BLACK-BOX CONCURRENT ZERO-KNOWLEDGE REQUIRES (ALMOST) LOGARITHMICALLY MANY ROUNDS*

RAN CANETTI†, JOE KILIAN‡, EREZ PETRANK§, AND ALON ROSEN¶

Abstract. We show that any concurrent zero-knowledge protocol for a nontrivial language (i.e., for a language outside $\mathcal{BPP}$), whose security is proven via black-box simulation, must use at least $\tilde{\Omega}(\log n)$ rounds of interaction. This result achieves a substantial improvement over previous lower bounds and is the first bound to rule out the possibility of constant-round concurrent zero-knowledge when proven via black-box simulation. Furthermore, the bound is polynomially related to the number of rounds in the best known concurrent zero-knowledge protocol for languages in $\mathcal{NP}$ (which is established via black-box simulation).

Key words. cryptography, interactive protocols, zero knowledge, concurrent zero knowledge, round complexity, lower bounds

1. Introduction.

Zero-knowledge proof-systems, introduced by Goldwasser, Micali, and Rackoff [21], are efficient interactive proofs that have the remarkable property of yielding nothing beyond the validity of the assertion being proved. The generality of zero-knowledge proofs has been demonstrated by Goldreich, Micali, and Wigderson [19], who showed that every NP-statement can be proved in zero-knowledge provided that one-way functions exist [23, 27]. Since then, zero-knowledge proofs have turned out to be an extremely useful tool in the design of various cryptographic protocols.

The original setting in which zero-knowledge proofs were investigated consisted of a single prover and a verifier that executed only one instance of the protocol at a time. A more realistic setting, especially in the age of the internet, is one that allows the *concurrent* execution of zero-knowledge protocols. In the concurrent setting (see Feige [14] and the more extensive treatment by Dwork, Naor, and Sahai [12]), many protocols (sessions) are executed at the same time, involving many verifiers which may be talking with the same (or many) provers simultaneously. (The so-called parallel composition considered in [18, 15, 17, 6, 4] is merely a special case.) This setting presents the new risk of a coordinated attack in which an adversary controls many verifiers, interleaving the executions of the protocols and choosing verifiers' messages based on other partial executions of the protocol. Since it seems unrealistic (and certainly undesirable) for honest provers to coordinate their actions so that zero-

knowledge is preserved, we must assume that, in each prover-verifier pair, the prover acts independently.

Loosely speaking, a zero-knowledge proof is said to be *concurrent zero-knowledge* if it remains zero-knowledge even when executed in the concurrent setting. Recall that, in order to demonstrate that a certain protocol is zero-knowledge, it is required to demonstrate that the view of every probabilistic polynomial-time adversary interacting with the prover can be simulated by a probabilistic polynomial-time machine (also known as the *simulator*). In the concurrent setting, the verifiers' view may include multiple sessions running at the same time. Furthermore, the verifiers may have control over the scheduling of the messages in these sessions (i.e., the order in which the interleaved execution of these sessions should be conducted). As a consequence, the simulator's task in the concurrent setting becomes considerably more complicated. In particular, standard techniques, based on "rewinding the adversary," run into trouble.

1.1. Previous work. Constructing a "round-efficient" concurrent zero-knowledge protocol for all languages in $\mathcal{NP}$ or even nontrivial languages (outside of $\mathcal{BPP}$) seems to be a challenging task. Intuition on the difficulty of this problem is given in [12], where it was argued that, for a specific 4-round zero-knowledge protocol and a specific recursive scheduling of n sessions, the straightforward adaptation of the simulator to the concurrent setting requires time exponential in n. The first lower bound demonstrating the difficulty of concurrent zero-knowledge was given by Kilian, Petrank, and Rackoff [26], who showed, building on the techniques of Goldreich and Krawczyk [18], that, for every language outside $\mathcal{BPP}$, there is no 4-round protocol whose concurrent execution is simulatable in polynomial time by a *black-box simulator*. (A black-box simulator is a simulator that has only black-box access to the adversarial verifier. Essentially all previously known proofs of security of zero-knowledge protocols use black-box simulators. An exception is the protocol of [22], which uses a nonstandard assumption of a "non black-box" nature.) This lower bound was later improved by Rosen to seven rounds [29].

Indeed, even ignoring issues of round efficiency, it was not clear whether there exists a concurrent zero-knowledge protocol for nontrivial languages without modifying the underlying model. Richardson and Kilian [28] exhibited a family of concurrent zero-knowledge protocols (parameterized by the number of rounds) for all languages in $\mathcal{NP}$. Their original analysis showed how to simulate in polynomial time $n^{O(1)}$ concurrent sessions only when the number of rounds in the protocol is at least n^{ϵ} (for some arbitrary $\epsilon > 0$). This result has recently been substantially improved by Kilian and Petrank [25], who show that the Richardson–Kilian protocol remains concurrent zero-knowledge even if it has $O(g(n) \cdot \log^2 n)$ rounds, where $g(\cdot)$ is any nonconstant function (e.g., $g(n) = \log \log n$).

We note that previously there was a considerable gap between the known upper and lower bounds on the round complexity of concurrent zero-knowledge (i.e., [25, 29]): the best known protocol has $\tilde{O}(\log^2 n)$ rounds, whereas the lower bound necessitates 7 rounds (via black-box simulation).[1] In particular, the question consisting of whether constant-round concurrent zero-knowledge protocols exist has been open.

1.2. Our result. We substantially narrow the above gap by presenting a lower bound on the number of rounds required by concurrent zero-knowledge. We show that,

[1] $f(n) = \tilde{O}(h(n))$ if there exist constants $c_1, c_2 > 0$ so that, for all sufficiently large n, $f(n) \leq c_1 \cdot (\log h(n))^{c_2} \cdot h(n)$.

in the context of black-box concurrent zero-knowledge, $\tilde{\Omega}(\log n)$ rounds of interaction are essential for nontrivial proof-systems.[2] This bound is the first to rule out the possibility of constant-round concurrent zero-knowledge, when proven via black-box simulation. Furthermore, the bound is polynomially related to the number of rounds in the best-known concurrent zero-knowledge protocol for languages outside $\mathcal{BPP}$ [25]. Our main result is stated in the following theorem.

THEOREM 1.1. *Let $r : N \to N$ be a function so that $r(n) = o(\frac{\log n}{\log \log n})$. Suppose that $\langle P, V \rangle$ is an $r(\cdot)$-round proof-system for a language L (i.e., on input x, the number of messages exchanged is at most $r(|x|)$) and that concurrent executions of P can be simulated in polynomial time using black-box simulation. Then $L \in \mathcal{BPP}$. The theorem holds even if the proof-system is only computationally sound (with negligible soundness error) and the simulation is only computationally indistinguishable (from the actual executions).*

1.3. Techniques. The proof of Theorem 1.1 builds on the works of Goldreich and Krawczyk [18], Kilian, Petrank, and Rackoff [26], and Rosen [29]. On a very high level, the proof proceeds by constructing a specific concurrent schedule of sessions and demonstrating that a black-box simulator cannot successfully generate a simulated accepting transcript for this schedule unless it "rewinds" the verifier *many times.* The work spent on these rewindings will be superpolynomial unless the number of rounds used by the protocol obeys the bound, or $L \in \mathcal{BPP}$. While the general outline of the proof remains roughly the same as in [18, 26, 29], the actual schedule of sessions and its analysis are new. One main idea that, together with other ideas, enables the proof of the bound is to have the verifier *abort* sessions depending on the history of the interaction. A more detailed outline, presenting both the general structure and the new ideas in the proof, appears in section 3.

Remark. The concurrent schedule in our proof is fixed and known to everybody. As a consequence, Theorem 1.1 is actually stronger than stated. It will hold even if the simulator knows the schedule in advance (in particular, it knows the number of concurrent sessions) and even if the schedule of the messages does not change dynamically (as a function of the history of the interaction).

1.4. Conclusions and open problems.

1.4.1. Alternative models. The lower bound presented here draws severe limitations on the ability of black-box simulators to cope with the standard concurrent zero-knowledge setting and provides motivation to consider relaxations of and augmentations to the standard model. Indeed, several works have managed to "bypass" the difficulty in constructing concurrent zero-knowledge protocols by modifying the standard model in a number of ways. Dwork, Naor, and Sahai augment the communication model with assumptions on the maximum delay of messages and skews of local clocks of parties [12, 13]. Damgård uses a common random string [11], and Canetti et al. use a public registry file [7].

A different approach would be to try to achieve security properties that are weaker than zero-knowledge but are still useful. For example, Feige and Shamir consider the notion of *witness indistinguishability* [14, 15], which is preserved under concurrent composition.

[2] $f(n) = \tilde{\Omega}(h(n))$ if there exist constants $c_1, c_2 > 0$ so that, for all sufficiently large n, $f(n) \geq c_1 \cdot h(n)/(\log h(n))^{c_2}$.

1.4.2. Alternative simulation techniques. Loosely speaking, the only advantage that a black-box simulator may have over the honest prover is the ability to "rewind" the interaction and explore different execution paths before proceeding with the simulation (as its access to the verifier's strategy is restricted to the examination of input/output behavior). As we show in our proof, such a mode of operation (i.e., the necessity to rewind every session) is a major contributor to the hardness of simulating many concurrent sessions. It is thus natural to think that a simulator that deviates from this paradigm (i.e., is non black-box in the sense that it does not have to rewind the adversary in order to obtain a faithful simulation of the conversation) would essentially bypass the main problem that arises while trying to simulate many concurrent sessions.

Hada and Tanaka [22] have considered some weaker variants of zero-knowledge and have exhibited a three-round protocol for $\mathcal{NP}$ (whereas only $\mathcal{BPP}$ has three-round black-box zero-knowledge [18]). Their protocol was an example for a zero-knowledge protocol not proven secure via black-box simulation. Alas, their analysis was based in an essential way on a strong and highly nonstandard hardness assumption.

In a recent breakthrough result, Barak [2] constructs a constant-round protocol for all languages in $\mathcal{NP}$ whose zero-knowledge property is proved using a *non black-box* simulator. Such a method of simulation enables him to bypass our impossiblity result (as well as [18, 26, 29]) and to perform cryptographic tasks otherwise considered unachievable. In particular, for every (predetermined) polynomial $p(\cdot)$, there exists a version of Barak's protocol that preserves its zero-knowledge property even when it is executed $p(n)$ times concurrently (where n denotes the size of the common input). As we show in our work, this task is unachievable via black-box simulation (unless $\mathcal{NP} \subseteq \mathcal{BPP}$).

1.4.3. Open problems. At first glance, it seems that Barak's protocol completely resolves the question of whether constant-round concurrent zero-knowledge protocols exist. Taking a closer look, however, one notices that the (polynomial) number of concurrent sessions relative to which the protocol should be secure is determined *before* the protocol is specified. Moreover, it turns out that the messages in the protocol are required to be longer than the number of concurrent sessions. Thus, from both a theoretical and a practical point of view, Barak's protocol is still not satisfactory. What we would like to have is a *single* protocol that preserves its zero-knowledge property even when it is executed concurrently for *any* (not predetermined) polynomial number of times. Such a property is indeed satisfied by the protocols of [28, 25] (alas, these protocols are not constant-round). This leaves open the question of whether constant-round concurrent zero-knowledge protocols indeed exist for all languages in $\mathcal{NP}$.

2. Preliminaries.

2.1. Probabilistic notation. Denote by $x \stackrel{R}{\leftarrow} X$ the process of uniformly choosing an element x in a set X. If $B(\cdot)$ is an event depending on the choice of $x \stackrel{R}{\leftarrow} X$, then $\Pr_{x \leftarrow X}[B(x)]$ (alternatively, $\Pr_x[B(x)]$) denotes the probability that $B(x)$ holds when x is chosen with probability $1/|X|$. Namely,

$$\Pr_{x \leftarrow X}[B(x)] = \sum_x \frac{1}{|X|} \cdot \chi(B(x)),$$

where χ is an indicator function so that $\chi(B) = 1$ if event B holds and equals zero otherwise. This notation extends in the natural way for events $B(\cdot, \ldots, \cdot)$ that depend

on k variables $x_1, x_2, \ldots, x_k$ that are uniformly chosen in k (possibly different) sets $X_1, X_2, \ldots, X_k$. That is, we denote by $\Pr_{x_1,x_2,\ldots,x_k}[B(x_1, x_2, \ldots, x_k)]$ the probability that $B(x_1, x_2, \ldots, x_k)$ holds when $x_1, x_2, \ldots, x_k$ are chosen with probability $1/(|X_1| \cdot |X_2| \cdots |X_k|)$.

2.2. Interactive proofs. We use the standard definitions of interactive proofs (interactive Turing machines) [21, 16] and arguments (also known as *computationally sound* proofs) [5]. Given a pair of interactive Turing machines, P and V, we denote by $\langle P, V\rangle(x)$ the random variable representing the (local) output of V when interacting with machine P on common input x, when the random input to each machine is uniformly and independently chosen. We consider interactive proof-systems in which the soundness error is negligible. The term *negligible* is used for denoting functions that are (asymptotically) smaller than one over any polynomial. More precisely, a function $\nu(\cdot)$ from nonnegative integers to reals is called *negligible* if, for every constant $c > 0$ and all sufficiently large n, it holds that $\nu(n) < n^{-c}$.

DEFINITION 2.1 (interactive proof-system). *A pair of interactive machines $\langle P, V\rangle$ is called an* interactive proof-system *for a language L if machine V is polynomial-time and the following two conditions hold with respect to some negligible function $\nu(\cdot)$:*

- Completeness. *For every $x \in L$,*

$$\Pr[\langle P, V\rangle(x) = 1] \geq 1 - \nu(|x|).$$

- Soundness. *For every $x \notin L$ and every interactive machine B,*

$$\Pr[\langle B, V\rangle(x) = 1] \leq \nu(|x|).$$

Definition 2.1 can be relaxed to require only the soundness error that is bounded away from $1 - \nu(|x|)$. This is so since the soundness error can always be made negligible by sufficiently many parallel repetitions of the protocol (as such may occur anyhow in the concurrent model). However, we do not know whether this condition can be relaxed in the case of computationally sound proofs (i.e., when the soundness condition is required to hold only for machines B that are implementable by polysize circuits). In particular, in this case, parallel repetitions do not necessarily reduce the soundness error (cf. [3]).

2.3. Concurrent zero-knowledge. Let $\langle P, V\rangle$ be an interactive proof for a language L, and consider a *concurrent adversary* (verifier) V^* that, given input $x \in L$, interacts with an unbounded number of independent copies of P (all on common input x). The concurrent adversary V^* is allowed to interact with the various copies of P concurrently, without any restrictions over the scheduling of the messages in the different interactions with P. (In particular, V^* has control over the scheduling of the messages in these interactions.) The *transcript* of a concurrent interaction consists of the common input x followed by the sequence of prover and verifier messages exchanged during the interaction. We denote by $\text{view}^P_{V^*}(x)$ a random variable describing the content of the random tape of V^* and the transcript of the concurrent interaction between P and V^* (that is, all messages that V^* sends and receives during the concurrent interactions with P, on common input x).

Remark. The actual definition of concurrent zero-knowledge requires that the concurrent adversary V^* explicitly specifies to which session the next scheduled message belongs. However, in the proof of Theorem 1.1, we consider a "weaker" concurrent

adversary V^* that is running only a fixed scheduling of sessions (and so does not determine the schedule dynamically). In particular, there will be no need to use a formalism for specifying to which session the next scheduled message belongs.

DEFINITION 2.2 (concurrent zero-knowledge). *Let $\langle P, V\rangle$ be an interactive proof-system for a language L. We say that $\langle P, V\rangle$ is* concurrent zero-knowledge *if, for every polynomial-time concurrent adversary V^*, there exists a probabilistic polynomial-time algorithm S_{V^*} such that the ensembles $\{\text{view}^P_{V^*}(x)\}_{x\in L}$ and $\{S_{V^*}(x)\}_{x\in L}$ are computationally indistinguishable.*

2.4. Black-box concurrent zero-knowledge. Loosely speaking, the definition of black-box zero-knowledge requires that there exists a "universal" simulator, S, so that, for every $x \in L$ and every probabilistic polynomial-time adversary V^*, the simulator S produces a distribution that is indistinguishable from $\text{view}^P_{V^*}(x)$ while using V^* as an oracle (i.e., in a "black-box" manner). We assume concurrent adversaries V^* are modeled by polysized circuits (capturing nonuniform, deterministic verifiers viewed as an oracle; cf. [18, 16, 26]).

Before we proceed with the formal definition, we will have to overcome a technical difficulty arising from an inherent difference between the concurrent setting and the "stand-alone" setting. In "stand-alone" zero-knowledge, the length of the output of the simulator depends only on the protocol and the size of the common input x. It is thus reasonable to require that the simulator run in time that depends only on the size of x, regardless of the running time of its black-box. However, in black-box concurrent zero-knowledge, the output of the simulator is an entire schedule, and its length depends on the running time of the concurrent adversary. Therefore, if we naively require that the running time of the simulator be a fixed polynomial in the size of x, then we end up with an unsatisfiable definition. (As for any simulator S, there is an adversary V^* that generates a transcript that is longer than the running time of S.)

One way to solve the above problem is to have for *each* fixed polynomial $q(\cdot)$ a simulator S_q that simulates "only" all $q(\cdot)$-sized circuits V^*. Clearly, the running time of the simulator now depends on the running time of V^* (which is an upper bound on the size of the schedule), and the above problem does not occur anymore. Another (more restrictive) way to overcome the above problem would be to consider a simulator S_q that simulates "only" all adversaries V^* which run at most $q(|x|)$ sessions during their execution. (We stress that $q(\cdot)$ is chosen *after* the protocol is determined.) Such simulators should run in worst-case time that is a fixed polynomial in $q(|x|)$ and in the size of the common input x. (Note that by letting S_q "know" $q(\cdot)$ in advance, we actually *strengthen* the lower bound.) In what follows, we choose to adopt the latter formalization. We stress that both formalizations are general enough to include all *known* black-box zero-knowledge proofs.

DEFINITION 2.3 (black-box concurrent zero-knowledge). *Let $\langle P, V\rangle$ be an interactive proof-system for a language L. We say that $\langle P, V\rangle$ is black-box concurrent zero-knowledge if, for every polynomial $q(\cdot)$, there exists a probabilistic polynomial-time[3] algorithm S_q so that, for every concurrent adversary circuit V^* that runs at most $q(|x|)$ concurrent sessions, $S_q(x)$ runs in time polynomial in $q(|x|)$ and $|x|$ and satisfies that the ensembles $\{\text{view}^P_{V^*}(x)\}_{x\in L}$ and $\{S_q(x)\}_{x\in L}$ are computationally indistinguishable.*

[3]See below for a discussion on expected versus strict probabilistic polynomial time.

2.5. Additional conventions.

Deviation gap and expected polynomial-time simulators. The *deviation gap* of a simulator S for a proof-system $\langle P, V \rangle$ is defined, somewhat informally, as follows. Consider a distinguisher D that is required to decide whether its input consists of $\text{view}^P_{V^*}(x)$ or the transcript that was produced by S. The deviation gap of D is the difference between the probability that D outputs 1 given an output of S and the probability that D outputs 1 given $\text{view}^P_{V^*}(x)$. The deviation gap of S is the deviation gap of the best polynomial-time distinguisher D. In our definitions of concurrent zero-knowledge (Definitions 2.2 and 2.3), the deviation gap of the simulator is required to be negligible in $|x|$.

For our lower bound, we allow simulators that run in strict (worst-case) polynomial time and have a deviation gap of at most 1/4. As for expected polynomial-time simulators, one can use a standard argument to show that any simulator running in expected polynomial time and having a deviation gap of at most 1/8 can be transformed into a simulator that runs in strict (worst-case) polynomial time and has a deviation gap of at most 1/4. In particular, our lower bound (on simulators that run in strict polynomial time and have a deviation gap of at most 1/4) extends to a lower bound on simulators running in expected polynomial time (and having a deviation gap of as large as 1/8).

Query conventions. By k-round protocols, we mean protocols in which $2k + 2$ messages are exchanged subject to the following conventions. The first message is a fixed initiation message by the verifier, denoted by $\mathtt{v}_1$, which is answered by the prover's first message, denoted by $\mathtt{p}_1$. The following verifier and prover messages are denoted by $\mathtt{v}_2, \mathtt{p}_2, \ldots, \mathtt{v}_{k+1}, \mathtt{p}_{k+1}$, where $\mathtt{v}_{k+1}$ is an `ACCEPT/REJECT` message indicating whether the verifier has accepted its input, and the last message (i.e., $\mathtt{p}_{k+1}$) is a fixed acknowledgment message sent by the prover.[4] Clearly, any protocol in which $2k$ messages are exchanged can be modified to fit this form (by adding at most two messages).

We impose the following technical restrictions on the simulator (but claim that each of these restrictions can be easily satisfied): As in [18], the queries of the simulator are prefixes of possible execution transcripts (in the concurrent setting).[5] Such a prefix is a sequence of alternating prover and verifier messages (which may belong to different sessions as determined by the fixed schedule) that ends with a prover message. The answer to the queries made by the simulator consists of a single verifier message (which belongs to the next scheduled session). We assume that the simulator never repeats the same query twice. In addition, we assume that, before making a query $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$, where the a's are prover messages, the simulator has made queries to all relevant prefixes (i.e., $(b_1, a_1, \ldots, b_i, a_i)$ for every $i < t$) and has obtained the b_i's as answers. Finally, we assume that, before producing output $(b_1, a_1, \ldots, b_T, a_T)$, the simulator makes the query $(b_1, a_1, \ldots, b_T, a_T)$.

3. Proof outline. This section contains an outline of the proof of Theorem 1.1. The actual proof will be given in sections 4 and 5. To facilitate reading, we partition the outline into two parts: The first part reviews the general framework. (This part mainly follows previous works, namely, [17, 26, 29].) The second part concentrates on the actual schedule and the specifics of our lower bound argument.

[4] The $\mathtt{p}_{k+1}$ message is an artificial message included in order to "streamline" the description of the adversarial schedule. (The schedule will be defined in section 4.1.1.)

[5] For the sake of simplicity, we choose to omit the input x from the transcript's representation (as it is implicit in the description of the verifier anyway).

3.1. The high-level framework. Consider a k-round concurrent zero knowledge proof-system $\langle P, V\rangle$ for language L, and let S be a black-box simulator for $\langle P, V\rangle$. We use S to construct a $\mathcal{BPP}$ decision procedure for L. For this purpose, we construct a family $\{V_h\}$ of "cheating verifiers." To decide on an input x, run S with a cheating verifier V_h that was chosen at random from the constructed family, and decide that $x \in L$ iff S outputs an accepting transcript of V_h.

The general structure of the family $\{V_h\}$ is roughly as follows. A member V_h in the family is identified via a hash function h taken from a hash-function family H having "much randomness" (or high independence). Specifically, the independence of H will be larger than the running time of S. This guarantees that, for our purposes, a function drawn randomly from H behaves like a random function. We define some fixed concurrent schedule of a number of sessions between V_h and the prover. In each session, V_h runs the code of the honest verifier V on input x and random input $h(a)$, where a is the current history of the (*multisession*) interaction at the point where the session starts. V_h accepts if all of the copies of V accept.

The proof of validity of the decision procedure is structured as follows. Say that S *succeeds* if it outputs an accepting transcript of V_h. It is first claimed that, if $x \in L$, then a valid simulator S must succeed with high probability. Roughly speaking, this is so because each session behaves like the original proof-system $\langle P, V\rangle$, and $\langle P, V\rangle$ accepts x with high probability, demonstrating that the simulator almost never succeeds when $x \notin L$ is much more involved. Given S, we construct a "cheating prover" P^* that makes the honest verifier V accept x with probability that is polynomially related to the success probability of S. The soundness of $\langle P, V\rangle$ now implies that, in this case, S succeeds only with negligible probability. See the details below.

3.1.1. Session-prefixes and useful session-prefixes. In order to complete the high-level description of the proof, we must first define the following notions that play a central role in the analysis. Consider the conversation between V_h and a prover. A *session-prefix* a is a prefix of this conversation that ends at the point where some new session starts (including the first verifier message in that session). (Recall that V's random input for that new session is set to $h(a)$.) Next, consider the conversation between S and V_h in some run of S. (Such a conversation may contain many interleaved and incomplete conversations of V_h with a prover.) Roughly speaking, a message sent by S to the simulated V_h is said to have a session-prefix a if it relates to the session where the verifier randomness is $h(a)$. A session-prefix a is called *useful* in a run of S if the following hold.

1. It was accepted (i.e., V_h sent an `ACCEPT` message for session-prefix a).
2. V_h has sent exactly $k+1$ messages for session-prefix a.

Loosely speaking, condition 2 implies that S did not rewind the relevant session-prefix, where "rewind session-prefix a" is an informal term meaning that S rewinds V_h to a point where V_h provides a second continuation for session-prefix a. By rewinding session-prefix a, the simulator is able to obtain more than $k+1$ verifier messages for session-prefix a. This is in contrast to an actual execution of the protocol $\langle P, V\rangle$, in which V sends exactly $k+1$ messages.

3.1.2. The construction of the cheating prover. Using the above terms, we sketch the construction of the cheating prover P^*. It first randomly chooses a function $h \stackrel{R}{\leftarrow} H$ and an index (of a session-prefix) i. It then emulates an interaction between S and V_h, with the exception that P^* uses the messages sent by S that have the ith session-prefix as the messages that P^* sends to the actual verifier it interacts

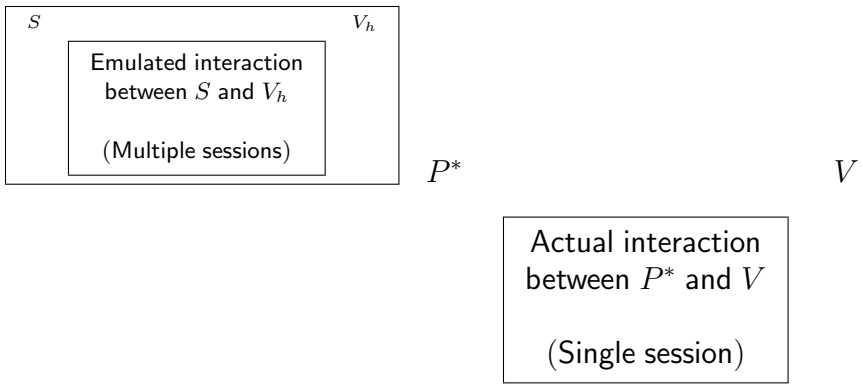

FIG. 3.1. *The above describes the strategy of the cheating prover P^*. The box on the left-hand side represents the (multiple session) emulation of the interaction between S and V_h (executed "internally" by P^*). The box on the right-hand side represents the actual execution of a single session between P^* and V. (Recall that P^* relays some of the actual interaction messages to its internal emulation.)*

with; similarly, it uses the messages received from the actual verifier V instead of V_h's messages in the ith session-prefix. The strategy of the cheating prover is depicted in Figure 3.1.

3.1.3. The success probability of the cheating prover. We next claim that, if the session-prefix chosen by P^* is useful, then $\langle P^*, V\rangle(x)$ accepts. The key point is that, whenever P^* chooses a useful session-prefix, the following two conditions (corresponding to the two conditions in the definition of a useful session-prefix) are satisfied:

1. The session corresponding to the ith session-prefix is accepted by V_h (and so by V).
2. P^* manages to reach the end of the $\langle P^*, V\rangle$ interaction without "getting into trouble."[6]

Loosely speaking, item 1 is implied by condition 1 in the definition of a useful session-prefix. As for item 2, this just follows from the fact that S does not rewind the ith session-prefix (as implied by condition 2 in the definition of a useful session-prefix). In particular, P^* (playing the role of V_h) will not have to send the jth verifier message with the ith session-prefix more than once to S (since the number of messages sent by V_h for that session-prefix is exactly $k+1$).

Since the number of session-prefixes in an execution of S is bounded by a polynomial, it follows that, if the conversation between S and V_h contains a useful session-prefix with nonnegligible probability, then $\langle P^*, V\rangle(x)$ accepts with nonnegligible probability.

3.2. The schedule and additional ideas. Using the above framework, the crux of the lower bound is to come up with a schedule and V_h's that allow us to demonstrate that, whenever S succeeds, the conversation between S and V_h contains

[6]The problem is that P^* does not know V's random coins, and so it cannot compute the verifier's answers by himself. Thus, whenever P^* is required in the emulation to send the jth verifier message in the protocol more than once to S, it might get into trouble (since it gets the jth verifier message only once from V).

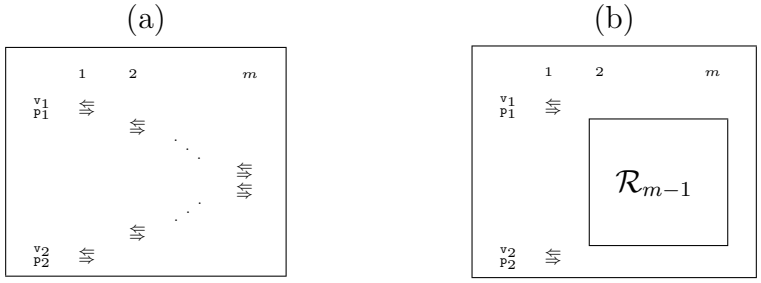

FIG. 3.2. *The "telescopic" schedule used by* [26] *to demonstrate the impossibility of black-box concurrent zero-knowledge in* 2 *rounds. a useful session-prefix. (As we have argued above, it is in fact sufficient that the conversation between S and V_h contains a useful session-prefix with nonnegligible probability.) This is done next.

3.2.1. The 2-round case. Our starting point is the schedule used in [26] to demonstrate the impossibility of black-box concurrent zero-knowledge with protocols in which 4 messages are exchanged (i.e., $\mathtt{v}_1, \mathtt{p}_1, \mathtt{v}_2, \mathtt{p}_2$). The schedule is recursive and consists of n concurrent sessions. (n is polynomially related to the security parameter.) Given parameter $m \leq n$, the scheduling on m sessions (denoted $\mathcal{R}_m$) proceeds as follows (see Figure 3.2 for a graphical description):

1. If $m = 1$, the relevant session exchanges all of its messages (i.e., $\mathtt{v}_1, \mathtt{p}_1, \mathtt{v}_2, \mathtt{p}_2$).
2. Otherwise (i.e., if $m > 1$):
   Initial message exchange. The first session (out of m sessions) exchanges 2 messages (i.e., messages $\mathtt{v}_1, \mathtt{p}_1$);
   Recursive call. The schedule is applied recursively on the remaining $m - 1$ sessions;
   Final message exchange. The first session (out of m sessions) exchanges 2 messages (i.e., messages $\mathtt{v}_2, \mathtt{p}_2$).

At the end of each session, V_h continues in the interaction iff the transcript of the session that has just terminated would have been accepted by the prescribed verifier V. This means that, in order to proceed beyond the ending point of the ℓth session, the simulator must make the honest verifier accept the sth session for all $s > \ell$.

Suppose now that S succeeds in simulating the above V_h, but the conversation between S and V_h does not contain a useful session-prefix. Since V_h proceeds beyond the ending point of a session only if this session is accepted, then the only reason for which the corresponding session-prefix can be nonuseful is because S has rewound that session-prefix. In other words, a session-prefix becomes nonuseful iff S resends the first prover message in the protocol (i.e., $\mathtt{p}_1$).[7] This should cause V_h to resend the second verifier message (i.e., $\mathtt{v}_2$), thus violating condition 2 in the definition of a useful session-prefix (see section 3.1.1).

[7]Notice that the first prover message in the protocol (i.e., $\mathtt{p}_1$) is the only place in which rewinding the interaction may cause a session-prefix to be nonuseful. The reason for this is that the first verifier message in the protocol (i.e., $\mathtt{v}_1$) is part of the session-prefix. Rewinding past this message (i.e., $\mathtt{v}_1$) would modify the session-prefix itself. As for $\mathtt{p}_2$, it is clear that rewinding this message would not cause any change in verifier messages that correspond to the relevant session-prefix (since $\mathtt{v}_1$ and $\mathtt{v}_2$ occur before $\mathtt{p}_2$ anyway).

The key observation is that, whenever the first prover message in the ℓth session is modified, so is the session-prefix of the sth session for *all* $s > \ell$. Thus, whenever S resends the first prover message in the ℓth session, it must do so also in the sth session for all $s > \ell$ (since otherwise the "fresh" session-prefix of the sth session that is induced by resending the above message will be useful). However, this means that the work $W(m)$, invested in the simulation of a schedule with m levels, must satisfy $W(m) \geq 2 \cdot W(m-1)$ for all m. Thus either the conversation between V_h and S contains a useful session-prefix (in which case we are done), or the simulation requires exponential time (since $W(m) \geq 2 \cdot W(m-1)$ solves to $W(n) \geq 2^{n-1}$).

3.2.2. The *k*-round case—first attempt. The case of k rounds may proceed as follows. Given the parameter $m \leq n$ (denoting the number of sessions in $\mathcal{R}_m$), do:

1. If $m = 1$, the relevant session exchanges all of its messages (i.e., messages $\mathtt{v}_1, \mathtt{p}_1, \ldots, \mathtt{v}_{k+1}, \mathtt{p}_{k+1}$).
2. Otherwise, for $j = 1, \ldots, k+1$:
   Message exchange. The first session (out of m sessions) exchanges two messages (i.e., $\mathtt{v}_j, \mathtt{p}_j$);
   Recursive call. If $j < k+1$, the scheduling is applied recursively on $\lfloor \frac{m-1}{k} \rfloor$ new sessions.
   (This is done using the next $\lfloor \frac{m-1}{k} \rfloor$ remaining sessions out of $2, \ldots, m$.)

As before, at the end of each session, V_h continues in the interaction iff the transcript of the session that has just terminated would have been accepted by the prescribed verifier V. The schedule is depicted in Figure 3.3.

The crucial problem of the above schedule is that one can come up with a k-round protocol and a corresponding simulator that manages to successfully simulate V_h *and*

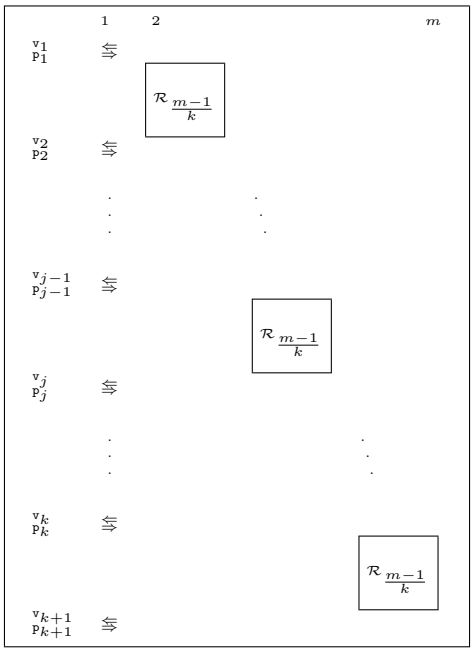

FIG. 3.3. *First attempt to generalize the recursive schedule ($\mathcal{R}_m$ with m sessions) for k-round protocols. Columns correspond to m individual sessions, and rows correspond to the time progression.*

cause all session-prefixes in its conversation with V_h to be nonuseful. Specifically, there exist protocols (cf. [28]) in which the simulator is required to successfully rewind an honestly behaving verifier exactly once for every session. Whereas, in the case of 2 rounds, this could have had devastating consequences (since, in the case of the previous schedule, it would have implied $W(m) \geq (k+1) \cdot W(m-1) = 2 \cdot W(m-1)$, which solves to $W(n) \geq 2^{n-1}$) in the general case (i.e., when $k+1 > 2$) when any rewinding of the schedule that we have suggested would have forced the simulator to reinvest simulation "work" only for $\frac{m-1}{k}$ sessions. Note that such a simulator satisfies $W(m) = (k+1) \cdot W(\frac{m-1}{k})$, which solves to $k^{O(\log_k n)} = n^{O(1)}$. In particular, by investing a polynomial amount of work, the simulator is able to make all session-prefixes not useful while successfully simulating all sessions.

3.2.3. The *k*-round case—second attempt. One method of circumventing this difficulty was used in [29]. However, that method extends the lower bound only up to 3 rounds (more precisely, 7 messages). Here we use a different method. What we do is let the cheating verifier abort (i.e., refuse to answer) every message in the schedule with some predetermined probability (independently of other messages). To do this, we first add another, binary hash function, g, to the specification of V_h. This hash function is taken from a family G with sufficient independence so that it looks like a random binary function. Now, before generating the next message in some session, $V_{g,h}$ first applies g to some predetermined part of the conversation so far. If g returns 0, then $V_{g,h}$ aborts the session by sending an `ABORT` message. If g returns 1, then $V_{g,h}$ is run as usual.

The rationale behind the use of aborts can be explained as follows. Recall that a session-prefix a stops being useful only when $V_{g,h}$ sends more than k messages whose session-prefix is a. This means that a stops being useful only if S rewinds the session-prefix a *and, in addition,* g returns 1 in at least two of the continuations of a. This means that S is expected to rewind session-prefix a several times before it stops being useful. Since each rewinding of a involves extra work of S on higher-level sessions, this may force S to invest considerably more work before a session stops being useful.

