this distance. (*Comment: *$i_w \leq k$ or else the leaf descendants of w in tree T would be unreachable from the outside in graph G.)*
   (b) *Find the neighbor γ of α such that all leaf descendants of w in T are contained in $U(\gamma, \alpha)$.*
   (c) *Delete all descendants (excluding w, of course) of w, and assign the pair (γ, i_w) to w.*
2. *Unroot T.*

Then the resultant R has the following properties:

- *For every temporary leaf v of R, $c_R(v)$ is a neighbor of α in $\mathcal{D}$.*
- *For every two temporary leaves u and v of R with different colors, it holds that $t_R(u) + t_R(v) + d_R(u, v) > k$.*
- *For every neighbor γ of α in $\mathcal{D}$, every temporary leaf v of R with $c_R(v) = \gamma$, and every final leaf w of R with $w \notin B_\gamma$, it holds that $d_R(v, w) + t_R(v) > k$.*
- *For every internal node v of R, either there is a final leaf u of R with $d_R(u, v) \leq k - 1$ or at least one descendant of v in R' is a final leaf of R, where R' is obtained from R by rooting it at an arbitrary final leaf.*

Proof. Obviously, R is a relaxed phylogeny for B_α. Since T is a phylogeny of G, it follows immediately that R has the first three properties in the lemma. To prove the fourth property, first note that the construction of R from T is independent of the choice of the root of T as long as it is a final leaf. So, it suffices to prove that for every critical node w of T whose parent p in T has no leaf descendant contained in B_α, there is a vertex u in B_α such that $d_T(u,p) \leq k-1$. To this end, let v be a leaf descendant of p that is closest to p among all leaf descendants of p in T. Let $u_1, u_2, \ldots, u_q$ be all leaves in T that are at distance at most k apart from v in T but are not descendants of p in T. Since G is connected, $q \geq 1$. We claim that $\{u_1, u_2, \ldots, u_q\} \cap B_\alpha \neq \emptyset$. For the sake of a contradiction, assume that $\{u_1, u_2, \ldots, u_q\} \cap B_\alpha = \emptyset$. Then some connected component G_1 of $G[V - B_\alpha]$ contains all of $v, u_1, u_2, \ldots, u_q$. Let Q be the set of all leaf descendants of p in T that are not contained in G_1. Since p is not pure and no leaf descendant of p in T is in B_α, we have $|Q| \geq 1$. Also, no vertex of G_1 can be adjacent to any vertex of Q in G. Now, by the choices of u_1 through u_q and the assumption that G_1 contains all of $u_1, u_2, \ldots, u_q$, we conclude that G has no edge between any vertex of Q and any vertex of $V - Q$. This contradicts the connectivity of G. So, the claim holds. By this claim, there is a $u_i \in \{u_1, u_2, \ldots, u_q\} \cap B_\alpha$ such that $d_T(u_i, v) \leq k$. Thus, $d_T(u_i, p) \leq k-1$, establishing the fourth property. ∎

Each relaxed phylogeny R for B_α having the four properties in Lemma 3.2 is called a *skeleton* of α. The following lemma shows that there can be only a constant number of skeletons of α.

LEMMA 3.3. *For each node α of $\mathcal{D}$, the number of skeletons of α is bounded from above by a constant depending only on k and $|B_\alpha|$.*

Proof. First note that the color and the threshold of each temporary leaf can be chosen from a constant range. Further note that each internal node v in a skeleton S of α satisfies $deg_S(v) = 3$. So, to prove the lemma, it suffices to prove that the number of temporary leaves in a skeleton S of α is bounded from above by a constant.

Consider a skeleton S of α and root S at an arbitrary final leaf r. We claim that for every temporary leaf u of S, there is a final leaf w with $d_S(u,w) \leq k$. To see this, let u be a temporary leaf and v be the parent of u in S. Since the root of S is a final leaf, v must be an internal node of S. If there is a final leaf w with $d_S(v,w) \leq k-1$, then $d_S(u,w) \leq k$ and we are done. Otherwise, by the definition of a skeleton, at least one descendant x of v is a final leaf of S. Since $d_S(x,r) \leq k$, we have $\min\{d_S(x,v), d_S(r,v)\} \leq k-1$ and hence $\min\{d_S(x,u), d_S(r,u)\} \leq k$. This establishes the claim.

Since each pair of final leaves is at distance at most k apart in S and the maximum degree of a node in S is 3, there are only a constant number of temporary leaves by the claim. ∎

By Lemma 3.3, while processing a node α of $\mathcal{D}$, our algorithm can find out all skeletons of α in constant time. For each skeleton S of α, if possible, the algorithm then extends S to a relaxed phylogeny for $U(\alpha, \beta)$, where β is the parent of α in rooted $\mathcal{D}$. The algorithm records these relaxed phylogenies of α in the dynamic programming table for later use when processing the parent β. The following definition aims at removing unnecessary relaxed phylogenies of α from the dynamic programming table.

DEFINITION 3.4. *Let α and β be two adjacent nodes of $\mathcal{D}$. Let S be a skeleton of α. The* projection *of S to β is a relaxed phylogeny for $B_\alpha \cap B_\beta$ obtained from S by performing the following steps of operations:*

1. *Change each final leaf $v \notin B_\beta$ to a temporary leaf; set the threshold of v to be 0 and set the color of v to be α.*

2. *Root S at an arbitrary vertex of $B_\alpha \cap B_\beta$.*
3. *Find those nodes v in S such that* (i) *every leaf descendant of v in S is a temporary leaf whose color is not β, but* (ii) *the parent of v in S does not have property* (i).
4. *For each node v found in the last step, if v is a leaf in S, then set the color of v to be α; otherwise, perform the following steps of operations:*
   (a) *Set $m_v = \min_u\{t_S(u) + d_S(u, v)\}$, where u ranges over all leaf descendants of v in S.*
   (b) *Delete all descendants of v in S.*
   (c) *Set v to be a temporary leaf, α to be the color of v, and m_v to be the threshold of v.*
5. *Unroot S.*

Obviously, two different skeletons of α may have the same projection to β. For convenience, we say that these skeletons are *equivalent*. Among equivalent skeletons of α, our algorithm will extend only a hopeful one of them to a relaxed phylogeny for $U(\alpha, \beta)$ and record it in the dynamic programming table. This motivates the following definition.

DEFINITION 3.5. *Let α and β be two adjacent nodes of $\mathcal{D}$. A* projection *of α to β is the projection of a skeleton of α to β. Let P be a projection of α to β. An* expansion *of P to $U(\alpha, \beta)$ is a relaxed phylogeny X for $U(\alpha, \beta)$ such that some subtree Y of X is isomorphic to P, and the bijection f from the node set of P to the node set of Y witnessing this isomorphism satisfies the following conditions:*

- *For every final leaf v of P, $f(v) = v$.*
- *For every temporary leaf v of P with $c_P(v) = \beta$, $f(v)$ is a temporary leaf of X with $c_X(f(v)) = c_P(v)$ and $t_X(f(v)) = t_P(v)$.*
- *Suppose that we root X at a vertex in $B_\alpha \cap B_\beta$. Then, for every temporary leaf v of P with $c_P(v) \neq \beta$ (hence $c_P(v) = \alpha$), all leaf descendants of $f(v)$ in X are final leaves and are contained in $U(\alpha, \beta) - B_\beta$, and the minimum distance between $f(v)$ and a leaf descendant of $f(v)$ in X equals $t_P(v)$.*

Note that a projection of α to β may have no expansion to $U(\alpha, \beta)$. The following lemma shows that if G has a kth root phylogeny T, then some subtree of T is a projection of α to β and another subtree of T is its expansion to $U(\alpha, \beta)$.

LEMMA 3.6. *Let α and β be two adjacent nodes in $\mathcal{D}$. Let T be a kth root phylogeny of G. Root T at an arbitrary leaf that is in B_α. Let R be the skeleton of α obtained from T as in Lemma* 3.2. *Let P be the projection of R to β. Define a* β-pure *node to be a node w of T such that all leaf descendants of w in T are contained in $U(\beta, \alpha) - B_\alpha$. Further, define a* β-critical *node to be a β-pure node of T whose parent is not β-pure. Let X be the relaxed phylogeny for $U(\alpha, \beta)$ obtained from T by performing the following steps of operations:*

1. *For every β-critical node w of T, perform the following:*
   (a) *Compute the minimum distance from w to a leaf descendant of w in T; let i_w denote this distance. (*Comment: *$i_w \leq k$ or else the leaf descendants of w in tree T would be unreachable from the outside in graph G.)*
   (b) *Delete all descendants (excluding w, of course) of w, and assign the pair (β, i_w) to w.*
2. *Unroot T.*

Then X is an expansion of P to $U(\alpha, \beta)$.

Proof. The proof is straightforward. ∎

By Lemma 3.6, whenever G has a kth root phylogeny, there is always a projection of α to β that has an expansion to $U(\alpha, \beta)$. While processing α, our algorithm will find out those projections that have expansions to $U(\alpha, \beta)$ and record the expansions in the dynamic programming table.

3.2. Details of dynamic programming for 3PR*k*. To solve the 3PRk problem for G, we perform a dynamic programming on the tree-decomposition $\mathcal{D}$ as follows. To simplify the description of the algorithm, we add a new node r to $\mathcal{D}$, connect r to an arbitrary leaf α of $\mathcal{D}$, and copy the bag at α to r (that is, $B_r = B_\alpha$). Clearly, the resultant $\mathcal{D}$ is still a required tree-decomposition of G. Root $\mathcal{D}$ at r.

The dynamic programming starts at the leaves of $\mathcal{D}$ and proceeds upwards; after the unique child of the root r of $\mathcal{D}$ is processed, we will know whether G has a kth root phylogeny or not. The invariant maintained during the dynamic programming is that after each nonroot node α has been processed, for each projection P of α to its parent β, we will have found out whether P has an expansion X to $U(\alpha, \beta)$, and we will have found and recorded such an X if any exists.

Now consider how a nonroot node α of $\mathcal{D}$ is processed. Let β be the parent of α in $\mathcal{D}$. First suppose that α is a leaf of $\mathcal{D}$. When processing α, we find and record all possible projections of α to β; moreover, for each projection P found, we also record a skeleton S of α such that P is the projection of S to β.

Next suppose that α is neither a leaf nor the root node of $\mathcal{D}$, and suppose that all descendants of α in $\mathcal{D}$ have been processed. To process α, we try all possible skeletons S of α. When trying S, for each child γ of α in $\mathcal{D}$, we first compute the projection P_γ of S to γ and then check whether P_γ is also a projection of γ to α and additionally has an expansion to $U(\gamma, \alpha)$. If the checking fails for at least one child of α, we proceed to try the next possible skeleton of α. Otherwise, we can conclude that the projection P_β of S to β has an expansion to $U(\alpha, \beta)$ because such an expansion can be constructed as follows:

1. For each child γ of α in $\mathcal{D}$, search the dynamic programming table to find the expansion X_γ of P_γ to $U(\gamma, \alpha)$, and find the bijection f_γ (from the node set of P_γ to the node set of some subtree of X_γ) witnessing that X_γ is an expansion of P_γ to $U(\gamma, \alpha)$. (*Comment:* To speed up the algorithm, we may have recorded this bijection in the dynamic programming table when processing γ.)
2. For each child γ of α in $\mathcal{D}$, root X_γ at an arbitrary vertex of $B_\gamma \cap B_\alpha$.
3. Modify S as follows: For each temporary leaf v of S with $c_S(v) \neq \beta$, replace v by the subtree rooted at $f_\gamma(v)$ of X_γ, where $\gamma = c_S(v)$. (*Comment:* Recall that by Definition 3.4 each temporary leaf v of S with $c_S(v) = \gamma$ is also a temporary leaf of P_γ.)

One can verify that the above construction indeed gives us an expansion of P_β. Since P_β is a possible projection of α to β, we record this expansion for P_β in the dynamic programming table. After trying all possible skeletons of α, if we find no projection of α to β that has an expansion to $U(\alpha, \beta)$, then we can conclude that G has no kth root phylogeny; otherwise, we proceed to the processing of the next node of $\mathcal{D}$.

Finally, suppose that α is the unique child of the root r of $\mathcal{D}$. Further suppose that α has been successfully processed (for otherwise we already knew that G has no kth root phylogeny). Then, by searching the dynamic programming table, we try to find a projection P of α to r such that (i) P has no temporary leaf whose color is r, and (ii) an expansion X of P to $U(\alpha, r)$ has been recorded in the dynamic programming table. If P is found, we can conclude that X is a kth root phylogeny for G; otherwise,

we can conclude that G has no kth root phylogeny.

The above discussion justifies the following theorem.

THEOREM 3.7. *Let k be a constant integer larger than or equal to 2. There is a linear-time algorithm determining if a given connected graph has a kth root phylogeny in which every internal node has degree 3, and if so, demonstrating one such phylogeny.*

We can easily generalize the above discussion to prove the following.

COROLLARY 3.8. *Let Δ and k be constant integers such that $\Delta \geq 3$ and $k \geq 2$. There is a linear-time algorithm determining if a given connected graph has a kth root phylogeny in which every internal node has degree in the range $[3, \Delta]$, and if so, demonstrating one such phylogeny.*

4. The hardness of closest phylogenetic root problems. We introduce some basic concepts (some of them from [5]) that will be used in the hardness proofs. Consider a set $S = \{s_1, s_2, \ldots, s_n\}$. Let M be a symmetric matrix with rows and columns indexed by the elements of S. M is a *binary dissimilarity matrix* on set S if $M(s_i, s_j) \in \{1, 2\}$ for every pair (s_i, s_j) of distinct elements of S and $M(s_i, s_i) = 0$ for every element $s_i \in S$.

A tree T is a 2-*ultrametric* on set S if T is a *rooted* tree whose leaves are labeled by the elements of S and each leaf-to-root path contains exactly two edges. Call a node in T that is neither a leaf nor the root a *middle* node, to avoid ambiguity. The *half-distance* between two leaves s_i and s_j, denoted by $h_T(s_i, s_j)$, is one half of the number of edges on the unique path in T connecting s_i and s_j. Clearly, $h_T(s_i, s_j) \in \{1, 2\}$ if $i \neq j$, and $h_T(s_i, s_i) = 0$ for every i.

Given a binary dissimilarity matrix M and a 2-ultrametric T on set S, define

$$D(T, M) = \sum_{i<j} |h_T(s_i, s_j) - M(s_i, s_j)|,$$

which measures how well T matches the inter-leaf (half-)distances specified by M.[2] The following *fitting ultrametric trees problem* has been shown to be NP-complete by Křivánek and Morávek [7].

FITTING ULTRAMETRIC TREES (FUT). *Given a binary dissimilarity matrix M on set S and a nonnegative integer ℓ, decide if there is a 2-ultrametric T on S such that $D(T, M) \leq \ell$.*

Kearney and Corneil [5] proved that CTRk is NP-hard for any fixed $k \geq 3$ by a (polynomial-time) reduction from FUT (to CTR3). Using a more dexterous reduction, Jiang, Lin, and Xu [4] recently proved that CTR2 is intractable too.

4.1. CPR2. Given a binary dissimilarity matrix M on a set $S = \{s_1, \ldots, s_n\}$, let $S' = \{s_{n+1}, s_{n+2}, \ldots, s_{2n}\}$ be another set of n elements. Define a binary dissimilarity matrix M' on set $S \cup S'$, from M as follows:

For every pair of (not necessarily distinct) integers $i, j \in \{1, 2, \ldots, n\}$,

- $M'(s_i, s_j) = M(s_i, s_j)$;
- $M'(s_{n+i}, s_{n+j}) = M(s_i, s_j)$;
- $M'(s_i, s_{n+j}) = M(s_i, s_j)$ if $i \neq j$;
- $M'(s_i, s_{n+i}) = 1$.

[2] So, here the entries in M are supposed to represent the half-distances between species instead of full distances.

LEMMA 4.1. *If there is a 2-ultrametric T on set S such that $D(T, M) = \ell$, then there is a 2-ultrametric T' on set $S \cup S'$ such that $D(T', M') = 4\ell$.*

Proof. Given a 2-ultrametric T on set S such that $D(T, M) = \ell$, construct a 2-ultrametric T' on set $S \cup S'$ in the following way: The root and middle nodes of T' are the same as those in T; if an $s_i \in S$ is adjacent to a middle node u in T, then both s_i and s_{n+i} are adjacent to u in T'. Clearly, for every pair of (not necessarily distinct) integers $i, j \in \{1, 2, \ldots, n\}$,

- $h_{T'}(s_i, s_j) = h_T(s_i, s_j)$;
- $h_{T'}(s_{n+i}, s_{n+j}) = h_T(s_i, s_j)$;
- $h_{T'}(s_i, s_{n+j}) = h_T(s_i, s_j)$ if $i \neq j$;
- $h_{T'}(s_i, s_{n+i}) = 1$.

Thus, $D(T', M') = 4D(T, M) = 4\ell$. □

LEMMA 4.2. *Let T be a 2-ultrametric on set $S \cup S'$; then there is another 2-ultrametric T' on set $S \cup S'$ such that (1) $D(T', M') \leq D(T, M')$ and (2) for every $i \in \{1, 2, \ldots, n\}$, $s_i \in S$ and $s_{n+i} \in S'$ are adjacent to a common middle node in tree T'.*

Proof. Suppose that $s_i \in S$ is adjacent to a middle node u and $s_{n+i} \in S'$ is adjacent to another middle node $u' \neq u$ in tree T. Let

- $\widetilde{S} = (S \cup S') - \{s_i, s_{n+i}\}$;
- a be the number of $s \in \widetilde{S}$ adjacent to u in T with $M'(s, s_i) = 1$;
- b be the number of $s \in \widetilde{S}$ adjacent to u in T with $M'(s, s_i) = 2$;
- a' be the number of $s \in \widetilde{S}$ adjacent to u' in T with $M'(s, s_{n+i}) = 1$; and
- b' be the number of $s \in \widetilde{S}$ adjacent to u' in T with $M'(s, s_{n+i}) = 2$.

If $a' + b \leq a + b'$, we can modify T by deleting edge (s_{n+i}, u') and adding edge (s_{n+i}, u). Otherwise, we can modify T by deleting edge (s_{n+i}, u) and adding edge (s_{n+i}, u'). In either case, $D(T, M')$ does not increase and, s_i and s_{n+i} are adjacent to a common middle node of the modified T. Repeating this process results in a desired 2-ultrametric. □

From now on, we will only consider those 2-ultrametrics on set $S \cup S'$ such that for every $i \in \{1, \ldots, n\}$, $s_i \in S$ and $s_{n+i} \in S'$ are connected to a common middle node.

LEMMA 4.3. *Given a binary dissimilarity matrix M on set S, there is a 2-ultrametric T on S such that $D(T, M) \leq \ell$ if and only if there is a 2-ultrametric T' on $S \cup S'$ such that $D(T', M') \leq 4\ell$.*

Proof. The "only if" part is implied by Lemmas 4.1 and 4.2. The "if" is straightforward by observing that deleting elements in S' from T' gives a 2-ultrametric T on set S such that $D(T, M) = D(T', M')/4$. □

THEOREM 4.4. CPR2 *is NP-complete.*

Proof. CPR2 is clearly in NP. The hardness proof is done by a reduction from FUT. Consider an instance I of FUT, i.e., a dissimilarity matrix M on set $S = \{s_1, s_2, \ldots, s_n\}$ and a nonnegative integer ℓ. Without loss of generality, we may assume that $n \geq 4$ and $\ell \leq n(n-1)/2$. Construct the corresponding set S' and the dissimilarity matrix M' on $S \cup S'$, from M as in the above. Construct a graph G on a set V of $2n$ vertices as follows. For every $s_i \in S \cup S'$, there is a corresponding vertex v_i in V.[3] Two distinct vertices v_i and v_j are adjacent in G if and only if $M'(s_i, s_j) = 1$.

Let the instance of CPR2 consist of graph G and a nonnegative integer $\ell' = 4\ell$.

[3]We use a different name v_i instead of s_i here in order to avoid ambiguity, although they should be viewed as identical.

We claim that there is an approximate phylogenetic square root T' of graph G with $|E(G) \oplus E(T'^2)| \leq \ell'$ if and only if there is a 2-ultrametric T on set S with $D(T, M) \leq \ell$.

To see the "if" part, suppose that there is a 2-ultrametric T on set S such that $D(T, M) \leq \ell$. This implies there is a 2-ultrametric T'' on set $S \cup S'$ such that $D(T'', M') \leq 4\ell = \ell'$. Recall that for all $i \in \{1, 2, \ldots, n\}$, $s_i \in S$ and $s_{n+i} \in S'$ are adjacent to a common middle node in tree T''. It follows that every middle node in T'' has degree at least 3. Then replacing every leaf s_i in T'' by vertex v_i gives a tree (still denoted by T'') whose leaves are the elements of V. So, if there are three or more middle nodes, then T'' is a phylogeny on V and we are done by setting $T' = T''$. If there is only one middle node in T'', then we obtain T' from T'' by deleting the root as well as its incident edge. If there are exactly two middle nodes in T'', then we obtain T' from T'' by removing the root and connecting the two middle nodes by an edge. Clearly, the final tree T' is a phylogeny on set V. Moreover, $d_{T'}(v_i, v_j) \leq 2$ if and only if $h_{T''}(v_i, v_j) = h_{T''}(s_i, s_j) = 1$ for all distinct $i, j \in \{1, 2, \ldots, n\}$. It follows that edge (v_i, v_j) is in exactly one of $E(G)$ and $E(T'^2)$ if and only if either $h_{T''}(s_i, s_j) = 1$ and $M'(s_i, s_j) = 2$, or $h_{T''}(s_i, s_j) = 2$ and $M'(s_i, s_j) = 1$. That is, the number of such edges is equal to $D(T'', M')$. Thus, $|E(G) \oplus E(T'^2)| = D(T'', M') \leq \ell'$.

To prove the "only if" part, let us assume that T' is a phylogeny interconnecting the vertices in V such that $|E(G) \oplus E(T'^2)| \leq \ell'$. If T' contains only one internal node, i.e., T'^2 is complete, then a 2-ultrametric T'' on set $S \cup S'$ can be constructed to have only one middle node with all elements of $S \cup S'$ attached to it. So, suppose in the following that T' contains two or more internal nodes. We obtain a rooted tree T'' by modifying T' as follows:

1. Select an arbitrary internal edge of T', i.e., an edge connecting two internal nodes, and split the edge into two edges by adding a new internal node, say r, on the edge.
2. Root the new tree at r.
3. Delete all internal edges from the tree. This results in a (possibly empty) set of isolated nodes and a set of stars whose centers are internal nodes of the original T'.
4. Connect the centers of the stars to the root r.

Clearly, the leaves of T'' are the elements of V, T'' is of height 2, and every leaf-to-root path is of length exactly 2. Furthermore, $E(T'^2) = E(T''^2)$. Now replacing leaf v_i in T'' by s_i gives a 2-ultrametric (still denoted by T'') on set $S \cup S'$. Again, an edge (v_i, v_j) is in exactly one of $E(G)$ and $E(T'^2)$ if and only if either $h_{T''}(s_i, s_j) = 1$ and $M'(s_i, s_j) = 2$, or $h_{T''}(s_i, s_j) = 2$ and $M'(s_i, s_j) = 1$. Thus, $D(T'', M') = |E(G) \oplus E(T'^2)| \leq \ell' = 4\ell$. According to Lemmas 4.2 and 4.3, we may easily obtain a 2-ultrametric T on set S, from T'', such that $D(T, M) \leq \ell$. This finishes the proof. □

4.2. CPR*k*. We extend the above NP-completeness result to CPRk for $k > 2$. In doing so, we need to design several gadgets that facilitate the proof.

4.2.1. Gadgets. A *critical clique* [8] of a graph is a maximal subset of vertices that are adjacent to each other and have a common neighborhood. As for constructing a phylogenetic root, the vertices in a critical clique can be identified because they are interchangeable in every phylogenetic root. When we say that one critical clique C_1 is adjacent to another C_2, we mean every vertex in C_1 is adjacent to every vertex in C_2. Consider a graph $H = (V, E)$ consisting of $4k - 7$ critical cliques C_1 through C_{4k-7} such that

- $|C_i| = N$ for $1 \le i \le 4k-7$;
- C_i is adjacent to $C_1, C_2, \ldots, C_{k-2+i}$ for $1 \le i \le k-1$;
- C_i is adjacent to $C_{i-k+2}, C_{i-k+3}, \ldots, C_{i+k-2}$ for $k \le i \le 3k-5$;
- C_i is adjacent to $C_{i-k+2}, C_{i-k+3}, \ldots, C_{4k-7}$ for $3k-4 \le i \le 4k-7$.

Assume that T is an approximate kth root phylogeny of graph H such that $|E(T^k) \oplus E(H)| \le \ell < N$. We present some enforced structural properties of T below.

LEMMA 4.5. *In T, no two vertices from different critical cliques can be adjacent to a common internal node.*

Proof. For the sake of a contradiction, assume that $v_i \in C_i$ and $v_j \in C_j$ with $i \ne j$ are both adjacent to an internal node u in T. Then v_i and v_j have the same neighborhood in the kth phylogenetic power T^k. On the other hand, by the construction of H, there is another critical clique C_h with $h \notin \{i, j\}$ such that C_h is adjacent to exactly one of C_i and C_j in H. So, $|E(T^k) \oplus E(H)|$ is at least as large as N—a contradiction. ∎

Let R be the skeleton obtained from T by deleting all the leaves. In light of Lemma 4.5, a node of R adjacent to some vertex of C_i in tree T is called a *node for* C_i or simply a *C_i-node*. We also call a vertex in clique C_i a *C_i-vertex*. Let R_i be the minimal subtree of R that contains all C_i-nodes. Clearly, R_i can be obtained from R by deleting some nodes and their incident edges. Call R_i the *C_i-subtree*.

LEMMA 4.6. *For every $j \in \{k-1, k, \ldots, 3k-5\}$ and every $i \ne j$, there is no C_i-node in R_j. That is, for every $j \in \{k-1, k, \ldots, 3k-5\}$, the C_j-nodes form a subtree of T.*

Proof. Fix a $j \in \{k-1, k, \ldots, 3k-5\}$. Notice that for every $i \in \{1, 2, \ldots, j-1\}$, if there is a C_i-node, say t_i, in R_j, then t_i must be an internal node in R_j. In tree T, every vertex in C_{j+k-2} is either at distance greater than $k-2$ from some C_j-node or at distance at most $k-2$ from every C_j-node. A C_{j+k-2}-vertex which is at distance at most $k-2$ from every C_j-node is at distance less than $k-2$ from t_i. Therefore, in T^k, each C_{j+k-2}-vertex is either adjacent to no C_j-vertex or adjacent to some C_i-vertex (which is adjacent to t_i in T). This, together with the fact that C_{j+k-2} is adjacent to C_j but adjacent to none of C_1 through C_{j-1}, implies that $|E(T^k) \oplus E(H)| \ge N$—a contradiction. Similarly, using C_{j-k+2} instead of C_{j+k-2}, we can show that R_j contains no C_i-node for every $i \ge j+1$. This proves the lemma. ∎

LEMMA 4.7. *For every $i \in \{k-1, k, \ldots, 3k-5\}$, there is exactly one C_i-node, denoted by t_i, in tree T. Moreover, the nodes $t_{k-1}, t_k, \ldots, t_{3k-5}$ appear consecutively in this order on a path of tree T.*

Proof. Let t_{2k-2} be a C_{2k-2}-node. If t_{2k-2} were within distance $k-2$ from all C_{k-1}-nodes, then the vertices of C_{2k-2} adjacent to t_{2k-2} in tree T would be at distance at most k from every vertex of C_{k-1} in tree T. This would result in at least N edges in $E(T^k) - E(H)$ and is thus impossible. Let t_{k-1} be a C_{k-1}-node such that $d_R(t_{k-1}, t_{2k-2}) > k-2$, and let P denote the path in R connecting them. It holds that for every $i \in \{k, k+1, \ldots, 2k-3\}$, there must be a C_i-node, say t_i, such that $d_R(t_i, t_{k-1}) \le k-2$ and $d_R(t_i, t_{2k-2}) \le k-2$ (otherwise $|E(T^k) \oplus E(H)|$ would be at least N because both C_{k-1} and C_{2k-2} are adjacent to C_i in H). Therefore, in tree R, t_i is closer to some node on path P than to either of t_{k-1} and t_{2k-2}. If subtree R_i contains some node from the path P, then we choose an arbitrary node in $R_i \cap P$ as the *representative* node for R_i. Otherwise, choose the node on P that is the closest to subtree R_i as the representative node for R_i. Denote the representative node for R_i by r_i.

We claim that $r_i \neq r_j$ for every pair of distinct $i, j \in \{k, k+1, \ldots, 2k-3\}$. To prove the claim, for every $i \in \{k, k+1, \ldots, 2k-3\}$, let t'_i be the closest C_i-node to r_i in R. Then $d_R(r_i, t'_i)$ should be less than or equal to both $d_R(r_i, t_{k-1})$ and $d_R(r_i, t_{2k-2})$. It follows that if R_i and R_j with $i < j$ share some representative node, say $r_i = r = r_j$ and $d_R(r, t'_i) \leq d_R(r, t'_j)$ (respectively, $d_R(r, t'_i) \geq d_R(r, t'_j)$), then for every vertex $x \in C_{j+k-2}$ (respectively, $x \in C_{i-k+2}$), either $d_T(x, t'_i) \leq k-1$ or $\max\{d_T(x, t_{2k-2}), d_T(x, t'_j)\} > k-1$ (respectively, either $d_T(x, t'_j) \leq k-1$ or $\max\{d_T(x, t_{k-1}), d_T(x, t'_i)\} > k-1$). This again contradicts the fact that $|E(T^k) \oplus E(H)| < N$.

A similar argument to the proof of the above claim shows that $k \leq i < j \leq 2k-3$ if and only if $d_R(t_{k-1}, r_i) < d_R(t_{k-1}, r_j)$. Since some C_k-node should be within distance $k-2$ from t_{2k-2}, we conclude that the representative node r_k is in fact a C_k-node. Analogously, for every $i \in \{k, k+1, \ldots, 2k-3\}$, r_i is in fact a C_i-node. It further follows that $d_R(t_{k-1}, r_k) = d_R(r_k, r_{k+1}) = \cdots = d_R(r_{2k-3}, t_{2k-2}) = 1$, that is, the path P connecting t_{k-1} and t_{2k-2} is t_{k-1}-r_k-r_{k+1}-…-r_{2k-3}-t_{2k-2}. It is then easy to argue that there is only one C_i-node for every $i \in \{k-1, k, \ldots, 2k-3\}$.

The lemma is proved by considering analogously the C_{2k-4}-node and a C_{3k-5}-node, and the index interval $[2k-4, 3k-5]$. □

By Lemma 4.7, letting t_i denote the unique C_i-node for $i \in \{k-1, k, \ldots, 3k-5\}$, we get a rough structure of R, as shown in Figure 4.1 (where $k = 5$ and t_i indicates a possible C_i-node for $i \in \{1, 2, \ldots, k-2\} \cup \{3k-4, 3k-3, \ldots, 4k-7\}$).

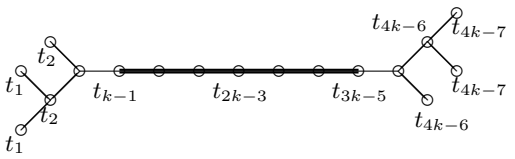

FIG. 4.1. *The rough structure of R.*

4.2.2. Proof of hardness.

THEOREM 4.8. CPRk *is NP-complete when* $k \geq 3$.

Proof. The proof is also a reduction from FUT, but it is more complicated than that of Theorem 4.4. To simplify the presentation, we assume that k is even. It is trivial to extend the proof to odd k. Given a binary dissimilarity matrix M on a set $S = \{s_1, \ldots, s_n\}$, let $S_h = \{s_{hn+1}, s_{hn+2}, \ldots, s_{(h+1)n}\}$ be another set of n elements for all $h = 1, 2, \ldots, 2^{k/2} - 1$. For convenience, let S_0 denote the set S. Define a dissimilarity matrix M' on set $\widetilde{S} = \bigcup_{h=0}^{2^{k/2}-1} S_h$ from M as follows. For every pair of integers $i, j \in \{1, 2, \ldots, n\}$ and every pair of integers $h_1, h_2 \in \{0, 1, \ldots, 2^{k/2} - 1\}$,

- $M'(s_{h_1 n+i}, s_{h_2 n+j}) = M(s_i, s_j)$ if $i \neq j$;
- $M'(s_{h_1 n+i}, s_{h_2 n+i}) = 1$ if $h_1 \neq h_2$;
- $M'(s_{h_1 n+i}, s_{h_1 n+i}) = 0$.

Similarly to the proofs of Lemmas 4.1, 4.2, and 4.3, we can show the following:

(i) There exists a 2-ultrametric T on set S with $D(T, M) \leq \ell$ if and only if there exists a 2-ultrametric T' on set $\widetilde{S}$ with $D(T', M') \leq 2^k \ell$.

(ii) We can consider only those 2-ultrametrics on set $\widetilde{S}$ in which s_{hn+i}, where $h = 0, 1, \ldots, 2^{k/2} - 1$, are adjacent to a common middle node.

Let $\ell' = 2^k\ell$ and $N = \ell' + 1$. The instance of CPRk consists of the nonnegative integer ℓ' and graph G constructed as follows:

- G takes $\widetilde{S}$ as a vertex subset;
- two distinct vertices $s_i, s_j \in \widetilde{S}$ are adjacent in G if and only if $M'(s_i, s_j) = 1$;
- G also contains the graph H consisting of the $4k-7$ critical cliques as discussed in the last subsubsection as a subgraph; and
- for every $i \in \{\frac{3k}{2} - 1, \frac{3k}{2}, \ldots, \frac{5k}{2} - 5\}$, each vertex in C_i is adjacent to every vertex in $\widetilde{S}$.

Lemma 4.7 guarantees that if G has an approximate phylogeny T' such that $|E(G) \oplus E(T'^k)| \le \ell' < N$, then the vertices in each critical clique C_i in subgraph H (where $i \in \{k-1, k, \ldots, 3k-5\}$) are adjacent to the unique internal C_i-node t_i in T'. Since every vertex in $\widetilde{S}$ is adjacent to all vertices in C_i for all $i \in \{\frac{3k}{2} - 1, \frac{3k}{2}, \ldots, \frac{5k}{2} - 5\}$, and the length of the path consisting of those $k-3$ C_i-nodes has length $k-4$, every vertex in $\widetilde{S}$ must be within distance $\frac{k}{2} + 1$ from the (unique) C_{2k-3}-node t_{2k-3} in T'.

Let T'' denote the minimal subtree of T' that contains all vertices in $\widetilde{S}$. The first observation is that T'' contains no vertex outside $\widetilde{S}$. Secondly, since every vertex in $\widetilde{S}$ is adjacent to neither vertex in $C_{\frac{3k}{2}-2}$ nor vertex in $C_{\frac{5k}{2}-4}$, we conclude that every vertex in $\widetilde{S}$ is at distance exactly $\frac{k}{2} + 1$ from the C_{2k-3}-node t_{2k-3}. Furthermore, the path connecting any vertex in $\widetilde{S}$ to t_{2k-3} does not intersect the backbone path formed by the C_i-nodes for $i \in \{k-1, k, \ldots, 3k-5\}$ (except at t_{2k-3}).

Therefore, if subtree T'' does not include node t_{2k-3}, then we can construct a 2-ultrametric tree, denoted also by T'', on set $\widetilde{S}$ by connecting all the elements to a single middle node. Otherwise, rooting T'' at t_{2k-3} and letting every leaf be adjacent to its closest child node of the root, which serves as the middle node, give a 2-ultrametric, denoted still by T'', on set $\widetilde{S}$. In any case, the 2-ultrametric T'' on set $\widetilde{S}$ satisfies $D(T'', M') \le \ell' = 2^k\ell$, which immediately implies that we can construct a 2-ultrametric T on set S such that $D(T, M) \le \ell$.

On the other hand, if we have a 2-ultrametric T on set S such that $D(T, M) \le \ell$, we can easily construct a 2-ultrametric T'' on set $\widetilde{S}$ such that $D(T'', M') \le 2^k\ell = \ell'$ and in which elements s_{hn+i}, $h = 0, 1, \ldots, 2^{k/2} - 1$, are adjacent to a common middle node. It is also easy to transform the subtree of T'' under each middle node into a $\frac{k}{2}$-height subtree rooted at the middle node so that every leaf is at distance exactly $\frac{k}{2}$ from the middle node and every internal node of the whole tree (except its root), still denoted by T'', has degree at least 3. At the same time, we can also easily build a tree for subgraph H in which all vertices in C_i are adjacent to a single C_i-node t_i, and these $4k-7$ C_i-nodes are connected consecutively into a path (such that t_i is adjacent to t_{i-1} and t_{i+1}). We then identify the root of T'' with the C_{2k-3}-node t_{2k-3}. This gives a phylogeny, which is denoted by T', such that $|E(G) \oplus E(T'^k)| = D(T'', M') \le \ell'$. ∎

4.3. Steiner kth root problem. We study another problem closely related to PRk and TRk, which is the *Steiner kth root problem* [8]. Recall that given a graph $G = (V, E)$, TRk asks for a tree whose node set is exactly V, and PRk asks for a tree whose leaf-set is exactly V. A more general problem is to ask for a tree T whose node set is a superset of V and whose leaf-set is a subset of V, and such that for every pair of vertices u and v in V, $d_T(u, v) \le k$ if and only if $(u, v) \in E$. We call a tree T whose node set is a superset of V and whose leaf-set is a subset of V a *Steiner tree* on V.

STEINER kTH ROOT PROBLEM (SRk). *Given a graph $G = (V, E)$, find a Steiner tree T on V such that for each pair of vertices $u, v \in V$, $(u, v) \in E$ if and only if $d_T(u, v) \le k$.*

Such a Steiner tree T (if it exists) is called a *Steiner kth root* or a *kth root Steiner tree* of G. G is called the *kth Steiner power* of T. We also abuse T^k to denote the *kth Steiner power* of T when there is no confusion from the context.

Notice that here we do not require a nonleaf node in a Steiner tree to have degree at least 3. This requirement is not necessary from the tree root point of view. But one may do so, as this requirement is natural from the phylogenetic root point of view. Steiner trees satisfying this additional requirement are called *restricted Steiner trees*. Graphs having a restricted Steiner kth root for $k = 1, 2$ can be recognized in linear time [8]. The recognition algorithm can be extended to find an ordinary Steiner kth root for $k = 1$ and $k = 2$. However, when $k \geq 3$, no polynomial-time recognition algorithm has been reported yet to find either a Steiner kth root or a restricted Steiner kth root. In the following, we will consider only ordinary Steiner roots and show that the closest Steiner kth root problem (CSRk), defined in a straightforward way, is NP-complete when $k \geq 2$.

We call the nodes in a Steiner tree T that are not vertices in V *Steiner nodes*.

For CSR1, we notice that deleting all Steiner nodes from an (approximate) 1st root Steiner tree T results in a collection of subtrees such that vertices in different subtrees are not adjacent in T^1. Therefore, for any input graph G, the best way to build the closest 1st root Steiner tree is to construct a spanning tree for each connected component in G and then connect these spanning trees together via a Steiner node. That is, a closest 1st root Steiner tree can be computed in $O(n)$ time, where n is the number of vertices in the input graph. The complexity changes when k marches from 1 to 2. In fact, by designing similar yet more careful gadgets, we are able to construct a reduction from FUT to CSRk for every fixed $k \geq 2$.

THEOREM 4.9. CSRk *is NP-complete for every* $k \geq 2$.

We omit the proof of Theorem 4.9 in this paper because it is quite long and somewhat tedious (especially given the proof of Theorem 4.8). The complete proof can be found in the technical report [3].

5. Open problems. Since CPRk is NP-complete for all $k \geq 2$, it would be interesting to know how well we can approximate the closest phylogenetic kth root. Also, it would be nice to extend Theorem 3.7 and Corollary 3.8 to disconnected graphs.

Acknowledgments. The authors thank the referee for helpful comments. The third author thanks Paul Kearney for bringing CPRk to his attention and thanks Bin Ma and Jinbo Xu for many helpful discussions.

LEXICOGRAPHICAL GENERATION OF A GENERALIZED DYCK LANGUAGE*

JENS LIEBEHENSCHEL†

Abstract. We consider a generalization of the Dyck language. We have a set of opening and a set of closing brackets and a relation that gives the pairs of brackets that can be used in the generalized Dyck language. This Dyck language is a handy coding for several classes of labeled trees.

We present an algorithm that generates all words of length $2n$ of the generalized Dyck language lexicographically. Thereby, each word is computed from its predecessor according to the lexicographical order without any knowledge about the words generated before.

Additionally, we introduce a condition on the relation for the generalized Dyck language to be simply generated, which means that an algorithm needs to read only the suffix to be changed in order to compute the successor of a word according to the lexicographical order. We present an algorithm that checks whether a Dyck language is simply generated or not.

For an arbitrary relation, we compute the sth moments of the random variable describing the length of the suffix to be changed in the computation of the successor of a Dyck word. In particular, the mean value and the variance are constant.

1. Overview and definitions.

In this section, we introduce the generalization of the Dyck language, the lexicographical order needed for the lexicographical generation, and all definitions—illustrated by several examples—for the whole paper. We also point out the contents of the following sections.

In this paper, we present an algorithm that generates all words of length $2n$ of the generalized Dyck language given in Definition 1.1 lexicographically. The algorithm reads a word from right to left and changes a suffix of that word in order to generate the next word according to the lexicographical order given in Definition 1.2.

DEFINITION 1.1. *Let* $T_{\lfloor} := \{\lfloor_1, \lfloor_2, \ldots, \lfloor_{t_1}\}$ *(resp.,* $T_{\rfloor} := \{\rfloor_1, \rfloor_2, \ldots, \rfloor_{t_2}\}$*) with* t_1, $t_2 \in \mathbb{N}$ *be the* set of opening *(resp.,* closing*)* brackets*. Let* $|S|$ *be the cardinality of the set* S*, so* $|T_{\lfloor}| = t_1$ *and* $|T_{\rfloor}| = t_2$*. With* $T := T_{\lfloor} \dot{\cup} T_{\rfloor}$*, where* $\dot{\cup}$ *denotes the* disjoint union *of sets, and a relation* $\mathcal{R} \subseteq T_{\lfloor} \times T_{\rfloor}$*, we obtain the* generalized Dyck language associated with $\mathcal{R}$ *(cf.* [Ke96]*) by*

$$D := \{w \in T^\star \mid w \equiv \varepsilon \bmod \delta\},$$

where ε *denotes the* empty word *and* δ *is the congruence over* T *which is defined by* $(\forall(\lfloor_a, \rfloor_b) \in \mathcal{R})(\lfloor_a \rfloor_b \equiv \varepsilon \bmod \delta)$*. The* set of all Dyck words of length $2n$ *is given by* $D_{2n} := D \cap T^{2n}$.

Remark 1.1. Obviously, there is a unique *corresponding closing* (resp., *opening*) bracket to each opening (resp., closing) bracket in every Dyck word $w \in D$.

*Received by the editors August 28, 2001; accepted for publication (in revised form) September 8, 2002; published electronically June 10, 2003.

The closing bracket corresponding to an opening bracket in a Dyck word $w \in D$ can be found by searching for the first closing bracket behind the shortest word $w_2 \in D$ (w_2 might be ε) on the right side of the opening bracket. If the opening (resp., its corresponding closing) bracket is $[_a$ (resp., $]_b$), we have $w = w_1\,[_a\,w_2\,]_b\,w_3$ with $w_1\,w_3, w_2 \in D$. The corresponding opening bracket to a closing bracket can be found in an analogous way.

DEFINITION 1.2. *Let $\lessdot \subseteq T \times T$ be an irreflexive linear ordering on T. The* lexicographical order $\prec$ over T^+ *is defined as the extension of $\lessdot$ to $\prec \subseteq T^+ \times T^+$ by*

$$\begin{aligned} x \prec y :\Longleftrightarrow \quad & \big(\exists z \in T^+\big)(xz = y) \\ & \vee \big(\exists\,(w, x', y', a, b) \in T^{\star 3} \times T^2\big)(x = wax' \wedge y = wby' \wedge a \lessdot b)\,, \end{aligned}$$

cf. [Ke98]. *Note that in this paper we consider the lexicographical order on words of length $2n$ only.*

We use the following ordering on T:

$$[_{|T_[|} \lessdot \cdots \lessdot [_1 \lessdot\ ]_1 \lessdot \cdots \lessdot\ ]_{|T_]|}.$$

Now, let us have a closer look at the relation $\mathcal{R}$. From the existence of the lexicographical order $\prec$ on D results the existence of a unique *lexicographically minimal (resp., maximal) tuple in* $\mathcal{R}$ which is denoted by $\mathcal{R}_{\min}$ (resp., $\mathcal{R}_{\max}$).

DEFINITION 1.3. *Let $p_{\min}$ (resp., $p_{\max}$) be the* lexicographically minimal *(resp., maximal) pair of brackets in $\mathcal{R}$. Further, let $[_{p_{\min}}, [_{p_{\max}} \in T_[$ and $\ ]_{p_{\min}},]_{p_{\max}} \in T_]$. Then we get*

$$\begin{aligned} p_{\min} := [_{p_{\min}}\,]_{p_{\min}} &\iff \mathcal{R}_{\min} = \big([_{p_{\min}},]_{p_{\min}}\big) \text{ and} \\ p_{\max} := [_{p_{\max}}\,]_{p_{\max}} &\iff \mathcal{R}_{\max} = \big([_{p_{\max}},]_{p_{\max}}\big). \end{aligned}$$

Obviously, $[_{p_{\min}}$ (resp., $]_{p_{\min}}$) is the opening *(resp.,* closing*)* bracket of the lexicographically minimal pair of brackets, *and $[_{p_{\max}}$ (resp., $]_{p_{\max}}$) is the* opening *(resp.,* closing*)* bracket of the lexicographically maximal pair of brackets. *Now, we are able to compute the* minimal *(resp.,* maximal*)* word of D_{2n} according to the lexicographical order $w_{\min}^{D_{2n}}$ *(resp., $w_{\max}^{D_{2n}}$)*:

$$w_{\min}^{D_{2n}} = \big([_{p_{\min}}\big)^n \big(]_{p_{\min}}\big)^n \quad \text{and} \quad w_{\max}^{D_{2n}} = \big(p_{\max}\big)^n.$$

In this paper, we assume that there are no useless symbols in T, so we find $[_{p_{\min}} = [_{|T_[|}$ and $[_{p_{\max}} = [_1$.

DEFINITION 1.4. *Given $([_a,]_b) \in \mathcal{R}$, $]_b$ is called* minimal *(resp.,* maximal*)* with respect to $[_a$ *if there is no smaller (resp., larger) closing bracket that corresponds to $[_a$ in $\mathcal{R}$. For the sake of clear presentation, we use "minimal (resp., maximal)" instead of "minimal (resp., maximal) with respect to the corresponding opening bracket". A string of closing brackets is called minimal (resp., maximal) if each bracket in the string is minimal (resp., maximal).*

Note that the property of being minimal (resp., maximal) depends not only on the closing bracket, but also on the corresponding opening bracket. For example, $]_b$ of $([_{a_1},]_b)$ can be minimal even if $]_b$ of $([_{a_2},]_b)$ is not minimal.

Let us demonstrate the above definitions by two simple examples.

Example 1.1. Let $T := \{[_1, [_2,]_1,]_2\}$, $\mathcal{R} := \{([_1,]_1), ([_2,]_2)\}$, and $n := 2$. We get the ordering on the alphabet $[_2 \lessdot [_1 \lessdot\ ]_1 \lessdot\ ]_2$. The lexicographically minimal (resp.,

$$\begin{array}{ccccccccccccc} & & & & [_2\,[_2\,]_2\,]_2 & \prec & [_2\,[_1\,]_1\,]_2 & \prec & [_2\,]_2\,[_2\,]_2 & \prec & [_2\,]_2\,[_1\,]_1 \\ \prec & [_1\,[_2\,]_2\,]_1 & \prec & [_1\,[_1\,]_1\,]_1 & \prec & [_1\,]_1\,[_2\,]_2 & \prec & [_1\,]_1\,[_1\,]_1 & & & \end{array}$$

FIG. 1. *All Dyck words of Example* 1.1 *arranged according to the lexicographical order* $\prec$.

$$\begin{array}{ccccccccccccc} & & [_2\,[_2\,]_2\,]_2 & \prec & [_2\,[_1\,]_1\,]_2 & \prec & [_2\,[_1\,]_2\,]_2 & \prec & [_2\,]_2\,[_2\,]_2 & \prec & [_2\,]_2\,[_1\,]_1 & \prec & [_2\,]_2\,[_1\,]_2 \\ \prec & [_1\,[_2\,]_2\,]_1 & \prec & [_1\,[_2\,]_2\,]_2 & \prec & [_1\,[_1\,]_1\,]_1 & \prec & [_1\,[_1\,]_1\,]_2 & \prec & [_1\,[_1\,]_2\,]_1 & \prec & [_1\,[_1\,]_2\,]_2 & \\ \prec & [_1\,]_1\,[_2\,]_2 & \prec & [_1\,]_1\,[_1\,]_1 & \prec & [_1\,]_1\,[_1\,]_2 & \prec & [_1\,]_2\,[_2\,]_2 & \prec & [_1\,]_2\,[_1\,]_1 & \prec & [_1\,]_2\,[_1\,]_2 & \end{array}$$

FIG. 2. *All Dyck words of Example* 1.2 *arranged according to the lexicographical order* $\prec$.

maximal) word is given by $w_{\min}^{D_4} = [_2\,[_2\,]_2\,]_2$ (resp., $w_{\max}^{D_4} = [_1\,]_1\,[_1\,]_1$). In Figure 1, we find all Dyck words of this example.

Example 1.2. Let $T := \{[_1, [_2,]_1,]_2\}$, $\mathcal{R} := \{([_1,]_1), ([_1,]_2), ([_2,]_2)\}$, and $n := 2$. Again, we obtain the ordering on the alphabet $[_2 \lessdot [_1 \lessdot\,]_1 \lessdot\,]_2$. The lexicographically minimal (resp., maximal) word is given by $w_{\min}^{D_4} = [_2\,[_2\,]_2\,]_2$ (resp., $w_{\max}^{D_4} = [_1\,]_2\,[_1\,]_2$). Given $([_1,]_1)$, we see that $]_1$ is minimal but not maximal. Analogously, $]_2$ of $([_1,]_2)$ is maximal but not minimal. Regarding $([_2,]_2)$, we find $]_2$ to be both minimal and maximal. In Figure 2, all Dyck words of this example are arranged lexicographically.

Now, in the following two definitions, let us recall some functions defined in [Ke98]; the formal definitions can be found in [Li98] as well.

DEFINITION 1.5. *For an arbitrary language* L *and* $w \in L$, *the* successor function $\mathsf{next}(w)$ *computes the* successor of w according to the lexicographical order; $\mathsf{next}(w_{\max}^L)$ *is undefined.*

DEFINITION 1.6. *Let* $\mathsf{pre}(w)$ *be the* longest common prefix of w and $\mathsf{next}(w)$; $\mathsf{old}(w)$ (*resp.,* $\mathsf{new}(w)$) *is the* suffix of w (*resp.,* $\mathsf{next}(w)$) to the right of $\mathsf{pre}(w)$. *Thus* $w = \mathsf{pre}(w)\mathsf{old}(w)$ *and* $\mathsf{next}(w) = \mathsf{pre}(w)\mathsf{new}(w)$ *are factorizations of* w *and its successor. The language* $L \subseteq \Sigma^\star$ *is called* simply generated *with respect to* $\prec$ *iff it satisfies the property*

$$\big(\forall (w, w') \in L^2\big)\big(\mathsf{old}(w) = \vartheta\,\mathsf{old}(w'), \vartheta \in \Sigma^\star \rightsquigarrow \big(\vartheta, \mathsf{new}(w)\big) = \big(\varepsilon, \mathsf{new}(w')\big)\big).$$

This means that a language L is called simply generated if it is possible to determine the suffix $\mathsf{old}(w)$ and replace it by the suffix $\mathsf{new}(w)$ in a unique way for all $w \in L \setminus \{w_{\max}^L\}$ without any knowledge about $\mathsf{pre}(w)$. So, a language L is called simply generated if it is sufficient to read the suffix to be changed only for all $w \in L \setminus \{w_{\max}^L\}$ in order to compute $\mathsf{next}(w)$.

Example 1.3. Considering Example 1.1, with $w = [_2\,[_2\,]_2\,]_2$ we find $\mathsf{next}(w) = [_2\,[_1\,]_1\,]_2$. Obviously, we get $\mathsf{pre}(w) = [_2$, $\mathsf{old}(w) = [_2\,]_2\,]_2$, and $\mathsf{new}(w) = [_1\,]_1\,]_2$. It is easy to check that the Dyck language D_4 with $\mathcal{R} := \{([_1,]_1), ([_2,]_2)\}$ is simply generated.

In section 2, we formalize the successor function; for that purpose we have to define some functions that give information on the relation $\mathcal{R}$. In the algorithm, we use the notation $w = w_0 \dots w_{2n-1} \in D_{2n}$ with $w_i \in T$, $0 \le i \le 2n-1$.

The first three functions depend on the relation $\mathcal{R}$ and a given Dyck word w. Their formal definitions can be found in [Li98].

The function $\mathsf{succ\_pair}$. The function $\mathsf{succ\_pair}([_a\,]_b)$ computes to a given pair of brackets $[_a\,]_b$ the next pair of brackets according to the lexicographical order $\prec$ and

the relation $\mathcal{R}$. Thus it computes the successor of a Dyck word of length two.

Note that for all $(r_1, r_2) \in \mathcal{R} \setminus \{\mathcal{R}_{\max}\}$, the function $\mathsf{succ\_pair}(r_1\, r_2)$ is always defined.

The function succ. The function $\mathsf{succ}(w, i)$ computes to a given closing bracket $w_i =]_b$ in a Dyck word the next closing bracket according to the lexicographical order $\prec$ and the relation $\mathcal{R}$. For some closing brackets, the unique corresponding opening bracket to $]_b$ in the Dyck word w has to be known. It can be determined as described in Remark 1.1.

Note that, for all closing brackets that are not maximal, succ is always defined.

The function min_pred. Given a Dyck word with $w_i =]_b$, and $[_a$ being the corresponding opening bracket to $]_b$, the function $\mathsf{min\_pred}(w, i)$ computes the minimal closing bracket that corresponds to $[_a$ according to the lexicographical order $\prec$ and the relation $\mathcal{R}$.

Note that, for all closing brackets, min_pred is always defined. Further, the function min_pred can be applied to $w_i \dots w_j \in T_]^\star$; we define

$$\mathsf{min\_pred}(w, i, j) := \mathsf{min\_pred}(w, i)\, \mathsf{min\_pred}(w, i+1) \dots \mathsf{min\_pred}(w, j).$$

If $w_i \dots w_j = \varepsilon$, we obtain $\mathsf{min\_pred}(w, i, j) = \varepsilon$.

Remark 1.2. The functions succ and min_pred need some more information, namely, the corresponding opening bracket to the function's argument, which is a closing bracket. For some relations $\mathcal{R}$ it is necessary to read that opening bracket; for others it is not necessary, because the information needed can be determined by the relation $\mathcal{R}$. A condition for this requirement of information will be given in section 3.

The following boolean functions depend on the relation $\mathcal{R}$ only.

The function no_succ. The function $\mathsf{no\_succ}(\,]_b)$ is true iff the given closing bracket $]_b$ is maximal with respect to all pairs of brackets in which it appears.

The function succ_unique. The function $\mathsf{succ\_unique}(\,]_b)$ is true iff the call of the function succ for any closing bracket $]_b$ leads to the same result—independently of the corresponding opening bracket to $]_b$.

The function min_pred_unique. The function $\mathsf{min\_pred\_unique}(\,]_b)$ is true iff the result of min_pred for a given closing bracket $]_b$ is the same—independently of the corresponding opening bracket to $]_b$.

Again, these three functions are formally defined in [Li98].

Example 1.4. Let us revisit Example 1.2 with $\mathcal{R} := \{([_1,]_1), ([_1,]_2), ([_2,]_2)\}$. As the lexicographical order on the pairs of brackets is given by $[_2\,]_2 \prec [_1\,]_1 \prec [_1\,]_2$, we obtain $\mathsf{succ\_pair}([_2\,]_2) = [_1\,]_1$, $\mathsf{succ\_pair}([_1\,]_1) = [_1\,]_2$, $\mathsf{succ\_pair}([_1\,]_2) =$ undefined. Now, we regard

$$w = w_0\, w_1\, w_2\, w_3\, w_4\, w_5 = [_1\,]_2\, [_1\, [_2\,]_2\,]_1 \in D_6.$$

Obviously,

$$\mathsf{succ}(w, 1) = \text{undefined}, \mathsf{succ}(w, 4) = \text{undefined}, \mathsf{succ}(w, 5) =]_2,$$

$$\mathsf{min\_pred}(w, 1) =]_1, \mathsf{min\_pred}(w, 4, 5) =]_2\,]_1.$$

The boolean functions immediately yield

$$\mathsf{no\_succ}(\,]_1) = \text{false}, \mathsf{no\_succ}(\,]_2) = \text{true},$$

$$\mathsf{succ\_unique}(\,]_1) = \text{true}, \mathsf{succ\_unique}(\,]_2) = \text{true},$$

$$\mathsf{min\_pred\_unique}(\,]_1) = \text{true}, \mathsf{min\_pred\_unique}(\,]_2) = \text{false}.$$

In section 3, we formalize the condition on the relation $\mathcal{R}$ whether a given language D_{2n} is simply generated or not. Further, we present an algorithm that decides whether or not a relation $\mathcal{R}$ results in a simply generated Dyck language. The following two definitions are needed for section 3.

DEFINITION 1.7. *Let* $\mathsf{open}(\,]_j) := \{[_i \mid ([_i,]_j) \in \mathcal{R}\}$ *(resp.,* $\mathsf{close}([_i) := \{\,]_j \mid ([_i,]_j) \in \mathcal{R}\}$*) be the* set of all corresponding opening (resp., closing) brackets to a given closing (resp., opening) bracket according to the relation $\mathcal{R}$.

Further, let $\mathsf{successor}(\,]_j, [_i)$ *be the function that computes the same closing bracket for a relation* $\mathcal{R}$ *as* succ *does for a closing bracket of a Dyck word. The only difference is that the function needs to know the corresponding closing bracket to the opening bracket, because it is not able to determine it as* succ*, because* succ *gets the whole word as a parameter and not only a closing bracket.*

For the formal definition of successor*, refer to* [Li98].

Note that open, close, and successor depend on the relation $\mathcal{R}$ only and not on a Dyck word.

DEFINITION 1.8. *The* matrix representation *of a relation* $\mathcal{R}$ *is given by*

$$M := (m_{i,j})_{1\le i\le|T_]|,1\le j\le|T_]|} \quad \textit{with} \quad m_{i,j} := \begin{cases} 1 & \textit{if} \quad ([_i,]_j) \in \mathcal{R}, \\ 0 & \textit{if} \quad ([_i,]_j) \notin \mathcal{R}. \end{cases}$$

Example 1.5. Considering the relation $\mathcal{R} := \{([_1,]_1), ([_1,]_2), ([_2,]_2)\}$ of Example 1.2, we immediately find $\mathsf{open}(\,]_1) = \{[_1\}$, $\mathsf{open}(\,]_2) = \{[_1, [_2\}$, $\mathsf{close}([_1) = \{\,]_1,]_2\}$, and $\mathsf{close}([_2) = \{\,]_2\}$. The matrix representation of $\mathcal{R}$ is given by $M = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$.

In section 4, we analyze the length of the suffix to be changed in order to generate the next word according to the lexicographical order on the average. This average-case analysis is based on a general approach to the average length of the shortest suffix to be changed when generating words of a language lexicographically, cf. [Ke98].

In section 5, we point out that the generalized Dyck language is a handy coding for several classes of labeled trees. Hence we are able to generate classes of labeled trees lexicographically.

2. Algorithm for the generation of Dyck words. In this section, we will present an algorithm that generates all words $w \in D_{2n}$ lexicographically. We follow a classical method for lexicographical generation of combinatorial objects, cf. [Wi77], [NW78], and [Ke98]; the lexicographical generation will be carried out by successive calls of a function which obtains a word and computes its successor according to the lexicographical order. The successor is computed by changing a suffix of the word.

In contrast to the above method, all objects of a desired length can be generated modifying all (recursively generated) objects of the next shorter length, cf. [BLP98]. The latter method does not allow the computation of the successor of a word, if

```
function generate ()
  begin
    w := w_min^{D_2n}
      while w ≠ undefined do
        w := next(w)
  end;
```

FIG. 3. *Algorithm* 1. *Function that generates all words of the language D_{2n} lexicographically.*

merely that word is known; at least one word of shorter length is required. Thus, for saving the state of the generation process, not less than one word of each length has to be stored. In the method used here, only one word needs to be saved. So, we can interrupt the computation without extra cost.

The reason for generating according to the lexicographical order is the following: For the lexicographical generation (following the classical method), it is known that the mean length of the suffix to be changed is as short as possible, cf. [Ke98]. Our algorithm is optimal with respect to the length of the suffix to be changed.

The function generate (see Algorithm 1) starts with the generation of the lexicographically minimal word $w_{\min}^{D_{2n}}$ and successively generates the successor $\mathsf{next}(w)$ of $w \in D_{2n}$ according to the lexicographical order until the lexicographically maximal word $w_{\max}^{D_{2n}}$ has been generated. Remember that $\mathsf{next}(w_{\max}^{D_{2n}})$ is undefined.

Note that in the function generate, the lexicographical generation is a transformation from one word to its successor. So, each word $w \in D_{2n} \setminus \{w_{\min}^{D_{2n}}\}$ depends on its *predecessor* only; there is no need for more information on the words previously generated.

For the function next we need two technical lemmas. In Lemma 2.1, we prove that D_{2n} can be split into four disjoint sets. In Lemma 2.2, we show that each Dyck word $w = w_0 \dots w_{2n-1} \in D_{2n}$ has a unique factorization. The existence of the unique factorization is required for the function next.

LEMMA 2.1. *Let $S_{2n}^{(j)} \subseteq D_{2n}$, $1 \le j \le 4$. With $w \in D_{2n}$, the following hold:*

$$w \in S_{2n}^{(1)} \iff w = w_{\max}^{D_{2n}},$$

$$w \in S_{2n}^{(2)} \iff w = \underbrace{x}_{\in T^+} \quad \underbrace{w_\alpha}_{\substack{\in T_\rfloor \\ \text{not maximal}}} \quad \underbrace{w_{\alpha+1} \dots w_\beta}_{\substack{\in T_\rfloor^\star \\ \text{maximal}}} \quad \underbrace{w_{\max}^{D_{2i}}}_{\substack{\text{with} \\ 0 \le i \le n-1}},$$

$$w \in S_{2n}^{(3)} \iff w = \underbrace{x}_{\in T^\star} \quad \underbrace{w_\alpha\, w_{\alpha+1}}_{\substack{\in D_2 \setminus \{w_{\max}^{D_2}\} \\ w_{\alpha+1} \text{ maximal}}} \quad \underbrace{w_{\alpha+2} \dots w_\beta}_{\substack{\in T_\rfloor^\star \\ \text{maximal}}} \quad \underbrace{w_{\max}^{D_{2i}}}_{\substack{\text{with} \\ 0 \le i \le n-1}},$$

$$w \in S_{2n}^{(4)} \iff w = \underbrace{x}_{\in T^+} \quad w_{\max}^{D_2} \quad \underbrace{w_\alpha \dots w_\beta}_{\substack{\in T_\rfloor^+ \\ \text{maximal}}} \quad \underbrace{w_{\max}^{D_{2i}}}_{\substack{\text{with} \\ 0 \le i \le n-2}}.$$

Then the following equation holds:

$$D_{2n} = S_{2n}^{(1)} \,\dot\cup\, S_{2n}^{(2)} \,\dot\cup\, S_{2n}^{(3)} \,\dot\cup\, S_{2n}^{(4)}.$$

Proof. We present only the sketch of the proof here; the proof is worked out in [Li98] in detail.

With $S_{2n}^{(j)} \subseteq D_{2n}$, $1 \le j \le 4$, it follows that every word that is not a Dyck word is in none of these sets.

Now, we have to prove that every Dyck word is in at least one set. We assume that a Dyck word w exists which is in none of the sets $S_{2n}^{(j)}$, $1 \le j \le 4$. Then we factorize w by splitting off first the longest suffix $p_{\max} \dots p_{\max}$ and second the longest suffix consisting of maximal closing brackets only. Several cases arise, and in each case we obtain a contradiction; thus each Dyck word is in at least one of the sets defined above.

Finally, we just have to prove that the sets $S_{2n}^{(1)}$, $S_{2n}^{(2)}$, $S_{2n}^{(3)}$, and $S_{2n}^{(4)}$ are pairwise disjoint. We obtain six cases; in each case, the assumption that a Dyck word is in both sets leads to a contradiction. □

Remark 2.1. If $n = 1$, we find $S_2^{(4)} = \emptyset$.

LEMMA 2.2. *Each Dyck word $w \in D_{2n}$ has a unique factorization.*

Proof. Again, we outline the proof; the formal proof can be found in [Li98].

As we have already shown that $S_{2n}^{(1)}$, $S_{2n}^{(2)}$, $S_{2n}^{(3)}$, and $S_{2n}^{(4)}$ are pairwise disjoint, we have only to prove that, for each word w, there is only one factorization according to the set it belongs to. The assumption to find two different factorizations for a Dyck word leads to a contradiction for each set. □

Now we are able to point out the successor function $\mathsf{next}(w)$ of a word $w \in D_{2n}$ according to the lexicographical order. With Lemmas 2.1 and 2.2, we can compute the successor for each of the sets $S_{2n}^{(j)}$, $1 \le j \le 4$, separately.

THEOREM 2.3. *The successor of a Dyck word $w \in D_{2n}$ is computed as follows.*

$w \in S_{2n}^{(1)}$:

$$\begin{aligned} w &= w_{\max}^{D_{2n}} \\ \mathsf{next}(w) &= \textit{undefined} \end{aligned}$$

$w \in S_{2n}^{(2)}$:

$$\begin{array}{rcl} w & = & \overbrace{x}^{\in T^+}\ \overbrace{w_\alpha}^{\in T_\rfloor \textit{ not maximal}}\ \overbrace{w_{\alpha+1} \dots w_\beta}^{\in T_\rfloor^\star \textit{ maximal}}\ \overbrace{w_{\max}^{D_{2i}}}^{\textit{with } 0 \le i \le n-1} \\ \mathsf{next}(w) & = & \underbrace{x}_{\in T^+}\ \underbrace{\mathsf{succ}(w,\alpha)}_{\in T_\rfloor}\ \underbrace{w_{\min}^{D_{2i}}}_{\substack{\textit{with} \\ 0 \le i \le n-1}}\ \underbrace{\mathsf{min\_pred}(w,\alpha+1,\beta)}_{\substack{\in T_\rfloor^\star \\ \textit{minimal}}} \end{array}$$

$w \in S_{2n}^{(3)}$:

$$\begin{array}{rcl} w & = & \overbrace{x}^{\in T^\star}\ \overbrace{w_\alpha\, w_{\alpha+1}}^{\substack{\in D_2 \setminus \{w_{\max}^{D_2}\} \\ w_{\alpha+1}\ \textit{maximal}}}\ \overbrace{w_{\alpha+2} \dots w_\beta}^{\in T_\rfloor^\star \textit{ maximal}}\ \overbrace{w_{\max}^{D_{2i}}}^{\textit{with } 0 \le i \le n-1} \\ \mathsf{next}(w) & = & \underbrace{x}_{\in T^\star}\ \underbrace{\widehat{w_\alpha}}_{\in T_\lfloor}\ \underbrace{w_{\min}^{D_{2i}}}_{\substack{\textit{with} \\ 0 \le i \le n-1}}\ \underbrace{\widehat{w_{\alpha+1}}}_{\substack{\in T_\rfloor \\ \textit{minimal}}}\ \underbrace{\mathsf{min\_pred}(w,\alpha+2,\beta)}_{\substack{\in T_\rfloor^\star \\ \textit{minimal}}} \end{array}.$$

Here, $\mathsf{succ\_pair}(w_\alpha\, w_{\alpha+1}) = \widehat{w_\alpha}\ \widehat{w_{\alpha+1}}$.

$$
\begin{array}{lcl}
w \in S_{2n}^{(4)}: & & \\
w & = & \overbrace{x}^{\in T^+}\ w_{\max}^{D_2}\ \overbrace{w_\alpha}^{\substack{\in T_\rfloor \\ maximal}}\ \overbrace{w_{\alpha+1}\ldots w_\beta}^{\substack{\in T_\rfloor^\star \\ maximal}}\ \overbrace{w_{\max}^{D_{2i}}}^{\substack{with \\ 0\le i\le n-2}} \\
\mathsf{next}(w) & = & \underbrace{x}_{\in T^+}\ \underbrace{\mathsf{min\_pred}(w,\alpha)}_{\substack{\in T_\rfloor \\ minimal}}\ \underbrace{w_{\min}^{D_{2(i+1)}}}_{\substack{with \\ 0\le i\le n-2}}\ \underbrace{\mathsf{min\_pred}(w,\alpha+1,\beta)}_{\substack{\in T_\rfloor^\star \\ minimal}}\ .
\end{array}
$$

Proof. As the proofs for the sets $S_{2n}^{(2)}$, $S_{2n}^{(3)}$, and $S_{2n}^{(4)}$ are similar, some cases can be omitted here. All cases are treated in [Li98] completely.

$w \in S_{2n}^{(1)}$: $\rightsquigarrow w = w_{\max}^{D_{2n}}$; $w_{\max}^{D_{2n}}$ has no successor.

Regarding $w \in S_{2n}^{(j)}$, $2 \le j \le 4$, and $\mathsf{next}(w)$, we see that $w \prec \mathsf{next}(w)$. Hence we have only to prove that there is no Dyck word between w and $\mathsf{next}(w)$.

$w \in S_{2n}^{(2)}$: We assume that $(\exists v \in D_{2n})(w \prec v \prec \mathsf{next}(w)) \rightsquigarrow v = x\,\tilde{v}$, $x \in T^+$, with

$$
\begin{array}{lcl}
\underbrace{w_\alpha}_{\substack{\in T_\rfloor \\ \text{not maximal}}}\ \overbrace{\underbrace{w_{\alpha+1}\ldots w_\beta}_{\substack{\in T_\rfloor^\star \\ \text{maximal}}}\ w_{\max}^{D_{2i}}}^{\substack{\text{lexicographically} \\ \text{largest suffix for } x\,w_\alpha}} & \prec & \tilde{v} \\
& \prec & \underbrace{\mathsf{succ}(w,\alpha)}_{\in T_\rfloor}\ \overbrace{w_{\min}^{D_{2i}}\ \underbrace{\mathsf{min\_pred}(w,\alpha+1,\beta)}_{\substack{\in T_\rfloor^\star \\ \text{minimal}}}}^{\substack{\text{lexicographically} \\ \text{smallest suffix for } x\,\mathsf{succ}(w,\alpha)}}\ .
\end{array}
$$

Obviously, $w_\alpha \lessdot \mathsf{succ}(w,\alpha)$. Note that w_α and $\mathsf{succ}(w,\alpha)$ are the only possibilities for the first symbol in $\tilde{v}$. Further, we know that every $v \in D_{2n}$ has exactly n opening and n closing brackets.

Case 1: $\tilde{v} = w_\alpha\,\hat{v}$. $\rightsquigarrow w_{\alpha+1}\ldots w_\beta\, w_{\max}^{D_{2i}} \prec \hat{v}$. This is a contradiction, as w is the lexicographically largest Dyck word with the prefix $x\,w_\alpha$. Obviously, $\hat{v}$ must contain i opening brackets and $(\beta-\alpha+i)$ closing brackets, but all closing brackets in $w_{\alpha+1}\ldots w_\beta$ are maximal (so none of them can be substituted by a larger one), and there is no larger Dyck word in D_{2i} than $w_{\max}^{D_{2i}}$.

As each opening bracket is smaller than each closing bracket, a rearrangement of the brackets does not lead to a lexicographically larger Dyck word.

Thus such $\hat{v}$ does not exist.

Case 2: $\tilde{v} = \mathsf{succ}(w,\alpha)\,\hat{v}$. $\rightsquigarrow \hat{v} \prec w_{\min}^{D_{2i}}\,\mathsf{min\_pred}(w,\alpha+1,\beta)$. Similarly to Case 1, we can prove that $\mathsf{next}(w)$ is the smallest Dyck word with the prefix $x\,\mathsf{succ}(w,\alpha)$.

Hence such $\hat{v}$ does not exist.

$w \in S_{2n}^{(3)}$, $w \in S_{2n}^{(4)}$. These cases can be proved analogously to the previous case. □

Remark 2.2.

1. When regarding the definition of $\mathsf{next}(w)$ of $w \in D_{2n}$, we notice that we need some information on the relation $\mathcal{R}$:
   - Is a closing bracket maximal?
   - If a closing bracket is not maximal, what is its next closing bracket according to the relation $\mathcal{R}$ $\left(\widehat{=}\ \mathsf{succ}\right)$?
   - If a closing bracket is maximal, what is its minimal closing bracket according to the relation $\mathcal{R}$ $\left(\widehat{=}\ \mathsf{min\_pred}\right)$?

   In the next section, we will focus on the condition for the following:
   - This information can be obtained from the relation $\mathcal{R}$.
   - This information cannot be obtained from the relation $\mathcal{R}$, but it can be obtained by reading a part of the Dyck word—especially the opening bracket corresponding to that closing bracket.
2. If $n = 1$, the function next simplifies to

$$\mathsf{next}(w) = \begin{cases} \text{undefined} & \text{if} \quad w = w_{\max}^{D_2} \in S_2^{(1)}, \\ w_0\, \mathsf{succ}(w, 1) & \text{if} \quad w = w_0\, w_1 \in S_2^{(2)}, \\ & \quad (w_0, w_1) \in \mathcal{R},\ w_1 \text{ is not maximal}, \\ \mathsf{succ\_pair}(w_0\, w_1) & \text{if} \quad w = w_0\, w_1 \in S_2^{(3)}, \\ & \quad (w_0, w_1) \in \mathcal{R} \setminus \{\mathcal{R}_{\max}\},\ w_1 \text{ is maximal} \end{cases}$$
$$= \mathsf{succ\_pair}(w_0\, w_1).$$

Note that the function $\mathsf{min\_pred}$ is not needed for $n = 1$ because $S_2^{(4)} = \emptyset$.

Now, we are able to present the algorithmic definition of the function next. Regarding Theorem 2.3, we see that it has to read the Dyck word w from right to left. First, the algorithm reads all lexicographically maximal pairs of brackets $p_{\max}$ at the end of w. Then it has to read the string consisting of maximal closing brackets. Having read an opening bracket or a closing bracket that is not maximal, it finds the suffix to be changed and can generate the successor. We see that the function next uses the existence of the unique factorization according to the suffix of every Dyck word, cf. Lemma 2.2. The successor is computed for each of the sets defined in Lemma 2.1.

Sometimes there are one or more closing brackets in the suffix to be changed for which it is undecidable (in consideration of the suffix read only) whether the brackets are maximal or what the next or minimal closing brackets according to the order on the alphabet and the relation $\mathcal{R}$ are. If such a bracket is read, the function init is called. It reads to the left until the corresponding opening bracket is found (see Remark 1.1). The function init makes the information on this part of the Dyck word accessible to the functions succ and $\mathsf{min\_pred}$ in the algorithm.

Now, we are able to present the algorithm (see Algorithm 2) that generates all words in D_{2n} lexicographically. Note that $w = w_0 \dots w_{2n-1} \in D_{2n}$ in the algorithm.

3. On the length of the suffixes read and changed. In the preceding section, we noticed that, for the generation of the successor of a word $w \in D_{2n}$, according to the lexicographical order it might sometimes be necessary to read more than just the word's suffix to be changed (function init). In this section, we will show that this necessity depends on the relation $\mathcal{R}$.

Now, we formalize the condition for a simply generated Dyck language D_{2n}. We will see that this condition depends on $\mathcal{R}$ only and that we have to distinguish between the cases $n = 1$ and $n \geq 2$.

FIG. 6. *Matrix representation of a relation* $\mathcal{R}$ *(Case* b*).*

THEOREM 3.1.
Case 1: $n = 1$.

D_2 *is simply generated*
$\iff \big(\forall\,]_j \in T_]\big)\big(\forall\, [_{i_1}, [_{i_2} \in \mathsf{open}(\,]_j)\big)\big(\mathsf{successor}(\,]_j, [_{i_1}) = \mathsf{successor}(\,]_j, [_{i_2})\big)$.

Case 2: $n \geq 2$.

D_{2n} *is simply generated* $\iff \big(\forall\,]_j \in T_]\big)\big(\forall\, [_{i_1}, [_{i_2} \in \mathsf{open}(\,]_j)\big)\big(\mathsf{close}([_{i_1}) = \mathsf{close}([_{i_2})\big)$.

Proof. We just outline the proof of the theorem; the formal proof is presented in [Li98] in detail.

First, let us take a look at some columns of two rows of the matrix representation M given in Figures 5 and 6. In both figures, we have $1 \leq \kappa < \kappa + \mu \leq |T_[|$ and $1 \leq \lambda < \lambda + \nu \leq |T_]|$. We distinguish between two cases, which we will refer to in the sketch of the proof.

Case a (see Figure 5):

$$\begin{pmatrix} m_{\kappa,\lambda} & m_{\kappa,\lambda+\nu} \\ m_{\kappa+\mu,\lambda} & m_{\kappa+\mu,\lambda+\nu} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix} \text{ or } \begin{pmatrix} m_{\kappa,\lambda} & m_{\kappa,\lambda+\nu} \\ m_{\kappa+\mu,\lambda} & m_{\kappa+\mu,\lambda+\nu} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}.$$

Case b (see Figure 6):

$$\begin{pmatrix} m_{\kappa,\lambda} & m_{\kappa,\lambda+\nu} \\ m_{\kappa+\mu,\lambda} & m_{\kappa+\mu,\lambda+\nu} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \text{ or } \begin{pmatrix} m_{\kappa,\lambda} & m_{\kappa,\lambda+\nu} \\ m_{\kappa+\mu,\lambda} & m_{\kappa+\mu,\lambda+\nu} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}.$$

Let us remember Remark 2.2. Generating the successor $\mathsf{next}(w)$ of $w \in D_{2n}$, we need to decide whether a given closing bracket $w_i =]_j \in T_]$ is maximal. If it is not maximal, then we need to compute $\mathsf{succ}(w, i)$; otherwise, we need to compute $\mathsf{min\_pred}(w, i)$, but only if $n \geq 2$.

Case 1: $n = 1$. This case implies Case a (Figure 5).

$\Rightarrow$: We assume

$$\big(\exists\,]_j \in T_]\big)\big(\exists\, [_{i_1}, [_{i_2} \in \mathsf{open}(\,]_j)\big)\big(\mathsf{successor}(\,]_j, [_{i_1}) \neq \mathsf{successor}(\,]_j, [_{i_2})\big).$$

We have either Case i or Case ii.

Case i: $\mathsf{successor}(\,]_j, [_{i_1}) =]_a \neq]_b = \mathsf{successor}(\,]_j, [_{i_2})$.

Case ii: $\mathsf{successor}(\,]_j, [_{i_1}) =]_a \neq$ undefined $= \mathsf{successor}(\,]_j, [_{i_2})$.

In both cases, we can conclude that the Dyck language is not simply generated, since the condition for a language to be simply generated (see Definition 1.6) is not fulfilled.

$\Leftarrow$: We assume that D_2 is not simply generated, i.e.,

$$\big(\exists w, w' \in D_2\big)\big(\mathsf{old}(w) = \vartheta\, \mathsf{old}(w'), \vartheta \in T^\star \rightsquigarrow (\vartheta, \mathsf{new}(w)) \neq (\varepsilon, \mathsf{new}(w'))\big).$$

Again, we have two cases.

Case i: $\vartheta \neq \varepsilon$.

Case ii: $\vartheta = \varepsilon \ \wedge\ \mathsf{new}(w) \neq \mathsf{new}(w')$.

In either case, we obtain a contradiction to

$$\big(\forall\,]_j \in T_]\big)\big(\forall\, [_{i_1}, [_{i_2} \in \mathsf{open}(\,]_j)\big)\big(\mathsf{successor}(\,]_j, [_{i_1}) = \mathsf{successor}(\,]_j, [_{i_2})\big).$$

Case 2: $n \geq 2$. This case implies Case a (Figure 5) or Case b (Figure 6); it can be proved in a way analogous to the proof of Case 1. □

Remark 3.1.

1. From Theorem 3.1 it follows immediately that a Dyck language D_{2n} is simply generated for $n \geq 1$ if $|\mathsf{open}(\,]_j)| = 1$, $1 \leq j \leq |T_]|$.
2. In order to compute $\mathsf{next}(w)$ of $w \in D_{2n}$, we have to read a suffix of w. If D_{2n} is simply generated, we have to change exactly the brackets we need to read in order to generate the successor of $w \in D_{2n}$. In that case, the information required by the functions succ, min_pred, no_succ, succ_unique, and min_pred_unique can be directly deduced from the relation $\mathcal{R}$. This is in contrast to a language not simply generated, whereas—for at least one word —a part of the common prefix of the Dyck word and its successor has to be inspected.
3. The familiar Dyck languages with the following relations are simply generated:
   - $\mathcal{R} = \{([_1,]_1)\}$, i.e., with one pair of brackets,
   - $\mathcal{R} = \{([_1,]_1), \ldots, ([_t,]_t)\}$, i.e., with t pairs of brackets, $t \geq 1$, where every opening (resp., closing) bracket corresponds to one closing (resp., opening) bracket only (cf. [Ha78, p. 313], [Li96]), and
   - $\mathcal{R} = \{([_1,]_1), \ldots, ([_1,]_r), ([_2,]_1), \ldots, ([_2,]_r), \ldots, ([_l,]_1), \ldots, ([_l,]_r)\}$, i.e., with $l \cdot r$ pairs of brackets, $l, r \geq 1$, where each opening (resp., closing) bracket corresponds to each closing (resp., opening) bracket.
4. Let

$$\widetilde{M} := \begin{pmatrix} A^{(1)} & & & & \\ & A^{(2)} & & 0 & \\ & & \ddots & & \\ & 0 & & A^{(k-1)} & \\ & & & & A^{(k)} \end{pmatrix}$$

be the *normal form* of a matrix M. Here, $A^{(l)}$, $1 \leq l \leq k$, are submatrices.

```
boolean function simply_generated ()
    begin
        simply_generated := true
        /⋆ check for all closing brackets ]_j, ... ⋆/
        for j := 1 to |T_]| do
            begin
                /⋆ ... if successor(]_j, [_i) is the same for all corresponding [_i ⋆/
                k := 0
                for i := 1 to |T_[| do
                    if m_{i,j} = 1 and k = 0 then
                        k := search_next(i, j)
                    else if m_{i,j} = 1 and k ≠ search_next(i, j) then
                        begin
                            simply_generated := false
                            return
                        end
            end
    end;
```

FIG. 7. *Algorithm* 3. *Function that checks whether the language D_2 is simply generated.*

- If $n = 1$, the first row of $A^{(l)}$ consists of 1's only. The following rows have the form

$$\underbrace{0 \cdots 0}_{\geq 0} \underbrace{1 \cdots 1}_{\geq 1},$$

  where the number of 1's is monotonically decreasing from the first to the last row. For example, the matrices

$$\begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \text{ and } \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$$

  have that property.
- In the case in which $n \geq 2$, each entry in $A^{(l)}$ is equal to 1.

The matrix representation M of the Dyck language D_{2n} with relation $\mathcal{R}$ can be transformed into its normal form $\widetilde{M}$ by permutating rows and columns iff D_{2n} is simply generated.

Example 3.1. D_{2n} with relation $\mathcal{R} = \{([_1,]_1), ([_2,]_2)\}$ of Example 1.1 is simply generated for $n \geq 1$, as $|\mathsf{open}(\,]_1)| = 1$ and $|\mathsf{open}(\,]_2)| = 1$.

For the language D_{2n} with relation $\mathcal{R} = \{([_1,]_1), ([_1,]_2), ([_2,]_2)\}$ of Example 1.2, we find $\mathsf{open}(\,]_1) = \{[_1\}$ and $\mathsf{open}(\,]_2) = \{[_1, [_2\}$. As $\mathsf{successor}(\,]_2, [_1) =$ undefined $= \mathsf{successor}(\,]_2, [_2)$, D_{2n} is simply generated for $n = 1$. Since $\mathsf{close}([_1) = \{\,]_1,]_2\} \neq \{\,]_2\} = \mathsf{close}([_2)$, D_{2n} is not simply generated for $n \geq 2$.

Now, one can determine how to decide algorithmically whether D_{2n} is simply generated or not. As we have seen, the property of being simply generated depends on the relation $\mathcal{R}$ only; we have to distinguish between $n = 1$ and $n \geq 2$. Let us have a look at an algorithm that decides whether D_{2n} is simply generated or not. We discuss the algorithm for $n = 1$; an algorithm for $n \geq 2$ is similar.

Algorithm 3 checks if the language D_2 is simply generated. It operates on the matrix representation of $\mathcal{R}$.

The function simply_generated uses another function that computes $\mathsf{successor}(\,]_j, [_i)$ for any $([_i,]_j) \in \mathcal{R}$ by looking up the column of the next 1 on the right side of the

```
integer function search_next (i, j : integer)
    begin
        search_next := j + 1
        while search_next ≤ |T⌋| and m_{i,search_next} = 0 do
            search_next := search_next + 1
    end;
```

FIG. 8. *Algorithm* 4. *Function that looks up the column of the next* 1 *on the right of an entry in* M.

entry for $([_i,]_j)$ in M in the same row. If such a 1 does not exist, $\left|T_{\rfloor}\right| + 1$ will be returned, which means $\mathsf{successor}(\,]_j, [_i) =$ undefined. The function search_next is defined in Algorithm 4.

Note that each entry in the matrix M is regarded twice at most. So, it can be checked in $\mathcal{O}\big(\left|T_{\lfloor}\right| \left|T_{\rfloor}\right|\big)$ if the language D_2 is simply generated. The same fact holds for the case in which $n \geq 2$. Hence the amount of time to decide whether the language is simply generated is constant with respect to n, i.e., independent of the number of pairs of brackets in the words of the language.

4. Analysis of the algorithm. In this section, we analyze the length of the suffix to be changed in order to compute the successor $\mathsf{next}(w)$ of a Dyck word $w \in D_{2n}$. Remember that for every word the suffix to be changed is equal to the suffix to be read if D_{2n} is simply generated. If D_{2n} is not simply generated, then there is at least one Dyck word $w \in D_{2n} \setminus \{w_{\max}^{D_{2n}}\}$ for which an algorithm has to inspect the common prefix $\mathsf{pre}(w)$ of w and $\mathsf{next}(w)$. So, the length of the suffix to be read is larger than the length of the suffix to be changed.

Let $X_{\mathsf{sufl}}(D_{2n})$ be the random variable that describes the length of the suffix to be changed. We proved in section 2 that the function generate generates the Dyck words in D_{2n} with respect to the lexicographical order $\prec$. Thus every word is generated exactly once. Further, the function next reads the words from right to left. Under these conditions, the sth moments, $s \geq 1$, about the origin of the random variable $X_{\mathsf{sufl}}(D_{2n})$ are given by [Ke98]:

$$\mathbb{E}[X_{\mathsf{sufl}}^s(D_{2n})] := 1 + |D_{2n}|^{-1} \sum_{k=1}^{2n-1} [(k+1)^s - k^s] \; |\mathsf{INIT}_{2n-k}(D_{2n})| \,. \tag{4.1}$$

Here, $\mathsf{INIT}_k(D_{2n}) := \mathsf{INIT}(D_{2n}) \cap T^k$ denotes the *set of all prefixes of length* k *appearing in words belonging to* D_{2n}; thereby, the *set of all prefixes appearing in words belonging to* D_{2n} is defined by $\mathsf{INIT}(D_{2n}) := \{u \in T^\star \mid (\exists v \in T^\star)\,(uv \in D_{2n})\}$.

Now, our interest is $|\mathsf{INIT}_k(D_{2n})|$, $1 \leq k < 2n$. For that purpose we consider the well-known one-to-one correspondence between the Dyck language and paths on the lattice given in Figure 9.

Thereby, an *up-segment* $\nearrow$ (resp., *down-segment* $\searrow$) corresponds to an opening (resp., closing) bracket. Since we have a correspondence between opening and closing brackets (see Remark 1.1), there must also be a correspondence between up-segments and down-segments of a path in the lattice. To each up-segment of any path there is a corresponding down-segment and vice versa: The down-segment (resp., up-segment) corresponding to an up-segment (resp., down-segment) is the next segment on the right (resp., left) side in the same row.

Thus each Dyck word of length $2n$ corresponds to a path from $(0, 0)$ to $(2n, 0)$. The segments are labeled by the symbols of the alphabet; the labels of up-segments (resp.,

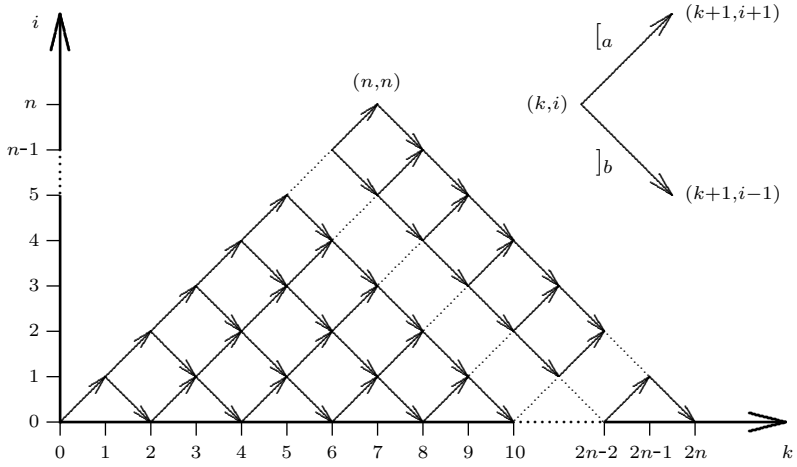

FIG. 9. *One-to-one correspondence between Dyck words of length* $2n$ *and the paths from* $(0,0)$ *to* $(2n,0)$

down-segments) are opening (resp., closing) brackets. Obviously, an up-segment and its corresponding down-segment must be labeled by some $[_a$ and $]_b$ with $\big([_a,]_b\big) \in \mathcal{R}$.

With the number of paths from $(0,0)$ to (k,i) in the lattice in Figure 9 given by the ballot number [CRS71]

$$\mathsf{p}(k,i) = \binom{k}{\frac{1}{2}(k-i)} - \binom{k}{\frac{1}{2}(k-i)-1}, \tag{4.2}$$

we have

$$|\mathsf{INIT}_k(D_{2n})| = \sum_{\substack{0\le i\le \min\{k,2n-k\}\\ k+i\ \equiv\ 0 \bmod 2}} |\mathcal{R}|^{\frac{1}{2}(k-i)}\ \big|T_{[}\big|^{i}\ \mathsf{p}(k,i)\ . \tag{4.3}$$

This formula can be found in [Ke96].

Distinguishing between the terms for even k and those for odd k in (4.3), we immediately obtain by inserting (4.2)

$$\begin{aligned} |\mathsf{INIT}_k(D_{2n})| \quad = \quad & \sum_{i=0}^{\min\{\lfloor \frac{k}{2}\rfloor,\, n-\lfloor \frac{k+1}{2}\rfloor\}} |\mathcal{R}|^{\lfloor \frac{k}{2}\rfloor - i}\ \big|T_{[}\big|^{2i+k-2\lfloor \frac{k}{2}\rfloor} \\ & \times \left[\binom{k}{\lfloor \frac{k}{2}\rfloor - i} - \binom{k}{\lfloor \frac{k}{2}\rfloor - i - 1}\right]\ . \end{aligned} \tag{4.4}$$

By (4.1), $|D_{2n}| = |\mathsf{INIT}_{2n}(D_{2n})|$, and (4.4), we get

$$\begin{aligned} \mathbb{E}[X^s_{\mathsf{sufl}}(D_{2n})] = |D_{2n}|^{-1} \sum_{k=0}^{2n-1} [(k+1)^s - k^s] & \sum_{i=0}^{\min\{\lfloor \frac{2n-k}{2}\rfloor,\, n-\lfloor \frac{2n-k+1}{2}\rfloor\}} |\mathcal{R}|^{\lfloor \frac{2n-k}{2}\rfloor - i} \\ \times \big|T_{[}\big|^{2i+2n-k-2\lfloor \frac{2n-k}{2}\rfloor} & \left[\binom{2n-k}{\lfloor \frac{2n-k}{2}\rfloor - i} - \binom{2n-k}{\lfloor \frac{2n-k}{2}\rfloor - i - 1}\right]\ . \end{aligned}$$

Splitting the first sum into two parts and letting the index of the second sum go to infinity, we obtain with $|D_{2n}| = \frac{1}{n+1}\binom{2n}{n}|\mathcal{R}|^n$ after rearranging the sums and applying

some simplifications

$$\mathbb{E}[X^s_{\mathsf{sufl}}(D_{2n})] = \frac{n+1}{\binom{2n}{n}}\left[F^{(1)}_{s,|\mathcal{R}|,|T_{\lfloor}|}(n) + F^{(2)}_{s,|\mathcal{R}|,|T_{\lfloor}|}(n) - F^{(3)}_{s,|\mathcal{R}|,|T_{\lfloor}|}(n) - F^{(4)}_{s,|\mathcal{R}|}(n)\right],$$

where

$$F^{(1)}_{s,a,b}(n) := \sum_{i\geq 0} a^{-i}\, b^{2i} \sum_{k=0}^{n} \left[(2k+1)^s - (2k)^s\right] a^{-k} \times \left[\binom{2n-2k}{n-k-i} - \binom{2n-2k}{n-k-i-1}\right],$$

$$F^{(2)}_{s,a,b}(n) := \sum_{i\geq 0} a^{-i-1}\, b^{2i+1} \sum_{k=0}^{n} \left[(2k+2)^s - (2k+1)^s\right] a^{-k} \times \left[\binom{2n-2k-1}{n-k-i-1} - \binom{2n-2k-1}{n-k-i-2}\right],$$

$$F^{(3)}_{s,a,b}(n) := \sum_{i\geq 0} a^{-i-1}\, b^{2i+2} \sum_{k=0}^{n} \left[(k+1)^s - k^s\right] a^{-k}\, b^k \times \left[\binom{2n-k}{n-k-i-1} - \binom{2n-k}{n-k-i-2}\right],$$

$$F^{(4)}_{s,a}(n) := \frac{(2n+1)^s - (2n)^s}{a^n}\ .$$

In order to gain an asymptotic for $n \to \infty$ for $\mathbb{E}[X^s_{\mathsf{sufl}}(D_{2n})]$, we need to study the asymptotic behavior of $F^{(1)}_{s,a,b}(n)$, $F^{(2)}_{s,a,b}(n)$, $F^{(3)}_{s,a,b}(n)$, and $F^{(4)}_{s,a}(n)$; that is why we consider the generating functions for these functions in Lemma 4.1.

LEMMA 4.1. *Let s, a, $b \in \mathbb{N}$, and $u := \sqrt{1-4z}$. The generating functions of $F^{(1)}_{s,a,b}(n)$, $F^{(2)}_{s,a,b}(n)$, $F^{(3)}_{s,a,b}(n)$, and $F^{(4)}_{s,a}(n)$ are given by*

$$G^{(1)}_{s,a,b}(z) := \sum_{n\geq 0} F^{(1)}_{s,a,b}(n)\, z^n = \frac{2}{(1+u)\left(1-\frac{b^2(1-u)^2}{4az}\right)} \times \left(\frac{1}{1-\frac{z}{a}} + \sum_{j=1}^{s-1}\binom{s}{j} 2^j\, \mathsf{A}_j\left(\frac{z}{a}\right) \frac{1}{\left(1-\frac{z}{a}\right)^{j+1}}\right),$$

$$G^{(2)}_{s,a,b}(z) := \sum_{n\geq 0} F^{(2)}_{s,a,b}(n)\, z^n = \frac{b(1-u)}{a(1+u)\left(1-\frac{b^2(1-u)^2}{4az}\right)} \left(\frac{(-1)^{s+1}}{1-\frac{z}{a}} + \frac{a}{z}\sum_{j=1}^{s-1}\binom{s}{j} 2^j\, (-1)^{s-j+1}\, \mathsf{A}_j\left(\frac{z}{a}\right) \frac{1}{\left(1-\frac{z}{a}\right)^{j+1}}\right),$$

$$G^{(3)}_{s,a,b}(z) := \sum_{n\geq 0} F^{(3)}_{s,a,b}(n)\, z^n = \frac{4b}{(1+u)^2\left(1-\frac{b^2(1-u)}{a(1+u)}\right)} \mathsf{A}_s\left(\frac{b(1-u)}{2a}\right) \frac{1}{\left(1-\frac{b(1-u)}{2a}\right)^s},$$

$$G^{(4)}_{s,a}(z) := \sum_{n\geq 0} F^{(4)}_{s,a}(n)\, z^n = \frac{1}{1-\frac{z}{a}} + \sum_{j=1}^{s-1}\binom{s}{j} 2^j\, \mathsf{A}_j\left(\frac{z}{a}\right) \frac{1}{\left(1-\frac{z}{a}\right)^{j+1}}\ .$$

Here, $\mathsf{A}_l(x)$ *denotes the* l*th Eulerian polynomial* [Ke84, p. 214] *with*

$$\mathsf{A}_l(x) = (1-x)^{l+1} \sum_{m\geq 0} m^l x^m = x \sum_{i=1}^{l} i! \left\{ {l \atop i} \right\} (x-1)^{l-i},$$

where $\left\{ {n \atop k} \right\}$ *stands for the Stirling number of the second kind* [GKP94, p. 258].

Proof. In order to find the generating function for $F^{(1)}_{s,a,b}(n)$, we consider the convolution of two functions first.

$$\left(\sum_{\mu\geq 0} [(2\mu+1)^s - (2\mu)^s]\, a^{-\mu}\, z^\mu \right) \left(\sum_{\lambda\geq 0} \left[\binom{2\lambda}{\lambda-i} - \binom{2\lambda}{\lambda-i-1} \right] z^\lambda \right)$$

$$= \sum_{\kappa\geq 0} z^\kappa \sum_{\nu=0}^{\kappa} [(2\nu+1)^s - (2\nu)^s]\, a^{-\nu} \left[\binom{2\kappa-2\nu}{\kappa-\nu-i} - \binom{2\kappa-2\nu}{\kappa-\nu-i-1} \right]. \tag{4.5}$$

With $u = \sqrt{1-4z} \rightsquigarrow 4z = (1+u)(1-u)$ and the identity

$$\sum_{m\geq 0} \binom{2m+\alpha}{m} z^m = \frac{1}{\sqrt{1-4z}} \left(\frac{1-\sqrt{1-4z}}{2z} \right)^\alpha = \frac{1}{u} \left(\frac{1-u}{2z} \right)^\alpha,\ \alpha \in \mathbb{N}_0 \tag{4.6}$$

[GKP94, p. 203], a straightforward computation leads to

$$\sum_{\lambda\geq 0} \left[\binom{2\lambda}{\lambda-i} - \binom{2\lambda}{\lambda-i-1} \right] z^\lambda = \frac{2}{1+u} \left(\frac{(1-u)^2}{4z} \right)^i. \tag{4.7}$$

In consideration of (4.5) and (4.7), we obtain

$$\begin{aligned} G^{(1)}_{s,a,b}(z) &= \sum_{i\geq 0} a^{-i}\, b^{2i} \left(\sum_{\lambda\geq 0} \left[\binom{2\lambda}{\lambda-i} - \binom{2\lambda}{\lambda-i-1} \right] z^\lambda \right) \\ &\qquad \times \left(\sum_{\mu\geq 0} [(2\mu+1)^s - (2\mu)^s]\, a^{-\mu}\, z^\mu \right) \\ &= \frac{2}{(1+u)\left(1 - \frac{b^2(1-u)^2}{4az}\right)} \left(\sum_{\mu\geq 0} [(2\mu+1)^s - (2\mu)^s]\, a^{-\mu}\, z^\mu \right) \end{aligned} \tag{4.8}$$

by the expansion of the geometric series. Now, let us have a closer look at the sum in (4.8). Splitting off the first term, applying the binomial theorem to $(2\mu+1)^s$, and using again the expansion of the geometric series yield

$$\begin{aligned} \sum_{\mu\geq 0} [(2\mu+1)^s - (2\mu)^s]\, a^{-\mu}\, z^\mu &= \sum_{\mu\geq 0} \left(\frac{z}{a}\right)^\mu + \sum_{j=1}^{s-1} \binom{s}{j} 2^j \sum_{\mu\geq 0} \mu^j \left(\frac{z}{a}\right)^\mu \\ &= \frac{1}{1-\frac{z}{a}} + \sum_{j=1}^{s-1} \binom{s}{j} 2^j\, \mathsf{A}_j\left(\frac{z}{a}\right) \frac{1}{\left(1-\frac{z}{a}\right)^{j+1}}. \end{aligned} \tag{4.9}$$

Inserting the expression (4.9) into (4.8) results in the generating function $G^{(1)}_{s,a,b}(z)$ for the numbers $F^{(1)}_{s,a,b}(n)$ stated in the lemma. $G^{(2)}_{s,a,b}(z)$ can be computed analogously.

For the generating function $G^{(3)}_{s,a,b}(z)$, we consider the function

$$H_{s,c,d}(z) := \sum_{n\geq 0} z^n \sum_{k=0}^{n} [(k+1)^s - k^s] \binom{2n-k}{n+c} d^k, \quad c \in \mathbb{N}_0,\ d > 0.$$

A rearrangement of the terms of $H_{s,c,d}(z)$ and the application of the identity $\binom{n}{k} = \binom{n}{n-k}$, n, $k \in \mathbb{N}_0$, results with (4.6) in

$$\begin{aligned} H_{s,c,d}(z) &= \sum_{k\geq 0} [(k+1)^s - k^s]\, d^k\, z^{k+c} \sum_{n\geq 0} z^n \binom{2n+k+2c}{n} \\ &= \frac{1}{u}\left(\frac{1-u}{1+u}\right)^c \sum_{k\geq 0} [(k+1)^s - k^s] \left(\frac{d(1-u)}{2}\right)^k. \end{aligned}$$

Moreover, a simple computation shows that

$$\sum_{k\geq 0} [(k+1)^s - k^s]\, y^k = \mathsf{A}_s(y)\, \frac{1}{y(1-y)^s}$$

holds; applying this identity, we obtain

$$H_{s,c,d}(z) = \frac{1}{u}\left(\frac{1-u}{1+u}\right)^c \mathsf{A}_s\left(\frac{d(1-u)}{2}\right) \frac{1}{\frac{d(1-u)}{2}\left(1-\frac{d(1-u)}{2}\right)^s}. \tag{4.10}$$

Now, by (4.10), we get after simplifications

$$\begin{aligned} G^{(3)}_{s,a,b}(z) &= \sum_{n\geq 0} z^n \sum_{i\geq 0} \left(\frac{b^2}{a}\right)^{i+1} \sum_{k=0}^{n} [(k+1)^s - k^s] \left(\frac{b}{a}\right)^k \\ &\qquad \times \left[\binom{2n-k}{n+i+1} - \binom{2n-k}{n+i+2}\right] \\ &= \frac{4b}{(1+u)^2\left(1-\frac{b^2(1-u)}{a(1+u)}\right)} \mathsf{A}_s\left(\frac{b(1-u)}{2a}\right) \frac{1}{\left(1-\frac{b(1-u)}{2a}\right)^s}. \end{aligned}$$

$G^{(4)}_{s,a}(z)$ can be calculated similarly to $G^{(1)}_{s,a,b}(z)$. □

With this lemma, we are able to formalize the following theorem.

THEOREM 4.2. *Let all $w \in D_{2n}$ be equally likely. The sth moments, $s \geq 1$, about the origin of the random variable $X_{\mathsf{sufl}}(D_{2n})$ are constant. They are given by*

$$\mathbb{E}[X^s_{\mathsf{sufl}}(D_{2n})] \sim C_{s,|\mathcal{R}|,|T_{\lceil}|},\ n \to \infty,\ \textit{where}$$

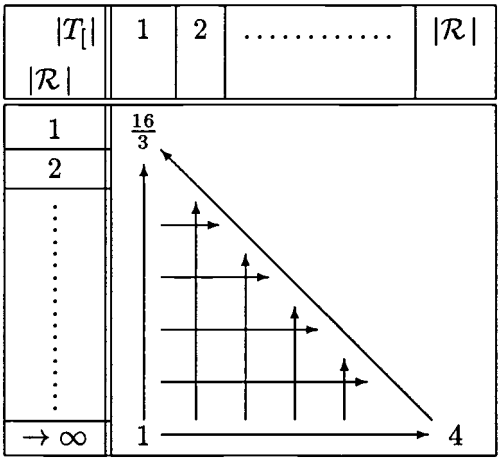
$$C_{s,|\mathcal{R}|,|T_\llcorner|} := \frac{|\mathcal{R}|}{\left(|\mathcal{R}| - |T_\llcorner|^2\right)^2} \Bigg[\sum_{j=1}^{s-1} \binom{s}{j} 2^j \, \mathsf{A}_j\left(\frac{1}{4|\mathcal{R}|}\right) \frac{|\mathcal{R}| + |T_\llcorner|^2 + 4|\mathcal{R}||T_\llcorner|(-1)^{s-j+1}}{\left(1 - \frac{1}{4|\mathcal{R}|}\right)^{j+1}}$$
$$- \frac{2^s |\mathcal{R}|^{s-1}|T_\llcorner|}{(2|\mathcal{R}| - |T_\llcorner|)^{s+1}} \Bigg[2|\mathcal{R}|\left(4|\mathcal{R}|^2 + (s-2)|\mathcal{R}||T_\llcorner| - s|T_\llcorner|^3\right) \mathsf{A}_s\left(\frac{|T_\llcorner|}{2|\mathcal{R}|}\right)$$
$$+ |T_\llcorner|\left(2|\mathcal{R}| - |T_\llcorner|\right)\left(|\mathcal{R}| - |T_\llcorner|^2\right) \mathsf{A}_s'\left(\frac{|T_\llcorner|}{2|\mathcal{R}|}\right) \Bigg]$$
$$+ \frac{4|\mathcal{R}|\left(|\mathcal{R}| + |T_\llcorner|^2 - |T_\llcorner|(-1)^s\right)}{4|\mathcal{R}| - 1} \Bigg].$$

Proof. Using the results of the preceding lemma, we get the following formula after a simple computation:

$$\begin{aligned}
&\mathbb{E}[X_{\mathsf{sufl}}^s(D_{2n})] \\
&= \frac{n+1}{\binom{2n}{n}} [z^n] \left\{ G_{s,|\mathcal{R}|,|T_\llcorner|}^{(1)}(z) + G_{s,|\mathcal{R}|,|T_\llcorner|}^{(2)}(z) - G_{s,|\mathcal{R}|,|T_\llcorner|}^{(3)}(z) - G_{s,|\mathcal{R}|}^{(4)}(z) \right\} \\
&= \frac{n+1}{\binom{2n}{n}} [z^n] \Bigg\{ \frac{1}{(1+u)\left(1 - \frac{|T_\llcorner|^2(1-u)}{|\mathcal{R}|(1+u)}\right)} \Bigg[\left(2 - (1+u)\left(1 - \frac{|T_\llcorner|^2(1-u)}{|\mathcal{R}|(1+u)}\right)\right) \\
&\quad \times \left(\frac{1}{1 - \frac{z}{|\mathcal{R}|}} + \sum_{j=1}^{s-1} \binom{s}{j} 2^j \, \mathsf{A}_j\left(\frac{z}{|\mathcal{R}|}\right) \frac{1}{\left(1 - \frac{z}{|\mathcal{R}|}\right)^{j+1}} \right) + (1-u)\frac{|T_\llcorner|}{|\mathcal{R}|} \\
&\quad \times \left(\frac{(-1)^{s+1}}{1 - \frac{z}{|\mathcal{R}|}} + \frac{|\mathcal{R}|}{z} \sum_{j=1}^{s-1} \binom{s}{j} 2^j \, (-1)^{s-j+1} \, \mathsf{A}_j\left(\frac{z}{|\mathcal{R}|}\right) \frac{1}{\left(1 - \frac{z}{|\mathcal{R}|}\right)^{j+1}} \right) \\
&\quad - \frac{4|T_\llcorner|}{(1+u)} \mathsf{A}_s\left(\frac{|T_\llcorner|(1-u)}{2|\mathcal{R}|}\right) \frac{1}{\left(1 - \frac{|T_\llcorner|(1-u)}{2|\mathcal{R}|}\right)^s} \Bigg] \Bigg\}.
\end{aligned}$$

Now, we are looking for the singularity of smallest modulus that is not equal to 0. We find candidates for singularities at $z = \frac{1}{4}$, $z = |\mathcal{R}|$, $z = \frac{|\mathcal{R}||T_\llcorner|^2}{(|\mathcal{R}|+|T_\llcorner|^2)^2}$, and $z = \frac{|\mathcal{R}|(|T_\llcorner|-|\mathcal{R}|)}{|T_\llcorner|^2}$. We do not have to take $z = |\mathcal{R}| > \frac{1}{4}$ into account. As the expansions of $G_{s,|\mathcal{R}|,|T_\llcorner|}^{(1)}(z) + G_{s,|\mathcal{R}|,|T_\llcorner|}^{(2)}(z) - G_{s,|\mathcal{R}|,|T_\llcorner|}^{(3)}(z) - G_{s,|\mathcal{R}|}^{(4)}(z)$ around $z = \frac{|\mathcal{R}||T_\llcorner|^2}{(|\mathcal{R}|+|T_\llcorner|^2)^2}$ and $z = \frac{|\mathcal{R}|(|T_\llcorner|-|\mathcal{R}|)}{|T_\llcorner|^2}$ result in Taylor series, i.e., neither $z = \frac{|\mathcal{R}||T_\llcorner|^2}{(|\mathcal{R}|+|T_\llcorner|^2)^2}$ nor $z = \frac{|\mathcal{R}|(|T_\llcorner|-|\mathcal{R}|)}{|T_\llcorner|^2}$ is a singularity, the singularity nearest to the origin is given by $z = \frac{1}{4}$. Expanding $G_{s,|\mathcal{R}|,|T_\llcorner|}^{(1)}(z) + G_{s,|\mathcal{R}|,|T_\llcorner|}^{(2)}(z) - G_{s,|\mathcal{R}|,|T_\llcorner|}^{(3)}(z) - G_{s,|\mathcal{R}|}^{(4)}(z)$ around $y := 1 - 4z$ yields

TABLE 1
Values for $C_{1,|\mathcal{R}|,|T_{[}|}$, $1 \le |T_{[}| \le |\mathcal{R}|, |\mathcal{R}| \to \infty$.



$$G^{(1)}_{s,|\mathcal{R}|,|T_{[}|}(z) + G^{(2)}_{s,|\mathcal{R}|,|T_{[}|}(z) - G^{(3)}_{s,|\mathcal{R}|,|T_{[}|}(z) - G^{(4)}_{s,|\mathcal{R}|}(z)$$
$$= C'_{s,|\mathcal{R}|,|T_{[}|} - 2\,C_{s,|\mathcal{R}|,|T_{[}|}\,\sqrt{y} + \mathcal{O}(y),$$

where $C_{s,|\mathcal{R}|,|T_{[}|}$ is given in the theorem and $C'_{s,|\mathcal{R}|,|T_{[}|} = \mathcal{O}(1)$ is another constant. An application of Darboux's method [GK82] immediately gives the asymptotic behavior of the sth moments of the random variable $X_{\mathsf{sufl}}(D_{2n})$ stated in the theorem with $\frac{1}{n+1}\binom{2n}{n} \sim \frac{4^n}{\sqrt{\pi} n^{\frac{3}{2}}}$, $n \to \infty$, obtained by Stirling's formula [GKP94, p. 454]. □

COROLLARY 4.3. *For the random variable* $X_{\mathsf{sufl}}(D_{2n})$*, we obtain the mean value* $\mu_{\mathsf{sufl}}(D_{2n}) = \mathbb{E}[X^1_{\mathsf{sufl}}(D_{2n})]$ *and the variance* $\sigma^2_{\mathsf{sufl}}(D_{2n}) = \mathbb{E}[X^2_{\mathsf{sufl}}(D_{2n})] - \mathbb{E}[X^1_{\mathsf{sufl}}(D_{2n})]^2$ *for* $n \to \infty$:

$$\mu_{\mathsf{sufl}}(D_{2n}) \sim \frac{16|\mathcal{R}|^3}{\big(4|\mathcal{R}|-1\big)\big(2|\mathcal{R}|-|T_{[}|\big)^2},$$
$$\sigma^2_{\mathsf{sufl}}(D_{2n}) \sim \frac{16|\mathcal{R}|^3\big(16|\mathcal{R}|^2|T_{[}| + 12|\mathcal{R}|^2 - 12|\mathcal{R}||T_{[}|^2 - 20|\mathcal{R}||T_{[}| + 7|T_{[}|^2\big)}{\big(4|\mathcal{R}|-1\big)^2\big(2|\mathcal{R}|-|T_{[}|\big)^4}\ .$$

Remark 4.1. Now, we focus on $\mu_{\mathsf{sufl}}(D_{2n})$. According to Theorem 4.2, we have $\mu_{\mathsf{sufl}}(D_{2n}) \sim C_{1,|\mathcal{R}|,|T_{[}|}$, $n \to \infty$. A moment's reflection shows that

$$C_{1,1,1} = \frac{16}{3},$$
$$C_{1,|\mathcal{R}|,1} = \frac{16|\mathcal{R}|^3}{\big(4|\mathcal{R}|-1\big)\big(2|\mathcal{R}|-1\big)^2} = 1 + \mathcal{O}\left(\frac{1}{|\mathcal{R}|}\right), \quad |\mathcal{R}| \to \infty,$$
$$C_{1,|\mathcal{R}|,|\mathcal{R}|} = \frac{16|\mathcal{R}|}{\big(4|\mathcal{R}|-1\big)} = 4 + \mathcal{O}\left(\frac{1}{|\mathcal{R}|}\right), \quad |\mathcal{R}| \to \infty,$$

hold. We further find with $1 \le |T_{[}| \le |\mathcal{R}|$

$$C_{1,|\mathcal{R}|,|T_{[}|} > C_{1,|\mathcal{R}|+1,|T_{[}|}, \tag{4.11}$$

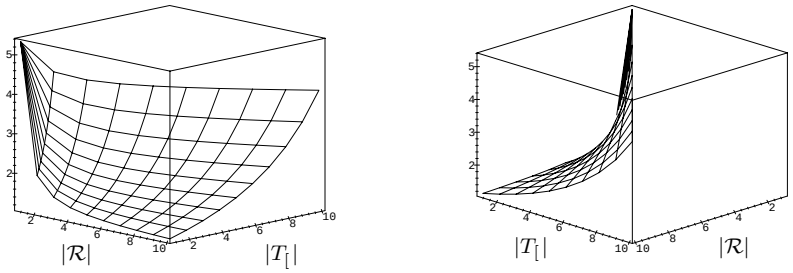


FIG. 10. *Two views of* $C_{1,|\mathcal{R}|,|T_{[}|}$ *for* $1 \le |T_{[}| \le |\mathcal{R}| \le 10$

Altogether, we obtain the following values for $C_{1,|\mathcal{R}|,|T_{\lfloor}|}$ given in Table 1. Here, $\uparrow$, $\nwarrow$, and $\rightarrow$ stand for strictly increasing sequences. Obviously, $\uparrow$, $\nwarrow$, and $\rightarrow$ correspond to (4.11), (4.12), and (4.13), respectively.

Now, we take a look at two plots of $C_{1,|\mathcal{R}|,|T_{\lfloor}|}$ for $1 \leq |T_{\lfloor}| \leq |\mathcal{R}| \leq 10$ from two different points of view, analytically continued to $\mathbb{R}$.

By these plots, we get a better idea of the behavior of $\mu_{\mathsf{sufl}}(D_{2n})$ for different combinations of the two parameters $|\mathcal{R}|$ and $|T_{\lfloor}|$. In the left plot of Figure 10, we see clearly the inequations (4.11) and (4.12); in the right plot we recognize (4.13).

Remark 4.2. In [Li96] the lexicographical generation of the *Dyck language with t types of brackets* D^t [Ha78, p. 313] has been analyzed. The results are presented in [Ke98]. Following our definitions, $D^t = D$ with the relation $\mathcal{R} = \{([_1,]_1), ([_2,]_2), \ldots, ([_t,]_t)\}$, and thus $D^t_{2n} = D_{2n}$. Obviously, D^t_{2n} is simply generated (see Remark 3.1). The mean value and the variance of the random variable $X_{\mathsf{sufl}}(D^t_{2n})$ describing the number of symbols to be changed while generating the successor of a word were found to be

$$\mu_{\mathsf{sufl}}(D^t_{2n}) \sim \frac{16t}{4t-1}, \quad n \to \infty, \quad \text{and} \quad \sigma^2_{\mathsf{sufl}}(D^t_{2n}) \sim \frac{16t}{4t-1}, \quad n \to \infty.$$

For $\mathcal{R} = \{([_1,]_1), \ldots, ([_t,]_t)\}$, we obtain $|\mathcal{R}| = |T_{\lfloor}| = t$ and so by Corollary 4.3 $\mu_{\mathsf{sufl}}(D_{2n}) \sim \frac{16t}{4t-1}$, $n \to \infty$, and $\sigma^2_{\mathsf{sufl}}(D_{2n}) \sim \frac{16t}{4t-1}$, $n \to \infty$, evidently.

In Tables 2 and 3, we give some exact and asymptotical values for $\mu_{\mathsf{sufl}}(D_{2n})$ and $\sigma^2_{\mathsf{sufl}}(D_{2n})$ for various relations $\mathcal{R}$.

5. Lexicographical generation of labeled trees. It is well known that the normal Dyck language (with only one pair of brackets) is a coding for unlabeled trees such as ordered trees (with arbitrary degree of the nodes) and extended ordered binary trees (each node is a leaf or has exactly two sons); see, e.g., [Za80]. Other representations of the shape of trees are the integer sequences: level-representation, leaf-representation, and leaf-level-representation (see, e.g., [Ke98]). In contrast to the aforementioned representation of trees, the generalized Dyck language is a handy coding not only for the shape but also for the labels at the nodes and/or edges of several classes of trees. Some classes of labeled trees, coded by the generalized Dyck language, are discussed in [Li00]. There, a tree is coded in one Dyck word and not in two independent parts (one for the shape of the tree and another one for the labels). Nevertheless, the structure of the tree and its labels can be determined in a very simple way. Thus, with the algorithm presented here, we are able to generate classes of labeled trees lexicographically.

6. Concluding remarks. In this paper, we have presented an algorithm that generates all words of a generalized Dyck language lexicographically. The Dyck language is defined by a relation $\mathcal{R}$ which describes the pairs of brackets that can be used. We introduced a function that computes from one Dyck word the next one according to the lexicographical order. For that purpose, no knowledge about the words generated before is required.

Since the generalized Dyck language is a coding for several classes of labeled trees, we can generate these classes of trees lexicographically with the algorithm presented here.

Further, we found a condition for the generalized Dyck language to be simply generated, which means that for every word it is possible to compute its successor by reading only the suffix to be changed. We saw that this condition depends on the relation $\mathcal{R}$ only and not on the length of the words. We introduced an algorithm that computes whether the Dyck language—implied by the relation $\mathcal{R}$—is simply generated or not. The running time of that algorithm depends on the relation only, so it has a constant amount of time with respect to the length of the words.

Following a general approach to the lexicographical generation of all words of a formal language [Ke98], we computed the sth moments, $s \geq 1$, of the random variable describing the length of the suffix of a word to be changed. In particular, we pointed out the mean value and the variance of the number of symbols to be changed in order to generate the successor of a Dyck word.

Acknowledgment. The author would like to thank Prof. Rainer Kemp for his idea of how to compute the sth moments of the random variable describing the length of the suffix to be changed.

PARTIAL MATCH QUERIES IN RANDOM QUADTREES*

HUA-HUAI CHERN† AND HSIEN-KUEI HWANG‡

Abstract. We propose a simple direct approach for computing the expected cost of random partial match queries in random quadtrees. This approach gives not only an explicit expression for the leading constant in the asymptotic approximation of the expected cost but also more terms in the asymptotic expansion if desired.

Key words. quadtrees, partial match queries, binomial transform, Mellin transform, Euler transform, Rice's integral

1. Introduction.

Quadtrees, originally proposed by Finkel and Bentley [2], represent one of the simplest, most prototypical, and most studied data structures for multidimensional data; see [13, 14]. We are concerned in this paper with the average-case analysis of random partial match queries in random quadtrees, a problem originally analyzed in detail by Flajolet et al. [3] and then extended by several authors.

The probabilistic model is as follows. First, a sequence of n points is generated uniformly and independently in $[0,1]^d$, where $d \geq 2$. From this sequence, we construct the (d-dimensional) quadtree and call it the *random quadtree*. (A quadtree of a sequence of points is constructed by placing the first element at the root, which splits the space $[0,1]^d$ into 2^d quadrants; the remaining points are compared to the root and are directed to each quadrant depending on the location of each point; points falling in each quadrant are constructed recursively as quadtrees.) Then we generate s independent random variables, with the same Uniform$[0,1]$ distribution, which correspond to the specified coordinates of the partial match query $\mathtt{q}$, where $1 \leq s < d$; the remaining $d-s$ coordinates are "wild-cards." We then perform the range search of this query $\mathtt{q}$ in the random tree and denote the expected number of nodes visited by $Q_n = Q_n^{(d,s)}$. Note that, by symmetry, only the number of specified coordinates matters; the order or positions of the specifications are immaterial.

Flajolet et al. [3] showed that Q_n can be computed recursively as follows (see Lemma 1 for a self-contained proof): $Q_0 = 0$ and for $n \geq 1$

$$Q_n = 1 + 2^d \sum_{1 \leq k < n} \pi_{n,k} Q_k, \tag{1.1}$$

where

(1.2)
$$\pi_{n,k} = \frac{1}{n(n+1)} \sum_{k \le \ell_{d-1} \le \cdots \le \ell_1 < n} \frac{1}{(\ell_1+2)\cdots(\ell_{s-1}+2)} \times \frac{1}{(\ell_{s+1}+1)\cdots(\ell_{d-1}+1)}.$$

From this recurrence, they studied the differential system satisfied by the generating function $Q(z) := \sum_n Q_n z^n$ and then showed that

$$Q_n \sim h_{d,s}\, n^{\alpha-1}$$

for some constant $h_{d,s}$, where $1 < \alpha < 2$ solves the indicial equation $\phi(z) = 0$, with

$$\phi(z) := z^{d-s}(z+1)^s - 2^d.$$

In particular, when $d = 2$, $\alpha = (\sqrt{17}-1)/2$ and

$$h_{2,1} = \frac{\Gamma(2\alpha)}{2\Gamma^3(\alpha)}.$$

The calculation of the leading constants $h_{d,s}$ remains open for other values of (d, s).

The aim of this paper is to derive more precise asymptotic approximations for Q_n with an explicit expression for $h_{d,s}$ for all cases of (d, s).

THEOREM 1. *The expected number of nodes visited by performing the range search of a random partial match query in a random quadtree of n nodes satisfies*

(1.3)
$$Q_n = h_{d,s} n^{\alpha-1} + O(1 + n^{\Re(\alpha_2)-1}),$$

where

$$h_{d,s} := \frac{1}{(2^{d-s}-1)\Gamma(\alpha)^{d-s}\Gamma(\alpha+1)^s} \prod_{2 \le j \le d} \frac{\Gamma(\alpha-\alpha_j)}{\Gamma(1-\alpha_j)}$$

for $1 \le s < d$ and $d \ge 2$, Γ is the Gamma function, and the α_j's are zeros of the polynomial $\phi(z)$:

$$\alpha = \alpha_1 > \Re(\alpha_2) \ge \cdots \ge \Re(\alpha_d).$$

See Table 1.1 for numeric values of α and $h_{d,s}$ for $d \le 6$.

Our approach indeed gives a closed-form expression for Q_n.

PROPOSITION 1. *For $n \ge 1$, Q_n satisfies*

(1.4)
$$Q_n = \sum_{1 \le k \le n} \binom{n}{k} (-1)^{k+1} \frac{2^s (2-\alpha_1)_{k-1} \cdots (2-\alpha_d)_{k-1}}{k!^{d-s}(k+1)!^s},$$

where $(x)_k := x(x+1)\cdots(x+k-1)$.

Once the exact formula (1.4) is known, the proof of (1.3) uses the integral representation (or the Rice integral) for (1.4); the remaining analysis is more or less standard (see Flajolet and Sedgewick [7]). The main step in deriving (1.3) is thus the proof of (1.4). We propose a very simple elementary proof for (1.4) which uses only the binomial transform of Q_n and a differencing argument. Such a proof was

originally motivated by a different approach based on the generating function, differential equations, and Euler transforms (cf. Flajolet et al. [4]). We will sketch this approach as well as an intuitive use of the Mellin–Barnes integral (see [12]) to give more insight into the problem. Although these approaches are essentially the same for Q_n, the elementary approach is computationally and technically much simpler; we will see later that it is also more general.

For other results on partial or exact match queries in random quadtrees, see [1, 5, 10, 11]. On the other hand, explicit characterization of the leading constants of partial match queries in random k-d trees (k being the dimension) is very different from that in quadtrees and is much harder (see [6]); this problem is treated elsewhere.

2. Splitting probabilities and recurrence. We first prove the recurrence (1.1), which is basic to our analysis.

LEMMA 1. *The expected cost Q_n satisfies the recurrence* (1.1) *with $\pi_{n,k}$ given by* (1.2).

Proof. Let $p_{n,k}$ denote the probability that the query is conducted in the first subtree (namely, its root is visited) whose size is k. By our independence assumptions and by symmetry, we may assume that the first s coordinates of the query are specified. It follows that Q_n satisfies (1.1) with

$$\begin{aligned}\pi_{n,k} &= 2^{-s} p_{n,k} \\ &= \binom{n-1}{k} \int_{(0,1)^d} x_1 \cdots x_s (x_1 \cdots x_d)^k (1 - x_1 \cdots x_d)^{n-1-k} \mathbf{dx}, \end{aligned} \tag{2.1}$$

where $\mathbf{dx} := \mathrm{d}x_1 \cdots \mathrm{d}x_d$. By expanding the factor $1 - x_1 \cdots x_d$ as

$$1 - x_1 \cdots x_d = 1 - x_1 + (1 - x_2)x_1 + \cdots + (1 - x_d)x_{d-1} \cdots x_1,$$

we then have (with the convention that $j_{d+1} = 0$)

$$\begin{aligned}\pi_{n,k} &= \binom{n-1}{k} \sum_{j_1+\cdots+j_d=n-1-k} \binom{n-1-k}{j_1,\ldots,j_d} \\ &\quad \times \int_{(0,1)^d} \left(\prod_{1\le i\le s} x_i^{k+1+j_{i+1}+\cdots+j_d} (1-x_i)^{j_i} \right) \\ &\quad \times \left(\prod_{s<i\le d} x_i^{k+j_{i+1}+\cdots+j_d} (1-x_i)^{j_i} \right) \mathbf{dx} \\ &= \sum_{j_1+\cdots+j_d=n-1-k} \frac{(n-1)!}{k!} \left(\prod_{1\le i\le s} \frac{(k+1+j_{i+1}+\cdots+j_d)!}{(k+2+j_i+\cdots+j_d)!} \right) \\ &\quad \times \left(\prod_{s<i\le d} \frac{(k+j_{i+1}+\cdots+j_d)!}{(k+1+j_i+\cdots+j_d)!} \right) \\ &= \frac{1}{n(n+1)} \sum_{j_1+\cdots+j_d=n-1-k} \frac{1}{(k+2+j_2+\cdots+j_d)\cdots(k+2+j_s+\cdots+j_d)} \\ &\quad \times \frac{1}{(k+1+j_{s+1}+\cdots+j_d)\cdots(k+1+j_d)},\end{aligned}$$

which is easily seen to be identical to (1.2). By symmetry, we then obtain (1.1). □

COROLLARY 1. *The sequence $\pi_{n,k}$ satisfies*

$$\pi_{n,k} = \sum_{k\le j<n} \binom{n-1}{j} \binom{j}{k} (-1)^{j+k} (j+1)^{-d+s} (j+2)^{-s}. \tag{2.2}$$

Proof. Expand the factor $(1-x_1\cdots x_d)^{n-1-k}$ in (2.1), and then evaluate the integral term by term. □

Note that, by (1.2) and (2.2), we have the identities

$$\begin{aligned}\sum_{k\le j<n} \binom{n-1}{j} \binom{j}{k} (-1)^{j+k} (j+1)^{-1} (j+2)^{-1} &= \frac{n-k}{n(n+1)}, \\ \sum_{k\le j<n} \binom{n-1}{j} \binom{j}{k} (-1)^{j+k} (j+1)^{-2} (j+2)^{-1} &= \frac{H_n - H_k}{n} - \frac{n-k}{n(n+1)}, \\ \sum_{k\le j<n} \binom{n-1}{j} \binom{j}{k} (-1)^{j+k} (j+1)^{-1} (j+2)^{-2} &= \frac{(n+2)(n-k)}{n(n+1)^2} \\ &\quad - \frac{(k+1)(H_n - H_k)}{n(n+1)},\end{aligned}$$

corresponding, respectively, to $(d,s) = (2,1), (3,1)$, and $(3,2)$, where $H_k := \sum_{1\le j\le k} 1/j$. More identities can be derived by considering higher values of d.

3. Binomial transform. The crucial step in proving (1.4) is to consider the binomial transform

$$Q_n^\star := \sum_{1\le k\le n} \binom{n}{k} (-1)^k Q_k \qquad (n \ge 1),$$

with $Q_0^\star := 0$.

LEMMA 2. *The sequence $Q_n^\star$ satisfies the first-order recurrence*

$$Q_n^\star - Q_{n-1}^\star = -\frac{2^d}{n^{d-s}(n+1)^s}\, Q_{n-1}^\star \qquad (n \geq 2), \tag{3.1}$$

with $Q_1^\star = -1$.

Proof. By (1.1),

$$\begin{aligned} Q_n^\star - Q_{n-1}^\star &= 2^d \sum_{1\leq m\leq n} \binom{n-1}{m-1} (-1)^m \sum_{1\leq k<m} \pi_{m,k} Q_k \\ &= -2^d \sum_{1\leq k<n} Q_k \sum_{k\leq m<n} \binom{n-1}{m} (-1)^m \pi_{m+1,k}. \end{aligned}$$

Now the inner sum can be simplified by using (2.1) as follows:

$$\begin{aligned} &\sum_{k\leq m<n} \binom{n-1}{m} (-1)^m \pi_{m+1,k} \\ &\quad = \sum_{k\leq m<n} \binom{n-1}{m} (-1)^m \binom{m}{k} \int_{(0,1)^d} x_1\cdots x_s (x_1\cdots x_d)^k (1-x_1\cdots x_d)^{m-k} \mathbf{dx} \\ &\quad = \binom{n-1}{k} (-1)^k \sum_{0\leq m\leq n-1-k} \binom{n-1-k}{m} (-1)^m \\ &\qquad \times \int_{(0,1)^d} x_1\cdots x_s (x_1\cdots x_d)^k (1-x_1\cdots x_d)^m \mathbf{dx} \\ &\quad = \binom{n-1}{k} (-1)^k \int_{(0,1)^d} x_1\cdots x_s (x_1\cdots x_d)^{n-1} \mathbf{dx} \\ &\quad = \binom{n-1}{k} (-1)^k n^{-d+s} (n+1)^{-s}, \end{aligned}$$

which holds for $n \geq 2$. □

Proof of (1.4). From Lemma 2, it follows that, for $n \geq 2$,

$$Q_n^\star = -\prod_{2\leq j\leq n} \left(1 - \frac{2^d}{(j+1)^s j^{d-s}}\right) = -\prod_{2\leq j\leq n} \frac{\phi(j)}{(j+1)^s j^{d-s}},$$

which leads to (1.4) by the relation

$$Q_n = \sum_{1\leq j\leq n} \binom{n}{j} (-1)^j Q_j^\star.$$

This proves (1.4). □

4. Generating function, differential equation, and Euler transform. While binomial transform is shown to be the "Eureka!" to our elementary proof of (1.4), it leaves open how such a transform was linked and applied to our problem. In this section, we give an alternative approach to deriving the simple recurrence (3.1),

relying on the generating function $Q(z) := \sum_n Q_n z^n$ and the Euler transform (see [4])

$$Q^\star(z) = \frac{1}{1-z}\, Q\left(\frac{z}{z-1}\right). \tag{4.1}$$

Note that the coefficients f_n of a function $f(z)$ and those $f_n^\star$ of its Euler transform $f^\star(z)$ satisfy the inversion pair

$$\begin{cases} f_n = \displaystyle\sum_{0\le k\le n} \binom{n}{k} (-1)^k f_k^\star, \\ f_n^\star = \displaystyle\sum_{0\le k\le n} \binom{n}{k} (-1)^k f_k. \end{cases} \tag{4.2}$$

We start by substituting the expression (2.2) into the sum $\sum_{1\le k<n} \pi_{n,k} Q_k$, which gives

$$\begin{aligned} \sum_{1\le k<n} \pi_{n,k} Q_k &= \sum_{1\le k<n} \sum_{k\le j<n} \binom{n-1}{j}\binom{j}{k} (-1)^{j+k} (j+1)^{-d+s} (j+2)^{-s} Q_k \\ &= \sum_{1\le j<n} \binom{n-1}{j} (-1)^j (j+1)^{-d+s} (j+2)^{-s} Q_j^\star. \end{aligned}$$

In terms of generating functions, the recurrence (1.1) then translates into (in view of (4.2))

$$Q(z) = \frac{z}{1-z} + 2^d \frac{z}{1-z} S\left(\frac{z}{z-1}\right), \tag{4.3}$$

where

$$S(w) = \sum_{n\ge 1} (n+1)^{-d+s} (n+2)^{-s} Q_n^\star w^n.$$

Note that $S(w)$ satisfies

$$\vartheta^{d-s}\left(w^{-1}\vartheta^s\left(w^2 S(w)\right)\right) = w \sum_{n\ge 1} Q_n^\star w^n = \frac{w}{1-w} Q\left(\frac{w}{w-1}\right), \tag{4.4}$$

where $\vartheta := w(\mathrm{d}/\mathrm{d}w)$.

Thus it is natural to consider the Euler transform. Taking $z = w/(w-1)$ and then multiplying (4.3) by $-w$, we obtain

$$w(w-1)Q^\star(w) = w^2 + 2^d w^2 S(w).$$

From (4.4), it follows that

$$\vartheta^{d-s}\left(w^{-1}\vartheta^s\left(w(w-1)Q^\star(w)\right)\right) - 2^d w Q^\star(w) = 2^s w. \tag{4.5}$$

Taking the coefficients of w^n on both sides yields (3.1).

5. Differential equation and Mellin–Barnes integrals. More light can be shed on "why the Euler transform really helps" by looking at yet another approach, this one based on the differential equation derived by using the original form (1.2) for $\pi_{n,k}$ used in [3].