A bit more specifically, let p denote the probability, taken over the choice of g, that g returns 1 on a given input. In each attempt, the session is not aborted with probability p. Thus S is expected to rewind a session prefix $1/p$ times before it becomes nonuseful. This gives us hope that, in order to make sure that no session-prefix is useful, S must do work that satisfies a condition of the following sort:

$$W(m) \geq \Omega(1/p) \cdot W\left(\tfrac{m-1}{k}\right). \tag{3.1}$$

This would mean that the work required to successfully simulate n sessions *and* make all session-prefixes nonuseful is at least $\Omega(p^{-\log_k n})$. Consequently, when the expression $p^{-\log_k n}$ is superpolynomial, there is hope that the conversation between S and V_h contains a useful session-prefix with nonnegligible probability.

3.2.4. The *k*-round case—final version. However, demonstrating (3.1) brings up the following difficulty. Once the verifier starts aborting sessions, the probability that a session is ever completed may become too small. As a consequence, it is not clear anymore that the simulator must invest simulation "work" for all sessions in the schedule. It may very well be the case that the simulator will go about the simulation task while "avoiding" part of the simulation "work" in some recursive invocations (as some of these invocations may be aborted anyway during the simulation). In other

words, there is no guarantee that the recursive "work" invested by the simulator behaves like (3.1).[8]

To overcome this problem, we replace each session in the above schedule with a "block" of, say, n sessions (see Figure 4.1). We now have n^2 sessions in a schedule. (This choice of parameters is arbitrary and is made for convenience of presentation.) The modified $V_{g,h}$ accepts a block of n sessions if at least $1/2$ of the nonaborted sessions in this block were accepted and not too many of the sessions in this block were aborted. Once a block is rejected, $V_{g,h}$ halts. At the end of the execution, $V_{g,h}$ accepts if all blocks were accepted. The above modification guarantees that, with a careful setting of the parameters, the simulator's recursive "work" must satisfy (3.1) at least with overwhelming probability.

3.2.5. Setting the value of p. It now remains to set the value of p so that the simuatior's work behaves as in (3.1). Clearly, the smaller p is chosen to be, the larger $p^{-\log_k n}$ is. However, p cannot be too small, or else the probability that a session will ever be completed will be too small, and condition 1 in the definition of a useful session-prefix (section 3.1.1) will not be satisfied. Specifically, a k-round protocol is completed with probability p^k. We thus have to make sure that p^k is not negligible (and, furthermore, that $p^k \cdot n \gg 1$).

In the proof, we set $p = n^{-1/2k}$. This will guarantee that a session is completed with probability $p^k = n^{-1/2}$. (Thus condition 1 will hopefully be satisfied.) Furthermore, since $p^{-\log_k n}$ is superpolynomial whenever $k = o(\log n/\log\log n)$, there is hope that condition 2 in the definition of a useful session-prefix (section 3.1.1) will be satisfied for $k = o(\log n/\log\log n)$.

3.3. The actual analysis. Demonstrating that there exist many accepted session-prefixes is straightforward. Demonstrating that one of these session-prefixes is useful requires arguing on the dependency between the expected work done by the simulator and its success probability. This is a tricky business since the choices made by the simulator (and, in particular, the amount of effort spent on making each session nonuseful) may depend on past events.

We go about this task by pinpointing a special (combinatorial) property that holds for *any* successful run of the simulator, unless the simulator runs in superpolynomial time (Lemma 5.9). Essentially, this property states that there exists a block of sessions such that none of the session-prefixes in this block were rewound too many times. Using this property, we show (in Lemma 5.7) that the probability (over the choices of $V_{g,h}$ and the simulator) that a run of the simulator contains no useful session-prefix is negligible.

4. The actual proof (of Theorem 1.1). Assuming toward the contradiction that a black-box simulator, denoted S, contradicting Theorem 1.1 exists, we will describe a probabilistic polynomial-time decision procedure for L based on S. The first step toward describing the decision procedure for L involves the construction of an adversarial verifier in the concurrent model. This is done next.

4.1. The concurrent adversarial verifier. The description of the adversarial strategy proceeds in several steps. We start by describing the underlying fixed sched-

[8] To see this, imagine that the value of p is set to some negligible function (in n). In such a case, with overwhelming probability, *all* sessions in the schedule are aborted by $V_{g,h}$. However, this means that the distribution of interactions of P with $V_{g,h}$ can be easily simulated by a simulator that "does nothing." All that it has to do in order to produce a faithful simulation (at least with overwhelming probability) is output a transcript in which all sessions in the schedule are aborted.

ule of messages. Once the schedule is presented, we describe the adversary's strategy regarding the contents of the verifier messages.

4.1.1. The schedule. For each $x \in \{0,1\}^n$, we consider the following concurrent scheduling of n^2 sessions, all run on common input x.[9] The scheduling is defined recursively, where the scheduling of $m \leq n^2$ sessions (denoted $\mathcal{R}_m$) proceeds as follows:[10]

1. If $m \leq n$, sessions $1, \ldots, m$ are executed sequentially until they are all completed;
2. Otherwise, for $j = 1, \ldots, k+1$:
   Message exchange. Each of the first n sessions exchanges two messages (i.e., $\mathtt{v}_j, \mathtt{p}_j$);
   (These first n sessions out of $\{1, \ldots, m\}$ will be referred to as the *main sessions* of $\mathcal{R}_m$.)
   Recursive call. If $j < k+1$, the scheduling is applied recursively on $\lfloor \frac{m-n}{k} \rfloor$ new sessions.
   (This is done using the next $\lfloor \frac{m-n}{k} \rfloor$ remaining sessions out of $1, \ldots, m$.)

The schedule is depicted in Figure 4.1. We stress that the verifier typically postpones its answer (i.e., $\mathtt{v}_j$) to the last prover's message (i.e., $\mathtt{p}_{j-1}$) until after a recursive subschedule is executed and that, in the jth iteration of step 2, $\lfloor \frac{m-n}{k} \rfloor$ new sessions are initiated (with the exception of the first iteration, in which the first n (main) sessions are initiated as well). The order in which the messages of various sessions are exchanged (in the first part of step 2) is fixed but immaterial. Say that we let the first session proceed, and then the second, and so on. That is, we have the order $\mathtt{v}_j^{(1)}, \mathtt{p}_j^{(1)}, \ldots, \mathtt{v}_j^{(n)}, \mathtt{p}_j^{(n)}$, where $\mathtt{v}_j^{(i)}$ (resp., $\mathtt{p}_j^{(i)}$) denotes the verifier's (resp., prover's) jth message in the ith session.

The set of n sessions that are explicitly executed during the message exchange phase of the recursive invocation (i.e., the main sessions) is called a *recursive block*. (Notice that each recursive block corresponds to exactly one recursive invocation of the schedule.) Taking a closer look at the schedule, we observe that every session in the schedule is explicitly executed in exactly one recursive invocation (that is, belongs to exactly one recursive block). Since the total number of sessions in the schedule is n^2, and since the message exchange phase in each recursive invocation involves the explicit execution of n sessions (in other words, the size of each recursive block is n), we have that the total number of recursive blocks in the schedule equals n. Since each recursive invocation of the schedule involves the invocation of k additional subschedules, the recursion actually corresponds to a k-ary tree with n nodes. The depth of the recursion is thus $\lfloor \log_k((k-1)n+1) \rfloor$, and the number of "leaves" in the recursion (i.e., subschedules of size at most n) is at least $\lfloor \frac{(k-1)n+1}{k} \rfloor$.

Identifying sessions according to their recursive block. To simplify the exposition of the proof, it will be convenient to associate every session appearing in the schedule with a pair of indices $(\ell, i) \in \{1, \ldots, n\} \times \{1, \ldots, n\}$ rather than with a single index $s \in \{1, \ldots, n^2\}$. The value of $\ell = \ell(s) \in \{1, \ldots, n\}$ will represent the index of the recursive block to which session s belongs (according to some canonical enumeration of the n invocations in the recursive schedule, say, according to the order in which

[9] Recall that each session consists of $2k+2$ messages, where $k \stackrel{\text{def}}{=} k(n) = o(\log n / \log \log n)$.

[10] In general, we may want to define a recursive scheduling for sessions $i_1, \ldots, i_m$ and denote it by $\mathcal{R}_{i_1,\ldots,i_m}$ (see Appendix A for a more formal description of the schedule). We choose to simplify the exposition by renaming these sessions as $1, \ldots, m$, and we denote the scheduling by $\mathcal{R}_m$.

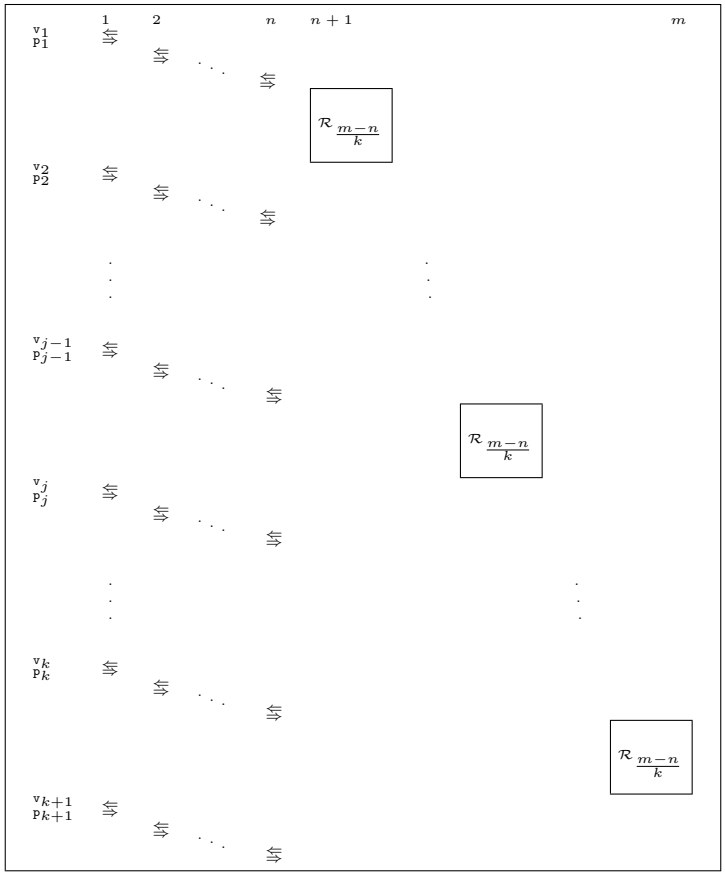

FIG. 4.1. *The recursive schedule $\mathcal{R}_m$ for m sessions. Columns correspond to m individual sessions, and rows correspond to the time progression.*

they are invoked), whereas the value of $i = i(s) \in \{1, \ldots, n\}$ will represent the index of session s within the n sessions that belong to the ℓth recursive block. (In other words, session (ℓ, i) is the ith main session of the ℓth recursive invocation in the schedule.) Typically, when we explicitly refer to messages of session (ℓ, i), the index of the corresponding recursive block (i.e., ℓ) is easily deducible from the context. In such cases, we will sometimes omit the index ℓ from the "natural" notation $\mathtt{v}_j^{(\ell,i)}$ (resp., $\mathtt{p}_j^{(\ell,i)}$) and stick to the notation $\mathtt{v}_j^{(i)}$ (resp., $\mathtt{p}_j^{(i)}$). Note that the values of (ℓ, i) and the session index s are completely interchangeable (in particular, $\ell = s \mathsf{\ div\ } n$ and $i = s \mathsf{\ mod\ } n$).

DEFINITION 4.1 (identifiers of the next message). *The schedule defines a mapping from partial execution transcripts ending with a prover message to the* identifiers of the next verifier message*—that is, the session and round number to which the next verifier message belongs.* (Recall that such partial execution transcripts correspond to queries of a black-box simulator, and so the mapping defines the identifier of the answer.) *For such a query $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$, we denote by $\pi_{\mathrm{sn}}(\overline{q}) = (\ell, i) \in \{1, \ldots, n\} \times \{1, \ldots, n\}$ the session to which the next verifier message belongs and by $\pi_{\mathrm{msg}}(\overline{q}) = j \in \{1, \ldots, k+1\}$ its index within the verifier's messages in this session.*

We stress that the identifiers of the next message are uniquely determined by the

number of messages appearing in the query (and are not affected by the contents of these messages).

4.1.2. Toward constructing an adversarial verifier. Once the identifiers of the next verifier message are deduced from the query's length, one has to specify a strategy according to which the contents of the next verifier message will be determined. Loosely speaking, our adversary verifier has two options: Either it will send the answer that would have been sent by an honest verifier (given the messages in the query that are relevant to the current session), or it will choose to deviate from the honest verifier strategy and abort the interaction in the current session. (This will be done by answering with a special `ABORT` message.) Since, in a nontrivial zero-knowledge proof-system, the honest verifier is always probabilistic (cf. [20]), and since the "abort behavior" of the adversary verifier should be "unpredictable" for the simulator, we have that both options require a source of randomness (either for computing the contents of the honest verifier answer or for deciding whether to abort the conversation). As is already customary in works of this sort [18, 26, 29], we let the source of randomness be a hash function with sufficiently high independence (which is "hard-wired" into the verifier's description), and we consider the execution of a black-box simulator that is given access to such a random verifier. (Recall that the simulator's queries correspond to partial execution transcripts and thus contain the whole history of the interaction so far.)

Determining the randomness for a session. Focusing (first) on the randomness required to compute the honest verifier's answers, we ask what the input of the above hash function should be. A naive solution would be to let the randomness for a session depend on the session's index. That is, to obtain randomness for session $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$, apply the hash function on the value (ℓ, i). This solution will indeed imply that every two sessions have independent randomness (as the hash function will have different inputs). However, the solution seems to fail to capture the difficulty arising in the simulation (of multiple concurrent sessions). What we would like to have is a situation in which, whenever the simulator rewinds a session (that is, feeds the adversary verifier with a different query of the same length), it causes the randomness of some other session (say, one level down in the recursive schedule) to be completely modified. To achieve this, we must cause the randomness of a session to depend also on the history of the entire interaction. Changing even a single message in this history would immediately result in an unrelated instance of the current session and would thus force the simulator to redo the simulation work on this session.

So where in the schedule should the randomness of session (ℓ, i) be determined? On the one hand, we would like to determine the randomness of a session as late as possible (in order to maximize the effect of changes in the history of the interaction on the randomness of the session). On the other hand, we cannot afford to determine the randomness after the session's initiating message is scheduled (since the protocol's specification may require that the verifier's randomness be completely determined before the first verifier message is sent). For technical reasons, the point at which we choose to determine the randomness of session (ℓ, i) is the point at which recursive block number ℓ is invoked. That is, to obtain the randomness of session $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$, we feed the hash function with the prefix of query $\overline{q}$ that ends just before the first message in block number ℓ. (This prefix is called the *block-prefix* of query $\overline{q}$ and is defined below.) In order to achieve independence with other sessions in block number ℓ, we will also feed the hash function with the value of i. This (together with the above choice) guarantees us the following properties: (1) The input to the

hash function (and thus the randomness for session (ℓ, i)) does not change once the interaction in the session begins (that is, once the first verifier message is sent). (2) For every pair of different sessions, the input to the hash function is different (and thus the randomness for each session is independent). (3) Even a single modification in the prefix of the interaction up to the first message in block number ℓ induces fresh randomness for all sessions in block number ℓ.

DEFINITION 4.2 (block-prefix). *The* block-prefix *of a query* $\overline{q}$ *satisfying* $\pi_{\mathrm{sn}}(\overline{q}) = (\ell, i)$ *is the prefix of* $\overline{q}$ *that is answered with the first verifier message of session* $(\ell, 1)$ *(that is, the first main session in block number* ℓ*). More formally,* $bp(\overline{q}) = (b_1, a_1, \ldots, b_\gamma, a_\gamma)$ *is the block-prefix of* $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$ *if* $\pi_{\mathrm{sn}}(bp(\overline{q})) = (\ell, 1)$ *and* $\pi_{\mathrm{msg}}(bp(\overline{q})) = 1$*. The block-prefix will be said to correspond to recursive block number* ℓ*.*[11] (Note that i may be any index in $\{1, \ldots, n\}$ and that a_t need not belong to session (ℓ, i).)

Determining whether and when to abort sessions. Whereas the randomness that is used to compute the honest verifier's answers in each session is determined before a session begins, the randomness that is used in order to decide whether to abort a session is chosen independently every time the execution of the schedule reaches the next verifier message in this session. As before, the required randomness is obtained by applying a hash function on the suitable prefix of the execution transcript. This time, however, the length of the prefix increases each time the execution of the session reaches the next verifier message (rather than being fixed for the whole execution of the session). This way, the decision of whether to abort a session also depends on the contents of messages that were exchanged after the initiation of the session has occurred. Specifically, in order to decide whether to abort session $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$ at the jth message (where $j = \pi_{\mathrm{msg}}(\overline{q})$), we feed the hash function with the prefix (of query $\overline{q}$) that ends with the $(j-1)$st prover message in the nth main session of block number ℓ. (As before, the hash function is also fed with the value of i in order to achieve independence from other sessions in the block.) This prefix is called the *iteration-prefix* of query $\overline{q}$ and is defined next. (See Figure 4.2 for a graphical description of the block-prefix and iteration-prefix of a query.)

DEFINITION 4.3 (iteration-prefix). *The* iteration-prefix *of a query* $\overline{q}$ *satisfying* $\pi_{\mathrm{sn}}(\overline{q}) = (\ell, i)$ *and* $\pi_{\mathrm{msg}}(\overline{q}) = j > 1$ *is the prefix of* $\overline{q}$ *that ends with the* $(j-1)$*st prover message in session* (ℓ, n) *(that is, the* n*th main session in block number* ℓ*). More formally,* $ip(\overline{q}) = (b_1, a_1, \ldots, b_\delta, a_\delta)$ *is the iteration-prefix of* $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$ *if* a_δ *is of the form* $\mathtt{p}_{j-1}^{(n)}$ *(where* $\mathtt{p}_{j-1}^{(n)}$ *denotes the* $(j-1)$*st prover message in the* n*th main session of block number* ℓ*). This iteration-prefix is said to correspond to the block-prefix of* $\overline{q}$*.* (Again, note that i may be any index in $\{1, \ldots, n\}$ and that a_t need not belong to session (ℓ, i). Also note that the iteration-prefix is defined only for $\pi_{\mathrm{msg}}(\overline{q}) > 1$.)

We stress that two queries $\overline{q}_1, \overline{q}_2$ may have the same iteration-prefix even if they do not correspond to the same session. This could happen whenever $bp(\overline{q}_1) = bp(\overline{q}_2)$ and $\pi_{\mathrm{msg}}(\overline{q}_1) = \pi_{\mathrm{msg}}(\overline{q}_2)$ (which is possible even if $\pi_{\mathrm{sn}}(\overline{q}_1) \neq \pi_{\mathrm{sn}}(\overline{q}_2)$).

Motivating Definitions 4.2 *and* 4.3. The choices made in Definitions 4.2 and 4.3 are designed to capture the difficulties encountered whenever many sessions are to be simulated concurrently. As was previously mentioned, we would like to create a situation in which every attempt of the simulator to rewind a specific session will result in a loss of work done for other sessions (and so will cause the simulator to do

[11] In the special case that $\ell = 1$ (that is, we are in the first block of the schedule), we define $bp(\overline{q}) = \perp$.

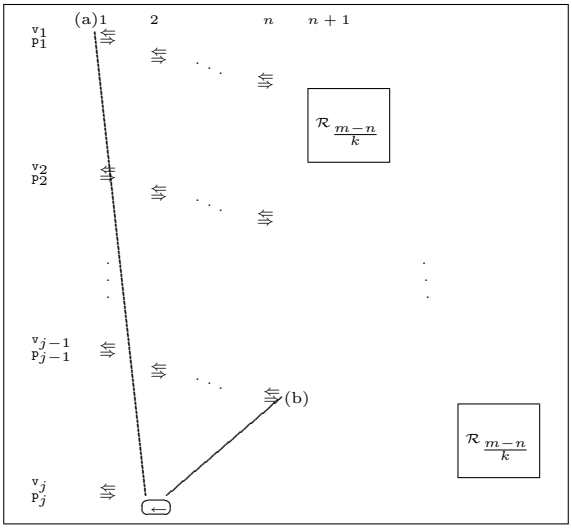

FIG. 4.2. *Determining the prefixes of query $\overline{q}$ (in this example, query $\overline{q}$ ends with a $\mathtt{p}_j^{(1)}$ message and is to be answered by $\mathtt{v}_j^{(2)}$, represented by the marked arrow):* (a) *indicates the* block-prefix *of $\overline{q}$ (i.e., messages up to this point are used by $V_{g,h}$ to determine the randomness to be used for computing message $\mathtt{v}_j^{(2)}$).* (b) *indicates the* iteration-prefix *of $\overline{q}$ (i.e., messages up to this point are used by $V_{g,h}$ to determine whether or not message $\mathtt{v}_j^{(2)}$ will be set to* `ABORT`*).*

the same amount of work all over again). In order to force the simulator to repeat each such rewinding attempt many times, we make each rewinding attempt fail with some predetermined probability (by letting the verifier send an `ABORT` message instead of a legal answer).[12]

To see that Definitions 4.2 and 4.3 indeed lead to the fulfillment of the above requirements, we consider the following example. Suppose that, at some point during the simulation, the adversary verifier aborts session (ℓ, i) at the jth message (while answering query $\overline{q}$). Further suppose that (for some unspecified reason) the simulator wants to get a "second chance" in receiving a legal answer to the jth message in session (ℓ, i) (hoping that it will not receive the `ABORT` message again). Recall that the decision of whether to abort a session depends on the outcome of a hash function when applied to the iteration-prefix $ip(\overline{q})$ of query $\overline{q}$. In particular, to obtain a "second chance," the black-box simulator has no choice but to change at least one prover message in the above iteration-prefix. (In other words, the simulator must rewind the interaction to some message occurring in iteration-prefix $ip(\overline{q})$.) At first glance, it may seem that the effect of changes in the iteration-prefix of query $\overline{q}$ is confined to the messages that belong to session $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$ (or at most to messages that belong to other sessions in block number ℓ). However, taking a closer look at the schedule, we observe that every iteration-prefix (and, in particular, $ip(\overline{q})$) can also be viewed as the block-prefix of a recursive block one level down in the recursive construction. Viewed this way, it is clear that the effect of changes in $ip(\overline{q})$ is not confined only to messages that correspond to recursive block number ℓ but rather extends also to sessions at lower levels in the recursive schedule. By changing even a single message

[12]Recall that all of the above is required in order to make the simulator's work accumulate too much and eventually cause its running time to be superpolynomial.

in iteration-prefix $ip(\overline{q})$, the simulator is actually modifying the block-prefix of all recursive blocks in a subschedule one level down in the recursive construction. This means that the randomness for all sessions in these blocks is completely modified (recall that the randomness of a session is determined by applying a hash function on the corresponding block-prefix) and that all the simulation work done for these sessions is lost. In particular, by changing even a single message in iteration-prefix $ip(\overline{q})$, the simulator will find himself doing the simulation work for these lower-level sessions all over again.

Having established the effect of changes in iteration-prefix $ip(\overline{q})$ on sessions at lower levels in the recursive schedule, we now turn to examine the actual effect on session $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$ itself. One possible consequence of changes in iteration-prefix $ip(\overline{q})$ is that they may also affect the contents of the block-prefix $bp(\overline{q})$ of query $\overline{q}$. (Notice that, by definition, the block-prefix $bp(\overline{q})$ of query $\overline{q}$ is contained in the iteration-prefix $ip(\overline{q})$ of query $\overline{q}$.) Whenever this happens, the randomness used for session (ℓ, i) is completely modified, and all simulation work done for this session will be lost. A more interesting consequence of a change in the contents of iteration-prefix $ip(\overline{q})$ is that it will result in a completely independent decision of whether session (ℓ, i) is to be aborted at the jth message. (The decision of whether to abort is taken whenever the simulator makes a query $\overline{q}$ satisfying $\pi_{\mathrm{sn}}(\overline{q}) = (\ell, i)$ and $\pi_{\mathrm{msg}}(\overline{q}) = j$.) In other words, each time the simulator attempts to get a "second chance" in receiving a legal answer to the jth message in session (ℓ, i) (by rewinding the interaction to a message that belongs to iteration-prefix $ip(\overline{q})$), it faces the risk of being answered with an `ABORT` message independently of all previous rewinding attempts.

4.1.3. The actual verifier strategy $V_{g,h}$. We consider what happens when a simulator S (for the above schedule) is given oracle access to a verifier strategy $V_{g,h}$ defined as follows (depending on hash functions g, h and the input x). Recall that we may assume that S runs in strict polynomial time: we denote such time bound by $t_S(\cdot)$. Let G denote a small family of $t_S(n)$-wise independent hash functions mapping $\mathrm{poly}(n)$-bit long sequences into a single bit of output so that, for every α, we have $\Pr_{g \leftarrow G}[g(\alpha) = 1] = n^{-1/2k}$. Let H denote a small family of $t_S(n)$-wise independent hash functions mapping $\mathrm{poly}(n)$-bit long sequences to $\rho_V(n)$-bit sequences so that, for every α, we have $\Pr_{h \leftarrow H}[h(\alpha) = 1] = 2^{-\rho_V(n)}$ (where $\rho_V(n)$ is the number of random bits used by an honest verifier V on an input $x \in \{0,1\}^n$).[13] We describe a family $\{V_{g,h}\}_{g \in G, h \in H}$ of adversarial verifier strategies (where x is implicit in $V_{g,h}$). On query $\overline{q} = (b_1, a_1, \ldots, a_{t-1}, b_t, a_t)$, the verifier acts as follows:

1. First, $V_{g,h}$ checks whether the execution transcript given by the query is legal (i.e., corresponds to a possible execution prefix) and halts with a special `ERROR` message if the query is not legal.[14]
2. Next, $V_{g,h}$ determines the block-prefix, $bp(\overline{q}) = (b_1, a_1, \ldots, b_\gamma, a_\gamma)$, of query $\overline{q}$. It also determines the identifiers of the next message $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$ and $j = \pi_{\mathrm{msg}}(\overline{q})$, the iteration-prefix $ip(\overline{q}) = (b_1, a_1, \ldots, b_\delta, \mathtt{p}_{j-1}^{(n)})$, and the $j-1$ prover messages of session i appearing in query $\overline{q}$ (which we denote by $\mathtt{p}_1^{(i)}, \ldots, \mathtt{p}_{j-1}^{(i)}$).

[13] We stress that functions in such families can be described by strings of polynomial length in a way that enables polynomial-time evaluation (cf. [24, 9, 10, 1]).

[14] In particular, $V_{g,h}$ checks whether the query is of the prescribed format (as described in section 2.5 and as determined by the schedule) and whether the content of its messages is consistent with $V_{g,h}$'s prior answers. (That is, for every proper prefix $\overline{q}' = (b_1, a_1, \ldots, b_u, a_u)$ of query $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$, the verifier checks whether the value of b_{u+1} (as it appears in $\overline{q}$) is indeed equal to the value of $V_{g,h}(\overline{q}')$.)

(*Motivating discussion.* The next message is the jth verifier message in the ith session of block ℓ. The value of the block-prefix, $bp(\overline{q})$, is used in order to determine the randomness of session (ℓ, i), whereas the value of the iteration-prefix, $ip(\overline{q})$, is used in order to determine whether session (ℓ, i) is about to be aborted at this point (i.e., jth message) in the schedule (by answering with a special `ABORT` message).)

3. If $j = 1$, then $V_{g,h}$ answers with the verifier's fixed initiation message for session i (i.e., $\mathtt{v}_1^{(i)}$).
4. If $j > 1$, then $V_{g,h}$ determines $b_{i,j} = g(i, ip(\overline{q}))$ (i.e., a bit deciding whether to abort session i):
   (a) If $b_{i,j} = 0$, then $V_{g,h}$ sets $\mathtt{v}_j^{(i)} = \mathtt{ABORT}$ (indicating that $V_{g,h}$ aborts session i).
   (b) If $b_{i,j} = 1$, then $V_{g,h}$ determines $r_i = h(i, bp(\overline{q}))$ (as coins to be used by V) and computes the message $\mathtt{v}_j^{(i)} = V(x, r_i; \mathtt{p}_1^{(i)}, \ldots, \mathtt{p}_{j-1}^{(i)})$ that would have been sent by the honest verifier on common input x, random-pad r_i, and prover's messages $\mathtt{p}_1^{(i)}, \ldots, \mathtt{p}_{j-1}^{(i)}$.
   (c) Finally, $V_{g,h}$ answers with $\mathtt{v}_j^{(i)}$.

Dealing with `ABORT` *messages.* Note that, once $V_{g,h}$ has aborted a session, the interaction in this session essentially stops, and there is no need to continue exchanging messages in this session. However, for simplicity of exposition, we assume that the verifier and prover stick to the fixed schedule of section 4.1.1 and exchange `ABORT` messages whenever an aborted session is scheduled. Specifically, if the jth verifier message in session i is `ABORT`, then all subsequent prover and verifier messages in that session will also equal `ABORT`.

On the arguments to g and h. The hash function h, which determines the random input for V in a session, is applied both on i (the identifier of the relevant session within the current block) and on the entire block-prefix of the query $\overline{q}$. This means that, even though all sessions in a specific block have the same block-prefix, for every pair of two different sessions, the corresponding random inputs of V will be independent of each other (as long as the number of applications of h does not exceed $t_S(n)$, which is indeed the case in our application). The hash function g, which determines whether and when the verifier aborts sessions, is applied both on i and on the entire iteration-prefix of the query $\overline{q}$. As in the case of h, the decision whether to abort a session is independent from the same decision for other sessions (again, as long as g is not applied more than $t_S(n)$ times). However, there is a significant difference between the inputs of h and g: Whereas the input of h is *fixed* once i and the block-prefix are fixed (and is unaffected by mesages that belong to that session), the input of g *varies* depending on previous messages sent in that session. In particular, whereas the randomness of a session is completely determined once the session begins, the decision of whether to abort a session is taken independently each time that the schedule reaches the next verifier message of this session.

On the number of different prefixes that occur in interactions with $V_{g,h}$. Since the number of recursive blocks in the schedule is equal to n, and since there is a one-to-one correspondence between recursive blocks and block-prefixes, we have that the number of different block-prefixes that occur during an interaction between an *honest prover* P and the verifier $V_{g,h}$ is always equal to n. Since the number of iterations in the message exchange phase of a recursive invocation of the schedule equals $k + 1$, and since there is a one-to-one correspondence between such iterations and iteration-

prefixes,[15] we have that the number of different iteration-prefixes that occur during an interaction between an honest prover P and the verifier $V_{g,h}$ is always equal to $k \cdot n$ (that is, k different iteration-prefixes for each one of the n recursive invocations of the schedule). In contrast, the number of different block-prefixes (resp., iteration-prefixes) that occur during an execution of a black-box simulator S that is given oracle access to $V_{g,h}$ may be considerably larger than n (resp., $k \cdot n$). The reason for this is that there is nothing that prevents the simulator from feeding $V_{g,h}$ with different queries of the same length. (This corresponds to the so-called rewinding of an interaction.) Still, the number of different prefixes in an execution of S is always upper bounded by the running time of S; that is, $t_S(n)$.

On the probability that a session is never aborted. A typical interaction between an honest prover P and the verifier $V_{g,h}$ will contain sessions whose execution has been aborted prior to completion. Recall that, at each point in the schedule, the decision of whether or not to abort the next scheduled session depends on the outcome of g. Since the function g returns 1 with probability $n^{-1/2k}$, a specific session is never aborted with probability $(n^{-1/2k})^k = n^{-1/2}$. Using the fact that, whenever a session is not aborted, $V_{g,h}$ operates as the honest verifier, we infer that the probability that a specific session is eventually accepted by $V_{g,h}$ is at least $1/2$ times the probability that the very same session is never aborted (where $1/2$ is an arbitrary lower bound on the completeness probability of the protocol). In other words, the probability that a session is accepted by $V_{g,h}$ is at least $\frac{n^{-1/2}}{2}$. In particular, for every set of n sessions, the expected number of sessions that are eventually accepted by $V_{g,h}$ (when interacting with the honest prover P) is at least $n \cdot \frac{n^{-1/2}}{2} = \frac{n^{1/2}}{2}$, and, with overwhelming high probability, at least $\frac{n^{1/2}}{4}$ sessions are accepted by $V_{g,h}$.

A slight modification of the verifier strategy. To facilitate the analysis, we slightly modify the verifier strategy $V_{g,h}$ so that it does not allow the number of accepted sessions in the history of the interaction to deviate much from its "expected behavior." Loosely speaking, given a prefix of the execution transcript (ending with a prover message), the verifier will check whether the recursive block that has just been completed contains at least $\frac{n^{1/2}}{4}$ accepted sessions. (To this end, it will be sufficient to inspect the history of the interaction only when the execution of the schedule reaches the end of a recursive block—that is, whenever the schedule reaches the last prover message in the last session of a recursive block (i.e., some $\mathtt{p}_{k+1}^{(n)}$ message).) The modified verifier strategy (which we continue to denote by $V_{g,h}$) is obtained by adding to the original strategy an additional step 1' (to be executed after step 1 of $V_{g,h}$):

1'. If a_t is of the form $\mathtt{p}_{k+1}^{(n)}$ (i.e., in case query $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$ ends with the last prover message of the nth main session of a recursive block), $V_{g,h}$ checks whether the transcript $\overline{q} = (b_1, a_1, \ldots, b_t, \mathtt{p}_{k+1}^{(n)})$ contains the accepting conversations of at least $\frac{n^{1/2}}{4}$ main sessions in the block that has just been completed. In case it does not, $V_{g,h}$ halts with a special `DEVIATION` message (indicating that the number of accepted sessions in the block that has just been completed deviates from its expected value).

Motivating discussion. Since the expected number of accepted sessions in a specific block is at least $\frac{n^{1/2}}{2}$, the probability that the block contains less than $\frac{n^{1/2}}{4}$

[15] The only exception is the first iteration in the message exchange phase. Since only queries $\overline{q}$ that satisfy $\pi_{\mathrm{msg}}(\overline{q}) > 1$ have an iteration-prefix, the first iteration will never have a corresponding iteration-prefix.

accepted sessions is negligible. Still, the above modification is not superfluous (even though it refers to events that occur only with negligible probability); it allows us to assume that every recursive block that is completed *during the simulation* (including those that *do not* appear in the simulator's output) contains at least $\frac{n^{1/2}}{4}$ accepted sessions. In particular, whenever the simulator feeds $V_{g,h}$ with a partial execution transcript (i.e., a query), we are guaranteed that, for every completed block in this transcript, the simulator has indeed "invested work" to simulate the at least $\frac{n^{1/2}}{4}$ accepted sessions in the block.

A slight modification of the simulator. Before presenting the decision procedure, we slightly modify the simulator so that it never makes a query that is answered with either the `ERROR` or the `DEVIATION` messages by the verifier $V_{g,h}$. Note that the corresponding condition can be easily checked by the simulator (which can easily produce this special message by itself)[16] and that the modification does not affect the simulator's output. From this point on, when we talk of the simulator (which we continue to denote by S), we mean the modified one.

4.2. The decision procedure for *L*. We are now ready to describe a probabilistic polynomial-time decision procedure for L, based on the black-box simulator S and the verifier strategies $V_{g,h}$. On input $x \in \{0,1\}^n$, the procedure operates as follows:

1. Uniformly select hash functions $g \stackrel{R}{\leftarrow} G$ and $h \stackrel{R}{\leftarrow} H$.
2. Invoke S on input x, providing it with black-box access to $V_{g,h}$ (as defined above). That is, the procedure emulates the execution of the oracle machine S on input x along with emulating the answers of $V_{g,h}$, where g and h are as determined in step 1.
3. Accept iff S outputs a legal transcript (as determined by steps 1 and 1' of $V_{g,h}$).[17]

By our hypothesis, the above procedure runs in probabilistic polynomial time. We next analyze its performance.

LEMMA 4.4 (performance on YES-instances). *For all but finitely many $x \in L$, the above procedure accepts x with probability at least* 2/3.

Proof sketch. Let $x \in L$, $g \stackrel{R}{\leftarrow} G$, and $h \stackrel{R}{\leftarrow} H$, and consider the honest prover P. We show below that, except for negligible probability (where the probability is taken over the random choices of g, h, and P's coin tosses), when $V_{g,h}$ interacts with P, all recursive blocks in the resulting transcript contain the accepting conversations of at least $\frac{n^{1/2}}{4}$ main sessions. Since, for *every* g and h, the simulator $S^{V_{g,h}}(x)$ must generate a transcript whose deviation gap from $\langle P, V_{g,h}\rangle(x)$ is at most 1/4, it follows that $S^{V_{g,h}}(x)$ has deviation gap at most 1/4 from $\langle P, V_{g,h}\rangle(x)$ when $g \stackrel{R}{\leftarrow} G$ and $h \stackrel{R}{\leftarrow} H$ also. Consequently, when S is run by the decision procedure for L, the transcript $S^{V_{g,h}}(x)$ will not be legal with probability at most 1/3. Details follow.

[16] We stress that, as opposed to the `ERROR` and `DEVIATION` messages, the simulator cannot predict whether its query is about to be answered with the `ABORT` message.

[17] Recall that we are assuming that the simulator never makes a query that is ruled out by steps 1 and 1' of $V_{g,h}$. Since, before producing output $(b_1, a_1, \ldots, b_T, a_T)$, the simulator makes the query $(b_1, a_1, \ldots, b_T, a_T)$, checking the legality of the transcript in step 3 is not really necessary (as, in case that the modified simulator indeed reaches the output stage "safely," we are guaranteed that it will produce a legal output). In particular, we are always guaranteed that the simulator either produces execution transcripts in which every recursive block contains at least $n^{1/2}/4$ sessions that were accepted by $V_{g,h}$ or does not produce any output at all.

Let τ denote the random variable describing the transcript of the interaction between the honest prover P and $V_{g,h}$, where the probability is taken over the choices of g, h, and P. Let $s \in \{1, \ldots, n^2\}$. We first calculate the probability that the sth session in τ is completed and accepted (i.e., $V_{g,h}$ sends the message $\mathtt{v}_{k+1}^{(s)} = \texttt{ACCEPT}$), conditioned on the event that $V_{g,h}$ did not abandon the interaction beforehand (i.e., $V_{g,h}$ did not send the `DEVIATION` message before).[18] For uniformly selected $g \stackrel{R}{\leftarrow} G$, the probability that $V_{g,h}$ does not abort the session in each of the k rounds, given that it has not already aborted, is $n^{-1/2k}$. Thus, conditioned on the event that $V_{g,h}$ did not output `DEVIATION` beforehand, the session is completed (without being aborted) with probability $(n^{-1/2k})^k = n^{-1/2}$.

The key observation is that, if h is uniformly chosen from H, then, conditioned on the event that $V_{g,h}$ did not output `DEVIATION` beforehand and the current session is not aborted, the conversation between $V_{g,h}$ and P is distributed identically to the conversation between the honest verifier V and P on input x. By the completeness requirement for zero-knowledge protocols, we have that V accepts in such an interaction with probability at least $1/2$. (This probability is actually higher, but $1/2$ is more than enough for our purposes.) Consequently, for uniformly selected g and h, conditioned on the event that $V_{g,h}$ did not output `DEVIATION` beforehand, the probability that a session is accepted by $V_{g,h}$ is at least $\frac{n^{-1/2}}{2}$.

We calculate the probability that τ contains a block such that less than $\frac{n^{1/2}}{4}$ of its sessions are accepted. Say that a block B in a transcript has been completed if all the messages of sessions in B have been sent during the interaction. Say that B is admissible if the number of accepted sessions that belong to block B in the transcript is at least $\frac{n^{1/2}}{4}$. Enumerating blocks in the order in which they are completed (that is, when we refer to the ℓth block in τ, we mean the ℓth block that is completed in τ), we denote by γ_ℓ the event that all of the blocks up to and including the ℓth block are admissible in τ.

For $i \in \{1, \ldots, n\}$, define a boolean indicator α_i^ℓ to be 1 iff the ith session in the ℓth block is accepted by $V_{g,h}$. We have seen that, conditioned on the event $\gamma_{\ell-1}$, each α_i^ℓ is 1 with probability at least $\frac{n^{-1/2}}{2}$. As a consequence, for every ℓ, the expectation of $\sum_{i=1}^n \alpha_i^\ell$ (i.e., the number of accepted main sessions in block number ℓ) is at least $\frac{n^{1/2}}{2}$. Since, conditioned on $\gamma_{\ell-1}$, the α_i^ℓ's are independent of each other, we can apply the Chernoff bound and infer that $\Pr[\gamma_\ell | \gamma_{\ell-1}] > 1 - e^{-\Omega(n^{1/2})}$. Furthermore, since no session belongs to more than one block, we have $\Pr[\gamma_\ell] \geq \Pr[\gamma_l | \gamma_{\ell-1}] \cdot \Pr[\gamma_{l-1}]$. It follows (by induction on the number of completed blocks in a transcript) that all blocks in τ are admissible with probability at least $(1 - e^{-\Omega(n^{1/2})})^n > 1 - n \cdot e^{-\Omega(n^{1/2})}$. The lemma follows. □

LEMMA 4.5 (performance on NO-instances). *For all but finitely many $x \notin L$, the above procedure rejects x with probability at least* $2/3$.

We can actually prove that, for every positive polynomial $p(\cdot)$ and for all but finitely many $x \notin L$, the above procedure accepts x with probability at most $1/p(|x|)$. Assuming toward contradiction that this is not the case, we will construct a (probabilistic polynomial-time) strategy for a cheating prover that fools the honest verifier V with success probability at least $1/\mathrm{poly}(n)$ in contradiction to the soundness (and

[18] Note that, since we are dealing with the honest prover P, there is no need to consider the `ERROR` message at all (since, in an interaction with the honest prover P, the adversary verifier $V_{g,h}$ will never output `ERROR` anyway).

even computational soundness) of the proof-system.

5. Proof of Lemma 4.5 (performance on NO-instances). Let us fix an $x \in \{0,1\}^n \setminus L$ as above.[19] Denote by $\mathtt{AC} = \mathtt{AC}_x$ the set of triplets (σ, g, h) so that, on input x, internal coins σ, and oracle access to $V_{g,h}$, the simulator outputs a legal transcript (which we denote by $S_\sigma^{V_{g,h}}(x)$). Recall that our contradiction assumption is that $\Pr_{\sigma,g,h}[(\sigma,g,h) \in \mathtt{AC}] > 1/p(n)$ for some fixed positive polynomial $p(\cdot)$. Before proceeding with the proof of Lemma 4.5, we formalize what we mean by referring to the "execution of the simulator."

DEFINITION 5.1 (execution of the simulator). *Let $x, \sigma \in \{0,1\}^*$, $g \in G$, and $h \in H$. The* execution *of simulator S, denoted $\mathrm{EXEC}_x(\sigma, g, h)$, is the sequence of queries made by S, given input x, random coins σ, and oracle access to $V_{g,h}(x)$.*

Since the simulator has the ability to "rewind" the verifier $V_{g,h}$ and explore $V_{g,h}$'s output on various execution prefixes (i.e., queries) of the same length, the number of distinct block-prefixes that appear in $\mathrm{EXEC}_x(\sigma, g, h)$ may be strictly larger than n. (Recall that the schedule consists of n invocations to recursive blocks and that, in an interaction between the honest prover P and $V_{g,h}$, there is a one-to-one correspondence between recursive blocks and block-prefixes.) As a consequence, the ℓth distinct block-prefix appearing in $\mathrm{EXEC}_x(\sigma, g, h)$ does not necessarily correspond to the ℓth recursive block in the schedule. Nevertheless, given $\mathrm{EXEC}_x(\sigma, g, h)$ and ℓ, one can easily determine for the ℓth distinct block-prefix in the execution of the simulator the index of its corresponding block in the schedule (say, by extracting the ℓth distinct block-prefix in $\mathrm{EXEC}_x(\sigma, g, h)$ and then analyzing its length).

In what follows, given a specific block-prefix $\overline{bp}$, we let $\ell^{(\overline{bp})} \in \{1, \ldots, n\}$ denote the index of its corresponding block in the schedule (as determined by $\overline{bp}$'s length). Note that two different block-prefixes $\overline{bp}_1$ and $\overline{bp}_2$ in $\mathrm{EXEC}_x(\sigma, g, h)$ may satisfy $\ell^{(\overline{bp}_1)} = \ell^{(\overline{bp}_2)}$ (as they may correspond to two different instances of the same recursive block). In particular, session $(\ell^{(\overline{bp}_1)}, i)$ may have more than a single occurrence during the execution of the simulator (whereas, in an interaction of the honest prover P with $V_{g,h}$, each session index will occur exactly once). This means that, whenever we refer to an instance of session (ℓ, i) in the simulation, we will also have to explicitly specify to which block-prefix this instance corresponds.

In order to avoid cumbersome statements, we will abuse the notation $\ell^{(\overline{bp})}$ and also use it in order to specify to which instance the recursive block $\ell^{(\overline{bp})}$ corresponds. That is, whenever we refer to recursive block number $\ell^{(\overline{bp})}$, we will actually mean "the specific instance of recursive block number ℓ $(= \ell^{(\overline{bp})})$ that corresponds to block-prefix $\overline{bp}$ in $\mathrm{EXEC}_x(\sigma, g, h)$." Viewed this way, for $\ell^{(\overline{bp}_1)} = \ell^{(\overline{bp}_2)}$, sessions $(\ell^{(\overline{bp}_1)}, i)$ and $(\ell^{(\overline{bp}_2)}, i)$ actually correspond to two different instances of the same session in the schedule.

5.1. The cheating prover. The cheating prover (denoted by P^*) starts by uniformly selecting a triplet (σ, g, h) while hoping that $(\sigma, g, h) \in \mathtt{AC}$. It next uniformly selects a pair $(\xi, \eta) \in \{1, \ldots, t_S(n)\} \times \{1, \ldots, n\}$, where the simulator's running time, $t_S(n)$, acts as a bound on the number of (different block-prefixes induced by the)

[19] Actually, we need to consider infinitely many such x's.

queries made by S on input $x \in \{0,1\}^n$. The prover next emulates an execution of $S_\sigma^{V_{g,h^{(r)}}}(x)$ (where $h^{(r)}$, which is essentially equivalent to h, will be defined below) while interacting with $V(x,r)$ (that is, the honest verifier, running on input x and using coins r). The prover handles the simulator's queries as well as the communication with the verifier as follows: Suppose that the simulator makes query $\overline{q} = (b_1, a_1, \ldots, b_t, a_t)$, where the a's are prover messages.

1. Operating as $V_{g,h}$, the cheating prover determines the block-prefix $bp(\overline{q}) = (b_1, a_1, \ldots, b_\gamma, a_\gamma)$. It also determines $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$, $j = \pi_{\mathrm{msg}}(\overline{q})$, the iteration-prefix $ip(\overline{q}) = (b_1, a_1, \ldots, b_\delta, \mathtt{p}_{j-1}^{(n)})$, and the $j-1$ prover messages $\mathtt{p}_1^{(i)}, \ldots, \mathtt{p}_{j-1}^{(i)}$ appearing in the query $\overline{q}$ (as done by $V_{g,h}$ in step 2). (Note that, by the modification of S, there is no need to perform steps 1 and 1' of $V_{g,h}$.)
2. If $j = 1$, the cheating prover answers the simulator with the verifier's fixed initiation message for session i (as done by $V_{g,h}$ in step 3).
3. If $j > 1$, the cheating prover determines $b_{i,j} = g(i, ip(\overline{q}))$ (as done by $V_{g,h}$ in step 4).
4. If $bp(\overline{q})$ is the ξth distinct block-prefix resulting from the simulator's queries so far and if, in addition, i equals η, then the cheating prover operates as follows:
   (a) If $b_{i,j} = 0$, then the cheating prover answers the simulator with `ABORT`.
   Motivating discussion for substeps b and c. The cheating prover has now reached a point in the schedule at which it is supposed to feed the simulator with $\mathtt{v}_j^{(i)}$. To do so, it first forwards $\mathtt{p}_{j-1}^{(i)}$ to the honest verifier $V(x,r)$ and only then feeds the simulator with the verifier's answer $\mathtt{v}_j^{(i)}$ (as if it were the answer given by $V_{g,h^{(r)}}$). We stress the following two points: (1) The cheating prover cannot forward more than one $\mathtt{p}_{j-1}^{(i)}$ message to V (since P^* and V engage in an actual execution of the protocol $\langle P, V\rangle$). (2) The cheating prover will wait and forward $\mathtt{p}_{j-1}^{(i)}$ to the verifier only when $\mathtt{v}_j^{(i)}$ is the next scheduled message.
   (b) If $b_{i,j} = 1$ and the cheating prover has sent only $j-2$ messages to the actual verifier, the cheating prover forwards $\mathtt{p}_{j-1}^{(i)}$ to the verifier and feeds the simulator with the verifier's response (i.e., which is of the form $\mathtt{v}_j^{(i)}$).[20]
   (We comment that, by our conventions regarding the simulator, it cannot be the case that the cheating prover has sent less than $j-2$ prover messages to the actual verifier. The prefixes of the current query dictate $j-2$ sequences of prover messages with distinct lengths so that none of these sequences was answered with `ABORT`. In particular, the last message of each one of these sequences was already forwarded to the verifier.)
   (c) If $b_{i,j} = 1$ and the cheating prover has already sent $j-1$ messages (or more) to the actual verifier, then it retrieves the $(j-1)$st answer it has received and feeds it to the simulator.

[20] Note that, in the special case that $j = 1$ (i.e., when the verifier's response is the fixed initiation message $\mathtt{v}_1^{(i)}$), the cheating prover cannot really forward $\mathtt{p}_{j-1}^{(i)}$ to the honest verifier (since no such message exists). Still, since $\mathtt{v}_1^{(i)}$ is a fixed initiation message, the cheating prover can produce $\mathtt{v}_1^{(i)}$ without actually having to interact with the honest verifier (as it indeed does in step 2 of the cheating prover strategy).

(We comment that this makes sense provided that the simulator never makes two queries with the same block-prefix and the same number of prover messages but with a different sequence of such messages. However, for $j \geq 2$, it may be the case that a previous query regarding the same block-prefix had a different $\mathtt{p}_{j-1}^{(i)}$ message. This is the case in which the cheating prover may fail to conduct step 4c (see further discussion below).)

5. If either $bp(\overline{q})$ is NOT the ξth distinct block-prefix resulting from the queries so far, or if i is NOT equal to η, the prover emulates $V_{g,h}$ in the obvious manner (i.e., as in step 4 of $V_{g,h}$):
   (a) If $b_{i,j} = 0$, then the cheating prover answers the simulator with `ABORT`.
   (b) If $b_{i,j} = 1$, then the cheating prover determines $r_i = h(i, bp(\overline{q}))$ and then answers the simulator with $V(x, r_i; \mathtt{p}_1^{(i)}, \ldots, \mathtt{p}_{j-1}^{(i)})$, where all notation is as above.

On the efficiency of the cheating prover. Notice that the strategy of the cheating prover can be implemented in polynomial time (that is, given that the simulator's running time, $t_S(\cdot)$, is polynomial as well). Thus Lemma 4.5 (and so Theorem 1.1) will also hold if $\langle P, V \rangle$ is an *argument* system (since, in the case of argument systems, the existence of an *efficient* P^* leads to a contradiction of the computational soundness of $\langle P, V \rangle$).

The cheating prover may "do nonsense" in step 4c. The cheating prover is hoping to convince an honest verifier by focusing on the ηth session in recursive block number $\ell^{(\overline{bp}_\xi)}$, where $\overline{bp}_\xi$ denotes the ξth distinct block-prefix in the simulator's execution. Prover messages in session $(\ell^{(\overline{bp}_\xi)}, \eta)$ are received from the (multisession) simulator and are forwarded to the (single-session) verifier. The honest verifier's answers are then fed back to the simulator as if they were answers given by $V_{g,h^{(r)}}$ (defined below). For the cheating prover to succeed in convincing the honest verifier, the following two conditions must be satisfied: (1) Session $(\ell^{(\overline{bp}_\xi)}, \eta)$ is eventually accepted by $V_{g,h^{(r)}}$. (2) The cheating prover never "does nonsense" in step 4c during its execution. Let us clarify the meaning of this "nonsense."

One main problem that the cheating prover is facing while conducting step 4c emerges from the following fact: Whereas the black-box simulator is allowed to "rewind" $V_{g,h^{(r)}}$ (impersonated by the cheating prover) and attempt different execution prefixes before proceeding with the interaction of a session, the prover cannot do so while interacting with the actual verifier. In particular, the cheating prover may reach step 4c with a $\mathtt{p}_{j-1}^{(\eta)}$ message that is different from the $\mathtt{p}_{j-1}^{(\eta)}$ message that was previously forwarded to the honest verifier (in step 4b). Given that the verifier's answer to the current $\mathtt{p}_{j-1}^{(\eta)}$ message is most likely to be different from the answer which was given to the "previous" $\mathtt{p}_{j-1}^{(\eta)}$ message, by answering (in step 4c) in the same way as before, the prover action "makes no sense."[21]

We stress that, at this point in its execution, the cheating prover might as well have stopped with some predetermined "failure" message (rather than "doing non-

[21] We stress that the cheating prover does not know the random coins of the honest verifier, and so it cannot compute the verifier's answers by itself. In addition, since P^* and V are engaging in an actual execution of the specified protocol $\langle P, V \rangle$ (in which every message is sent exactly once), the cheating prover cannot forward the "recent" $\mathtt{p}_{j-1}^{(\eta)}$ message to the honest verifier in order to obtain the corresponding answer (because it has already forwarded the previous $\mathtt{p}_{j-1}^{(\eta)}$ message to the honest verifier).

sense"). However, for simplicity of presentation, it is more convenient for us to let the cheating prover "do nonsense."

The punchline of the analysis is that, with noticeable probability (over choices of (σ, g, h)), there exists a choice of (ξ, η) so that the above "bad" event will not occur for session $(\ell^{(\overline{bp}_\xi)}, \eta)$. That is, using the fact that the success of a "rewinding" also depends on the output of g (which determines whether and when sessions are aborted), we show that, with nonnegligible probability, step 4c is never reached with two different $\mathtt{p}_{j-1}^{(\eta)}$ messages. Specifically, for every $j \in \{2, \ldots, k+1\}$, once a $\mathtt{p}_{j-1}^{(\eta)}$ message is forwarded to the verifier (in step 4b), all subsequent $\mathtt{p}_{j-1}^{(\eta)}$ messages either are equal to the forwarded message or are answered with `ABORT`. (Here we assume that session $(\ell^{(\overline{bp}_\xi)}, \eta)$ is eventually accepted by $V_{g,h^{(r)}}$, and every $\mathtt{p}_{j-1}^{(\eta)}$ message is forwarded to the verifier at least once.)

Defining $h^{(r)}$ (mentioned above). Let (σ, g, h) and (ξ, η) be the initial choices made by the cheating prover, let $\overline{bp}_\xi$ be the ξth block-prefix appearing in $\text{EXEC}_x(\sigma, g, h)$, and suppose that the honest verifier uses coins r. Then the function $h^{(r)} = h^{(r,\sigma,g,h,\xi,\eta)}$ is defined to be uniformly distributed among the functions h', which satisfy the following conditions: The value of h', when applied on $(\eta, \overline{bp}_\xi)$, equals r, whereas, for $(\eta', \xi') \neq (\eta, \xi)$, the value of h', when applied on $(\eta', \overline{bp}_{\xi'})$, equals the value of h on this prefix. (The set of such functions h' is not empty due to the hypothesis that the functions are selected in a family of $t_S(n)$-wise independent hash functions.) We note that replacing h by $h^{(r)}$ does not affect step 5 of the cheating prover and that the cheating prover does not know $h^{(r)}$. In particular, whenever the honest verifier V uses coins r, one may think of the cheating prover as if it is answering the simulator's queries with the answers that would have been given by $V_{g,h^{(r)}}$.

CLAIM 5.2. *For every value of σ, g, ξ, and η, if h and r are uniformly distributed, then so is $h^{(r)}$.*

Proof sketch. Fix some simulator coins $\sigma \in \{0,1\}^*$ and $g \in G$, block-prefix index $\xi \in \{1, \ldots, t_S(n)\}$, and session index $\eta \in \{1, \ldots, n\}$. The key for proving Claim 5.2 is to view the process of picking a function $h \in H$ as consisting of two stages. The first stage is an iterative process in which up to $t_S(n)$ different arguments are adversarially chosen, and, for each such argument, the value of h on this argument is uniformly selected in its range. In the second stage, a function h is chosen uniformly from all h's in H under the constraints that are introduced in the first stage. The iterative process in which the arguments are chosen (that is, the first stage above) corresponds to the simulator's choice of the various block-prefixes $\overline{bp}$ (along with the indices i), on which h is applied.

At first glance, it seems obvious that the function $h^{(r)}$, which is uniformly distributed amongst all functions that are defined to be equal to h on all inputs (except for the input $(\eta, \overline{bp}_\xi)$, on which it equals r), is uniformly distributed in H. Taking a closer look, however, one realizes that a rigorous proof for the above claim is more complex than one may initially think, since it is not even clear that an h that is defined by the above process actually belongs to the family H.

The main difficulty in proving the above lies in the fact that the simulator's queries may "adaptively" depend on previous answers it has received (which, in turn, may depend on previous outcomes of h). The key observation used in order to overcome this difficulty is that, for *every* family of $t_S(n)$-wise independent functions and for *every* sequence of at most $t_S(n)$ arguments (and, in particular, for an adaptively chosen sequence), the values of a uniformly chosen function when applied to the arguments

in the sequence are uniformly and independently distributed. Thus, as long as the values assigned to the function in the first stage of the above process are uniformly and independently distributed (which is indeed the case, even if we constrain one output to be equal to r), the process will yield a uniformly distributed function from H. □

5.2. The success probability of the cheating prover. We start by introducing two important notions that will play a central role in the analysis of the success probability of the cheating prover.

5.2.1. Grouping queries according to their iteration-prefixes. In what follows, it will be convenient to group the queries of the simulator into different classes based on different iteration-prefixes. (Recall that the iteration-prefix of a query $\overline{q}$ (satisfying $\pi_{\mathrm{sn}}(\overline{q}) = (\ell, i)$ and $\pi_{\mathrm{msg}}(\overline{q}) = j > 1$) is the prefix of $\overline{q}$ that ends with the $(j-1)$st prover message in session (ℓ, n).) Grouping by iteration-prefixes particularly makes sense in the case in which two queries are of the same length (see discussion below). Nevertheless, by Definition 4.3, two queries may have the same iteration-prefix even if they are of *different* lengths (see below).

DEFINITION 5.3 (ip-different queries). *Two queries, $\overline{q}_1$ and $\overline{q}_2$ (of possibly different lengths), are said to be* ip-different *iff they have different iteration-prefixes (that is, $ip(\overline{q}_1) \neq ip(\overline{q}_2)$).*

By Definition 4.3, if two queries, $\overline{q}_1$ and $\overline{q}_2$, satisfy $ip(\overline{q}_1) = ip(\overline{q}_2)$, then the following two conditions must hold: (1) $\pi_{\mathrm{sn}}(\overline{q}_1) = (\ell, i_1)$, $\pi_{\mathrm{sn}}(\overline{q}_2) = (\ell, i_2)$, and (2) $\pi_{\mathrm{msg}}(\overline{q}_1) = \pi_{\mathrm{msg}}(\overline{q}_2)$. However, it is not necessarily true that $i_1 = i_2$. In particular, it may very well be the case that q_1, q_2 have different lengths (i.e., $i_1 \neq i_2$) but are *not* ip-different. (Note that, if $i_1 = i_2$, then q_1 and q_2 are of equal length.) Still, even if two queries are of the same length and have the same iteration-prefix, it is not necessarily true that they are equal, as they may be different at some message which occurs after their iteration-prefixes.

Motivating Definition 5.3. Recall that a necessary condition for the success of the cheating prover is that, for every j, once a $\mathtt{p}_{j-1}^{(\eta)}$ message has been forwarded to the verifier (in step 4b), all subsequent $\mathtt{p}_{j-1}^{(\eta)}$ messages (that are not answered with ABORT) are equal to the forwarded message. In order to satisfy the above condition, it is sufficient to require that the cheating prover never reach steps 4b and 4c with two ip-different queries of equal length. The reason for this is that, if two queries of the same length have the same iteration-prefix, then they contain the *same* sequence of prover messages for the corresponding session (since all such messages are contained in the iteration-prefix), and so they agree on their $\mathtt{p}_{j-1}^{(\eta)}$ message. In particular, once a $\mathtt{p}_{j-1}^{(\eta)}$ message has been forwarded to the verifier (in step 4b), all subsequent queries that reach step 4c and are of the same length will have the same $\mathtt{p}_{j-1}^{(\eta)}$ messages as the first such query (since they have the same iteration-prefix).

In light of the above discussion, it is only natural to require that the number of ip-different queries that reach step 4c of the cheating prover be exactly one (as, in such a case, the above necessary condition is indeed satisfied).[22] Jumping ahead, we comment that the smaller the number of ip-different queries that correspond to block-

[22] In order to ensure the cheating prover's success, the above requirement should be augmented by the condition that session $(\ell^{(\overline{bp}_\xi)}, \eta)$ is accepted by $V_{g,h^{(r)}}$.

prefix $\overline{bp}_\xi$ is the smaller the probability that more than one ip-different query reaches step 4c is. The reason for this lies in the fact that the number of ip-different queries that correspond to block-prefix $\overline{bp}_\xi$ is equal to the number of different iteration-prefixes that correspond to $\overline{bp}_\xi$. In particular, the smaller the number of such iteration-prefixes is the smaller the probability that g will evaluate to 1 on more than a single iteration-prefix is (thus reaching step 4c with more than one ip-different query).

5.2.2. Useful block-prefixes. The probability that the cheating prover makes the honest verifier accept will be lower bounded by the probability that the ξth distinct block-prefix in $\text{EXEC}_x(\sigma, g, h)$ is η-useful (in the sense hinted above and defined next).

DEFINITION 5.4 (useful block-prefix). *A specific block-prefix* $\overline{bp} = (b_1, a_1, \ldots, b_\gamma, a_\gamma)$, *appearing in* $\text{EXEC}_x(\sigma, g, h)$, *is called* i-useful *if it satisfies the following two conditions:*

1. *For every* $j \in \{2, \ldots, k+1\}$, *the number of* ip*-different queries* $\overline{q}$ *in* $\text{EXEC}_x(\sigma, g, h)$ *that correspond to block-prefix* $\overline{bp}$ *and satisfy* $\pi_{\text{sn}}(\overline{q}) = (\ell^{(\overline{bp})}, i)$, $\pi_{\text{msg}}(\overline{q}) = j$, *and* $g(i, ip(\overline{q})) = 1$ *is exactly one.*
2. *The (only) query* $\overline{q}$ *in* $\text{EXEC}_x(\sigma, g, h)$ *that corresponds to block-prefix* $\overline{bp}$ *and that satisfies* $\pi_{\text{sn}}(\overline{q}) = (\ell^{(\overline{bp})}, i)$, $\pi_{\text{msg}}(\overline{q}) = k + 1$, *and* $g(i, ip(\overline{q})) = 1$ *is answered with* ACCEPT *by* $V_{g,h}$.

If there exists an $i \in \{1, \ldots, n\}$ *so that a block-prefix is* i*-useful, then this block-prefix is called* useful.

Condition 1 in Definition 5.4 states that, for every fixed value of j, there exists exactly one iteration-prefix, $\overline{ip}$, that corresponds to queries of the block-prefix $\overline{bp}$ and the jth message so that $g(i, \overline{ip})$ evaluates to 1. Condition 2 asserts that the last verifier message in the ith main session of recursive block number $\ell = \ell^{(\overline{bp})}$ is equal to ACCEPT. It follows that, if the cheating prover happens to select $(\sigma, g, h, \xi, \eta)$ so that block-prefix $\overline{bp}_\xi$ (i.e., the ξth distinct block-prefix in $\text{EXEC}_x(\sigma, g, h^{(r)})$) is η-useful, then it convinces $V(x, r)$. The reason is that (by condition 2) the last message in session $(\ell^{(\overline{bp}_\xi)}, \eta)$ is answered with ACCEPT[23] and that (by condition 1) the emulation does not get into trouble in step 4c of the cheating prover. (To see this, notice that each prover message in session $(\ell^{(\overline{bp}_\xi)}, \eta)$ will end up reaching step 4c only once.)

Let $\langle P^*, V\rangle(x) = \langle P^*(\sigma, g, h, \xi, \eta), V(r)\rangle(x)$ denote the random variable representing the (local) output of the honest verifier V when interacting with the cheating prover P^* on common input x, where σ, g, h, ξ, η are the initial random choices made by the cheating prover P^* and r is the randomness used by the honest verifier V. Adopting this notation, we will say that the cheating prover $P^* = P^*(x, \sigma, g, h, \xi, \eta)$ has convinced the honest verifier $V = V(x, r)$ if $\langle P^*, V\rangle(x) = \text{ACCEPT}$. With this notation, we are ready to formalize the above discussion.

CLAIM 5.5. *If the cheating prover happens to select* $(\sigma, g, h, \xi, \eta)$ *so that the* ξ*th distinct block-prefix in* $\text{EXEC}_x(\sigma, g, h^{(r)})$ *is* η*-useful, then the cheating prover convinces* $V(x, r)$ *(i.e.,* $\langle P^*, V\rangle(x) = \text{ACCEPT}$*).*

Proof. Let us fix $x \in \{0,1\}^n$, $\sigma \in \{0,1\}^*$, $g \in G$, $h \in H$, $r \in \{1, \ldots, \rho_V(n)\}$, $\eta \in \{1, \ldots, n\}$, and $\xi \in \{1, \ldots, t_S(n)\}$. We show that, if the ξth distinct block-prefix in $\text{EXEC}_x(\sigma, g, h^{(r)})$ is η-useful, then the cheating prover $P^*(x, \sigma, g, h, \xi, \eta)$ convinces the honest verifier $V(x, r)$.

[23] Notice that $V(x, r)$ behaves exactly as $V_{g,h^{(r)}}$ behaves on queries that correspond to the ξth distinct iteration-prefix in $\text{EXEC}_x(\sigma, g, h^{(r)})$.

By the definition of the cheating prover, the prover messages that are actually forwarded to the honest verifier (in step 4b) correspond to session $(\ell^{(\overline{bp}_\xi)}, \eta)$. Specifically, messages that are forwarded by the cheating prover are of the form $\mathtt{p}_{j-1}^{(\eta)}$ and correspond to queries $\overline{q}$ that satisfy $\pi_{\mathrm{sn}}(\overline{q}) = (\ell^{(\overline{bp}_\xi)}, \eta)$, $\pi_{\mathrm{msg}}(\overline{q}) = j$, and $g(\eta, ip(\overline{q})) = 1$. Since the ξth distinct block-prefix in $\mathrm{EXEC}_x(\sigma, g, h^{(r)})$ is η-useful, we have that, for every $j \in \{2, \ldots, k+1\}$, there is exactly one query $\overline{q}$ that satisfies the above conditions. Thus, for every $j \in \{2, \ldots, k+1\}$, the cheating prover never reaches step 4c with two different $\mathtt{p}_{j-1}^{(\eta)}$ messages. Here we use the fact that, if two queries of the same length are not ip-different (i.e., have the same iteration-prefix), then the answers given by $V_{g,h^{(r)}}$ to these queries are identical (see the discussion above). This, in particular, means that P^* is answering the simulator's queries with the answers that would have been given by $V^{g,h^{(r)}}$ itself. (In other words, whenever the ξth distinct block-prefix in $\mathrm{EXEC}_x(\sigma, g, h^{(r)})$ is η-useful, the emulation does not "get into trouble" in step 4c of the cheating prover.)

At this point, we have that the cheating prover never fails to perform step 4c, and so the interaction that it is conducting with $V(x, r)$ "safely" reaches the $(k+1)$st verifier message in the protocol. To complete the proof, we have to show that, at the end of the interaction with the cheating-prover, $V(x, r)$ outputs `ACCEPT`. This is true since, by condition 2 of Definition 5.4, the query $\overline{q}$ that corresponds to block-prefix $\overline{bp}_\xi$ and satisfies $\pi_{\mathrm{sn}}(\overline{q}) = (\ell^{(\overline{bp}_\xi)}, \eta)$, $\pi_{\mathrm{msg}}(\overline{q}) = j$, and $g(\eta, ip(\overline{q})) = 1$, is answered with `ACCEPT`. Here we use the fact that $V(x, r)$ behaves exactly as $V_{g,h^{(r)}}$ behaves on queries that correspond to the ξth distinct block-prefix in $\mathrm{EXEC}_x(\sigma, g, h^{(r)})$. □

5.2.3. Reduction to rareness of legal transcripts without useful block-prefixes. Lemma 5.6 establishes the connection between the success probability of the simulator and the success probability of the cheating prover. Loosely speaking, the lemma asserts that, if S outputs a legal transcript with nonnegligible probability, then the cheating prover will succeed in convincing the honest verifier with nonnegligible probability. Since this is in contradiction to the computational soundness of the proof-system, we have that Lemma 5.6 actually implies the correctness of Lemma 4.5. (Recall that the contradiction hypothesis of Lemma 4.5 is that the probability that the simulator outputs a legal transcript is nonnegligible.)

LEMMA 5.6. *Suppose that* $\Pr_{\sigma,g,h}[(\sigma, g, h) \in \mathtt{AC}] > 1/p(n)$ *for some fixed polynomial* $p(\cdot)$. *Then the probability* (*taken over* $\sigma, g, h, \xi, \eta, r$) *that* $\langle P^*, V\rangle(x) = \mathtt{ACCEPT}$ *is at least* $\frac{1}{2 \cdot p(n) \cdot t_S(n) \cdot n}$.

Proof. Define $\mathsf{useful}_{\xi,\eta}(\sigma, g, h)$ to be true iff the ξth distinct block-prefix in $\mathrm{EXEC}_x(\sigma, g, h)$ is η-useful. Using Claim 5.5, we have

$$\Pr_{\sigma,g,h,\xi,\eta,r}\left[\langle P^*, V\rangle(x) = \mathtt{ACCEPT}\right] \geq \Pr_{\sigma,g,h,\xi,\eta,r}[\mathsf{useful}_{\xi,\eta}(\sigma, g, h^{(r)})], \tag{5.1}$$

where the second probability refers to an interaction between S and $V_{g,h^{(r)}}$. Since, for every value of σ, g, η, and ξ, when h and r are uniformly selected, the function $h^{(r)}$ is uniformly distributed (see Claim 5.2), we infer that

$$\Pr_{\sigma,g,h,\xi,\eta,r}[\mathsf{useful}_{\xi,\eta}(\sigma, g, h^{(r)})] = \Pr_{\sigma,g,h',\xi,\eta}[\mathsf{useful}_{\xi,\eta}(\sigma, g, h')]. \tag{5.2}$$

On the other hand, since ξ and η are distributed independently of (σ, g, h), we have

$$\begin{aligned}
\Pr_{\sigma,g,h,\xi,\eta}[\mathsf{useful}_{\xi,\eta}(\sigma,g,h)] &= \sum_{d=1}^{t_S(n)}\sum_{i=1}^{n}\Pr_{\sigma,g,h,\xi,\eta}[\mathsf{useful}_{d,i}(\sigma,g,h)\ \&\ (\xi=d\ \&\ \eta=i)] \\
&= \sum_{d=1}^{t_S(n)}\sum_{i=1}^{n}\Pr_{\sigma,g,h}[\mathsf{useful}_{d,i}(\sigma,g,h)]\cdot\Pr_{\xi,\eta}[\xi=d\ \&\ \eta=i] \\
&= \sum_{d=1}^{t_S(n)}\sum_{i=1}^{n}\Pr_{\sigma,g,h}[\mathsf{useful}_{d,i}(\sigma,g,h)]\cdot\frac{1}{t_S(n)\cdot n} \\
&\geq \Pr_{\sigma,g,h}[\exists d,i \text{ s.t. } \mathsf{useful}_{d,i}(\sigma,g,h)]\cdot\frac{1}{t_S(n)\cdot n}, \qquad (5.3)
\end{aligned}$$

where $t_S(n)$ is the bound used by the cheating prover (for the number of distinct block-prefixes in $\text{EXEC}_x(\sigma, g, h)$). Combining (5.1), (5.2), and (5.3), we get

$$\begin{aligned}
&\Pr_{\sigma,g,h,\xi,\eta,r}[\langle P^*,V\rangle(x)=\texttt{ACCEPT}] \\
&\qquad \geq \Pr_{\sigma,g,h}[\exists d,i \text{ s.t. } \mathsf{useful}_{d,i}(\sigma,g,h)]\cdot\frac{1}{t_S(n)\cdot n}. \qquad (5.4)
\end{aligned}$$

Recall that, by our hypothesis, $\Pr[(\sigma, g, h) \in \texttt{AC}] > 1/p(n)$ for some fixed polynomial $p(\cdot)$. We can thus rewrite and lower bound the value of $\Pr_{\sigma,g,h}[\exists d, i \text{ s.t. } \mathsf{useful}_{d,i}(\sigma, g, h)]$ in the following way:

$$\begin{aligned}
&\Pr[\exists d,i \text{ s.t. } \mathsf{useful}_{d,i}(\sigma,g,h)] \\
&\quad = 1-\Pr[\forall d,i\ \neg\mathsf{useful}_{d,i}(\sigma,g,h)] \\
&\quad = 1-\Pr[(\forall d,i\ \neg\mathsf{useful}_{d,i}(\sigma,g,h))\,\&\,((\sigma,g,h)\notin\texttt{AC})] \\
&\qquad -\Pr[(\forall d,i\ \neg\mathsf{useful}_{d,i}(\sigma,g,h))\,\&\,((\sigma,g,h)\in\texttt{AC})] \\
&\quad \geq 1-\Pr[(\sigma,g,h)\notin\texttt{AC}]-\Pr[(\forall d,i\ \neg\mathsf{useful}_{d,i}(\sigma,g,h))\ \&\ (\sigma,g,h)\in\texttt{AC}] \\
&\quad > 1/p(n)-\Pr[(\forall d,i\ \neg\mathsf{useful}_{d,i}(\sigma,g,h))\ \&\ (\sigma,g,h)\in\texttt{AC}],
\end{aligned}$$

where all of the above probabilities are taken over (σ, g, h). It follows that, in order to show that $\Pr_{\sigma,g,h,\xi,\eta,r}[\langle P^*, V\rangle(x) = \texttt{ACCEPT}] > \frac{1}{2\cdot p(n)\cdot t_S(n)\cdot n}$, it will be sufficient to prove that, for every fixed polynomial $p'(\cdot)$, it holds that

$$\Pr_{\sigma,g,h}[(\forall d,i\ \neg\mathsf{useful}_{d,i}(\sigma,g,h))\ \&\ (\sigma,g,h)\in\texttt{AC}] \ < \ 1/p'(n).$$

Thus Lemma 5.6 is satisfied provided that $\Pr_{\sigma,g,h}[\forall d, i\ \neg\mathsf{useful}_{d,i}(\sigma, g, h)\ \&\ (\sigma, g, h) \in \texttt{AC}]$ is negligible. Consequently, Lemma 5.6 will follow by establishing Lemma 5.7.