The proof starts by showing that the generating function $Q(z)$ satisfies, by (1.1) and (1.2), the integro-differential equation

$$\left(z(1-z)\frac{\mathrm{d}}{\mathrm{d}z}-\mathbf{1}\right)\frac{z}{1-z}\,Q(z)=\frac{z^2}{(1-z)^2}+2^d\mathbf{J}^s\frac{z}{1-z}\mathbf{J}^{d-s-1}(zQ(z)), \tag{5.1}$$

where $\mathbf{1}$ is the identity operator and

$$\mathbf{J}f(z):=\int_0^z\frac{f(t)}{t(1-t)}\,\mathrm{d}t.$$

Introduce now the differential operator $\mathcal{J}:=z(1-z)\,\mathrm{d}/\,\mathrm{d}z$. Then (5.1) can be shown to be of the form

$$\mathcal{J}^{d-s}\frac{1-z}{z}\mathcal{J}^s\left(\frac{z}{1-z}\,Q(z)-\frac{z^2}{(1-z)^2}\right)-2^dzQ(z)=0.$$

An inspiring way to see how to further proceed from this differential equation is to use the Mellin–Barnes integrals (see [12]) as follows. If a function is expressible formally as an integral of the form

$$f(z)=\frac{1}{2\pi i}\int_{\mathcal{C}}\tilde{f}(v)z^v(1-z)^{-v}\,\mathrm{d}v$$

for some contour $\mathcal{C}$ in the v-plane, then

$$\begin{aligned}\mathcal{J}^kf(z)&=\frac{1}{2\pi i}\int_{\mathcal{C}}\tilde{f}(v)\mathcal{J}^k\left(z^v(1-z)^{-v}\right)\,\mathrm{d}v\\&=\frac{1}{2\pi i}\int_{\mathcal{C}}\tilde{f}(v)v^kz^v(1-z)^{-v}\,\mathrm{d}v\qquad(k\ge1).\end{aligned}\tag{5.2}$$

Note that no such simplification is available if we use the usual Mellin–Barnes integrals

$$f(z)=\frac{1}{2\pi i}\int_{\mathcal{C}}\tilde{f}(v)(1-z)^{-v}\,\mathrm{d}v$$

or

$$f(z)=\frac{1}{2\pi i}\int_{\mathcal{C}}\tilde{f}(v)z^{-v}\,\mathrm{d}v.$$

The relation (5.2) suggests that it is natural to apply the Euler transform (4.1), and we obtain again (4.5).

6. Asymptotics of $Q(z)$. Since Q_n is essentially the nth difference of $Q_n^\star$, we have (see [7])

$$Q_n=\frac{1}{2\pi i}\int_{\sigma-i\infty}^{\sigma+i\infty}\frac{(-1)^nn!}{v(v-1)\cdots(v-n)}\,K(v+1)\,\mathrm{d}v, \tag{6.1}$$

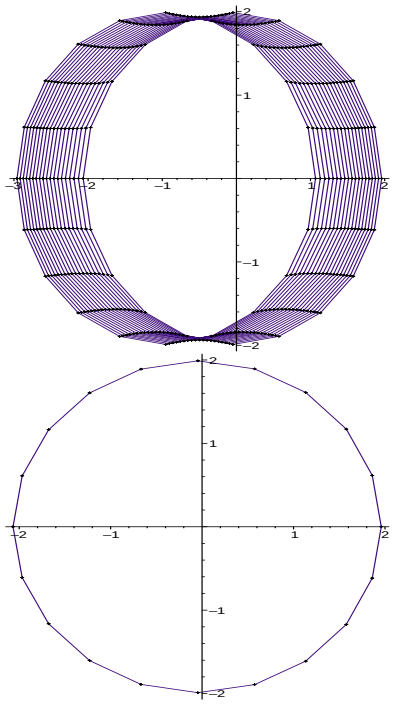

FIG. 6.1. *Distribution of the zeros of the polynomial* $z^{20-s}(z+1)^s = 2^{20}$ *for* $1 \le s \le 19$ *(top) and for* $s = 1$ *(bottom).*

where $\alpha_1 - 1 < \sigma < 1$ and

$$K(v) := \frac{2^s \Gamma(v-\alpha_1)\cdots\Gamma(v-\alpha_d)}{\Gamma(v)^{d-s}\Gamma(v+1)^s\Gamma(2-\alpha_1)\cdots\Gamma(2-\alpha_d)}.$$

We list some properties of the zeros α_j of $\phi(z)$ as follows; see Figure 6.1 for a plot of the zeros of $\phi(z)$ when $d = 20$ and $1 \le s \le 19$.

(i) *All zeros lie within the ring* $3/2 < |z + 1/2| < 5/2$. This follows by noting that

$$(|z| - 1/2)^d \le |z - 1/2|^{d-s}|z + 1/2|^s \le (|z| + 1/2)^d$$

and by using the bounds $|z| - 1/2 \ge 2$ and $|z| + 1/2 \le 2$.

(ii) *The zero with the largest real part is* α. To see this, assume that $\alpha_j = x + iy$ with $x \ge \alpha$ and $|y| > 0$; then we have

$$\begin{aligned} |\,(x+iy)^{d-s}\,(x+iy+1)^s| &= \left(x^2+y^2\right)^{(d-s)/2}\left((x+1)^2+y^2\right)^{s/2} \\ &> x^{d-s}(x+1)^s \ge \alpha^{d-s}(\alpha+1)^s = 2^d. \end{aligned}$$

(iii) *If* d *is odd, then* $\phi(z)$ *has only one real zero* α_1; *if* d *is even, then* $\phi(z)$ *has an additional real root lying between* -2 *and* -3.

(iv) *All zeros of* $\phi(z)$ *are simple.*

From these properties, it follows that the origin is a simple pole of the integrand in (6.1) (with residue $-(2^{d-s}-1)^{-1}$), and there are simple poles at $\alpha_j - 1 - \ell$ for $1 \le j \le d$ and $\ell \ge 0$. Other singularities are a pole of order $d - s$ at -1 and a pole at

$-\ell$ of order d for $\ell \geq 2$. In particular, the dominant singularity (the singularity with the largest real part in the half-plane $\Re(v) < 1$) is a simple pole at $v = \alpha - 1$. Also, by the asymptotic estimate

$$|\Gamma(\sigma + it)| = O(|t|^{\sigma-1/2} e^{-\pi|t|/2}) \qquad (|t| \to \infty)$$

for fixed σ, we can shift, by absolute convergence, the integration line in (6.1) to $\Re(v) = \sigma_1$, where

$$\max\{0, \Re(\alpha_2) - 1\} < \sigma_1 < \alpha - 1,$$

and compute the residue encountered at $v = \alpha - 1$, which gives

$$Q_n = \frac{(-1)^n n!}{(\alpha-1)\cdots(\alpha-n-1)} \lim_{v\to\alpha} (v-\alpha)K(v) + E_n,$$

where

$$E_n := \frac{1}{2\pi i} \int_{\sigma_1 - i\infty}^{\sigma_1 + i\infty} \frac{(-1)^n n!}{v(v-1)\cdots(v-n)} K(v+1)\, \mathrm{d}v.$$

Observe that

$$\begin{aligned}
&\frac{(-1)^n n!}{(\alpha-1)\cdots(\alpha-n-1)} \lim_{v\to\alpha} (v-\alpha)K(v) \\
&\quad = \frac{2^s \Gamma(n+1)}{(\alpha-1)\Gamma(n+2-\alpha)\Gamma(\alpha)^{d-s}\Gamma(\alpha+1)^s} \prod_{2\leq j\leq d} \frac{\Gamma(\alpha-\alpha_j)}{\Gamma(2-\alpha_j)} \\
&\quad = h_{d,s} \frac{\Gamma(n+1)}{\Gamma(n+2-\alpha)},
\end{aligned}$$

where we used the identity $\phi(1) = (1-\alpha_1)\cdots(1-\alpha_d) = 2^s - 2^d$.

By applying the asymptotic approximation

$$\frac{\Gamma(n+1)}{\Gamma(n+2-\alpha)} = n^{\alpha-1}\left(1 + O(n^{-1})\right),$$

we deduce that

$$Q_n = h_{d,s} n^{\alpha-1}\left(1 + O(n^{-1})\right) + E_n.$$

By a similar argument, we have

$$E_n = O(1 + n^{\Re(\alpha_2)-1}).$$

This proves (1.3). □

Remarks. (i) If $\Re(\alpha_2) < 1$, then

$$Q_n = h_{d,s} n^{\alpha-1} - \frac{1}{2^{d-s}-1} + O(n^{\alpha-2} + n^{\Re(\alpha_2)-1}). \tag{6.2}$$

In particular, $\Re(\alpha_2) < 1$ for all $d \leq 6$ and $1 \leq s < d$. See Figure 6.2 for a plot of $(Q_n + (2^{d-s}-1)^{-1})/n^{\alpha-1}$ when $d = 3$.

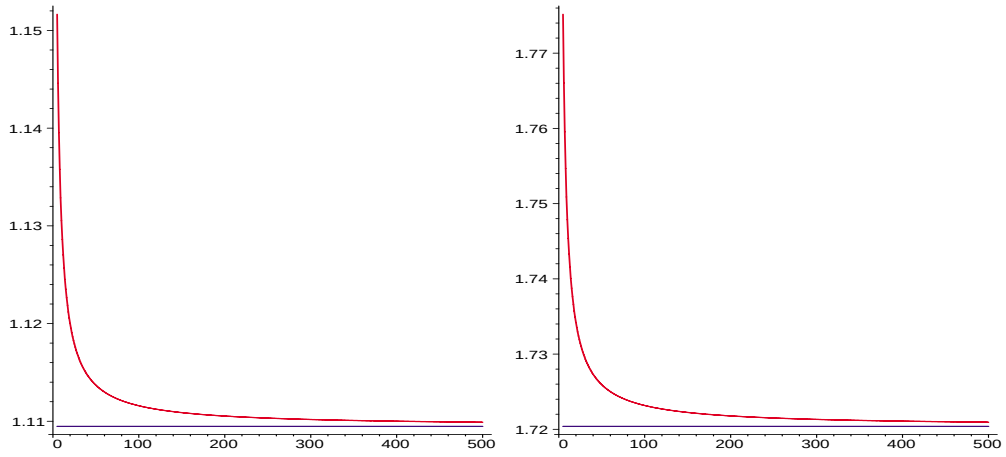

FIG. 6.2. *Convergence of* $(Q_n + (2^{d-s}-1)^{-1})/n^{\alpha-1}$ *to* $h_{d,s}$ *for* $(d,s) = (3,1)$ *(left) and* $(3,2)$ *(right), where* $n = 5, \dots, 500$.

(ii) If $\Re(\alpha_2) = \Re(\alpha_3) > 1$, then

$$Q_n = h_{d,s} n^{\alpha-1} + 2\Re(Y_{d,s}(\alpha_2) n^{i\Im(\alpha_2)}) n^{\Re(\alpha_2)-1} + O(n^{\alpha-2} + 1 + n^{\Re(\alpha_4)-1}),$$

where

$$Y_{d,s}(z) = \frac{2^s}{(z-1)\Gamma(z)^{d-s}\Gamma(z+1)^s} \prod_{\alpha_j \neq z} \frac{\Gamma(z-\alpha_j)}{\Gamma(2-\alpha_j)}.$$

Note that $h_{d,s} = Y_{d,s}(\alpha)$. More terms can be obtained by refining the same analysis.

(iii) By (1.4), the generating function $Q(z)$ can be expressed in terms of the generalized hypergeometric function (see [8]) as

$$Q(z) = \frac{z}{(z-1)^2}\, {}_{d+1}F_d\left(\begin{matrix} 2-\alpha_1, \dots, 2-\alpha_d, 1 \\ \underbrace{3, \dots, 3}_{s \text{ times}}, \underbrace{2, \dots, 2}_{d-s \text{ times}} \end{matrix} \,\middle|\, \frac{z}{z-1} \right),$$

where

$${}_{d+1}F_d\left(\begin{matrix} a_1, \dots, a_{d+1} \\ b_1, \dots, b_d \end{matrix} \,\middle|\, z \right) := \sum_{n \geq 0} \frac{(a_1)_n \cdots (a_{d+1})_n}{(b_1)_n \cdots (b_d)_n} \cdot \frac{z^n}{n!}.$$

7. General toll functions. The approaches we used can also be applied to a more general recurrence of the form

$$f_n = t_n + 2^d \sum_{1 \leq k < n} \pi_{n,k} f_k, \qquad (n \geq 1), \tag{7.1}$$

where t_n is some given sequence, and we may assume that $f_0 = 0$. We obtain the following first-order recurrence:

$$f^\star_n - f^\star_{n-1} = t^\star_n - t^\star_{n-1} - \frac{2^d}{n^{d-s}(n+1)^s} f^\star_{n-1} \qquad (n \geq 1),$$

with $t_0^\star = t_0 := 0$. Solving this recurrence yields

$$f_n^\star = \sum_{1\le k\le n} \left(t_k^\star - t_{k-1}^\star\right) \prod_{k<j\le n} \left(1 - \frac{2^d}{j^{d-s}(j+1)^s}\right) \qquad (n \ge 1). \tag{7.2}$$

By the binomial inversion formula (4.2), we obtain

$$f_n = \sum_{1\le k\le n} (t_k^\star - t_{k-1}^\star) \sum_{k\le m\le n} \binom{n}{m} (-1)^m \prod_{k<j\le m} \left(1 - \frac{2^d}{j^{d-s}(j+1)^s}\right)$$

for $n \ge 1$, where $t_n^\star := \sum_{1\le k\le n} \binom{n}{k}(-1)^k t_k$.

From this explicit form, the asymptotics of f_n can be derived if those of t_n are known.

8. Random full-specified queries. Our elementary approach is also useful for simplifying the recurrence encountered in the analysis of full-specified queries in random quadtrees (see [4, 5]):

$$f_n = t_n + 2^d \sum_{1\le k<n} \varpi_{n,k} f_k \qquad (n \ge 1), \tag{8.1}$$

with $f_0 = t_0 := 0$, where

$$\varpi_{n,k} = \binom{n-1}{k} \int_{(0,1)^d} (x_1 \cdots x_d)^k (1 - x_1 \cdots x_d)^{n-1-k} \mathbf{dx}.$$

From this, we then easily derive the recurrence relation (see [4, 10])

$$f_n^\star - f_{n-1}^\star = t_n^\star - t_{n-1}^\star - \frac{2^d}{n^d} f_{n-1}^\star \qquad (n \ge 1).$$

More generally, if

$$f_n = t_n + \sum_{1\le k<n} \beta_{n,k} f_k \qquad (n \ge 1),$$

where the sequence $\beta_{n,k}$ satisfies

$$\sum_{k\le m<n} \binom{n-1}{m} (-1)^m \beta_{m+1,k} = -\binom{n-1}{k} (-1)^k \varepsilon_n$$

for some sequence ε_n independent of k, then the recurrence for $f_n^\star$ can be "linearized,"

$$f_n^\star - f_{n-1}^\star = t_n^\star - t_{n-1}^\star - \varepsilon_n f_{n-1}^\star,$$

and we obtain the same pattern as above. Note that by (4.2),

$$\beta_{n,k} = \sum_{k\le j<n} \binom{n-1}{j} \binom{j}{k} (-1)^{j+k+1} \varepsilon_{j+1};$$

cf. (2.2).

A trivial example is the quicksort recurrence for which $\beta_{n,k} = 2/n$ for $0 \le k < n$. Then $\varepsilon_n = 2/n$. For other examples for which the Euler transform is particularly helpful, see [9] and the references therein.

This consideration also shows the limitation of the approach via the generating function and differential equations, since ε_n may be very complicated in general, so that the associated generating functions may not be reduced to simple solvable forms.

THE HIDDEN SUBGROUP PROBLEM AND QUANTUM COMPUTATION USING GROUP REPRESENTATIONS*

SEAN HALLGREN†, ALEXANDER RUSSELL‡, AND AMNON TA-SHMA§

Abstract. The hidden subgroup problem is the foundation of many quantum algorithms. An efficient solution is known for the problem over abelian groups, employed by both Simon's algorithm and Shor's factoring and discrete log algorithms. The nonabelian case, however, remains open; an efficient solution would give rise to an efficient quantum algorithm for graph isomorphism. We fully analyze a natural generalization of the algorithm for the abelian case to the nonabelian case and show that the algorithm determines the normal core of a hidden subgroup: in particular, normal subgroups can be determined. We show, however, that this immediate generalization of the abelian algorithm does not efficiently solve graph isomorphism.

1. Introduction.

Peter Shor's seminal article [27] presented efficient quantum algorithms for computing integer factorizations and discrete logarithms, problems thought to be intractable for classical computation models. A primary ingredient in these algorithms is an efficient solution to the *hidden subgroup problem* for certain abelian groups; indeed computing discrete logarithms directly reduces to the hidden subgroup problem. Formally, the hidden subgroup problem is the following.

DEFINITION 1.1. Hidden subgroup problem (HSP). *Given an efficiently computable function $f : G \to S$, from a finite group G to a set S, that is constant on (left) cosets of some subgroup H and takes distinct values on distinct cosets, determine the subgroup H.*

The general paradigm, which gives rise to efficient quantum algorithms for this problem over abelian groups, is the following.

EXPERIMENT 1.1 (experiment for the abelian HSP).

1. *Prepare the state*

$$\frac{1}{\sqrt{|G|}} \sum_{g \in G} |g, f(g)\rangle$$

and measure the second register $f(g)$. As f takes distinct values on the left cosets of

H, the resulting state is

$$\frac{1}{\sqrt{|H|}} \sum_{h \in H} |ch, f(ch)\rangle, \tag{1.1}$$

where c is an element of G selected uniformly at random.

2. *Compute the Fourier transform of the "coset" state* (1.1), *resulting in*

$$\sum_{\rho \in \hat{G}} \sqrt{\frac{1}{|G|}} \sqrt{\frac{1}{|H|}} \sum_{h \in H} \rho(ch) |\rho\rangle,$$

where $\hat{G}$ denotes the set of homomorphisms $\{\rho : G \to \mathbb{C}\}$.

3. *Measure the first register and observe a homomorphism ρ.*

A key fact about this procedure is that the resulting distribution over ρ is independent of the coset cH arising after the first stage (as the support of the first register in (1.1)). Thus, repetitions of this experiment result in the same distribution over $\hat{G}$. We note that by the principle of delayed measurement (see, e.g., [21]), measuring the second register in the first step can in fact be delayed until the end of the experiment.

It is well known that an efficient solution to the HSP for the symmetric group S_n gives, in particular, an efficient quantum algorithm for graph isomorphism. It is also known how to efficiently compute the Fourier transform over many nonabelian groups, most notably over S_n [2]. This article provides the first general understanding of the HSP over nonabelian groups: We study a natural generalization of Experiment 1.1 to nonabelian groups and explicitly describe the resulting measurement distribution. Specifically, we study the following experiment.

EXPERIMENT 1.2.

1. *Prepare the state $\sum_{g \in G} |g, f(g)\rangle$ and measure the second register $f(g)$. The resulting state is $\sum_{h \in H} |ch, f(ch)\rangle$, where c is an element of G selected uniformly at random. As above, this state is supported on a left coset cH of H.*

2. *Let $\hat{G}$ denote the set of irreducible representations of G and, for each $\rho \in \hat{G}$, fix a basis for the space on which ρ acts. Let d_ρ denote the dimension of ρ. Compute the Fourier transform of the "coset" state, resulting in*

$$\sum_{\rho \in \hat{G}} \sum_{i}^{d_\rho} \sum_{j}^{d_\rho} \sqrt{\frac{d_\rho}{|G|}} \sqrt{\frac{1}{|H|}} \left(\sum_{h \in H} \rho(ch) \right)_{i,j} |\rho, i, j\rangle.$$

3. *Measure the first register and observe a representation ρ.*

A brief discussion of the representation theory of finite groups and the associated Fourier transform appears in section 2. As before, we wish the resulting distribution to be *independent* of the actual coset cH (and so depend only on the subgroup H). This is guaranteed by measuring only the name of the representation ρ and leaving the matrix indices (the values i and j) unobserved. The question we study is whether this procedure retains enough information to determine H or, more precisely, whether $O(\log(|G|))$ samples of this distribution are enough to determine H with high probability. Our analysis of Experiment 1.2 depends on the following theorem, which describes the distribution resulting from the measurements in the above experiment.

THEOREM 1.2. *Let H be a subgroup of a group G and let ρ be an irreducible representation of G with dimension d_ρ. Let $R_H(\rho)$ denote the number of times that the trivial representation appears in ρ when decomposed as a representation of H, and*

let $I_H(\rho)$ denote the number of times that ρ appears in the permutation representation of G on the left cosets of H. Then the probability of measuring the representation ρ in Experiment 1.2 *when H is the hidden subgroup is*

$$\frac{d_\rho \cdot R_H(\rho) \cdot |H|}{|G|} = \frac{d_\rho \cdot I_H(\rho) \cdot |H|}{|G|}. \tag{1.2}$$

We first apply this to obtain the following positive result.

THEOREM 1.3. *Let H be an arbitrary subgroup of G, and let H^G be the largest subgroup of H that is normal in G. With high probability, H^G is uniquely determined by observing $m = O(\log |G|)$ independent trials of Experiment* 1.2 *when H is the hidden subgroup.*

When H is normal in G, $H = H^G$, so that this algorithm determines H with high probability. In fact, we shall see that if $\rho_1, \ldots, \rho_m$ are the representations sampled by m independent runs of Experiment 1.2 and m is sufficiently large, then $H^G = \cap_i \ker \rho_i$ with high probability. (Here $\ker \rho$ denotes the kernel of the representation ρ.)

Our reconstruction result applies to any normal subgroup H of any group G without reference to the specific way that the representations or the group elements are expressed. We proceed at this level of abstraction because there is no known canonical concise presentation for the representations (or, indeed, the elements) of a finite group G. In the same vein, there is no general method for computing the Fourier transform over an arbitrary group. Thus, while we cannot give a unified algorithm for computing the Fourier transform or a set of generators for a hidden subgroup, this does yield an algorithm for any group which admits (i) a succinct representation over which the Fourier transform can be computed, and (ii) an efficient algorithm for computing the intersection of a (polynomial-size) family of representation kernels. See section 6, where the above approach is applied to solve the HSP for Hamiltonian groups, where all subgroups are normal.

Note that it is known [8] that the HSP has polynomial (in $\log |G|$) *query* complexity for any subgroup, though the only known algorithm which achieves this uses an exponential number of quantum measurements and, hence, does not give rise to an efficient quantum algorithm for the HSP.

A corollary of Theorem 1.2 is that conjugate subgroups H_1 and H_2 (where $H_2 = gH_1g^{-1}$ for some $g \in G$) produce exactly the same distribution over ρ and hence cannot be distinguished by this process. In particular, the HSP cannot be solved by Experiment 1.2 for a group G with two distinct conjugate subgroups H_1, H_2; the symmetric group S_n is such a group.

In light of this, one may ask whether Experiment 1.2 can distinguish between a coset cH of a nontrivial subgroup H and a coset $cH_e = \{c\}$ of the trivial subgroup $H_e = \{e\}$, as even this would be enough for solving graph isomorphism. However, even for this weaker problem we show (in section 5) the following.

THEOREM 1.4. *For the symmetric group S_n, there is a subgroup H_n so that Experiment* 1.2 *does not distinguish (even information-theoretically) the case that the hidden subgroup is the trivial subgroup from the case that the hidden subgroup is H_n. (Specifically, the distributions induced on ρ in these two cases have exponentially small distance in total variation.)*

1.1. Related work. The HSP plays a central role in most known quantum algorithms. Simon's algorithm [28] implicitly involves distinguishing the trivial subgroup from an order 2 subgroup over the group $\mathbb{Z}_2^n$. Furthermore, he has shown that a classical probabilistic oracle machine would require exponentially many oracle queries

to successfully distinguish the two cases with probability greater than 1/2. Shor [27] then gave efficient algorithms for integer factorization and the discrete log problem. In addition to solving a special case of the HSP, he also solved specific cases where the size of the underlying group is not fully known. Other generalizations have been studied by Boneh and Lipton [3], focusing on cases when a periodic function is not fixed on a coset, and Hales and Hallgren [11, 12], who generalized the results for the case when the underlying abelian group is unknown.

The efficient algorithm for the abelian HSP using the Fourier transform is well known. Other methods have been applied to this same problem by Mosca and Ekert [19]. Related problems have been studied by Kitaev [17], who gave an algorithm using eigenvalue estimation for the abelian stabilizer problem, and Hallgren [13], who gave polynomial-time quantum algorithms for Pell's equation and the principal ideal problem.

As for computing the Fourier transform, Kitaev showed how to efficiently compute the Fourier transform over any abelian group. The fastest currently known (quantum) algorithm for computing the Fourier transform over abelian groups was given by Hales and Hallgren [12]. Shallow parallel circuits for approximating the Fourier transform have been given by Cleve and Watrous in [4]. Beals [2] showed how to efficiently compute the Fourier transform over the symmetric group S_n.

For general groups, Ettinger, Høyer, and Knill [8] have shown that the HSP has polynomial query complexity, giving an algorithm that makes an exponential number of measurements. On the other hand, if one considers arbitrary functions rather than those that arise from HSPs, Aaronson [1] shows that it is not possible to distinguish a 1-1 function from a 2-1 function, even with a quantum algorithm. Several specific nonabelian groups have been studied in the context of the HSP. Ettinger and Høyer [7] give a solution for the HSP over the (nonabelian) dihedral group D_n using polynomially many measurements and exponential (classical) time. Rötteler and Beth [24] and Püschel, Rötteler, and Beth [22] have shown similar results for other specific classes of nonabelian groups. Ivanyos, Mangniez, and Santha [16] have shown how to solve certain nonabelian HSP instances using a reduction to the abelian case.

Grigni et al. [10] independently showed that measuring the representation is not enough for graph isomorphism, and they give stronger negative results. They establish the same bounds even when the row of the representation (i.e., i in Experiment 1.2 above) is measured, and similar bounds if the column (j) is measured, under the assumption that random bases are selected for each representation. They also show that the problem can be solved when the intersection of the normalizers of all subgroups of G is large. Other impossibility results have been given by Ettinger and Høyer [6, 5], determining whether *any* measurement can distinguish certain subgroup states.

2. Representation theory background. To define the Fourier transform (over a general group) we require the basic elements of representation theory, defined briefly below. For complete accounts, consult the books of Serre [26] or Harris and Fulton [15]. Throughout, we let $\mathbb{I}_d$ denote the $d \times d$ identity matrix, dropping the subscript when it can be inferred from context.

Linear representations. A representation ρ of a finite group G is a homomorphism $\rho : G \to GL(V)$, where V is a (finite-dimensional) vector space over $\mathbb{C}$ and $\mathrm{GL}(V)$ denotes the group of invertible linear operators on V. Fixing a basis for V, each $\rho(g)$ may be realized as a $d \times d$ matrix over $\mathbb{C}$, where d is the dimension of V. As ρ is a homomorphism, for any $g, h \in G$, $\rho(gh) = \rho(g)\rho(h)$ (this second product being matrix multiplication). The *dimension* d_ρ of the

representation ρ is d, the dimension of V.

A representation provides a means for investigating a group by homomorphically mapping it into a family of matrices. With this realization, the group operation is matrix multiplication, and tools from linear algebra can be applied to study the group. We shall be concerned with complex-valued functions on a group G; the representations of the group are relevant to this study, as they give rise to the natural Fourier transform in this nonabelian setting.

If $\rho : G \to \mathrm{GL}(V)$ is a representation and there is an inner product $\langle \cdot \,|\, \cdot \rangle$ defined on V, it is always possible to define a new inner product on V so that each $\rho(g)$ is unitary; we will always work under this assumption. In particular, we shall always assume an orthonormal basis for V in which the matrices corresponding to $\rho(g)$ are unitary. We let $\rho(g)_{ij}$ denote the i,jth entry of the matrix for $\rho(g)$ in this fixed basis. (See, e.g., [26] for more discussion.)

We say that two representations $\rho_1 : G \to \mathrm{GL}(V)$ and $\rho_2 : G \to \mathrm{GL}(W)$ of a group G are *isomorphic* when there is a linear isomorphism of the two vector spaces $\phi : V \to W$ so that for all $g \in G$ the diagram

$$\begin{array}{ccc} V & \xrightarrow{\rho_1(g)} & V \\ {\scriptstyle\phi}\downarrow & & {\scriptstyle\phi}\downarrow \\ W & \xrightarrow{\rho_2(g)} & W \end{array}$$

commutes. That is, for all $g \in G$, $\phi\rho_1(g) = \rho_2(g)\phi$. In this case, we write $\rho_1 \cong \rho_2$. Up to isomorphism, a finite group has a finite number of irreducible representations; we let $\hat{G}$ denote this collection (of representations).

Irreducibility. We say that a subspace $W \subset V$ is an *invariant* subspace of a representation $\rho : G \to \mathrm{GL}(V)$ if $\rho(g)W \subseteq W$ for all $g \in G$. The zero subspace and the subspace V are always invariant. If no nonzero proper subspaces are invariant, the representation is said to be *irreducible*.

Decomposition and reducibility. When a representation *does* have a nonzero proper invariant subspace $V_1 \subsetneq V$, it is always possible to find a complementary subspace V_2 (so that $V = V_1 \oplus V_2$) that is also invariant. Since V_1 is invariant, for each $g \in G$, $\rho(g)$ defines a linear map $\rho_1(g)$ from V_1 to V_1 by restriction, and it is not hard to see that $\rho_1 : G \to \mathrm{GL}(V_1)$ is in fact a representation. Similarly, define $\rho_2(g)$ to be $\rho(g)$ restricted to V_2. As $V = V_1 \oplus V_2$, the linear map $\rho(g)$ is completely determined by $\rho_1(g)$ and $\rho_2(g)$, and in this case we write $\rho = \rho_1 \oplus \rho_2$. Repeating this process, any representation ρ may be written $\rho = \rho_1 \oplus \rho_2 \oplus \cdots \oplus \rho_k$, where each ρ_i is irreducible. In particular, there is a basis in which every matrix $\rho(g)$ is block diagonal, the ith block corresponding to the ith representation in the decomposition. While this decomposition is not, in general, unique, the *number* of times a given irreducible representation appears in this decomposition (up to isomorphism) depends only on the original representation ρ.

Characters. The *character* $\chi_\rho : G \to \mathbb{C}$ of a representation ρ is defined by $\chi_\rho(g) = \mathbf{tr}\,(\rho(g))$, where $\mathbf{tr}\,(\cdot)$ denotes the trace. This function is basis independent and, as it turns out, completely determines the representation ρ. Elementary properties of trace imply that characters are in fact *class* functions, depending

only on the conjugacy class of their argument. (Specifically, for every g and h we have $\chi_\rho(hgh^{-1}) = \chi_\rho(g)$.)

Orthogonality. For two complex-valued functions f_1 and f_2 on a group G, there is a natural inner product $\langle f_1 \,|\, f_2 \rangle_G$ given by $\frac{1}{|G|}\sum_g f_1(g) f_2(g)^*$. The matrix entries of the representations of a group G are orthogonal according to this inner product: let ρ and σ be two irreducible representations of G; then

$$\langle \rho(\cdot)_{ij} \,|\, \sigma(\cdot)_{kl} \rangle_G = \begin{cases} 0 & \text{if } \rho \ncong \sigma, \\ \delta_{ik}\delta_{jl} & \text{if } \rho = \sigma. \end{cases}$$

(It is assumed here that when $\rho = \sigma$, the same basis has been selected for each.) An immediate consequence is that if χ_σ is the character of a representation σ and χ_{ρ_i} is the character of an irreducible representation ρ_i, the inner product $\langle \chi_\sigma \,|\, \chi_{\rho_i} \rangle_G$ is precisely the number of times the representation ρ_i appears in the decomposition of σ. Note that since each ρ_i is unitary, we may write

$$\langle \chi_\rho \,|\, \chi_{\rho_i} \rangle_G = \frac{1}{|G|} \sum_{g \in G} \chi_\rho(g) \chi_{\rho_i}(g^{-1}).$$

Orthogonality of the second kind. Let C be a conjugacy class of G. As mentioned before, any character χ_ρ is fixed on any conjugacy class C; we denote this value by $\chi_\rho(C)$. It holds that

$$\sum_{\rho \in \hat{G}} |\chi_\rho(C)|^2 = \frac{|G|}{|C|}. \tag{2.1}$$

This is a special case of a more general principle, and we refer the interested reader to Sagan's excellent book [25, Theorem 1.10.3].

Restriction. A representation ρ of a group G is also automatically a representation of any subgroup H. We refer to this *restricted* representation on H as $\mathrm{Res}_H \rho$. Note that even representations that are irreducible over G may be reducible when restricted to H.

Induction. There is a dual notion, that of *induction*, whereby a representation of a subgroup $H < G$ may be induced to a representation of the whole group G. We delay discussion of this to section 3.1.

We let $\ker(\rho) = \{g \in G : \rho(g) = \mathbb{I}\}$ denote the kernel of a representation ρ. As a representation ρ is a homomorphism, $\ker(\rho)$ is always a normal subgroup of G. In fact, we shall see that any normal subgroup H of G can be written $\cap_{\rho \in I} \ker(\rho)$ for some set I of irreducible representations.

As mentioned above, any representation ρ of G may be decomposed into a direct sum of irreducible representations. In fact, reiterating the comments above, if $\rho_1, \ldots, \rho_k$ are the irreducible representations of G and χ_σ is the character of the representation σ, the value

$$n_i = \langle \chi_\sigma \,|\, \chi_{\rho_i} \rangle_G$$

is precisely the number of times the irreducible representation ρ_i appears in the decomposition of the representation σ into irreducible representations. Specifically, after a unitary change of basis, the matrices $\sigma(g)$ are block diagonal, consisting of n_1

copies of $\rho_1(g)$, followed by n_2 copies of $\rho_2(g)$, etc. We denote this state of affairs by $\sigma = n_1\rho_1 \oplus \cdots \oplus n_k\rho_k$.

There are two representations which shall play a central role in our discussion:

The trivial representation. The trivial representation **1** maps every group element $g \in G$ to the 1×1 identity matrix $\mathbb{I}$. Recalling the orthogonality relations above, the function $g \mapsto 1$ is orthogonal to $\rho(\cdot)_{ij}$ for any nontrivial irreducible representation ρ; this results in the identity

$$\sum_g \rho(g) = 0 \cdot \mathbb{I}, \tag{2.2}$$

which we record in anticipation of the proof of Theorem 1.2.

The regular representation. Fix a vector space V with an orthonormal basis consisting of vectors e_g, one for every element $g \in G$. The regular representation $\mathrm{reg}_G : G \to \mathrm{GL}(V)$ is defined by $\mathrm{reg}_G(g) : e_x \mapsto e_{gx}$ for any $x \in G$. V has dimension $|G|$ and, with the basis above, $\mathrm{reg}_G(g)$ is a permutation matrix for any $g \in G$.

An interesting fact about the regular representation is that it contains every irreducible representation of G. In particular, if $\rho_1, \ldots, \rho_k$ are the irreducible representations of G with dimensions $d_{\rho_1}, \ldots, d_{\rho_k}$, then

$$\mathrm{reg}_G = d_{\rho_1}\rho_1 \oplus \cdots \oplus d_{\rho_k}\rho_k,$$

so that the regular representation contains each irreducible representation ρ exactly d_ρ times. Counting dimensions yields an important relation between the dimensions d_ρ and the order of the group:

$$|G| = \sum_{\rho \in \hat{G}} d_\rho^2. \tag{2.3}$$

The main tool in quantum polynomial-time algorithms is the Fourier transform. When G is nonabelian, this takes the form described below.

DEFINITION 2.1. *Let $f : G \to \mathbb{C}$. The* Fourier transform of f at the irreducible representation ρ, *denoted $\hat{f}(\rho)$, is the $d_\rho \times d_\rho$ matrix*

$$\hat{f}(\rho) = \sqrt{\frac{d_\rho}{|G|}} \sum_{g \in G} f(g)\rho(g).$$

We refer to the collection of matrices $\langle \hat{f}(\rho) \rangle_{\rho \in \hat{G}}$ as the *Fourier transform* of f. Thus f is mapped into $|\hat{G}|$ matrices of varying dimensions. The total number of entries in these matrices is $\sum d_\rho^2 = |G|$, by (2.3) above. The Fourier transform is linear in f; with the constants used above ($\sqrt{d_\rho / |G|}$) it is in fact unitary, taking the $|G|$ complex numbers $\langle f(g) \rangle_{g \in G}$ to $|G|$ complex numbers organized into matrices.

A familiar case in computer science is when the group is cyclic of order n. Then the linear transformation (i.e., the Fourier transform) is a Vandermonde matrix over the nth roots of unity and the representations are all one-dimensional.

In the quantum setting we identify the state $\sum_{g \in G} f_g |g\rangle$ with the function $f : G \to \mathbb{C}$ defined by $f(g) = f_g$. In this notation, $\sum_{g \in G} f(g)|g\rangle$ is mapped under the Fourier transform to

$$\sum_{\rho \in \hat{G}} \sum_{1 \le i,j \le d_\rho} \hat{f}(\rho)_{i,j} |\rho, i, j\rangle.$$

We remind the reader that $\hat{f}(\rho)_{i,j}$ is a complex number and that when the first portion of this triple is measured, we observe $\rho \in \hat{G}$ with probability

$$\sum_{1 \le i,j \le d_\rho} \left| \hat{f}(\rho)_{i,j} \right|^2 = \left\| \hat{f}(\rho) \right\|_2^2,$$

where $\|A\|_2$ is the natural norm given by $\|A\|_2^2 = \mathbf{tr}\ A^* A$.

Let f be the indicator function of a left coset of H in G; i.e., for some $c \in G$,

$$f(g) = \begin{cases} \frac{1}{\sqrt{|H|}} & \text{if } g \in cH, \\ 0 & \text{otherwise.} \end{cases}$$

Our goal is to understand the Fourier transform of f, as this determines the probability of observing ρ. Our choice to measure only the representation ρ (and not the matrix indices) depends on the following key fact about the Fourier transform, also relevant to the abelian solution.

CLAIM 2.1. *The probability of observing ρ is independent of the coset.*

Proof. We have

$$\hat{f}(\rho) = \sqrt{\frac{d_\rho}{|G|}\frac{1}{|H|}} \sum_{h \in H} \rho(ch) = \sqrt{\frac{d_\rho}{|G|}\frac{1}{|H|}} \rho(c) \sum_{h \in H} \rho(h)$$

and, since $\rho(c)$ is a unitary matrix,

$$\left\| \hat{f}(\rho) \right\|_2^2 = \frac{d_\rho}{|G|}\frac{1}{|H|} \left\| \rho(c) \sum_{h \in H} \rho(h) \right\|_2^2 = \frac{d_\rho}{|G|}\frac{1}{|H|} \left\| \sum_{h \in H} \rho(h) \right\|_2^2. \qquad \square$$

Given this we may assume, without loss of generality, that our function f is $1/\sqrt{|H|}$ on the subgroup H itself, and zero elsewhere.

3. The probability of measuring ρ. The primary question is that of the probability of observing a given ρ in Experiment 1.2. We have seen that this is determined by the linear operator $\sum_{h \in H} \rho(h)$ and begin by showing that $\frac{1}{|H|} \sum_h \rho(h)$ is a projection.

LEMMA 3.1. *Let ρ be an irreducible representation of G. For every subgroup $H \le G$, $\frac{1}{|H|} \sum_{h \in H} \rho(h)$ is a projection operator.*

With the right basis, then, $\frac{1}{|H|} \sum_{h \in H} \rho(h)$ is diagonal, each diagonal entry being either one or zero. The probability of observing a particular representation ρ is then proportional to the rank of $\hat{f}(\rho)$.

Proof of Lemma 3.1. Given an irreducible representation ρ of G, we are interested in the sum of the matrices $\rho(h)$ over all $h \in H$. Since we evaluate only ρ on H, we may instead consider $\mathrm{Res}_H \rho$ without changing anything. As mentioned before, though ρ is irreducible (over G), $\mathrm{Res}_H \rho$ may *not* be irreducible over H. We may, however, decompose $\mathrm{Res}_H \rho$ into irreducible representations over H, writing $\mathrm{Res}_H \rho = \sigma_1 \oplus \cdots \oplus \sigma_t$ for a sequence σ_i of (possibly repeating) irreducible representations of H. In an appropriate basis $\sum_{h \in H} \rho(h)$ is then comprised of blocks, one corresponding to

each σ_i. In particular, the matrix $\sum_{h\in H}\rho(h)$ is

$$U\begin{bmatrix} \sum_{h\in H}\sigma_1(h) & 0 & \cdots & 0 \\ 0 & \sum_{h\in H}\sigma_2(h) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \sum_{h\in H}\sigma_t(h) \end{bmatrix} U^\dagger \tag{3.1}$$

for some unitary transformation U and some irreducible representations σ_i of H (with possible repetitions). (Here † denotes conjugate transpose.) Recalling (2.2), each sum appearing on the diagonal is nonzero only when the irreducible representation is trivial, in which case it is $|H|$. □

As in the previous section, we let $f : G \to \mathbb{C}$ be the function $f(g) = \frac{1}{\sqrt{|H|}}$ for $g \in H$, and 0 otherwise. Then the probability of observing ρ in Experiment 1.2 is

$$\left\|(\hat{f}(\rho))\right\|_2^2 = \frac{d_\rho}{|G|}\frac{1}{|H|}\left\|\sum_{h\in H}\rho(h)\right\|_2^2 = \frac{d_\rho}{|G|}\frac{1}{|H|}|H|^2\left\langle \chi_\rho \,|\, \chi_{\mathbf{1}}\right\rangle_H$$
$$= \frac{|H|}{|G|}d_\rho\left\langle \chi_\rho \,|\, \chi_{\mathbf{1}}\right\rangle_H.$$

We record this result in the following theorem.

THEOREM 3.2. *For every subgroup $H \le G$, the probability of measuring ρ in Experiment* 1.2, *with hidden subgroup H, is*

$$\left\|\hat{f}(\rho)\right\|_2^2 = \frac{|H|}{|G|}d_\rho\left\langle \chi_\rho \,|\, \chi_{\mathbf{1}}\right\rangle_H.$$

Observe that this establishes the first part of Theorem 1.2, that the measurement probability equals the first expression of (1.2). Another consequence of the theorem is that the probability of observing a representation ρ depends only on the character of ρ restricted to H. As the characters are class functions, conjugate subgroups (two subgroups H_1 and H_2 are conjugate if $H_1 = gH_2g^{-1}$ for some $g \in G$) produce exactly the same distribution over ρ; this rules out using the paradigm of Experiment 1.2 with representations names alone to solve the HSP for any group containing a nonnormal subgroup.

3.1. Induced representations. We have discussed the restriction of a representation ρ of G to a subgroup H of G. There is a dual operation, *induction*, which extends to all of G a representation ρ defined on a subgroup H. We will only need to work with the representation induced from the trivial representation on H.

Let $G/H \stackrel{\text{def}}{=} \{\alpha_1, \ldots, \alpha_t\}$ be a canonical transversal for H, so that G can be written as the disjoint union $\alpha_1 H \cup \cdots \cup \alpha_t H$. Then the *induced* representation $\mathrm{Ind}_H^G\mathbf{1} : G \to \mathrm{GL}(W)$ is defined over the vector space W that has one basis vector $e_{[\alpha_i]}$ for each coset $\alpha_i H$. It is defined by linearly extending the rule

$$\mathrm{Ind}_H^G\mathbf{1}(g) : e_{[\alpha_i]} \to e_{[\alpha_j]},$$

where $\alpha_j H$ is the coset containing $g\alpha_i$. Observe that this representation is a permutation representation. As suggested by the notation, selection of a different transversal results in an isomorphic representation.

Example 3.1. $\mathrm{Ind}_{\{\mathbf{id}\}}^G\mathbf{1} \cong \mathrm{reg}_G$.

We now invoke a standard representation-theoretic result to obtain Theorem 1.2.

LEMMA 3.3 (a special case of Frobenius reciprocity; see [15, section 3.20]). *Let $H < G$ and let $\rho : G \to GL(V)$ be an irreducible representation of G. Then*

$$\langle \chi_{\mathbf{1}} \mid \chi_\rho \rangle_H = \left\langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} \,\middle|\, \chi_\rho \right\rangle_G .$$

Combining this with Theorem 3.2 establishes Theorem 1.2.

Proof of Theorem 1.2. Theorem 3.2 asserts that the probability of measuring the representation ρ in Experiment 1.2 is $\frac{|H|}{|G|} d_\rho \langle \chi_{\mathbf{1}} \mid \chi_\rho \rangle_H$. By reciprocity, the number of times that the trivial representation of H appears in $\mathrm{Res}_H \rho$ is the same as the number of times that ρ appears in $\mathrm{Ind}_H^G \mathbf{1}$, that is,

$$\langle \chi_{\mathbf{1}} \mid \chi_\rho \rangle_H = \left\langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} \,\middle|\, \chi_\rho \right\rangle_G .$$

Theorem 1.2 follows. □

4. A positive result: Normal subgroups and the core of H. In this section we show that $O(\log |G|)$ queries suffice to reconstruct any normal subgroup of G. In general, we show that for any subgroup H of G, the algorithm below outputs H^G, the *core of* H, which is the largest subgroup of H that is normal in G. As the product $H_1 H_2$ of two normal subgroups is again a normal subgroup of G, the core is well-defined. (In fact, the core is precisely $\bigcap_{g \in G} g H g^{-1}$.) The algorithm we study is the following.

ALGORITHM 4.1. *H is an arbitrary unknown subgroup of G; we are provided an efficiently computable function $f : G \to S$, which is constant on (left) cosets of H and takes distinct values on distinct cosets.*

1. *For $i = 1, \ldots, s = 4 \log_2 |G|$, run Experiment* 1.2 *and measure an irreducible representation, $\sigma_i \in \hat{G}$.*
2. *Let $N_i = \bigcap_{j=1}^{i} \ker \sigma_j$.*
3. *Output $N = N_s$.*

Recall that each $\ker \sigma_i$ is a normal subgroup of G, so that the resulting subgroup $N = N_s$ is normal. We will show that Algorithm 4.1 converges quickly to H^G with high probability in Theorem 4.3. We reduce the proof of this theorem to two lemmas, described in the following section. Two different sets of proofs of these lemmas are then presented in sections 4.2 and 4.3, one from the perspective of restricted representations, and one from the perspective of induced representations. The proof presented in terms of induction shows that the theorem is a consequence of the standard proof of the Mackey irreducibility criterion; for readers already acquainted with the criterion this approach may be more mnemonic than the elementary approach by restriction.

4.1. The general structure. As discussed above, Theorem 4.3 is a consequence of the following two lemmas.

LEMMA 4.1. *If the irreducible representation σ can be sampled by Experiment* 1.2 *(i.e., has nonzero probability), then $H^G \subseteq \ker(\sigma)$.*

This shows, in particular, that $H^G \trianglelefteq N_s \trianglelefteq \cdots \trianglelefteq N_1 \trianglelefteq N_0 = G$.

LEMMA 4.2. *For any subgroup $H \leq G$, if $N_i \not\subseteq H$, then* $\Pr[N_{i+1} = N_i] \leq 1/2$.

Before discussing the proofs of these lemmas, we show that together they imply Theorem 4.3. Observe that for a representation ρ of G, if $\ker \rho \subset H$, then we must have $\ker \rho \subset H^G$, as $\ker \rho$ is normal.

THEOREM 4.3. *Algorithm* 4.1 *returns H^G with probability at least* $1 - 2e^{-\log_2 |G|/8}$.

Proof of Theorem 4.3. Let $\mathcal{D}_H$ denote the probability distribution over irreducible representations induced by Experiment 1.2. We now apply a standard martingale bound (see [20]) to prove the theorem (based on Lemmas 4.2 and 4.1). Let $\sigma_1, \ldots, \sigma_k$ be independent random variables distributed according to $\mathcal{D}_H$ with $k = 4\log_2 |G|$. Our goal is to show that

$$\Pr[N_s \neq H^G] \leq 2e^{-\log_2|G|/8}.$$

For each $i \in \{1, \ldots, k\}$, let X_i be the indicator random variable taking value 1 if $N_i \subseteq H$ or $N_{i+1} \neq N_i$, and zero otherwise. The random variables $X_1, \ldots, X_k$ are not necessarily independent, but by Lemma 4.2, $\Pr[X_i = 0 \,|\, X_1, \ldots, X_{i-1}] \leq \frac{1}{2}$, and we may apply a martingale bound. As the variables take values in the set $\{0, 1\}$, the sum $\sum_i X_i$ satisfies the Lipschitz condition (with constant 1), and we can apply Azuma's inequality to conclude that $\sum_i X_i$ is unlikely to deviate far from its expected value, which is at least $\frac{k}{2}$. In particular, we have $\Pr\left[|\sum_i X_i - \frac{k}{2}| \geq \lambda\right] \leq 2e^{-\lambda^2/2k}$, so with $\lambda = \log_2(|G|)$ we have $\Pr\left[\sum_{i=0}^{k-1} X_i \leq \log_2(|G|)\right] \leq 2e^{-\log_2(|G|)/8}$.

Therefore, with probability at least $1 - 2e^{-\log_2(|G|)/8}$ we have $N_s \subseteq H$. As N_s is normal in G, it must be the case that $N_s \subseteq H^G$. From Lemma 4.1, $H^G \subseteq N_s$; hence $N_s = H^G$, and the algorithm converges to the correct subgroup. ∎

4.2. Restricted representations. We begin by proving Lemmas 4.1 and 4.2 from the perspective of restricted representations.

By Claim 2.1, we may assume that f is distributed over H itself without loss of generality. In this case, Lemma 3.1 implies that, up to a scalar multiple, each $\hat{f}(\sigma)$ is a projection. We begin by showing that when the subgroup H is *normal*, $\hat{f}(\sigma)$ is in fact a multiple of the identity, and is nonzero precisely when H is in the kernel of σ.

LEMMA 4.4. *Let $H \trianglelefteq G$, $\rho \in \hat{G}$ have dimension d_ρ, and let $f : G \to \mathbb{C}$ be the function*

$$f(g) = \begin{cases} \frac{1}{\sqrt{H}} & \text{if } g \in H, \\ 0 & \text{otherwise.} \end{cases}$$

Then $\hat{f}(\rho) = \lambda \cdot \mathbb{I}$, where

$$\lambda = \begin{cases} \sqrt{\frac{|H|}{|G|} d_\rho} & \text{if } H \subseteq \ker \rho, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. The lemma follows from an application of Schur's lemma (see, e.g., [26]). If $H \subseteq \ker \rho$, then the lemma follows from the discussion in the previous section.

Suppose $H \not\subseteq \ker \rho$. We will show that $\hat{f}(\rho)$ must be the zero map. By Lemma 3.1 we can decompose V as $W_f \bigoplus W_a$, where $\frac{1}{|H|}\sum_{h \in H} \rho(h)$ pointwise fixes W_f and annihilates W_a. Our goal is to see that $W_f = \{0\}$. Observe that since $H \not\subseteq \ker \rho$, there is some $h_0 \in H$ for which $\rho(h_0)$ is not the identity operator and, considering that each $\rho(h)$ is unitary, their average cannot be the identity operator. (Specifically, consider a unit vector v for which $\rho(h_0)v \neq v$; note now that the average over h of $\rho(h)v$ can have unit length only if for all h_1, $\rho(h_0)v = \rho(h_1)v \neq v$.) Hence $W_f \neq V$.

Assume that $W_f \neq \{0\}$. Since ρ is irreducible over G and $W_f \neq V$, there is a vector $w'_f \in W_f$ and $g \in G$ such that $\rho(g)w'_f \notin W_f$; we may write $\rho(g)w'_f = w_f + w_a$,

with $w_a \in W_a$, $w_f \in W_f$, and $w_a \neq 0$. As $\frac{1}{|H|}\sum_{h\in H}\rho(h)$ pointwise fixes W_f we have

$$w_f + w_a = \rho(g)w'_f = \rho(g)\frac{1}{|H|}\sum_{h\in H}\rho(h)w'_f$$
$$\stackrel{*}{=} \frac{1}{|H|}\sum_{h\in H}\rho(h)\rho(g)w'_f = \frac{1}{|H|}\sum_{h\in H}\rho(h)(w_f + w_a) = w_f,$$

where equality $\stackrel{*}{=}$ follows since H is normal in G. This is a contradiction; hence $W_f = \{0\}$, as desired. □

We will now prove Lemma 4.1, which states that if the irreducible representation σ can be sampled by Experiment 1.2, then $H^G \subseteq \ker(\sigma)$.

Proof of Lemma 4.1. Let C be a set of coset representatives for H^G in H. We have

$$\sum_{h\in H}\rho(h) = \Big(\sum_{c\in C}\rho(c)\Big)\Big(\sum_{h\in H^G}\rho(h)\Big),$$

so by Lemma 4.4 we only observe ρ if $\sum_{h\in H^G}\rho(h)$ is a multiple of the identity (in which case $H^G \subseteq \ker\rho$). □

Before proving Lemma 4.2, which is for general subgroups, we will show how the statement can be proved for normal subgroups.

LEMMA 4.5. *If $H \trianglelefteq G$ and $N_i \neq H$, then* $\Pr[N_{i+1} = N_i] \leq 1/2$.

Proof. By Lemma 4.4, Theorem 3.2, and (2.3) we have

$$\Pr[N_i \subseteq \ker\rho_{i+1}] = \sum_{\rho\in\hat{G}N_i\subseteq\ker\rho}\Pr[\text{Observe }\rho]$$
$$= \sum_{\rho\in\hat{G}N_i\subseteq\ker\rho}\frac{|H|}{|G|}d_\rho^2$$
$$= \frac{|H|}{|G|}\sum_{\rho\in\widehat{G/N_i}}d_\rho^2 = \frac{|H|}{|G|}\frac{|G|}{|N_i|} \leq \frac{1}{2},$$

where changing the sum follows from the fact that representations of G that map N_i to the identity can be identified with representations of G/N_i. □

We proceed to prove Lemma 4.2, which states that for any $H \leq G$, if $N_i \not\subseteq H$, then $\Pr[N_{i+1} = N_i] \leq 1/2$.

Proof of Lemma 4.2. This proof is due to Umesh Vazirani. Let $N = \cap_{j=1}^{i}\ker\sigma_j$ be the intersection of the kernels up to step i. For an irreducible representation ρ, let r_ρ be the rank of $\hat{f}(\rho)$, i.e., the number of times the trivial representation of H appears in ρ. When $N \not\subseteq H$, we will show that the probability of N being contained in the kernel of the next representation we measure is at most $1/2$ by showing that

$$\sum_{\rho:N\subseteq\ker\rho}\frac{|H|}{|G|}d_\rho r_\rho \leq \frac{|N\cap H|}{|N|},$$

which is at most $1/2$ when $N \not\subseteq H$. Now, if the hidden subgroup had been HN, Theorem 3.2 would imply

$$\sum_{\rho:\rho\in\hat{G}}\frac{|HN|}{|G|}d_\rho r'_\rho = 1,$$

where r'_ρ is the number of times the trivial representation of HN appears in ρ. Note that $r'_\rho = r_\rho$ when $N \subseteq \ker \rho$, since

$$|H \cap N| \sum_{l \in HN} \rho(l) = \Big(\sum_{h \in H} \rho(h) \Big) \Big(\sum_{n \in N} \rho(n) \Big),$$

and $\rho(n)$ is the identity. Since $|HN| \cdot |H \cap N| = |H| \cdot |N|$, we have that

$$\sum_{\rho : N \subseteq \ker \rho} \frac{|H|}{|G|} d_\rho r_\rho = \sum_{\rho : N \subseteq \ker \rho} \frac{|H|}{|G|} d_\rho r'_\rho \leq \sum_{\rho \in \hat{G}} \frac{|H|}{|G|} d_\rho r'_\rho \leq \frac{|H \cap N|}{|N|},$$

as desired. ∎

4.3. Induced representations. We now reprove these two lemmas from the perspective of induced representations. We begin by computing the kernel of the representation $\mathrm{Ind}_H^G \mathbf{1}$.

LEMMA 4.6. $\ker(\mathrm{Ind}_H^G \mathbf{1}) = H^G$.

Proof. We begin with the forward inclusion. Indeed, if $x \in \ker(\mathrm{Ind}_H^G \mathbf{1})$, then $\mathrm{Ind}_H^G \mathbf{1}(x)$ is the identity mapping, i.e., for every $g \in G$, $\mathrm{Ind}_H^G \mathbf{1}(x) : [gH] \to [gH]$, or equivalently, $[xgH] = [gH]$. In particular, for $g = e$ we get $xH = H$, and therefore $x \in H$. Now, as $\ker(\mathrm{Ind}_H^G \mathbf{1})$ is normal and is contained in H we must have $\ker(\mathrm{Ind}_H^G \mathbf{1}) \subseteq H^G$.

For the reverse inclusion, suppose that $x \in H^G$. Then for any $g \in G$, there is some $x' \in H^G \subseteq H$ such that $xg = gx'$. Therefore, $\mathrm{Ind}_H^G \mathbf{1}(x)[gH] = [xgH] = [gx'H] = [gH]$, and we see that $\mathrm{Ind}_H^G \mathbf{1}(x)$ is the identity mapping. Hence, $x \in \ker(\mathrm{Ind}_H^G \mathbf{1})$. ∎

Now, by Theorem 1.2, any σ that can be sampled by Experiment 1.2 appears in $\mathrm{Ind}_H^G \mathbf{1}$, and we therefore conclude that $H^G \subseteq \ker(\mathrm{Ind}_H^G \mathbf{1}) \subseteq \ker(\sigma)$; Lemma 4.1 follows. This also gives a simple decomposition of $\mathrm{Ind}_H^G \mathbf{1}$ when H is normal.

LEMMA 4.7. *Let $N \trianglelefteq G$. Then* $\mathrm{Ind}_N^G \mathbf{1} = \bigoplus_{\rho \in \hat{G}, N \subseteq \ker(\rho)} d_\rho \rho$.

Proof. Suppose $\mathrm{Ind}_N^G \mathbf{1} = \bigoplus_{\rho \in \hat{G}} n_\rho \rho$. We have

$$n_\rho = \Big\langle \chi_{\mathrm{Ind}_N^G \mathbf{1}} \Big| \chi_\rho \Big\rangle_G \;=\; \langle \chi_{\mathbf{1}} \,|\, \chi_\rho \rangle_N \;=\; \frac{1}{|N|} \sum_{x \in N} \chi_\rho(x) \;=\; d_\rho,$$

where the second equality is by Frobenius reciprocity, and the last one is because $N \subseteq \ker \rho$. Note that $n_\rho = 0$ if $N \not\subset \ker \rho$. ∎

We now prove Lemma 4.2.

Proof of Lemma 4.2. Denote $N = N_i$. For $\rho \in \hat{G}$, let $m_\rho = \langle \chi_\rho \,|\, \chi_{\mathbf{1}} \rangle_H$. We know that

$$\Pr_{\sigma \in \mathcal{D}_H} [N_i \subseteq \ker \sigma] = \frac{|H|}{|G|} \sum_{\substack{\rho \in \hat{G} \\ N_i \subseteq \ker(\rho)}} m_\rho d_\rho,$$

$$\mathrm{Ind}_H^G \mathbf{1} = \bigoplus_{\rho \in \hat{G}} m_\rho \rho,$$

$$\mathrm{Ind}_N^G \mathbf{1} = \bigoplus_{\substack{\rho \in \hat{G} \\ N \subseteq \ker(\rho)}} d_\rho \rho,$$

where the first equation is by Theorem 3.2, the second because $m_\rho = \langle \chi_\rho \,|\, \chi_{\mathbf{1}} \rangle_H = \langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} | \chi_\rho \rangle_G$ by Frobenius reciprocity (Lemma 3.3), and the last one by Lemma 4.7. We observe that

$$\left\langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} \,\middle|\, \chi_{\mathrm{Ind}_N^G \mathbf{1}} \right\rangle_G = \sum_{\substack{\rho \in \hat{G} \\ N \subseteq \ker(\rho)}} d_\rho m_\rho \langle \chi_\rho \,|\, \chi_\rho \rangle_G = \sum_{\substack{\rho \in \hat{G} \\ N \subseteq \ker(\rho)}} d_\rho m_\rho$$

and thus is proportional to the probability that $N_i \subseteq \ker(\sigma_i)$. We complete the proof with an argument similar to that given in Serre [26] for the proof of Mackey's irreducibility criterion. By Frobenius reciprocity,

$$\left\langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} \,\middle|\, \chi_{\mathrm{Ind}_N^G \mathbf{1}} \right\rangle_G = \left\langle \chi_{\mathbf{1}} \,\middle|\, \chi_{\mathrm{Res}_H \ \mathrm{Ind}_N^G \mathbf{1}} \right\rangle_H .$$

Decomposing the restricted induction (see [26, section 7.3]) we have

$$\left\langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} \,\middle|\, \chi_{\mathrm{Ind}_N^G \mathbf{1}} \right\rangle_G = \bigoplus_{g \in H \backslash G / N} \left\langle \chi_{\mathbf{1}} \,\middle|\, \chi_{\mathrm{Ind}_{N_g}^H \mathbf{1}} \right\rangle_H ,$$

where $N_g = H \cap gNg^{-1}$ is a subgroup of H, and g runs over all representatives of the double cosets $H \setminus g/N$ of G. Using Frobenius reciprocity again we see that

$$\begin{aligned} \left\langle \chi_{\mathrm{Ind}_H^G \mathbf{1}} \,\middle|\, \chi_{\mathrm{Ind}_N^G \mathbf{1}} \right\rangle_G &= \bigoplus_{g \in H \backslash G / N} \langle \chi_{\mathbf{1}} \,|\, \chi_{\mathbf{1}} \rangle_{N_g} \\ &= |H \setminus G / N|. \end{aligned}$$

However, N is normal in G. Hence for any $g \in G$, $H \backslash g/N = HNg$. Furthermore, as H is a group and N is normal in G, HN is also a group. Hence, $|H \setminus G/N| = |G|/|HN|$. Thus,

$$\Pr_{\sigma \in \mathcal{D}_H} [N_i \subseteq \ker \sigma] = \frac{|H|}{|G|} \sum_{\substack{\rho \in \hat{G} \\ N_i \subseteq \ker(\rho)}} m_\rho d_\rho = \frac{|H|}{|G|} \frac{|G|}{|HN|} = \frac{|H|}{|HN|},$$

which is at most $1/2$ when $N \not\subseteq H$. ∎

5. A negative result: Determining triviality in S_n. In this section we show that a well-known reduction of graph isomorphism for finding a hidden subgroup over S_n cannot work using Experiment 1.2.

Graph automorphism is the problem of determining whether a graph G has a nontrivial automorphism and is easier than graph isomorphism [18]. A natural special case occurs when the graph G consists of two disjoint connected rigid graphs G_1, G_2 (i.e., $\mathrm{Aut}(G_1) = \mathrm{Aut}(G_2) = \{e\}$). In this case there are two possibilities for the automorphism group of G.

CLAIM 5.1. *Let the graph G be the disjoint union of the two connected rigid graphs G_1 and G_2 and let n denote the number of vertices of G. Then*

1. *if $G_1 \not\approx G_2$, then $\mathrm{Aut}(G) = \{e\}$, and*
2. *if $G_1 \approx G_2$, then $\mathrm{Aut}(G) = \{e, \sigma\}$, where $\sigma \in S_n$ is a permutation with $n/2$ disjoint 2-cycles.*

Proof. For the first part notice that any automorphism maps a connected component onto a connect component. In our case we have two connected components

G_1 and G_2. However, G_1 and G_2 are not isomorphic and have no nontrivial automorphisms.

For the second part, let σ reflect an automorphism between G_1 and G_2. Now, suppose there was another nontrivial automorphism τ. Then $\sigma\tau$ is also an automorphism, and $\sigma\tau$ maps the connected component of G_1 onto G_1, and G_2 onto G_2. As G_1 and G_2 have no nontrivial automorphisms it follows that $\sigma\tau = 1$, $\tau = \sigma^{-1} = \sigma$. □

Thus, if one knows how to solve the HSP for S_n, or if one knows how to distinguish between cosets of a trivial subgroup and the cosets of a nontrivial subgroup, one can give an efficient quantum algorithm for graph automorphism. In particular, one might attempt to reconstruct $H = \mathrm{Aut}(G)$ based on the result of the following experiment.

EXPERIMENT 5.1. *Let G be a graph such that either $\mathrm{Aut}(G) = \{e\}$ or $\mathrm{Aut}(G) = \{e, \sigma\}$.*

1. *Compute $\Sigma_{\pi\in S_n}|\pi, \pi(G)\rangle$ and measure the second register $\pi(G)$. The resulting state is $\Sigma_{h\in H}|ch, f(ch)\rangle$ for some coset cH of H. Furthermore, c is uniformly distributed over G.*
2. *Compute the Fourier transform of the coset state, which is*

$$\sum_{\rho\in\hat{G}} \sqrt{\frac{d_\rho}{|G|}} \sqrt{\frac{1}{|H|}} \Bigg(\sum_{h\in H} \rho(ch) \Bigg)_{i,j} |\rho, i, j\rangle.$$

3. *Measure the first register and observe a representation ρ.*

We show that even for this particular case of graph isomorphism (and graph automorphism) the experiment fails to distinguish nonisomorphic pairs of graphs from isomorphic pairs of graphs; Theorem 1.4 follows.

THEOREM 5.1. *Let G_1 and G_2 be two rigid, connected graphs with n vertices. Let $\mathcal{D}_N(\rho)$ be the probability of sampling ρ in Experiment 5.1 when $G_1 \not\approx G_2$, and let $\mathcal{D}_I(\rho)$ be the probability when $G_1 \approx G_2$. Then $|\mathcal{D}_N - \mathcal{D}_I|_1 \le 2^{-\Omega(n)}$.*

Proof. We present the proof from [10], which simplifies the proof of [14]. When $G_1 \not\approx G_2$, $H = \{e\}$, so $\mathcal{D}_N(\rho) = d_\rho^2/n!$ by Theorem 3.2. When $G_1 \approx G_2$, and G_1 and G_2 are both connected and rigid, $H = \{e, \tau\}$. By Theorem 3.2,

$$\mathcal{D}_I(\rho) \;=\; \frac{|H|}{|G|} d_\rho \left\langle \chi_{\mathbf{1}} \,|\, \chi_\rho \right\rangle_H .$$

The subgroup H has only two elements, e and τ; hence

$$\left\langle \chi_{\mathbf{1}} \,|\, \chi_\rho \right\rangle_H = \frac{1}{2}(\chi_\rho(e) + \chi_\rho(\tau)) = \frac{1}{2}(d_\rho + \chi_\rho(\tau)).$$

That is, $\mathcal{D}_I(\rho) = \frac{d_\rho}{n!}(d_\rho + \chi_\rho(\tau))$, and so

$$\begin{aligned} \sum_\rho |\mathcal{D}_I(\rho) - \mathcal{D}_N(\rho)| &= \frac{1}{n!} \sum_\rho d_\rho |\chi_\rho(\tau)| \\ &\le \frac{1}{n!} \sqrt{\sum_\rho d_\rho^2} \sqrt{\sum_\rho |\chi_\rho(\tau)|^2} = \frac{1}{\sqrt{n!}} \sqrt{\sum_\rho |\chi_\rho(\tau)|^2} \end{aligned}$$

by the Cauchy–Schwarz inequality and (2.3).

By (2.1), $\sum_{\rho\in\hat{G}} |\chi_\rho(\tau)|^2 = |G|/|\{\tau\}|$, where $\{\tau\}$ is the conjugacy class of τ. However, two permutations share the same conjugacy class if and only if they have

the same cycle decomposition. In our case τ has cycle decomposition into $n/2$ pairs. Thus

$$|\{\tau\}| = \frac{\binom{n}{n/2}(\frac{n}{2})!}{2^{n/2}},$$

where $\binom{n}{n/2}$ is the number of possibilities for choosing the first element in each of the $n/2$ pairs, $(\frac{n}{2})!$ is the number of possibilities for arranging the remaining $n/2$ elements in the pairs, and each ordering is counted exactly $2^{n/2}$ times.

Altogether,

$$\sum_{\rho} |\mathcal{D}_I(\rho) - \mathcal{D}_N(\rho)| \leq \frac{1}{\sqrt{n!}}\sqrt{\frac{n!}{|\{\tau\}|}} \;=\; \sqrt{\frac{2^{(n/2)}(n/2)!}{n!}} \;\leq\; 2^{-\Omega(n)},$$

as desired. □

6. Finding hidden subgroups in Hamiltonian groups. A group G is Hamiltonian if all subgroups are normal. In light of Theorem 3.2, a hidden subgroup of a Hamiltonian group G is determined with high probability by $O(\log |G|)$ samples of the distribution induced by Experiment 1.2. In this section we show that for Hamiltonian groups, generators for the hidden subgroup can be computed efficiently from these samples. As the Fourier transform over such groups can be efficiently computed, this gives an efficient quantum algorithm for the HSP over Hamiltonian groups.

All abelian groups are Hamiltonian; the only nonabelian Hamiltonian groups are of the form

$$G \cong \mathbb{Z}_2^k \times B \times Q,$$

where $Q = \{\pm 1, \pm i, \pm j, \pm k\}$ is the quaternion group and B is an abelian group with exponent b coprime with 2. For a detailed description of such groups, see Rotman's excellent book [23].

We begin by briefly discussing the case when G is abelian. If G is simply the cyclic group $\mathbb{Z}_n$, the representations are the functions $\rho_s : z \mapsto \exp(2\pi isz/n)$, and the reconstruction algorithm, when it succeeds, yields a collection $\{\rho_s | s \in S\}$ with the property that $H = \cap_{s\in S} \ker \rho_s$. Observe that $\rho_s(h)\rho_t(h) = \rho_{s+t \bmod n}(h)$ and that $\rho_s(h) = 1$ implies $\rho_{st \bmod n}(h) = 1$ for all $t \in \mathbb{Z}$. Hence $\cap_s \ker \rho_s = \ker \rho_d$, where d is the greatest common divisor of n and the elements in S. Then H is the cyclic subgroup of $\mathbb{Z}_n$ generated by n/d.

In general, an abelian group G is isomorphic to a direct sum $\mathbb{Z}_{n_1} \oplus \cdots \oplus \mathbb{Z}_{n_k}$, and we assume that this decomposition is known. The irreducible representations are the functions $\rho_{s_1,\ldots,s_k}(z_1, \ldots, z_k) = \prod_{j=1}^{k} \exp(2\pi i s_j z_j/n_j)$, and, as above, we begin with a collection $\{\rho_{\vec{s}} \mid \vec{s} = (s_1, \ldots, s_k) \subset S\}$ so that $H = \cap_S \ker \rho_{\vec{s}}$. Then

$$\begin{aligned} (h_1, \ldots, h_k) \in H \quad &\Leftrightarrow \quad \text{for all } \vec{s} \in S,\ \exp\left(\sum_j \frac{2\pi i s_j h_j}{n_j}\right) = 1 \\ &\Leftrightarrow \quad \text{for all } \vec{s} \in S,\ \sum_j s_j q_j h_j \equiv 0 \bmod N, \end{aligned} \tag{6.1}$$

where N is the least common multiple of the n_j, and $q_j = N/n_j$. For convenience, we treat the family of equalities appearing in line (6.1) as a system of equations over

the ring $\mathbb{Z}_N$; then a solution $\vec{h}$ of this system corresponds to the element ($h_1 \bmod n_1, \ldots, h_k \bmod n_k$) of H. Collect these equations together into a matrix R. Though $\mathbb{Z}_N$ may not be a field, it is easy to check that a matrix over $\mathbb{Z}_N$ may be diagonalized in polynomial time with the following two operations:

- for some pair $i \neq j$, swap row (column) i with row (column) j;
- for some pair $i \neq j$, add a multiple of row (column) i to row (column) j.

This results in a system $D \cdot F \cdot \vec{h} = \vec{0}$, where D is diagonal and F is invertible. Any vector $\vec{h}'$ for which $D\vec{h}' = \vec{0}$ may then be transformed into a solution $\vec{h}$ of the original equation and, moreover, if $\vec{h}'$ is selected at random in the null space of D, then the resulting $\vec{h}'$ will give rise to a random element of H. Selection of $O(\log |G|)$ random elements in this way yields a generating set for H with high probability.

Finally, consider a Hamiltonian group of the form $G = \mathbb{Z}_2^k \times B \times Q$. An irreducible representation ρ of G is a tensor product $\zeta \otimes \beta \otimes \kappa$, where $\zeta \in \widehat{\mathbb{Z}_2^k}$, $\beta \in \hat{B}$, and $\kappa \in \hat{Q}$. (As $\mathbb{Z}_2^k$ and B are abelian, in this case the tensor product may be replaced with the regular product in $\mathbb{C}$.)

We briefly review the representation theory of the quaternion group. Q has five irreducible representations: four one-dimensional and one two-dimensional. The one-dimensional representations arise as the irreducible representations of the abelian quotient $Q/\{\pm 1\} \cong \mathbb{Z}_2 \oplus \mathbb{Z}_2$. The two-dimensional representation τ realizes Q as a subgroup of $\mathbf{SU}_2$, where

$$\tau(1) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \qquad \tau(i) = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix},$$
$$\tau(j) = \begin{bmatrix} i & 0 \\ 0 & -i \end{bmatrix}, \qquad \tau(k) = \begin{bmatrix} 0 & -i \\ -i & 0 \end{bmatrix},$$

and $\tau(-q) = -\tau(q)$ for each $q \in Q$.

As above, we assume that we have a set of samples S so that

$$H = \bigcap_{\zeta \otimes \beta \otimes \kappa \in S} \ker(\zeta \otimes \beta \otimes \kappa).$$

It is sufficient to show that for a given element $q \in Q$, one can generate a collection of random elements of $H \cap \mathbb{Z}_2^k \times B \times \{q\}$, for if these collections are large enough, then their union yields a set of generators for H with high probability.

Fixing an element $q \in Q$, consider a specific sample $\zeta \otimes \beta \otimes \kappa$. There are two cases to consider:

- If κ is one-dimensional, the condition $\zeta(z) \otimes \beta(b) \otimes \kappa(q) = 1$ may be interpreted as an equation over $\mathbb{Z}_N$, where $N = b2^{k+1}$, as in the abelian case above. (Note that $\kappa(q) = \pm 1$ contributes a constant to the equation; as $2 \mid N$, this constant can be suitably represented as $\exp(2\pi i t/N)$ for $t = N/2$.)
- If κ is two-dimensional, the condition

  $$\zeta(z) \otimes \beta(b) \otimes \kappa(q) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

  cannot be satisfied unless $q = \pm 1$. When $q = \pm 1$, this may be interpreted as a pair of equations over $\mathbb{Z}_N$, where $N = 2^{k+1}b$, each equation corresponding to a diagonal entry of the matrix. (Note that $\kappa(q)$ contributes a constant ± 1 to each equation; as $2 \mid N$, these constants can be suitably represented as $\exp(2i\pi t/N)$ for $t = N/2$.)

Now the solution proceeds as in the abelian case. For each $q \in Q$, the above procedure is used to compute $c \log |G|$ random elements of $H \cap \mathbb{Z}_2^n \times B \times \{q\}$ (unless this intersection is empty). If c is chosen appropriately, the union of these sets generates H with high probability.

Acknowledgment. The authors thank Umesh Vazirani for many helpful discussions and the simplification of several of the proofs.

MODELS FOR RANDOM CONSTRAINT SATISFACTION PROBLEMS*

MICHAEL MOLLOY†

Abstract. We introduce a class of models for random constraint satisfaction problems. This class includes and generalizes many previously studied models. We characterize those models from our class which are asymptotically interesting in the sense that the limiting probability of satisfiability changes significantly as the number of constraints increases. We also discuss models which exhibit a sharp threshold for satisfiability in the sense that the limiting probability jumps from 0 to 1 suddenly as the number of constraints increases.

Key words. constraint satisfaction problems, random models, threshold, sharp threshold

DOI. 10.1137/S0097539700368667

Introduction. In this paper, we introduce a new general model for generating random constraint satisfaction problems (CSPs). We will generate problems on n variables, where each variable has a domain of $d \geq 2$ permissible values, and each constraint is on k variables for some fixed $k \geq 2$. For the sake of simplicity, we assume that each variable has the same domain, $\mathcal{D} = \{\delta_1, \ldots, \delta_k\}$, although this model can be easily modified to deal with more general situations. All asymptotics will be as $n \to \infty$, and so d, k are considered to be constants. Thus, typically n will be much larger than either d or k.

This model generalizes many previously studied models, including virtually all well-studied models of CSPs, random instances of k-SAT, and CSPs which are equivalent to determining whether a random graph is k-colorable. Using straightforward methods to simulate constraints of size r by constraints of size t for any $t > r$, this model also generalizes models with mixed constraint sizes, such as the $(2 + p)$-SAT model studied in [4].

Given a k-tuple of variables, $(x_1, \ldots, x_k)$, a *restriction* on $(x_1, \ldots, x_k)$ is a k-tuple of values $R = (\delta_1, \ldots, \delta_k)$, where each $\delta_i \in \mathcal{D}$. For each k-tuple $(x_1, \ldots, x_k)$, the set of restrictions on that k-tuple is called a *constraint*. The *empty constraint* is the constraint which contains no restrictions. We say that an assignment of values to the variables of a constraint C *satisfies* C if that assignment is not one of the restrictions in C. An assignment of values to all variables in a CSP satisfies that CSP if every constraint is simultaneously satisfied. The *constraint hypergraph* of a CSP is the k-uniform hypergraph whose vertices correspond to the variables and whose hyperedges correspond to the k-tuples of variables which have *constraints*.

In studying large random CSPs one of the most natural questions is to determine the likelihood of the problem being satisfiable. For example, we might show that for some settings of the parameters in the model, a random CSP is almost surely[1] (a.s.) satisfiable, while for other settings it is a.s. nonsatisfiable. Of particular interest

[1]A random CSP almost surely satisfies property P if $\lim_{n\to\infty} \mathbf{Pr}(P) = 1$.

are situations where we have a *threshold* behavior, such as a situation where, as we modify the number of constraints, a random CSP moves from being a.s. satisfiable to a.s. not satisfiable.

Some natural and important models are known to have a threshold behavior, most notably random instances of k-SAT. This fact is probably what led others to assume that the same is true of many models of random CSP. Unfortunately, and somewhat surprisingly, such assumptions often turned out to be invalid, as discussed below. Thus, a mathematically rigorous examination of the threshold behavior of models of random CSP is necessary. Such a study is the goal of the present paper.

Until recently, the most commonly used random CSP models were the following:

Model A1. Specify M, p (typically $M = cn$ for some constant c and $0 < p \leq 1$ is independent of n). First choose a random k-uniform hypergraph on n vertices with M hyperedges (where each such hypergraph is equally likely), which will be the constraint hypergraph of our problem. Next, for each hyperedge e, we choose a constraint on the k variables of e as follows: Each of the d^k possible restrictions is chosen to be present with probability p (where each choice is, of course, independent of the corresponding choices for other potential constraints).

Model A2. Specify M, m (typically $M = cn$ for some constant c and $0 < p \leq 1$ is independent of n). Choose the constraint hypergraph as in Model A1. For each hyperedge e, we choose a constraint with exactly m restrictions uniformly at random from the set of $\binom{d^k}{m}$ such constraints.

Remark 1. Alternatively, we could have chosen the constraint hypergraphs by making an independent choice for each potential hyperedge, deciding to put it in the hypergraph with probability $p = \frac{c \times k!}{n^{k-1}}$. This variation produces models which are equivalent to Models A1 and A2 in the sense that the models will be a.s. satisfiable and a.s. unsatisfiable for the same values of c. A similar remark applies to the other two models described below.

In [5], we observed that Model A1 is asymptotically uninteresting in the sense that as long as M grows with n, the random CSP will be a.s. unsatisfiable. The problem is quite simple: a.s. there will be at least one constraint which is overconstraining in that there is no assignment to its variables which satisfies even that constraint, i.e., a constraint which includes every possible restriction amongst its k variables. Model A2 avoided this particular problem but had other equally damaging problems as long as M was of order $\Theta(n)$ (as is usually the case) for all but small values of m: $m < d^{k-1}$ (Gent et al. [12] showed that these small values of m are indeed not flawed). [12] provides a survey of models used in previous research and found that roughly 3/4 of papers used models which were uninteresting in the sense described above. Furthermore, those models which were interesting (mostly Model A2 with $m < d^{k-1}$) seem to have been "accidentally" interesting in the sense that the authors were unaware that the small value they chose for m was crucial.

So we proposed an alternative model [5]:

Model B. Specify M (typically $M = cn$ for some constant c). Choose a random CSP containing M restrictions, where each such CSP is equally likely to be chosen.

We showed that this model was asymptotically interesting in the sense that for small values of c a random CSP is a.s. satisfiable, while for large values of c it is a.s. unsatisfiable.

Nevertheless, this model is rather unsatisfactory in the sense that the CSPs which it generates do not resemble CSPs that researchers tend to find interesting. In particular, almost every constraint contains only one restriction, while in typical CSPs

most constraints tend to have several restrictions.

Here, we propose a model which is both asymptotically interesting and which overcomes the main disadvantage of Model B in that it can generate CSPs whose constraints have several restrictions. We aim to keep the model as simple as possible, while at the same time meeting these two (somewhat conflicting) goals. In particular, our model is symmetric in the variables. It is not necessarily symmetric among the values of $\mathcal{D}$, although the parameters of the model can be set so that it is.

Gent et al. [12] proposed another model which is both asymptotically interesting and generates reasonably complex constraints. Their model turns out to be a special case of the model introduced here. In the terminology introduced subsequently in this paper, they proved that their model is *very well-behaved* en route to showing that it exhibits a *transition*.

Our New Model is similar in flavor to Models A1 and A2, but we must take some care in the way that we choose the constraints in order to avoid overconstrained constraints and similar problems. In particular, we cannot just independently choose whether or not to put each potential restriction in the constraint—we must choose the entire constraint en masse.

So, we consider a canonical set of variables, $X_1, \ldots, X_k$, and the set of $2^{d^k} - 1$ potential nonempty constraints on $X_1, \ldots, X_k$. We specify a probability distribution $\mathcal{P}$ which selects a single random constraint, where $\mathcal{P}$ does not depend on n.

New Model. Specify $M, \mathcal{P}$ (typically $M = cn$ for some constant c). First choose a random constraint hypergraph with M hyperedges in the usual manner. Next, for each hyperedge e, we choose a constraint on the k variables of e as follows: we take a random permutation from the k variables onto $\{X_1, \ldots, X_k\}$ and then we select a random constraint according to $\mathcal{P}$, mapping it onto a constraint on our k variables in the obvious manner.

Remark 2. Again, we could have chosen the constraint hypergraph by making an independent choice for each potential hyperedge, deciding to put it in the hypergraph with probability $p = \frac{c \times k!}{n^{k-1}}$. This variation produces a model which is, for our purposes, equivalent to the model described above.

We use $CSP_{n,M}(\mathcal{P})$ to denote a random CSP drawn from our New Model with parameters $n, M, \mathcal{P}$. We occasionally omit the subscript n, M, depending on the context. We say that $CSP(\mathcal{P})$ exhibits a *partial transition* if there exist constants $c_1, c_2 > 0$ such that

(i) if $M < c_1 n$, then $CSP_{n,M}(\mathcal{P})$ is not a.s. unsatisfiable;
(ii) if $M > c_2 n$, then $CSP_{n,M}(\mathcal{P})$ is a.s. unsatisfiable.

We say that $CSP(\mathcal{P})$ exhibits a *transition* if there exist $c_1, c_2 > 0$ such that

(i) if $M < c_1 n$, then $CSP_{n,M}(\mathcal{P})$ is a.s. satisfiable;
(ii) if $M > c_2 n$, then $CSP_{n,M}(\mathcal{P})$ is a.s. unsatisfiable.

Note that if $CSP(\mathcal{P})$ exhibits a transition, then it exhibits a partial transition. Note also that having a *transition* is a weaker property than having a "sharp threshold," a notion that will be discussed in the final section of this paper.

Remark 3. It turns out that there is no choice of $CSP(\mathcal{P})$ and c_2 such that for all $M > c_2 n$, $CSP_{n,M}(\mathcal{P})$ is neither a.s. satisfiable nor a.s. unsatisfiable. Thus there is no need for the obvious 3rd and 4th notions of "transition."

In the next two sections, we will characterize those models $CSP(\mathcal{P})$ which have transitions and partial transitions. In the final section, we will discuss choices for $\mathcal{P}$ for which $CSP(\mathcal{P})$ has a very sharp threshold of satisfiability.

We set $\mathcal{C} = \text{supp}(\mathcal{P})$, i.e., the set of constraints, C, for which $\mathcal{P}(C) > 0$. We

will see that, perhaps surprisingly, for each $\mathcal{C}$, $CSP(\mathcal{P})$ exhibits a transition (partial transition) for at least one choice of $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$ iff $CSP(\mathcal{P})$ exhibits a transition (partial transition) for *every* such choice of $\mathcal{P}$. Thus, it makes sense to say that $\mathcal{C}$ exhibits a *transition* or a *partial transition*.

A constraint C is *unsatisfiable* if it has no satisfying assignments, i.e., if it contains every possible restriction. A constraint C *forbids* $X_i = \delta$ if it has no satisfying assignments for which $X_i = \delta$. $X_i = \delta$ *implies* $X_j = \gamma$ *in* C if there are no satisfying assignments for C in which $X_i = \delta$ and $X_j \neq \gamma$. A constraint C *implies* a property P if every satisfying truth assignment for C has P.

An *automorphism* of $\mathcal{C}$ is a bijection $\phi : \mathcal{D} \to \mathcal{D}$ such that $C = \{(\delta_1^1, \ldots, \delta_k^1), \ldots, (\delta_1^t, \ldots, \delta_k^t)\} \in \mathcal{C}$ iff $\phi(C) = \{(\phi(\delta_1^1), \ldots, \phi(\delta_k^1)), \ldots, (\phi(\delta_1^t), \ldots, \phi(\delta_k^t))\} \in \mathcal{C}$. We say that $\mathcal{C}$ is *symmetric with respect to* $\mathcal{D}$ if it is symmetric in the following sense: For any two values $\delta, \gamma \in \mathcal{D}$, there is an automorphism ϕ of $\mathcal{C}$ such that $\phi(\delta) = \gamma$.

Note that we do not require the symmetry to extend to $\mathcal{P}$; i.e., it is possible that $\mathcal{P}(C) \neq \mathcal{P}(\phi(C))$. Furthermore, $\mathcal{C}$ does not need to be symmetric in $X_1, \ldots, X_k$. For example, it could be that every constraint $C \in \mathcal{C}$ implies that $X_1 = X_2 \neq X_3$, while at the same time $\mathcal{C}$ is symmetric with respect to $\mathcal{D}$. However, the fact that our model takes a random mapping of the variables from an edge of the constraint hypergraph onto $(X_1, \ldots, X_k)$ implies that the model is symmetric with respect to the variables.

Our New Model generalizes several previously studied models of CSP and other problems which reduce to being random instances of CSP. For example, Model A1 is simply this model where $\mathcal{P}(C) = p^{|C|}(1-p)^{d^k - |C|}$. Model A2 is the case where $\mathcal{P}(C) = \binom{d^k}{m}^{-1}$ if $|C| = m$, and $\mathcal{P}(C) = 0$ otherwise. Model B is virtually equivalent to the case where $\mathcal{P}(C) = \frac{1}{d^k}$ if $|C| = 1$, and $\mathcal{P}(C) = 0$ otherwise. The well-studied problem of whether a random instance of k-SAT is satisfiable is equivalent to Model B where $d = 2$. The problem of deciding whether a random graph is c-colorable is equivalent to the case where $k = 2, d = c$ and $\mathcal{P}(C) = 1$ where $C = \{(\delta_1, \delta_1), \ldots, (\delta_c, \delta_c)\}$. In each of these examples, $\mathcal{C}$ is symmetric. It is already known that the first of these examples does not exhibit even a partial transition, that the second one exhibits a partial transition only if $m < d^{k-1}$, the third exhibits a transition, and the other two exhibit transitions for $k, c > 2$ and partial transitions for $k, c = 2$.

One final definition: a *hypercycle* of a k-uniform hypergraph is a set of hyperedges $e_1, \ldots, e_m$, such that each e_i contains a vertex which it shares with e_{i-1}, a different vertex which it shares with e_{i+1} (addition and subtraction are mod m), and $k - 2$ vertices which do not lie in any $e_j, j \neq i$. The *length* of the hypercycle is m, and we sometimes say that it is an m-hypercycle. If there are no other hyperedges in the hypergraph, then we say that the hypergraph itself is a hypercycle.

It is important to note that by the nature of the asymptotics involved, this study is only relevant as the number of variables grows very high. So these asymptotic results might be completely out-of-sync with experimental results which, due to technological limitations, are usually performed on a small number of variables, often less than 50. In fact, it is precisely this difference between the behavior of the model on small instances and its asymptotic behavior which led to earlier false assumptions about the asymptotic behavior of Models A1 and A2.

I have recently learned that Creignou and Daudé [8] have independently considered the special case of this New Model where $d = 2$ and $\mathcal{P}$ is the uniform distribution over $\text{supp}(\mathcal{P})$. They obtain, for those choices of $\mathcal{P}$, results which are similar to those in sections 1 and 2 below.

1. The symmetric case. In this section, we focus on the case where $\mathcal{C}$ is symmetric with respect to $\mathcal{D}$. We say that such a $\mathcal{C}$ is *well-behaved* if it satisfies the following two properties:

1. There is no $C \in \mathcal{C}$, $\delta \in \mathcal{D}$, and canonical variable X_i such that C forbids $X_i = \delta$.
2. For every $\delta \in \mathcal{D}$, there is at least one $C \in \mathcal{C}$ such that $X_1 = \delta, X_2 = \delta, \ldots, X_k = \delta$ does not satisfy C.

$\mathcal{C}$ is *very well-behaved* if, in addition to properties 1 and 2, it also satisfies the following:

3. If a CSP is formed using constraints from $\mathcal{C}$, and its constraint hypergraph is a cycle, then it must be satisfiable.

It is worth noting that if property 1 holds, then there is no unsatisfiable constraint $C \in \mathcal{C}$, and so we avoid the main problem with Model A1. However, as we will see, for $CSP(\mathcal{P})$ to not be a.s. unsatisfiable, it does not suffice to merely have no unsatisfiable constraint $C \in \mathcal{C}$—we need the full power of property 1 in order to avoid a more subtle problem.

THEOREM 1. *If $\mathcal{C}$ is well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ exhibits a partial transition. If $\mathcal{C}$ is not well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ does not exhibit a partial transition.*

Note that Theorem 1 immediately implies that Model A2 exhibits a partial transition iff $1 \leq m < d^{k-1}$, as first shown by Gent et al. [12].

THEOREM 2. *If $\mathcal{C}$ is very well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ exhibits a transition. If $\mathcal{C}$ is not very well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ does not exhibit a transition.*

Proof of Theorem 1. First we prove that our two properties are necessary for $CSP(\mathcal{P})$ to have a partial transition.

Suppose that property 2 does not hold. Then for at least one value δ, setting each $X_i = \delta$ will satisfy any $C \in \mathcal{C}$, and so setting every variable in our CSP equal to δ will satisfy our formula with probability 1, regardless of M (in fact, since $\mathcal{C}$ is symmetric in $\mathcal{D}$, this is true for every $\delta \in \mathcal{D}$). Thus, there is no value of M for which $CSP_{n,M}(\mathcal{P})$ is a.s. unsatisfiable.

Suppose that property 1 does not hold, i.e., that there is some value $\delta \in \mathcal{D}$, canonical variable X_i, and $C \in \mathcal{C}$ such that C forbids $X_i = \delta$. Since $\mathcal{C}$ is symmetric in $\mathcal{D}$, we have that for *every* $\delta \in \mathcal{D}$ there is some $C(\delta) \in \mathcal{C}$ such that C forbids $X_i = \delta$.

We say that a variable x is *impossible* if x lies in at least d hyperedges of our constraint hypergraph, $e_1^j, \ldots, e_d^j$, and each e_ℓ^j has the constraint $C(\delta_\ell)$ where x is mapped onto X_i.

It is not hard to see that if x is impossible, then our formula is not satisfiable, since x is forbidden from being assigned any of $\delta_1, \ldots, \delta_d$.

Suppose that $M = cn$ for any value of c.

Claim. A.s. $CSP_{n,M}(\mathcal{P})$ has an impossible variable.

Proof. First choose the constraint hypergraph. It is well known[2] (and an easy application of Chebyshev's Inequality) that a.s. there will be at least ζn vertices with degree exactly d for a particular constant $\zeta = \zeta(c, k, d) > 0$. Let E_1 be the event that we do have this many such vertices. If E_1 holds, then a simple greedy algorithm will produce an independent set I of size at least $\frac{\zeta}{(k-1)d+1} n$ containing only vertices of

[2]See [7] for a proof of the case $k = 2$. The proof for higher values of k is similar.

degree d: Simply add vertices of degree d to I one at a time. Each time we add a vertex to I, we forbid any of its $d(k-1)$ neighbors from being added to I. We will always be able to continue until $|I| > \frac{\zeta}{(k-1)d+1}n$.

Next we choose the constraints for each hyperedge. Each vertex $v \in I$ will become impossible with some positive probability $p_1 > 0$. Furthermore, each such event is independent of the corresponding events for the other vertices in I, since I is an independent set. Therefore, the probability that there is no impossible variable is at most $\mathbf{Pr}(\overline{E_1}) + (1-p)^{\frac{\zeta}{(k-1)d+1}n} = o(1)$.

Thus, we have shown that if $\mathcal{C}$ is not well-behaved, then either $CSP_{n,M}(\mathcal{P})$ is always a.s. unsatisfiable or it is always a.s. satisfiable, regardless of $\mathcal{P}$, and so $\mathcal{C}$ does not exhibit a partial transition.

Now we show that if $\mathcal{C}$ is well-behaved, then it exhibits a partial transition for any choice of $\mathcal{P}$. First, we prove that property 1 implies that we can take c_1 to be any constant less than $\frac{1}{k(k-1)}$; i.e., for every $c < \frac{1}{k(k-1)}$ and $M < cn$, $CSP_{n,M}(\mathcal{P})$ is a.s. satisfiable.

It is well known[3] that for $c < \frac{1}{k(k-1)}$, the probability that our constraint hypergraph is acyclic tends to a constant $\rho(c) > 0$. It is not hard to show that if our constraint hypergraph is acyclic, then property 1 implies that our CSP is satisfiable. Thus the probability of satisfiability is at least ρ, and so we are not a.s. unsatisfiable.

For each component of the constraint hypergraph, we pick a variable to be the root and set it arbitrarily. We then process each hyperedge in sequence, i.e., assign values to the variables of that hyperedge, such that every time we process a hyperedge, exactly one of its variables has already been set. Since no $C \in \mathcal{C}$ forbids any values from any variables, we will be able to find an assignment for the other variables on that hyperedge without violating the corresponding constraint.

Finally, we complete our proof by showing that property 2 implies the existence of c_2, using what is by now a standard first moment argument.

Let A be the number of satisfying assignments of our random CSP. We will prove that there exists c_2 such that if $p = c/n$ where $c > c_2$, then $\mathbf{Exp}(A) = o(1)$. This implies that a.s. $A = 0$, i.e., our CSP is unsatisfiable.

There are d^n truth assignments. Consider any one particular assignment $\mathcal{A}$. There is a value δ such that some set S of at least $\frac{n}{d}$ variables are assigned δ in $\mathcal{A}$. By property 2, there is some constraint $C^* \in \mathcal{C}$ such that setting each $X_i = \delta$ violates C^*. The probability that $\mathcal{A}$ is a satisfying assignment is at most the probability that none of the k-tuples of S is constrained by C^*. The probability that a randomly chosen constraint is C^* applied to a k-tuple of S is

$$\mathcal{P}(C^*) \times \binom{n/d}{k} / \binom{n}{k} \approx \frac{\mathcal{P}(C^*)}{d^k}.$$

From this fact, standard easy arguments yield that

$$\begin{aligned}\mathbf{Exp}(A) &\leq d^n \left(1 - \frac{\mathcal{P}(C^*)}{d^k}\right)^{cn} \\ &< \mathrm{e}^{n \times \left(\ln d - \frac{c\mathcal{P}(C^*)}{d^k}\right)} \\ &= o(1)\end{aligned}$$

[3]See [7] for a proof of the case $k = 2$. See also the branching argument inspired by Karp [13] in [6]. The proof for higher values of k is similar.

for $c > c_2 = \frac{d^k \ln d}{\mathcal{P}(C^*)}$. ∎

Remark 4. In fact, note that we have shown that our CSP is always a.s. unsatisfiable iff property 1 does not hold, and it is always a.s. satisfiable iff property 2 does not hold.

Proof of Theorem 2. First we show why property 3 is necessary for our model to have a transition. Suppose that it doesn't hold, i.e., that there is some unsatisfiable CSP formula C consisting of constraints from $\mathcal{C}$ and whose constraint hypergraph forms an ℓ-cycle.

For any value of $c > 0$, it is well known[4] that the probability that a random hypergraph with cn edges has an ℓ-cycle tends to a constant $\zeta_1 = \zeta_1(c, \ell) > 0$. If our constraint hypergraph has an ℓ-cycle, then the probability of that ℓ-cycle being constrained by C is equal to some constant $\zeta_2 > 0$. Therefore, the probability of being unsatisfiable tends to at least $\zeta_1\zeta_2 > 0$, and so we are not a.s. satisfiable for any value of c.

On the other hand, if property 3 does hold, then for $c < \frac{1}{k(k-1)}$ our CSP is a.s. satisfiable. It is well known that a.s. the constraint hypergraph will have no component with more than 1 cycle. If this happens, then the variables of each tree component can be set as in the proof of Theorem 1. The variables of each unicyclic component can be set as follows: first set the variables of the cycle in a satisfactory manner (which will always be possible by property 3), and then set the remaining variables in the same manner as in a tree component.

The remainder of the theorem follows as in the proof of Theorem 1. ∎

In our proof, we showed that if $\mathcal{C} = \text{supp}(\mathcal{P})$ exhibits a transition, then $CSP(\mathcal{P})$ is a.s. satisfiable when $M = cn$ where c is below $\frac{1}{k(k-1)}$, the threshold for the constraint hypergraph to have a giant component. Not surprisingly, for many choices of $\mathcal{P}$, the same is still true for higher values of M. For example, see the following theorem.

THEOREM 3. *Suppose that $\mathcal{C}$ is such that for every minimally unsatisfiable formula F whose constraints are drawn from C, the ratio of constraints to variables of F is at least $\frac{1}{k-1}(1+\epsilon)$ for some constant $\epsilon > 0$. Then there is a constant $\delta > 0$ such that for any $\mathcal{P}$ with $\text{supp}(\mathcal{P}) = \mathcal{C}$, $CSP(\mathcal{P})$ is a.s. satisfiable for $M \leq \frac{1}{k(k-1)}(1+\delta)n$.*

Note that for the hypothesis of Theorem 3 to hold, $\mathcal{C}$ must be very well-behaved since a cycle has a hyperedge/vertex ratio of exactly $\frac{1}{k-1}$, and a tree has an even smaller ratio.

Proof. This is a standard type of argument in random graph theory, but we include it here because it is not well known.

We can assume that ϵ is arbitrarily small, say $\epsilon \leq \frac{1}{2}$. Suppose that $M = cn$ where $c = \frac{1}{k(k-1)}(1+\delta)$, and $\delta < \epsilon$ is a small constant to be specified later. We will show that the expected number of subgraphs of our random constraint hypergraph which have the required hyperedge/vertex ratio is $o(1)$. Thus, a.s. none exist and so the CSP must be satisfiable since any unsatisfiable formula contains a minimally unsatisfiable subformula.

We can assume that such a subgraph has no tree or unicyclic components, since deleting such a component will only increase the hyperedge/vertex ratio. Thus, the subgraph must lie within the giant component. The size of the giant component is well studied[5] and is a.s. at most αn where α tends to zero with δ. Thus, we can

[4]See [7] for a proof of the case $k = 2$. The proof for higher values of k is similar.

[5]See, for example, [7] for the case $k = 2$. The case $k > 2$ is amenable to similar analysis or to the simpler branching process analysis found in [6] and inspired by [13].

restrict our attention to subgraphs of size at most αn.

For any $0 < a \leq \alpha n$, we consider the expected number of subgraphs on a vertices with $b = \frac{1}{k-1}(1+\epsilon)a$ edges. There are $\binom{a}{2}$ choices for the vertices and $\binom{M}{b}$ choices for the edges. Given such choices, the probability that all the b edges lie within the a vertices is at most $\left(\frac{a}{n}\right)^{kb}$. Therefore, the expected number of such subgraphs is at most

$$\begin{aligned}\binom{n}{a}\binom{M}{b}\left(\frac{a}{n}\right)^{kb} &\leq \left(\frac{\mathrm{e}n}{a}\right)^a \left(\frac{\mathrm{e}M}{b}\right)^b \left(\frac{a}{n}\right)^{kb} \\ &= \left(\frac{\mathrm{e}^{1+(1+\epsilon)/(k-1)}c^{(1+\epsilon)/(k-1)}(k-1)}{1+\epsilon}\left(\frac{a}{n}\right)^{\epsilon}\right)^a \\ &= \left(K\left(\frac{a}{n}\right)^{\epsilon}\right)^a,\end{aligned}$$

where $K = K(\epsilon)$ is a constant. For $a \leq n^{\epsilon/4}$, this expression is $(\Theta(n^{-\epsilon(1-\epsilon/4)}))^a < n^{-\epsilon/2}$. And for $a < \alpha n$, it is less than $(\frac{1}{2})^a$, where α is sufficiently small in terms of ϵ. Thus the expected number of subgraphs is less than

$$\sum_{a=1}^{n^{\epsilon/4}} n^{-\epsilon/2} + \sum_{a \geq n^{\epsilon/4}} \left(\frac{1}{2}\right)^a = o(1)$$

for $\delta = \delta(\alpha)$ sufficiently small. □

Theorem 3 applies to several common models. For example, a minimally non-r-colorable graph has edge/vertex ratio at least $r/2$ since such a graph has minimum degree at least r. Also, a minimally unsatisfiable instance of k-SAT has clause/variable ratio at least $2/k$ since it cannot contain any pure literals. In a future publication [14], we will characterize the distributions $\mathcal{P}$ for which $CSP(\mathcal{P})$ is a.s. unsatisfiable with $M = cn$ for all $c > \frac{1}{k(k-1)}$.

2. The asymmetric case. Here we extend the definitions and theorems of the previous section to the case where $\mathcal{C}$ is not necessarily symmetric in $\mathcal{D}$.

We say that a value δ is 0-*bad* if there is some canonical variable X_i and constraint $C \in \mathcal{C}$ such that C forbids $X_i = \delta$. We say that δ is j-*bad* if there is some canonical variable X_i and constraint $C \in \mathcal{C}$ such that C implies that if $X_i = \delta$, then at least one other canonical variable must be assigned a j'-bad value for some $j' < j$. A value is *bad* if it is j-bad for some j. A value is *good* if it is not bad.

If $\mathcal{C}$ is symmetric, then, of course, if one value is bad, then all values are bad, and so the existence of a bad value would violate property 1 from the previous section. However, to allow for the case that $\mathcal{C}$ is asymmetric, we must modify property 1. We say that $\mathcal{C}$ is *well-behaved* if it satisfies the following two properties:

1′. There is at least one good value in $\mathcal{D}$.

2. For every $\delta \in \mathcal{D}$, there is at least one $C \in \mathcal{C}$ such that $X_1 = \delta, X_2 = \delta, \ldots, X_k = \delta$ does not satisfy C.

Remark 5. It is an easy exercise to show that properties 1′ and 2 imply that there are at least 2 good values in $\mathcal{D}$.

We also must modify property 3 slightly. We say that $\mathcal{D}$ is *very well-behaved* if, in addition to properties 1′ and 2, it also satisfies the following:

3′. If a CSP is formed using constraints from $\mathcal{C}$, and its constraint hypergraph is a cycle, then it must have a satisfying assignment where no variable is assigned a bad value.

We have the analogous results from the previous section.

THEOREM 4. *If $\mathcal{C}$ is well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ exhibits a partial transition. If $\mathcal{C}$ is not well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ does not exhibit a partial transition.*

THEOREM 5. *If $\mathcal{C}$ is very well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ exhibits a transition. If $\mathcal{C}$ is not very well-behaved, then for every distribution $\mathcal{P}$ with $\mathcal{C} = \text{supp}(\mathcal{P})$, $CSP(\mathcal{P})$ does not exhibit a transition.*

The proofs are along the same lines as those in the previous section. We present only the portions of the proofs which are different.

Proof of Theorem 4. First we show that if condition $1'$ does not hold, then for every distribution $\mathcal{P}$ and value $c > 0$, $CSP(\mathcal{P})$ is a.s. unsatisfiable.

For each $j \geq 0$ we let b_j denote the number of j-bad values. Thus $\sum_{j \geq 0} b_j = d$. For each 0-bad value δ, we let $C(\delta)$ be the constraint and $X_{i(\delta)}$ be the canonical variable such that $C(\delta)$ forbids $X_{i(\delta)} = \delta$. Similarly, if $j \geq 1$, then for each j-bad value δ, we let $C(\delta)$ be the constraint and $X_{i(\delta)}$ be the canonical variable such that if $X_{i(\delta)} = \delta$, then at least one other canonical variable must take a j'-bad value for some $j' < j$.

We define a *j-bad tree* rooted at a variable v as follows:

- A 0-bad tree rooted at v is a set of b_0 hyperedges intersecting at v such that for each 0-bad value δ, one of the hyperedges receives the constraint $C(\delta)$ with $X_{i(\delta)}$ mapped onto v.
- For $j \geq 1$, a j-bad tree rooted at v consists of a j'-bad tree $T_{j'}$ rooted at v for each $0 \leq j' < j$, along with b_j hyperedges $e_1, \ldots, e_{b_j}$ intersecting at v such that
  - (i) for each j-bad value δ, a hyperedge e_i receives the constraint $C(\delta)$ with $X_{i(\delta)}$ mapped onto v;
  - (ii) for every vertex $u \neq v$ in each e_i, u is the root of a $(j-1)$-bad tree T_u;
  - (iii) all of the bad trees $\{T_0, \ldots, T_{j-1}\} \cup \{T_u : u \text{ is in some } e_i\}$ are disjoint except that $T_0, \ldots, T_{j-1}$ all contain v.

It is not hard to argue inductively that if v roots a j-bad tree, then v cannot receive a j'-bad value for any $j' \leq j$: If $j = 0$, then for each 0-bad value δ, v is forbidden δ by $C(\delta)$. For $j \geq 1$, since for each $j' < j$, v roots a j'-bad tree, v cannot receive a j'-bad value. If v receives some j-bad value, δ, then since v lies in a $C(\delta)$-constraint, at least one of the other variables in that constraint must receive a j'-bad value for some $j < j$. But each of those variables roots a $(j-1)$-bad tree and hence roots a j'-bad tree. Thus it cannot take any j'-bad value.

A *bad tree* is a j-bad tree where j is the maximum value such that $b_j > 0$. If $1'$ does not hold, then every value is a j'-bad value for some $j' < j$, and so the root of a bad tree cannot receive any of them. Therefore, if a CSP contains a bad tree, then it is unsatisfiable.

Now, we show that for any distribution $\mathcal{P}$ and $c > 0$, a.s. $CSP(\mathcal{P})$ contains a bad tree. The following fact is well known in random graph theory.

Fact. For any fixed hypertree T independent of n, there exists a constant $z > 0$ such that a.s. our random constraint hypergraph will contain at least ζn copies of T.

The basic outline for the proof of this fact is as follows: (1) The expected number of copies of T is $\zeta' n$ by a simple but tedious calculation. (2) Because n grows much larger than the (constant) size of T, individual potential appearances of T occur nearly independently. An application of Chebyshev's Inequality formalizes this and shows

that the number of copies of T is highly concentrated. In particular, it is a.s. at least ζn for any $\zeta < \zeta'$. See [7] for details of the case $k = 2$. The analysis for higher k is the same.

Naturally, we will apply this fact where T is equal to the underlying hypertree of a minimum-sized bad tree. Let E_1 be the event that our hypergraph contains at least ζn copies of T. If E_1 holds, then using a simple greedy procedure as in the proof of Theorem 1, we can easily find a set I of $\frac{\zeta}{|T|}n$ disjoint copies of T (where $|T|$ denotes the number of vertices in T). Upon choosing the constraints, a copy becomes bad with probability p_1 for some $p_1 > 0$ which is not a function of n. Therefore, the probability that our CSP contains no bad trees is at most

$$\mathbf{Pr}(E_1) + (1 - p_1)^{\frac{\zeta}{|T|}n} = o(1).$$

To prove that if $1'$ holds, then for any $\mathcal{P}$ and $c < \frac{1}{k(k-1)}$, $CSP(\mathcal{P})$ is not a.s. unsatisfiable we just have to show that any CSP with constraints from $\mathcal{C}$ and whose constraint hypergraph is a tree is satisfiable.

For such a CSP, choose any variable v to be the root. Assign v a good value. Since v is good, it is possible to assign good values to every variable which shares a constraint with v without violating any of those constraints. Now continue through the CSP as in the proof of Theorem 1, each time assigning only good values, thus satisfying the CSP.

The remainder of the proof, namely, the relevance of property 2, is identical to the proof of Theorem 1. □

Proof of Theorem 5. This follows almost exactly as the proof of Theorem 2.

If property $3'$ does not hold, then with probability tending to some positive constant $CSP(\mathcal{P})$ will contain a subproblem whose constraint hypergraph is a unicyclic component and (i) the cycle of that component is constrained such that at least one variable must receive a bad value, and (ii) each variable on that cycle roots a bad tree. Clearly, such a subproblem is unsatisfiable.

If property $3'$ holds, then it is enough to show that any CSP with constraints from $\mathcal{C}$ and whose constraint hypergraph is unicyclic is satisfiable. To satisfy such a CSP, first assign good values to each variable on the cycle without violating any of the cycle constraints, and then continue to assign good values to each of the other variables as in the proof of Theorem 4. □

Theorem 3 also applies to the asymmetric case. Again, it would be interesting to characterize the distributions $\mathcal{P}$ for which $CSP(\mathcal{P})$ is a.s. unsatisfiable with $M = cn$ for all $c > \frac{1}{k(k-1)}$.

3. Sharp thresholds. If a model $CSP(\mathcal{P})$ exhibits a transition, then it is natural to ask if it satisfies the following stronger property:

There exists a constant $c > 0$ such that for any $\epsilon > 0$, if $M < (c - \epsilon)n$, then $CSP(\mathcal{P})$ is a.s. satisfiable, and if $M > (c + \epsilon)n$, then $CSP(\mathcal{P})$ is a.s. satisfiable.

The current "state-of-the-art" in the analysis of sharp thresholds does not allow us to prove a property this strong even for CNF-satisfiability. Instead, we must weaken the property slightly as follows.

$CSP(\mathcal{P})$ is said to have a *sharp threshold* of satisfiability if there exists a function $c(n)$ bounded away from 0 such that for any $\epsilon > 0$, if $M < (c(n) - \epsilon)n$, then $CSP_{n,M}(\mathcal{P})$ is a.s. satisfiable, and if $M > (c(n) + \epsilon)n$, then $CSP_{n,M}(\mathcal{P})$ is a.s. satisfiable.

Note that the only difference between this and the stronger property is that here we allow c to vary with n. All natural models which are known to have sharp thresholds are conjectured to also satisfy the stronger property where $c(n) = c$ for all n. However, we do not know how to prove this.

This notion of sharp thresholds was introduced (in a broader context than that in the preceding definition) by Friedgut [11], who proved that random instances of k-SAT exhibit a sharp threshold. In doing so, he proved a general theorem characterizing random graph properties which have sharp thresholds. To describe this theorem, we must introduce some definitions.

A graph property, P, is *monotonically increasing* if (i) P is invariant under graph automorphisms, and (ii) whenever H is a subgraph of G, and H has P, then G must have P. This definition extends in the obvious manner to properties of CSPs—condition (ii) becomes the following: if F_1, F_2 are CSPs where every constraint in F_1 is also contained in F_2, and if F_1 has P, then F_2 must have P. The only property which concerns us in this paper is that of being unsatisfiable, which is clearly monotonically increasing.

Given two properties P_1, P_2, their *symmetric difference*, $P_1 \triangle P_2$, is the property of satisfying one but not both of P_1, P_2. Given a set of graphs $\mathcal{H} = \{H_1, \ldots, H_k\}$, we define $Q(\mathcal{H})$ to be the property of having a subgraph which is isomorphic to one of the members of $\mathcal{H}$.

$G_{n,M}$ is the random graph with n vertices and M edges, where each such graph is equally likely to be chosen.

We extend our definitions of *transition* and *sharp threshold* to the setting of random graphs in the obvious manner. A monotonically increasing graph property, P, exhibits a transition if there exist $c_1, c_2 > 0$ such that if $M < c_1 n$, then a.s. $G_{n,M}$ does not have P, and if $M > c_2 n$, then a.s. $G_{n,M}$ has P. A graph property P with a transition has a sharp threshold if there exists a function $c(n)$ bounded away from 0 such that for any $\epsilon > 0$, if $M < (c(n) - \epsilon)n$, then a.s. $G_{n,M}$ does not have P, and if $M > (c(n) + \epsilon)n$, then a.s. $G_{n,M}$ has P.

Friedgut's Theorem yields the following.

FRIEDGUT'S THEOREM (see [11]).[6] *If a monotonically increasing graph property P with a transition does not have a sharp threshold, then for infinitely many values of n there exists some $c(n)$ such that for every $\delta > 0$ there is a set of graphs $\mathcal{H} = \{H_1, \ldots, H_k\}$, each with at most one cycle, such that when $M = c(n) \times n$, the probability of $G_{n,M}$ having $P \triangle Q(\mathcal{H})$ is less than δ. Furthermore, there is a function $B = B(P, \delta)$ such that each H_i has at most B vertices.*

In other words, when $M = c(n)$, P can be arbitrarily closely approximated in probability by the property of having a subgraph from a list of graphs with at most one cycle, where the sizes of these graphs do not grow with n.

This theorem also extends to random hypergraphs and to random CNF-formulae, and Friedgut [10] reports that it extends to the random CSP models discussed here. Thus, roughly speaking, $CSP(\mathcal{P})$ has a sharp threshold of satisfiability iff unsatisfiability cannot be arbitrarily well approximated by containing a subproblem isomorphic to one of a list of problems whose constraint hypergraphs have at most one cycle and whose constraints are drawn from $\mathcal{C}$. If $CSP(\mathcal{P})$ exhibits a transition, then all such

[6] Friedgut's Theorem is in fact much more general than this in that (i) it shows that this is essentially an "if and only if" statement, and (ii) it allows for the possibility of a sharp threshold which occurs when M is not linear in n. We include only this version here for the sake of simplicity and because it covers all situations which are relevant to this paper.

problems are satisfiable. Thus, it would be natural to further expect that $CSP(\mathcal{P})$ has a sharp threshold of satisfiability iff it exhibits a transition. However, this is not the case, as the following example shows.

Example 1. Suppose that $k = 2, d = 4$, and that $\mathcal{C}$ contains exactly two constraints. The first one, C_1, forbids (X_1, X_2) from receiving any pair of values from $\{(1,1),(2,2),(3,3),(4,4)\}$. The second, C_2, forbids any pair (x, y) where one member of the pair is from $\{1,2\}$ and the other member is from $\{3,4\}$. $\mathcal{P}(C_1) = \frac{1}{3}$ and $\mathcal{P}(C_2) = \frac{2}{3}$.

Note that it is easy to verify that $CSP(\mathcal{P})$ exhibits a transition.

Suppose that $M = cn$, where $\frac{3}{4} < c < \frac{3}{2}$. Let G_i be the constraint graph induced by constraints of type C_i. A.s. G_1 will have $\frac{1}{3}M + o(M) = (\frac{1}{2} - c_1)n + o(n)$ edges and G_2 will have $(\frac{1}{2} + c_2)n + o(n)$ edges for some constants $c_1, c_2 > 0$. Therefore, by the most fundamental theorem in random graph theory (see [9]), a.s. no component of G_1 will have size greater than $O(\log n)$, while G_2 will have a *giant component* of size $\alpha n + o(n)$ for a constant $\alpha = \alpha(c) > 0$, and every other component of G_2 will have size at most $O(\log n)$.

Let T be the vertices of the giant component of G_2. Define B to be the event that G_1 has an odd cycle whose vertices all lie in T. It is easy to see that if B holds, then our CSP is unsatisfiable: the C_2 constraints imply that either all variables in T receive 1 or 2, or they all receive 3 or 4. However, if a set of vertices belongs to an odd cycle in G_1, then among them there must be at least 3 values. Furthermore, it is not difficult to verify that the probability that B does not hold and the CSP is unsatisfiable is $o(1)$. Therefore, the probability of satisfiability is $1 - \mathbf{Pr}(B) + o(1)$. It is also easily computed that $\mathbf{Pr}(B)$ tends to a constant (in terms of c) which is strictly between 0 and 1, and so our CSP is neither a.s. satisfiable nor a.s. unsatisfiable—G_1 and G_2 are very close to being two independent random graphs, so this is essentially the probability that a random graph with αn vertices and $(\frac{1}{2} - c_1)n$ edges contains an odd cycle. Therefore this model does not have a sharp threshold despite the fact that it exhibits a transition.

Achlioptas [2] and Friedgut [10] each pointed out that the following set of problems are of the type that Friedgut's Theorem guarantees; i.e., having a subproblem from this set is a good approximation of being unsatisfiable. For each i, let $\mathcal{H}_i$ denote the set of subproblems such that, when G_1, G_2 are defined as above,

(i) G_1 is a cycle of length $2r + 1$ for some positive integer r, with vertices $v_1, \ldots, v_{2r+1}$;
(ii) G_2 consists of r disjoint trees $T_1, \ldots, T_r$ each of size i;
(iii) for each i, v_i is in T_i, and these are the only vertices that G_1, G_2 have in common.

Let P be the property that our random problem is unsatisfiable. For any $\delta > 0$, we can choose i large enough that $\mathbf{Pr}(P \triangle Q(\mathcal{H})) < \delta$. Almost surely, if G_1 has an odd cycle lying in the giant component of G_2, then breadth-first searches, in G_2, from each vertex of the cycle will yield a collection of disjoint trees of length i for any constant i. Therefore, $\mathbf{Pr}(P - Q(\mathcal{H}_i)) = o(1)$. On the other hand, the probability that G_1 has a cycle through the vertex of any nongiant component of G_2 which has size at least i tends to a constant δ_i which tends to 0 as i grows. Choosing i so that $\delta_i < \delta$ yields $\mathbf{Pr}(Q(\mathcal{H}_i)) < \delta$. We omit the details, which are straightforward to a reader who is experienced in random graph theory.

It would be quite interesting to determine some necessary and sufficient conditions on $\mathcal{P}$ for $CSP(\mathcal{P})$ to have a sharp threshold. We close this section by noting the

following sufficient condition.

THEOREM 6. *If*

(a) $\mathcal{C}$ *is very well-behaved;*

(b) *every constraint in* $\mathcal{C}$ *has the property that for each value* δ *and canonical variable* X_i *there is at most one restriction with* $X_i = \delta$*; and*

(c) *for each* $C \in \mathcal{C}$, $\mathcal{P}(C) = \frac{1}{|\mathcal{C}|}$,

then $CSP(\mathcal{P})$ *has a sharp threshold.*

Remark 6. It is not difficult to weaken conditions (b) and (c) somewhat, but (a) is, of course, necessary.

Note that this theorem generalizes the fact that random instances of k-SAT have a sharp threshold for $k \geq 3$ and the fact that k-colorability of random graphs has a sharp threshold for $k \geq 3$. This latter fact was proven by Achlioptas and Friedgut [3], and the proof of Theorem 6 is nearly identical to their proof. To avoid a long repetition of a proof which is readily available, we only give an outline of our proof.

Proof of Theorem 6. Rather than using Friedgut's Theorem, we will make use of a similar theorem proved by Bourgain subsequent to Friedgut's proof. The statement of this theorem is somewhat weaker, but it is easily applied to a more general situation, including the random models considered here.

Consider a set $\mathcal{A}$ of items $\{a_1, \ldots, a_r\}$ and a *selection probability* p. We will choose a random subset $A \subseteq \mathcal{A}$ as follows: for each a_i, we make an independent choice as to whether to include a_i in A, placing it in A with probability p. For example, if $\mathcal{A}$ is the set of possible edges of an n vertex graph, then we are simply choosing the random graph $G_{n,p}$, which is well known (see, for example, [7]) to be in many ways equivalent to $G_{n,M}$, where $M = p\binom{n}{2}$. Under the assumption that $\mathbf{Pr}(C)$ is rational for each $C \in \mathcal{C}$, we can also simulate $CSP(\mathcal{P})$ using this model as follows:

Following Remark 2, we will work in the equivalent model whereby we select each possible hyperedge to be in the constraint hypergraph independently with probability $p = \frac{c \times k!}{n^{k-1}}$.

$\mathcal{A}$ is the set of all $\binom{n}{k} k! |\mathcal{C}|$ possible constraints. We place each constraint into A with selection probability p' (to be named later), and we let our CSP consist of each constraint C such that (i) $C \in A$, and (ii) none of the other $k!|\mathcal{C}| - 1$ possible constraints on the same k-tuple of variables is in A. For any k-tuple of variables, that k-tuple forms a constraint with probability exactly $k!|\mathcal{C}| \times p'(1-p')^{k!|\mathcal{C}|-1}$, and we choose p' so that this value is equal to p. Furthermore, each member of $\mathcal{C}$ is equally likely to be that constraint. Thus, this represents our model precisely. (Note that p' is very close to p—in fact $p' = p(1 + O(n^{-(k-1)}))$.)

This transformation allows us to apply Bourgain's Theorem to $CSP(\mathcal{P})$. As with Friedgut's Theorem, we will not state Bourgain's Theorem in its full power; instead, we will only state its implication to this setting, thus avoiding some technicalities.

BOURGAIN'S THEOREM (see [11]). *Suppose that for each* $c \in \mathcal{C}$, $\mathcal{P}(C) = \frac{1}{|\mathcal{C}|}$. *If* $CSP(\mathcal{P})$ *does not have a sharp threshold of satisfiability, then there exist absolute constants* T, $0 < \alpha < \frac{1}{2}$, *and* $\beta > 0$, *and for infinitely many values of* n *there exists* $c(n)$ *such that when* $M = c(n) \times n$, *the probability that* $CSP(\mathcal{P})$ *is satisfiable is* γ *for some* $\alpha < \gamma < 1 - \alpha$ *and either*

(i) *with probability at least* β, $CSP(\mathcal{P})$ *contains an unsatisfiable subproblem* F_1 *of size at most* T*; or*

(ii) *there exists a satisfiable subproblem* F_1 *of size at most* T *such that conditioning on* $CSP(\mathcal{P})$ *containing* F_1 *lowers the probability of satisfiability to below* $\gamma - \beta$.

In the remainder of this proof, we will only consider values of n from the infinite set of values referred to by Bourgain's Theorem. Because this set is infinite, we can choose arbitrarily high values of n, and so an asymptotic analysis is valid.

A straightforward and well-known[7] random graph argument implies that a.s. every subproblem with at most T constraints is unicyclic. If $\mathcal{C}$ is very well-behaved, all such problems are satisfiable. Thus, (i) does not hold, and so we only need to eliminate the possibility of (ii).

So consider a CSP F_1 as in (ii). Without loss of generality, we can assume that F_1 is on the variables $x_1, \ldots, x_t$ for some $t \leq T$. Consider any satisfying assignment $x_1 = \delta_1, \ldots, x_t = \delta_t$ for F_1. The probability that $CSP(\mathcal{P})$ is satisfiable, conditional on $CSP(\mathcal{P})$ containing F_1, is at most the probability that $CSP(\mathcal{P})$ has a satisfying assignment with $x_1 = \delta_1, \ldots, x_t = \delta_t$.

Let $\mathcal{D}$ be the set of constraints, other than those in F_1, which involve $x_1, \ldots, x_t$. A straightforward argument shows that there is an absolute constant R such that with probability at least $\frac{1-\beta}{2}$ (a) $|\mathcal{D}| \leq R$, (b) no constraint in $\mathcal{D}$ involves two variables from $\{x_1, \ldots, x_t\}$, and (c) no variable outside of $\{x_1, \ldots, x_t\}$ lies in more than one constraint in $\mathcal{D}$.

Consider any constraint $D \in \mathcal{D}$, say on variables $x_i, x_{j_1}, \ldots, x_{j_{k-1}}$ where $1 \leq i \leq t$ and each other index is greater than t. Since each constraint in $\mathcal{C}$ contains at most one restriction involving $x_i = \delta_i$, insisting that $x_i = \delta_i$ at worst reduces to imposing a single restriction of size $k-1$ on $x_{j_1}, \ldots, x_{j_{k-1}}$. This is no more restrictive than forbidding a single value for each x_{j_l}. Thus, conditional on (a), (b), and (c) holding, the probability that $CSP(\mathcal{P})$ has a satisfying assignment with $x_1 = \delta_1, \ldots, x_t = \delta_t$ is bounded from below by the following experiment:

Fix some collection of values $\zeta_1, \ldots, \zeta_{R\times(k-1)}$. Choose a random CSP from $CSP(\mathcal{P})$ with $M = c(n)$. Pick $R \times (k-1)$ variables at random and add the additional requirements that the ith variable cannot receive ζ_i.

Since the probability that either (a), (b), or (c) fails is at most $\frac{\beta}{2}$, condition (ii) implies that these additional requirements do not decrease the probability of satisfiability by more than $\frac{\beta}{2}$. We will show that this is impossible. To do so requires two steps:

(1) We show that if adding these $R\times(k-1)$ additional requirements decreases the probability of satisfiability by at least $\frac{\beta}{2}$, then so would increasing M from $c(n) \times n$ to $c(n) \times n + R^{'}$ for an absolute constant $R^{'}$ defined in terms of $R \times (k-1)$.

(2) Increasing M from $c(n)\times n$ to $c(n)\times n + R^{'}$ will only decrease the probability of unsatisfiability by $o(1)$.

Step (2) is at least intuitively obvious: adding a relatively very small number of constraints should not have a significant effect on the probability of satisfiability. However, it takes a little work to prove it.

The proof of step (1) goes as follows: Suppose that we were adding only one additional requirement: we pick a random variable and forbid it from receiving ζ_1. Let X_1 be the set of variables such that, before this requirement, the only satisfying assignments set all of X_1 equal to ζ_1. If this requirement causes our problem to turn from satisfiable to unsatisfiable, then we must have chosen a random variable in X_1. Thus, in order for this to have a significant probability of happening, X_1 would have to contain at least αn variables for some constant $\alpha > 0$. Suppose that this is the case. Then if instead of adding this extra requirement, we added a single additional

[7] See [7] for a proof of the case $k = 2$. The proof for higher values of k is similar.

constraint, we would cause the CSP to become unsatisfiable with probability at least $\alpha^k \times \frac{1}{|\mathcal{C}|}$, which is a positive constant. The reason is that this is the probability that the entire k-tuple is from X_1 and that we choose the restriction which forbids them from all being assigned the value ζ_1. Thus adding an additional constraint has a serious effect on the probability of satisfiability.

Modifying this argument to the case where we have $R(k-1)$ additional requirements uses the same ideas but is technically a little complicated.

The proofs of steps (1) and (2) are identical to the corresponding steps found in [3], [11], and [1]. We refer the reader to any of these for more details. □

Acknowledgment. I'm grateful to Ehud Friedgut for his many helpful comments and corrections.

MACRO TREE TRANSLATIONS OF LINEAR SIZE INCREASE ARE MSO DEFINABLE*

JOOST ENGELFRIET† AND SEBASTIAN MANETH†‡

Abstract. The first main result is that if a macro tree translation is of linear size increase, i.e., if the size of every output tree is linearly bounded by the size of the corresponding input tree, then the translation is MSO definable (i.e., definable in monadic second-order logic). This gives a new characterization of the MSO definable tree translations in terms of macro tree transducers: they are exactly the macro tree translations of linear size increase. The second main result is that given a macro tree transducer, it can be decided whether or not its translation is MSO definable, and if it is, then an equivalent MSO transducer can be constructed. Similar results hold for attribute grammars, which define a subclass of the macro tree translations.

Key words. tree transducers, monadic second-order logic, decidability

1. Introduction.

Very often a complex object has a structure that shows how it is composed from smaller objects by the application of certain operations. The smaller objects may themselves be composed of other objects. Such a structure can naturally be described as a tree, and hence the objects are "tree-structured." Examples of tree-structured objects are the words of a context-free language (with derivation trees as structure) or the graphs of bounded tree-width (with tree decompositions as structure). Now consider the transformation of a tree-structured object, based on its structure and independent of the interpretation of the operations, i.e., a tree-to-tree transformation. We are interested in models of such transformations: tree transducers. Well-known examples of tree transducers are top-down tree transducers [46, 48, 1, 32] and attribute grammars [17, 27, 28] (motivated by syntax-directed semantics and compilers; cf. [35, 37, 40, 53]), unranked tree transducers [43, 2] and pebble tree transducers [45] (motivated by the transformation of XML documents; cf. [51]), and macro tree transducers [15, 8, 9, 24, 28] (motivated by syntax-directed and denotational semantics [35, 47], and used as a model in, e.g., functional programming [52, 39, 41], language prototyping [49], and linguistics [38, 44]). Motivated by model theory is the idea of "interpretation," meaning the definition of a (logical) structure in terms of logical formulas over another structure (cf. Chapter 10 of [13]). For monadic second-order (MSO) logic, such MSO interpretations have recently been used to characterize the generation of graphs by context-free graph grammars [5, 7, 23, 16] (see also [36]). Taking trees as a logical structure, another type of tree transducer is obtained: the MSO tree transducer, studied in [3, 19] (for strings, see [18]). An important part of tree transducer theory is comparing the formal power of these different models of transformation of tree-structured objects and providing effective translations between these models. This paper compares the power of macro tree transducers and MSO tree transducers.

The macro tree transducer (MTT) is a finite state device that translates, in a recursive top-down fashion, an input tree into an output tree, handling context information by the use of parameters. The states of the MTT can be viewed as functions that call each other recursively; the initial state is the main function. The (tree-to-tree) translations of MTTs form a large class containing the translations of top-down tree transducers and attribute grammars. In order to prove our results, we add the feature of regular look-ahead (see, e.g., section 18 of [32]) to top-down tree transducers, attribute grammars, and MTTs. Note that in the case of MTTs this has no influence on the translations: the classes of translations realized by MTTs with and without regular look-ahead are the same [24].

The MSO tree transducer uses formulas in monadic second-order logic to define tree-to-tree translations. This provides a declarative way of defining a tree translation, as opposed to the operational way of an MTT. The idea is to define the nodes and edges of the output tree in terms of MSO formulas that are interpreted in the input tree, or, more precisely, in a fixed number of disjoint copies of the input tree. Tree translations definable in MSO logic have nice properties, comparable to those of finite state transductions on strings. In particular, they are closed under composition and they can be computed in linear time. Macro tree translations do not possess these properties.

The question arises, What is the precise relationship between these two different models? From [3, 19] it is known that every MSO definable tree translation can be realized by an MTT. However, the converse does not hold for obvious reasons: by definition, MSO definable tree translations are of linear size increase: the size of the output tree is at most k times the size of the input tree, where k is the number of disjoint copies of the input tree, used to define the output tree. On the other hand, the translations realized by MTTs can be of double exponential size increase (cf. Lemma 4.22 of [28]). Our first main result is that if we restrict ourselves to translations of linear size increase, then the two formalisms, MSO tree transducers and MTTs, have exactly the same power, i.e., the respective classes of translations coincide.

Let us briefly discuss the proof of the first main result. As mentioned before, our MTTs are equipped with regular look-ahead. In [19] a characterization of the MSO definable tree translations in terms of MTTs is given: they are the translations realized by "finite copying" MTTs. The notion of finite copying was introduced in [1] for generalized syntax-directed translation schemes, which are closely related to top-down tree transducers. It requires that there be a bound on the number of occurrences of states that translate a given node of the input tree. For MTTs this requirement is called "finite copying in the input," and an MTT is finite copying [19] if it is both finite copying in the input and "finite copying in the parameters"; the latter means that there is a bound on the number of copies made of a parameter. We want to prove that if the translation realized by an MTT is of linear size increase, then it is MSO definable. By the above this is equivalent to showing that for every MTT M that is of linear size increase (i.e., which realizes a translation of linear size increase), there is an equivalent MTT M' that is finite copying. How can we construct M', given M? The idea is that every MTT M can be transformed into a normal form M', called the "proper normal form" of M, such that if M is of linear size increase, then M' is finite copying. Roughly speaking this normal form requires that all states and parameters of M' are really "needed"; more precisely, each state generates infinitely many output trees (considering all possible input trees), and for

each parameter y there are infinitely many actual parameter trees being substituted for y (for all possible input trees). Then for a proper MTT M' it can be shown that (i) if M' is of linear size increase, then it is finite copying in the parameters, and (ii) if M' is finite copying in the parameters and of linear size increase, then it is finite copying in the input. Both (i) and (ii) are proved by a pumping argument; i.e., it is shown that if M' is not finite copying in the parameters, then it is not of linear size increase, and similarly for (ii).

Our second main result concerns decidability. Given an MTT it can be decided whether or not its translation is MSO definable, and if so, an equivalent MSO tree transducer can be constructed. The proof is based on the following results: (1) the translation realized by an MTT M is MSO definable—i.e., of linear size increase—if and only if its proper normal form M' is finite copying (by the proof of our first main result, as discussed above); (2) for an MTT it is decidable whether or not it is finite copying (the proof is based on the fact that the finiteness of ranges of MTTs is decidable [12]); and (3) from [19, 3] it follows that given a finite copying MTT, an equivalent MSO tree transducer can be constructed.

Note that very often membership in a subclass is undecidable (such as regularity of a context-free language). In cases of decidability there is often a characterization of the subclass that is independent of the device that defines the whole class, i.e., a "semantic" rather than "syntactic" characterization, such as our linear size increase characterization. As another example, in [6] it is shown that an NR (node replacement) context-free graph language can be generated by an HR (hyperedge replacement) context-free graph grammar if and only if the number of edges of its graphs is linearly bounded by the number of nodes.

The idea for our main results stems from [1]; there it is shown that a generalized syntax-directed translation (gsdt) scheme can be realized by a tree-walking transducer if and only if it is of linear size increase. Since gsdt schemes are a variation of top-down tree transducers, and tree-walking transducers are closely related to finite copying top-down tree transducers [22], our result can be viewed as a generalization of the result of [1], from top-down tree transducers to MTTs. In fact, since the proper normal form of a top-down tree transducer is again a top-down tree transducer, we reobtain their result (in our formalism): the top-down tree translations of linear size increase are exactly the translations realized by finite copying top-down tree transducers. Moreover, they are exactly the MSO definable top-down tree translations.

The main result of [19], on which this paper is based, is in turn based on the main result of [3], which states that the MSO definable tree translations can be characterized by attribute grammars (more precisely, by attributed tree transducers with look-ahead) that are single-use restricted. The single-use restriction [33, 30, 39, 41] is interesting, because attribute grammars are closed under left-composition with single-use restricted attribute grammars. Our results now imply that given an attributed tree transducer (with look-ahead) it can be decided whether or not there exists an equivalent one that is single-use restricted, and furthermore that the linear size increase attributed tree translations are precisely the MSO definable tree translations.

This paper is structured as follows. In section 2 trees and tree substitutions are defined. In particular, the definition of second-order tree substitution is given, which is the type of substitution that MTTs are based on. Various results about these substitutions are proved, for example, how to compute the number of occurrences of a particular symbol in a tree to which a second-order tree substitution is applied. Then tree languages and tree translations are defined, and the notion of MSO definable tree

translation is recalled briefly. Section 3 defines MTTs, which are total deterministic and equipped with regular look-ahead. Some basic results needed in the paper are recalled, and two subclasses defined by restrictions on the parameters are considered. Section 4 recalls the notion of finite copying, which consists of two parts: finite copying in the input and finite copying in the parameters. It is proved that it is decidable for an MTT whether or not it is finite copying. Moreover, although this is already known from the result of [19], it is proved for the sake of completeness that if an MTT is finite copying, then it is of linear size increase. The proof is based on an intermediate, very natural notion of bounded copying: "finite contribution." An MTT is of finite contribution if there is a bound on the number of output nodes that are contributed by a given node of the input tree. Also in this section the notion of "finite nested copying in the input" is introduced; it requires a bound on the amount of nesting of the states that translate a given node of the input tree. In section 5 the proper normal form is introduced, and it is shown how to construct, given an MTT, an equivalent one in proper normal form. Section 6 proves our main results: if the translation realized by a proper MTT M is of linear size increase (for short, "M is lsi"), then M is finite copying. The proof goes in three stages: (I) If M is lsi, then it is finite nested copying in the input. (II) If M is lsi and finite nested copying in the input, then it is finite copying in the parameters. And finally, (III) if M is lsi, finite nested copying in the input, and finite copying in the parameters, then it is finite copying in the input. Section 7 presents the main results and their consequences for top-down tree transducers, attribute grammars, and context-free graph grammars. At last, some open problems and further research topics are mentioned.

We note that technically this paper is concerned with MTTs only. The links to MSO tree transducers were established in [3, 19].

2. Preliminaries. The set $\{0, 1, \dots\}$ of natural numbers is denoted by $\mathbb{N}$. The empty set is denoted by $\varnothing$. For $k \in \mathbb{N}$, $[k]$ denotes the set $\{1, \dots, k\}$; thus $[0] = \varnothing$. For a set A, $|A|$ is the cardinality of A, and A^* is the set of all strings over A. The empty string is denoted by ε. The length of a string w is denoted $|w|$, and the number of occurrences of the symbol a in w is denoted by $\#_a(w)$. For a set $B \subseteq A$, $\#_B(w) = \sum\{\#_a(w) \mid a \in B\}$. For strings $v, w_1, \dots, w_n \in A^*$ and distinct $a_1, \dots, a_n \in A$, we denote by $v[a_1 \leftarrow w_1, \dots, a_n \leftarrow w_n]$ the result of (simultaneously) substituting w_i for every occurrence of a_i in v. Note that the substitution $[a_1 \leftarrow w_1, \dots, a_n \leftarrow w_n]$ is a homomorphism on strings. Let P be a condition on a and w such that $\{(a, w) \mid P\}$ is a partial function; then we use, similar to set notation, $[a \leftarrow w \mid P]$ to denote the substitution $[L]$, where L is the list of all $a \leftarrow w$ for which condition P holds.

2.1. Trees. A set Σ together with a mapping $\mathrm{rank}_\Sigma\colon \Sigma \to \mathbb{N}$ is called a *ranked set*. For $k \geq 0$, $\Sigma^{(k)}$ is the set $\{\sigma \in \Sigma \mid \mathrm{rank}_\Sigma(\sigma) = k\}$; we also write $\sigma^{(k)}$ to indicate that $\mathrm{rank}_\Sigma(\sigma) = k$. For sets Σ and A, $\langle \Sigma, A\rangle = \Sigma \times A$; if Σ is ranked, then so is $\langle \Sigma, A\rangle$, with $\mathrm{rank}_{\langle \Sigma, A\rangle}(\langle \sigma, a\rangle) = \mathrm{rank}_\Sigma(\sigma)$ for every $\langle \sigma, a\rangle \in \langle \Sigma, A\rangle$. A *ranked alphabet* is a finite ranked set.

For the rest of this paper we choose the *set of input variables* to be $X = \{x_1, x_2, \dots\}$ and the *set of parameters* to be $Y = \{y_1, y_2, \dots\}$. For $k \geq 0$, $X_k = \{x_1, \dots, x_k\}$ and $Y_k = \{y_1, \dots, y_k\}$. In this paper (as opposed to other papers) we allow a ranked set to contain parameters. However, by convention, if a parameter is an element of a ranked set Σ, then we require that it have rank zero; i.e., we require that $\Sigma \cap Y \subseteq \Sigma^{(0)}$. Thus, *parameters have rank zero.*

Let Σ be a ranked set. The *set of trees over* Σ, denoted by T_Σ, is the smallest set of strings $T \subseteq \Sigma^*$ such that if $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $t_1, \dots, t_k \in T$, then $\sigma\, t_1 \cdots t_k \in T$.

For better readability we will usually write $\sigma(t_1, \ldots, t_k)$ for $\sigma\, t_1 \cdots t_k$. For a set of parameters $Y' \subseteq Y$ we will also use $T_\Sigma(Y')$ to denote the set of trees $T_{\Sigma \cup Y'}$, where $\Sigma \cup Y'$ is the ranked set with $\mathrm{rank}_{\Sigma\cup Y'}(\sigma) = \mathrm{rank}_\Sigma(\sigma)$ for $\sigma \in \Sigma$, and $\mathrm{rank}_{\Sigma\cup Y'}(y) = 0$ for $y \in Y'$.

For every tree $t \in T_\Sigma$, the *set of nodes of* t, denoted by $V(t)$, is a subset of $\mathbb{N}^*$ which is inductively defined as follows: if $t = \sigma(t_1, \ldots, t_k)$ with $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and for all $i \in [k], t_i \in T_\Sigma$, then $V(t) = \{\varepsilon\} \cup \{iu \mid u \in V(t_i), i \in [k]\}$. Thus, ε represents the root of a tree, and for a node u the ith child of u is represented by ui. A *leaf* is a node without children. If $u = vw$ with $w \in \mathbb{N}^*$, then v is an *ancestor of* u and u is a *descendant of* v; if $w \neq \varepsilon$, then v is a *proper ancestor of* u, and u is a *proper descendant of* v. The *label of* t *at node* u is denoted by $t[u]$; we also say that $t[u]$ occurs in t (at u). The *subtree of* t *at node* u is denoted by t/u. The *substitution of the tree* $s \in T_\Sigma$ *at node* u *in* t is denoted by $t[u \leftarrow s]$; it means that the subtree t/u is replaced by s. Formally, these notions can be defined as follows: $t[\varepsilon]$ is the first symbol of t (in Σ), $t/\varepsilon = t$, $t[\varepsilon \leftarrow s] = s$, and if $t = \sigma(t_1, \ldots, t_k)$, $i \in [k]$, and $u \in V(t_i)$, then $t[iu] = t_i[u]$, $t/iu = t_i/u$, and $t[iu \leftarrow s] = \sigma(t_1, \ldots, t_i[u \leftarrow s], \ldots, t_k)$.

The usual preorder of the nodes of t (which, in fact, is the lexicographical order on $\mathbb{N}^*$) is denoted $<$; thus, $\varepsilon < iu$ (for $i \geq 1$), if $u < v$, then $iu < iv$, and if $i < j$, then $iu < jv$.

The *size* of a tree t, denoted by $\mathrm{size}(t)$, is the number $|V(t)|$ of nodes of t. For $t = \sigma(t_1, \ldots, t_k)$, $\mathrm{size}(t)$ equals $1 + \mathrm{size}(t_1) + \cdots + \mathrm{size}(t_k)$; note that $\mathrm{size}(t) = \sum_{\sigma\in\Sigma} \#_\sigma(t) = |t|$. For $\sigma \in \Sigma$, $V_\sigma(t)$ denotes the set of nodes of t which are labeled by σ, i.e., $\{u \in V(t) \mid t[u] = \sigma\}$; note that $|V_\sigma(t)| = \#_\sigma(t)$: the number of occurrences of σ in t. For a set $S \subseteq \Sigma$, $V_S(t) = \bigcup_{\sigma\in S} V_\sigma(t)$. The *height* of t is denoted by $\mathrm{height}(t)$; for $t = \sigma(t_1, \ldots, t_k)$ it equals $1 + \max\{\mathrm{height}(t_i) \mid i \in [k]\}$.

2.2. Tree substitution. In the previous subsection on trees we already defined a particular tree substitution: for trees t, s and a node u of t, $t[u \leftarrow s]$ is the result of replacing in t the subtree t/u by s. Now we want to consider replacing in t all occurrences of a symbol σ.

Trees are particular strings and therefore string substitution as defined in the beginning of these preliminaries is applicable to a tree. In order to guarantee that the resulting string is again a tree, we require that only symbols of rank zero, i.e., leaves, may be replaced by trees; we refer to this type of substitution as "first-order tree substitution." Note that top-down tree transducers are based on first-order tree substitution. In contrast to this, "second-order tree substitution" means that symbols of arbitrary rank can be replaced by a tree. This is the type of substitution MTTs are based on. Consider the replacement of a symbol σ of rank k by a tree s in which the parameter symbols $y_1, \ldots, y_k$ occur to indicate where the subtrees of σ have to be inserted. Now, if σ occurs at a node u of the tree t, then replacing it by s means to replace the subtree t/u of t by the tree $s[y_1 \leftarrow t/u1, \ldots, y_k \leftarrow t/uk]$. (Hence the first-order tree substitution is used to define the second-order one.) Now we define second-order tree substitution formally. Since all occurrences of σ have to be replaced simultaneously, an inductive definition is appropriate.

Let Σ be a ranked set and let $\sigma_1, \ldots, \sigma_n$ be distinct elements of $\Sigma - Y$, $n \geq 1$, and for each $i \in [n]$ let s_i be a tree in $T_{\Sigma-Y}(Y_{\mathrm{rank}_\Sigma(\sigma_i)})$. For $t \in T_\Sigma$, the *second-order tree substitution of* σ_i *by* s_i *in* t, denoted by $t[\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$, is inductively defined as follows (abbreviating $[\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ by $[\![\ldots]\!]$): For $t = \sigma(t_1, \ldots, t_k)$ with $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $t_1, \ldots, t_k \in T_\Sigma$, (i) if $\sigma = \sigma_i$ for an $i \in [n]$, then $t[\![\ldots]\!] = s_i[y_j \leftarrow t_j[\![\ldots]\!] \mid j \in [k]]$ and (ii) otherwise $t[\![\ldots]\!] = \sigma(t_1[\![\ldots]\!], \ldots, t_k[\![\ldots]\!])$.

We will say that $[\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ is a second-order tree substitution over Σ. Note that it is a mapping from T_Σ to T_Σ. In fact, it is a tree homomorphism [31]. Note also that (just as first-order tree substitution) second-order tree substitution is associative (by the closure of tree homomorphisms under composition; cf. Theorem IV.3.7 of [31]), i.e., $t[\![\sigma \leftarrow s]\!][\![\sigma \leftarrow s']\!] = t[\![\sigma \leftarrow s[\![\sigma \leftarrow s']\!]]\!]$, and if $\sigma' \neq \sigma$, then $t[\![\sigma \leftarrow s]\!][\![\sigma' \leftarrow s']\!] = t[\![\sigma' \leftarrow s', \sigma \leftarrow s[\![\sigma' \leftarrow s']\!]]\!]$, and similarly for the general case (cf. sections 3.4 and 3.7 of [4]). Let P be a condition on σ and s such that $\{(\sigma, s) \mid P\}$ is a partial function; then we use $[\![\sigma \leftarrow s \mid P]\!]$ to denote the substitution $[\![L]\!]$, where L is the list of all $\sigma \leftarrow s$ for which condition P holds. In second-order tree substitutions we use for the relabeling $\sigma \leftarrow \delta(y_1, \ldots, y_k)$ of $\sigma^{(k)}$ by $\delta^{(k)}$ the abbreviation $\sigma \leftarrow \delta$; note that this is, in fact, a string substitution.

Note that the restrictions on σ_i and s_i in the first sentence of the previous paragraph are rather subtle. Recall from section 2.1 that Σ can contain parameters. However, for technical reasons, we do not want a second-order tree substitution to replace parameters (hence $\sigma_i \in \Sigma - Y$), and we do not want it to introduce parameters (hence $s_i \in T_{\Sigma - Y}(Y_{\mathrm{rank}_\Sigma(\sigma_i)})$, which means that $s_i \in T_{\Sigma \cup Y}$, and if y_j occurs in s_i, then $j \leq \mathrm{rank}_\Sigma(\sigma_i)$).

The second-order tree substitution $[\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ is *nondeleting* if for every $i \in [n]$, $\#_{y_j}(s_i) \geq 1$ for all $j \in [\mathrm{rank}_\Sigma(\sigma_i)]$, and it is *nonerasing* if for every $i \in [n]$, $s_i \notin Y$. It is *productive* if it is both nondeleting and nonerasing.

LEMMA 2.1. *Let Σ be a ranked alphabet and $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ a nondeleting second-order tree substitution over Σ. For all $t, t' \in T_\Sigma$, if t' is a subtree of t, then $t'\Phi$ is a subtree of $t\Phi$. In particular, for $y \in Y$, if $\#_y(t) \geq 1$, then $\#_y(t\Phi) \geq 1$.*

Proof. For $t = \sigma(t_1, \ldots, t_k)$, $t_j\Phi$ is a subtree of $t\Phi$. Hence the result follows immediately by induction on the structure of t.

If $\#_y(t) \geq 1$, then y is a subtree of t (because, by convention, the parameter y has rank 0). This means, by the first part of this lemma, that y is also a subtree of $t\Phi$, i.e., $\#_y(t\Phi) \geq 1$. Note that $y\Phi = y$ because, by the definition of second-order tree substitution, $\sigma_i \notin Y$ for all $i \in [n]$. □

LEMMA 2.2. *Let Σ be a ranked alphabet and $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ a nonerasing second-order tree substitution over Σ. For every $t \in T_\Sigma$, if $t \notin Y$, then $t\Phi \notin Y$.*

Proof. Let $t = \sigma(t_1, \ldots, t_k)$ with $\sigma \in \Sigma^{(k)} - Y$. If $\sigma \notin \{\sigma_1, \ldots, \sigma_n\}$, then $t\Phi = \sigma(t_1\Phi, \ldots, t_k\Phi) \notin Y$. If $\sigma = \sigma_i$ for some $i \in [n]$, then $t\Phi = s_i[y_j \leftarrow t_j\Phi \mid j \in [k]] \notin Y$ (because $s_i \notin Y$). □

In order to calculate the number of times that a particular node u of a tree is copied by the application of a second-order tree substitution, we need to know which symbols occur at the ancestors of u. For this we define the string obtained by reading the labels of the ancestors of u in descending order, starting at the root; if u is labeled by a parameter, then we do not include its label in this string, because in trees of the form $t[\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ the parameters present in the trees s_i do not appear (by the requirement that $s_i \in T_{\Sigma - Y}(Y_{\mathrm{rank}_\Sigma(\sigma_i)})$).

For a tree $t \in T_\Sigma$ and a node $u \in V(t)$, the *label path to u (in t)*, denoted by $\mathrm{lpath}(t, u)$, is the string in $(\Sigma - Y)^*$ defined recursively as follows: $\mathrm{lpath}(t, \varepsilon) = \varepsilon$ if $t \in Y$, and otherwise $\mathrm{lpath}(t, \varepsilon) = t[\varepsilon]$; for $i \geq 1$ and $u \in \mathbb{N}^*$, $\mathrm{lpath}(t, iu) = t[\varepsilon]\,\mathrm{lpath}(t/i, u)$. For example, let t be the tree $\gamma(\sigma(a, y_1))$; then $\mathrm{lpath}(t, 12) = \gamma\,\mathrm{lpath}(\sigma(a, y_1), 2) = \gamma\sigma\,\mathrm{lpath}(y_1, \varepsilon) = \gamma\sigma$, $\mathrm{lpath}(t, 1) = \gamma\sigma$, and $\mathrm{lpath}(t, 11) = \gamma\sigma a$.

The following lemma shows how a label path in t changes if a second-order tree

substitution is applied to t.

LEMMA 2.3. *Let Σ be a ranked alphabet, Φ the second-order tree substitution $[\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ over Σ, and $t \in T_\Sigma$.*

(i) *Every label path in $t\Phi$ is of the form $w_0 v_1 w_1 \cdots v_m w_m$, where $m \geq 0$, $w_0 \sigma_{i_1} w_1 \cdots \sigma_{i_m} w_m$ is a label path in t, $i_1, \ldots, i_m \in [n]$, v_j is a label path in s_{i_j} for $j \in [m]$, and $w_0, \ldots, w_m \in (\Sigma - \{\sigma_1, \ldots, \sigma_n\})^*$.*

(ii) *If Φ is nondeleting, then for every $w, v \in \Sigma^*$ such that $w\sigma_i$ is a label path in t and v is a label path in s_i, there is a $w' \in \Sigma^*$ such that $w'v$ is a label path in $t\Phi$.*

2.3. Number of occurrences. Since this paper is about the size increase of MTTs, and they are based on second-order tree substitution, we need to know how the size of a tree t changes when a second-order tree substitution Φ is applied to t. Recall that $\mathrm{size}(t\Phi)$ is the sum of the numbers $\#_\sigma(t\Phi)$ of occurrences of σ in $t\Phi$ for all symbols σ. Thus, we need to determine the number $\#_\sigma(t\Phi)$. Since second-order tree substitution is based on first-order tree substitution which is a particular string substitution, we first determine the number $\#_a(w[\ldots])$, where w is a string and $[\ldots]$ is a string substitution.

The following lemma can be proved by straightforward induction on the length of w.

LEMMA 2.4. *Let A be an alphabet. Let $w, v_1, \ldots, v_n \in A^*$ and let $a_1, \ldots, a_n$ be distinct elements of A. For every $a \in A$,*

$$\#_a(w[a_1 \leftarrow v_1, \ldots, a_n \leftarrow v_n]) = S^a + \sum_{i \in [n]} \#_{a_i}(w) \cdot \#_a(v_i),$$

where $S^a = \#_a(w)$ if $a \notin \{a_1, \ldots, a_n\}$, and otherwise $S^a = 0$.

In the next lemma we prove the generalization of Lemma 2.4 to second-order tree substitution. Intuitively we now have to take into account, for a node u of the tree t, how many times it is copied by the application of the second-order tree substitution $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$. For each σ_i that occurs at a proper ancestor u' of u, u is in some subtree $t/u'j$ of u'; thus, replacing σ_i by s_i generates $\#_{y_j}(s_i)$ copies of $t/u'j$. Hence, the product of these numbers $\#_{y_j}(s_i)$, for all proper ancestors u', determines the number of copies of u in $t\Phi$. In the lemma this product is denoted $\prod F^\Phi_{t,u}$, where the family $F^\Phi_{t,u}$ of numbers is defined as follows.

DEFINITION 2.5 (the family $F^\Phi_{t,u}$). *Let Σ be a ranked alphabet and $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ a second-order tree substitution over Σ. For every $t \in T_\Sigma$ and $u \in V(t)$, define the family $F^\Phi_{t,u}$ as*

$$F^\Phi_{t,u} = \{f_{u'}\}_{u' \text{ proper ancestor of } u},$$

where

$$f_{u'} = \begin{cases} 1 & \text{if } t[u'] \notin \{\sigma_1, \ldots, \sigma_n\}, \\ \#_{y_j}(s_i) & \text{if } t[u'] = \sigma_i, i \in [n], \text{ and } u = u'ju'' \text{ with } j \geq 1, u'' \in \mathbb{N}^*. \end{cases}$$

Note that if $u = \varepsilon$, i.e., $F^\Phi_{t,u}$ is empty, then $\prod F^\Phi_{t,u} = 1$.

LEMMA 2.6. *Let Σ be a ranked alphabet, $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ a second-order tree substitution over Σ, and $t \in T_\Sigma$. For every $\sigma \in \Sigma$,*

$$\#_\sigma(t\Phi) = S^\sigma_1 + S^\sigma_2,$$

where

$$S_1^\sigma = \sum_{u \in V_\sigma(t)} \prod F_{t,u}^\Phi \quad \textit{if } \sigma \notin \{\sigma_1, \ldots, \sigma_n\}, \textit{ and otherwise } S_1^\sigma = 0,$$

$$S_2^\sigma = \sum_{u \in V_{\sigma_i}(t), i \in [n]} \#_\sigma(s_i) \cdot \prod F_{t,u}^\Phi \quad \textit{if } \sigma \notin Y, \textit{ and otherwise } S_2^\sigma = 0.$$

Proof. Denote $\{\sigma_1, \ldots, \sigma_n\}$ by Σ_n. Let $O_\varepsilon = V_\sigma(t) \cap \{\varepsilon\}$, $O = V_\sigma(t) - \{\varepsilon\}$, and for $i \in [n]$, $O_{\varepsilon,i} = V_{\sigma_i}(t) \cap \{\varepsilon\}$ and $O_i = V_{\sigma_i}(t) - \{\varepsilon\}$. Clearly, $S_1^\sigma = T_1 + S_1$, where for $\sigma \notin \Sigma_n$, $T_1 = \sum_{u \in O_\varepsilon} \prod F_{t,u}^\Phi$ and $S_1 = \sum_{u \in O} \prod F_{t,u}^\Phi$, and otherwise $T_1 = 0$ and $S_1 = 0$. Similarly, $S_2^\sigma = T_2 + S_2$, where for $\sigma \notin Y$, $T_2 = \sum_{u \in O_{\varepsilon,i}, i \in [n]} \#_\sigma(s_i) \cdot \prod F_{t,u}^\Phi$ and $S_2 = \sum_{u \in O_i, i \in [n]} \#_\sigma(s_i) \cdot \prod F_{t,u}^\Phi$, and otherwise $T_2 = 0$ and $S_2 = 0$.

The proof that $S_1^\sigma + S_2^\sigma$ equals $\#_\sigma(t\Phi)$ is by induction on the structure of t. Let $t = \sigma'(t_1, \ldots, t_k)$ with $\sigma' \in \Sigma^{(k)}$, $k \geq 0$, and $t_1, \ldots, t_k \in T_\Sigma$.

Case 1. $\sigma' \in \Sigma - \Sigma_n$.

Then $t[\varepsilon] \notin \Sigma_n$ and hence, for every $j \in [k]$ and $v \in V(t_j)$, $\prod F_{t,jv}^\Phi = \prod F_{t_j,v}^\Phi$. Since O equals $\bigcup_{j \in [k]} \{jv \mid v \in V_\sigma(t_j)\}$, it follows that $\sum_{u \in O} \prod F_{t,u}^\Phi$ is equal to $\sum_{v \in V_\sigma(t_j), j \in [k]} \prod F_{t_j,v}^\Phi$, and similarly for O_i. We can apply the induction hypothesis for t_j to $S_{1,j}^\sigma + S_{2,j}^\sigma$, where $S_{1,j}^\sigma = \sum_{v \in V_\sigma(t_j)} \prod F_{t_j,v}^\Phi$ if $\sigma \notin \Sigma_n$, and otherwise $S_{1,j}^\sigma = 0$, and $S_{2,j}^\sigma = \sum_{v \in V_{\sigma_i}(t_j), i \in [n]} \#_\sigma(s_i) \cdot \prod F_{t_j,v}^\Phi$ if $\sigma \notin Y$, and otherwise $S_{2,j}^\sigma = 0$. Since $O_{\varepsilon,i} = \varnothing$ we get that $T_2 = 0$ and hence

$$S_1^\sigma + S_2^\sigma = T_1 + \sum_{j \in [k]} \#_\sigma(t_j\Phi).$$

Now T_1 equals 1 if $\sigma' = \sigma$, and 0 otherwise. By the definition of $\#_\sigma$ this means that the above is equal to $\#_\sigma(\sigma'(t_1\Phi, \ldots, t_k\Phi))$. This equals $\#_\sigma(t\Phi)$ by the definition of second-order tree substitution.

Case 2. $\sigma' = \sigma_i$ for some $i \in [n]$.

For every $j \in [k]$ and $v \in V(t_j)$, $\prod F_{t,jv}^\Phi = \#_{y_j}(s_i) \cdot \prod F_{t_j,v}^\Phi$. Thus, $S_1 = \sum_{j \in [k]} \#_{y_j}(s_i) \cdot S_{1,j}^\sigma$ and $S_2 = \sum_{j \in [k]} \#_{y_j}(s_i) \cdot S_{2,j}^\sigma$. By induction, $S_{1,j}^\sigma + S_{2,j}^\sigma = \#_\sigma(t_j\Phi)$. Hence $S_1 + S_2 = \sum_{j \in [k]} \#_{y_j}(s_i) \cdot \#_\sigma(t_j\Phi)$. Now $T_1 = 0$, and if $\sigma \notin Y$, then $T_2 = \#_\sigma(s_i)$, and otherwise $T_2 = 0$. We can apply Lemma 2.4 to $T_1 + T_2 + S_1 + S_2$ (with $a = \sigma$ and $S^a = T_2$) to obtain $\#_\sigma(s_i[y_j \leftarrow t_j\Phi \mid j \in [k]])$, which equals $\#_\sigma(t\Phi)$ by the definition of second-order tree substitution. □

Recall from section 2.2 that the second-order tree substitution $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ is nondeleting if each s_i contains at least one occurrence of y_j for every $j \in [\mathrm{rank}_\Sigma(\sigma_i)]$, and nonerasing if no s_i is in Y. We can now use Lemma 2.6 to prove that if Φ is productive, i.e., both nondeleting and nonerasing, then its application does not decrease the size of a tree.

LEMMA 2.7. *Let Σ be a ranked alphabet and $\Phi = [\![\sigma_1 \leftarrow s_1, \ldots, \sigma_n \leftarrow s_n]\!]$ a second-order tree substitution over Σ. If Φ is productive, then size$(t\Phi) \geq$ size(t) for every $t \in T_\Sigma$.*

Proof. Let $\Sigma_n = \{\sigma_1, \ldots, \sigma_n\}$. Since $\mathrm{size}(t\Phi) = \sum_{\sigma \in \Sigma} \#_\sigma(t\Phi)$, we can apply Lemma 2.6 to obtain $\sum_{\sigma \in \Sigma} S_1^\sigma + \sum_{\sigma \in \Sigma} S_2^\sigma$, where S_1^σ and S_2^σ are as in Lemma 2.6.

Since Φ is nondeleting, for every $u \in V_\sigma(t)$, $\prod F_{t,u}^\Phi \geq 1$. Thus

$$\mathrm{size}(t\Phi) \geq \sum_{\sigma \in \Sigma - \Sigma_n, u \in V_\sigma(t)} 1 + \sum_{u \in V_{\sigma_i}(t), i \in [n]} \sum_{\sigma \in \Sigma - Y} \#_\sigma(s_i).$$

Since Φ is nonerasing, each s_i contains at least one symbol in $\Sigma - Y$. Hence

$$\text{size}(t\Phi) \geq \sum_{\sigma\in\Sigma-\Sigma_n, u\in V_\sigma(t)} 1 + \sum_{\sigma\in\Sigma_n, u\in V_\sigma(t)} 1 = \sum_{\sigma\in\Sigma, u\in V_\sigma(t)} 1 = \text{size}(t). \qquad \square$$

2.4. Tree languages. A *tree language* is a subset of T_Σ for some ranked alphabet Σ.

A *finite state tree automaton* is a tuple (P, Σ, h), where P is a finite set of *states*, Σ is a ranked alphabet of *input symbols* such that Σ is disjoint with P, and h is a collection of mappings such that for every $\sigma \in \Sigma^{(k)}$, h_σ is a mapping from P^k to P. The extension $\tilde{h}$ of h to a mapping from T_Σ to P is recursively defined as $\tilde{h}(\sigma(s_1, \ldots, s_k)) = h_\sigma(\tilde{h}(s_1), \ldots, \tilde{h}(s_k))$ for every $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in T_\Sigma$. Throughout this paper we simply write $h(s)$ to mean $\tilde{h}(s)$ for $s \in T_\Sigma$. A tree language L is *regular* (or *recognizable*) if there is a finite state tree automaton (P, Σ, h) and a subset F of P such that $L = \{s \in T_\Sigma \mid h(s) \in F\}$. For $p \in P$ the tree language $\{s \in T_\Sigma \mid h(s) = p\}$ is denoted by L_p. Note that, in particular, L_p is regular for every $p \in P$.

2.5. Tree translations. Let Σ and Δ be ranked alphabets. A (total) function $\tau : T_\Sigma \to T_\Delta$ is called a *tree translation* or simply a translation. For a tree language $L \subseteq T_\Sigma$, $\tau(L)$ denotes the set $\{t \in T_\Delta \mid t = \tau(s) \text{ for some } s \in L\}$, and for $L \subseteq T_\Delta$, $\tau^{-1}(L)$ denotes $\{s \in T_\Sigma \mid \tau(s) \in L\}$. For a class $\mathcal{T}$ of tree translations and a class $\mathcal{L}$ of tree languages, $\mathcal{T}(\mathcal{L})$ denotes the class of tree languages $\{\tau(L) \mid \tau \in \mathcal{T}, L \in \mathcal{L}\}$.

A tree translation $\tau : T_\Sigma \to T_\Delta$ is *of linear size increase* (for short, *lsi*) if there is a $c \in \mathbb{N}$ such that $\text{size}(\tau(s)) \leq c \cdot \text{size}(s)$ for all $s \in T_\Sigma$. The class of all tree translations of linear size increase is denoted *LSI*.

We will now shortly define MSO definability of a tree translation. This definition will, however, not be needed in the paper. Let k be the maximal rank of a symbol in Δ. The tree translation $\tau : T_\Sigma \to T_\Delta$ is *MSO definable* (i.e., definable in monadic second-order logic) if there is an *MSO tree transducer* which realizes τ, that is, if there exist a finite set C and MSO(Σ)-formulas $\nu_c(x)$, $\psi_{\delta,c}(x)$, and $\chi_{i,c,d}(x, y)$, with $c, d \in C$, $\delta \in \Delta$, and $1 \leq i \leq k$, such that for every $s \in T_\Sigma$, $\tau(s) \in T_\Delta$ is isomorphic to the tree t with set of nodes $\{(c, x) \in C \times V(s) \mid s \models \nu_c(x)\}$, node (c, x) has label δ if and only if $s \models \psi_{\delta,c}(x)$, and (d, y) is the ith child of (c, x) if and only if $s \models \chi_{i,c,d}(x, y)$. An MSO($\Sigma$)-formula is a formula of MSO logic that uses atomic formulas $\text{lab}_\sigma(x)$ and $\text{child}_i(x, y)$, with $\sigma \in \Sigma$ and $i \geq 1$, to express that x has label σ and y is the ith child of x, respectively. The class of all MSO definable tree translations is denoted *MSOTT*. For examples and more details, see, e.g., [5, 3]. Note that, by definition, every MSO definable tree translation τ is of linear size increase: $\text{size}(\tau(s)) \leq |C| \cdot \text{size}(s)$. Thus, $MSOTT \subseteq LSI$.

3. Macro tree transducers. In this section we recall the definition of MTTs and some basic lemmas about them. Furthermore, we consider two subclasses of MTTs which are defined by certain (static) restrictions on the rules of the transducers.

3.1. Basic definitions and results. A macro tree transducer is a syntax-directed translation device in which the translation of an input tree may depend on its subtrees, represented by input variables $x_1, x_2, \ldots$, and on its context, represented by parameters $y_1, y_2, \ldots$. A rule of an MTT is of the form $\langle q, \sigma(x_1, \ldots, x_k)\rangle(y_1, \ldots, y_m) \to \zeta$, where q is a state of rank m and σ is an input symbol of rank k. The left-hand side will be viewed as a tree with a root, labeled $\langle q, \sigma(x_1, \ldots, x_k)\rangle$, and m children, labeled

$y_1, \ldots, y_m$, respectively. The right-hand side ζ is a tree over output symbols, the parameters $y_1, \ldots, y_m$, and symbols $\langle q', x_i \rangle$, where q' is a (ranked) state and $1 \leq i \leq k$. Thus, the MTT generalizes the top-down tree transducer in the sense that states have parameters. Note that symbols $\langle q', x_i \rangle$ can occur at any node of ζ, not just at leaves as in the case of top-down tree transducers.

We consider only *total deterministic* MTTs. For technical reasons we add the feature of regular look-ahead to them (this does not change the class of translations; cf. Theorem 4.21 of [24]). Regular look-ahead means that in a rule as above the input variables $x_1, \ldots, x_k$ range over regular tree languages. Formally, these regular tree languages are combined into one finite state tree automaton.

DEFINITION 3.1 (MTT with regular look-ahead). *A* macro tree transducer with regular look-ahead *(for short, MTT$^{\mathrm{R}}$) is a tuple $M = (Q, P, \Sigma, \Delta, q_0, R, h)$, where Q is a ranked alphabet of* states, *Σ and Δ are ranked alphabets of* input *and* output symbols, *respectively, $\Delta \cap Y = \varnothing$, $q_0 \in Q^{(0)}$ is the* initial state, *(P, Σ, h) is a finite state tree automaton, called the* look-ahead automaton of *M, and R is a finite set of* rules *of the following form: For every $q \in Q^{(m)}$, $\sigma \in \Sigma^{(k)}$, and $p_1, \ldots, p_k \in P$ with $m, k \geq 0$ there is exactly one rule of the form*

$$(*) \qquad \langle q, \sigma(x_1, \ldots, x_k) \rangle (y_1, \ldots, y_m) \to \zeta \quad \langle p_1, \ldots, p_k \rangle$$

in R, where $\zeta \in T_{\langle Q, X_k \rangle \cup \Delta}(Y_m)$.

A rule r of the form $(*)$ is called the $(q, \sigma, \langle p_1, \ldots, p_k \rangle)$-rule and its right-hand side ζ is denoted by $\mathrm{rhs}(r)$ or by $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k \rangle)$; it is also called a q-rule, a σ-rule, or a (q, σ)-rule. A *top-down tree transducer with regular look-ahead* (for short, T$^{\mathrm{R}}$) is an MTT$^{\mathrm{R}}$ all states of which are of rank zero. If the look-ahead automaton is trivial, i.e., $P = \{p\}$ and $h_\sigma(p, \ldots, p) = p$ for all $\sigma \in \Sigma$, then M is called an *MTT*, and if M is a T$^{\mathrm{R}}$, then M is called a *top-down tree transducer*. In such cases we omit the look-ahead automaton and simply denote M by $(Q, \Sigma, \Delta, q_0, R)$; we also omit the look-ahead part $\langle p_1, \ldots, p_k \rangle$ in every rule $(*)$.

We now define the derivation relation induced by an MTT$^{\mathrm{R}}$ M. Recall from section 2.2 that in a second-order tree substitution $\langle q', x_i \rangle \leftarrow \langle q', s_i \rangle$ is shorthand for $\langle q', x_i \rangle \leftarrow \langle q', s_i \rangle (y_1, \ldots, y_n)$, where n is the rank of q'.

DEFINITION 3.2 (derivation relation). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. The* derivation relation induced by *M, denoted by $\Rightarrow_M$, is the binary relation on $T_{\langle Q, T_\Sigma \rangle \cup \Delta}(Y)$ such that, for every $\xi_1, \xi_2 \in T_{\langle Q, T_\Sigma \rangle \cup \Delta}(Y)$, $\xi_1 \Rightarrow_M \xi_2$ if and only if there exist $u \in V(\xi_1)$, $\sigma \in \Sigma^{(k)}$, $s_1, \ldots, s_k \in T_\Sigma$, $q \in Q^{(m)}$, and $t_1, \ldots, t_m \in T_{\langle Q, T_\Sigma \rangle \cup \Delta}(Y)$ such that $\xi_1/u = \langle q, \sigma(s_1, \ldots, s_k) \rangle (t_1, \ldots, t_m)$ and $\xi_2 = \xi_1[u \leftarrow \zeta]$, where ζ equals*

$$\mathrm{rhs}_M(q, \sigma, \langle h(s_1), \ldots, h(s_k) \rangle) [\![\langle q', x_i \rangle \leftarrow \langle q', s_i \rangle \mid \langle q', x_i \rangle \in \langle Q, X_k \rangle]\!] [y_j \leftarrow t_j \mid j \in [m]].$$

Since the derivation relation $\Rightarrow_M$ induced by M is confluent and terminating (cf., e.g., Chapter 4 of [28]) there is, for every tree $\xi \in T_{\langle Q, T_\Sigma \rangle \cup \Delta}(Y_m)$, a unique tree $t \in T_\Delta(Y_m)$ such that $\xi \Rightarrow_M^* t$ (in fact, t is the normal form of ξ with respect to $\Rightarrow_M$).

DEFINITION 3.3 (translation). *For every $q \in Q^{(m)}$ and $s \in T_\Sigma$ the* q-translation of *s, denoted by $M_q(s)$, is the unique tree $t \in T_\Delta(Y_m)$ such that $\langle q, s \rangle (y_1, \ldots, y_m) \Rightarrow_M^* t$. Thus, for $q \in Q^{(m)}$, M_q is a (total) function from T_Σ to $T_\Delta(Y_m)$. The* translation realized by *M, denoted by τ_M, is the (total) function $M_{q_0} : T_\Sigma \to T_\Delta$.*

Thus, $\tau_M = M_{q_0}$ and for $s \in T_\Sigma$, $\tau_M(s) = M_{q_0}(s)$ is the unique tree $t \in T_\Delta$ such that $\langle q_0, s \rangle \Rightarrow_M^* t$. If $\tau_M(s) = t$, then s is an *input tree* (of M) and t is the corresponding *output tree* (of M).

An $\mathrm{MTT}^{\mathrm{R}}$ is *of linear size increase* (for short, lsi) if τ_M is lsi (cf. section 2.5). Two $\mathrm{MTT}^{\mathrm{R}}$s M and M' are *equivalent* if $\tau_M = \tau_{M'}$. The class of all translations which can be realized by MTTs and $\mathrm{MTT}^{\mathrm{R}}$s is denoted by MTT and MTT^R, respectively. The class of all translations which can be realized by T^{R}s is denoted by T^R.

LEMMA 3.4 (Theorem 4.21 of [24]). *$MTT^R = MTT$ (effectively).*

The q-translations $M_q(s)$ of trees $s \in T_\Sigma$ can be characterized inductively as follows, using second-order tree substitution.

LEMMA 3.5 (Lemma 4.8 of [26]). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. For every $q \in Q$, $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in T_\Sigma$,*

$$M_q(\sigma(s_1, \ldots, s_k)) = \mathrm{rhs}_M(q, \sigma, \langle h(s_1), \ldots, h(s_k)\rangle)[\![\langle q', x_i\rangle \leftarrow M_{q'}(s_i) \mid \langle q', x_i\rangle \in \langle Q, X_k\rangle]\!].$$

As mentioned in the introduction, macro tree translations can be of double exponential size increase. This is shown in the following example.

Example 3.6. Let $M = (Q, \Sigma, \Delta, q_0, R)$ be the MTT with $Q = \{q_0^{(0)}, q^{(1)}\}$, $\Sigma = \{\sigma^{(1)}, \alpha^{(0)}\}$, $\Delta = \{\delta^{(2)}, \beta^{(0)}\}$, and R consisting of the following rules:

$$\begin{array}{lcl} \langle q_0, \sigma(x_1)\rangle & \to & \langle q, x_1\rangle(\beta), \\ \langle q_0, \alpha\rangle & \to & \beta, \\ \langle q, \sigma(x_1)\rangle(y_1) & \to & \langle q, x_1\rangle(\langle q, x_1\rangle(y_1)), \\ \langle q, \alpha\rangle(y_1) & \to & \delta(y_1, y_1). \end{array}$$

The MTT M translates α into β, and for $n \geq 0$ it translates the input tree $s_n = \sigma(\sigma^n(\alpha))$ into a full binary tree of height $2^n + 1$ (with 2^{2^n} leaves). Figure 3.1 shows a derivation of M: First $\langle q_0, s_n\rangle \Rightarrow_M \langle q, \sigma^n(\alpha)\rangle(\beta)$. Then, due to the copying of states of the (q, σ)-rule, $\langle q, \sigma^n(\alpha)\rangle(\beta)$ is translated into the monadic tree $\langle q, \alpha\rangle(\langle q, \alpha\rangle(\cdots\langle q, \alpha\rangle(\beta)\cdots))$ containing 2^n occurrences of $\langle q, \alpha\rangle$. At last, due to the copying of parameters of the (q, α)-rule, this monadic tree is translated into a full binary tree of height $2^n + 1$. Thus, the input tree s_n of size $n + 2$ is translated into a tree of size $2^{2^n+1} - 1$, and hence the translation realized by M is of double exponential size increase. Note that the q-translation $M_q(\sigma^n(\alpha)) \in T_\Delta(\{y_1\})$ is the full binary tree of height $2^n + 1$ in which each leaf is labeled y_1, denoted t_n in what follows. In fact, a derivation $\langle q, \sigma^n(\alpha)\rangle(y_1) \Rightarrow_M \langle q, \sigma^{n-1}(\alpha)\rangle(\langle q, \sigma^{n-1}(\alpha)\rangle(y_1)) \Rightarrow_M^* t_n$ can be obtained from Figure 3.1 by removing the first derivation step and changing every β into y_1. Another way of showing that $M_q(\sigma^n(\alpha)) = t_n$ is by induction on n, using Lemma 3.5. For $n = 0$, $M_q(\alpha) = \mathrm{rhs}_M(q, \alpha) = \delta(y_1, y_1) = t_0$. The induction step is proved as follows: $M_q(\sigma(\sigma^n(\alpha))) = \mathrm{rhs}_M(q, \sigma)[\![\langle q, x_1\rangle \leftarrow M_q(\sigma^n(\alpha))]\!] = \langle q, x_1\rangle(\langle q, x_1\rangle(y_1))[\![\langle q, x_1\rangle \leftarrow t_n]\!] = t_n[y_1 \leftarrow t_n] = t_{n+1}$. This ends the example.

The following two results are often used in this paper.

LEMMA 3.7 (Lemma 7.4(1) of [24]). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. For every $q \in Q^{(m)}$, $m \geq 0$, and regular tree language $L \subseteq T_\Delta(Y_m)$, $M_q^{-1}(L)$ is regular and can be defined effectively.*

Proof. In Lemma 7.4(1) of [24] the result is stated for the case $m = 0$. The general case can be reduced to this case as follows: For every $r \in Q$ let $\overline{r}$ be a symbol not in Σ. Define the $\mathrm{MTT}^{\mathrm{R}}$ $\overline{M} = (Q, P, \Sigma \cup \{\overline{r}^{(1)} \mid r \in Q\}, \Delta \cup \{\overline{y}_j^{(0)} \mid j \in [\overline{m}]\}, q_0, R \cup \overline{R}, h \cup \overline{h})$, where $\overline{m}$ is the maximal rank of a state of M. For every $r \in Q^{(n)}$, $n \geq 0$, and $p \in P$ let $\overline{h}_{\overline{r}}(p) = p$, and let the rule

$$\langle q_0, \overline{r}(x_1)\rangle \to \langle r, x_1\rangle(\overline{y}_1, \ldots, \overline{y}_n) \quad \langle p\rangle$$

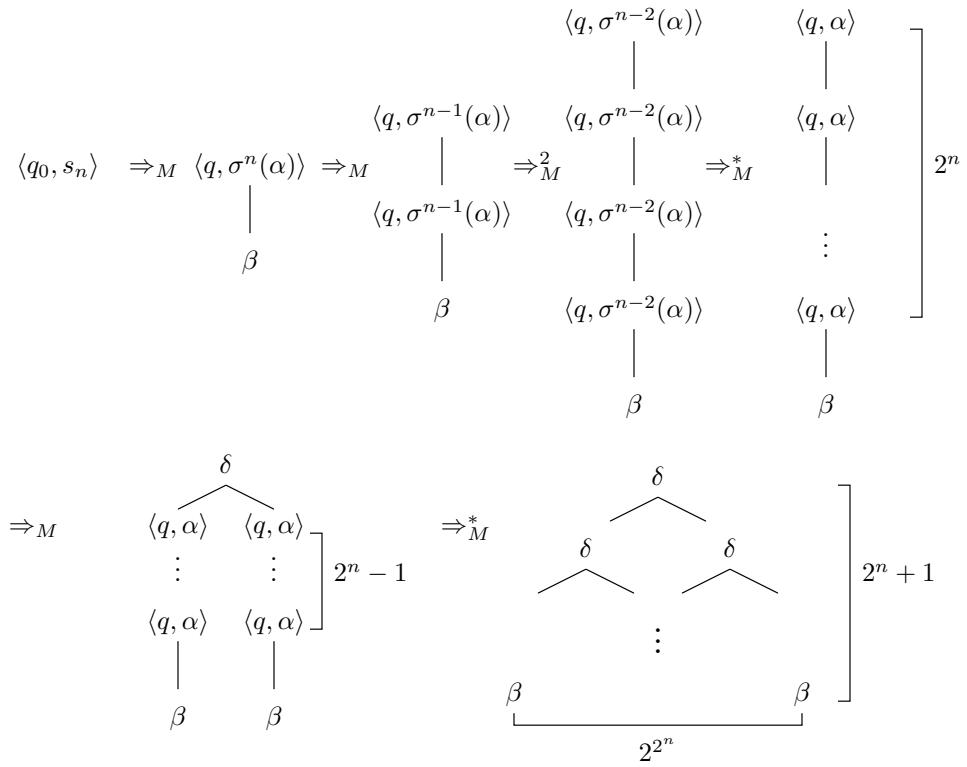

FIG. 3.1. *Derivation by* $\Rightarrow_M$.

be in $\overline{R}$. Clearly, $\tau_{\overline{M}}(\overline{r}(s)) = M_r(s)[y_j \leftarrow \overline{y}_j \mid j \in [n]]$ for every $s \in T_\Sigma$. Let $\overline{L} = \{t[y_j \leftarrow \overline{y}_j \mid j \in [m]] \mid t \in L\}$. By Lemma 7.4(1) of [24], $\tau_{\overline{M}}^{-1}(\overline{L})$ is (effectively) regular. Then also $\tau_{\overline{M}}^{-1}(\overline{L}) \cap \overline{q}(T_\Sigma) = \overline{q}(M_q^{-1}(L))$ is (effectively) regular (because regular tree languages are effectively closed under intersection; cf., e.g., Theorem II.4.2 of [31]). Since there is a linear top-down tree transducer that translates each tree $\overline{q}(t)$ into the tree t, and regular tree languages are (effectively) closed under linear top-down tree translations (see, e.g., Corollary IV.6.6 of [31]), we obtain that $M_q^{-1}(L)$ is (effectively) regular. □

The next lemma follows from Theorem 4.5 of [12] and Theorem 7.3 of [24] (and from the obvious fact that every regular tree language is the range of a nondeterministic top-down tree transducer; cf., e.g., Proposition 20.1(ii) of [32]). Note that we have not defined nondeterministic MTT$^{\mathrm{R}}$s and that we need to apply Lemma 3.8 only once to a nondeterministic (top-down) tree transducer (in Lemma 5.7).

LEMMA 3.8 (Theorem 4.5 of [12]). *For a regular tree language L and a finite number of (possibly nondeterministic) MTT^{R}s $M_1, \ldots, M_n$ it is decidable whether or not $\tau_{M_n}(\tau_{M_{n-1}}(\cdots \tau_{M_1}(L) \cdots))$ is finite. Moreover, if it is finite, it can be constructed.*

3.2. Subclasses defined by restrictions on the parameters. We now define two restrictions on the occurrences of parameters in the right-hand sides of the rules of an MTT$^{\mathrm{R}}$ M and then show that these restrictions carry over to the q-translations $M_q(s)$ of M.

DEFINITION 3.9 (nondeleting, nonerasing, productive). *Let* $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ *be an* MTT^R. *If for every* $q \in Q^{(m)}$, $m \geq 1$, $\sigma \in \Sigma^{(k)}$, $k \geq 0$, $p_1, \ldots, p_k \in P$, *and* $j \in [m]$,

- y_j *occurs at least once in* $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k \rangle)$, *then* M *is* nondeleting;
- $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k \rangle) \notin Y$, *then* M *is* nonerasing.

If M *is both nondeleting and nonerasing, then it is* productive.

LEMMA 3.10 (Lemma 7.11 of [19]). *For every* MTT^R M *there is a productive* MTT^R M' *equivalent to* M.

The following lemma shows that the restrictions nondeleting and nonerasing carry over from the right-hand sides of an $\mathrm{MTT^R}$ to the q-translations of M. In Lemma 6.7 of [19] a similar result is proved: if in the right-hand side of every q-rule each parameter y_j of q occurs exactly once, then y_j occurs exactly once in $M_q(s)$.

LEMMA 3.11. *Let* $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ *be an* MTT^R. *For every* $q \in Q^{(m)}$, $m \geq 0$, $j \in [m]$, *and* $s \in T_\Sigma$,

(1) *if* M *is nondeleting, then* $\#_{y_j}(M_q(s)) \geq 1$; *and*

(2) *if* M *is nonerasing, then* $M_q(s) \notin Y$.

Proof. The proof is by induction on the structure of s. Let $s = \sigma(s_1, \ldots, s_k)$ with $k \geq 0$ and $s_1, \ldots, s_k \in T_\Sigma$. Denote by t the tree $\mathrm{rhs}_M(q, \sigma, \langle h(s_1), \ldots, h(s_k) \rangle)$. By Lemma 3.5, $M_q(s) = t\Phi$ with $\Phi = [\![\langle q', x_i \rangle \leftarrow M_{q'}(s_i) \mid \langle q', x_i \rangle \in \langle Q, X_k \rangle]\!]$.

(1) By induction $\#_{y_\nu}(M_{q'}(s_i)) \geq 1$ for all $\langle q', x_i \rangle \in \langle Q, X_k \rangle^{(n)}$ and $\nu \in [n]$; i.e., the substitution Φ is nondeleting. Since M is nondeleting, $\#_{y_j}(t) \geq 1$ and thus, by Lemma 2.1, $\#_{y_j}(t\Phi) \geq 1$.

(2) By induction $M_{q'}(s_i) \notin Y$ for all $\langle q', x_i \rangle \in \langle Q, X_k \rangle$; i.e., the substitution Φ is nonerasing. Since M is nonerasing, $t \notin Y$ and thus, by Lemma 2.2, $t\Phi \notin Y$. □

4. Finite copying restrictions. In this section we define various restrictions on the copying that is performed by an $\mathrm{MTT^R}$. First, in section 4.1, copying restrictions for the input variables and for the parameters are defined. Both together form the "finite copying" restriction which was introduced in [19]; there it was shown (in Theorem 7.1) that the translations realized by finite copying $\mathrm{MTT^R}$s are precisely the MSO definable tree translations (cf. section 2.5). Since, by their definition, the MSO definable tree translations are lsi, this means that finite copying $\mathrm{MTT^R}$s are lsi. To keep this paper self-contained, we give, in section 4.3, a direct proof of this fact, which is based on the notion of "finite contribution." Intuitively, an $\mathrm{MTT^R}$ is of finite contribution if there is a bound on the number of output nodes contributed by a single node u of the input tree. In the terminology of [50], the node u is called the "origin" of the nodes of the output tree that it contributes; so, finite contribution means that there is a bound on the number of nodes that have the same origin. In [50] it is shown that for a primitive recursive scheme, which is an MTT, every node of an output tree has exactly one origin.

We also define, in section 4.2, a restriction on the copying that occurs on one path of the output tree, i.e., a restriction on the amount of nesting of states that occurs during the derivation of an $\mathrm{MTT^R}$. This notion will play an essential role in section 6, where it is proved that if the translation of an $\mathrm{MTT^R}$ is lsi, then it can also be realized by a finite copying $\mathrm{MTT^R}$ (and hence is MSO definable).

4.1. Finite copying in the input and in the parameters. Here we recall the definition of finite copying $\mathrm{MTT^R}$s from [19] and show that for an $\mathrm{MTT^R}$ it is decidable whether or not it is finite copying. The finite copying restriction was introduced in [1] for generalized syntax-directed translation schemes. For top-down tree transducers it was investigated in [22]. A top-down tree transducer is finite copying if every subtree

of the input tree is translated by boundedly many occurrences of states, i.e., the length of the state sequence is bounded, where the state sequence at a subtree s/u consists of the states that translate s/u. For an MTT this restriction is called finite copying in the input (fci), and we additionally have a restriction for the parameters, called finite copying in the parameters (fcp). The fcp restriction requires that, for every state q and input tree s, the number of parameters that occur in the q-translation $M_q(s)$ of s is bounded.

In order to define the state sequence of a tree s at the node u of s, we first extend an $\mathrm{MTT}^{\mathrm{R}}$ in such a way that the output tree t, for the input tree $s[u \leftarrow p]$, contains the states which process the subtree s/u (assuming that $p = h(s/u)$). More precisely, t contains $\langle\langle q, p\rangle\rangle$ if the state q translates s/u. Analogous to the definition of $\langle \Sigma, A\rangle$ let, for a ranked set Σ and a set A, $\langle\langle \Sigma, A\rangle\rangle$ be the ranked set of all symbols $\langle\langle \sigma, a\rangle\rangle$ of rank m for $\sigma \in \Sigma^{(m)}$ and $a \in A$.

Definition 4.1 (Definition 3.5 of [19]: extension). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. The* extension of M, *denoted by $\hat{M}$, is the MTT^R $(Q, P, \hat{\Sigma}, \hat{\Delta}, q_0, \hat{R}, \hat{h})$, where $\hat{\Sigma} = \Sigma \cup \{p^{(0)} \mid p \in P\}$, $\hat{\Delta} = \Delta \cup \langle\langle Q, P\rangle\rangle$, $\hat{R} = R \cup \{\langle q, p\rangle(y_1, \ldots, y_m) \to \langle\langle q, p\rangle\rangle(y_1, \ldots, y_m) \mid \langle q, p\rangle \in \langle Q, P\rangle^{(m)}\}$, $\hat{h}_p() = p$ for $p \in P$, and $\hat{h}_\sigma(p_1, \ldots, p_k) = h_\sigma(p_1, \ldots, p_k)$ for $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $p_1, \ldots, p_k \in P$.*

Note that if M is nondeleting or nonerasing, then so is $\hat{M}$. Before state sequences and the fci and fcp properties are defined, we present two useful lemmas about the q-translations of $\hat{M}$. The first lemma shows that the q-translation of an input tree s can be obtained by replacing in the q-translation of the "context" of a node u of s, $\hat{M}_q(s[u \leftarrow p])$, each occurrence of $\langle\langle q', p\rangle\rangle$ by the q'-translation $M_{q'}(s/u)$ of the subtree of s at u. In fact, the lemma is stated in the more general case that s/u may contain occurrences of symbols in P. The lemma can be seen as a generalization of Lemma 3.5 from the application of a rule at the root of s, to the translation of the context of an arbitrary node u.

Lemma 4.2 (Lemma 3.6 of [19]). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R and $\hat{M} = (Q, P, \hat{\Sigma}, \hat{\Delta}, q_0, \hat{R}, \hat{h})$ its extension. Let $q \in Q$, $s \in T_{\hat{\Sigma}}$, $u \in V(s)$, and $p = \hat{h}(s/u)$ such that $s[u \leftarrow p]$ contains exactly one occurrence of an element of P. Then*

$$\hat{M}_q(s) = \hat{M}_q(s[u \leftarrow p])[\![\langle\langle q', p\rangle\rangle \leftarrow \hat{M}_{q'}(s/u) \mid q' \in Q]\!].$$

The next lemma is obtained by application of Lemma 3.5 to the $\hat{M}_{q'}(s/u)$ in the substitution of Lemma 4.2. It shows how to express the translation of the context of a child node in terms of the translation of the context of its parent and the translations of the subtrees of its siblings.

Lemma 4.3. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. Let $q \in Q$, $s \in T_\Sigma$, and $u \in V(s)$. If $s[u] = \sigma \in \Sigma^{(k)}$, $i \in [k]$, $p_i \in P$, $p_j = h(s/uj)$ for every $j \in [k] - \{i\}$, and $p = h_\sigma(p_1, \ldots, p_k)$, then*

$$\hat{M}_q(s[ui \leftarrow p_i]) = \hat{M}_q(s[u \leftarrow p])[\![rhs]\!][\![..]\!][\![i]\!],$$

where

$$\begin{aligned} [\![\mathrm{rhs}]\!] &= [\![\langle\langle q', p\rangle\rangle \leftarrow \mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle) \mid q' \in Q]\!], \\ [\![..]\!] &= [\![\langle r, x_j\rangle \leftarrow M_r(s/uj) \mid r \in Q, j \in [k] - \{i\}]\!], \text{ and} \\ [\![i]\!] &= [\![\langle r, x_i\rangle \leftarrow \langle\langle r, p_i\rangle\rangle \mid r \in Q]\!]. \end{aligned}$$

Proof. Let $s' = s[ui \leftarrow p_i]$. Since $p = \hat{h}(s'/u)$ and $s'[u \leftarrow p]$ contains exactly one occurrence of an element of P, we can apply Lemma 4.2 to get $\hat{M}_q(s') = \hat{M}_q(s[u \leftarrow$

$p])[\![\langle\!\langle q', p\rangle\!\rangle \leftarrow \hat{M}_{q'}(s'/u) \mid q' \in Q]\!]$. Now $s'/u = \sigma(s_1, \ldots, s_k)$ with $s_i = p_i$ and $s_j = s/uj$ for every $j \in [k] - \{i\}$. By application of Lemma 3.5 to $\hat{M}_{q'}(s'/u)$ the above equals $\hat{M}_q(s[u \leftarrow p])[\![\langle\!\langle q', p\rangle\!\rangle \leftarrow \mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle)[\![\ldots]\!] \mid q' \in Q]\!]$, where $[\![\ldots]\!]$ denotes $[\![\langle r, x_j\rangle \leftarrow \hat{M}_r(s_j) \mid r \in Q, j \in [k]]\!]$. We now use the associativity of second-order tree substitution; cf. section 2.2. Since $\hat{M}_q(s[u \leftarrow p])$ does not contain elements of $\langle Q, X_k\rangle$ we can move $[\![\ldots]\!]$ out of the substitution to get $\hat{M}_q(s[u \leftarrow p])[\![\mathrm{rhs}]\!][\![\ldots]\!]$. For every $j \in [k] - \{i\}$, $\hat{M}_r(s_j) = M_r(s_j)$ does not contain elements of $\langle Q, \{x_i\}\rangle$; moreover, $\hat{M}_r(s_i) = \langle\!\langle r, p_i\rangle\!\rangle$. Thus we can write $[\![\ldots]\!]$ as $[\![..]\!][\![i]\!]$. ∎

We now turn to the definition of state sequence and the finite copying properties. Recall that the preorder of the nodes of a tree is denoted by $<$.

Definition 4.4 (Definition 3.7 of [19]: state sequence). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R, $s \in T_\Sigma$, and $u \in V(s)$. Let $p = h(s/u)$ and $\xi = \hat{M}_{q_0}(s[u \leftarrow p]) \in T_{\langle\!\langle Q,\{p\}\rangle\!\rangle \cup \Delta}$, and let $\{v \in V(\xi) \mid \xi[v] \in \langle\!\langle Q, \{p\}\rangle\!\rangle\} = \{v_1, \ldots, v_n\}$ with $v_1 < \cdots < v_n$. The* state sequence of s at u, *denoted by $\mathrm{sts}_M(s, u)$, is the sequence of states $q_1 \cdots q_n$ such that $\xi[v_i] = \langle\!\langle q_i, p\rangle\!\rangle$ for every $i \in [n]$.*

Observe that $|\mathrm{sts}_M(s, u)| = \#_{\langle\!\langle Q,\{p\}\rangle\!\rangle}(\hat{M}_{q_0}(s[u \leftarrow p]))$, where $p = h(s/u)$.

Definition 4.5 (Definition 6.1 of [19]: fci). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. Then M is* fci *if there is an $N \in \mathbb{N}$ such that for every $s \in T_\Sigma$ and $u \in V(s)$: $|\mathrm{sts}_M(s, u)| \le N$. The number N is an* input copying bound for M.

Definition 4.6 (Definition 6.2 of [19]: fcp). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. Then M is* fcp *if there is an $N \in \mathbb{N}$ such that for every $q \in Q^{(m)}$, $s \in T_\Sigma$, and $j \in [m]$, $\#_{y_j}(M_q(s)) \le N$. The number N is a* parameter copying bound for M.

Note that the MTT M of Example 3.6 is neither fci nor fcp. There is exponential state copying: the state sequence $\mathrm{sts}_M(s_n, 11^n)$ of $s_n = \sigma(\sigma^n(\beta))$ at 11^n equals q^{2^n}, and there is double exponential parameter copying: $\#_{y_1}(M_q(\sigma^n(\beta))) = 2^{2^n}$.

The following lemma shows that if M is fcp, i.e., if the number of occurrences of y_j in $M_q(s)$ is bounded by some N, for all states q and parameters y_j of q, then also for the q-translations of $\hat{M}$ of input trees $s[u \leftarrow p]$, the number of occurrences of y_j is bounded by N. However, we must assume that M is nondeleting.

Lemma 4.7. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting fcp MTT^R and let N be a parameter copying bound for M. For every $q \in Q^{(m)}$, $j \in [m]$, $s \in T_\Sigma$, and $u \in V(s)$, $\#_{y_j}(\hat{M}_q(s[u \leftarrow h(s/u)])) \le N$.*

Proof. Let $p = h(s/u)$. By Lemma 4.2, $M_q(s) = \xi[\![\ldots]\!]$ with $\xi = \hat{M}_q(s[u \leftarrow p])$ and $[\![\ldots]\!] = [\![\langle\!\langle q', p\rangle\!\rangle \leftarrow M_{q'}(s/u) \mid q' \in Q]\!]$. By Lemma 2.6, $\#_{y_j}(\xi[\![\ldots]\!]) = \sum_{v \in V_{y_j}(\xi)} \prod F_{\xi,v}^{[\![\ldots]\!]}$. Let $V_{y_j}(\xi) = \{v_1, \ldots, v_n\}$. Then the above sum equals

$$\prod F_{\xi,v_1}^{[\![\ldots]\!]} + \cdots + \prod F_{\xi,v_n}^{[\![\ldots]\!]} = \#_{y_j}(M_q(s)) \le N,$$

which implies that $n = \#_{y_j}(\xi) \le N$ because $\prod F_{\xi,v_i}^{[\![\ldots]\!]} \ge 1$ for every $i \in [n]$, by the fact that M is nondeleting, and hence, by Lemma 3.11(1), $\#_{y_k}(M_{q'}(s/u)) \ge 1$ for every $q' \in Q^{(m')}$ and $k \in [m']$. ∎

Finally, the combination of fci and fcp yields the finite copying property.

Definition 4.8 (finite copying). *An MTT^R is* finite copying *if it is both fci and fcp.*

We use the subscripts "fci," "fcp," or "fc" for classes of translations to denote that the corresponding MTT$^{\mathrm{R}}$s are fci, fcp, or finite copying, respectively. Thus $MTT^R_{\mathrm{fc}} = MTT^R_{\mathrm{fci,fcp}}$. The main result of [19] is that the translations of finite copying MTT$^{\mathrm{R}}$s are precisely the MSO definable tree translations (see section 2.5).

LEMMA 4.9 (Theorem 7.1 of [19]). *$MSOTT = MTT^R_{fc}$ (effectively).*

The main results of this paper are the following: (i) the translations of finite copying $\mathrm{MTT^R}$s are precisely the translations of $\mathrm{MTT^R}$s that are of linear size increase (i.e., $MTT^R \cap LSI = MTT^R_{\mathrm{fc}}$), and (ii) it is decidable for an $\mathrm{MTT^R}$ M whether or not there exists an equivalent finite copying $\mathrm{MTT^R}$ (i.e., whether $\tau_M \in MTT^R_{\mathrm{fc}}$). We now show that it is decidable for an $\mathrm{MTT^R}$ M whether or not M is finite copying. The proof is based on Lemma 3.8.

LEMMA 4.10. *It is decidable for an MTT^R M*

(i) *whether or not M is fci, and*

(ii) *whether or not M is fcp,*

and if so, a copying bound can be obtained effectively.

Proof. Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$.

(i) To decide fci we define the MTT N that, when applied to $\tau_{\hat{M}}(s[u \leftarrow h(s/u)])$, generates the state sequence $\mathrm{sts}_M(s,u)$ as a monadic tree. Let $N = (Q', \Delta \cup \langle\langle Q, P\rangle\rangle, \Gamma, r_0, R')$ with $Q' = \{r_0^{(0)}, r^{(1)}\}$ and $\Gamma = \{q^{(1)} \mid q \in Q\} \cup \{e^{(0)}\}$. For every $k \geq 0$, $\langle\langle q,p\rangle\rangle \in \langle\langle Q,P\rangle\rangle^{(k)}$, and $\delta \in \Delta^{(k)}$ let the following rules be in R':

$$\begin{array}{lcl}
\langle r_0, \langle\langle q,p\rangle\rangle(x_1,\dots,x_k)\rangle & \to & q(\langle r,x_1\rangle(\langle r,x_2\rangle(\cdots\langle r,x_k\rangle(e)\cdots))),\\
\langle r_0, \delta(x_1,\dots,x_k)\rangle & \to & \langle r,x_1\rangle(\langle r,x_2\rangle(\cdots\langle r,x_k\rangle(e)\cdots)),\\
\langle r, \langle\langle q,p\rangle\rangle(x_1,\dots,x_k)\rangle(y_1) & \to & q(\langle r,x_1\rangle(\langle r,x_2\rangle(\cdots\langle r,x_k\rangle(y_1)\cdots))),\\
\langle r, \delta(x_1,\dots,x_k)\rangle(y_1) & \to & \langle r,x_1\rangle(\langle r,x_2\rangle(\cdots\langle r,x_k\rangle(y_1)\cdots)).
\end{array}$$

Then, for every $s \in T_\Sigma$ and $u \in V(s)$, $\mathrm{lpath}(\tau_N(\tau_{\hat{M}}(s[u \leftarrow h(s/u)])), v) = \mathrm{sts}_M(s,u)e$, where v is the unique leaf of $\tau_N(\tau_{\hat{M}}(s[u \leftarrow h(s/u)]))$.

Let L be the tree language $\{s[u \leftarrow h(s/u)] \mid s \in T_\Sigma, u \in V(s)\}$. Then M is fci if and only if $K = \tau_N(\tau_{\hat{M}}(L))$ is finite. Note that $L = \{s \in T_\Sigma(P') \mid \#_{P'}(s) = 1\}$, where $P' = \{p \in P \mid L_p \neq \varnothing\}$; hence L is (effectively) regular. Thus, finiteness of K can be decided by Lemma 3.8; in case of finiteness, K can be constructed and an input copying bound for M is $\max\{\mathrm{size}(t) \mid t \in K\} - 1$.

(ii) Let $\overline{M}$ be the $\mathrm{MTT^R}$ defined in the proof of Lemma 3.7 and let $\overline{\Delta} = \Delta \cup \{\overline{y}_j^{(0)} \mid j \in [\overline{m}]\}$ be its output alphabet, where $\overline{m}$ is the maximal rank of a state of M. Let $N = (\{r_0^{(0)}, r^{(1)}\}, \overline{\Delta}, \Gamma, r_0, R_N)$ be the MTT with $\Gamma = \{\overline{y}_j^{(1)} \mid j \in [\overline{m}]\} \cup \{e^{(0)}\}$. For $\delta \in \Delta^{(k)}$ with $k \geq 0$ the (r_0,δ)- and (r,δ)-rules are defined as for N in (i). For $j \in [\overline{m}]$ let the rules $\langle r_0, \overline{y}_j\rangle \to \overline{y}_j(e)$ and $\langle r, \overline{y}_j\rangle(y_1) \to \overline{y}_j(y_1)$ be in R_N.

Clearly, for every $q \in Q$ and $s \in T_\Sigma$, $\mathrm{size}(\tau_N(\tau_{\overline{M}}(\overline{q}(s)))) = 1 + \#_Y(M_q(s))$. Now, for the regular tree language $L = \{\overline{q}(s) \mid q \in Q, s \in T_\Sigma\}$, M is fcp if and only if $K = \tau_N(\tau_{\overline{M}}(L))$ is finite. As in (i), this can be decided by Lemma 3.8; in case of finiteness, K can be constructed and a parameter copying bound for M is $\max\{\mathrm{size}(t) \mid t \in K\} - 1$. □

In fact, the effectiveness of Lemma 4.9 was not completely proved in [19], but with Lemma 4.10 it can be shown as follows: Given an $\mathrm{MTT^R_{fc}}$ M we can use Lemma 4.10 to obtain a parameter copying bound N for M. Then, given M and N we can, by the proof of Lemma 6.3 of [19], construct an $\mathrm{MTT^R_{fci,surp}}$ M' equivalent to M (where "surp" means "single-use restricted in the parameters"). Now, again by Lemma 4.10 we can determine an input copying bound N for M'. Then, given M' and N we can, by the proof of Lemma 6.10 of [19], construct a single-use restricted $\mathrm{MTT^R}$ M'' equivalent to M'. Now by the proofs of Lemmas 5.9, 5.12, and 4.1 of [19], a single-use restricted attributed tree transducer with look-ahead (for short, $\mathrm{ATT^R}$) A equivalent to M'' can be constructed. Given A, the proof of Lemma 7 of [3] shows

how to construct an equivalent MSO tree transducer. This proves the effectiveness going from MTT^R_{fc} to $MSOTT$. For the other direction, that is, starting with an MSO tree transducer M, we can proceed as follows: The proof of Theorem 14 of [3] gives a construction of an equivalent single-use restricted $\mathrm{ATT}^{\mathrm{R}}$ A. The proofs of Lemmas 4.2 and 5.11 of [19] show how to construct an equivalent single-use restricted $\mathrm{MTT}^{\mathrm{R}}$ M'. By the proof of Theorem 6.12 of [19], M' is finite copying.

4.2. Finite nested copying in the input. Consider the translation $\xi = \hat{M}_{q_0}(s[u \leftarrow p])$ of the context of a node u of the input tree s, where $p = h(s/u)$. The symbols of $\langle\langle Q, \{p\}\rangle\rangle$ can occur nested in ξ; i.e., they can occur on a common label path $\mathrm{lpath}(\xi, v)$ to some node v of ξ. Assuming that M is nondeleting, this means that a lot of copies of v will be generated; namely, $\prod F_{\xi,v}^{[\![\ldots]\!]}$ copies, where $[\![\ldots]\!]$ replaces $\langle\langle q, p\rangle\rangle$ by $M_q(s/u)$. Thus, a way to bound the copying carried out by M is to bound by some $B \in \mathbb{N}$ the number of elements of $\langle\langle Q, \{p\}\rangle\rangle$ that occur on a label path in ξ, i.e., to bound the nesting of states. This implies that the number of elements in the family $F_{\xi,v}^{[\![\ldots]\!]}$ is bounded by B. We call this property *finite nested copying in the input* (for short, fnest). Clearly, it is a much weaker restriction than the fci restriction. However, if an $\mathrm{MTT}^{\mathrm{R}}$ is fnest and fcp, then $\prod F_{\xi,v}^{[\![\ldots]\!]}$ is bounded by N^B if N is a parameter copying bound for M.

Definition 4.11 (fnest). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. Then M is* fnest *if there is a $B \in \mathbb{N}$ such that for every $s \in T_\Sigma$, $u \in V(s)$, $p = h(s/u)$, and label path π in $\hat{M}_{q_0}(s[u \leftarrow p])$, $\#_{\langle\langle Q,\{p\}\rangle\rangle}(\pi) \le B$. The number B is a* nesting bound for M.

We use the subscript "fnest" for classes of translations of $\mathrm{MTT}^{\mathrm{R}}$s to denote that the corresponding transducers are fnest. The next lemma shows that the nesting bound B also holds for trees $\hat{M}_q(s[u \leftarrow p])$ with $s \in L_{p'}$, provided that $\langle\langle q, p'\rangle\rangle$ is reachable in the following sense.

Definition 4.12 (reachable). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R, $q \in Q$, and $p \in P$. Then $\langle\langle q, p\rangle\rangle$ is* reachable *if there are $s \in T_\Sigma$ and $u \in V(s)$ such that $\langle\langle q, p\rangle\rangle$ occurs in $\hat{M}_{q_0}(s[u \leftarrow p])$.*

Note that reachability does not require that $h(s/u) = p$; however, for $L_p \neq \varnothing$ this can always be assumed (simply take $s' = s[u \leftarrow t]$ for some $t \in L_p$ if $h(s/u) \neq p$). Note that in that case, q occurs in the state sequence of s at u.

Lemma 4.13. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting fnest MTT^R and let B be a nesting bound for M. If $\langle\langle q, p\rangle\rangle \in \langle\langle Q, P\rangle\rangle$ is reachable, then for every $s \in L_p$, $u \in V(s)$, $p_u = h(s/u)$, and label path π in $\hat{M}_q(s[u \leftarrow p_u])$, $\#_{\langle\langle Q,\{p_u\}\rangle\rangle}(\pi) \le B$.*

Proof. Since $\langle\langle q, p\rangle\rangle$ is reachable, there are $t \in T_\Sigma$, $v \in V(t)$, and $\rho \in V_{\langle\langle q,p\rangle\rangle}(\hat{M}_{q_0}(t[v \leftarrow p]))$. We may assume that $t/v = s$ and hence $t/vu = s/u$. By Lemma 4.2, $\hat{M}_{q_0}(t[vu \leftarrow p_u]) = \hat{M}_{q_0}(t[v \leftarrow p])[\![\ldots]\!]$ with $[\![\ldots]\!] = [\![\langle\langle q', p\rangle\rangle \leftarrow \hat{M}_{q'}(s[u \leftarrow p_u]) \mid q' \in Q]\!]$. Clearly, $\mathrm{lpath}(\hat{M}_{q_0}(t[v \leftarrow p]), \rho) = w\langle\langle q, p\rangle\rangle$ for some $w \in (\langle\langle Q, \{p\}\rangle\rangle \cup \Delta)^*$. Since M is nondeleting (and hence so is $\hat{M}$), the substitution $[\![\ldots]\!]$ is nondeleting by Lemma 3.11(1), and thus, by Lemma 2.3(ii), there is a $w' \in (\langle\langle Q, \{p_u\}\rangle\rangle \cup \Delta)^*$ such that $w'\pi$ is a label path in $\hat{M}_{q_0}(t[v \leftarrow p])[\![\ldots]\!]$, i.e., in $\hat{M}_{q_0}(t[vu \leftarrow p_u])$. Now, $\#_{\langle\langle Q,\{p_u\}\rangle\rangle}(\pi) \le \#_{\langle\langle Q,\{p_u\}\rangle\rangle}(w'\pi)$, which is $\le B$, because B is a nesting bound for M. ∎

Consider a nondeleting $\mathrm{MTT}^{\mathrm{R}}$ M and an input tree $s \in T_\Sigma$. In section 6 we will often be interested in the part of s that lies between two nodes u and v of s, where v is a descendant of u; this part can be represented by the tree $s/u[v' \leftarrow p_v]$, where $v = uv'$ and $p_v = h(s/v)$. The shaded region in Figure 4.1 shows such a part of s.

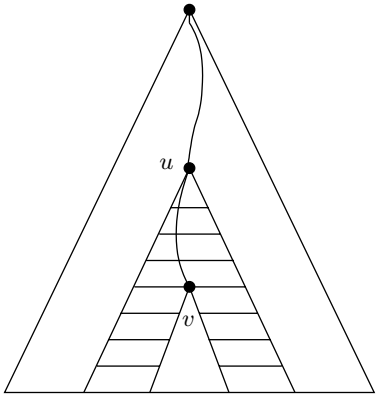

FIG. 4.1. *The tree s with shaded part $s/u[v' \leftarrow p_v]$.*

In particular, in section 6.2, we will need to know, if a state q of M processes this part, how many times the node v' is processed by a state q', i.e., how many times $\langle\langle q', p_v\rangle\rangle$ occurs in the tree $\hat{M}_q(s/u[v' \leftarrow p_v])$. If M is nondeleting and w is a node between u and v, i.e., a descendant of u and ancestor of v, then a lower bound for this number is given by summing for all states r the product of the number of occurrences of $\langle\langle r, p_w\rangle\rangle$ in $\hat{M}_q(s/u[w' \leftarrow p_w])$ and $\#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_r(s/w[v'' \leftarrow p_v]))$, where $v = wv''$. This is intuitively true because, due to nondeletion, for each occurrence of $\langle\langle r, p_w\rangle\rangle$ in $\hat{M}_q(s/u[w' \leftarrow p_w])$ there is in $\hat{M}_q(s/u[v' \leftarrow p_v])$ at least one occurrence of the tree $\hat{M}_r(s/w[v'' \leftarrow p_v])$ (without the parameters), and, due to parameter copying, there could be more than one such occurrence. This is stated in part (i) of the following lemma. Part (ii) of the lemma considers the case that M is fnest and fcp; then we can also give an upper bound for the number of occurrences of $\langle\langle q', p_v\rangle\rangle$ in $\hat{M}_q(s/u[v' \leftarrow p_v])$, because each occurrence of $\langle\langle r, p_w\rangle\rangle$ in $\hat{M}_q(s/u[w' \leftarrow p_w])$ can only be copied a bounded number of times.

LEMMA 4.14. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting MTT^R. Let $q, q' \in Q$, $s \in T_\Sigma$, and $u, w, v \in V(s)$ such that u is an ancestor of w and w is an ancestor of v, i.e., $w = uw'$ and $v = wv''$ for some $w', v'' \in \mathbb{N}^*$, and let $v' = w'v''$, $p_w = h(s/w)$, and $p_v = h(s/v)$. Finally, let*

$$S = \sum_{r \in Q} \#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_r(s/w[v'' \leftarrow p_v])) \cdot \#_{\langle\langle r, p_w\rangle\rangle}(\hat{M}_q(s/u[w' \leftarrow p_w])).$$

Then the following two statements hold:

(i) $\#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_q(s/u[v' \leftarrow p_v])) \geq S$.

(ii) *If M is fnest and fcp with nesting bound B and parameter copying bound N, and $\langle\langle q, h(s/u)\rangle\rangle$ is reachable, then $\#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_q(s/u[v' \leftarrow p_v])) \leq N^B \cdot S$.*

Proof. Note that for $s' = s/u[v' \leftarrow p_v]$, $\hat{h}(s'/w') = p_w$, $s'[w' \leftarrow p_w] = s/u[w' \leftarrow p_w]$, and $s'/w' = s/w[v'' \leftarrow p_v]$. Hence, by Lemma 4.2 applied to s' and w', $\hat{M}_q(s/u[v' \leftarrow p_v]) = \xi[\![\ldots]\!]$, where $\xi = \hat{M}_q(s/u[w' \leftarrow p_w])$ and $[\![\ldots]\!] = [\![\langle\langle r, p_w\rangle\rangle \leftarrow \hat{M}_r(s/w[v'' \leftarrow p_v]) \mid r \in Q]\!]$, and thus, by Lemma 2.6,

$$(\times) \quad \#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_q(s/u[v' \leftarrow p_v])) = \sum_{\tilde{u} \in V_{\langle\langle r, p_w\rangle\rangle}(\xi), r \in Q} \#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_r(s/w[v'' \leftarrow p_v])) \prod F_{\xi,\tilde{u}}^{[\![\ldots]\!]}.$$

Since M is nondeleting, by Lemma 3.11(1), $\#_{y_j}(\hat{M}_{r'}(s/w[v'' \leftarrow p_v])) \geq 1$ for every $r' \in Q^{(m)}$ and $j \in [m]$. This implies that $\prod F_{\xi,\tilde{u}}^{[\![\ldots]\!]} \geq 1$. Thus, the sum in $(\times)$ is $\geq S$, because $|V_{\langle\!\langle r,p_w\rangle\!\rangle}(\xi)|$ equals $\#_{\langle\!\langle r,p_w\rangle\!\rangle}(\hat{M}_q(s/u[w' \leftarrow p_w]))$. This proves part (i).

For (ii), $\prod F_{\xi,\tilde{u}}^{[\![\ldots]\!]} \leq N^B$, because the number of elements of $\langle\!\langle Q, \{p_w\}\rangle\!\rangle$ that occur in $\mathrm{lpath}(\xi, \tilde{u})$ is $\leq B$ by Lemma 4.13 (using the assumption that $\langle\!\langle q, h(s/u)\rangle\!\rangle$ is reachable) and because, by Lemma 4.7, $\#_{y_j}(\hat{M}_{r'}(s/w[v'' \leftarrow p_v])) \leq N$ for every $r' \in Q^{(m)}$ and $j \in [m]$. Thus, the sum in $(\times)$ is $\leq N^B \cdot \sum_{\tilde{u} \in V_{\langle\!\langle r,p_w\rangle\!\rangle}(\xi), r \in Q} \#_{\langle\!\langle q',p_v\rangle\!\rangle}(\hat{M}_r(s/w[v'' \leftarrow p_v])) = N^B \cdot S$. □

Note that point (ii) of Lemma 4.14 can be strengthened by proving an upper bound of $N^{B-1} \cdot S$ for the number of occurrences of $\langle\!\langle q', p_v\rangle\!\rangle$ in $\hat{M}_q(s/u[v' \leftarrow p_v]))$. This is true because in $F_{\xi,\tilde{u}}^{[\![\ldots]\!]}$, the node $\tilde{u}$ itself (which is labeled by $\langle\!\langle r, p_w\rangle\!\rangle$ for some state r) is not taken into account; i.e., only proper ancestors of $\tilde{u}$ that are labeled by elements of $\langle\!\langle Q, \{p_w\}\rangle\!\rangle$ are counted; thus there are at most $B-1$ of them. We decided to leave out the "-1," because in the application of the lemma in the proof of Lemma 6.5 this will make the numbers more readable.

4.3. Finite copying implies linear size increase. In this subsection it is proved that if an $\mathrm{MTT^R}$ is finite copying, then it is lsi. Note that this result is not needed, because it follows from Lemma 4.9 (as discussed in the beginning of this section). The proof uses an intermediate, very natural notion, called *finite contribution*. Intuitively, an $\mathrm{MTT^R}$ M is of finite contribution if there is a bound c on the number of output nodes that are contributed by a node of the input tree. Clearly, if M is of finite contribution, then it is lsi (with bound c). Thus, in order to prove that finite copying implies lsi, it suffices to prove that if M is finite copying, then it is of finite contribution (Lemma 4.18). In fact, since one of the main results of this paper is that $\mathrm{MTT^R}$s of linear size increase realize the same class of translations as finite copying $\mathrm{MTT^R}$s (Theorem 7.2 and Lemma 4.9), it means that this is also the class of translations realized by $\mathrm{MTT^R}$s that are of finite contribution.

In order to compute the contribution by a node of the input tree s, we define an $\mathrm{MTT^R}$ M^s, which keeps in the label of each output node v the corresponding input node u that generated v. More precisely, if Δ is the output alphabet of M, then M^s has output alphabet $\langle \Delta, V(s)\rangle$, and the contribution by the node u of s is the number of symbols in $\langle \Delta, \{u\}\rangle$ that appear in $M_{q_0}^s(s')$, where s' is the "decorated version" of s; i.e., s' is obtained from s by changing, for every node w, its label σ into $\langle \sigma, w\rangle$.

Definition 4.15 (the $\mathrm{MTT^R}$ M^s, decorated version, contribution). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R and $s \in T_\Sigma$. Then $M^s = (Q, P, \langle \Sigma, V(s)\rangle, \langle \Delta, V(s)\rangle, q_0, R^s, h^s)$ is the MTT^R such that for every $\langle \sigma, u\rangle \in \langle \Sigma, V(s)\rangle^{(k)}$, $k \geq 0$, and $p_1, \ldots, p_k \in P$,*

- $h^s_{\langle \sigma,u\rangle}(p_1, \ldots, p_k) = h_\sigma(p_1, \ldots, p_k)$, *and*
- $\mathrm{rhs}_{M^s}(q, \langle \sigma, u\rangle, \langle p_1, \ldots, p_k\rangle) = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)[\![\delta \leftarrow \langle \delta, u\rangle \mid \delta \in \Delta]\!]$.

The decorated version of s, *denoted by* $\mathrm{dec}(s)$, *is the unique tree in $T_{\langle \Sigma, V(s)\rangle}$ such that $V(\mathrm{dec}(s)) = V(s)$, and for every $u \in V(s)$, $\mathrm{dec}(s)[u] = \langle s[u], u\rangle$.*

For a node u of s, the set $V_{\langle \Delta,\{u\}\rangle}(M_{q_0}^s(\mathrm{dec}(s))) \subseteq V(M_{q_0}(s))$ is the set of output nodes contributed by u, *and the* contribution by u, *denoted by* $\mathrm{Contrib}_M(s, u)$, *is the cardinality $\#_{\langle \Delta,\{u\}\rangle}(M_{q_0}^s(\mathrm{dec}(s)))$ of this set.*

Note that every output node is contributed by a unique input node u (called its origin in [50]). Before we prove our first lemma about contribution, let us note some easy properties of the $\mathrm{MTT^R}$ M^s. Let $u \in V(s)$ and $q \in Q$.

(P1) $h^s(\mathrm{dec}(s)/u) = h(s/u)$.

(P2) For $s' \in T_{\langle\Sigma,V(s)\rangle}$, $\pi_\Delta(M^s_q(s')) = M_q(\pi_\Delta(s'))$, where π_Δ changes each symbol $\langle\delta,u\rangle$ into δ; i.e., it is the canonical projection from $\langle\Delta,V(s)\rangle$ to Δ. For $\hat{M}^s$ and $\hat{M}$ a similar statement holds.

Additionally, note the following two obvious facts about the projection π_Δ. Let Ω be a ranked alphabet disjoint with $\langle\Delta,V(s)\rangle$, $\xi \in T_{\Omega\cup\langle\Delta,V(s)\rangle}(Y)$, and $\xi' \in T_{\Omega\cup\langle\Delta,\{u\}\rangle}(Y)$. We assume that π_Δ is the identity on elements of Ω.

(D1) For $\beta \in (\Omega \cup Y)$, $V_\beta(\pi_\Delta(\xi)) = V_\beta(\xi)$.

(D2) For $\delta \in \Delta$, $V_\delta(\pi_\Delta(\xi')) = V_{\langle\delta,u\rangle}(\xi')$.

(P3) Let $P_0 = \{p^{(0)} \mid p \in P\}$.

(a) For $\xi \in T_{\langle\Sigma,V(s)\rangle}$, if $\#_{\langle\Sigma,\{u\}\rangle}(\xi) = 0$, then $\#_{\langle\Delta,\{u\}\rangle}(M^s_q(\xi)) = 0$.

(b) For $\xi \in T_{\langle\Sigma,V(s)\rangle\cup P_0}$, if $\#_{\langle\Sigma,\{u\}\rangle}(\xi) = 0$, then $\#_{\langle\Delta,\{u\}\rangle}(\hat{M}^s_q(\xi)) = 0$.

Let us prove property (P3) by induction on the structure of ξ. Let $\xi = \langle\sigma,v\rangle(\xi_1,\dots,\xi_k)$ with $\langle\sigma,v\rangle \in \langle\Sigma,V(s)\rangle^{(k)}$ and $k \geq 0$ such that $\#_{\langle\Sigma,\{u\}\rangle}(\xi) = 0$. By Lemma 3.5, $M^s_q(\xi) = \zeta[\![\langle q',x_i\rangle \leftarrow M^s_{q'}(\xi_i) \mid \langle q',x_i\rangle \in \langle Q,X_k\rangle]\!]$ with $\zeta = \mathrm{rhs}_{M^s}(q,\langle\sigma,v\rangle,\langle h^s(\xi_1),\dots,h^s(\xi_k)\rangle)$, and thus, by Lemma 2.6, $\#_{\langle\Delta,\{u\}\rangle}(M^s_q(\xi)) = S_1^{\langle\Delta,\{u\}\rangle} + S_2^{\langle\Delta,\{u\}\rangle}$, where $S_1^{\langle\Delta,\{u\}\rangle}$ and $S_2^{\langle\Delta,\{u\}\rangle}$ are the sums defined in that lemma (summed over all $\sigma \in \langle\Delta,\{u\}\rangle$). Now $S_1^{\langle\Delta,\{u\}\rangle} = 0$ because $V_{\langle\Delta,\{u\}\rangle}(\zeta) = \varnothing$ by the definition of the rules of M^s and by the fact that $v \neq u$ (because $\#_{\langle\Sigma,\{u\}\rangle}(\xi) = 0$). By induction, $\#_{\langle\Delta,\{u\}\rangle}(M^s_{q'}(\xi_i)) = 0$ and therefore also $S_2^{\langle\Delta,\{u\}\rangle} = 0$, which concludes the proof for the (a) case. For the (b) case the same proof holds, except that we have to consider the additional case $\xi = p \in P_0$: the right-hand side ζ of the p-rule of $\hat{M}^s$ is in $T_{\langle\langle Q,\{p\}\rangle\rangle}(Y)$ and thus $\#_{\langle\Delta,\{u\}\rangle}(\zeta) = 0$.

First, we want to present a lemma that computes, in the style of Lemma 2.6, the number $\mathrm{Contrib}_M(s,u)$ of output nodes contributed by u.

LEMMA 4.16. *Let $M = (Q,P,\Sigma,\Delta,q_0,R,h)$ be an MTT^R, $s \in T_\Sigma$, and $u \in V(s)$. Then*

$$\mathrm{Contrib}_M(s,u) = \sum_{\substack{v \in V_{\langle\langle q,p\rangle\rangle}(t)\\ q \in Q}} \sum_{w \in V_\Delta(\zeta_q)} \prod F^{[\![\text{-}]\!]}_{\zeta_q,w} \prod F^{[\![\dots]\!]}_{t,v}$$

with $p = h(s/u)$, $t = \hat{M}_{q_0}(s[u \leftarrow p])$, $\zeta_q = \mathrm{rhs}_M(q,\sigma,\langle p_1,\dots,p_k\rangle)$ for all $q \in Q$, where $\sigma = s[u] \in \Sigma^{(k)}$, $k \geq 0$, and $p_i = h(s/ui)$ for all $i \in [k]$, $[\![\text{-}]\!] = [\![\langle q',x_i\rangle \leftarrow M_{q'}(s/ui) \mid \langle q',x_i\rangle \in \langle Q,X_k\rangle]\!]$, and $[\![\dots]\!] = [\![\langle\langle q,p\rangle\rangle \leftarrow M_q(s/u) \mid q \in Q]\!]$.

Proof. By definition, $\mathrm{Contrib}_M(s,u) = \#_{\langle\Delta,\{u\}\rangle}(M^s_{q_0}(\mathrm{dec}(s)))$. Since, by the definition of dec, $\mathrm{dec}(s)[u] = \langle\sigma,u\rangle \in \langle\Sigma,V(s)\rangle^{(k)}$, we get by Lemmas 4.2 and 3.5 and property (P1), $M^s_{q_0}(\mathrm{dec}(s)) = t'[\![\mathrm{rhs}]\!][\![\text{-}]\!]'$, where $t' = \hat{M}^s_{q_0}(\mathrm{dec}(s)[u \leftarrow p])$, $[\![\mathrm{rhs}]\!] = [\![\langle\langle q,p\rangle\rangle \leftarrow \zeta'_q \mid q \in Q]\!]$ with $\zeta'_q = \mathrm{rhs}_{M^s}(q,\langle\sigma,u\rangle,\langle p_1,\dots,p_k\rangle)$ for $q \in Q$, and $[\![\text{-}]\!]' = [\![\langle q,x_i\rangle \leftarrow M^s_q(\mathrm{dec}(s)/ui) \mid \langle q,x_i\rangle \in \langle Q,X_k\rangle]\!]$. The application of Lemma 2.6 to $\#_{\langle\Delta,\{u\}\rangle}(t''[\![\text{-}]\!]')$ with $t'' = t'[\![\mathrm{rhs}]\!]$ gives $S_1 + S_2$, where $S_2 = 0$ because $\#_{\langle\Delta,\{u\}\rangle}(M^s_q(\mathrm{dec}(s)/ui)) = 0$ by property (P3)(a) and the fact that $\mathrm{dec}(s)/ui$ contains no symbol in $\langle\Sigma,\{u\}\rangle$ (by the definition of dec). Thus, $\mathrm{Contrib}_M(s,u) = S_1$, which equals

$$(*) \qquad \sum_{v \in V_{\langle\Delta,\{u\}\rangle}(t'[\![\mathrm{rhs}]\!])} \prod F^{[\![\text{-}]\!]'}_{t'[\![\mathrm{rhs}]\!],v}.$$

By the claim below, for $\Phi = [\![\mathrm{rhs}]\!]$ and $\Psi = [\![\text{-}]\!]'$, the sum in $(*)$ equals

$$\sum_{\gamma \in \langle\Delta,\{u\}\rangle} (S_1^\gamma + S_2^\gamma).$$

Now S_1^γ equals zero, because $V_{\langle\Delta,\{u\}\rangle}(t') = \varnothing$, which holds by property (P3)(b) and the fact that $\mathrm{dec}(s)[u \leftarrow p]$ contains no symbol in $\langle\Sigma,\{u\}\rangle$. Thus, the sum in $(*)$ equals $\sum_{\gamma\in\langle\Delta,\{u\}\rangle} S_2^\gamma =$

$$\sum_{\substack{v \,\in\, V_{\langle\langle q,p\rangle\rangle}(t') \\ q \,\in\, Q}} \; \sum_{w\in V_{\langle\Delta,\{u\}\rangle}(\zeta'_q)} \prod F^{[\![\text{-}]\!]'}_{\zeta'_q,w} \prod F^{[\![\cdots]\!]'}_{t',v},$$

where $[\![\ldots]\!]'$ is the substitution $[\![\langle\langle q,p\rangle\rangle \leftarrow M^s_q(\mathrm{dec}(s)/u) \mid q\in Q]\!]$. Let us now show that this sum equals the one of the lemma. For every $q\in Q$ it follows from property (D1) (for $\Omega = \langle\langle Q,\{p\}\rangle\rangle$ and $\beta = \langle\langle q,p\rangle\rangle$) that $V_{\langle\langle q,p\rangle\rangle}(t') = V_{\langle\langle q,p\rangle\rangle}(\pi_\Delta(t'))$, which equals $V_{\langle\langle q,p\rangle\rangle}(t)$ by (the $\hat{M}$-version of) property (P2), where π_Δ is the projection defined in that property. Since $\zeta'_q \in T_{\langle Q,X_k\rangle\cup\langle\Delta,\{u\}\rangle}(Y)$ it follows from property (D2) that $V_{\langle\Delta,\{u\}\rangle}(\zeta'_q) = V_\Delta(\pi_\Delta(\zeta'_q))$, which equals $V_\Delta(\zeta_q)$ because $\pi_\Delta(\zeta'_q) = \zeta_q$ by the definition of the rules of M^s. Now for $w\in V(\zeta'_q) = V(\zeta_q)$, $\prod F^{[\![\text{-}]\!]'}_{\zeta'_q,w} = \prod F^{[\![\text{-}]\!]}_{\zeta_q,w}$ because for $q'\in Q$, by (D1), $V_{\langle q',x_i\rangle}(\zeta'_q) = V_{\langle q',x_i\rangle}(\pi_\Delta(\zeta'_q))$, which equals $V_{\langle q',x_i\rangle}(\zeta_q)$, and for $y\in Y$, by (D1), $\#_y(M^s_q(\mathrm{dec}(s)/ui)) = \#_y(\pi_\Delta(M^s_q(\mathrm{dec}(s)/ui)))$, which equals $\#_y(M_q(s/ui))$ by (P2). Similarly, $\prod F^{[\![\cdots]\!]'}_{t',v} = \prod F^{[\![\cdots]\!]}_{t,v}$ for $v\in V(t') = V(t)$ because, as shown above, $V_{\langle\langle q,p\rangle\rangle}(t') = V_{\langle\langle q,p\rangle\rangle}(t)$ for $q\in Q$, and for $y\in Y$, by (D1), $\#_y(M^s_q(\mathrm{dec}(s)/u)) = \#_y(\pi_\Delta(M^s_q(\mathrm{dec}(s)/u)))$, which equals $\#_y(M_q(s))$ by (P2).

It remains to show the following claim, which is a generalization of Lemma 2.6 to two second-order tree substitutions Φ and Ψ. (More precisely, taking the substitution Ψ as the identity on $\Gamma - Y$ gives Lemma 2.6 for the case $\sigma = \gamma \notin \{\sigma_1,\ldots,\sigma_n\}\cup Y$.) Note that $\Phi\Psi$ denotes the composition of Ψ after Φ, i.e., $t(\Phi\Psi) = (t\Phi)\Psi$.

Claim. Let Γ be a ranked alphabet, $\Phi = [\![\sigma_i \leftarrow s_i \mid i\in[n]]\!]$ and $\Psi = [\![\tau_j \leftarrow \xi_j \mid j\in[m]]\!]$ second-order tree substitutions over Γ, and $t\in T_\Gamma$. For every $\gamma\in\Gamma - (\{\sigma_1,\ldots,\sigma_n,\tau_1,\ldots,\tau_m\}\cup Y)$,

$$(\times)\qquad \sum_{v\in V_\gamma(t\Phi)} \prod F^\Psi_{t\Phi,v} = S_1^\gamma + S_2^\gamma,$$

where

$$S_1^\gamma = \sum_{v\in V_\gamma(t)} \prod F^{\Phi\Psi}_{t,v} \qquad \text{and} \qquad S_2^\gamma = \sum_{\substack{v \,\in\, V_{\sigma_i}(t) \\ i \,\in\, [n]}} \; \sum_{w\in V_\gamma(s_i)} \prod F^\Psi_{s_i,w} \prod F^{\Phi\Psi}_{t,v}.$$

Proof of the claim. Note that the statement does not depend on the numbers $\#_\gamma(\xi_j)$. This is true because the substitution Ψ appears only in the Fs. In fact, for any node v of a tree ζ, $\prod F^\Psi_{\zeta,v} = \prod F^{\Psi'}_{\zeta,v}$ for every substitution $\Psi' = [\![\tau_j \leftarrow \xi'_j \mid j\in[m]]\!]$ with the property that $\#_y(\xi'_j) = \#_y(\xi_j)$ for every $y\in Y$ and $j\in[m]$; we denote this property by $E(\Psi,\Psi')$. For S_1^γ and S_2^γ a similar statement holds. (Note that if $E(\Psi,\Psi')$, then $E(\Phi\Psi,\Phi\Psi')$; this is true because, by associativity of second-order substitution, $\Phi\Psi = [\![\sigma_i \leftarrow s_i\Psi, \tau_j \leftarrow \xi_j \mid G]\!]$ and $\Phi\Psi' = [\![\sigma_i \leftarrow s_i\Psi', \tau_j \leftarrow \xi'_j \mid G]\!]$, where G denotes the statement "$i\in[n], j\in[m]$ with $\tau_j \notin \{\sigma_1,\ldots,\sigma_n\}$"; by the above, $E(\Psi,\Psi')$ implies that $\prod F^\Psi_{s_i,v} = \prod F^{\Psi'}_{s_i,v}$ for any node v of s_i, and thus for every $y\in Y$, $\sum_{v\in V_y(s_i)} \prod F^\Psi_{s_i,v} = \sum_{v\in V_y(s_i)} \prod F^{\Psi'}_{s_i,v}$, which means, by Lemma 2.6, that $\#_y(s_i\Psi) = \#_y(s_i\Psi')$.)

The idea of the proof is as follows. We will apply Lemma 2.6 twice: first to $\#_\gamma(t'\Psi')$, where $t' = t\Phi$ and Ψ' is a substitution with $E(\Psi,\Psi')$, and second to $\#_\gamma(tB)$

with $B = \Phi\Psi'$. The first application will give the left-hand side of the equation ($\times$), and the second one will give the right-hand side of that equation. Clearly, by definition of the composition of second-order tree substitutions, $\#_\gamma(t'\Psi') = \#_\gamma(tB)$.

Define $\Psi' = [\![\tau_j \leftarrow \xi'_j \mid j \in [m]]\!]$ with $E(\Psi, \Psi')$ and $\#_\gamma(\xi'_j) = 0$ for all $j \in [m]$. Then for $t' = t\Phi$, $\#_\gamma(t'\Psi')$ equals, by Lemma 2.6, $R_1^\gamma + R_2^\gamma$ with $R_1^\gamma = \sum_{v \in V_\gamma(t\Phi)} \prod F^{\Psi'}_{t\Phi,v}$ and $R_2^\gamma = 0$ because all the numbers $\#_\gamma(\xi'_j)$ are zero by the definition of Ψ'. Since $E(\Psi, \Psi')$, this means that $\#_\gamma(t'\Psi') = \sum_{v \in V_\gamma(t\Phi)} \prod F^{\Psi}_{t\Phi,v}$, which is the left-hand side of equation ($\times$).

By the associativity of second-order tree substitution, $B = \Phi\Psi'$ equals

$$[\![\sigma_i \leftarrow s_i\Psi', \tau_j \leftarrow \xi'_j \mid i \in [n], j \in [m] \text{ with } \tau_j \notin \Sigma_n]\!],$$

where $\Sigma_n = \{\sigma_1, \ldots, \sigma_n\}$. The application of Lemma 2.6 to $\#_\gamma(tB)$ gives $R_1^\gamma + R_2^\gamma$ with $R_1^\gamma = \sum_{v \in V_\gamma(t)} \prod F^{\Phi\Psi'}_{t,v}$ and

$$R_2^\gamma = \sum_{v \in V_{\sigma_i}(t), i \in [n]} \#_\gamma(s_i\Psi') \cdot \prod F^{\Phi\Psi'}_{t,v} + \sum_{v \in V_{\tau_j}(t), j \in [m], \tau_j \notin \Sigma_n} \#_\gamma(\xi'_j) \cdot \prod F^{\Phi\Psi'}_{t,v}.$$

Since $\#_\gamma(\xi'_j) = 0$, the second term of R_2^γ equals zero. In the first term of R_2^γ we apply Lemma 2.6 to $\#_\gamma(s_i\Psi')$, which gives $T_1^\gamma + T_2^\gamma$, where $T_2^\gamma = 0$ because $\#_\gamma(\xi'_j) = 0$, and $T_1^\gamma = \sum_{v \in V_{\sigma_i}(t), i \in [n]} \sum_{w \in V_\gamma(s_i)} \prod F^{\Psi'}_{s_i,w} \prod F^{\Phi\Psi'}_{t,v}$. Since $E(\Psi, \Psi')$, $R_1^\gamma = S_1^\gamma$ and $T_1^\gamma = S_2^\gamma$, which concludes the proof of the claim. □

Using Lemma 4.16 we can now prove that if an MTT$^{\mathrm{R}}$ is finite copying, then it is of finite contribution, which is defined next.

Definition 4.17 (finite contribution). *Let M be an MTT^R with input alphabet Σ. Then M is of* finite contribution *if there is a $c \in \mathbb{N}$ such that* $\mathrm{Contrib}_M(s, u) \leq c$ *for every $s \in T_\Sigma$ and $u \in V(s)$.*

Consider now a finite copying MTT$^{\mathrm{R}}$ M. In the translations of M, every node of the input tree is translated at most $I \cdot N^{I-1}$ times (cf. the discussion on page 71 of [19]), where I and N are input and parameter copying bounds for M, respectively. This implies that the number $\mathrm{Contrib}_M(s, u)$ of output nodes contributed by the node u is bounded.

Lemma 4.18. *Let M be an MTT^R. If M is finite copying, then it is of finite contribution.*

Proof. Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$, $s \in T_\Sigma$, and $u \in V(s)$. Let I be an input copying bound for M and let N be a parameter copying bound for M. Furthermore, let m be the maximal size of the right-hand side of a rule of M. By the definition of fci it follows that for $t = \hat{M}_{q_0}(s[u \leftarrow p])$ and $p = h(s/u)$, $\#_{\langle\langle Q, \{p\}\rangle\rangle}(t) \leq I$. By the definition of fcp it follows that, for every $v \in V_{\langle\langle q,p\rangle\rangle}(t)$ and $q \in Q$, $\prod F^{[\![\ldots]\!]}_{t,v} \leq N^{I-1}$, where $[\![\ldots]\!] = [\![\langle\langle q, p\rangle\rangle \leftarrow M_q(s/u) \mid q \in Q]\!]$. By Lemma 4.16 this means that $\mathrm{Contrib}_M(s, u) \leq I \cdot N^{I-1} \cdot \max\{\sum_{w \in V_\Delta(\zeta_q)} \prod F^{[\![\_]\!]}_{\zeta_q,w} \mid q \in Q\}$, where $[\![\_]\!] = [\![\langle q', x_i\rangle \leftarrow M_{q'}(s/ui) \mid \langle q', x_i\rangle \in \langle Q, X_k\rangle]\!]$. By the definition of m this is $\leq I \cdot N^{I-1} \cdot m \cdot \max\{\prod F^{[\![\_]\!]}_{\zeta_q,w} \mid q \in Q, w \in V_\Delta(\zeta_q)\} \leq I \cdot N^{I-1} \cdot m \cdot N^{m-1}$. Hence $\mathrm{Contrib}_M(s, u) \leq c$ for $c = I \cdot N^{I-1} \cdot m \cdot N^{m-1}$. □

As discussed in the beginning of this subsection, if an MTT$^{\mathrm{R}}$ is of finite contribution, then it is lsi. This holds because, by (P2), $\mathrm{size}(M_{q_0}(s)) = \mathrm{size}(M^s_{q_0}(\mathrm{dec}(s)))$ $= \sum_{u \in V(s)} \mathrm{Contrib}_M(s, u) \leq c \cdot \mathrm{size}(s)$. Together with Lemma 4.18 this gives us the desired result: finite copying implies lsi.

Theorem 4.19. *If an MTT^R is finite copying, then it is of linear size increase.*

5. Proper normal form. In section 4.3 we showed that if an $\mathrm{MTT}^{\mathrm{R}}$ is finite copying, then it is lsi. In sections 6 and 7 we want to prove that the converse also holds, i.e., that lsi implies finite copying. However, in general this does *not* hold: there are lsi $\mathrm{MTT}^{\mathrm{R}}$s that are not finite copying. Roughly speaking, the reason for this is that the part of the output tree of which unboundedly many copies are generated, by means of input variables or parameters, might be a fixed tree that does not change for different inputs. So, it can happen that an input tree s_n of size n generates a state sequence of length n, but the number of different output trees that are eventually generated by the states in the state sequence is finite. Then the $\mathrm{MTT}^{\mathrm{R}}$ is not finite copying in the input, but the translation it realizes can still be lsi (cf. the $\mathrm{MTT}^{\mathrm{R}}$ M at the beginning of section 5.1). Similarly, a tree $M_q(s_n)$ might contain n copies of a parameter y_j, but there are only finitely many different output trees that will be substituted for y_j in the actual output $M_{q_0}(s)$. Then M is not finite copying in the parameters, but the translation it realizes can be lsi (cf. the $\mathrm{MTT}^{\mathrm{R}}$ at the beginning of section 5.2).

Intuitively it should be clear that a state that generates, for any input, only a finite number of different output trees t is not needed; it can be eliminated by immediately substituting the correct tree t, which can be determined by regular look-ahead. This gives rise to a normal form, called *input proper*, which is treated in section 5.1. Similarly for a parameter y_j of a state q, if the number of actual output trees t that will be substituted for y_j is finite, then this parameter is not needed; it can be eliminated by immediately substituting the correct t, which can be computed in the states of the $\mathrm{MTT}^{\mathrm{R}}$. This gives rise to a normal form, called *parameter proper*; it is treated in section 5.2.

Altogether, an $\mathrm{MTT}^{\mathrm{R}}$ will be called *proper* if it is input proper, parameter proper, and productive. Again, this is a normal form; i.e., for every $\mathrm{MTT}^{\mathrm{R}}$ there is an equivalent one which is proper. Then in section 6 it can be proved that if a proper $\mathrm{MTT}^{\mathrm{R}}$ is lsi, then it is finite copying.

5.1. Input proper. Consider the following $\mathrm{MTT}^{\mathrm{R}}$ M, which is lsi but *not* fci. Let $M = (Q, \Sigma, \Delta, q_0, R)$ with $Q = \{q_0^{(0)}, q^{(0)}, q'^{(0)}\}$, $\Sigma = \{\gamma^{(1)}, a^{(0)}, b^{(0)}\}$, $\Delta = \{\sigma^{(2)}, a^{(0)}, b^{(0)}\}$, and R consisting of the following rules:

$$\begin{array}{lcl} \langle q_0, \gamma(x_1)\rangle & \to & \sigma(\langle q, x_1\rangle, \langle q', x_1\rangle), \\ \langle q, \gamma(x_1)\rangle & \to & \langle q, x_1\rangle, \\ \langle q', \gamma(x_1)\rangle & \to & \sigma(\langle q, x_1\rangle, \langle q', x_1\rangle), \\ \langle r, \alpha\rangle & \to & \alpha \quad (\text{for every } r \in Q \text{ and } \alpha \in \{a, b\}). \end{array}$$

Note that M is in fact a top-down tree transducer. Intuitively, M translates every monadic tree $s_n = \gamma(\dots\gamma(\alpha)\dots) = \gamma^n(\alpha)$ of height n (with $\alpha \in \{a, b\}$) into a comb $t_n = \sigma(\alpha, \sigma(\alpha, \dots\sigma(\alpha, \alpha)\dots))$ of height n. Thus, $\mathrm{size}(\tau_M(s)) \le 2 \cdot \mathrm{size}(s)$ for every $s \in T_\Sigma$ and so M is lsi. Clearly, M is not fci because $\mathrm{sts}_M(s_n, u) = q^n q'$ for $n \ge 1$ and $u = 1^n$ the unique leaf of s_n. The reason for this is that M generates n copies of q, but q generates only a finite number of different trees (viz. the trees a and b). How can we change M into an equivalent $\mathrm{MTT}^{\mathrm{R}}$ which is fci? The idea is to simply delete the state q and to determine by regular look-ahead the appropriate tree in $\{a, b\}$. In this example we just need $L_p = \{\gamma^n(a) \mid n \ge 0\}$ and $L_{p'} = \{\gamma^n(b) \mid n \ge 0\}$, and then the q_0-rule of M is replaced by two q_0-rules with right-hand sides $\sigma(a, \langle q', x_1\rangle)$ and $\sigma(b, \langle q', x_1\rangle)$ for look-ahead p and p', respectively, and similarly for the q'-rule.

We will say that an $\mathrm{MTT}^{\mathrm{R}}$ M is "input proper" if every state, except possibly the initial one, produces infinitely many output trees (in $T_\Delta(Y)$). More precisely, for

every look-ahead state p of M and every state $q \neq q_0$, M should produce infinitely many output trees taking L_p (the trees for which the look-ahead automaton arrives in state p) as input; in fact, this is only required if $\langle\langle q, p\rangle\rangle$ is reachable, i.e., if $\langle\langle q, p\rangle\rangle$ occurs in $\hat{M}_{q_0}(s[u \leftarrow p])$ for some s and u (see Definition 4.12). Note that q_0 is the only state that *may* generate only finitely many output trees; this is to make sure that an $\mathrm{MTT}^{\mathrm{R}}$ that generates only finitely many output trees can be transformed into one that is input proper.

The notion of input properness was defined in [1] for generalized syntax-directed translation schemes (which are a variant of top-down tree transducers) and was there called "reduced." We add two useful technical properties to it.

DEFINITION 5.1 (input proper). *An MTT^R $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ is* input proper *(for short, i-proper) if*

(i) *for every $q \in Q$ and $p \in P$ such that $q \neq q_0$ and $\langle\langle q, p\rangle\rangle$ is reachable, the set $\mathrm{Out}(q, p) = \{M_q(s) \mid s \in L_p\}$ is infinite;*
(ii) *q_0 does not occur in the right-hand sides of the rules in R; and*
(iii) *$L_p \neq \varnothing$ for every $p \in P$.*

Note that $\mathrm{Out}(q, p) \subseteq T_\Delta(Y_m)$ for $q \in Q^{(m)}$. Before it is proved (in Lemma 5.4) that i-properness is a normal form for $\mathrm{MTT}^{\mathrm{R}}$s, we need the following two straightforward lemmas about finiteness of $\mathrm{Out}(q, p)$.

LEMMA 5.2. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. For given $q \in Q^{(m)}$ and $p \in P$ it is decidable whether or not $\mathrm{Out}(q, p)$ is finite. Moreover, $\mathrm{Out}(q, p)$ can be constructed if it is finite.*

Proof. Let $\overline{M}$ be the $\mathrm{MTT}^{\mathrm{R}}$ constructed in the proof of Lemma 3.7. Then, for every $s \in T_\Sigma$, $\tau_{\overline{M}}(\overline{q}(s)) = M_q(s)[y_j \leftarrow \overline{y}_j \mid j \in [m]]$ and hence $M_q(s) = \tau_{\overline{M}}(\overline{q}(s))\Pi$, where $\Pi = [\overline{y}_j \leftarrow y_j \mid j \in [m]]$. The substitution Π can be realized by a (very simple) top-down tree transducer. Thus, for the regular tree language $L = \{\overline{q}(s) \mid s \in L_p\}$, $\mathrm{Out}(q, p) = \{M_q(s) \mid s \in L_p\} = \{\tau_{\overline{M}}(s)\Pi \mid s \in L\} = \tau_N(\tau_{\overline{M}}(L))$. By Lemma 3.8 the finiteness of $\tau_N(\tau_{\overline{M}}(L))$ is decidable, and in case of finiteness $\tau_N(\tau_{\overline{M}}(L))$ can be constructed. □

LEMMA 5.3. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting MTT^R. Let $q \in Q$, $\sigma \in \Sigma^{(k)}$, $k \geq 1$, and $p, p_1, \ldots, p_k \in P$ such that $p = h_\sigma(p_1, \ldots, p_k)$ and $L_{p_j} \neq \varnothing$ for every $j \in [k]$. If $\langle r, x_i\rangle \in \langle Q, X_k\rangle$ occurs in $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $\mathrm{Out}(q, p)$ is finite, then $\mathrm{Out}(r, p_i)$ is finite.*

Proof. For $j \in [k] - \{i\}$ fix trees $s_j \in T_\Sigma$ with $h(s_j) = p_j$. Let $\xi = \zeta[\![\ldots]\!]$ with $\zeta = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $[\![\ldots]\!] = [\![\langle q', x_j\rangle \leftarrow M_{q'}(s_j) \mid q' \in Q, j \in [k] - \{i\}]\!]$. By the definition of $\mathrm{Out}(q, p)$, Lemma 3.5, and associativity of second-order tree substitution, $O = \{M_q(\sigma(s_1, \ldots, s_k)) \mid s_i \in L_{p_i}\} = \{\xi[\![s_i]\!] \mid s_i \in L_{p_i}\}$, where $[\![s_i]\!]$ denotes the substitution $[\![\langle q', x_i\rangle \leftarrow M_{q'}(s_i) \mid q' \in Q]\!]$ is a subset of $\mathrm{Out}(q, p)$ and hence finite. Since M is nondeleting, both $[\![\ldots]\!]$ and $[\![s_i]\!]$ are nondeleting by Lemma 3.11(1). Hence, by Lemma 2.1, ξ has a subtree $\langle r, x_i\rangle(\xi_1, \ldots, \xi_m)$, where $m = \mathrm{rank}_Q(r)$. Again by Lemma 2.1, $\xi[\![s_i]\!]$ has a subtree $\langle r, x_i\rangle(\xi_1, \ldots, \xi_m)[\![s_i]\!] = M_r(s_i)[y_j \leftarrow \xi_j[\![s_i]\!] \mid j \in [m]]$. Thus, for every $t \in \mathrm{Out}(r, p_i)$ (i.e., $t = M_r(s_i)$ for some $s_i \in L_{p_i}$) the tree $t[y_j \leftarrow \xi_j[\![s_i]\!] \mid j \in [m]]$ is a subtree of $\xi[\![s_i]\!]$, i.e., it is a subtree of a tree in the finite set O. This implies finiteness of $\mathrm{Out}(r, p_i)$. □

We are now ready to prove that i-properness is a normal form. The construction involved is similar to the one of Lemma 5.5 of [1] except that we apply it repeatedly to obtain an i-proper $\mathrm{MTT}^{\mathrm{R}}$ as opposed to their single application, which is insufficient (also in their formalism, which means that their proof of the lemma is incorrect).

LEMMA 5.4. *For every MTT^R M there is (effectively) an i-proper and productive*

MTT^R M' equivalent to M. If M is a T^R, then so is M'.

Proof. Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT$^{\mathrm{R}}$. By Lemma 3.10 we may assume that M is productive. Moreover, we may assume that q_0 does not occur in the right-hand side of any rule of M (if it does, replace it in all rules by a new state q_0' which has the same rules as q_0).

Before we construct the MTT$^{\mathrm{R}}$ M' which is i-proper and realizes the same translation as M, let us define an auxiliary notion. For each $p \in P$, let F_p denote the set $\{q \in Q \mid \mathrm{Out}(q,p) \text{ is finite}\}$ of states which produce finitely many output trees in $T_\Delta(Y)$ on input trees in L_p. Note that F_p can be constructed effectively, because, by Lemma 5.2, it is decidable whether or not $\mathrm{Out}(q,p)$ is finite. Moreover, $\mathrm{Out}(q,p)$ can be constructed for every $q \in F_p$.

The MTT$^{\mathrm{R}}$ M' is constructed in such a way that if $\langle r, x_i\rangle$ occurs in $\mathrm{rhs}_{M'}(q, \sigma, \langle p_1, \ldots, p_k\rangle)$, then $r \notin F_{p_i}$. This implies point (i) of i-properness of M' as follows: If $\langle\langle r, p\rangle\rangle \in \langle\langle Q, P\rangle\rangle$ is reachable (with $r \neq q_0$), then there are $s \in T_\Sigma$ and $u \in V(s)$ such that $\langle\langle r, p\rangle\rangle$ occurs in $\hat{M}'_{q_0}(s[u \leftarrow p])$. Since $r \neq q_0$, $u = vi$ for some $i \geq 1$ and $v \in \mathbb{N}^*$. By Lemma 4.3 this implies that $\langle r, x_i\rangle$ occurs in the right-hand side of a rule of M' with $p_i = p$. This means that $r \notin F_p$, i.e., $\mathrm{Out}(r,p)$ is infinite.

Note that an example for the construction in this proof can be found in Example 5.5.

We first construct the MTT$^{\mathrm{R}}$ $\pi(M)$ by simply deleting occurrences of $\langle r, x_i\rangle$ with $r \in F_{p_i}$ and replacing them by the correct tree in $\mathrm{Out}(r, p_i)$, which is determined by regular look-ahead. Due to the change of look-ahead automaton, an occurrence of $\langle r, x_i\rangle$ in the $(q, \sigma, \langle p_1, \ldots, p_k\rangle)$-rule of M with $r \notin F_{p_i}$ might produce only finitely many trees for the new look-ahead states (p_i, φ_i). For this reason we have to iterate the application of π until the sets F_p do not change anymore. This results in the desired MTT$^{\mathrm{R}}$ M'.

For each $p \in P$ let Φ_p be the (finite) set of all mappings $\varphi : F_p \to T_\Delta(Y)$ such that there is an $s \in L_p$ with $\varphi(q) = M_q(s)$ for every $q \in F_p$. Note that Φ_p is finite because $\varphi(q) \in \mathrm{Out}(q,p)$, which is finite for $q \in F_p$. This also implies that Φ_p can be obtained effectively by checking, for the (finitely many) mappings $\varphi : F_p \to \bigcup_{q \in F_p} \mathrm{Out}(q,p)$, whether or not φ is in Φ_p. This is decidable because $\varphi \in \Phi_p$ if and only if $K_{p,\varphi} = L_p \cap \bigcap_{q \in F_p} M_q^{-1}(\{\varphi(q)\})$ is nonempty; $K_{p,\varphi}$ is regular by Lemma 3.7 (and the closure of the regular tree languages under intersection) and hence has a decidable emptiness problem (cf., e.g., Theorem II.10.2 of [31]). The mappings in Φ_p partition L_p into the sets $K_{p,\varphi}$, which can be determined by regular look-ahead.

We now construct the MTT$^{\mathrm{R}}$ $\pi(M) = (Q, P', \Sigma, \Delta, q_0, R', h')$ as follows. Let $P' = \{(p, \varphi) \mid p \in P, \varphi \in \Phi_p\}$. For $\sigma \in \Sigma^{(k)}$ and $(p_1, \varphi_1), \ldots, (p_k, \varphi_k) \in P'$ let, for every $q \in Q^{(m)}$, the rule

$$\langle q, \sigma(x_1, \ldots, x_k)\rangle(y_1, \ldots, y_m) \to \zeta_q\Theta \quad \langle (p_1, \varphi_1), \ldots, (p_k, \varphi_k)\rangle$$

be in R', where $\zeta_q = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $\Theta = [\![\langle r, x_i\rangle \leftarrow \varphi_i(r) \mid r \in F_{p_i}, i \in [k]]\!]$, and let $h'_\sigma((p_1, \varphi_1), \ldots, (p_k, \varphi_k)) = (p, \varphi)$, where $p = h_\sigma(p_1, \ldots, p_k)$ and $\varphi = \{(q, \zeta_q\Theta) \mid q \in F_p, \zeta_q = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)\}$.

Before we prove that the look-ahead automaton of $\pi(M)$ is as desired, let us show that it is well defined, i.e., that $\varphi \in \Phi_p$. We must show that there is an $s \in L_p$ such that, for every $q \in F_p$, $\varphi(q) = M_q(s)$. Since $\varphi_i \in \Phi_{p_i}$ for $i \in [k]$, there are $s_i \in L_{p_i}$ such that $\varphi_i(r) = M_r(s_i)$ for all $i \in [k]$ and $r \in F_{p_i}$. Hence, for $q \in F_p$, $\varphi(q) = \zeta_q\Theta$ with $\zeta_q = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $\Theta = [\![\langle r, x_i\rangle \leftarrow M_r(s_i) \mid \langle r, x_i\rangle \in \langle F_{p_i}, X_k\rangle]\!]$. By

Lemma 5.3 and the definition of F_p, only $\langle r, x_i\rangle$ with $r \in F_{p_i}$ occur in ζ_q. Therefore we can extend Θ to all elements of $\langle Q, X_k\rangle$. By Lemma 3.5 we get $\varphi(q) = M_q(s)$ for $s = \sigma(s_1, \ldots, s_k)$. Since $p = h_\sigma(p_1, \ldots, p_k)$, $s \in L_p$.

Claim 1. Let $s \in T_\Sigma$. If $h'(s) = (p, \varphi)$, then $p = h(s)$ and $\varphi(q) = M_q(s)$ for every $q \in F_p$.

The proof is by induction on the structure of s. Let $s = \sigma(s_1, \ldots, s_k)$ with $s_1, \ldots, s_k \in T_\Sigma$ and $h'(s_i) = (p_i, \varphi_i) \in P'$ for $i \in [k]$. By definition, p equals $h_\sigma(p_1, \ldots, p_k) = h(s)$. For $q \in F_p$, $\varphi(q) = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)\Theta$. By induction, $\varphi_i(r) = M_r(s_i)$ for all $i \in [k]$ and $r \in F_{p_i}$. For the same reason as above we can extend Θ to all elements of $\langle Q, X_k\rangle$ to get $M_q(s)$.

This claim implies that $\pi(M)$ satisfies point (iii) of i-properness. In fact, if $(p, \varphi) \in P'$, then $\varphi \in \Phi_p$, and so there exists $s \in L_p$ such that $\varphi(q) = M_q(s)$ for every $q \in F_p$. Thus, by Claim 1, $h'(s) = (p, \varphi)$. Hence, $L_{(p,\varphi)} \neq \varnothing$.

The $\mathrm{MTT}^{\mathrm{R}}$ $\pi(M)$ realizes the same translation as M. This follows from Claim 2 for $q = q_0$.

Claim 2. For $q \in Q$ and $s \in T_\Sigma$, $\pi(M)_q(s) = M_q(s)$.

Again we prove this by induction on s. Let $s = \sigma(s_1, \ldots, s_k)$ with $s_1, \ldots, s_k \in T_\Sigma$ and $h'(s_i) = (p_i, \varphi_i) \in P'$ for $i \in [k]$. By the definition of the rules of $\pi(M)$ and by Lemma 3.5, $\pi(M)_q(s)$ equals $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)\Theta[\![\_]\!]$, where $[\![\_]\!] = [\![\langle q', x_i\rangle \leftarrow \pi(M)_{q'}(s_i) \mid \langle q', x_i\rangle \in \langle Q, X_k\rangle]\!]$. By Claim 1, Θ equals $[\![\langle r, x_i\rangle \leftarrow M_r(s_i) \mid r \in F_{p_i}, i \in [k]]\!]$, and by induction $[\![\_]\!] = [\![\langle q', x_i\rangle \leftarrow M_{q'}(s_i) \mid \langle q', x_i\rangle \in \langle Q, X_k\rangle]\!]$. Thus $\Theta[\![\_]\!] = [\![\_]\!]$ and we get $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)[\![\_]\!]$, which, by Lemma 3.5, equals $M_q(s)$.

The $\mathrm{MTT}^{\mathrm{R}}$ $\pi(M)$ is productive because M is productive and the application of Θ does not delete nodes. Formally, consider a right-hand side $\zeta_q\Theta$ of $\pi(M)$ with $\zeta_q = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$, $q \in Q^{(m)}$, and $m \geq 0$. For every $r \in F_{p_i}$, $\varphi_i(r) = M_r(s)$ for some $s \in T_\Sigma$. Thus, by Lemma 3.11(1), $\#_{y_\nu}(\varphi_i(r)) \geq 1$ for every $\nu \in [\mathrm{rank}_Q(r)]$; i.e., the substitution Θ is nondeleting. Since, for $j \in [m]$, $\#_{y_j}(\zeta_q) \geq 1$ this implies, by Lemma 2.1, that $\#_{y_j}(\zeta_q\Theta) \geq 1$; i.e., $\pi(M)$ is nondeleting. Analogously, by Lemma 3.11(2), $\#_{y_\nu}(\varphi_i(r)) \notin Y$ for $r \in F_{p_i}$ and $\nu \in [\mathrm{rank}_Q(r)]$; i.e., the substitution Θ is nonerasing. Since, for $j \in [m]$, $\zeta_q \notin Y$ this implies, by Lemma 2.2, that $\zeta_q\Theta \notin Y$; i.e., $\pi(M)$ is nonerasing.

Since $\pi(M)$ has the same states as M, $\pi(M)$ is a T^{R} if M is.

We now discuss the reason for iterating π. Consider an occurrence of $\langle r, x_i\rangle$ in the right-hand side of a rule of $\pi(M)$. We know that $r \notin F_{p_i}$, because each such occurrence is removed by the substitution Θ in the definition of the rules of $\pi(M)$. Thus, $\mathrm{Out}(r, p_i)$ is infinite. However, through the new look-ahead, the set L_{p_i} is partitioned into sets $L_{(p_i,\varphi_i)}$, $\varphi_i \in \Phi_{p_i}$ (to see this, consider an $s \in L_{p_i}$; then, by Claim 1, $s \in L_{(p_i,\varphi_i)}$, where φ_i is defined as $\varphi_i(q) = M_q(s)$ for every $q \in F_{p_i}$). Thus, we merely know, by Claim 2, that the union of $\mathrm{Out}(r, (p_i, \varphi_i))$ for all $\varphi_i \in \Phi_{p_i}$ is infinite, but for a particular $\varphi_i \in \Phi_{p_i}$, $\mathrm{Out}(r, (p_i, \varphi_i))$ might be finite, which means that $\pi(M)$ is not i-proper (see Example 5.5).

Let us now show that the iterative application of π yields an i-proper $\mathrm{MTT}^{\mathrm{R}}$. In particular, we iterate the application of π until

$$(*) \qquad F_{(p,\varphi)} = F_p \quad \text{for every } (p, \varphi) \in P'.$$

It follows from $(*)$ that if $\langle r, x_i\rangle$ occurs in the right-hand side of a rule of $\pi(M)$, then by the definition of Θ, $r \notin F_{p_i}$, and hence by $(*)$, $r \notin F_{(p_i,\varphi_i)}$. Thus $(*)$ implies (point (i) of) i-properness of $\pi(M)$, as argued in the beginning of this proof.

It remains to show that after a finite number of applications of π, $(*)$ holds. Clearly, $F_p \subseteq F_{(p,\varphi)} \subseteq Q$, because $\mathrm{Out}(q, (p, \varphi)) \subseteq \mathrm{Out}(q, p)$, as argued above. Let

us first show that, for every $(p,\varphi) \in P'$, $F_{(p,\varphi)} = F_p$ implies that (after constructing $\pi(\pi(M))$) $F_{((p,\varphi),\varphi')} = F_{(p,\varphi)}$ for every $\varphi' \in \Phi_{(p,\varphi)}$. Let $\varphi' \in \Phi_{(p,\varphi)}$; i.e., there is an $s \in L_{(p,\varphi)}$ such that $\varphi'(q) = \pi(M)_q(s)$ for every $q \in F_{(p,\varphi)} = F_p$. Since, by Claims 1 and 2, $\pi(M)_q(s) = M_q(s) = \varphi(q)$ for every $q \in F_p$, it follows that $\varphi' = \varphi$. This means that $L_{((p,\varphi),\varphi')} = \{s \in L_{(p,\varphi)} \mid \pi(M)_q(s) = \varphi'(q) \text{ for all } q \in F_{(p,\varphi)}\}$ equals $\{s \in L_{(p,\varphi)} \mid M_q(s) = \varphi(q) \text{ for all } q \in F_p\} = L_{(p,\varphi)}$. This implies that $\mathrm{Out}(q,((p,\varphi),\varphi')) = \mathrm{Out}(q,(p,\varphi))$ and thus $F_{((p,\varphi),\varphi')} = \{q \in Q \mid \mathrm{Out}(q,((p,\varphi),\varphi')) \text{ is finite}\} = \{q \in Q \mid \mathrm{Out}(q,(p,\varphi)) \text{ is finite}\} = F_{(p,\varphi)}$.

Now, after at most $k = |Q|$ iterations of π, $(*)$ holds. Let $(\cdots((p,\varphi_1),\varphi_2)\ldots,\varphi_k)$ be denoted by $(p,\varphi_1,\ldots,\varphi_k)$. Then, for every look-ahead state $(p,\varphi_1,\ldots,\varphi_k)$ of $\pi^k(M)$, $F_{(p,\varphi_1,\ldots,\varphi_{k-1})} = F_{(p,\varphi_1,\ldots,\varphi_k)}$. This is true because $F_p = \varnothing$ implies $F_{(p,\varphi_1)} = \varnothing$ (since $\Phi_p = \{\varphi_1\}$), and $F_{(p,\varphi_1,\ldots,\varphi_i)} = F_{(p,\varphi_1,\ldots,\varphi_{i+1})}$ implies that $F_{(p,\varphi_1,\ldots,\varphi_j)} = F_{(p,\varphi_1,\ldots,\varphi_i)}$ for all $j \geq i$ (by the above). Since a sequence of nonempty subsets of Q in which each set is a proper subset of the next one has length at most $|Q| = k$, $F_{(p,\varphi_1,\ldots,\varphi_{k-1})} = F_{(p,\varphi_1,\ldots,\varphi_k)}$. Thus, $M' = \pi^k(M)$ is i-proper. □

The next example illustrates the construction of an i-proper $\mathrm{MTT}^{\mathrm{R}}$ following the proof of Lemma 5.4.

Example 5.5. For simplicity let us consider an $\mathrm{MTT}^{\mathrm{R}}$ without parameters, i.e., a T^{R}. Let $M = (Q,P,\Sigma,\Delta,q_0,R,h)$ be a T^{R} with $Q = \{q_0,q,q',i\}$, $P = \{p\}$, $\Sigma = \{\alpha^{(0)},\gamma^{(1)},\sigma^{(1)}\}$, $\Delta = \{\alpha^{(0)},\beta^{(0)},\gamma^{(1)},\sigma^{(1)},\delta^{(2)}\}$, and let R consist of the following rules:

$$\begin{array}{lcll}
\langle q_0,\gamma(x_1)\rangle & \to & \delta(\langle q,x_1\rangle,\langle i,x_1\rangle) & \langle p\rangle,\\
\langle q_0,\sigma(x_1)\rangle & \to & \langle q',x_1\rangle & \langle p\rangle,\\
\langle q,\gamma(x_1)\rangle & \to & \alpha & \langle p\rangle,\\
\langle q,\sigma(x_1)\rangle & \to & \beta & \langle p\rangle,\\
\langle q',\gamma(x_1)\rangle & \to & \alpha & \langle p\rangle,\\
\langle q',\sigma(x_1)\rangle & \to & \sigma(\langle i,x_1\rangle) & \langle p\rangle,\\
\langle i,\gamma(x_1)\rangle & \to & \gamma(\langle i,x_1\rangle) & \langle p\rangle,\\
\langle i,\sigma(x_1)\rangle & \to & \sigma(\langle i,x_1\rangle) & \langle p\rangle,\\
\langle r,\alpha\rangle & \to & \alpha & \text{for each } r \in Q.
\end{array}$$

Let us now define $M_1 = \pi(M) = (Q,P',\Sigma,\Delta,q_0,R',h')$. We obtain $F_p = \{q\}$ and $\Phi_p = \{\varphi_\alpha,\varphi_\beta\}$ with $\varphi_\alpha = \{(q,\alpha)\}$ and $\varphi_\beta = \{(q,\beta)\}$, and thus $P' = \{(p,\varphi_\alpha),(p,\varphi_\beta)\}$. As can easily be verified, the rules of the look-ahead automaton of M_1 are the following: $h'_\alpha = (p,\varphi_\alpha)$, $h'_\gamma((p,\varphi_\alpha)) = h'_\gamma((p,\varphi_\beta)) = (p,\varphi_\alpha)$, $h'_\sigma((p,\varphi_\alpha)) = h'_\sigma((p,\varphi_\beta)) = (p,\varphi_\beta)$.

The q-, q'-, and i-rules in R' are identical to the ones in R for both new look-ahead states. The q_0-rules in R' are the following:

$$\begin{array}{lcll}
\langle q_0,\gamma(x_1)\rangle & \to & \delta(\alpha,\langle i,x_1\rangle) & \langle(p,\varphi_\alpha)\rangle,\\
\langle q_0,\gamma(x_1)\rangle & \to & \delta(\beta,\langle i,x_1\rangle) & \langle(p,\varphi_\beta)\rangle,\\
\langle q_0,\sigma(x_1)\rangle & \to & \langle q',x_1\rangle & \langle(p,\varphi_\alpha)\rangle,\\
\langle q_0,\sigma(x_1)\rangle & \to & \langle q',x_1\rangle & \langle(p,\varphi_\beta)\rangle.
\end{array}$$

Note that $L_{(p,\varphi_\alpha)} = \{\alpha\} \cup \{\gamma(s) \mid s \in T_\Sigma\}$ and $L_{(p,\varphi_\beta)} = \{\sigma(s) \mid s \in T_\Sigma\}$. Hence $\mathrm{Out}(q',(p,\varphi_\alpha)) = \{\alpha\}$, and so the T^{R} M_1 is not i-proper yet, because $F_{(p,\varphi_\alpha)} = \{q,q'\} \neq F_p$. Thus we have to apply π again. Let $M' = \pi(M_1) = (Q,P'',\Sigma,\Delta,q_0,R'',h'')$. We get $\Phi_{(p,\varphi_\alpha)} = \{\varphi\}$, with $\varphi = \{(q,\alpha),(q',\alpha)\}$ and $\Phi_{(p,\varphi_\beta)} = \{\varphi_\beta\}$. Thus $P'' = \{((p,\varphi_\alpha),\varphi),((p,\varphi_\beta),\varphi_\beta)\}$. The look-ahead automaton of M' stays the same as for M_1 except for a renaming of states: (p,φ_α) becomes $((p,\varphi_\alpha),\varphi)$ and (p,φ_β)

becomes $((p,\varphi_\beta),\varphi_\beta)$. The q-, q'-, and i-rules in R'' are identical to the ones in R' (and R) for all look-ahead states. The q_0-rules in R'' are the following:

$$\begin{array}{lcll}
\langle q_0,\gamma(x_1)\rangle & \to & \delta(\alpha,\langle i,x_1\rangle) & \langle((p,\varphi_\alpha),\varphi)\rangle,\\
\langle q_0,\gamma(x_1)\rangle & \to & \delta(\beta,\langle i,x_1\rangle) & \langle((p,\varphi_\beta),\varphi_\beta)\rangle,\\
\langle q_0,\sigma(x_1)\rangle & \to & \alpha & \langle((p,\varphi_\alpha),\varphi)\rangle,\\
\langle q_0,\sigma(x_1)\rangle & \to & \langle q',x_1\rangle & \langle((p,\varphi_\beta),\varphi_\beta)\rangle.
\end{array}$$

The T^{R} M' is i-proper because $F_{((p,\varphi_\alpha),\varphi)}=\{q,q'\}=F_{(p,\varphi_\alpha)}$ and $F_{((p,\varphi_\beta),\varphi_\beta)}=\{q\}=F_{(p,\varphi_\beta)}$. We finally note that it is easy to transform M into a generalized syntax-directed translation scheme that forms a counterexample to the proof of Lemma 5.5 of [1].