LEMMA 5.7. *The probability (taken over σ, g, h) that, for all pairs (d, i), $\mathsf{useful}_{d,i}$ (σ, g, h) does not hold and that $(\sigma, g, h) \in \texttt{AC}$ is negligible. That is, the probability that $\text{EXEC}_x(\sigma, g, h)$ does not contain a useful block-prefix and S outputs a legal transcript is negligible.*

This completes the proof of Lemma 5.6. The rest of this section is devoted to proving Lemma 5.7. □

5.3. Proof of Lemma 5.7 (existence of useful block-prefixes in legal transcripts). The proof of Lemma 5.7 will proceed as follows. We first define a special kind of block-prefixes called *potentially useful* block-prefixes. Loosely speaking, these are block-prefixes in which the simulator does not make too many "rewinding" attempts. (Each "rewinding" corresponds to a different iteration-prefix.) Intuitively, the larger the number of "rewindings" is, the smaller the probability that a specific block-prefix is useful is. A block-prefix with a small number of "rewindings" is thus more likely to cause its block-prefix to be useful. Thus our basic approach will be to show the following.

1. In *every* "successful" execution (i.e., producing a legal transcript), the simulator generates a potentially useful block-prefix. This is proved by demonstrating, based on the structure of the schedule, that if no potentially useful block-prefix exists, then the simulation must take superpolynomial time.
2. Any potentially useful block-prefix is in fact useful with considerable probability. The argument that demonstrates this claim proceeds basically as follows. Consider a specific block-prefix $\overline{bp}$, let $\ell = \ell^{(\overline{bp})}$, and focus on a specific instance of session (ℓ, i) (that is, the specific instance of session (ℓ, i) that corresponds to block-prefix $\overline{bp}$). Suppose that block-prefix $\overline{bp}$ is potentially useful and that the above instance of session (ℓ, i) happens to be accepted by $V_{g,h}$. This means that there exist k queries with block-prefix $\overline{bp}$ that consist of the "main thread" that leads to acceptance (i.e., all queries that were not answered with `ABORT`). Recall that the decision to abort a session (ℓ, i) is made by applying the function g to i and the iteration-prefix of the corresponding query. Thus, if there are only a few different iteration-prefixes that correspond to block-prefix $\overline{bp}$ (which, as we said, is potentially useful), then there is considerable probability that *all* the queries having block-prefix $\overline{bp}$, but which do not belong to that "main thread," will be answered with `ABORT`. (That is, g will evaluate to 0 on the corresponding input.) If this lucky event occurs, then block-prefix $\overline{bp}$ will indeed be useful. (Recall that, for a block-prefix to be useful, we require that there exist a corresponding session that is accepted by $V_{g,h}$ and satisfies that for every $j \in \{2, \ldots, k+1\}$ there is a single iteration-prefix that makes g evaluate to 1 at the jth message of this session.)

Returning to the actual proof, we start by introducing the necessary definition (of a potentially useful block-prefix). Recall that, for any $g \in G$ and $h \in H$, the running time of the simulator S with oracle access to $V_{g,h}$ is bounded by $t_S(n)$. Let c be a constant such that $t_S(n) \leq n^c$ for all sufficiently large n.

DEFINITION 5.8 (potentially useful block-prefix). *A specific block-prefix* $\overline{bp} = (b_1, a_1, \ldots, b_\gamma, a_\gamma)$, *appearing in* $\text{EXEC}_x(\sigma, g, h)$, *is called* potentially useful *if it satisfies the following two conditions:*

1. *The number of* ip*-different queries that correspond to block-prefix* $\overline{bp}$ *is at most* k^{c+1}.
2. *The execution of the simulator reaches the end of the block that corresponds to block-prefix* $\overline{bp}$. *That is,* $\text{EXEC}_x(\sigma, g, h)$ *contains a query* $\overline{q}$ *that ends with the* $(k+1)$*st prover message in the* n*th main session of recursive block number* $\ell^{(\overline{bp})}$ (*i.e., some* $\mathsf{p}_{k+1}^{(\ell^{(\overline{bp})}, n)}$ *message*).

We stress that the bound k^{c+1} in condition 1 above refers to the same constant $c > 0$ that is used in the time bound $t_S(n) \leq n^c$. Using Definition 5.3 (of ip-different queries), we have that a bound of k^{c+1} on the number of ip-different queries that cor-

respond to block-prefix $\overline{bp}$ induces an upper bound on the total number of iteration-prefixes that correspond to block-prefix $\overline{bp}$. Note that this is in contrast to the definition of a useful block-prefix (Definition 5.4), in which we have a bound only on the number of ip-different queries of a specific length (i.e., the number of ip-different queries that correspond to a specific message in a specific session).

Turning to condition 2 of Definition 5.8, we recall that the query $\overline{q}$ ends with a $\mathsf{p}_{k+1}^{(\ell^{(\overline{bp})},n)}$ message (i.e., the last prover message of recursive block number $\ell^{(\overline{bp})}$). Technically speaking, this means that $\overline{q}$ does not actually correspond to block-prefix $\overline{bp}$ (since, by definition of the recursive schedule, the answer to query $\overline{q}$ is a message that does not belong to recursive block number $\ell^{(\overline{bp})}$). Nevertheless, since, before making query $\overline{q}$, the simulator has made queries to all prefixes of $\overline{q}$, we are guaranteed that, for every $i \in \{1,\ldots,n\}$ and $j \in \{1,\ldots,k+1\}$, the simulator has made a query $\overline{q}_{i,j}$ that is a prefix of $\overline{q}$, corresponds to block-prefix $\overline{bp}$, and satisfies $\pi_{\mathrm{sn}}(\overline{q}) = (\ell^{(\overline{bp})}, i)$ and $\pi_{\mathrm{msg}}(\overline{q}) = j$. (In other words, all messages of all sessions in recursive block number $\ell^{(\overline{bp})}$ have occurred during the execution of the simulator.) Furthermore, since the (modified) simulator does not make a query that is answered with a `DEVIATION` message (in step 1' of $V_{g,h}$) and it does make the query $\overline{q}$, we are guaranteed that the partial execution transcript induced by the query $\overline{q}$ contains the accepting conversations of at least $\frac{n^{1/2}}{4}$ sessions in recursive block number $\ell^{(\overline{bp})}$. (The latter observation will be used only at a later stage (while proving Lemma 5.7).)

It is worth noting that, whereas the definition of a useful block-prefix refers to the contents of iteration-prefixes (induced by the queries) that are sent by the simulator, the definition of a potentially useful block-prefix refers only to their quantity (and neither to their contents nor to the effect of the application of g on them).[24] It is thus natural that statements referring to potentially useful block-prefixes tend to have a combinatorial flavor. The following lemma is no exception. It asserts that *every* "successful" execution of the simulator must contain a potentially useful block-prefix (or, otherwise, the simulator will run in superpolynomial time).

LEMMA 5.9. *For any* $(\sigma,g,h) \in \mathtt{AC}_x$, $\mathrm{EXEC}_x(\sigma,g,h)$ *contains a potentially useful block-prefix.*

5.3.1. Proof of Lemma 5.9 (existence of potentially useful block-prefixes). The proof of Lemma 5.9 is by contradiction. We assume the existence of a triplet $(\sigma,g,h) \in \mathtt{AC}$ so that every block-prefix in $\mathrm{EXEC}_x(\sigma,g,h)$ is not potentially useful, and we show that this implies that $S_\sigma^{V_h}(x)$ made strictly more than n^c queries (which contradicts the explicit hypothesis that the running time of S is bounded by n^c).

The query-and-answer tree. Throughout the proof of Lemma 5.9, we will fix an arbitrary $(\sigma,g,h) \in \mathtt{AC}$ as above and study the corresponding $\mathrm{EXEC}_x(\sigma,g,h)$. A key vehicle in this study is the notion of a *query-and-answer tree* introduced in [26] (and also used in [29]).[25] This is a rooted tree (corresponding to $\mathrm{EXEC}_x(\sigma,g,h)$) in which vertices are labeled with verifier messages and edges are labeled with prover messages. The root is labeled with the fixed verifier message initializing the first session and has outgoing edges corresponding to the prover's messages initializing this session. In

[24] In particular, whereas the definition of a useful block-prefix refers to the outcome of g on iteration-prefixes that correspond to the relevant block-prefix, the definition of a potentially useful block-prefix refers only to the number of ip-different queries that correspond to the block-prefix (ignoring the outcomes of g on the relevant iteration-prefixes).

[25] The query-and-answer tree should not be confused with the tree that is induced by the recursive schedule.

general, paths down the tree (i.e., from the root to some vertices) correspond to queries. The query associated with such a path is obtained by concatenating the labeling of the vertices and edges along the path in the order traversed. We stress that each vertex in the query-and-answer tree corresponds to a query actually made by the simulator.

The index of the verifier (resp., prover) message labeling a specific vertex (resp., edge) in the tree is completely determined by the level in which the vertex (resp., edge) lies. That is, all vertices (resp., edges) in the ωth level of the tree are labeled with the ωth verifier (resp., prover) message in the schedule (out of a total of $n^2 \cdot (k+1)$ scheduled messages). For example, if $\omega = n^2 \cdot (k+1)$, all vertices (resp., edges) at the ωth level (which is the lowest possible level in the tree) are labeled with $\mathrm{v}_{k+1}^{(n,n)}$ (resp., $\mathrm{p}_{k+1}^{(n,n)}$). The difference between "sibling" vertices in the same level of the tree lies in the difference in the labels of their incoming edges (as induced by the simulator's "rewindings"). Specifically, whenever the simulator "rewinds" the interaction to the ωth verifier message in the schedule (i.e., makes a new query that is answered with the ωth verifier message), the corresponding vertex in the tree (which lies at the ωth level) will have multiple descendants one level down in the tree (i.e., at the $(\omega+1)$st level). The edges to each one of these descendants will be labeled with a different prover message.[26] We stress that the difference between these prover messages lies in the contents of the corresponding message (and not in its index).

By the above discussion, the outdegree of every vertex in the query-and-answer tree corresponds to the number of "rewindings" that the simulator has made to the relevant point in the schedule. (The order in which the outgoing edges appear in the tree does not necessarily correspond to the order in which the "rewindings" were actually performed by the simulator.) Vertices in which the simulator does not perform a "rewinding" will thus have a single outgoing edge. In particular, in case that the simulator follows the prescribed prover strategy P (sending each scheduled message exactly once), all vertices in the tree will have outdegree one, and the tree will actually consist of a single path of total length $n^2 \cdot (k+1)$ (ending with an edge that is labeled with a $\mathrm{p}_{k+1}^{(n,n)}$ message).

Recall that, by our conventions regarding the simulator, before making a query $\overline{q}$, the simulator has made queries to all prefixes of $\overline{q}$. Since every query corresponds to a path down the tree, we have that every particular path down the query-and-answer tree is developed from the root downward. (That is, within a specific path, a level $\omega < \omega'$ vertex is always visited before a level ω' vertex.) However, we cannot say anything about the order in which *different* paths in the tree are developed. (For example, we cannot assume that the simulator has made all queries that end at a level ω vertex before making any other query that ends at a level $\omega' > \omega$ vertex or that it has visited all vertices of level ω in some specific order.) To summarize, the only guarantee that we have about the order in which the query-and-answer tree is developed is implied by the convention that, before making a specific query, the simulator has made queries to all relevant prefixes.

Satisfied path. A path from one node in the tree to some of its descendants is said to *satisfy session* i if the path contains edges (resp., vertices) for each of the messages sent by the prover (resp., verifier) in session i. A path is called *satisfied* if

[26] In particular, the shape of the query-and-answer tree is completely determined by the contents of prover messages in $\mathrm{EXEC}_x(\sigma, g, h)$ (whereas the contents of verifier answers given by $V_{g,h}$ have no effect on the shape of the tree).

it satisfies all sessions for which the verifier's first message appears along the path. One important example for a satisfied path is the path that starts at the root of the query-and-answer tree and ends with an edge that is labeled with a $\mathtt{p}_{k+1}^{(n,n)}$ message. This path contains all $n^2 \cdot (k+1)$ messages in the schedule (and so satisfies all n^2 sessions in the schedule). We stress that the contents of messages (occurring as labels) along a path are completely irrelevant to the question of whether the path is satisfied or not. In particular, a path may be satisfied even if some (or even all) of the vertices along it are labeled with `ABORT`.

Recall that, by our conventions, the simulator never makes a query that is answered with the `DEVIATION` message. We are thus guaranteed that, for every completed block along a path in the tree, at least $\frac{n^{1/2}}{4}$ sessions are accepted by $V_{g,h}$. In particular, the vertices corresponding to messages of these accepted sessions cannot be labeled with `ABORT`.

Good subtree. Consider an arbitrary subtree (of the query-and-answer tree) that satisfies the following two conditions:

1. The subtree is rooted at a vertex corresponding to the first message of some session so that this session is the first main session of some recursive invocation of the schedule.
2. Each path in the subtree is truncated at the last message of the relevant recursive invocation.

The full tree (i.e., the tree rooted at the vertex labeled with the first message in the schedule) is indeed such a tree, but we will need to consider subtrees which correspond to m sessions in the recursive schedule construction (i.e., correspond to $\mathcal{R}_m$). We call such a subtree *m-good* if it contains a satisfied path starting at the root of the subtree. Since $(\sigma, g, h) \in \mathtt{AC}$, we have that the simulator has indeed produced a "legal" transcript as output. It follows that the full tree contains a path from the root to a leaf that contains vertices (resp., edges) for each of the messages sent by the verifier (resp., prover) in all n^2 sessions of the schedule (as otherwise the transcript $S_\sigma^{V_{g,h}}(x)$ would not have been legal). In other words, the full tree contains a satisfied path and is thus n^2-good.

Note that, by the definition of the recursive schedule, two m-good subtrees are always disjoint. On the other hand, if $m' < m$, it may be the case that an m'-good subtree is contained in another m-good subtree. As a matter of fact, since an m-good subtree contains all messages of all sessions in a recursive block corresponding to $\mathcal{R}_m$, then it must contain at least k disjoint $\frac{m-n}{k}$-good subtrees (i.e., that correspond to the k recursive invocations of $\mathcal{R}_{\frac{m-n}{k}}$ made by $\mathcal{R}_m$).

The next lemma (which can be viewed as the crux of the proof) states that, if the contradiction hypothesis of Lemma 5.9 is satisfied, then the number of disjoint $\frac{m-n}{k}$-good subtrees that are contained in an m-good subtree is actually considerably larger than k.

LEMMA 5.10. *Suppose that every block-prefix that appears in* $\text{EXEC}_x(\sigma, g, h)$ *is not potentially useful. Then, for every $m \geq n$, every m-good subtree contains at least k^{c+1} disjoint $\frac{m-n}{k}$-good subtrees.*

Denote by $W(m)$ the size of an m-good subtree. (That is, $W(m)$ actually represents the work performed by the simulator on m concurrent sessions in our fixed scheduling.) It follows (from Lemma 5.10) that any m-good subtree must satisfy

$$W(m) \geq \begin{cases} 1 & \text{if } m \leq n, \\ k^{c+1} \cdot W\left(\frac{m-n}{k}\right) & \text{if } m > n. \end{cases} \tag{5.5}$$

Since, for all but finitely many n, (5.5) solves to $W(n^2) > n^c$ (see Appendix B), and since every vertex in the query-and-answer tree corresponds to a query actually made by the simulator, it follows that the hypothesis that the simulator runs in time that is bounded by n^c (and hence the full n^2-good tree must have been of size at most n^c) is contradicted. Thus Lemma 5.9 will actually follow from Lemma 5.10.

Proof of Lemma 5.10. Let T be an arbitrary m-good subtree of the query-and-answer tree. Considering the m sessions corresponding to an m-good subtree, we focus on the n main sessions of this level of the recursive construction. Let B_T denote the recursive block to which the indices of these n sessions belong. A *T-query* is a query $\overline{q}$ whose corresponding path down the query-and-answer tree ends with a node that belongs to T (recall that every query $\overline{q}$ appearing in $\text{EXEC}_x(\sigma, g, h)$ corresponds to a path down the full tree) and that satisfies $\pi_{\text{sn}}(\overline{q}) \in B_T$.[27] We first claim that all T-queries $\overline{q}$ in $\text{EXEC}_x(\sigma, g, h)$ have the same block-prefix. This block-prefix corresponds to the path from the root of the full tree to the root of T and is denoted by $\overline{bp}_T$.

FACT 5.11. *All T-queries in $\text{EXEC}_x(\sigma, g, h)$ have the same block-prefix (denoted by $\overline{bp}_T$).*

Proof. Assume, toward contradiction, that there exist two different T-queries $\overline{q}_1, \overline{q}_2$ so that $bp(\overline{q}_1) \neq bp(\overline{q}_2)$. In particular, $bp(\overline{q}_1)$ and $bp(\overline{q}_2)$ must differ in a message that precedes the first message of the first main session in B_T. (Note that, if two block-prefixes are equal in all messages preceding the first message of the first session of the relevant block, then, by definition, they are equal.[28]) This means that the paths that correspond to $\overline{q}_1$ and $\overline{q}_2$ split from each other before they reach the root of T. (Remember that T is rooted at a node corresponding to the first main session of recursive block B_T.) However, this contradicts the fact that both paths that correspond to these queries end with a node in T, and the fact follows. □

Using the hypothesis that no block-prefix in $\text{EXEC}_x(\sigma, g, h)$ is potentially useful, we prove the following claim.

CLAIM 5.12. *Let T be an m-good subtree. Then the number of* ip*-different queries that correspond to block-prefix $\overline{bp}_T$ is at least k^{c+1}.*

Proof. Since all block-prefixes that appear in $\text{EXEC}_x(\sigma, g, h)$ are not potentially useful (by the hypothesis of Lemma 5.10), this holds as a special case for block-prefix $\overline{bp}_T$. Let $\ell = \ell^{(\overline{bp}_T)}$ be the index of the recursive block that corresponds to block-prefix $\overline{bp}_T$ in $\text{EXEC}_x(\sigma, g, h)$. Since block-prefix $\overline{bp}_T$ is not potentially useful, at least one of the two conditions of Definition 5.8 is violated. In other words, one of the following two conditions is satisfied:

1. The number of ip-different queries that correspond to block-prefix $\overline{bp}_T$ is at least k^{c+1}.
2. The execution of the simulator does not reach the end of the block that corresponds to block-prefix $\overline{bp}_T$ (i.e., there is no query in $\text{EXEC}_x(\sigma, g, h)$ that ends with a $\mathsf{p}_{k+1}^{(\ell,n)}$ message that corresponds to block-prefix $\overline{bp}_T$).

Now, since T is an m-good subtree, it must contain a satisfied path. Such a path starts at the root of T and satisfies all sessions whose first verifier message appears

[27] Note that queries $\overline{q}$ that satisfy $\pi_{\text{sn}}(\overline{q}) \in B_T$ do not necessarily correspond to a path that ends with a node in T (as $\text{EXEC}_x(\sigma, g, h)$ may contain a different subtree T' that satisfies $B_T = B_{T'}$). Also note that there exist queries $\overline{q}$ whose corresponding path ends with a node that belongs to T but that satisfy $\pi_{\text{sn}}(\overline{q}) \notin B_T$. This is so since T may also contain vertices that correspond to messages in sessions which are not main sessions of B_T (in particular, all sessions that belong to the lower-level recursive blocks that are invoked by block B_T).

[28] Recall that the index of the relevant block is determined by the length of the corresponding block-prefix.

along the path. The key observation is that every satisfied path that starts at the root of subtree T must satisfy all of the main sessions in B_T (to see this, notice that the first message of all main sessions in B_T will always appear along such a path), and so it contains all messages of all main sessions in recursive block B_T. In particular, the subtree T contains a path that starts at the root of T and ends with an edge that is labeled with the last prover message in session number (ℓ, n) (i.e., a $\mathtt{p}_{k+1}^{(\ell,n)}$ message). In other words, the execution of the simulator *does* reach the end of the block that corresponds to block-prefix $\overline{bp}_T$ (since, for the above path to exist, the simulator must have made a query that ends with a $\mathtt{p}_{k+1}^{(\ell,n)}$ message that corresponds to block-prefix $\overline{bp}_T$), and so condition 2 does not apply. Thus the only reason that may cause block-prefix $\overline{bp}_T$ not to be potentially useful is condition 1. We conclude that the number of ip-different queries that correspond to block-prefix $\overline{bp}_T$ is at least k^{c+1}, as required. □

The following claim establishes the connection between the number of ip-different queries that correspond to block-prefix $\overline{bp}_T$ and the number of $\frac{m-n}{k}$-good subtrees contained in T. Loosely speaking, this is achieved based on the following three observations: (1) Two queries are said to be ip-different iff they have different iteration-prefixes. (2) Every iteration-prefix is a block-prefix of some subschedule one level down in the recursive construction (consisting of $\frac{m-n}{k}$ sessions). (3) Every such distinct block-prefix yields a distinct $\frac{m-n}{k}$-good subtree.

CLAIM 5.13. *Let T be an m-good subtree. Then, for every pair of ip-different queries that correspond to block-prefix $\overline{bp}_T$, the subtree T contains two disjoint $\frac{m-n}{k}$-good subtrees.*

Once Claim 5.13 is proved, we can use it in conjunction with Claim 5.12 to infer that T contains at least k^{c+1} disjoint $\frac{m-n}{k}$-good subtrees.

Proof. Before we proceed with the proof of Claim 5.13, we introduce the notion of an *iteration-suffix* of a query $\overline{q}$. This is the suffix of $\overline{q}$ that starts at the ending point of the query's iteration-prefix. A key feature satisfied by an iteration-suffix of a query is that it contains all of the messages of all sessions belonging to some invocation of the schedule one level down in the recursive construction. (This follows directly from the structure of our fixed schedule.)

DEFINITION 5.14 (iteration-suffix). *The* iteration-suffix *of a query $\overline{q}$ (satisfying $j = \pi_{\mathrm{msg}}(\overline{q}) > 1$), denoted by $is(\overline{q})$, is the suffix of $\overline{q}$ that begins at the ending point of the iteration-prefix of query $\overline{q}$. That is, for $\overline{q} = (b_1, a_1, \ldots, a_t, b_t)$, if $ip(\overline{q}) = (b_1, a_1, \ldots, b_{\delta-1}, a_\delta)$, then $is(\overline{q}) = (a_\delta, b_{\delta+1}, \ldots, a_t, b_t)$.*[29]

Let $\overline{q}$ be a query, and let $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$, $j = \pi_{\mathrm{msg}}(\overline{q})$. Let $\mathcal{P}(\overline{q})$ denote the path corresponding to query $\overline{q}$ in the query-and-answer tree. Let $\mathcal{P}_{ip}(\overline{q})$ denote the subpath of $\mathcal{P}(\overline{q})$ that corresponds to the iteration-prefix $ip(\overline{q})$ of $\overline{q}$, and let $\mathcal{P}_{is}(\overline{q})$ denote the subpath of $\mathcal{P}(\overline{q})$ that corresponds to the iteration-suffix $is(\overline{q})$ of $\overline{q}$. That is, the subpath $\mathcal{P}_{ip}(\overline{q})$ starts at the root of the full tree and ends at a $\mathtt{p}_{j-1}^{(\ell,n)}$ message, whereas the subpath $\mathcal{P}_{is}(\overline{q})$ starts at a $\mathtt{p}_{j-1}^{(\ell,n)}$ message and ends at a $\mathtt{v}_{j}^{(\ell,i)}$ message. (In particular, path $\mathcal{P}(\overline{q})$ can be obtained by concatenating $\mathcal{P}_{ip}(\overline{q})$ with $\mathcal{P}_{is}(\overline{q})$.[30])

[29] This means that a_δ is of the form $\mathtt{p}_{j-1}^{(\ell,n)}$, where $(\ell, i) = \pi_{\mathrm{sn}}(\overline{q})$ and $j = \pi_{\mathrm{msg}}(\overline{q})$.

[30] To be precise, one should delete from the resulting concatenation one of the two consecutive edges which are labeled with $a_\delta = \mathtt{p}_{j-1}^{(\ell,n)}$. (One edge is the last in $\mathcal{P}_{ip}(\overline{q})$, and the other edge is the first in $\mathcal{P}_{is}(\overline{q})$.)

FACT 5.15. *For every query* $\overline{q} \in \text{EXEC}_x(\sigma, g, h)$*, the subpath* $\mathcal{P}_{is}(\overline{q})$ *is satisfied. Moreover,*

1. *the subpath* $\mathcal{P}_{is}(\overline{q})$ *satisfies all* $\frac{m-n}{k}$ *sessions of a recursive invocation one level down in the recursive construction (i.e., corresponding to* $\mathcal{R}_{\frac{m-n}{k}}$*);*
2. *if* $\overline{q}$ *corresponds to block-prefix* $\overline{bp}_T$*, then the subpath* $\mathcal{P}_{is}(\overline{q})$ *is contained in* T*.*

Proof. Let $(\ell, i) = \pi_{\text{sn}}(\overline{q})$ and $j = \pi_{\text{msg}}(\overline{q})$. By the nature of our fixed scheduling, the vertex in which subpath $\mathcal{P}_{is}(\overline{q})$ begins precedes the first message of all (nested) sessions in the $(j-1)$st recursive invocation made by recursive block number ℓ (i.e., an instance of $\mathcal{R}_{\frac{m-n}{k}}$ which is invoked by $\mathcal{R}_m$). Since query $\overline{q}$ is answered with a $\mathtt{v}_j^{(\ell,i)}$ message, we have that the subpath $\mathcal{P}_{is}(\overline{q})$ eventually reaches a vertex labeled with $\mathtt{v}_j^{(\ell,i)}$. In particular, the subpath $\mathcal{P}_{is}(\overline{q})$ (starting at a $\mathtt{p}_{j-1}^{(\ell,n)}$ edge and ending at a $\mathtt{v}_j^{(\ell,i)}$ vertex) contains the first and last messages of each of the above (nested) sessions and so contains edges (resp., vertices) for each prover (resp., verifier) message in these sessions. By definition, this means that all of these (nested) sessions are satisfied by $\mathcal{P}_{is}(\overline{q})$. Since the above (nested) sessions are the only sessions whose first message appears along the subpath $\mathcal{P}_{is}(\overline{q})$, we have that $\mathcal{P}_{is}(\overline{q})$ is satisfied. To see that whenever $\overline{q}$ corresponds to block-prefix $\overline{bp}_T$ the subpath $\mathcal{P}_{is}(\overline{q})$ is contained in the subtree T, we observe that both its starting point (i.e., a $\mathtt{p}_{j-1}^{(\ell,n)}$ edge) and its ending point (i.e., a $\mathtt{v}_j^{(\ell,i)}$ vertex) are contained in T. □

FACT 5.16. *Let* $\overline{q}_1, \overline{q}_2$ *be two* ip*-different queries. Then* $\mathcal{P}_{is}(\overline{q}_1)$ *and* $\mathcal{P}_{is}(\overline{q}_2)$ *are disjoint.*

Proof. Let $\overline{q}_1$ and $\overline{q}_2$ be two ip-different queries, let $(\ell_1, i_1) = \pi_{\text{sn}}(\overline{q}_1)$, $(\ell_2, i_2) = \pi_{\text{sn}}(\overline{q}_2)$, and let $j_1 = \pi_{\text{msg}}(\overline{q}_1)$, $j_2 = \pi_{\text{msg}}(\overline{q}_2)$. Recall that queries $\overline{q}_1$ and $\overline{q}_2$ are said to be ip-different iff they have different iteration-prefixes. Since $\overline{q}_1$ and $\overline{q}_2$ are assumed to be ip-different, so are iteration-prefixes $ip(\overline{q}_1)$ and $ip(\overline{q}_2)$. In particular, the paths $\mathcal{P}_{ip}(\overline{q}_1)$ and $\mathcal{P}_{ip}(\overline{q}_2)$ are different. We distinguish between the following two cases:

1. *Path* $\mathcal{P}_{ip}(\overline{q}_1)$ *splits from* $\mathcal{P}_{ip}(\overline{q}_2)$. In such a case, the ending points of paths $\mathcal{P}_{ip}(\overline{q}_1)$ and $\mathcal{P}_{ip}(\overline{q}_2)$ must belong to different subtrees of the query-and-answer tree. Since the starting point of an iteration-suffix is the ending point of the corresponding iteration-prefix, we must have that paths $\mathcal{P}_{is}(\overline{q}_1)$ and $\mathcal{P}_{is}(\overline{q}_2)$ are disjoint.
2. *Path* $\mathcal{P}_{ip}(\overline{q}_1)$ *is a prefix of path* $\mathcal{P}_{ip}(\overline{q}_2)$. That is, both $\mathcal{P}_{ip}(\overline{q}_1)$ and $\mathcal{P}_{ip}(\overline{q}_2)$ reach a $\mathtt{v}_{j_1-1}^{(\ell_1,n)}$ vertex, while path $\mathcal{P}_{ip}(\overline{q}_2)$ continues down the tree and reaches a $\mathtt{v}_{j_2-1}^{(\ell_2,n)}$ vertex. The key observation in this case is that either ℓ_1 is strictly smaller than ℓ_2 or j_1 is strictly smaller than j_2. The reason for this is that, in the case that both $\ell_1 = \ell_2$ and $j_1 = j_2$ hold, iteration-prefix $ip(\overline{q}_1)$ must be equal to iteration-prefix $ip(\overline{q}_2)$,[31] in contradiction to our hypothesis. Since path $\mathcal{P}_{is}(\overline{q}_1)$ starts at a $\mathtt{p}_{j_1-1}^{(\ell_1,n)}$ vertex and ends with a $\mathtt{v}_{j_1}^{(\ell_1,i_1)}$ vertex, and since path $\mathcal{P}_{is}(\overline{q}_2)$ starts with a $\mathtt{p}_{j_2-1}^{(\ell_2,n)}$ vertex, we have that the ending point of path $\mathcal{P}_{is}(\overline{q}_1)$ precedes the starting point of path $\mathcal{P}_{is}(\overline{q}_2)$. (This is so since, if $j_1 < j_2$, the $\mathtt{p}_{j_1}^{(\ell_1,i_1)}$ message will always precede/equal the $\mathtt{p}_{j_2-1}^{(\ell_2,n)}$ message.) In particular, paths $\mathcal{P}_{is}(\overline{q}_1)$ and $\mathcal{P}_{is}(\overline{q}_2)$ are disjoint.

[31] That is, unless $bp(\overline{q}_1) \neq bp(\overline{q}_2)$. However, in such a case, paths $\mathcal{P}_{ip}(\overline{q}_1)$ and $\mathcal{P}_{ip}(\overline{q}_2)$ must split from each other (since they differ in some message that belongs to their block-prefix), and we are back to case 1.

It follows that, for every two ip-different queries, $\overline{q}_1$ and $\overline{q}_2$, subpaths $\mathcal{P}_{is}(\overline{q}_1)$ and $\mathcal{P}_{is}(\overline{q}_2)$ are disjoint, as required. □

Returning to the proof of Claim 5.13, let $\overline{q}_1$ and $\overline{q}_2$ be two ip-different queries that correspond to block-prefix $\overline{bp}_T$ (as guaranteed by the hypothesis of Claim 5.13), and let $\mathcal{P}_{is}(\overline{q}_1)$ and $\mathcal{P}_{is}(\overline{q}_2)$ be as above. Consider the two subtrees, T_1 and T_2, of T that are rooted at the starting point of subpaths $\mathcal{P}_{is}(\overline{q}_1)$ and $\mathcal{P}_{is}(\overline{q}_2)$, respectively. (Note that, by Fact 5.15, T_1 and T_2 are indeed subtrees of T.) By definition of our recursive schedule, T_1 and T_2 correspond to $\frac{m-n}{k}$ sessions one level down in the recursive construction (i.e., to an instance of $\mathcal{R}_{\frac{m-n}{k}}$). Using Fact 5.15, we infer that subpath $\mathcal{P}_{is}(\overline{q}_1)$ (resp., $\mathcal{P}_{is}(\overline{q}_2)$) contains all messages of all sessions in T_1 (resp., T_2), and so the subtree T_1 (resp., T_2) is $\frac{m-n}{k}$-good. In addition, since subpaths $\mathcal{P}_{is}(\overline{q}_1)$ and $\mathcal{P}_{is}(\overline{q}_2)$ are disjoint (by Fact 5.16) and since, by definition of an $\frac{m-n}{k}$-good tree, two different $\frac{m-n}{k}$-good trees are always disjoint, then T_1 and T_2 (which, being rooted at different vertices, must be different) are also disjoint. It follows that, for every pair of different queries that correspond to block-prefix $\overline{bp}_T$, the subtree T contains two disjoint $\frac{m-n}{k}$-good subtrees. □

We are finally ready to establish Lemma 5.10 (using Claims 5.12 and 5.13). By Claim 5.12, we have that the number of different queries that correspond to block-prefix $\overline{bp}_T$ is at least k^{c+1}. Since (by Claim 5.13), for every pair of different queries that correspond to block-prefix $\overline{bp}_T$, the subtree T contains two disjoint $\frac{m-n}{k}$-good subtrees, we infer that T contains a total of at least k^{c+1} disjoint $\frac{m-n}{k}$-good subtrees (corresponding to the (at least) k^{c+1} different queries mentioned above). Lemma 5.10 follows. □

5.3.2. Back to the proof of Lemma 5.7 (existence of useful block-prefixes). Once the correctness of Lemma 5.9 is established, we may proceed with the proof of Lemma 5.7. Let $x \in \{0,1\}^n$. We bound from above the probability, taken over the choices of $\sigma \in \{0,1\}^*, g \xleftarrow{R} G$, and $h \xleftarrow{R} H$, that $(\sigma, g, h) \in \mathtt{AC}$ and that, for all $d \in \{1, \ldots, t_S(n)\}$ and all $i \in \{1, \ldots, n\}$, the dth distinct block-prefix in $\text{EXEC}_x(\sigma, g, h)$ is not i-useful. Specifically, we would like to show that

$$\Pr_{\sigma,g,h}[(\forall d, i\ \neg\mathsf{useful}_{d,i}(\sigma, g, h))\ \&\ ((\sigma, g, h) \in \mathtt{AC})] \tag{5.6}$$

is negligible. Define a boolean indicator $\mathsf{pot}-\mathsf{use}_d(\sigma, g, h)$ to be true iff the dth distinct block-prefix in $\text{EXEC}_x(\sigma, g, h)$ is potentially useful. As proved in Lemma 5.9, for any $(\sigma, g, h) \in \mathtt{AC}$, there exists an index $d \in \{1, \ldots, t_S(n)\}$ so that the dth block-prefix in $\text{EXEC}_x(\sigma, g, h)$ is potentially useful. In other words, for every $(\sigma, g, h) \in \mathtt{AC}$, $\mathsf{pot}-\mathsf{use}_d(\sigma, g, h)$ holds for some value of d. Thus (5.6) is upper bounded by

$$\Pr_{\sigma,g,h}\left[\bigvee_{d=1}^{t_S(n)} \mathsf{pot}-\mathsf{use}_d(\sigma, g, h)\ \&\ (\forall i \in \{1, \ldots, n\}\ \neg\mathsf{useful}_{d,i}(\sigma, g, h))\right]. \tag{5.7}$$

Consider a specific $d \in \{1, \ldots, t_S(n)\}$ so that $\mathsf{pot}-\mathsf{use}_d(\sigma, g, h)$ is satisfied (i.e., the dth block prefix in $\text{EXEC}_x(\sigma, g, h)$ is potentially useful). By condition 2 in the definition of a potentially useful block-prefix (Definition 5.8), the execution of the simulator reaches the end of the corresponding block in the schedule. In other words, there exists a query $\overline{q} \in \text{EXEC}_x(\sigma, g, h)$ that ends with the $(k+1)$st prover message in the nth main session of recursive block number $\ell^{(\overline{bp}_d)}$, where $\overline{bp}_d$ denotes the dth distinct block-prefix in $\text{EXEC}_x(\sigma, g, h)$ and $\ell^{(\overline{bp}_d)}$ denotes the index of the recursive block that corresponds to block-prefix $\overline{bp}_d$ in $\text{EXEC}_x(\sigma, g, h)$. Since, by our convention and the

modification of the simulator, S never generates a query that is answered with a DEVIATION message, we have that the partial execution transcript induced by query $\overline{q}$ must contain the accepting conversations of at least $\frac{n^{1/2}}{4}$ main sessions in block number $\ell^{(\overline{bp}_d)}$ (as otherwise query $\overline{q}$ would have been answered with the DEVIATION message in step 1' of $V_{g,h}$).