5.2. Parameter proper. Consider the following MTT M which is lsi but *not* fcp. Let $M=(Q,\Sigma,\Delta,q_0,R)$ with $Q=\{q_0^{(0)},q^{(1)}\}$, $\Sigma=\{\sigma^{(2)},\gamma^{(2)},\alpha^{(0)},\beta^{(0)}\}$, and $\Delta=\{\sigma^{(2)},\gamma^{(2)},\alpha^{(1)},\beta^{(1)},\bar\sigma^{(0)},\bar\gamma^{(0)}\}$. For all $\delta\in\{\sigma,\gamma\}$ and $a\in\{\alpha,\beta\}$, let the following rules be in R:

$$\begin{array}{lcl}
\langle q_0,\delta(x_1,x_2)\rangle & \to & \delta(\langle q,x_1\rangle(\bar\delta),\langle q,x_2\rangle(\bar\delta)),\\
\langle q,\delta(x_1,x_2)\rangle(y_1) & \to & \delta(\langle q,x_1\rangle(y_1),\langle q,x_2\rangle(y_1)),\\
\langle q_0,a\rangle & \to & a(\bar a),\\
\langle q,a\rangle(y_1) & \to & a(y_1).
\end{array}$$

Intuitively, M moves the root symbol of the input tree to each of its leaves; e.g., for $s=\sigma(\gamma(\alpha,\beta),\alpha)$ we get $\tau_M(s)=\sigma(\gamma(\alpha(\bar\sigma),\beta(\bar\sigma),\alpha(\bar\sigma)))$. Thus, M is lsi (because $\mathrm{size}(\tau_M(s))\le 2\cdot\mathrm{size}(s)$). Clearly, M is not fcp, because $\#_{y_1}(M_q(s))$ equals the number of leaves of s. This time, the reason is that M generates a lot of parameter occurrences which have only finitely many "argument trees" (viz., $\bar\sigma$ and $\bar\gamma$). A jth argument tree for q and p is a tree ξ_j such that $\langle\!\langle q,p\rangle\!\rangle(\xi_1,\dots,\xi_m)$ is a subtree of some $\hat M_{q_0}(s[u\leftarrow p])$.

The idea of the next normal form is to eliminate parameters y_j of q for which there are only finitely many jth argument trees (for look-ahead p). This can be done by keeping the information on these argument trees in the states of the new $\mathrm{MTT}^{\mathrm{R}}$ and by appropriately replacing y_j by the correct argument tree in each right-hand side. For the example MTT M above, we have to add states $q_{\bar\delta}$, $\delta\in\{\sigma,\gamma\}$ of rank zero, and take as rules

$$\begin{array}{lcll}
\langle q_0,\delta(x_1,x_2)\rangle & \to & \delta(\langle q_{\bar\delta},x_1\rangle,\langle q_{\bar\delta},x_2\rangle), & \\
\langle q_{\bar\delta},\rho(x_1,x_2)\rangle & \to & \rho(\langle q_{\bar\delta},x_1\rangle,\langle q_{\bar\delta},x_2\rangle) & \text{for } \rho\in\{\sigma,\gamma\},\\
\langle q_0,a\rangle & \to & a(\bar a) & \text{for } a\in\{\alpha,\beta\},\\
\langle q_{\bar\delta},a\rangle & \to & a(\bar\delta) & \text{for } a\in\{\alpha,\beta\}.
\end{array}$$

This shows that the translation τ_M can actually be realized by a top-down tree transducer (which is in general, of course, not the case).

DEFINITION 5.6 (parameter proper, proper). *An MTT^R $M=(Q,P,\Sigma,\Delta,q_0,R,h)$ is* parameter proper *(for short, p-proper) if for every $q\in Q^{(m)}$, $m\ge 1$, $j\in[m]$, and $p\in P$*

(i) *if $\langle\!\langle q,p\rangle\!\rangle$ is reachable, then the set* $\mathrm{Arg}(q,j,p)$ *defined as*

$$\{t/vj \mid \exists s\in T_\Sigma, u\in V(s): t=\hat M_{q_0}(s[u\leftarrow p]), v\in V(t), t[v]=\langle\!\langle q,p\rangle\!\rangle\}$$

is infinite; and

(ii) *if* $\langle\!\langle q,p\rangle\!\rangle$ *is not reachable, then* $\#_{y_j}(M_q(s)) \leq 1$ *for all* $s \in L_p$.

The MTT^R M *is* proper *if it is productive and both i-proper and p-proper.*

Note that $\mathrm{Arg}(q,j,p) \subseteq T_{\langle\!\langle Q,\{p\}\rangle\!\rangle \cup \Delta}$. Note also that $\langle\!\langle q,p\rangle\!\rangle$ is reachable if and only if $\mathrm{Arg}(q,j,p) \neq \varnothing$.

Point (ii) in Definition 5.6 says that if a parameter appears more than once in $M_q(s)$, then $\langle\!\langle q, h(s)\rangle\!\rangle$ is reachable. This (mild) additional requirement is needed to force an lsi $\mathrm{MTT^R}$ to be fcp, because Definition 4.6 of the fcp property requires $\#_{y_j}(M_q(s)) \leq N$ for *all* states q; i.e., $\langle\!\langle q, h(s)\rangle\!\rangle$ might *not* be reachable.

Similar to the case of i-properness, we present two lemmas concerning the finiteness of $\mathrm{Arg}(q,j,p)$. First, let us show that it is decidable whether $\mathrm{Arg}(q,j,p)$ is infinite.

LEMMA 5.7. *Let* $M = (Q,P,\Sigma,\Delta,q_0,R,h)$ *be an* MTT^R. *For given* $q \in Q^{(m)}$, $m \geq 1$, $j \in [m]$, *and* $p \in P$, *it is decidable whether or not* $\mathrm{Arg}(q,j,p)$ *is finite. Moreover,* $\mathrm{Arg}(q,j,p)$ *can be constructed if it is finite.*

Proof. Let K_p be the regular tree language $\{s \in T_{\hat{\Sigma}} \mid p \text{ occurs exactly once in } s\}$ with $\hat{\Sigma} = \Sigma \cup \{p^{(0)}\}$. Then $\tau_{\hat{M}}(K_p) \subseteq T_{\langle\!\langle Q,\{p\}\rangle\!\rangle \cup \Delta}$. We now construct a partial nondeterministic top-down tree transducer N which takes a tree in $T_{\langle\!\langle Q,\{p\}\rangle\!\rangle \cup \Delta}$ as input and generates as output the jth subtree of an occurrence of $\langle\!\langle q,p\rangle\!\rangle$. (A partial nondeterministic top-down tree transducer is defined as in Definitions 3.1 and 3.2, but for q and σ there may be no or several rules of the form $\langle q,\sigma(x_1,\ldots,x_k)\rangle \to \zeta$.) Let $N = (\{r^{(0)},\mathrm{id}^{(0)}\},\Gamma,\Gamma,r,R')$, where $\Gamma = \langle\!\langle Q,\{p\}\rangle\!\rangle \cup \Delta$ and R' consists of the following rules:

$$\begin{array}{lcll}
\langle r,\gamma(x_1,\ldots,x_k)\rangle & \to & \langle r,x_i\rangle & \text{for all } \gamma \in \Gamma^{(k)}, k \geq 1, i \in [k],\\
\langle r,\langle\!\langle q,p\rangle\!\rangle(x_1,\ldots,x_m)\rangle & \to & \langle \mathrm{id},x_j\rangle, & \\
\langle \mathrm{id},\gamma(x_1,\ldots,x_k)\rangle & \to & \gamma(\langle \mathrm{id},x_1\rangle,\ldots,\langle \mathrm{id},x_k\rangle) & \text{for all } \gamma \in \Gamma^{(k)}, k \geq 0.
\end{array}$$

Clearly, $\tau_N(\tau_{\hat{M}}(K_p)) = \mathrm{Arg}(q,j,p)$, because every tree t in $\tau_{\hat{M}}(K_p)$ equals $\hat{M}_{q_0}(s[u \leftarrow p])$ for some s and u, and for every subtree $\langle\!\langle q,p\rangle\!\rangle(\xi_1,\ldots,\xi_m)$ of t, $(t,\xi_j) \in \tau_N$. The finiteness of $L = \tau_N(\tau_{\hat{M}}(K_p))$ can be decided by Lemma 3.8, and in case of finiteness L can be constructed. □

LEMMA 5.8. *Let* $M = (Q,P,\Sigma,\Delta,q_0,R,h)$ *be an i-proper and productive* MTT^R. *Let* $q \in Q^{(n)}$, $\sigma \in \Sigma^{(k)}$, $n,k \geq 0$, *and* $p,p_1,\ldots,p_k \in P$ *such that* $p = h_\sigma(p_1,\ldots,p_k)$ *and* $\langle\!\langle q,p\rangle\!\rangle$ *is reachable. Let* $\langle r,x_i\rangle(t_1,\ldots,t_m)$ *be a subtree of* $\mathrm{rhs}_M(q,\sigma,\langle p_1,\ldots,p_k\rangle)$ *with* $r \in Q^{(m)}$, $m \geq 0$, $i \in [k]$, *and* $t_1,\ldots,t_m \in T_{\langle Q,X_k\rangle \cup \Delta}(Y_n)$.

For $j \in [m]$, *the set* $\mathrm{Arg}(r,j,p_i)$ *is infinite if in* t_j *there is*

(i) *an occurrence of* $y_\mu \in Y_n$, *where* $\mathrm{Arg}(q,\mu,p)$ *is infinite, or*

(ii) *an occurrence of an element of* $\langle Q, X_k - \{x_i\}\rangle$, *or*

(iii) *an occurrence of* $y_\mu \in Y_n$ *such that there is a* $\xi \in \mathrm{Arg}(q,\mu,p)$ *for which* $\xi[\![\mathrm{rhs}]\!]$ *contains an occurrence of an element of* $\langle Q, X_k - \{x_i\}\rangle$, *where* $[\![\mathrm{rhs}]\!]$ *denotes the substitution* $[\![\langle\!\langle q',p\rangle\!\rangle \leftarrow \mathrm{rhs}_M(q',\sigma,\langle p_1,\ldots,p_k\rangle) \mid q' \in Q]\!]$.

Proof. Informally, and roughly speaking, the idea of this lemma is the following. Consider the given rule

$$\langle q,\sigma(x_1,\ldots,x_k)\rangle(y_1,\ldots,y_n) \to \ldots\langle r,x_i\rangle(t_1,\ldots,t_j,\ldots,t_m)\ldots \qquad \langle p_1,\ldots,p_k\rangle.$$

In case (i), if $\xi_\mu \in \mathrm{Arg}(q,\mu,p)$, i.e., ξ_μ is a μth argument tree of q and p, then, due to the application of the above rule, the tree $t_j[y_\mu \leftarrow \xi_\mu[\![\mathrm{rhs}]\!]]$ determines a jth argument tree of r and p_i, i.e., an element of $\mathrm{Arg}(r,j,p_i)$. By "determines" we mean that the remaining parameters and the input variables $\neq x_i$ have to be substituted by

appropriate trees, and then all $\langle q', s_\nu\rangle$ (where s_ν is substituted for $x_\nu \neq x_i$) have to be substituted by $M_{q'}(s_\nu)$, and $\langle q', x_i\rangle$ by $\langle\!\langle q', p_i\rangle\!\rangle$. Now, since it is given that there are infinitely many such ξ_μ, there are also infinitely many $t_j[y_\mu \leftarrow \xi_\mu[\![\mathrm{rhs}]\!]]$, and these determine infinitely many elements of $\mathrm{Arg}(r, j, p_i)$ because all involved substitutions are productive (see Lemma 2.7). In case (ii), if t_j contains an occurrence of $\langle q', x_\nu\rangle$ with $\nu \neq i$, and $t \in \mathrm{Out}(q', p_\nu)$, then the tree $t_j[\![\langle q', x_\nu\rangle \leftarrow t]\!]$ determines an element of $\mathrm{Arg}(r, j, p_i)$. Since M is i-proper, $\mathrm{Out}(q', p_\nu)$ is infinite and hence so is $\mathrm{Arg}(r, j, p_i)$. Finally, in case (iii), if $\xi[\![\mathrm{rhs}]\!]$ contains an occurrence of $\langle q', x_\nu\rangle$ with $\nu \neq i$, and $t \in \mathrm{Out}(q', p_\nu)$, then $t_j[y_\mu \leftarrow \xi[\![\mathrm{rhs}]\!][\![\langle q', x_\nu\rangle \leftarrow t]\!]]$ determines an element of $\mathrm{Arg}(r, j, p_i)$. We now turn to the formal proof.

Consider $s \in T_\Sigma$, $u \in V(s)$, and $\xi_1, \ldots, \xi_n \in T_{\langle\!\langle Q,\{p\}\rangle\!\rangle \cup \Delta}$ such that $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_n)$ is a subtree of $\hat{M}_{q_0}(s[u \leftarrow p])$. Consider also $s_\nu \in L_{p_\nu}$ for $\nu \in [k]$. Note that such trees exist because $\langle\!\langle q, p\rangle\!\rangle$ is reachable and because M satisfies point (iii) of i-properness.

Let $s' = s[u \leftarrow \sigma(s_1, \ldots, s_k)]$. Note that $s'/u = \sigma(s_1, \ldots, s_k)$ is in L_p and that $s'[u \leftarrow p] = s[u \leftarrow p]$. By Lemma 4.3, $\hat{M}_{q_0}(s'[ui \leftarrow p_i]) = \hat{M}_{q_0}(s[u \leftarrow p])[\![\mathrm{rhs}]\!]\Psi_{s_1,\ldots,s_k}[\![i]\!]$, with $[\![\mathrm{rhs}]\!]$ as in (iii), $\Psi_{s_1,\ldots,s_k} = [\![\langle q', x_\nu\rangle \leftarrow M_{q'}(s_\nu) \mid q' \in Q, \nu \in [k] - \{i\}]\!]$, and $[\![i]\!] = [\![\langle q', x_i\rangle \leftarrow \langle\!\langle q', p_i\rangle\!\rangle \mid q' \in Q]\!]$.

Since M is nondeleting, so is $[\![\mathrm{rhs}]\!]$ and, by Lemma 3.11(1), so is $\Psi_{s_1,\ldots,s_k}$. Then, by Lemma 2.1, the tree $\hat{M}_{q_0}(s'[ui \leftarrow p_i])$ has a subtree $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_n)[\![\mathrm{rhs}]\!]\Psi_{s_1,\ldots,s_k}[\![i]\!]$ $= \zeta\Pi_{\xi_1,\ldots,\xi_n}\Psi_{s_1,\ldots,s_k}[\![i]\!]$ with $\zeta = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $\Pi_{\xi_1,\ldots,\xi_n} = [y_\eta \leftarrow \xi_\eta[\![\mathrm{rhs}]\!] \mid \eta \in [n]]$. Again by Lemma 2.1 it has a subtree $\langle\!\langle r, p_i\rangle\!\rangle(t'_1, \ldots, t'_m)$, where, for $j \in [m]$,

$$(*) \qquad t'_j = t_j\Pi_{\xi_1,\ldots,\xi_n}\Psi_{s_1,\ldots,s_k}[\![i]\!] \in \mathrm{Arg}(r, j, p_i).$$

(i) Let $j \in [m]$ such that y_μ is a subtree of t_j. By Lemma 2.1, $y_\mu\Pi_{\xi_1,\ldots,\xi_n}\Psi_{s_1,\ldots,s_k}[\![i]\!]$ $= \xi_\mu[\![\mathrm{rhs}]\!]\Psi_{s_1,\ldots,s_k}[\![i]\!]$ is a subtree of t'_j. Thus $\mathrm{size}(t'_j) \geq \mathrm{size}(\xi_\mu[\![\mathrm{rhs}]\!]\Psi_{s_1,\ldots,s_k}[\![i]\!])$, which is $\geq \mathrm{size}(\xi_\mu)$ by Lemma 2.7 and the fact that $[\![\mathrm{rhs}]\!]$ and $\Psi_{s_1,\ldots,s_k}$ are productive by Lemma 3.11. We now let $\xi_1, \ldots, \xi_n$ vary in $(*)$: For every ξ_μ in the infinite set $\mathrm{Arg}(q, \mu, p)$ there are $s \in T_\Sigma$, $u \in V(s)$, and ξ_η, $\eta \in [n] - \{\mu\}$ such that $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_n)$ is a subtree of $\hat{M}_{q_0}(s[u \leftarrow p])$; then the size of $t_j\Pi_{\xi_1,\ldots,\xi_n}\Psi_{s_1,\ldots,s_k}[\![i]\!] \in \mathrm{Arg}(r, j, p_i)$ is $\geq \mathrm{size}(\xi_\mu)$. Thus, $\mathrm{Arg}(r, j, p_i)$ is infinite.

(ii) Let $j \in [m]$, $q' \in Q^{(l)}$, $l \geq 0$, and $\nu \in [k] - \{i\}$ such that t_j has a subtree $\langle q', x_\nu\rangle(\bar{t}_1, \ldots, \bar{t}_l)$ for some trees $\bar{t}_1, \ldots, \bar{t}_l$. Then $\langle\!\langle q', p_\nu\rangle\!\rangle$ is reachable by the same argument as given above equation $(*)$ (where we showed that $\langle\!\langle r, p_i\rangle\!\rangle$ is reachable). By Lemma 2.1, t'_j has the subtree $M_{q'}(s_\nu)[y_\eta \leftarrow \bar{t}_\eta\Pi_{\xi_1,\ldots,\xi_n}\Psi_{s_1,\ldots,s_k}[\![i]\!] \mid \eta \in [l]]$, the size of which is $\geq \mathrm{size}(M_{q'}(s_\nu))$. Since M satisfies points (i) and (ii) of i-properness, the set $\mathrm{Out}(q', p_\nu) = \{M_{q'}(s_\nu) \mid s_\nu \in L_{p_\nu}\}$ is infinite. We now let s_ν vary in $(*)$: For every $s_\nu \in L_{p_\nu}$ the size of $t_j\Pi_{\xi_1,\ldots,\xi_n}\Psi_{s_1,\ldots,s_k}[\![i]\!] \in \mathrm{Arg}(r, j, p_i)$ is $\geq \mathrm{size}(M_{q'}(s_\nu))$. Thus, $\mathrm{Arg}(r, j, p_i)$ is infinite.

(iii) Let $s \in T_\Sigma$ and $u \in V(s)$ such that $\hat{M}_{q_0}(s[u \leftarrow p])$ has a subtree $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_n)$ for trees $\xi_1, \ldots, \xi_n$ and $\xi_\mu[\![\mathrm{rhs}]\!]$ has a subtree $\langle q', x_\nu\rangle(\bar{t}_1, \ldots, \bar{t}_l)$ for some $q' \in Q^{(l)}$, $l \geq 0$, $\nu \in [k] - \{i\}$, and trees $\bar{t}_1, \ldots, \bar{t}_l$. It follows from Lemma 2.6 ($S_1^{\langle q', x_\nu\rangle} = 0$) that ξ_μ contains some $\langle\!\langle q'', p\rangle\!\rangle$, $q'' \in Q$, such that $\mathrm{rhs}_M(q'', \sigma, \langle p_1, \ldots, p_k\rangle)$ contains $\langle q', x_\nu\rangle$. Since $\langle\!\langle q'', p\rangle\!\rangle$ is reachable (because ξ_μ is a subtree of $\hat{M}_{q_0}(s[u \leftarrow p])$), $\langle\!\langle q', p_\nu\rangle\!\rangle$ is reachable by the same argument as used above $(*)$. Thus, $\mathrm{Out}(q', p_\nu)$ is infinite. Let $j \in [m]$ such that y_μ occurs in t_j. Then, by Lemma 2.1, t'_j has a subtree $M_{q'}(s_\nu)[y_\eta \leftarrow \bar{t}_\eta\Psi_{s_1,\ldots,s_k}[\![i]\!] \mid \eta \in [l]]$, the size of which is $\geq \mathrm{size}(M_{q'}(s_\nu))$. Letting s_ν range over L_{p_ν} in $(*)$ this implies, analogous to case (ii), that $\mathrm{Arg}(r, j, p_i)$ is infinite. □

We are now ready to prove that properness (i.e., i-properness, p-properness, and productivity) is a normal form for $\mathrm{MTT^R}$s.

THEOREM 5.9. *For every MTT^R M there is (effectively) a proper MTT^R $\mathrm{prop}(M)$ equivalent to M. If M is a T^R, then so is $\mathrm{prop}(M)$.*

Proof. Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$. By Lemma 5.4 we may assume that M is productive and i-proper. Let $q \in Q^{(n)}$ and $p \in P$. The idea of constructing $\mathrm{prop}(M)$ is to delete all parameters y_j of q for which $\mathrm{Arg}(q, j, p)$ is finite and to keep the parameters $y_{j_1}, \ldots, y_{j_m}$ of q for which $\mathrm{Arg}(q, j_\nu, p)$ is infinite. The information on the actual parameter tree which has to be substituted for y_j is stored in the states of $\mathrm{prop}(M)$. More precisely, a state of $\mathrm{prop}(M)$ will be of the form (q, φ), where φ is a mapping which associates with j_ν the new parameter y_ν, and with j a tree ξ_j in the finite set $\mathrm{Arg}(q, j, p)$.

Let us first define an auxiliary notion. For every $q \in Q^{(n)}$, $n \geq 0$, and $p \in P$, let $\Phi_{q,p}$ be the (finite) set of all mappings φ from $[n]$ to $T_{\langle\langle Q,\{p\}\rangle\rangle \cup \Delta} \cup Y$ such that there are $s \in T_\Sigma$, $u \in V(s)$, and $\xi_1, \ldots, \xi_n \in T_{\langle\langle Q,\{p\}\rangle\rangle \cup \Delta}$: $\hat{M}_{q_0}(s[u \leftarrow p])$ has a subtree $\langle\langle q, p\rangle\rangle(\xi_1, \ldots, \xi_n)$ and $F_{q,p}(\varphi, \xi_1, \ldots, \xi_n)$. The predicate $F_{q,p}(\varphi, \xi_1, \ldots, \xi_n)$ holds if for all $j \in [n]$ the following holds: if $j = j_\eta$ for an $\eta \in [m]$, then $\varphi(j) = y_\eta$, and otherwise $\varphi(j) = \xi_j$, where $\{j_1, \ldots, j_m\} = \{j \in [n] \mid \mathrm{Arg}(q, j, p) \text{ is infinite}\}$ and $j_1 < \cdots < j_m$.

By the definition of Arg, $\varphi(j) \notin Y$ implies $\varphi(j) \in \mathrm{Arg}(q, j, p)$. Note that $\Phi_{q,p}$ is finite because $\varphi(j) \in Y_m \cup K_j$ with $K_j = \mathrm{Arg}(q, j, p)$ for finite $\mathrm{Arg}(q, j, p)$, and $K_j = \varnothing$ otherwise. Therefore, $\Phi_{q,p}$ can be obtained effectively by checking, for the (finitely many) mappings $\varphi : [n] \to K$, whether or not $\varphi \in \Phi_{q,p}$ (where $K = Y_m \cup \bigcup_{j \in [n]} K_j$ can be constructed by Lemma 5.7). This is decidable because, apart from the requirement that $\varphi(j_\eta) = y_\eta$ for all $\eta \in [m]$ (which is decidable by Lemma 5.7), φ is in $\Phi_{q,p}$ if and only if $\tau_{\hat{M}}^{-1}(L) \cap S$ is nonempty, where $S = \{s[u \leftarrow p] \mid s \in T_\Sigma, u \in V(s)\}$ and L consists of all trees in $T_{\langle\langle Q,\{p\}\rangle\rangle \cup \Delta}$ which have a subtree $\langle\langle q, p\rangle\rangle(\xi_1, \ldots, \xi_n)$ with $\xi_j = \varphi(j)$ for all $j \notin \varphi^{-1}(Y)$. Clearly, L is regular and hence, by Lemma 3.7, $\tau_{\hat{M}}^{-1}(L)$ is regular. Since S is regular, so is $\tau_{\hat{M}}^{-1}(L) \cap S$, which implies that its emptiness is decidable.

We first construct the $\mathrm{MTT^R}$ $\pi(M)$ by deleting, in the right-hand side of a rule (with look-ahead $\langle p_1, \ldots, p_k\rangle$), all parameters y_j of $\langle r, x_i\rangle$ for which $\mathrm{Arg}(r, j, p_i)$ is finite and replacing them by the appropriate tree in $\mathrm{Arg}(r, j, p_i)$. This tree is coded in the states of $\pi(M)$. Due to the new states of $\pi(M)$, a parameter y_{j_ν} of r with $\mathrm{Arg}(r, j_\nu, p_i)$ infinite might correspond in $\pi(M)$ to the parameter y_ν of a state (r, φ) with finite $\mathrm{Arg}((r, \varphi), \nu, p_i)$. For this reason we have to iterate the application of π (as in the construction in the proof of Lemma 5.4) until the ranks of the states do not change anymore. This results in the desired $\mathrm{MTT^R}$ $\mathrm{prop}(M)$.

Define $\pi(M) = (Q', P, \Sigma, \Delta, (q_0, \varnothing), R', h)$ with $Q' = \{(q, \varphi)^{(m)} \mid q \in Q, \exists p \in P : \varphi \in \Phi_{q,p}, m = |\varphi^{-1}(Y)|\}$. For every $(q, \varphi) \in Q'^{(m)}$, $\sigma \in \Sigma^{(k)}$, $q \in Q^{(n)}$, $m, n, k \geq 0$, and $p, p_1, \ldots, p_k \in P$ with $p = h_\sigma(p_1, \ldots, p_k)$, let the rule

$$\langle (q, \varphi), \sigma(x_1, \ldots, x_k)\rangle(y_1, \ldots, y_m) \to \zeta \quad \langle p_1, \ldots, p_k\rangle$$

be in R' such that if $\varphi \notin \Phi_{q,p}$, then ζ is an arbitrary ("dummy") tree in $T_\Delta(Y_m) - Y$ with $\#_{y_j}(\zeta) = 1$ for every $j \in [m]$, and if $\varphi \in \Phi_{q,p}$, then $\zeta = \mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$, where ρ is the $(q, \sigma, \langle p_1, \ldots, p_k\rangle)$-rule of M, Π denotes the substitution

$$[y_j \leftarrow \varphi(j)[\![\mathrm{rhs}]\!] \mid j \in [n]] \quad \text{with} \quad [\![\mathrm{rhs}]\!] = [\![\langle\langle r, p\rangle\rangle \leftarrow \mathrm{rhs}_M(r, \sigma, \langle p_1, \ldots, p_k\rangle) \mid r \in Q]\!],$$

and for every subtree $t \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$ of $\mathrm{rhs}(\rho)\Pi$ the tree $\mathrm{repl}(t)$ is recursively defined as follows:

- for $t \in Y_m$, $\mathrm{repl}(t) = t$,
- for $t = \delta(t_1, \ldots, t_l)$ with $\delta \in \Delta^{(l)}$, $l \geq 0$, and $t_1, \ldots, t_l \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$, $\mathrm{repl}(t) = \delta(\mathrm{repl}(t_1), \ldots, \mathrm{repl}(t_l))$, and
- for $t = \langle q', x_i\rangle(t_1, \ldots, t_l)$, $\langle q', x_i\rangle \in \langle Q, X_k\rangle^{(l)}$, $l \geq 0$, and $t_1, \ldots, t_l \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$,

$$\mathrm{repl}(t) = \langle (q', \varphi'), x_i\rangle(\mathrm{repl}(t_{j_1}), \ldots, \mathrm{repl}(t_{j_\mu})),$$

where $\{j_1, \ldots, j_\mu\} = \{j \in [l] \mid \mathrm{Arg}(q', j, p_i) \text{ is infinite}\}$, $j_1 < \cdots < j_\mu$, and for $j \in [l]$,

$$\varphi'(j) = \begin{cases} y_\eta & \text{if } j = j_\eta \text{ for an } \eta \in [\mu], \\ t_j[\![i]\!] & \text{otherwise} \end{cases}$$

with $[\![i]\!] = [\![\langle r, x_i\rangle \leftarrow \langle\!\langle r, p_i\rangle\!\rangle \mid r \in Q]\!]$.

This ends the construction of $\pi(M)$.

Well-definedness of $\pi(M)$. To prove that $\pi(M)$ is well defined, we have to show that $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$ is in $T_{\langle Q', X_k\rangle \cup \Delta}(Y_m)$. Since $\mathrm{rhs}(\rho) \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_n)$ and $\varphi(Y_n) \subseteq Y_m \cup T_{\langle\!\langle Q, \{p\}\rangle\!\rangle \cup \Delta}$ (because $\varphi \in \Phi_{q,p}$), it follows that $\mathrm{rhs}(\rho)\Pi \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$. To prove that $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi) \in T_{\langle Q', X_k\rangle \cup \Delta}(Y_m)$ we must show that, in the definition of repl, if $\langle q', x_i\rangle(t_1, \ldots, t_l)$ is a subtree of $\mathrm{rhs}(\rho)\Pi$, then $(q', \varphi') \in Q'$; i.e., there is a p' such that $\varphi' \in \Phi_{q',p'}$.

We will show that $\varphi' \in \Phi_{q',p_i}$, i.e., that there are $s' \in T_\Sigma$, $u' \in V(s')$, and $\xi'_1, \ldots, \xi'_l \in T_{\langle\!\langle Q, \{p_i\}\rangle\!\rangle \cup \Delta}$ such that $\langle\!\langle q', p_i\rangle\!\rangle(\xi'_1, \ldots, \xi'_l)$ is a subtree of $\hat{M}_{q_0}(s'[u' \leftarrow p_i])$ and $F_{q',p_i}(\varphi', \xi'_1, \ldots, \xi'_l)$. Since $\varphi \in \Phi_{q,p}$, there are $s \in T_\Sigma$, $u \in V(s)$, and $\xi_1, \ldots, \xi_n \in T_{\langle\!\langle Q, \{p\}\rangle\!\rangle \cup \Delta}$ such that $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_n)$ is a subtree of $\hat{M}_{q_0}(s[u \leftarrow p])$ and $F_{q,p}(\varphi, \xi_1, \ldots, \xi_n)$. Note in particular that $\langle\!\langle q, p\rangle\!\rangle$ is reachable. Take $s' = s[u \leftarrow \sigma(s_1, \ldots, s_k)]$ with $s_\nu \in L_{p_\nu}$ for all $\nu \in [k]$, and take $u' = ui$. The s_ν exist, because M is i-proper (point (iii)). By Lemma 4.3, $\hat{M}_{q_0}(s'[u' \leftarrow p_i])$ equals $\hat{M}_{q_0}(s[u \leftarrow p])[\![\mathrm{rhs}]\!][..][\![i]\!]$, where $[\![..]\!]$ denotes $[\![\langle r, x_\nu\rangle \leftarrow M_r(s_\nu) \mid \langle r, x_\nu\rangle \in \langle Q, X_k - \{x_i\}\rangle]\!]$, and $[\![\mathrm{rhs}]\!]$ and $[\![i]\!]$ are as in the definition of $\pi(M)$. Since $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_n)$ is a subtree of $\hat{M}_{q_0}(s[u \leftarrow p])$ it follows, by Lemma 2.1 and the fact that $[\![..]\!]$ is nondeleting by Lemma 3.11(1), that $\hat{M}_{q_0}(s'[u' \leftarrow p_i])$ has a subtree $\mathrm{rhs}(\rho)\Pi'[\![..]\!][\![i]\!]$, where $\Pi' = [y_\mu \leftarrow \xi_\mu[\![\mathrm{rhs}]\!] \mid \mu \in [n]]$.

Consider the following two cases: (i) there are $t'_1, \ldots, t'_l \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_n)$ such that $\langle q', x_i\rangle(t'_1, \ldots, t'_l)$ is a subtree of $\mathrm{rhs}(\rho)$ and $t'_j\Pi = t_j$ for all $j \in [l]$, and (ii) $\langle q', x_i\rangle(t_1, \ldots, t_l)$ is a subtree of $\varphi(\mu)[\![\mathrm{rhs}]\!]$ for some $\mu \in [n]$.

(i) Since $\mathrm{rhs}(\rho)$ has a subtree $\langle q', x_i\rangle(t'_1, \ldots, t'_l)$, it follows, by application of $\Pi'[\![..]\!][\![i]\!]$ (and Lemma 2.1), that $\hat{M}_{q_0}(s'[u' \leftarrow p_i])$ has a subtree $\langle\!\langle q', p_i\rangle\!\rangle(\xi'_1, \ldots, \xi'_l)$ with $\xi'_j = t'_j\Pi'[\![..]\!][\![i]\!]$ for every $j \in [l]$. Let $j \in [l]$ such that $\mathrm{Arg}(q', j, p_i)$ is finite. Then by Lemma 5.8(ii) and (iii), both t'_j and all $\xi_\mu[\![\mathrm{rhs}]\!]$ such that y_μ occurs in t'_j do not contain elements of $\langle Q, X_k - \{x_i\}\rangle$. Thus $\xi'_j = t'_j\Pi'[\![..]\!][\![i]\!]$ equals $t'_j\Pi'[\![i]\!]$. By Lemma 5.8(i), t'_j does not contain any $y_\mu \in Y_n$ such that $\mathrm{Arg}(q, \mu, p)$ is infinite. Thus, since $F_{q,p}(\varphi, \xi_1, \ldots, \xi_n)$, $t'_j\Pi'[\![i]\!] = t'_j\Pi[\![i]\!] = t_j[\![i]\!]$. By the definition of φ' this shows that $F_{q',p_i}(\varphi', \xi'_1, \ldots, \xi'_l)$.

(ii) There is an occurrence of y_μ in $\mathrm{rhs}(\rho)$, because M is nondeleting. Since $\varphi(\mu) = \xi_\mu$, by the fact that $F_{q,p}(\varphi, \xi_1, \ldots, \xi_n)$ holds, this means that in $\mathrm{rhs}(\rho)\Pi'[\![..]\!][\![i]\!]$ there is a subtree $\langle\!\langle q', p_i\rangle\!\rangle(\xi'_1, \ldots, \xi'_l)$ with $\xi'_j = t_j[\![..]\!][\![i]\!]$ for $j \in [l]$. Since $\langle q', x_i\rangle(t_1, \ldots, t_l)$ is a subtree of $\xi_\mu[\![\mathrm{rhs}]\!]$, it follows from the definition of second-order tree substitution that ξ_μ has a subtree $\langle\!\langle q'', p\rangle\!\rangle(\zeta_1, \ldots, \zeta_\lambda)$ and the right-hand side of the $(q'', \sigma, \langle p_1, \ldots, p_k\rangle)$-rule ρ'' has a subtree $\langle q', x_i\rangle(t'_1, \ldots, t'_l)$ such that $t_j = t'_j[y_\nu \leftarrow \zeta_\nu[\![\mathrm{rhs}]\!] \mid \nu \in [\lambda]]$ for

every $j \in [l]$. Note that $\langle\langle q'', p\rangle\rangle$ is reachable because it occurs in ξ_μ. Now let $j \in [l]$ such that $\mathrm{Arg}(q', j, p_i)$ is finite. Then, as in case (i), by Lemma 5.8(ii) and (iii) applied to ρ'', both t'_j and all $\zeta_\nu[\![\mathrm{rhs}]\!]$ such that y_ν occurs in t'_j do not contain elements of $\langle Q, X_k - \{x_i\}\rangle$. Hence t_j does not contain elements of $\langle Q, X_k - \{x_i\}\rangle$ and thus $\xi'_j = t_j[\![..]\!][\![i]\!] = t_j[\![i]\!]$. By the definition of φ' this shows that $F_{q',p_i}(\varphi', \xi'_1, \ldots, \xi'_l)$.

Equivalence of $\pi(M)$ and M. We now prove that $\pi(M)$ realizes the same translation as M. This follows from Claim 1 for $(q, \varphi) = (q_0, \varnothing)$.

Claim 1. Let $s \in T_\Sigma$, $q \in Q^{(n)}$, $n \geq 0$, and $p = h(s)$. For every $\varphi \in \Phi_{q,p}$, $\pi(M)_{(q,\varphi)}(s) = M_q(s)\Pi'$, where $\Pi' = [y_j \leftarrow \varphi(j)[\![\langle\langle r, p\rangle\rangle \leftarrow M_r(s) \mid r \in Q]\!] \mid j \in [n]]$.

This claim is proved by induction on the structure of s. Let the induction hypothesis be denoted by IH1. Let $s = \sigma(s_1, \ldots, s_k)$ with $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in T_\Sigma$. For $i \in [k]$ let $p_i = h(s_i)$ and let $m = \mathrm{rank}_{Q'}((q, \varphi))$.

By Lemma 3.5, $\pi(M)_{(q,\varphi)}(\sigma(s_1, \ldots, s_k)) = \mathrm{rhs}_{\pi(M)}((q, \varphi), \sigma, \langle p_1, \ldots, p_k\rangle)[\![\_]\!]$, where $[\![\_]\!] = [\![\langle r, x_i\rangle \leftarrow \pi(M)_r(s_i) \mid \langle r, x_i\rangle \in \langle Q', X_k\rangle]\!]$. By the definition of the right-hand sides of the rules of $\pi(M)$ we get $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)[\![\_]\!]$, where repl, ρ, and Π are as in the definition of the rules of $\pi(M)$.

For $t = \mathrm{rhs}(\rho)\Pi$ it follows from Claim 2 that $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)[\![\_]\!] = \mathrm{rhs}(\rho)\Pi[\![\ldots]\!]$, where $[\![\ldots]\!] = [\![\langle r, x_i\rangle \leftarrow M_r(s_i) \mid \langle r, x_i\rangle \in \langle Q, X_k\rangle]\!]$. If we apply $[\![\ldots]\!]$ to $\mathrm{rhs}(\rho)\Pi$ and use Lemma 3.5 for M, then we get $M_q(s)\Pi'$, which proves Claim 1.

Claim 2. Let $t \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$ be a subtree of $\mathrm{rhs}(\rho)\Pi$. Then $\mathrm{repl}(t)[\![\_]\!] = t[\![\ldots]\!]$.

This claim is proved by induction on the structure of t. The induction hypothesis is denoted by IH2.

If $t \in Y_m$, then $\mathrm{repl}(t)[\![\_]\!] = t[\![\_]\!] = t = t[\![\ldots]\!]$. If $t = \delta(t_1, \ldots, t_l)$ with $\delta \in \Delta^{(l)}$, $l \geq 0$, and $t_1, \ldots, t_l \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$, then $\mathrm{repl}(\delta(t_1, \ldots, t_l))[\![\_]\!]$ equals $\delta(\mathrm{repl}(t_1)[\![\_]\!], \ldots, \mathrm{repl}(t_l)[\![\_]\!])$. By IH2 this equals $\delta(t_1[\![\ldots]\!], \ldots, t_l[\![\ldots]\!]) = t[\![\ldots]\!]$.

If $t = \langle q', x_i\rangle(t_1, \ldots, t_l)$ with $\langle q', x_i\rangle \in \langle Q, X_k\rangle^{(l)}$, $l \geq 0$, and $t_1, \ldots, t_l \in T_{\langle Q, X_k\rangle \cup \Delta}(Y_m)$, then $\mathrm{repl}(t)[\![\_]\!]$ equals $\langle(q', \varphi'), x_i\rangle(\mathrm{repl}(t_{j_1}), \ldots, \mathrm{repl}(t_{j_\mu}))[\![\_]\!]$ with $\{j_1, \ldots, j_\mu\} = \{j \in [l] \mid \mathrm{Arg}(q', j, p_i) \text{ is infinite}\}$ and φ' as in the definition of repl. Applying the substitution $[\![\_]\!]$ we get

$$\pi(M)_{(q',\varphi')}(s_i)[y_\eta \leftarrow \mathrm{repl}(t_{j_\eta})[\![\_]\!] \mid \eta \in [\mu]].$$

Since $\varphi' \in \Phi_{q',p_i}$ (as shown for the well-definedness of $\pi(M)$), we can apply IH1 to $\pi(M)_{(q',\varphi')}(s_i)$ and IH2 to $\mathrm{repl}(t_{j_\eta}[\![\_]\!])$ to get

$$M_{q'}(s_i)\Pi''[y_\eta \leftarrow t_{j_\eta}[\![\ldots]\!] \mid \eta \in [\mu]]$$

with $\Pi'' = [y_j \leftarrow \varphi'(j)[\![.]\!] \mid j \in [l]]$ and $[\![.]\!] = [\![\langle\langle r, p_i\rangle\rangle \leftarrow M_r(s_i) \mid r \in Q]\!]$.

By the definition of φ' we can write this as

$$M_{q'}(s_i)[y_j \leftarrow t_j[\![i]\!][\![.]\!] \mid j \in [l], j \neq j_\eta \text{ for } \eta \in [\mu]] \\ [y_{j_\eta} \leftarrow y_\eta \mid \eta \in [\mu]]\,[y_\eta \leftarrow t_{j_\eta}[\![\ldots]\!] \mid \eta \in [\mu]].$$

Since $\varphi' \in \Phi_{q',p_i}$, t_j is in $T_{\langle Q, \{x_i\}\rangle \cup \Delta}$ for $j \neq j_\eta$. Therefore, in $t_j[\![i]\!][\![.]\!] = t_j[\![\langle r, x_i\rangle \leftarrow M_r(s_i) \mid r \in Q]\!]$ we can extend the substitution to all elements of $\langle Q, X_k\rangle$ to get $t_j[\![\ldots]\!]$. Altogether we get

$$M_{q'}(s_i)[y_j \leftarrow t_j[\![\ldots]\!] \mid j \in [l], j \neq j_\eta \text{ for } \eta \in [\mu]][y_{j_\eta} \leftarrow t_{j_\eta}[\![\ldots]\!] \mid \eta \in [\mu]],$$

which equals $M_{q'}(s_i)[y_j \leftarrow t_j[\![\ldots]\!] \mid j \in [l]] = \langle q', x_i\rangle(t_1, \ldots, t_l)[\![\ldots]\!]$. This ends the proof of Claim 2.

Nondeleting of $\pi(M)$. Consider the $((q,\varphi),\sigma,\langle p_1,\dots,p_k\rangle)$-rule r of $\pi(M)$ and let $\varphi^{-1}(Y_m)=\{j_1,\dots,j_m\}$ with $j_1<\cdots<j_m$. Let $\nu\in[m]$. If r is a dummy rule, then $\#_{y_\nu}(\mathrm{rhs}(r))=1$. Otherwise $\mathrm{rhs}(r)=\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$, where ρ is the $(q,\sigma,\langle p_1,\dots,p_k\rangle)$-rule of M. Since M is nondeleting, y_{j_ν} occurs in $\mathrm{rhs}(\rho)$. Since $\varphi\in\Phi_{q,p}$, $\varphi(j_\nu)=y_\nu$; this means that the substitution Π replaces y_{j_ν} by y_ν, and hence y_ν occurs in $\mathrm{rhs}(\rho)\Pi$. To show that y_ν occurs in $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$, we prove that for $t\in T_{\langle Q,X_k\rangle\cup\Delta}(Y_m)$, if y_ν occurs in t, then it also occurs in $\mathrm{repl}(t)$. The proof is by induction on the structure of t. It is obvious for $t\in Y_m$ and $t=\delta(t_1,\dots,t_l)$. For $t=\langle q',x_i\rangle(t_1,\dots,t_l)$, let $j\in[l]$ such that y_ν occurs in t_j, and let φ' be as in the definition of repl. By induction, y_ν occurs in $\mathrm{repl}(t_j)$. Then y_ν occurs also in $t_j[\![i]\!]$, where $[\![i]\!]$ is as in the definition of repl. This means that $t_j[\![i]\!]\notin T_{\langle\langle Q,\{p_i\}\rangle\rangle\cup\Delta}$ and since $\varphi'\in\Phi_{q',p_i}$, this implies that $\varphi'(j)=y_\eta$ for some $\eta\in[\mu]$ with $j=j'_\eta$, where $\{j'_1,\dots,j'_\mu\}={\varphi'}^{-1}(Y_\mu)$ and $j'_1<\cdots<j'_\mu$. By the definition of repl, $\mathrm{repl}(t_{j'_\eta})=\mathrm{repl}(t_j)$ is a subtree of $\mathrm{repl}(t)$ and therefore y_ν occurs in $\mathrm{repl}(t)$.

Nonerasing of $\pi(M)$. Clearly, from the definition of repl, if $\mathrm{repl}(t)\in Y$, then $t\in Y$. Hence $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)\in Y$ implies $\mathrm{rhs}(\rho)\Pi\in Y$ and so, obviously, $\mathrm{rhs}(\rho)\in Y$. Thus, since M is nonerasing, so is $\pi(M)$.

I-properness of $\pi(M)$. Since $\pi(M)$ has the same look-ahead automaton as M, point (iii) of i-properness is preserved. It follows from the definition of Π and repl and from i-properness of M that no (q_0,φ) appears in the right-hand side of a rule of $\pi(M)$. Using Lemma 4.3 (and the fact that, in the definition of $\mathrm{repl}(t)$, $\varphi'\in\Phi_{q',p_i}$) it is not difficult to see that if $\langle\langle(q,\varphi),p\rangle\rangle$ is reachable, then $\varphi\in\Phi_{q,p}$ and hence, by the definition of $\Phi_{q,p}$, $\langle\langle q,p\rangle\rangle$ is reachable. Also by Lemma 4.3, if $(q,\varphi)\neq(q_0,\varnothing)$, then (q,φ) appears in the right-hand side of a rule of $\pi(M)$, and so $q\neq q_0$. By Claim 1, $\pi(M)_{(q,\varphi)}(s)=M_q(s)\Pi'$ with $\Pi'=[y_j\leftarrow\varphi(j)[\![\langle\langle r,p\rangle\rangle\leftarrow M_r(s)\mid r\in Q]\!]\mid j\in[n]]$. Since $\mathrm{size}(M_q(s)\Pi')\geq\mathrm{size}(M_q(s))$, $\mathrm{Out}((q,\varphi),p)=\{M_q(s)\Pi'\mid s\in L_p\}$ is infinite if $\{M_q(s)\mid s\in L_p\}=\mathrm{Out}(q,p)$ is infinite, which holds by i-properness of M.

P-properness. By constructing $\pi(M)$ we have kept only those parameter positions j of q for which $\mathrm{Arg}(q,j,p)$ is infinite. But even if $\mathrm{Arg}(q,j,p)$ is infinite, there might be a $\varphi\in\Phi_{q,p}$ for which $\mathrm{Arg}((q,\varphi),j,p)$ is finite. This means that $\pi(M)$ need not be p-proper yet (see Example 5.10), and, as in the case of i-properness, we have to iterate the application of π. For the termination condition of this iteration we only need to consider particular states which are actually used in the derivations of $\pi^k(M)$. Denote the state $(\cdots((q,\varphi_1),\varphi_2)\dots,\varphi_k)$ of $\pi^k(M)$ by $(q,\varphi_1,\dots,\varphi_k)$. The state $(q,\varphi_1,\dots,\varphi_k)$ is *p-uniform* if for each $0\leq i\leq k-1$, $\varphi_{i+1}\in\Phi_{(q,\varphi_1,\dots,\varphi_i),p}$. We iterate the application of π until we obtain the $\mathrm{MTT}^{\mathrm{R}}$ N (with set of states Q_N) such that

$(*)$ for every $p\in P$ and p-uniform state (q,φ) of $M'=\pi(N)$,
$$\mathrm{rank}_{Q'}((q,\varphi))=\mathrm{rank}_{Q_N}(q),$$

where Q' is the set of states of M'.

Let us now show that, indeed, after a finite number of applications of π, $(*)$ holds. For $q\in Q$ and $p\in P$, define the tree $T_{q,p}$ as follows. For $k\geq 0$, the state $(q,\varphi_1,\dots,\varphi_k)$ of $\pi^k(M)$ is a node of $T_{q,p}$ if it is p-uniform and there is a p-uniform state $(q,\varphi_1,\dots,\varphi_k,\dots,\varphi_l)$ of $\pi^l(M)$ with $l>k$ which is of smaller rank than $(q,\varphi_1,\dots,\varphi_k)$. There is an edge in $T_{q,p}$ from every node $(q,\varphi_1,\dots,\varphi_k)$ to every node $(q,\varphi_1,\dots,\varphi_k,\varphi_{k+1})$. Clearly, if $T_{q,p}$ is finite for every $q\in Q$ and $p\in P$, then the iteration of π terminates: Let l be maximal such that $(q,\varphi_1,\dots,\varphi_l)$ is a leaf of $T_{q,p}$ for some $q\in Q$ and $p\in P$. Then the statement in $(*)$ holds for $N=\pi^{l+1}(M)$, because

no p-uniform state $(q, \varphi_1, \ldots, \varphi_l, \varphi_{l+1})$ is a node of $T_{q,p}$ and hence, by the definition of the nodes of $T_{q,p}$, every p-uniform state $(q, \varphi_1, \ldots, \varphi_{l+1}, \varphi_{l+2})$ has the same rank as $(q, \varphi_1, \ldots, \varphi_{l+1})$. To show the finiteness of $T_{q,p}$ it suffices, by König's lemma, to show that every path ρ of $T_{q,p}$ is finite. Assume to the contrary that ρ is infinite. Let $u = (q, \varphi_1, \ldots, \varphi_k)$ be a node of ρ. Then there is a descendant of u on the path ρ, that has lower rank than u. This can be seen as follows: By the definition of the node u, there is a p-uniform state $(q, \varphi_1, \ldots, \varphi_k, \ldots, \varphi_l)$ of $\pi^l(M)$, $l > k$, which has lower rank than u. Now, for each $i \in \{k+1, \ldots, l\}$ such that $v = (q, \varphi_1, \ldots, \varphi_k, \ldots, \varphi_{i-1})$ is on the path ρ, either $v' = (v, \varphi_i) = (q, \varphi_1, \ldots, \varphi_k, \ldots, \varphi_i)$ has the same rank as v and then v' is on the path ρ because $\Phi_{v,p} = \{v'\}$ by the definition of $\Phi_{v,p}$ or v' has a lower rank n than v, and then, by the definition of $\Phi_{v,p}$, each state (v, φ) has rank n, in particular the child of v that is on the path ρ. Since each node u of ρ has a descendant on ρ that has a lower rank than u, there is an infinite sequence of nodes on ρ with strictly decreasing ranks. This contradicts the finiteness of the rank of q.

Before we show that M' is p-proper, we prove a claim about p-uniformity.

Claim 3. Let $k \geq 0$, let q be a state of $\pi^k(M)$, and let $p \in P$.

(i) If $\langle q, x_i \rangle$ appears in the right-hand side of a $(q', \sigma, \langle p_1, \ldots, p_{k'} \rangle)$-rule of $\pi^k(M)$ for some state q' of $\pi^k(M)$, $k' \geq 0$, $i \in [k']$, and $p_1, \ldots, p_{k'} \in P$, then q is p_i-uniform.

(ii) If $\langle\langle q, p \rangle\rangle$ is reachable (by $\pi^k(M)$), then q is p-uniform.

The proof of part (i) of Claim 3 is by induction on k. For $k = 0$, every state is p-uniform for all $p \in P$, and thus the statement holds. Now assume the statement holds for $\pi^k(M)$. If $\langle (q, \varphi), x_i \rangle$ appears in the right-hand side ζ of the $((q', \varphi'), \sigma, \langle p_1, \ldots, p_{k'} \rangle)$-rule of $\pi(\pi^k(M))$, then, by the definition of the rules of $\pi(\pi^k(M))$, ζ is of the form $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$, where ρ is the $(q', \sigma, \langle p_1, \ldots, p_{k'} \rangle)$-rule of $\pi^k(M)$. Thus, by the definition of repl and Π, $\langle q, x_i \rangle$ occurs in $\mathrm{rhs}(\rho)$, which means, by induction, that q is p_i-uniform. In the proof of well-definedness of $\pi(M)$ it is shown that $\varphi \in \Phi_{q,p_i}$, and hence also (q, φ) is p_i-uniform. This proves part (i) of the claim. To prove part (ii), we may assume that $q \neq r_0$, the initial state of $\pi^k(M)$; in fact, $r_0 = (q_0, \varnothing, \ldots, \varnothing)$ is p-uniform for every p. If $\langle\langle q, p \rangle\rangle$ is reachable (by $\pi^k(M)$), then, by definition, it appears in $\widehat{\pi^k(M)}_{r_0}(s[u \leftarrow p])$ for some tree s and node u of s, where $\widehat{\pi^k(M)}$ denotes the extension of $\pi^k(M)$. Since $q \neq r_0$, u must be of the form $u'j$ with $u' \in \mathbb{N}^*$ and $j \geq 1$. Hence, by Lemma 4.3, $\langle q, x_j \rangle$ must occur in the right-hand side of some rule of $\pi^k(M)$ with look-ahead $\langle p_1, \ldots, p_l \rangle$, $l \geq 1$, and $p_j = p$. By part (i) of the claim this implies that q is p-uniform. This concludes the proof of Claim 3.

Let us now prove (i) of p-properness for N. Let $\langle\langle q, p \rangle\rangle$ be reachable (by N). By Claim 3(ii), q is p-uniform. Since $\langle\langle q, p \rangle\rangle$ is reachable, the set $\Phi_{q,p}$ must, by definition, contain some element φ. Then (q, φ) is p-uniform, and it follows from $(*)$ that $n = |\varphi^{-1}(Y)|$ and thus $\{j \in [n] \mid \mathrm{Arg}(q, j, p) \text{ is infinite}\} = \{1, \ldots, n\}$. Thus (i) of p-properness holds for N. Now consider M'. Note that, by the previous argument, if (q, φ) is a p-uniform state of M', then $\varphi = \varphi_n$, where $q \in Q_N^{(n)}$ and $\varphi_n(j) = y_j$ for every $j \in [n]$. Clearly, (i) of p-properness also holds for M'. Formally this can be shown by proving that $\mathrm{Arg}((q, \varphi_n), j, p) = \mathrm{Arg}(q, j, p)[\![\mathrm{rel}]\!]$, where $[\![\mathrm{rel}]\!]$ denotes the relabeling $[\![\langle\langle q', p \rangle\rangle \leftarrow \langle\langle (q', \varphi_{n'}), p \rangle\rangle \mid q' \in Q_N^{(n')}, n' \geq 0]\!]$. This follows from Claim 4 (for q equal to the initial state of N and φ equal to $\varnothing$).

Claim 4. Let $s \in T_\Sigma$, $u \in V(s)$, and $p \in P$, and let (q, φ) be an $h(s[u \leftarrow p])$-uniform state of M'. Then

$$\hat{M}'_{(q,\varphi)}(s[u \leftarrow p]) = \hat{N}_q(s[u \leftarrow p])[\![\mathrm{rel}]\!].$$

The proof is by induction on the structure of s. Let $s = \sigma(s_1, \ldots, s_k)$ with $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in T_\Sigma$. For $u = \varepsilon$ we get $\hat{M}'_{(q,\varphi)}(s[u \leftarrow p]) = \langle\langle (q, \varphi), p\rangle\rangle$. Since $\varphi = \varphi_n$, where n is the rank of q, $\langle\langle (q, \varphi), p\rangle\rangle = \langle\langle q, p\rangle\rangle[\![\mathrm{rel}]\!] = \hat{N}_q(s[u \leftarrow p])[\![\mathrm{rel}]\!]$. For $u = ju'$ with $j \geq 1$ and $u' \in \mathbb{N}^*$, $s[u \leftarrow p] = \sigma(\tilde{s}_1, \ldots, \tilde{s}_k)$ with $\tilde{s}_j = s_j[u' \leftarrow p]$ and $\tilde{s}_i = s_i$ for $i \in [k] - \{j\}$. By Lemma 3.5 and the definition of the right-hand sides of M', $\hat{M}'_{(q,\varphi)}(s[u \leftarrow p]) = \mathrm{repl}(\mathrm{rhs}(\rho)\Pi)[\![\_]\!]$, where ρ is the $(q, \sigma, \langle h(\tilde{s}_1), \ldots, h(\tilde{s}_k)\rangle)$-rule of N and $[\![\_]\!] = [\![\langle (q', \varphi'), x_i\rangle \leftarrow \hat{M}'_{(q',\varphi')}(\tilde{s}_i) \mid \langle (q', \varphi'), x_i\rangle \in \langle Q', X_k\rangle]\!]$. By Claim 3(i), if $\langle (q', \varphi'), x_i\rangle$ occurs in $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$, then (q', φ') is $h(\tilde{s}_i)$-uniform and, by the argument given above Claim 4, $\varphi' = \varphi_{n'}$, where $q' \in Q_N^{(n')}$. Clearly, $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$ equals $\mathrm{rhs}(\rho)[\![\ ]\!]$ with $[\![\ ]\!] = [\![\langle q', x_i\rangle \leftarrow \langle (q', \varphi_{n'}), x_i\rangle \mid \langle q', x_i\rangle \in \langle Q_N, X_k\rangle^{(n')}, n' \geq 0]\!]$. Furthermore, we can restrict the substitution $[\![\_]\!]$ to those $\langle (q', \varphi'), x_i\rangle$ which occur in $\mathrm{repl}(\mathrm{rhs}(\rho)\Pi)$ and then apply the induction hypothesis to $\tilde{s}_j = s_j[u \leftarrow p]$. If we combine the resulting substitution with $[\![\ ]\!]$ and apply Claim 1 to $\tilde{s}_i = s_i$ for $i \in [k]-\{j\}$ (where Π' is the identity), then we get $\mathrm{rhs}(\rho)[\![\langle q', x_i\rangle \leftarrow \hat{N}_{q'}(\tilde{s}_i)[\![\mathrm{rel}]\!] \mid \langle q', x_i\rangle \in \langle Q_N, X_k\rangle$ occurs in $\mathrm{rhs}(\rho)]\!] = \mathrm{rhs}(\rho)[\![\langle q', x_i\rangle \leftarrow \hat{N}_{q'}(\tilde{s}_i)[\![\mathrm{rel}]\!] \mid \langle q', x_i\rangle \in \langle Q_N, X_k\rangle]\!]$, which equals $\hat{N}_q(s[u \leftarrow p])[\![\mathrm{rel}]\!]$. This proves Claim 4.

To show (ii) of p-properness of M', note that if $\varphi \in \Phi_{q,p}$, then $\langle\langle q, p\rangle\rangle$ is reachable (by N), and hence, by Claim 3(ii), q is p-uniform; then also (q, φ) is p-uniform, $\varphi = \varphi_n$, and, by Claim 4, $\langle\langle (q, \varphi), p\rangle\rangle$ is reachable (by M'). Thus, if $\langle\langle (q, \varphi), p\rangle\rangle$ is not reachable, then $\varphi \notin \Phi_{q,p}$. This implies a dummy right-hand side for all $((q, \varphi), \sigma, \langle p_1, \ldots, p_k\rangle)$-rules with $h_\sigma(p_1, \ldots, p_k) = p$ and therefore $\#_{y_j}(M'_{(q,\varphi)}(s)) = 1$ for all $s \in L_p$. This proves (ii) of p-properness and concludes the proof of properness of M'. Hence, the lemma holds for $\mathrm{prop}(M) = M'$. □

The following example illustrates the construction of a proper $\mathrm{MTT}^{\mathrm{R}}$ as given in the proof of Theorem 5.9.

Example 5.10. Let $M = (Q, \{p\}, \Sigma, \Delta, q_0, R, h)$ be the MTT with $Q = \{q_0^{(0)}, q^{(2)}\}$, $\Sigma = \{a^{(1)}, b^{(1)}, e^{(0)}\}$, $\Delta = \{\sigma^{(3)}, \gamma^{(1)}, a^{(0)}, b^{(0)}, e^{(0)}\}$, and R consisting of the following rules (where the only look-ahead $\langle p\rangle$ is omitted, as usual):

$$\begin{array}{llll}
\langle q_0, a(x_1)\rangle & \to & \langle q, x_1\rangle(a, a), & \langle q, a(x_1)\rangle(y_1, y_2) \to \sigma(y_1, y_2, \langle q, x_1\rangle(a, a)),\\
\langle q_0, b(x_1)\rangle & \to & \langle q, x_1\rangle(b, b), & \langle q, b(x_1)\rangle(y_1, y_2) \to \sigma(y_1, y_2, \langle q, x_1\rangle(b, \gamma(y_2))),\\
\langle q_0, e\rangle & \to & e, & \langle q, e\rangle(y_1, y_2) \to \sigma(y_1, y_2, e).
\end{array}$$

Note that M is productive and i-proper. Let us now construct the MTT $\pi(M)$ as defined in the proof of Theorem 5.9. Clearly, $\mathrm{Arg}(q, 1, p) = \{a, b\}$ and $\mathrm{Arg}(q, 2, p) = \{\gamma^n(c) \mid n \geq 0, c \in \{a, b\}\}$. Thus, $\Phi_{q,p}$ consists of the two mappings φ_a and φ_b with $\varphi_a(1) = a$, $\varphi_a(2) = y_1$, $\varphi_b(1) = b$, and $\varphi_b(2) = y_1$. Therefore the states of $M_1 = \pi(M)$ are $(q_0, \varnothing)^{(0)}, (q, \varphi_a)^{(1)}, (q, \varphi_b)^{(1)}$, abbreviated by q_0, q_a, q_b, respectively. For every $c \in \{a, b\}$, M_1 has the following rules.

$$\begin{array}{llll}
\langle q_0, a(x_1)\rangle & \to & \langle q_a, x_1\rangle(a), & \langle q_c, a(x_1)\rangle(y_1) \to \sigma(c, y_1, \langle q_a, x_1\rangle(a)),\\
\langle q_0, b(x_1)\rangle & \to & \langle q_b, x_1\rangle(b), & \langle q_c, b(x_1)\rangle(y_1) \to \sigma(c, y_1, \langle q_b, x_1\rangle(\gamma(y_1))),\\
\langle q_0, e\rangle & \to & e, & \langle q_c, e\rangle(y_1) \to \sigma(c, y_1, e).
\end{array}$$

Now for M_1, $\mathrm{Arg}(q_a, 1, p) = \{a\}$ and $\mathrm{Arg}(q_b, 1, p) = \{\gamma^n(c) \mid n \geq 0, c \in \{a, b\}\}$. Since $\langle\langle q_a, p\rangle\rangle$ is reachable this means that M_1 is not p-proper.

Following the proof of Theorem 5.9, we have to construct the MTT $N = \pi(M_1)$, because $\mathrm{rank}_{Q'}((q, \varphi_a)) < \mathrm{rank}_Q(q)$. Clearly, $\Phi_{q_a,p} = \{\varphi'_a\}$ with $\varphi'_a(1) = a$, and $\Phi_{q_b,p} = \{\varphi_1\}$ with $\varphi_1(1) = y_1$. Thus, the states of N are $(q_0, \varnothing)^{(0)}, (q_a, \varphi'_a)^{(0)}$, and

$(q_b, \varphi_1)^{(1)}$, abbreviated by q_0, q_a, and q_b, respectively. The rules of N are as follows:

$$\begin{array}{lcl}
\langle q_0, a(x_1)\rangle & \to & \langle q_a, x_1\rangle, \\
\langle q_0, b(x_1)\rangle & \to & \langle q_b, x_1\rangle(b), \\
\langle q_0, e\rangle & \to & e, \\
\langle q_a, a(x_1)\rangle & \to & \sigma(a, a, \langle q_a, x_1\rangle), \\
\langle q_b, a(x_1)\rangle(y_1) & \to & \sigma(b, y_1, \langle q_a, x_1\rangle), \\
\langle q_a, b(x_1)\rangle & \to & \sigma(a, a, \langle q_b, x_1\rangle(\gamma(a))), \\
\langle q_b, b(x_1)\rangle(y_1) & \to & \sigma(b, y_1, \langle q_b, x_1\rangle(\gamma(y_1))), \\
\langle q_a, e\rangle & \to & \sigma(a, a, e), \\
\langle q_b, e\rangle(y_1) & \to & \sigma(b, y_1, e).
\end{array}$$

The MTT N is p-proper because $\mathrm{Arg}(q_b, 1, p) = \{\gamma^n(c) \mid n \geq 0, c \in \{a, b\}\}$ (and all elements of $\langle\langle Q_N, \{p\}\rangle\rangle$ are reachable). It is easy to see that N is equivalent to M.

6. From linear size increase to finite copying. In this section we prove that if a proper $\mathrm{MTT}^{\mathrm{R}}$ M is lsi, then it is finite copying (i.e., both fci and fcp; see section 4.1). The proof is split up into the following three stages, using fnest (see section 4.2) as an intermediate notion:

(I) If M is lsi, then it is fnest.
(II) If M is lsi and fnest, then it is fcp.
(III) If M is lsi, fnest, and fcp, then it is fci.

We first prove (II), then (III), and finally (I). The reason for this order is that the proof of (I) will use results that are proved in (III). The idea in each stage is roughly as follows: First, it is proved that if M's copying is *not* bounded (i.e., M is not fcp, not fci, and not fnest for (II), (III), and (I), respectively), then we can find an input tree in which some part s can be pumped, i.e., repeated; each repetition of s will produce a copy of a certain parameter (for (II)) or of a certain state (for (III) and (I)). Second, it is shown that this repetition gives a size increase that is not linearly bounded (by any c); in this part the properness of M is used: it is shown that for any c we can pick a sufficiently large output tree t, a copy of which is generated with each repetition of s, and a sufficiently large i such that after i repetitions of s the size of the corresponding output tree is larger than c times the size of the input tree.

6.1. From lsi and fnest to fcp (II). We now present (in Lemma 6.2) a pumping lemma for non-fcp $\mathrm{MTT}^{\mathrm{R}}_{\mathrm{fnest}}$s, which allows us to prove (in Theorem 6.3) that if a proper $\mathrm{MTT}^{\mathrm{R}}_{\mathrm{fnest}}$ is lsi, then it is fcp.

First, for an $\mathrm{MTT}^{\mathrm{R}}$ M, consider the number k of occurrences of y_ν in $\hat{M}_r(t[u \leftarrow p])$ with $p = h(t/u)$. Clearly, if $\hat{M}_r(t[u \leftarrow p])$ has a subtree $\langle\langle r_1, p\rangle\rangle(\xi_1, \ldots, \xi_{m_1})$ such that y_ν occurs in ξ_{ν_1} for some $\nu_1 \in [m_1]$, then, assuming that M is nondeleting, the number of y_ν's in $M_r(t)$ must be at least $k-1$ plus the number of y_{ν_1}'s in $M_{r_1}(t/u)$. This is proved in the next lemma, in such a way that the idea can be iterated.

LEMMA 6.1. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting MTT^R. For $r_0 \in Q^{(m_0)}$, $r_1 \in Q^{(m_1)}$, $\nu_0 \in [m_0]$, $\nu_1 \in [m_1]$, $t_0 \in T_\Sigma$, $u_1 \in V(t_0)$, and $k \in \mathbb{N}$, let $\mathcal{P}(r_0, \nu_0, t_0, r_1, \nu_1, u_1, k)$ be the following statement, with p_1 denoting $h(t_0/u_1)$:*

$$\#_{y_{\nu_0}}(\hat{M}_{r_0}(t_0[u_1 \leftarrow p_1])) \geq k \text{ and } \hat{M}_{r_0}(t_0[u_1 \leftarrow p_1]) \text{ has a subtree } \langle\langle r_1, p_1\rangle\rangle(\xi_1, \ldots, \xi_{m_1}) \text{ for certain } \xi_1, \ldots, \xi_{m_1} \text{ such that } \#_{y_{\nu_0}}(\xi_{\nu_1}) \geq 1.$$

Let $r_2 \in Q^{(m_2)}$, $\nu_2 \in [m_2]$, $u_2 \in V(t_0/u_1)$, and $l \in \mathbb{N}$. If $\mathcal{P}(r_0, \nu_0, t_0, r_1, \nu_1, u_1, k)$ and $\mathcal{P}(r_1, \nu_1, t_0/u_1, r_2, \nu_2, u_2, l)$, then $\mathcal{P}(r_0, \nu_0, t_0, r_2, \nu_2, u_1u_2, k+l-1)$.

Proof. Note that $t_0/u_1u_2 = (t_0/u_1)/u_2$. Let $t_1 = t_0/u_1$, $p_1 = h(t_1)$, and $p_2 = h(t_0/u_1u_2) = h(t_1/u_2)$. By Lemma 4.2, $\hat{M}_{r_0}(t_0[u_1u_2 \leftarrow p_2])$ equals $t[\![\ldots]\!]$ with $t = \hat{M}_{r_0}(t_0[u_1 \leftarrow p_1])$ and $[\![\ldots]\!] = [\![\langle\!\langle q', p_1\rangle\!\rangle \leftarrow \hat{M}_{q'}(t_1[u_2 \leftarrow p_2]) \mid q' \in Q]\!]$. We use Lemma 2.6 to compute the number of occurrences of y_{ν_0}'s in this tree. By the first assumption, t has at least k leaves $u \in V_{y_{\nu_0}}(t)$, and it has a subtree $\langle\!\langle r_1, p_1\rangle\!\rangle(\xi_1, \ldots, \xi_{m_1})$ with $\#_{y_{\nu_0}}(\xi_{\nu_1}) \geq 1$. Thus, t has a leaf $u \in V_{y_{\nu_0}}(t)$ such that $\prod F_{t,u}^{[\![\ldots]\!]} \geq \#_{y_{\nu_1}}(\hat{M}_{r_1}(t_1[u_2 \leftarrow p_2]))$, which is $\geq l$ by the second assumption. Hence, $S_1^{y_{\nu_0}} + S_2^{y_{\nu_0}}$ of Lemma 2.6 equals $S_1^{y_{\nu_0}} \geq k - 1 + l$. We have used the fact that $\#_{y_\nu}(\hat{M}_{q'}(t_1[u_2 \leftarrow p_2])) \geq 1$ for all ν and q', which follows from Lemma 3.11(1) because M is nondeleting (and hence so is $\hat{M}$).

The substitution $[\![\ldots]\!]$ is nondeleting, because $\hat{M}$ is nondeleting. Thus, since t has a subtree $\langle\!\langle r_1, p_1\rangle\!\rangle(\xi_1, \ldots, \xi_{m_1})$, it follows from Lemma 2.1 that $\hat{M}_{r_0}(t_0[u_1u_2 \leftarrow p_2]) = t[\![\ldots]\!]$ has a subtree $\langle\!\langle r_1, p_1\rangle\!\rangle(\xi_1, \ldots, \xi_{m_1})[\![\ldots]\!] = \hat{M}_{r_1}(t_1[u_2 \leftarrow p_2])[\ldots]$, where $[\ldots]$ denotes $[y_j \leftarrow \xi_j[\![\ldots]\!] \mid j \in [m_1]]$.

By the second assumption, $\hat{M}_{r_1}(t_1[u_2 \leftarrow p_2])$ has a subtree $\langle\!\langle r_2, p_2\rangle\!\rangle(\zeta_1, \ldots, \zeta_{m_2})$ with $\#_{y_{\nu_1}}(\zeta_{\nu_2}) \geq 1$. Thus we obtain a subtree $\langle\!\langle r_2, p_2\rangle\!\rangle(\zeta_1[\ldots], \ldots, \zeta_{m_2}[\ldots])$ and $\zeta_{\nu_2}[\ldots]$ has a subtree $\xi_{\nu_1}[\![\ldots]\!]$ which contains y_{ν_0} (because $\#_{y_{\nu_0}}(\xi_{\nu_1}) \geq 1$ and M is nondeleting). □

LEMMA 6.2. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting MTT^R_{fnest} with the property: if $\langle\!\langle q, p\rangle\!\rangle \in \langle\!\langle Q, P\rangle\!\rangle^{(m)}$ is not reachable, then $\#_{y_j}(M_q(s)) \leq 1$ for all $j \in [m]$ and $s \in L_p$ (property* (ii) *of Definition* 5.6 *of p-properness).*

If M is not fcp, then there are $m \geq 1$, $q \in Q^{(m)}$, $j \in [m]$, $s \in T_\Sigma$, $u \in V(s)$, and $p \in P$ such that

(1) $\#_{y_j}(\hat{M}_q(s[u \leftarrow p])) \geq 2$,

(2) $\hat{M}_q(s[u \leftarrow p])$ *has a subtree* $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_m)$ *with* $\#_{y_j}(\xi_j) \geq 1$, *and*

(3) $p = h(s) = h(s/u)$.

Proof. We first define an auxiliary notion. For $t \in T_\Sigma$, u an ancestor of $v \in V(t)$, $q \in Q^{(m)}$, $\mu \in [m]$, $q' \in Q^{(m')}$, $\mu' \in [m']$, define $(q, \mu) \to_{u,v} (q', \mu')$ if, for $\xi_{q,u,v} = \hat{M}_q(t/u[v' \leftarrow p_v])$ with $v = uv'$ and $p_v = h(t/v)$, $\#_{y_\mu}(\xi_{q,u,v}) \geq 2$ and $\xi_{q,u,v}$ has a subtree $\langle\!\langle q', p_v\rangle\!\rangle(\xi_1, \ldots, \xi_{m'})$ such that $\#_{y_\mu}(\xi_{\mu'}) \geq 1$. Note that $(q, \mu) \to_{u,v} (q', \mu')$ if and only if $\mathcal{P}(q, \mu, t/u, q', \mu', v', 2)$, where $\mathcal{P}$ is the statement of Lemma 6.1. The relation $\to$ is transitive; i.e., for a descendant w of v,

$$\text{if } (q, \mu) \to_{u,v} (q', \mu') \text{ and } (q', \mu') \to_{v,w} (q'', \mu''), \text{ then } (q, \mu) \to_{u,w} (q'', \mu'').$$

This follows from Lemma 6.1, because $(q, \mu) \to_{u,v} (q', \mu')$ and $(q', \mu') \to_{v,w} (q'', \mu'')$ imply that $\mathcal{P}(q, \mu, t/u, q'', \mu'', v'w', 3)$ with $w' \in \mathbb{N}^*$ such that $w = vw'$, and thus $(q, \mu) \to_{u,w} (q'', \mu'')$.

Assume that M is not fcp. Then, in terms of the $\to$ notation, the lemma says that there are $m \geq 1$, $q \in Q^{(m)}$, $j \in [m]$, $s \in T_\Sigma$, $u \in V(s)$, and $p \in P$ such that

- $(q, j) \to_{\varepsilon,u} (q, j)$ (points (1) and (2) of the lemma),
- $p = h(s) = h(s/u)$ (point (3) of the lemma).

Since M is not fcp, for every $n \in \mathbb{N}$, there are $q \in Q^{(m)}$, $j \in [m]$, and $t \in T_\Sigma$ such that $\#_{y_j}(M_q(t)) > n$. The following claim shows that if $\#_{y_j}(M_q(t/u))$ is "large" for a node u of t, then there must be a descendant v of u, a state r, and a parameter y_ν of r such that $(q, j) \to_{u,v} (r, \nu)$ and $\#_{y_\nu}(M_r(t/v))$ is still "large." The application of this claim can be iterated to show the existence of a sequence of descendants v and a sequence of steps $\to$, which will eventually lead to a repetition of a state-parameter pair that allows us to define s and u such that (1)–(3) hold.

Let B be a nesting bound for M. Let η be the maximal height of the right-hand side of a rule of M, i.e., $\eta = \max\{\text{height}(\text{rhs}(\rho)) \mid \rho \in R\}$, and let $\kappa \geq 1$ be an upper bound for the number of occurrences of one particular parameter in the right-hand side of a rule of M, i.e., $\#_y(\text{rhs}(\rho)) \leq \kappa$ for every $y \in Y$ and $\rho \in R$.

Claim. For every $c \geq 1$, $t \in T_\Sigma$, $u \in V(t)$, $q \in Q^{(m)}$, and $\mu \in [m]$, if $\#_{y_\mu}(M_q(t/u))$ is greater than $c^{B\eta} \cdot \kappa^B$, then there exist a descendant v of u, a state $r \in Q^{(m')}$, and a $\nu \in [m']$ such that $(q,\mu) \to_{u,v} (r,\nu)$ and $\#_{y_\nu}(M_r(t/v)) > c$.

Proof of the claim. Let w be a longest descendant of u such that $\#_{y_\mu}(\xi_{q,u,w}) = 1$. Clearly, such a w exists, because $\#_{y_\mu}(\xi_{q,u,u}) = 1$. Then there must be a child v of w that satisfies the requirements of the claim. Assume to the contrary, that if v is a child of w, then it does *not* satisfy the requirements, i.e., for every $r \in Q^{(m')}$ and $\nu \in [m']$ with $(q,\mu) \to_{u,v} (r,\nu)$, $\#_{y_\nu}(M_r(t/v)) \leq c$. This will lead to a contradiction.

By Lemmas 4.2 (applied to t/u and w) and 3.5,

$$M_q(t/u) = \xi_{q,u,w}[\![\text{rhs}]\!][\![\ldots]\!],$$

where $[\![\text{rhs}]\!] = [\![\langle\!\langle r, p_w\rangle\!\rangle \leftarrow \text{rhs}_M(r,\sigma,\langle p_1,\ldots,p_k\rangle) \mid r \in Q]\!]$ with $\sigma = t[w] \in \Sigma^{(k)}$, $k \geq 0$, $p_w = h(t/w)$, $p_i = h(t/wi)$ for $i \in [k]$, and $[\![\ldots]\!] = [\![\langle r, x_i\rangle \leftarrow M_r(t/wi) \mid \langle r, x_i\rangle \in \langle Q, X_k\rangle]\!]$. Now, $\#_{y_\mu}(\xi_{q,u,w}[\![\text{rhs}]\!]) \leq \kappa^B$. This is true because by Lemma 2.6, $\#_{y_\mu}(\xi_{q,u,w}[\![\text{rhs}]\!]) = S_1^{y_\mu} = \sum_{z \in V_{y_\mu}(\xi_{q,u,w})} \prod F^{[\![\text{rhs}]\!]}_{\xi_{q,u,w},z}$, which equals $\prod F^{[\![\text{rhs}]\!]}_{\xi_{q,u,w},z}$ for the unique z with $V_{y_\mu}(\xi_{q,u,w}) = \{z\}$. Since $\#_{y_\mu}(M_q(t/u)) > 1$, $\langle\!\langle q, h(t/u)\rangle\!\rangle$ is reachable by the assumption of the lemma. Thus, by Lemma 4.13, there are at most B occurrences of elements of $\langle\!\langle Q, \{p_w\}\rangle\!\rangle$ on the label path $\text{lpath}(\xi_{q,u,w}, z)$. Hence, $\prod F^{[\![\text{rhs}]\!]}_{\xi_{q,u,w},z}$ is the product of at most B numbers $\#_{y_\nu}(\text{rhs}_M(r,\sigma,\langle p_1,\ldots,p_k\rangle)) \leq \kappa$ for $r \in Q$ and $\nu \in [\text{rank}_Q(r)]$, and therefore $\prod F^{[\![\text{rhs}]\!]}_{\xi_{q,u,w},z} \leq \kappa^B$.

Since every label path of $\xi_{q,u,w}$ is of the form $w_0\langle\!\langle q_1, p_w\rangle\!\rangle w_1 \cdots \langle\!\langle q_l, p_w\rangle\!\rangle w_l$ with $l \leq B$, $q_1,\ldots,q_l \in Q$, and $w_0,\ldots,w_l \in \Delta^*$, it follows from Lemma 2.3(i) that every label path π in $\xi_{q,u,w}[\![\text{rhs}]\!]$ is of the form $w_0v_1w_1\cdots v_lw_l$, where each v_i is a label path in $\text{rhs}_M(q_i,\sigma,\langle p_1,\ldots,p_k\rangle)$. By the definition of η, the length of v_i is $\leq \eta$. Thus, $\#_{\langle Q,X_k\rangle}(\pi) = \sum_{i\in[l]} \#_{\langle Q,X_k\rangle}(v_i) \leq B\eta$.

Let $\zeta = \xi_{q,u,w}[\![\text{rhs}]\!]$. By Lemma 2.6, $\#_{y_\mu}(\zeta[\![\ldots]\!]) = \sum_{z\in V_{y_\mu}(\zeta)} \prod F^{[\![\ldots]\!]}_{\zeta,z}$. This is $\leq \kappa^B \cdot \prod F^{[\![\ldots]\!]}_{\zeta,z}$, where $z \in V_{y_\mu}(\zeta)$ such that $\prod F^{[\![\ldots]\!]}_{\zeta,z}$ is maximal, because $\#_{y_\mu}(\zeta) \leq \kappa^B$. Since $\#_{\langle Q,X_k\rangle}(\pi) \leq B\eta$ for $\pi = \text{lpath}(\zeta,z)$, $\prod F^{[\![\ldots]\!]}_{\zeta,z}$ is the product of at most $B\eta$ numbers $\#_{y_\nu}(M_r(t/wi))$. Let us now show that each such number is $\leq c$. We need to show that $(q,\mu) \to_{u,wi} (r,\nu)$. By the definition of w, $\#_{y_\mu}(\xi_{q,u,wi}) \neq 1$. Since M is nondeleting it follows from Lemma 3.11(1) that $\#_{y_\mu}(\xi_{q,u,wi}) \geq 1$, and thus $\#_{y_\mu}(\xi_{q,u,wi}) \geq 2$. Since $\langle r, x_i\rangle$ occurs in ζ at some node z' with $z = z'\nu z''$, ζ has a subtree $\langle r, x_i\rangle(\zeta_1,\ldots,\zeta_{m'})$ for some $\zeta_1,\ldots,\zeta_{m'} \in T_{\langle Q,X_k\rangle\cup\Delta}(Y_m)$, and y_μ occurs in ζ_ν. By Lemma 4.3, $\xi_{q,u,wi} = \zeta[\![..]\!][\![i]\!]$, with $[\![..]\!]$ and $[\![i]\!]$ as in that lemma. It follows from Lemma 3.11(1) that $[\![..]\!][\![i]\!]$ is nondeleting. Thus, by Lemma 2.1, $\xi_{q,u,wi}$ has a subtree $\langle\!\langle r, p_i\rangle\!\rangle(\zeta_1[\![..]\!][\![i]\!],\ldots,\zeta_{m'}[\![..]\!][\![i]\!])$ and y_μ occurs in $\zeta_\nu[\![..]\!][\![i]\!]$. This proves that $(q,\mu) \to_{u,wi} (r,\nu)$ and thus, by assumption, $\#_{y_\nu}(M_r(t/wi)) \leq c$. We get $\#_{y_\mu}(M_q(t/u)) \leq c^{B\eta} \cdot \kappa^B$, which is a contradiction and ends the proof of the claim.

Now, let $c_0 = 1$ and $c_i = c_{i-1}^{B\eta}\kappa^B$ for $i \geq 1$. Since M is not fcp, for every $n \geq 1$ there exist $r_0 \in Q^{(m_0)}$, $\nu_0 \in [m_0]$, and $t \in T_\Sigma$ such that $\#_{y_{\nu_0}}(M_{r_0}(t)) > c_n$. Let $v_0 = \varepsilon$. We apply the claim for $i = 0,1,\ldots,n-1$ to $u = v_i$, $q = r_i$, and $\mu = \nu_i$ to obtain that there exist a descendant v_{i+1} of v_i, a state $r_{i+1} \in Q^{(m_{i+1})}$, and $\nu_{i+1} \in [m_{i+1}]$ such that $(r_i,\nu_i) \to_{v_i,v_{i+1}} (r_{i+1},\nu_{i+1})$ and $\#_{y_{\nu_{i+1}}}(M_{r_{i+1}}(t/v_{i+1})) > c_{n-(i+1)}$.

Take $n = |Q| \cdot \overline{m} \cdot |P|$, where $\overline{m}$ is the maximal rank of a state of M. Then there are indices $0 \leq i < i' \leq n$ such that $q = r_i = r_{i'}$, $j = \nu_i = \nu_{i'}$, and $p = h(t/v_i) = h(t/v_{i'})$. Then $(q, j) \to_{v_i, v_{i'}} (q, j)$ by the transitivity of $\to$. Let $s = t/v_i$ and $v_i u = v_{i'}$. Clearly (3) holds. Moreover, in s, $(q, j) \to_{\varepsilon, u} (q, j)$, which means that (1) and (2) hold. ∎

We now prove that if a proper $\mathrm{MTT}^{\mathrm{R}}_{\mathrm{fnest}}$ M is lsi, then it is fcp; i.e., we prove step (II). The idea is to assume that M is not fcp, and then to "pump" the tree $s[u \leftarrow p]$ of Lemma 6.2 in order to show that this implies that M is not lsi. We use the following notation to pump a tree. For $s \in T_\Sigma$, $u \in V(s)$, $p \in P$, and $s' \in T_\Sigma(P)$, let $s[u \leftarrow p] \bullet s'$ denote $s[u \leftarrow s']$. Let $(s[u \leftarrow p])^0 = p$, and for $n \in \mathbb{N}$ let $(s[u \leftarrow p])^{n+1} = (s[u \leftarrow p]) \bullet (s[u \leftarrow p])^n$. Thus, e.g.,

$$\begin{aligned}
&(s[u \leftarrow p])^1 = s[u \leftarrow p] \bullet p = s[u \leftarrow p],\\
&(s[u \leftarrow p])^2 = (s[u \leftarrow p]) \bullet (s[u \leftarrow p]) = s[u \leftarrow s[u \leftarrow p]], \quad \text{and}\\
&(s[u \leftarrow p])^3 = (s[u \leftarrow p]) \bullet s[u \leftarrow s[u \leftarrow p]] = s[u \leftarrow s[u \leftarrow s[u \leftarrow p]]].
\end{aligned}$$

We will only pump the tree $s[u \leftarrow p]$, for a given $\mathrm{MTT}^{\mathrm{R}}$, if $\hat{h}(s[u \leftarrow p]) = p$. Note that this condition is satisfied in Lemma 6.2 by point (3).

THEOREM 6.3. *Let M be a proper MTT^R_{fnest}. If M is lsi, then it is fcp.*

Proof. Let $M = (Q, \Sigma, \Delta, q_0, R, P, h)$ be lsi; i.e., there is a $c \in \mathbb{N}$ such that for every input tree t,

$$(*) \qquad \mathrm{size}(\tau_M(t)) \leq c \cdot \mathrm{size}(t).$$

Assume now that M is not fcp. We will derive a contradiction by constructing an input tree t such that $\mathrm{size}(\tau_M(t)) > c \cdot \mathrm{size}(t)$. Let $q \in Q^{(m)}$, $m \geq 1$, $j \in [m]$, $s \in T_\Sigma$, $p = h(s)$, and $u \in V(s)$ be such that (1)–(3) of Lemma 6.2 hold. Note that since M is proper it satisfies the conditions of Lemma 6.2.

The idea of constructing a t such that $(*)$ does not hold is as follows: Let $s_0 \in T_\Sigma$ and $u_0 \in V(s_0)$ such that

$$(\dagger) \qquad \hat{M}_{q_0}(s_0[u_0 \leftarrow p]) \text{ has a subtree } \langle\!\langle q, p \rangle\!\rangle(\xi_1, \ldots, \xi_m)$$

for some trees $\xi_1, \ldots, \xi_m$. Consider input trees t_i obtained by i times pumping the tree $s[u \leftarrow p]$ in the tree $s_0[u_0 \leftarrow s]$. Then the size of the trees t_i grows at most linearly with constant $\mathrm{size}(s[u \leftarrow p])$. In the output tree $\tau_M(t_i)$ there are at least i occurrences of the subtree $\xi_j[\![\ldots]\!]$ for some second-order tree substitution $[\![\ldots]\!]$. Hence, the size of the trees $\tau_M(t_i)$ grows at least linearly with constant $\mathrm{size}(\xi_j)$. Thus, if we choose s_0 and u_0 in such a way that $\mathrm{size}(\xi_j)$ is larger than the product of c and $\mathrm{size}(s[u \leftarrow p])$, then $\mathrm{size}(\tau_M(t_i))$ grows faster than $c \cdot \mathrm{size}(t_i)$, which implies that we can find an i such that $(*)$ does not hold for $t = t_i$.

Recall Definition 5.6 of p-properness. In order to choose s_0 and u_0 appropriately we need the set $\mathrm{Arg}(q, j, p)$ to be infinite, i.e., to contain arbitrarily large trees. This is guaranteed by point (i) of Definition 5.6 if $\langle\!\langle q, p \rangle\!\rangle$ is reachable. The latter holds for the following reason: Since M is nondeleting, by Lemma 3.11(1), $\#_{y_\nu}(M_r(s/u)) \geq 1$ for every $r \in Q^{(m')}$ and $\nu \in [m']$. By Lemmas 4.2 and 2.6 and the fact that $\#_{y_j}(\hat{M}_q(s[u \leftarrow p])) \geq 2$ by (1), this implies that $\#_{y_j}(M_q(s)) \geq 2$. Thus, $\langle\!\langle q, p \rangle\!\rangle$ is reachable by point (ii) of Definition 5.6.

We now show the effect of pumping the tree $s[u \leftarrow p]$ in the input tree $s = s[u \leftarrow p] \bullet s/u$. For $i \geq 0$ let $t'_i = (s[u \leftarrow p])^i \bullet s/u$. Then $\#_{y_j}(M_q(t'_i)) > i$. Using the fact that M is nondeleting, this follows (as above, by Lemmas 4.2 and 2.6) from

$\#_{y_j}(\hat{M}_q(t'_i[u^i \leftarrow p])) > i$, which is a consequence of the next claim and the definition of $\mathcal{P}$ (cf. Lemma 6.1).

Claim. For $i \geq 0$, $\mathcal{P}(q, j, t'_i, q, j, u^i, i+1)$.

The proof of this claim is by induction on i. For $i = 0$, $\mathcal{P}(q, j, t'_i, q, j, u_1^i, i+1)$ because $\xi = \hat{M}_q(s/u[\varepsilon \leftarrow p]) = \langle\!\langle q, p\rangle\!\rangle(y_1, \ldots, y_m)$ and thus $\#_{y_j}(\xi) \geq 1$ and ξ has a subtree $\langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_m)$ with $\#_{y_j}(\xi_j) = \#_{y_j}(y_j) = 1$. For $i + 1 > 0$, by induction, $\mathcal{P}(q, j, t'_i, q, j, u^i, i+1)$. Clearly, by (3), $h(t'_{i+1}/u^i) = h(s) = p = h(s/u) = h(t'_i/u^i)$, and $t'_{i+1}[u^i \leftarrow p] = t'_i[u^i \leftarrow p]$. Thus, $\mathcal{P}(q, j, t'_{i+1}, q, j, u^i, i+1)$. By (1) and (2), $\mathcal{P}(q, j, s, q, j, u, 2)$, which is equivalent to $\mathcal{P}(q, j, t'_{i+1}/u^i, q, j, u, 2)$ because $t'_{i+1}/u^i = s$. By Lemma 6.1 this means that $\mathcal{P}(q, j, t'_{i+1}, q, j, u^i u, i+2)$, which concludes the proof of the claim.

Now let $t_i = s_0[u_0 \leftarrow t'_i]$, where $s_0 \in T_\Sigma$ and $u_0 \in V(s_0)$ satisfy (†). Thus, t_i is the result of pumping the tree $s[u \leftarrow p]$ in the input tree $s_0[u_0 \leftarrow s]$. Since $\#_{y_j}(\hat{M}_q(t'_i) > i$, we obtain $\mathrm{size}(\tau_M(t_i)) > i \cdot \mathrm{size}(\xi_j)$ as follows: By Lemma 4.2, $\tau_M(t_i) = \hat{M}_{q_0}(s_0[u_0 \leftarrow p])[\![\ldots]\!]$, where $[\![\ldots]\!] = [\![\langle\!\langle r, p\rangle\!\rangle \leftarrow M_r(t'_i) \mid r \in Q]\!]$. By Lemma 2.1, $\hat{M}_{q_0}(s_0[u_0 \leftarrow p])[\![\ldots]\!]$ has a subtree $\xi = \langle\!\langle q, p\rangle\!\rangle(\xi_1, \ldots, \xi_m)[\![\ldots]\!] = M_q(t'_i)[y_\nu \leftarrow \xi_\nu[\![\ldots]\!] \mid \nu \in [m]]$. By Lemma 2.4 (summing for all $\delta \in \Delta$), $\mathrm{size}(\xi) = \#_\Delta(\xi) = \#_\Delta(M_q(t'_i)) + \sum_{\nu \in [m]} \#_{y_\nu}(M_q(t'_i)) \cdot \#_\Delta(\xi_\nu[\![\ldots]\!]) \geq \sum_{\nu=j} \#_{y_\nu}(M_q(t'_i)) \cdot \#_\Delta(\xi_\nu[\![\ldots]\!]) = \#_{y_j}(M_q(t'_i)) \cdot \mathrm{size}(\xi_j[\![\ldots]\!])$. Since M is productive, Lemmas 2.7 and 3.11 imply that $\mathrm{size}(\xi_j[\![\ldots]\!]) \geq \mathrm{size}(\xi_j)$. Since $\#_{y_j}(M_q(t'_i)) > i$, this implies that $\mathrm{size}(\tau_M(t_i)) > i \cdot \mathrm{size}(\xi_j)$.

Since $\mathrm{Arg}(q, j, p)$ is infinite, we can choose s_0 and u_0 such that (†) and

$$\mathrm{size}(\xi_j) > c \cdot c_1,$$

where $c_1 = \mathrm{size}(s[u \leftarrow p]) - 1$. Let $i = c(c_0 + c_2)$ for $c_0 = \mathrm{size}(s_0[u_0 \leftarrow p]) - 1$ and $c_2 = \mathrm{size}(s/u)$. Since $\mathrm{size}(t_i) = c_0 + ic_1 + c_2$ this means that $\mathrm{size}(\tau_M(t_i)) > c \cdot \mathrm{size}(t_i)$ because $\mathrm{size}(\tau_M(t_i)) > i \cdot \mathrm{size}(\xi_j) \geq i \cdot (c \cdot c_1 + 1) = icc_1 + c(c_0 + c_2) = c(c_0 + ic_1 + c_2) = c \cdot \mathrm{size}(t_i)$. This contradicts $(*)$ and concludes the proof. □

6.2. From lsi, fnest, and fcp to fci (III). Here we present a pumping lemma for $\mathrm{MTT}^{\mathrm{R}}_{\mathrm{fnest,fcp}}$s that are not fci (Lemma 6.5) and apply it in Lemma 6.6 to show that if an $\mathrm{MTT}^{\mathrm{R}}_{\mathrm{fnest,fcp}}$ is lsi, then it is fci. We first define, in general, what is required of an $\mathrm{MTT}^{\mathrm{R}}$ in order to get a repetition of states by pumping a part of an input tree; this is called *input pumpable*. It means that there is a state q_1 that is reachable, i.e., appears in $\hat{M}_{q_0}(s_0[u_0 \leftarrow p])$ for some input tree s_0 and node u_0 of s_0 (with $p = h(s_0/u_0)$), and going from node u_0 to node u_0u_1 in s_0, q_1 will generate a copy of itself and of a state q_2; furthermore, the state q_2 generates a copy of itself when going from u_0 to u_0u_1.

Definition 6.4 (input pumpable). *An MTT^R $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ is* input pumpable *if there are $q_1, q_2 \in Q$, $s_0 \in T_\Sigma$, $u_0 \in V(s_0)$, $u_1 \in V(s_0/u_0)$, and $p \in P$ such that the following four conditions hold:*

(1) *$\langle\!\langle q_1, p\rangle\!\rangle$ occurs in $\hat{M}_{q_0}(s_0[u_0 \leftarrow p])$,*

(2) *$\langle\!\langle q_1, p\rangle\!\rangle$ and $\langle\!\langle q_2, p\rangle\!\rangle$ occur at distinct nodes of $\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])$,*

(3) *$\langle\!\langle q_2, p\rangle\!\rangle$ occurs in $\hat{M}_{q_2}(s_0/u_0[u_1 \leftarrow p])$, and*

(4) *$p = h(s_0/u_0) = h(s_0/u_0u_1)$.*

The following pumping lemma can be viewed as a generalization of Lemma 4.2 of [1] from top-down tree transducers to MTTs.

Lemma 6.5. *Let M be a nondeleting $MTT^R_{fnest,fcp}$. If M is not fci, then it is input pumpable.*

Proof. Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$. We first define some auxiliary notions. Let $t \in T_\Sigma$ and $u, v \in V(t)$ such that u is an ancestor of v, i.e., $v = uv'$ for some $v' \in \mathbb{N}^*$,

and let $p_v = h(t/v)$. For $q \in Q$, if $n = \#_{\langle\langle Q,\{p_v\}\rangle\rangle}(\hat{M}_q(t/u[v' \leftarrow p_v]))$, then we say that q *contributes* n *states at* u *to* v. If $n \geq 1$, then we say that q contributes at u to v. For $q, q' \in Q$ we write $q \to_{u,v} q'$ if $\langle\langle q', p_v\rangle\rangle$ occurs in $\hat{M}_q(t/u[v' \leftarrow p_v])$. For $r_1, r_2 \in Q$ we write $q \to_{u,v} r_1, r_2$ if $\langle\langle r_1, p_v\rangle\rangle$ and $\langle\langle r_2, p_v\rangle\rangle$ occur at distinct nodes of $\hat{M}_q(t/u[v' \leftarrow p_v])$. Observe the following easy properties:

(P0) $q \to_{v,v} q'$ if and only if $q = q'$; q contributes one state at v to v.

(P1) $q_0 \to_{\varepsilon,v} q$ if and only if q occurs in $\mathrm{sts}_M(t, v)$; q_0 contributes $|\mathrm{sts}_M(t, v)|$ states at ε to v.

(P2) q contributes at u to v if and only if there is a $q' \in Q$ such that $q \to_{u,v} q'$.

Let w be a node of t that is a descendant of u and an ancestor of v.

(P3) If $q \to_{u,w} q''$ and $q'' \to_{w,v} q'$, then $q \to_{u,v} q'$.

(P4) If $q \to_{u,v} q'$, then there is a $q'' \in Q$ such that $q \to_{u,w} q''$ and $q'' \to_{w,v} q'$.

Note that (P3) and (P4) can be proved using Lemma 4.14: Let $w', v'' \in \mathbb{N}^*$ such that $w = uw'$ and $v = wv''$ (and so v' above equals $w'v''$), and let $p_w = h(t/w)$. For (P3), the number $\#_{\langle\langle q'', p_w\rangle\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w]))$ is ≥ 1 because $q \to_{u,w} q''$, and $\#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_{q''}(t/w[v'' \leftarrow p_v]))$ is ≥ 1 because $q'' \to_{w,v} q'$; hence the product of these two numbers is ≥ 1 and so the sum S of Lemma 4.14 is ≥ 1. Thus, by part (i) of that lemma, $\#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_q(t/u[v' \leftarrow p_v])) \geq 1$, i.e., $q \to_{u,v} q'$. For (P4), $q \to_{u,v} q'$ implies that the sum in $(\times)$ of the proof of Lemma 4.14 is ≥ 1, and thus there is an occurrence of some $\langle\langle q'', p_w\rangle\rangle \in \langle\langle Q, \{p_w\}\rangle\rangle$ in $\hat{M}_q(s/u[w' \leftarrow p_w])$ with $\#_{\langle\langle q', p_v\rangle\rangle}(\hat{M}_{q''}(t/w[v'' \leftarrow p_v])) \geq 1$; i.e., there is a $q'' \in Q$ such that $q \to_{u,w} q''$ and $q'' \to_{w,v} q'$.

(P5) q contributes ≥ 2 states at u to v if and only if there are $r_1, r_2 \in Q$ such that $q \to_{u,v} r_1, r_2$.

(P6) Let $r_1', r_2' \in Q$ and w as above. If $q \to_{u,w} r_1, r_2$ and $r_i \to_{w,v} r_i'$ for $i \in [2]$, then $q \to_{u,v} r_1', r_2'$.

Let us prove property (P6). If $r_1' \neq r_2'$, then by (P3), $q \to_{u,v} r_1'$ and $q \to_{u,v} r_2'$, which means that $q \to_{u,v} r_1', r_2'$. Now assume that $r_1' = r_2'$. By Lemma 4.14(i), $\#_{\langle\langle r_1', p_v\rangle\rangle}(\hat{M}_q(t/u[v' \leftarrow p_v]))$ is greater than or equal to

$$(*) \qquad \sum_{r \in Q} \#_{\langle\langle r_1', p_v\rangle\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v])) \cdot \#_{\langle\langle r, p_w\rangle\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])),$$

where p_w, w', and v'' are as in the proof of (P3). We distinguish the following two cases:

(i) $r_1 \neq r_2$: For $r = r_1$ and $r = r_2$, $\#_{\langle\langle r, p_w\rangle\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])) \geq 1$, because $q \to_{u,w} r_1, r_2$. Thus, the sum in $(*)$ is $\geq \#_{\langle\langle r_1', p_v\rangle\rangle}(\hat{M}_{r_1}(t/w[v'' \leftarrow p_v])) + \#_{\langle\langle r_1', p_v\rangle\rangle}(\hat{M}_{r_2}(t/w[v'' \leftarrow p_v]))$, which is ≥ 2, because $r_i \to_{w,v} r_i'$ for $i \in [2]$.

(ii) $r_1 = r_2$: For $r = r_1$, $\#_{\langle\langle r, p_w\rangle\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])) \geq 2$, because $q \to_{u,w} r_1, r_1$. Thus, the sum in $(*)$ is $\geq \#_{\langle\langle r_1', p_v\rangle\rangle}(\hat{M}_{r_1}(t/w[v'' \leftarrow p_v])) \cdot 2$, which is ≥ 2, because $r_1 \to_{w,v} r_1'$.

In terms of the $\to$ notation the four conditions of input pumpability (cf. Definition 6.4) say that there are states q_1 and q_2, a tree $s_0 \in T_\Sigma$, and nodes u_0 and u_0u_1 of s_0 such that

(1) $q_0 \to_{\varepsilon,u_0} q_1$,

(2) $q_1 \to_{u_0,u_0u_1} q_1, q_2$,

(3) $q_2 \to_{u_0,u_0u_1} q_2$, and

(4) $h(s_0/u_0) = h(s_0/u_0u_1)$.

Since M is not fci, arbitrary long state sequences can be generated. Thus, for every $m \geq 1$ there are $t \in T_\Sigma$ and $v \in V(t)$ such that $|\mathrm{sts}_M(t, v)| > m$, which, by (P1),

means that q_0 contributes more than m states at ε to v. In Claim 1 below we will show that if a state q contributes "many" states at u to v, then there must be an intermediate node w (a descendant of u and ancestor of v) such that q contributes at least two states at u to w that contribute at w to v, and at least one of these states still contributes "many" states at w to v. The application of this claim can be iterated to show the existence of a sequence of intermediate nodes w, which will eventually lead to an appropriate repetition of states (and look-ahead states) that allows us to define s_0 and nodes u_0, u_0u_1 for which (1)–(4) hold.

Let $\kappa \geq 1$ be an upper bound for the number of occurrences of elements of $\langle Q, \{x_i\}\rangle$ for an $i \geq 1$ in the right-hand side of any rule of R, i.e., $\kappa \geq \#_{\langle Q,\{x_i\}\rangle}(\mathrm{rhs}(\rho))$ for every $\rho \in R$ and $i \geq 1$. Let η be the maximal height of the right-hand side of any rule in R, i.e., $\eta = \max\{\mathrm{height}(\mathrm{rhs}(\rho)) \mid \rho \in R\}$. Let $N \geq 1$ be a parameter copying bound for M and let $B \geq 1$ be a nesting bound for M.

Claim 1. Let $\langle\!\langle q, p\rangle\!\rangle \in \langle\!\langle Q, P\rangle\!\rangle$ be reachable, $t \in T_\Sigma$, and $u, v \in V(t)$ such that $t/u \in L_p$ and u is an ancestor of v. Let $c \geq 1$. If q contributes more than $(\kappa N^{2B+\eta}) \cdot c$ states at u to v, then there is a proper descendant w of u which is an ancestor of v and there are states $r, r' \in Q$ such that

(a) $q \to_{u,w} r, r'$,

(b) r contributes more than c states at w to v, and

(c) r' contributes at w to v.

Proof of Claim 1. Let w be the first (shortest) descendant of u and ancestor of v such that there are $r_1, r_2 \in Q$ with $q \to_{u,w} r_1, r_2$ and r_1,r_2 contribute at w to v. Clearly such a w exists, because q contributes ≥ 2 states at u to v, and thus, by (P5), there are $r_1, r_2 \in Q$ such that $q \to_{u,v} r_1, r_2$, and, by (P0), r_1, r_2 contribute at v to v. By (P0), q contributes exactly one state at u to u and therefore $w \neq u$. It remains to show that there is an $r \in Q$ such that $q \to_{u,w} r$ and r contributes more than c states at w to v; then r' is chosen to be one of the r_1, r_2 such that (a) holds.

In (sub)Claim 2 below we will show that q contributes at most $\kappa \cdot N^{B+\eta}$ states r at u to w that contribute at w to v. We now show that the number of states that q contributes at u to v is at most N^B times the sum of the contributions of the states r at w to v, and hence that at least one of these r must contribute $> c$ states.

Let $w', v', v'' \in \mathbb{N}^*$ such that $w = uw'$ and $v = uv' = wv''$. Let $p_w = h(t/w)$ and $p_v = h(t/v)$. By assumption, q contributes $> (\kappa N^{2B+\eta}) \cdot c$ states at u to v, i.e., $(\kappa N^{2B+\eta}) \cdot c$ is smaller than $\#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_q(t/u[v' \leftarrow p_v]))$, which, by Lemma 4.14(ii) (using the fact that $\langle\!\langle q, h(t/u)\rangle\!\rangle$ is reachable, and summing over all elements of $\langle\!\langle Q, \{p_v\}\rangle\!\rangle$), is

$$\leq N^B \cdot \sum_{r \in Q} \#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v])) \cdot \#_{\langle\!\langle r,p_w\rangle\!\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])).$$

If $\#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v])) \neq 0$, then r contributes at w to v. Thus, we can restrict the above sum to states in $Q_{w,v} = \{r \in Q \mid r \text{ contributes at } w \text{ to } v\}$. Now let $r \in Q_{w,v}$ be such that $q \to_{u,w} r$ (i.e., $\#_{\langle\!\langle r,p_w\rangle\!\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])) \geq 1$) and the number of states it contributes at w to v is maximal; i.e., for all $r' \neq r$ with $q \to_{u,w} r'$, $\#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_{r'}(t/w[v'' \leftarrow p_v])) \leq \#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v]))$. Then the above number is

$$\leq N^B \cdot \#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v])) \cdot \#_{\langle\!\langle Q_{w,v},\{p_w\}\rangle\!\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])),$$

which, by Claim 2, is $\leq N^B \cdot \#_{\langle\!\langle Q,\{p_v\}\rangle\!\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v])) \cdot (\kappa N^{B+\eta})$. Thus we get

$c < \#_{\langle\langle Q,\{p_v\}\rangle\rangle}(\hat{M}_r(t/w[v'' \leftarrow p_v]))$, i.e., r contributes more than c states at w to v, which concludes the proof of Claim 1.

Claim 2. $\#_{\langle\langle Q_{w,v},\{p_w\}\rangle\rangle}(\hat{M}_q(t/u[w' \leftarrow p_w])) \leq \kappa \cdot N^{B+\eta}$.

Proof of Claim 2. Since $w \neq u$ it follows that $w' \neq \varepsilon$; i.e., there are $i \geq 1$ and $\omega' \in \mathbb{N}^*$ such that $w' = \omega' i$. Let $\omega = u\omega'$; i.e., w is the ith child of ω. In the remainder of this proof we will always write ωi in place of w and $\omega' i$ in place of w', in particular, $p_{\omega i} = p_w$ and $Q_{\omega i,v} = Q_{w,v}$. Let $p_\omega = h(t/\omega)$. Using the fact that $\langle\langle q, h(t/u)\rangle\rangle$ is reachable, we can apply Lemma 4.14(ii) to t and $u, \omega, \omega i \in V(t)$, summing over all $\langle\langle q', p_{\omega i}\rangle\rangle$ in $\langle\langle Q_{\omega i,v}, \{p_{\omega i}\}\rangle\rangle$, to get that $\#_{\langle\langle Q_{\omega i,v},\{p_{\omega i}\}\rangle\rangle}(\hat{M}_q(t/u[\omega' i \leftarrow p_{\omega i}]))$ is

$$\leq N^B \cdot \sum_{r \in Q} \#_{\langle\langle Q_{\omega i,v},\{p_{\omega i}\}\rangle\rangle}(\hat{M}_r(t/\omega[i \leftarrow p_{\omega i}])) \cdot \#_{\langle\langle r,p_\omega\rangle\rangle}(\hat{M}_q(t/u[\omega' \leftarrow p_\omega])).$$

If $\#_{\langle\langle Q_{\omega i,v},\{p_{\omega i}\}\rangle\rangle}(\hat{M}_r(t/\omega[i \leftarrow p_{\omega i}])) \neq 0$, then there is an occurrence of some $\langle\langle r', p_{\omega i}\rangle\rangle$ in $\hat{M}_r(t/\omega[i \leftarrow p_{\omega i}])$, i.e., $r \rightarrow_{\omega,\omega i} r'$, and r' contributes at ωi to v, i.e., $r' \rightarrow_{\omega i,v} r''$ for some $r'' \in Q$. Thus, by (P3), $r \rightarrow_{\omega,v} r''$, which means by (P2) that r contributes at ω to v. By the definition of the node ωi there is at most one occurrence of a $\langle\langle q', p_\omega\rangle\rangle \in \langle\langle Q, \{p_\omega\}\rangle\rangle$ in $\hat{M}_q(t/u[\omega' \leftarrow p_\omega])$ such that q' contributes at ω to v, and since q contributes at u to v, by (P4) there is at least one such occurrence. Hence, in the above sum there is only one nonzero product, namely, for $r = q'$, and $\#_{\langle\langle q',\{p_\omega\}\rangle\rangle}(\hat{M}_q(t/u[\omega' \leftarrow p_\omega])) = 1$. We get

$$N^B \cdot \#_{\langle\langle Q_{\omega i,v},\{p_{\omega i}\}\rangle\rangle}(\hat{M}_{q'}(t/\omega[i \leftarrow p_{\omega i}])) \leq N^B \cdot \#_{\langle\langle Q,\{p_{\omega i}\}\rangle\rangle}(\hat{M}_{q'}(t/\omega[i \leftarrow p_{\omega i}])).$$

By Lemma 4.3 with $s = t/\omega$ and $u = \varepsilon$, and since $\hat{M}_{q'}(t/\omega[\varepsilon \leftarrow p_\omega]) = \langle\langle q', p_\omega\rangle\rangle$, the tree $\hat{M}_{q'}(t/\omega[i \leftarrow p_{\omega i}])$ equals $\mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle)[\![..]\!][\![i]\!]$, where $[\![..]\!] = [\![\langle r', x_j\rangle \leftarrow M_{r'}(t/\omega j) \mid r' \in Q, j \in [k] - \{i\}]\!]$ and $[\![i]\!] = [\![\langle r', x_i\rangle \leftarrow \langle\langle r', p_{\omega i}\rangle\rangle \mid r' \in Q]\!]$ with $t[\omega] = \sigma \in \Sigma^{(k)}$, $k \geq 1$, and $p_j = h(t/\omega j)$ for each $j \in [k]$. Thus, $N^B \cdot \#_{\langle\langle Q,\{p_{\omega i}\}\rangle\rangle}(\hat{M}_{q'}(t/\omega[i \leftarrow p_{\omega i}]))$ equals $N^B \cdot \#_{\langle\langle Q,\{p_{\omega i}\}\rangle\rangle}(\mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle)[\![..]\!][\![i]\!])$, which, avoiding the relabeling $[\![i]\!]$, can be written as

$$N^B \cdot \#_{\langle Q,\{x_i\}\rangle}(\mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle)[\![\langle r', x_j\rangle \leftarrow M_{r'}(t/\omega j) \mid r' \in Q, j \neq i]\!]).$$

The application of Lemma 2.6 and the fact that the trees $M_{r'}(t/\omega j)$ do not contain elements of $\langle Q, \{x_i\}\rangle$ gives the number $N^B \cdot \sum_{\tilde{u} \in V_{\langle Q,\{x_i\}\rangle}(\zeta)} \prod F_{\zeta,\tilde{u}}^{[\![..]\!]}$, where $\zeta = \mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle)$. Since the height of ζ is at most η, $\prod F_{\zeta,\tilde{u}}^{[\![..]\!]} \leq N^\eta$, and thus the above number is $\leq N^{B+\eta} \cdot |V_{\langle Q,\{x_i\}\rangle}(\zeta)|$, which is $\leq \kappa \cdot N^{B+\eta}$ by the definition of κ. This ends the proof of Claim 2.

Let $\gamma = \kappa N^{2B+\eta}$. Since M is not fci, for every $n \geq 1$ there are $t_n \in T_\Sigma$ and $v_n \in V(t_n)$ such that $|\mathrm{sts}_M(t_n, v_n)| > \gamma^n$. Let $r_0 = q_0$ and $w_0 = \varepsilon$. We now apply Claim 1 for $i = 0, \ldots, n-1$ to $q = r_i$, $p = h(t_n/w_i)$, $t = t_n$, $u = w_i$, $v = v_n$, and $c = \gamma^{n-i-1}$. For $i = 0$ this is possible because $\langle\langle q_0, h(t_n)\rangle\rangle$ is reachable, and by (P1), q_0 contributes more than γ^n states at ε to v_n. We obtain that there exists a proper descendant w_{i+1} of w_i and states r_{i+1}, r'_{i+1} such that $r_i \rightarrow_{w_i,w_{i+1}} r_{i+1}, r'_{i+1}$, the state r_{i+1} contributes more than γ^{n-i-2} states at w_{i+1} to v_n, and r'_{i+1} contributes at w_{i+1} to v_n. Note that since $q_0 \rightarrow_{\varepsilon,w_{i+1}} r_{i+1}$ and $q_0 \rightarrow_{\varepsilon,w_{i+1}} r'_{i+1}$ by (P3), both r_{i+1} and r'_{i+1} occur in $\mathrm{sts}_M(t_n, w_{i+1})$ by (P1) (and thus $\langle\langle r_{i+1}, h(t_n/w_{i+1})\rangle\rangle$ is reachable). For an ancestor w of v_n let $\mathrm{csts}(w)$ denote $\mathrm{sts}_M(t_n, w)$ restricted to the states q which contribute at w to v_n (i.e., all states that do not contribute to v_n are erased from

$\mathrm{sts}_M(t_n, w)$). Hence, r occurs in $\mathrm{csts}(w)$ if and only if $q_0 \to_{\varepsilon,w} r \to_{w,v} q$ for some state q. In particular, r_{i+1} and r'_{i+1} occur in $\mathrm{csts}(w_{i+1})$. Figure 6.1 shows the nodes w_i and the corresponding sequences $\mathrm{csts}(w_i)$ with the states r_i, r'_i; the arrows mean $\to_{w_i,w_{i+1}}$.

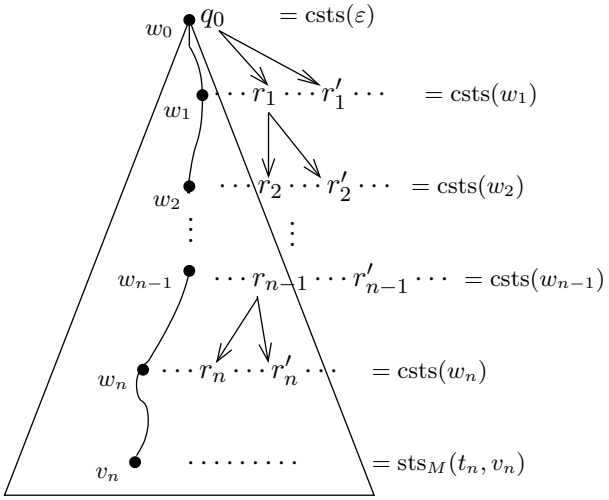

FIG. 6.1. *The tree t_n with contributing states.*

Now take $n = |Q| \cdot |P| \cdot 2^{|Q|}$ and let t_n, v_n, w_i, r_i, and r'_i be as above for $0 \le i \le n$. Clearly this means that there are indices $0 \le i < j \le n$ such that

- $r_i = r_j$,
- $p = h(t_n/w_i) = h(t_n/w_j)$, and
- $\{r \in Q \mid r \text{ occurs in } \mathrm{csts}(w_i)\} = \{r \in Q \mid r \text{ occurs in } \mathrm{csts}(w_j)\}$,

because there are exactly $|Q| \cdot |P| \cdot 2^{|Q|}$ different possibilities (r_i, p, S) for $r_i \in Q$, $p \in P$, and $S \subseteq Q$. Let $q'_1 = r_i$ and let $q'_2 \in Q$ such that $r'_{i+1} \to_{w_{i+1},w_j} q'_2$ and q'_2 occurs in $\mathrm{csts}(w_j)$. Such a q'_2 exists by the fact that r'_{i+1} contributes at w_{i+1} to v_n, using property (P4) (and also (P2) and (P3)). Since $r_{i+1} \to_{w_{i+1},w_j} r_i$, we can apply (P6) to get $q'_1 \to_{w_i,w_j} q'_1, q'_2$. Thus, conditions (1), (2), and (4) of input pumpability hold for $q_1 = q'_1$, $q_2 = q'_2$, $s_0 = t_n$, $u_0 = w_i$, and $u_0u_1 = w_j$. Clearly, if $q'_1 = q'_2$, then also (3) holds, which proves the lemma for that case. Thus, from now on we assume that $q'_1 \ne q'_2$. To realize (3), we will pump the tree $t_n/w_i[w'_j \leftarrow p]$ in t_n, where $w_j = w_i w'_j$.

For every $r \in Q$ that occurs in $\mathrm{csts}(w_i)$, there is an $r' \in Q$ with $r \to_{w_i,w_j} r'$, and r' occurs in $\mathrm{csts}(w_j)$ by (P4). Since the same states appear in $\mathrm{csts}(w_i)$ and $\mathrm{csts}(w_j)$, this means that r' also occurs in $\mathrm{csts}(w_i)$. Thus, there is a sequence

$$q'_1 \to_{w_i,w_j} q'_2 \to_{w_i,w_j} q'_3 \to_{w_i,w_j} \cdots \to_{w_i,w_j} q'_m \to_{w_i,w_j} q'_{m-\nu},$$

where $2 \le m \le |Q|$, $0 \le \nu < m$, and $q'_1, \ldots, q'_m$ are pairwise different states that occur in $\mathrm{csts}(w_i)$. Hence, after $m - \nu - 1$ steps of $\to_{w_i,w_j}$, starting at q'_1, states will repeat with period $\nu + 1$. Let d be a multiple of $\nu + 1$ with $d \ge m - \nu - 1$. Then there is a $\mu \in \{m - \nu, \ldots, m\}$ such that after d steps of $\to_{w_i,w_j}$, q'_1 reaches q'_μ and q'_μ reaches q'_μ.

Let $q_1 = q'_1$, $q_2 = q'_\mu$,

$$s_0 = (t_n[w_i \leftarrow p]) \bullet (t_n/w_i[w'_j \leftarrow p])^d \bullet (t_n/w_j),$$

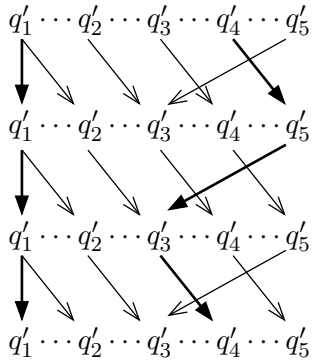

FIG. 6.2. *Conditions* (2) *and* (3) *of input pumpability for* $q_1 = q'_1$ *and* $q_2 = q'_4$.

$u_0 = w_i$, and $u_1 = (w'_j)^d$. Then $h(s_0/w_i(w'_j)^\gamma) = p$ for all $0 \le \gamma \le d$, which easily follows by induction, using the fact that $\hat{h}(t_n/w_i[w'_j \leftarrow p]) = \hat{h}(t_n/w_i[w'_j \leftarrow h(t_n/w_j)]) = h(t_n/w_i) = p$. In particular $h(s_0/u_0) = h(s_0/u_0u_1) = p$; i.e., condition (4) of input pumpability holds. Clearly, for $0 \le \gamma < d$, $q \to_{w_i,w_j} q'$ in the tree t_n if and only if $q \to_{w_i(w'_j)^\gamma, w_i(w'_j)^{\gamma+1}} q'$ in the tree s_0, and similarly $q \to_{w_i,w_j} q', q''$ in the tree t_n if and only if $q \to_{w_i(w'_j)^\gamma, w_i(w'_j)^{\gamma+1}} q', q''$ in the tree s_0; this is true because $s_0/w_i(w'_j)^\gamma[w'_j \leftarrow p] = t_n/w_i[w'_j \leftarrow p]$. Thus, in s_0, $q_2 \to_{u_0,u_0u_1} q_2$ by the definition of q'_μ (using (P3)), which proves condition (3) of the input pumpable property. To show condition (2) we use (P6): Since $q'_1 \to_{w_i,w_iw'_j} q'_1, q'_2$, also $q'_1 \to_{w_i,w_iw'_j} q'_1$ and thus, by the above and by (P3), $q'_1 \to_{w_iw'_j, w_i(w'_j)^d} q'_1$ holds in s_0. By the definition of q'_μ, $q'_2 \to_{w_iw'_j, w_i(w'_j)^d} q'_\mu$. Therefore, by (P6), $q_1 \to_{u_0,u_0u_1} q_1, q_2$. Clearly, (1) of input pumpability holds because $q_0 \to_{\varepsilon,w_i} r_i$ in t_n by the definition of r_i, $s_0[u_0 \leftarrow p] = t_n[w_i \leftarrow p]$, and consequently $q_0 \to_{\varepsilon,u_0} r_i = q_1$ holds in s_0. Figure 6.2 outlines the choice of q_2 for $m = 5$ and $\nu = 2$ (thus $d = 3$ and $\mu = 4$). □

LEMMA 6.6. *Let* M *be a proper* MTT^R. *If* M *is input pumpable, then it is not lsi.*

Proof. Let $M = (Q, \Sigma, \Delta, q_0, R, P, h)$ be input pumpable; i.e., there are $q_1, q_2 \in Q$, $s_0 \in T_\Sigma$, $u_0 \in V(s_0)$, $u_1 \in V(s_0/u_0)$, and $p \in P$ such that (1)–(4) of Definition 6.4 hold. Assume now that M is lsi; i.e., there is a $c \in \mathbb{N}$ such that for every input tree $t \in T_\Sigma$,

$$(*) \qquad \text{size}(\tau_M(t)) \le c \cdot \text{size}(t).$$

In what follows we will derive a contradiction by constructing an input tree t such that $\text{size}(\tau_M(t)) > c \cdot \text{size}(t)$. Note first that if we replace in s_0 the subtree at u_0u_1 by any tree s in L_p, then (1)–(4) still hold. Similar to the proof of Theorem 6.3, the idea of constructing t is as follows: Consider input trees t_i obtained by i times pumping the tree $s_0/u_0[u_1 \leftarrow p]$ in the tree $s_0[u_0u_1 \leftarrow s]$. Then the trees t_i grow at most linearly with constant $\text{size}(s_0/u_0[u_1 \leftarrow p])$. In the output tree $\tau_M(t_i)$ there are at least i occurrences of the tree $M_{q_2}(s)$. Hence, the trees $\tau_M(t_i)$ grow at least linearly with constant $\text{size}(M_{q_2}(s))$. Thus, if we choose s in such a way that $\text{size}(M_{q_2}(s))$ is larger than the product of c and the size of $s_0/u_0[u_1 \leftarrow p]$, then $\text{size}(\tau_M(t_i))$ grows faster than $c \cdot \text{size}(t_i)$; i.e., we can find an i such that $(*)$ does not hold for $t = t_i$.

In order to choose the tree s appropriately, we need the set $\text{Out}(q_2, p) = \{M_{q_2}(s) \mid s \in L_p\}$ to be infinite, i.e., to contain trees with arbitrarily many output symbols.

This is guaranteed by i-properness (cf. point (i) of Definition 5.1) if (a) $\langle\langle q_2, p\rangle\rangle$ is reachable and (b) $q_2 \neq q_0$.

(a) Clearly, $\langle\langle q_2, p\rangle\rangle$ is reachable because it occurs in $\hat{M}_{q_0}(s_0[u_0u_1 \leftarrow p])$; this follows from (1) and (2) using Lemma 4.14(i) (analogous to the proof of (P3) in the proof of Lemma 6.5; in fact, using the $\rightarrow$ notation of the proof of that lemma, it follows from (1) and (2) by (P3) that $q_0 \rightarrow_{\varepsilon,u_0u_1} q_2$, which means that $\langle\langle q_2, p\rangle\rangle$ occurs in $\hat{M}_{q_0}(s_0[u_0u_1 \leftarrow p])$).

(b) By (2), $\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p]) \neq \langle\langle q_1, p\rangle\rangle = \hat{M}_{q_1}(s_0/u_0[\varepsilon \leftarrow p])$, and thus $u_1 \neq \varepsilon$; i.e., $u_1 = u_1'i$ for some $u_1' \in \mathbb{N}^*$ and $i \geq 1$. Also by (2), $\langle\langle q_2, p\rangle\rangle$ occurs in $\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])$. Hence (by Lemma 4.3 applied to q_1, s_0/u_0, and u_1'), $\langle q_2, x_i\rangle$ occurs in the right-hand side of a rule of M. By (ii) of i-properness this implies that $q_2 \neq q_0$.

We now pump the tree $s_0/u_0[u_1 \leftarrow p]$ in the tree $s_0[u_0u_1 \leftarrow s] = (s_0[u_0 \leftarrow p]) \bullet (s_0/u_0[u_1 \leftarrow p]) \bullet s$: for $i \geq 0$, let $t_i = (s_0[u_0 \leftarrow p]) \bullet (s_0/u_0[u_1 \leftarrow p])^i \bullet s$. It follows from (1)–(4) that for every $i \geq 0$, $\mathrm{sts}_M(t_i, u_0u_1^i)$ contains at least one occurrence of q_1 and at least i occurrences of q_2; this is sketched in Figure 6.3 and formalized in the following claim.

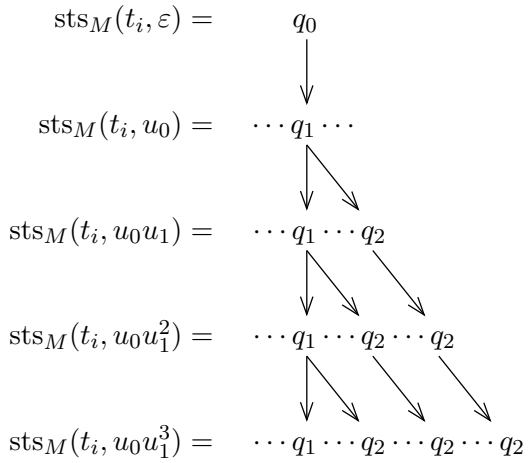

FIG. 6.3. *States that appear in state sequences of* t_i.

Claim. For all $i \geq 0$, $\#_{\langle\langle q_1,p\rangle\rangle}(\xi_i) \geq 1$ and $\#_{\langle\langle q_2,p\rangle\rangle}(\xi_i) \geq i$, where ξ_i is the tree $\hat{M}_{q_0}(t_i[u_0u_1^i \leftarrow p])$.

The proof of the claim is by induction on i. For $i = 0$, $t_i[u_0u_1^i \leftarrow p] = s_0[u_0 \leftarrow p]$ and by (1), $\#_{\langle\langle q_1,p\rangle\rangle}(\hat{M}_{q_0}(s_0[u_0 \leftarrow p])) \geq 1$. For $i+1$ we apply Lemma 4.14(i) to t_{i+1}, $u = \varepsilon$, $w = u_0u_1^i$, $v = u_0u_1^{i+1}$, and $q = q_0$. Since $h(t_{i+1}/u_0u_1^i) = h(s_0/u_0[u_1 \leftarrow s]) = \hat{h}(s_0/u_0[u_1 \leftarrow p]) = p$ by (4) and the fact that $s \in L_p$, $h(t_{i+1}/u_0u_1^{i+1}) = h(s) = p$, and $t_{i+1}[u_0u_1^i \leftarrow p] = t_i[u_0u_1^i \leftarrow p]$, we get

$$\#_{\langle\langle q',p\rangle\rangle}(\xi_{i+1}) \geq \sum_{r \in Q} \#_{\langle\langle q',p\rangle\rangle}(\hat{M}_r(s_0/u_0[u_1 \leftarrow p])) \cdot \#_{\langle\langle r,p\rangle\rangle}(\xi_i).$$

Let $q' = q_1$. Surely restricting the above sum to $r = q_1$ does not increase the result. Thus, the sum is $\geq \#_{\langle\langle q_1,p\rangle\rangle}(\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])) \cdot \#_{\langle\langle q_1,p\rangle\rangle}(\xi_i)$. This is ≥ 1 because $\#_{\langle\langle q_1,p\rangle\rangle}(\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])) \geq 1$ by (2), and $\#_{\langle\langle q_1,p\rangle\rangle}(\xi_i) \geq 1$ by induction.

Let $q' = q_2$. Now restrict the sum to $r \in \{q_1, q_2\}$. If $q_1 = q_2$, then the sum is $\geq \#_{\langle\langle q_2,p\rangle\rangle}(\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])) \cdot \#_{\langle\langle q_1,p\rangle\rangle}(\xi_i)$; this is $\geq 2 \cdot \max\{1, i\} \geq i + 1$, because, by (2), $\#_{\langle\langle q_2,p\rangle\rangle}(\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])) \geq 2$, and by induction $\#_{\langle\langle q_1,p\rangle\rangle}(\xi_i) = \#_{\langle\langle q_2,p\rangle\rangle}(\xi_i) \geq \max\{1, i\}$. If $q_1 \neq q_2$, then the sum is $\geq \#_{\langle\langle q_2,p\rangle\rangle}(\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])) \cdot \#_{\langle\langle q_1,p\rangle\rangle}(\xi_i) + \#_{\langle\langle q_2,p\rangle\rangle}(\hat{M}_{q_2}(s_0/u_0[u_1 \leftarrow p])) \cdot \#_{\langle\langle q_2,p\rangle\rangle}(\xi_i)$; this is $\geq i + 1$, because $\#_{\langle\langle q_2,p\rangle\rangle}(\hat{M}_{q_1}(s_0/u_0[u_1 \leftarrow p])) \geq 1$ by (2), $\#_{\langle\langle q_2,p\rangle\rangle}(\hat{M}_{q_2}(s_0/u_0[u_1 \leftarrow p])) \geq 1$ by (3), and, by induction, $\#_{\langle\langle q_1,p\rangle\rangle}(\xi_i) \geq 1$ and $\#_{\langle\langle q_2,p\rangle\rangle}(\xi_i) \geq i$. This ends the proof of the claim.

Since $\#_{\langle\langle q_2,p\rangle\rangle}(\xi_i) \geq i$, we obtain $\mathrm{size}(\tau_M(t_i)) \geq i \cdot \#_\Delta(M_{q_2}(s))$ as follows. By Lemma 4.2 and the fact that $t_i/u_0u_1^i = s$, $\tau_M(t_i) = M_{q_0}(t_i) = \xi_i[\![\ldots]\!]$ with $[\![\ldots]\!] = [\![\langle\langle q, p\rangle\rangle \leftarrow M_q(s) \mid q \in Q]\!]$. By Lemma 2.6 (summing for all $\delta \in \Delta$), $\mathrm{size}(\tau_M(t_i)) = \#_\Delta(\xi_i[\![\ldots]\!]) = S_1^\Delta + S_2^\Delta \geq S_2^\Delta = \sum_{u \in V_{\langle\langle q,p\rangle\rangle}(\xi_i), q \in Q} \#_\Delta(M_q(s)) \cdot \prod F_{\xi_i,u}^{[\![\ldots]\!]}$. Since M is nondeleting, it follows from Lemma 3.11(1) that $\#_{y_j}(M_q(s)) \geq 1$ for all $q \in Q^{(m)}$ and $j \in [m]$, and thus $\prod F_{\xi_i,u}^{[\![\ldots]\!]} \geq 1$. We get $S_2^\Delta \geq \sum_{u \in V_{\langle\langle q,p\rangle\rangle}(\xi_i), q \in Q} \#_\Delta(M_q(s)) \geq \sum_{u \in V_{\langle\langle q_2,p\rangle\rangle}(\xi_i)} \#_\Delta(M_{q_2}(s)) \geq i \cdot \#_\Delta(M_{q_2}(s))$.

Now let $s \in L_p$ such that

$$\#_\Delta(M_{q_2}(s)) > c \cdot c_1,$$

where $c_1 = \mathrm{size}(s_0/u_0[u_1 \leftarrow p]) - 1$. Then $\mathrm{size}(\tau_M(t_i)) \geq i \cdot (cc_1 + 1) = icc_1 + i$. Let $i > c(c_0 + c_2)$, where $c_0 = \mathrm{size}(s_0[u_0 \leftarrow p]) - 1$ and $c_2 = \mathrm{size}(s)$. Since $\mathrm{size}(t_i) = c_0 + ic_1 + c_2$ this means that $\mathrm{size}(\tau_M(t_i)) > c \cdot \mathrm{size}(t_i)$ because $\mathrm{size}(\tau_M(t_i)) > icc_1 + c(c_0 + c_2) = c(c_0 + ic_1 + c_2) = c \cdot \mathrm{size}(t_i)$. This contradicts $(*)$ and concludes the proof. □

We are now ready to prove step (III).

THEOREM 6.7. *Let M be a proper $MTT^R_{fnest,fcp}$. If M is lsi, then it is fci.*

Proof. If M is not fci, then, by Lemma 6.5, M is input pumpable and thus, by Lemma 6.6, M is not lsi. □

6.3. From lsi to fnest (I). In Lemma 6.6 it was proved that if a proper MTT^R M is input pumpable, then it is not lsi. So, in order to prove that M is not lsi if it is not fnest, we would like to show that if M is not fnest, then it is input pumpable. This could be done by proving a pumping argument that works on the paths of trees $\hat{M}_{q_0}(s[u \leftarrow p])$. We have chosen the following alternative: We can associate with M a top-down tree transducer A (with the same regular look-ahead as M) in such a way that

(i) the number of elements $\langle\langle q', p\rangle\rangle$ of $\langle\langle Q, \{p\}\rangle\rangle$ that appear on a path of $\hat{M}_q(s[u \leftarrow p])$ is bounded by the number of such elements that appear in $\hat{A}_q(s[u \leftarrow p])$; and

(ii) if there are n occurrences of $\langle\langle q', p\rangle\rangle$ in $\hat{A}_q(s[u \leftarrow p])$, then there are at least n occurrences of $\langle\langle q', p\rangle\rangle$ in $\hat{M}_q(s[u \leftarrow p])$.

Thus, (i) implies that if M is not fnest, then A is not fci, and (ii) implies that if A is input pumpable, then so is M. Hence we need to show that if A is not fci, then A is input pumpable. This is exactly what the application of Lemma 6.5 to A gives. (The lemma is applicable because, obviously, every top-down tree transducer is nondeleting, fnest with nesting bound 1, and fcp.)

In order to prove (i) and (ii) we merely need to require that T^R A have the same states as M (but of rank zero) and that every rule of A have the same number of occurrences of each element of $\langle Q, X\rangle$ as the corresponding rule of M.

DEFINITION 6.8 (associated T^{R}, globally fci). *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R. The T^R $A = (Q_A, P, \Sigma, \Delta, q_0, R_A, h)$ is* associated with M *if $Q_A = \{q^{(0)} \mid q \in Q\}$ and for every $q, q' \in Q$, $\sigma \in \Sigma^{(k)}$, $k \geq 0$, $i \in [k]$, and $p_1, \ldots, p_k \in P$,*

$$\#_{\langle q', x_i\rangle}(\mathrm{rhs}_A(q, \sigma, \langle p_1, \ldots, p_k\rangle)) = \#_{\langle q', x_i\rangle}(\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)).$$

The MTT^R M is globally fci *(for short, gfci) if every T^R associated with M is fci.*

We use the subscript "gfci" for classes of translations of $\mathrm{MTT}^{\mathrm{R}}$s to denote that the corresponding transducers are gfci. Note that for T^{R}s A_1 and A_2 associated with M, $\mathrm{sts}_{A_1}(s, u)$ is a permutation of $\mathrm{sts}_{A_2}(s, u)$ (cf. Lemma 6.9 of [19]). Hence, M is gfci if and only if there *exists* a $\mathrm{T}^{\mathrm{R}}_{\mathrm{fci}}$ associated with M. For every $\mathrm{MTT}^{\mathrm{R}}$ M there is (effectively) an associated T^{R} A; it can be obtained from M by simply changing every right-hand side of M into an arbitrary right-hand side in $T_{\langle Q_A, X_k\rangle \cup \Delta}$ while preserving the number of occurrences of $\langle q, x_i\rangle$ for every $\langle q, x_i\rangle \in \langle Q, X_k\rangle$.

Let us first prove property (ii) mentioned above.

LEMMA 6.9. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting MTT^R and $A = (Q_A, P, \Sigma, \Delta, q_0, R_A, h)$ a T^R associated with M. For every $q, q' \in Q$, $s \in T_\Sigma$, $u \in V(s)$, and $p \in P$, $\#_{\langle\langle q', p\rangle\rangle}(\hat{M}_q(s[u \leftarrow p])) \geq \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_q(s[u \leftarrow p]))$.*

Proof. The proof is by induction on the structure of s. Let $s = \sigma(s_1, \ldots, s_k)$ with $\sigma \in \Sigma^{(k)}$ and $k \geq 0$. Let $m = \mathrm{rank}_Q(q)$.

If $u = \varepsilon$, then $\#_{\langle\langle q', p\rangle\rangle}(\hat{M}_q(s[u \leftarrow p])) = \#_{\langle\langle q', p\rangle\rangle}(\langle\langle q, p\rangle\rangle(y_1, \ldots, y_m))$, which equals (now with $q \in Q_A^{(0)}$) $\#_{\langle\langle q', p\rangle\rangle}(\langle\langle q, p\rangle\rangle) = \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_q(s[u \leftarrow p]))$.

Otherwise $u = iv$ with $i \in [k]$ and $v \in V(s_i)$. Thus $\hat{M}_q(s[u \leftarrow p])$ equals $\hat{M}_q(\sigma(\tilde{s}_1, \ldots, \tilde{s}_k))$, where $\tilde{s}_\nu = s_\nu$ for $\nu \in [k] - \{i\}$ and $\tilde{s}_i = s_i[v \leftarrow p]$. For $\nu \in [k]$ let $p_\nu = \hat{h}(\tilde{s}_\nu)$. By Lemma 3.5, $\hat{M}_q(\sigma(\tilde{s}_1, \ldots, \tilde{s}_k)) = t[\![\ldots]\!]$, where $t = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $[\![\ldots]\!] = [\![\langle r, x_\nu\rangle \leftarrow \hat{M}_r(\tilde{s}_\nu) \mid \langle r, x_\nu\rangle \in \langle Q, X_k\rangle]\!]$. Applying Lemma 2.6 we obtain that $\#_{\langle\langle q', p\rangle\rangle}(t[\![\ldots]\!])$ equals

$$\sum_{\substack{w \in V_{\langle r, x_\nu\rangle}(t),\\ \langle r, x_\nu\rangle \in \langle Q, X_k\rangle}} \#_{\langle\langle q', p\rangle\rangle}(\hat{M}_r(\tilde{s}_\nu)) \cdot \prod F_{t,w}^{[\![\ldots]\!]}.$$

Since M is nondeleting, by Lemma 3.11(1), $\#_{y_j}(\hat{M}_r(\tilde{s}_\nu)) \geq 1$ for all $r \in Q^{(n)}$, $j \in [n]$, and $\nu \in [k]$. This implies that $\prod F_{t,w}^{[\![\ldots]\!]} \geq 1$. Hence,

$$(*) \qquad \#_{\langle\langle q', p\rangle\rangle}(\hat{M}_q(s[u \leftarrow p])) \geq \sum_{\substack{w \in V_{\langle r, x_\nu\rangle}(t),\\ \langle r, x_\nu\rangle \in \langle Q, X_k\rangle}} \#_{\langle\langle q', p\rangle\rangle}(\hat{M}_r(\tilde{s}_\nu)).$$

By induction, $\#_{\langle\langle q', p\rangle\rangle}(\hat{M}_r(\tilde{s}_i)) \geq \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_r(\tilde{s}_i))$. For $\nu \in [k] - \{i\}$, $\tilde{s}_\nu \in T_\Sigma$, and therefore $\#_{\langle\langle q', p\rangle\rangle}(\hat{M}_r(\tilde{s}_\nu)) = \#_{\langle\langle q', p\rangle\rangle}(M_r(\tilde{s}_\nu)) = 0 = \#_{\langle\langle q', p\rangle\rangle}(A_r(\tilde{s}_\nu)) = \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_r(\tilde{s}_\nu))$. Thus, the sum in $(*)$ is $\geq \sum_{w \in V_{\langle r, x_\nu\rangle}(t), \langle r, x_\nu\rangle \in \langle Q, X_k\rangle} \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_r(\tilde{s}_\nu))$. Since A is associated with M, $|V_{\langle r, x_\nu\rangle}(\zeta)| = |V_{\langle r, x_\nu\rangle}(t)|$ for every $\langle r, x_\nu\rangle \in \langle Q, X_k\rangle$, where $\zeta = \mathrm{rhs}_A(q, \sigma, \langle p_1, \ldots, p_k\rangle)$. Therefore the above sum does not change if we replace t by ζ. Then by Lemma 2.4 we get $\#_{\langle\langle q', p\rangle\rangle}(\zeta[\ldots])$ with $[\ldots] = [\langle r, x_\nu\rangle \leftarrow \hat{A}_r(\tilde{s}_\nu) \mid \langle r, x_\nu\rangle \in \langle Q_A, X_k\rangle]$. By Lemma 3.5 and the fact that $\hat{A}$ is a T^{R}, this equals $\#_{\langle\langle q', p\rangle\rangle}(\hat{A}_q(s[u \leftarrow p]))$. □

For a nondeleting $\mathrm{MTT}^{\mathrm{R}}$ M it follows immediately from Lemma 6.9 and Definition 6.4 that if a T^{R} A associated with M is input pumpable, then M is also input pumpable.

LEMMA 6.10. *Let M be a nondeleting MTT^R and A a T^R associated with M. If A is input pumpable, then so is M.*

From Lemma 6.9 it also follows that gfci is a generalization of fci: if $\#_{\langle\langle Q,\{p\}\rangle\rangle}(\hat{M}_{q_0}(s[u \leftarrow p]))$ is bounded by some N, then so is $\#_{\langle\langle Q,\{p\}\rangle\rangle}(\hat{A}_{q_0}(s[u \leftarrow p]))$; i.e., if M is fci, then it is gfci. However, the converse is not true: there are $\mathrm{MTT^R}$s which are gfci but not fci. In fact, even for fcp $\mathrm{MTT^R}$s, gfci does *not* imply fci. To see this consider an MTT M which contains the following rules (and trivial look-ahead $P = \{p\}$):

$$\begin{array}{lcl} \langle q_0, \sigma(x_1, x_2)\rangle & \to & \langle q, x_1\rangle(\langle q_0, x_2\rangle), \\ \langle q_0, \alpha\rangle & \to & \alpha, \\ \langle q, \sigma(x_1, x_2)\rangle(y_1) & \to & \sigma(y_1, y_1), \\ \langle q, \alpha\rangle(y_1) & \to & \sigma(y_1, y_1). \end{array}$$

Now let $s_0 = \alpha$ and for $n \geq 0$ let $s_{n+1} = \sigma(\alpha, s_n)$. Then

$$\begin{aligned} \langle q_0, s_n\rangle &\Rightarrow_M \langle q, \alpha\rangle(\langle q_0, s_{n-1}\rangle) \\ &\Rightarrow_M \sigma(\langle q_0, s_{n-1}\rangle, \langle q_0, s_{n-1}\rangle) \\ &\Rightarrow^*_M \sigma(\sigma(\langle q_0, s_{n-2}\rangle, \langle q_0, s_{n-2}\rangle), \sigma(\langle q_0, s_{n-2}\rangle, \langle q_0, s_{n-2}\rangle)). \end{aligned}$$

Hence, $\hat{M}_{q_0}(s_n[2^n \leftarrow p])$ is a full binary tree of height n with all leaves labeled $\langle\langle q_0, p\rangle\rangle$. Thus $\mathrm{sts}_M(s_n, 2^n) = q_0^{2^n}$, which means that M is not fci. However, M is gfci and fcp, with bounds 1 and 2, respectively. To see that M is gfci, consider the $\mathrm{T^R}$ A with right-hand side $\sigma(\langle q, x_1\rangle, \langle q_0, x_2\rangle)$ for the (q_0, σ)-rule and right-hand side α for all other rules. Now A is associated with M, and it is linear in the input variables x_i; i.e., A is fci with bound 1. Moreover, M is not lsi (because $\tau_M(s_n)$ is a full binary tree of height n). Thus, gfci plus fcp cannot be taken as an alternative to the definition of finite copying: $MTT^R_{\mathrm{fci,fcp}} \subsetneq MTT^R_{\mathrm{gfci,fcp}}$.

As illustrated by the example above, a gfci $\mathrm{MTT^R}$ M need not be fci, and thus the number of occurrences of elements of $\langle\langle Q, \{p\}\rangle\rangle$ in $\hat{M}_{q_0}(s[u \leftarrow p])$ is in general unbounded due to parameter copying (in the example above by the rules with right-hand side $\sigma(y_1, y_1)$). However, the number of such elements that appear on *one path* in $\hat{M}_{q_0}(s[u \leftarrow p])$ is bounded, and thus M is fnest. To see this intuitively, consider a label path π in a tree in $T_{\langle Q, T_\Sigma\rangle \cup \Delta}$. The application of a rule r of an $\mathrm{MTT^R}$ does not copy any states on the path π; thus, it increases the number of occurrences of q' on π by at most $\#_{\langle\{q'\},X\rangle}(\mathrm{rhs}(r))$, which equals $\#_{\langle\{q'\},X\rangle}(\mathrm{rhs}(r'))$ for the corresponding rule r' of a $\mathrm{T^R}$ associated with M. We now give a formal proof of property (i) mentioned above.

LEMMA 6.11. *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an MTT^R and $A = (Q_A, P, \Sigma, \Delta, q_0, R_A, h)$ a T^R associated with M. For every $q, q' \in Q$, $s \in T_\Sigma$, $u \in V(s)$, $p \in P$, and every label path π in $\hat{M}_q(s[u \leftarrow p])$, $\#_{\langle\langle q', p\rangle\rangle}(\pi) \leq \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_q(s[u \leftarrow p]))$.*

Proof. The proof is by induction on the length of u.

For $u = \varepsilon$, $\#_{\langle\langle q', p\rangle\rangle}(\pi) = \#_{\langle\langle q', p\rangle\rangle}(\langle\langle q, p\rangle\rangle) = \#_{\langle\langle q', p\rangle\rangle}(\hat{A}_q(s[u \leftarrow p]))$.

For $u = u'i$ it follows from Lemma 4.3 that $\hat{M}_q(s[u \leftarrow p]) = t[\![i]\!][\![..]\!]$ with $t = \hat{M}_q(s[u' \leftarrow p'])[\![\mathrm{rhs}]\!]$, $p' = \hat{h}(s/u'[i \leftarrow p])$, and the substitutions $[\![\mathrm{rhs}]\!]$, $[\![..]\!]$, and $[\![i]\!]$ defined as in Lemma 4.3 (with u' instead of u, p' instead of p, and p instead of p_i). By Lemma 2.3(i) applied to $t'[\![..]\!]$ with $t' = t[\![i]\!]$, the label path π is of the form $w_0 v_1 w_1 \cdots v_m w_m$, $m \geq 0$, where $\pi' = w_0\langle r_1, x_{\nu_1}\rangle w_1 \cdots \langle r_m, x_{\nu_m}\rangle w_m$ is a label path in t', and for $j \in [m]$, $r_j \in Q$, $\nu_j \in [k] - \{i\}$, v_j is a label path in $M_{r_j}(s/u'\nu_j)$, and

$w_0, \dots, w_m$ do not contain elements of $\langle Q, X_k - \{x_i\}\rangle$. Since $M_{r_j}(s/u'\nu_j) \in T_\Delta(Y)$, $\#_{\langle\langle q',p\rangle\rangle}(v_j) = 0$ for all $j \in [m]$, which means that $\#_{\langle\langle q',p\rangle\rangle}(\pi) = \#_{\langle\langle q',p\rangle\rangle}(\pi')$.

Clearly, by the definition of $[\![i]\!]$, $\#_{\langle\langle q',p\rangle\rangle}(\pi') = \#_{\langle q',x_i\rangle}(\pi'')$ for some label path π'' in t. Hence, it remains to show that $\#_{\langle q',x_i\rangle}(\pi'') \le \#_{\langle\langle q',p\rangle\rangle}(\hat{A}_q(s[u \leftarrow p])) = \#_{\langle\langle q',p\rangle\rangle}(\xi[\mathrm{rhs}][..][i]) = \#_{\langle q',x_i\rangle}(\xi[\mathrm{rhs}])$, where $\xi = \hat{A}_q(s[u' \leftarrow p'])$ and [rhs], [..], [i] are the (corresponding first-order variants of the) substitutions of Lemma 4.3.

By Lemma 2.3(i) applied to the tree $t = \hat{M}_q(s[u' \leftarrow p'])[\![\mathrm{rhs}]\!]$, π'' is of the form $w_0v_1w_1\cdots v_mw_m$, $m \ge 0$, where $\rho = w_0\langle\langle r_1, p'\rangle\rangle w_1 \cdots \langle\langle r_m, p'\rangle\rangle w_m$ is a label path in $\hat{M}_q(s[u' \leftarrow p'])$ and for $j \in [m]$, $r_j \in Q$, v_j is a label path in $\mathrm{rhs}_M(r_j, \sigma, \langle p_1, \dots, p_k\rangle)$, and $w_0, \dots, w_m$ contain no elements of $\langle\langle Q, \{p'\}\rangle\rangle$ (i.e., w_j is a string over $\Delta \cup Y$). Thus, $\#_{\langle q',x_i\rangle}(\pi'') = \sum_{j\in[m]} \#_{\langle q',x_i\rangle}(v_j)$. Since, for $j \in [m]$, v_j is a label path in $\mathrm{rhs}_M(r_j, \sigma, \langle p_1, \dots, p_k\rangle)$, this sum is surely

$$\le \sum_{j\in[m]} \#_{\langle q',x_i\rangle}(\mathrm{rhs}_M(r_j, \sigma, \langle p_1, \dots, p_k\rangle)) = \sum_{j\in[m]} \#_{\langle q',x_i\rangle}(\mathrm{rhs}_A(r_j, \sigma, \langle p_1, \dots, p_k\rangle)),$$

which can be written as

$$\sum_{r\in Q} \#_{\langle\langle r,p'\rangle\rangle}(\rho) \cdot \#_{\langle q',x_i\rangle}(\mathrm{rhs}_A(r, \sigma, \langle p_1, \dots, p_k\rangle)).$$

By induction this is $\le \sum_{r\in Q} \#_{\langle\langle r,p'\rangle\rangle}(\xi) \cdot \#_{\langle q',x_i\rangle}(\mathrm{rhs}_A(r, \sigma, \langle p_1, \dots, p_k\rangle))$, which equals $\#_{\langle q',x_i\rangle}(\xi[\mathrm{rhs}])$ by Lemma 2.4. □

It follows immediately from Lemma 6.11, by taking $q = q_0$ and summing over all $q' \in Q$, that if A is fci, then M is fnest, with the same bound. This is stated in the next lemma.

LEMMA 6.12. *If an MTT^R is gfci, then it is fnest.*

We are now ready to prove step (I), i.e., that for a proper MTT$^{\mathrm{R}}$, lsi implies fnest.

THEOREM 6.13. *Let M be a proper MTT^R. If M is lsi, then it is fnest.*

Proof. If M is not fnest, then by Lemma 6.12 it is not gfci. By the definition of gfci this means that any T$^{\mathrm{R}}$ A associated with M is not fci. The application of Lemma 6.5 to A gives that A is input pumpable, and thus by Lemma 6.10 M is input pumpable. Now Lemma 6.6 implies that M is not lsi. □

From Theorems 6.13, 6.3, and 6.7 we obtain the main result of this section: the converse of Theorem 4.19 for proper MTT$^{\mathrm{R}}$s.

THEOREM 6.14. *Let M be a proper MTT^R. If M is lsi, then it is finite copying.*

Recall from section 4.3 the notion of finite contribution. By Lemma 4.18, every finite copying MTT$^{\mathrm{R}}$ is of finite contribution, and by the discussion before Theorem 4.19, every MTT$^{\mathrm{R}}$ of finite contribution is lsi. Together with Theorem 6.14 this shows that a proper MTT$^{\mathrm{R}}$ is finite copying if and only if it is of finite contribution. It can be proved that this even holds for a productive MTT$^{\mathrm{R}}$ that satisfies (ii) of Definition 5.6 (of p-properness). Thus, the notions of finite copying and finite contribution are closely related.

7. Main results and consequences. In this final section we prove our main results: (i) a translation is MSO definable if and only if it is a macro tree translation of linear size increase, and (ii) for a given MTT M it is decidable whether or not τ_M is MSO definable. Then we discuss some consequences of these results for top-down tree transducers, attributed tree transducers, and context-free graph grammars. At last some open problems and further research topics are mentioned.

THEOREM 7.1. *Let M be an MTT^R. Then the following statements are equivalent:*

(1) *τ_M is MSO definable.*

(2) *τ_M is lsi.*

(3) *prop(M) is finite copying.*

Proof. Since every MSO definable tree translation is lsi (see section 2.5), (1) $\Rightarrow$ (2). Note that this can also be proved using the results from section 4: If τ_M is MSO definable, then by Lemma 4.9, $\tau_M \in MTT^R_{\text{fc}}$ and thus, by Theorem 4.19, τ_M is lsi. To show (2) $\Rightarrow$ (3), let τ_M be lsi. By Theorem 5.9, there is a proper MTT$^{\text{R}}$ prop(M) with $\tau_{\text{prop}(M)} = \tau_M$; i.e., $\tau_{\text{prop}(M)}$ is lsi. By Theorem 6.14, prop(M) is finite copying. Finally, if prop(M) is finite copying, then, by Lemma 4.9, $\tau_M = \tau_{\text{prop}(M)}$ is MSO definable. Thus (3) $\Rightarrow$ (1). □

Note that, as discussed at the end of section 6, we could have included "(4) prop(M) is of finite contribution" as another equivalent statement in Theorem 7.1.

Theorem 7.1 shows that the class *MSOTT* of MSO definable tree translations can be characterized as those macro tree translations that are lsi. Recall (from section 2.5) that *LSI* denotes the class of all lsi tree translations.

THEOREM 7.2. *$MSOTT = MTT \cap LSI$.*

Proof. If $\tau \in MTT \cap LSI$, then there is an MTT M such that $\tau_M = \tau$ is lsi. By Theorem 7.1 τ_M is MSO definable, and thus $MTT \cap LSI \subseteq MSOTT$. If $\tau \in MSOTT$, then by Lemma 4.9 there is an MTT$^{\text{R}}$ M with $\tau_M = \tau$. By Theorem 7.1 τ_M is lsi, and thus $MSOTT \subseteq MTT^R \cap LSI$. By Lemma 3.4, $MTT^R = MTT$. □

By Theorem 7.1, the proper normal form prop(M) (which can be constructed by Theorem 5.9) of an MTT M is finite copying if and only if τ_M is MSO definable. Since the finite copying property is decidable (Lemma 4.10) this implies that for M it is decidable whether or not τ_M is MSO definable. If prop(M) is finite copying, then an MSO tree transducer that realizes τ_M can be constructed, because the equality $MSOTT = MTT^R_{\text{fc}}$ of Lemma 4.9 is effective (cf. the discussion following Lemma 4.10).

THEOREM 7.3. *It is decidable for an MTT M whether or not τ_M is MSO definable, and if it is, then an MSO tree transducer for τ_M can be constructed.*

7.1. Top-down tree transducers. A top-down tree transducer can translate a monadic tree (of height n) into a full binary tree (of height n). This translation is of exponential size increase, and hence it is not MSO definable. On the other hand, there are MSO definable tree translations that cannot be realized by top-down tree transducers: consider the translation that associates with a tree its yield (i.e., the left-to-right sequence of the labels of its leaves), seen as a monadic tree. This translation is MSO definable (cf. Example 1(6, yield) of [3]) but it cannot be realized by a top-down tree transducer, because it is of exponential height increase (viz. it translates a full binary tree of height n into its yield, a monadic tree of height 2^n), whereas top-down tree translations are of linear height increase (cf. Lemma 3.27 of [28]). Now, which translations realized by top-down tree transducers (with regular look-ahead) are MSO definable? By our results, they are exactly the translations realized by finite copying T$^{\text{R}}$s.

THEOREM 7.4. *$T^R \cap MSOTT = T^R_{fc}$.*

Proof. Let M be a T$^{\text{R}}$ such that τ_M is MSO definable. By Theorem 7.1, prop(M) is finite copying. By Theorem 5.9, prop(M) is a T$^{\text{R}}$. Thus, $\tau_M = \tau_{\text{prop}(M)} \in T^R_{\text{fc}}$. Hence, $T^R \cap MSOTT \subseteq T^R_{\text{fc}}$. The inclusion $T^R_{\text{fc}} \subseteq T^R \cap MSOTT$ is immediate from Lemma 4.9. □

It is shown in Theorem 7.4 of [19] that $T^R_{\mathrm{fc}} = MSOTT_{\mathrm{dir}}$: the so-called direction preserving MSO definable tree translations. An MSO tree transducer (see section 2.5) is direction preserving if $s \models \chi_{i,c,d}(x,y)$ implies that y is a descendant of x in the input tree s. Thus, the descendant relation in the output tree can only hold between nodes that are also (copies of) descendants in the input tree.

Note that it follows immediately from Theorem 7.1 that $T^R \cap MSOTT = T^R \cap LSI$. Thus, $T^R_{\mathrm{fc}} = T^R \cap LSI$. Since $\mathrm{T}^{\mathrm{R}}_{\mathrm{fc}}$s are closely related to tree-walking transducers (see Theorem 4.9 of [22]), this may be viewed as the result of [1] that the translations realized by tree-walking transducers are exactly the generalized syntax-directed translations of linear size increase.

7.2. Attributed tree transducers. Attributed tree transducers [27, 28] serve as a formal model for attribute grammars [37]. As argued in [3], adding the feature of look-ahead to them yields a better model of attribute grammars and a more robust class of tree translations. Let ATT^R denote the class of translations realized by attributed tree transducers with look-ahead (see [3, 19]) and let the subscript "sur" denote that the transducers are "single-use restricted" (cf. section 5 in [19]); i.e., for every input symbol σ, each outside attribute is used at most once in the set of rules for σ. It is proved in Theorem 17 of [3] that $MSOTT = ATT^R_{\mathrm{sur}}$. Hence $MSOTT \subseteq ATT^R \cap LSI$. Equality of these classes now follows from Theorem 7.2 and the fact that $ATT^R \subseteq MTT$. (The latter inclusion can be proved as follows: By definition, ATT^R consists of all translations that can be realized by the composition of an attributed relabeling, followed by an attributed tree translation. It follows from Theorem 4.4 of [19] that attributed relabelings can be realized by T^{R}s. Thus, $ATT^R \subseteq T^R \circ ATT$, where ATT denotes the class of translations realized by attributed tree transducers. By Lemma 5.11 of [19], $ATT \subseteq MTT^R$ and so $T^R \circ ATT \subseteq T^R \circ MTT^R$, which, by Lemma 3.4, equals $T^R \circ MTT$. Since regular look-ahead can be realized by first running a finite state relabeling, i.e., applying a translation in $DBQREL$ (cf. Theorem 2.6 of [14]), we get the inclusion in $DBQREL \circ T \circ MTT$, which is $\subseteq DBQREL \circ MTT$ by Corollary 4.10 of [24], and thus we have the inclusion in $MTT^R = MTT$.)

THEOREM 7.5. *$MSOTT = ATT^R \cap LSI$.*

From the fact that $ATT^R \subseteq MTT$ (effectively) together with Theorem 7.3 and the fact that $MSOTT = ATT^R_{\mathrm{sur}}$ (effectively), we obtain the following decidability result for attributed tree transducers.

THEOREM 7.6. *For an ATT^R A it is decidable whether or not there exists an equivalent single-use restricted ATT^R A', and if so, A' can be constructed.*

The interpretation of Theorem 7.6 in terms of classical attribute grammars involves a technical detail: roughly speaking, the look-ahead part of an $\mathrm{ATT}^{\mathrm{R}}$ corresponds to the underlying context-free grammar of an attribute grammar. If we want to apply Theorem 7.6 to an attribute grammar G, then we first have to turn G into an equivalent $\mathrm{ATT}^{\mathrm{R}}$ A, i.e., into an $\mathrm{ATT}^{\mathrm{R}}$ that realizes the same tree-to-tree translation as G (translating the non-derivation-trees of G into some error symbol). Now assume that for A there is an equivalent single-use restricted $\mathrm{ATT}^{\mathrm{R}}$ A'. In general the look-ahead of A' will be different from the one of A, which implies that an attribute grammar G' equivalent to A' does *not* have the same underlying context-free grammar as G, and hence the tree-to-tree translation realized by G' is different from the one realized by G. This problem can be avoided by adding boolean-valued attributes to G' (cf. the introduction of [3]), which simulate the look-ahead part of A'. In this way G' and G have the same underlying context-free grammar and they realize the

same tree-to-tree translation (however, the boolean-valued attributes are, in general, not single-use restricted).

7.3. Context-free graph grammars. A context-free graph grammar (see, e.g., [16]) generates a graph language. If the graphs are restricted to trees, then we obtain a tree language. As discussed in the introduction of [19], the class of tree languages that can be generated by context-free graph grammars (either by hyperedge replacement (HR), or by node replacement (NR); cf. Section 6 of [16]) can be obtained by applying the MSO definable tree translations to the regular tree languages. By Theorem 7.2 it means that this class of tree languages can be obtained by the application of lsi macro tree translations to the regular tree languages. This is just a straightforward variation of similar statements in the literature: for single-use restricted ATTs in Corollary 19 of [3], for "single-use restricted" MTTs and for finite copying MTTs in Corollary 7.3 of [19], and for nondeleting MTTs that are finite copying and linear in the parameters in Theorem 5 of [20] (based on Theorem 8.1 of [10]).

THEOREM 7.7. *The output tree languages of MTTs of linear size increase applied to the regular tree languages are the tree languages generated by (HR or NR) context-free graph grammars.*

7.4. Open problems and further research topics. We have proved that for an MTT it is decidable whether or not the translation it realizes is MSO definable. What is the complexity of this problem? In fact, the complexity of deciding the finiteness of ranges of (compositions of) MTTs [12] (cf. Lemma 3.8) is not known, and our decidability proof is based on this result. Generally speaking, complexity issues have not yet been studied in the area of MTTs. A first result in that direction is [42], which shows that for a composition τ of deterministic macro tree translations and an input tree s, the corresponding output tree $\tau(s)$ can be computed in time linear in the sum of the sizes of s and t.

Is it decidable for an MSO tree transducer whether its translation is in T^R, i.e., whether it can be simulated by a top-down tree transducer with regular look-ahead (see section 7.1)?

It would be interesting to find a classification of the possible size increases of MTTs. For top-down tree transducers such a classification is given in [1], and it is shown that the size increase of every top-down tree transducer is either polynomial or exponential. For MTTs it could be the case that every size increase is either polynomial, exponential, or double exponential.

Is polynomial size increase decidable for MTTs? If so, what is the complexity? For top-down tree transducers it is shown in [11] that this problem is NLOGSPACE-complete. It is not clear how MSO definability could be generalized in order to obtain the class of polynomial size increase macro tree translations. (Note that there are well-established models of polynomial size increase transducers based on first-order logic; see, e.g., [13, 34].)

Composition of MTTs yields a proper hierarchy; i.e., there are translations which can be realized by the composition of $m + 1$ MTTs but not by the composition of m MTTs (Theorem 4.16 of [24]). Now, what happens if we restrict our attention to translations that are of linear size increase? Maybe then composition does *not* yield a proper hierarchy, but rather it remains the class of MSO definable tree translations, i.e., is $LSI \cap \bigcup_n MTT^n = MSOTT$. Since compositions of MTTs can be realized by high-level tree transducers (and vice versa) [25] this question is equivalent to the following: Are lsi high-level tree translations MSO definable? Again, this question could also be considered for polynomial instead of linear size increase.

Recently we have shown that the k-pebble tree transducer, introduced in [45] as a formal model for XML query languages, can be simulated by the composition of MTTs [21]. Thus, if, as discussed in the previous paragraph, our results would even hold for compositions of MTTs, then they would also hold for k-pebble tree transducers.

For both MTTs and MSO transducers there are nondeterministic variants (cf. [24] and [5], respectively). We would like to know whether our result carries over to the nondeterministic case, i.e., whether the nondeterministic macro tree translations of linear size increase are precisely the nondeterministic MSO definable tree translations.

Last but not least: Given an MTT M, is it decidable whether the translation τ_M realized by M can be realized by an attributed tree transducer (with look-ahead), i.e., is it decidable whether $\tau_M \in ATT$ (or ATT^R)? This question is of interest because, as shown in [3], ATT^R is the class of tree translations that are MSO definable (by an MSO tree-to-graph transducer; see [5]) when subtrees can be shared in the output tree. Of course, if τ_M is MSO definable (without sharing of subtrees), which can be decided by Theorem 7.3, then the answer to the above question is positive, because $MSOTT = ATT^R_{\mathrm{sur}}$ by the result of [3] (other positive criteria are discussed in [8, 9, 29]). On the other hand, note that $\mathrm{ATT^R}$s are of linear size-to-height increase (cf., e.g., Lemma 5.40 of [28]). Denote by *LSHI* the class of all translations of linear size-to-height increase. Probably it can be proved (by methods similar to those in this paper) that $MTT \cap LSHI = MTT^R_{\mathrm{fnest}}$ and that $\tau_M \in LSHI$ if and only if $\mathrm{prop}(M)$ is fnest, which is decidable. Thus, it would be decidable for an MTT whether or not it is of linear size-to-height increase. If it is not, then it cannot be realized by an $\mathrm{ATT^R}$. But these are only partial answers.

Acknowledgment. We thank the referees for their constructive comments.

THE IMPACT OF TIMING KNOWLEDGE ON THE SESSION PROBLEM*

INJONG RHEE† AND JENNIFER L. WELCH‡

Abstract. The *session* problem is an abstraction of fundamental synchronization problems in distributed systems. It has previously been used as a test case to demonstrate the differences in the time needed to solve problems in several timing models.

The goal of this paper is to compare the computational power of a family of partially synchronous models by studying the time needed to solve the session problem. Four timing parameters are considered: the maximum and minimum process step times and message delays. Timing models are obtained by considering independently whether each parameter is known (i.e., is hard-wired into the processes' code) or unknown, giving rise to four shared memory models and 16 message passing models. The models are compared based on the time complexity, measured in real time, of the session problem.

This paper presents a modular proof technique for obtaining asymptotically tight bounds on the time complexity of the session problem for the four shared memory models and the 16 message passing models. Timing information known in each particular model can be exploited by algorithms to count sessions in different ways. This paper reports five different counting algorithms. The matching lower bound for each model suggests that they are the optimal ways to count sessions. Based on these bounds, a lattice among unknown parameter models is constructed, which confirms the common belief that as more timing information is known in a model, the model behaves more like a synchronous system.

Key words. session problem, partially synchronous models, timing information, distributed computing, upper bounds, lower bounds

1. Introduction.

Early work in distributed computing usually assumed one of two extreme timing models: the completely synchronous model, in which processes operate in lockstep rounds of computation and a message sent in a round is delivered in the next round, or the completely asynchronous model, in which there are no bounds on process step time or message delay. However, in most distributed systems, processes operate neither in lockstep nor at completely independent rates. Furthermore, the asynchrony assumption makes it very difficult to design and verify distributed algorithms, whereas the perfect synchrony assumption is very expensive, if not impossible, to implement in real distributed systems.

Based on these observations, researchers (e.g., [1, 2, 4, 5, 8, 9, 10, 11, 17]) began to investigate the impact on distributed computing if those timing assumptions are relaxed or tightened to some extent in order to reflect more realistic situations. The new timing models that are obtained by relaxing or tightening the two extreme timing assumptions are called *partially synchronous models*.

The goal of this paper is to compare the computational power of a family of partially synchronous models by studying the time needed to solve a distributed computing problem called the *session problem*.

1.1. The session problem. The (s, n)-session problem was first presented in [3] and further studied in [5]. Informally, a *session* is a minimal-length computation fragment that involves at least one special "synchronization" step by every process in a distinguished set of n processes. An algorithm that solves the (s, n)-session problem must guarantee that in every computation there are at least s disjoint sessions and that eventually all the n processes become idle.

The (s, n)-session problem is an abstraction of the synchronization used in many distributed computing settings. The (s, n)-session problem, like the mutual exclusion and dining philosophers problems, concerns possible ordering of process events (e.g., a process finishing its assigned task) rather than the computation of particular outputs.

Consider, for example, *barrier synchronization* [13], a fundamental mechanism in concurrent systems which guarantees that all processes have finished a specified task in their execution before any proceeds. Barrier synchronization is a special case of the (s, n)-session problem when $s = 2$, and solutions for the $(2, n)$-session problem can be used to construct barrier synchronization: after each process finishes its specified task, it keeps taking synchronization steps until the $(2, n)$-session algorithm terminates.

As discussed in [5], another example of the (s, n)-session problem can be found in a distributed linear equation solver, where each process holds part of the input data (cf. [7]) and iterates to solve equations by relaxation. Each process takes one synchronization step when it changes its data. Sufficient interleavings of synchronization steps by different processes ensure a correct output since they imply sufficient interaction among the intermediate values computed by the processes.

The (s, n)-session problem is also an abstraction of a simple message distribution system in which a sending process writes a sequence of s messages one at a time on a board (e.g., port or mailbox) visible to all and waits after each message until all $n-1$ other processes have read the message before writing the next one. Each reading step by a process is one synchronization step of the process. Any protocol which ensures that the sender has waited sufficiently long solves the (s, n)-session problem.

Since the time complexity of the session problem is very sensitive to the timing assumptions of the underlying model, it has been used as a test case to demonstrate the theoretical differences in the time needed to solve problems in various timing models [3, 5, 16, 18, 19]. Using the session problem, we can quantify differences between various models in terms of the time complexity needed to solve distributed computing problems. Precise time complexities for various timing models allow us to show complexity gaps among the models. Time complexity gaps can provide valuable information to system designers in evaluating and comparing the various timing models and deciding what timing guarantees they have to provide or do not have to provide to build efficient yet cost-effective distributed systems.

A solution for the (s, n)-session problem normally involves several methods for counting sessions during execution. In particular, the first or last session is often counted in a different way than the other sessions. Hence, the time complexity of a solution is usually expressed as a function of s, n and some additional terms to account for the complexity of counting the first or last session. When we qualitatively evaluate relative time complexities of different timing models, the term associated with s has more weight than the other terms in deciding the time complexity hierarchy.

1.2. Timing models. We consider two different interprocess communication models: *shared memory* (SM) and *message passing* (MP). In the SM model, processes communicate only by means of shared variables.

In the MP model, communication is done by exchanging messages across a network. A process can broadcast a message at a step; the message is guaranteed to be delivered to every process after some finite time.

Process step time is the amount of time between two consecutive steps of the same process, and *message delay* is the amount of time between when a message is sent and when the message is received. The relevant timing parameters of a model are the minimum step time, c_1, the maximum step time, c_2, and additionally, for the MP model, the minimum message delay, d_1, and the maximum message delay, d_2.

We consider families of timing models for both SM and MP systems. The timing models are obtained by considering independently whether each parameter is known (i.e., can be hard-wired into the processes' code) or unknown, giving rise to four SM models and 16 MP models. Some of these models have been studied previously in both practical and theoretical contexts.

Models with known maximum and minimum step times are commonly called *semisynchronous models* and have been previously studied for various distributed computing problems, including the consensus problem, the mutual exclusion problem, and the session problem (see [1, 2, 4, 5, 6, 8, 14, 15, 17, 18, 19]). The semisynchrony models systems where information about timing parameters, such as process step time, is only approximately known; e.g., processes may have access to inaccurate clocks that operate at approximately, but not exactly, the same rate.

Models with unknown step times have been studied for the consensus problem [11] and for the mutual exclusion problem [1]. As those papers argue, these models provide a useful abstraction of the timing constraints in real systems.

Models in which the minimum step time is known but the maximum step time is unknown abstract event-driven processing such as responding to user inputs or nonperiodic device interrupts [18]. In these models, processes can be blocked for an arbitrarily long (but finite) time waiting for a certain condition to be true or a certain event to occur but cannot take two consecutive steps faster than a certain amount of time.

A lower bound result or impossibility result shown for an asynchronous model does not automatically carry over to a model with unknown bounds. For instance, the work on the consensus problem in [11] showed that fault-tolerant consensus can be solved in a model with unknown bounds, although it cannot be solved in an asynchronous system [12]. There is more leeway in constructing "bad" executions in an asynchronous system than there is in one with unknown bounds. Thus, it is worth investigating how knowledge of step time and message delay affects the session problem.

1.3. Previous work on the session problem. The upper and lower bounds on the time required to solve the session problem in an asynchronous SM system shown by Arjomandi, Fischer, and Lynch [3] demonstrated the first such case where asynchronous systems are less efficient than synchronous systems. In the synchronous model, all processes run in lockstep, while in the asynchronous model no bounds on process running rates exist. Their result showed an inherent time complexity gap between the synchronous and asynchronous models: s steps are sufficient for s sessions in the synchronous model, i.e., no interprocess communication is needed, but $(s-1)\lfloor \log_a n \rfloor$ steps are necessary for the asynchronous model. The $\lfloor \log_a n \rfloor$

factor is essentially the cost of communication, where a is the maximum number of distinct processes that are ever allowed to access any given shared variable. Thus, one interprocess communication per session is needed in the asynchronous SM model.

Attiya and Mavronicolas [5] show a similar result for an asynchronous MP system in which there is a maximum message delay d_2 but the minimum message delay d_1 is zero. Their results show that the asynchronous MP model requires $(s-1)\cdot d_2$ time to solve the (s,n)-session problem (at least one message delay per session).

The session problem has been studied in a semisynchronous model as well, in which there are known minimum and maximum step times and there is a (not necessarily known) maximum message delay. The upper bound in the MP model shown by Attiya and Mavronicolas [5] is $(s-1)\cdot\min\{\frac{c_2}{2c_1}c_2, d_2\}$. A nearly matching lower bound (within a factor of 2 of the upper bound) also appears in [5]. These results imply that the efficiency of the semisynchronous SM model lies between those of the synchronous and asynchronous models.

In a *periodic* model where processes run at a fixed unknown periodic rate, nearly matching lower and upper bounds shown by [18, 19] indicate that at least one communication is required to solve the session problem. These bounds also indicate the inherent cost of synchronizing periodically running processes and the existence of time complexity gaps among the synchronous, periodic, and asynchronous timing models.

1.4. Our results. Our complexity results are organized around "ways to count" s sessions in a computation. The intuition is that processes must have some way to count the passage of the other processes' steps in order to "know" when a session has occurred.

Note that $s\cdot c_2$ is an obvious lower bound for all models because each process has to take at least s steps to solve the (s,n)-session problem and each step takes up to c_2 time [3]. We omit from the discussion the obvious lower bound $s\cdot c_2$.

1.4.1. Shared memory results. In order for our results to be comparable to prior work, we study SM systems with a constant parameter a, which is the maximum number of distinct processes that are ever allowed to access any given shared variable. When a is smaller than the total number of processes in the system, it is not possible for all processes to exchange information in a single step. Instead, information must be propagated from process to process. Thus, as a gets smaller, the amount of propagation required increases. The motivation for this restriction on communication comes from the fact that in a distributed SM system, some part of memory is local to a process and can be accessed quickly, while the rest is remote and requires more time for accesses.

Table 1.1 summarizes our results on the time complexity of solving the (s,n)-session problem in SM models.

Our results indicate that if either the minimum or maximum step time (or both) is unknown, then the running time for the (s,n)-session problem is $(s-1)\cdot c_2\cdot\Theta(\log n)$, i.e., roughly one communication cost $(c_2\cdot\Theta(\log n))$ is required for each session. On the other hand, if both step times are known, then the running time is $(s-1)\cdot c_2\cdot\min\{\frac{c_2}{2c_1}, \Theta(\log n)\}$. In this model, processes can use timing information about relative step times to count locally in order to determine when enough sessions have elapsed. We call this counting technique the *step time* (ST) *method*. It was first proposed in [5] for the semisynchronous MP model. However, if the gap between the minimum and maximum step times is sufficiently large, then it is more cost-effective to use explicit communication. We call this counting technique the *explicit communication* (EC) *method*. It was first proposed in [3] for the asynchronous SM model.

TABLE 1.1
Time bounds for the (s,n)-session problem in SM models; a is the maximum number of processes that can access a shared variable, c_1 and c_2 are the minimum and maximum step times.

c_1	c_2	Lower bound	Upper bound
unknown	unknown	$(s-1)\cdot c_2\cdot \log_a n$	$(s-1)\cdot c_2\cdot \Theta(\log n)$
unknown	known	$(s-1)\cdot c_2\cdot \log_a n$	$(s-1)\cdot c_2\cdot \Theta(\log n)$
known	unknown	$(s-1)\cdot c_2\cdot \log_a n$	$(s-1)\cdot c_2\cdot \Theta(\log n)$
known	known	$(s-1)\cdot c_2\cdot \min\{\frac{c_2}{2c_1}, \log_a n\}$	$(s-1)\cdot c_2\cdot \min\{\frac{c_2}{2c_1}, \Theta(\log n)\}$

These results are analogous to those of [3]: intuitively, if either bound is unknown, then the system can be considered somewhat "asynchronous"; otherwise the system behaves "more synchronously." As we discussed in the introduction, the asynchronous lower bound of [3] does not automatically imply any of the lower bounds in the unknown bound models; however, it is the case that the proof in [3] also works in the case where both bounds are unknown. Mavronicolas [16] independently and concurrently also developed the same bounds for the model where both minimum and maximum step times are known.

1.4.2. Message passing results. In the MP case, we discovered a pattern of upper bounds consisting of eight different groups of models. As in the SM case, the pattern is based on different counting methods. However, there are three additional counting methods available in message passing, so the relationships are more involved.

In the following, we specify each model by a tuple (c_1, c_2, d_1, d_2). Each entry in a tuple is a real value if that parameter is known, and "?" if it is unknown. For example, we denote the model in which only the maximum step time is known by $(?, c_2, ?, ?)$.

In addition to the two counting methods available in the SM model (EC and ST), three other counting methods are used in the MP model: (1) The *message delay* (MD) *method* uses the known difference between the minimum and maximum message delays; (2) *combination method* 1 (CB1) uses the known minimum step time in combination with the difference between the minimum and maximum message delays; and (3) *combination method* 2 (CB2) uses the known maximum message delay in combination with the known minimum step time.

Table 1.2 shows the approximate per-session cost for each counting method that is applicable when specific timing information about the system is available. The upper bound on the time complexity for a particular timing model is the minimum, over all applicable counting methods, of the time complexity of the counting methods.

These counting methods divide the models into eight groups, as shown in Table 1.3. Figure 1.1 shows a lattice of timing models based on the counting methods that a model can use. In the figure, an arrow from one group to another means that the time required to compute a session in the models comprising the source group is asymptotically equal to or larger than the time required to compute a session in the models comprising the target group. For instance, the arrow from G1 to G2 indicates that computing a session in G1 takes at least as much time as doing so in G2.

The results for group G4, when step time bounds are known, were previously shown by Attiya and Mavronicolas [5]. All the remaining results are new; as mentioned before, the asynchronous results in [5] do not automatically imply the same results in the unknown bound cases, although the proof techniques are similar.

We show that the upper bounds on the time complexity for the timing models are asymptotically optimal. Some of our lower bounds require certain relationships to

TABLE 1.2

The approximate per-session cost of each counting method used to solve the session problem when the required timing knowledge is available; c_1 and c_2 are the minimum and maximum step times, d_1 and d_2 are the minimum and maximum message delays, and $u = d_2 - d_1$ is the uncertainty in message delay.

Counting methods	Required knowledge	Approximate per-session cost
Explicit communication (EC)	none	d_2
Step times (ST)	c_1, c_2	$\frac{c_2}{c_1} c_2$
Message delays (MD)	d_1, d_2	$\frac{d_2}{d_1} u$
Combination 1 (CB1)	c_1, d_1, d_2	$\frac{c_2}{c_1} u$
Combination 2 (CB2)	c_2, d_1	$\frac{d_2}{d_1} c_2$

TABLE 1.3

Groups of models that can use the same counting methods.

Group	Models	Usable counting method(s)
$G1$	$(?,?,?,?), (?,?,?,d_2), (?,?,d_1,?), (?,c_2,?,?),$ $(?,c_2,?,d_2), (c_1,?,?,?), (c_1,?,?,d_2), (c_1,?,d_1,?)$	EC
$G2$	$(?,?,d_1,d_2)$	EC, MD
$G3$	$(?,c_2,d_1,?)$	EC, CB2
$G4$	$(c_1,c_2,?,?), (c_1,c_2,?,d_2)$	EC, ST
$G5$	$(c_1,?,d_1,d_2)$	EC, MD, CB1
$G6$	$(?,c_2,d_1,d_2)$	EC, CB2, MD
$G7$	$(c_1,c_2,d_1,?)$	EC, CB2, ST
$G8$	(c_1,c_2,d_1,d_2)	EC, CB2, CB1, ST, MD

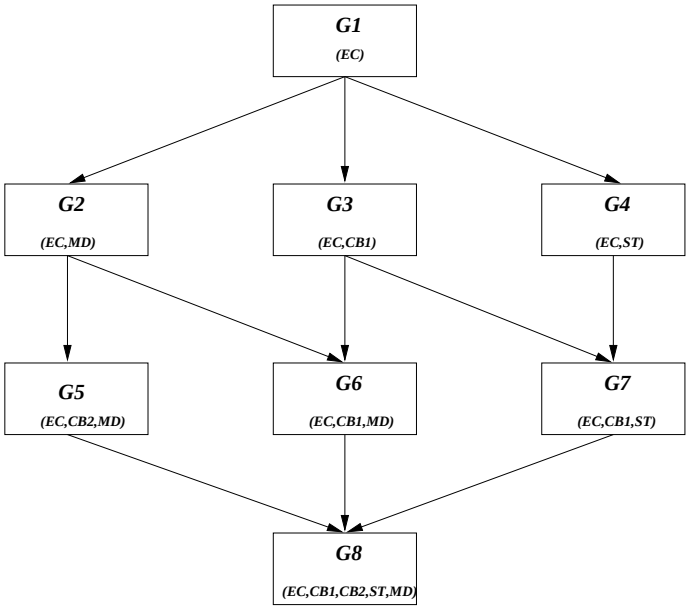

FIG. 1.1. *A lattice of model groups can be formed based on the counting methods (shown in parenthesis) and tight time complexity bounds of the timing models.*

hold between some of the parameters. For example, consider the model in which only c_2 and d_1 are known. The only applicable counting methods are EC and CB2. Thus, the per-session cost is (approximately) $\min\{d_2, \frac{d_2}{d_1} \cdot c_2\}$. The lower bound we prove for this model gives a per-session cost of approximately $\frac{2d_2}{3d_1} \cdot c_2$, assuming $2c_2 \leq d_1$. Since $2c_2 \leq d_1$, algebraic manipulation shows that this lower bound is less than d_2. Thus our upper and lower bounds are asymptotically tight if $2c_2 \leq d_1$.

As in the case of the SM models, the general trend of these bounds is that if a smaller number of the parameters in a model are known, the model behaves more like "asynchronous," and otherwise, more like "synchronous."

As the time complexity gaps (i.e., the difference between the upper bound in a model and the lower bound in another model) among the models sometimes overlap, it is rather difficult to analyze the relative strength qualitatively without making assumptions on parameters. However, when specific values for each known parameters are given, the actual bounds can be used to analyze the relative strength of the models quantitatively.

As process step times become more synchronous (i.e., $c_1 \simeq c_2$) and message delays become erratic (i.e., $c_2 \ll d_1 \ll d_2$), the general trend of the bounds is that $\{G1, G2, G5\} > \{G3, G4\} > \{G6, G7, G8\} > S$, where S is the synchronous model and ">" denotes that it takes more time to solve the session problem. As message delays become more synchronous and smaller (i.e., $d_1 \simeq d_2$ and $d_2 \geq c_2^2/2c_1$) and process step times become more erratic (i.e., $c_1 \ll c_2$), the trend is that $\{G1, G6\} > \{G2, G5, G3, G4, G7, G8\} > S$. These trends suggest that when process step times are fairly "synchronous," the ST method can be more cost-effective than MD, CB2, and CB1, while when process step times are more "asynchronous" than message delays, the opposite is true.

1.4.3. Proof techniques. We unify the lower bound proof techniques of [3] in the SM model and [5] in the MP model into one "modular" lower bound proof. Our technique is unique in that, instead of obtaining a lower bound for each model independently, we develop one sufficient condition for any given lower bound to hold in any given timing model. This sufficient condition consists of a set of algebraic relations involving (1) the timing parameters of the given model; (2) the given lower bound; and (3) some input parameters that need to be provided to prove the lower bound. Testing whether a lower bound holds in a timing model is a simple algebraic exercise of finding those input parameters that satisfy the relations.

The upper bounds are also obtained in a modular way. We first find algorithms (i.e., ways to count sessions) that work correctly when a certain set of timing parameters is known. Since several algorithms can be applicable to a model, we provide a scheme to combine these algorithms without increasing the time complexity of any of its applicable algorithms. The resulting upper bound of a model is simply the minimum of the time complexity of all the algorithms applicable to the model.

1.5. Organization. The rest of this paper is organized as follows. Section 2 gives the definition of the system model. Section 3 contains our modular lower bound result for the time complexity of the session problem. Our algorithmic counting methods are presented in section 4. Section 5 draws together the results for shared memory and section 6 does the same for message passing. We conclude in section 7.

2. Definitions.

2.1. Systems. The system model definition is similar to that defined in [3].

There are finite sets P of processes and V of shared variables. A *process* has a set of internal states, including an initial state. Each *shared variable* has a set of values that it can contain, including an initial value. A *global state* is a tuple of internal states of each process, and values of each shared variable. The *initial* global state contains the initial state for each process and the initial value for each shared variable.

A process can both read and write a shared variable in a single atomic step (i.e., the variable supports read-modify-write operations); we do not assume any upper bound on the size of the variables. A *step* π consists of simultaneous changes to the state of some process p and the value of some set of variables $x_1, \ldots, x_k$ (for some integer k), where p is allowed to access x_i, $1 \leq i \leq k$, depending on the current state of that process and current values of the variables. More formally, we represent the step π with a tuple $((q, p, r), (u_1, x_1, v_1), \ldots, (u_k, x_k, v_k))$, where q and r are old and new states of a process $p \in P$, and u_i and v_i are old and new values of a shared variable $x_i \in V$. We define $proc(\pi) = p$ and $var(\pi) = \{x_1, \ldots, x_k\}$. We say that step π is *applicable* to a global state if p is in state q and x_i has value u_i for all i in the global state.

An *algorithm* consists of P, V, and set Σ of possible steps. For all processes $p \in P$ and all global states g, there must exist some step in Σ involving process p that is applicable to global state g. This condition ensures that p never blocks. A *computation* of a system is a sequence of steps $\pi_1, \pi_2, \ldots$ such that (1) π_1 is applicable to the initial global state; (2) each subsequent step is applicable to the global state resulting from the previous step; and (3) if the sequence is infinite, then every process takes an infinite number of steps. That is, there is no process failure.

A *timed computation* (α, T) of a system is a computation $\alpha = \pi_1, \pi_2, \ldots$ together with a mapping T from positive integers to nonnegative real numbers that associates a real time with each step in the computation. T must be nondecreasing and, if the computation is infinite, increase without bound. This way of modeling processes assumes that the time taken for local computation at a step is negligible.

2.1.1. SM model. We specialize the general system into the SM system in which processes communicate with each other by means of shared variables. Each step π involves only one shared variable. Associated with each variable is a set of at most a processes that are allowed to access that variable.

2.1.2. MP model. We specialize the general system into the MP system, in which processes communicate with each other by exchanging messages. P consists of the *regular* processes, denoted by the set R, plus a distinguished process N, called the *network*. The network schedules the delivery of messages sent among the regular processes. V, the set of shared variables, equals $\{net\} \cup \{buf_p : p \in R\}$, where the values taken on by each variable are sets of messages. The variable *net* models the state of the network, i.e., the set of messages in transit. The variable buf_p holds the set of messages that have been delivered to p by the network but not yet received by p.

A step of a process p in R consists of p receiving the set M of messages in its buffer buf_p and based solely on those messages and its current state, changing its local state and sending out some message m to all the regular processes. More formally, the result of the step is to set buf_p to empty (i.e., receive messages), to add (m, q) to

net for all q in R (i.e., send a message), and to change state. So, the step involves two shared variables, buf_p and *net*. A step of N is to deliver some message of the form (m, q) in *net* to q. More formally, the result of the step is to remove (m, q) from *net* and add m to buf_q. We call this step the *delivery step* of m. Accordingly, the step also involves two shared variables, *net* and buf_q. We define $msg(\sigma)$ to be the message that is involved in a step σ of a process in P.

This definition of the MP model is an abstract model of a reliable strongly connected network with any topology (i.e., for every pair of processes, there exists a communication path between the two processes).

In a timed computation, each message has a *delay*, defined to be the difference between the time of the step that adds it to *net* and the time of the step that removes it from *net*. If the message is never removed, then it has infinite delay. The delay only counts the time in transit in the network and does not include the time that the recipient takes to receive the message. Note that after a message is delivered to a destination process p, p has to take at least one step to receive the message. That is, the time elapsed between the delivery step of a message m and the step of the destination process which finally removes m from the buffer is not counted toward the message delay.

2.2. Timing models. First we consider SM models. Let v and w be two positive real numbers with $v \leq w$. $M(v, w)$, called a *submodel*, is the set of all timed computations of a system in which all step times (the time between two consecutive steps by the same process) are within $[v, w]$.

An SM model is specified by indicating whether the minimum and maximum step times are known, and if so, what their values are. Formally, an *SM model* is denoted $\mathcal{M}[c_1, c_2]$, where $c_i \in \{?\} \cup \mathcal{R}^+$ ($\mathcal{R}^+$ is the set of positive reals). If the minimum step time is known, then c_1 is some positive real; otherwise, $c_1 = ?$. If the maximum step time is known, then c_2 is some positive real; otherwise, $c_2 = ?$.

We define the four SM models of interest as follows:

$$\begin{aligned}
\mathcal{M}[c_1, c_2] &= \{M(c_1, c_2)\} \quad \text{if } c_1 \in \mathcal{R}^+ \text{ and } c_2 \in \mathcal{R}^+.\\
\mathcal{M}[c_1, ?] &= \{M(c_1, w) : w \geq c_1\} \quad \text{if } c_1 \in \mathcal{R}^+.\\
\mathcal{M}[?, c_2] &= \{M(v, c_2) : 0 < v \leq c_2\} \quad \text{if } c_2 \in \mathcal{R}^+.\\
\mathcal{M}[?, ?] &= \{M(v, w) : 0 < v \leq w\}.
\end{aligned}$$

We now consider MP models. Let v, w, x, and y be four positive real numbers with $v \leq w$ and $x \leq y$. $M(v, w, x, y)$, called a *submodel*, is the set of all timed computations in which all step times are within $[v, w]$ and all message delays are within $[x, y]$.

The 16 MP models are defined analogously to the four SM models. For example,

$$\mathcal{M}[?, c_2, d_1, ?] = \{M(v, c_2, d_1, y) : 0 < v \leq c_2 \text{ and } y \geq d_1\} \quad \text{if } c_2 \text{ and } d_1 \in \mathcal{R}^+.$$

We number the models 0 through 15 using the binary representation, assuming a parameter that equals ? is replaced with 0 and otherwise with 1. For instance, $\mathcal{M}[?, c_2, d_1, ?]$ is numbered $0110_2 = 6$.

We say that a timed computation α is *admissible* for a submodel M if α is in M, and is *admissible* for a model $\mathcal{M}$ if α is admissible for some M in $\mathcal{M}$.

2.3. The (s, n)-session problem. We now state the conditions that must be satisfied for a system to *solve the* (s, n)*-session problem*.

There is a distinguished set Y of n shared variables called *ports*; Y is a subset of V in SM models; and Y is the set of *buf* variables in MP models. There is a unique process in P (in R in MP models) corresponding to each port, which is called a *port process*, and no two port processes can be assigned to the same port. A *port step* is any step involving a port and its corresponding port process. A port can be accessed by processes in addition to its corresponding port process, but such a step is not a port step. There may be some processes which are not port processes; i.e., it is possible for $|P|$ to be larger than n.[1]

Each port process in P must have a subset of special states, called *idle* states. The set Σ of steps of the system must guarantee that once a process is in an idle state, it always remains in an idle state, and after a process enters an idle state, it does not access a port.

A *session* is a minimal sequence of steps containing at least one port step for each port in Y. A computation *performs* s sessions if it can be partitioned into s segments, each of which is one session. Every infinite admissible timed computation must perform at least s sessions and eventually all port processes must be in idle states.

2.4. Time complexity. We give the definitions for the SM models. The time complexity definitions for MP models are analogous to those for SM models.

An algorithm A in a submodel $M(x, y)$ has *running time* t if t is the maximal time, over all admissible computations of A for $M(x, y)$, until all port processes become idle.

Let f be a function from $\mathcal{R}^+ \times \mathcal{R}^+$ to $\mathcal{R}^+$. We abuse notation and say that an algorithm A in model $\mathcal{M}[c_1, c_2]$ has *upper bound* $f(c_1, c_2)$ if A has running time at most $f(x, y)$ in every submodel $M(x, y)$ in $\mathcal{M}[c_1, c_2]$. (This is an abuse of notation because c_1 or c_2 might equal ? instead of being a positive real constant.)

$\mathcal{M}[c_1, c_2]$ has *lower bound* $f(c_1, c_2)$ if for every algorithm A, there is a submodel $M(x, y)$ such that A has running time at least $f(x, y)$ in that submodel.

3. Modular lower bound. In this section, we give a modular lower bound proof that holds for all the timing models, both SM and MP. Our lower bound proof is motivated by the proofs in [3] and [5]. Our technique is unique in that, instead of obtaining a lower bound for each model independently, we develop a sufficient condition for a lower bound to hold in any given timing model. This sufficient condition consists of a set of algebraic relations on (1) the timing parameters of the given model; (2) the given lower bound; and (3) some other input parameters (shown below). Thus, testing whether a lower bound holds in a timing model is a simple algebraic exercise of finding those input parameters that satisfy the relations. The theorem below proves the sufficient condition; in its statement, c, c'_1, c'_2, d'_1, d'_2, and B are the input parameters, and SC1 to SC3 and MC1 to MC5 are the algebraic relations. In the proof of the theorem, we present some intuitive ideas behind the theorem and then formalize the ideas.

THEOREM 3.1. *Let M be a timing model that satisfies the following.*

If $M = \mathcal{M}[c_1, c_2]$ is an SM model, then there exist positive real numbers c, c'_1, c'_2 and a function f with $B = f(c'_1, c'_2)$ such that

[1] This possibility is implicitly contained in [3], which refers to making the port processes the leaves of a tree network.

$$\begin{array}{lllll}
\text{SC1.} & (B \le c_2' \cdot \log_a n) & \wedge & (c_1' \le c_2'). & \\
\text{SC2.} & (c_1' \le \frac{1}{2}c) & \wedge & ((c_1' = c_1) & \text{if } c_1 \ne ?). \\
\text{SC3.} & (c_2' \ge B\frac{c}{c_2'}) & \wedge & ((c_2' = c_2) & \text{if } c_2 \ne ?).
\end{array}$$

If $M = \mathcal{M}[c_1, c_2, d_1, d_2]$ is an MP model, then there exist positive real numbers c, c_1', c_2', d_1', d_2' and a function f with $B = f(c_1', c_2', d_1', d_2')$ such that

$$\begin{array}{lllll}
\text{MC1.} & (B \le d_2') & \wedge & (c_1' \le c_2') \wedge (d_1' \le d_2'). & \\
\text{MC2.} & (c_1' \le \frac{1}{2}c) & \wedge & ((c_1' = c_1) & \text{if } c_1 \ne ?). \\
\text{MC3.} & (c_2' \ge B\frac{c}{c_2'}) & \wedge & ((c_2' = c_2) & \text{if } c_2 \ne ?). \\
\text{MC4.} & (d_1' \le (d_2' - B)\frac{c}{c_2'} + c) & \wedge & ((d_1' = d_1) & \text{if } d_1 \ne ?). \\
\text{MC5.} & (d_2' \ge (d_2' + B)\frac{c}{c_2'} - c) & \wedge & ((d_2' = d_2) & \text{if } d_2 \ne ?).
\end{array}$$

Then a lower bound on the time complexity of the (s, n)-session problem for M is $(s-1) \cdot f(c_1, c_2)$ if M is an SM model, and $(s-1) \cdot f(c_1, c_2, d_1, d_2)$ if M is an MP model.

3.1. Proof of Theorem 3.1.

Informal description. By way of contradiction we assume that there exists such an algorithm A that solves the (s, n)-session problem in model M within less time than the stated lower bound. We prove that there exists an infinite timed computation of A that is admissible for M yet contains fewer than s sessions, contradicting the assumed correctness of A.

More specifically, we first fix a submodel M' of M and pick an infinite timed computation (α, T) of A that is admissible for M'. Then we retime and reorder some steps in α to obtain a new infinite timed computation (α', T') that has only $s-1$ sessions, yet is admissible for some submodel M'' of M. (M' and M'' are not necessarily the same.)

Real numbers c_1', c_2', d_1', and d_2' are the minimum and maximum step times and message delays of submodel M', respectively, for which (α, T) is admissible. Real numbers $\frac{1}{2}c$, $B\frac{c}{c_2'}$, $(d_2' - B)\frac{c}{c_2'} + c$, and $(d_2' + B)\frac{c}{c_2'} - c$ are the minimum and maximum step times and message delays of M'' for which (α', T') is admissible.

The conditions in the theorem statement are used to prove that M' and M'' really are submodels of M. Below we provide some intuition for these conditions.

1. B is roughly the time for a process to "recognize" one session in a computation. The first clause in conditions SC1 and MC1 states that B does not take more than the lower bound on the maximum communication delay in the SM and MP models.
2. Conditions SC1 and MC1 ensure that minimum and maximum step times and message delays (c_1', c_2', d_1', and d_2') in submodel M' satisfy the property that the minimum is not larger than the maximum.
3. Conditions SC2 and MC2 ensure that, if the minimum step time (c_1) is known in M, then in M' it is equal to that of M, and in M'' it is at least as large as that of M.
4. Conditions SC3 and MC3 ensure that, if the maximum step time (c_2) is known in M, then in M' it is equal to that of M, and in M'' it is not larger than that of M.
5. Condition MC4 ensures that, if the minimum message delay (d_1) is known in M, then in M' it is equal to that of M, and in M'' it is at least as large as that of M.

6. Condition MC5 ensures that, if the maximum step time (d_2) is known in M, then in M' it is equal to that of M, and in M'' it is not larger than that of M.

Since B is roughly the upper bound on the time to have one session, the time complexity lower bound to solve the (s,n)-session problem cannot be less than $(s-1)$ times the maximum B, which is determined by the timing parameters of M.

We now need to prove that satisfying the above conditions is sufficient to prove the time complexity lower bound for solving the (s,n)-session problem. This involves several procedures.

1. We prove that (α, T) is admissible for M', and M' is a submodel of M. In (α, T), processes enter an idle state before $B \cdot (s-1)$.
2. We then reorder steps in α to obtain α' without violating the causal dependency among process steps. The causal dependency among two process steps happens, for example, because one step receives a message sent by the other step. Thus, for example, α' should not order the receive step before the send step. This procedure involves several other steps.
   (a) We first break α into two segments. The first segment, β, is up to the last step taken by any process before all processes enter the idle state. The second segment, γ, is the rest of α. It is clear that β should contain s sessions because α is a computation of A that solves the (s,n)-session problem.
   (b) We then break β into $s-1$ equal nonoverlapping segments of time period B. We reorder the process steps only within each segment without violating their causal dependency so that each segment by itself does not contain one session. Since each segment contains less than one session, the reordered sequence β' does not contain more than $s-1$ sessions. Since each segment does not violate the causal dependency, all the port processes will be in the same state as they are in the corresponding segment in β. Thus, in the end of β', all the port processes are in the same state as in β, and $\alpha' = \beta'\gamma$ is an admissible computation for M because $\alpha = \beta\gamma$ is.
3. Reordering steps perturbs the timings of process steps. We show a timing mapping T' for β' whose minimum and maximum step times are $c/2$ and $B\frac{c}{c_2'}$, and whose minimum and maximum message delays are $(d_1' \leq (d_2' - B)\frac{c}{c_2'} + c)$ and $(d_2' \geq (d_2' + B)\frac{c}{c_2'} - c)$. The conditions in the theorem are used to show that these retimed parameters are within the constraints of a submodel M'' of M.
4. Since there is a timed computation (α', T') that is admissible for a submodel of M which contains less than $s-1$ sessions, this is a contradiction.

Formal description. We now formalize these ideas.

Let M' be the submodel of M that has minimum and maximum step times and message delays equal to c_1', c_2', d_1', and d_2', respectively, where the following hold: (a) $c_1' \leq c_2'$; (b) $c_1' = c_1$ if the minimum step time of M (c_1) is known; and (c) $c_2' = c_2$ if the maximum step time of M (c_2) is known. Furthermore, if M is an MP model, (d) $d_1' \leq d_2'$; (e) $d_1' = d_1$ if the minimum message delay of M (d_1) is known; and (f) $d_2' = d_2$ if the maximum message delay of M (d_2) is known.

Since M' is a submodel of M, by the assumption that algorithm A is correct for M, A has running time in M' less than $(s-1) \cdot B$, where $B = f(c_1', c_2')$ if M is an

SM model, and $B = f(c_1', c_2', d_1', d_2')$ if M is an MP model.

Let (α, T) be the infinite timed computation of A in which all the regular processes take steps at the same speed in round robin order and each process's ith step occurs at time $i \cdot c_2'$. Furthermore, if M is an MP model, all the message delays in (α, T) are exactly d_2'. Note that (α, T) is admissible for M' (and thus for M).

Let $\alpha = \beta\gamma$, where β contains all the steps that occur in (α, T) during time interval $[0, (s-1) \cdot B)$ and γ contains the rest of α. Note that all the states in γ are idle states because A solves the (s, n)-session problem in time less than $(s-1) \cdot B$.

Case 1. If $B \leq c_2'$, then β contains only $s-1$ sessions because each process takes only $s-1$ steps in β. This is a contradiction since all regular processes are in an idle state in γ.

Case 2. For the rest of the proof, assume that $B > c_2'$. For convenience of presentation, we assume that B is divisible by c_2'.[2]

We will reorder and retime (i.e., assign new times to) steps in β to obtain (β', T'). To ensure that the retimed computation leads to the same global state, this retiming should not violate the dependencies among process steps. Informally, a dependency arises between two steps if they are steps of the same process; if one step reads a variable previously accessed by the other; or if one step is the receipt of a message sent by the other. A more precise definition of dependency is given below.

We construct a partial order $\leq_\beta$ on the steps in β, representing dependency. Let $\sigma \leq_\beta \tau$ for every pair of steps σ and τ in β, and say that τ *depends* on σ if

- $\sigma = \tau$, or
- $T(\sigma) < T(\tau)$ and $proc(\sigma) = proc(\tau) \neq N$, or
- $T(\sigma) < T(\tau)$ and $msg(\sigma) = msg(\tau)$ if M is an MP model, or
- $T(\sigma) < T(\tau)$ and $var(\sigma) = var(\tau)$ if M is an SM model.

Close $\leq_\beta$ under transitivity.

Let $\beta = \beta_1 \ldots \beta_{s-1}$ such that each β_k, which we call *segment* k, $1 \leq k \leq s-1$, consists of all the steps in (α, T) during time interval $[(k-1)B, kB)$. Note that in an MP model, no message sent in β_k is received in β_k since $B \leq d_2'$ by MC1 and d_2' is the message delay in (α, T).

Informally speaking, we will reorder steps in each segment β_k without violating the dependencies as follows. We first pick one port variable for each segment in such a way that the same port variable is not picked for two consecutive segments. Let y_i be the port variable picked for segment β_i. Then we reorder the steps of each segment, resulting in two "subsegments" such that the first subsegment does not contain any port event accessing y_i and the second subsegment does not contain any port event accessing y_{i+1}. The reordered sequence will contain only $s-1$ sessions. Figure 3.1 illustrates an example when $s = 4$.

However, for the reordered computation to end in the same state as β, this reordering should not violate relation $\leq_\beta$ within each segment (relation $\leq_\beta$ is not violated across segments by the reordering because steps are not reordered out of their own segments). Thus, we must choose the port y_k for each segment β_k such that the first step in β_k to access y_{k-1} does not depend on the last step in β_k to access y_k. The following claim shows that this can be done.

CLAIM 3.2. *Let y_0 be an arbitrary port in Y. For all k, $1 \leq k \leq s-1$, there exists a port variable y_k such that it is false that $\tau_k \leq_\beta \sigma_k$, where τ_k is the first step in β_k that accesses y_{k-1} and σ_k is the last step in β_k that accesses y_k.*

[2] If B is not divisible by c_2', the lower bound we obtain is $(s-1) \cdot \lfloor \frac{f(c_1, c_2)}{c_2} \rfloor \cdot c_2$ instead of $(s-1) \cdot f(c_1, c_2)$ in the SM case, and similarly for the MP case.

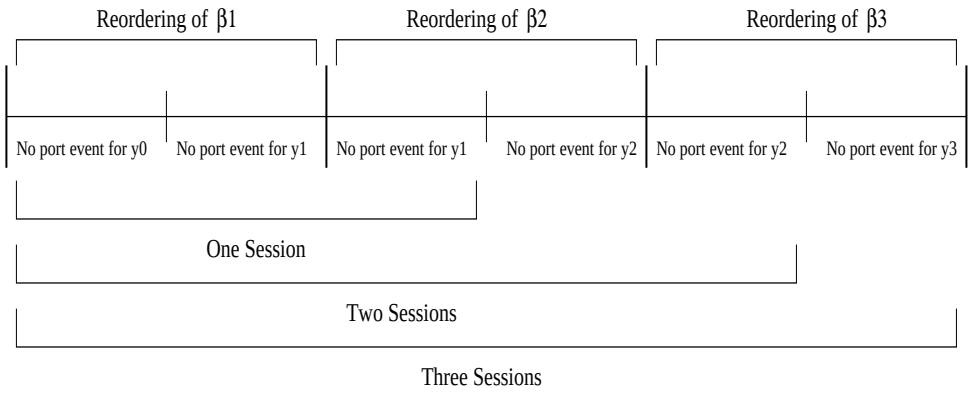

FIG. 3.1. *An example of reordering when* $s = 4$.

Proof. If M is an MP model, no message sent in β_k is delivered in β_k because the size of each segment is less than d_2', and d_2' is the message delay. Because there is no $\leq_\beta$ relation between any two steps of different processes in β_k, any port variable except y_{k-1} can be chosen as y_k.

If M is an SM model, part of the proof of Theorem 2 of [3][3] proves that there exists such y_k if each process takes fewer than $\log_a n$ steps in a segment. Because in β_k each process takes fewer than $\log_a n$ steps (cf. SC1), there exists such y_k in β_k. □

Claim 3.2 allows us to use the y_k's to reorder β to obtain a new sequence with less than s sessions (shown in Claim 3.4). However, the steps in the sequence are not mapped to time. Thus, we need a scheme to assign new times to the reordered steps so that the new timed computation does not violate the timing constraints of M. This is the major difference between our lower bound proof for unknown parameter models and that in [3] for the asynchronous model; in the latter no timing scheme is necessary because the asynchronous model imposes no timing constraints.

In the following, we define a retiming scheme that also encompasses the reordering scheme presented above.

Let us first assign a new mapping T'' to every step π in $\beta\gamma$, including all the steps of the network N if M is an MP model, such that $T''(\pi) = T(\pi) \cdot \frac{c}{c_2'}$. That is, every process (except N) takes a step at every time that is a multiple of c. Since in an MP model, the delivery steps of N are retimed along with other steps, the message delay is now changed from d_2' to $d_2' \cdot \frac{c}{c_2'}$. Note that the assignment of T'' does not change the relative ordering of the steps in β because it changes every step time by the same proportion (namely, $\frac{c}{c_2'}$).

We now reorder and assign new times (the mapping T') to every step in (β_k, T''). Intuitively, in order to obtain a timed computation as in Figure 3.1, σ_k and every step that σ_k depends on have to move earlier in time into the first half of (β_k, T''), and τ_k and every step that depends on τ_k have to move later in time into the second half of (β_k, T''). As a result, σ_k will occur before τ_k.

Let $t_k = k \cdot \frac{Bc}{c_2'}$, where $0 \leq k \leq s-1$. Thus, β_k occurs during $[t_{k-1}, t_k)$ under T''. Note that $t_k - t_{k-1} = \frac{Bc}{c_2'}$.

[3]The statement of Theorem 2 in [3] does not explicitly include this result. For conciseness, we do not include a copy of the relevant part of the proof (the middle of pp. 453–455).

1. (Earlier retiming.) Let π be any step in β_k by a process in P that σ_k depends on (in an MP model, this means $proc(\pi) = proc(\sigma_k)$). Retime π such that $T'(\pi) = \frac{t_{k-1}+T''(\pi)}{2}$. The step is moved backward halfway to the beginning of β_k.
2. (Later retiming.) Let σ be any step in β_k by a process in P that depends on τ_k (in an MP model, this means $proc(\sigma) = proc(\tau_k)$). Retime σ such that $T'(\sigma) = \frac{T''(\sigma)+t_k-c}{2}$. The step is moved forward approximately halfway to the end of β_k.
3. (Stationary retiming.) All other steps in β_k and all steps in γ are assigned the same times as in T''.

For all k, $1 \le k \le s-1$, let β''_k be the result of reordering and retiming steps in β_k according to T', and let $\beta'' = \beta''_1\beta''_2 \dots \beta''_{s-1}$.

If M is an MP model, let β' be the result of changing the states of the network in β'' so that in each step of the network, the state of the network is consistent with all the send steps of regular processes and all the deliver steps of the network in β'' that have happened so far ("consistent" means that a delivery step of a message happens after its send step). If M is an SM model, let $\beta' = \beta''$.

In summary, (β, T) is now transformed to (β', T') using (β'', T'') as an intermediate computation. To show the theorem, it suffices to show that (1) β' is a computation leading to the same global state as β (Claim 3.3); (2) β' contains less than s sessions (Claim 3.4); and (3) $(\beta'\gamma, T')$ is admissible for M (Claim 3.5).

CLAIM 3.3. *β' is a computation that leaves the system in the same global state as β does.*

Proof. We first prove that $\le_\beta$ holds in β'.

For any k, $1 \le k \le s-1$, pick any two steps π and π' in β_k such that $\pi \le_\beta \pi'$. Thus $T(\pi) \le T(\pi')$ (recall that T is the original timing). We only need to prove that $T'(\pi) \le T'(\pi')$ because π occurs earlier than π' in T.

Each of π and π' was retimed by one of the earlier, later, or stationary retiming methods. Clearly the desired ordering is preserved

(1) when π stays the same and π' either stays the same or moves later in time; or

(2) when π' stays the same and π either stays the same or moves earlier in time; or

(3) when π and π' both move in the same direction.

The other cases cannot occur, since if π moves later in time, then so does π', and if π' moves earlier in time, then so does π.

Since β' does not violate $\le_\beta$ in both SM and MP models, and all the states of *net* in β' are consistent with the steps of β'' by the definition of β' in MP, it follows that β' is a computation resulting in the same global state as β. □

CLAIM 3.4. *β' contains at most $s-1$ sessions.*

Proof. For all k, $1 \le k \le s-1$, let $h_k = T'(\tau_k)$. We show, by induction on k, that time period $[0, h_k)$ in (β', T') contains at most $k-1$ sessions.

For the basis, $[0, h_1)$ contains no session because it does not contain any port event for y_0.

Assume, by way of induction, that $[0, h_{k-1})$ contains at most $k-2$ sessions. We prove that $[0, h_k)$ contains at most $k-1$ sessions. It is clear from the construction that $(h_{k-1}, t_{k-1}]$ contains no session because it does not contain any port event of y_{k-1} and, similarly, $[t_{k-1}, h_k)$ does not contain any session because it contains no port event of y_{k-1}. Since the port process of y_{k-1} takes only one step at h_{k-1}, it is clear

that $[h_{k-1}, h_k)$ contains at most one session. Therefore, $[0, h_k)$ contains at most $k-1$ sessions.

A similar argument shows that $[h_{s-1}, t_{s-1}]$ contains at most one session. Since $[0, h_{s-1})$ contains at most $s-2$ sessions, it follows that there are at most $s-1$ sessions in $[0, t_{s-1}]$. □

CLAIM 3.5. *$(\beta'\gamma, T')$ is a timed computation that is admissible for M.*

Proof. By Claim 3.3, β' is a computation that leads to the same global state as β. Therefore, $\beta'\gamma$ is also a computation because $\beta\gamma$ is a computation. Since γ is infinite, so is $\beta'\gamma$. It remains to show that the timing T' conforms to the timing constraints of model M.

Constraints on step time. Let π_i and π_{i+1} be consecutive steps of a single process in β_k for some k. Then, for some $\Delta \geq 0$, it is true that $T''(\pi_i) = t_{k-1} + \Delta$ and $T''(\pi_{i+1}) = t_{k-1} + \Delta + c$.

The distance between the two steps is minimized when both steps are retimed by the same retiming method because it is not possible that π_i is retimed by the later retiming while π_{i+1} is retimed by the earlier retiming. If both π_i and π_{i+1} are retimed by the same retiming method (either later or earlier retiming), $T'(\pi_{i+1}) - T'(\pi_i)$ is equal to $c/2$.

None of the retiming methods retimes a step outside its original segment: If a step is in segment β_k, after the retiming, it is still in segment β'_k. Thus, neither π_i nor π_{i+1} is retimed outside the segment. Since the maximum time elapsed between π_i and π_{i+1} in β_k is B, and in T'', all times are shrunk in proportion to $\frac{c}{c'_2}$, the distance between the two steps can never be larger than $t_k - t_{k-1} \leq B\frac{c}{c'_2}$.

For the timing of steps in different segments, let π_j and π_{j+1} be the consecutive steps of a process, each of which is in a different segment, say, β_k and β_{k+1}, respectively. Then $T''(\pi_j) = t_k$ and $T''(\pi_{j+1}) = t_k + c$ (this is because B is divisible by c'_2). Since the two steps are in different segments, the distance between the two steps is minimized when π_j is retimed by the later retiming while π_{j+1} is retimed by the earlier retiming. However, neither of these retimings results in a change, i.e., $T'(\pi_j) = T''(\pi_j)$ and $T'(\pi_{j+1}) = T''(\pi_{j+1})$. Therefore, $T'(\pi_{i+1}) - T'(\pi_i) = c$. Since the two steps are in different segments, the distance between the two steps is maximized when π_j is retimed by the earlier retiming while π_{j+1} is retimed by the later retiming. In this case, π_j moves to $(t_{k-1} + t_k - c)/2$ and π_{j+1} moves to $(t_k + t_{k+1} - c)/2$. Therefore, the distance between the two steps cannot be larger than $B\frac{c}{c'_2}$ because $T'(\pi_{i+1}) - T'(\pi_i) = \frac{t_{k+1} - t_{k-1}}{2} \leq B\frac{c}{c'_2}$.

We first check the minimum step time.

- If c_1 is unknown, then there exists a positive constant (namely $c/2$) which is the minimum step time in (β', T').
- If c_1 is known, by condition SC2 (or MC2), the minimum step $(c/2)$ in (β', T') is bigger than or equal to the minimum step time of M.
- If c_2 is known, the minimum step $(c/2)$ is less than or equal to c_2 because (1) by SC3 (MC3), $c'_2 = c_2$ and $B\frac{c}{c_2} \leq c_2$; and (2) by the assumption for Case 2 of the main proof, $B > c_2$.

Now we check the maximum step time.

- If c_2 is unknown, then there exists a positive constant (namely $B\frac{c}{c'_2}$) which is the maximum step time in (β', T').
- If c_2 is known, the maximum step time $(B\frac{c}{c'_2})$ in (β', T') is less than or equal to c_2 because of SC3 and MC3.

- If c_1 is known, the maximum step time ($B\frac{c}{c_2'}$) in (β', T') is bigger than or equal to c_1 because (1) by the assumption for Case 2, $B > c_2'$ and thus $B\frac{c}{c_2'} > c$; and (2) by SC2 and MC2, $c \geq c_1$.

Constraints on message delay. The steps that move the farthest due to the earlier retiming from T'' to T' are those at the end of each segment because they do not move outside their segments. Let π_{last} be the step at the end of β_k. $T''(\pi_{last}) = t_k - c$. By the earlier retiming, $T'(\pi_{last}) = (t_{k-1} + t_k - c)/2 = t_k - \frac{1}{2}B\frac{c}{c_2'} - c/2$.

The steps that move the farthest due to the later retiming from T'' to T' are those at the start of each segment because they do not move outside their segments. Let π_{start} be the step at the start of β_k. $T''(\pi_{start}) = t_{k-1}$. By the later retiming, $T'(\pi_{start}) = (t_{k-1} + t_k - c)/2 = t_k - \frac{1}{2}B\frac{c}{c_2'} - c/2$. Therefore, the maximum distance that a step can move from T'' to T' is bounded by $\frac{1}{2}B\frac{c}{c_2'} - c/2$.

Let π_s and π_r be the send and receive steps of any message in β. Recall that under T'', all the message delays are $d_2'\frac{c}{c_2'}$. Thus, $T''(\pi_r) - T''(\pi_s) = d_2'\frac{c}{c_2'}$. Let $d' = d_2'\frac{c}{c_2'}$. Because both π_r and π_s can move $\frac{1}{2}(B\frac{c}{c_2'} - c)$ time from T' to T'', each in opposite directions, $d' - B\frac{c}{c_2} + c \leq T'(\pi_r) - T'(\pi_s) \leq d' + B\frac{c}{c_2} - c$.

We first check the minimum message delay.

- If d_1 is unknown, then there exists a positive constant that is the minimum message delay in (β', T') because (1) $T'(\pi_r) - T'(\pi_s) \geq d' - B\frac{c}{c_2} + c$; (2) by MC1, $d' - B\frac{c}{c_2'} = (d_2' - B)\frac{c}{c_2'} \geq 0$; and (3) c is a positive real.
- If d_1 is known, the minimum message delay $(d' - B\frac{c}{c_2'} + c)$ in (β', T') is bigger than or equal to d_1 because of MC4.

We now check the maximum message delay.

- If d_2 is unknown, then there exists a positive constant (namely $d' + B\frac{c}{c_2'} - c$) that is the maximum message delay in (β', T') because $d' + B\frac{c}{c_2'} - c \geq T'(\pi_r) - T'(\pi_s) > 0$.
- If d_2 is known, the maximum message delay $(d' + B\frac{c}{c_2'} - c)$ is less than or equal to d_2 because of MC5. □

To finish the proof of the main theorem, $(\beta'\gamma, T')$ is an infinite timed computation admissible for M but with fewer than s sessions, by Claims 3.4 and 3.5. This contradicts the assumed correctness of A. □

4. Algorithmic counting methods. We develop five methods to count the number of sessions during a computation (cf. Table 4.1). These methods differ in the ways they use the known timing information of a model to count sessions. An (s, n)-session algorithm can be obtained for a model simply by combining all the applicable methods to the model without increasing the asymptotic time complexity of any of those methods. This can be done by running each method "side by side," halting when the first of them finishes [5]. Since there is only a constant number of methods running at the same time, the combination does not affect the asymptotic time complexity of the algorithm. The resulting upper bound on the time needed to solve the session problem in a model is the minimum of the time complexity of all the methods applicable to the model.

We now describe each of the counting methods. A message is denoted $m(i, j, k)$, where i is the identifier of the sending process p_i, j is an integer in $[0, s-1]$, and k is an integer. We let $*$ be a "don't care" value. The port for a port process i is denoted y_i. In an MP model, y_i denotes process i's buffer of incoming messages.

TABLE 4.1
Counting methods.

Technique	Timing information	Running time
Explicit communication (EC)	None	$(s-1)\cdot d_2 + c_2$ or $(s-1)\cdot c_2\Theta(\log n) + c_2$
Step time (ST)	c_1, c_2	$(s-1)\cdot \frac{c_2}{c_1}\cdot c_2 + c_2$
Combination 1 (CB1)	c_1, d_1, d_2	$(s-2)\cdot(\frac{c_2}{c_1}\cdot u + u + 2c_2) + d_2 + 3c_2$
Message delay (MD)	d_1, d_2	$(s-2)(\frac{d_2}{d_1}\cdot u + u + 2c_2) + d_2 + 2c_2$
Combination 2 (CB2)	c_2, d_1	$(s-1)\cdot c_2 \cdot \frac{d_2+c_2}{d_1} + c_2$

In describing the methods, we use a subroutine called *broadcast* as a generic operator for communication. In MP models, *broadcast* is accomplished by having each process send a message to all the processes, including itself. In specifying the algorithm for counting, we use a message format with three fields, $m(i, j, k)$, where i indicates the identifier of the process sending the message; j is the session number that process i is currently in; and k is an integer used as a local variable in the algorithm. When marked with $*$, the field denotes "don't care" (i.e., a message with any value on that field).

We now explain how to achieve a broadcast in an SM model. Recall that at most a processes can access any specific shared variable. We conceptually organize the processes and shared variables into a tree with $\Theta(\log n)$ levels. In order for a port process to broadcast information to all other port processes, the information travels up the tree to the root and then down from the root to all the leaves. See Appendix A for more details.

4.1. Explicit communication (EC). The EC method (see Figure 4.1), originally presented and analyzed in [3] for the asynchronous SM model, and in [5] for the asynchronous MP model, does not require any timing information to solve the (s, n)-session problem. It can be used in any timing model because the correctness of the method does not depend on specific step time or message delay.

```
session := 0; msgs := ∅;
while ( session < s − 1 )
    msgs := msgs ∪ y_i; /* port event; recall y_i = buf_i in MP */
    if for all j ∈ {1, ..., n}, m(j, session, *) is in msgs
    then
        session := session + 1;
    end if;
    broadcast m(i, session, *); /* port event */
end while;
Enter an idle state.
```

FIG. 4.1. *Technique EC for process i.*

THEOREM 4.1. *EC solves the (s, n)-session problem in time $(s-1)\cdot c_2\cdot\Theta(\log n)+c_2$ in an SM model and in time $(s-1)\cdot d_2 + c_2$ in an MP model.*

The basic intuition for the method is that since it does not use any timing information, a process relies only on communication with other processes at every session to recognize that there is one session. Each process executes one port event, broad-

```
B := c2/c1;
count := session := 0;
while ( session < s − 1 )
    if (count ≥ B)
    then
        count := 0;
        session := session + 1;
    end if;
    count := count + 1;
    access y_i; /* port event; recall y_i = buf_i in MP */
end while;
Enter an idle state.
```

FIG. 4.2. *Technique ST for process i.*

casts the fact to every process at each step, and repeats this step until it hears that every process has executed another port event. Then it increments *session*. It performs these steps $s-1$ times. Then, after it executes one additional port event, it enters an idle state.

4.2. Step time (ST). The ST method (see Figure 4.2), originally presented and analyzed in [5] for the semisynchronous model, requires information about the maximum and minimum step times (c_2 and c_1). For convenience of presentation, we assume that c_2 is divisible by c_1. This method can also be used for both an SM model and an MP model.

In this method, processes use timing information about relative step times to determine when a session occurs. Each process executes $\frac{c_2}{c_1}$ port events. During this interval, at least $\frac{c_2}{c_1} \cdot c_1 = c_2$ time elapses, since c_1 is the minimum step time. Since every process performs at least one port event within time c_2 (since c_2 is the maximum step time), at least one session has occurred by the time that the process finishes $\frac{c_2}{c_1}$ port events. Each process repeats the above procedure $s-1$ times. After it executes one additional port event, it enters an idle state.

THEOREM 4.2. *ST solves the (s,n)-session problem in time $(s-1) \cdot \frac{c_2}{c_1} c_2 + c_2$ in both an SM model and an MP model.*

4.3. Combination 1 (CB1). The CB1 method (see Figure 4.3) requires information about the minimum step time (c_1) and the minimum and maximum message delays (d_1 and d_2). For convenience of presentation, we assume that $u = d_2 - d_1$ is divisible by c_1.

The correctness of this method relies on the following observation. If a process p_i receives a message m from a process p_j at time t, then the message must have been sent no later than $t - d_1$, because it takes at least d_1 time for a message to be delivered. All the messages received by p_i after $t + d_2 - d_1$ must have been sent after m was, because it takes at most d_2 time for a message to be delivered. Based on this idea, each process broadcasts a message at every step. (1) When a process initially receives one message from every process, it recognizes there is one session because each process must have taken one step to send the message. (2) Then when it receives another set of messages from every process after time $u = d_2 - d_1$, there must have been another session after the initial session because the second set of messages must have been sent after the first session occurred. Time u can be measured by counting

```
B := u/c1; /* u = d2 − d1 */
count := session := 0;
msgs := ∅;
while (session < s − 1)
    msgs := msgs ∪ buf_i; /* port event */
    if (session = 0) or (count ≥ B)
    then
        if for all j ∈ {1, ..., n}, m(j, ∗, ∗) is in msgs
        then /∗ condition 1 ∗/
            count := 0;
            session := session + 1;
            msgs := ∅;
        end if;
    end if;
    broadcast m(i, ∗, ∗); /* port event */
    count := count + 1;
end while;
Enter an idle state.
```

FIG. 4.3. *Technique CB*1 *for process i.*

steps, using the known minimum step time (c_1) (i.e., when a process takes $\frac{u}{c_1}$ local steps, at least u time is guaranteed to be elapsed).

Each process performs the second procedure $s-2$ times. Then it enters an idle state after taking an additional step. The running time of CB1 is $(\frac{c_2}{c_1}u+u+2c_2)(s-2)+d_2+3c_2$, as we now explain. It takes at most $\frac{u}{c_1}\cdot c_2$ time to count $\frac{u}{c_1}$ steps, at most $u+2c_2$ time for a process to receive another set of message after it recognizes there was a session, at most d_2+2c_2 time to receive the initial set of messages, and finally one more step to accomplish the last session. The detailed proof of the following theorem can be found in Appendix A.

THEOREM 4.3. *CB*1 *solves the* (s,n)*-session problem within time* $(s-2)\cdot(\frac{c_2}{c_1}u+u+2c_2)+d_2+3c_2$ *if* c_1*,* d_1*, and* d_2 *are known.*

4.4. Message delay (MD). The MD method (see Figure 4.4) requires information about the lower bound d_1 and upper bound d_2 on message delay. MD differs from CB1 only in one way: a process recognizes that time u has elapsed by counting the number of times that a certain message is being passed between two processes, using the known minimum message delay. For example, when a process p_i broadcasts a message at time t, the message is received by p_j no earlier than time $t+d_1$. So if the message is passed between them (or any process because of the minimum message delay) more than u/d_1 times, then we know at least u time has elapsed. The running time of MD is equal to that of CB1 with the $\frac{c_2}{c_1}$ factor replaced by $\frac{d_2}{d_1}$.

The detailed proof of the following theorem can be found in Appendix A.

THEOREM 4.4. *MD solves the* (s,n)*-session problem within time* $(s-2)\cdot(\frac{d_2}{d_1}u+u+2c_2)+d_2+3c_2$ *if* d_1 *and* d_2 *are known.*

4.5. Combination 2 (CB2). The CB2 method (see Figure 4.5) can be used if the maximum step time c_2 and the minimum message delay d_1 are known. The known minimum message delay (d_1) can be used to measure the elapsed time between the send time of a message and the receive time of the same message. We know at

$B := \frac{u}{d_1}$;
$count := session := 0$;
$msgs := \emptyset$;
while($session < s - 1$)
  $msgs := msgs \cup buf_i$;
  if $(session = 0)$ or $(count \geq B)$
  then
    if for all $j \in [n]$, $m(j, *, *)$ is in $msgs$
    then /* condition 1 */
      $count := 0$;
      $session := session + 1$;
      $msgs := \emptyset$;
    end if;
  end if;
  if there is any $m(*, session, *)$ in $msgs$
  then $count := \max\{count, k : m(*, session, k) \in msgs\ \}$;
  broadcast $m(i, session, count + 1)$;
end while;
Enter an idle state.

FIG. 4.4. *Technique MD for process i.*

$count := 0$;
$msgs := \emptyset$;
while($count < s - 1$)
  $msgs := msgs \cup buf_i$;
  $count := \max\{k, count : m(*, *, k) \in msgs\ \}$;
  broadcast $m(i, *, count + \frac{c_2}{d_1})$;
end while;
Enter an idle state.

FIG. 4.5. *Technique CB2 for process i.*

least d_1 time has passed between the send and receive. In addition, because of the known maximum step time, it is possible to estimate how many steps a process takes within time d_1 (at least $\frac{d_1}{c_2}$ steps). Therefore, a process can deduce that if it receives a message sent after the last session, there have been at least $\frac{d_1}{c_2}$ sessions after that last session.

We can inductively apply the above argument starting from session 0. Initially, a process starts by sending a message to all, and as soon as it receives a message from all other processes, it knows that there are at least $\frac{d_1}{c_2}$ sessions in the computation. It increments its counter by $\frac{d_1}{c_2}$ and sends another message piggybacking the value of that counter. If it receives a message with a counter x, it knows that there are at least $x + \frac{d_1}{c_2}$ sessions. Then it updates its counter to $x + \frac{d_1}{c_2}$ and sends another message with the value of that counter. It continues the above until its counter is larger than $s - 1$. Then it takes one more step and enters an idle state.

The detailed proof of the following theorem can be found in Appendix A.

THEOREM 4.5. *Technique CB2 solves the* (s, n)*-session problem in time* $(s-1) \cdot \frac{d_2+c_2}{d_1} c_2 + c_2$ *if* c_2 *and* d_1 *are known.*

5. Shared memory results. In this section, we show that the upper bounds we presented in section 4 for the SM models are asymptotically tight by obtaining the matching lower bounds. We use Theorem 3.1 to obtain the lower bounds. To prove a given lower bound for an SM model, we simply check whether there exist c, c'_1, and c'_2 that satisfy SC1, SC2, and SC3.

5.1. Counting with EC. Suppose that only EC is used. The resulting upper bound is $(s-1) \cdot c_2 \cdot \Theta(\log n)$.

We now show that this bound is asymptotically tight. In particular, we show that if either c_1 or c_2 (or both) is unknown, then the lower bound is $(s-1) \cdot c_2 \cdot \log_a n$.

COROLLARY 5.1. *Let $c_2 \in \mathcal{R}^+$. For $\mathcal{M}[?, c_2]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1) \cdot c_2 \cdot \log_a n$.*

Proof. Let $c = c_2 / \log_a n$. Let c'_1 be some constant less than or equal to c_2. Let $c'_2 = c_2$. Let $f(x,y) = y \cdot \log_a n$.

As $c'_1 \leq c_2$ and $B = f(c'_1, c'_2) = c'_2 \cdot \log_a n$, SC1 is satisfied. As $B \frac{c}{c'_2} = c'_2$, SC3 is satisfied. As c_1 is unknown, we do not consider SC2. □

COROLLARY 5.2. *Let $c_1 \in \mathcal{R}^+$. For $\mathcal{M}[c_1, ?]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1) \cdot c_2 \cdot \log_a n$.*

Proof. Let $c = 2 \cdot c_1$. Let $c'_1 = c_1$. Let c'_2 be some constant greater than or equal to c_1. Let $f(x,y) = y \cdot \log_a n$.

As $B = f(c'_1, c'_2) = c'_2 \cdot \log_a n$, SC1 is satisfied. As $\frac{1}{2}c = c_1$ and $c'_1 = c_1$, SC2 is satisfied. As c_2 is unknown, we do not consider SC3. □

Each of Corollaries 5.1 and 5.2 separately implies that a lower bound for $\mathcal{M}[?, ?]$ is $(s-1) \cdot c_2 \cdot \log_a n$.

5.2. Counting with EC and ST bounds. If processes know c_1 and c_2, then they can use both methods ST and EC in order to count. This results in an algorithm with running time $(s-1) \cdot c_2 \cdot \min\{\frac{c_2}{2c_1}, \Theta(\log n)\} + c_2$.

We now show that this bound is asymptotically tight.

COROLLARY 5.3. *Let $c_1, c_2 \in \mathcal{R}^+$. For $\mathcal{M}[c_1, c_2]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1) \cdot c_2 \cdot \min\{\frac{c_2}{2c_1}, \log_a n\}$.*

Proof. Let $c = 2c_1$. Let $c'_1 = c_1$. Let $c'_2 = c_2$. Let $f(x,y) = y \cdot \min\{\frac{y}{x}, \log_a n\}$.

SC1 holds because $B = f(c'_1, c'_2) = c'_2 \cdot \min\{\frac{c'_2}{2c'_1}, \log_a n\} \leq c'_2 \cdot \log_a n$. SC2 holds because $c'_1 = c_1 \leq \frac{c}{2}$. SC3 holds because $B \frac{c}{c'_2} = f(c'_1, c'_2) \cdot \frac{c}{c'_2} = c'_2 \cdot \min\{\frac{c'_2}{2c'_1}, \log_a n\} \frac{2c_1}{c'_2} \leq c'_2$. □

6. Message passing results. In this section, we show that the upper bounds we presented in section 4 for the MP models are asymptotically tight by obtaining the matching lower bounds. We use Theorem 3.1 to obtain the lower bounds. To prove a given lower bound for an MP model, we simply check whether there exist c, c'_1, c'_2, d'_1, and d'_2 that satisfy MC1 through MC5.

6.1. Counting with EC. The use of EC alone in an MP model gives an upper bound of $(s-1) \cdot d_2 + c_2$.

We show that if no other method can be used, then this bound is asymptotically tight. The models that allow the use of EC only are models 0, 1, 2, 4, 5, 8, 9, and 10. Using corollaries to Theorem 3.1, we show that the lower bounds for models 5, 9, and 10 are $(s-1) \cdot d_2$. The result for model 5 implies the same lower bound for models 1 and 4 (since 1 and 4 have less timing information than model 5). The result for model 10 implies the same lower bound for models 2 and 8. The result for model 1 implies the same lower bound for model 0.

First, we give the corollary for model 5.

COROLLARY 6.1. *Let c_2 and d_2 be positive reals. For $\mathcal{M}[?, c_2, ?, d_2]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1)\cdot d_2$.*

Proof. Let $c = \min\{\frac{c_2^2}{d_2}, \frac{c_2}{2}\}$. Let c_1' be some constant less than or equal to c_2. Let $c_2' = c_2$. Let d_1' be some constant less than or equal to d_2. Let $d_2' = d_2$. Let $f(w,x,y,z) = z$.

MC1 is satisfied by the choice of c_1', c_2', d_1', and d_2' and because $B = f(c_1', c_2', d_1', d_2') = d_2' = d_2$.

MC3 is satisfied because $B \cdot \frac{c}{c_2'} \le d_2 \cdot \frac{c_2^2/d_2}{c_2'} \le c_2$.

MC5 is satisfied because $(d_2' + B)\frac{c}{c_2'} - c \le 2d_2 \cdot \frac{c_2/2}{c_2} - c < d_2$.

MC2 and MC4 are not considered because c_1 and d_1 are unknown. □

Next we give the corollary for model 9.

COROLLARY 6.2. *Let c_1 and d_2 be positive reals. For $\mathcal{M}[c_1, ?, ?, d_2]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1)d_2$.*

Proof. Let $c = 2c_1$. Let $c_1' = c_1$. Let $c_2' = 4c_1$. Let d_1' be some constant less than or equal to d_2. Let $d_2' = d_2$. Let $f(w,x,y,z) = z$.

MC1 is satisfied because $B = f(c_1', c_2', d_1', d_2') = d_2' = d_2$.

MC2 is satisfied because $\frac{c}{2} = c_1$.

MC5 is satisfied because $(d_2' + B)\frac{c}{c_2'} - c \le 2d_2\frac{2c_1}{4c_1} = d_2$.

MC3 and MC4 are not considered because c_2 and d_1 are unknown. □

Finally, we give the corollary for model 10.

COROLLARY 6.3. *Let c_1 and d_1 be positive reals. For $\mathcal{M}[c_1, ?, d_1, ?]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1)\cdot d_2$.*

Proof. Let $c = \max\{2c_1, d_1\}$. Let $c_1' = c_1$. Let c_2' be some constant bigger than or equal to c_1. Let $d_1' = d_1$. Let d_2' be some constant bigger than or equal to d_1. Let $f(w,x,y,z) = z$.

MC1 is satisfied because $B = f(c_1', c_2', d_1', d_2') = d_2'$.

MC2 is satisfied because $\frac{c}{2} \ge \frac{2c_1}{2} = c_1$.

MC4 is satisfied because $(d_2' - B)\frac{c}{c_2'} + c = c \ge d_1 = d_1'$.

MC3 and MC5 are not considered because c_2 and d_2 are unknown. □

6.2. Counting with EC and ST bounds. If both methods EC and ST can be used, the resulting algorithm gives an upper bound of $(s-1)\cdot\min\{d_2, \frac{c_2}{c_1}\cdot c_2\} + c_2$.

We show that this bound is asymptotically tight if no other methods can be used and the following is true:

- $c_2 \le d_2$.

The models that allow the use of EC and ST alone are models 12 and 13. We prove a corollary to Theorem 3.1 for model 13, which implies the same lower bound for model 12.

COROLLARY 6.4. *Let c_1, c_2, and d_2 be positive reals such that $c_2 \le d_2$. For $\mathcal{M}[c_1, c_2, ?, d_2]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1)\cdot\min\{\frac{c_2}{2c_1}c_2, d_2\}$.*

Proof. Let $c = 2c_1$. Let $c_1' = c_1$. Let $c_2' = c_2$. Let d_1' be some constant less than or equal to d_2. Let $d_2' = d_2$. Let $f(w,x,y,z) = \min\{\frac{x}{2w}x, z\}$.

MC1 is satisfied because $B = f(c_1', c_2', d_1', d_2') = \min\{\frac{c_2^2}{2c_1}, d_2\} \le d_2$.

MC2 is satisfied because $\frac{c}{2} = c_1 = c_1'$.

MC3 is satisfied because $B \cdot \frac{c}{c_2'} = \min\{\frac{c_2^2}{2c_1}, d_2\} \cdot \frac{2c_1}{c_2} \le c_2$.

For MC5, we need to show that $(d_2' + B)\frac{c}{c_2'} - c \leq d_2$. Then it suffices to prove that $d_2 - ((d_2' + B)\frac{c}{c_2'} - c) \geq 0$.

$d_2 - ((d_2' + B)\frac{c}{c_2'} - c) \geq d_2 - ((d_2 + \frac{c_2^2}{2c_1})\frac{2c_1}{c_2} - 2c_1) = d_2(1 - \frac{2c_1}{c_2}) - (c_2 - 2c_1) \geq 0$ since $c_2 \leq d_2$.

MC4 is not considered because d_1 is unknown. □

6.3. Counting with EC and MD. Suppose methods EC and MD are used. The only model that can use these two methods alone is model 3 ($\mathcal{M}[?, ?, d_1, d_2]$). The resulting asymptotic upper bound on the per-session cost is $\min\{d_2, \frac{d_2}{d_1}u + 2c_2\}$, where $u = d_2 - d_1$.

We now argue that this bound is asymptotically tight if no other method can be used. First note that if the $2c_2$ term in the MD cost dominates the $\frac{d_2}{d_1}u$ term, then the upper bound is $\Theta(c_2)$ per session, which is obviously tight. Thus we ignore the $2c_2$ term.

Corollary 6.8 in section 6.7 below shows that the lower bound for model 11 ($\mathcal{M}[c_1, ?, d_1, d_2]$) is $(s-1) \cdot \frac{d_2}{d_2+d_1}u$. Since model 3 is weaker than model 11, the same lower bound holds for model 3.

(Case 1) Suppose $d_2 \leq \frac{d_2}{d_1}u$. Then $\frac{d_2}{d_2+d_1}u \geq \frac{d_2}{3}$. Thus the asymptotic per-session upper bound for model 3 is d_2 and the lower bound is $\frac{d_2}{3}$.

(Case 2) Suppose $\frac{d_2}{d_1}u < d_2$. Then $\frac{d_2}{d_2+d_1}u \geq \frac{d_2}{3d_1}u$. Thus the asymptotic per-session upper bound for model 3 is $\frac{d_2}{d_1}u$ and the lower bound is $\frac{d_2}{3d_1}u$.

6.4. Counting with EC and CB2. If methods EC and CB2 are used, the resulting asymptotic upper bound on the per-session cost is $\min\{d_2, \frac{d_2+c_2}{d_1} \cdot c_2\}$. The only model that can use these two methods alone is model 6 ($\mathcal{M}[?, c_2, d_1, ?]$).

We now show this bound is asymptotically tight if

- $2c_2 \leq 3d_1$.

Under this assumption, the CB2 term, $\frac{d_2+c_2}{d_1} \cdot c_2$, is at most $\frac{5d_2}{2d_1} \cdot c_2$, which is at most $\frac{15}{4}d_2$.

COROLLARY 6.5. *Let c_2 and d_1 be positive reals such that $c_2 \leq \frac{3}{2}d_1$. For $\mathcal{M}[?, c_2, d_1, ?]$, there exists no algorithm that solves the (s, n)-session problem within time less than $(s-1) \cdot \frac{2d_2}{3d_1} \cdot c_2$.*

Proof. Let c_1' be some constant less than or equal to c_2. Let c_2' equal c_2. Let d_1' equal d_1. Let d_2' be some constant bigger than d_1. Let $c = \frac{3d_1}{2d_2'} \cdot c_2$. Let $f(w, x, y, z) = \frac{2z}{3y} \cdot x$.

MC1 holds because $B = f(c_1', c_2', d_1', d_2') = \frac{2d_2'}{3d_1'} \cdot c_2'$. By the assumption that $c_2 \leq \frac{3}{2}d_1$, B is less than or equal to d_2'.

MC3 holds because $B \cdot \frac{c}{c_2'} = c_2'$.

MC4 holds because $c_2 \leq \frac{3}{2}d_1$, and $(d_2' - B) \cdot \frac{c}{c_2'} + c = 3d_1 - c_2 + c \geq 3d_1 - 3/2d_1 + c > d_1 = d_1'$.

MC2 and MC5 are not considered because c_1 and d_2 are unknown. □

6.5. Counting with EC, ST, and CB2. If methods EC, ST, and CB2 are used, the resulting asymptotic upper bound on the per-session cost is $\min\{d_2, \frac{c_2}{c_1} \cdot c_2, \frac{d_2+c_2}{d_1} \cdot c_2\}$. The only model in which exactly these methods can be used is model 14 ($\mathcal{M}[c_1, c_2, d_1, ?]$).

We now argue that this bound is asymptotically tight if no other method can be used, assuming

- $2c_2 \leq d_1$.

Corollary 6.6 shows that the lower bound for model 14 is $(s-1)\cdot\min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2\}$, assuming $2c_2 \le d_1$. We show that this bound is asymptotically tight.

Because $2c_2 \le d_1$, $\frac{2d_2}{3d_1}c_2 \le d_2$, and $\frac{d_2+c_2}{d_1} \le \frac{3d_2}{2d_1}$. Thus the per-session lower bound is $\min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2\}$, and the per-session upper bound is $\min\{d_2, \frac{c_2}{c_1}c_2, \frac{3d_2}{2d_1}c_2\} = \min\{\frac{c_2}{c_1}c_2, \frac{3d_2}{2d_1}c_2\}$.

COROLLARY 6.6. *Let c_2 and d_1 be positive reals such that $2c_2 \le d_1$. For $\mathcal{M}[c_1, c_2, d_1, ?]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1)\cdot\min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2\}$.*

Proof. By the hypothesis of the corollary,

$$d_1 \ge 2c_2. \tag{6.1}$$

Let $c_1' = c_1$. Let $c_2' = c_2$. Let $d_1' = d_1$. Let d_2' be some real number bigger than $\frac{c_2}{2c_1}c_2$. Let $c = \max\{2c_1, \frac{3d_1}{2d_2'}c_2\}$.

Let $f(w,x,y,z) = \min\{\frac{x}{2w}x, \frac{2z}{3y}x\}$.

We show that they satisfy the hypothesis of Theorem 3.1. MC5 is not considered since d_2 is unknown.

Note that $B = f(c_1', c_2', d_1', d_2') = \min\{\frac{c_2}{2c_1}c_2, \frac{2d_2'}{3d_1}c_2\}$.

Case 1. Suppose $\frac{c_2}{2c_1}c_2 < \frac{2d_2}{3d_1}c_2$. Then

$$\frac{2c_1}{c_2} > \frac{3d_1}{2d_2'}, \tag{6.2}$$

and thus $c = 2c_1$. For MC1, clearly $B = \frac{c_2}{2c_1}c_2 < d_2'$ by the definition of d_2'.

For MC2, $\frac{c}{2} = c_1$.

For MC3, $B\frac{c}{c_2'} = c_2$.

For MC4,

$$\begin{aligned}(d_2' - B)\tfrac{c}{c_2'} + c &= d_2'\tfrac{2c_1}{c_2} - c_2 + 2c_1 \\ &\ge d_2'\tfrac{3d_1}{2d_2'} - c_2 && \text{because of (6.2)} \\ &\ge \tfrac{3d_1}{2} - \tfrac{d_1}{2} && \text{because of (6.1)} \\ &= d_1.\end{aligned}$$

Case 2. Suppose $\frac{c_2}{2c_1}c_2 \ge \frac{2d_2'}{3d_1}c_2$. Then

$$\frac{2c_1}{c_2} \le \frac{3d_1}{2d_2'}, \tag{6.3}$$

and thus $c = \frac{3d_1}{2d_2'}\cdot c_2$. For MC1, $B = \frac{2d_2'}{3d_1}\frac{d_1}{2} < d_2'$ because of (6.1).

For MC2, $\frac{c}{2} = \frac{1}{2}\frac{3d_1}{2d_2'}c_2 \ge c_1$ because of (6.3).

For MC3,

$$B\frac{c}{c_2'} \le \frac{2d_2'}{3d_1}c_2\frac{\frac{3d_1}{2d_2'}c_2}{c_2} = c_2.$$

For MC4,

$$\begin{aligned}(d_2' - B)\tfrac{c}{c_2'} + c &= (d_2' - \tfrac{2d_2'}{3d_1}c_2)\tfrac{c}{c_2'} + c \\ &= \tfrac{3d_1}{2} - c_2 + c \\ &> \tfrac{3d_1}{2} - c_2 \\ &\ge \tfrac{3d_1}{2} - \tfrac{d_1}{2} && \text{because of (6.1)} \\ &= d_1. \qquad \square\end{aligned}$$

6.6. Counting with EC, MD, and CB2. If methods EC, MD, and CB2 are used, the resulting asymptotic upper bound on the per-session cost is $\min\{d_2, \frac{d_2}{d_1} \cdot u + 2c_2, \frac{d_2+c_2}{d_1} \cdot c_2\}$. The only model in which exactly these methods can be used is model 7 ($\mathcal{M}[?, c_2, d_1, d_2]$).

We now show this upper bound is asymptotically tight if

- $2c_2 \leq d_1$, and
- $d_2 \leq \frac{3}{2}d_1$ or $\frac{3}{2}d_1 + c_2 \leq d_2$.

As in section 6.3, we ignore the $2c_2$ term in the MD expression.

Corollary 6.7 proves that the per-session lower bound is $(s-1)\min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$. We show that this bound is asymptotically tight.

(Case 1) If $\frac{d_2}{d_1}u \leq \min\{d_2, \frac{d_2+c_2}{d_1}c_2\}$, then the upper bound is $\Theta(\frac{d_2}{d_1}u)$. The lower bound is $\frac{d_1}{3d_2}u$ because $\frac{d_2}{d_2+d_1}u \geq \max\{\frac{d_2}{3}, \frac{d_1}{3d_2}u\}$ (cf. section 6.3); and since $c_2 \leq \frac{1}{2}d_1$, $\frac{d_2}{d_1}u \leq \frac{d_2+c_2}{d_1}c_2 \leq \frac{3d_2}{2d_1}c_2$, and thus $\frac{d_2}{3d_1}u < \frac{2d_2}{3d_1}c_2$.

(Case 2) If $\frac{d_2+c_2}{d_1}c_2 \leq \min\{d_2, \frac{d_2}{d_1}u\}$, then $\frac{d_2+c_2}{d_1}c_2 \leq \frac{3d_2}{2d_1}c_2$ because $c_2 \leq \frac{1}{2}d_1$. Thus the per-session upper bound is $\Theta(\frac{d_2}{d_1}c_2)$. The lower bound is $\frac{d_1}{3d_2}c_2$ because $\frac{d_2}{d_2+d_1}u \geq \max\{\frac{d_2}{3}, \frac{d_1}{3d_2}u\}$, and because $\frac{d_2}{d_1}u \geq \frac{d_2+c_2}{d_1}c_2 > \frac{d_2}{d_1}c_2$, $\frac{d_2}{3d_1}u > \frac{d_2}{3d_1}c_2$.

(Case 3) If $d_2 \leq \min\{\frac{d_2}{d_1}u, \frac{d_2+c_2}{d_1}c_2\}$, then the upper bound is $\Theta(d_2)$. The lower bound is $\frac{1}{3}d_2$ because $\frac{d_2}{d_2+d_1}u \geq \max\{\frac{d_2}{3}, \frac{d_1}{3d_2}u\}$, and since $c_2 \leq \frac{1}{2}d_1$, $d_2 \leq \frac{d_2+c_2}{d_1}c_2 \leq \frac{3d_2}{2d_1}c_2$, and thus $\frac{1}{3}d_2 < \frac{2d_2}{3d_1}c_2$.

COROLLARY 6.7. *Let c_2, d_1, and d_2 be positive reals such that $2c_2 \leq d_1$ and either $d_2 \leq \frac{3}{2}d_1$ or $\frac{3}{2}d_1 + c_2 \leq d_2$. For $\mathcal{M}[?, c_2, d_1, d_2]$, there exists no algorithm that solves the (s, n)-session problem within time less than $(s-1)\min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$,*

Proof.

Case 1. $d_2 \leq \frac{3}{2}d_1$.

Then $\min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\} \leq \frac{2d_2}{3d_1}c_2 = c_2$. The lower bound holds because a process has to take at least s steps to solve the (s, n)-session problem.

Case 2. $d_2 \geq \frac{3}{2} \cdot d_1 + c_2$ and $c_2 \leq \frac{3}{2}d_1$.

Let $c = \frac{3d_1}{2d_2}c_2$. Let c_1' be some constant less than or equal to c_2. Let c_2' equal c_2. Let d_1' equal d_1. Let d_2' equal d_2. Let $f(w, x, y, z) = \min\{\frac{2z}{3y}x, \frac{z}{z+y}(z-y)\}$.

Note that $B = f(c_1', c_2', d_1', d_2') = \min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$.

MC1 holds because $B \leq \frac{2d_2}{3d_1}c_2 < d_2$, since $2c_2 \leq d_1$.

MC3 holds because $B \cdot \frac{c}{c_2} \leq \frac{2d_2}{3d_1} \cdot c_2 \cdot \frac{c}{c_2} \leq c_2$.

MC4 holds because $(d_2' - B)\frac{c}{c_2} + c > (d_2' - \frac{2d_2}{3d_1}c_2)\frac{3d_1}{2d_2}\frac{c_2}{c_2} = \frac{3}{2}d_1 - c_2$. This quantity is greater than or equal to $\frac{3}{2}d_1 - \frac{1}{2}d_1$ since $d_1 \geq 2c_2$. Thus the expression is greater than or equal to d_1. MC5 holds because $(d_2' + B)\frac{c}{c_2} - c < (d_2 + \frac{2d_2}{3d_1}c_2)\frac{3d_1}{2d_2}\frac{c_2}{c_2} = \frac{3}{2}d_1 + c_2 \leq d_2$ since $\frac{3}{2}d_1 + c_2 \leq d_2$.

MC2 is not considered because c_1 is unknown. ∎

6.7. Counting with EC, MD, and CB1. Suppose methods EC, MD, and CB1 are used. The resulting asymptotic upper bound on the per-session cost is $\min\{d_2, \frac{d_2}{d_1} \cdot u + 2c_2, \frac{c_2}{c_1} \cdot u + 2c_2\}$. The only model in which exactly these methods can be used is model 11 ($\mathcal{M}[c_1, ?, d_1, d_2]$).

Corollary 6.8 below proves that the lower bound for model 11 is $(s-1) \cdot \frac{d_2}{d_2+d_1}u$. We now show this bound is asymptotically tight. As in section 6.3, we ignore the $2c_2$ term in the MD and CB1 expressions.

(Case 1) If $\frac{c_2}{c_1}u \le \frac{d_2}{d_1}u \le d_2$, the upper bound is $\Theta(\frac{c_2}{c_1}u)$. Because $\frac{d_2}{d_1}u \le d_2$, then $d_2 \le 2d_1$. Also $\frac{d_2}{d_1+d_2}u \ge \frac{d_2}{3d_1}u \ge \frac{c_2}{3c_1}u$. Thus, the lower bound is $\frac{c_2}{3c_1}u$.

(Case 2) If $\frac{c_2}{c_1}u \le d_2 < \frac{d_2}{d_1}u$, the upper bound is $\Theta(\frac{c_2}{c_1}u)$. Because $\frac{d_2}{d_1}u > d_2$, then $d_2 > 2d_1$. Also $\frac{d_2}{d_1+d_2}u \ge \frac{c_2}{c_1}u \cdot \frac{d_2-d_1}{d_2+d_1}$, which is greater than and equal to $\frac{d_2}{3c_1}u$ because $\frac{d_2-d_1}{d_2+d_1} \ge \frac{1}{3}$. Thus, the lower bound is $\frac{c_2}{3c_1}u$.

(Case 3) If $\frac{d_2}{d_1}u \le \min\{d_2, \frac{c_2}{c_1}u\}$, then the upper bound is $\Theta(\frac{d_2}{d_1}u)$. The lower bound is $\frac{d_2}{3d_1}u$ because $\frac{d_2}{d_2+d_1}u \ge \max\{\frac{d_2}{3}, \frac{d_1}{3d_2}u\}$.

(Case 4) If $d_2 < \min\{\frac{d_2}{d_1}u, \frac{c_2}{c_1}u\}$, the upper bound is $\Theta(d_2)$. The lower bound is $\frac{d_2}{3}$ because $\frac{d_2}{d_2+d_1}u \ge \max\{\frac{d_2}{3}, \frac{d_1}{3d_2}u\}$, and $\frac{d_2}{3} \le \frac{2d_2}{3d_1}c_2$.

COROLLARY 6.8. *Let c_1, d_1, and d_2 be positive reals. For $\mathcal{M}[c_1, ?, d_1, d_2]$, there exists no algorithm that solves the (s,n)-session problem within time less than $(s-1)\cdot\frac{d_2}{d_2+d_1}u$.*

Proof. Let $c = 2c_1$. Let $c_1' = c_1$. Let $c_2' = \frac{4d_2c_1}{d_2+d_1}$. Let $d_1' = d_1$. Let $d_2' = d_2$. Let $f(w,x,y,z) = \frac{z}{z+y}\cdot(z-y)$.

MC1 is satisfied because $B = f(c_1', c_2', d_1', d_2') = \frac{d_2'}{d_2'+d_1'}\cdot(d_2'-d_1') = \frac{d_2}{d_2+d_1}\cdot(d_2-d_1) < d_2$.

MC2 is satisfied because $\frac{c}{2} = c_1$.

MC4 is satisfied because $(d_2'-B)\frac{c}{c_2'} + c = (d_2 - \frac{d_2u}{d_2+d_1})\frac{2c_1}{\frac{4d_2c_1}{d_2+d_1}} + c = d_1 + c > d_1$.

MC5 is satisfied because $(d_2'+B)\frac{c}{c_2'} - c = (d_2 + \frac{d_2u}{d_2+d_1})\frac{2c_1}{\frac{4d_2c_1}{d_2+d_1}} - c = d_2 - c < d_2$.

MC3 is not considered because c_2 is not known. □

6.8. Counting with all methods. Suppose all five methods (EC, ST, MD, CB1, and CB2) are used. The resulting asymptotic upper bound on the per-session cost is $\min\{d_2, \frac{c_2}{c_1}\cdot c_2, \frac{d_2}{d_1}\cdot u + 2c_2, \frac{d_2+c_2}{d_1}\cdot c_2, \frac{c_2}{c_1}\cdot u + 2c_2\}$. The only model in which all these methods can be used is model 15 ($\mathcal{M}[c_1, c_2, d_1, d_2]$).

We now show this upper bound is asymptotically tight if

- $2c_2 \le d_1$, and
- $d_2 \le \frac{3}{2}d_1$ or $\frac{3}{2}d_1 + c_2 \le d_2$.

Corollary 6.9 shows that the per-session lower bound for model 15 is $\min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$. As in section 6.3, we ignore the $2c_2$ term in the MD and CB1 expressions.

(Case 1) If $\frac{c_2}{c_1}c_2 \le \min\{d_2, \frac{d_2}{d_1}u, \frac{d_2+c_2}{d_1}c_2, \frac{c_2}{c_1}\cdot u\}$, then the upper bound is $\Theta(\frac{c_2}{c_1}c_2)$. The lower bound is $\frac{c_2}{3c_1}c_2$ because (1) $\frac{c_2}{2c_1}c_2 \ge \frac{c_2}{3c_1}c_2$; (2) $\frac{3d_2}{2d_1}c_2 \ge \frac{d_2+c_2}{d_1}c_2 \ge \frac{c_2}{c_1}c_2$, and thus $\frac{2d_2}{3d_1}c_2 > \frac{c_2}{3c_1}c_2$; and (3) $\frac{d_2}{d_2+d_1}u \ge \max\{\frac{d_2}{3}, \frac{d_2}{3d_1}u\}$, and $\frac{d_2}{3d_1}u \ge \frac{c_2}{3c_1}c_2$.

(Case 2) If $\frac{d_2}{d_1}u \le \min\{d_2, \frac{c_2}{c_1}c_2, \frac{d_2+c_2}{d_1}c_2, \frac{c_2}{c_1}u\}$, then the upper bound is $\Theta(\frac{d_2}{d_1}u)$. The lower bound is $\frac{d_2}{3d_1}u$ because (1) $\frac{c_2}{c_1}c_2 \ge \frac{d_2}{d_1}u$, and thus $\frac{c_2}{2c_1}c_2 \ge \frac{d_2}{3d_1}u$; (2) $\frac{3d_2}{2d_1}c_2 \ge \frac{d_2+c_2}{d_1}c_2 \ge \frac{d_2}{d_1}u$, and thus $\frac{2d_2}{3d_1}c_2 > \frac{d_2}{3d_1}u$; and (3) $\frac{d_2}{d_2+d_1}u \ge \max\{\frac{d_2}{3}, \frac{d_2}{3d_1}u\}$ and $\frac{d_2}{3d_1}u$.

(Case 3) If $\frac{c_2}{c_1}u \le \min\{d_2, \frac{c_2}{c_1}c_2, \frac{d_2+c_2}{d_1}c_2, \frac{d_2}{d_1}u\}$, then the upper bound is $\Theta(\frac{c_2}{c_1}u)$. The lower bound is $\frac{4c_2}{15c_1}u$ because (1) $\frac{c_2}{2c_1}c_2 \ge \frac{c_2}{2c_1}u \ge \frac{c_2}{3c_1}u$; (2) $\frac{3d_2}{2d_1}c_2 \ge \frac{d_2+c_2}{d_1}c_2 \ge \frac{c_2}{c_1}u$, and thus $\frac{2d_2}{3d_1}c_2 > \frac{c_2}{3c_1}u$; and (3) $\frac{d_2}{d_2+d_1}u \ge \max\{\frac{d_2}{3}, \frac{d_2}{3d_1}u\}$, and $\frac{d_2}{3d_1}u \ge \frac{c_2}{3c_1}u$.

(Case 4) If $\frac{d_2+c_2}{d_1}c_2 \le \min\{d_2, \frac{c_2}{c_1}c_2, \frac{c_2}{c_1}u, \frac{d_2}{d_1}u\}$, then $\frac{d_2+c_2}{d_1}c_2 \ge \frac{d_2}{d_1}c_2$, and the upper bound is $\Theta(\frac{d_2}{d_1}c_2)$. The lower bound is $\frac{d_2}{3d_1}c_2$ because (1) $\frac{c_2}{2c_1}c_2 \ge \frac{d_2}{2d_1}c_2 \ge \frac{d_2}{3d_1}c_2$; and (2) $\frac{d_2}{d_2+d_1}u \ge \max\{\frac{d_2}{3}, \frac{d_2}{3d_1}u\}$, and $\frac{d_2}{3d_1}u \ge \frac{d_2+c_2}{3d_1}c_2 > \frac{d_2}{3d_1}c_2$; and (3) $\frac{d_2+c_2}{d_1}c_2 \ge \frac{d_2}{d_1}c_2 \ge \frac{d_2}{3d_1}c_2$.

(Case 5) If $d_2 \geq \min\{\frac{c_2}{c_1}c_2, \frac{c_2}{c_1}u, \frac{d_2+c_2}{d_1}c_2, \frac{d_2}{d_1}u\}$, then the upper bound is $\Theta(d_2)$. The lower bound is $\frac{d_2}{3}$ because (1) $\frac{c_2}{2c_1}c_2 \geq \frac{d_2}{3}$; (2) $\frac{d_2}{d_2+d_1}u \geq \max\{\frac{d_2}{3}, \frac{d_2}{3d_1}u\}$; and (3) $\frac{3d_2}{2d_1}c_2 \geq \frac{d_2+c_2}{d_1}c_2 \geq d_2$, and $\frac{3d_2}{3d_1}c_2 > \frac{d_2}{3}$.

COROLLARY 6.9. *Let c_1, c_2, d_1, and d_2 be positive reals such that $2c_2 \leq d_1$ and either $d_2 \leq \frac{3}{2}d_1$ or $\frac{3}{2}d_1 + c_2 \leq d_2$. For $\mathcal{M}[c_1, c_2, d_1, d_2]$, there exists no algorithm that solves the (s, n)-session problem within time less than* $\min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}(s-1)$.

Proof.

Case 1. $c_2 \geq \min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$.

The lower bound clearly holds because all processes have to take at least s steps to solve the (s, n)-session problem and c_2 is the upper bound on step time.

Case 2. $c_2 < \min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$.

Note that in this case, by the hypothesis of the corollary, the following are true:

$$d_1 \geq 2c_2, \tag{6.4}$$

$$d_2 \geq \frac{3d_1}{2} + c_2. \tag{6.5}$$

Let $c = \max\{2c_1, \frac{3d_1}{2d_2}c_2\}$. Let $c_1' = c_1$. Let $c_2' = c_2$. Let $d_1' = d_1$. Let $d_2' = d_2$. Let $f(w, x, y, z) = \min\{\frac{x}{2w}x, \frac{2z}{3y}x, \frac{z}{z+y}(z-y)\}$.

We show that they satisfy the hypothesis of Theorem 3.1.

Note that $B = f(c_1', c_2', d_1', d_2') = \min\{\frac{c_2}{2c_1}c_2, \frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$.

Case 2.1. Suppose $\frac{c_2}{2c_1}c_2 < \min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$. Then $B = \frac{c_2}{2c_1}c_2$ and $c = 2c_1$. Furthermore,

$$\frac{c_2}{2c_1} \leq \frac{2d_2}{3d_1}. \tag{6.6}$$

For MC1, clearly $B = \frac{c_2}{2c_1}c_2 \leq \frac{d_2}{d_2+d_1}u < d_2$.

For MC2, $\frac{c}{2} = c_1$.

For MC3, $B\frac{c}{c_2'} = c_2$.

For MC4,

$$\begin{aligned}
(d_2' - B)\tfrac{c}{c_2'} + c &= d_2\tfrac{2c_1}{c_2} - c_2 + 2c_1 \\
&\geq d_2\tfrac{3d_1}{2d_2} - c_2 && \text{because of (6.6)} \\
&\geq \tfrac{3d_1}{2} - \tfrac{d_1}{2} && \text{because of (6.4)} \\
&= d_1.
\end{aligned}$$

For MC5, it suffices to prove that $d_2 - ((d_2' + B)\frac{c}{c_2'} - c) \geq 0$:

$$\begin{aligned}
d_2 - ((d_2' + B)\tfrac{c}{c_2'} - c) &\geq d_2 - ((d_2 + \tfrac{c_2^2}{2c_1})\tfrac{2c_1}{c_2} - 2c_1) \\
&= d_2(1 - \tfrac{2c_1}{c_2}) - (c_2 - 2c_1) \\
&\geq 0 && \text{because of (6.4).}
\end{aligned}$$

Case 2.2. Suppose $\frac{c_2}{2c_1}c_2 \geq \min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$. Then $B = \min\{\frac{2d_2}{3d_1}c_2, \frac{d_2}{d_2+d_1}u\}$ and $c = \frac{3d_1}{2d_2}c_2$. Furthermore,

$$\frac{c_2}{2c_1} > \frac{2d_2}{3d_1}. \tag{6.7}$$

For MC1, $B \leq \frac{d_2}{d_2+d_1}u < d_2$.
For MC2, $\frac{c}{2} = \frac{1}{2}\frac{3d_1}{2d_2}c_2 \geq c_1$ because of (6.7).
For MC3,

$$B\frac{c}{c_2'} \leq \frac{2d_2}{3d_1}c_2\frac{\frac{3d_1}{2d_2}c_2}{c_2} = c_2.$$

For MC4,

$$\begin{aligned}(d_2' - B)\tfrac{c}{c_2'} + c &\geq (d_2' - \tfrac{2d_2}{3d_1}c_2)\tfrac{c}{c_2'} + c \\ &= \tfrac{3d_1}{2} - c_2 + c \\ &> \tfrac{3d_1}{2} - c_2 \\ &\geq \tfrac{3d_1}{2} - \tfrac{d_1}{2} \qquad \text{because of (6.4)} \\ &= d_1.\end{aligned}$$

For MC5,

$$\begin{aligned}(d_2' + B)\tfrac{c}{c_2'} - c &\leq (d_2' + \tfrac{2d_2}{3d_1}c_2)\tfrac{c}{c_2'} - c \\ &= \tfrac{3d_1}{2} + c_2 - c \\ &< \tfrac{3d_1}{2} + c_2 \\ &\leq d_2 \qquad \text{because of (6.5).} \quad \square\end{aligned}$$

7. Conclusion and discussion. This paper concerns timing models in distributed systems that lie between the synchronous and asynchronous models. Four timing parameters are considered: the maximum and minimum process step times and message delays. Timing models are obtained by considering independently whether each parameter is known (i.e., is hard-wired into the processes' code) or unknown, giving rise to four SM models and 16 MP models.

The session problem is an abstraction of synchronization problems in distributed systems. It has been used as a test case to demonstrate the differences in the time needed to solve problems in various timing models, for both SM and MP systems. In this paper, we continue to use the session problem to compare quantitatively a family of models in which various parameters are either known or unknown.

For each unknown parameter model, we obtain an asymptotically tight time complexity bound on the session problem. Two of the algorithms were previously known, while the other three are new. We categorize the algorithms in terms of "ways to count." The intuition is that processes must have some way to count the passage of other processes' steps in order to "know" when a session has occurred. Our matching lower and upper bounds indicate that the algorithms are the optimal ways to count and allow us to construct a lattice of timing models in terms of the counting algorithms that are applicable to a model (cf. Figure 1.1). This hierarchy confirms the common belief that as a model has more timing knowledge, it behaves more like the synchronous model.

All but one of our lower bound results are new and all of them are obtained by one modular lower bound proof. The lower bound technique combines those of [3] for the asynchronous model in the SM system and [5] for the asynchronous and semisynchronous models in the MP systems. Our technique identifies one sufficient condition for a lower bound in a timing model to hold in solving the (s, n)-session problem and is applicable to every unknown parameter model as well as to those models previously studied for the session problem.

For several unknown parameter models, we were not able to show the lower bound without making some assumptions about the timing parameters. It will be interesting to develop a new lower bound technique that can show either the same or tighter lower bounds without such assumptions.

It will be also interesting to see whether our modular lower bound proof technique can be applied to show lower bounds for other distributed computing problems, such as the mutual exclusion problem and the dining philosophers problem, in many different timing models.

Appendix A. Communication in SM. Consider an $(a-1)$-ary tree with n leaves in which each level, except possibly the lowest, has the maximum number of nodes. The number of levels in the tree is $\lceil \log_{a-1} n \rceil + 1$. Associated with each node in the tree are a process and a shared variable. Each port process and its port variable are associated with a leaf node; the processes and variables associated with internal nodes are called *relay* processes and variables. The relay variable associated with a node is accessed by the process associated with the node and the processes associated with that node's children in the tree. Figure A.1 illustrates a tree with $a = 4$ and $n = 7$.