Let $\overline{q}^{(\overline{bp}_d)} = \overline{q}^{(\overline{bp}_d)}(\sigma, g, h)$ denote the first query in $\text{EXEC}_x(\sigma, g, h)$ that is as above (i.e., that ends with the $(k+1)$st prover message in the nth main session of recursive block number $\ell^{(\overline{bp}_d)}$, where $\overline{bp}_d$ denotes the dth block-prefix appearing in $\text{EXEC}_x(\sigma, g, h)$).[32] Define an additional boolean indicator $\mathsf{accept}_{d,i}(\sigma, g, h)$ to be true iff query $\overline{q}^{(\overline{bp}_d)}$ contains an accepting conversation for session $(\ell^{(\overline{bp}_d)}, i)$. (That is, no prover message in session $(\ell^{(\overline{bp}_d)}, i)$ is answered with ABORT, and the last verifier message of this session equals ACCEPT.[33]) It follows that, for every $d \in \{1, \ldots, t_S(n)\}$ that satisfies $\mathsf{pot} - \mathsf{use}_d(\sigma, g, h)$ (as above), there exists a set $\mathcal{S} \subset \{1, \ldots, n\}$ of size $\frac{n^{1/2}}{4}$ such that $\mathsf{accept}_{d,i}(\sigma, g, h)$ holds for every $i \in \mathcal{S}$. Thus (5.7) is upper bounded by

$$\Pr_{\sigma,g,h}\left[\bigvee_{d=1}^{t_S(n)} \bigvee_{\substack{\mathcal{S}\subset\{1,\ldots,n\} \\ |\mathcal{S}|=\frac{n^{1/2}}{4}}} \big(\mathsf{pot} - \mathsf{use}_d(\sigma, g, h)\ \&\big(\forall i \in \mathcal{S},\ \neg\mathsf{useful}_{d,i}(\sigma, g, h)\right.$$

$$\left.\ \&\ \mathsf{accept}_{d,i}(\sigma, g, h)\big)\big)\right]. \tag{5.8}$$

Using the union bound, we upper bound (5.8) by

$$\sum_{d=1}^{t_S(n)} \sum_{\substack{\mathcal{S}\subset\{1,\ldots,n\} \\ |\mathcal{S}|=\frac{n^{1/2}}{4}}} \Pr_{\sigma,g,h}\left[\mathsf{pot} - \mathsf{use}_d(\sigma, g, h)\,\&\big(\forall i \in \mathcal{S},\ \neg\mathsf{useful}_{d,i}(\sigma, g, h)\right.$$

$$\left.\ \&\ \mathsf{accept}_{d,i}(\sigma, g, h)\big)\right]. \tag{5.9}$$

The last expression is upper bounded using the following lemma, which bounds the probability that a specific set of different sessions corresponding to the same (in index) potentially useful block-prefix are accepted (at the first time that the recursive block to which they belong is completed) but still do not turn it into a useful block-prefix. In fact, we prove something stronger.

[32] Since the simulator is allowed to feed $V_{g,h}$ with different queries of the same length, we have that the execution of the simulator may reach the end of the corresponding block more than once (and thus $\text{EXEC}_x(\sigma, g, h)$ may contain more than a single query that ends with the $(k+1)$st prover message in the nth main session of block number $\ell^{(\overline{bp}_d)}$). Since each time that the simulator reaches the end of the corresponding block the above set of accepted sessions may be different, we are not able to pinpoint a specific set of accepted sessions without explicitly specifying to which one of the above queries we are referring. We solve this problem by explicitly referring to the first query that satisfies the above conditions. (Note that, in our case, such a query is always guaranteed to exist.)

[33] Note that the second condition implies the first one. Namely, if the last verifier message of session $(\ell^{(\overline{bp}_d)}, i)$ equals ACCEPT, then no prover message in this session could have been answered with ABORT.

LEMMA 5.17. *For every $\sigma \in \{0,1\}^*$, every $h \in H$, every $d \in \{1,\ldots,t_S(n)\}$, and every set of indices $S \subset \{1,\ldots,n\}$ so that $|S| > k$,*

$$\Pr_g\left[\mathsf{pot}-\mathsf{use}_d(\sigma,g,h)\ \&\ \left(\forall i \in S,\ \neg\mathsf{useful}_{d,i}(\sigma,g,h)\ \&\ \mathsf{accept}_{d,i}(\sigma,g,h)\right)\right] < (n^{-\left(\frac{1}{2}+\frac{1}{4k}\right)})^{|S|}.$$

Proof. Let $x \in \{0,1\}^*$. Fix some $\sigma \in \{0,1\}^*$, $h \in H$, $d \in \{1,\ldots,t_S(n)\}$, and a set $S \subset \{1,\ldots,n\}$. Denote by $\overline{bp}_d = \overline{bp}_d(g)$ the dth distinct block-prefix in $\text{EXEC}_x(\sigma,h,g)$ and by $\ell^{(\overline{bp}_d)}$ the index of its corresponding recursive block in the schedule. We bound the probability, taken over the choice of $g \xleftarrow{R} G$, that, for all $i \in S$, block-prefix $\overline{bp}_d$ is not i-useful even though it is potentially useful, and, for all $i \in S$, the query $\overline{q}^{(\overline{bp}_d)}$ contains an accepting conversation for session $(\ell^{(\overline{bp}_d)}, i)$.

A technical problem resolved. In order to prove Lemma 5.17, we need to focus on the dth distinct block-prefix in $\text{EXEC}_x(\sigma,h,g)$ (denoted by $\overline{bp}_d$) and analyze the behavior of a uniformly chosen g when applied to the various iteration-prefixes that correspond to $\overline{bp}_d$. However, in trying to do so we encounter a technical problem. This problem is caused by the fact that the contents of block-prefix $\overline{bp}_d$ depend on g.[34] In particular, it does not make sense to analyze the behavior of a uniformly chosen g on iteration-prefixes that correspond to an "undetermined" block-prefix (since it is not possible to determine the iteration-prefixes that correspond to $\overline{bp}_d$ when $\overline{bp}_d$ itself is not determined). To overcome the above problem, we rely on the following observations:

1. Whenever σ, h, and d are fixed, the content of block-prefix $\overline{bp}_d$ is completely determined by the output of g on inputs that have occurred *before* $\overline{bp}_d$ has been reached (i.e., has appeared as a block-prefix of some query) for the first time.
2. All iteration-prefixes that correspond to block-prefix $\overline{bp}_d$ occur *after* $\overline{bp}_d$ has been reached for the first time.

It is thus possible to carry out the analysis by considering the output of g only on inputs that have occurred *after* $\overline{bp}_d$ has been determined. That is, fixing σ, h, and d, we distinguish between: (a) the outputs of g that have occurred *before* the dth distinct block-prefix in $\text{EXEC}_x(\sigma,g,h)$ (i.e., $\overline{bp}_d$) has been reached and (b) the outputs of g that have occurred *after* $\overline{bp}_d$ has been reached. For every possible outcome of (a), we will analyze the (probabilistic) behavior of g only over the outcomes of (b). (Recall that once (a)'s outcome has been determined, the identities (but not the contents) of all relevant prefixes are well defined.) Since for *every* possible outcome of (a) the analysis will hold, it will particularly hold over all choices of g.

More formally, consider the following (alternative) way of describing a uniformly chosen $g \in G$ (at least as far as $\text{EXEC}_x(\sigma,g,h)$ is concerned). Let g_1, g_2 be two $t_S(n)$-wise independent hash functions uniformly chosen from G, and let σ, h, d be as above. We define $g^{(g_1,g_2)} = g^{(\sigma,h,d,g_1,g_2)}$ to be uniformly distributed among the functions g' that satisfy the following conditions: the value of g', when applied to an input α that has occurred *before* $\overline{bp}_d$ has been reached (in $\text{EXEC}_x(\sigma,g,h)$), is equal to $g_1(\alpha)$, whereas the value of g', when applied to an input α that has occurred *after* $\overline{bp}_d$ has been reached, is equal to $g_2(\alpha)$.

[34] Clearly, the contents of queries that appear in $\text{EXEC}_x(\sigma,g,h)$ may depend on the choice of the hash function g. (This is because the simulator may dynamically adapt its queries depending on the outcome of g on iteration-prefixes of past queries.) As a consequence, the contents of $\overline{bp}_d = \overline{bp}_d(g)$ may vary together with the choice of g.

Similarly to the proof of Claim 5.2, it can be shown that, for every σ, h, d as above, if g_1 and g_2 are uniformly distributed, then so is $g^{(g_1,g_2)}$. In particular,

$$\begin{aligned}\Pr_g\left[\mathsf{pot}-\mathsf{use}_d(\sigma,g,h)\ \&\ \left(\forall i\in S,\ \neg\mathsf{useful}_{d,i}(\sigma,g,h)\ \&\ \mathsf{accept}_{d,i}(\sigma,g,h)\right)\right]\\ =\Pr_{g_1,g_2}\left[\mathsf{pot}-\mathsf{use}_d(\sigma,g^{(g_1,g_2)},h)\ \&\ \left(\forall i\in S,\ \neg\mathsf{useful}_{d,i}(\sigma,g^{(g_1,g_2)},h)\right.\right.\\ \left.\left.\&\ \mathsf{accept}_{d,i}(\sigma,g^{(g_1,g_2)},h)\right)\right].\end{aligned}$$

By fixing g_1 and then analyzing the behavior of a uniformly chosen g_2 on the relevant iteration-prefixes, we resolve the above technical problem. This is due to the following two reasons: (1) For every choice of σ, h, d and for *every* fixed value of g_1, the block-prefix $\overline{bp}_d$ is completely determined (and the corresponding iteration-prefixes are well defined). (2) Once $\overline{bp}_d$ has been reached, the outcome of $g^{(g_1,g_2)}$, when applied to the *relevant* iteration-prefixes, is completely determined by the choice of g_2. Thus all we need to show in order to prove Lemma 5.17 is that, for *every* choice of g_1, the value of

$$\begin{aligned}\Pr_{g_2}\left[\mathsf{pot}-\mathsf{use}_d(\sigma,g^{(g_1,g_2)},h)\,\&\left(\forall i\in S,\ \neg\mathsf{useful}_{d,i}(\sigma,g^{(g_1,g_2)},h)\right.\right.\\ \left.\left.\&\ \mathsf{accept}_{d,i}(\sigma,g^{(g_1,g_2)},h)\right)\right]\end{aligned}\tag{5.10}$$

is upper bounded by $(n^{-(1/2+1/4k)})^{|S|}$.

Back to the actual proof of Lemma 5.17. Consider the block-prefix $\overline{bp}_d$, as determined by the choices of σ, h, d, and g_1, and focus on the iteration-prefixes that correspond to $\overline{bp}_d$ in $\text{EXEC}_x(\sigma, g, h)$. We next analyze the implications of $\overline{bp}_d$ being not i-useful, even though it is potentially useful, and, for all $i \in S$, query $\overline{q}^{(\overline{bp}_d)}$ contains an accepting conversation for session $(\ell^{(\overline{bp}_d)}, i)$.

Claim 5.18. *Let $\sigma \in \{0,1\}^*$, $g \in G$, $h \in H$, $d \in \{1,\ldots,t_S(n)\}$, and $S \subset \{1,\ldots,n\}$. Suppose that the indicator*

$$\left(\mathsf{pot}-\mathsf{use}_d(\sigma,g,h)\ \&\ (\forall i\in S,\neg\mathsf{useful}_{d,i}(\sigma,g,h)\ \&\ \mathsf{accept}_{d,i}(\sigma,g,h))\right)$$

is true. Then the following hold.

1. *The number of different iteration-prefixes that correspond to block-prefix $\overline{bp}_d$ is at most k^{c+1}.*
2. *For every $j \in \{2,\ldots,k+1\}$, there exists an iteration-prefix $\overline{ip}_j$ (corresponding to block-prefix $\overline{bp}_d$) so that, for every $i \in S$, we have $g(i, \overline{ip}_j) = 1$.*
3. *For every $i \in S$, there exists an (additional) iteration-prefix $\overline{ip}^{(i)}$ (corresponding to block-prefix $\overline{bp}_d$) so that, for every $j \in \{2,\ldots,k+1\}$, we have $\overline{ip}^{(i)} \neq \overline{ip}_j$, and $g(i, \overline{ip}^{(i)}) = 1$.*

In accordance with the discussion above, Claim 5.18 will be invoked with $g = g^{(g_1,g_2)}$.

Proof. Loosely speaking, item 1 follows directly from the hypothesis that block-prefix $\overline{bp}_d$ is potentially useful. In order to prove item 2, we also use the hypothesis that, for all $i \in S$, query $\overline{q}^{(\overline{bp}_d)}$ contains an accepting conversation for session $(\ell^{(\overline{bp}_d)}, i)$, and, in order to prove item 3, we additionally use the hypothesis that, for all $i \in S$, block-prefix $\overline{bp}_d$ is not i-useful. Details follow.

Proof of Item 1. The hypothesis that block-prefix $\overline{bp}_d$ is potentially useful (i.e., $\mathsf{pot}-\mathsf{use}_d(\sigma,g,h)$ holds) implies that the number of iteration-prefixes that correspond to block-prefix $\overline{bp}_d$ is at most k^{c+1} (as otherwise, the number of ip-different queries that correspond to $\overline{bp}_d$ would have been greater than k^{c+1}).

Proof of Item 2. Let $i \in S$, and recall that $\mathsf{accept}_{d,i}(\sigma,g,h)$ holds. In particular, we have that query $\overline{q}^{(\overline{bp}_d)}$ (i.e., the first query in $\text{EXEC}_x(\sigma,g,h)$ that ends with the $(k+1)$st prover message in the nth main session of recursive block number $\ell^{(\overline{bp}_d)}$) contains an accepting conversation for session $(\ell^{(\overline{bp}_d)},i)$. That is, no prover message in session $(\ell^{(\overline{bp}_d)},i)$ is answered with ABORT, and the last verifier message of this session equals ACCEPT. Since, by our conventions regarding the simulator, before making query $\overline{q}^{(\overline{bp}_d)}$, the simulator has made queries to all relevant prefixes, then it must be the case that all prefixes of query $\overline{q}^{(\overline{bp}_d)}$ have previously occurred as queries in $\text{EXEC}_x(\sigma,g,h)$. In particular, for every $i \in S$ and for every $j \in \{2,\ldots,k+1\}$, the execution of the simulator must contain a query $\overline{q}_{i,j}$ that is a prefix of $\overline{q}^{(\overline{bp}_d)}$ and that satisfies $bp(\overline{q}_{i,j}) = \overline{bp}_d$, $\pi_{\text{sn}}(\overline{q}_{i,j}) = (\ell^{(\overline{bp}_d)},i)$, $\pi_{\text{msg}}(\overline{q}_{i,j}) = j$, and $g(i,ip(\overline{q}_{i,j})) = 1$. (If $g(i,ip(\overline{q}_{i,j}))$ would have been equal to 0, query $\overline{q}^{(\overline{bp}_d)}$ would have contained a prover message in session $(\ell^{(\overline{bp}_d)},i)$ that is answered with ABORT, in contradiction to the fact that $\mathsf{accept}_{d,i}(\sigma,g,h)$ holds.) Since, for every $j \in \{2,\ldots,k+1\}$ and for every $i_1,i_2 \in S$, we have that $ip(\overline{q}_{i_1,j}) = ip(\overline{q}_{i_2,j})$ (as queries $\overline{q}_{i,j}$ are all prefixes of $\overline{q}_\ell$ and $|ip(\overline{q}_{i_1,j})| = |ip(\overline{q}_{i_2,j})|$), we can set $\overline{ip}_j = ip(\overline{q}_{i,j})$. It follows that, for every $j \in \{2,\ldots,k+1\}$, iteration-prefix $\overline{ip}_j$ corresponds to block-prefix $\overline{bp}_d$ (as queries $\overline{q}_{i,j}$ all have block-prefix $\overline{bp}_d$), and, for every $i \in S$, we have that $g(i,\overline{ip}_j) = 1$.

Proof of Item 3. Let $i \in S$, and recall that, in addition to the fact that $\mathsf{accept}_{d,i}(\sigma,g,h)$ holds, we have that $\mathsf{useful}_{d,i}(\sigma,g,h)$ does not hold. Notice that the only reason for which $\mathsf{useful}_{d,i}(\sigma,g,h)$ can be false (i.e., the dth block-prefix is not i-useful), is that condition 1 in Definition 5.4 is violated by $\text{EXEC}_x(\sigma,g,h)$. (Recall that $\mathsf{accept}_{d,i}(\sigma,g,h)$ holds, and so condition 2 in Definition 5.4 is indeed satisfied by query $\overline{q}_{i,k+1}$ (as defined above). This query corresponds to block-prefix $\overline{bp}_d$, satisfies $\pi_{\text{sn}}(\overline{q}_{i,k+1}) = (\ell^{(\overline{bp}_d)},i)$, $\pi_{\text{msg}}(\overline{q}_{i,k+1}) = k+1$, and $g(i,ip(\overline{q}_{i,k+1})) = 1$, and is answered with ACCEPT.)

For condition 1 in Definition 5.4 to be violated, there must exist a $j \in \{2,\ldots,k+1\}$, with two ip-different queries, $\overline{q}_1$ and $\overline{q}_2$, that correspond to block-prefix $\overline{bp}_d$ and satisfy $\pi_{\text{sn}}(\overline{q}_1) = \pi_{\text{sn}}(\overline{q}_2) = (\ell^{(\overline{bp}_d)},i)$, $\pi_{\text{msg}}(\overline{q}_1) = \pi_{\text{msg}}(\overline{q}_2) = j$, and $g(i,ip(\overline{q}_1)) = g(i,ip(\overline{q}_2)) = 1$. Since, by definition, two queries are considered ip-different only if they differ in their iteration-prefixes, we have that there exist two different iteration-prefixes $\overline{ip}(\overline{q}_1)$ and $\overline{ip}(\overline{q}_2)$ (of the same length) that correspond to block-prefix $\overline{bp}_d$ and satisfy $g(i,\overline{ip}(\overline{q}_1)) = g(i,\overline{ip}(\overline{q}_2)) = 1$. Since iteration-prefixes $\overline{ip}_2,\ldots,\overline{ip}_{k+1}$ (from item 2 above) are all of distinct length, and since the only iteration-prefix in $\overline{ip}_2,\ldots,\overline{ip}_{k+1}$ that can be equal to either $\overline{ip}(\overline{q}_1)$ or $\overline{ip}(\overline{q}_2)$ is $\overline{ip}_j$ (note that this is the only iteration-prefix having the same length as $\overline{ip}(\overline{q}_1)$ and $\overline{ip}(\overline{q}_2)$), then it must be the case that at least one of $\overline{ip}(\overline{q}_1),\overline{ip}(\overline{q}_2)$ is different from all of $\overline{ip}_2,\ldots,\overline{ip}_{k+1}$. (Recall that $\overline{ip}(\overline{q}_1)$ and $\overline{ip}(\overline{q}_2)$ are different, which means

that they cannot both be equal to $\overline{ip}_j$.) In particular, for every $i \in S$ (that satisfies $\mathsf{useful}_{d,i}(\sigma, g, h)$ & $\mathsf{accept}_{d,i}(\sigma, g, h)$), there exists at least one (extra) iteration-prefix, $\overline{ip}^{(i)} \in \{\overline{ip}(\overline{q}_1), \overline{ip}(\overline{q}_2)\}$ that corresponds to block-prefix $\overline{bp}_d$, differs from $\overline{ip}_j$ for every $j \in \{2, \ldots, k+1\}$, and satisfies $g_2(i, \overline{ip}^{(i)}) = 1$.

This completes the proof of Claim 5.18. □

Recall that the hash function g_2 is chosen at random from a $t_S(n)$-wise independent family. Since, for every pair of different iteration-prefixes, the function g_2 will have different inputs, g_2 will have independent outputs when applied to different iteration-prefixes (since no more than $t_S(n)$ queries are made by the simulator). Similarly, for every pair of different $i, i' \in S$, g_2 will have different input and thus independent output. In other words, all outcomes of g_2 that are relevant to block-prefix $\overline{bp}_d$ are independent of each other. Since a uniformly chosen g_2 will output 1 with probability $n^{-1/2k}$, we may view every application of g_2 on iteration-prefixes that correspond to $\overline{bp}_d$ as an independently executed experiment that succeeds with probability $n^{-1/2k}$.[35]

Using item 1 of Claim 5.18, the applications of g_2 which are relevant to sessions $\{(\ell^{(\overline{bp}_d)}, i)\}_{i \in S}$ can be viewed as a sequence of at most k^{c+1} experiments (corresponding to at most k^{c+1} different iteration-prefixes). Each of these experiments consists of $|S|$ independent subexperiments (corresponding to the different $i \in S$), and each subexperiment succeeds with probability $n^{-1/2k}$. Item 2 of Claim 5.18 now implies that at least k of the above experiments will fully succeed (that is, all of their subexperiments will succeed), while item 3 implies that, for every $i \in S$, there exists an additional successful subexperiment (that is, a subexperiment of one of the $k^{c+1} - k$ remaining experiments). Using the fact that the probability that a subexperiment succeeds is $n^{-1/2k}$, we infer that the probability that an experiment fully succeeds is equal to $(n^{-1/2k})^{|S|}$. In particular, the probability in (5.10) is upper bounded by the probability that the following two events occur (these events correspond to items 2 and 3 of Claims 5.18, respectively):

Event 1. *In a sequence of* (*at most* k^{c+1}) *experiments, each succeeding with probability* $(n^{-1/2k})^{|S|}$, *there exist* k *successful experiments.* (The success probability corresponds to the probability that, for every $i \in S$, we have $g_2(i, \overline{ip}_j) = 1$ (see item 2 of Claim 5.18).)

Event 2. *For every one out of* $|S|$ *sequences of the remaining* (*at most* $k^{c+1} - k$) *subexperiments, each succeeding with probability* $n^{-1/2k}$, *there exists at least one successful experiment.* (In this case, the success probability corresponds to the probability that iteration-prefix $\overline{ip}^{(i)}$ satisfies $g_2(i, \overline{ip}^{(i)}) = 1$ (see item 3 of Claim 5.18).)

For $i \in |S|$ and $j \in [k^{c+1}]$, let us denote the success of the ith subexperiment in the jth experiment by $\chi_{i,j}$. By the above discussion for every i, j, the probability that $\chi_{i,j}$ holds is $n^{-1/2k}$ (independently of other $\chi_{i,j}$'s). We now have that, for Event 1 to succeed, there must exist a set of k experiments, $K \subseteq [k^{c+1}]$, so that, for all $(i, j) \in S \times K$, the event $\chi_{i,j}$ holds. For Event 2 to succeed, it must be the case that, for every $i \in S$, there exists one additional experiment (i.e., some $j \in [k^{c+1}] \setminus K$) so

[35] We may describe the process of picking $g_2 \xleftarrow{R} G$ as the process of independently letting the output of g_2 be equal to 1 with probability $n^{-1/2k}$ (each time a new input is introduced). Note that we will be doing so only for inputs that occur after block-prefix $\overline{bp}_d$ has been determined (as, in the above case, all inputs for g_2 are iteration-prefixes that correspond to block-prefix $\overline{bp}_d$, and such iteration-prefixes will occur only after $\overline{bp}_d$ has already been determined).

that $\chi_{i,j}$ holds. It follows that (5.10) is upper bounded by

$$\begin{aligned}
&\sum_{\substack{K\subseteq[k^{c+1}]\\|K|=k}} \Pr\left[\forall j\in K,\ \forall i\in S\ \text{ s.t. }\ \chi_{i,j}\right]\cdot\Pr\left[\forall i\in S,\ \exists j\in[k^{c+1}]\setminus K\ \text{ s.t. }\ \chi_{i,j}\right]\\
&\quad=\binom{k^{c+1}}{k}\cdot\left(\left(n^{-\frac{1}{2k}}\right)^{|S|}\right)^{k}\cdot\left(1-\left(1-n^{-\frac{1}{2k}}\right)^{k^{c+1}-k}\right)^{|S|}\\
&\quad<\left(k^{c+1}\right)^{k}\cdot\left(\left(n^{-\frac{1}{2k}}\right)^{|S|}\right)^{k}\cdot\left(k^{c+1}\cdot n^{-\frac{1}{2k}}\right)^{|S|} \qquad (5.11)\\
&\quad=\left(k^{c+1}\right)^{k+|S|}\cdot\left(n^{-\frac{1}{2k}}\right)^{k\cdot|S|+|S|}\\
&\quad=\left(k^{c+1}\right)^{k+|S|}\cdot\left(n^{-\frac{1}{4k}}\right)^{|S|}\left(n^{-\left(\frac{1}{2}+\frac{1}{4k}\right)}\right)^{|S|}\\
&\quad<\left(n^{-\left(\frac{1}{2}+\frac{1}{4k}\right)}\right)^{|S|}, \qquad (5.12)
\end{aligned}$$

where (5.11) holds whenever $k^{c+1}-k=o(n^{1/2k})$ (which is satisfied if $k=o(\frac{\log n}{\log\log n})$) and (5.12) holds whenever $(k^{c+1})^{k+|S|}\cdot(n^{-1/4k})^{|S|}<1$ (which is satisfied if both $|S|>k$ and $k=o(\frac{\log n}{\log\log n})$). This means that (5.10) is upper bounded by $(n^{-(1/2+1/4k)})^{|S|}$, and the proof of Lemma 5.17 is complete. □

Using Lemma 5.17, we upper bound (5.9) by

$$\begin{aligned}
t_S(n)\cdot\binom{n}{\frac{n^{1/2}}{4}}\cdot\left(n^{-\left(\frac{1}{2}+\frac{1}{4k}\right)}\right)^{\frac{n^{1/2}}{4}} &< t_S(n)\cdot\left(\frac{4\cdot e\cdot n}{n^{1/2}}\right)^{\frac{n^{1/2}}{4}}\cdot\left(n^{-\left(\frac{1}{2}+\frac{1}{4k}\right)}\right)^{\frac{n^{1/2}}{4}}\\
&= t_S(n)\cdot\left(\frac{4\cdot e}{n^{1/4k}}\right)^{\frac{n^{1/2}}{4}}\\
&< t_S(n)\cdot 2^{-\frac{n^{1/2}}{4}}, \qquad (5.13)
\end{aligned}$$

where inequality (5.13) holds whenever $8\cdot e<n^{1/4k}$ (which holds for $k<\frac{\log n}{4\cdot(3+\log e)}$). This completes the proof of Lemma 5.7 (since $\mathrm{poly}(n)\cdot 2^{-\Omega(n^{1/2})}$ is negligible).

Appendix A. Alternative description of the recursive schedule. The schedule consists of n^2 sessions. (Each session consists of $k+1$ prover messages and $k+1$ verifier messages.) It is defined recursively, where, for each $m\le n^2$, the schedule for sessions $i_1,\ldots,i_m$ (denoted $\mathcal{R}_{i_1,\ldots,i_m}$) proceeds as follows:

1. If $m\le n$, execute sessions $i_1,\ldots,i_m$ sequentially until they are all completed;
2. otherwise, for $j=1,\ldots,k+1$:
   (a) for $\ell=1,\ldots,n$:
      i. send the jth verifier message in session i_ℓ (i.e., $\mathtt{v}_j^{(i_\ell)}$);
      ii. send the jth prover message in session i_ℓ (i.e., $\mathtt{p}_j^{(i_\ell)}$);
   (b) if $j<k+1$, invoke a recursive copy of $\mathcal{R}_{i_{(n+(j-1)\cdot t+1)},\ldots,i_{(n+j\cdot t)}}$ (where $t\stackrel{\text{def}}{=}\lfloor\frac{m-n}{k}\rfloor$);
   (sessions $i_{(n+(j-1)\cdot t+1)},\ldots,i_{(n+j\cdot t)}$ are the next t remaining sessions out of $i_1,\ldots,i_m$).

Appendix B. Solving the recursion.

CLAIM B.1. *Suppose that* (5.5) *holds. Then, for all sufficiently large* n, $W(n^2) > n^c$.

Proof. By applying (5.5) iteratively $\log_k(n-1)$ times, we get

$$\begin{aligned} W(n^2) &\geq \left(k^{c+1}\right)^{\log_k(n-1)} \cdot W(n) \\ &\geq \left(k^{c+1}\right)^{\log_k(n-1)} \cdot 1 \\ &= (n-1)^{c+1} \\ &> n^c, \qquad \text{(B.1)} \end{aligned}$$

where (B.1) holds for all sufficiently large n. ∎

Acknowledgment. We are indebted to Oded Goldreich for his devoted help and technical contribution to this project.

THE NONSTOCHASTIC MULTIARMED BANDIT PROBLEM*

PETER AUER†, NICOLÒ CESA-BIANCHI‡, YOAV FREUND§, AND ROBERT E. SCHAPIRE¶

Abstract. In the multiarmed bandit problem, a gambler must decide which arm of K nonidentical slot machines to play in a sequence of trials so as to maximize his reward. This classical problem has received much attention because of the simple model it provides of the trade-off between exploration (trying out each arm to find the best one) and exploitation (playing the arm believed to give the best payoff). Past solutions for the bandit problem have almost always relied on assumptions about the statistics of the slot machines.

In this work, we make no statistical assumptions whatsoever about the nature of the process generating the payoffs of the slot machines. We give a solution to the bandit problem in which an adversary, rather than a well-behaved stochastic process, has complete control over the payoffs. In a sequence of T plays, we prove that the per-round payoff of our algorithm approaches that of the best arm at the rate $O(T^{-1/2})$. We show by a matching lower bound that this is the best possible.

We also prove that our algorithm approaches the per-round payoff of *any* set of strategies at a similar rate: if the best strategy is chosen from a pool of N strategies, then our algorithm approaches the per-round payoff of the strategy at the rate $O((\log N)^{1/2}T^{-1/2})$. Finally, we apply our results to the problem of playing an unknown repeated matrix game. We show that our algorithm approaches the minimax payoff of the unknown game at the rate $O(T^{-1/2})$.

Key words. adversarial bandit problem, unknown matrix games

1. Introduction.

In the multiarmed bandit problem, originally proposed by Robbins [17], a gambler must choose which of K slot machines to play. At each time step, he pulls the arm of one of the machines and receives a reward or payoff (possibly zero or negative). The gambler's purpose is to maximize his return, i.e., the sum of the rewards he receives over a sequence of pulls. In this model, each arm is assumed to deliver rewards that are independently drawn from a fixed and unknown distribution. As reward distributions differ from arm to arm, the goal is to find the arm with the highest expected payoff as early as possible and then to keep gambling using that best arm.

The problem is a paradigmatic example of the trade-off between exploration and exploitation. On the one hand, if the gambler plays exclusively on the machine that he thinks is best ("exploitation"), he may fail to discover that one of the other arms actually has a higher expected payoff. On the other hand, if he spends too much time

trying out all the machines and gathering statistics ("exploration"), he may fail to play the best arm often enough to get a high return.

The gambler's performance is typically measured in terms of "regret." This is the difference between the expected return of the optimal strategy (pulling consistently the best arm) and the gambler's expected return. Lai and Robbins proved that the gambler's regret over T pulls can be made, for $T \to \infty$, as small as $O(\ln T)$. Furthermore, they prove that this bound is optimal in the following sense: there is no strategy for the gambler with a better asymptotic performance.

Though this formulation of the bandit problem allows an elegant statistical treatment of the exploration-exploitation trade-off, it may not be adequate to model certain environments. As a motivating example, consider the task of repeatedly choosing a route for transmitting packets between two points in a communication network. To cast this scenario within the bandit problem, suppose there is a only a fixed number of possible routes and the transmission cost is reported back to the sender. Now, it is likely that the costs associated with each route cannot be modeled by a stationary distribution, so a more sophisticated set of statistical assumptions would be required. In general, it may be difficult or impossible to determine the right statistical assumptions for a given domain, and some domains may exhibit dependencies to an extent that no such assumptions are appropriate.

To provide a framework where one could model scenarios like the one sketched above, we present the adversarial bandit problem, a variant of the bandit problem in which *no* statistical assumptions are made about the generation of rewards. We assume only that each slot machine is initially assigned an arbitrary and unknown sequence of rewards, one for each time step, chosen from a bounded real interval. Each time the gambler pulls the arm of a slot machine, he receives the corresponding reward from the sequence assigned to that slot machine. To measure the gambler's performance in this setting we replace the notion of (statistical) regret with that of worst-case regret. Given any sequence $(j_1, \ldots, j_T)$ of pulls, where $T > 0$ is an arbitrary time horizon and each j_t is the index of an arm, the worst-case regret of a gambler for this sequence of pulls is the difference between the return the gambler would have had by pulling arms $j_1, \ldots, j_T$ and the actual gambler's return, where both returns are determined by the initial assignment of rewards. It is easy to see that, in this model, the gambler cannot keep his regret small (say, sublinear in T) for *all* sequences of pulls and with respect to the worst-case assignment of rewards to the arms. Thus, to make the problem feasible, we allow the regret to depend on the "hardness" of the sequence of pulls for which it is measured, where the hardness of a sequence is roughly the number of times one has to change the slot machine currently being played in order to pull the arms in the order given by the sequence. This trick allows us to effectively control the worst-case regret *simultaneously* for all sequences of pulls, even though (as one should expect) our regret bounds become trivial when the hardness of the sequence $(j_1, \ldots, j_T)$ we compete against gets too close to T.

As a remark, note that a deterministic bandit problem was also considered by Gittins [9] and Ishikida and Varaiya [13]. However, their version of the bandit problem is very different from ours: they assume that the player can compute ahead of time exactly what payoffs will be received from each arm, and their problem is thus one of optimization, rather than exploration and exploitation.

Our most general result is a very efficient, randomized player algorithm whose expected regret for any sequence of pulls is[1] $O(S\sqrt{KT\ln(KT)})$, where S is the hardness

[1]Though in this introduction we use the compact asymptotic notation, our bounds are proven for each finite T and almost always with explicit constants.

of the sequence (see Theorem 8.1 and Corollaries 8.2, 8.4). Note that this bound holds simultaneously for all sequences of pulls, for any assignments of rewards to the arms, and uniformly over the time horizon T. If the gambler is willing to impose an upper bound S on the hardness of the sequences of pulls for which he wants to measure his regret, an improved bound $O(\sqrt{SKT\ln(KT)})$ on the expected regret for these sequences can be proven (see Corollaries 8.3 and 8.5).

With the purpose of establishing connections with certain results in game theory, we also look at a special case of the worst-case regret, which we call "weak regret." Given a time horizon T, call "best arm" the arm that has the highest return (sum of assigned rewards) up to time T with respect to the initial assignment of rewards. The gambler's weak regret is the difference between the return of this best arm and the actual gambler's return. In the paper we introduce a randomized player algorithm, tailored to this notion of regret, whose expected weak regret is $O(\sqrt{KG_{\max}\ln K})$, where $G_{\max}$ is the return of the best arm—see Theorem 4.1 in section 4. As before, this bound holds for any assignments of rewards to the arms and uniformly over the choice of the time horizon T. Using a more complex player algorithm, we also prove that the weak regret is $O(\sqrt{KT\ln(KT/\delta)})$ with probability at least $1-\delta$ over the algorithm's randomization, for any fixed $\delta > 0$; see Theorems 6.3 and 6.4 in section 6. This also implies that, asymptotically for $T \to \infty$ and K constant, the weak regret is $O(\sqrt{T(\ln T)^{1+\varepsilon}})$ with probability 1 for any fixed $\varepsilon > 0$; see Corollary 6.5.

Our worst-case bounds may appear weaker than the bounds proved using statistical assumptions, such as those shown by Lai and Robbins [14] of the form $O(\ln T)$. However, when comparing our results to those in the statistics literature, it is important to point out an important difference in the asymptotic quantification. In the work of Lai and Robbins, the assumption is that the distribution of rewards that is associated with each arm is *fixed* as the total number of iterations T increases to infinity. In contrast, our bounds hold for any finite T, and, by the generality of our model, these bounds are applicable when the payoffs are randomly (or adversarially) chosen in a manner that does depend on T. It is this quantification order, and not the adversarial nature of our framework, which is the cause for the apparent gap. We prove this point in Theorem 5.1, where we show that, for *any* player algorithm for the K-armed bandit problem and for any T, there exists a set of K reward distributions such that the expected weak regret of the algorithm when playing on these arms for T time steps is $\Omega(\sqrt{KT})$.