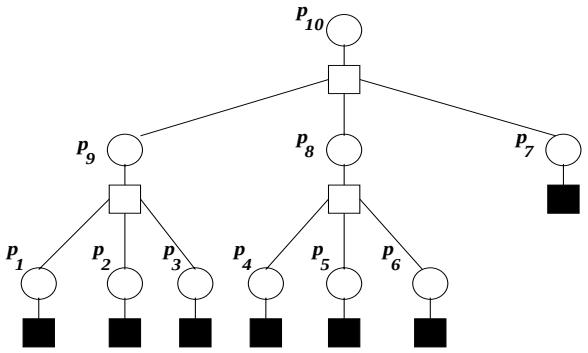

FIG. A.1. *A tree network with $a = 4$ and $n = 7$, where circles represent processes, empty squares relay variables, dark squares port variables, and solid lines memory access patterns of processes. Port processes are p_1 through p_7.*

Each relay variable has two fields, *up* and *down*. Each process has two local variables, *lup* and *ldown*; initially they are empty except that *lup* at a port process holds the information to be propagated.

Each relay process p other than the root repeats the following two steps. First, p accesses its own shared variable, saving the contents of the *up* field in *lup* and appending the contents of *ldown* to the *down* field. Second, p accesses its parent's variable, appending *lup* to the *up* field and saving the *down* field in *ldown*.

The root continuously accesses its own variable; at each access it copies the *up* field to the *down* field.

In the example of Figure A.1, a piece of information m is transferred from p_2 to p_6 as follows: p_2 appends m to $v_9.up$; p_9 obtains the contents of $v_9.up$ and appends them to $v_{10}.up$; p_{10} copies the contents of $v_{10}.up$ to $v_{10}.down$; p_8 obtains the contents of $v_{10}.down$ and appends them to $v_8.down$; p_6 obtains the contents of $v_8.down$ and gets m.

It takes at most $c_2 \cdot \lceil \log_{a-1} n \rceil$ time for a piece of information (or a "message") to be relayed up to the root for the following reason. In each time interval of length c_2,

every process takes at least one step, and thus every relay process other than the root passes the message up to its parent. Likewise, it takes additional $c_2 \cdot (\lceil \log_{a-1} n \rceil + 1)$ time for the message at the root to be relayed down to a leaf node in the tree (the one additional c_2 is for the root to move the message from its *up* to its *down*). Thus, the broadcast is accomplished in $c_2 \cdot \Theta(\log_{a-1} n)$ time. A similar tree network is mentioned in [3].

When we say *broadcast* in the SM model, it implies all of the interactions between processes in the tree network that are needed to accomplish the broadcasting. We only describe the role of port processes in an algorithm and assume that broadcast encapsulates the interactions among port processes and other processes which participate in the tree-network communication. In addition, we use the term "step" interchangeably with "port step"; when necessary, we make the proper distinction.

Appendix B. Correctness proofs of counting methods.

B.1. Correctness proof of CB1.

THEOREM B.1. *CB1 solves the (s, n)-session problem within time $(s-2) \cdot (\frac{c_2}{c_1} u + u + 2c_2) + d_2 + 3c_2$ if c_1, d_1, and d_2 are known.*

Proof. Consider an arbitrary admissible timed computation C of technique CB1.

For each k, $0 \le k \le s-1$, let p_{i_k} be the first process that sets its *session* variable to k in C. To increment *session*, a process must receive a set of messages that satisfy condition 1 in Figure 4.3. Let M_k be the set of messages received by p_{i_k} that cause p_{i_k} to set $session_{i_k}$ to k (M_0 is the empty set); let m_k be the message which is sent last among M_k (if there is a tie, choose an arbitrary message among them).

LEMMA B.2. *Let π be the step which sends m_k. There are at least k sessions by the time that π occurs in C.*

Proof. We proceed by induction on k. For the basis, when $k = 0$, it is always true that there are at least 0 sessions in C.

Inductively when $k > 0$, assuming the lemma is true for $k-1$, we show that when π occurs, there are at least k sessions.

Let τ be the step that sends m_{k-1} and let σ be the step in which $p_{i_{k-1}}$ sets $session_{i_{k-1}}$ to $k-1$. Such a step exists because $session_{i_{k-1}}$ is always incremented by 1. For $p_{i_{k-1}}$ to update $session_{i_{k-1}}$, condition 1 in Figure 4.3 must hold.

Let t be the time when τ occurs and t' be the time when σ occurs.

The message m_{k-1} must arrive at $buf_{i_{k-1}}$ at time between $[t+d_1, t+d_2]$ because of the bounds on message delays. Thus, $t' - t \ge d_1$ because σ occurs after $p_{i_{k-1}}$ receives m_{k-1}. Note that *count* in the algorithm is reset whenever *session* is updated. Let t'' be the time that p_{i_k} sets $session_{i_k}$ to k. From the code, because condition 1 should be true before *session* is updated, $count_{i_k}$ must equal to B at time t''. Thus, when $count_{i_k}$ is equal to B, at least $B \cdot c_1$ time has elapsed since time t' because t' is the time that *session* is updated to $k-1$ for the first time in computation C and $count_{i_k}$ must be reinitialized after time t. Thus, $t'' \ge t' + Bc_1 = t' + d_2 - d_1 \ge t + d_2$ because $t' - t \ge d_1$.

Therefore, the difference between times t and t'' is bigger than d_2. Thus, all messages received at time t'' or later must be sent after time t, at which time there were $k-1$ sessions by the inductive assumption. Since at least one message is sent by each process after time t, there must be at least one additional step by all processes between time t and the time π occurs. Therefore, there are at least k sessions by the time π occurs. □

From Lemma B.2, it follows that there are at least $s-1$ sessions at the time that m_{s-1} is sent. All processes will eventually set their *session*'s to $s-1$. Since

all processes take additional steps after there are at least $s-1$ sessions (to receive a message), there are at least s sessions in C. Thus the algorithm is correct.

We now calculate the running time of the algorithm. We define for each k, $2 \le k \le s-1$, $T_k = \max\{t : p_i \text{ sets } session_i \text{ to } k \text{ at time } t \text{ in } C \text{ for all } p_i \in R\}$. T_k is the latest time that a process sets *session* to k.

LEMMA B.3. *For each k, $2 \le k \le s-1$, $T_{k+1} \le T_k + \frac{c_2}{c_1}u + u + 2c_2$.*

Proof. After a process p_i sets $session_i$ to k, it takes at most $\frac{u}{c_1}c_2$ time for *count* to be bigger than B. Then it takes at most Δ time additionally for condition 1 to be true (i.e., for at least one message from every process to be received after *count* becomes bigger than B). We prove that $\Delta \le u + 2c_2$.

Let m_1 be the message that is received from process p_j by p_i just before condition 1 becomes true in p_i (i.e., p_i has waited $\frac{u}{c_1}c_2$ time). Message m_1 exists because condition 1 becomes true only if there are enough messages in *msgs*, which is emptied only after condition 1 becomes true. Let t be the time that m_1 is sent. p_j must broadcast another message m_2 within $t + c_2$ to process i because according to the code, all processes broadcast a message at every step. m_2 will be delivered to buf_i by time $t + c_2 + d_2$ (because it takes at most d_2 delay for a message to arrive at a buffer) and be received by time $t + 2c_2 + d_2$ (because it takes at most c_2 time for a process to take a step).

Process p_i will receive m_1 at time bigger than or equal to $t + d_1$ because it is sent at time t and it takes at least d_1 time delay for a message to arrive at a buffer. Since process i receives m_2 by time $t + 2c_2 + d_2$, the maximum time difference between the time that process i receives m_1 and the time that it receives m_2 is $(t + 2c_2 + d_2) - (t + d_1) = d_2 - d_1 + 2c_1 = u + 2c_2$. Therefore, $\Delta = u + 2c_2$. □

By the algorithm, initially it takes at most $d_2 + 2c_2$ time to receive at least one message from all processes in order to accomplish the first session. Therefore $T_1 = d_2 + 2c_1$. Using Lemma B.3, T_{s-1}, which is the latest time that a process sets *session* to $s-1$, is at most $(s-2)\cdot(\frac{c_2}{c_1}u + u + 2c_2) + T_1$. After T_{s-1}, a process takes one step to complete s sessions. Therefore, a process enters the idle state by time $(s-2)\cdot(\frac{c_2}{c_1}u + u + 2c_2) + d_2 + 2c_2 + c_2$. □

B.2. Correctness proof of MD.

THEOREM B.4. *MD solves the (s,n)-session problem within time $(s-2)\cdot(\frac{d_2}{d_1}u + u + 2c_2) + d_2 + 2c_2$ if d_1 and d_2 are known.*

Proof. MD differs from CB1 only in the way that *count* is incremented and in that B is set to u/d_1. The rest of the code is the same. The correctness proof is similar to that of technique CB1.

Since *count* and B affect condition ($count \ge B$) in the code, we only need to prove that when $B < count$, at least time u has passed since the last time *session* was incremented. *count* is incremented to k only when a process receives $m(j, session, k-1)$ for any j and for some value of *session*. When we apply this argument inductively, we prove that there must be a chain of processes $p_{i_1}, p_{i_2}, \ldots, p_{i_k}$, where p_{i_r} receives $m(i_{r-1}, session, r-1)$ from $p_{i_{r-1}}$. Thus, when *count* is B, at least time $Bd_1 = d_2 - d_1 = u$ has passed after p_{i_1} sent $m(i_1, session, 1)$ because it takes at least d_1 message delay for a message to be received after it is sent.

For time complexity, it takes at most time $d_2 + c_2$ for p_{i_k} to receive $m(i_{k-1}, session, k-1)$ after $p_{i_{k-1}}$ receives $m(i_{k-2}, session, k-2)$. Therefore, for *count* to be bigger than or equal to B, it takes at most $B(d_2 + c_2)$. After that, for condition 1 in the code to be true it takes at most $(u + 2c_2)$, as proved in the proof of Lemma B.3. Therefore, the running time of technique MD is $(s-2)\cdot(\frac{d_2+c_2}{d_1}u + u + 2c_2) + d_2 + 2c_2$. □

B.3. Correctness proof of CB2.

THEOREM B.5. *Technique CB2 solves the* (s,n)*-session problem in time* $(s-1)\cdot \frac{d_2+c_2}{d_1}c_2 + c_2$ *if* c_2 *and* d_1 *are known.*

Proof. count is incremented to k only when a process receives $m(j,*,k-1)$ for any j. When we apply this argument inductively, we prove that there must be a chain of processes $p_{i_1}, p_{i_2}, \ldots, p_{i_k}$, where p_{i_r} receives $m(i_{r-1},*,r-1)$ from $p_{i_{r-1}}$. Thus, when *count* is B, at least time $Bd_1 = \frac{c_2}{d_1}(s-1)d_1$ has passed after p_{i_1} sent $m(i_1,*,1)$ because it takes at least d_1 message delay for a message to be received after it is sent. Thus, when $count > B$, at least time $c_2(s-1)$ has passed since the start of the computation. The theorem follows. □

MULTIRATE REARRANGEABLE CLOS NETWORKS AND A GENERALIZED EDGE-COLORING PROBLEM ON BIPARTITE GRAPHS*

HUNG Q. NGO† AND VAN H. VU‡

Abstract. Chung and Ross [*SIAM J. Comput.*, 20 (1991), pp. 726–736] conjectured that the minimum number $m(n,r)$ of middle-stage switches for the symmetric 3-stage Clos network $C(n, m(n,r), r)$ to be rearrangeable in the multirate environment is at most $2n-1$. This problem is equivalent to a generalized version of the bipartite graph edge-coloring problem. The best bounds known so far on this function $m(n,r)$ are $11n/9 \le m(n,r) \le 41n/16 + O(1)$, for $n, r \ge 2$, derived by Du et al. [*SIAM J. Comput.*, 28 (1999), pp. 464–471]. In this paper, we make several contributions. First, we give evidence to show that even a stronger result might hold. In particular, we give a coloring algorithm to show that $m(n,r) \le \lceil (r+1)n/2 \rceil$, which implies $m(n,2) \le \lceil 3n/2 \rceil$—stronger than the conjectured value of $2n-1$. Second, we derive that $m(2,r) = 3$ by an elegant argument. Last, we improve both the best upper and lower bounds given above: $\lceil 5n/4 \rceil \le m(n,r) \le 2n-1+\lceil (r-1)/2 \rceil$, where the upper bound is an improvement over $41n/16$ when r is relatively small compared to n. We also conjecture that $m(n,r) \le \lfloor 2n(1-1/2^r) \rfloor$.

Key words. Clos network, multirate rearrangeable, bipartite graph, generalized edge-coloring

1. Introduction.

The Clos network has been widely used for data communications and parallel computing systems. Quite a lot of research efforts [1, 2, 3, 5, 6, 9, 10, 11, 13, 14, 15, 16, 17, 22] have been put into investigating the nonblocking properties and rearrangeability of the Clos network. The 3-stage Clos network was paid special attention to since it can be expanded in a "straightforward" way to the multistage Clos network. Recently, Ngo and Pan [18] observed that the 3-stage Clos network is "equivalent" to the wavelength division multiplexed (WDM) split cross-connects [20, 21], giving new applications to the classic Clos networks. Let us first formally introduce some related concepts.

The Clos network $C(n_1, r_1, m, n_2, r_2)$ is a 3-stage interconnection network, where the first stage consists of r_1 crossbars of size $n_1 \times m$, the last stage has r_2 crossbars of dimension $m \times n_2$, and the middle stage has m crossbars of dimension $r_1 \times r_2$ (see Figure 1). Each input switch I_i $(i = 1, \ldots, r_1)$ is connected to each middle switch M_j $(j = 1, \ldots, m)$. Similarly, the middle stage and the last stage are fully connected. When $n_1 = n_2 = n$ and $r_1 = r_2 = r$, the network is called the *symmetric 3-stage Clos network*, denoted by $C(n, m, r)$. Any switch is assumed to be nonblocking; i.e., any inlet can be connected to any outlet as long as there is no conflict on the outlet. A switch of dimension $p \times q$ could be thought of as a crossbar of size $p \times q$ with pq cross-points. Having too many cross-points is expensive, and we would like to design a huge switch using smaller switches with fewer cross-points than when a brute-force

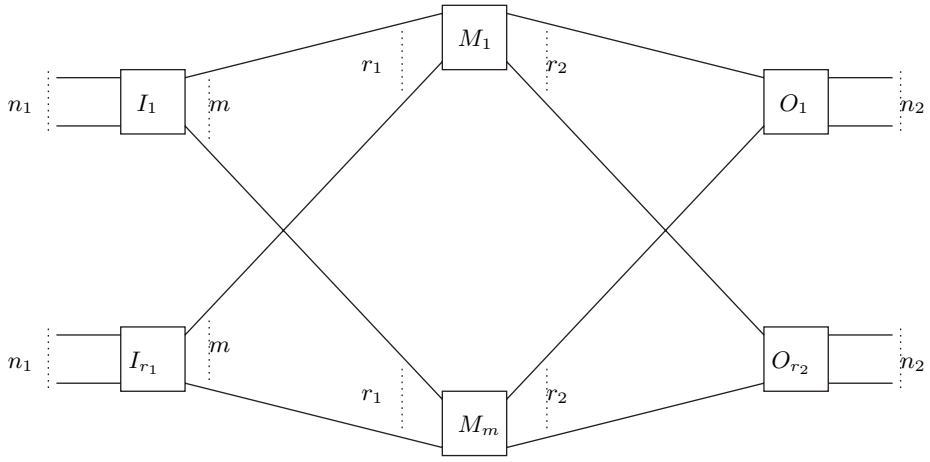

FIG. 1. *The 3-stage Clos network* $C(n_1, r_1, m, n_2, r_2)$.

design is used. The inlets (outlets) of the input (output) switches are the *inputs* (*outputs*) of the network. Inputs and outputs are referred to as *external links*, while links between switches are referred to as *internal links*.

In the multirate environment, a *connection request* is a triple (i, j, w), where i is an inlet, j an outlet, and w the weight. A *request frame* is a collection of requests such that the total weight of all requests in the frame involving a fixed inlet or outlet does not exceed unity. To discuss routing it is convenient to assume that all links are directed from left to right. Thus a *path* from an inlet to any outlet always consists of the following sequence: an inlet link $\rightarrow$ an input switch $\rightarrow$ a link $\rightarrow$ a center switch $\rightarrow$ a link $\rightarrow$ an output switch $\rightarrow$ an outlet link. Furthermore, since the crossbars are assumed to be nonblocking, a request (i, j, w) is *routable* if and only if there exists a path from i to j such that every link on this path has unused capacity at least $1 - w$ before carrying out this request. A request frame is routable if there exists a set of paths, one for each request, such that for every link the sum of weights of all requests going through it does not exceed unity. The Clos network $C(n, m, r)$ is said to be *multirate rearrangeable* (or just rearrangeable, as in this paper we consider only the multirate environment) if *every* request frame is routable.

Let $m(n, r)$ denote the minimum value of m such that $C(n, m, r)$ is multirate rearrangeable for $n, r \geq 2$. (The cases where either n or r are 1 are trivial; hence we consider only $n, r \geq 2$ from here on.) Our problem is to find $m(n, r)$ or at least some good bounds for this function.

The problem appears to be difficult. Let us preview some previous works on this problem. Melen and Turner [16] initiated the research on multirate switching networks. In 1991, Chung and Ross [3] conjectured that $m(n, r) \leq 2n - 1$ and until now no one has been able to prove or disprove the conjecture. The best bounds known so far on this function $m(n, r)$ were obtained by Du et al. [5]:

$$11n/9 \leq m(n, r) \leq 41n/16 + O(1).$$

Lin et al. [14] confirmed Chung–Ross conjecture for a restricted discrete bandwidth case where each connection has a weight chosen from a set $\{1 \geq w_1 > \cdots > w_h > 1/2 \geq w_{h+1} > \cdots > w_k\}$ which satisfies the condition that w_i is an integer multiple of w_{i+1} for $i = h + 1, \ldots, k - 1$. Hu et al. [10] studied the monotone routing strategy

and showed that under this strategy

$$m(n,r) \le 2n+1 \quad \text{for } n=2,3,4, \tag{1}$$

$$m(n,r) \le 2n+3 \quad \text{for } n=5,6. \tag{2}$$

Ngo [17] proposed the grouping algorithm which shows that $m(n,r) \le 2n-1+r$ and that $m(n,r) \le 2n + \frac{n-1}{2^k}$ whenever $r \le \frac{n}{2^k-1}$.

In this paper, we give evidence to show that a stronger version of Chung-Ross conjecture might hold. In particular, we show that $m(n,r) \le \lceil \frac{(r+1)n}{2} \rceil$, which implies $m(n,2) \le \lceil \frac{3n}{2} \rceil$. This is stronger than the conjectured value of $2n-1$. We conjecture that

$$m(n,r) \le \left\lfloor 2n\left(1-\frac{1}{2^r}\right)\right\rfloor, \quad n,r \ge 2.$$

We believe that the new conjectured upper bound is also the correct value for $m(n,r)$. Second, we verify that Chung and Ross were right on target when $n=2$, i.e., $m(2,r)=3$, by a new elegant argument. Last, we give better upper and lower bounds for the general case:

$$\left\lceil \frac{5n}{4} \right\rceil \le m(n,r) \le 2n-1+\left\lceil \frac{r-1}{2} \right\rceil.$$

All these are done in the context of a generalized version of the edge-coloring problem on weighted bipartite graphs to be introduced in the next section. These weighted graphs have maximum degree n in the weighted sense.

As a side note, Ngo and Pan [18] showed that the 3-stage Clos network is equivalent to the WDM split cross-connects [20, 21] under this multirate environment; hence the results in this paper also apply to the split cross-connects. Each rate can be thought of as the bandwidth fraction of a wavelength obtained from time division multiplexing.

2. A generalized bipartite graph edge-coloring problem. Given a request frame $\mathcal{F}$, define a weighted bipartite multigraph $G_{\mathcal{F}} = (I, O; E)$, where I (respectively, O) contains all the input (respectively, output) switches. There is an edge with weight w between vertices X, Y of G for each request (x, y, w), where x (respectively, y) is an inlet (respectively, outlet) of X (respectively, Y). $C(n,m,r)$ is rearrangeable if and only if for all $\mathcal{F}$ the edges of $G_{\mathcal{F}}$ can be m-colored such that at every vertex the total weight of edges of the same color incident to this vertex is at most unity. To see this, just associate each color with a center switch.

We now formally define the equivalent bipartite graph edge-coloring problem. Throughout this paper we assume $n, r \ge 2$ are integers. Let $\mathcal{B}_r^n$ be the collection of edge-weighted $r \times r$ bipartite multigraphs $G = (A, B; E)$ ($|A| = |B| = r$) with weight function $w : E \to (0,1]$ satisfying the condition that for every $v \in V(G) = A \cup B$, the set $I(v)$ of edges incident to v can be partitioned into n groups $g(v,i)$, $1 \le i \le n$, such that

$$\sum_{e \in g(v,i)} w(e) \le 1 \quad \forall i = 1, \ldots, n. \tag{3}$$

We shall refer to condition (3) as the *grouping condition*. The grouping condition simply refers to the fact that the total weight of all requests from an inlet or to an outlet is at most unity.

A k-edge-coloring of $G \in \mathcal{B}_r^n$ is a coloring $l : E(G) \to C$, where C is a set of k colors, such that for every $v \in V(G)$ and every color $c \in C$

$$\sum_{\substack{e \in I(v) \\ l(e)=c}} w(e) \leq 1. \tag{4}$$

Let $m(n,r)$ be the minimum integer k such that every $G \in \mathcal{B}_r^n$ is k-edge-colorable. Our job is to find good bounds for $m(n,r)$ or the exact value if possible. Notice that when all the weights are 1, this problem reduces to the edge-coloring of a bipartite graph with maximum degree at most n. Thus, $m(n,r) = n$ when the weights are all unity. This can be shown as a trivial consequence of P. Hall's matching condition or of König's line coloring theorem [12].

3. A new lower bound. The main result of this section is the following theorem.

THEOREM 3.1. *For integers $n, r \geq 2$, we have*

$$m(n,r) \geq m(n,2) \geq \left\lceil \frac{5n}{4} \right\rceil \text{ when } n \text{ is even}$$

and

$$m(n,r) \geq m(n,2) \geq \left\lceil \frac{5n-1}{4} \right\rceil \text{ when } n \text{ is odd.}$$

Proof. The natural approach to find a lower bound k for $m(n,r)$ is to find a particular graph $G \in \mathcal{B}_r^n$ which requires at least k colors. The fact that $m(n,r) \geq m(n,2)$ is trivial. To show the inequality for even n, consider the following graph $G \in \mathcal{B}_r^2$:

- $G = (\{1,2\}, \{1',2'\}; E)$.
- There are n edges from 1 to $1'$ with weight 0.6.
- There are n edges from 1 to $2'$ with weight 0.4.
- There are $n/2$ edges from 2 to $2'$ with weight 1.

The grouping condition is easily seen to be satisfiable. The 0.6-edges in $I(1)$ require n colors. Let k be the number of colors shared by the 0.6-edges and 0.4-edges of $I(1)$. Then, looking from vertex 1 we need at least $n + \frac{n-k}{2}$ colors. On the other hand, looking from vertex $2'$ we need at least $\frac{n}{2} + k + \frac{n-k}{2}$ colors. Consequently, the total number of colors needed is at least

$$\max\left\{ n + \frac{n-k}{2}, \quad \frac{n}{2} + k + \frac{n-k}{2} \right\} \geq \frac{(n + \frac{n-k}{2}) + (\frac{n}{2} + k + \frac{n-k}{2})}{2}$$
$$= \frac{5n}{4}.$$

The case when n is odd can be shown similarly. ∎

4. The exact value of $m(2,r)$. The main result of this section is an algorithm to color all graphs in $\mathcal{B}_r^2$ using at most three colors.

THEOREM 4.1. *When $r \geq 2$, we have*

$$m(2,r) = 3.$$

Proof. Theorem 3.1 implies $m(2,r) \geq 3$. We are left to show that every graph $G \in \mathcal{B}_r^2$ is 3-colorable. For $G = (A, B; E) \in \mathcal{B}_r^2$, let $A = B = \{1, 2, \ldots, r\}$. The grouping condition indicates that edges incident to each vertex v could be partitioned into two groups $g(v,1)$ and $g(v,2)$ with total weight at each group at most 1. For $i, j \in \{1,2\}$ and $a \in A, b \in B$, let

$$w_{ij}(a,b) = \sum_{\substack{e=(a,b)\in E \\ e\in g(a,i)\cap g(b,j)}} w(e). \tag{5}$$

In other words, $w_{ij}(a,b)$ is the total weight of all edges e from $a \in A$ to $b \in B$, where e belongs to group i of vertex a and group j of vertex b. The grouping condition implies that for a fixed $i_0 \in \{1,2\}$ and $a_0 \in A$, we have

$$\sum_{b\in B} (w_{i_0 1}(a_0, b) + w_{i_0 2}(a_0, b)) \leq 1. \tag{6}$$

Similarly, for a fixed $j_0 \in \{1,2\}$ and $b_0 \in B$, we get

$$\sum_{a\in A} (w_{1 j_0}(a, b_0) + w_{2 j_0}(a, b_0)) \leq 1. \tag{7}$$

Clearly, the number of colors needed to color G does not change if at any vertex $v \in V$ we relabel the groups $g(v,1)$ and $g(v,2)$. (Namely, group 1 becomes group 2 and vice versa.) This relabelling does change the values $w_{ij}(v,b)$ or $w_{ij}(a,v)$, though. Now, relabel the groups at all vertices of G to maximize the following sum:

$$\sum_{\substack{a\in A, \\ b\in B}} (w_{11}(a,b) + w_{22}(a,b)). \tag{8}$$

To this end, we use three colors to color all edges of G as follows:

- One color is for all edges in

$$\bigcup_{\substack{a\in A, \\ b\in B}} (g(a,1) \cap g(b,1)). \tag{9}$$

- Another color is for all edges in

$$\bigcup_{\substack{a\in A, \\ b\in B}} (g(a,2) \cap g(b,2)). \tag{10}$$

- The last color is for all edges in

$$\bigcup_{\substack{a\in A, \\ b\in B}} (g(a,1) \cap g(b,2)) \bigcup \bigcup_{\substack{a\in A, \\ b\in B}} (g(a,2) \cap g(b,1)). \tag{11}$$

It is straightforward to verify that all edges belong to one of the three color classes. To show that this is a valid coloring, we shall verify that the total weight of edges at each color class which are incident to the same vertex is at most 1. The total weight of edges of color class (9) which are incident to vertex $a \in A$ is

$$\sum_{b\in B} w_{11}(a,b) \leq \sum_{b\in B} (w_{11}(a,b) + w_{12}(a,b)) \leq 1.$$

The cases of color class (9) with a vertex $b \in B$ and of color class (10) are done similarly.

Last, the total weight of edges of color class (11) which are incident to vertex $a \in A$ is

$$\sum_{b \in B} \left(w_{12}(a,b) + w_{21}(a,b) \right). \tag{12}$$

If this sum is > 1, then

$$\sum_{b \in B} \left(w_{11}(a,b) + w_{22}(a,b) \right) < 1, \tag{13}$$

since

$$\begin{aligned} &\sum_{b \in B} \left(w_{12}(a,b) + w_{21}(a,b) \right) + \sum_{b \in B} \left(w_{11}(a,b) + w_{22}(a,b) \right) \\ &= \sum_{b \in B} \left(w_{11}(a,b) + w_{12}(a,b) \right) + \sum_{b \in B} \left(w_{21}(a,b) + w_{22}(a,b) \right) \\ &\leq 2. \end{aligned}$$

However, (13) and the fact that the sum (12) is > 1 imply that relabelling the two groups $g(a,1)$ and $g(a,2)$ would increase the sum (8), contradicting the maximality of (8). □

The above result can be extended in a "straightforward" way to show the following corollary.

COROLLARY 4.2.

(i) $m(2^k, r) \leq 3^k$ *for any positive integer* $k \geq 1$.

(ii) $m(n,r) \leq 3^{\lceil \log_2 n \rceil}$.

Basically, for part (i) we can induct on k, and part (ii) follows from (i). This extended result gives good bounds when n is small. In fact, we can also show results such as $m(3,r) \leq 6$ by the same idea, with more tedious analysis. Since these results are not generally good and the arguments, though intuitively simple, are too tedious to present, we omit their proofs here.

5. The new upper bounds. Next, we give a coloring algorithm yielding a general upper bound which is good for small values of r. The new upper bound implies a stronger value than the conjectured value of $2n-1$ when $r = 2$.

THEOREM 5.1. *When* $n, r \geq 2$, *we have*

$$m(n,r) \leq \left\lceil \left(\frac{r+1}{2} \right) n \right\rceil.$$

Proof. Consider $G = (A, B; E) \in \mathcal{B}_r^n$. Recall that for each $v \in V = A \cup B$, we use $I(v)$ to denote the set of edges incident to v and $g(v,i)$ to denote the set of edges in group i of v. Now, for each vertex $u \in A$ (respectively, B) and each vertex $v \in B$ (respectively, A), define n sets of edges $S_u(v,i)$ as follows:

$$S_u(v,i) = g(u,i) \cap I(v), \quad i = 1, \ldots, n. \tag{14}$$

In other words, $S_u(v,i)$ is the set of edges in group i of u which are incident to v. Let $w_u(v,i)$ be the total weight of edges in $S_u(v,i)$. (We set $w_u(v,i) = 0$ if $S_u(v,i) = \emptyset$.)

Then the grouping condition on G implies that

$$\sum_{b\in B} w_a(b,i) \le 1 \quad \forall a \in A, i = 1,\dots,n, \tag{15}$$

$$\sum_{a\in A} w_b(a,i) \le 1 \quad \forall b \in B, i = 1,\dots,n. \tag{16}$$

To this end, for each $u \in A$ (respectively, B) and each $v \in B$ (respectively, A), let $L_u(v)$ be the set of group names i, $1 \le i \le n$, for which $w_u(v,i) > 1/2$, and let $\bar{L}_u(v)$ be the set of the rest of the indices. More formally,

$$L_u(v) = \{i \mid w_u(v,i) > 1/2, i = 1,\dots,n\}, \tag{17}$$

$$\bar{L}_u(v) = \{1,\dots,n\} - L_u(v). \tag{18}$$

Due to (15), for each index i and a particular vertex $a \in A$, there can be at most one $b \in B$ where $w_a(b,i) > 1/2$. Hence, for each $a \in A$ we must have

$$\sum_{b\in B} |L_a(b)| \le n. \tag{19}$$

Similarly, due to (16), for each $b \in B$ the following holds:

$$\sum_{a\in A} |L_b(a)| \le n. \tag{20}$$

Now, define a weighted bipartite multigraph $G' = (A, B; E')$ as follows.

- For each $a \in A$ and $b \in B$, there are n edges between a and b in G', denoted by $e(a,b,i)$, $1 \le i \le n$. The weight of $e(a,b,i)$, denoted by $w'(a,b,i)$, is defined below. Note that G' is rn-regular.
- For each $a \in A$ and $b \in B$, if $|L_a(b)| \le |L_b(a)|$, then

$$w'(a,b,i) = w_a(b,i), \quad i = 1,\dots,n.$$

Otherwise, when $|L_a(b)| > |L_b(a)|$ define

$$w'(a,b,i) = w_b(a,i), \quad i = 1,\dots,n.$$

First, we claim that any valid coloring of G' induces a valid coloring of G. The term "valid coloring" here means that the total weight of same color edges which are incident to a particular vertex of G' is at most 1. To see this, suppose we are given a valid coloring of G' where the edge $e(a,b,i)$ is colored $c(a,b,i)$, say. Then when $|L_a(b)| \le |L_b(a)|$ we color all edges in the set $S_a(b,i)$ with color $c(a,b,i)$. On the other hand, when $|L_a(b)| > |L_b(a)|$ the set $S_b(a,i)$ gets the color instead.

To this end, let H be the spanning bipartite subgraph of G' obtained from G' by taking only edges whose weights are $> 1/2$. We claim that H has maximum degree at most n. To see this, consider any vertex $a \in A$ of H. We have

$$deg_H(a) = \sum_{b\in B} \min\{|L_a(b)|, |L_b(a)|\} \le \sum_{b\in B} L_a(b) \le n, \tag{21}$$

by (19). Similarly, $deg_H(b) \le n$ for all $b \in B$. Add more edges of G' into H so that H is n-regular. This is possible since G' has n parallel edges between any pair

$(a, b) \in A \times B$. König's line coloring theorem [12] implies that H is n-edge-colorable. (The actual coloring algorithms can be found in [4, 7, 8], for instance.) The graph $G' - E(H)$ is $(r-1)n$-regular; hence it is $(r-1)n$-edge-colorable. However, each edge of $G' - E(H)$ has weight at most $1/2$; hence every two colors can be combined into one without violating the condition that the total weight of same color edges at each vertex is at most 1. Consequently, we can color edges of G' with

$$n + \left\lceil \left(\frac{r-1}{2} \right) n \right\rceil = \left\lceil \left(\frac{r+1}{2} \right) n \right\rceil$$

colors. □

Note that this theorem gives the best upper bounds so far for $m(n, r)$ when r is small, as formally put in the following corollary.

COROLLARY 5.2. *When $n \geq 2$, we have*

(i) $m(n, 2) \leq \lceil \frac{3n}{2} \rceil$,
(ii) $m(n, 3) \leq 2n$,
(iii) $m(n, 4) \leq \lceil \frac{5n}{2} \rceil$.

The argument given in Theorem 5.1 can be extended easily to show the following corollary, whose proof we omit.

COROLLARY 5.3. *The general 3-stage Clos network $C(n_1, r_1, m, n_2, r_2)$ is multirate rearrangeable when*

$$m \geq \frac{(r+1)n}{2},$$

where $n = \max\{n_1, n_2\}$, and $r = \max\{r_1, r_2\}$.

Theorem 3.1 and part (i) of Corollary 5.2 imply $5n/4 \leq m(n, 2) \leq 6n/4$. Given that the number $5/4$ is somewhat "ugly," we make the following conjecture.

CONJECTURE 5.4.

$$m(n, 2) = \left\lfloor \frac{3n}{2} \right\rfloor, \ n \geq 2.$$

In fact, recalling $m(2, r) = 3$, it is very tempting to also make the following conjecture.

CONJECTURE 5.5. *The symmetric 3-stage Clos network $C(n, m, r)$ is multirate rearrangeable if there are at least*

$$\left\lfloor \left(1 + \frac{1}{2} + \cdots + \frac{1}{2^{r-1}} \right) n \right\rfloor = \left\lfloor 2n \left(1 - \frac{1}{2^r} \right) \right\rfloor$$

middle-stage switches. In other words,

$$m(n, r) \leq \left\lfloor 2n \left(1 - \frac{1}{2^r} \right) \right\rfloor.$$

We believe that the upper bound is also the exact value for $m(n, r)$. However, as there is no rigorous evidence yet, we have conjectured a weaker result. Next, we give another upper bound which beats all existing bounds when r is relatively small compared to n.

THEOREM 5.6. *When $n, r \geq 2$, we have*

$$m(n, r) \leq 2n - 1 + \left\lceil \frac{r-1}{2} \right\rceil. \tag{22}$$

Proof. Consider $G = (A, B; E) \in \mathcal{B}_r^n$. Suppose e and e' are two edges connecting two vertices $a \in A$ and $b \in B$, with $w(e) + w(e') \leq 1$. Create a new graph G' from G by collapsing e and e' into one edge with weight $w(e) + w(e')$. Then a valid coloring of G' induces a valid coloring of G.

Now, for every pair $(a, b) \in A \times B$, as long as there are two edges e and e' between a and b for which $w(e) + w(e') \leq 1$, collapse e and e' into one as described. After this procedure is finished, between any pair a and b there is at most one edge with weight $\leq 1/2$, and the rest have weights $> 1/2$. Let H be the resulting graph. Call the edges of H with weight $> 1/2$ *heavy* and the rest of the edges *light*. Since the total weight of edges incident to each vertex of G is at most n, every vertex of H is incident to at most $2n - 1$ heavy edges. In other words, the heavy degree of any vertex of H is at most $2n - 1$.

We claim that the light degree of any vertex of H is at most $r - 1$. To see this, consider $a \in A$. If the heavy degree of A is $2n-1$, then no light edge incident to a can share the same neighbor as a heavy edge of a. Suppose, on the contrary, that there is a heavy edge e and a light edge e', both of which connect a and b. Then the total weight of the other $2n-2$ heavy edges of a except e is $> n-1$; hence $w(e)+w(e') < 1$, as the total weight associated with a is at most n. Consequently, e and e' must have been collapsed by our procedure. Thus, the light degree of a is at most $r-1$. Now, if the heavy degree of a is at most $2n - 2$, then there is also a vertex $b \in B$ with heavy degree at most $2n - 2$. If there was no light edge between a and b, then the light degree of a is at most $r - 1$. If there was one light edge between a and b, relabel this light edge "heavy," which does not change the fact that the maximum heavy degree of H is at most $2n - 1$. Again, the light degree of a is now at most $r - 1$.

König's line coloring theorem [12] implies that we can use at most $2n-1$ colors to color the heavy edges of H and at most $r - 1$ colors to color the light edges of H. As the light edges have weights $\leq 1/2$, every two colors of $r - 1$ colors can be combined into one, for a total of at most $2n - 1 + \lceil (r - 1)/2 \rceil$ colors as desired. (Again, the actual coloring algorithms can be found in [4, 7, 8].) □

As we have mentioned, the new bound is good when r is relatively small. This is formally put in the following corollary.

COROLLARY 5.7. *When* $r \leq \frac{n}{2^{k-1}} + 1$, *we have*

$$m(n, r) \leq 2n - 1 + \left\lceil \frac{n}{2^k} \right\rceil.$$

For example, if $r \leq n + 1$, the Clos network $C(n, m, r)$ is multirate rearrangeable with at most $\lceil 5n/2 \rceil - 1$ middle-stage switches; when $r \leq n/4 + 1$, we need only about $17n/8 - 1$ middle-stage switches, and so on .... The argument given in Theorem 5.6 generalizes straightforwardly to the general Clos network case. Hence, we get the following result.

COROLLARY 5.8. *The general 3-stage Clos network* $C(n_1, r_1, m, n_2, r_2)$ *is multirate rearrangeable when*

$$m \geq 2n - 1 + \left\lceil \frac{r - 1}{2} \right\rceil,$$

where $n = \max\{n_1, n_2\}$, *and* $r = \max\{r_1, r_2\}$.

AN APPROXIMATION ALGORITHM FOR THE MINIMUM-COST k-VERTEX CONNECTED SUBGRAPH*

JOSEPH CHERIYAN†, SANTOSH VEMPALA‡, AND ADRIAN VETTA§

Abstract. We present an approximation algorithm for the problem of finding a minimum-cost k-vertex connected spanning subgraph, assuming that the number of vertices is at least $6k^2$. The approximation guarantee is six times the kth harmonic number (which is $O(\log k)$), and this is also an upper bound on the integrality ratio for a standard linear programming relaxation.

Key words. approximation algorithm, ℓ-critically k-connected graph, linear programming relaxation, network design, k-outconnected graph, vertex connectivity

1. Introduction.

Let $G = (V, E)$ be an undirected graph, let each edge $e \in E$ have a nonnegative cost c_e, and let k be a positive integer. The *minimum-cost k-vertex connected spanning subgraph (mincost k-VCSS)* problem is to find a spanning subgraph H of minimum cost such that H is k-vertex connected. (A graph is called *k-vertex connected* if it has at least $k+1$ vertices, and the removal of any $k-1$ vertices leaves a connected graph.) The problem is NP-hard for $k \geq 2$, and for $k = 1$ it is the minimum spanning tree problem. Our paper addresses the "special case" of the problem where the graph has order $|V| \geq 6k^2$; this too is NP-hard for $k \geq 2$. (So for a fixed k, our method handles all graphs except a finite set of "small" graphs, and our method fails on each of the "small" graphs.) Our approximation guarantee is six times the kth harmonic number, which is $O(\log k)$. Also, this is an upper bound on the integrality ratio for a standard linear programming relaxation. Several previous papers have attacked the mincost k-VCSS problem (without restrictions on $|V|$), with the goal of improving on the approximation guarantee (see the references). An approximation guarantee of more than $k/2$ has been presented in [11]; also, an upper bound of $O(k)$ on the integrality ratio was known [4, 5]. Better results were not known for our "special case," but we mention that our results may not improve on previous results for small k ($k = 2, 3, 4, \ldots$). (An $O(\log k)$ approximation guarantee was claimed earlier in [15], but subsequently an error has been found, and that claim has been withdrawn; see [16].) For more discussion on related problems and results, see the introduction of [3].

Our algorithm is based on two results: (1) a polynomial-time algorithm of Frank and Tardos [5] for finding a minimum-cost k-outconnected subdigraph of a digraph

(directed graph), and (2) an upper bound on the order of 3-critical graphs by Mader [12]. The Frank–Tardos algorithm has been applied earlier to the mincost k-VCSS problem by several authors, starting with Khuller and Raghavachari [10]; see also [1, 2, 11]. The scaling trick used in Lemma 3.2 below has been used earlier by [8, 9].

2. Notation and preliminary results. Throughout, we assume that the input graph $G = (V, E)$ is k-vertex connected. Let n denote $|V|$.

2.1. A linear programming relaxation. Let H^* denote a k-VCSS of minimum cost, and let $z^* = c(H^*) = \sum_{e \in E(H^*)} c_e$ denote its cost. The following linear program (LP) $P(k)$ gives a lower bound $z(k)$ on z^* (Frank discusses this LP in [4]). There is a variable x_e, $0 \le x_e \le 1$, for each edge e in G. The intention is that the edge incidence vector of every k-VCSS H (possibly $H = H^*$) forms a feasible solution for $P(k)$. A setpair $W = (W_t, W_h)$ is an ordered pair of disjoint vertex sets, so $W_t \subseteq V$, $W_h \subseteq V$, and $W_t \cap W_h = \emptyset$. An edge uv of G is said to *cover* W if $u \in W_t, v \in W_h$ or $v \in W_t, u \in W_h$. Let $\delta(W)$ denote the set of all edges in G that cover W. If W_t contains at least one vertex, say, p, and W_h contains at least one vertex, say, q, then note that H has at least $k - (n - |W_t \cup W_h|)$ edges in $\delta(W)$, because on removing the vertices in $V - (W_t \cup W_h)$ from H, the resulting graph has at least this number of openly disjoint paths between p and q, and each of these paths contributes one (or more) distinct edges to $\delta(W)$. (Two paths are called *openly disjoint* if every vertex that belongs to both paths is an end vertex of both paths.) Let $\mathcal{S}$ denote the set of all setpairs (W_t, W_h) such that $W_t \ne \emptyset$ and $W_h \ne \emptyset$. It is convenient to keep a parameter ℓ, where ℓ is a positive integer, and write the LP relaxation $P(\ell)$ for the mincost ℓ-VCSS problem.

$$
\begin{aligned}
P(\ell): \qquad z(\ell) \;=\; \text{minimize} \quad & \sum_{e \in E} c_e\, x_e \\
\text{subject to} \quad & \sum_{e \in \delta(W)} x_e \ge \ell \;-\; (n - |W_t \cup W_h|) && \forall\, W \in \mathcal{S}, \\
& 0 \;\le\; x_e \le 1 && \forall\, e \in E.
\end{aligned}
$$

LEMMA 2.1. *Let $z^*(\ell)$ be the minimum cost of an ℓ-VCSS. Then $z^*(\ell) \ge z(\ell)$.*

2.2. k-outconnected subgraphs. A graph is said to be *k-outconnected* from a so-called *root* vertex r if there exist k openly disjoint paths from r to v for each vertex v, $v \ne r$. The *mincost k-OC* problem is as follows: given an undirected graph $G = (V, E)$, a root vertex $r \in V$, and nonnegative costs on the edges, find a minimum-cost subgraph H of G such that H is k-outconnected from r. This problem is NP-hard for $k \ge 2$.

THEOREM 2.2 (see [5, 10]). *Let $G = (V, E)$, r, and $c : E \to \mathbb{R}_+$ be as above. There is a 2-approximation algorithm for the mincost k-OC problem. Moreover, the subgraph found by this algorithm has cost at most $2z(k)$.*

Proof. In the directed version $\widehat{G}$ of G, each edge e of G is replaced by two oppositely oriented arcs, and each of these two arcs has cost c_e. Here is an LP relaxation (in fact, an LP formulation) $\widehat{P}$ of the directed mincost k-OC problem on $\widehat{G}$ (with any vertex r as the root): There is a variable x_a for each arc a in $\widehat{G}$; let $\mathcal{R}$ denote the set of all setpairs $W = (W_t, W_h)$ such that the root r is in W_t and $W_h \ne \emptyset$; and for $W \in \mathcal{R}$ let $\hat{\delta}(W)$ denote the set of arcs (u, v) in $\widehat{G}$ with $u \in W_t$, $v \in W_h$.

$$\widehat{P}: \quad \text{minimize} \quad \sum_{a \in E(\widehat{G})} c_a\, x_a$$

$$\text{subject to} \quad \sum_{a \in \hat{\delta}(W)} x_a \geq k \;-\; (n - |W_t \cup W_h|) \qquad \forall\, W \in \mathcal{R},$$

$$0 \;\leq\; x_a \leq 1 \qquad \forall\, a \in E(\widehat{G}).$$

This LP $\widehat{P}$ has an integer optimal solution (see [4, Theorems 2.1, 2.2]). The Frank–Tardos algorithm solves the directed mincost k-OC problem on $\widehat{G}$ by finding a minimum-cost subdigraph $\widehat{H}$ that is k-outconnected from r, and the cost $c(\widehat{H})$ equals the optimal value of $\widehat{P}$. (The arc incidence vector of $\widehat{H}$ forms an optimal solution of $\widehat{P}$.) Finally, we claim that the optimal value of $\widehat{P}$ is at most $2z(k)$; hence the undirected version of $\widehat{H}$ satisfies the theorem. (It is a subgraph of G that is k-outconnected from r, and it has cost at most $2z(k)$.)

To see that the optimal value of $\widehat{P}$ is at most $2z(k)$, observe that the LP relaxation of the directed mincost k-VCSS problem on $\widehat{G}$ has optimal value at most $2z(k)$ (because a feasible solution $\boldsymbol{x}$ of $P(k)$ (the k-VCSS LP on G) gives a feasible solution of the directed k-VCSS LP on $\widehat{G}$ by assigning the value x_e to each of the two arcs corresponding to each edge e). Moreover, an optimal solution of the directed k-VCSS LP on $\widehat{G}$ is also a feasible solution of $\widehat{P}$. Our claim follows. □

Remark. Our algorithm may apply this result to find a solution to the mincost ℓ-OC problem that has cost at most $2z(\ell)$, where $1 \leq \ell \leq k$.

2.3. 3-critical graphs. For a graph G, let $\kappa(G)$ denote the *vertex connectivity*, i.e., the minimum number of vertices whose removal results in a disconnected graph or the trivial graph (namely, K_1). An *ℓ-separator* of a connected graph is a set of ℓ vertices whose removal results in a disconnected graph.

A graph $G = (V, E)$ is called 3-*critical* if the vertex connectivity decreases by $|S|$ on removing the vertices in any set S of at most three vertices, that is, if $\kappa(G - S) = \kappa(G) - |S|$ for all $S \subseteq V$, $|S| \leq 3$. If G is *not* 3-critical, then note that there exists a set S of three vertices such that no $\kappa(G)$-separator contains all the vertices in S. Mader gives an upper bound on the order of 3-critical graphs [12]. (The proof is written in German, and the result is discussed (without proof) in two survey papers written in English [13, 14].)

THEOREM 2.3 (see Mader [12]). *A 3-critical graph with vertex connectivity k has fewer than $6k^2$ vertices.*

3. The algorithm and its analysis. The algorithm starts with $i := 1$ and a minimum-cost spanning tree H_1. Each iteration $i = 1, 2, \ldots$, augments H_i to H_{i+1} by adding edges from $E(G) - E(H_i)$ such that the vertex connectivity increases by at least one, and the "augmenting cost" $c(H_{i+1}) - c(H_i)$ is approximately minimum. A detailed description of an iteration follows. Let $\ell = \kappa(H_i)$. If $\ell = k$, then we stop and output H_i as the desired k-VCSS. Now, suppose $\ell < k$. For each edge in H_i, we change the cost to zero (the other edges keep the original costs). By Mader's theorem (and the fact that n is at least $6k^2$), there exist three vertices such that no ℓ-separator of H_i contains all three vertices. We find three such vertices r_1, r_2, r_3 by exhaustively checking for each vertex set S of cardinality three whether $\kappa(H_i - S) > \ell - 3$. For each of these three vertices, we apply the Frank–Tardos algorithm with root r_j ($j = 1$, 2, or 3) and the modified edge costs to find a supergraph $H_{i,j}$ of H_i that is $(\ell + 1)$-outconnected from r_j. We take (the edge set of) H_{i+1} to be the union of (the edge

sets of) $H_{i,1}$, $H_{i,2}$, and $H_{i,3}$.

LEMMA 3.1. *At every iteration $i = 1, 2, \ldots$, we have $\kappa(H_{i+1}) \geq \kappa(H_i) + 1$.*

Proof. Let $\ell = \kappa(H_i)$. Note that $\ell < k$. Suppose that $\kappa(H_{i+1}) = \ell$. Then H_{i+1} has an ℓ-separator C, $C \subset V$. Now, H_i is not 3-critical by Mader's theorem, since $n \geq 6k^2 > 6\ell^2$. Hence, there exist three vertices in H_i such that for each ℓ-separator of H_i, at least one of these three vertices is absent from the ℓ-separator. The algorithm finds three such vertices r_1, r_2, r_3. Without loss of generality, r_1 is absent from C. The graph $H_{i,1}$, which is a subgraph of H_{i+1}, is $(\ell+1)$-outconnected from r_1. Hence H_{i+1} has $(\ell+1)$ openly disjoint paths between r_1 and v, for every other vertex v, and one of these paths survives in $H_{i+1} - C$. We have a contradiction, since $H_{i+1} - C$ is connected. The lemma follows. □

LEMMA 3.2. *At every iteration $i = 1, 2, \ldots$, we have $c(H_{i+1}) - c(H_i) \leq \frac{6z(k)}{k-\ell}$, where $\ell = \kappa(H_i)$.*

Proof. Note that $\ell < k$. We will prove that for each of the three supergraphs $H_{i,j}$ ($j = 1$, 2, or 3) of H_i, the augmenting cost $c(H_{i,j}) - c(H_i)$ is at most $2z(k)/(k-\ell)$. Then the lemma follows immediately.

Let $\boldsymbol{x} : E \to \mathbb{R}_+$ be an optimal solution to the LP $P(k)$; note that the cost of $\boldsymbol{x}$ (with respect to the original edge costs c) is $z(k)$.

Recall that (during the construction of $H_{i,j}$, $j = 1, 2, 3$) the edge costs are modified such that an edge already in H_i has zero cost, while the other edges have the original costs. Let $\boldsymbol{x'} : E \to \mathbb{R}_+$ be given by

$$x'_e = \begin{cases} 1 & \text{if } e \text{ is in } H_i, \\ \dfrac{x_e}{k-\ell} & \text{otherwise.} \end{cases}$$

Clearly, $\boldsymbol{x'}$ has modified cost at most $z(k)/(k-\ell)$. We claim that $\boldsymbol{x'}$ is a feasible solution to the LP $P(\ell+1)$. Then, by Theorem 2.2, the Frank–Tardos algorithm finds an $(\ell+1)$-outconnected supergraph of H_i with augmenting cost at most $2z(k)/(k-\ell)$.

To see the claim, consider any setpair $W \in \mathcal{S}$ and its constraint in the LP $P(\ell+1)$,

$$\sum_{e \in \delta(W)} x'_e \geq (\ell+1) - q,$$

where $q = n - |W_t \cup W_h|$. First, suppose that H_i has no edges in $\delta(W)$. Then since H_i is ℓ-vertex connected, we have $q \geq \ell$. If $q \geq \ell + 1$, then, obviously, $\boldsymbol{x'}$ satisfies this constraint. Otherwise, if $q = \ell$, then $\boldsymbol{x'}$ satisfies this constraint because (i) $\boldsymbol{x}$ satisfies the constraint of W in the LP $P(k)$, namely, $\sum_{e \in \delta(W)} x_e \geq k - \ell$, and (ii) each edge $e \in \delta(W)$ has $x'_e = x_e/(k-\ell)$. Now, suppose that H_i has $p \geq 1$ edges in $\delta(W)$. If $p < (\ell+1) - q$, then delete $\leq p$ vertices from W_t and W_h to obtain a new setpair $\hat{W}$ such that $\hat{W}_t \neq \emptyset \neq \hat{W}_h$ and H_i has no edges in $\delta(\hat{W})$, and then apply the previous reasoning to $\hat{W}$ to infer that $\boldsymbol{x'}$ satisfies the constraint of $\hat{W}$ and hence also of W. If $p \geq (\ell+1) - q$, then $\sum_{e \in \delta(W)} x'_e \geq |E(H_i) \cap \delta(W)| = p \geq (\ell+1) - q$. Thus the claim holds. □

THEOREM 3.3. *Suppose that the input graph $G = (V, E)$ is k-vertex connected and has order $|V| \geq 6k^2$. Then the algorithm terminates with a k-VCSS that has cost at most $6(1 + \frac{1}{2} + \frac{1}{3} + \ldots + \frac{1}{k})z(k)$, where $z(k)$ is the optimal value of the LP relaxation. The algorithm runs in time $O(k^2 n^4 (n + k^{2.5}))$.*

Proof. The vertex connectivity of H_i increases by at least one in every iteration, starting from one, so the algorithm terminates with a k-VCSS in at most $k - 1$

iterations. The cost of the k-VCSS is

$$\leq c(H_1) + \sum_{i=1}^{k-1}(c(H_{i+1}) - c(H_i)) \leq \frac{2z(k)}{k} + \sum_{\ell=1}^{k-1}\frac{6z(k)}{k-\ell}$$
$$\leq 6\left(1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{k}\right) z(k).$$

(Note that the minimum spanning tree H_1 is an optimal solution to the mincost 1-OC problem (with any vertex as the root), and an optimal solution $\boldsymbol{x}$ of the LP $P(k)$ gives a feasible solution $\frac{1}{k}\boldsymbol{x}$ of the LP $P(1)$; hence by the proof of Theorem 2.2, $c(H_1) \leq 2z(1) \leq \frac{2z(k)}{k}$.)

To see the running time, note that each iteration i $(1 \leq i < k)$ runs the Frank–Tardos algorithm at most three times and tests $\kappa(H_i - S)$ for at most n^3 sets of vertices S of cardinality three. Gabow's algorithm [7] tests the vertex connectivity κ in time $O((n + \kappa^{2.5}) \cdot \kappa n)$, and there is a version of the Frank–Tardos algorithm, due to Gabow, that runs in time $O(k^2 n^2 |E|)$ [6, Theorem 4.5]. □

Acknowledgment. We thank Zeev Nutov for several discussions.

TREE PATTERN MATCHING TO SUBSET MATCHING IN LINEAR TIME*

RICHARD COLE† AND RAMESH HARIHARAN‡

Abstract. In this paper, we show an $O(n+m)$ time Turing reduction from the tree pattern matching problem to another problem called the *subset matching* problem. Subsequent works have given efficient deterministic and randomized algorithms for the subset matching problem. Together, these works yield an $O\left(n\log^2 m+m\right)$ time deterministic algorithm and an $O(n\log n+m)$ time Monte Carlo algorithm for the tree pattern matching problem.

Key words. tree pattern matching, subset matching

1. Introduction.

In the tree pattern matching problem, the text and the pattern are ordered, binary trees, and all occurrences of the pattern in the text are sought. Here, the pattern occurs at a particular text position if placing the pattern with root at that text position leads to a situation in which each pattern node overlaps some text node. This problem has a number of applications (see [6]). Actually, in these applications, the tree need not be binary and the edges may be labelled; however, as shown in [4], this general problem can be converted to a problem on binary trees with unlabelled edges but with a blow-up in size proportional to the logarithm of the size of the pattern. In fact, this blow-up can also be avoided in our approach, as we will indicate in our description.

The naive algorithm for tree pattern matching takes time $O(nm)$, where n is the text size and m is the pattern size. Hoffman and O'Donell [6] gave another algorithm with the same worst case bound. This algorithm decomposes the pattern into strings, each string representing a root-to-leaf path. It then finds all occurrences of each of these strings in the text tree. The first $o(nm)$ algorithm was obtained by Kosaraju [9], who first noticed the connection of the tree pattern matching problem to the problem of string matching with don't-cares and the problem of convolving two strings. Kosaraju's algorithm takes $O(nm^{.75}\log m)$ time. Dubiner, Galil, and Magen [4] improved Kosaraju's algorithm by discovering and exploiting periodicities in paths in the pattern. They obtained a bound of $O(nm^{.5}\log m)$. This was the best bound known to date. Dubiner, Galil, and Magen also made the observation that the naive algorithm actually takes $O(nh)$ time, where h is the height of the pattern.

In this paper, we show how to reduce the tree pattern matching problem to the *subset matching* problem in linear time. The subset matching problem is to find all

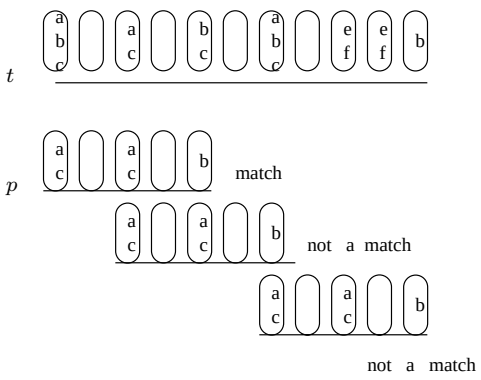

FIG. 1. *Example of subset matching.*

occurrences of a pattern string p of length m in a text string t of length n, where each pattern and text location is a set of characters drawn from some alphabet. The pattern is said to occur at text position i if the set $p[j]$ is a subset of the set $t[i+j-1]$ for all j, $1 \leq j \leq m$. It is required to find all text locations at which the pattern matches; i.e., each pattern set is a subset of the aligned text set (see Figure 1).

The reduction from tree pattern matching to subset matching proceeds in two steps.

• We show that the general tree pattern matching problem can be reduced to the following special case, called *spine pattern matching*, by a linear time Turing reduction. In spine pattern matching, there is a special path in each of the pattern and text called their spines. The spine begins at the root of its tree, and in addition each node on the spine has at most one nonspine child. Spines have additional properties as well, which will be described later. All matches of the pattern in the text are sought with the additional restriction that the spine of the pattern must match a portion of the spine of the text; i.e., nodes on the pattern spine must be aligned with nodes on the text spine. For intuition, one can think of the spine as being the path of left children starting at the root (and in fact one can reduce the general problem to this case in linear time, although we will not do so).

The above reduction may create several instances of the spine pattern matching problem, but the sum of the sizes of these instances will be linear. This reduction is completely deterministic. It proceeds by using the periodicity structure of paths and by decomposing the text tree into periodic paths in a nontrivial manner. Each path then gives a spine for the spine pattern matching problem.

• Next, we reduce the spine pattern matching problem to the subset matching problem in linear time. This is, in fact, readily done. The spine of the text tree gives the text string for the subset matching problem; the subtrees hanging from this spine determine the various text sets. Analogous facts hold for the pattern.

The two reductions above imply that the tree pattern matching problem can be reduced to several instances of the subset matching problem, the sum of the sizes of these instances being linear. Therefore, an algorithm for the subset matching problem yields an algorithm for the tree pattern matching problem with the same time complexity.

Cole and Hariharan [1] gave a randomized algorithm for the subset matching problem running in time $O((n+s)\log^3 m)$, where s is the sum of the sizes of all

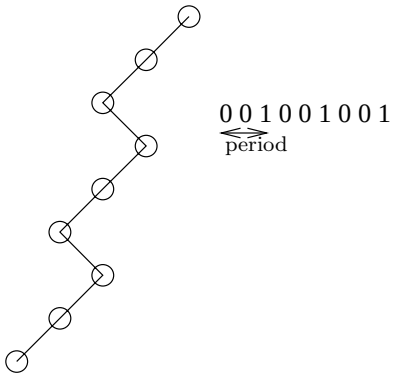

FIG. 2. *A path and its associated string.*

the pattern and text sets. Subsequently, Indyk [7] gave a deterministic algorithm for the subset matching problem running in time $O((n+s)m^{\sqrt{\frac{\log\log m}{\log m}}(1+o(1))})$. Later, Cole, Hariharan, and Indyk [3] gave a deterministic algorithm running in time $O((n+s)\log^3 m)$ and a randomized algorithm running in time $O((n+s)\frac{\log^3 m}{\log\log m})$. Indyk [8] also gave a randomized Monte Carlo algorithm with running time $O(cn\log n)$ and failure probability $O(1/n^c)$ for any fixed constant $c \geq 1$. Finally, Cole and Hariharan [2] gave a deterministic algorithm running in time $O(n\log^2 m)$. It follows that there is a deterministic algorithm running in time $O(n\log^2 m)$ and a Monte Carlo randomized algorithm running in time $O(n\log n)$ for the tree pattern matching problem.

This paper is organized as follows. Section 2 gives some required definitions. Section 3 describes the reduction of the spine pattern matching problem to the subset matching problem. Section 4 describes the reduction from the tree pattern matching problem to the spine pattern matching problem.

2. Definitions.

DEFINITION 2.1 (tree pattern matching). *We consider ordered binary trees; i.e., each internal node has a left and/or a right child. The text tree t has n nodes and the pattern tree p has m nodes. The problem entails finding all nodes v in t where p matches; i.e., when the root of p is aligned with v, each node in p is aligned with a node in t.*

DEFINITION 2.2 (paths, strings, and periods). *Note that paths in trees p and t can be expressed as strings over a two character alphabet, one character signifying a left edge and the other a right edge (see Figure* 2: 0 *represents a left edge and* 1 *a right edge). The* period *of a string $s[1\ldots|s|]$ is the smallest number $j > 0$ such that $s[i] = s[i+j]$ for all i, $1 \leq i \leq |s| - j$. If no such j exists, then the period of s is defined to be $|s|$. The* period *of a path is defined to be the period of its associated string.*

It is well known that the period can be computed in linear time [5]. The following lemma is classical [10].

LEMMA 2.3. *If $k \leq |s| - j$ is such that the period j of s does not divide k, then the string $s[k+1\ldots k+j]$ differs from the string $s[1\ldots j]$.*

DEFINITION 2.4 (spine pattern matching). *This is a restricted version of the tree pattern matching problem. In this problem, the text and the pattern each have one designated path, called their* spines. *The text and pattern spines originate at their*

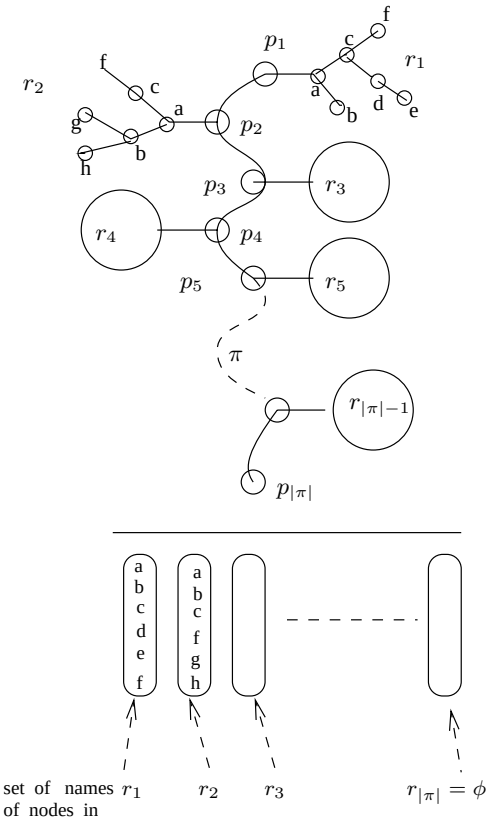

FIG. 3. *The spine and its associated set string.*

respective roots and are maximal paths having the same period, θ say (the θ needed for tree pattern matching will be determined later). If the input does not have this form, it is not a legitimate input for this problem. In fact, both spines when represented as strings will have the form $x^k x'$, where $|x| = \theta$ and x' is a prefix of x (here, the values of k and x' could differ for the pattern spine and the text spine, but x is identical for both spines). All matches of the pattern in which the pattern spine falls completely on the text spine are sought.

From maximality, it follows that both spines terminate at nodes with at most one child (a child which when added to the spine destroys its periodic structure). Since both spines have the same period θ, it follows that the pattern spine will fall completely on the text spine only if the root of the pattern is placed at certain nodes on the text spine. These nodes will occur at integer multiples of θ from the text root and will be designated "anchor nodes."

3. Reducing spine pattern matching to subset matching. The spines of the pattern p and the text t will define the strings for the subset matching problem. The subsets at each location in these strings will correspond to the off-spine subtrees of the spine nodes; an *off-spine subtree* is a subtree whose root is a nonspine node but the parent of whose root is on the spine. These subsets are obtained by labelling the nodes of the off-spine subtrees as follows (see Figure 3). The key fact about this labelling is that two nodes in two distinct off-spine subtrees (both of which could be

in the pattern or in the text, or, alternatively, one could be in the pattern and the other in the text) get the same label if and only if the paths from these nodes to the roots of their respective off-spine subtrees represent identical strings.

The off-spine subtrees of p are labelled first. The subtrees are overlaid to form a *combined pattern subtree*; the overlaying aligns the roots of the off-spine subtrees and recursively overlays their subtrees. Then the combined pattern subtree is traversed by any convenient method, e.g., a breadth first traversal, and the nodes are labelled by the associated numbering. For each spine node, we form a subset consisting of the collection of numbers labelling the nodes of its off-spine subtree. This collection of subsets defines the pattern for the subset matching problem instance. The off-spine subtrees of t are labelled using the same labelling. To do this, each off-spine text subtree and the combined pattern subtree are traversed in lock-step. Consider the text subtree laid over the combined pattern subtree. Clearly, any text node that lies beyond the combined pattern subtree will not be part of any match in which the pattern spine is aligned with a portion of the text spline. Consequently, these text nodes need not be and are not given labels, and indeed need not be and are not traversal. As a result, we have the following easy fact about the time complexity of the above computation.

FACT 1. *The labels to nodes in off-spine subtrees of the pattern can be given in* $O(m)$ *time. The labels to any one off-spine subtree* t' *in the text can be given in time* $O(\min\{|t'|, m\})$. *The total time taken for the labelling is thus* $O(n+m)$*; consequently, the size of the resulting subset matching problem is also* $O(n+m)$.

Recall our remark from the introduction that the case of larger degree and labelled trees can be handled without any extra overhead. Larger degree is simply handled by the usual binarization. Labelled trees are handled by pairing the given labels with the labels obtained here.

Clearly, there is a match in the subset matching problem beginning at a location corresponding to an anchor node if and only if there is a match in the spine pattern matching problem with the pattern tree root aligned with the corresponding anchor node. This completes the reduction from spine pattern matching to subset matching.

4. Reducing tree pattern matching to one or more instances of spine pattern matching. Consider two matches of the pattern with the text in which the pattern instances overlap in $m/2$ or more locations. To avoid checking such matches independently, we seek to have the roots of both pattern instances lie on the same instance of a spine obtained from t.

DEFINITION 4.1. *The* size *of a node* v *in a tree is defined to be the number of nodes in the subtree rooted at* v. *Let* t_v *denote the subtree of* t *rooted at a node* v *in* t, *and let* p_v *denote the subtree of* p *rooted at a node* v *in* p.

4.1. Processing the pattern. We define the spine π of the pattern p to be the following path from the root to a node with at most one child. π consists of two segments, π_1 and π_2. π_1 is a centroid path; i.e., it is obtained by moving to the child with larger size at each step, with ties broken arbitrarily. π_1 ends when a node x such that $|p_x| \leq \frac{m}{2}$ is reached. Note that $|p_x| \geq \frac{m}{4}$. Let θ be the period of π_1. π_2 is the longest path starting at x such that the path π continues to have period θ. Note that π_2 has a vertex in common with π_1. π is readily computed in linear time. π_1 is terminated at x rather than at a node with at most one child to guarantee an overall linear-sized construction.

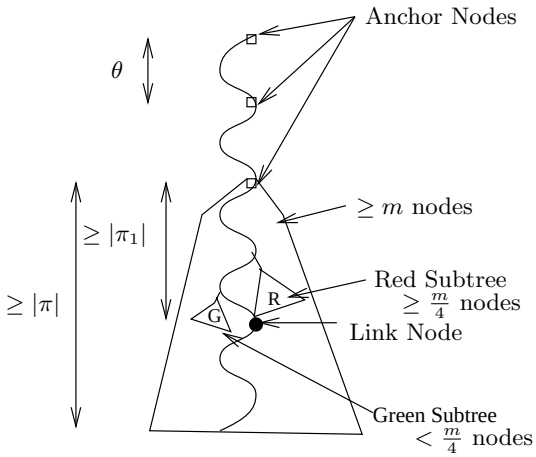

FIG. 4. *A θ-Path in C.*

4.2. Decomposing the text.

DEFINITION 4.2 (see Figure 4). *A path in t from a node u to a node v in t_u is a* θ-path *if it has period θ and is identical to the spine of the pattern in the first θ locations (when both paths are viewed as strings). This path is* maximal *if extending it to the distance θ ancestor of u or either child of v results in a path which is not a θ-path (in fact, v can have only one child). These paths are the candidate spline paths in the text, but we need to impose some further restrictions. Continuing with the definitions, the* link *node l in this path is the node closest to v such that $|t_l| \geq \frac{m}{4}$. An* anchor *node on this path is a node at distance an integer multiple of θ from the start node. The strong* anchor *nodes w on this path also satisfy the following properties. As we will see, matches occur only when the pattern root is aligned with a strong anchor node.*

1. *t_w has at least m nodes.*
2. *The distance from w to l is at least $|\pi_1|$, and thus has length at least θ.*
3. *The distance from w to v is at least $|\pi|$.*
4. *Consider the subtrees hanging from the maximal θ-*path *starting at w. Classify them as* red *subtrees if they have at least $\frac{m}{4}$ nodes and as* green *subtrees otherwise. If all these subtrees except exactly one are green, then the green subtrees plus the path together have at least $m/2$ nodes.*
5. *Either $u = w$ or the distance from u to w is an integer multiple of θ.*

We form a collection C of maximal θ-paths in t, whose start nodes are strong anchor nodes; i.e., they satisfy properties 1–5 above.

Clearly, if any of properties 1–3 or 5 do not hold, there cannot be a match with p's root aligned with w. To see the need for property (4) we argue as follows. Consider a match of p in which at most one of the off-spine subtrees R in t is red. As the spine of p does not match any nodes in R, the subtree of p matching R has size less than $m/2$. Consequently, the remainder of p, of size at least $m/2$, matches the aligned spine portion in t and its green subtrees, which therefore have combined size at least $m/2$.

Note that the paths in C need not be disjoint; however, their combined length will still be $O(n)$, as we shall show later in Lemma 5.18.

The algorithm for constructing these paths is given next.

The path decomposition algorithm. The decomposition is obtained using the following algorithm. For each node x in T, this algorithm first determines the longest θ-path which begins at x. This is done in $O(n)$ time using a Knuth–Morris–Pratt-type automaton in conjunction with a depth-first traversal of t as in the algorithm of Hoffman and O'Donell [6]. Next, the algorithm determines those maximal θ-paths found above which satisfy properties 1–4, discarding all other paths. To this end, it computes the size of each subtree, which allows property 1 to be tested. Properties 2–4 are readily tested by means of a subsequent traversal of each path. It will also be useful to determine, for each such maximal θ-path, whether the node at distance θ from the start of the path is also a strong anchor node. Since, as we will see, the sum of the length of paths in C is $O(n)$, the total time taken above is $O(n)$.

Thus determining matches of p at strong anchor nodes on paths in C suffices to determine all matches of p in t. Further, note that when p is placed with its root at a strong anchor node on some path in C, the spine of p lies completely on that path.

4.3. Processing paths in C. The purpose of processing a path $\rho \in C$ is to determine whether or not p matches at w for each anchor node w on ρ. Each path ρ in C will be processed as follows.

Let u be the node at which ρ starts. u itself is a strong anchor node. Whether or not the pattern matches at u is determined in a brute force manner. This requires $O(m)$ time. We will show in Lemma 5.17 that there are $O(n/m)$ paths, and hence the total time taken over all paths in this process is just $O(n)$.

Matches at other strong anchor nodes on ρ are determined differently, i.e., by reduction to an instance of the spine pattern matching problem.

Consider the portion of ρ starting from the second anchor node onwards, denoted $trunc(\rho)$. If $trunc(\rho)$ starts with a strong anchor node, it provides the spine of the text instance. Clearly, there is a match of p rooted at an anchor node on $trunc(\rho)$ if and only if there is a match at the same location in the corresponding spine pattern matching problem instance.

This concludes the reduction.

5. The analysis. Let $s_1, \ldots, s_{|\rho|-\theta}$ denote the off-spine subtrees, if any, for $trunc(\rho)$, in increasing order of distance from the start node of ρ. Some of the s_i's might not exist. By Fact 1, reducing this instance of the spine pattern matching problem to the subset matching problem takes time $O(\sum_{i=1}^{|\rho|-\theta} \min\{|s_i|, m\} + |\rho| - \theta)$ (plus, of course, $O(m)$ time for processing the pattern, which is common to all the instances of the spine pattern matching problem which result above); also, it yields a text of size $O(\sum_{i=1}^{|\rho|-\theta} \min\{|s_i|, m\} + |\rho| - \theta)$ and a pattern of size $O(m)$.

The total time taken to process ρ is thus $O(m + \sum_{i=1}^{|\rho|-\theta} \min\{|s_i|, m\} + |\rho| - \theta)$. This quantity can be split into four parts: $O(m)$ time for checking for an occurrence of p at the first anchor node, time proportional to its size for each green subtree hanging from $trunc(\rho)$, $O(m)$ time for each red subtree hanging from $trunc(\rho)$, and $O(|\rho| - \theta)$ time for the path itself. We need to show that this sums to $O(n)$ over all paths ρ. By Lemma 5.17, there are $O(n/m)$ paths; hence the first part sums to $O(n)$ time. By Corollary 5.3, the green subtrees in the truncated paths are disjoint; hence the second part sums to $O(n)$. By Lemma 5.8, there are $O(n/m)$ red subtrees; hence the third part sums to $O(n)$. Finally, by Corollary 5.2, the truncated path lengths sum to $O(n)$, and hence the fourth part sums to $O(n)$ also. This yields $O(n)$ time overall. The same argument shows the resulting subset matching problems have texts of total size $O(n)$; also, they each have the same pattern of size $O(m)$.

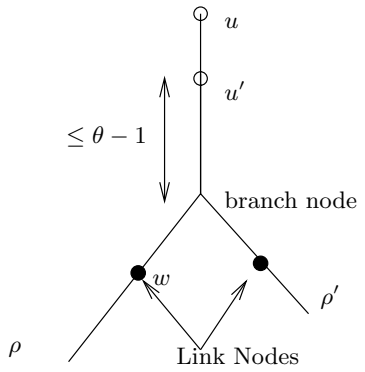

FIG. 5. *Overlap is at most* $\theta - 1$.

5.1. Showing $O(n)$ time.

5.1.1. Some properties of paths in C.

LEMMA 5.1. *Consider two paths* ρ, ρ' *in* C *starting at nodes* u *and* u'*, respectively (see Figure* 5*). Suppose* u' *lies on* ρ*. Then at most the first* $\theta - 1$ *edges of* ρ' *are also present in* ρ*.*

Proof. From the construction of C, the length of the path between u and u' is not divisible by θ. The lemma then follows from Lemma 2.3. ∎

COROLLARY 5.2. *If the first* θ *edges are removed from each path in* C*, then the resulting collection of paths is node disjoint. Hence the truncated paths have total lengths* $O(n)$*. Also, as the link node is not among the first* θ *nodes by property* 2 *of paths in* C*, the link node of* ρ' *cannot lie on* ρ*.*

COROLLARY 5.3. *The green subtrees hanging from the truncated paths are all disjoint.*

Proof. It suffices to consider the green subtrees hanging from two paths $\rho, \rho' \in C$, starting at u, u', respectively, where u is a proper ancestor of u' (for if u and u' are unrelated, then clearly the green trees hanging from ρ and ρ' are disjoint). By Corollary 5.2, $trunc(\rho)$ and $trunc(\rho')$ are disjoint. For a contradiction, suppose that G is a green subtree hanging from $trunc(\rho)$ and containing v, a node in a green subtree hanging from $trunc(\rho')$. It follows from Lemma 5.1 that $trunc(\rho')$ lies within G. But $trunc(\rho')$ includes the first anchor node w' on ρ', and the subtree of t rooted at w' contains at least m nodes. Then G, which contains this subtree, would be red. ∎

LEMMA 5.4. *Let* ρ, ρ' *be as in Lemma* 5.1 *(see Figure* 5*). Then* ρ' *cannot overlap a node in* ρ *which is a proper descendant of* ρ*'s link node* w*. Therefore, if* ρ' *overlaps the link node* w *of* ρ*, then it branches away from* ρ *at* w*.*

Proof. By Corollary 5.2, the link node l' of ρ' is not on ρ. If ρ' overlaps a node w' in ρ which is a proper descendant of w, then $|t_{w'}| \geq |t_{l'}| \geq \frac{m}{4}$, and therefore w cannot be the link node of ρ, a contradiction. ∎

LEMMA 5.5. *Let* ρ*,* ρ'*, and* ρ'' *be three paths whose start nodes appear in this order on the path from the root of* t *to the start node of* ρ''*. Suppose that* ρ'' *overlaps* ρ'*'s link node, and suppose that* ρ' *shares at least one edge with* ρ*. Then* ρ *and* ρ'' *do not overlap.*

Proof. Suppose, for a contradiction, that ρ and ρ'' overlap. Consider the portion q of ρ' up to the start node of ρ''. By assumption, q lies entirely on ρ, and thus by Lemma 5.1, $|q| \leq \theta - 1$. But q is a period of the portion of ρ' from its start node

to its link node, as can be seen by considering the overlap of ρ' with ρ''. Further, this portion of ρ' has π_1 as a prefix, and as $|\pi_1| \geq \theta$, q would also be a period of π_1, contrary to the definition of θ. □

5.1.2. Bounding the number of red subtrees. We bound the number of red subtrees hanging from the truncated paths in C by associating them in part with a set of $O(n/m)$ nodes of t, called *marked* nodes. A path with k red subtrees will have $k-1$ marked nodes.

DEFINITION 5.6. *A node in t is marked if its left and right subtrees both contain at least $\frac{m}{4}$ nodes.*

LEMMA 5.7. *The number of marked nodes in t is $O(\frac{n}{m})$.*

Proof. Each subtree of $m/4$ or more unmarked nodes is contracted to a single unmarked leaf if its parent is marked. Each maximal subtree of unmarked nodes whose parent is unmarked is discarded. Finally, maximal paths of unmarked nodes are replaced by single edges. This reduces the original tree to a new tree in which all internal nodes are marked and correspond one to one to the original marked nodes, and all leaves are unmarked, each corresponding to $m/4$ or more distinct unmarked nodes in t. Further, each internal node has two children. Thus, as there are at most $4n/m$ leaves, there are fewer than $4n/m$ internal nodes. □

LEMMA 5.8. *There are $O(n/m)$ red subtrees hanging from truncated paths whose first node is a strong anchor.*

Proof. Suppose strongly anchored truncated path ρ has $k > 1$ red subtrees hanging from it. Such a path has $k-1$ marked nodes (namely the *lcas* of the red subtree roots). By Corollary 5.3, as these truncated paths are disjoint, and by Lemma 5.7, as there are $O(n/m)$ marked nodes, there can be only $O(n/m)$ anchored truncated paths with two or more red subtrees.

If a strongly anchored truncated path has only one red subtree then by property 4 of the paths, the path together with its green subtrees contains at least $m/2$ nodes. This is also true if it has no red subtrees. By Corollaries 5.2 and 5.3, the paths and their green subtrees are disjoint from each other. Consequently, there are only $O(n/m)$ such paths. □

5.1.3. Bounding the number of paths. It remains to bound the number of paths. To this end, we form suitable collections of paths.

Consider the following procedure for forming collections of paths. A collection starts with a path $\tilde{\rho}$ whose start node is not overlapped by any other path; $\tilde{\rho}$ is called the *root* path of the collection. The collection is built up by iterating the following step. For each path ρ in the collection, every path ρ', whose start node is on ρ but which does not overlap the link node of any other path, is added to the collection. Call these level 1 collections. Level $i+1$ collections are formed in the same way from paths not in any level h collection, $h \leq i$, and ignoring overlaps with paths in level h collections, $h \leq i$.

We will show that there are $O(n/m)$ paths in the collections containing two or more paths. We will then characterize the one path collections and show that they too contain $O(n/m)$ paths.

DEFINITION 5.9. *The* point of attachment *for a level $i+1$ collection C, $i \geq 1$, is defined in terms of C's root path ρ and the parent $\tilde{\rho}$ whose link node $\tilde{l}$ is overlapped by ρ; the point of attachment for C is link node $\tilde{l}$.*

DEFINITION 5.10. *The tree for collection C is the tree formed by the edges on its paths. The reduced tree for collection C is the subtree of its tree rooted at its point of attachment.*

LEMMA 5.11. *Each node in the tree for collection C on the path from the tree's root to its attachment point has a single child.*

Proof. Let $\tilde{C}$ be the collection containing $\tilde{\rho}$, the path whose link node is overlapped by ρ, the root path of C. Suppose, for a contradiction, that ρ' were a path in C, with start node on ρ and which branches away from ρ at or before C's point of attachment. We argue that ρ' would in fact have been added to $\tilde{C}$. Clearly, ρ''s start node lies on $\tilde{\rho}$. By assumption, ρ' does not branch away from $\tilde{\rho}$ at its link node $\tilde{l}$; hence by Lemma 5.4, it branches away before. If ρ' overlapped the link node of another path in $\tilde{C}$, then $\tilde{\rho}$ would overlap this link node too, which is not the case. Thus ρ' can be added to $\tilde{C}$, and so would not be in C, a contradiction. □

LEMMA 5.12. *Let C be a level $i+1$ collection, $i \geq 1$, ρ its root path, $\tilde{\rho}$ the path whose link node is overlapped by ρ, and $\tilde{C}$ the collection containing $\tilde{\rho}$. Then every path overlapping $\tilde{\rho}$'s link node is in C.*

Proof. By Lemma 5.5, if ρ and ρ' both overlap $\tilde{\rho}$'s link node, they do not overlap each other's link nodes. Thus they would both be added to C. □

LEMMA 5.13. *The reduced trees for the collections are disjoint.*

Proof. Without loss of generality, suppose that all the paths are connected (otherwise consider each connected component of paths separately). We will prove that not only are the reduced trees disjoint but that for each i, the reduced trees for level i collections are unrelated (for short the level i reduced trees); i.e., no tree is ancestral to another. The proof is by induction on i, the collection level. Clearly, the trees for level 1 collections are disjoint and unrelated. Now suppose that the reduced trees for each level h collection, $h \leq i$, are all disjoint and that the level i reduced trees are unrelated. Then the link nodes appearing in the level i reduced trees are also unrelated, for each link node appears on only one path in a collection. By construction, the root path of each level $i+1$ collection overlaps the link node of a path in a level i collection. By Lemma 5.12, each such root path overlaps a distinct link node, and thus the level $i+1$ reduced trees are disjoint from each other and are unrelated. □

LEMMA 5.14. *Each collection of $k > 1$ paths has its own $k-1$ distinct marked nodes.*

Proof. The marked nodes for a collection C of k paths are simply the least common ancestors (LCAs) of the link nodes for these paths. As t is binary, and these k link nodes are distinct, there are $k-1$ LCAs. Each LCA has a link node in each of its two subtrees, and consequently each LCA is marked. Finally, Lemma 5.11 implies that the LCAs all lie in the reduced tree for C, and as by Lemma 5.13 these reduced trees are disjoint, the marked nodes associated with each collection are distinct. □

COROLLARY 5.15. *There are $O(n/m)$ paths in collections of two or more paths.*

Now consider the paths in collections of size one. These paths form chains of paths in which each successive path overlaps the link node of its predecessor.

LEMMA 5.16. *There are $O(n/m)$ paths in the above chains.*

Proof. Two sets C_e and C_o of paths are formed. C_e comprises every even index path on the chains (the second, fourth, ... paths) and C_e the odd index paths.

By construction, none of the chains overlap. By Lemma 5.5, none of the paths in C_e overlap (apply the lemma to successive paths ρ_{2i}, ρ_{2i+1}, ρ_{2i+2} on a chain), and the same holds for paths in C_o.

Now we argue in a similar way to the proof of Lemma 5.11. There are $O(n/m)$ paths in C_e with one or more marked nodes (as marked nodes on distinct paths must be distinct). The remaining paths on C_e have at most one red subtree each; by property 4, each such path includes between its nodes and those of its green subtrees

at least $m/2$ distinct nodes (i.e. unshared with any other such path). This is a further $O(n/m)$ paths. Thus C_e includes $O(n/m)$ paths. The same is true for C_o. □

We have shown the following lemmas:

LEMMA 5.17. *There are $O(n/m)$ paths.*

LEMMA 5.18. *The paths have total length $O(n)$.*

This leads to the following theorem.

THEOREM 5.19. *There is a linear time reduction from the tree pattern matching problem to a collection of instances of the subset matching problem of overall linear size.*

Proof. This is immediate from Corollary 5.2 and Lemma 5.17. □

6. Further comments. It is not completely clear whether this construction maps unlabelled trees to the set strings as compactly as possible, for ancestral information is lost in the reduction. Indeed, an unlabelled n-node tree can be represented using $O(n)$ bits, whereas a size n set problem in general requires $\Theta(n \log n)$ bits and will do so after our reduction. In general, n labels would require $\Theta(n \log n)$ bits, so it appears the reduction is tight for labelled trees. Thus this raises the question of whether there are algorithms for unlabelled tree pattern matching that are faster by a $\Theta(\log n)$ factor.

Acknowledgment. We thank the referees for their suggestions which helped improve the presentation.

REVISITING TUCKER'S ALGORITHM TO COLOR CIRCULAR ARC GRAPHS*

MARIO VALENCIA-PABON†

Abstract. The circular arc coloring problem consists of finding a minimum coloring of a circular arc family F such that no two intersecting arcs share a color. Let l be the minimum number of circular arcs in F that are needed to cover the circle. Tucker shows in [*SIAM J. Appl. Math.*, 29 (1975), pp. 493–502], that if $l \geq 4$, then $\lfloor \frac{3}{2}L \rfloor$ colors suffice to color F, where L denotes the load of F. We extend Tucker's result by showing that if $l \geq 5$, then $\lceil (\frac{l-1}{l-2})L \rceil$ colors suffice to color F, and this upper bound is tight.

1. Introduction.

The *circular arc coloring problem* consists of finding a minimum coloring of a set of arcs of a circle such that no two intersecting arcs share a color. Applications include the problem of allocating bandwidth in all-optical WDM (wavelength division multiplexing) ring networks [5, 2], compiler design, and scheduling [9].

There are several results on the circular arc coloring problem [1, 9, 4, 6, 7, 3, 5, 2]. Garey et al. [1] have shown that this problem is NP-hard, and Gavril shows in [3] that this problem remains NP-hard for Helly circular arc graphs, a subclass of circular arc graphs. Tucker [9] gave a simple 2-approximation algorithm and conjectured that $\frac{3}{2}\omega(F)$ colors are sufficient to color any family F of arcs, where $\omega(F)$ represents the size of a maximum set of pairwise intersecting arcs in F. Karapetyan [4] shows Tucker's conjecture. Recently, Kumar [5] gave a randomized $(1 + 1/e + o(1))$-approximation algorithm for instances of this problem needing at least $\omega(\ln n)$ colors, where n is the number of arcs to be colored. For special cases of this problem, Orlin, Bonuccelli, and Bovet [6] found a $O(m^2 \ln m)$ algorithm to color a family of m *proper* circular arcs (i.e., no arc is contained in any other). The result of Orlin, Bonuccelli, and Bovet was improved by Shih and Hsu [7], who found a $O(m^{1.5})$ algorithm to color a family of m proper circular arcs. Recently, Gargano and Rescigno [2] show that a family of *hereditary* circular arcs can be optimally colored in polynomial time, and they show that there exists a $\frac{4}{3}$-approximation algorithm to color a larger class of families called *quasi-hereditary* families of arcs.

In this paper we give a tighter analysis of a greedy algorithm proposed by Tucker in [9] to color circular arc graphs.

The organization of the rest of the paper is as follows. In section 2 we give the preliminaries. Section 3 contains a tighter analysis of Tucker's greedy algorithm to color circular arc graphs, and section 4 contains concluding remarks.

2. Preliminaries. Let $F = \{A_1, A_2, \ldots, A_m\}$ be a family of circular arcs, where each A_i represents an open real interval (a_i, b_i) on a circle, with $a_i, b_i \in \mathbb{Z}^+$ and $a_i \neq b_i$. Let n denote the largest integer among all a_i's and b_i's. Then we can regard the circle as being divided into n parts by n equally spaced points numbered clockwise as $1, 2, \ldots, n$, and each $A_i = (a_i, b_i)$ represents the circular arc from point a_i, which we call the beginning point of A_i, to point b_i, which we call the ending point of A_i, in the clockwise direction. We may assume that $n \leq 2m$ (in the worst case, the beginning and ending points of any two arcs in F are different).

Let $\chi(F)$ denote the minimum number of colors needed to color the arcs of F such that no two intersecting arcs share a color, and let $\omega(F)$ denote the size of a maximum set of pairwise intersecting arcs in F. We call the *load* of F, which we denote by $L(F)$, the largest number of arcs containing a common point on the circle. Tucker shows in [9] that $\chi(F)$ verifies $L(F) \leq \chi(F) \leq 2L(F) - 1$. Note that $L(F)$ is not necessarily equal to $\omega(F)$. In [9] some families of arcs for which $\omega(F) = 2L(F) - 1$ are given. Moreover, as $\chi(F) \geq \omega(F)$ holds for any family F of arcs, Karapetyan's result [4] is the best deterministic approximation algorithm known for this problem. We denote by $\mathcal{G}(F)$ the intersection (undirected) graph corresponding to a circular arc family F, which is called a circular arc graph. Tucker [9] gives the following greedy algorithm to properly color a family F of circular arcs.

TUCKER'S ALGORITHM.

1. Pick a point p in the circle such that S_p, the set of arcs in F containing p, has size $L(F)$. Let $A_1 = (a_1, b_1)$ be the arc in S_p that extends the least on the counterclockwise side of p, and let $cmax = 1$. Assign color $cmax$ to arc A_1.
2. For $i = 1, 2, \ldots, |F| - 1$, we move clockwise round and round the circle indexing the arc $A_{i+1} = (a_{i+1}, b_{i+1})$ in $F \setminus \{A_1, A_2, \ldots, A_i\}$ by the following rule: A_{i+1} is the first unindexed arc to begin after the ending point of A_i. Assign color $cmax$ to A_{i+1} unless there exists an arc A_j, $j < i + 1$, already colored with color $cmax$ which intersects A_{i+1}, in which case we color A_{i+1} with color $cmax + 1$ and increment $cmax$.

In Figure 2.1 we show an example of the execution of Tucker's algorithm.

FIG. 2.1. *Example of the execution of Tucker's algorithm.*

DEFINITION 2.1. *Let F be a family of circular arcs. We define the* circular-cover *of F to be the smallest size of any subset of arcs of F needed to cover the circle.*

Using the previous algorithm, Tucker shows the following theorem, which we rephrase in terms of the circular-cover of a family of circular arcs.

THEOREM 2.2 (see Tucker [9]). *Let F be a family of circular arcs with load*

$L = L(F)$. If the circular-cover of F is at least equal to four, then $\lfloor \frac{3}{2}L \rfloor$ colors suffice to color F.

Note that it must often be the case in practical situations that the circular-cover of a family of arcs is significantly greater than four. For instance, consider the task of assigning workers to jobs in a cyclic schedule. The time periods occupied by the jobs are the arcs, the colors assigned to the arcs are the workers, and the constraint that no worker can work on two jobs at once is realized by the constraint that no intersecting arcs can have the same color. The goal is to minimize the number of workers employed. Now, if the durations of the jobs are short compared with the period of the cyclic schedule, then the circular-cover of the corresponding family of arcs will be large. Therefore, in the following section, we analyze the performance of Tucker's greedy algorithm to color circular arc graphs in terms of the circular-cover of the associated family of arcs.

3. Analysis of Tucker's greedy algorithm. In this section we give a detailed analysis of Tucker's algorithm. Our main result is the following theorem, which extends Tucker's given in Theorem 2.2.

THEOREM 3.1. *Let F be a family of circular arcs with load $L = L(F)$. If the circular-cover of F is equal to l, with $l \geq 5$, then $\lceil (\frac{l-1}{l-2})L \rceil$ colors suffice to color F.*

In order to prove Theorem 3.1, we need the following definitions. Let F be a family of circular arcs with load $L(F)$, and assume that we use Tucker's greedy algorithm to color the arcs in F. Let $A_1 = (a_1, b_1)$ be the first arc in F considered by Tucker's algorithm. Let us denote the beginning point of arc A_1 as t. We say that Tucker's algorithm has completed k rounds if the algorithm has traversed the point t $k+1$ times, where arc A_1 counts. We let T_k be the set of arcs colored during the kth round, and we let $F_k = \bigcup_{i=1}^{k} T_i$ be the subfamily of arcs colored until the kth round.

Proof of Theorem 3.1. Let m be the largest integer used in the description of the arcs in F. W.l.o.g. assume that each two consecutive points p and $p+1$ on the circle, $1 \leq p \leq m$, are traversed by exactly L arcs from F. Otherwise, if some two consecutive points p and $p+1$ are traversed by $r < L$ arcs, then we add $L - r$ arcs of the form $(p, p+1)$ (or $(m, 1)$ if $p = m$) to F without changing its colorability. We assume that we use Tucker's algorithm to color the arcs in F, and we proceed by induction on L. If $L = 1$, the result is trivial. Assume that the result holds when $L(F) < L$ for any F and some $L \geq 2$, and we shall prove that the result holds for any F with $L(F) = L$. By hypothesis, the circular-cover l of F verifies $l \geq 5$. Let A_1 be the first arc in F colored by Tucker's algorithm, and let t be the beginning point of arc A_1. For $i = 1, 2, \ldots$, let A_i denote the first arc in F colored i. Thus, considering the way Tucker's algorithm colors the arcs in F, we can deduce the following properties. We prove only Property 3, because Properties 1 and 2 can be easily deduced.

PROPERTY 1. *For each i, $i > 1$, A_i intersects A_{i-1}.*

PROPERTY 2. *For each i, $i \geq 1$, $L(F \setminus F_i) \leq L(F) - i$, where $L(F \setminus F_i)$ is the load induced by the subfamily of arcs $F \setminus F_i$.*

PROPERTY 3. *For each i, $1 \leq i \leq l-2$, Tucker's algorithm uses at most $i+1$ colors to color the arcs in F_i, where l is the circular-cover of the family F.*

Proof of Property 3. We proceed by induction on i. If $i = 1$, the result is trivial. Assume that the result holds for $j < i$, and we will prove that the result holds for $j = i$. Let $i > 1$. Let A_i be the first arc in T_{i-1} colored with color i, and let A_i^f be the last arc in T_{i-1} colored with color i that traverses the point t for the ith time (note that A_i and A_i^f can be the same arc (see Figure 3.1(b)). By induction hypothesis, these arcs exist; otherwise, the number of colors used by the algorithm to color the

arcs in F_{i-1} is at most $i-1$, and the result trivially follows. Now, let A_{i+1} be the first arc in T_i colored with color $i+1$. By Property 1, we have that A_{i+1} intersects A_i. Let A^f_{i+1} be the last arc in T_i that traverses the point t for the $(i+1)$th time. Suppose that A^f_{i+1} cannot be colored with color $i+1$. Thus, by Property 1, we have that A_{i+1} intersects A^f_{i+1}, and so the $i+1$ arcs $A_2, A_3, \ldots, A_i, A_{i+1}, A^f_{i+1}$ cover the circle (see Figure 3.1(c)). However, $i \leq l-2$, which implies that the circular-cover of F is at most $l-1$, which is a contradiction. This ends the proof of this property.

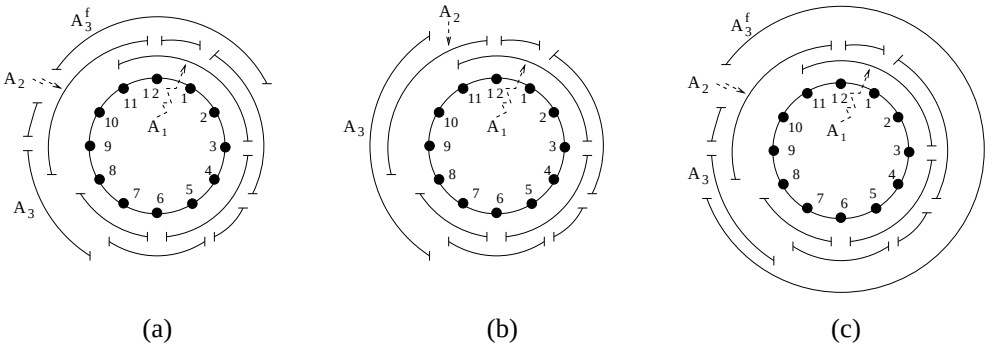

FIG. 3.1. (a), (b) *Examples of possible configurations in the proof of Property* 3 *for* $i = 2$ *and* $l = 7$. (c) *Example of forbidden configuration in the proof of Property* 3 *for* $i = 2$ *and* $l = 7$.

Now, the proof of Theorem 3.1 can be easily deduced from Properties 2 and 3 as follows. By Property 2, we have that $L(F \setminus F_{l-2}) \leq L-(l-2)$ and, by Property 3, we have that Tucker's algorithm uses at most $l-1$ colors to color the arcs in F_{l-2}. Therefore, by induction hypothesis, the theorem holds. □

The following corollary can be deduced directly from Theorem 3.1.

COROLLARY 3.2. *Let F be a family of circular arcs with load $L = L(F)$ on a circle on n points. For all $k \geq 3$, if each arc in F spans at most n/k points of the circle, then the number of colors used by Tucker's algorithm to color F is at most* $\lceil (\frac{k}{k-1})L \rceil$.

It is easy to verify that in the complementary case of Corollary 3.2, i.e., when each circular arc in a family F spans more than half of the points in a circle, the intersection graph of the arcs in F is a complete graph on $|F|$ vertices.

PROPOSITION 3.3. *Let F be a family of circular arcs on a circle. If each arc in F spans more than half of the points in the circle, then F can be optimally colored in linear time.*

The following proposition gives us an idea of the tightness of the upper bound obtained in Theorem 3.1.

PROPOSITION 3.4. *For any odd integer l, $l \geq 3$, and for any even integer L, $L \geq 2$, there exists a family F of circular arcs with load L and circular-cover l such that* $\chi(F) = \lceil (\frac{l}{l-1})L \rceil$.

Proof. In order to prove Proposition 3.4, we use a result of Stahl [8] concerning the *r-tuple* colorings of graphs. An r-tuple coloring of a graph G is an assignment of r distinct colors to each vertex of G in such a manner that no two adjacent vertices share a color. In the special case of a cycle C_l with odd length l, $l \geq 3$, Stahl shows in [8] that the minimum number of colors for an r-tuple coloring of C_l, $r \geq 1$, is equal to $2r+1+\lfloor \frac{2(r-1)}{l-1} \rfloor$. Thus, F is constructed as follows. Let $r = L/2$, and assume that

the vertices of C_l are labeled clockwise by $0, 1, \ldots, l-1$. For all $i = 0, 1, \ldots, l-1$, F contains r copies of the arc $(i, i+2 \mod l)$. By construction, it is easy to verify that if $L = 2$ (and thus $r = 1$), then the intersection graph of the arcs in F is isomorphic to C_l and therefore the circular-cover of F is equal to l. Hence, for any even integer $L = 2r$, with $r \geq 1$, there exists a family F of circular arcs with load L and circular-cover l such that $\chi(F) = 2r + 1 + \lfloor \frac{2r-2}{l-1} \rfloor = L + 1 + \lfloor \frac{L-2}{l-1} \rfloor = \lceil (\frac{l}{l-1})L \rceil$. □

Note that we cannot hope that, for any family F with load L and circular-cover $l \geq 5$, $\lfloor (\frac{l-1}{l-2})L \rfloor$ colors suffice to color the arcs in F. In fact, by Proposition 3.4, we have that any cycle graph C_l with odd length l, $l \geq 5$, can be represented by a family of l arcs with load 2 and circular-cover equal to l. Thus, $\lfloor (\frac{l-1}{l-2})2 \rfloor = 2$, but the chromatic number of C_l is 3. The following proposition shows that there are instances of the circular arc coloring problem where the upper bound in Theorem 3.1 is reached.

PROPOSITION 3.5. *The upper bound in Theorem* 3.1 *is tight.*

Proof. Let C_l be a cycle graph on l vertices, with $l = 2k + 1$ for any positive integer $k \geq 2$. By Proposition 3.4, we have that for all r, $1 \leq r \leq k-1$, an r-tuple coloring of C_l can be represented by a family F of arcs with load $L = 2r$ and circular-cover l. Moreover, the minimum number of colors needed to color F is exactly $2r + 1$. By Theorem 3.1, we have that the arcs in F can be colored using at most $\lceil (\frac{l-1}{l-2})L \rceil = \lceil \frac{4kr}{2k-1} \rceil = \lceil 2r + \frac{2r}{2k-1} \rceil = 2r + 1$ colors. This ends the proof of this proposition. □

Let F be a family of arcs with load $L(F)$. By Property 2 in Theorem 3.1, we have that for each i, $i \geq 1$, the load of the subfamily $F \setminus F_i$ is at most equal to $L(F) - i$. Moreover, for each round i, Tucker's algorithm uses at most two new colors to color the arcs in T_i. Therefore, in the general case (i.e., if the circular-cover l of F verifies $l < 4$), the number of colors used by Tucker's algorithm to color the arcs in F is at most equal to $2L(F)$, and thus it gives a 2-approximation algorithm for the circular arc coloring problem, as noted earlier by Tucker in [9].

4. Conclusion. We have shown a tighter analysis of Tucker's greedy algorithm to color a family of circular arcs. We have proved that Tucker's algorithm is quasi-optimal for families of arcs having a large circular-cover. Our results extend a previous one given by Tucker. An interesting open problem is the complexity of the circular arc coloring problem for families of arcs having bounded spans and unbounded load.

Acknowledgment. The author gratefully acknowledges the helpful comments and suggestions of two anonymous referees.

GENETIC DESIGN OF DRUGS WITHOUT SIDE-EFFECTS*

XIAOTIE DENG†, GUOJUN LI‡, ZIMAO LI§, BIN MA¶, AND LUSHENG WANG†

Abstract. Consider two sets of strings, $\mathcal{B}$ (bad genes) and $\mathcal{G}$ (good genes), as well as two integers d_b and d_g ($d_b \leq d_g$). A frequently occurring problem in computational biology (and other fields) is to find a (distinguishing) substring s of length L that distinguishes the bad strings from good strings, i.e., such that for each string $s_i \in \mathcal{B}$ there exists a length-L substring t_i of s_i with $d(s, t_i) \leq d_b$ (close to bad strings), and for every substring u_i of length L of every string $g_i \in \mathcal{G}$, $d(s, u_i) \geq d_g$ (far from good strings).

We present a polynomial time approximation scheme to settle the problem; i.e., for any constant $\epsilon > 0$, the algorithm finds a string s of length L such that for every $s_i \in \mathcal{B}$ there is a length-L substring t_i of s_i with $d(t_i, s) \leq (1 + \epsilon)d_b$, and for every substring u_i of length L of every $g_i \in \mathcal{G}$, $d(u_i, s) \geq (1 - \epsilon)d_g$ if a solution to the original pair ($d_b \leq d_g$) exists. Since there is a polynomial number of such pairs (d_b, d_g), we can exhaust all the possibilities in polynomial time to find a good approximation required by the corresponding application problems.

1. Introduction.

Research effort in molecular biology, such as the human genome project, has been revealing the secret of our genetic composition, the long DNA sequences that can determine many aspects of life. Applications that use this information have posed new challenges to the design and analysis of efficient computational methods.

A frequently recurring problem in biological applications is to find one substring of length L that appears (with a few substitutions) at least once in each of a set of bad strings (such as bacterial sequences) and is not "close" to any substring of length L in *each* of another set of good strings (such as human and livestock sequences). The problem has various applications in molecular biology such as the design of universal PCR primers, identification of genetic drug targets, and design of genetic probes [8, 2, 12, 5]. In particular, the genetic drug target identification problem searches for a sequence of genes that is close to bad genes (the target) but far from all good genes (to avoid side-effects). Our study develops a polynomial time approximation scheme in both measures simultaneously.

1.1. The mathematical model. The *distinguishing substring selection* problem has as input two sets of strings, $\mathcal{B}$ and $\mathcal{G}$. It is required to find a substring of unspecified length (denoted by L) that is, informally, close to a substring of every string in $\mathcal{B}$ and far away from every length-L substring of strings in $\mathcal{G}$. Since $\mathcal{G}$ can be reconstructed to contain all substrings of length L in each of all the good strings, we can assume that every string in $\mathcal{G}$ has the same length L.

Therefore, here we formally define the problem as follows: Given a set $\mathcal{B} = \{s_1, s_2, \ldots, s_{n_1}\}$ of n_1 (bad) strings of length at least L, a set $\mathcal{G} = \{g_1, g_2, \ldots, g_{n_2}\}$ of n_2 (good) strings of length exactly L, and two integers d_b and d_g ($d_b \leq d_g$), the distinguishing substring selection problem (DSSP) is to find a string s such that for each string $s_i \in \mathcal{B}$ there exists a length-L substring t_i of s_i with $d(s, t_i) \leq d_b$, and for any string $g_i \in \mathcal{G}$, $d(s, g_i) \geq d_g$. Here $d(,)$ represents the Hamming distance between two strings. If all strings in $\mathcal{B}$ are also of the same length L, the problem is called the distinguishing string problem (DSP).

1.2. Previous results. The best previous known approximation ratio for DSSP (and DSP) is 2 [5]. In another direction, many simplified versions were proposed to make the task easier in terms of computation/approximation, conceding more general applicability.

The problem is NP-hard, even when only one objective is to be met [1, 5]. To approximate the center string that is far away from each of the good strings is not difficult and is shown to have a polynomial time approximation scheme by Lanctot et al. [5]. The problem of finding a center string s that is close to all the bad strings is nontrivial, and it has taken intensive investigation by several research groups [5, 3] to finally develop a polynomial time approximation scheme [6].

There are also several modifications and variations on this initial strategy, e.g., the *d-characteristic string* [4], the *far from most string* [5], and the formulation of Ben-Dor et al. [1].

The DSSP problem that contains two objective functions has remained elusive despite the above-mentioned intensive research effort. To meet the requirements of many application problems, however, we would need to have a solution for DSSP.

1.3. Our contribution. In this paper, we settle this difficult problem by presenting a polynomial time approximation scheme in both requirements. If a solution to the original problem exists, for any constant $\epsilon > 0$, our algorithm computes a string s of length L such that for every $s_i \in \mathcal{S}$ there is a length-L substring t_i of s_i with $d(t_i, s) \leq (1 + \epsilon)d_b$, and for every $g_i \in \mathcal{G}$, $d(g_i, s) \geq (1 - \epsilon)d_g$. Here d_b and d_g are two important parameters supplied by users to specify the distances from the distinguishing string s to the set of bad strings and the set of good strings. Our algorithm gives a solution that approximately meets the requirements, i.e., $(1 + \epsilon)d_b$ and $(1 - \epsilon)d_g$, if a solution to the original requirements, i.e., d_b and d_g, exists.

1.4. Sketch of our approach. Design and analysis of good algorithms for approximating multiple objective functions are not simple in general (see [11] for a general approach and related works).

The standard techniques for related center string problems follow a linear program approach combined with randomized rounding. That works for DSP and DSSP when the parameters are sufficiently large. The main difficulty for our problem lies in the case when objective function value is relatively small but still too large for enumeration methods to work.

To overcome this difficulty, we sample a constant number of strings and find the

positions at which the samples have the same letters (bases). We denote this set of positions by Q and the set of the rest by P. Our breakthrough starts with a key lemma that states that there is a set of samples for which there are y positions in Q such that, when we choose the y positions in Q carefully, choose the letters of the rest of $|Q|-y$ positions to be the same as the samples, and choose letters at positions in P by the linear program approach, then we can obtain the right approximate solution.

An interesting case is when $y < O(\log(n))$, i.e., y is small, but not small enough for a brute-force enumeration method to go through directly. A new method is designed to handle this case. Since similar situations occur in many combinatorial optimization problems, we expect that this idea may have wider application.

1.5. Organization of the paper. We focus on the polynomial time approximation scheme for DSP in sections 2 through 4. Section 2 introduces the related notation and the standard integer programming formulation, which works well when both d_b and d_g are large, i.e., at least $\Omega(L)$. Section 3 gives the key lemma. We discuss the methods for finding a good approximation of the set of y positions in Q in section 4.

In section 5, we show that the established algorithm for DSP can be extended to work for the general case, the DSSP. We conclude our work in section 6 with discussion and remarks.

2. Preliminaries. We consider two sets of strings: $\mathcal{G}$ (good strings) and $\mathcal{B}$ (bad strings). We call d_b the *upper* radius for bad strings ($\mathcal{B}$) and d_g the *lower* radius for good strings ($\mathcal{G}$). Let $n = n_1 + n_2$ be the total number of good and bad strings in $\mathcal{G} \cup \mathcal{B}$.

For the DSP, every good or bad string is of the same length L. The distance $d(x, y)$ of two strings x and y is their Hamming distance, i.e., the number of positions at which they differ from each other. We are to find the string x of length L such that

$$\begin{cases} d(s_i, x) \le d_b, \quad s_i \in \mathcal{B}, & i = 1, \ldots, n_1, \\ d(g_j, x) \ge d_g, \quad g_j \in \mathcal{G}, & j = 1, \ldots, n_2. \end{cases} \tag{1}$$

In this section, we present an approximation algorithm that works well for a special case of the DSP. The restriction is that L, d_b, and d_g are large; more specifically, $L \ge (4\log(n_1 + n_2))/\epsilon^2$, $d_g = \Omega(L)$, and $d_b = \Omega(L)$, where ϵ is the parameter controlling the performance ratio and n_1 and n_2 are the numbers of bad and good strings, respectively.

This is achieved via a standard method using integer linear programming. Define $\chi(s, i, k, a) = 0$ if $s_i[k] = a$, and $\chi(s, i, k, a) = 1$ if $s_i[k] \ne a$. Similarly, define $\chi(g, j, k, a) = 0$ if $g_j[k] = a$, and $\chi(g, j, k, a) = 1$ if $g_j[k] \ne a$. The problem becomes the following integer linear programming (LP) problem:

$$\begin{cases} \sum_{a \in \Sigma} x_{k,a} = 1, \quad k = 1, 2, \ldots, L, \\ \sum_{1 \le k \le L} \sum_{a \in \Sigma} \chi(s, i, k, a)\, x_{k,a} \le d_b, \quad i = 1, 2, \ldots, n_1, \\ \sum_{1 \le k \le L} \sum_{a \in \Sigma} \chi(g, j, k, a)\, x_{k,a} \ge d_g, \quad j = 1, 2, \ldots, n_2, \\ x_{k,a} \in \{0, 1\}, \quad a \in \Sigma, \ k = 1, 2, \ldots, L. \end{cases} \tag{2}$$

Let $\bar{x}_{k,a}$ be a solution for LP relaxation of (2). For each $0 \le k \le L$, with probability $\bar{x}_{k,a}$, we set $x_{k,a} = 1$ and set $x_{k,a'} = 0$ for any $a' \ne a$. We choose the random variables independently for different k. This results in an integer solution for (2) (and hence a solution for (1)) if d_b is replaced by $(1 + \epsilon)d_b$ and d_g by $(1 - \epsilon)d_g$, as shown in Theorem 2. Standard derandomization methods [10] transfer it to a

deterministic algorithm in Theorem 3. The following lemma is useful for the proof of Theorem 2.

LEMMA 1. *Let $X_1, X_2, \ldots, X_n$ be n independent random* 0-1 *variables, where X_i takes* 1 *with probability p_i, $0 < p_i < 1$. Let $X = \sum_{i=1}^{n} X_i$ and $\mu = E[X]$. Then for any $0 < \delta \leq 1$, $\mathbf{Pr}(X > \mu + \delta n) < \exp(-\frac{1}{3}n\delta^2)$, and $\mathbf{Pr}(X < \mu - \delta n) \leq \exp(-\frac{1}{2}n\delta^2)$.*

THEOREM 2. *Let $\delta > 0$ be any constant. Suppose that $L \geq (4\log(n_1 + n_2))/\delta^2$, $d_g \geq c_g L$, and $d_b \geq c_b L$. There is a randomized algorithm that finds a solution, i.e., a string x of length L, with high probability such that for each string s_i in $\mathcal{B}$, $d(s_i, x) < (1 + \delta/c_b)d_b$, and for any string g_j in $\mathcal{G}$, $d(g_j, x) > (1 - \delta/c_g)d_g$.*

Proof. We can see that $\sum_{a\in\Sigma} \chi(s, i, k, a)\, x_{k,a}$ and $\sum_{a\in\Sigma} \chi(g, j, k, a)\, x_{k,a}$ take 1 or 0 randomly and independently for different k's. Thus we have that $d(s, i, x) = \sum_{1\leq k\leq L} \sum_{a\in\Sigma} \chi(s, i, k, a)\, x_{k,a}$ is a sum of L independent 0-1 random variables. Similarly, $d(g, j, x) = \sum_{1\leq k\leq L} \sum_{a\in\Sigma} \chi(g, j, k, a)\, x_{k,a}$ is also a sum of L independent 0-1 random variables. Moreover,

$$\begin{aligned} E[d(s, i, x)] &= \sum_{1\leq k\leq L} \sum_{a\in\Sigma} \chi(s, i, k, a)\, E[x_{k,a}] \\ &= \sum_{1\leq k\leq L} \sum_{a\in\Sigma} \chi(s, i, k, a)\, \bar{x}_{k,a} \\ &\leq \bar{d} \leq d_b, \end{aligned} \tag{3}$$

$$\begin{aligned} E[d(g, j, x)] &= \sum_{1\leq k\leq L} \sum_{a\in\Sigma} \chi(g, j, k, a)\, E[x_{k,a}] \\ &= \sum_{1\leq k\leq L} \sum_{a\in\Sigma} \chi(g, j, k, a)\, \bar{x}_{k,a} \\ &\geq d_g. \end{aligned} \tag{4}$$

Thus, for any fixed $\delta > 0$, using Lemma 1, we have

$$\mathbf{Pr}\left(d(s, i, x) > d_b + \delta L\right) < \exp\left(-\frac{1}{3}\delta^2 L\right),$$

$$\mathbf{Pr}\left(d(g, j, x) < d_g - \delta L\right) \leq \exp\left(-\frac{1}{2}\delta^2 L\right).$$

Considering all bad and good strings, respectively, we have

$$\mathbf{Pr}\left(d(s, i, x) > d_b + \delta L \text{ for at least one } s_i \in \mathcal{B}\right) < n_1 \times \exp\left(-\frac{1}{3}\delta^2 L\right)$$

and

$$\mathbf{Pr}\left(d(g, j, x) < d_g - \delta L \text{ for at least one } g_j \in \mathcal{G}\right) \leq n_2 \times \exp\left(-\frac{1}{2}\delta^2 L\right).$$

When $L \geq (4\log(n_1 + n_2))/\delta^2$, we get $n_1 \times \exp(-\frac{1}{3}\delta^2 L) \leq n_1^{-\frac{1}{3}}$ and $n_2 \times \exp(-\frac{1}{2}\delta^2 L) \leq n_2^{-1}$. For $d_b = \Omega(L)$ and $d_g = \Omega(L)$, there exist positive constants c_b and c_g such that $d_b \geq c_b L$ and $d_g \geq c_g L$. Thus we get a randomized algorithm to find a

solution x for (1) with probability at least $1-(n_1^{-\frac{1}{3}}+n_2^{-1})$ such that for $i=1,2,\ldots,n_1$, $d(s,i,x) \leq (1+\delta/c_b)d_b$, and for $j=1,2,\ldots,n_2$, $d(g,j,x) \geq (1-\delta/c_g)d_g$. □

THEOREM 3. *There exists a polynomial time approximation scheme (PTAS) for a DSP when $d_g = \Omega(L)$ and $d_b = \Omega(L)$. Specifically, when $d_g = c_g \times L$ and $d_b = c_b \times L$, the PTAS runs in $O(L \times |\Sigma|^{(4\log(n_1+n_2))/\delta^2})$ time and finds a solution, i.e., a string x of length L, such that for each string s_i in $\mathcal{B}$, $d(s_i,x) < (1+\epsilon)d_b$, and for any string g_j in $\mathcal{G}$, $d(g_j,x) > (1-\epsilon)d_g$, where $\delta = \epsilon \times \min\{c_g, c_b\}$.*

Proof. When $L \geq (4\log(n_1+n_2))/\delta^2$, the following derandomized algorithm is a PTAS.

Let $x_{j,a}$ be a fractional solution for (2) for $j=1,2,\ldots,L$. We can arbitrarily decompose the L positions into disjoint sets of positions $L_1, L_2, \ldots, L_k$ such that $|L_i| \geq (4\log(n_1+n_2))/\delta^2$ and $|L_i| < (8\log(n_1+n_2))/\delta^2$ for $i=1,2,\ldots,k$. Let $\mu_{s,l,i} = \sum_{1\leq j\leq |L_i|}\sum_{a\in\Sigma}\chi(s,l,j,a)x_{j,a}$ and $\mu_{g,l,i} = \sum_{1\leq j\leq |L_i|}\sum_{a\in\Sigma}\chi(g,l,j,a)x_{j,a}$. For each L_i, replacing $\{1,2,\ldots,L\}$ with L_i in (2), we know that there exists a string x_i of length $|L_i|$ such that for each string $s_l \in \mathcal{B}$,

$$d(s_l|_{L_i}, x_i) \leq \mu_{s,l,i} + \delta|L_i|,$$

and for each string $g_l \in \mathcal{G}$,

$$d(g_l|_{L_i}, x_i) \geq \mu_{g,l,i} - \delta|L_i|.$$

Thus, we can enumerate all strings of length $|L_i|$ in $|\Sigma|^{(4\log(n_1+n_2))/\delta^2}$ time to determine x_i. Concatenating all x_i's, we have a string x of length L such that for each string $s_l \in \mathcal{B}$,

$$d(s_l,x) \leq \sum_{i=1}^{k}(\mu_{s,l,i} + \delta|L_i|) = d_b + \delta L \leq d_b + \epsilon d_b,$$

and for each string $g_l \in \mathcal{G}$,

$$d(g_l,x) \geq \sum_{i=1}^{k}(\mu_{l,i} - \delta|L_i|) = d_g - \delta L \geq d_g - \epsilon d_g.$$

Thus, we obtain a desired string x in $O(L \times |\Sigma|^{(4\log(n_1+n_2))/\delta^2})$ time, which is polynomial in terms of the input size when $|\Sigma|$ is a constant.

When $L \leq (4\log(n_1+n_2))/\delta^2$, we can enumerate all possible strings of length L in $O(|\Sigma|^{(4\log(n_1+n_2))/\delta^2})$ time. Thus, we can get a desired solution. □

3. A key lemma. To obtain our PTAS algorithm, we need to introduce two parameters: an integer r and a positive number δ. The constant r is introduced in this section and depends purely on ϵ. The constant $\delta > 0$ will be introduced in the next section and depends on both $\epsilon > 0$ and r.

For any $r > 2$, let $1 \leq i_1, i_2, \ldots, i_r \leq n_1$ be r distinct numbers. Let $Q_{i_1,i_2,\ldots,i_r}$ be the set of positions at which $s_{i_1}, s_{i_2}, \ldots, s_{i_r}$ agree. Let s be a feasible solution of length L for the distinguishing string selection problem with the upper radius d_b for bad strings ($\mathcal{B}$) and lower radius d_g for good strings ($\mathcal{G}$). $P_{i_1,i_2,\ldots,i_r} = \{1,2,\ldots,L\} - Q_{i_1,i_2,\ldots,i_r}$ is the set of positions at which at least one pair of strings s_{i_j} and $s_{i_{j'}}$ differ. Then, at such positions, s differs from at least one of s_{i_j}. The number of positions at which s differs from one of s_{i_j} is no more than d_b. Therefore, the total number of

positions at which s differs from at least one of s_{i_j} $(j = 1, 2, \ldots, r)$ is no more than rd_b. It follows that $rd_b \geq |P_{i_1,i_2,\ldots,i_r}| = L - |Q_{i_1,i_2,\ldots,i_r}|$. That is, $|Q_{i_1,i_2,\ldots,i_r}| \geq L - rd_b$. In addition, we immediately obtain the following result, which is often applied late in the proof of our main result.

CLAIM 4. *Assuming that $d_g \geq d_b$, we have $rd_g \geq rd_b \geq L - |Q_{i_1,i_2,\ldots,i_r}| = |P_{i_1,i_2,\ldots,i_r}|$.*

Let $\mathcal{B} = \{s_1, s_2, \ldots, s_{n_1}\}$. Let $p_{i_1,i_2,\ldots,i_k}$ be the number of mismatches between s_{i_1} and s at the positions in $Q_{i_1,i_2,\ldots,i_k}$. Let $\rho_k = \min_{1 \leq i_1,i_2,\ldots,i_k \leq n_1} p_{i_1,i_2,\ldots,i_k}/d_b$. The following claim is a variant of a claim in [6], but the proof is identical.

CLAIM 5. *For any k such that $2 \leq k \leq r$, where r is a constant, there are indices $1 \leq i_1, i_2, \ldots, i_r \leq n_1$ such that for any $1 \leq l \leq n_1$*

$$|\{j \in Q_{i_1,i_2,\ldots,i_r} \mid s_{i_1}[j] \neq s_l[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \leq (\rho_k - \rho_{k+1})\, d_b.$$

Proof. Consider indices $1 \leq i_1, i_2, \ldots, i_k \leq n$ such that $p_{i_1,i_2,\ldots,i_k} = \rho_k d_{opt}$. Then for any $1 \leq i_{k+1}, i_{k+2}, \ldots, i_r \leq n$ and $1 \leq l \leq n$ we have

$$\begin{aligned}
&|\{j \in Q_{i_1,i_2,\ldots,i_r} \mid s_{i_1}[j] \neq s_l[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \\
&\leq |\{j \in Q_{i_1,i_2,\ldots,i_k} \mid s_{i_1}[j] \neq s_l[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \qquad (5)\\
&= |\{j \in Q_{i_1,i_2,\ldots,i_k} \mid s_{i_1}[j] \neq s[j]\} \\
&\quad - \{j \in Q_{i_1,i_2,\ldots,i_k} \mid s_{i_1}[j] = s_l[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \\
&= |\{j \in Q_{i_1,i_2,\ldots,i_k} \mid s_{i_1}[j] \neq s[j]\} - \{j \in Q_{i_1,i_2,\ldots,i_k,l} \mid s_{i_1}[j] \neq s[j]\}| \\
&= p_{i_1,i_2,\ldots,i_k} - p_{i_1,i_2,\ldots,i_k,l} \qquad (6)\\
&\leq (\rho_k - \rho_{k+1})\, d_{opt},
\end{aligned}$$

where inequality (5) holds because $Q_{i_1,i_2,\ldots,i_r} \subseteq Q_{i_1,i_2,\ldots,i_k}$ and equality (6) holds because $Q_{i_1,i_2,\ldots,i_k,l} \subseteq Q_{i_1,i_2,\ldots,i_k}$. ∎

From Claim 5, we can immediately obtain the following proposition.

PROPOSITION 6. *For any constant r, there are indices $1 \leq i_1, i_2, \ldots, i_r \leq n_1$ such that for any $s_l \in \mathcal{B}$,*

$$|\{j \in Q_{i_1,i_2,\ldots,i_r} \mid s_{i_1}[j] \neq s_l[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \leq \frac{1}{r-1}\, d_b.$$

Proof. Note that

$$(\rho_2 - \rho_3) + (\rho_3 - \rho_4) + \cdots + (\rho_r - \rho_{r+1}) = \rho_2 - \rho_{r+1} \leq 1.$$

Therefore, one of $(\rho_k - \rho_{k+1})$ is at most $\frac{1}{r-1}$. Thus, Claim 5 immediately implies that the lemma is true. ∎

The following corollary will also be useful later.

COROLLARY 7. *For any $Q \subseteq Q_{i_1,i_2,\ldots,i_r}$ (as in Proposition 6), we have that, for any $s_l \in \mathcal{B}$,*

$$|\{j \in Q \mid s_{i_1}[j] \neq s_l[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \leq \frac{1}{r-1}\, d_b.$$

Moreover, let $P = \{1, 2, \ldots, L\} - Q$. Then, for any $s_l \in \mathcal{B}$,

$$d(s_l, s_{i_1}|Q) + d(s_l, s|P) \leq \frac{r}{r-1} d_b.$$

Proof. The first part is obvious by Proposition 6. For the second part, consider

$$A_k = \{j \in Q \mid s_{i_1}[j] \neq s_k[j] \text{ and } s_{i_1}[j] \neq s[j]\}$$

and

$$B_k = \{j \in Q \mid s_{i_1}[j] \neq s_k[j] \text{ and } s_{i_1}[j] = s[j]\}.$$

Then $d(s_k, s_{i_1}|Q) = |A_k| + |B_k|$. By the first part of the corollary, $|A_k|$ is no more than $\frac{1}{r-1}d_b$. By definition, $|B_k| \leq d(s_k, s|Q)$. Therefore, $|B_k| + d(s_k, s|P) \leq d(s_k, s|Q) + d(s_k, s|P) = d(s_k, s) \leq d_b$. The rest of the corollary follows. □

Informally, Proposition 6 implies that s_{i_1} is a good approximation of s at positions in $Q_{i_1,i_2,\ldots,i_r}$ for the bad strings; i.e., for any $Q \subseteq Q_{i_1,i_2,\ldots,i_r}$,

$$d(s_l, s_{i_1}|Q) \leq d(s_l, s|Q) + \frac{1}{r-1}\, d_b.$$

Before we present our key lemma, we need a boosting proposition that, when applied together with Corollary 7, obtains a better and better solution.

PROPOSITION 8. *Let $Q \subset Q_{i_1,i_2,\ldots,i_r}$ (as in Proposition 6). Consider the index $k : 1 \leq k \leq n_1$ and the number $y \geq 0$ such that, for any $s_l \in \mathcal{B}$, $d(s_l, s_{i_1}|Q) + d(s_l, s|P) \leq d(s_k, s_{i_1}|Q) + d(s_k, s|P) = \frac{r}{r-1}d_b - y$ (where $P = \{1, 2, \ldots, L\} - Q$). Then we have*

$$|\{j \in Q^k | s_{i_1}[j] \neq s[j]\}| \leq y,$$

where $Q^k = \{j \in Q : s_{i_1}[j] = s_k[j]\}$.

Proof. Dividing $d(s_k, s_{i_1}|Q)$ into two parts, we have

$$d(s_k, s_{i_1}|Q - Q^k) + d(s_k, s_{i_1}|Q^k) + d(s_k, s|P) = \frac{r}{r-1}d_b - y. \tag{7}$$

By Corollary 7 and with the further restriction that $s_l[j] = s[j]$, we have that, for any string $s_l \in \mathcal{B}$,

$$|\{j \in Q \mid s_{i_1}[j] \neq s_l[j] \text{ and } s_{i_1}[j] \neq s[j] \text{ and } s_l[j] = s[j]\}| \leq \frac{1}{r-1}\, d_b.$$

That is, for any string $s_l \in \mathcal{B}$,

$$|\{j \in (Q - Q^l) | s_l[j] = s[j]\}| \leq \frac{1}{r-1}\, d_b. \tag{8}$$

From (8), there exists β with $\beta \leq 1$ such that for any $s_l \in \mathcal{B}$, $|\{j \in (Q - Q^l) \mid s_l[j] = s[j]\}| \leq |\{j \in (Q - Q^k) \mid s_k[j] = s[j]\}| = \beta\frac{1}{r-1}\, d_b$. On the other hand, $|\{j \in (Q - Q^k) \mid s_k[j] \neq s_{i_1}[j]\}|$ is no more than $|\{j \in (Q - Q^k) \mid \}|$, which is the sum of $|\{j \in (Q - Q^k) \mid s_k[j] = s[j]\}|$ and $|\{j \in (Q - Q^k) \mid s_k[j] \neq s[j]\}|$. Combining those two formulae, we have

$$d(s_k, s|Q - Q^k) \geq d(s_k, s_{i_1}|Q - Q^k) - \beta\frac{1}{r-1}\, d_b. \tag{9}$$

Moreover, combining (7) and (9), we have

$$\begin{aligned} d(s_k, s|Q - Q^k) + \frac{\beta}{r-1}\, d_b + d(s_k, s_{i_1}|Q^k) + d(s_k, s|P) \\ \geq \frac{r}{r-1}d_b - y. \end{aligned} \tag{10}$$

Since

$$d(s_k, s|Q - Q^k) + d(s_k, s|Q^k) + d(s_k, s|P) \le d_b, \tag{11}$$

then (10) implies

$$\begin{aligned} d(s_k, s|Q^k) &\le d(s_k, s_{i_1}|Q^k) + \frac{\beta - 1}{r - 1} d_b + y \\ &= \frac{\beta - 1}{r - 1} d_b + y \le y. \end{aligned} \tag{12}$$

Here (12) is from the facts that $d(s_k, s_{i_1}|Q^k) = 0$ and $\beta \le 1$. Therefore,

$$|\{j \in Q^k | s_{i_1}[j] \ne s[j]\}| \le y. \tag{13}$$

This completes the proof. ∎

Here is our main lemma.

LEMMA 9. *For any constant r, there exist indices $1 \le i_1, i_2, \ldots, i_t \le n_1$, $r \le t \le 2r$, and a number $0 \le y \le d_b$ such that $|\{j \in Q_{i_1,i_2,\ldots,i_t} | s_{i_1}[j] \ne s[j]\}| \le y$. (Note that this implies $d(g, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \ge d(g, s|Q_{i_1,i_2,\ldots,i_t}) - y$.) If we use s_{i_1} as the distinguishing string at positions in $Q_{i_1,i_2,\ldots,i_t}$, and s (the original distinguishing string) at the rest of the positions, then for any $s_l \in \mathcal{B}$, $d(s_l, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) + d(s_l, s|P_{i_1,i_2,\ldots,i_t}) \le \frac{r+1}{r-1} d_b - y$, where $P_{i_1,i_2,\ldots,i_t} = \{1, 2, \ldots, L\} - Q_{i_1,i_2,\ldots,i_t}$.*

Proof. We shall repeatedly apply Proposition 8 up to r times for the proof.

We start with $Q = Q_{i_1,i_2,\ldots,i_r}$. By Corollary 7, for any $s_l \in \mathcal{B}$, $d(s_l, s_{i_1}|Q) - |\{j \in Q \,|\, s_{i_1}[j] \ne s_l[j] \text{ and } s_{i_1}[j] = s_l[j]\}| \le \frac{1}{r-1} d_b$. Notice that $|\{j \in Q \,|\, s_{i_1}[j] \ne s_l[j] \text{ and } s_{i_1}[j] = s_l[j]\}| \le d(s_l, s \,|\, Q)$. We get

$$d(s_l, s_{i_1}|Q) + d(s_l, s|P)| \le \frac{1}{r - 1} d_b + d(s_l, s) \le \frac{r}{r - 1} d_b.$$

Therefore, there exist an index k (denoted by i_{r+1}) and number z^0 ($\frac{r}{r-1} d_b \ge z^0 \ge 0$) such that for any $s_l \in \mathcal{B}$,

$$d(s_l, s_{i_1}|Q) + d(s_l, s|P)| \le d(s_{i_{r+1}}, s_{i_1}|Q) + d(s_{i_{r+1}}, s|P)| = \frac{1}{r - 1} d_b - z^0.$$

By Proposition 8, $|\{j \in Q_{i_1,i_2,\ldots,i_r,i_{r+1}} | s_{i_1}[j] \ne s[j]\}| \le z^0$. Now apply Corollary 7 again to the index set $Q' = Q_{i_1,i_2,\ldots,i_{r+1}}$. Then, for any $s_l \in \mathcal{B}$, $d(s_l, s_{i_1}|Q_{i_1,i_2,\ldots,i_{r+1}}) + d(s_l, s|\{1, \ldots, L\} - Q_{i_1,i_2,\ldots,i_{r+1}}) \le \frac{r}{r-1} d_b$. Again, choose k' (and denote it by i_{r+2} later) and $y' \ge 0$ such that

$$d(s_l, s_{i_1}|Q_{i_1,i_2,\ldots,i_{r+1}}) + d(s_l, s|\{1, \ldots, L\} - Q_{i_1,i_2,\ldots,i_{r+1}}) \le \frac{r}{r - 1} d_b - y'$$

and such that equality holds for $l = k'$.

If $y' \ge z^0 - \frac{1}{r-1} d_b$, then our lemma follows with $t = r + 1$ and $y = z^0$. Therefore, we need to consider only the case $y' \le z^0 - \frac{1}{r-1} d_b$. Notice that if $z^0 < \frac{1}{r-1} d_b$, we will reach a contradiction here. We should also have $z^0 \ge \frac{1}{r-1} d_b$, or the lemma holds.

Define $z^1 = y'$. The conditions of Proposition 8 hold with $y = z^1$ and $Q = Q_{i_1,i_2,\ldots,i_{r+1}}$. Therefore, we are able to repeat the above process. Notice that $z^1 \le z^0 - \frac{1}{r-1} d_b$, and it is no smaller than $\frac{1}{r-1} d_b$. The same holds each time we repeat the

process. Therefore, the process can only be repeated up to r times before we obtain the result as claimed. □

In Lemma 9, we decompose the L positions into two parts, $Q_{i_1,i_2,\ldots,i_t}$ and $P_{i_1,i_2,\ldots,i_t}$. In $P_{i_1,i_2,\ldots,i_t}$, either the linear programming approach in section 2 or a brute-force enumeration method can go through since $|P_{i_1,i_2,\ldots,i_t}| \leq rd_b$. Details will be given in the next section. Thus, we can get a good approximation solution at positions in $P_{i_1,i_2,\ldots,i_t}$.

By Lemma 9, at positions in $Q_{i_1,i_2,\ldots,i_t}$ there are at most y positions where the letters for a feasible (optimal) solution are different from the letters in s_{i_1}. This implies that $d(g, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \geq d(g, s|Q_{i_1,i_2,\ldots,i_t}) - y$. We may need to carefully choose y positions in $Q_{i_1,i_2,\ldots,i_t}$ in s_{i_1} to change to s'_{i_1} so that the condition $d(g, s'_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \geq d(g, s|Q_{i_1,i_2,\ldots,i_t})$ is satisfied (with negligible error) for each $g \in \mathcal{G}$.

On the other hand, again by Lemma 9, if any y positions chosen in $Q_{i_1,i_2,\ldots,i_t}$ are changed to obtain a string s'_{i_1}, i.e, $d(s_{i_1}, s'_{i_1}) = y$, then $d(s_l, s|P_{i_1,i_2,\ldots,i_t}) + d(s_l, s'_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \leq (1+\frac{1}{r-1})d_b$. That is, the total error produced for every string in $\mathcal{B}$ will be at most $\frac{1}{r-1}d_b$ no matter which y positions in $Q_{i_1,i_2,\ldots,i_t}$ are chosen. Therefore, to choose y positions in $Q_{i_1,i_2,\ldots,i_t}$, we can simply consider the good strings in $\mathcal{G}$ and ignore the strings in $\mathcal{B}$. This dramatically reduces the difficulty of the problem.