So far we have considered notions of regret that compare the return of the gambler to the return of a sequence of pulls or to the return of the best arm. A further notion of regret which we explore is the regret for the best strategy in a given set of strategies that are available to the gambler. The notion of "strategy" generalizes that of "sequence of pulls": at each time step a strategy gives a recommendation, in the form of a probability distribution over the K arms, as to which arm to play next. Given an assignment of rewards to the arms and a set of N strategies for the gambler, call "best strategy" the strategy that yields the highest return with respect to this assignment. Then the regret for the best strategy is the difference between the return of this best strategy and the actual gambler's return. Using a randomized player that combines the choices of the N strategies (in the same vein as the algorithms for "prediction with expert advice" from [3]), we show that the expected regret for the best strategy is $O(\sqrt{KT\ln N})$—see Theorem 7.1. Note that the dependence on the number of strategies is only logarithmic, and therefore the bound is quite reasonable even when the player is combining a very large number of strategies.

The adversarial bandit problem is closely related to the problem of learning to

play an unknown N-person finite game, where the same game is played repeatedly by N players. A desirable property for a player is Hannan-consistency, which is similar to saying (in our bandit framework) that the weak regret per time step of the player converges to 0 with probability 1. Examples of Hannan-consistent player strategies have been provided by several authors in the past (see [5] for a survey of these results). By applying (slight extensions of) Theorems 6.3 and 6.4, we can provide an example of a simple Hannan-consistent player whose convergence rate is optimal up to logarithmic factors.

Our player algorithms are based in part on an algorithm presented by Freund and Schapire [6, 7], which in turn is a variant of Littlestone and Warmuth's [15] weighted majority algorithm and Vovk's [18] aggregating strategies. In the setting analyzed by Freund and Schapire, the player scores on each pull the reward of the chosen arm but gains access to the rewards associated with *all* of the arms (not just the one that was chosen).

2. Notation and terminology. An *adversarial bandit problem* is specified by the number K of possible actions, where each action is denoted by an integer $1 \leq i \leq K$, and by an *assignment of rewards*, i.e., an infinite sequence $\boldsymbol{x}(1), \boldsymbol{x}(2), \ldots$ of vectors $\boldsymbol{x}(t) = (x_1(t), \ldots, x_K(t))$, where $x_i(t) \in [0,1]$ denotes the reward obtained if action i is chosen at time step (also called "trial") t. (Even though throughout the paper we will assume that all rewards belong to the $[0,1]$ interval, the generalization of our results to rewards in $[a,b]$ for arbitrary $a < b$ is straightforward.) We assume that the player knows the number K of actions. Furthermore, after each trial t, we assume the player knows only the rewards $x_{i_1}(1), \ldots, x_{i_t}(t)$ of the previously chosen actions $i_1, \ldots, i_t$. In this respect, we can view the player algorithm as a sequence $I_1, I_2, \ldots$, where each I_t is a mapping from the set $(\{1, \ldots, K\} \times [0,1])^{t-1}$ of action indices and previous rewards to the set of action indices.

For any reward assignment and for any $T > 0$, let

$$G_A(T) \stackrel{\text{def}}{=} \sum_{t=1}^{T} x_{i_t}(t)$$

be the *return at time horizon* T of algorithm A choosing actions $i_1, i_2, \ldots$. In what follows, we will write G_A instead of $G_A(T)$ whenever the value of T is clear from the context.

Our measure of performance for a player algorithm is the *worst-case regret*, and in this paper we explore variants of the notion of regret. Given any time horizon $T > 0$ and any sequence of actions $(j_1, \ldots, j_T)$, the (worst-case) regret of algorithm A for $(j_1, \ldots, j_T)$ is the difference

$$G_{(j_1,\ldots,j_T)} - G_A(T), \tag{1}$$

where

$$G_{(j_1,\ldots,j_T)} \stackrel{\text{def}}{=} \sum_{t=1}^{T} x_{j_t}(t)$$

is the return, at time horizon T, obtained by choosing actions $j_1, \ldots, j_T$. Hence, the regret (1) measures how much the player lost (or gained, depending on the sign of the difference) by following strategy A instead of choosing actions $j_1, \ldots, j_T$. A special

case of this is the regret of A for the best single action (which we will call *weak regret* for short), defined by

$$G_{\max}(T) - G_A(T),$$

where

$$G_{\max}(T) \stackrel{\text{def}}{=} \max_j \sum_{t=1}^{T} x_j(t)$$

is the return of the single globally best action at time horizon T. As before, we will write $G_{\max}$ instead of $G_{\max}(T)$ whenever the value of T is clear from the context.

As our player algorithms will be randomized, fixing a player algorithm defines a probability distribution over the set of all sequences of actions. All the probabilities $\mathbf{P}\{\cdot\}$ and expectations $\mathbf{E}[\cdot]$ considered in this paper will be taken with respect to this distribution.

In what follows, we will prove two kinds of bounds on the performance of a (randomized) player A. The first is a bound on the *expected regret*

$$G_{(j_1,\ldots,j_T)} - \mathbf{E}\left[G_A(T)\right]$$

of A for an arbitrary sequence $(j_1, \ldots, j_T)$ of actions. The second is a confidence bound on the weak regret. This has the form

$$\mathbf{P}\left\{G_{\max}(T) > G_A(T) + \varepsilon\right\} \leq \delta$$

and states that, with high probability, the return of A up to time T is not much smaller than that of the globally best action.

Finally, we remark that all of our bounds hold for *any* sequence $\boldsymbol{x}(1), \boldsymbol{x}(2), \ldots$ of reward assignments, and most of them hold *uniformly* over the time horizon T (i.e., they hold for all T without requiring T as input parameter).

3. Upper bounds on the weak regret. In this section we present and analyze our simplest player algorithm, **Exp3** (which stands for "exponential-weight algorithm for exploration and exploitation"). We will show a bound on the expected regret of **Exp3** with respect to the single best action. In the next sections, we will greatly strengthen this result.

The algorithm **Exp3**, described in Figure 1, is a variant of the algorithm **Hedge** introduced by Freund and Schapire [6] for solving a different worst-case sequential allocation problem. On each time step t, **Exp3** draws an action i_t according to the distribution $p_1(t), \ldots, p_K(t)$. This distribution is a mixture of the uniform distribution and a distribution which assigns to each action a probability mass exponential in the estimated cumulative reward for that action. Intuitively, mixing in the uniform distribution is done to make sure that the algorithm tries out all K actions and gets good estimates of the rewards for each. Otherwise, the algorithm might miss a good action because the initial rewards it observes for this action are low and large rewards that occur later are not observed because the action is not selected.

For the drawn action i_t, **Exp3** sets the estimated reward $\hat{x}_{i_t}(t)$ to $x_{i_t}(t)/p_{i_t}(t)$. Dividing the actual gain by the probability that the action was chosen compensates the reward of actions that are unlikely to be chosen. This choice of estimated rewards guarantees that their expectations are equal to the actual rewards for each action; that is, $\mathbf{E}[\hat{x}_j(t) \mid i_1, \ldots, i_{t-1}] = x_j(t)$, where the expectation is taken with respect to

Algorithm Exp3
Parameters: Real $\gamma \in (0,1]$.
Initialization: $w_i(1) = 1$ for $i = 1, \dots, K$.

For each $t = 1, 2, \dots$

1. Set
$$p_i(t) = (1-\gamma)\frac{w_i(t)}{\sum_{j=1}^{K} w_j(t)} + \frac{\gamma}{K} \qquad i = 1, \dots, K.$$
2. Draw i_t randomly accordingly to the probabilities $p_1(t), \dots, p_K(t)$.
3. Receive reward $x_{i_t}(t) \in [0,1]$.
4. For $j = 1, \dots, K$ set
$$\hat{x}_j(t) = \begin{cases} x_j(t)/p_j(t) & \text{if } j = i_t, \\ 0 & \text{otherwise,} \end{cases}$$
$$w_j(t+1) = w_j(t) \exp\left(\gamma \hat{x}_j(t)/K\right) .$$

FIG. 1. *Pseudocode of algorithm* **Exp3** *for the weak regret.*

the random choice of i_t at trial t given the choices $i_1, \dots, i_{t-1}$ in the previous $t-1$ trials.

We now give the first main theorem of this paper, which bounds the expected weak regret of algorithm **Exp3**.

THEOREM 3.1. *For any $K > 0$ and for any $\gamma \in (0,1]$,*

$$G_{\max} - \mathbf{E}[G_{\mathbf{Exp3}}] \le (e-1)\gamma G_{\max} + \frac{K \ln K}{\gamma}$$

holds for any assignment of rewards and for any $T > 0$.

To understand this theorem, it is helpful to consider a simpler bound which can be obtained by an appropriate choice of the parameter γ.

COROLLARY 3.2. *For any $T > 0$, assume that $g \ge G_{\max}$ and that algorithm* **Exp3** *is run with input parameter*

$$\gamma = \min\left\{1, \sqrt{\frac{K \ln K}{(e-1)g}}\right\}.$$

Then

$$G_{\max} - \mathbf{E}[G_{\mathbf{Exp3}}] \le 2\sqrt{e-1}\sqrt{gK \ln K} \le 2.63\sqrt{gK \ln K}$$

holds for any assignment of rewards.

Proof. If $g \le (K \ln K)/(e-1)$, then the bound is trivial since the expected regret cannot be more than g. Otherwise, by Theorem 3.1, the expected regret is at most

$$(e-1)\gamma G_{\max} + \frac{K \ln K}{\gamma} \le 2\sqrt{e-1}\sqrt{gK \ln K},$$

as desired. □

To apply Corollary 3.2, it is necessary that an upper bound g on $G_{\max}(T)$ be available for tuning γ. For example, if the time horizon T is known, then, since no action can have payoff greater than 1 on any trial, we can use $g = T$ as an upper bound. In section 4, we give a technique that does not require prior knowledge of such an upper bound, yielding a result which uniformly holds over T.

If the rewards $x_i(t)$ are in the range $[a, b]$, $a < b$, then **Exp3** can be used after the rewards have been translated and rescaled to the range $[0, 1]$. Applying Corollary 3.2 with $g = T$ gives the bound $(b-a)2\sqrt{e-1}\sqrt{TK \ln K}$ on the regret. For instance, this is applicable to a standard loss model where the "rewards" fall in the range $[-1, 0]$.

Proof of Theorem 3.1. The theorem is clearly true for $\gamma = 1$, so assume $0 < \gamma < 1$. Here (and also throughout the paper without explicit mention) we use the following simple facts, which are immediately derived from the definitions:

$$\hat{x}_i(t) \le 1/p_i(t) \le K/\gamma, \tag{2}$$

$$\sum_{i=1}^{K} p_i(t)\hat{x}_i(t) = p_{i_t}(t)\frac{x_{i_t}(t)}{p_{i_t}(t)} = x_{i_t}(t), \tag{3}$$

$$\sum_{i=1}^{K} p_i(t)\hat{x}_i(t)^2 = p_{i_t}(t)\frac{x_{i_t}(t)}{p_{i_t}(t)}\hat{x}_{i_t}(t) \le \hat{x}_{i_t}(t) = \sum_{i=1}^{K} \hat{x}_i(t). \tag{4}$$

Let $W_t = w_1(t) + \cdots + w_K(t)$. For all sequences $i_1, \ldots, i_T$ of actions drawn by **Exp3**,

$$\begin{aligned}
\frac{W_{t+1}}{W_t} &= \sum_{i=1}^{K} \frac{w_i(t+1)}{W_t} \\
&= \sum_{i=1}^{K} \frac{w_i(t)}{W_t} \exp\left(\frac{\gamma}{K}\hat{x}_i(t)\right) \\
&= \sum_{i=1}^{K} \frac{p_i(t) - \frac{\gamma}{K}}{1-\gamma} \exp\left(\frac{\gamma}{K}\hat{x}_i(t)\right) && (5) \\
&\le \sum_{i=1}^{K} \frac{p_i(t) - \frac{\gamma}{K}}{1-\gamma} \left[1 + \frac{\gamma}{K}\hat{x}_i(t) + (e-2)\left(\frac{\gamma}{K}\hat{x}_i(t)\right)^2\right] && (6) \\
&\le 1 + \frac{\frac{\gamma}{K}}{1-\gamma}\sum_{i=1}^{K} p_i(t)\hat{x}_i(t) + \frac{(e-2)(\frac{\gamma}{K})^2}{1-\gamma}\sum_{i=1}^{K} p_i(t)\hat{x}_i(t)^2 && (7) \\
&\le 1 + \frac{\frac{\gamma}{K}}{1-\gamma}x_{i_t}(t) + \frac{(e-2)(\frac{\gamma}{K})^2}{1-\gamma}\sum_{i=1}^{K} \hat{x}_i(t). && (8)
\end{aligned}$$

Equation (5) uses the definition of $p_i(t)$ in Figure 1. Equation (6) uses the fact that $e^x \le 1 + x + (e-2)x^2$ for $x \le 1$; the expression in the preceding line is at most 1 by (2). Equation (8) uses (3) and (4). Taking logarithms and using $1 + x \le e^x$ gives

$$\ln \frac{W_{t+1}}{W_t} \le \frac{\frac{\gamma}{K}}{1-\gamma}x_{i_t}(t) + \frac{(e-2)(\frac{\gamma}{K})^2}{1-\gamma}\sum_{i=1}^{K} \hat{x}_i(t).$$

Summing over t we then get

$$\ln \frac{W_{T+1}}{W_1} \le \frac{\frac{\gamma}{K}}{1-\gamma}G_{\mathbf{Exp3}} + \frac{(e-2)(\frac{\gamma}{K})^2}{1-\gamma}\sum_{t=1}^{T}\sum_{i=1}^{K} \hat{x}_i(t)\ . \tag{9}$$

For any action j,

$$\ln \frac{W_{T+1}}{W_1} \geq \ln \frac{w_j(T+1)}{W_1} = \frac{\gamma}{K} \sum_{t=1}^{T} \hat{x}_j(t) - \ln K.$$

Combining this with (9), we get

$$G_{\mathbf{Exp3}} \geq (1-\gamma) \sum_{t=1}^{T} \hat{x}_j(t) - \frac{K \ln K}{\gamma} - (e-2) \frac{\gamma}{K} \sum_{t=1}^{T} \sum_{i=1}^{K} \hat{x}_i(t) \ . \tag{10}$$

We next take the expectation of both sides of (10) with respect to the distribution of $\langle i_1, \ldots, i_T \rangle$. For the expected value of each $\hat{x}_i(t)$, we have

$$\mathbf{E}[\hat{x}_i(t) \mid i_1, \ldots, i_{t-1}] = \mathbf{E}\left[p_i(t) \cdot \frac{x_i(t)}{p_i(t)} + (1 - p_i(t)) \cdot 0 \right] = x_i(t) \ . \tag{11}$$

Combining (10) and (11), we find that

$$\mathbf{E}[G_{\mathbf{Exp3}}] \geq (1-\gamma) \sum_{t=1}^{T} x_j(t) - \frac{K \ln K}{\gamma} - (e-2) \frac{\gamma}{K} \sum_{t=1}^{T} \sum_{i=1}^{K} x_i(t) \ .$$

Since j was chosen arbitrarily and

$$\sum_{t=1}^{T} \sum_{i=1}^{K} x_i(t) \leq K \, G_{\max},$$

we obtain the inequality in the statement of the theorem. □

Additional notation. As our other player algorithms will be variants of **Exp3**, we find it convenient to define some further notation based on the quantities used in the analysis of **Exp3**.

For each $1 \leq i \leq K$ and for each $t \geq 1$, define

$$G_i(t+1) \stackrel{\text{def}}{=} \sum_{s=1}^{t} x_i(s),$$

$$\hat{G}_i(t+1) \stackrel{\text{def}}{=} \sum_{s=1}^{t} \hat{x}_i(s),$$

$$\hat{G}_{\max}(t+1) \stackrel{\text{def}}{=} \max_{1 \leq i \leq K} \hat{G}_i(t+1).$$

4. Bounds on the weak regret that uniformly hold over time. In section 3, we showed that **Exp3** yields an expected regret of $O(\sqrt{Kg \ln K})$ whenever an upper bound g on the return $G_{\max}$ of the best action is known in advance. A bound of $O(\sqrt{KT \ln K})$, which holds uniformly over T, could be easily proven via the "guessing techniques" which will be used to prove Corollaries 8.4 and 8.5 in section 8. In this section, instead, we describe an algorithm, called **Exp3.1**, whose expected weak regret is $O(\sqrt{KG_{\max} \ln K})$ uniformly over T. As $G_{\max} = G_{\max}(T) \leq T$, this bound is never worse than $O(\sqrt{KT \ln K})$ and is substantially better whenever the return of the best arm is small compared to T.

Algorithm Exp3.1
Initialization: Let $t = 1$, and $\hat{G}_i(1) = 0$ for $i = 1, \ldots, K$.

Repeat for $r = 0, 1, 2, \ldots$

1. Let $g_r = (K \ln K)/(e-1)\, 4^r$.
2. Restart **Exp3** choosing $\gamma_r = \min\left\{1, \sqrt{\frac{K \ln K}{(e-1)g_r}}\right\}$.
3. **While** $\max_i \hat{G}_i(t) \le g_r - K/\gamma_r$ **do**:
   (a) Let i_t be the random action chosen by **Exp3** and $x_{i_t}(t)$ the corresponding reward.
   (b) $\hat{G}_i(t+1) = \hat{G}_i(t) + \hat{x}_i(t)$ for $i = 1, \ldots, K$.
   (c) $t := t + 1$.

FIG. 2. *Pseudocode of algorithm* **Exp3.1** *to control the weak regret uniformly over time.*

Our algorithm **Exp3.1**, described in Figure 2, proceeds in *epochs*, where each epoch consists of a sequence of trials. We use $r = 0, 1, 2, \ldots$ to index the epochs. On epoch r, the algorithm "guesses" a bound g_r for the return of the best action. It then uses this guess to tune the parameter γ of **Exp3**, restarting **Exp3** at the beginning of each epoch. As usual, we use t to denote the current time step.[2] **Exp3.1** maintains an estimate $\hat{G}_i(t+1)$ of the return of each action i. Since $\mathbf{E}[\hat{x}_i(t)] = x_i(t)$, this estimate will be unbiased in the sense that $\mathbf{E}[\hat{G}_i(t+1)] = G_i(t+1)$ for all i and t. Using these estimates, the algorithm detects (approximately) when the actual gain of some action has advanced beyond g_r. When this happens, the algorithm goes on to the next epoch, restarting **Exp3** with a larger bound on the maximal gain.

The performance of the algorithm is characterized by the following theorem which is the main result of this section.

THEOREM 4.1. *For any* $K > 0$,

$$\begin{aligned} G_{\max} - \mathbf{E}[G_{\mathbf{Exp3.1}}] &\le 8\sqrt{e-1}\sqrt{G_{\max} K \ln K} + 8(e-1)K + 2K \ln K \\ &\le 10.5\, \sqrt{G_{\max} K \ln K} + 13.8\, K + 2K \ln K \end{aligned}$$

holds for any assignment of rewards and for any $T > 0$.

The proof of the theorem is divided into two lemmas. The first bounds the regret suffered on each epoch, and the second bounds the total number of epochs.

Fix T arbitrarily and define the following random variables: Let R be the total number of epochs (i.e., the final value of r). Let S_r and T_r be the first and last time steps completed on epoch r (where, for convenience, we define $T_R = T$). Thus, epoch r consists of trials $S_r, S_r + 1, \ldots, T_r$. Note that, in degenerate cases, some epochs may be empty in which case $S_r = T_r + 1$. Let $\hat{G}_{\max} = \hat{G}_{\max}(T+1)$.

LEMMA 4.2. *For any action* j *and for every epoch* r,

$$\sum_{t=S_r}^{T_r} x_{i_t}(t) \ge \sum_{t=S_r}^{T_r} \hat{x}_j(t) - 2\sqrt{e-1}\sqrt{g_r K \ln K}\ .$$

[2] Note that, in general, this t may differ from the "local variable" t used by **Exp3** which we now regard as a subroutine. Throughout this section, we will only use t to refer to the total number of trials as in Figure 2.

Proof. If $S_r > T_r$ (so that no trials occur on epoch r), then the lemma holds trivially since both summations will be equal to zero. Assume then that $S_r \le T_r$. Let $g = g_r$ and $\gamma = \gamma_r$. We use (10) from the proof of Theorem 3.1:

$$\sum_{t=S_r}^{T_r} x_{i_t}(t) \ge \sum_{t=S_r}^{T_r} \hat{x}_j(t) - \gamma \sum_{t=1}^{T_r} \hat{x}_j(t) - \frac{K \ln K}{\gamma} - (e-2)\frac{\gamma}{K} \sum_{t=S_r}^{T_r} \sum_{i=1}^{K} \hat{x}_i(t) \ .$$

From the definition of the termination condition we know that $\hat{G}_i(T_r) \le g - K/\gamma$. Using (2), we get $\hat{x}_i(t) \le K/\gamma$. This implies that $\hat{G}_i(T_r + 1) \le g$ for all i. Thus,

$$\sum_{t=S_r}^{T_r} x_{i_t}(t) \ge \sum_{t=S_r}^{T_r} \hat{x}_j(t) - g\left(\gamma + \gamma(e-2)\right) - \frac{K \ln K}{\gamma} \ .$$

By our choice for γ, we get the statement of the lemma. □

The next lemma gives an implicit upper bound on the number of epochs R. Let $c = (K \ln K)/(e-1)$.

LEMMA 4.3. *The number of epochs R satisfies*

$$2^{R-1} \le \frac{K}{c} + \sqrt{\frac{\hat{G}_{\max}}{c}} + \frac{1}{2} \ .$$

Proof. If $R = 0$, then the bound holds trivially. So assume $R \ge 1$. Let $z = 2^{R-1}$. Because epoch $R-1$ was completed, by the termination condition,

$$\hat{G}_{\max} \ge \hat{G}_{\max}(T_{R-1} + 1) > g_{R-1} - \frac{K}{\gamma_{R-1}} = c\, 4^{R-1} - K\, 2^{R-1} = cz^2 - Kz \ . \tag{12}$$

Suppose the claim of the lemma is false. Then $z > K/c + \sqrt{\hat{G}_{\max}/c}$. Since the function $cx^2 - Kx$ is increasing for $x > K/(2c)$, this implies that

$$cz^2 - Kz > c\left(\frac{K}{c} + \sqrt{\frac{\hat{G}_{\max}}{c}}\right)^2 - K\left(\frac{K}{c} + \sqrt{\frac{\hat{G}_{\max}}{c}}\right) = K\sqrt{\frac{\hat{G}_{\max}}{c}} + \hat{G}_{\max} \ ,$$

contradicting (12). □

Proof of Theorem 4.1. Using the lemmas, we have that

$$\begin{aligned}
G_{\mathbf{Exp3.1}} = \sum_{t=1}^{T} x_{i_t}(t) &= \sum_{r=0}^{R} \sum_{t=S_r}^{T_r} x_{i_t}(t) \\
&\ge \max_j \sum_{r=0}^{R} \left(\sum_{t=S_r}^{T_r} \hat{x}_j(t) - 2\sqrt{e-1}\sqrt{g_r K \ln K} \right) \\
&= \max_j \hat{G}_j(T+1) - 2K \ln K \sum_{r=0}^{R} 2^r \\
&= \hat{G}_{\max} - 2K \ln K (2^{R+1} - 1) \\
&\ge \hat{G}_{\max} + 2K \ln K - 8K \ln K \left(\frac{K}{c} + \sqrt{\frac{\hat{G}_{\max}}{c}} + \frac{1}{2} \right) \\
&= \hat{G}_{\max} - 2K \ln K - 8(e-1)K - 8\sqrt{e-1}\sqrt{\hat{G}_{\max} K \ln K} \ . \qquad (13)
\end{aligned}$$

Here, we used Lemma 4.2 for the first inequality and Lemma 4.3 for the second inequality. The other steps follow from definitions and simple algebra.

Let $f(x) = x - a\sqrt{x} - b$ for $x \geq 0$, where $a = 8\sqrt{e-1}\sqrt{K \ln K}$ and $b = 2K \ln K + 8(e-1)K$. Taking expectations of both sides of (13) gives

$$\mathbf{E}[G_{\mathbf{Exp3.1}}] \geq \mathbf{E}[f(\hat{G}_{\max})] \ . \tag{14}$$

Since the second derivative of f is positive for $x > 0$, f is convex so that, by Jensen's inequality,

$$\mathbf{E}[f(\hat{G}_{\max})] \geq f(\mathbf{E}[\hat{G}_{\max}]) \ . \tag{15}$$

Note that

$$\mathbf{E}[\hat{G}_{\max}] = \mathbf{E}\left[\max_j \hat{G}_j(T+1)\right] \geq \max_j \mathbf{E}[\hat{G}_j(T+1)] = \max_j \sum_{t=1}^{T} x_j(t) = G_{\max} \ .$$

The function f is increasing if and only if $x > a^2/4$. Therefore, if $G_{\max} > a^2/4$, then $f(\mathbf{E}[\hat{G}_{\max}]) \geq f(G_{\max})$. Combined with (14) and (15), this gives that $\mathbf{E}[G_{\mathbf{Exp3.1}}] \geq f(G_{\max})$, which is equivalent to the statement of the theorem. On the other hand, if $G_{\max} \leq a^2/4$, then, because f is nonincreasing on $[0, a^2/4]$,

$$f(G_{\max}) \leq f(0) = -b \leq 0 \leq \mathbf{E}[G_{\mathbf{Exp3.1}}],$$

so the theorem trivially follows in this case as well. □

5. Lower bounds on the weak regret. In this section, we state a lower bound on the expected weak regret of any player. More precisely, for any choice of the time horizon T we show that there exists a strategy for assigning the rewards to the actions such that the expected weak regret of any player algorithm is $\Omega(\sqrt{KT})$. Observe that this does not match the upper bound for our algorithms **Exp3** and **Exp3.1** (see Corollary 3.2 and Theorem 4.1); it is an open problem to close this gap.

Our lower bound is proven using the classical (statistical) bandit model with a crucial difference: the reward distribution depends on the number K of actions and on the time horizon T. This dependence is the reason why our lower bound does not contradict the upper bounds of the form $O(\ln T)$ for the classical bandit model [14]. There, the distribution over the rewards is fixed as $T \to \infty$.

Note that our lower bound has a considerably stronger dependence on the number K of action than the lower bound $\Theta(\sqrt{T \ln K})$, which could have been directly proven from the results in [3, 6]. Specifically, our lower bound implies that no upper bound is possible of the form $O(T^{\alpha}(\ln K)^{\beta})$, where $0 \leq \alpha < 1$, $\beta > 0$.

THEOREM 5.1. *For any number of actions $K \geq 2$ and for any time horizon T, there exists a distribution over the assignment of rewards such that the expected weak regret of any algorithm (where the expectation is taken with respect to both the randomization over rewards and the algorithm's internal randomization) is at least*

$$\frac{1}{20} \min\{\sqrt{KT}, T\}.$$

The proof is given in Appendix A.

The lower bound implies, of course, that for any algorithm there is a particular choice of rewards that will cause the expected weak regret (where the expectation is now with respect to the algorithm's internal randomization only) to be larger than this value.

Algorithm Exp3.P
Parameters: Reals $\alpha > 0$ and $\gamma \in (0, 1]$.
Initialization: For $i = 1, \ldots, K$

$$w_i(1) = \exp\left(\frac{\alpha\gamma}{3}\sqrt{\frac{T}{K}}\right).$$

For each $t = 1, 2, \ldots, T$

1. For $i = 1, \ldots, K$ set

$$p_i(t) = (1-\gamma)\frac{w_i(t)}{\sum_{j=1}^{K} w_j(t)} + \frac{\gamma}{K}.$$

2. Choose i_t randomly according to the distribution $p_1(t), \ldots, p_K(t)$.
3. Receive reward $x_{i_t}(t) \in [0, 1]$.
4. For $j = 1, \ldots, K$ set

$$\hat{x}_j(t) = \begin{cases} x_j(t)/p_j(t) & \text{if } j = i_t, \\ 0 & \text{otherwise,} \end{cases}$$

$$w_j(t+1) = w_j(t)\exp\left(\frac{\gamma}{3K}\left(\hat{x}_j(t) + \frac{\alpha}{p_j(t)\sqrt{KT}}\right)\right).$$

FIG. 3. *Pseudocode of algorithm* **Exp3.P** *achieving small weak regret with high probability.*

6. Bounds on the weak regret that hold with probability 1. In section 4 we showed that the *expected* weak regret of algorithm **Exp3.1** is $O(\sqrt{KT \ln K})$. In this section we show that a modification of **Exp3** achieves a weak regret of $O(\sqrt{KT \ln(KT/\delta)})$ with probability at least $1 - \delta$, for any fixed δ and uniformly over T. From this, a bound on the weak regret that holds with probability 1 easily follows.

The modification of **Exp3** is necessary since the variance of the regret achieved by this algorithm is large—so large that an interesting high probability bound may not hold. The large variance of the regret comes from the large variance of the estimates $\hat{x}_i(t)$ for the payoffs $x_i(t)$. In fact, the variance of $\hat{x}_i(t)$ can be close to $1/p_i(t)$, which, for γ in our range of interest, is (ignoring the dependence of K) of magnitude $\sqrt{T}$. Summing over trials, the variance of the return of **Exp3** is about $T^{3/2}$, so that the regret might be as large as $T^{3/4}$.

To control the variance we modify algorithm **Exp3** so that it uses estimates which are based on upper confidence bounds instead of estimates with the correct expectation. The modified algorithm **Exp3.P** is given in Figure 3. Let

$$\hat{\sigma}_i(t+1) \stackrel{\text{def}}{=} \sqrt{KT} + \sum_{s=1}^{t} \frac{1}{p_i(t)\sqrt{KT}}.$$

Whereas algorithm **Exp3** directly uses the estimates $\hat{G}_i(t)$ when choosing i_t at random, algorithm **Exp3.P** uses the upper confidence bounds $\hat{G}_i(t) + \alpha\hat{\sigma}_i(t)$. The next

lemma shows that, for appropriate α, these are indeed upper confidence bounds. Fix some time horizon T. In what follows, we will use $\hat{\sigma}_i$ to denote $\hat{\sigma}_i(T+1)$ and $\hat{G}_i$ to denote $\hat{G}_i(T+1)$.

LEMMA 6.1. *If* $2\sqrt{\ln(KT/\delta)} \le \alpha \le 2\sqrt{KT}$, *then*

$$\mathbf{P}\left\{\exists i : \hat{G}_i + \alpha\hat{\sigma}_i < G_i\right\} \le \delta.$$

Proof. Fix some i and set

$$s_t \stackrel{\text{def}}{=} \frac{\alpha}{2\hat{\sigma}_i(t+1)}.$$

Since $\alpha \le 2\sqrt{KT}$ and $\hat{\sigma}_i(t+1) \ge \sqrt{KT}$, we have $s_t \le 1$. Now

$$\begin{aligned}
&\mathbf{P}\left\{\hat{G}_i + \alpha\hat{\sigma}_i < G_i\right\} \\
&= \mathbf{P}\left\{\sum_{t=1}^{T}(x_i(t) - \hat{x}_i(t)) - \frac{\alpha}{2}\hat{\sigma}_i > \frac{\alpha}{2}\hat{\sigma}_i\right\} \\
&\le \mathbf{P}\left\{s_T\sum_{t=1}^{T}\left(x_i(t) - \hat{x}_i(t) - \frac{\alpha}{2p_i(t)\sqrt{KT}}\right) > \frac{\alpha^2}{4}\right\} \qquad (16) \\
&= \mathbf{P}\left\{\exp\left(s_T\sum_{t=1}^{T}\left(x_i(t) - \hat{x}_i(t) - \frac{\alpha}{2p_i(t)\sqrt{KT}}\right)\right) > \exp\left(\frac{\alpha^2}{4}\right)\right\} \\
&\le e^{-\alpha^2/4}\mathbf{E}\left[\exp\left(s_T\sum_{t=1}^{T}\left(x_i(t) - \hat{x}_i(t) - \frac{\alpha}{2p_i(t)\sqrt{KT}}\right)\right)\right], \qquad (17)
\end{aligned}$$

where in step (16) we multiplied both sides by s_T and used $\hat{\sigma}_i \ge \sum_{t=1}^{T} 1/(p_i(t)\sqrt{KT})$, while in step (17) we used Markov's inequality. For $t = 1, \ldots, T$ set

$$Z_t \stackrel{\text{def}}{=} \exp\left(s_t\sum_{\tau=1}^{t}\left(x_i(\tau) - \hat{x}_i(\tau) - \frac{\alpha}{2p_i(\tau)\sqrt{KT}}\right)\right).$$

Then, for $t = 2, \ldots, T$

$$Z_t = \exp\left(s_t\left(x_i(t) - \hat{x}_i(t) - \frac{\alpha}{2p_i(t)\sqrt{KT}}\right)\right)\cdot(Z_{t-1})^{\frac{s_t}{s_{t-1}}}.$$

Denote by $\mathbf{E}_t[Z_t] = \mathbf{E}[Z_t \mid i_1, \ldots, i_{t-1}]$ the expectation of Z_t with respect to the random choice in trial t and conditioned on the past $t-1$ trials. Note that when the past $t-1$ trials are fixed the only random quantities in Z_t are the $\hat{x}_i(t)$'s. Note also that $x_i(t) - \hat{x}_i(t) \le 1$ and that

$$\begin{aligned}
\mathbf{E}_t\left[(x_i(t) - \hat{x}_i(t))^2\right] &= \mathbf{E}_t\left[\hat{x}_i(t)^2\right] - x_i(t)^2 \\
&\le \mathbf{E}_t\left[\hat{x}_i(t)^2\right] \\
&= \frac{x_i(t)^2}{p_i(t)} \le \frac{1}{p_i(t)}. \qquad (18)
\end{aligned}$$

Hence, for each $t = 2, \ldots, T$

$$\mathbf{E}_t\left[Z_t\right] \le \mathbf{E}_t\left[\exp s_t\left(x_i(t) - \hat{x}_i(t) - \frac{s_t}{p_i(t)}\right)\right]\left(Z_{t-1}\right)^{\frac{s_t}{s_{t-1}}} \tag{19}$$

$$\le \mathbf{E}_t\left[1 + s_t(x_i(t) - \hat{x}_i(t)) + s_t^2(x_i(t) - \hat{x}_i(t))^2\right]\exp\left(-\frac{s_t^2}{p_i(t)}\right)\left(Z_{t-1}\right)^{\frac{s_t}{s_{t-1}}} \tag{20}$$

$$\le \left(1 + s_t^2/p_i(t)\right)\exp\left(-\frac{s_t^2}{p_i(t)}\right)\left(Z_{t-1}\right)^{\frac{s_t}{s_{t-1}}} \tag{21}$$

$$\le \left(Z_{t-1}\right)^{\frac{s_t}{s_{t-1}}} \tag{22}$$

$$\le 1 + Z_{t-1}. \tag{23}$$

Equation (19) uses

$$\frac{\alpha}{2p_i(t)\sqrt{KT}} \ge \frac{\alpha}{2p_i(t)\hat{\sigma}_i(t+1)} = \frac{s_t}{p_i(t)}$$

since $\hat{\sigma}_i(t+1) \ge \sqrt{KT}$. Equation (20) uses $e^a \le 1 + a + a^2$ for $a \le 1$. Equation (21) uses $\mathbf{E}_t\left[\hat{x}_i(t)\right] = x_i(t)$. Equation (22) uses $1 + x \le e^x$ for any real x. Equation (23) uses $s_t \le s_{t-1}$ and $z^u \le 1 + z$ for any $z > 0$ and $u \in [0, 1]$. Observing that $\mathbf{E}\left[Z_1\right] \le 1$, we get by induction that $\mathbf{E}[Z_T] \le T$, and the lemma follows by our choice of α. □

The next lemma shows that the return achieved by algorithm **Exp3**.**P** is close to its upper confidence bounds. Let

$$\hat{U} \stackrel{\text{def}}{=} \max_{1 \le i \le K}\left(\hat{G}_i + \alpha\hat{\sigma}_i\right).$$

LEMMA 6.2. *If* $\alpha \le 2\sqrt{KT}$, *then*

$$G_{\mathbf{Exp3.P}} \ge \left(1 - \frac{5\gamma}{3}\right)\hat{U} - \frac{3}{\gamma}K\ln K - 2\alpha\sqrt{KT} - 2\alpha^2\ .$$

Proof. We proceed as in the analysis of algorithm **Exp3**. Set $\eta = \gamma/(3K)$ and consider any sequence $i_1, \ldots, i_T$ of actions chosen by **Exp3**.**P**. As $\hat{x}_i(t) \le K/\gamma$, $p_i(t) \ge \gamma/K$, and $\alpha \le 2\sqrt{KT}$, we have

$$\eta\hat{x}_i(t) + \frac{\alpha\eta}{p_i(t)\sqrt{KT}} \le 1\ .$$

Therefore,

$$\begin{aligned}
\frac{W_{t+1}}{W_t} &= \sum_{i=1}^{K}\frac{w_i(t+1)}{W_t} \\
&= \sum_{i=1}^{K}\frac{w_i(t)}{W_t}\exp\left(\eta\hat{x}_i(t) + \frac{\alpha\eta}{p_i(t)\sqrt{KT}}\right) \\
&= \sum_{i=1}^{K}\frac{p_i(t) - \gamma/K}{1-\gamma}\exp\left(\eta\hat{x}_i(t) + \frac{\alpha\eta}{p_i(t)\sqrt{KT}}\right) \\
&\le \sum_{i=1}^{K}\frac{p_i(t) - \gamma/K}{1-\gamma}\left[1 + \eta\hat{x}_i(t) + \frac{\alpha\eta}{p_i(t)\sqrt{KT}} + 2\eta^2\hat{x}_i(t)^2 + \frac{2\alpha^2\eta^2}{p_i(t)^2KT}\right]
\end{aligned}$$

$$\leq 1 + \frac{\eta}{1-\gamma} \sum_{i=1}^{K} p_i(t)\hat{x}_i(t) + \frac{\alpha\eta}{1-\gamma} \sum_{i=1}^{K} \frac{1}{\sqrt{KT}}$$
$$+ \frac{2\eta^2}{1-\gamma} \sum_{i=1}^{K} p_i(t)\hat{x}_i(t)^2 + \frac{2\alpha^2\eta^2}{1-\gamma} \sum_{i=1}^{K} \frac{1}{p_i(t)KT}$$
$$\leq 1 + \frac{\eta}{1-\gamma} x_{i_t}(t) + \frac{\alpha\eta}{1-\gamma}\sqrt{\frac{K}{T}} + \frac{2\eta^2}{1-\gamma} \sum_{i=1}^{K} \hat{x}_i(t) + \frac{2\alpha^2\eta}{1-\gamma}\frac{1}{T} \ .$$

The second inequality uses $e^a \leq 1+a+a^2$ for $a \leq 1$, and $(a+b)^2 \leq 2(a^2+b^2)$ for any a, b. The last inequality uses (2), (3), and (4). Taking logarithms, using $\ln(1+x) \leq x$, and summing over $t = 1, \ldots, T$, we get

$$\ln \frac{W_{T+1}}{W_1} \leq \frac{\eta}{1-\gamma} G_{\mathbf{Exp3.P}} + \frac{\alpha\eta}{1-\gamma}\sqrt{KT} + \frac{2\eta^2}{1-\gamma} \sum_{i=1}^{K} \hat{G}_i + \frac{2\alpha^2\eta}{1-\gamma} \ .$$

Since

$$\ln W_1 = \alpha\eta\sqrt{KT} + \ln K$$

and for any j

$$\ln W_{T+1} \geq \ln w_j(T+1) \geq \eta\hat{G}_j + \alpha\eta\hat{\sigma}_j,$$

this implies

$$G_{\mathbf{Exp3.P}} \geq (1-\gamma)\left(\hat{G}_j + \alpha\hat{\sigma}_j\right) - \frac{1}{\eta}\ln K - 2\alpha\sqrt{KT} - 2\eta\sum_{i=1}^{K}\hat{G}_i - 2\alpha^2$$

for any j. Finally, using $\eta = \gamma/(3K)$ and

$$\sum_{i=1}^{K} \hat{G}_i \leq K\hat{U}$$

yields the lemma. □

Combining Lemmas 6.1 and 6.2 gives the main result of this section.