The main contribution of Lemma 9 is to transform the original DSP into the problem of how to choose y positions in $Q_{i_1,i_2,\ldots,i_t}$ to modify the string s_{i_1} into a string s' such that $d(g, s'_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \geq d(g, s|Q_{i_1,i_2,\ldots,i_t})$. Though we do not know the value of y, we can enumerate all y: $y = 0, 1, \ldots, d_b$ in the algorithm. We will elaborate on this in the next section.

4. Choice of a distinguishing string. In general, we aim at constructing an approximate solution s'_{i_1} that differs from s_{i_1} at y positions (up to negligible error) in $Q_{i_1,i_2,\ldots,i_t}$. Though we do not know the value of y, we can enumerate all y: $y = 0, 1, \ldots, d_b$ in the algorithm. However, if $d_g \geq (r-1)y$, we can simply use s_{i_1} at all positions in $Q_{i_1,i_2,\ldots,i_t}$. For good strings $g \in \mathcal{G}$, the error at positions in $Q_{i_1,i_2,\ldots,i_t}$ will be $\frac{1}{r-1}d_g$, which will be good enough for a PTAS. For bad strings $s_l \in \mathcal{B}$, the error created by making s_{i_1} the approximate solution at positions in $Q_{i_1,i_2,\ldots,i_t}$ will be at most $\frac{2}{r-1}d_b$ (again, good enough for a PTAS) by Lemma 9. Therefore, we can assume that $d_g < (r-1)y$.

For any string $g_i \in \mathcal{G}$, if $d(g_i, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \geq (r-1)y$, then the selected y positions in $Q_{i_1,i_2,\ldots,i_t}$ will cause error by at most $\frac{1}{r-1}d_g$. In fact, let s'_{i_1} be the string obtained from s_{i_1} by changing y positions in $Q_{i_1,i_2,\ldots,i_t}$. Then $d(g_i, s'_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \geq (r-2)y$. Recalling the assumption that $d_g < (r-1)y$, we get for any $g_i \in \mathcal{G}$,

$$d(g_i, s'_{i_1}) \geq d(g_i, s'_{i_1}|Q_{i_1,i_2,\ldots,i_t}) \geq \frac{r-2}{r-1}d_g = \left(1 - \frac{1}{r-1}\right)d_g.$$

Therefore, we have to consider only the strings $g_i \in \mathcal{G}$ with the restriction that $d(g_i, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) < (r-1)y$. (This condition can be verified in polynomial time for each $g \in \mathcal{G}$.) In summary, without loss of generality, we have the following.

Assumption 1. For every string $g_i \in \mathcal{G}$, $d(g_i, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) < (r-1)y$ and $d_g \leq (r-1)y$.

In the remaining part of the section, several different methods will be used to carefully select y positions in $Q_{i_1,i_2,\ldots,i_t}$, each dealing with one of the three cases. Let $L' = |Q_{i_1,i_2,\ldots,i_t}|$. The complete algorithm is given in Figure 1.

In addition to the constant integer r, we need to introduce another positive number $\delta_0 > 0$. We should first choose r to be sufficiently large but remain a constant.

Algorithm gdistString

Input $\mathcal{B} = \{s_1, s_2, \ldots, s_{n_1}\}$ and $\mathcal{G} = \{g_1, g_2, \ldots, g_{n_2}\}$.
Output a center string s of length L.

1. **if** Case 1 holds, **then** use the method in section 2 to solve the problem.
2. **for** each $2r$-element subset $\{s_{i_1}, s_{i_2}, \ldots, s_{i_{2r}}\}$ of the n_1 input strings in $\mathcal{B}$ **do**
   (a) $Q = \{1 \le j \le L \mid s_{i_1}[j] = s_{i_2}[j] = \cdots = s_{i_t}[j]\}$, $P = \{1, 2, \ldots, L\} - Q$.
   (b) For the positions in $Q_{i_1,i_2,\ldots,i_t}$, use the methods described in Cases 2 and 3 to obtain a string of length $|Q_{i_1,i_2,\ldots,i_t}|$. Notice that the algorithm described in Case 1 produces directly a string s' of length L which is a PTAS.
   (c) Solve the optimization problem at the positions in $|P|$ using either an LP formulation (randomized rounding approach) (when $|P| \ge O(\log n)$) or an exhaustive search method (when $|P| \le O(\log n)$) to get an approximate solution x of length $|P|$.
3. Output the best solution obtained above.

FIG. 1. *Algorithm for DSP.*

Then we should choose δ_0 to be sufficiently small to achieve the required bound $(1+\epsilon)$ (and $(1-\epsilon)$) for PTAS. Notice that, since δ_0 is chosen after r is fixed, it may be a function of r. However, since r is a constant, we can make δ_0 sufficiently small (as a function of r) and at the same time δ_0 remains a constant. Therefore, in some of the asymptotic notation (Ω and big-O) used in this section, the constant may be a function of r. However, since we should set the value of r to a sufficiently large constant first, both r and δ_0 are constant when we later set the value of $\delta_0 > 0$ sufficiently small.

Case 1. $L' \le (r-1)^2 y$ and $y \ge (4\log(n_1+n_2))/{\delta_0}^2$. In this case, it follows that $d_b \ge y \ge (8\log(n_1+n_2))/{\delta_0}^2$. Moreover, we should prove that $d_b \ge c_b L$ and $d_g \ge c_g L$, where $c_b = c_g = \min\{\frac{1}{4r}, \frac{1}{2(r-1)^2}\}$.

Because $L' \ge y$ and $L' \le (r-1)^2 y$, it follows that $y = eL'$ for some $e : \frac{1}{(r-1)^2} \le e \le 1$. Since $d_b \ge y$ and $d_b \le d_g \le (r-1)y$ (from Assumption 1), we have $d_b = xy$ for $1 \le x \le r-1$. Thus, $d_b = xy = xeL'$ and $\frac{1}{(r-1)^2} \le xe \le r-1$. Note that $L = L' + |P|$ and $|P| \le td_b$ by Claim 4. We consider two subcases. (a) $|P| \le 0.5L$. Then $L' \ge 0.5L$. Thus $d_b = xeL' \ge 0.5xeL$. Since $d_b \le L$, we have $d_b = c'L$ for some $c' : \frac{1}{2(r-1)^2} \le c' \le 0.5(r-1)$. (b) $|P| > 0.5L$. Then by Claim 4, $d_b \ge |P|/t \ge 0.5L/t \ge L/4r$. Recall that we also assume that $d_g \ge d_b$ in the problem setting. It follows that $d_g \ge d_b > c_g L$.

Since $d_b \ge c_b L$ and $d_g \ge c_g L$, we can directly use the method described in section 2.

Case 2. $L' > (r-1)^2 y$ and $y \ge (4\log(n_1+n_2))/{\delta_0}^2$. By Assumption 1, $d(g_i, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) < (r-1)y$. Thus, for any $g_i \in \mathcal{G}$, s_{i_1} and g_i agree at most of the positions (at least $(r-1)(r-2)$ out of $(r-1)^2$ positions) in $Q_{i_1,i_2,\ldots,i_t}$. Intuitively, if we randomly select y positions in $Q_{i_1,i_2,\ldots,i_t}$ and change them into any different letters from s_{i_1} to get y_{i_1}, then y_{i_1} and g_i should differ at most of the y positions. Therefore, we can apply the following simple randomized algorithm:

1. Arbitrarily divide the L' positions into y sets of positions $Y_1, Y_2, \ldots, Y_y$ such that $|Y_1| = |Y_2| = \cdots = |Y_{y-1}| = \lfloor \frac{L'}{y} \rfloor$.

2. For each Y_i, independently randomly select a position in Y_i.
3. Let $Y = \{j_1, j_2, \ldots, j_y\}$ be the y selected positions in step 2, and y_{i_1} be a string of length $|Q_{i_1,i_2,\ldots,i_t}|$ obtained from s_{i_1} by changing the letters at these positions in Y (to any different letters) such that $d(y_{i_1}, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) = y$.

This algorithm gives us the needed solution for Case 2. We have the following proposition.

PROPOSITION 10. *The randomized algorithm for Case* 2 *produces a center string* y_{i_1} *of length* $|Q_{i_1,i_2,\ldots,i_t}|$ *with high probability such that*

(i) *for any* $s_i \in \mathcal{B}$, $d(y_{i_1}, s_i|Q_{i_1,i_2,\ldots,i_t}) + d(s, s_i|P_{i_1,i_2,\ldots,i_t}) \leq \frac{r+1}{r-1} d_b$, *and*

(ii) *for any* $g_j \in \mathcal{G}$, $d(y_{i_1}, g_j|Q_{i_1,i_2,\ldots,i_t}) + d(s, g_j|P_{i_1,i_2,\ldots,i_t}) \geq (1 - \frac{2}{r-1} - 2\delta_0) d_g$, *where* s *is a feasible (optimal) distinguishing string.*

Proof. (i) arises directly from Lemma 9.

Now, we show that (ii) is true for the case where $\lfloor \frac{L'}{y} \rfloor = \frac{L'}{y}$. (The general case is left to interested readers.) Consider a string $g \in \mathcal{G}$. Let Z_i be the set of positions j in Y_i with $s_{i_1}[j] = g[j]$. Let X_i be a 0/1 random variable. $X_i = 1$ indicates that j_i is in Z_i. The probability that $X_i = 1$ is $\frac{|Z_i|}{|Y_i|}$. Then we get

$$\mu = E\left[\sum_{i=1}^{y} X_i\right] = \sum_{i=1}^{y} \frac{|Z_i|}{|Y_i|} = \frac{y}{L'} \sum_{i=1}^{y} |Z_i| \geq \frac{y(L' - (r-1)y)}{L'}.$$

The last inequality is by the fact from Assumption 1 that $d(g, s_{i_1}|Q_{i_1,i_2,\ldots,i_t}) < (r-1)y$. Since $L' > (r-1)^2 y$, $\mu \geq \frac{y(r-2)}{r-1}$. By Lemma 1,

$$\mathbf{Pr}\left(\sum_{i=1}^{y} X_i < \mu - \delta_0 y\right) < \exp\left(-\frac{1}{2}\delta_0^2 y\right) \leq n_2^{-2}.$$

The last inequality is from the fact that $y \geq 4\log(n_1 + n_2)/\delta_0^2$.

Let y_{i_1} be the string obtained from s_{i_1} by changing the letters at y positions using the randomized algorithm. Then for the string $g \in \mathcal{G}$,

$$d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) + \left(y - \sum_{i=1}^{y} X_i\right) - d(s_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) \geq \sum_{i=1}^{y} X_i.$$

The above inequality is due to the facts that (1) s_{i_1} and y_{i_1} differ at the y selected positions, (2) y_{i_1} and g differ at every position i with $X_i = 1$, and (3) y_{i_1} and g may agree at the rest of the $y - \sum_{i=1}^{y} X_i$ positions. Thus, we have

$$\frac{d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) - d(s_{i_1}, g_l|Q_{i_1,i_2,\ldots,i_t}) + y}{2} \geq \sum_{i=1}^{y} X_i.$$

Therefore, we get

$$\begin{aligned} & \mathbf{Pr}\left(\frac{d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) - d(s_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) + y}{2} < \mu - \delta_0 y\right) \\ \leq \quad & \mathbf{Pr}\left(\sum_{i=1}^{y} X_i < \mu - \delta_0 y\right) < \exp\left(-\frac{1}{2} y \delta_0^2\right) \leq n_2^{-2}. \end{aligned}$$

Substituting $\mu \geq \frac{y(r-2)}{r-1}$ into the above inequality, and after some calculation, we have

$$\mathbf{Pr}\left(d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) - d(s_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) \leq \frac{y(r-3)}{r-1} - 2\delta_0 y\right) \leq n_2^{-2}.$$

From Lemma 9, $d(s_i, g|Q_{i_1,i_2,\ldots,i_t}) \geq d(s, g||Q_{i_1,i_2,\ldots,i_t}) - y$, so we get

$$\mathbf{Pr}\left(d(s, g|Q_{i_1,i_2,\ldots,i_t}) - d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) > 2\delta_0 y + \frac{2y}{r-1}\right) \leq n_2^{-2}.$$

Considering all good strings, we get

$$\mathbf{Pr}\left(d(s, g|Q_{i_1,i_2,\ldots,i_t}) - d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) > 2\delta_0 y + \frac{2y}{r-1} \text{ for any } g \in \mathcal{G}\right) \leq n_2^{-1}.$$

Therefore, with high probability we get that

$$d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) \geq d(s, g|Q_{i_1,i_2,\ldots,i_t}) - \left(\frac{2}{r-1} + 2\delta_0\right) d_g,$$

that is,

$$\begin{aligned} & d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) + d(s, g|P_{i_1,i_2,\ldots,i_t}) \\ \geq \quad & d(s, g_l) - \left(\tfrac{2}{r-1} + 2\delta_0\right) d_g \geq d_g - \left(\tfrac{2}{r-1} + 2\delta_0\right) d_g = \left(1 - \tfrac{2}{r-1} - 2\delta_0\right) d_g. \qquad \square \end{aligned}$$

Now, we give a derandomized algorithm for Case 2.

LEMMA 11. *There is a deterministic algorithm that runs in time equal to* $O(d_b^2(n_1+n_2)^{\log(2(r-1)^2e)8/\delta_0^2})$ *and finds a string* y_{i_1} *from* s_{i_1} *such that for any* $g \in \mathcal{G}$,

$$d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_{2r}}) - d(s_{i_1}, g|Q_{i_1,i_2,\ldots,i_{2r}}) \geq \frac{r-3}{r-1} y - 2\delta_0 y.$$

Proof. Proposition 10 holds when $L' = (r-1)^2 y$, since in that case $\mu = \frac{y(r-2)}{r-1}$. Therefore, if $L' > (r-1)^2 y$, we can arbitrarily select a subset $Q \subset Q_{i_1,i_2,\ldots,i_t}$ of size $(r-1)^2 y$ and try to select y positions in Q.

Next, if y is big enough, i.e., $y = (4\log(n_1+n_2))/{\delta_0}^2$, then Proposition 10 holds. That is, a good approximation solution, i.e., a set of y positions, exists in Q. We can try all possible ways to choose y positions in Q. The time required is $C^y_{(r-1)^2 y}$. Note that

$$C_m^y = \frac{m(m-1)\cdots(m-y+1)}{y!} \leq \frac{m^y}{y!} \leq \left(\frac{m}{y}\right)^y e^y.$$

We have

$$C^y_{(r-1)^2 y} \leq ((r-1)^2)^y e^y = (n_1+n_2)^{\log((r-1)^2 e)4/\delta_0^2}.$$

Thus, the time required is at most $O((n_1+n_2)^{\log((r-1)^2 e)4/\delta_0^2})$ if $y = (4\log(n_1 + n_2))/{\delta_0}^2$.

When $y > (4\log(n_1+n_2))/{\delta_0}^2$, we cannot directly choose y positions from Q since the time complexity is higher. Let $y = x \times (4\log(n_1+n_2))/{\delta_0}^2 + z$, where $x \geq 1$ is an integer and $z < (4\log(n_1+n_2))/{\delta_0}^2$. We divide Q into x disjoint subsets $Q_1, Q_2, \ldots, Q_x$ such that $|Q_i| = (r-1)^y/x$ for $i = 1, 2, \ldots, x-1$ and $Q_x = Q - Q_1 - Q_2 - \cdots - Q_{x-1}$. Proposition 10 ensures that each Q_i contains a good approximation solution, i.e., a set of $(4\log(n_1+n_2))/{\delta_0}^2$ positions, such that y_1 and g differ at most of the positions (at least $\frac{(r-2)}{r-1}\%$). Thus, we can try all possible ways to choose the right $(4\log(n_1+n_2))/{\delta_0}^2$ positions from each Q_i. (We have to choose

$(4\log(n_1+n_2))/{\delta_0}^2 + z$ positions from Q_x.) Therefore, the time required for each Q_i is $O((n_1+n_2)^{\log(2(r-1)^2e)8/\delta_0^2})$. Since there are at most y Q_i's and we have to try different values of y, the total time required is $O(d_b^2(n_1+n_2)^{\log(2(r-1)^2e)8/\delta_0^2})$. □

Case 3. $y < (4\log(n_1+n_2))/{\delta_0}^2$. For any q good strings $g_{j_1}, g_{j_2}, \ldots, g_{j_q}$, we define

$$R_{j_1,j_2,\ldots,j_q} = \{j \in Q_{i_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq g_{j_l}[j] \text{ for at least one } l \in \{1,2,\ldots,q\}\}$$

and

$$\bar{R}_{j_1,j_2,\ldots,j_q} = Q_{i_1,i_2,\ldots,i_t} - R_{j_1,j_2,\ldots,j_q}.$$

From the definition of $R_{j_1,j_2,\ldots,j_q}$ and $\bar{R}_{j_1,j_2,\ldots,j_q}$, we have that for any integers p, q $(p<q)$,

$$R_{j_1,j_2,\ldots,j_p} \subseteq R_{j_1,j_2,\ldots,j_q}, \qquad \bar{R}_{j_1,j_2,\ldots,j_q} \subseteq \bar{R}_{j_1,j_2,\ldots,j_p}.$$

Let $y_1 = d(s_{i_1}, s|R_{j_1,j_2,\ldots,j_r})$ and $y_2 = d(s_{i_1}, s|\bar{R}_{j_1,j_2,\ldots,j_r})$. Then $y_1 + y_2 \leq y$.

The following lemma is important in dealing with Case 3.

LEMMA 12. *There exist* r *indices* $1 \leq j_1, j_2, \ldots, j_r \leq n_2$ *such that for any* $g \in \mathcal{G}$,

$$|\{j \in \bar{R}_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq g[j] \text{ and } s_{i_1}[j] \neq s[j]\}| \leq \frac{y}{r}.$$

Proof. Take $g_{j_1} \in \mathcal{G}$, and let

$$U_{j_1} = \{j \in Q_{i_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_1}[j]\}$$

such that $|U_{j_1}|$ is as large as possible. Clearly, $U_{j_1} \subseteq R_{j_1}$.

If $|U_{j_1}| \leq \frac{y}{r}$, let $j_2, \ldots, j_r$ be any other indices and $g \in \mathcal{G}$ be any good string; it follows that

$$\begin{array}{ll} & |\{j \in \bar{R}_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g[j]\}| \\ \leq & |\{j \in Q_{j_1,j_2,\ldots,j_t} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_1}[j]\}| \\ = & |U_{j_1}| \leq \frac{y}{r}. \end{array}$$

Thus we may assume that $|U_{j_1}| > \frac{y}{r}$. Take $g_{j_2} \in \mathcal{G}$, and let

$$U_{j_1,j_2} = \{j \in Q_{i_1,i_2,\ldots,i_t} - U_{j_1} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_2}[j]\}$$

such that $|U_{j_1,j_2}|$ is as large as possible. Clearly, $U_{j_1,j_2} \subseteq R_{j_1,j_2}$.

If $|U_{j_1,j_2}| \leq \frac{y}{r}$, let $j_3, \ldots, j_r$ be any other indices and $g \in \mathcal{G}$ be any good string; it follows that

$$\begin{array}{ll} & |\{j \in \bar{R}_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g[j]\}| \\ = & |\{j \in Q_{1_1,i_2,\ldots,i_t} - R_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g[j]\}| \\ \leq & |\{j \in Q_{1_1,i_2,\ldots,i_t} - U_{j_1} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_2}[j]\}| \\ = & |U_{j_1,j_2}| \leq \frac{y}{r}. \end{array}$$

The inequality comes from the fact $U_{j_1} \subseteq R_{j_1} \subseteq R_{j_1,j_2,\ldots,j_r}$ and the choice of g_{j_2}. So we have to consider only $|U_{j_1,j_2}| > \frac{y}{r}$ since otherwise we are done.

In general, we can get a list of sets of positions

$$U_{j_1}, U_{j_1,j_2}, \ldots, U_{j_1,j_2,\ldots,j_q},$$

where $U_{j_1,j_2,\ldots,j_q} = \{j \in Q_{1_1,i_2,\ldots,i_t} - U_{j_1,j_2,\ldots,j_{q-1}} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_q}[j]\}$ and $|U_{j_1,j_2,\ldots,j_q}|$ is as large as possible such that

- $U_{j_1,j_2,\ldots,j_s} \cap U_{j_1,j_2,\ldots,j_t} = \emptyset$, $1 \leq s \neq t \leq q$,
- $|U_{j_1,j_2,\ldots,j_p}| > \frac{y}{r}$, $p = 1, \ldots, q$,
- q is as large as possible.

Note that $U_{j_1} \cup U_{j_1,j_2} \cup \cdots \cup U_{j_1,j_2,\ldots,j_q} \subseteq \{j \in Q_{i_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_l}[j] \text{ for at least one } l \in \{1,2,\ldots,q\}\} \subseteq \{j \in Q_{i_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq s[j]\}$. Therefore, we get

$$\frac{qy}{r} < |U_{j_1} \cup U_{j_1,j_2} \cup \cdots \cup U_{j_1,j_2,\ldots,j_q}| \leq |\{j \in Q_{i_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq s[j]\}| \leq y,$$

and thus $q < r$.

Finally, take $g_{j_{q+1}} \in \mathcal{G}$, and let

$$U_{j_1,j_2,\ldots,j_{q+1}} = \{j \in Q_{i_1,i_2,\ldots,i_t} - U_{j_1,j_2,\ldots,j_q} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_{q+1}}[j]\}$$

such that $|U_{j_1,j_2,\ldots,j_{q+1}}|$ is as large as possible. Clearly, $U_{j_1,j_2,\ldots,j_{q+1}} \subseteq R_{j_1,j_2,\ldots,j_{q+1}}$.

By the maximality of q, $|U_{j_1,j_2,\ldots,j_{q+1}}| \leq \frac{y}{r}$, let $j_{q+2}, \ldots, j_r$ be any other indices and $g \in \mathcal{G}$ be any good string; it follows that

$$\begin{array}{rl} & |\{j \in \bar{R}_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g[j]\}| \\ = & |\{j \in Q_{i_1,i_2,\ldots,i_t} - R_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g[j]\}| \\ \leq & |\{j \in Q_{i_1,i_2,\ldots,i_t} - U_{j_1,j_2,\ldots,j_q} \mid s_{i_1}[j] \neq s[j] \text{ and } s_{i_1}[j] \neq g_{j_{q+1}}[j]\}| \\ = & |U_{j_1,j_2,\ldots,j_{q+1}}| \leq \frac{y}{r}. \end{array}$$

Lemma 12 is now proved. □

Now, we consider the two parts $R_{j_1,j_2,\ldots,j_r}$ and $\bar{R}_{j_1,j_2,\ldots,j_r}$, respectively.

Assumption 1 and the definition of $R_{j_1,j_2,\ldots,j_r}$ ensure that

$$\begin{array}{rcl} |R_{j_1,j_2,\ldots,j_r}| & = & |\{j \in Q_{1_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq g_{j_l}[j] \text{ for at least one } l \in \{1,2,\ldots,r\}\}| \\ & \leq & \sum_{l=1}^{r} |\{j \in Q_{1_1,i_2,\ldots,i_t} \mid s_{i_1}[j] \neq g_{j_l}[j]\}| \\ & = & \sum_{l=1}^{r} d(s_{i_1}, g_{j_l}|Q_{1_1,i_2,\ldots,i_t}) \leq r(r-1)y < r^2 y. \end{array}$$

Keep in mind that we are dealing with the case $y \leq (4\log(n_1+n_2))/{\delta_0}^2$. Thus, we have $|R_{j_1,j_2,\ldots,j_r}| \leq (4\log(n_1+n_2))/{\delta_0}^2$. We can try all possible ways to achieve the optimal distinguishing string s at the positions in $R_{j_1,j_2,\ldots,j_r}$. The time required is

$$\sum_{y_1=0}^{y} C_{r^2 y}^{y_1} \leq 2^{r^2 y} \leq O((n_1+n_2)^{4r^2/\delta_0^2}).$$

Thus we can assume that we know the optimal distinguishing string s at the positions in $R_{j_1,j_2,\ldots,j_r}$.

Now, let us focus on the positions in $\bar{R}_{j_1,j_2,\ldots,j_r}$. For any $g \in \mathcal{G}$, define $Set(g, s_{i_1})$ be the set of positions in $\bar{R}_{j_1,j_2,\ldots,j_r}$, where g and s_{i_1} do not agree. From Lemma 12, we know that there exists a set of y_2 positions $K_{y_2} = \{k_j \in \bar{R}_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[k_j] \neq s[k_j]\}$ such that for any $g \in \mathcal{G}$, $|K_{y_2} \cap Set(g, s_{i_1})| \leq \frac{y}{r}$. Though we do not know the exact value of y_2, again we can guess it in $O(y)$ time. Thus, we can assume that y_2 is known.

Let $s_{i_1}(K_{y_2})$ be the string obtained from s_{i_1} by changing the letters at the positions in K_{y_2} to any different letters. From Lemma 12, we can see that for any $g \in \mathcal{G}$,

$$d(g, s_{i_1}(K_{y_2})|\bar{R}_{j_1,j_2,\ldots,j_r}) \geq d(g, s|\bar{R}_{j_1,j_2,\ldots,j_r}) - \frac{1}{r}y. \tag{14}$$

Now, the only remaining task is to select y_2 positions in $\bar{R}_{j_1,j_2,\ldots,j_r}$ to approximate the set K_{y_2}. Recall that $|\{j \in \bar{R}_{j_1,j_2,\ldots,j_r} \mid s_{i_1}[j] \neq s[j]\}| = y_2$. From this we have that for every good string $g \in \mathcal{G}$,

$$d(g, s_{i_1}|\bar{R}_{j_1,j_2,\ldots,j_r}) - d(g, s|\bar{R}_{j_1,j_2,\ldots,j_r}) \geq -y_2. \tag{15}$$

Next we are going to show that we can find a set K'_{y_2} of y_2 positions in $\bar{R}_{j_1,j_2,\ldots,j_r}$ in polynomial time such that for any $g \in \mathcal{G}$, $|K'_{y_2} \cap Set(g, s_{i_1})| \leq \frac{y}{r}$. If this is true, by changing the letters of s_{i_1} on the positions in K'_{y_2}, the distance between $s_{i_1}(K'_{y_2})$ and g has to increase at least $y_2 - \frac{y}{r}$. To do this, let $m \leq |\bar{R}_{j_1,j_2,\ldots,j_r}|$ be an integer and $\bar{R}_{j_1,j_2,\ldots,j_r}(m) \subseteq \bar{R}_{j_1,j_2,\ldots,j_r}$ be any subset of $\bar{R}_{j_1,j_2,\ldots,j_r}$ with m elements.

The following two lemmas are the keys to solving the problem.

LEMMA 13. *If $m \geq 2^{r^2} \times y \times (n+1)^{\frac{r}{y}} + \frac{y}{r}$, then there exists a set $K'_{y_2} \subseteq \bar{R}_{j_1,j_2,\ldots,j_r}(m)$ of y_2 positions such that for any $g \in \mathcal{G}$,*

$$|K'_{y_2} \cap Set(g, s_{i_1})| \leq \frac{y}{r}.$$

Proof. Consider a string g in $\mathcal{G}$. Let $K''_{y_2} \subseteq \bar{R}_{j_1,j_2,\ldots,j_r}(m)$ denote a set of y_2 positions. By Assumption 1, that $d(s_{i_1}, g|Q_{i_1,i_2,\ldots,i_t}) < ry$, for any fixed $g \in \mathcal{G}$, the number of different K''_{y_2}'s such that

$$|K''_{y_2} \cap Set(g, s_{i_1})| \geq \frac{y}{r}$$

is at most

$$\begin{aligned} C_{m-ry}^{y_2-\frac{y}{r}} C_{ry}^{\frac{y}{r}} + C_{m-ry}^{y_2-\frac{y}{r}-1} C_{ry}^{\frac{y}{r}+1} + \cdots + 1 &\leq C_{m-ry}^{y_2-\frac{y}{r}} (C_{ry}^{\frac{y}{r}} + C_{ry}^{\frac{y}{r}+1} + \cdots + 1) \\ &\leq C_{m-ry}^{y_2-\frac{y}{r}} 2^{ry}. \end{aligned} \tag{16}$$

There are at most $n_2 \leq n_2 + n_1 = n$ strings in $\mathcal{G}$. Thus, if there is no $K''_{y_2} \subseteq \bar{R}_{j_1,j_2,\ldots,j_r}(m)$ such that

$$|K''_{y_2} \cap Set(g, s_{i_1})| \leq \frac{y}{r},$$

then

$$\begin{aligned} n_2 &\geq \frac{C_m^{y_2}}{2^{ry} C_{m-ry}^{y_2-\frac{y}{r}}} \\ &= \frac{m(m-1)\cdots(m-y_2+1)(y_2-\frac{y}{r})!}{y_2!(m-ry)(m-ry-1)\cdots(m-ry-y_2+\frac{y}{r}+1)2^{ry}} \\ &\geq \frac{m(m-1)\cdots(m-\frac{y}{r}+1)}{y_2(y_2-1)\cdots(y_2-\frac{y}{r}+1)2^{ry}} \\ &\geq \frac{(m-\frac{y}{r}+1)^{\frac{y}{r}}}{y^{\frac{y}{r}} \cdot 2^{ry}} > \frac{(m-\frac{y}{r})^{\frac{y}{r}}}{y^{\frac{y}{r}} 2^{ry}} = \frac{(m-\frac{y}{r})^{\frac{y}{r}}}{y^{\frac{y}{r}} (2^{r^2})^{\frac{y}{r}}} \\ &= \left(\frac{m-\frac{y}{r}}{2^{r^2} y}\right)^{\frac{y}{r}} \geq n+1. \end{aligned}$$

The last inequality is from the fact that $m \geq 2^{r^2} \times y \times (n+1)^{\frac{r}{y}} + \frac{y}{r}$. This is a contradiction. Thus, we can conclude that the lemma holds. ∎

Lemma 13 says that a good solution exists at the positions in $\bar{R}_{j_1,j_2,\ldots,j_r}(m)$ if $m = 2^{r^2} \times y \times (n+1)^{\frac{r}{y}} + \frac{y}{r}$. On the other hand, the following lemma shows that $m = 2^{r^2} \times y \times (n+1)^{\frac{r}{y}} + \frac{y}{r}$ is not too big so that we can find such a good solution in polynomial time by looking at all $C_m^{y_2}$ possible choices.

LEMMA 14. *If* $m = 2^{r^2} \times y \times (n+1)^{\frac{r}{y}} + \frac{y}{r}$ *and* $y \le (4\log(n_1+n_2))/{\delta_0}^2$, *then* C_m^y *is* $O((n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+r}$.

Proof.

$$C_m^y = \frac{m(m-1)\cdots(m-y+1)}{y!} \le \frac{m^y}{y!}$$

$$\le \left(\frac{m}{y}\right)^y e^y \le \left(\frac{2(m-\frac{y}{r})}{y}\right)^y e^y \tag{17}$$

$$= \left(\frac{2(m-\frac{y}{r})}{2^{r^2}y}\right)^y (2^{r^2})^y e^y = 2^y (n+1)^r (2^{r^2})^y e^y. \tag{18}$$

Since $y \le (4\log(n_1+n_2))/{\delta_0}^2$, from (18), C_m^y is $O((n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+r}$. ∎

LEMMA 15. *For Case* 3, *the time required to select* y *positions in* $Q_{i_1,i_2,\ldots,i+2r}$ *is* $O(rLd_b^2(n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+2r})$.

Proof. The time to deal with $R_{j_1,j_2,\ldots,j_r}$ is smaller than that of $\bar{R}_{j_1,j_2,\ldots,j_r}$. It requires $O((n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+r})$ time to deal with an $\bar{R}_{j_1,j_2,\ldots,j_r}$. Obtaining an $\bar{R}_{j_1,j_2,\ldots,j_r}$ needs $O(n_2^r Lr)$ time. We also have to guess y and y_2 (thus y_1) in d_b^2 time. Thus, the total time required to select y positions in $Q_{i_1,i_2,\ldots,i+2r}$ is $O(rLd_b^2(n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+2r})$. ∎

THEOREM 16. *There is a PTAS for the DSP. The PTAS runs in* $O(L \times |\Sigma|^{O(\log(n_1+n_2)(r-1)^6)})$ *time and finds a distinguishing string* s *such that for every* $s_i \in \mathcal{B}$, $d(s_i,s) \le (1+\frac{1}{r-1})d_b$, *and for every* $g_i \in \mathcal{G}$, $d(g_i,s) \ge (1-\frac{1}{r-1})d_g$ *if a solution to the original pair* $(d_b \le d_g)$ *exists.*

Proof. According to Theorem 3, step 1 in Algorithm gdistString (Figure 1) requires $O(L \times |\Sigma|^{4\log(n_1+n_2)/\delta^2})$ time, where $\delta = \epsilon \min\{\frac{1}{4r}, \frac{1}{2(r-1)^2}\}$, and the performance ratios are $(1+\epsilon)$ and $(1-\epsilon)$ for bad strings and good strings, respectively.

Consider step 2 of Algorithm gdistString. We discuss Cases 2 and 3 separately.

Case 2. Lemma 11 shows that for a fixed $Q_{i_1,i_2,\ldots,i_{2r}}$ we can find a string y_{i_1} from s_{i_1} such that for each $g \in \mathcal{G}$ we have

$$d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_{2r}}) - d(s_{i_1}, g|Q_{i_1,i_2,\ldots,i_{2r}}) \ge \frac{r-3}{r-1}y - 2\delta_0 y$$

in $O(d_b^2(n_1+n_2)^{\log((r-1)^2e)8/\delta_0^2})$ time.

For the positions in $P_{i_1,i_2,\ldots,i_{2r}}$, we can use the LP approach to solve the following inequalities:

$$\begin{cases} \sum_{a\in\Sigma} x_{k,a} = 1, \quad k = 1,2,\ldots,|P_{i_1,i_2,\ldots,i_{2r}}|, \\ \sum_{k\in P_{i_1,i_2,\ldots,i_{2r}}} \sum_{a\in\Sigma} \chi(s,i,k,a)\, x_{k,a} \le \frac{r+1}{r-1} d_b - d(s_{i_1}, s_i|Q_{i_1,i_2,\ldots,i_{2r}}) - y, \\ \qquad i = 1,2,\ldots,n_1, \\ \sum_{k\in P_{i_1,i_2,\ldots,i_{2r}}} \sum_{a\in\Sigma} \chi(g,j,k,a)\, x_{k,a} \ge d_g - d(s_{i_1}, g_j|Q_{i_1,i_2,\ldots,i_{2r}}) - y, \\ \qquad j = 1,2,\ldots,n_2, \\ x_{k,a} \in \{0,1\}, \quad a \in \Sigma, \ k \in P_{i_1,i_2,\ldots,i_{2r}}. \end{cases} \tag{19}$$

Since $|P_{i_1,i_2,\ldots,i_{2r}}| \le 2rd_b$, from Theorem 3, the run time required is $O(2rd_b^2 \times |\Sigma|^{4\log(n_1+n_2)\times/\delta^2})$ for $\delta = \epsilon/(2r)$ since we have to guess the value of y. Since we

have to try all $Q_{i_1,i_2,\ldots,i_{2r}}$'s and the values of d_b and d_g, the total time required is $O(L^4 n_1^{2r}[(n_1+n_2)^{\log((r-1)^2 e)8/\delta_0^2} + r \times |\Sigma|^{4\log(n_1+n_2)\times/\delta^2}])$. The total errors are $(1+\epsilon+\frac{2}{r-1})d_b$ and $(1-\epsilon-\frac{2}{r}-2\delta_0)d_g$.

Case 3. Lemmas 13 and 15 show that we can find a string y_{i_1} in $O(rLy^2(n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+2r})$ time such that for any $g \in \mathcal{G}$ we have $d(y_{i_1}, g|Q_{i_1,i_2,\ldots,i_{2r}}) \geq d(s, g|Q_{i_1,i_2,\ldots,i_{2r}}) - \frac{2}{r}$.

For positions in $P_{i_1,i_2,\ldots,i_{2r}}$, we do the same thing as in Case 2. The time required is $O(rd_b^2 \times |\Sigma|^{4\log(n_1+n_2)\times/\delta^2})$ for $\delta = \epsilon/(2r)$. Thus, the total time required is $O(rd^4 n_1^{2r}[L(n_1+n_2)^{(4r^2+4+4\log e)/\delta_0^2+2r} + |\Sigma|^{4\log(n_1+n_2)\times/\delta^2}])$. The total errors are $(1+\epsilon+\frac{2}{r-1})d_b$ and $(1-\epsilon-\frac{2}{r})d_g$ in this case.

Case 1 dominates the time complexity when the errors are small. For example, if $e = \frac{1}{r-1}$, then the algorithm finds a distinguishing string s such that for every $s_i \in \mathcal{B}$, $d(s_i, s) \leq (1+\frac{1}{r-1})d_b$; for every $g_i \in \mathcal{G}$, $d(g_i, s) \geq (1-\frac{1}{r-1})d_g$; and the running time is $O(L \times |\Sigma|^{O(\log(n_1+n_2)(r-1)^6)})$. □

5. The DSSP. In this section, we present the algorithm for the DSSP. The idea is to combine the sampling technique in [9] with the algorithm for the DSP. The difficulty here is that for each $s_i \in \mathcal{B}$, we do not know the substring t_i of s_i. The sampling approach in [9] is as follows: For any fixed $r > 0$, by trying all the choices of r substrings of length L from $\mathcal{B}$, we can assume that $t_{i_1}, t_{i_2}, \ldots, t_{i_r}$ are the r substrings of length L that satisfy Lemma 13 by replacing s_l with t_l and s_{i_j} with t_{i_j}. Let Q be the set of positions at which $t_{i_1}, t_{i_2}, \ldots, t_{i_r}$ agree and $P = \{1, 2, \ldots, L\} - Q$. By Lemma 13, $t_{i_1}|Q$ is a good approximation to $s|Q$. However, we do not know the letters at positions in P. Thus, we randomly pick $O(\log(mn))$ positions from P, where m is the length of bad strings. Suppose that the multiset of these random positions is R. By trying all length-$|R|$ strings, we can assume that we know $s|R$. Then for each $1 \leq i \leq n_1$ we find the substring t_i' from s_i such that $f(t_i') = d(s, t_i'|R) \times \frac{|P|}{|R|} + d(t_{i_1}, t_i'|Q)$ is minimized. Let s be the optimal distinguishing string. Then t_i denotes the substring of s_i that is closest to s. Let s^* be a string such that $s^*|P = s|P$ and $s^*|Q = t_{i_1}|Q$. Then [9] shows the following.

Fact 1. With probability $1 - ((nm)^{-2} + (nm)^{-\frac{4}{3}})$, $d(s^*, t_i') \leq d(s^*, t_i) + 2\epsilon|P|$ for all $1 \leq i \leq n$.

After obtaining a t_i' of s_i for every $s_i \in \mathcal{B}$, we have the DSP, which can be solved by using the algorithms developed in section 3.

THEOREM 17. *There is a polynomial time approximation scheme that takes $\epsilon > 0$ as part of the input and computes a center string s of length L such that for every $s_i \in \mathcal{B}$ there is a length-L substring t_i of s_i with $d(s_i, s) \leq (1+\epsilon)d_b$, and for every $g_i \in \mathcal{G}$, $d(g_i, s) \geq (1-\epsilon)d_g$ if a solution exists.*

Proof. Let s' be the solution obtained by our algorithm. Lemma 9 and Fact 1 ensure that for each $s_i \in \mathcal{B}$, $s(t_i', s') \leq \frac{r}{r-1}d_b + \epsilon'|P|$, where $\frac{1}{r-1}d_b$ is the error at the positions in Q and $\epsilon'|P|$ ($\epsilon' = 2\epsilon + \epsilon''$) is the total error at the positions in P produced by both the random sampling method and the algorithm for the DSP. Lemma 9, together with sections 3 and 4, ensures that for each $g \in \mathcal{G}$, $d(g, s') \geq (1-\epsilon)d_g$, where ϵ is the error rate introduced by the algorithm for the DSP.

The randomized algorithm can be derandomized by the standard methods; [7] gives a short and clear explanation. □

6. Discussion and remarks. Our work concludes the search for provably good algorithms for the DSSP by presenting a PTAS. Some techniques have been developed

here dealing with values of parameters smaller than $\log(n)$ but larger than $O(1)$. They may have other applications to similar problems.

WINDOWS SCHEDULING PROBLEMS FOR BROADCAST SYSTEMS*

AMOTZ BAR-NOY† AND RICHARD E. LADNER‡

Abstract. The *windows scheduling problem* is defined by the positive integers n, h, and $w_1, \ldots, w_n$. There are n pages where the *window* w_i is associated with *page* i, and h is the number of *slotted channels* available for broadcasting the pages. A schedule that solves the problem assigns pages to slots such that the gap between any two consecutive appearances of page i is at most w_i slots. We investigate two optimization problems. (i) The *optimal windows scheduling problem*: given $w_1, \ldots, w_n$ find a schedule in which h is minimized. (ii) The *optimal harmonic windows scheduling problem*: given h find a schedule for the windows $w_i = i$ in which n is maximized. The former is a formulation of the problem of minimizing the bandwidth in push systems that support guaranteed delay, and the latter is a formulation of the problem of minimizing the startup delay in media-on-demand systems. For the optimal windows scheduling problem we present an algorithm that constructs asymptotically close to optimal schedules, and for the optimal harmonic windows scheduling problem we show how to achieve the largest known n's for all values of h.

Key words. scheduling algorithms, windows scheduling, broadcast systems, media-on-demand systems, push systems

DOI. 10.1137/S009753970240447X

1. Introduction.

The *windows scheduling problem* is defined as follows, using terminology borrowed from a broadcasting system environment:

> Given are h slotted channels and n pages, $1, \ldots, n$, each associated with a window $w_i \geq 1$ that is an integral number. Is it possible to schedule the n pages on the h channels, one page per one channel at each time slot, such that the gap between two consecutive appearances of page i is no more than w_i?

If for a given h and $W = \langle w_1, \ldots, w_n \rangle$ the answer to the windows scheduling problem is positive, the schedule that solves the problem is called an $\langle h, W \rangle$-schedule. The natural optimization problem is to find for a given W the minimum h, denoted by $H(W)$, such that there exists an $\langle h, W \rangle$-schedule. We call this problem the *optimal windows scheduling problem.* Since a restricted version of the optimal windows scheduling problem is NP-hard even for one channel [3], we will be looking for approximation solutions.

As an example of a windows scheduling problem consider the vector $W = \langle 2, 4, 5 \rangle$, which can be scheduled on one channel as follows:

$$(1) \qquad \left[\begin{array}{cccccccccc} 2 & 4 & 2 & 5 & 2 & 4 & 2 & 5 & \cdots \end{array} \right].$$

Note that 2 is scheduled every 2 slots and 4 is scheduled every 4 slots, but 5 is scheduled every 4 slots. Clearly, this problem cannot be solved in any fewer number of channels so that $H(W) = 1$.

The *harmonic windows scheduling problem* is a special case of the windows scheduling problem in which $w_i = i$ for $1 \leq i \leq n$. If for given h and n the answer to the harmonic windows scheduling problem is positive, then the schedule that solves the problem is called an $\langle h, n\rangle$-schedule. Here, for a given n the minimum h such that there exists an $\langle h, n\rangle$-schedule is denoted by $H(n)$. However, an optimization objective that is more natural to the harmonic windows scheduling problem is to find for a given h the maximum n, denoted by $N(h)$, such that there exists an $\langle h, n\rangle$-schedule. We call this problem the *optimal harmonic windows scheduling problem*.

It is not difficult to see that $N(1) = 1$ and $N(2) = 3$ using the $\langle 2, 3\rangle$-schedule

$$\begin{bmatrix} 1 & 1 & 1 & 1 & \cdots \\ 2 & 3 & 2 & 3 & \cdots \end{bmatrix}. \tag{2}$$

A more interesting example is the $\langle 3, 9\rangle$-schedule demonstrating that $N(3) \geq 9$:

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & \cdots \\ 2 & 4 & 2 & 5 & 2 & 4 & 2 & 5 & 2 & 4 & 2 & 5 & \cdots \\ 3 & 6 & 7 & 3 & 8 & 9 & 3 & 6 & 7 & 3 & 8 & 9 & \cdots \end{bmatrix}. \tag{3}$$

This $\langle 3, 9\rangle$-schedule is known from the literature [15], but it is unknown whether the schedule is optimal. There may be a $\langle 3, 10\rangle$-schedule, but there is no $\langle 3, 11\rangle$-schedule (as implied by Theorem 3). Note also that the windows scheduling problem $W = \langle 2, 4, 5\rangle$ has a solution as the second channel of the $\langle 3, 9\rangle$-schedule above. Thus, the windows scheduling problem is not only a generalization of the harmonic windows scheduling problem, but solutions to windows scheduling problems can be merged together to solve a harmonic windows scheduling problem.

We note that the performance criterion for these two optimization problems is based on the *max* metric and not the *average* metric. That is, the next appearance of a page depends only on its previous appearance. In the traditional scheduling problems the focus was on the average metric, where in a way the next appearance of a page depends on all of its previous appearances.

The optimal windows scheduling problem is a formulation of the problem of minimizing the bandwidth of push systems that support guaranteed delay for the broadcasted pages. The optimal harmonic windows scheduling problem is an alternative formulation of the problem of minimizing the guaranteed startup delay in recently proposed media-on-demand systems.

1.1. The push systems application. In *push systems*, servers broadcast pages over broadcast channels to clients. Clients who wish to access one of the broadcasted pages listen to the channels until they receive this page. In traditional push systems (e.g., the Teletext problem [2] and the broadcast disks problem [1]), the server broadcasts more popular pages more frequently to minimize the average access time for clients. In some situations, the server does not have this freedom since it broadcasts information of some providers who "paid" for a certain quality of service.

These situations were considered by [7, 4]. In their push systems model they assume that the broadcasting environment is composed of three groups of "players": (i) Clients who wish to access information pages from broadcast channels. (ii) Servers who broadcast the information pages on channels. (iii) Providers who supply the information pages. Servers "sell" quality of service to providers who "pay" proportionally

to the inverse of the maximum gap (access time) between any two appearances of their page on any of the channels.

After the selling process, the server is left with the optimal windows scheduling problem. That is, the server tries to minimize the number of channels that are needed to guarantee the quality of service "bought" by the providers.

1.2. The media-on-demand application. Media-on-demand is the demand by clients to play back, view, listen, or read various types of media such as video, audio, or large files with startup delays as small as possible and with no interruptions. The solution of dedicating a private channel to each client for the required media is implausible even with the ever-growing availability of network bandwidth. Thus, multicasting popular media to groups of clients seems to be the ultimate solution to the ever-growing demand for media. The first, and most natural, idea to exploit the advantage of multicasting is to batch clients together. This implies a tradeoff between the overall server bandwidth and the guaranteed startup delay. The main advantage of the batching solutions lies in their simplicity. The main disadvantage is that the guaranteed startup delay may still be too large.

The pyramid broadcasting paradigm, pioneered by Viswanathan and Imielinski [17], was the first solution that reduced dramatically the bandwidth requirements for servers by using a larger receiving bandwidth for clients and by adding buffers to clients. The novelty of the pyramid broadcasting paradigm is that clients with more complicated equipment are able to receive more bandwidth than they need for playback. This way they can buffer later portions of the required transmission to play them back on time. Many papers followed this line of research with various models. All of them demonstrated that with added complexity to the system, a huge improvement can be achieved over the traditional batching solutions.

To demonstrate the huge gain, suppose first that a server dedicates two channels to a two-hour movie. In traditional systems, by staggering the transmissions over the two channels, the server can guarantee a one-hour startup delay. In systems with the new paradigm, the server can guarantee a startup delay of 40 minutes. Now suppose that a server dedicates 12 channels to a two-hour movie. In this case, the improvement will be from ten minutes to less than two seconds with a simple solution using the new paradigm and to less than one-tenth of a second with a more complicated solution found in this paper.

In this paper, we adopt the model of [9, 11] that focuses on the tradeoff between the server bandwidth and the guaranteed startup delays and ignores the other two parameters, the receiving bandwidth of clients and their buffer size. In this model, the transmission is divided into n equal-size segments and the time is slotted with slots of size $1/n$ of the transmission length. Servers broadcast the n segments on h channels according to some transmission schedule. Clients who wish to receive the transmission wait for a beginning of a slot, and thereafter they buffer the first appearance of segment i for $1 \leq i \leq n$. If for all $1 \leq i \leq n$ segment i appears in one of the ith slots after the client arrival time, then the client is guaranteed an uninterrupted playback. This is because when the client needs to play back the ith segment, it is either in its buffer or transmitted on one of the channels. It is assumed that clients have large enough buffers that can store a full transmission and that they can receive data from all the channels concurrently.

We demonstrate this model with the simple case of a server with two channels (see schedule (1) in the introduction). The transmission is divided into three segments. The first segment is broadcasted repeatedly on the first channel. The second and

third segments are broadcasted alternately on the second channel. A client has two possible starting times for receiving the transmission. The first is before a slot in which the second segment is broadcasted on the second channel and the second is before a slot in which the third segment is broadcasted on the second channel. (i) In the first time slot, in both cases, the client plays back the first segment from the first channel. At the same time, in the first case the client buffers segment two, and in the second case the client buffers segment three. (ii) In the second time slot, in the first case the client plays back segment two from its buffer while buffering segment three. In the second case, the client plays back segment two from the second channel. (iii) In the third time slot, in both cases, the client plays back segment three from its buffer. In this example, the guaranteed startup delay is one-third the transmission length.

A necessary and sufficient condition for clients to view the transmission with no interruptions is that segment i is broadcasted at least once in any consecutive i slots. In particular, a channel must be dedicated to the first segment, and the second segment must appear in at least every other slot on one of the other channels. Thus, if an $\langle h, n\rangle$-schedule exists, then clients can view the movie with no interruption with a guaranteed startup delay of $1/n$ of the movie length. To see this, assume first that clients arrive only at the beginning of slots; in this case a client may view the movie immediately with no interruptions. This is because the ith segment will be either on one of the channel's i time slots after the arrival time of the client or in the client's buffer. As a result, clients who arrive in arbitrary times need to wait for a beginning of a slot in order to view the movie with no interruptions. The maximum startup delay is therefore $1/n$ of the movie length.

Remark. A "fractional" version of the problem allows mixing segments together in each channel. With this capability, the papers [10, 13, 14] present solutions that almost match the lower bound of [6]. However, this fractional model does not apply to the general windows scheduling problem and to the push systems application. Furthermore, even for the media-on-demand application, in many systems the "integral" version of the problem is more realistic.

1.3. Previous results and our contributions. To the best of our knowledge there are no published solutions for the optimal windows scheduling problem as formulated in this paper. Papers [8, 11] present a simple $\langle h, 2^h - 1\rangle$-schedule for the harmonic windows scheduling problem. The best known results for the harmonic windows scheduling problem appear in [15, 12]. The pagoda scheme [15] starts with a $\langle 3, 9\rangle$-schedule and then generalizes this schedule for $h > 3$ as follows. For an even $h > 3$, the Pagoda scheme is an $\langle h, (4/5)\sqrt{5}^h - 1\rangle$-schedule, and for an odd $h > 3$, it is an $\langle h, (2/\sqrt{5})\sqrt{5}^h - 1\rangle$-schedule. Asymptotically, the pagoda scheme implies an $N(h) = O(\sqrt{5}^h) \approx O(2.236^h)$ solution. The new pagoda scheme [12] deals with small values of h. Their lower bounds on $N(h)$ for $h = 3, 4, 5, 6, 7$ are $9, 26, 66, 172, 442$, respectively (see Table 1).

We first present an asymptotic result for the optimal windows scheduling problem. Define $h(W) = \sum_{i=1}^{n} 1/w_i$. A simple argument shows that $\lceil h(W)\rceil$ is a lower bound for $H(W)$ since page i requires at least a $1/w_i$ portion of a channel. We show that a schedule exists that uses at most $h(W) + e\ln(h(W)) + 7.3595$ channels.[1] In other words, this schedule is within a factor of $1 + O\left(\ln(h(W))/h(W)\right)$ of optimal. This translates into a solution with $\left(e - O\left(\ln(h)/h\right)\right)^h$ pages for the harmonic windows

[1] The symbol e is the base of the natural logarithm ln. All decimal constants are at the precision provided by the software package *Mathematica* for a predetermined number of decimal points [18].

scheduling problem where h is the number of given channels and $0.561463e^h$ is an upper bound for $N(h)$.

The second part of our contribution focuses on "practical" approximate solutions to the optimal harmonic windows scheduling problem. Recall that in this case we fix the number of channels h and seek to find an $\langle h, n\rangle$-schedule for the largest possible n. An optimal solution would be an $\langle h, N(h)\rangle$-schedule. The asymptotic result implied by the solution to the optimal windows scheduling problem does not generate schedules "good" enough for small h. Most of the known constructions are based on more restrictive schedules. For example, the $\langle h, 2^h - 1\rangle$-schedule (see section 2) schedules each page at fixed intervals, schedules a page only on one channel, and on each channel schedules only consecutive pages. In this paper, all of the constructions schedule each page on only one channel. Most of them will schedule a page at fixed intervals. We call such schedules *perfect schedules*.

We first describe a greedy schedule that approaches the upper bound for $N(h)$ for small values of h. This greedy scheme is based on a tree representation of perfect schedules introduced in [5]. The greedy strategy can be applied to the general windows scheduling problem as well to obtain good bounds for $H(W)$ for cases in which $h(W)$ is small. Next we develop a technique that combines an $\langle h_1, n_1\rangle$-schedule with an $\langle h_2, n_2\rangle$-schedule to get an $\langle h_1 + h_2, ((n_1 + 1)(n_2 + 1))/2 - 1\rangle$-schedule. With this technique, we get the best results for the number of channels for which we cannot run the greedy algorithm. Finally, we present our nontrivial nonperfect schedules for $h = 4, 5, 6$ channels. These schedules were constructed using the tree representation technique with some modifications to accommodate nonperfect schedules.

TABLE 1
Results for 1 *to* 12 *channels.*

# of channels	1	2	3	4	5	6	7	8	9	10	11	12
Upper bound	1	3	10	30	82	226	615	1673	4549	12366	33616	91379
Best bound	1	3	9	28	77	211	570	1573	4325	11759	31677	86428
Greedy	1	3	9	25	73	201	565	1522	4284	11637	31677	86428
Pagoda	1	3	9	26	66	172	442	499	1249	2499	6249	12499

We summarize the bounds for 1 to 12 channels in Table 1. For a given h, we compare four values for $N(h)$: the upper bound, our best lower bound, the bound of the basic greedy algorithm described in section 4, and the best lower bound of the pagoda scheme [15] and the new pagoda scheme [12]. Our best bounds for small h $(4, 5, 6)$ were achieved by hand tuning the results of the greedy algorithm and for larger h by modifications to the greedy algorithm. To interpret Table 1 imagine that we can devote 8 channels to a two-hour movie. Without any of these schemes a new movie can start every $120/8 = 15$ minutes. With the pagoda scheme a movie can start every $7200/499 \approx 14.5$ seconds. With our best bound a movie can start every $7200/1573 \approx 4.6$ seconds. No such scheme can guarantee starting any faster than every $7200/1673 \approx 4.3$ seconds.

1.4. Organization. Section 2 presents some definitions and notation used later in the paper. Section 3 presents the upper bound and the asymptotic lower bounds for the optimal windows scheduling problem and the optimal harmonic windows scheduling problem. Section 4 describes the greedy algorithm which is an approximation algorithm for the optimal harmonic windows scheduling problem. Section 5 presents the combination technique for the optimal harmonic windows scheduling problem. Section 6 illustrates our best solutions for small numbers for the harmonic windows

scheduling problem. Finally, section 7 discusses some work in progress and open problems.

2. Preliminaries. In subsection 2.1, we present some of our definitions in a more formal way. In subsection 2.2, we describe a tree representation for perfect schedules that does not cover all the possible perfect schedules but is enough to serve as a base for our greedy algorithm and to represent most of our solutions for small numbers. The idea is borrowed from [5]. We describe what is needed to understand this paper.

2.1. Definitions and notation. A more formal definition of the windows scheduling problem and its special case, the harmonic windows scheduling problem, is as follows. We are asked to create an $h \times \infty$ matrix C in which the entry $C(j,t)$ is the page number that is scheduled at time slot t on the jth channel for $1 \le j \le h$ and $1 \le t \le \infty$. The requirement from the matrix is that for any $1 \le i \le n$ and $1 \le t \le \infty$, i is an element in the submatrix $C[1..h, t..t + w_i - 1]$. That is, i appears in one of the entries in the following submatrix:

$$\begin{bmatrix} C(1,t) & \dots & C(1,t+w_i-1) \\ \vdots & & \vdots \\ C(h,t) & \dots & C(h,t+w_i-1) \end{bmatrix}.$$

For the harmonic windows scheduling problem the same definition holds where $w_i = i$. Although a schedule is formally defined by an infinite matrix, any reasonable solution will be defined as the infinite concatenation of a finite schedule C which is a finite $h \times \ell$ matrix for some ℓ. Although it is not required, in all of our solutions each page is scheduled on a single channel. Such a solution has the property that for each page i, there is a channel h_i such that $i \notin \{C(h',t) : h' \ne h_i \text{ and } 1 \le t \le \ell\}$. Because of this we can focus on the schedules for individual channels.

Let $W = \langle w_1, \dots, w_n \rangle$ be a window vector. For a sequence $S = \langle s_0, \dots, s_{\ell-1} \rangle$ with $s_i \in \{0, 1, \dots, n\}$, define $M_S \subseteq \{1, \dots, n\}$ as the set of nonzero numbers in the sequence S. The sequence S is a potential row of a finite schedule for W. If $s_i = 0$, then no page is assigned to position i in the schedule. We define $S = \langle s_0, \dots, s_{\ell-1} \rangle$ to be a *channel schedule* for W if for each $i \in M_S$, if $i(1) < i(2) < \cdots < i(n_i)$ are all the indices such that $s_{i(j)} = i$, then $i(j+1) - i(j) \le w_i$ for $1 \le j < n_i$ and $\ell - i(n_i) + i(1) \le w_i$. This is equivalent to saying that when we repeat the schedule infinitely, for each i, i appears in the infinite schedule in every consecutive w_i slots. A channel schedule S is *perfect* if there exists a $w'_i \le w_i$ such that $i(j+1) - i(j) = w'_i$ for $1 \le j < n_i$ and $\ell - i(n_i) + i(1) = w'_i$. We call w'_i the window size of i in the perfect channel schedule S. If we repeat a perfect schedule infinitely, then in the infinite schedule, for each i, i appears periodically every w'_i slots. A channel schedule S is *fully utilized* if $s_i \ne 0$ for all i, that is, every position in the schedule has some page assigned to it. The following proposition should be clear.

PROPOSITION 1. *If S is a (perfect) channel schedule, then so is the result of a finite concatenation of S with itself, a cyclic shift of S, and the reversal of S.*

A finite schedule for W can be formed from h channel schedules $S_1, \dots, S_h$ of lengths $\ell_1, \dots, \ell_h$, respectively, where $\cup_{i=1}^{h} M_{S_i} = \{1, 2, \dots, n\}$. Let ℓ be the least common multiple of $\{\ell_1, \dots, \ell_h\}$. By a finite concatenation of each channel schedule with itself, S_i can be transformed into a channel schedule of length ℓ. These channel schedules form the rows of a finite schedule matrix. A *perfect schedule* for W is one

formed from perfect channel schedules. We define a perfect $\langle h, n\rangle$-schedule to be a perfect schedule for the window vector $\langle 1, 2, \ldots, n\rangle$ using h channels.

2.2. A tree representation for perfect channel schedules. Let T be an ordered tree with n labeled leaves. Assume first that all the labels (pages) are distinct. We describe a procedure that generates a perfect channel schedule on the n pages from T, computes the length of this channel schedule, and computes the window size of each page.

PROCEDURE TREE-TO-SCHEDULE.

Input: A tree T with n leaves that are labeled with the labels $p_1, \ldots, p_n$ that represent the pages. Assume T has $d \geq 0$ subtrees.

Output: A perfect channel schedule S for these pages in which each page p_i has a fixed window size w'_i.

A leaf tree: If $n = 1$, then the schedule is $S = \langle p_1\rangle$.

The recursive step: If $n > 1$ and therefore $d > 0$, do the following:

- Recursively construct the channel schedules $S_1, \ldots, S_d$ of all the d subtrees of T. Assume their respective lengths are $\ell_1, \ldots, \ell_d$.
- Replicate each channel schedule and make all of them have the same length $\ell' = LCM\{\ell_1, \ldots, \ell_d\}$. Let the new schedules be $S'_1, \ldots, S'_d$. By Proposition 1, a replication of a perfect channel schedule results in a perfect channel schedule.
- The final channel schedule S of length $\ell = d\ell'$ is constructed by alternately picking ℓ' times the next page from the d channel schedules $S'_1, \ldots, S'_d$.

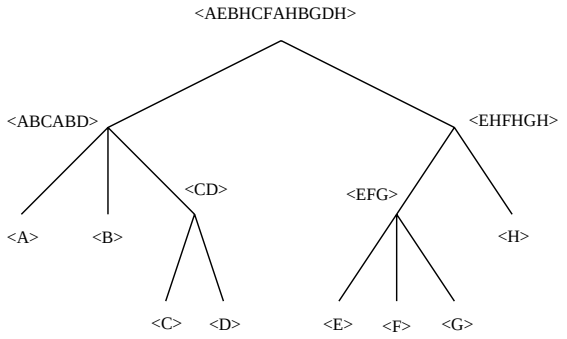

FIG. 1. *An example of a tree for pages* A, B, C, D, E, F, G, H.

A simple example is the round-robin tree. This is a tree whose root has d children, all of them leaves. If they are labeled by the numbers $p_1, p_2, \ldots, p_d$, then the channel schedule represented by this tree is the round-robin channel schedule $S = \langle p_1, p_2, \ldots, p_d\rangle$. A more complicated example is the tree in Figure 1. The labels are $A, B, \ldots, H$. Applying Procedure Tree-to-Schedule on the left and right subtrees yields the channel schedules $\langle ABCABD\rangle$ and $\langle EHFHGH\rangle$, respectively. Hence, the schedule representation of the tree is $\langle AEBHCFAHBGDH\rangle$.

We now give the condition for when Procedure Tree-to-Schedule generates a perfect channel schedule. Let $W = \langle w_1, \ldots, w_n\rangle$ be a window vector and let T be a tree with leaf labels $L \subseteq \{1, \ldots, n\}$. Let $W' = \cup_{i\in L}\{w_i\}$ be the window vector W restricted to the labels L. For $i \in L$, define $w'_i = \prod_{j=1}^{k} d_j$, where $d_1, \ldots, d_k$ are the

degrees of all the ancestors of the leaf labeled i in T from the root to the parent of the leaf labeled i. That is, d_1 is the degree of the root and d_k is the degree of the parent of the leaf labeled i. Let $\ell = LCM\{w'_1, \ldots, w'_{|L|}\}$.

THEOREM 2. *Procedure Tree-to-Schedule always produces a perfect channel schedule. This schedule satisfies W' if $w'_i \le w_i$ for all $i \in L$. In this case, w'_i is the window size of i in a channel schedule of length ℓ.*

Proof. We prove by induction on $|L|$ that the sequence $S = \langle s_0, \ldots, s_{\ell-1} \rangle$ produced by Procedure Tree-to-Schedule has the following *perfect* property:

> for each $i \in L$, if $i(1) < i(2) < \cdots < i(n_i)$ are all the indices such that $s_{i(j)} = i$, then $i(j+1) - i(j) = w'_i$ for $1 \le j < n_i$ and $\ell - i(n_i) + i(1) = w'_i$.

The theorem follows immediately from this.

For trees with one leaf this is clearly true. If the root of T has d_1 children, then by the induction hypothesis the procedure run on each of the d_1 subtrees produces the sequences $S_1, \ldots, S_{d_1}$, each with the perfect property. It follows that $S'_1, \ldots, S'_{d_1}$ defined by the procedure also have the perfect property because each is just a replication of a sequence with the perfect property (Proposition 1). In the final schedule S produced by the procedure, the label i occurs once every $w'_i = d_1 w''_i$ slots, where $w''_i = \prod_{j=2}^{k} d_j$ and $d_2, \ldots, d_k$ are the degrees of ancestors of the leaf labeled i in the subtree of T that contains i. Hence, the sequence S satisfies the perfect property. Finally, it is not hard to verify from the definition of the procedure that the length of S is $\ell = LCM\{w'_1, \ldots, w'_{|L|}\}$. □

Remark. So far we assumed that all the labels are distinct. This is not imperative. However, if two labels are the same, then the window size of the corresponding page may get more than one value. We use nonperfect trees in our solutions for $h = 4, 5, 6$.

Example. Figure 2 illustrates the h trees representing all the channel schedules in the $\langle h, 2^h - 1 \rangle$ perfect schedule. The window size of $1 \le i \le 2^h - 1$ is 2^j, where $2^j \le i < 2^{j+1}$.

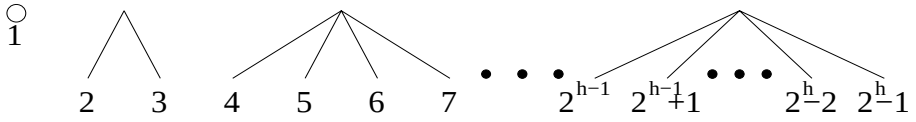

FIG. 2. *The $\langle h, 2^h - 1 \rangle$-schedule.*

3. Asymptotic bounds. Let $W = \langle w_1, w_2, \ldots, w_n \rangle$ be a window vector and let $h(W) = \sum_{i=1}^{n} 1/w_i$. Recall that $H(W)$ is the minimum h such that there exists an $\langle h, W \rangle$-schedule. In subsection 3.1 we show that $\lceil h(W) \rceil \le H(W)$. In subsection 3.4 we show that $H(W) \le h(W) + e \ln(h(W)) + O(1)$. The lower bound comes from a simple observation, while the upper bound comes from the construction of a perfect schedule for W with the required bound on the number of channels. For the upper bound, in subsection 3.2 we present optimal solutions to special cases for the window vector, and then in subsection 3.3 we give an outline of our algorithm and demonstrate it with an example. We conclude this section with subsection 3.5 that shows that these bounds translate to bounds for $N(h)$ for the optimal harmonic windows scheduling problem.

3.1. Lower bound for $H(W)$. We begin with the lower bound.

THEOREM 3. *For any window vector $W = \langle w_1, \ldots, w_n \rangle$,*

$$H(W) \ge \lceil h(W) \rceil .$$

Proof. We need at least h channels where $h-1 < \sum_{i=1}^{n} 1/w_i \le h$. This is because page i requires at least a $1/w_i$ fraction of a channel. □

3.2. Optimal solutions to special window vectors. The upper bound on $H(W)$ is achieved by constructing a perfect schedule. There are a number of steps in the construction, and we start with the simple case where the window sizes are all powers of 2. In this case there is a perfect schedule in which page i is scheduled exactly every w_i slots.

LEMMA 4. *If all the w_i are of the form 2^{v_i} for some $v_i \ge 0$, then there exists a perfect schedule for the windows scheduling problem that uses exactly $H(W) = \lceil h(W) \rceil$ channels, where $\lfloor h(W) \rfloor$ channels are fully utilized.*

Proof. To start, assume that $h(W)$ is an integer and, without loss of generality, that $w_1 \le \cdots \le w_n$. The proof is by induction on n. If $n = 1$, then $w_1 = 1$ and the lemma holds using exactly $h(W) = 1$ channel. If $n > 1$, then there are two cases. In the first case $w_n = 1$, which immediately implies that $w_1 = \cdots = w_n = 1$. Then $n = h(W)$ and the solution dedicates a separate channel to each page. In the second case $w_n > 1$. We claim that $w_n = w_{n-1}$, since otherwise the sum cannot be an integral number because all the $1/w_i$ for $1 \le i \le n-1$ are strictly larger than $1/w_n$. Let W' be the window vector that is constructed from W by deleting w_{n-1} and w_n and adding $w' = w_n/2$. Since $w_{n-1} = w_n$, it follows that $h(W') = h(W)$. By the induction hypothesis on W', we get a solution with $h(W')$ channels in which page $1 \le i \le n-2$ is scheduled every w_i slots and the new page is scheduled every $w_n/2 = w_{n-1}/2$ slots. Furthermore, all $h(W')$ channels are fully utilized. We replace this new page alternately with pages n and $n-1$. In this way these two pages are scheduled perfectly each every $w_n = w_{n-1}$ slots and all the $h(W)$ channels are fully utilized.

Now, suppose that $h(W)$ is not an integer. Because we are assuming powers of 2, the window vector W can be partitioned into two vectors W' and W'' such that $h(W') = \lfloor h(W) \rfloor$ and $h(W'') < 1$. By the proof above W' can be scheduled perfectly in $\lfloor h(W) \rfloor$ fully utilized channels. The window vector W'' can be scheduled in one additional channel as follows. Choose a positive integer $y < 2^{v_n}$ such that $h(W'') + y/2^{v_n} = 1$. Such a y exists since 2^{v_n} is divided by w_i for $1 \le i \le n$. Add y dummy pages each with a window of size 2^{v_n} to the window vector W'' to form a window vector W^* with $h(W^*) = 1$. By the proof above we obtain a perfect schedule for W^* using one channel. To obtain a perfect one channel schedule for W'' we simply omit the dummy pages. □

As a consequence of Lemma 4, we have our first upper bound that is achieved by simply rounding the window sizes down to the nearest power of 2.

LEMMA 5. *For any window vector W, there exists a perfect schedule that uses no more than $\lceil 2h(W) \rceil$ channels.*

Proof. Let $W = \langle w_1, w_2, \ldots, w_n \rangle$. For each w_i let v_i be the nonnegative integer such that $2^{v_i} \le w_i < 2^{v_i+1}$. Let $W' = \langle 2^{v_1}, \ldots, 2^{v_n} \rangle$. Any schedule for W' is also a schedule for W. By Lemma 4, there is a perfect schedule for W' that uses $\lceil h(W') \rceil$ channels. Since $w_i/2 < 2^{v_i}$,

$$h(W') = \sum_{i=1}^{n} \frac{1}{2^{v_i}} < 2 \sum_{i=1}^{n} \frac{1}{w_i} = 2h(W).$$

Thus, at most $\lceil 2h(W) \rceil$ channels are used in the schedule. □

We now improve the upper bound by generalizing Lemma 4. We consider instances in which all the window sizes are powers of 2 multiplied by the same number.

LEMMA 6. *If all the w_i are of the form $u2^{v_i}$ for some $u \geq 1$ and some $v_i \geq 0$, then there exists a perfect schedule for the windows scheduling problem that uses exactly $H(W) = \lceil h(W) \rceil$ channels, where $\lfloor h(W) \rfloor$ channels are fully utilized.*

Proof. Consider the set of windows $w'_i = w_i/u$. By Lemma 4, we can schedule the pages with the w'_i windows on

$$\left\lceil \sum_{i=1}^{n} \frac{1}{w'_i} \right\rceil = \left\lceil u \sum_{i=1}^{n} \frac{1}{w_i} \right\rceil \leq u \lceil h(W) \rceil$$

channels, where

$$\left\lfloor \sum_{i=1}^{n} \frac{1}{w'_i} \right\rfloor = \left\lfloor u \sum_{i=1}^{n} \frac{1}{w_i} \right\rfloor \geq u \lfloor h(W) \rfloor$$

channels are fully utilized. If needed, we add dummy channels with empty schedules to get a schedule with exactly $u \lceil h(W) \rceil$ channels. We now combine sets of u channels together in a round-robin fashion by picking pages alternately from the u channels. In this way the window of each page is multiplied by u. This is fine since by definition $w_i = uw'_i$. Overall, we reduced the number of channels by a factor of u. Hence we used at most $\lceil h(W) \rceil$ channels. When combining the channels, we do it so that the $u \lfloor h(W) \rfloor$ fully utilized channels are combined u at a time. This yields $\lfloor h(W) \rfloor$ fully utilized combined channels. □

3.3. Algorithm outline. Our goal is to construct an algorithm that for a given window vector W creates a perfect schedule with about $h(W) + e \ln(h(W))$ channels (see Lemma 7 for the exact bound). The algorithm is recursive and is based on Lemmas 4 and 6. We first give a high-level description of the algorithm with an illustrative example. The exact details of the algorithm and its analysis appear in subsection 3.4.

An instance of the algorithm is determined by two parameters k and x that are optimized to obtain the best bound. The parameter k represents the depth of the recursion, and the parameter x is optimized for each value of k. First assume that $k = 1$. Here we use Lemma 5 to get a schedule with at most $\lceil 2h(W) \rceil$ channels. Now, fix $k > 1$. Partition the vector of windows into x vectors denoted by W_u for $x \leq u < 2x$. Each window $w_i \in W_u$ will be rounded down to a window w'_i such that $w'_i = 2^{v_i}u'$, where $u = 2^v u'$ for an odd number u'. We round down the window w_i such that w'_i is maximal. The set of all the windows w'_i such that $w_i \in W_u$ is denoted by W'_u. By Lemma 6, we need $\lceil h(W'_u) \rceil$ channels to schedule all the new windows in W'_u. This schedule uses $\lfloor h(W'_u) \rfloor$ channels perfectly with no "waste," while the remaining windows (if they exist) are scheduled on the last channel. This implies a partition of the set W into the perfect vector W^p and the residual vector W^r. Each window $w_i \in W^p$ is scheduled perfectly according to its corresponding w'_i. To schedule the windows in W^r, we recursively apply the algorithm for some $k' < k$.

For each k, we pick the best value for x. We will show that when x is larger, then the w'_i values are closer to the original w_i values. However, the residual set W^r is too big. In order to use the recursion on a smaller residual set, we need a smaller value for x that in turn implies that some of the w'_i are too small compared with their corresponding w_i. This is the tradeoff that dictates the optimization process for the value of x. Finally, we will find the maximum value for k that can be used by this recursive algorithm to get our desired bound.

Example. Consider the following window vector:

$$W = \langle 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19 \rangle .$$

It follows that $2 < h(W) < 3$, and therefore we need at least 3 channels to schedule the windows in W. Let us examine first the case $k = 1$ (cf. Lemma 5), in which the new set of windows is

$$W' = \langle 2, 2, 4, 4, 4, 4, 8, 8, 8, 8, 8, 8, 8, 8, 16, 16, 16, 16 \rangle .$$

The best schedule for W' requires 4 channels. Now assume $k = 2$ and choose $x = 3$. We get the following three vectors W_3, W_4, W_5 and their corresponding three vectors W_3', W_4', W_5':

$$\begin{aligned}
W_3 &= \langle 3, 6, 7, 12, 13, 14, 15 \rangle , \\
W_3' &= \langle 3, 6, 6, 12, 12, 12, 12 \rangle , \\
W_4 &= \langle 2, 4, 8, 9, 16, 17, 18, 19 \rangle , \\
W_4' &= \langle 2, 4, 8, 8, 16, 16, 16, 16 \rangle , \\
W_5 &= \langle 5, 10, 11 \rangle , \\
W_5' &= \langle 5, 10, 10 \rangle .
\end{aligned}$$

For example, the window 7 is rounded down to 6 and therefore belongs to W_3, and the windows $16, 17, 18, 19$ all are rounded down to 16 and therefore belong to W_4. We can use one channel to schedule all the windows in W_3'. We use another channel to schedule the windows $\langle 2, 4, 8, 8 \rangle$ from W_4'. Hence, we get

$$\begin{aligned}
W^p &= \langle 2, 3, 4, 6, 7, 8, 9, 12, 13, 14, 15 \rangle , \\
W^r &= \langle 5, 10, 11, 16, 17, 18, 19 \rangle .
\end{aligned}$$

Now we apply the case $k = 1$ to schedule the windows in W^r. We get

$$W^{r\prime} = \langle 4, 8, 8, 16, 16, 16, 16 \rangle ,$$

which needs only one channel. All together, we need 3 channels: 2 for W^p and 1 for W^r.

3.4. Upper bound for $H(W)$. We are now ready for the major technical lemma which leads to our upper bound. Define r to be a mapping from the positive integers to the reals by

$$r(k) = \begin{cases} 1 & \text{for } k = 1, \\ r(k-1) + \frac{e^{(k-1)/k}}{(e^{(k-1)^2/k} - 1)} & \text{for } k \geq 2. \end{cases}$$

Obviously, the function r is a monotonic increasing function. Furthermore, the $\lim_{k \to \infty} r(k)$ exists and is approximately 4.6412.

LEMMA 7. *For any window vector W and all positive integers k, if $e^{k-1} < h(W) \leq e^k$, then there exists a perfect schedule with the number of channels bounded above by*

$$h(W) + kh(W)^{1/k} + r(k) .$$

Proof. Let $W = \langle w_1, w_2, \ldots, w_n \rangle$. We begin with $k = 1$. By Lemma 5, for any value of $h(W)$, there exists a perfect schedule, denoted by S_1, that uses no more than $\lceil 2h(W) \rceil < 2h(W) + 1 = h(W) + 1h(W)^{1/1} + r(1)$ channels.

Let $k > 1$. Let $e^{k-1} < h(W) \leq e^k$ and assume that the lemma holds for k', $1 \leq k' < k$, using the perfect schedule $S_{k'}$. The schedule S_k for W is defined as follows. Let $x = \lfloor h(W)^{(k-1)/k} \rfloor$. We partition the n windows of window vector W into the x window vectors $W_x, \ldots, W_{2x-1}$ and define a new window size $w'_i \leq w_i$ for each window w_i as follows.

Case $w_i < x$. Let $u = 2^{v_i} w_i$ for v_i such that $x \leq 2^{v_i} w_i < 2x$. Put w_i in W_u and set $w'_i = w_i$.

Case $w_i \geq x$. Let u, $x \leq u < 2x$, be such that $2^{v_i} u \leq w_i < 2^{v_i}(u+1)$ for some $v_i \geq 1$. Put w_i in W_u and set $w'_i = 2^{v_i} u$.

Let W'_u contain those w'_i such that $w_i \in W_u$. This implies a partition into x independent window vectors $W'_x, \ldots, W'_{2x-1}$. All the windows in W'_u have the form $u'2^v$ for an odd u' such that $u = u'2^{v'}$. Hence by Lemma 6, there exists a perfect schedule T_u for W'_u with $\lceil h_u \rceil$ channels, where $h_u = h(W'_u) = \sum_{w'_i \in W'_u} 1/w'_i$. A careful inspection of the proof of this lemma reveals that this schedule uses $\lfloor h_u \rfloor$ channels perfectly with no "waste," where the remaining windows (if they exist) are scheduled on the last channel. This implies a partition of the vector W_u into the perfect vector W^p_u and the residual vector W^r_u. W^p_u contains all the windows $w_i \in W_u$ for which their corresponding pages are scheduled on one of these no-waste channels. W^r_u contains the rest of the windows in W_u. As a result, $h^p_u = \sum_{\{i | w_i \in W^p_u\}} 1/w'_i$ is an integer and $\sum_{\{i | w_i \in W^r_u\}} 1/w'_i < 1$. Since $1/w_i \leq 1/w'_i$, it follows that $h^r_u = \sum_{\{i | w_i \in W^r_u\}} 1/w_i < 1$. Define $W^p = \cup_{x \leq u < 2x} W^p_u$ and $W^r = \cup_{x \leq u < 2x} W^r_u$. The schedule S_k schedules all the windows in W^p using the perfect schedules T_u with exactly $\sum_{u=x}^{2x-1} h^p_u$ channels.

Before describing how to schedule the pages whose windows are in W^r, we analyze the number of channels needed for W^p. For the windows scheduling problem W^p, window sizes $< 2x$ do not change and window sizes $\geq 2x$ are rounded down in each schedule T_u. The worst case happens when $w_i = 2^{v_i}(u+1) - 1$ for $u = x$ and therefore $w'_i = 2^{v_i} x$. This implies that $\frac{w_i}{w'_i} \leq \frac{x+1}{x}$. Hence, the number of channels in the schedule for W^p is

$$\sum_{w_i \in W^p} \frac{1}{w'_i} \leq \frac{x+1}{x} \sum_{w_i \in W^p} \frac{1}{w_i} = \frac{x+1}{x} h(W^p) = \frac{x+1}{x}(h(W) - h(W^r))$$

$$\leq h(W) + \frac{h(W)}{x} - h(W^r)\ . \tag{4}$$

The quantity $h(W)/x$ can be bounded as follows. Since $x = \lfloor h(W)^{(k-1)/k} \rfloor$, $k > 1$, and $e^{k-1} < h(W)$, we have

$$\begin{aligned} h(W)/x &= h(W) / \left\lfloor h(W)^{(k-1)/k} \right\rfloor \\ &\leq h(W)/(h(W)^{(k-1)/k} - 1) \\ &= h(W)^{1/k}/(1 - h(W)^{-(k-1)/k}) \\ &= h(W)^{1/k} \sum_{i=0}^{\infty} (h(W)^{-(k-1)/k})^i \\ &= h(W)^{1/k} + h(W)^{1/k}/(h(W)^{(k-1)/k} - 1) \\ &< h(W)^{1/k} + e^{(k-1)/k}/(e^{(k-1)^2/k} - 1). \end{aligned} \tag{5}$$

The final inequality holds because the function $z/(z^{k-1}-1)$ is decreasing for all $k>1$ and $z>1$.

We are left with the remaining windows, W^r, to be scheduled. Because $h_u^r<1$ for each u and $h(W)\le e^k$, we have $h(W^r)\le e^{k-1}$, as can be seen in the derivation

$$h(W^r)=\sum_{w_i\in W^r}\frac{1}{w_i}=\sum_{u=x}^{2x-1}h_u^r\le x=\left\lfloor h(W)^{(k-1)/k}\right\rfloor\le h(W)^{(k-1)/k} \tag{6}$$

$$\le (e^k)^{(k-1)/k}=e^{k-1}\ . \tag{7}$$

There are two cases to consider depending on whether $h(W^r)\le 1$.

Case 1. $h(W^r)\le 1$. In this case by Lemma 5, W^r has a perfect schedule with the number of channels bounded above by $\lceil 2h(W^r)\rceil\le 2h(W^r)+1$. By this and inequalities (4) and (5), there is a perfect schedule for W that has the number of channels bounded above by

$$h(W)+h(W)^{1/k}+h(W^r)+1+e^{(k-1)/k}/(e^{(k-1)^2/k}-1)\ .$$

Since $k-1\ge 1$ and $h(W)>e^{k-1}$ it follows that $1<(k-1)h(W)^{1/k}$. Since $h(W^r)\le 1$ it follows that $h(W^r)<(k-1)h(W)^{1/k}$. Furthermore, $1+e^{(k-1)/k}/(e^{(k-1)^2/k}-1)\le r(k)$. Hence, we have our bound.

Case 2. $h(W^r)>1$. By inequality (7), we have $e^{k'-1}<h(W^r)\le e^{k'}$ for some $k'<k$. By the induction hypothesis, the perfect schedule $S_{k'}$ for W^r has the number of channels bounded by

$$h(W^r)+k'h(W^r)^{1/k'}+r(k')\ .$$

Claim. $k'h(W^r)^{1/k'}\le (k-1)h(W^r)^{1/(k-1)}$.

Proof of Claim. We show that $az^{1/a}\le bz^{1/b}$ for $1\le a\le b$ for $1\le z\le e^a$. If $a=b$, we are done. If $a<b$, then the function $z^{1/a-1/b}$ is increasing for $z\ge 1$ and has value 1 at $z=1$. Hence, the equation $z^{1/a-1/b}=b/a$ has exactly one solution. Equivalently, the functions $az^{1/a}$ and $bz^{1/b}$ intersect exactly once. Since $az^{1/a}<bz^{1/b}$ for $z=1$, it suffices to show that $az^{1/a}\le bz^{1/b}$ for $z=e^a$. By calculus the function e^y/y in the range $(0,\infty)$ has a minimum at $y=1$. Hence, $e\le e^y/y$ for all $y>0$. Letting $y=a/b$ we have $e\le e^{a/b}/(a/b)$, which is equivalent to $a(e^a)^{1/a}\le b(e^a)^{1/b}$. The claim follows for $a=k'\le b=k-1$ since $h(W^r)\le e^{k'}$.

Because of the above claim and the fact that $r(m)$ is increasing in m, we have that the number of channels for the schedule $S_{k'}$ for W^r is bounded by

$$h(W^r)+(k-1)h(W^r)^{1/(k-1)}+r(k-1)\ .$$

By inequality (6), we have that the number of channels for the schedule $S_{k'}$ for W^r is bounded by

$$h(W^r)+(k-1)h(W)^{1/k}+r(k-1)\ . \tag{8}$$

Combining the bounds (4), (5), and (8), we have that the number of channels for the combined perfect schedules for W^p and W^r together is bounded by

$$h(W)+kh(W)^{1/k}+r(k-1)+e^{(k-1)/k}/(e^{(k-1)^2/k}-1)\ ,$$

which by the definition of r yields our result. □

We are now ready to prove the upper bound on $H(W)$.

THEOREM 8. *Every window vector W, with $h(W) > 1$, has a perfect schedule using the number of channels bounded above by $h(W)+e\ln(h(W))+\eta$, where $\eta < 7.36$.*

Proof. The quantity $\eta = e + \lim_{k\to\infty} r(k)$. Choose $k = \lceil \ln(h(W)) \rceil$. Hence, $e^{k-1} < h(W) \le e^k$. By Lemma 7, there exists a perfect schedule with the number of channels bounded above by $h(W) + kh(W)^{1/k} + r(k)$. This is no more than $h(W) + (\ln(h(W)) + 1)(e^k)^{1/k} + r(k)$, which is equivalent to the claim of the theorem. □

The proof of Theorem 8 implies an approximation algorithm for the optimal windows scheduling problem.

THEOREM 9. *There exists an algorithm for the optimal windows scheduling problem yielding a solution that is within a factor of $1+O(\ln(h(W))/h(W))$ of the optimal solution for any window vector W.*

Proof. Let the algorithm of Theorem 8 produce a schedule with $A(W)$ channels. Recall that $H(W)$ is the optimal number of channels. Without loss of generality we can assume that $h(W) \ge 2$. We have

$$h(W) \le H(W) \le A(W) \le h(W) + e\ln(h(W)) + \eta \ .$$

Hence,

$$\frac{A(W)}{H(W)} \le \frac{h(W) + e\ln(h(W)) + \eta}{h(W)} = 1 + O\left(\frac{\ln(h(W))}{h(W)}\right). \qquad \square$$

3.5. Bounds on $N(h)$. In the optimal harmonic windows scheduling problem the window vectors are restricted to be of the form $W_n = \langle 1, 2, \ldots, n\rangle$. Our lower bound on $H(W_n) = H(n)$ (Theorem 3) leads to the following natural upper bound on $N(h)$.

THEOREM 10.

$$N(h) \le c \cdot e^h$$

for $c = e^{-0.57721} < 0.5615$.

Proof. By Theorem 3, $H(n) \ge h(W_n) = \sum_{i=1}^{n} 1/n$. The quantities $\sum_{i=1}^{n} 1/n$ $(n \ge 1)$ are the well-known harmonic numbers which are known to be bounded below by $\ln(n) + \gamma$, where $\gamma \approx 0.57721...$ is Euler's constant. Hence, $h = H(N(h)) > \ln(N(h)) + \gamma$, which implies the theorem. □

We conclude this section with a lower bound for $N(h)$ that is derived from the upper bound on $H(W)$ from Theorem 8.

THEOREM 11.

$$N(h) \ge \frac{e^h}{e^{\eta+\gamma}h^e} \approx \frac{e^h}{e^{7.93669}h^e} \ .$$

Proof. By Theorem 8, we are looking for n such that $h(W_n)+e\ln(h(W_n))+\eta \le h$. For any such n, $N(h) \ge n$. Since $h(n) = \ln(n) + \gamma$, it follows that for $n = \lfloor \frac{e^h}{e^{\eta+\gamma}h^e} \rfloor$,

$$h(W_n) = h\left(\left\lfloor \frac{e^h}{e^{\eta+\gamma}h^e} \right\rfloor\right) = \ln\left(\left\lfloor \frac{e^h}{e^{\eta+\gamma}h^e} \right\rfloor\right) + \gamma \le h - e\ln(h) - \eta \ .$$

Hence,

$$h(W_n) + e\ln(h(W_n)) + \eta \le h - e\ln(h) - \eta + e\ln(h) + \eta = h \ . \qquad \square$$

With some arithmetic manipulations, one can prove the following corollary.

COROLLARY 12. *For large enough value of h we have that $N(h) \geq (e - \frac{c \ln(h)}{h})^h$ for some constant c.*

Later, in section 5, we will see that the pagoda scheme [15] and our combination technique generalization yield asymptotic results in which $N(h) \geq (e - c')^h$ for some constant c'. Thus, obviously Corollary 12 presents a better asymptotic result.

4. The greedy algorithm. In this section, we describe a greedy strategy for the harmonic windows scheduling problem. It will be clear how this strategy can be generalized to the general windows scheduling problem. However, we do not have analytical bounds for this greedy approach, and we use it only as a heuristic to get better bounds than those produced by our other methods for the harmonic scheduling problem.

The greedy algorithm proceeds in rounds, where in the rth round a perfect placement for page r is found in the channel that minimizes the difference $r - r'$, where r' is the distance between placements of page r. The best placement would be to choose, if possible, the channel in which $r' = r$. This might not be possible; for example, when there are just two channels and we have already perfectly placed 1 in the first channel and 2 in the second channel, then 3 must be placed in the second channel with a distance of 2 apart. In this case $r - r' = 1$. In order to keep track of where placements can be made we represent each channel by a tree, where pages are assigned only to some of the leaves of the tree. If, in some round r, page r cannot be placed perfectly in any tree, then the algorithm terminates having successfully placed $r - 1$ pages.

More formally, let an *open tree* be a tree whose leaves are labeled with two types of labels: pages and windows. A *closed tree* is an open tree that has only page labels. An *open forest* is a collection of open trees, and a *closed forest* is a collection of closed trees. The algorithm maintains an open forest composed of h trees. Initially, all the trees are singleton open trees with window labels whose value is 1. The algorithm terminates when the forest becomes a closed forest. The algorithm runs in rounds. In round r, the algorithm places page r in one of the open trees as follows:

1. Let $w_1 \leq w_2 \leq \cdots \leq w_k$ be the ordered list of the labels of all the leaves in the forest whose labels are of type window.
   (a) Let $m_j = (r \bmod w_j)$ for $1 \leq j \leq k$.
   (b) Let i be an index for which m_i is the minimum among all the m_j. We break ties by selecting the index that is associated with the largest window label.
   (c) Let $d_i = \lfloor r/w_i \rfloor$.
   (d) Let T_s be the tree that contains w_i.
2. If $d_i = 1$, then replace the window label w_i with the page label r in the tree T_s. We call this the *replacement* operation.
3. Otherwise, add d_i children to the leaf associated with w_i replacing this leaf with d_i new leaves. The first child is labeled with the page label r, and the rest are labeled with the window label $w_i \cdot d_i$. We call this the *split* operation.

Note that since $m_i = r - w_i d_i$, we see that our choice of m_i achieves the goal of minimizing $r - r'$, where $r' = w_i d_i$ is the distance between placements of r in the perfect channel schedule that is produced by T_s.

THEOREM 13. *The greedy algorithm constructs a perfect $\langle h, n \rangle$-schedule for some value n.*

Proof. By definition, the algorithm produces h trees that represent h perfect

schedules. The value of n is the last round r in which the forest was still an open forest. It remains to show that indeed the window size of page i is no larger than i. This is true since in both the replacement operation and the split operation, the window size assigned to page i is $w_i d_i$, which is less than r by definition (step (1c)). □

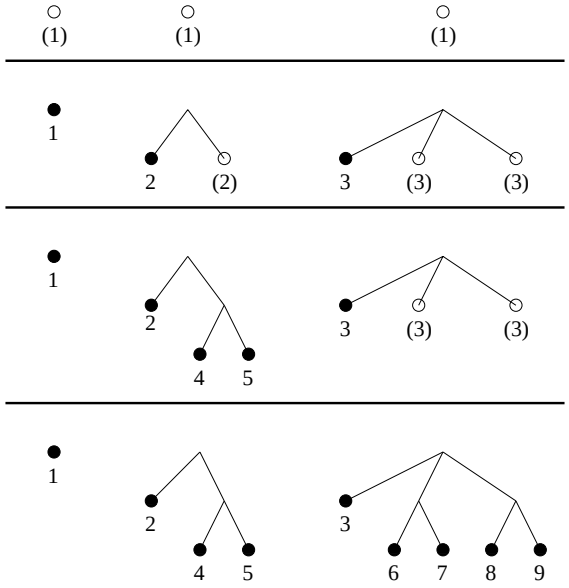

FIG. 3. *The evolution of the greedy algorithm for* $h = 3$.

In Figure 3, we show the evolution of the greedy algorithm for $h = 3$. The final schedule is the perfect $\langle 3, 9 \rangle$-schedule that first appeared in [15]. In the illustration, we use numbers for page labels and numbers in parenthesis for window labels. In addition, we use black circles and white circles to denote leaves with page labels and leaves with window labels, respectively. At the top level, we illustrate the initial open forest that is composed of three singleton open trees whose labels are windows of size 1. In round 1, the label of the first tree becomes the page label 1. This tree is now a closed tree. In round 2, a split operation occurs in the second tree, and it becomes a tree whose root has two children, one with a page label 2 and one with a window label 2. In round 3, a split operation occurs in the third tree, and it becomes a tree whose root has three children, one with a page label 3 and two with a window label 3. Note that since $(3 \bmod 1) < (3 \bmod 2)$, the algorithm selects for the split operation the window label 1 in the third tree rather than the window label 2 in the second tree. The second level of the figure illustrates the three trees after the third round. In round 4, the algorithm splits the node in the second tree with the window label 2 and creates two new leaves: one with a page label 4 and one with a window label 4. This is because $(4 \bmod 2) < (4 \bmod 3)$. Hence, before round 5, the list of available window sizes is $3, 3, 4$. Therefore, the algorithm assigns the page label 5 to the leaf in the second tree with the window label 4. Hereafter, the second tree is closed. The third level of the figure illustrates the three trees after the fifth round. In round 6, the second child of the root of the third tree is split into two leaves: one gets the page label 6 in round 6 and the other gets the page label 7 in round 7. Finally, in round 8, the third child of the root of the third tree is split into two leaves: one gets

the page label 8 in round 8 and the other gets the page label 9 in round 9. At this stage all the trees are closed and the algorithm terminates with the final round $r = 9$, and therefore $n = 9$ as well. The output of the algorithm is illustrated in the fourth level of the figure. Note that pages $2, 3, 4, 6$ get the maximum possible window size, whereas pages $5, 7, 8, 9$ get a smaller than required window size. However, this is the best known solution to the harmonic window scheduling problem for $h = 3$.

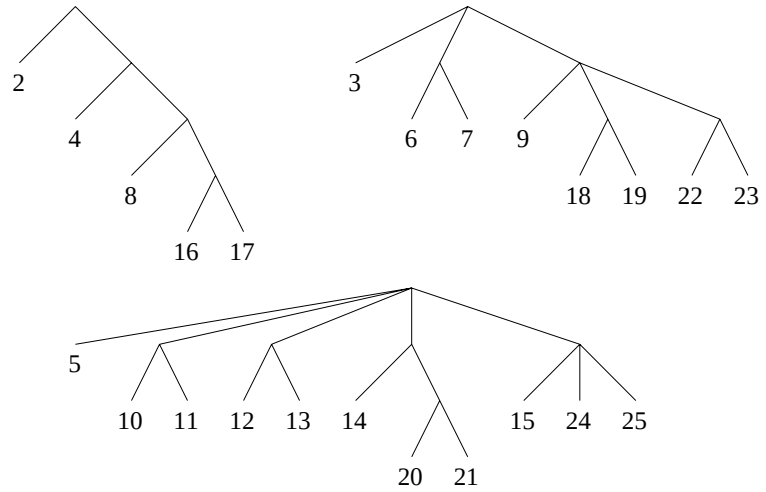

FIG. 4. *The greedy* $\langle 4, 25\rangle$*-schedule.*

Figure 4 illustrates the output of the greedy algorithm for $h = 4$. The greedy algorithm outputs a $\langle 4, 25\rangle$-schedule where there exists a $\langle 4, 26\rangle$-schedule [12]. In particular, this version of the greedy algorithm is not efficient for pages 24 and 25. It could do better by assigning 16 and 17 as siblings of 15 and then assigning 24, 25, and 26 as the children of the sibling of 8.

This leads us to modify the greedy algorithm. We propose two possible modifications. Both try to keep leaves with small window labels open as long as possible.

- The first modification changes the split operation. When d_i is a composite number, it is done in several steps following an increasing order of the prime factors of d_i. For example, if $d_i = 12$ for a node with a window label w_i, then the node is twice split into two nodes and once into three nodes, thus creating five new leaves whose window labels are $2w_i, 4w_i, 12w_i, 12w_i, 12w_i$. One of the window labels $12w_i$ becomes a page label, but the rest remain window labels. In the greedy algorithm that was described earlier, there will be 11 new window labels $12w_i$ and one page label $12w_i$.
- In the second modification, the algorithm follows a different rule in step 1(b) of the algorithm. It sometimes becomes biased towards assigning the new label r to a large window label at the expense of not minimizing $r - r'$. This way, it leaves in the tree smaller window labels for possibly better split operations.

We implemented the greedy algorithm with and without the two modifications above. Unfortunately, it was not the case that one version always outperforms the other versions. However, in most cases the basic greedy algorithm with both modifications was the best. We were able to run our implementations of the basic greedy algorithms for $1 \leq h \leq 20$ and modified versions for $1 \leq h \leq 10$. Table 1 shows

results of the greedy algorithm for $1 \leq h \leq 12$. The best results for $5 \leq h \leq 10$ come from modifications of the basic greedy algorithm. Note that for $h = 12$ the greedy algorithm is within 6% of optimal. In results not shown in the table, for $15 \leq h \leq 20$ the greedy solution is within 3% of optimal.

5. The combination technique. In this section, we develop a technique for solving the optimal harmonic windows scheduling problem. We generalize the technique of [15]. Their pagoda scheme is a special case of the results of this section. We show how to combine schedules together to get new schedules for a larger number of channels. For example, we can combine the $\langle 3, 9\rangle$-schedule with the $\langle 4, 28\rangle$-schedule to produce a $\langle 7, 289\rangle$-schedule (see Theorem 15). However, for $h \leq 20$, the greedy algorithm outperforms any possible combination. Since we have the output of the greedy algorithm only for $h \leq 20$, the combination technique yields our best results for $21 \leq h < H$ for some large integer H. An estimate for H is 1789 and is computed at the end of this section. For $h \geq H$ the asymptotic algorithm of section 3 yields the best bound.

We start with a technical lemma. For $u \leq v$, let an $\langle h, u, v\rangle$-schedule be a schedule on the pages $u, \ldots, v$ on h channels such that page i appears at least once in any consecutive i slots for $u \leq i \leq v$. In particular, an $\langle h, n\rangle$-schedule is an $\langle h, 1, n\rangle$-schedule and an $\langle h-1, 2, n\rangle$ schedule since page 1 gets a dedicated channel. The techniques of this section show how to build new schedules from old ones. As such we define the following notation:

$$\langle h_1, u_1, v_1\rangle, \ldots, \langle h_m, u_m, v_m\rangle \Rightarrow \langle h, u, v\rangle$$

if an $\langle h, u, v\rangle$-schedule can be built from $\langle h_1, u_1, v_1\rangle$- , $\ldots$, $\langle h_m, u_m, v_m\rangle$-schedules. The next lemma shows how to transform an $\langle h, u, v\rangle$ schedule into another schedule for pages from a larger range. We call this the magnification lemma.

LEMMA 14 (magnification lemma). $\langle h, u, v\rangle \Rightarrow \langle h, \ell u, \ell(v+1)-1\rangle$ *for any integer* $\ell \geq 1$.

Proof. Let S be an $\langle h, u, v\rangle$-schedule. We transform S, which is a schedule on the pages $u, \ldots, v$, into another schedule S' on the pages $\ell u, \ldots, \ell(v+1)-1$. We replace page u with pages $\ell u, \ldots, \ell(u+1)-1$ by "stretching" the schedule by a factor of ℓ. In general, we replace the appearances of page $u+j$ in S with the pages $\ell(u+j), \ldots, \ell(u+j+1)-1$ for $0 \leq j \leq v-u$. Since in S the window size of $u+j$ is at most $u+j$, it follows that each of the pages $\ell(u+j), \ldots, \ell(u+j+1)-1$ is guaranteed to have a window of size $\ell(u+j)$. Thus the scheduling of these pages is as required. The smallest page that replaces an appearance of u is ℓu, and the largest page that replaces an appearance of v is $\ell(u+(v-u+1))-1 = \ell(v+1)-1$. This gives us an $\langle h, \ell u, \ell(v+1)-1\rangle$-schedule. □

As an example of Lemma 14, we magnify the $\langle 2, 1, 3\rangle$-schedule

$$\begin{bmatrix} 1 & 1 & 1 & 1 & \cdots \\ 2 & 3 & 2 & 3 & \cdots \end{bmatrix}.$$

Choosing $\ell = 10$, we can create the $\langle 2, 10, 39\rangle$-schedule

$$\begin{bmatrix} 10 & \cdots & 19 & 10 & \cdots & 19 & 10 & \cdots & 19 & 10 & \cdots & 19 & \cdots \\ 20 & \cdots & 29 & 30 & \cdots & 39 & 20 & \cdots & 29 & 30 & \cdots & 39 & \cdots \end{bmatrix}.$$

The above lemma implies our main combination theorem. Here we use $\langle h, n\rangle$ as an abbreviation for $\langle h, 1, n\rangle$.

THEOREM 15 (combination theorem).

$$\langle h_1, n_1\rangle, \langle h_2, n_2\rangle \Rightarrow \langle h_1 + h_2, (n_1+1)(n_2+1)-1\rangle.$$

Proof. The $\langle h_2, n_2\rangle$-schedule is by definition an $\langle h_2, 1, n_2\rangle$-schedule. By Lemma 14, for $\ell = n_1 + 1$, there exists an $\langle h_2, n_1+1, (n_1+1)(n_2+1)-1\rangle$-schedule. The schedule with $h_1 + h_2$ channels is obtained by scheduling pages $1, \ldots, n_1$ on the first h_1 channels following the $\langle h_1, n_1\rangle$-schedule and scheduling pages $n_1+1, \ldots, (n_1+1)(n_2+1)-1$ on the last h_2 channels. ∎

From our examples in the introduction of $\langle 3, 9\rangle$ and $\langle 2, 3\rangle$ we can construct a $\langle 5, 39\rangle$. The first three channels consist of the $\langle 3, 1, 9\rangle$-schedule and the last two channels consist of the $\langle 2, 10, 39\rangle$-schedule constructed above as an example of Lemma 14.

COROLLARY 16. $\langle h, n\rangle \Rightarrow \langle h+1, 2n+1\rangle$.

Proof. Apply Theorem 15 using $\langle 1, 1\rangle$ and $\langle h, n\rangle$. ∎

The above corollary is simple but serves as the base in constructing the folklore $\langle h, 2^h - 1\rangle$-schedule. This schedule is obtained by applying $h-1$ times Corollary 16 starting with the $\langle 1, 1\rangle$-schedule. A better asymptotic result than the $\langle h, 2^h - 1\rangle$-schedule may be obtained by taking a known schedule on $h > 1$ channels and applying the combination theorem, Theorem 15, again and again as in the next theorem.

THEOREM 17. $\langle k, n\rangle \Rightarrow \langle \ell k, (n+1)^\ell - 1\rangle$ *for any integer* $\ell \geq 1$.

Proof. We prove the theorem by induction on ℓ. For $\ell = 1$ the theorem follows trivially. For $\ell > 1$, assume the claim holds for $\ell - 1$. That is, there exists an $\langle (\ell-1)k, (n+1)^{\ell-1} - 1\rangle$-schedule. Then by Theorem 15, using this schedule and the $\langle k, n\rangle$-schedule, there exists an $\langle (\ell-1)k + k, ((n+1)^{\ell-1} - 1 + 1)(n+1) - 1\rangle = \langle \ell k, (n+1)^\ell - 1\rangle$-schedule. ∎

The following corollary is equivalent to Theorem 17.

COROLLARY 18. $\langle k, n\rangle \Rightarrow \langle h, \left(\sqrt[k]{n+1}\right)^h - 1\rangle$ *for* $h = \ell k$.

Corollary 18 implies the existence of an $\langle h, \left(\sqrt[3]{10}\right)^h\rangle$-schedule, provided that 3 divides h, and the existence of an $\langle h, \left(\sqrt[4]{29}\right)^h\rangle$-schedule, provided that 4 divides h. The former is based on the $\langle 3, 9\rangle$-schedule and the latter on the $\langle 4, 28\rangle$-schedule. Both are better than the $\langle h, 2^h - 1\rangle$-schedule but asymptotically far from a potential $\langle h, 0.56147e^h\rangle$-schedule that is implied by Theorem 10. A slightly better asymptotic result than the one in Theorem 17 can be obtained by using the fact that an $\langle h, n\rangle$-schedule is also an $\langle h-1, 2, n\rangle$-schedule.

THEOREM 19. *For an odd* n, $\langle k, n\rangle \Rightarrow \langle \ell(k-1)+1, 2((n+1)/2)^\ell - 1\rangle$ *for any* $\ell \geq 1$.

Proof. We prove the theorem by induction on ℓ. For $\ell = 1$ the theorem follows since $\ell(k-1)+1 = k$ and $2((n+1)/2)^\ell - 1 = n$. For $\ell > 1$ assume the claim holds for $\ell - 1$. That is, there exists an $\langle (\ell-1)(k-1)+1, 2((n+1)/2)^{\ell-1} - 1\rangle$-schedule. We have a $\langle k, n\rangle \Rightarrow \langle k-1, 2, n\rangle$-schedule by deleting the first channel. By Lemma 14 using the factor $((n+1)/2)^{\ell-1}$, we get $\langle k-1, 2, n\rangle \Rightarrow \langle k-1, 2((n+1)/2)^{\ell-1}, 2((n+1)/2)^\ell - 1\rangle$. The claim of the theorem follows by adding the $k-1$ channels of the $\langle k-1, 2((n+1)/2)^{\ell-1}, 2((n+1)/2)^\ell - 1\rangle$-schedule on the pages $2((n+1)/2)^{\ell-1}, \ldots, 2((n+1)/2)^\ell - 1$ to the $(\ell-1)(k-1)+1$ channels of the $\langle (\ell-1)(k-1)+1, 2((n+1)/2)^{\ell-1} - 1\rangle$-schedule on pages $1, \ldots, 2((n+1)/2)^{\ell-1} - 1$ to obtain an $\langle \ell(k-1)+1, 2((n+1)/2)^\ell - 1\rangle$-schedule. ∎

The following corollary is equivalent to Theorem 19.

COROLLARY 20. *For an odd* n, $\langle k, n\rangle \Rightarrow \langle h, 2(\sqrt[k-1]{(n+1)/2})^{h-1} - 1\rangle$ *for* $h =$

$\ell(k-1)+1$. *Equivalently,* $\langle k,n\rangle \Rightarrow \langle h, c(\sqrt[k-1]{(n+1)/2})^h - 1\rangle$ *for* $h = \ell(k-1)+1$ *and* $c = 2/\sqrt[k-1]{(n+1)/2}$.

By the preceding corollary, the $\langle 3,9\rangle$-schedule implies an approximately $\langle h, 0.894427\,(2.23607)^h\rangle$-schedule, provided that 2 divides $h-1$ (the pagoda scheme of [15]), and the $\langle 4,27\rangle$-schedule implies an approximately $\langle h, 0.829827\,(2.41014)^h\rangle$-schedule, provided that 3 divides $h-1$. Note that we cannot use the $\langle 4,28\rangle$-schedule since in this case n is even.

Comparing the asymptotic results. We implemented the greedy algorithm for $1 \le h \le 20$, yielding in particular for $h = 20$ a $\langle 20, 265133521\rangle$-schedule. This in turn implies an asymptotic $\langle h, 0.747366(2.67606)^h\rangle$-schedule, provided that 19 divides $h-1$ (Corollary 20). This value is "close" to the upper bound of $0.56147e^h$ on $N(h)$ (Theorem 10). Using *Mathematica* [18], we get that this schedule is smaller than the $e^h/(e^{7.93669}h^e)$ bound (Theorem 11) for $h > 1789$. That is, the combination technique yields our best results for h in the range [21..1789]. However, implementing the greedy algorithm for $h > 20$ would increase the 1789 threshold. On the other hand, implementing the asymptotic algorithm for $W = \langle 1,\ldots,n\rangle$ would definitely imply a better bound than the one from Theorem 11 and hence would decrease the 1789 threshold. This is because the bounds in section 3 are mainly for the general windows scheduling problem.

6. Solutions for small *h*. In this section we describe our best constructions to the harmonic windows scheduling problem for small h. For $h = 2$ the general $\langle h, 2^h - 1\rangle$-schedule shown in Figure 2 yields a $\langle 2,3\rangle$-schedule, which is optimal. For $h = 3$ the greedy algorithm example shown in Figure 3 yields a $\langle 3,9\rangle$-schedule, which is not known to be optimal. The best possible would be a $\langle 3,10\rangle$-schedule. For $h = 4,5$, we illustrate the $\langle 4,28\rangle$ and the $\langle 5,77\rangle$ nonperfect schedules using the tree representation. We omit the details of our tree representation for the $\langle 6,211\rangle$ nonperfect schedule.

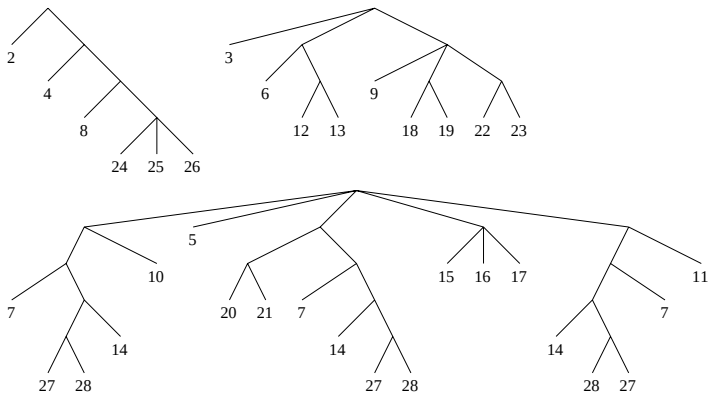

FIG. 5. *The* $\langle 4,28\rangle$*-schedule.*

Our $\langle 4,28\rangle$-schedule is not a perfect schedule. The first channel is dedicated to page 1. Figure 5 uses the tree representation to illustrate the schedules of the second, third, and fourth channels. Channels 1, 2, and 3 have perfect channel schedules but channel 4 does not. This is because pages $7, 14, 27, 28$ occur at multiple leaves of tree 4. The window sizes for page 7 are $7, 7, 6$ repeatedly, for page 14 they are

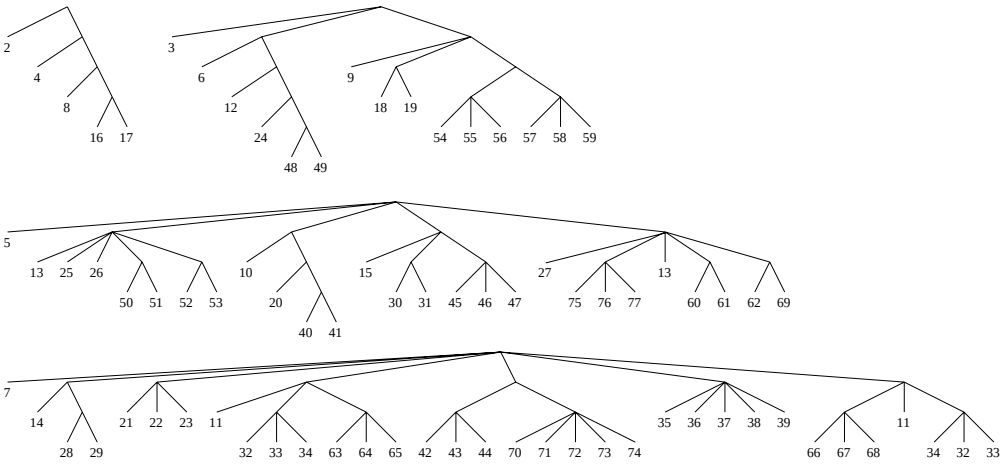

FIG. 6. *The* $\langle 5, 77\rangle$*-schedule.*

$14, 13, 13$ repeatedly, and for pages $27, 28$ they are $27, 27, 26$ repeatedly.

Figure 6 illustrates the four trees representing the second, third, fourth, and fifth schedules in the nonperfect $\langle 5, 77\rangle$-schedule. The first two trees represent perfect schedules; in the other two trees pages $11, 13, 32, 33, 34$ do not have a fixed window size.

7. Open problems. In this section, we discuss some open problems related to the windows scheduling problem, to the harmonic windows scheduling problem, and to the two motivating applications, the push systems with guaranteed delay and the new media-on-demand systems.

The harmonic windows scheduling problem.

- Is the $\langle 3, 9\rangle$-schedule optimal? We conjecture that the answer is yes. However, to show this, more complicated arguments are needed to improve the upper bound of $N(3) \leq 10$ to be $N(3) \leq 9$. These arguments should rely on the *gcd* relationship among the numbers 2 to 9. However, we are able to show that for perfect schedules $N(3) \leq 9$.
- For the media-on-demand application efficient solutions for small values of h are important. Are there better schedules for $h = 4, 5, 6$? The gap for $h = 4$ is $28 \leq N(4) \leq 30$, for $h = 5$ it is $77 \leq N(5) \leq 82$, and for $h = 6$ it is $211 \leq N(5) \leq 226$. For $7 \leq h \leq 20$, our best solutions are outputs of the greedy algorithm. Is there a better algorithm?
- Is there any analytic bound for our greedy algorithm?
- The combination technique yields our best results for $21 \leq h \leq 1789$. A further improvement would be obtained by looking for the best combination for any h using a dynamic programming implementation of the combination theorem.
- We believe that for the optimal harmonic windows scheduling we can get a better lower bound than that given in Theorem 11. This is because we know the exact behavior of the algorithm described in the proof of Lemma 7 in the first stage of the recursion for any choice of x. In the work in progress, we plan to implement the asymptotic algorithm and will probably get better bounds than those implied by the combination technique for $h \leq 1789$.

- Is there another new technique that can yield a provably better asymptotic algorithm for the harmonic windows scheduling problem?

The optimal windows scheduling problem.

- Our asymptotic approximation uses $h(W) + e\ln(h(W)) + O(1)$ channels. Is there an $h(W) + O(1)$ solution, or can that be shown to be impossible?
- Unlike the special case of the optimal harmonic scheduling problem, it is not clear how to define the dual problem of the general windows scheduling problem. One needs a notion of "throughput" to evaluate the performance of a solution for a given number of channels that cannot accommodate all the requested windows.

The media-on-demand and the push systems applications.

- Apparently, the windows scheduling problem does not require a fixed window size or that a page appear only on one channel. Combinatorially, adding these two restrictions separately or combined could be very interesting. Moreover, one could imagine a media-on-demand model in which these restrictions could be useful. In this paper, we have two nonperfect schedules for the small values of $h = 4, 5$. Still, each page is scheduled only on one channel. On one hand, we conjecture that without these restrictions better solutions can be found. On the other hand, we conjecture that asymptotically these restrictions do not reduce the value of $N(h)$.
- Consider the case in which the receiving bandwidth of the clients is less than h. Capitalizing on the work of [16] and with the help of this paper's results we can improve the tradeoff results between $N(r, h)$ and r/h, where $N(r, h)$ is the maximum number of pages that can be scheduled on h channels, provided that the receiving bandwidth of clients is $r < h$. This is a work in progress. The main idea is that having good solutions for $N(r)$ can improve the results for $N(r, h)$.
- In the push systems application, if the servers have a fixed number of channels, there is a need to devise a strategy for "selling" windows. (This is related to the last item of the previous paragraph.)

Acknowledgments. Thanks to Dan Hoke for implementing the greedy algorithm and helping to calculate some of the values in Table 1 and the result of the greedy algorithm for $h \leq 20$. Thanks to Tami Tamir, who carefully read the paper and provided suggestions for improvements. Finally, thanks to the two anonymous referees, whose suggestions improved the presentation of the paper.

A POLYNOMIAL-TIME ALGORITHM FOR NEAR-PERFECT PHYLOGENY*

DAVID FERNÁNDEZ-BACA† AND JENS LAGERGREN‡

Abstract. A parameterized version of the Steiner tree problem in phylogeny is defined, where the parameter measures the amount by which a phylogeny differs from "perfection." This problem is shown to be solvable in polynomial time for any fixed value of the parameter.

Key words. algorithms, computational biology, character-based methods, evolutionary trees, parsimony, perfect phylogeny, phylogeny, Steiner tree

1. Introduction.

A fundamental problem in biology and linguistics is that of inferring the evolutionary history of a set of taxa, each of which is specified by the set of *traits* or *characters* that it exhibits [4, 6, 15]. Formally, let C be a set of *characters*, and for every $c \in C$ let $\mathcal{A}_c$ be the set of allowable *states* for character c. Let $m = |C|$ and $r_c = |\mathcal{A}_c|$. A *species* s is an element of $\mathcal{A}_1 \times \cdots \times \mathcal{A}_m$; $c(s)$ is referred to as the *state of character* c *for* s. A *phylogeny* for a set of n distinct species S is tree T with the following properties:

(C1) $S \subseteq V(T) \subseteq \mathcal{A}_1 \times \cdots \times \mathcal{A}_m$,

(C2) every leaf in T is in S.

Define the *length* of a phylogeny T for S as

$$\text{length}(T) = \sum_{(u,v)\in E(T)} \text{dist}(u, v),$$

where, for any two species u, v, $\text{dist}(u, v)$ denotes the number of character states in which u and v differ (that is, $\text{dist}(u, v)$ is the Hamming distance between u and v). The *Steiner tree problem in phylogeny* (STP) is to find a phylogeny T of minimum length for a given set of species S.

STP and many of its variants are known to be NP-hard [7, 3]. While polynomial-time approximation algorithms with constant ratio bound are known for this problem (for a recent example, see [11]), there are limits to the approximability of STP [5].

STP is related to the problem of determining whether S has a *perfect* phylogeny, i.e., one that satisfies (C1), (C2), and the following:

(C3) For every $c \in C$ and every $\sigma \in \mathcal{A}_c$, the set of all $u \in V(T)$ such that $c(u) = \sigma$ induces a subtree of T.

The perfect phylogeny problem was shown to be NP-complete by Bodlaender, Fellows, and Warnow [2] and, independently, by Steel [14]. This motivated the study of the fixed-parameter versions of the problem, where either m or r is fixed. Both versions have been shown to be polynomially solvable, the first by McMorris, Warnow, and Wimer [13], and the second by Agarwala and Fernández-Baca [1]. The time bound of the latter's algorithm was improved by Kannan and Warnow [12].

If a set of species admits a perfect phylogeny, the underlying set of characters C is *compatible*; thus, the perfect phylogeny problem is often called the *character compatibility problem*. In practice most sets of characters are incompatible, and thus a natural problem is to find a maximum-cardinality subset of C that is compatible. This problem is, unfortunately, equivalent to CLIQUE [8] and hence not only NP-hard, but also extremely hard to solve approximately [10].

The difference between m and the maximum-cardinality compatible subset of C is one measure of the degree of compatibility of a set of species. Here we study a measure of incompatibility that we believe is equally natural, which is motivated by the following result [1, 9].

THEOREM 1. *Let T^* be a phylogeny for S. Then* $\text{length}(T^*) \geq \sum_{c \in C}(r_c - 1)$ *and T^* is a perfect phylogeny if and only if* $\text{length}(T^*) = \sum_{c \in C}(r_c - 1)$.

Thus, the length of a perfect phylogeny (assuming one exists) gives a tight lower bound on the length of any phylogeny for S. Motivated by this observation, let us define the *penalty* of a phylogeny T as

$$\text{penalty}(T) = \text{length}(T) - \sum_{c \in C}(r_c - 1).$$

Obviously, STP can be rephrased as the problem of finding a phylogeny T such that $\text{penalty}(T)$ is minimum. We are interested in the fixed-parameter version of the problem, namely, given a set of species S and an integer q, does S have a phylogeny with penalty at most q? We show that for each fixed q and r, the resulting "near-perfect" phylogeny problem can be solved in polynomial time. The running time of our algorithm is a polynomial whose degree depends on the parameters, making the algorithm practical only for small values of the parameters. On the other hand, the flexibility of allowing one or more characters to violate condition (C3) by some fixed amount may extend the range of applicability of character-based methods.

Our near-perfect phylogeny algorithm shares several ideas with earlier work on the perfect phylogeny problem [1, 12]. As in the algorithms for the latter problem, we rely on the observation that there is a polynomially bounded number of ways in which species can be partitioned into subfamilies that respect state boundaries for some character. (See section 2 for a precise definition.) The approach is to build subphylogenies for these subfamilies, proceeding by increasing cardinality. Subphylogenies are joined through their roots to form subphylogenies for larger subfamilies.

The construction of subphylogenies is complicated by issues that do not arise in the perfect phylogeny problem. Each edge in a perfect phylogeny corresponds to a *character partition*, i.e., a partition of S into subfamilies such that there exists a character c on which no state is shared between species of different subfamilies. This property and the fact that the number of character partitions is polynomially bounded when r is fixed are keys to the efficient solution of the perfect phylogeny problem. Unfortunately, it can easily be seen that imperfect phylogenies may have bad edges, i.e., edges not inducing character partitions. We show, however, that the number of bad edges is polynomially bounded when the penalty is bounded.

Our strategy to build a subphylogeny for a subset of species is therefore to generate different candidate trees consisting only of bad edges and use them as skeletons from which to hang subphylogenies for character subfamilies. From among all of the trees thus enumerated, we select the one that results in the least penalty. It is nontrivial to determine which subphylogenies to connect to a candidate bad tree, because there is no a priori bound on the degree of a vertex. (Such a bound would imply that the subphylogenies could be found in polynomial time by simply trying all combinations of character subfamilies.) We show that it suffices to enumerate a polynomially bounded number of labeled candidate trees.

The rest of the paper is organized as follows. Section 2 gives definitions and notation. Section 3 explains how to compute perfect phylogenies. The properties of low-penalty phylogenies and subphylogenies are studied in section 4. In particular, bounds are derived there on the number of bad edges in a near-perfect phylogeny and on the amount of information that must be enumerated to construct such a phylogeny. Our near-perfect phylogeny algorithm is presented in section 5. Section 6 concludes the paper.

2. Basic definitions and notation. The vertex sets of all trees are assumed to be subsets of $\mathcal{A}_1 \times \cdots \times \mathcal{A}_m$. Note that this implies that every two adjacent nodes are distinct. No generality is lost, since a tree that does not satisfy this condition can be transformed into one that does and that has at most the same length.

Throughout the paper, r denotes $\max_{c \in C} r_c$.

Let c be a character. We assume that each state in $\mathcal{A}_c$ is exhibited by some element of S. Obviously, any state that is not exhibited by any species can be deleted from $\mathcal{A}_c$. We assume that $\mathcal{A}_i \cap \mathcal{A}_j = \emptyset$ for $i \neq j$. No generality is lost by making this assumption, since it can always be enforced by replacing each state σ on every character c by the state (σ, c).

Let T be a tree, and let $\sigma \in \mathcal{A}_c$. Then $T[\sigma]$ denotes the subgraph of T induced by all nodes v such that $c(v) = \sigma$. For any edge $(u, v) \in T$, T_u and T_v denote the components of $T - \{(u, v)\}$ containing u and v, respectively.

DEFINITION 1. *Let T be a phylogeny for S. Character c is* convex *in T if for every $\sigma \in \mathcal{A}_c$, $T[\sigma]$ is connected. If $T[\sigma]$ is not connected, σ is a* penalty state *in T and c is* nonconvex *in T.*

In what follows, $C_p \subseteq C$ denotes a set of characters that are required to be convex.

DEFINITION 2. *Let T be a phylogeny for S. T is q-*near-perfect *if* penalty$(T) \leq q$. *T is C_p-*perfect *if every $c \in C_p$ is convex in T. If $C_p = C$, T is simply called* perfect. *A* minimum C_p-perfect phylogeny *is a C_p-perfect phylogeny of minimum length.*

An example of a C_p-perfect phylogeny is shown in Figure 1. For clarity, the set of states for every character is written as $\{0, 1, 2, 3, 4\}$; in reality, $\mathcal{A}_{c_i} = \{(j, c_i)\}_{j=0}^{4}$ for $i = 1, 2, 3, 4$. We shall refer to Figure 1 throughout the paper to illustrate various concepts.

Clearly, a C_p-perfect phylogeny may not exist for a given set C_p. Note also that, by Theorem 1, all perfect phylogenies have the same (minimum) length, so it is redundant to talk about minimum perfect phylogenies.

DEFINITION 3. *Two subsets X, Y of S* share a state *on $c \in C$ if there exists a state σ of c such that $c(x) = c(y) = \sigma$ for some $x \in X$, $y \in Y$. State σ is referred to as a* shared state.

DEFINITION 4. *A* character partition *with respect to a character c is a partition (S_1, S_2) of S such that no species in S_1 shares a state of c with any species of S_2. The subsets S_1 and S_2 are* character subfamilies. *A character subfamily Q is* proper *if at*

	c_1	c_2	c_3	c_4
s_1	0	2	1	2
s_2	4	2	1	1
s_3	0	2	3	1
s_4	0	4	4	0
s_5	0	1	0	0
s_6	3	2	1	0
s_7	2	0	1	3
s_8	1	0	1	2
s_9	0	2	2	4
s_{10}	0	3	2	2

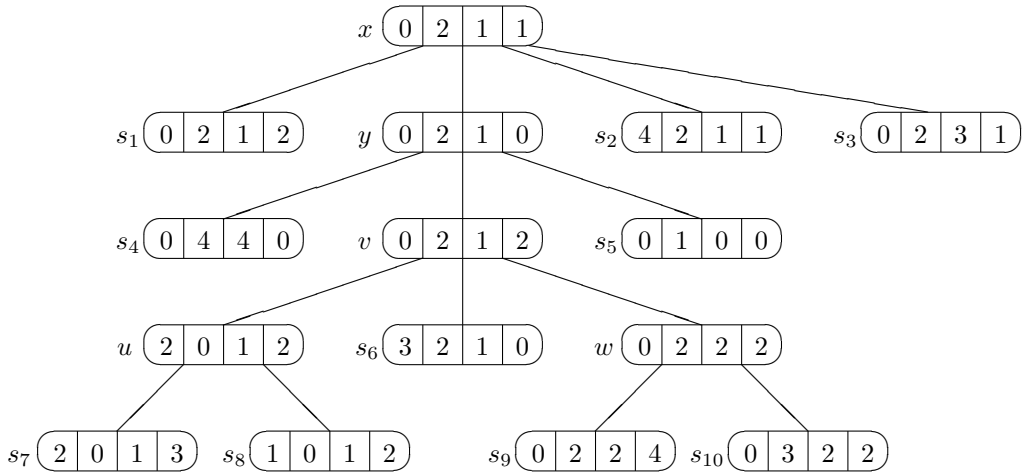

FIG. 1. *Top: A set of ten species described by their states on a set of characters* $C = \{c_1, c_2, c_3, c_4\}$*, each with five states. Bottom: A* C_p*-perfect phylogeny for the set of species, where* $C_p = \{c_1, c_2, c_3\}$*. The length of the tree is* 18*; its penalty is* 2.

most one state is shared between Q *and* $S - Q$ *for every* $c \in C_p$*.*

From this point forward, all character subfamilies that we consider are assumed to be proper.

The number of character subfamilies is $O(2^r m)$, since at most 2^r are defined by the states of any given character [1]. This bound is polynomial when r is fixed, which motivates the following approach to computing minimum C_p-perfect phylogenies: Enumerate the subfamilies by increasing cardinality, and for each subfamily find a minimum-length rooted C_p-perfect phylogeny made up of phylogenies for smaller subfamilies. Since our goal is to compose the phylogenies by linking roots through edges, the permissible states for the roots are partially determined by convexity. To formalize these ideas, we need some definitions. In what follows, $*$ denotes an unspecified state, which is in none of the $\mathcal{A}_i$'s.

DEFINITION 5. *Let* $Q \subseteq S$ *be a character subfamily. The* splitting vector *of* Q *is the species* $Sv(Q)$ *where, for each character* c*, if* $c \in C_p$ *and* Q *and* $S - Q$ *share state* σ *on character* c*, then* $c(Sv(Q)) = \sigma$*; otherwise,* $c(Sv(Q)) = *$*.*

DEFINITION 6. *Let* Q*,* Q_1 *be character subfamilies such that* $Q_1 \subset Q$*.* Q *and* Q_1 *are* compatible *if for every* $c \in C_p$ *such that* $c(Sv(Q)), c(Sv(Q_1)) \neq *$*,* $c(Sv(Q)) =$

$c(Sv(Q_1))$.

Intuitively, if Q and Q_1 are compatible, there conceivably exists a C_p-perfect phylogeny for $Q \cup \{Sv(Q)\}$ such that one of the subtrees of $Sv(Q)$ is a phylogeny for $Q_1 \cup \{Sv(Q_1)\}$. In such a phylogeny, the states of the root on some characters $c \in C_p$ such that $c(Sv(Q)) = *$ may have to take on specific values, because a state on c may be shared between Q_1 and $S - Q_1$ that is not shared between Q and $S - Q$. This motivates the following definition.

DEFINITION 7. *Let Q, Q_1 be compatible character subfamilies such that $Q_1 \subset Q$. The* splitting vector *for (Q, Q_1) is the species $Sv(Q, Q_1)$ where for each character c, if $c \in C_p$ and state σ is shared between Q and $S - Q$ or between Q_1 and $S - Q_1$, then $c(Sv(Q, Q_1)) = \sigma$; otherwise, $c(Sv(Q, Q_1)) = *$.*

DEFINITION 8. *Let $Q \subseteq S$ and x be a species. Then $\sim_x$ denotes the equivalence relation on Q defined as the transitive closure of the following relation R_x: For $s, t \in Q$, $(s, t) \in R_x$ if there exists a character c such that $c(s) = c(t) \neq c(x) \neq *$. Denote by Q/x the collection of equivalence classes of $\sim_x$.*

Observe that each of the sets in Q/x must be in the same connected component of $T - \{x\}$ for any perfect (not just C_p-perfect) phylogeny T for $Q \cup \{x\}$.

DEFINITION 9. *Let T be a phylogeny for S and let $e = (u, v)$ be an edge of T. Then $(S \cap V(T_u), S \cap V(T_v))$ is an* edge partition *of S (with respect to T). The subsets $S \cap V(T_u)$ and $S \cap V(T_v)$ are* edge subfamilies. *Edge (u, v) is* good *if the partition $(S \cap V(T_u), S \cap V(T_v))$ induced by e is a character partition; otherwise, e is* bad.

To close this section, we illustrate some of the concepts introduced here, making reference to Figure 1. Let $Q_1 = \{s_9, s_{10}\}$ and $Q = \{s_7, s_8, s_9, s_{10}\}$. Then, $Sv(Q_1) = (0, 2, *, *)$ and $Sv(Q) = (0, 2, 1, *)$; thus, Q_1 and Q are compatible, and $Sv(Q, Q_1) = (0, 2, 1, *)$. In the phylogeny shown, edges (s_1, x), (x, y), and (y, v) are bad; all other edges are good.

3. Finding perfect phylogenies. Before studying near-perfect phylogenies, we review the perfect phylogeny algorithm of Agarwala and Fernández-Baca and the improvements devised by Kannan and Warnow. The algorithm relies on two facts. The first is the aforementioned polynomial bound (for fixed r) on the number of character subfamilies. The second is that perfect phylogenies can be assembled from phylogenies for character subfamilies, because, as shown in [1], every edge in a perfect phylogeny for S is good.

DEFINITION 10. *Let Q be a character subfamily. A* perfect subphylogeny *for Q is a rooted perfect phylogeny for Q, whose root x satisfies $c(x) = c(Sv(Q))$ for all c such that $c(Sv(Q)) \neq *$, and $c(x) = c(s)$ for some $s \in Q$ otherwise.*

It is straightforward to verify that if Q_1 and $Q_2 = S - Q_1$ have perfect subphylogenies T_1 and T_2, respectively, then the tree obtained by connecting the roots of T_1 and T_2 by an edge is a perfect phylogeny for S.

DEFINITION 11. *Let Q, Q_1 be compatible character subfamilies such that $Q_1 \subset Q$. A* perfect subphylogeny *for (Q, Q_1) is a rooted perfect phylogeny for Q, whose root x is such that* (i) *$c(x) = c(Sv(Q, Q_1))$ for all c such that $c(Sv(Q)) \neq *$, and $c(x) = c(s)$ for some $s \in Q$ otherwise, and* (ii) *the removal of x partitions Q into subsets some of which union to Q_1.*

The following result is proved in [12, 1].

LEMMA 2. *Suppose that Q is a character subfamily and that $Q_1 \subset Q$ has a subphylogeny. Let $Q_2 = Q - Q_1$. Then, (Q, Q_1) has a subphylogeny if and only if* (i) *Q_2 has a subphylogeny or* (ii) *every element of $Q_2/Sv(Q, Q_1)$ has a subphylogeny. In case* (ii)*, $c(Sv(Q, Q_1)) \neq *$ for every character c.*

SUBPHYLOGENY(Q).
For each subfamily $Q_1 \subset Q$ compatible with Q do the following:

1. Let $T_{Q_1} = \mathcal{N}(Q_1)$.
2. If $T_{Q_1} \neq \emptyset$, then do the following:
   (a) Let $Q_2 = Q - Q_1$ and $T_{Q_2} = \mathcal{N}(Q_2)$.
   (b) If $T_{Q_2} \neq \emptyset$, then let T_Q be the subphylogeny for Q whose root is a node x_Q satisfying $c(x_Q) = c(Sv(Q, Q_1))$ for every $c \in C$ such that $c(Sv(Q, Q_1)) \neq *$, and $c(x_Q) = c(x_{Q_1})$ for every other c, where x_{Q_1} is the root of T_{Q_1}. Set $\mathcal{N}(Q) = T_Q$ and return.
   (c) Otherwise, let $\{P_i\}_{i=1}^{k}$ be the set of equivalence classes $Q_2/Sv(Q, Q_1)$. If $T_{P_i} = \mathcal{N}(P_i) \neq \emptyset$ for every $i \in \{1, \ldots, k\}$, then let T_Q be the subphylogeny for Q whose root x_Q satisfies $c(x_Q) = c(Sv(Q, Q_1))$ for every $c \in C$ and whose subtrees are T_{Q_1} and $T_{P_1}, \ldots, T_{P_k}$. Set $\mathcal{N}(Q) = T_Q$ and return.

PERFECT-PHYLOGENY(S, C).

1. Allocate a table $\mathcal{N}$ with one entry for each character subfamily Q. Set $\mathcal{N}(Q) = \emptyset$ for each such Q.
2. Enumerate, by increasing cardinality, each character subfamily Q, and run SUBPHYLOGENY(Q).
3. If there exists a pair of subfamilies Q_1, Q_2 such that $Q_2 = S - Q_1$ and $\mathcal{N}(Q_1), \mathcal{N}(Q_2) \neq \emptyset$, then return the tree T obtained by linking the roots of $T_{Q_1} = \mathcal{N}(Q_1)$ and $T_{Q_2} = \mathcal{N}(Q_2)$ by an edge. Otherwise, return $\emptyset$.