THEOREM 6.3. *For any fixed $T > 0$, for all $K \geq 2$ and for all $\delta > 0$, if*

$$\gamma = \min\left\{\frac{3}{5}, 2\sqrt{\frac{3}{5}\frac{K\ln K}{T}}\right\} \qquad \text{and} \qquad \alpha = 2\sqrt{\ln(KT/\delta)} \ ,$$

then

$$G_{\max} - G_{\mathbf{Exp3.P}} \leq 4\sqrt{KT\ln\frac{KT}{\delta}} + 4\sqrt{\frac{5}{3}KT\ln K} + 8\ln\frac{KT}{\delta}$$

holds for any assignment of rewards with probability at least $1-\delta$.

Proof. We assume without loss of generality that $T \geq (20/3)K\ln K$ and that $\delta \geq KTe^{-KT}$. If either of these conditions do not hold, then the theorem holds trivially. Note that $T \geq (20/3)K\ln K$ ensures $\gamma \leq 3/5$. Note also that $\delta \geq KTe^{-KT}$

Algorithm Exp3.P.1
Parameters: Real $0 < \delta < 1$.
Initialization: For each $r \geq 1$ let $T_r = 2^r$, $\delta_r = \frac{\delta}{(r+1)(r+2)}$, and set

$$r^* = \min\{r \in \mathbb{N} : \delta_r \geq KT_r e^{-KT_r}\}. \tag{24}$$

Repeat for $r = r^*, r^*+1, \ldots$
Run **Exp3.P** for T_r trials choosing α and γ as in Theorem 6.3 with $T = T_r$ and $\delta = \delta_r$.

FIG. 4. *Pseudocode of algorithm* **Exp3.P.1** *(see Theorem* 6.4*).*

implies $\alpha \leq 2\sqrt{KT}$ for our choice of α. So we can apply Lemmas 6.1 and 6.2. By Lemma 6.2 we have

$$G_{\mathbf{Exp3.P}} \geq \left(1 - \frac{5\gamma}{3}\right)\hat{U} - \frac{3}{\gamma}K\ln K - 2\alpha\sqrt{KT} - 2\alpha^2 \ .$$

By Lemma 6.1 we have $\hat{U} \geq G_{\max}$ with probability at least $1 - \delta$. Collecting terms and using $G_{\max} \leq T$ gives the theorem. □

It is not difficult to obtain an algorithm that does not need the time horizon T as input parameter and whose regret is only slightly worse than that proven for the algorithm **Exp3.P** in Theorem 6.3. This new algorithm, called **Exp3.P.1** and shown in Figure 4, simply restarts **Exp3.P** doubling its guess for T each time. The only crucial issue is the choice of the confidence parameter δ and of the minimum length of the runs to ensure that Lemma 6.1 holds for all the runs of **Exp3.P**.

THEOREM 6.4. *Let* r^* *be as in* (24)*. Let* $K \geq 2$*,* $\delta \in (0,1)$*, and* $T \geq 2^{r^*}$*. Let* $c_T = 2\ln(2 + \log_2 T)$*. Then*

$$G_{\max} - G_{\mathbf{Exp3.P.1}} \leq \frac{10}{\sqrt{2}-1}\sqrt{2KT\left(\ln\frac{KT}{\delta} + c_T\right)} + 10(1+\log_2 T)\left(\ln\frac{KT}{\delta} + c_T\right)$$

holds with probability at least $1 - \delta$*.*

Proof. Choose the time horizon T arbitrarily and call *epoch* the sequence of trials between two successive restarts of algorithm **Exp3.P**.

For each $r > r^*$, where r^* is defined in (24), let

$$G_i(r) \stackrel{\text{def}}{=} \sum_{t=2^r+1}^{2^{r+1}} x_i(t) \ , \quad \hat{G}_i(r) \stackrel{\text{def}}{=} \sum_{t=2^r+1}^{2^{r+1}} \hat{x}_i(t) \ , \quad \hat{\sigma}_i(r) \stackrel{\text{def}}{=} \sqrt{KT_r} + \sum_{t=2^r+1}^{2^{r+1}} \frac{1}{p_i(t)\sqrt{KT_r}}$$

and similarly define the quantities $G_i(r^*)$ and $\hat{G}_i(r^*)$ with sums that go from $t = 1$ to $t = 2^{r^*+1}$.

For each $r \geq r^*$, we have $\delta_r \geq KT_r e^{-KT_r}$. Thus we can find numbers α_r such that, by Lemma 6.1,

$$\mathbf{P}\left\{(\exists r \geq r^*)(\exists i) : \hat{G}_i(r) + \alpha_r\hat{\sigma}_i(r) < G_i(r)\right\} \leq \sum_{r=r^*}^{\infty} \mathbf{P}\left\{\exists i : \hat{G}_i(r) + \alpha_r\hat{\sigma}_i(r) < G_i(r)\right\}$$

$$\leq \sum_{r=0}^{\infty} \frac{\delta}{(r+1)(r+2)}$$
$$= \delta \ .$$

We now apply Theorem 6.3 to each epoch. Since $T \geq 2^{r^*}$, there is an $\ell \geq 1$ such that

$$2^{r^*+\ell-1} \leq T = \sum_{r=0}^{\ell-1} 2^{r^*+r} < 2^{r^*+\ell} \ .$$

With probability at least $1-\delta$ over the random draw of **Exp3.P.1**'s actions $i_1, \ldots, i_T$,

$$\begin{aligned}
&G_{\max} - G_{\mathbf{Exp3.P.1}} \\
&\leq \sum_{r=0}^{\ell-1} 10 \left[\sqrt{K T_{r^*+r} \ln \frac{K T_{r^*+r}}{\delta_{r^*+r}}} + \ln \frac{K T_{r^*+r}}{\delta_{r^*+r}} \right] \\
&\leq 10 \left[\sqrt{K \ln \frac{K T_{r^*+\ell-1}}{\delta_{r^*+\ell-1}}} \sum_{r=0}^{\ell-1} \sqrt{T_{r^*+r}} + \ell \ln \frac{K T_{r^*+\ell-1}}{\delta_{r^*+\ell-1}} \right] \\
&\leq 10 \left[\sqrt{K \ln \frac{K T_{r^*+\ell-1}}{\delta_{r^*+\ell-1}}} \left(\frac{2^{(r^*+\ell)/2}}{\sqrt{2}-1} \right) + \ell \ln \frac{K T_{r^*+\ell-1}}{\delta_{r^*+\ell-1}} \right] \\
&\leq \frac{10}{\sqrt{2}-1} \sqrt{2KT \left(\ln \frac{KT}{\delta} + c_T \right)} + 10(1+\log_2 T) \left(\ln \frac{KT}{\delta} + c_T \right),
\end{aligned}$$

where $c_T = 2\ln(2+\log_2 T)$. □

From the above theorem we get, as a simple corollary, a statement about the almost sure convergence of the return of algorithm **Exp3.P**. The rate of convergence is almost optimal, as one can see from our lower bound in section 5.

COROLLARY 6.5. *For any $K \geq 2$ and for any function $f : \mathbb{R} \to \mathbb{R}$ with $\lim_{T\to\infty} f(T) = \infty$,*

$$\lim_{T\to\infty} \frac{G_{\max} - G_{\mathbf{Exp3.P.1}}}{\sqrt{T(\ln T) f(T)}} = 0$$

holds for any assignment of rewards with probability 1.

Proof. Let $\delta = 1/T^2$. Then, by Theorem 6.4, there exists a constant C such that for all T large enough

$$G_{\max} - G_{\mathbf{Exp3.P.1}} \leq C\sqrt{KT \ln T}$$

with probability at least $1 - 1/T^2$. This implies that

$$\mathbf{P}\left\{ \frac{G_{\max} - G_{\mathbf{Exp3.P.1}}}{\sqrt{(T \ln T) f(T)}} > C\sqrt{\frac{K}{f(T)}} \right\} \leq \frac{1}{T^2},$$

and the theorem follows from the Borel–Cantelli lemma. □

7. The regret against the best strategy from a pool. Consider a setting where the player has preliminarily fixed a set of strategies that could be used for choosing actions. These strategies might select different actions at different iterations. The strategies can be computations performed by the player or they can be

external advice given to the player by "experts." We will use the more general term "expert" (borrowed from Cesa-Bianchi et al. [3]) because we place no restrictions on the generation of the advice. The player's goal in this case is to combine the advice of the experts in such a way that its return is close to that of the best expert.

Formally, an expert i is an infinite sequence $\boldsymbol{\xi}^i(1), \boldsymbol{\xi}^i(2), \ldots \in [0,1]^K$ of probability vectors, where the jth component $\xi^i_j(t)$ of $\boldsymbol{\xi}^i(t)$ represents the recommended probability of playing action j at time t. An *adversarial bandit problem with N experts* is thus specified by both an assignment of rewards to actions and by an assignment of probability vectors to each expert. We assume that the player, prior to choosing an action at time t, is provided with the set $\boldsymbol{\xi}^1(t), \ldots, \boldsymbol{\xi}^N(t) \in [0,1]^K$. (As a special case, the distribution can be concentrated on a single action, which represents a deterministic recommendation.) If the vector of rewards at time t is $\boldsymbol{x}(t)$, then the expected reward for expert i, with respect to the chosen probability vector $\boldsymbol{\xi}^i(t)$, is simply $\boldsymbol{\xi}^i(t) \cdot \boldsymbol{x}(t)$. In analogy of $G_{\max}$, we define

$$\tilde{G}_{\max} \stackrel{\text{def}}{=} \max_{1 \le i \le N} \sum_{t=1}^{T} \boldsymbol{\xi}^i(t) \cdot \boldsymbol{x}(t)$$

measuring the expected return of the best strategy. Then the *regret for the best strategy* at time horizon T, defined by $\tilde{G}_{\max}(T) - G_A(T)$, measures the difference between the return of the best expert and player's A return up to time T.

We could at this point view each expert as a "meta-action" in a higher-level bandit problem with payoff vector defined at trial t as $(\boldsymbol{\xi}^1(t) \cdot \boldsymbol{x}(t), \ldots, \boldsymbol{\xi}^N(t) \cdot \boldsymbol{x}(t))$. We could then immediately apply Corollary 3.2 to obtain a bound of $O(\sqrt{gN \log N})$ on the player's regret relative to the best expert (where g is an upper bound on $\tilde{G}_{\max}$). However, this bound is quite weak if the player is combining many experts (i.e., if N is very large). We show below that the algorithm **Exp3** from section 3 can be modified yielding a regret term of the form $O(\sqrt{gK \log N})$. This bound is very reasonable when the number of actions is small, but the number of experts is quite large (even exponential).

Our algorithm **Exp4** is shown in Figure 5, and is only a slightly modified version of **Exp3**. (**Exp4** stands for "exponential-weight algorithm for exploration and exploitation using expert advice.") Let us define $\boldsymbol{y}(t) \in [0,1]^N$ to be the vector with components corresponding to the gains of the experts: $y_i(t) = \boldsymbol{\xi}^i(t) \cdot \boldsymbol{x}(t)$.

The simplest possible expert is one which always assigns uniform weight to all actions so that $\xi_j(t) = 1/K$ on each round t. We call this the *uniform expert*. To prove our results, we need to assume that the uniform expert is included in the family of experts.[3] Clearly, the uniform expert can always be added to any given family of experts at the very small expense of increasing N by one.

THEOREM 7.1. *For any $K, T > 0$, for any $\gamma \in (0,1]$, and for any family of experts which includes the uniform expert,*

$$\tilde{G}_{\max} - \mathbf{E}[G_{\mathbf{Exp4}}] \le (e-1)\gamma \tilde{G}_{\max} + \frac{K \ln N}{\gamma}$$

holds for any assignment of rewards.

[3] In fact, we can use a slightly weaker sufficient condition, namely, that the uniform expert is included in the convex hull of the family of experts, i.e., that there exists nonnegative numbers $\alpha_1, \ldots, \alpha_N$ with $\sum_{j=1}^N \alpha_j = 1$ such that, for all t and all i, $\sum_{j=1}^N \alpha_j \xi^j_i(t) = 1/K$.

Algorithm Exp4
Parameters: Real $\gamma \in (0,1]$.
Initialization: $w_i(1) = 1$ for $i = 1, \ldots, N$.

For each $t = 1, 2, \ldots$

1. Get advice vectors $\boldsymbol{\xi}^1(t), \ldots, \boldsymbol{\xi}^N(t)$.
2. Set $W_t = \sum_{i=1}^N w_i(t)$ and for $j = 1, \ldots, K$ set
$$p_j(t) = (1-\gamma) \sum_{i=1}^N \frac{w_i(t)\xi_j^i(t)}{W_t} + \frac{\gamma}{K} \ .$$
3. Draw action i_t randomly according to the probabilities $p_1(t), \ldots, p_K(t)$.
4. Receive reward $x_{i_t}(t) \in [0,1]$.
5. For $j = 1, \ldots, K$ set
$$\hat{x}_j(t) = \begin{cases} x_j(t)/p_j(t) & \text{if } j = i_t, \\ 0 & \text{otherwise.} \end{cases}$$
6. For $i = 1, \ldots, N$ set
$$\hat{y}_i(t) = \boldsymbol{\xi}^i(t) \cdot \hat{\boldsymbol{x}}(t),$$
$$w_i(t+1) = w_i(t) \exp\left(\gamma \hat{y}_i(t)/K\right) \ .$$

FIG. 5. *Pseudocode of algorithm* **Exp4** *for using expert advice.*

Proof. We prove this theorem along the lines of the proof of Theorem 3.1. Let $q_i(t) = w_i(t)/W_t$. Then

$$\begin{aligned} \frac{W_{t+1}}{W_t} &= \sum_{i=1}^N \frac{w_i(t+1)}{W_t} \\ &= \sum_{i=1}^N q_i(t) \exp\left(\frac{\gamma}{K}\hat{y}_i(t)\right) \\ &\le \sum_{i=1}^N q_i(t) \left[1 + \frac{\gamma}{K}\hat{y}_i(t) + (e-2)\left(\frac{\gamma}{K}\hat{y}_i(t)\right)^2\right] \\ &= 1 + \left(\frac{\gamma}{K}\right) \sum_{i=1}^N q_i(t)\hat{y}_i(t) + (e-2)\left(\frac{\gamma}{K}\right)^2 \sum_{i=1}^N q_i(t)\hat{y}_i(t)^2 \ . \end{aligned}$$

Taking logarithms and summing over t we get

$$\ln \frac{W_{T+1}}{W_1} \le \left(\frac{\gamma}{K}\right) \sum_{t=1}^T \sum_{i=1}^N q_i(t)\hat{y}_i(t) + (e-2)\left(\frac{\gamma}{K}\right)^2 \sum_{t=1}^T \sum_{i=1}^N q_i(t)\hat{y}_i(t)^2 \ .$$

Since, for any expert k,

$$\ln \frac{W_{T+1}}{W_1} \geq \ln \frac{w_k(T+1)}{W_1} = \frac{\gamma}{K} \sum_{t=1}^{T} \hat{y}_k(t) - \ln N,$$

we get

$$\sum_{t=1}^{T} \sum_{i=1}^{N} q_i(t) \hat{y}_i(t) \geq \sum_{t=1}^{T} \hat{y}_k(t) - \frac{K \ln N}{\gamma} - (e-2) \frac{\gamma}{K} \sum_{t=1}^{T} \sum_{i=1}^{N} q_i(t) \hat{y}_i(t)^2 \ .$$

Note that

$$\begin{aligned} \sum_{i=1}^{N} q_i(t) \hat{y}_i(t) &= \sum_{i=1}^{N} q_i(t) \left(\sum_{j=1}^{K} \xi_j^i(t) \hat{x}_j(t) \right) \\ &= \sum_{j=1}^{K} \left(\sum_{i=1}^{N} q_i(t) \xi_j^i(t) \right) \hat{x}_j(t) \\ &= \sum_{j=1}^{K} \left(\frac{p_j(t) - \frac{\gamma}{K}}{1-\gamma} \right) \hat{x}_j(t) \leq \frac{x_j(t)}{1-\gamma} \ . \end{aligned}$$

Also,

$$\begin{aligned} \sum_{i=1}^{N} q_i(t) \hat{y}_i(t)^2 &= \sum_{i=1}^{N} q_i(t) (\xi_{i_t}^i(t) \hat{x}_{i_t}(t))^2 \\ &\leq \hat{x}_{i_t}(t)^2 \frac{p_{i_t}(t)}{1-\gamma} \\ &\leq \frac{\hat{x}_{i_t}(t)}{1-\gamma} \ . \end{aligned}$$

Therefore, for all experts k,

$$G_{\mathbf{Exp4}} = \sum_{t=1}^{T} \hat{x}_{i_t}(t) \geq (1-\gamma) \sum_{t=1}^{T} \hat{y}_k(t) - \frac{K \ln N}{\gamma} - (e-2) \frac{\gamma}{K} \sum_{t=1}^{T} \sum_{j=1}^{K} \hat{x}_j(t) \ .$$

We now take expectations of both sides of this inequality. Note that

$$\mathbf{E}[\hat{y}_k(t)] = \mathbf{E} \left[\sum_{j=1}^{K} \xi_j^k(t) \hat{x}_j(t) \right] = \sum_{j=1}^{K} \xi_j^k(t) x_j(t) = y_k(t) \ .$$

Further,

$$\frac{1}{K} \mathbf{E} \left[\sum_{t=1}^{T} \sum_{j=1}^{K} \hat{x}_j(t) \right] = \sum_{t=1}^{T} \frac{1}{K} \sum_{j=1}^{K} x_j(t) \leq \max_{1 \leq i \leq N} \sum_{t=1}^{T} y_i(t) = \tilde{G}_{\max}$$

since we have assumed that the uniform expert is included in the family of experts. Combining these facts immediately implies the statement of the theorem. □

Algorithm Exp3.S
Parameters: Reals $\gamma \in (0,1]$ and $\alpha > 0$.
Initialization: $w_i(1) = 1$ for $i = 1, \ldots, K$.

For each $t = 1, 2, \ldots$

1. Set

$$p_i(t) = (1-\gamma)\frac{w_i(t)}{\sum_{j=1}^{K} w_j(t)} + \frac{\gamma}{K}, \qquad i = 1, \ldots, K.$$

2. Draw i_t according to the probabilities $p_1(t), \ldots, p_K(t)$.
3. Receive reward $x_{i_t}(t) \in [0,1]$.
4. For $j = 1, \ldots, K$ set

$$\hat{x}_j(t) = \begin{cases} x_j(t)/p_j(t) & \text{if } j = i_t, \\ 0 & \text{otherwise,} \end{cases}$$

$$w_j(t+1) = w_j(t)\, \exp\left(\gamma \hat{x}_j(t)/K\right) + \frac{e\alpha}{K} \sum_{i=1}^{K} w_i(t)\ .$$

FIG. 6. *Pseudocode of algorithm* **Exp3.S** *to control the expected regret.*

8. The regret against arbitrary strategies. In this section we present a variant of algorithm **Exp3** and prove a bound on its expected regret for any sequence $(j_1, \ldots, j_T)$ of actions. To prove this result, we rank all sequences of actions according to their "hardness." The *hardness* of a sequence $(j_1, \ldots, j_T)$ is defined by

$$\mathrm{H}(j_1, \ldots, j_T) \stackrel{\text{def}}{=} 1 + \left|\{1 \le \ell < T : j_\ell \ne j_{\ell+1}\}\right|.$$

So, $\mathrm{H}(1, \ldots, 1) = 1$ and $\mathrm{H}(1, 1, 3, 2, 2) = 3$. The bound on the regret which we will prove grows with the hardness of the sequence for which we are measuring the regret. In particular, we will show that the player algorithm **Exp3.S** described in Figure 6 has an expected regret of $O(\mathrm{H}(j^T)\sqrt{KT\ln(KT)})$ for any sequence $j^T = (j_1, \ldots, j_T)$ of actions. On the other hand, if the regret is measured for any sequence j^T of actions of hardness $\mathrm{H}(j^T) \le S$, then the expected regret of **Exp3.S** (with parameters tuned to this S) reduces to $O(\sqrt{SKT\ln(KT)})$. In what follows, we will use G_{j^T} to denote the return $x_{j_1}(1) + \cdots + x_{j_T}(T)$ of a sequence $j^T = (j_1, \ldots, j_T)$ of actions.

THEOREM 8.1. *For any $K > 0$, for any $\gamma \in (0,1]$, and for any $\alpha > 0$,*

$$G_{j^T} - \mathbf{E}\left[G_{\mathbf{Exp3.S}}\right] \le \frac{K(\mathrm{H}(j^T)\ln(K/\alpha) + e\alpha T)}{\gamma} + (e-1)\gamma T$$

holds for any assignment of rewards, for any $T > 0$, and for any sequence $j^T = (j_1, \ldots, j_T)$ of actions.

COROLLARY 8.2. *Assume that algorithm* **Exp3.S** *is run with input parameters $\alpha = 1/T$ and*

$$\gamma = \min\left\{1, \sqrt{\frac{K\ln(KT)}{T}}\right\}\ .$$

Then

$$G_{j^T} - \mathbf{E}\left[G_{\mathbf{Exp3.S}}\right] \leq \mathrm{H}(j^T)\sqrt{KT\ln(KT)} + 2e\sqrt{\frac{KT}{\ln(KT)}}$$

holds for any sequence $j^T = (j_1, \ldots, j_T)$ *of actions.*

Note that the statement of Corollary 8.2 can be equivalently written as

$$\mathbf{E}\left[G_{\mathbf{Exp3.S}}\right] \geq \max_{j^T}\left(G_{j^T} - \mathrm{H}(j^T)\sqrt{KT\ln(KT)}\right) - 2e\sqrt{\frac{KT}{\ln(KT)}},$$

revealing that algorithm **Exp3.S** is able to automatically trade-off between the return G_{j^T} of a sequence j^T and its hardness $\mathrm{H}(j^T)$.

COROLLARY 8.3. *Assume that algorithm* **Exp3.S** *is run with input parameters* $\alpha = 1/T$ *and*

$$\gamma = \min\left\{1, \sqrt{\frac{K(S\ln(KT) + e)}{(e-1)T}}\right\}.$$

Then

$$G_{j^T} - \mathbf{E}\left[G_{\mathbf{Exp3.S}}\right] \leq 2\sqrt{e-1}\sqrt{KT\left(S\ln(KT) + e\right)}$$

holds for any sequence $j^T = (j_1, \ldots, j_T)$ *of actions such that* $\mathrm{H}(j^T) \leq S$.

Proof of Theorem 8.1. Fix any sequence $j^T = (j_1, \ldots, j_T)$ of actions. With a technique that closely follows the proof of Theorem 3.1, we can prove that for all sequences $i_1, \ldots, i_T$ of actions drawn by **Exp3.S**,

$$\frac{W_{t+1}}{W_t} \leq 1 + \frac{\gamma/K}{1-\gamma}x_{i_t}(t) + \frac{(e-2)(\gamma/K)^2}{1-\gamma}\sum_{i=1}^{K}\hat{x}_i(t) + e\alpha, \tag{25}$$

where, as usual, $W_t = w_1(t) + \cdots + w_K(t)$. Now let $S = \mathrm{H}(j^T)$ and partition $(1, \ldots, T)$ in *segments*

$$[T_1, \ldots, T_2), [T_2, \ldots, T_3), \ldots, [T_S, \ldots, T_{S+1}),$$

where $T_1 = 1$, $T_{S+1} = T + 1$, and $j_{T_s} = j_{T_s+1} = \cdots = j_{T_{s+1}-1}$ for each segment $s = 1, \ldots, S$. Fix an arbitrary segment $[T_s, T_{s+1})$ and let $\Delta_s = T_{s+1} - T_s$. Furthermore, let

$$G_{\mathbf{Exp3.S}}(s) \stackrel{\text{def}}{=} \sum_{t=T_s}^{T_{s+1}-1} x_{i_t}(t)\ .$$

Taking logarithms on both sides of (25) and summing over $t = T_s, \ldots, T_{s+1} - 1$, we get

$$\ln\frac{W_{T_{s+1}}}{W_{T_s}} \leq \frac{\gamma/K}{1-\gamma}G_{\mathbf{Exp3.S}}(s) + \frac{(e-2)(\gamma/K)^2}{1-\gamma}\sum_{t=T_s}^{T_{s+1}-1}\sum_{i=1}^{K}\hat{x}_i(t) + e\alpha\Delta_s\ . \tag{26}$$

Now let j be the action such that $j_{T_s} = \cdots = j_{T_{s+1}-1} = j$. Since

$$\begin{aligned} w_j(T_{s+1}) &\geq w_j(T_s+1)\exp\left(\frac{\gamma}{K}\sum_{t=T_s+1}^{T_{s+1}-1}\hat{x}_j(t)\right) \\ &\geq \frac{e\alpha}{K}W_{T_s}\exp\left(\frac{\gamma}{K}\sum_{t=T_s+1}^{T_{s+1}-1}\hat{x}_j(t)\right) \\ &\geq \frac{\alpha}{K}W_{T_s}\exp\left(\frac{\gamma}{K}\sum_{t=T_s}^{T_{s+1}-1}\hat{x}_j(t)\right), \end{aligned}$$

where the last step uses $\gamma\hat{x}_j(t)/K \leq 1$, we have

$$\ln\frac{W_{T_{s+1}}}{W_{T_s}} \geq \ln\frac{w_j(T_{s+1})}{W_{T_s}} \geq \ln\left(\frac{\alpha}{K}\right) + \frac{\gamma}{K}\sum_{t=T_s}^{T_{s+1}-1}\hat{x}_j(t)\ . \tag{27}$$

Piecing together (26) and (27) we get

$$G_{\mathbf{Exp3.S}}(s) \geq (1-\gamma)\sum_{t=T_s}^{T_{s+1}-1}\hat{x}_j(t) - \frac{K\ln(\frac{K}{\alpha})}{\gamma} - (e-2)\frac{\gamma}{K}\sum_{t=T_s}^{T_{s+1}-1}\sum_{i=1}^{K}\hat{x}_i(t) - \frac{e\alpha K\Delta_s}{\gamma}\ .$$

Summing over all segments $s = 1, \ldots, S$, taking expectation with respect to the random choices of algorithm **Exp3.S**, and using

$$G_{(j_1,\ldots,j_T)} \leq T \qquad \text{and} \qquad \sum_{t=1}^{T}\sum_{i=1}^{K}x_i(t) \leq KT$$

yields the inequality in the statement of the theorem. □

If the time horizon T is not known, we can apply techniques similar to those applied for proving Theorem 6.4 in section 6. More specifically, we introduce a new algorithm, **Exp3.S.1**, that runs **Exp3.S** as a subroutine. Suppose that at each new run (or epoch) $r = 0, 1, \ldots$, **Exp3.S** is started with its parameters set as prescribed in Corollary 8.2, where T is set to $T_r = 2^r$, and then stopped after T_r iterations. Clearly, for any fixed sequence $j^T = (j_1, \ldots, j_T)$ of actions, the number of segments (see proof of Theorem 8.1 for a definition of segment) within each epoch r is at most $\mathrm{H}(j^T)$. Hence the expected regret of **Exp3.S.1** for epoch r is certainly not more than

$$(\mathrm{H}(j^T) + 2e)\sqrt{KT_r\ln(KT_r)}\ .$$

Let ℓ be such that $2^\ell \leq T < 2^{\ell+1}$. Then the last epoch is $\ell \leq \log_2 T$ and the overall regret (over the $\ell+1$ epochs) is at most

$$(\mathrm{H}(j^T) + 2e)\sum_{r=0}^{\ell}\sqrt{KT_r\ln(KT_r)} \leq (\mathrm{H}(j^T) + 2e)\sqrt{K\ln(KT_\ell)}\sum_{r=0}^{\ell}\sqrt{T_r}\ .$$

Finishing up the calculations proves the following.

COROLLARY 8.4.

$$G_{j^T} - \mathbf{E}\left[G_{\mathbf{Exp3.S.1}}\right] \leq \frac{\mathrm{H}(j^T) + 2e}{\sqrt{2}-1}\sqrt{2KT\ln(KT)}$$

for any $T > 0$ and for any sequence $j^T = (j_1, \dots, j_T)$ of actions.

On the other hand, if **Exp3.S.1** runs **Exp3.S** with parameters set as prescribed in Corollary 8.3, with a reasoning similar to the one above we conclude the following.

COROLLARY 8.5.

$$G_{j^T} - \mathbf{E}\left[G_{\mathbf{Exp3.S.1}}\right] \leq \frac{2\sqrt{e-1}}{\sqrt{2}-1}\sqrt{2KT(S\ln(KT)+e)}$$

for any $T > 0$ and for any sequence $j^T = (j_1, \dots, j_T)$ of actions such that $\mathrm{H}(j^T) \leq S$.

9. Applications to game theory. The adversarial bandit problem can be easily related to the problem of playing repeated games. For $N > 1$ integer, an N-person finite game is defined by N finite sets $S_1, \dots, S_N$ of pure strategies, one set for each player, and by N functions $u_1, \dots, u_N$, where function $u_i : S_1 \times \cdots \times S_N \to \mathbb{R}$ is player's i payoff function. Note the each player's payoff depends both on the pure strategy chosen by the player and on the pure strategies chosen by the other players. Let $S = S_1 \times \cdots \times S_N$, and let $S_{-i} = S_1 \times \cdots \times S_{i-1} \times S_{i+1} \times \cdots \times S_N$. We use $\boldsymbol{s}$ and $\boldsymbol{s}_{-i}$ to denote typical members of, respectively, S and S_{-i}. Given $\boldsymbol{s} \in S$, we will often write $(j, \boldsymbol{s}_{-i})$ to denote $(s_1, \dots, s_{i-1}, j, s_{i+1}, \dots, s_N)$, where $j \in S_i$. Suppose that the game is repeatedly played through time. Assume for now that each player knows all payoff functions and, after each repetition (or round) t, also knows the vector $\boldsymbol{s}(t) = (s_1(t), \dots, s_N(t))$ of pure strategies chosen by the players. Hence, the pure strategy $s_i(t)$ chosen by player i at round t may depend on what player i and the other players chose in the past rounds. The *average regret* of player i for the pure strategy j after T rounds is defined by

$$R_i^{(j)}(T) = \frac{1}{T}\sum_{t=1}^{T}\left[u_i(j, \boldsymbol{s}_{-i}(t)) - u_i(\boldsymbol{s}(t))\right].$$

This is how much player i lost on average for not playing the pure strategy j on all rounds, given that all the other players kept their choices fixed.

A desirable property for a player is Hannan-consistency [8], defined as follows. Player i is *Hannan-consistent* if

$$\limsup_{T\to\infty} \max_{j\in S_i} R_i^{(j)}(T) = 0 \qquad \text{with probability 1.}$$

The existence and properties of Hannan-consistent players have been first investigated by Hannan [10] and Blackwell [2] and later by many others (see [5] for a nice survey).

Hannan-consistency can be also studied in the so-called unknown game setup, where it is further assumed that (1) each player knows neither the total number of players nor the payoff function of any player (including itself), (2) after each round each player sees its own payoffs but it sees neither the choices of the other players nor the resulting payoffs. This setup was previously studied by Baños [1], Megiddo [16], and by Hart and Mas-Colell [11, 12].

We can apply the results of section 6 to prove that a player using algorithm **Exp3.P.1** as mixed strategy is Hannan-consistent in the unknown game setup whenever the payoffs obtained by the player belong to a known bounded real interval. To do that, we must first extend our results to the case when the assignment of rewards can be chosen adaptively. More precisely, we can view the payoff $x_{i_t}(t)$, received by the gambler at trial t of the bandit problem, as the payoff $u_i(i_t, \boldsymbol{s}_{-i}(t))$ received by player i at the tth round of the game. However, unlike our adversarial bandit

framework where all the rewards were assigned to each arm at the beginning, here the payoff $u_i(i_t, \boldsymbol{s}_{-i}(t))$ depends on the (possibly randomized) choices of all players, which, in turn, are functions of their realized payoffs. In our bandit terminology, this corresponds to assuming that the vector $(x_1(t), \ldots, x_K(t))$ of rewards for each trial t is chosen by an adversary who knows the gambler's strategy and the outcome of the gambler's random draws up to time $t-1$. We leave to the interested reader the easy but lengthy task of checking that *all* of our results (including those of section 6) hold under this additional assumption.

Using Theorem 6.4 we then get the following.

THEOREM 9.1. *If player i has $K \geq 2$ pure strategies and plays in the unknown game setup (with payoffs in $[0,1]$) using the mixed strategy* **Exp3.P.1**, *then*

$$\max_{j \in S_i} R_i^{(j)}(T) \leq \frac{10}{\sqrt{2}-1} \sqrt{\frac{2K}{T}\left(\ln \frac{KT}{\delta} + c_T\right)} + \frac{10(1+\log_2 T)}{T}\left(\ln \frac{KT}{\delta} + c_T\right),$$

where $c_T = 2\ln(2+\log_2 T)$, holds with probability at least $1-\delta$, for all $0 < \delta < 1$ and for all $T \geq (\ln(K/\delta))^{1/(K-1)}$.

The constraint on T in the statement of Theorem 9.1 is derived from the condition $T \geq 2^{r^*}$ in Theorem 6.4. Note that, according to Theorem 5.1, the rate of convergence is optimal both in T and K up to logarithmic factors.

Theorem 9.1, along with Corollary 6.5, immediately implies the result below.

COROLLARY 9.2. *Player's strategy* **Exp3.P.1** *is Hannan-consistent in the unknown game setup.*

As pointed out in [5], Hannan-consistency has an interesting consequence for repeated zero-sum games. These games are defined by an $n \times m$ matrix $\mathbf{M}$. On each round t, the *row player* chooses a row i of the matrix. At the same time, the *column player* chooses a column j. The row player then gains the quantity $\mathbf{M}_{ij}$, while the column player loses the same quantity. In repeated play, the row player's goal is to maximize its expected total gain over a sequence of plays, while the column player's goal is to minimize its expected total loss.