FIG. 2. *The perfect phylogeny algorithm.*

This leads to the algorithm of Figure 2. The main procedure, PERFECT-PHYLOGENY, considers character subfamilies by increasing cardinality; it attempts to build a subphylogeny for each one using procedure SUBPHYLOGENY, inserting the result into a table $\mathcal{N}$.

PERFECT-PHYLOGENY iterates over all $O(2^r m)$ character subfamilies Q. For each of these, SUBPHYLOGENY considers $O(2^r m)$ choices of Q_1. Kannan and Warnow show how to find the equivalence classes of $Q_2/Sv(Q, Q_1)$ in $O(n)$ time at the expense of precomputing, in $O(2^r nm^2)$ time, the equivalence classes of $S/Sv(G)$ for every subfamily G (see [12]). An $O(2^{2r} nm^2)$ bound follows.

4. Near-perfect phylogenies. The algorithm of Figure 2 relies heavily on the fact that perfect phylogenies have no bad edges, a property that may not hold for near-perfect phylogenies. In this section, we show that near-perfect phylogenies can be decomposed into perfect and imperfect parts. The former can be handled by the techniques described in the previous section. We prove that the latter can be generated by examining an amount of information that is polynomial for each fixed q. As before, C_p denotes a set of characters required to be convex. Before proceeding, we need some definitions.

DEFINITION 12. *A* penalty state assignment *is a function α that maps each $c \in C - C_p$ to an element $\alpha(c)$ of $\mathcal{A}_c$. The* penalty state assignment *of a species s is the penalty state assignment α_s, where $\alpha_s(c) = c(s)$ for each $c \in C - C_p$.*

DEFINITION 13. *Let Q be a character subfamily and α be a penalty state assignment. A* subphylogeny *for (Q, α) is a rooted C_p-perfect phylogeny T for Q whose root x satisfies the following properties:*

(i) *For every* $c \in C_p$, $c(x) = c(Sv(Q))$ *if* $c(Sv(Q)) \neq *$; *otherwise,* $c(x) = c(u)$ *for some* $u \in Q$.
(ii) *For every* $c \in C - C_p$, $c(x) = \alpha(c)$.

T *is a* minimum-length subphylogeny *if it has the smallest length among all subphylogenies for* (Q, α).

DEFINITION 14. *Let* T *be a subphylogeny with root* x *for* (Q, α). *Let* (u, v) *be an edge of* T, *where* u *is the parent of* v. *Then,* (u, v) *is* good *if* $S \cap V(T_v)$ *is a character subfamily; otherwise* (u, v) *is* bad. *The maximal subtree* T *that contains* x *and only bad edges is the* bad tree *of* T *and is denoted* $B(T)$. T *is in* normal form *if, for every good edge* (u, v) *in* T *such that* u *is in* $B(T)$, T_v *is a subphylogeny for some pair* (Q_v, α_v), *where* $Q_v \subseteq Q$.

Note that, by the maximality of $B = B(T)$, if an edge of T is not in B but is adjacent to an edge of B, then it is good; i.e., the associated edge subfamily is a character subfamily as well.

DEFINITION 15. *Let* T *be a subphylogeny,* v *be a node of* $B = B(T)$, *and* u *be a child of* v *not in* B. *Then the subset of* S *contained in* T_u *is an* edge subfamily at v. *An edge subfamily* Q *at* v *is* perfect *if no state is shared between* Q *and* $S - Q$ *on a character* c *except (possibly)* $c(v)$, *and* $Q \cup \{v\}$ *has a perfect phylogeny. All other edge subfamilies at* Q *are* imperfect.

For a node v in B, $Pe(v)$ and $Im(v)$ stand for the sets of perfect and imperfect edge subfamilies at v, respectively. $\mathcal{P}(v)$ is the union of all perfect edge subfamilies at v, and $\mathcal{F}(v)$ is the union of all edge subfamilies at v.

Let T be a subphylogeny for (Q, α), and let v be a node in T. Then, by definition, the subtree of T consisting of v, together with all T_u such that $S \cap V(T_u)$ is a perfect edge subfamily at v, is a subphylogeny for $\mathcal{P}(v)$.

We now illustrate some of the notions introduced so far, making reference to Figure 1. The subtree rooted at y in that diagram is a subphylogeny for (Q, α), where $Q = \{s_4, s_5, s_6, s_7, s_8, s_9, s_{10}\}$ and $\alpha(c_4) = 0$; its bad tree consists of edge (y, v). Indeed, if the set $P = \{s_1, \ldots, s_{10}\}$ is a character subfamily within a larger set S such that P and $S - P$ share (say) state $(1, c_3)$, then the whole tree at x is a subphylogeny for (P, α), where $\alpha(c_4) = 1$. The bad tree in this case consists of edges (s_1, x), (x, y), and (y, v). Both of the subphylogenies we have described are in normal form. Observe that $Pe(v) = \{\{s_7, s_8\}, \{s_9, s_{10}\}\}$ and $Im(v) = \{\{s_6\}\}$.

The results that follow characterize the structure of near-perfect phylogenies and subphylogenies.

LEMMA 3. *Let* T *be a* C_p*-perfect phylogeny, and let* (u, v) *be a bad edge in* T. *Then, for each* $c \in C_p$, $c(u) = c(v)$. *Furthermore, there is some* $c \in C - C_p$ *such that* $c(u) \neq c(v)$.

Proof. We first show that for each $c \in C_p$ there exists a shared state on c between $Q_u = S \cap V(T_u)$ and $Q_v = S \cap V(T_v)$. Suppose that this is false. Then (Q_u, Q_v) is a character partition and (u, v) is, by definition, a good edge, a contradiction.

Because of the state shared between Q_u and Q_v on $c \in C_p$ and the fact that T is C_p-perfect, we must have $c(u) = c(v)$. We must have $c(u) \neq c(v)$ for some $c \in C - C_p$ because we are dealing with phylogenies where every two nodes differ in at least one state. □

LEMMA 4. *Let* T *be a* C_p*-perfect phylogeny such that* penalty$(T) \leq q$. *Then* T *has at most* qr *bad edges.*

Proof. Let $C' = C - C_p$. For each $c \in C'$ let l_c be the number of edges (u, v) in T such that $c(u) \neq c(v)$. Since penalty$(T) \leq q$, $|C'| \leq q$. By Lemma 3, for every

bad edge (u, v) there must be some $c \in C'$ such that $c(u) \neq c(v)$. Thus, the number of bad edges is at most $\sum_{c \in C'} l_c$. Moreover, $\sum_{c \in C'}(l_c - (r_c - 1)) \leq q$. Hence, the number of bad edges is bounded by $q + \sum_{c \in C'}(r_c - 1) \leq qr$. ∎

LEMMA 5. *Suppose that Q is a character subfamily having a rooted C_p-perfect phylogeny T, with root x such that, for every $c \in C_p$, $c(x) = c(Sv(Q))$ if $c(Sv(Q)) \neq *$. Let α be the penalty state assignment of x. Then, (Q, α) has a subphylogeny of length at most* length(T).

Proof. T is a subphylogeny for (Q, α), except that there might be some $c \in C_p$ such that $c(x) \neq c(u)$ for any $u \in Q$. For each such c, carry out the following step until it no longer applies:

> Let $c(x) = \sigma$ be such that $\sigma \neq c(u)$ for any $u \in Q$. Let A be the connected component of $T[\sigma]$ containing x, and let (u, v) be any edge of T such that $u \in A$ and $v \notin A$. Then, $c(u) = \beta \neq \sigma$. Set $c(w)$ equal to β for all w in A.

Each application of the above step preserves perfection with respect to C_p; furthermore, it does not affect the contribution of the nonconvex characters to the length. When the step no longer applies, T is a subphylogeny. ∎

LEMMA 6. *Suppose that the pair (Q, α) has a subphylogeny. Then, (Q, α) has a minimum-length subphylogeny in normal form.*

Proof. Let T be a minimum-length subphylogeny for (Q, α), and let $B = B(T)$. If T is in normal form, we are done, so suppose it is not. Successively consider each good edge (u, v) in T such that u is in B and T_v is not a subphylogeny for (Q_v, α_v), where $Q_v = S \cap V(T_v)$ and α_v is the penalty state assignment of v. For each such edge, apply the following transformation to T: Let T'_v be a subphylogeny for (Q_v, α_v) such that length$(T'_v) \leq$ length(T_v); such a tree T'_v exists by Lemma 5, since T_v is a C_p-perfect phylogeny for Q_v where, for every $c \in C_p$, $c(v) = c(Sv(Q_v))$ if $c(Sv(Q_v)) \neq *$. Replace T_v by T'_v by deleting T_v and making the root of T'_v a child of u.

Each application of the transformation preserves the properties that T is of minimum length and that T is a subphylogeny for (Q, α). After the final application, T is in normal form. ∎

LEMMA 7. *Let T be a subphylogeny for (Q, α), let $B = B(T)$, and let*

$$U = (S - Q) \cup \{u \in P : P \in Im(v), v \in B\}.$$

Then, for each $v \in V(B)$, $\mathcal{P}(v) = G(v) - U$ for some set $G(v) = \bigcap_{i=1}^{l} Q_i$, where $\{Q_i\}_{i=1}^{l}$ is a set of character subfamilies for different characters $c \in C - C_p$.

Proof. Pick $G(v)$ as follows. For each node v of B and each nonconvex character c, let $Q(v, c)$ be the character subfamily consisting of all species $s \in S$ such that $c(s) = c(x)$ for some $x \in \mathcal{P}(v)$. The set $G(v)$ is the intersection of $Q(v, c)$ over all characters $c \in C - C_p$.

To prove the claim, we show containment in both directions:

- Suppose $s \in \mathcal{P}(v)$. Then, $s \in Q(v, c)$ for each $c \in C - C_p$. Hence, $s \in G(v) - U$.
- Suppose $s \in G(v) - U$. By definition of $G(v)$, for each $c \in C - C_p$ there is a species $x \in \mathcal{P}(v)$ such that $c(x) = c(s)$. Also, there must exist a node $u \in B$ such that $s \in \mathcal{F}(u)$. Since $s \notin U$, $c(s) = c(v) = c(u)$ for every $c \in C - C_p$. But then, by Lemma 3 we must have $u = v$. Hence, $s \in \mathcal{P}(v)$. ∎

LEMMA 8. *Let T be a subphylogeny for (Q, α) such that* penalty$(T) \leq q$ *and B be the bad tree of T. Then, $|\bigcup_{v \in B} Im(v)| \leq 4q$.*

Proof. An edge subfamily P at v is imperfect if either (a) P shares a state σ with $S - P$ on character c and $c(v) \neq \sigma$ or (b) $P \cup \{v\}$ does not have a perfect

NEAR-PERFECT-PHYLOGENY(S, C, q).

1. Let $T =$ PERFECT-PHYLOGENY(S, C). If $T \neq$ NIL, then return T.
2. If $|S| \leq qr + 1$, then use exhaustive enumeration to search for a minimum-length q-near-perfect phylogeny for (S, C). Return NIL if no such phylogeny exists. Otherwise, return any such phylogeny.
3. For each $C_p \subseteq C$ such that $|C_p| \geq m - q$, find a minimum-length C_p-perfect phylogeny T_{C_p} of penalty at most q for S, if one exists, as follows:
   (a) Allocate a table $\mathcal{N}$ with one entry for each possible pair (Q, α), where α is a penalty state assignment and Q is a subfamily. Initialize $\mathcal{N}(Q, \alpha)$ to NIL for every pair (Q, α).
   (b) Enumerate, by increasing cardinality of Q, the pairs (Q, α) such that α is a penalty state assignment and Q is a subfamily. For each (Q, α), attempt (using Lemma 9) to find a minimum-length C_p-perfect subphylogeny of penalty at most q. If such a subphylogeny T_Q exists, set $\mathcal{N}(Q, \alpha) = T_Q$.
   (c) Let T_{C_p} be the minimum-length tree from among those that can be obtained by putting an edge between the roots of subphylogenies for (Q_1, α_1) and (Q_2, α_2) such that $Q_2 = S - Q_1$ and $\mathcal{N}(Q_1, \alpha_1), \mathcal{N}(Q_2, \alpha_2) \neq$ NIL.
4. Return the tree T_{C_p} that minimizes length(T_{C_p}) over all sets C_p enumerated in the previous step. If no tree exists, return NIL.

FIG. 3. *The near-perfect phylogeny algorithm.*

phylogeny. The number of subfamilies of the latter sort is at most q, since each of them contributes at least 1 to the total penalty. Let K be the set of subfamilies P that satisfy (a). Let K_0 be the subset of K consisting of all subfamilies P such that there is a character c and species $s \in P$ satisfying the requirements that P is a subfamily at $v \in V(B)$, $c(v) \neq c(s)$, and $c(s) = c(s')$ for some $s' \in S - Q$. Since each $P \in K_0$ contributes at least 1 to the total penalty, $|K_0| \leq q$. Let J be the graph whose vertex set is $K - K_0$ and whose edge set is defined as follows. Let $Q_u \in K - K_0$ and $Q_v \in K - K_0$ be imperfect subfamilies at u and v, respectively. There is an edge between Q_u and Q_v in J if and only if there are a character c and species $s_u \in Q_u$ and $s_v \in Q_v$ such that $c(u) \neq c(s_u) = c(s_v) \neq c(v)$. Let μ be the size of a maximum matching in J. One can verify that

$$q \geq \mu + |K - K_0| - 2\mu \geq |K - K_0|/2.$$

Therefore, $|K - K_0| \leq 2q$, and the lemma follows. □

5. The algorithm. Our near-perfect phylogeny algorithm is shown in Figure 3. Its analysis relies on the result below, proved in the next subsection.

LEMMA 9. *A minimum-length subphylogeny for a pair (Q, α) can be found in $|Q|m^{O(q)}2^{O(q^2r^2)}$ time and $O(q(r + \log m))$ space.*

We now have the main result of this paper.

THEOREM 10. *The algorithm* NEAR-PERFECT-PHYLOGENY *runs in time $|S|m^{O(q)}2^{O(q^2r^2)}$. That is, for fixed q and r, the problem of determining whether S has a q-near-perfect phylogeny, and, if so, finding such a tree of minimum length, can be solved in polynomial time.*

Proof. Step 1 takes $O(2^{2r}nm^2)$ time, as explained in section 3. By Theorem 1, if

S has a perfect phylogeny, this tree must also be an optimum near-perfect phylogeny. It can be shown that step 2 can be completed within the claimed time bound.

We now argue that step 3 of NEAR-PERFECT-PHYLOGENY finds an optimal phylogeny for each choice of C_p. Assume that step 3(b) correctly computes a minimum-length subphylogeny for each pair (Q, α) it considers (or determines that no such tree exists). Let T be any minimum-length C_p-perfect phylogeny for S. It suffices to prove that in step 3(c) the algorithm encounters a C_p-perfect phylogeny T' for S such that $\text{length}(T') = \text{length}(T)$.

By Lemma 4 and the fact that $|S| > qr + 1$, T must have at least one good edge $e = (u_1, u_2)$. For $i = 1, 2$, let α_i be the penalty state assignment of u_i, and let $Q_i = S \cap V(T_{u_i})$. Then, for $i = 1, 2$, Q_i is a character subfamily and, by Lemma 5, (Q_i, α_i) has a subphylogeny T_i' of length at most $\text{length}(T_i)$. Without loss of generality, assume that this T_i' is generated in step 3(b). Then, step 3(c) generates a tree T' by putting an edge between the roots of T_1 and T_2. By the minimality of T, $\text{length}(T') = \text{length}(T)$, as claimed.

Note that NEAR-PERFECT-PHYLOGENY enumerates only sets C_p of size at least $m - q$, because a q-near-perfect phylogeny has at most q nonconvex characters. Thus, the result returned by step 4 is a minimum-length q-near-perfect phylogeny for S, if one exists.

The total number of sets C_p considered in step 3 is

$$\sum_{i=m-q}^{m} \binom{m}{i} = O(qm^q),$$

and step 3(b) enumerates $O(m2^r r^q)$ (Q, α) pairs. By Lemma 9, this leads to a total running time of $|S| m^{O(q)} 2^{O(q^2 r^2)}$. □

5.1. Computing a subphylogeny. We now prove Lemma 9 by giving an algorithm to find a minimum-length C_p-perfect subphylogeny T for (Q, α). The key idea is given by Lemma 6, which suggests that, to find a C_p-perfect subphylogeny T of minimum penalty, it suffices to guess $B = B(T)$ and, for each node v of B, the perfect and imperfect edge subfamilies at v. Our procedure enumerates a sequence of *candidates*, each of which is used to generate a potential tree. A candidate consists of four pieces of information:

- $\tilde{B}$, a guess as to the bad tree of T.
- For each node v of $\tilde{B}$, a penalty state assignment α_v such that $\alpha_v = \alpha$ if v is the root of $\tilde{B}$.
- $\tilde{\mathcal{P}}$, a mapping from each vertex v of $\tilde{B}$ to a subset of S representing a guess as to the union of perfect edge subfamilies at v.
- $\tilde{Im}$, a mapping from each vertex v of $\tilde{B}$ to a collection of subsets of S representing a guess as to the collection of imperfect edge subfamilies at v.

Assume that the candidate is a correct guess as to the various components of a subphylogeny for (Q, α). We now describe how to construct such a subphylogeny from this information.

We first find, for each $v \in \tilde{B}$, the decomposition $\tilde{Pe}(v)$ of $\tilde{\mathcal{P}}(v)$ into perfect edge subfamilies. As in algorithm SUBPHYLOGENY (Figure 2), we rely on Lemma 2, which states that if we know one of the subfamilies R such that $R \subseteq \tilde{\mathcal{P}}(v)$, we have one of two possibilities:

(i) $\tilde{Pe}(v) = \{R, \tilde{\mathcal{P}}(v) - R\}$ or
(ii) $\tilde{Pe}(v) = R \cup (\tilde{\mathcal{P}}(v) - R)/v$, where $c(v) = c(Sv(\tilde{\mathcal{P}}(v), R))$ for every character $c \in C$.

In the latter case, $c(Sv(\tilde{\mathcal{P}}(v), R)) \neq *$ for every character c. There are polynomially many (for fixed r) choices for R; one of these must enable us to make the appropriate decomposition of $\mathcal{P}(v)$ if the candidate is a correct guess.

The distribution of perfect and imperfect edge subfamilies across the vertices of $\tilde{B}$ forces the states of some its nodes to assume certain values in order to maintain the convexity of the corresponding characters. For a vertex v in $\tilde{B}$, let Q_v be the set of all species in the subtree of T rooted at v. The state of vertex v in $\tilde{B}$ on character $c \in C_p$ is forced to equal σ if either Q_v and $S - Q_v$ share a state on character c or there are distinct subtrees T_1, T_2 at v, where T_1, T_2 contain species x_1, x_2, respectively, such that $c(x_1) = c(x_2)$. The remaining unforced states are set in any way that is consistent with convexity of the characters in C_p. This can be done in time polynomial in n, m, and r.

We now produce a subphylogeny for (Q, α) by doing the following for each $v \in \tilde{B}$:

(a) For each $R \in \tilde{Im}(v)$, enumerate all penalty state assignments γ to find the pair (R, γ) such that $T_R = \mathcal{N}(R, \gamma) \neq \emptyset$ and $\text{length}(T_R) + \text{dist}(u, v)$ is minimum, where u is the root of T_R. Connect the root of T_R to v.
(b) For every $R \in \tilde{Pe}(v)$, enumerate all penalty state assignments γ to find a pair (R, γ) such that $T_R = \mathcal{N}(R, \gamma) \neq \emptyset$ and the tree obtained by linking v to the root of T_R is a perfect phylogeny for $R \cup \{v\}$. Connect the root of T_R to v.

There is, of course, no guarantee that a candidate is a correct guess from which a minimum-length subphylogeny can be constructed. Indeed, it is possible that a candidate simply cannot be used to produce a subphylogeny for (Q, α). For instance, a candidate is invalid if some $s \in Q$ is neither a vertex in $\tilde{B}$ nor contained in some set in either $\tilde{Im}(v)$ or $\tilde{Pe}(v)$ for some $v \in V(\tilde{B})$. A candidate is also invalid if it is impossible to make a state assignment for $\tilde{B}$ on the characters in C_p in any consistent way. Finally, in either of steps (a) or (b) above, it may be impossible to find the required subtrees of a node $v \in \tilde{B}$. In any case, if an invalid candidate is encountered, we dismiss it. If no valid candidate can be generated for a (Q, α) pair, we set $\mathcal{N}(Q, \alpha) = \emptyset$.

It is also possible that a candidate allows us to generate a subphylogeny but not a minimum-length one. This issue is resolved by enumerating *all* potential candidates. The tree T stored in $\mathcal{N}(Q, \alpha)$ is the one that minimizes the length among all trees generated from valid candidates.

5.2. Generating candidates. We now describe how candidates are generated and derive a bound on their number. First, observe that, by Lemma 4, we need to consider only trees $\tilde{B}$ with at most qr edges. Thus, $qr^{O(qr)}$ distinct tree topologies $\tilde{B}$ are generated. Enumerating them takes time $qr^{O(qr)}$ and space $O(qr \log qr)$. The number of penalty state assignments enumerated for the nodes in $\tilde{B}$ is $r^{O(q^2 r)}$. These can be generated in time $2^{O(q^2 r^2)}$ and space $O(q^2 r^2)$.

Suppose that $\tilde{B}$ is indeed the bad tree of a subphylogeny T for (Q, α_Q). By Lemma 8, there is some set of at most $4q$ character subfamilies containing all imperfect edge subfamilies at v; each of these is a potential choice for $\tilde{Im}(v)$. There are $m^{O(q)} 2^{O(qr)}$ choices of subfamilies and $(qr)^{O(q)}$ ways in which these subfamilies can be distributed among the vertices of $\tilde{B}$.

By Lemma 7, for every $v \in \tilde{B}$ we can restrict our attention to $\tilde{\mathcal{P}}(v)$ of the form

$\tilde{\mathcal{P}}(v) = G(v) - U$, where

$$U = (S - Q) \cup \{u \in P \colon P \in \tilde{Im}(v), v \in \tilde{B}\} \qquad \text{and} \qquad G(v) = \bigcap_{i=1}^{k} Q_i$$

such that $\{Q_i\}_{i=1}^{k}$ is a set of character subfamilies for different characters $c \in C - C_p$. For every node v in $\tilde{B}$, $G(v)$ is the intersection induced by $\tilde{Im}(v)$.

Thus, the total number of candidates is $m^{O(q)}2^{O(q^2r^2)}$. These can be generated in time $m^{O(q)}2^{O(q^2r^2)}$ and space $O(q(\log m + r))$.

It can be verified that processing a candidate takes time $O(|Q|r^q)$. The total time to find a minimum-penalty subphylogeny for (Q, α) is therefore $|Q|m^{O(q)}2^{O(q^2r^2)}$, and the space used is $O(q(r + \log m))$. This concludes the proof of Lemma 9.

6. Conclusions and open questions. We have shown that a relaxed version of the perfect phylogeny problem, parameterized by the degree q to which the resulting phylogeny deviates from perfection, can be solved in polynomial time. Since the perfect phylogeny model is too restrictive, our algorithm may have some practical use. Unfortunately, its practicality is limited by its running time, which is bounded by a polynomial whose degree depends on q. We note, however, that the time bound is based on the perhaps overly pessimistic assumption that all bad edges can occur together in a bad tree. One may ask whether this is likely to happen in practice. Also, is there a parameter that is smaller than q in practice, in terms of which to express the time bound? One candidate is the maximum size of a bad tree.

Perhaps the most important open question raised by our algorithm is whether it is possible to make the degree of the polynomial describing the running time independent of the parameters; that is, whether there is an algorithm with running time $O(f(q)p(|S|, m))$, where p is a polynomial whose degree does not depend on q. Alternatively, one could try to show that the case where r is fixed and q is the only parameter is hard for $W[1]$.

Acknowledgments. We thank the referee and editor for their suggestions, which substantially improved the presentation.

THE 3-COLORABILITY PROBLEM ON GRAPHS WITH MAXIMUM DEGREE FOUR*

MARTIN KOCHOL†, VADIM LOZIN‡, AND BERT RANDERATH§

Abstract. The 3-colorability problem is known to be NP-complete in the class of graphs with maximum degree four. On the other hand, due to the celebrated theorem of Brooks, the problem has a polynomial-time solution for graphs with maximum degree three. To make the complexity gap more precise, we study a family of intermediate graph classes between these two extremes and classify all of them according to the computational complexity of the problem. In particular, we generalize Brooks's theorem in the case of 3-colorability to a larger class by showing that every connected graph in that class is 3-colorable, unless it is a complete graph on four vertices.

1. Introduction.

A 3-*coloring* of a graph is a mapping from the set of vertices to $\{1, 2, 3\}$ such that any two adjacent vertices have different colors. By Brooks's theorem [1] every connected graph with the maximum vertex degree at most three has a 3-coloring or is isomorphic to a complete graph on four vertices K_4. Hence, the decision problem, whether a given graph G has a 3-coloring, is trivial for graphs with maximum degree three. On the other hand, the complexity of the problem jumps from triviality to NP-completeness when we turn to the class of graphs with maximum degree four (see [4]). To make the complexity gap more precise, we study a family of graph classes that are intermediate between these two extremes. Every class $\mathcal{X}$ in the family is associated with a subset $\mathcal{H}'$ of the set of graphs on four vertices and is defined as follows: a graph G belongs to $\mathcal{X}$ if and only if each vertex of G has degree at most four, and the neighborhood of each 4-degree vertex induces a graph isomorphic to a member of the set $\mathcal{H}'$. The main result of the paper is that dichotomy holds: for a given subset $\mathcal{H}'$, the problem either

(1) is NP-complete or

(2) can be solved in linear time.

Subject to the assumption $P \neq NP$ both cases exclude each other. For the linear-time cases we present an algorithm which not only decides existence but also finds a 3-coloring, if there is one. One of the classes in the family is of particular interest because of the fact that every connected graph in that class is 3-colorable, except for a K_4. Thereby, we extend Brooks's theorem in the case of 3-colorability.

Our work is related to [6, 7, 9, 10, 11, 13], where the complexity of finding a 3-coloring in graphs defined by "forbidden induced subgraph" conditions is studied.

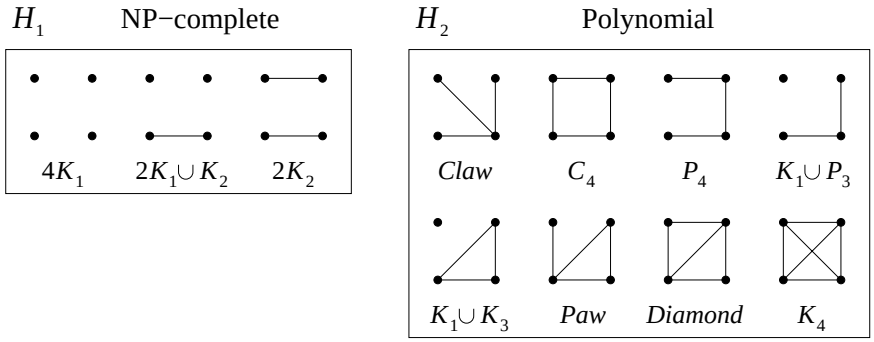

FIG. 2.1. *Problem-specific partition of* $\mathcal{H}$.

2. Basic notations and main result. For graph theoretic terminology not defined in this paper, the reader is referred to [3]. All graphs considered are finite, undirected, and without loops and multiple edges. The set of vertices and the set of edges of a graph G are denoted by $V(G)$ and $E(G)$, respectively. We let $n(G)$ denote the number of vertices of G and $n_4(G)$ denote the number of vertices of degree four in G. For a vertex $v \in V(G)$, we write $N_G(v)$ for the neighborhood of v, i.e., the set of vertices adjacent to v. The closed neighborhood of v is defined as $N_G[v] := N_G(v) \cup \{v\}$. The degree of v is denoted by $d_G(v)$ and the maximum degree of a vertex in G by $\Delta(G)$. If no confusion arises, we omit the subscript G in the above notations.

Given a subset $X \subseteq V(G)$, we denote by $G[X]$ the subgraph of G induced by the vertices in X, and let $G - X := G[V(G) - X]$. If $X = \{v\}$, we write $G - v$ for simplicity. We also write $G - e$ to denote the subgraph of G obtained by deleting an edge $e \in E(G)$. If G contains no induced subgraph isomorphic to a graph H, we say that G is H-free.

Throughout the paper, P_k and C_k stand, respectively, for a chordless path and a chordless cycle on k vertices, and K_r stands for a complete graph on r vertices. In particular, K_3 is a *triangle*. The set of all 4-vertex graphs will be denoted $\mathcal{H}$. This set contains 11 pairwise nonisomorphic graphs represented in Figure 2.1 along with their notations. By $\mathcal{H}_1$, $\mathcal{H}_2$, we refer to the subsets of $\mathcal{H}$ depicted in Figure 2.1.

A 4-vertex graph of particular interest is a *diamond* (see Figure 2.1). The nonadjacent vertices of a diamond will be called its *pick* vertices and the other two vertices the *diagonal* vertices. Importance of this graph for the 3-colorability problem is due to the following simple observation.

PROPOSITION 2.1. *Let G be a 3-colorable graph containing a diamond as an induced subgraph. Then the pick vertices of the diamond have the same color in any 3-coloring of G.*

In this paper we study the following problem. Let $\mathcal{H}'$ be a fixed subset of $\mathcal{H}$.

$\mathcal{H}'$-ISOM-3-COL

Instance: A graph G with maximum degree four in which the neighborhood of each 4-degree vertex induces a graph isomorphic to a member of $\mathcal{H}'$.

Question: Does there exist a 3-coloring of G?

Obviously, if $\mathcal{H}' = \emptyset$, we deal with the 3-colorability problem restricted to graphs with maximum degree three, which is polynomially solvable according to Brooks's theorem. The main result of this paper asserts that $\mathcal{H}'$-ISOM-3-COL is NP-complete *if and only if* $\mathcal{H}'$ contains one of the graphs in the set $\mathcal{H}_1$.

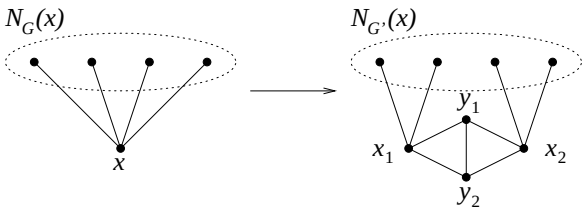

FIG. 2.2. *Reduction for the case* $2K_1 \cup K_2 \in \mathcal{H}'$.

THEOREM 2.2. *The problem* $\mathcal{H}'$-ISOM-3-COL *is*

(i) NP-*complete if* $\mathcal{H}' \cap \mathcal{H}_1 \neq \emptyset$,

(ii) *solvable in linear time if* $\mathcal{H}' \cap \mathcal{H}_1 = \emptyset$.

Proof. Now we prove only (i). The rest is proved in the next two sections.

Obviously, the problem is in NP for any choice of $\mathcal{H}'$. If $4K_1 \in \mathcal{H}'$, then the statement holds by the result of Maffray and Preissmann [9], who proved that the 3-colorability problem is NP-complete for K_3-free graphs with maximum degree four.

Applying the transformation shown in Figure 2.2 to every vertex of degree four in a K_3-free graph G with $\Delta(G) \leq 4$, we obtain a graph G', which is obviously an instance of $\mathcal{H}'$-ISOM-3-COL in the case that $2K_1 \cup K_2 \in \mathcal{H}'$. According to Proposition 2.1, G' is 3-colorable if and only if G is 3-colorable, which implies the statement in this case.

If $2K_2 \in \mathcal{H}'$, we refer the reader to the result of Holyer [5], who has shown that it is an NP-complete problem to decide whether a cubic K_3-free graph G is 3-*edge*-colorable. This result can be translated to the terminology of vertex colorability by associating with each graph G its line graph, denoted $L(G)$ and defined as follows: the vertex set of $L(G)$ is $E(G)$, and two vertices are adjacent in $L(G)$ if and only if the respective edges of G have a vertex in common. It is not hard to verify that if G is a triangle-free cubic graph, then $L(G)$ is a 4-regular diamond- and claw-free graph. Therefore, the result of Holyer implies NP-completeness of vertex 3-colorability in the class of 4-regular diamond- and claw-free graphs. Moreover, we may suppose that any graph G in this class is K_4-free, since a K_4 is not 3-colorable. But now G is an instance of the problem in question, and the conclusion holds. □

3. Polynomial-time results. Let $\mathcal{R}$ denote the class of graphs every vertex of which has degree at most four, and the neighborhood of each 4-degree vertex induces a graph isomorphic to a member of $\mathcal{H}_2$. If $G \in \mathcal{R}$, then $A(G)$ denotes the set of 4-degree vertices x in G such that $G[N(x)] \neq K_1 \cup P_3$.

LEMMA 3.1. *Suppose we have a graph* $G \in \mathcal{R}$ *together with* $A(G)$. *If* $A(G) \neq \emptyset$, *then we can construct in a constant time a graph* $G^* \in \mathcal{R}$ *together with* $A(G^*)$ *such that* $n(G^*) < n(G)$, G^* *is* 3-*colorable if and only if* G^* *is* 3-*colorable, and every* 3-*coloring* φ^* *of* G^* *can be transformed into a* 3-*coloring* φ *of* G *in a constant time.*

Proof. In order to construct the desired graph G^* we use finitely many operations of vertex/edge deletion/addition or set $G^* = K_4$. A trivial consequence of this is that $A(G)$ can be transformed into $A(G^*)$ in a constant time as well.

Let $x \in A(G)$. If $G[N(x)]$ contains a triangle, G is not 3-colorable, and we can set $G^* = K_4$. If $G[N(x)]$ contains no triangle, then exactly one of the following cases may occur.

Case 1. $G[N(x)]$ is a claw. Let $N(x) = \{y_1, y_2, y_3, x'\}$ and x' have degree three in $G[N(x)]$. Denote by G^* the graph obtained from G by deleting the vertices of $N[x]$ and introducing a new vertex y adjacent to those vertices in $V(G) - N[x]$ that have

a neighbor in $\{y_1, y_2, y_3\}$.

Clearly, $n(G^*) < n(G)$. Assume φ is a 3-coloring of G. Then, according to Proposition 2.1, y_1, y_2, y_3 have the same color, and we may transform φ into a 3-coloring of G^* by assigning to the vertex y the value $\varphi(y_1)$. The inverse direction follows by analogy. Thus G^* is 3-colorable if and only if G^* is, and every 3-coloring φ^* of G^* can be transformed into a 3-coloring φ of G in a constant time.

To prove that $G^* \in \mathcal{R}$, let us notice that each y_j has at most one neighbor in $V(G) - N[x]$, since otherwise $N(y_j)$ would induce in G a member of $\mathcal{H}_1$. This implies that y has degree at most three in G^*. Obviously, the degree of any other vertex of G^* is at most four. Suppose now that G^* contains a vertex z of degree four such that $N_{G^*}(z)$ induces a graph $H \in \mathcal{H}_1$. Notice that $G[N_G(z)]$ either coincides with H if $N_G(z) \cap \{y_1, y_2, y_3\} = \emptyset$ or is isomorphic to a spanning subgraph of H otherwise. In both cases, $G[N_G(z)] \in \mathcal{H}_1$, contradicting the assumption.

Case 2. $G[N(x)] = C_4$. Let $N(x) = \{y_0, y_1, y_2, y_3\}$ and y_i be adjacent to y_{i+1} for $i = 0, 1, 2, 3 \pmod 4$. Denote by G^* the graph obtained from G by deleting the vertices of $N[x]$, introducing a pair of adjacent vertices y_{odd} and y_{even}, and connecting y_{odd} (respectively, y_{even}) to those vertices in $V(G) - N[x]$ that have a neighbor in the set $\{y_1, y_3\}$ (respectively, $\{y_0, y_2\}$) in G. The proof of the lemma in this case is similar to the proof of Case 1.

Case 3. $G[N(x)] = P_4$. Let $N(x) = \{y_0, y_1, y_2, y_3\}$ and y_i be adjacent to y_{i+1} for $i = 0, 1, 2$. Denote by G' the graph obtained from G by deleting the vertices of $N[x]$, introducing a pair of adjacent vertices y_{odd} and y_{even}, and connecting y_{odd} (respectively, y_{even}) to those vertices in $V(G) - N[x]$ that have a neighbor in the set $\{y_1, y_3\}$ (respectively, $\{y_0, y_2\}$) in G. Clearly G' has a 3-coloring if and only if G does, and $n(G') < n(G)$. Furthermore, it is not difficult to verify that

(*) $\Delta(G') \leq 4$ and for every vertex $z \in V(G) - N[x]$ with $d_{G'}(z) = 4$, the neighborhood $N_{G'}(z)$ induces a member of $\mathcal{H}_2$.

If $G' \in \mathcal{R}$, then $G^* = G'$ has the desired properties.

Let $G' \notin \mathcal{R}$. Then by (*), the neighborhood of y_{odd} or y_{even} induces in G' a graph isomorphic to a member of $\mathcal{H}_1$. Assume

(0) y_{even} has degree four in G' with $N(y_{even}) = \{y_{odd}, z_0, z_1, z_2\}$ for some vertices $z_0, z_1, z_2 \in V(G) - N[x]$. Without loss of generality let $N_G(y_0) = \{x, y_1, z_0, z_1\}$ and $N_G(y_2) = \{x, y_1, y_3, z_2\}$.

(Note that the case when y_{odd} has degree four in G' is similar.) If the subgraph of G' induced by $N(y_{even})$ belongs to $\mathcal{H}_1$, then we have the following:

(1) z_1 (or z_0) is adjacent to y_1 in G, and hence to y_{odd} in G', since otherwise the neighborhood of y_0 would induce in G a graph isomorphic to a member of $\mathcal{H}_1$; thus $N_G(y_1) = \{x, y_0, y_2, z_1\}$.

(2) y_3 is adjacent neither to z_0 nor to z_2, since otherwise the subgraph of G' induced by $N(y_{even})$ does not belong to $\mathcal{H}_1$; for the same reason, z_1 is adjacent neither to z_0 nor to z_2.

(3) The subgraph of G' induced by $N(y_{odd})$ does not belong to $\mathcal{H}_1$, since otherwise z_2 should be adjacent to y_3 by analogy with (1).

Under conditions (0)–(3), let us define G^* to be the graph obtained from G by deleting the vertices of the set $U := \{x, y_1, y_3, z_1\}$, introducing a pair of adjacent vertices w and y_{odd}, and connecting y_{odd} (respectively, w) to those vertices in $V(G) - U$ that have a neighbor in the set $\{y_1, y_3\}$ (respectively, $\{x, z_1\}$) in G.

We check that $G^* \in \mathcal{R}$. It is obvious that for any vertex $z \in V(G) - U$, $d_{G^*}(z) \leq d_G(z)$. In order to show that w has degree at most four in G^*, let us observe that

z_1 has degree at most three in G, since otherwise $N_G(z_1)$ would induce in G a graph isomorphic to a member of $\mathcal{H}_1$. Denoting a possible third neighbor of z_1 in G (different from y_0 and y_2) by v, we therefore conclude that w has at most four neighbors in G^*: y_0, y_2, y_{odd}, and v. Similarly, y_3 has degree at most three in G, and hence y_{odd} is of degree at most four in G^*. In the subgraph H of G^* induced by $N(w)$ the vertex y_{odd} has degree at least two, and therefore $H \notin \mathcal{H}_1$. Analogously, the subgraph of G^* induced by $N(y_{odd})$ also is not a member of $\mathcal{H}_1$. For any other vertex z of the graph G^*, we use the same arguments as before: if z has degree four in G^*, then z has degree four in G as well. Moreover, the subgraph $G[N_G(z)]$ is isomorphic to a spanning subgraph of the graph induced by the neighborhood of z in G^*. Therefore, $G^* \notin \mathcal{R}$ would imply $G \notin \mathcal{R}$. To check the other desired properties for G^* is straightforward. □

4. Dart graphs. By means of reductions from Lemma 3.1, any graph $G \in \mathcal{R}$ can be transformed in linear time into a graph G' with $\Delta(G') \leq 4$ such that the neighborhood of each 4-degree vertex in G' induces either a $K_1 \cup P_3$ or a graph containing a triangle. In the latter case, G' obviously is not a 3-colorable graph, since it contains a K_4. Therefore, according to Lemma 3.1, the graph G is not 3-colorable too. In the present section we fix the remaining case; i.e., we solve the problem for graphs with maximum degree four in which the neighborhood of each 4-degree vertex induces a graph isomorphic to $K_1 \cup P_3$. In other words, each vertex of degree four together with its neighborhood induces the graph depicted in Figure 4.1. This graph is known in the literature under the name *dart*. Thus, we call the graphs in the class under consideration *dart graphs*.

The class of dart graphs is an extension of the graphs with maximum degree three. According to the classical result of Brooks [1], every connected graph with vertex degree at most three is 3-colorable, unless it is a K_4. It turns out that this proposition remains valid in the larger class of dart graphs.

In a dart graph G, a vertex v will be called a diagonal (respectively, pick) vertex if v is a diagonal (respectively, pick) vertex of an induced diamond in G.

LEMMA 4.1. *In a dart graph G, the subsets of pick and diagonal vertices are disjoint. As a result,*

(a) *in G no pick vertex has degree more than three;*
(b) *in the subgraph of G induced by the diagonal vertices, no vertex has degree more than two.*

Proof. Let u be a pick vertex of an induced diamond D in G with the diagonal (the edge connecting the diagonal vertices of D) v_1v_2. By contradiction, assume uw is the diagonal of another induced diamond D' in G. Notice that w neither coincides with v_i nor is adjacent to v_i, since otherwise $G[N[v_i]]$ is not a dart ($i = 1, 2$). But then u has at least five neighbors in G: v_1, v_2, w, and the two pick vertices of D'. This contradiction shows that the subsets of pick and diagonal vertices are disjoint in G.

By definition, every vertex of degree four in G is a diagonal vertex, which implies (a). Every diagonal vertex has at least two nondiagonal (pick) neighbors, which implies (b). □

Consider a connected component C of the graph induced by the diagonal vertices of a dart graph G. Due to Lemma 4.1(b), C is either a chordless path or a chordless cycle. By adding to C all the diamonds containing the vertices of C we obtain a subgraph of G (not necessarily induced) that will be denoted by F. If F contains a vertex which has degree four in G, we call F a *diamond bracelet*. The number of diamonds in the bracelet will be called the *size* of the bracelet. An example of a

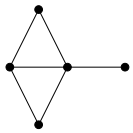

FIG. 4.1. *The dart.*

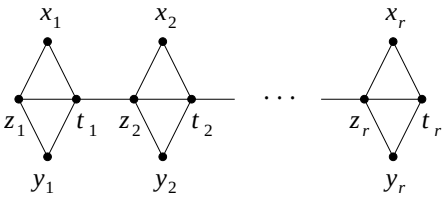

FIG. 4.2. *A diamond bracelet.*

bracelet of size r is depicted in Figure 4.2. Notice that the vertices z_1 and t_r may have degree three in G. They also may be adjacent if C is a cycle. We denote the family of diamond bracelets of G by $B(G)$. Notice that $B(G) = \emptyset$ if and only if $n_4(G) = 0$.

LEMMA 4.2. *Suppose we have a K_4-free dart graph G together with $B(G)$. If $n_4(G) > 0$, then we can construct in a constant time a K_4-free dart graph G^* together with $B(G^*)$ such that $n(G^*) \le n(G)$, $n_4(G^*) < n_4(G)$, and every 3-coloring φ^* of G^* can be transformed into a 3-coloring φ of G in a constant time.*

Proof. In order to construct the desired graph G^* we use finitely many operations of vertex/edge deletion/addition. A trivial consequence of this is that $B(G)$ can be transformed into $B(G^*)$ in a constant time as well. In most cases it is straightforward to see that G^* is a K_4-free dart graph. When this fact is not that obvious, we provide necessary explanations.

The lemma is trivial if G contains a vertex of degree four with a neighbor v of degree at most two: in this case $G^* = G - v$, and φ^* can be extended to φ by assigning to v a color missing in the neighborhood of v. Thus, in the course of the proof we shall assume that every neighbor of a 4-degree vertex has degree at least three.

Since $n_4(G) > 0$, we may consider a diamond bracelet $F \in B(G)$ of size $r \ge 1$. We use the notation of vertices of F as indicated in Figure 4.2. In our case analysis we distinguish the following seven cases that exhaust all possibilities for F.

1. $r \ge 3$.
2. $r \in \{1, 2\}$, and at least one of the vertices z_1 and t_r has degree three.

If $r \in \{1, 2\}$ and both vertices z_1 and t_r have degree four, we denote by t_0 and z_{r+1} the neighbors of z_1 and t_r different from x_1, t_1, y_1 and x_r, z_r, y_r, respectively. With these notations, we divide the general case when z_1 and t_r have degree four into the following subcases:

3. $r = 2$ and $z_1 t_2 \in E(G)$ (i.e., $t_0 = t_2$ and $z_3 = z_1$).
4. $r = 2$, $z_1 t_2 \notin E(G)$, and $t_0 \ne z_3$.
5. $r = 2$ and $t_0 = z_3$.
6. $r = 1$, and t_0, z_2 have no common neighbor of degree four.
7. $r = 1$, and t_0, z_2 have a common neighbor of degree four.

Moreover, cases 5 and 7 are subdivided into further subcases depending on certain specific conditions arising in the proof.

Having outlined the case analysis, let us proceed with the proof according to our plan.

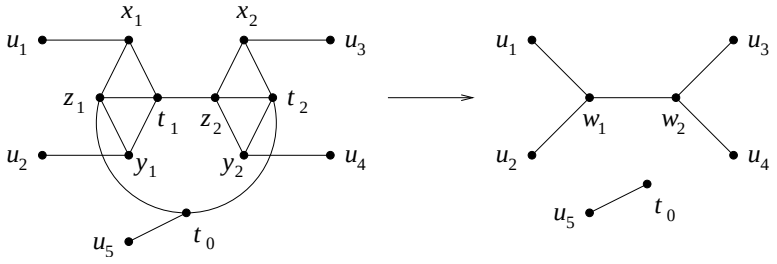

FIG. 4.3.

Case 1. $r \geq 3$. Let G^* be the K_4-free dart graph arising from G by deleting the edges t_1z_2, t_2z_3 and adding a new edge t_1z_3. Then $n(G^*) = n(G)$, $n_4(G^*) = n_4(G) - 2$ and for any 3-coloring φ^* of G^* the colors $\varphi^*(z_2)$ and $\varphi^*(t_2)$ are different and can interchange. Moreover, the colors $\varphi^*(t_1)$ and $\varphi^*(z_3)$ also are different. Therefore, by possible switching of colors of the vertices z_2 and t_2 we can transform φ^* into φ so that $\varphi(t_1) \neq \varphi(z_2)$ and $\varphi(t_2) \neq \varphi(z_3)$, which means φ is a 3-coloring of G.

Case 2. $r \in \{1, 2\}$, and at least one of the vertices z_1 and t_r has degree three. Assume t_r is of degree three. Then z_r has degree four in G (otherwise F does not cover any vertex of degree four). Let u denote the fourth neighbor of z_r, i.e., $u \neq t_r, x_r, y_r$. The vertices z_r and u are not the neighbors of a same 4-degree vertex. Therefore, $G^* = G - z_ru$ is a K_4-free dart graph, and furthermore $n(G^*) = n(G)$, $n_4(G^*) \leq n_4(G) - 1$. If φ^* is a 3-coloring of G^*, then, clearly, the colors $\varphi^*(z_r)$ and $\varphi^*(t_r)$ are different and can interchange, and hence we may transform φ^* into a 3-coloring φ of G in a constant time.

From now on, let $N(z_1) = \{t_0, x_1, y_1, t_1\}$ and $N(t_r) = \{z_r, x_r, y_r, z_{r+1}\}$.

Case 3. $r = 2$ and $z_1t_2 \in E(G)$ (i.e., $t_0 = t_2$ and $z_1 = z_3$). Consider $G^* = G - \{z_1t_2, z_2t_1\}$, which is clearly a K_4-free dart graph with $n(G^*) = n(G)$, $n_4(G^*) = n_4(G) - 4$. Since the colors $\varphi^*(z_1)$ and $\varphi^*(t_1)$ (and similarly $\varphi^*(z_2)$ and $\varphi^*(t_2)$) are different and can interchange, we conclude that φ^* can be transformed into φ in a constant time.

Case 4. $r = 2$, $z_1t_2 \notin E(G)$, and $t_0 \neq z_3$. If both t_0 and z_3 belong to F, say, $t_0 = x_2$ and $z_3 = x_1$, consider the graph $G^* = G - \{z_1, t_1, x_1, z_2, t_2, x_2\}$. Then $n(G^*) = n(G) - 6$, $n_4(G^*) = n_4(G) - 4$, and φ^* can be easily extended to a 3-coloring of G in a constant time.

If $z_3 \notin F$, then we apply exactly the same arguments as in Case 1: transform G into G^* by deleting the edges t_1z_2, t_2z_3 and adding a new edge t_1z_3, and then transform φ^* into φ by color interchanging, analogously if $t_0 \notin F$.

Case 5. $r = 2$ and $t_0 = z_3$. Remember that each of the vertices x_1, y_1, x_2, y_2, t_0 has degree exactly three. Let us denote their respective neighbors different from z_1, t_1, z_2, t_2 by u_1, u_2, u_3, u_4, u_5 (see Figure 4.3). Notice that $t_0 \neq u_1, \ldots, u_4$, but some of the vertices $u_1, \ldots, u_5$ may coincide.

Transform G into a graph G' by deleting the vertices of F and introducing a pair of new vertices w_1, w_2 with $N(w_1) = \{u_1, u_2, w_2\}$ and $N(w_2) = \{u_3, u_4, w_1\}$ (see Figure 4.3).

Case 5.1. Assume first that G' is a K_4-free dart graph. Then set $G^* = G'$. Now $n(G^*) = n(G) - 6$, $n_4(G^*) = n_4(G) - 4$, and φ^* can be transformed into φ in the following way. If at least two values among $\varphi^*(u_1)$, $\varphi^*(u_2)$, $\varphi^*(u_5)$ are equal, we can assign to the vertices x_1, y_1, t_0 the same color which is not in the set $\{\varphi^*(u_1), \varphi^*(u_2), \varphi^*(u_5)\}$.

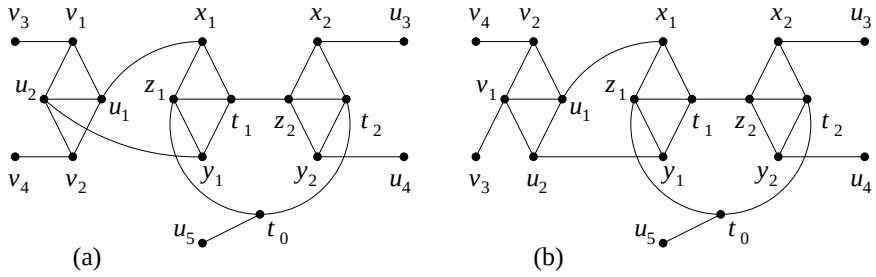

FIG. 4.4.

The rest is trivial: define $\varphi(x_2) = \varphi(y_2) \notin \{\varphi^*(u_3), \varphi^*(u_4)\}$, $\varphi(t_2) \notin \{\varphi(x_2), \varphi(t_0)\}$, $\varphi(z_2) \notin \{\varphi(x_2), \varphi(t_2)\}$, $\varphi(t_1) \notin \{\varphi(z_2), \varphi(x_1)\}$, $\varphi(z_1) \notin \{\varphi(x_1), \varphi(t_1)\}$. If $\varphi^*(u_1)$, $\varphi^*(u_2)$, $\varphi^*(u_5)$ are pairwise different, then at least two values among $\varphi^*(u_3)$, $\varphi^*(u_4)$, $\varphi^*(u_5)$ must be equal (otherwise φ^* is not a 3-coloring of G^*), and we can apply symmetrical arguments.

Case 5.2. Let G' be a dart graph containing a K_4. Then both new vertices w_1 and w_2 belong to the K_4 (indeed, $w_1 \notin K_4$ implies $w_2 \notin K_4$, since w_2 has at most two neighbors except w_1, but then G contains the same K_4). Therefore, up to symmetry, $u_1 = u_3$, $u_2 = u_4$, and $u_1u_2 \in E(G)$. Under this assumption, u_1 and u_2 cannot have degree four in G, and hence t_0 is a cut-point of G. Setting $G^* = G' - \{w_1, w_2, u_1, u_2\}$ we obtain a K_4-free dart graph G^* such that $n(G^*) = n(G) - 10$, $n_4(G^*) = n_4(G) - 4$. A 3-coloring φ^* of G^* can be extended to a 3-coloring φ of G as follows: $\varphi(z_1) = \varphi(z_2) = \varphi(u_1) \neq \varphi^*(t_0)$, $\varphi(t_1) = \varphi(t_2) = \varphi(u_2) \notin \{\varphi^*(t_0), \varphi(z_1)\}$, $\varphi(x_i) = \varphi(y_i) = \varphi^*(t_0)$, $i = 1, 2$.

Case 5.3. Suppose that G' is not a dart graph. Then at least one of the vertices $u_1, \ldots, u_4$, say u_1, has degree four in G', but $G'[N[u_1]]$ is not a dart. Therefore,

- u_1 has degree four in G;
- $u_1 \neq u_3, u_4$; otherwise $G[N[u_1]]$ is not a dart; as a result, $u_1w_2 \notin E(G')$;
- $u_1 \neq u_2$, and u_1 is adjacent to u_2; otherwise $G[N[u_1]]$ is not a dart;
- u_1 is not adjacent to t_0; otherwise $G[N[u_1]]$ is not a dart.

Denote the other two neighbors of u_1 in G, different from u_2 and x_1, by v_1 and v_2. A straightforward analysis reveals two possible combinations of the vertices in the neighborhood of u_1 in the graph G, shown in Figure 4.4. Notice that vertices v_3 and v_4 must exist in both cases. In the case of Figure 4.4(a), this follows from our assumption that every vertex in the neighborhood of u_1 has degree at least three. In the case of Figure 4.4(b), the vertex v_3 exists, since otherwise we could apply the arguments of Case 2 to the diamond induced by u_1, u_2, v_1, v_2.

Assume first that $v_3 = t_0$ (or, equivalently, $v_1 = u_5$). Then the subgraph H of G induced by the vertices of F together with u_1, u_2, v_1, v_2, t_0 has at most three neighbors in the remaining part of G: u_3, u_4, and v_4. In this case, we define $G^* = G - V(H)$ and extend φ^* to φ according to the following rules: $\varphi(x_2) = \varphi(y_2) = \varphi(t_0) \notin \{\varphi^*(u_3), \varphi^*(u_4)\}$, $\varphi(x_1) = \varphi(y_1) = \varphi(v_2) \notin \{\varphi^*(v_4), \varphi(x_2)\}$. The rest is simple. The case $v_4 = t_0$ can be analyzed by analogy.

If neither v_3 nor v_4 coincides with t_0, then we define G^* to be the graph obtained from G by deleting the vertices u_1, u_2, v_1, v_2 and adding new edges x_1v_3 and y_1v_4. Let us show that G^* is a dart graph without a K_4. The K_4-freeness is obvious. It is also easy to see that every vertex of G^* has degree at most four. Assume now that G^* contains a vertex w of degree four such that $G^*[N[w]]$ is not a dart. Then

$w \notin \{v_3, v_4\}$; otherwise $G[N[w]]$ also is not a dart. Therefore, the dart $G[N[w]]$ has been destroyed under the transformation $G \to G^*$ because of a new edge connecting two vertices adjacent to w, say y_1 and v_4. However, the vertices y_1 and v_4 have no common neighbor of degree four in G, unless $v_4 = t_0$. Thus G^* is the desired graph with $n(G^*) = n(G) - 4$, $n_4(G^*) = n_4(G) - 2$. A 3-coloring φ^* of G^* can be extended to a 3-coloring φ of G in the following way. For the configuration in Figure 4.4(a), define $\varphi(v_1) = \varphi(v_2) = \varphi^*(x_1)$, $\varphi(u_1) \neq \varphi^*(x_1)$, and $\varphi(u_2) \notin \{\varphi(u_1), \varphi^*(x_1)\}$. For the configuration in Figure 4.4(b), define $\varphi(u_1) = \varphi^*(v_4)$, $\varphi(v_1) = \varphi^*(x_1)$, $\varphi(u_2) = \varphi(v_2) \notin \{\varphi^*(x_1), \varphi^*(v_4)\}$.

Case 6. $r = 1$, and t_0, z_2 have no common neighbor of degree four. If t_0, z_2 have two common neighbors v_1, v_2 of degree three which are adjacent to each other, then $G^* = G - \{t_0, z_2, v_1, v_2\}$ is a K_4-free dart graph with $n(G^*) = n(G) - 4$, $n_4(G^*) = n_4(G) - 2$, and we can trivially extend φ^* to φ in a constant time. Suppose that t_0, z_2 have no common adjacent neighbors of degree three. Then deleting the edges t_0z_1, t_1z_2 and adding a new edge t_0z_2 (if $t_0z_2 \notin E(G)$) results in a K_4-free dart graph G^* such that $n(G^*) = n(G)$, $n_4(G^*) = n_4(G) - 2$. In any 3-coloring φ^* of G^* the colors of z_1, t_1 are different and can interchange, and the colors of t_0, z_2 are different. Therefore, φ^* can be transformed into a 3-coloring φ of G so that $\varphi(t_1) \neq \varphi(z_2)$ and $\varphi(z_1) \neq \varphi(t_0)$.

Case 7. $r = 1$, and t_0, z_2 have a common neighbor of degree four. Then, there must exist another diamond bracelet F' containing that neighbor. Without loss of generality we may suppose that the size of F' is 1, since otherwise we can apply to F' the arguments in Cases 1–5. Moreover, as for F, we assume that both diagonal vertices of F' have degree four, and we denote the vertices of F' and the respective neighbors of its diagonal vertices by analogy with F, i.e., $z'_1, t'_1, x'_1, y'_1, t'_0, z'_2$. Up to symmetry, we may suppose that the common neighbor of t_0 and z_2 is z'_1, and z_2 coincides with x'_1. For t_0, there remain two possibilities: either $t_0 = y'_1$, in which case we say that F *strongly depends* on F', or $t_0 = t'_0$, in which case we say that F *weakly depends* on F'. To avoid Case 6 for F', we conclude that there is a bracelet F'' of size 1 (else apply Cases 1–5 to F'') such that F' depends on F'' either strongly or weakly.

Case 7.1. F depends on F' weakly. Observe that in this case F' must depend on F'' weakly. Indeed, if F' depends on F'' strongly, then, according to the definition, t'_0 is a pick vertex of F'', and the neighborhood of t'_0 contains z_1, z'_1, and the two diagonal vertices of F'', contradicting Lemma 4.1.

Case 7.1.1. $z'_2 \in F$. Then $F = F''$ (see Figure 4.5(a)). In this case we obtain G^* by deleting from G all vertices of F and F' together with t_0. Clearly, G^* is a K_4-free dart graph with $n(G^*) = n(G) - 9$, $n_4(G^*) \leq n_4(G) - 4$. Given a 3-coloring φ^* of G^*, we can always extend it to a 3-coloring φ of G in such a way that $\varphi(y_1) = \varphi(y'_1) \notin \{\varphi^*(u_1), \varphi^*(u_2)\}$ and $\varphi(t_0) \notin \{\varphi^*(u_3), \varphi(y_1)\}$. The rest is trivial.

Case 7.1.2. $z'_2 \notin F$. With the help of Lemma 4.1 we conclude that F'' is disjoint from $F \cup F'$. Moreover, we may suppose that

- no diagonal vertex of F'' has a neighbor in F'; otherwise we are in conditions of Case 7.1.1 for the pair of bracelets F' and F'';
- one of the diagonal vertices of F'' is adjacent to t_0 by the definition of weak dependency;
- the other diagonal vertex of F'' is adjacent to a pick vertex of F; otherwise Case 6 can be applied to F''.

Therefore, we have the situation indicated in Figure 4.5(b). We define G^* to be

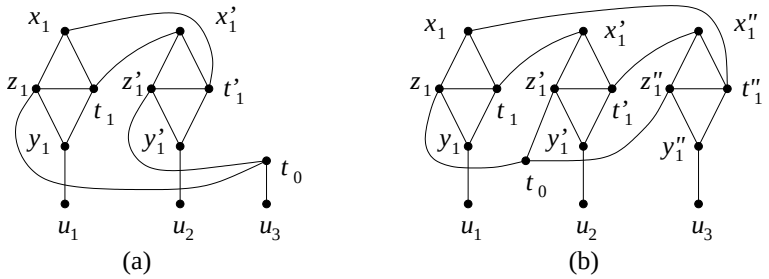

FIG. 4.5.

the graph obtain from G by deleting all vertices of F, F', and F" along with t_0. Given a 3-coloring φ^* of G^*, we can always extend it to a 3-coloring φ of G in such a way that $\varphi(y_1) = \varphi(y_1') \notin \{\varphi^*(u_1), \varphi^*(u_2)\}$, $\varphi(y_1'') \notin \{\varphi(y_1), \varphi^*(u_3)\}$, and $\varphi(t_0) \notin \{\varphi(y_1), \varphi(y_1'')\}$. The rest is trivial.

Case 7.2. F depends on F' strongly. If F' depends on F'' weakly, we are in conditions of Case 7.1 for the pair of bracelets F', F''. If F' depends on F'' strongly and $F \neq F''$, we delete from G the vertices of F' and connect the diagonal vertices of F to the pick vertices of F'', obtaining the desired K_4-free dart graph G^* with $n(G^*) = n(G) - 4$, $n_4(G^*) = n_4(G) - 2$. Any 3-coloring of G^* can be extended to a 3-coloring of G by coloring the vertices of F' analogously to the vertices of F. If $F = F''$, then $G[V(F \cup F')]$ is a 3-colorable component of G, and hence the graph $G^* = G - V(F \cup F')$ has the required properties. □

THEOREM 4.3. *A dart graph G is 3-colorable if and only if it has no component isomorphic to a K_4. If G is 3-colorable, then a 3-coloring of G can be found in linear time.*

Proof. The necessity of the first part of the theorem is trivial. To see the sufficiency, observe that a dart graph is K_4-free if and only if it has no component isomorphic to a K_4. The same is true if G is a graph with vertex degree at most three. Therefore, the sufficiency follows from Lemma 4.2 and Brooks's theorem [1].

We can check whether a dart graph G is K_4-free in linear time. Analogously, the set of 4-degree vertices and the set $B(G)$ of diamond bracelets of G can be found in linear time. Consequently, by means of Lemma 4.2 we can create in linear time a K_4-free graph G' without vertices of degree more than three such that any 3-coloring of G' can be transformed into a 3-coloring of G in linear time. By [8] (see also [12]), a 3-coloring of G' can be found in linear time, which proves the statement. □

End of the proof of Theorem 2.2. In linear time we can decide whether $G \in \mathcal{R}$ and construct $A(G)$. By Lemma 3.1, in linear time we can construct a graph G' such that $n(G') \leq n(G)$, $A(G') = \emptyset$, and G' is 3-colorable if and only if G is 3-colorable. If G' contains a K_4, which can be checked in linear time for graphs of bounded degree, then both G' and G are not 3-colorable. Otherwise, G' is a K_4-free dart graph, and hence both G' and G have a 3-coloring by Theorem 4.3. □

5. Outline of the algorithm. Let us summarize the above arguments in the following linear-time procedure, 3COL4MAX4, that decides not only existence but also finds a 3-coloring, if there is one, for any graph $G \in \mathcal{R}$.

PROCEDURE 3COL4MAX4.

Input: Graph $G \in \mathcal{R}$.

Output: "NO" if G is not 3-colorable; a 3-coloring of G otherwise.

(1) **While** G has a vertex v such that $G[N(v)]$ is either a claw or a C_4 or a P_4, apply reductions from Lemma 3.1.
(2) **If** G contains a K_4 as an induced subgraph, then output "NO" and STOP.
(3) Apply reductions of Lemma 4.2 to produce a graph of vertex degree at most three, color this graph, and then transform the found 3-coloring into a 3-coloring of the input graph as suggested by Lemmas 4.2 and 3.1.

The correctness and linear-time bound of the procedure follow from the results of the preceding sections, where we described in detail all steps of the algorithm, except for 3-coloring of graphs with vertex degree at most three. The algorithmic proof of Brooks's theorem proposed by Lovász [8] suggests an idea how to find a 3-coloring in such graphs. Recent developments in [12] provide a simpler way to implement Lovász's algorithm in linear time. To make the paper self-contained we present the algorithmic proof of Brooks's theorem below. Bryant [2] simplified this proof with the following characterization of cycles and complete graphs, highlighting thereby the exceptional role of the cycles and complete graphs in Brooks's theorem.

PROPOSITION 5.1. *Let G be a 2-connected graph. Then G is a cycle or a complete graph if and only if $G - \{u, v\}$ is not connected for every pair $\{u, v\}$ of vertices at distance two.*

Proof (Randerath and Schiermeyer [10]). Let G be a 2-connected graph of order n. If G is a cycle or a complete graph, then obviously $G - \{u, v\}$ is not connected for any pair $\{u, v\}$ of vertices at distance two. Hence, assume that G is neither a cycle nor a complete graph and that $G - \{u, v\}$ is not connected for each pair $\{u, v\}$ of vertices at distance two. Since G is 2-connected, there must exist at least one cycle in G. Let C be a longest cycle in G. Assume that C is not a Hamiltonian cycle of G. Since C is a longest cycle and G is connected, there exist vertices y, z of C and $x \in V(G) - V(C)$ such that z is adjacent to x and y, and x is not adjacent to y; i.e., $\mathrm{dist}_G(x, y) = 2$. Denote the path connecting x to y and containing all the vertices of C by P_1. According to our assumption, $G - \{x, y\}$ is not connected, and due to the 2-connectivity of G, there exists a second path P_2 connecting x to y, which is vertex disjoint with P_1, except for the endpoints. But then P_1 and P_2 form a cycle C' of length greater than C, a contradiction to the special choice of C. Thus, $C = v_0v_1, \ldots, v_{n-1}v_0$ is a Hamiltonian cycle. Now we consider a vertex v_i with $2 < d_G(v_i) < n - 1$, which must exist since G is neither a cycle nor a complete graph. Then there is $j \notin \{i - 1, i + 1\}$ such that v_i is adjacent to v_j but nonadjacent (without loss of generality) to v_{j-1}. Since $G - \{v_i, v_{j-1}\}$ is not connected, v_j is not adjacent to v_{j-2}. Therefore, $G - \{v_j, v_{j-2}\}$ is not connected, and hence $d_G(v_{j-1}) = 2$. Specifically, v_{j-1} is not adjacent to v_{j+1}. But now, on the one hand, $G - \{v_{j-1}, v_{j+1}\}$ is not connected according to our assumption, and, on the other hand, v_j is adjacent to v_i. This contradiction completes the proof of the proposition. □

THEOREM 5.2 (Brooks [1]). *Let G be a connected graph which is neither an odd cycle nor a complete graph. Then G is $\Delta(G)$-colorable.*

Algorithmic proof of Brooks's theorem [8]. Obviously, if the graph G with $\Delta(G) = \Delta$ is a cycle of even length, then G is 2-colorable. Hence, assume that G is neither a complete graph nor a cycle. Moreover, we shall assume that G is 2-connected, since otherwise the problem can be reduced to blocks of G. By Proposition 5.1 there exists a pair $\{u, v\}$ of vertices at distance two in graph G such that $G' = G - \{u, v\}$ is connected. Suppose that $w \in N_G(u) \cap N_G(v)$, and label the vertices of G as $v_1 = u$, $v_2 = v$, and the remainder as $v_3, v_4, \ldots, v_n = w$ in nonincreasing order of their distance from w in G'. Then color the vertices $v_1, v_2, \ldots, v_n$ in that order using

colors $1, 2, \ldots, \Delta$ so that at each step the color used for the vertex v_i is the lowest-numbered color not yet used at a vertex adjacent to v_i. Hence, we apply a greedy algorithm along our vertex ordering. The labeling of the vertices ensures that at each stage, v_i $(1 \leq i \leq n)$ is adjacent to at least one higher numbered (and hence presently uncolored) vertex. Thus, v_i is adjacent to at most $\Delta - 1$ colored vertices, and one of the Δ colors will be available for it. Finally, the vertex $v_n = w$ is adjacent to at most Δ vertices, at least two of which ($v_1 = u$ and $v_2 = v$) have the same color 1. Hence, there will be a color available for w. Therefore, the algorithm provides a vertex-coloring of G with at most Δ colors. □

ALGORITHMS FOR BOOLEAN FUNCTION QUERY PROPERTIES*

SCOTT AARONSON†

Abstract. We investigate efficient algorithms for computing Boolean function properties relevant to query complexity. Such properties include, for example, deterministic, randomized, and quantum query complexities; block sensitivity; certificate complexity; and degree as a real polynomial. The algorithms compute the properties, given an n-variable function's truth table (of size $N = 2^n$) as input.

Our main results are the following:

- $O(N^{\log_2 3} \log N)$ algorithms for many common properties,
- an $O(N^{\log_2 5} \log N)$ algorithm for block sensitivity,
- an $O(N)$ algorithm for testing "quasi symmetry,"
- a notion of a "tree decomposition" of a Boolean function, proof that the decomposition is unique, and an $O(N^{\log_2 3} \log N)$ algorithm for finding it,
- a subexponential-time approximation algorithm for space-bounded quantum query complexity. To develop this algorithm, we give a new way to search systematically through unitary matrices using finite-precision arithmetic.

The algorithms discussed have been implemented in a linkable library.

1. Introduction.

The query complexity of Boolean functions, also called black-box or decision-tree complexity, has been well studied for years [7, 9, 18]. Counting how many queries are needed to evaluate a function is easier than counting how many computational steps are needed; thus, nontrivial lower bounds are more readily shown for the former measure than for the latter. Also, query complexity has proved to be a powerful tool for studying the capabilities of quantum computers [2, 3, 4, 7, 13].

Numerous Boolean function properties relevant to query complexity have been defined, such as sensitivity, block sensitivity, randomized and quantum query complexity, and degree as a real polynomial. But many open questions remain concerning the relationships between the properties. For example, are sensitivity and block sensitivity polynomially related? How small can quantum query complexity be, relative to randomized query complexity? Lacking answers to these questions, we may wish to gain insight into them by using computer analysis of small Boolean functions. But to perform such analysis, we need efficient algorithms to compute the properties in question. Such algorithms are the subject of the present paper.

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function, and let $N = 2^n$ be the size of the truth table of f. We seek algorithms that have modest running time as a function of N, given the truth table as input. Table 1 lists some properties important for query complexity, together with the complexities of the most efficient algorithms for them of which we know.

TABLE 1

Properties important for query complexity, with the complexities of the most efficient current algorithms. Here "LP" stands for linear programming reduction, and "SDP" for semidefinite programming reduction.

Query property	**Complexity**	**Source**
Deterministic query complexity $\mathrm{D}(f)$	$O(N^{1.585} \log N)$	[12]
Certificate complexity $\mathrm{C}(f)$	$O(N^{1.585} \log N)$	[10]
Degree as a real polynomial $\deg(f)$	$O(N^{1.585} \log N)$	This paper
Approximate degree $\widetilde{\deg}(f)$	LP	Obvious
Randomized query complexity $\mathrm{R}_0(f)$	LP	This paper
Block sensitivity $\mathrm{bs}(f)$	$O(N^{2.322} \log N)$	This paper
Quasi symmetry	$O(N)$	This paper
Tree decomposition	$O(N^{1.585} \log N)$	This paper
Quantum query complexity $\mathrm{Q}_2(f)$	SDP	[5]
Randomized certificate complexity $\mathrm{RC}(f)$	LP	Obvious

There is also a complexity-theoretic rationale for studying algorithmic problems such as those considered in this paper. Much effort has been devoted to finding Boolean function properties that do not naturalize in the sense of Razborov and Rudich [20], and that might therefore be useful for proving circuit lower bounds. In our view, it would help this effort to have a better general understanding of the complexity of problems on Boolean function truth tables—both upper and lower bounds. This paper is a step towards such an understanding.

In an earlier version of this paper, we raised as our "most interesting" open question whether there exists a polynomial-time algorithm to compute (or even approximate) quantum query complexity. Subsequently Barnum, Saks, and Szegedy [5] managed to answer this question in the affirmative, using semidefinite programming. In section 7 we present a weaker result, namely an $O(N^{\mathrm{polylog}(N)})$ constant-factor approximation algorithm for bounded-error quantum query complexity if the memory of the quantum computer is restricted to $O(\log n)$ qubits. The main issue here, which is only partly addressed by results of Bernstein and Vazirani [8], is how to represent unitary operators with limited-precision arithmetic. Our results on this issue are used in the detailed analysis of the algorithm of Barnum, Saks, and Szegedy.

We have implemented most of the algorithms discussed in this paper in a linkable C library, which is available for download.[1]

The paper is organized as follows. Section 2 gives preliminaries, and section 3 reviews simple algorithms for deterministic query complexity, certificate complexity, degree as a real polynomial, randomized query complexity, and randomized certificate complexity. Section 4 gives an $O(N^{\log_2 5} \log N)$ algorithm for computing block sensitivity, and section 5 gives an $O(N)$ algorithm for testing "quasi symmetry." Section 6 defines a notion of the "tree decomposition" of a Boolean function, proves that the decomposition is unique, and gives an $O(N^{\log_2 3} \log N)$ algorithm for constructing it. Section 7 presents our results on algorithms for quantum query complexity, and section 8 concludes with some open problems.

2. Preliminaries. A Boolean function f is a total function from $\{0,1\}^n$ onto $\{0,1\}$. We use V_f to denote the set of variables of f, and use X, or alternatively $x_1, \ldots, x_n$, to denote an input to f. The restriction of f to R is denoted $f_{|R}$. If X is an input, $|X|$ denotes the Hamming weight of X; if S is a set, $|S|$ denotes the

[1] Available at http://www.cs.berkeley.edu/~aaronson/bfw

cardinality of S. Particular Boolean functions to which we refer are AND_n, OR_n, and XOR_n, the AND, OR, and XOR functions, respectively, on n inputs.

Throughout, we assume a RAM model of computation, in which for any input X, $f(X)$ can be obtained in $O(1)$ time.

3. Basic properties. To our knowledge, no algorithms for block sensitivity, quasi symmetry, or tree decomposition have been previously published. But algorithms for simpler query properties have appeared in the literature.

3.1. Deterministic query complexity. A *decision tree* T is a binary tree in which each nonleaf vertex is labeled with an index (1 through n) and each leaf vertex is labeled with an output (0 or 1). Evaluation begins at the root. At a vertex v labeled with i, if $x_i = 0$, we evaluate the left subtree of v, while if $x_i = 1$, we evaluate the right subtree. When we reach a leaf vertex we halt and return the appropriate output. T represents a Boolean function f if, for all settings of $x_1, \ldots, x_n$, the output of T equals $f(x_1, \ldots, x_n)$. Then the deterministic query complexity $\mathrm{D}(f)$ is the minimum height of a decision tree for f.

Guijarro, Lavín, and Raghavan [12] give a simple $O(N^{1.585} \log N)$ dynamic programming algorithm to compute $\mathrm{D}(f)$. We present a similar algorithm for completeness. The idea is that, at any time, a decision tree for f has reduced f to one of its 3^n possible restrictions: each of the n variables either (1) has been queried and is a 0, (2) has been queried and is a 1, or (3) has not yet been queried. Thus we can represent a restriction S by an element of $\{0, 1, *\}^n$, where the asterisk represents "not yet queried." We can also impose a lexicographic ordering on restrictions by stipulating that 0 comes before 1 comes before asterisk.

The algorithm consists of two loops, both of which proceed through all states in lexicographic order. The first loop fills in an array called A, which stores, for each restriction, whether it is a constant function and, if so, what its value is. The second loop uses A to fill in an array called D, which stores the deterministic query complexity of each restriction. In the algorithm, $S(i)$ represents the ith element of S, and $S_{S(i)=k}$ represents S with $S(i)$ set to the value k.

ALGORITHM 1 (computes deterministic query complexity).

loop over all $S \in \{0, 1, *\}^n$ *in lexicographic order* {
  if $(S \in \{0, 1\}^n)$, *then set* $A[S] := f(S)$ *else* {
    choose an i *such that* $S(i) = *$;
    if $(A[S_{S(i)=0}] = A[S_{S(i)=1}])$, *then set* $A[S] := A[S_{S(i)=0}]$;
    else set $A[S] :=$ NONCONSTANT;
  }
}
loop over all $S \in \{0, 1, *\}^n$ *in lexicographic order* {
  if $(A[S] \neq$ NONCONSTANT$)$, *then set* $D[S] := 0$;
  else set $D[S] := 1 + \min_{S(i)=*}[\max(D[S_{S(i)=0}], D[S_{S(i)=1}])]$;
}
return $D[*^n]$;

That f is given as a truth table is crucial: if f is nontotal and only the inputs for which f is defined are given, then deciding whether $\mathrm{D}(f) \leq k$ for some k is NP-complete [16]; a related problem is NP-hard even to approximate within a constant factor [23].

3.2. Certificate complexity. Given an input X to f, a *certificate* for X is a constant-valued restriction that agrees with X on the fixed variables. The *size* of

the certificate is the number of fixed variables; note that querying these variables is sufficient to prove that $f(X) = 0$ or $f(X) = 1$, as the case may be. The certificate complexity $\mathrm{C}_X(f)$ of X is the minimum size of any certificate for X. The certificate complexity $\mathrm{C}(f)$ of f is the maximum of $\mathrm{C}_X(f)$ over all inputs X. (Equivalently, $\mathrm{C}(f)$ is the minimum height of a nondeterministic decision tree for f.)

Czort [10] gives an $O(N^{1.585} \log N)$ algorithm to compute $\mathrm{C}(f)$. We can obtain such an algorithm by reusing the same array A that was used for deterministic query complexity in section 3.1. Consider a directed acyclic graph G in which the vertices are the 3^n possible restrictions of f, and an edge is drawn from S to T if and only if T is obtained from S by changing one 0 or 1 to an asterisk. The main loop of the algorithm fills in an array called q, proceeding in *reverse* lexicographic order. The array q stores, for each restriction S of f, the maximum length of any path in G from S to a nonconstant function, given that the path must halt once it reaches a nonconstant function. (Therefore, if S itself is nonconstant, then the length must be 0.) The certificate complexity is obtained by taking the maximum, over all $S \in \{0,1\}^n$, of $n - q[S] + 1$.

ALGORITHM 2 (computes certificate complexity).

loop over all $S \in \{0,1,*\}^n$ *in reverse lexicographic order* {
    if $(A[S] = \text{NONCONSTANT})$, *then*
        set $q[S] := 1 + \max(-1, \max_{S(i) \in \{0,1\}} q[S_{S(i)=*}])$;
    else set $q[S] := 1 + \max_{S(i) \in \{0,1\}} q[S_{S(i)=*}]$;
}
return $\max_{S \in \{0,1\}^n}(n - q[S])$;

Again, if f is not given as a full truth table, then deciding whether $\mathrm{C}(f) \leq k$ for some k is NP-complete [14].

3.3. Degree as a polynomial. Let $\deg(f)$ be the minimum degree of an n-variate real multilinear polynomial p such that, for all $X \in \{0,1\}^n$, $p(X) = f(X)$. Degree was introduced to query complexity by Nisan and Szegedy [19], who observed the relationship $\deg(f) \leq \mathrm{D}(f)$. Later Beals et al. [7] related degree to quantum query complexity by showing that $\deg(f) \leq 2\,\mathrm{Q}_E(f)$.

The following lemma, adapted from Lemma 4 of [9], is easily seen to yield an $O(n3^n) = O(N^{1.585} \log N)$ dynamic programming algorithm for $\deg(f)$. Say that a function obeys the *parity property* if the number of inputs X with odd parity for which $f(X) = 1$ equals the number of inputs X with even parity for which $f(X) = 1$.

LEMMA 3.1 (folklore). $\deg(f)$ *equals the size of the largest restriction of* f *for which the parity property fails.*

Proof. Let c_S be the coefficient of the monomial $\prod_{v_k \in S} v_k$. By the Möbius formula,

$$c_S = \sum_{X \subseteq S} (-1)^{|X|+|S|} f(X),$$

where $X \subseteq S$ means that every i for which $x_i = 1$ is in S. Now f has degree less than d if and only if, for all S with $|S| \geq d$, $c_S = 0$. But for each fixed value of $|S|$, $|S|$ (in the formula above) can affect the sign of c_S but not whether $c_S = 0$. Therefore for all δ, $c_S = 0$ for all S with $|S| = \delta$ is equivalent to the parity property holding for all restrictions of size δ. ∎

Lemma 3.1 leads to an $O(N^{\log_2 3} \log N)$ dynamic programming algorithm for computing $\deg(f)$, as follows.

ALGORITHM 3 (computes degree as a real polynomial).
loop over all $S \in \{0,1,*\}^n$ *in lexicographic order* {
    if $(S \in \{0,1\}^n)$*, then set* $d[S] := f(S)$*;*
    else set $d[S] := d[S_{S(i)=0}] - d[S_{S(i)=1}]$ *for some* i *such that* $S(i) = *$*;*
}
return $\max_{d[S]\neq 0}$(*number of* $*$*'s in* S*);*

3.4. Randomized query complexity. A randomized decision tree T_R is simply a collection $T_1, \ldots, T_k$ of ordinary decision trees, each T_i associated with a probability p_i satisfying $p_1 + \cdots + p_k = 1$. T_R represents f if each tree T_i in the collection represents f. Let $h(T, X)$ be the number of queries tree T makes on input X. Then we define

$$h(T_R) = \max_{X \in \{0,1\}^n} [p_1 h(T_1, X) + \cdots + p_k h(T_k, X)].$$

Then the zero-error randomized query complexity $\mathrm{R}_0(f)$ is the minimum height of a randomized decision tree that represents f. One can also discuss the bounded-error randomized query complexity $\mathrm{R}_2(f)$, which is the minimum height of a randomized decision tree that represents f with a probability of error at most 1/3. Nisan showed that $\mathrm{R}_0(f)^2 \geq \mathrm{D}(f)$ and $\mathrm{R}_2(f)^3 = \Theta(\mathrm{D}(f))$ (see [18]). On the other hand, the best known separation between deterministic and randomized query complexity is $\mathrm{R}_0(f) = \mathrm{R}_2(f) = \mathrm{D}(f)^{0.753\ldots}$ [21, 22] for f an AND/OR tree with two children per node.

Whether better separations are possible is a long-standing open question, and one that might be fruitfully investigated with computer analysis.[2] Unfortunately, though, we do not know how to compute $\mathrm{R}_0(f)$ or $\mathrm{R}_2(f)$ in polynomial time without reliance on linear programming. Here we sketch the reduction to a linear program.

As before, at any time the query algorithm has reduced f to one of its 3^n restrictions. Also, for each restriction, the algorithm has up to $n+2$ possible moves: it can query any variable not yet queried, halt and return 0, or halt and return 1. So consider a directed acyclic graph in which the vertices are the restrictions $S_1, \ldots, S_{3^n}$ (together with halting states $S_{(0)}$ and $S_{(1)}$) and the edges $(S_{i_1}, S_{j_1}), \ldots, (S_{i_m}, S_{j_m})$ are the possible moves of the algorithm. With each edge e we associate a probability weight $p(e)$; these weights are the variables of the linear program. Let $C(X)$ be the subset of N restrictions that are compatible with input X. There are four classes of constraints:

1. *Well-formedness.* The sum of the probability weights leaving the initial state must be 1. Formally $\sum_i p(S_0, S_i) = 1$, where S_0 is the initial state (no variables yet queried).
2. *Conservation of probability.* The sum of the probability weights entering each state must equal the sum of the probability weights leaving it. For all $j \neq 0$, $\sum_i p(S_i, S_j) = \sum_k p(S_j, S_k)$.
3. *Probability of correctness.* For each input, the probability of returning the correct answer must be at least $1 - \epsilon$, where $\epsilon = 0$ for $\mathrm{R}_0(f)$ and $\epsilon = 1/3$ for $\mathrm{R}_2(f)$. For all X with $f(X) = 1$, $\sum_{S_i \in C(X)} p(S_i, S_{(1)}) \geq 1 - \epsilon$. For $f(X) = 0$, substitute $p(S_i, S_{(0)})$.

[2] We have done such analysis for all 4-variable Boolean functions dependent on all 4 inputs. The two functions exhibiting the largest deterministic/randomized complexity gap ($D(f) = 4$, $R_0(f) = 3$) are both AND/OR trees, namely, A AND (B OR C OR D) and (A OR B) AND (C OR D). Randomization yields at least some speedup for 60 out of the 208 Boolean functions that are distinct up to negating inputs and outputs and permuting inputs.

4. *Minimum running time.* For each input, the expected running time must be at most T. For all X, $\sum_{S_i \in C(X)} Q(S_i)[p(S_i, S_{(0)}) + p(S_i, S_{(1)})] \leq T$, where $Q(S_i)$ is the number of queries that have been made in state S_i.

The objective is to minimize T.

Finally, let us briefly mention randomized and quantum certificate complexity. Given $X \in \{0,1\}^n$, Aaronson [1] defined the randomized certificate complexity $\mathrm{RC}_X(f)$ to be the minimum expected number of queries used by a randomized algorithm that accepts with 2/3 probability, given X as input, and rejects with 2/3 probability, given any Y for which $f(Y) \neq f(X)$. Then $\mathrm{RC}(f)$ is the maximum of $\mathrm{RC}_X(f)$ over all X. The quantum certificate complexity $\mathrm{QC}(f)$ is defined analogously, but with quantum instead of randomized algorithms. Aaronson showed that for any X, the optimal (up to a constant factor) randomized certificate for X queries the input nonadaptively. Furthermore, $\mathrm{QC}(f)$ is exactly characterized (again up to a constant factor) as the square root of $\mathrm{RC}(f)$. From these results, it readily follows that both $\mathrm{RC}(f)$ and $\mathrm{QC}(f)$ are approximable to within a constant factor in polynomial time, using linear programming.

4. Block sensitivity. Block sensitivity, introduced by Nisan [18], is a Boolean function property that is used to establish lower bounds. There are several open problems that an efficient algorithm for block sensitivity might help to investigate [18, 7, 9].

Let X be an input to Boolean function f, and let B (a *block*) be a nonempty subset of V_f. Let $X(B)$ be the input obtained from X by flipping the bits of B.

DEFINITION 4.1. *A block B is* sensitive *on X if $f(X) \neq f(X(B))$, and* minimal *on X if B is sensitive and no proper subblock S of B is sensitive. Then the block sensitivity $\mathrm{bs}_X(f)$ of X is the maximum number of disjoint minimal (or equivalently, sensitive) blocks on X. Finally $\mathrm{bs}(f)$ is the maximum of $\mathrm{bs}_X(f)$ over all X.*

The obvious algorithm for computing $\mathrm{bs}(f)$ (compute $\mathrm{bs}_X(f)$ for each X using dynamic programming, then take the maximum) uses $\Theta(N^{2.585} \log N)$ time. Here we show how to reduce the complexity to $O(N^{2.322} \log N)$ by exploiting the structure of minimal blocks. Our algorithm has two main stages: one to identify minimal blocks and store them for fast lookup, another to compute $\mathrm{bs}_X(f)$ for each X using only minimal blocks. The analysis proceeds by showing that no Boolean function has too many minimal blocks, and therefore that if the algorithm is slow for some inputs (because of an abundance of minimal blocks), then it must be faster for other inputs.

ALGORITHM 4 (computes $\mathrm{bs}(f)$). *For each input X do the following:*

1. *Construct an array M of all minimal blocks of X. To do this, loop over all blocks B in lexicographic order ($\{x_1\}, \{x_2\}, \{x_1, x_2\}, \{x_3\}, \ldots$), and mark* (i) *whether B is a minimal block and* (ii) *whether B contains a minimal block. B is minimal if B is sensitive and, for all $x_i \in B$, $B \setminus \{x_i\}$ does not contain a minimal block. B contains a minimal block if B is minimal or $B \setminus \{x_i\}$ contains a minimal block for some $x_i \in B$.*
2. *Create $2^n - 1$ lists, one list L_S for each nonempty subset S of variables. Then, for each minimal block B in M, insert a copy of B into each list L_S such that $B \subseteq S$. The result is that, for each S, $L_S = 2^S \cap M$, where 2^S is the power set of S.*
3. *Let a* state *be a partition (P, Q) of V_f. The set P represents a union of disjoint minimal blocks that have already been selected; the set Q represents the set of variables not yet selected. Then $\mathrm{bs}_X(f) = \theta(\emptyset, V_f)$, where $\theta(P, Q)$ is defined via the recursion $\theta(P, Q) \stackrel{\triangle}{=} 1 + \max_{B \in L_Q} \theta(P \cup B, Q \setminus B)$. Here the*

maximum evaluates to 0 *if* L_Q *is empty. Compute* $\theta(P,Q)$ *using depth-first recursion, caching the values of* $\theta(P,Q)$ *so that each needs to be computed only once.*

The block sensitivity is then the maximum of $\mathrm{bs}_X(f)$ over all X.

Let $m(X,k)$ be the number of minimal blocks of X of size k. The analysis of Algorithm 4's running time depends on the following lemma, which shows that large minimal blocks are rare in any Boolean function.

LEMMA 4.2. $\sum_X m(X,k) \leq 2^{n-k}\binom{n}{k}$ *for* $k \geq 2$.

Proof. The number of positions that can be occupied by a minimal block of size k is $\binom{n}{k}$ for each input, or $2^n\binom{n}{k}$ for all inputs. Consider an input X with a minimal block $B = \{b_1, \ldots, b_k\}$ of size k. Block B has $2^k - 1$ nonempty subsets; label them $S_1, \ldots, S_{2^k-1}$. By the minimality of B, for each S_i the input $X(S_i)$ has $\{b_1\}, \ldots, \{b_k\}$ as minimal blocks if $S_i = B$, and $B \setminus S_i$ as a minimal block if $S_i \neq B$. Therefore, since $k \geq 2$, $X(S_i)$ cannot have B as a minimal block. So of the $2^n\binom{n}{k}$ positions, only one out of 2^k can be occupied by a minimal block of size k. □

THEOREM 4.3. *Algorithm* 4 *takes* $O(N^{2.322}\log N)$ *time.*

Proof. Step 1 takes time $O(N^2 \log N)$, totaled over all inputs. Let us analyze step 2, which creates the $2^n - 1$ lists L_S. Since each minimal block B is contained in $2^{n-|B|}$ sets of variables, the total number of insertions is at most

$$\sum_X \sum_{k=0}^{n} m(X,k)2^{n-k} = \sum_{k=0}^{n}\left[2^{n-k}\sum_X m(X,k)\right] \leq \sum_{k=0}^{n} 2^{2n-2k}\binom{n}{k} = N^{\log_2 5}.$$

Since each insertion takes $O(\log N)$ time, the total time is $O(N^{2.322}\log N)$.

We next analyze step 3, which computes block sensitivity using the minimal blocks. Each $\theta(P,Q)$ evaluation is performed at most once and involves looping through a list of minimal blocks contained in Q, with each iteration taking $O(\log n)$ time. For each block B, the number of distinct (P,Q) pairs such that $B \subseteq Q$ is at most $2^{n-|B|}$. Therefore, by the previous calculation, the time for each input X is at most $(\log N)\sum_{k=0}^{n} m(X,k)2^{n-k}$, and a bound of $O(N^{2.322}\log N)$ follows. □

5. Quasi symmetry. A Boolean function $f(X)$ is *symmetric* if its output depends only on $|X|$. Query complexity is well understood for symmetric functions: for all nonconstant symmetric f, $\mathrm{D}(f) = n$, $\mathrm{R}_0(f) = \Theta(n)$, and $\mathrm{Q}_E(f) = \Theta(n)$ [7]. Thus, a program for analyzing Boolean functions might first check whether a function is symmetric, and if it is, dispense with many expensive tests. We call f *quasi-symmetric* if some subset of input bits can be negated to make f symmetric. There is an obvious $O(N^2)$ algorithm to test quasi symmetry; here we give a linear-time algorithm.

For an integer p, call a restriction of f a *p-left-restriction* if each variable v_i is fixed if and only if $i \leq p$. The basic idea of the algorithm is to loop through all $2^{n+1}-1$ such restrictions, with p decreasing from n to 0. Given a p-left-restriction S, let S_0 and S_1 be the two $(p+1)$-left-restrictions that agree with S. If either $f_{|S_0}$ or $f_{|S_1}$ is not quasi-symmetric, then $f_{|S}$ (and hence f) cannot be quasi-symmetric. If, on the other hand, $f_{|S_0}$ and $f_{|S_1}$ are both quasi-symmetric, then the algorithm tries to fit them together in such a way that $f_{|S}$ itself is seen to be quasi-symmetric. If the fitting-together process succeeds, then the algorithm returns a structure $g[S]$, containing both the output of $f_{|S}$ (encoded in compact form, as a symmetric function) and the *direction*, meaning the set of input bits that must be flipped to make $f_{|S}$ symmetric. Note that $g[S]$ occupies only $O(n-p)$ bits of space. Most of the algorithm deals with the special cases that $f_{|S}$ is an XOR function or a constant function; in both cases $f_{|S}$ is symmetric no matter

which set of input bits is flipped. In the pseudocode, these cases are handled using the tags XOR (for an XOR function), CONSTANT (for a constant function), and NORMAL (for any other quasi-symmetric function). Whenever the algorithm fails (meaning that f has been found not to be quasi-symmetric), the whole algorithm terminates; whenever $g[S]$ is assigned a value, the current iteration terminates. To avoid ambiguity about whether $f_{|S}$ is an XOR, CONSTANT, or NORMAL function, we start p at $n-2$ rather than n.

ALGORITHM 5 (tests quasi symmetry).

For all p-left-restrictions S for $p \le n-2$, with p decreasing from $n-2$ to 0,

1. *If $p = n-2$, then let $g[S]$ be the appropriate* NORMAL, CONSTANT, *or* XOR *function for the 2-input Boolean function $f_{|S}$. If $f_{|S}$ is not quasi-symmetric, then fail (meaning f is not quasi-symmetric).*
2. *If $g[S_0]$ and $g[S_1]$ are* NORMAL *functions but have different directions, then fail.*
3. *Let 0^k be a string of k zeroes. If $g[S_0]$ and $g[S_1]$ are* CONSTANT *functions, then*
   - *If $f_{|S_0}(0^{n-p-1}) = f_{|S_1}(0^{n-p-1})$, then let $g[S]$ be a* CONSTANT *function with output $f_{|S_0}(0^{n-p-1})$; otherwise fail.*
4. *If $g[S_0]$ and $g[S_1]$ are* XOR *functions, then*
   - *If $f_{|S_0}(0^{n-p-1}) \neq f_{|S_1}(0^{n-p-1})$, let $g[S]$ be an* XOR *function with $f_{|S}(0^{n-p}) = f_{|S_0}(0^{n-p-1})$; otherwise fail.*
5. *For $i \in \{0,1\}$, if $g[S_i]$ is a* CONSTANT *function and $g[S_{1-i}]$ is an* XOR *function, then halt and return failure.*
6. *For $i \in \{0,1\}$, if $g[S_i]$ is a* CONSTANT *or* XOR *function, then make $g[S_i]$ a* NORMAL *function with the same direction as $g[S_{1-i}]$.*
7. *For $i \in \{0,1\}$ and $j \in \{0,\dots,n-p-1\}$, let $a_j^{(i)} = f_{|S_i}(X)$ for all $X \in \{0,1\}^{n-p-1}$ of Hamming distance j from the direction string.*
   - *If the strings $a^{(0)}$ and $a^{(1)}$ overlap each other on $n-p-2$ bits, so that for either $i=0$ or $i=1$,*

$$a_1^{(i)} = a_2^{(1-i)}, \dots, a_{n-p-2}^{(i)} = a_{n-p-1}^{(1-i)},$$

   then let $g[S]$ be a NORMAL *function with outputs described by the $(n-p)$-bit overlap string and appropriate direction. Otherwise fail.*

Since the time used by each invocation is linear in $n-p$, the total time used is

$$\sum_{p=0}^{n} 2^p (n-p) = O(N).$$

The following lemma shows that the algorithm deals with all of the ways in which a function can be quasi-symmetric, which is key to the algorithm's correctness.

LEMMA 5.1. *Let f be a Boolean function on n inputs. If two distinct (and noncomplementary) sets of input bits A and B can be flipped to make f symmetric, then f is either* XOR_n, $1-\mathrm{XOR}_n$, *or a constant function.*

Proof. Assume without loss of generality that B is empty. Then A has cardinality less than n. We know that $f(X)$ depends only on $|X|$, and also that it depends only on $/X/ \stackrel{\triangle}{=} \sum_{i=1}^{n} \kappa(x_i)$, where $\kappa(x) = 1-x$ if $x_i \in A$ and $\kappa(x) = x$ otherwise. Choose any Hamming weight $0 \le w \le n-2$, and consider an input Y with $|Y| = w$ and with two variables v_i and v_j such that $v_i \in A$, $v_j \notin A$, and $Y(i) = Y(j) = 0$. Let Z be Y

with $Y(i) = Y(j) = 1$. We have $|Z| = |Y| + 2$, but, on the other hand, $/Z/ = /Y/$, and thus $f(Y) = f(Z)$ by symmetry. Again applying symmetry, $f(P) = f(Q)$ whenever $|P| = w$ and $|Q| = w + 2$. Therefore f is either XOR_n, $1 - \mathrm{XOR}_n$, or a constant function. □

6. Tree decomposition. Many of the Boolean functions of most interest to query complexity are naturally thought of as trees of smaller Boolean functions: for example, AND-OR trees and majority trees. Thus, given a function f, one of the most basic questions we might ask is whether it has a tree decomposition and, if so, what it is. In this section we define a sense in which every Boolean function has a unique tree decomposition, and we prove its uniqueness. We also sketch an $O(N^{1.585} \log N)$ algorithm for finding the decomposition.

DEFINITION 6.1. *A* distinct variable tree *is a tree in which*

(i) *every leaf vertex is labeled with a distinct variable (which may or may not be negated);*
(ii) *every nonleaf vertex v is labeled with a Boolean function having one variable for each child of v, and depending on all of its variables;*
(iii) *every nonleaf vertex has at least two children.*

Such a tree represents a Boolean function in the obvious way. We call the tree *trivial* if it contains exactly one nonleaf vertex. For instance, the majority function on 3 inputs can only be represented by a trivial tree.

A *tree decomposition* of f is a separation of f into the smallest possible components, with the exception of $(\neg)\,\mathrm{AND}_k$, $(\neg)\,\mathrm{OR}_k$, and $(\neg)\,\mathrm{XOR}_k$ components (where $(\neg)$ denotes possible negation), which are left intact. The choice of AND, OR, and XOR components is not arbitrary; these are precisely the three components that "associate," so that, for example, $\mathrm{AND}(x_1, \mathrm{AND}(x_2, x_3)) = \mathrm{AND}(\mathrm{AND}(x_1, x_2), x_3)$. Formally we have the following.

DEFINITION 6.2. *A* tree decomposition *of f is a distinct variable tree representing f such that*

(i) *no vertex is labeled with a function f that can be represented by a nontrivial tree, unless f is $(\neg)\,\mathrm{AND}_k$, $(\neg)\,\mathrm{OR}_k$, or $(\neg)\,\mathrm{XOR}_k$ for some k;*
(ii) *no vertex labeled with $(\neg)\,\mathrm{AND}_k$ has a child labeled with AND_l;*
(iii) *no vertex labeled with $(\neg)\,\mathrm{OR}_k$ has a child labeled with OR_l;*
(iv) *no vertex labeled with $(\neg)\,\mathrm{XOR}_k$ has a child labeled with $(\neg)\,\mathrm{XOR}_l$;*
(v) *any vertex labeled with a function that is constant on all but one input is labeled with $(\neg)\,\mathrm{AND}_k$ or $(\neg)\,\mathrm{OR}_k$.*

Let *double-negation* be the operation of negating the output of a function at some nonroot vertex v, then negating the corresponding input of the function at v's parent. Double-negation is a trivial way to obtain distinct decompositions. This caveat aside, we can assert uniqueness as follows.

THEOREM 6.3. *Every Boolean function has a unique tree decomposition, up to double-negation.*

We will build up to this uniqueness theorem via a sequence of preliminary results. Given a vertex v of a distinct variable tree, let $L(v)$ be the set of variables in the subtree of which v is the root. Assume that f is represented by two distinct tree decompositions, S and T, such that S has a vertex v_S and T has a vertex v_T with $L(v_S)$ and $L(v_T)$ incomparable (i.e., they intersect, but neither contains the other). We partition V_f into four sets of variables as follows: $A = L(v_S) - L(v_T)$, $B = L(v_T) - L(v_S)$, $I = L(v_S) \cap L(v_T)$, and $U = V_f - L(v_S) - L(v_T)$. Our strategy will be to derive increasingly strong constraints on how S and T can combine information

from A, B, I, and U. We do this by repeatedly restricting variables—considering f as, say, a function of I only—and then exploiting the fact that S and T must produce the same output, even though information travels along different routes in the two trees. Ultimately (in Lemma 6.5) we show that f is a function of $s(A)$, $r(I)$, and $t(B)$ for some Boolean functions s, r, and t. The problem thereby reduces to which Boolean functions of *three* variables have nonunique decompositions—and we can check that the only possibilities, AND, OR, and XOR, are ruled out by the definition of a tree decomposition.

Call a set of variables *unifiable* if there exists a vertex v, in *any* decomposition of f, such that $L(v) = V$. The preceding results imply that no pair of unifiable sets V_S, V_T is incomparable (Lemma 6.6): either $V_S \cap V_T = \phi$, $V_S \subseteq V_T$, or $V_T \subseteq V_S$. From there, it is readily shown that any decomposition must contain a vertex v with $L(v) = V$ for *every* unifiable V, from which the uniqueness theorem follows.

A remark on notation: we use subscripts to name Boolean functions (i.e., s_0, s_1, etc.) in order of their appearance, and superscripts to list which of A, B, I, and U are currently being restricted.

LEMMA 6.4. *There exist Boolean functions r, t_0^0, and t_0^1 such that f is a function of A, $r(I)$, $t_0^{r(I)}(B)$, and U.*

Proof. For any restriction u of U, we can write the output of S as $S^u[s_1(A, I), B]$, where S^u and s_1 are Boolean functions. Similarly we can write the output of T as $T^u[A, t_1(I, B)]$. We have that, for all settings of U,

$$S^u[s_1(A, I), B] = T^u[A, t_1(I, B)].$$

Consider a restriction b of B. This yields

$$S^{u,b}[s_1(A, I)] = T^u[A, t_2^b(I)]$$

for some Boolean function t_2^b. Therefore, for each b, s_1 depends on only a single bit obtained from I, namely, $t_2^b(I)$. Thus we can write $s_1(A, I)$ as $s_3(A, t_2^b(I))$ for some Boolean function s_3—or, even more strongly, as $s_3(A, s_4(I))$, since we know that s_1 does not depend on B. By analogous reasoning we can write $t_1(I, B)$ as $t_3(t_4(I), B)$ for some functions t_3 and t_4. Thus we have

$$S^u[s_3(A, s_4(I)), B] = T^u[A, t_3(t_4(I), B)].$$

Next we apply the restrictions $A = a$ and $B = b$, obtaining

$$S^{u,b}[s_3^a(s_4(I))] = T^{u,a}[t_3^b(t_4(I))],$$

which implies that, for some functions s_5 and t_5,

$$s_5(s_4(I)) = t_5(t_4(I))$$

for all I. This shows that $s_4(I)$ and $t_4(I)$ are equivalent up to negation of output, since S and T must depend on I for some restriction of A and B. Thus we have

$$(*) \qquad S^u[s_0^{r(I)}(A), B] = T^u[A, t_0^{r(I)}(B)]$$

for some Boolean functions $r(I)$, s_5^i, and t_5^i ($r \in \{0, 1\}$). ∎

We will henceforth think of $r(I)$ as a single Boolean variable.

LEMMA 6.5. *There exist Boolean functions s and t such that f is a function of $s(A)$, $r(I)$, $t(B)$, and U.*

Proof. Starting from (*), we next apply the restrictions $A = a$ and $r(I) = i$:

$$S^{u,a,i}[B] = T^{u,a}[t_0^i(B)].$$

Thus, for all restrictions of A and $r(I)$, S depends on only a single bit obtained from B, namely, $t_0^i(B)$. Note that t_0^i does not depend on A. Analogously, for both possible restrictions i of $r(I)$, T depends on only a single bit obtained from A, namely, $s_0^i(A)$. Thus we can write

$$s_6^u[s_0^i(A), t_0^i(B)] = t_6^u[s_0^i(A), t_0^i(B)],$$

where s_6^u and t_6^u are two-input Boolean functions. We claim that $s_0^0 = s_0^1$ and $t_0^0 = t_0^1$.

There must exist a restriction u of U such that s_6^u depends on both s_0^i and t_0^i. Suppose there exists a restriction b of B such that $t_0^0(b) \neq t_0^1(b)$. Now, s_0^i must be a nonconstant function, so find a constant c such that $s_6^u[c, t_0^i(b)]$ depends on t_0^i, and choose restrictions $A = a$ and $r(I) = i$ such that $s_0^i(a) = c$. (If s_6^u is an XOR function, then either $c = 0$ or $c = 1$ will work, whereas if s_6^u is an AND or OR function, then only one value of c will work.) For s_6^u to be well defined, we need that whenever $s_0^i(a) = c$, the value of i is determined, since

$$s_6^u[s_0^i(A), t_0^i(B)] = S^u[s_0^i(A), B]$$

and so the only access that s_6^u has to i is through s_0^i. This implies that s_0^i has the form $s(A) \wedge i$ or $s(A) \wedge \neg i$ for some function s. Therefore s_6^u can be written as $s_7^u[s(A), i, t_0^i(B)]$ for some function s_7^u. Now repeat the argument for t_6^u. We obtain that t_6^u can be written as $t_7^u[s_0^i(A), i, t(B)]$ for some functions t_7^u and t. Therefore

$$s_7^u[s(A), i, t_0^i(B)] = t_7^u[s_0^i(A), i, t(B)].$$

Thus we can take $t_0^i(B) = t(B)$ and $s_0^i(A) = s(A)$ and write s_7^u (as well as t_7^u) as $s_7^u[s(A), r(I), t(B)]$. □

Recall that a set $V \subseteq V_f$ is *unifiable* if there exists a vertex v, in some decomposition of f, such that $L(v) = V$.

LEMMA 6.6. *If V_S and V_T are unifiable, then either $V_S \cap V_T = \phi$, $V_S \subseteq V_T$, or $V_T \subseteq V_S$.*

Proof. Let $V_S = L(v_S)$ in decomposition S, and $V_T = L(v_T)$ in decomposition T, and suppose that V_S and V_T are incomparable. Let g_S be the function at v_S, and g_T the function at v_T. Defining A, I, B, and U as before, from Lemma 6.5 there exist Boolean functions $s(A)$, $r(I)$, and $t(B)$ such that

$$g_S = h_S(s(A), r(I)),$$
$$g_T = h_T(r(I), t(B))$$

for some two-variable Boolean h_S and h_T. Also, there exists a restriction $U = u$ for which f depends on all three of $s(A)$, $r(I)$, and $t(B)$. So the question reduces to which Boolean $\eta(a, i, b)$'s dependent on all three inputs are *associative*, in the sense that there exist Boolean η_1, η_2 and h_S, h_T for which

$$\eta(a, i, b) = \eta_1(h_S(a, i), b) = \eta_2(a, h_T(i, b)).$$

It is easily checked that the only possibilities are

$$(\neg)\,\mathrm{XOR}(a,i,b) \quad \text{or} \quad (\neg)\,\mathrm{AND}((\neg)a,(\neg)i,(\neg)b),$$

where $(\neg)$ denotes possible negation. Furthermore, η is determined up to negation, given h_S and h_T, so η cannot depend on u. In both the XOR and the AND (or equivalently OR) cases, v_S and v_T would have been collapsed to a single vertex in both S and T, by properties (ii)–(v) of a tree decomposition. Thus we have a contradiction. □

Now that we have ruled out the possibility of incomparable subtrees, we can establish uniqueness.

Proof of Theorem 6.3. It remains only to show that any decomposition must contain a vertex v with $L(v) = V$ for each unifiable V. Suppose that V is not represented in some decomposition F. Certainly $V \neq V_f$, so let V_P be the *parent set* of V in F: that is, the unique minimal set such that $V \subset V_P$ and there exists a vertex v_P in F with $L(v_P) = V_P$. Then the function at v_P is represented by a nontrivial tree containing a vertex v with $L(v) = V$. Were it not so represented, then for any Boolean function g on V there would exist a setting W of $V_P - V$ such that W, together with $g(V)$, would not suffice to determine the function h at v_P. Since f depends on h for some setting of $V_f - V_P$, it follows that v could not be a vertex in any decomposition. Furthermore, the function at v_P cannot be $(\neg)\,\mathrm{AND}_k$, $(\neg)\,\mathrm{OR}_k$, or $(\neg)\,\mathrm{XOR}_k$. If it were, then again v could not be a vertex in any decomposition, since it would need to be labeled correspondingly with $(\neg)\,\mathrm{AND}_k$, $(\neg)\,\mathrm{OR}_k$, or $(\neg)\,\mathrm{XOR}_k$. Having determined the unique set of vertices that comprise any decomposition, the vertices' labels are also determined up to double-negation. □

We now consider algorithms for finding the tree decomposition. First, given a subset G of V_f, there is a linear-time algorithm for deciding whether a Boolean function tree representing f could have a vertex u with $L(u) = G$. Consider the set F of $2^{n-|G|}$ restrictions on G induced by setting all the variables in $V_f - G$ to constant values. A vertex could have $L(u) = G$ if and only if all restrictions in F are identical up to negation, omitting constant functions. This can be checked in $O(N)$ time, which leads to an $O(N^2)$ algorithm for finding all vertices in the tree decomposition. (As a postprocessing step, the algorithm prunes superfluous AND_k, OR_k, and XOR_k vertices.)

However, we can reduce the running time to $O(N^{\log_2 3} \log N)$ by being more careful about how we check whether all restrictions in F are identical. The idea is to represent each restriction by a concise *code number*, which takes up only $O(n)$ bits rather than $2^{|G|}$ bits. We create the code numbers recursively, starting with the smallest restrictions and working up to larger ones. The code numbers need to satisfy the following conditions:

1. Two restrictions S and T over the same set of variables get mapped to identical code numbers if and only if $S = T$.
2. If S is constant or S is the negation of T, then these facts are easy to tell, given the code numbers of S and T.

We can satisfy these conditions by building up a binary tree of restrictions at each recursive call, then assigning each restriction a code number based on its position in the tree: 1 if it is the leftmost leaf, 2 if it is the second-to-leftmost, and so on. There are two exceptions: the constant 0 and 1 restrictions are assigned special code numbers Φ_0 and Φ_1, respectively, and if the negation of S was already assigned code number J, then S is assigned code number $-J$. For all $G \neq \phi$, each object inserted into the tree is two code numbers of size $|G| - 1$ restrictions concatenated together. Because this pair

of code numbers is then "hashed down" to a single number based on its position in the tree, the numbers always remain of size $O(n)$. In the pseudocode, B is the binary tree, $J[S]$ is the codeword of restriction S, and the operation $\odot$ denotes concatenation. The set VERTICES stores the final result, namely, all sets $H \subseteq V_f$ such that there is a vertex u in the decomposition of f having $L(u) = H$. After the main loop of the algorithm, a postprocessing step deletes redundant AND_k, OR_k, and $(\neg)\,\mathrm{XOR}_k$ vertices. This step looks for vertices u and v with $L(u)$ and $L(v)$ incomparable, which by Theorem 6.3 can only have arisen by AND_k, OR_k, or $(\neg)\,\mathrm{XOR}_k$.

ALGORITHM 6 (decomposes a Boolean function).

For all $G \subseteq V_f$ (in lexicographic order, starting with $G = \phi$):

1. *Initialize an empty self-balancing binary tree B.*
2. *Let Z be the set of all restrictions $S \in \{0, 1, *\}^n$ that fix exactly those variables not in G. Also, if $G \neq \phi$, then let k be the minimum i such that $v_i \in G$.*
3. *For all $S \in Z$,*
   - *If $G = \phi$, then insert $\Phi_{f(S)}$ into B. Otherwise, let S_0 and S_1 be further restrictions of S that fix v_k to 0 and 1, respectively, and insert $J[S_0] \odot J[S_1]$ into B.*
4. *For all $S \in Z$, assign S a code number $J[S]$ as follows:*
   - *For $i \in \{0, 1\}$, if $J[S_0] = J[S_1] = \Phi_i$, then $J[S] = \Phi_i$ also.*
   - *Otherwise, if $(-J[S_0]) \odot (-J[S_1])$ (corresponding to the negation $\neg S$ of S) is to the left of $J[S_0] \odot J[S_1]$ in B, then $J[S] = -J[\neg S]$.*
   - *Otherwise, if $J[S_0] \odot J[S_1]$ is the tth leaf of B in left-to-right order, then $J[S] = t$.*
5. *If $|G| \geq 2$ and, for all $S \in Z$, $|J[S]|$ is identical (omitting those S for which $J[S] = \Phi_0$ or $J[S] = \Phi_1$), then add G to* VERTICES*; otherwise do not.*

For each $i \in \{1, \ldots, n\}$, find all $G \in$ VERTICES *such that $v_i \in G$. Attempt to sort them into an ascending sequence $G_1 \subset G_2 \subset \cdots$. If a G_i to be inserted is incomparable with some G_j in the sequence, then leave G_j in the sequence, do not insert G_i, and flag both G_i and G_j for removal.*

Both the main loop and the second loop effectively perform an $O(\log N)$-time operation for all subsets of subsets of V_f. Therefore the total running time is $O(N^{\log_2 3} \log N)$.

7. Quantum query complexity. The quantum query complexity of a Boolean function f is the minimum number of oracle queries needed by a quantum computer to evaluate f. Here we are concerned only with the bounded-error query complexity $\mathrm{Q}_2(f)$ (defined in [7]), since approximating unitary matrices with finite precision introduces bounded error into any quantum algorithm. A quantum query algorithm Γ proceeds by an alternating sequence of $T + 1$ unitary transformations and T query transformations: $U_0 \to Q_1 \to U_1 \to \cdots \to Q_T \to U_{T+1}$. Then $\mathrm{Q}_2(f)$ is the minimum of T over all Γ that compute f with bounded error.

As mentioned in section 1, Barnum, Saks, and Szegedy [5] have recently obtained a polynomial-time algorithm to approximate $\mathrm{Q}_2(f)$. Here we show a weaker result: that if we limit the number of qubits, we can obtain a subexponential-time approximation algorithm via careful exhaustive search.

7.1. Overview of result. For what follows, it will be convenient to extend the quantum oracle model to allow intermediate observations. With an unlimited workspace, this cannot decrease the number of queries needed [8]. In the space-bounded setting, however, it might make a larger difference.

We define a *composite algorithm* Γ' to be an alternating sequence $\Gamma_1 \to D_1 \to \cdots \to \Gamma_t \to D_t$. Each Γ_i is a quantum query algorithm that uses T_i queries and at most m qubits of memory for some $m \geq \log_2 n + 2$. When Γ_i terminates, a basis state $|\psi_i\rangle$ is observed. Each D_i is a *decision point*, which takes as input the sequence $|\psi_1\rangle, \ldots, |\psi_i\rangle$, and as output decides whether to (1) halt and return $f = 0$, (2) halt and return $f = 1$, or (3) continue to Γ_{i+1}. (The final decision point, D_t, must choose between (1) and (2).) There are no computational restrictions placed on the decision points. However, a decision point cannot modify the quantum algorithms that come later in the sequence; it can only decide whether to continue with the sequence. For a particular input, let p_k be the probability, over all runs of Γ', that quantum algorithm Γ_k is invoked. Then Γ' uses a total number of queries $\sum_{k=1}^{t} p_k T_k$.

We define the space-bounded quantum query complexity $\mathrm{SQ}_{2,m}(f)$ to be the minimum number of queries used by any composite algorithm that computes f with error probability at most $1/3$ and that is restricted to m qubits. We give an approximation algorithm for $\mathrm{SQ}_{2,m}(f)$ taking time $2^{O(4^m mn)}$, which when $m = O(\log n)$ is $O(N^{\mathrm{polylog}(N)})$. The approximation ratio is $\sqrt{22}/3 + \epsilon$ for any $\epsilon > 0$. The difficulty in proving the result is as follows.

A unitary transformation is represented by a continuous-valued matrix, which might suggest that the quantum model of computation is analog rather than digital. But Bernstein and Vazirani [8] showed that, for a quantum computation taking T steps, the matrix entries need to be accurate only to within $O(\log T)$ bits of precision in the bounded-error model. However, when we try represent unitary transformations on a computer with finite precision, a new problem arises. On the one hand, if we allow only matrices that are exactly unitary, we may not be able to approximate every unitary matrix. So we also need to admit matrices that are *almost* unitary. For example, we might admit a matrix if the norm of each row is sufficiently close to 1, and if the inner product of each pair of distinct rows is sufficiently close to 0. But how do we know that every such matrix is close to some actual unitary matrix? If it is not, then the transformation it represents cannot even approximately be realized by a quantum computer.

We resolve this issue as follows. First, we show that every almost-unitary matrix is close to some unitary matrix in a standard metric. Second, we show that every unitary matrix is close to some almost-unitary matrix representable with limited precision. Third, we upper-bound the precision that suffices for a quantum algorithm, given a fixed accuracy that the algorithm needs to attain.

An alternative approach to approximating $\mathrm{SQ}_{2,m}(f)$ would be to represent each unitary matrix as a product of elementary gates. Kitaev [17] and independently Solovay [24] showed that a $2^m \times 2^m$ unitary matrix can be represented with arbitrary accuracy $\delta > 0$ by a product of $2^{O(m)\,\mathrm{polylog}(1/\delta)}$ unitary gates. But this yields a $2^{2^{O(m)\,\mathrm{polylog}(mn)}}$ algorithm, which is slower than ours. Perhaps the construction or its analysis can be improved; in any case, though, this approach is less natural for the setting of query complexity.

7.2. Almost-unitary matrices. Let $u \bullet v$ denote the conjugate inner product of u and v. The distance $|A - B|$ between matrices $A = (a_{ij})$ and $B = (b_{ij})$ in the $L_{\max}$ norm is defined to be $\max_{i,j} |a_{ij} - b_{ij}|$.

DEFINITION 7.1. *A matrix A is* q-almost-unitary *if* $|I - AA^\dagger| < q$.

In the following lemma, we start with an almost-unitary matrix A and construct an actual unitary matrix U that is close to A in the $L_{\max}$ norm.

LEMMA 7.2. *Let A be a q-almost-unitary $s \times s$ matrix, with $s \geq 2$ and $q \leq 1/4s$. Then there exists a unitary matrix U such that $|A - U| < 4.91q\sqrt{s}$.*

Proof. We first normalize each row A_i so that $A_i \bullet A_i = 1$. For each entry a_{ij},

$$|a_{ij}/(A_i \bullet A_i) - a_{ij}| = |a_{ij}||1 - (A_i \bullet A_i)|/|A_i \bullet A_i| < q(1+q)/(1-q).$$

We next form a unitary matrix B from A by using the classical Gram–Schmidt (CGS) orthogonalization procedure. The idea is to project A_2 to make it orthogonal to A_1, then project A_3 to make it orthogonal to both A_1 and A_2, and so on. Initially we set $B_1 \leftarrow A_1$. Then for each $2 \leq i \leq s$ we set $B_i \leftarrow A_i - \sum_{j=1}^{i-1}(A_i \bullet B_j)B_j$. Therefore

$$A_i \bullet B_k = (A_i \bullet A_k) - \sum_{j=1}^{k-1}(A_i \bullet B_j)(A_k \bullet B_j).$$

We need to show that the discrepancy between A and B does not increase too drastically as the recursion proceeds. Let $\sigma_k = \max_i A_i \bullet B_k$. By hypothesis, $\sigma_1 < q$. Then $\sigma_k \leq \sigma_1 + \sum_{j=1}^{k-1}\sigma_j^2$. Assume that $\sigma_k < q + 4q^2 s$ for all $k \leq K$. By induction,

$$\sigma_{K+1} < q + K(q + 4q^2 s)^2 \leq q + 4q^2 s$$

since $q \leq 1/4s$ and $K \leq s$. So for all k, $\sigma_k < q + 4q^2 s$.

Let $\phi = |A - B|$. By the definition of B, $\phi \leq \sigma_1|w_1| + \cdots + \sigma_s|w_s|$, where w is a column of B. Since $|w_1|^2 + \cdots + |w_s|^2 = 1$, ϕ is maximized when $w_i = \sigma_i\sqrt{s}/(\sigma_1 + \cdots + \sigma_s)$, or

$$\phi \leq \sigma_1^2 + \cdots + \sigma_s^2\sqrt{s}/(\sigma_1 + \cdots + \sigma_s) \leq (q + 4q^2 s)^2\sqrt{s}/q.$$

Adding $q(1+q)/(1-q)$ from normalization yields a quantity less than $(4 + 9\sqrt{2}/14)q\sqrt{s} \approx 4.91q\sqrt{s}$. This can be seen by working out the arithmetic for the worst case of $s = 2$, $q = 1/4s$. □

The next lemma, which is similar to Lemma 6.1.3 of [8], is a sort of converse to Lemma 7.2: we start with an arbitrary unitary matrix and show that truncating its entries to a precision $\delta > 0$ produces an almost-unitary matrix.

LEMMA 7.3. *Let U and V be $s \times s$ matrices with $s \geq 2$ and $|U - V| < \delta$. If U is unitary, then V is $(2\delta\sqrt{s} + \delta^2 s)$-almost-unitary.*

Proof. First,

$$U_i \bullet U_i = \sum_{k=1}^{s} |u_k + \gamma_k|^2 = 1 + \sum_{k=1}^{s}(u_k\gamma_k^* + u_k^*\gamma_k + \gamma_k\gamma_k^*),$$

where the u_k's are entries of U and the γ_k's are error terms satisfying $|\gamma_k| < \delta$. Thus, by the Cauchy–Schwarz inequality, $U_i \bullet U_i$ differs from 1 by at most $2\delta\sqrt{s} + \delta^2 s$. Second, for $i \neq j$,

$$U_i \bullet U_j = \sum_{k=1}^{s}(u_k + \gamma_k)(u_k + \eta_k)^*,$$

where the γ_k's and η_k's are error terms, and the argument proceeds analogously. □

7.3. Searching for quantum algorithms. In this section we use the results on almost-unitary matrices to construct an algorithm. First we need a lemma about error buildup in quantum algorithms, which is similar to Corollary 3.4.4 of [8] (though the proof technique is different).

LEMMA 7.4. *Let $U_1, \ldots, U_T$ be $s \times s$ unitary matrices, $\widehat{U_1}, \ldots, \widehat{U_T}$ be $s \times s$ arbitrary matrices, and v be an $s \times 1$ vector with $\|v\|_2 = 1$. Suppose that, for all i, $|\widehat{U_i} - U_i| < 1/cs$, where $c > T/2$. Then $\widehat{U_1} \cdots \widehat{U_T} v$ differs from $U_1 \cdots U_T v$ by at most $2T/[\sqrt{s}(2c - T)]$ in the L_2 norm.*

Proof. For each i, let $E_i = \widehat{U_i} - U_i$. By hypothesis, every entry of E_i has magnitude at most $1/cs$; thus, each row or column w of E_i has $\|w\|_2 \leq 1/(c\sqrt{s})$. Then

$$\widehat{U_1} \cdots \widehat{U_T} v = (U_1 + E_1) \cdots (U_T + E_T) v.$$

The right-hand side, when expanded, has 2^T terms. Any term containing k matrices E_i has L_2 norm at most $s^{-1/2} c^{-k}$ and can therefore add at most $c^{-k}/\sqrt{s}$ to the discrepancy with $U_1 \cdots U_T v$. Thus the total discrepancy is at most

$$s^{-1/2} \sum_{k=1}^{T} \binom{T}{k} (1/c)^k < s^{-1/2} (e^{T/c} - 1).$$

Since $d \ln t / dt$ evaluated at $t = 2c$ is $1/2c$ and since $\ln t$ is concave,

$$\ln(2c + T) - \ln(2c - T) \geq 2T/2c = T/c$$

when $T < 2c$. Therefore $e^{T/c} \leq (2c + T)/(2c - T)$, and the discrepancy is at most $2T/[\sqrt{s}(2c - T)]$ in the L_2 norm. □

Applying Lemmas 7.2, 7.3, and 7.4, we now prove the main theorem.

THEOREM 7.5. *There exists an approximation algorithm for $\mathrm{SQ}_{2,m}(f)$ taking time $2^{O(4^m mn)}$, with approximation ratio $\sqrt{22}/3 + \epsilon$.*

Proof. Given f, we want, subject to the following two constraints, to find an algorithm Γ that approximates f with a minimum number of queries. First, Γ uses at most m qubits, meaning that $s = 2^m$ and the relevant matrices are $2^m \times 2^m$. Second, the correctness probability of Γ is known to a constant accuracy $\pm\varepsilon$. Certainly the number T of queries never needs to be more than n, for, although each quantum algorithm is space-bounded, the *composite* algorithm need not be. Let λ be the $L_{\max}$ error we can tolerate in the matrices, and let Δ be the resultant L_2 error in the final states. Setting $c = 1/(\lambda 2^m)$, by Lemma 7.4 we have

$$\Delta \leq 2n/[2^{m/2}(2^{1-m}/\lambda - n)].$$

From the Cauchy–Schwarz inequality, one can show that $\varepsilon \leq 2\Delta$. Then solving for $1/\lambda$, $1/\lambda \leq 2^{m/2} n(2/\varepsilon + 1)$, which, since ε is constant, is $O(2^{m/2} n)$. Solving for c, we can verify that $c > T/2$, as required by Lemma 7.4. If we generate almost-unitary matrices, they need to be within λ of actual unitary matrices. By Lemma 7.2 we can use $\lambda/(4.91\sqrt{s})$-almost-unitary matrices. Finally we need to ensure that we approximate every unitary matrix. Let δ be the needed precision. Invoking Lemma 7.3, we set $\lambda/(4.91\sqrt{s}) \geq 2\delta\sqrt{s} + \delta^2 s$ and obtain that

$$\delta \leq \max[\lambda/(9.82s), \lambda^{1/2}/(2.22 s^{3/4})]$$

is sufficient.

Therefore the number of bits of precision needed per entry, $\log(1/\delta)$, is $O(m)$. We thus need only $O(4^m mn)$ bits to specify Γ, and can search through all possible Γ in time $2^{O(4^m mn)}$. The amount of time needed to evaluate a composite algorithm Γ' is polynomial in m and n and is absorbed into the exponent. The approximation algorithm is this: first let $\varepsilon > 0$ be a constant at most 0.0268, and let $\omega = \frac{22}{9} + \frac{4}{3}\varepsilon - 8\varepsilon^2$. Then find the smallest T such that the maximum probability of correctness over all T-query algorithms Γ' is at least $2/3 - \varepsilon$ (subject to $\pm\varepsilon$ uncertainty), and return $T\sqrt{\omega}$. The algorithm achieves an approximation ratio of $\sqrt{\omega}$, for the following reasons. First, $T \leq \mathrm{SQ}_{2,m}(f)$. Second, $\omega T \geq \mathrm{SQ}_{2,m}(f)$, since by repeating the optimal algorithm Γ^* until it returns the same answer twice (which takes either two or three repetitions), the correctness probability can be boosted above $2/3$. Finally, a simple calculation reveals that Γ^* returns the same answer twice after expected number of invocations ω. ∎

8. Open problems. Implicit in the paper of Ambainis [3] is a novel Boolean function property, which is used to obtain lower bounds on quantum query complexity. To take a special case, given a function f and a set S of inputs, let the "Ambainis density" $\mathrm{AD}_S(f)$ be the minimum, over all $X \in S$, of the number of i such that $X^{(i)} \in S$ and $f(X) \neq f(X^{(i)})$. (Here $X^{(i)}$ denotes X with the ith bit negated.) Then let $\mathrm{AD}(f)$ be the maximum of $\mathrm{AD}_S(f)$ over all S. Ambainis shows that $\mathrm{Q}_2(f) = \Omega(\mathrm{AD}(f))$. How efficient an algorithm can we find for $\mathrm{AD}(f)$? Additionally, Bar-Yossef, Kumar, and Sivakumar [6] have defined "approximate" versions of measures such as block sensitivity. Can we extend the algorithms given in this paper to compute those measures?

Acknowledgments. I thank Rob Pike and Lorenz Huelsbergen for sponsoring the internship during which this work was done and for helpful discussions; Andris Ambainis, Wim van Dam, Michael Saks, Umesh Vazirani, and the anonymous reviewers for their comments; Ronald de Wolf for discussions of space-bounded quantum query complexity; and Peter Bro Miltersen for correspondence.

ON TESTING CONVEXITY AND SUBMODULARITY*

MICHAL PARNAS†, DANA RON‡, AND RONITT RUBINFELD§

Abstract. Convex and submodular functions play an important role in many applications, and in particular in combinatorial optimization. Here we study two special cases: convexity in one dimension and submodularity in two dimensions. The latter type of functions are equivalent to the well-known *Monge matrices*. A matrix $V = \{v_{i,j}\}_{i,j=0}^{i=n_1,j=n_2}$ is called a Monge matrix if for every $0 \le i < i' \le n_1$ and $0 \le j < j' \le n_2$ we have $v_{i,j} + v_{i',j'} \le v_{i,j'} + v_{i',j}$. If inequality holds in the opposite direction, then V is an *inverse Monge* matrix (supermodular function). Many problems, such as the traveling salesperson problem and various transportation problems, can be solved more efficiently if the input is a Monge matrix.

In this work we present testing algorithms for the above properties. A testing algorithm for a predetermined property $\mathcal{P}$ is given query access to an unknown function f and a distance parameter ϵ. The algorithm should accept f with high probability if it has the property $\mathcal{P}$ and reject it with high probability if more than an ϵ-fraction of the function values should be modified so that f obtains the property. Our algorithm for testing whether a 1-dimensional function $f : [n] \to \mathbb{R}$ is convex (concave) has query complexity and running time of $O((\log n)/\epsilon)$. Our algorithm for testing whether an $n_1 \times n_2$ matrix V is a Monge (inverse Monge) matrix has query complexity and running time of $O((\log n_1 \cdot \log n_2)/\epsilon)$.

1. Introduction.

Convex functions and their combinatorial analogues, submodular functions, play an important role in many disciplines and applications, including combinatorial optimization, game theory, probability theory, and electronic trade. Such functions exhibit a rich mathematical structure (see Lovász [Lov83]), which often makes it possible to efficiently find their minimum [GLS81, IFF01, Sch00] and thus leads to efficient algorithms for many important optimization problems. Convex functions over discrete domains are defined as follows.

DEFINITION 1 (convex and concave). *Let f be a function defined over a discrete domain X. The function f is* convex *if for all $x, y \in X$ and for all $0 \le \alpha \le 1$ such that $\alpha x + (1-\alpha)y \in X$, it holds that $f(\alpha x + (1-\alpha)y) \le \alpha f(x) + (1-\alpha)f(y)$. The function f is* concave *if for all $x, y \in X$ and for all $0 \le \alpha \le 1$ such that $\alpha x + (1-\alpha)y \in X$, it holds that $f(\alpha x + (1-\alpha)y) \ge \alpha f(x) + (1-\alpha)f(y)$.*

Submodular functions are defined as follows: Let $\mathcal{I} = I_1 \times I_2 \times \cdots \times I_d$, $d \ge 2$, be a product space where $I_q \subseteq \mathbb{R}$. In particular, we are interested in discrete domains $I_q = \{0, \ldots, n_q\}$. The *join* and *meet* operations are defined for every $x, y \in \mathcal{I}$ as follows:

$$(x_1, \ldots, x_d) \vee (y_1, \ldots, y_d) \stackrel{\text{def}}{=} (\max\{x_1, y_1\}, \ldots, \max\{x_d, y_d\})$$

and

$$(x_1, \ldots, x_d) \wedge (y_1, \ldots, y_d) \stackrel{\text{def}}{=} (\min\{x_1, y_1\}, \ldots, \min\{x_d, y_d\}),$$

respectively.

DEFINITION 2 (submodularity and supermodularity). *A function $f : \mathcal{I} \to \mathbb{R}$ is* submodular *if for every $x, y \in \mathcal{I}$, $f(x \vee y) + f(x \wedge y) \leq f(x) + f(y)$. The function f is* supermodular *if for every $x, y \in \mathcal{I}$, $f(x \vee y) + f(x \wedge y) \geq f(x) + f(y)$.*

Certain subclasses of submodular functions are of particular interest. One such subclass is that of *submodular set* functions, which are defined over binary domains. That is, $I_q = \{0, 1\}$ for every $1 \leq q \leq d$, and so each $x \in \mathcal{I}$ corresponds to a subset of $\{1, \ldots, d\}$. Such functions are used, for example, in the scenario of combinatorial auctions on the Internet (e.g., [dVV00, LLN01]).

Another important subclass is the class of *Monge* functions, which are obtained when the domain is large but the dimension is $d = 2$. Since such functions are 2-dimensional, it is convenient to represent them as 2-dimensional matrices, which are referred to as *Monge matrices*. When the function is a 2-dimensional supermodular function the corresponding matrix is called an *inverse Monge matrix*.

The first problem that was shown to be solvable more efficiently if the underlying cost matrix is a Monge matrix is the classical Hitchcock transportation problem (see Hoffman [Hof63]). Since then it has been shown that many other combinatorial optimization problems can be solved more efficiently in this case (e.g., weighted bipartite matching and NP-hard problems such as the traveling salesperson problem). See [BKR96] for a comprehensive survey on Monge matrices and their applications.

1.1. Testing convexity and submodularity. In this paper we approach the questions of convexity and submodularity from within the framework of property testing [RS96, GGR98]. (For surveys on property testing see [Ron01, Fis01].) Let f be a fixed but unknown function, and let $\mathcal{P}$ be a fixed property of functions (such as the convexity or submodularity of a function). A testing algorithm for the property $\mathcal{P}$ should determine, by querying f, whether f has the property $\mathcal{P}$ or whether it is ϵ-*far* from having the property for a given distance parameter ϵ. By ϵ-*far* we mean that more than an ϵ-fraction of the values of f should be modified so that f obtains the desired property $\mathcal{P}$.

Our results. We present efficient testing algorithms for discrete convexity in one dimension and for Monge matrices. Specifically, we do the following:

- We describe and analyze an algorithm that tests whether a function $f : [n] \to \mathbb{R}$ is convex (concave). The running time of this algorithm is $O(\log n/\epsilon)$.
- We describe and analyze a testing algorithm for Monge and inverse Monge matrices whose running time is $O((\log n_1 \cdot \log n_2)/\epsilon)$ when given an $n_1 \times n_2$ matrix.

  Furthermore, the testing algorithm for inverse Monge matrices can be used to derive a testing algorithm, with the same complexity, for an important subfamily of Monge matrices called *distribution matrices*. A matrix $V = \{v_{i,j}\}$ is said to be a distribution matrix if there exists a nonnegative *density matrix* $D = \{d_{i,j}\}$ such that every entry $v_{i,j}$ in V is of the form $v_{i,j} = \sum_{k \leq i} \sum_{\ell \leq j} d_{k,\ell}$. In other words, the entry $v_{i,j}$ corresponds to the cumulative density of all entries $d_{k,\ell}$ such that $k \leq i$ and $\ell \leq j$.