Suppose in some round the row player chooses its next move i randomly according to a probability distribution on rows represented by a (column) vector $\boldsymbol{p} \in [0,1]^n$, and the column player similarly chooses according to a probability vector $\boldsymbol{q} \in [0,1]^m$. Then the expected payoff is $\boldsymbol{p}^T \mathbf{M} \boldsymbol{q}$. Von Neumann's minimax theorem states that

$$\max_{\boldsymbol{p}} \min_{\boldsymbol{q}} \boldsymbol{p}^T \mathbf{M} \boldsymbol{q} = \min_{\boldsymbol{q}} \max_{\boldsymbol{p}} \boldsymbol{p}^T \mathbf{M} \boldsymbol{q} \ ,$$

where maximum and minimum are taken over the (compact) set of all distribution vectors $\boldsymbol{p}$ and $\boldsymbol{q}$. The quantity v defined by the above equation is called the *value* of the zero-sum game with matrix $\mathbf{M}$. In words, this says that there exists a mixed (randomized) strategy $\overline{\mathbf{p}}$ for the row player that guarantees expected payoff at least v, regardless of the column player's action. Moreover, this payoff is optimal in the sense that the column player can choose a mixed strategy whose expected payoff is at most v, regardless of the row player's action. Thus, if the row player knows the matrix $\mathbf{M}$, it can compute a strategy (for instance, using linear programming) that is certain to bring an expected optimal payoff not smaller than v on each round.

Suppose now that the game $\mathbf{M}$ is entirely unknown to the row player. To be precise, assume the row player knows only the number of rows of the matrix and a bound on the magnitude of the entries of $\mathbf{M}$. Then, using the results of section 4, we

can show that the row player can play in such a manner that its payoff per round will rapidly converge to the optimal maximin payoff v.

THEOREM 9.3. *Let* $\mathbf{M}$ *be an unknown game matrix in* $[a,b]^{n\times m}$ *with value* v. *Suppose the row player, knowing only* a, b, *and* n, *uses the mixed strategy* **Exp3.1**. *Then the row player's expected payoff per round is at least*

$$v - 8(b-a)\left(\sqrt{e-1}\sqrt{\frac{n\ln n}{T}} - 8(e-1)\frac{n}{T} - 2\frac{n\ln n}{T}\right).$$

Proof. We assume that $[a,b]=[0,1]$; the extension to the general case is straightforward. By Theorem 4.1, we have

$$\begin{aligned}\mathbf{E}\left[\sum_{t=1}^{T}\mathbf{M}_{i_t j_t}\right] &= \mathbf{E}\left[\sum_{t=1}^{T} x_{i_t}(t)\right] \\ &\geq \max_i \mathbf{E}\left[\sum_{t=1}^{T} x_i(t)\right] - 8\sqrt{e-1}\sqrt{Tn\ln n} - 8(e-1)n - 2n\ln n\ .\end{aligned}$$

Let $\overline{\mathbf{p}}$ be a maxmin strategy for the row player such that

$$v = \max_{\boldsymbol{p}}\min_{\boldsymbol{q}} \boldsymbol{p}^T\mathbf{M}\boldsymbol{q} = \min_{\boldsymbol{q}} \overline{\mathbf{p}}^T\mathbf{M}\boldsymbol{q}\ ,$$

and let $\boldsymbol{q}(t)$ be a distribution vector whose j_tth component is 1. Then

$$\max_i \mathbf{E}\left[\sum_{t=1}^{T} x_i(t)\right] \geq \sum_{i=1}^{n}\overline{p}_i\mathbf{E}\left[\sum_{t=1}^{T} x_i(t)\right] = \mathbf{E}\left[\sum_{t=1}^{T}\overline{\mathbf{p}}\cdot\boldsymbol{x}(t)\right] = \mathbf{E}\left[\sum_{t=1}^{T}\overline{\mathbf{p}}^T\mathbf{M}\boldsymbol{q}(t)\right] \geq vT$$

since $\overline{\mathbf{p}}^T\mathbf{M}\boldsymbol{q}\geq v$ for all $\boldsymbol{q}$.

Thus, the row player's expected payoff is at least

$$vT - 8\sqrt{e-1}\sqrt{Tn\ln n} - 8(e-1)n - 2n\ln n\ .$$

Dividing by T to get the average per-round payoff gives the result. □

Note that the theorem is independent of the number of columns of $\mathbf{M}$ and, with appropriate assumptions, the theorem can be easily generalized to column players with an infinite number of strategies. If the matrix $\mathbf{M}$ is very large and all entries are small, then, even if $\mathbf{M}$ is known to the player, our algorithm may be an efficient alternative to linear programming.

Appendix A. Proof of Theorem 5.1. We construct the random distribution of rewards as follows. First, before play begins, one action I is chosen uniformly at random to be the "good" action. The T rewards $x_I(t)$ associated with the good action are chosen independently at random to be 1 with probability $1/2+\epsilon$ and 0 otherwise for some small, fixed constant $\epsilon\in(0,1/2]$ to be chosen later in the proof. The rewards $x_j(t)$ associated with the other actions $j\neq I$ are chosen independently at random to be 0 or 1 with equal odds. Then the expected reward of the best action is at least $(1/2+\epsilon)T$. The main part of the proof below is a derivation of an upper bound on the expected gain of any algorithm for this distribution of rewards.

We write $\mathbf{P}_*\{\cdot\}$ to denote probability with respect to this random choice of rewards, and we also write $\mathbf{P}_i\{\cdot\}$ to denote probability conditioned on i being the good

action: $\mathbf{P}_i\{\cdot\} = \mathbf{P}_*\{\cdot \mid I = i\}$. Finally, we write $\mathbf{P}_{unif}\{\cdot\}$ to denote probability with respect to a uniformly random choice of rewards for *all* actions (including the good action). Analogous expectation notation $\mathbf{E}_*[\cdot]$, $\mathbf{E}_i[\cdot]$, and $\mathbf{E}_{unif}[\cdot]$ will also be used.

Let A be the player strategy. Let $r_t = x_{i_t}(t)$ be a random variable denoting the reward received at time t, and let $\mathbf{r}^t$ denote the sequence of rewards received up through trial t: $\mathbf{r}^t = \langle r_1, \ldots, r_t \rangle$. For shorthand, $\mathbf{r} = \mathbf{r}^T$ is the entire sequence of rewards.

Any randomized playing strategy is equivalent to an a priori random choice from the set of all deterministic strategies. Thus, because the adversary strategy we have defined is oblivious to the actions of the player, it suffices to prove an upper bound on the expected gain of any *deterministic* strategy (this is not crucial for the proof but simplifies the notation). Therefore, we can formally regard the algorithm A as a fixed function which, at each step t, maps the reward history $\mathbf{r}^{t-1}$ to its next action i_t.

As usual, $G_A = \sum_{t=1}^{T} r_t$ denotes the return of the algorithm, and $G_{\max} = \max_j \sum_{t=1}^{T} x_j(t)$ is the return of the best action.

Let N_i be a random variable denoting the number of times action i is chosen by A. Our first lemma bounds the difference between expectations when measured using $\mathbf{E}_i[\cdot]$ or $\mathbf{E}_{unif}[\cdot]$.

LEMMA A.1. *Let $f : \{0,1\}^T \to [0, M]$ be any function defined on reward sequences $\mathbf{r}$. Then for any action i,*

$$\mathbf{E}_i[f(\mathbf{r})] \leq \mathbf{E}_{unif}[f(\mathbf{r})] + \frac{M}{2}\sqrt{-\mathbf{E}_{unif}[N_i]\ln(1-4\epsilon^2)}.$$

Proof. We apply standard methods that can be found, for instance, in Cover and Thomas [4]. For any distributions $\mathbf{P}$ and $\mathbf{Q}$, let

$$\|\mathbf{P} - \mathbf{Q}\|_1 \doteq \sum_{\mathbf{r} \in \{0,1\}^T} |\mathbf{P}\{\mathbf{r}\} - \mathbf{Q}\{\mathbf{r}\}|$$

be the variational distance, and let

$$\mathrm{KL}(\mathbf{P} \parallel \mathbf{Q}) \doteq \sum_{\mathbf{r} \in \{0,1\}^T} \mathbf{P}\{\mathbf{r}\} \lg\left(\frac{\mathbf{P}\{\mathbf{r}\}}{\mathbf{Q}\{\mathbf{r}\}}\right)$$

be the Kullback–Liebler divergence or relative entropy between the two distributions. (We use lg to denote $\log_2$.) We also use the notation

$$\mathrm{KL}\left(\mathbf{P}\{r_t \mid \mathbf{r}^{t-1}\} \parallel \mathbf{Q}\{r_t \mid \mathbf{r}^{t-1}\}\right) \doteq \sum_{\mathbf{r}^t \in \{0,1\}^t} \mathbf{P}\{\mathbf{r}^t\} \lg\left(\frac{\mathbf{P}\{r_t \mid \mathbf{r}^{t-1}\}}{\mathbf{Q}\{r_t \mid \mathbf{r}^{t-1}\}}\right)$$

for the conditional relative entropy of r_t given $\mathbf{r}^{t-1}$. Finally, for $p, q \in [0,1]$, we use

$$\mathrm{KL}(p \parallel q) \doteq p \lg\left(\frac{p}{q}\right) + (1-p)\lg\left(\frac{1-p}{1-q}\right)$$

as shorthand for the relative entropy between two Bernoulli random variables with parameters p and q.

We have that

$$\begin{aligned}\mathbf{E}_i\left[f(\mathbf{r})\right] - \mathbf{E}_{unif}\left[f(\mathbf{r})\right] &= \sum_{\mathbf{r}} f(\mathbf{r})(\mathbf{P}_i\{\mathbf{r}\} - \mathbf{P}_{unif}\{\mathbf{r}\}) \\ &\leq \sum_{\mathbf{r}:\mathbf{P}_i\{\mathbf{r}\}\geq\mathbf{P}_{unif}\{\mathbf{r}\}} f(\mathbf{r})(\mathbf{P}_i\{\mathbf{r}\} - \mathbf{P}_{unif}\{\mathbf{r}\}) \\ &\leq M \sum_{\mathbf{r}:\mathbf{P}_i\{\mathbf{r}\}\geq\mathbf{P}_{unif}\{\mathbf{r}\}} (\mathbf{P}_i\{\mathbf{r}\} - \mathbf{P}_{unif}\{\mathbf{r}\}) \\ &= \frac{M}{2}\|\mathbf{P}_i - \mathbf{P}_{unif}\|_1. \qquad (28)\end{aligned}$$

Also, Cover and Thomas's Lemma 12.6.1 states that

$$\|\mathbf{P}_{unif} - \mathbf{P}_i\|_1^2 \leq (2\ln 2)\mathrm{KL}\left(\mathbf{P}_{unif} \;\|\; \mathbf{P}_i\right). \qquad (29)$$

The "chain rule for relative entropy" (Cover and Thomas's Theorem 2.5.3) gives that

$$\begin{aligned}\mathrm{KL}\left(\mathbf{P}_{unif} \;\|\; \mathbf{P}_i\right) &= \sum_{t=1}^{T} \mathrm{KL}\left(\mathbf{P}_{unif}\{r_t \mid \mathbf{r}^{t-1}\} \;\|\; \mathbf{P}_i\{r_t \mid \mathbf{r}^{t-1}\}\right) \\ &= \sum_{t=1}^{T} \left(\mathbf{P}_{unif}\{i_t \neq i\}\ \mathrm{KL}\left(\tfrac{1}{2} \;\|\; \tfrac{1}{2}\right) + \mathbf{P}_{unif}\{i_t = i\}\ \mathrm{KL}\left(\tfrac{1}{2} \;\|\; \tfrac{1}{2}+\epsilon\right)\right) \\ &= \sum_{t=1}^{T} \mathbf{P}_{unif}\{i_t = i\}\left(-\tfrac{1}{2}\lg(1-4\epsilon^2)\right) \\ &= \mathbf{E}_{unif}\left[N_i\right]\left(-\tfrac{1}{2}\lg(1-4\epsilon^2)\right). \qquad (30)\end{aligned}$$

The second equality can be seen as follows: Regardless of the past history of rewards $\mathbf{r}^{t-1}$, the conditional probability distribution $\mathbf{P}_{unif}\{r_t \mid \mathbf{r}^{t-1}\}$ on the next reward r_t is uniform on $\{0,1\}$. The conditional distribution $\mathbf{P}_i\{r_t \mid \mathbf{r}^{t-1}\}$ is also easily computed: Given $\mathbf{r}^{t-1}$, the next action i_t is fixed by A. If this action is not the good action i, then the conditional distribution is uniform on $\{0,1\}$; otherwise, if $i_t = i$, then r_t is 1 with probability $1/2+\epsilon$ and 0 otherwise.

The lemma now follows by combining (28), (29), and (30). □

We are now ready to prove the theorem. Specifically, we show the following.

THEOREM A.2. *For any player strategy A, and for the distribution on rewards described above, the expected regret of algorithm A is lower bounded by*

$$\mathbf{E}_*\left[G_{\max} - G_A\right] \geq \epsilon\left(T - \frac{T}{K} - \frac{T}{2}\sqrt{-\frac{T}{K}\ln(1-4\epsilon^2)}\right).$$

Proof. If action i is chosen to be the good action, then clearly the expected payoff at time t is $1/2+\epsilon$ if $i_t = i$ and $1/2$ if $i_t \neq i$:

$$\begin{aligned}\mathbf{E}_i\left[r_t\right] &= \left(\tfrac{1}{2}+\epsilon\right)\mathbf{P}_i\{i_t = i\} + \tfrac{1}{2}\mathbf{P}_i\{i_t \neq i\} \\ &= \tfrac{1}{2} + \epsilon\ \mathbf{P}_i\{i_t = i\}.\end{aligned}$$

Thus, the expected gain of algorithm A is

$$\mathbf{E}_i\left[G_A\right] = \sum_{t=1}^{T} \mathbf{E}_i\left[r_t\right] = \frac{T}{2} + \epsilon\ \mathbf{E}_i\left[N_i\right]. \qquad (31)$$

Next, we apply Lemma A.1 to N_i, which is a function of the reward sequence $\mathbf{r}$ since the actions of player strategy A are determined by the past rewards. Clearly, $N_i \in [0, T]$. Thus,

$$\mathbf{E}_i [N_i] \leq \mathbf{E}_{unif} [N_i] + \frac{T}{2} \sqrt{-\mathbf{E}_{unif} [N_i] \ln(1 - 4\epsilon^2)},$$

and so

$$\begin{aligned} \sum_{i=1}^{K} \mathbf{E}_i [N_i] &\leq \sum_{i=1}^{K} \left(\mathbf{E}_{unif} [N_i] + \frac{T}{2} \sqrt{-\mathbf{E}_{unif} [N_i] \ln(1 - 4\epsilon^2)} \right) \\ &\leq T + \frac{T}{2} \sqrt{-TK \ln(1 - 4\epsilon^2)} \end{aligned}$$

using the fact that $\sum_{i=1}^{K} \mathbf{E}_{unif} [N_i] = T$, which implies that $\sum_{i=1}^{K} \sqrt{\mathbf{E}_{unif} [N_i]} \leq \sqrt{TK}$. Therefore, combining with (31),

$$\mathbf{E}_* [G_A] = \frac{1}{K} \sum_{i=1}^{K} \mathbf{E}_i [G_A] \leq \frac{T}{2} + \epsilon \left(\frac{T}{K} + \frac{T}{2} \sqrt{-\frac{T}{K} \ln(1 - 4\epsilon^2)} \right).$$

The expected gain of the best action is at least the expected gain of the good action, so $\mathbf{E}_* [G_{\max}] \geq T(1/2 + \epsilon)$. Thus, we get that the regret is lower bounded by the bound given in the statement of the theorem. □

For small ϵ, the bound given in Theorem A.2 is of the order

$$\Theta \left(T\epsilon - T\epsilon^2 \sqrt{\frac{T}{K}} \right).$$

Choosing $\epsilon = c\sqrt{K/T}$ for some small constant c gives a lower bound of $\Omega(\sqrt{KT})$. Specifically, the lower bound given in Theorem 5.1 is obtained from Theorem A.2 by choosing $\epsilon = (1/4) \min\{\sqrt{K/T}, 1\}$ and using the inequality $-\ln(1-x) \leq (4 \ln(4/3))x$ for $x \in [0, 1/4]$.

Acknowledgments. We express special thanks to Kurt Hornik for his advice and his patience when listening to our ideas and proofs for an earlier draft of this paper. We thank Yuval Peres and Amir Dembo for their help regarding the analysis of martingales. Last but not least we want to acknowledge the work of the anonymous referees whose very precise remarks helped us to improve the paper.

A VIRTUALLY SYNCHRONOUS GROUP MULTICAST ALGORITHM FOR WANS: FORMAL APPROACH*

IDIT KEIDAR† AND ROGER KHAZAN‡

Abstract. This paper presents a formal design for a novel group communication service targeted for wide-area networks (WANs). The service provides virtual synchrony semantics. Such semantics facilitate the design of fault tolerant distributed applications. The presented design is more suitable for WANs than previously suggested ones. In particular, it features the first algorithm to achieve virtual synchrony semantics in a single communication round. The design also employs a scalable WAN-oriented architecture: it effectively decouples the main two components of virtually synchronous group communication—group membership and reliable group multicast. The design is carried out formally and rigorously. This paper includes formal specifications of both safety and liveness properties. The algorithm is formally modeled and assertionally verified.

Key words. group communication, virtual synchrony, reliable multicast, formal modeling

1. Introduction.

Group communication services (GCSs) [1, 10] are powerful middleware systems that facilitate the development of fault tolerant distributed applications. These services provide a notion of *group abstraction*, which allows application processes to easily organize themselves into multicast groups. Application processes can communicate with the members of a group by addressing messages to the group. Most GCSs strive to present different members of the same group with mutually consistent perceptions of the communication done in the group. This perception is known as *virtual synchrony* (VS) semantics [12].

Traditionally, GCSs were designed for deployment in local-area networks (LANs). Efficient GCSs that operate in wide-area networks (WANs) is still an open area of research. Designing such GCSs is challenging because in WANs communication is more expensive and connectivity is less stable than in LANs.

In this paper we present a novel algorithm for a GCS targeted for WANs. The service provided by our GCS satisfies a variant of the VS semantics that has been shown to be useful for facilitating the design of distributed applications [16, 10]. Our algorithm for implementing this semantics is more appropriate for WANs than the existing solutions: it requires fewer rounds of communication and is designed for the scalable WAN-oriented architecture of [6, 31]. Our design is carried out at a very high level of formality and rigor, much higher than that of most previous designs of virtually synchronous GCSs. It includes formal and precise specifications, algorithms,

and proofs.

The rest of this section is organized as follows: In section 1.1 we present some basic background on GCSs and VS. Section 1.2 summarizes the contributions made by our work, and section 1.3 gives a roadmap to the rest of the paper.

1.1. Background. Modern distributed applications often involve large groups of geographically distributed processes that interact by sending messages over an asynchronous fault-prone network. Many of these applications maintain a replicated state of some sort. In order for these applications to be correct, the replicas must remain mutually consistent throughout the execution of the application. For example, in an online game, the states of the game maintained by different players must be mutually consistent in order for the game to be meaningful to the players. Designing algorithms that maintain state consistency is difficult however: different application processes may perceive the execution of the application inconsistently because of asynchrony and failures. For example, if Alice, Bob, and Carol are playing an online game, the following asymmetric scenario is possible: Alice and Bob perceive each other as alive and well, but they differ in the way they perceive Carol; one sees Carol as crashed or disconnected, while the other sees her as alive and well. Middleware systems that hide from the application some of the underlying inconsistencies and instead present them with a more consistent picture of the distributed execution facilitate development of distributed applications.

GCSs, such as [3, 5, 44, 12], are examples of such middleware systems. They are particularly useful for building applications that require reliable multipoint to multipoint communication among a group (or groups) of processes. Examples of such applications are data replication (for example, [29, 4, 22, 33, 24]), highly available servers (for example, [8]), and online games. GCSs allow application processes to organize themselves easily into groups and to communicate with all the members of a group by addressing messages to the group. The semantics of this abstraction are such that different members of the group have consistent perceptions of the communication done in the group. The abstraction is typically implemented through the integration of two types of services: membership and reliable multicast.

Membership services maintain information about membership of groups. The membership of a group can change dynamically due to new processes joining and current members departing, failing, or disconnecting. The membership service tracks these changes and reports them to group members. The report given by the membership service to a member is called a *view*. It includes a unique identifier and a list of currently active and mutually connected members. Failures can partition a group into disconnected components of mutually connected members. Membership services strive to form and deliver the same views to all mutually connected members of the group.[1] While this is not always possible, they typically succeed once network connectivity more or less stabilizes (see, for example, [31, 16]).

In addition, GCSs provide reliable multicast services that allow application processes to send messages to the entire membership of a group. GCSs guarantee that message delivery satisfies certain properties. For example, one property can be that messages sent by the same sender are delivered in the order in which they were sent; another property can ensure that all processes receive all messages in the same total order. Different GCSs differ in the specific message delivery properties they provide,

[1] In this paper, we consider *partitionable* membership services, which may deliver concurrent, disjoint views of the same group to disconnected members.

but most of them provide some variant of *VS* semantics. We refer to a GCS providing such semantics as a *virtually synchronous GCS*, and to an algorithm implementing this semantics as a *VS algorithm*.

VS semantics specifies how message deliveries are synchronized with view deliveries. This synchronization is done in a way that simulates a "benign" world in which message delivery is reliable within each view. Many variants of VS have been suggested (for example, [38, 23, 16, 12, 40, 9]). Nearly all of them include a key property, called *virtually synchronous delivery*, which guarantees that *processes that receive the same pair of views from the GCS receive the same sets of messages in between receiving the views.* Henceforth, when we refer to VS, we assume the semantics includes virtually synchronous delivery.

EXAMPLE 1.1. *Assume Alice, Bob, and Carol are playing an online game. Assume they communicate using totally ordered messages and modify their game states when they receive messages. Each of them is initially given a view* $\langle\{Alice, Bob, Carol\}, 1\rangle$*, where* $\{Alice, Bob, Carol\}$ *is a set of members and* 1 *is a view identifier. Then Carol disconnects, and Alice and Bob are given a new view* $\langle\{Alice, Bob\}, 2\rangle$*. The virtually synchronous delivery property guarantees that both Alice and Bob receive the same messages before receiving the new view. In particular, if Bob receives a message from Carol before it receives the new view, then Alice also receives this message before the new view. Therefore, Alice and Bob remain in consistent states and can safely continue playing the game after they receive the new view.*

In general, virtually synchronous GCSs are especially useful for building applications that maintain a replicated state of some sort using a variant of the well-known *state-machine/active replication* approach [34, 41] and [32, Chapter 10]. With such an approach, processes that maintain state replicas are organized into multicast groups. Actions that update the state are sent using a multicast primitive that delivers messages to different processes in the same order. When processes receive these actions, they apply them to their local replicas. VS guarantees that processes that remain connected receive the same messages. This implies that processes that remain connected apply the same sequences of actions to their replicas. Hence, their replicas remain mutually consistent. Examples of GCS applications that use this technique are [2, 4, 29, 42, 24, 8].

Let us consider what is involved in implementing the virtually synchronous delivery property. Imagine that GCS processes are forming a new view because someone has disconnected from their current view. The GCS processes must make sure that they deliver the same messages to their application clients before delivering to them the new view. However, it may be the case that some of these GCS processes received messages that others did not. In the scenario illustrated in Example 1.1, the last messages from Carol may have reached the GCS process of only Bob, and not of Alice; Bob and Alice need to agree on whether or not to deliver these messages. To ensure such agreement, GCS processes invoke a *synchronization* protocol whenever a new view is forming.

Designing correct and efficient algorithms that implement VS is not trivial. Different GCS processes may perceive connectivity changes inconsistently. Since the desired synchronization depends on who the members of the new view are, the algorithm has to tolerate transient inconsistent views and cascading connectivity changes.

In particular, a VS algorithm needs to know which synchronization messages sent by different processes pertain to the same view formation attempt. Existing algorithms, such as [23, 3, 40, 9, 26, 5], identify such synchronization messages by

tagging them with a common identifier. Some initial communication is performed first, before synchronization messages are communicated, in order to agree upon a common identifier and to distribute it to the members of the forming view.

While a view is forming and a synchronization protocol is executing, there may be changes in connectivity that call for views with altogether different memberships. When such situations happen, existing VS algorithms, for example [23, 26, 40, 9, 5], continue executing their current synchronization protocol to termination and then deliver to the application a view that does not reflect the already detected changes in connectivity; we refer to such views as *obsolete* [31]. Afterwards, the algorithm is invoked anew to incorporate the new changes. Obsolete views cause an overhead not just for the GCS but also for applications. Since application processes do not know when the views delivered to them are obsolete, they handle such views just as they do any other view, for example, by running state synchronization protocols [29, 22, 33].

1.2. Our contributions. In this paper, we present a novel design for a virtually synchronous GCS targeted for WANs. We make the following contributions:

1. We present a new algorithm for implementing VS. Our algorithm neither processes nor delivers views with obsolete memberships. Moreover, the synchronization protocol run by our algorithm involves just a single message exchange round among members of the new view. We are not aware of any other algorithm for implementing VS that has these two features.

2. Our design demonstrates how to effectively decouple the algorithm for achieving VS from the algorithm for maintaining membership. As suggested in [6, 31], such effective decoupling is important for providing scalable GCSs in WANs.

We define a membership service interface that allows the VS algorithm to execute in parallel with the membership algorithm. In contrast to previous designs, for example, [40, 11], we allow the membership algorithm to freely change memberships of forming views at any time. Moreover, the interaction between the membership and VS algorithms is only in one direction, from the former to the latter. Our interface was adopted by the Moshe [31] membership algorithm; other existing membership algorithms (for example, [20, 5]) can also be easily extended to provide the required interface and semantics.

3. Our design is carried out much more rigorously and formally than most previous designs of virtually synchronous GCSs. The presented specifications of our GCS and its environment, description of the algorithm, and proof of correctness are all precise and formal. Our project is the first to use formal methods for modeling a virtually synchronous GCS and to provide an assertional proof of its correctness.

Our algorithm has been implemented [43] (in C++) as part of a novel architecture for scalable group communication in WANs using the datagram service of [7] and the Moshe membership algorithm [31].

1.3. Roadmap. The rest of this paper is organized as follows. Section 2 gives an overview of our algorithm and overall design. Section 3 reviews the formal model and notation. In section 4 we present the client-server architecture of our GCS and formally specify the assumptions we make on the membership service and the underlying communication substrate. Section 5 contains precise specifications of the safety and liveness properties satisfied by our GCS. The algorithm is then given in section 6 and is accompanied by informal correctness arguments. Section 7 concludes the paper. A formal correctness proof that the algorithm of section 6 satisfies the specifications of section 5 is given in the appendixes: safety properties are given in Appendix B, and liveness properties are given in Appendix C. Appendix A reviews

the proof techniques used in Appendixes B and C.

2. Design overview. The novelty of our algorithm for achieving VS is concentrated in its synchronization protocol. Recall that this protocol is run among GCS processes in order for those that remain connected to agree upon a common set of messages each of them must deliver before moving into the new view. The protocol depends on a simple yet powerful idea. Instead of using common identifiers to designate which synchronization messages pertain to the same view formation attempt, we use locally generated identifiers. These identifiers are then included as part of the formed views.[2] Once a view formation completes at a GCS process, the process knows which synchronization messages of other members to consider for the view—the messages tagged with the identifiers that are included in the view.

EXAMPLE 2.1. *View* $\langle 8, \{Alice, Bob, Carol\}, [4, 3, 7]\} \rangle$ *has membership* $\{Alice, Bob, Carol\}$*, vector of local identifiers* $[4, 3, 7]$*, and view identifier* 8*. When a GCS process forms this view, it uses the synchronization messages from Alice, Bob, and Carol tagged, respectively, with* 4*,* 3*, and* 7 *to decide on the set of messages it must deliver before delivering this view to its application. Thus, if Alice, Bob, and Carol form the same view, they use the same synchronization messages, and thus agree on which application messages each of them needs to deliver.*

The use of local identifiers eliminates the need to preagree on common identifiers and allows the synchronization protocol to complete in a single message exchange round. It also allows the algorithm to promptly react to connectivity changes without wasting resources on obsolete views. The protocol works correctly even if, because of network instability, GCS processes send multiple synchronization messages during the same synchronization protocol.

2.1. Architecture for WAN. Our design decouples the algorithm for implementing virtually synchronous multicast from the algorithm for maintaining membership. The membership algorithm handles generation of local identifiers and formation of views. The algorithm for implementing virtually synchronous multicast synchronizes views and application messages to implement the VS semantics. In particular, it handles multicast requests submitted by the application, delivers application messages and views back to the application, and runs the synchronization protocol to synchronize processes that transition together into new views. The decoupling involves low-cost, one-directional communication from the membership to the virtually synchronous multicast algorithm. It also allows the synchronization protocol to execute in parallel with the membership algorithm forming views.

Efficient decoupling of membership and virtually synchronous multicast algorithms allows for an architecture in which the membership service is implemented by a small set of dedicated membership servers maintaining the membership information on behalf of a large set of clients. This architecture was proposed in [6, 31] for supporting scalable membership services in WANs. Our work extends this architecture by specifying how it can be used as a base for a virtually synchronous GCS. In particular, we present precise specifications of the interface and semantics that a membership service has to provide in order to be decoupled from the virtually synchronous multicast algorithm.

The interface consists of two types of messages, `start` and `view`, sent from membership servers to the processes executing the virtually synchronous multicast algo-

[2] A similar view structure is suggested in [40] for the purpose of not having concurrent views intersect.

rithm; we call these processes the GCS end-points. A `start` message is sent when a membership server starts forming a new view or adds new members to an already forming view. Each `start` message contains a prospective membership set and an identifier, which is *not* globally agreed upon; that is, different processes can be given different identifiers. A `view` message is sent when a server succeeds in forming a new view. The `view` message contains information that maps GCS end-points to the last start identifiers they were given prior to this view. The servers do not need to hear back from the end-points in order to complete the membership algorithm, and the end-points do not impose any restrictions on the servers' choices of views. These two features are in contrast with previously suggested external membership services, such as, for example, Maestro [11] and the service of [40], in which membership servers are not allowed to add new members once view formation begins and, furthermore, have to synchronize with the processes executing the virtually synchronous multicast algorithm before they can produce new views.

2.2. Algorithm for virtual synchrony. When the membership service starts forming a view, it sends a `start` notification with a prospective membership set and a new local identifier to each end-point `p` executing the virtually synchronous multicast algorithm. Upon receiving this notification, `p` sends a synchronization message tagged with this identifier to the end-points in the prospective membership set. In the synchronization message, `p` specifies its current view and the set of application messages that `p` commits to deliver in its current view before delivering the new view. If an end-point `q` joins the membership while a view formation is in progress, `p` will receive a new `start` notification and will then forward to `q` the same synchronization messages it sent when the view formation started.

When `p` receives a `view` message from its membership server, the local identifiers included in the view tell `p` which synchronization messages to consider—those messages that are tagged with the local identifiers included in the new view. Using the information contained in these messages, `p` computes two things: (a) the set of end-points, called the *transitional set* [16], containing those members of the new view that would transition into the new view together with `p` directly from `p`'s current view; and (b) the set of application messages that `p` must deliver in its current view before transitioning into the new view. End-point `p` computes the transitional set to include every end-point `q` that is a member of both `p`'s current view and the new view, and whose synchronization message was sent in the same view as `p`'s current view. As far as the set of application messages, end-point `p` decides on delivering the maximal set of messages identified by the synchronization messages of the transitional set members. Since the same views formed by different end-points contain the same local identifiers, the end-points use the same synchronization messages to compute the transitional set and the message set. After delivering the decided set of application messages, `p` delivers the new view and the transitional set to its application client. The transitional set tells the client about the members of the new view with whom the client is already synchronized.

Unlike previous algorithms, for example, those in [5, 26, 9, 40], our algorithm allows the membership service to change the membership of a forming view while the synchronization protocol is running; the protocol responds immediately to such membership changes. The following example demonstrates the benefits of this approach.

EXAMPLE 2.2. *Figure* 2.1 *presents a sample execution involving two clients,* `a` *and* `b`. *Vertical arrows represent the time passage at each client, empty circles represent* GCS*-level events, and gray circles represent* MEMB*-level events. In order*

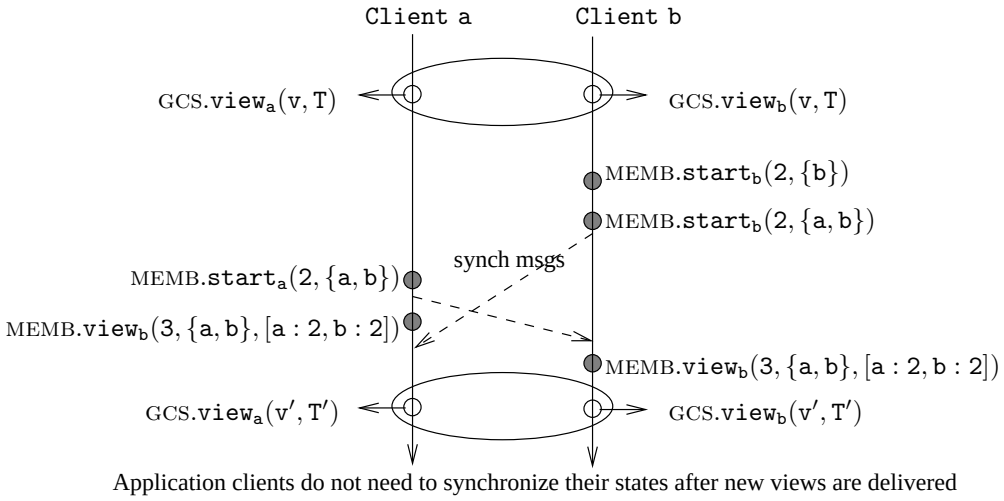

FIG. 2.1. *Handling membership changes while synchronization protocol is running.*

to disambiguate these events, we prefix events generated at the membership server by MEMB *and events generated by the virtually synchronous multicast algorithm by* GCS.

First, both clients receive the same view $\mathtt{v} = \langle 2, \{\mathtt{a}, \mathtt{b}\}, [\mathtt{a} : 1, \mathtt{b} : 1]\rangle$ *from their* GCS *end-points,* $\text{GCS}_\mathtt{a}$ *and* $\text{GCS}_\mathtt{b}$*; the ellipse around these view events highlights that the delivered views are the same. At some point, the* MEMB *service notifies* $\text{GCS}_\mathtt{b}$ *that it is starting to form a view without* a*. While doing so, it detects that* a *is connected to* b *after all, so it changes the membership of the forming view to* $\{\mathtt{a}, \mathtt{b}\}$*.* $\text{GCS}_\mathtt{b}$ *forwards to* $\text{GCS}_\mathtt{a}$ *its latest synchronization message; synchronization messages are denoted by dashed lines.* $\text{GCS}_\mathtt{a}$ *is also notified by* MEMB *of its attempt to form a new view with* b*; this causes* $\text{GCS}_\mathtt{a}$ *to send a synchronization message to* $\text{GCS}_\mathtt{b}$*. When* MEMB *completes its view formation, it delivers the new view* $\mathtt{v}' = \langle 3, \{\mathtt{a}, \mathtt{b}\}, [\mathtt{a} : 2, \mathtt{b} : 2]\rangle$ *to both* GCS *end-points. After the* GCS *end-points receive each others' synchronization messages, they compute their transitional sets to be* $\mathtt{T}' = \{\mathtt{a}, \mathtt{b}\}$*, decide on which application messages they need to deliver, deliver these messages, and then deliver* $\mathtt{v}'$ *and* $\mathtt{T}'$ *to their clients. From* $\mathtt{T}'$*,* a *and* b *can deduce that, due to virtually synchronous delivery, they received the same messages while in* v*, and therefore do not need to synchronize their states.*

Example 2.2 demonstrates two additional advantages of our algorithm: (a) the algorithm does not waste resources on synchronizing end-points in order to deliver views that are known to be obsolete; and (b) the application benefits from not seeing obsolete views, as it has to do fewer state synchronizations (or other view processing activity). Responding promptly to connectivity changes is therefore especially important in WANs, where transient connectivity changes may occur frequently due to variability of message latency and less reliable connectivity. In contrast to our algorithm, algorithms that do not allow new members to be added to the membership of an already forming view (such as [5, 26, 9, 40]) lack these advantages, as illustrated by the following example.

EXAMPLE 2.3. *When executed in the scenario of Example* 2.2*, algorithms that do not allow new members to be added to the membership of an already forming view would deliver an obsolete view* $\mathtt{v}_\mathtt{mid}$ *with membership* $\{\mathtt{b}\}$ *to client* b *and then restart*

the view formation and synchronization protocols anew in order to deliver to a *and* b *a new view with membership* {a, b}. *As part of the synchronization protocol,* a *and* b *would first exchange messages to agree upon a common identifier before actually exchanging synchronization messages. The synchronization protocol would* not *synchronize end-points* a *and* b *because they would be transitioning into the new view from different views,* a *from* v *and* b *from* v_{mid}. *As a result, after the clients get the new view from* GCS, *they would have to run an additional state synchronization protocol.*

2.3. Formal methodology. Our design has been carried out and is presented at a level more formal and rigorous than that of most previous designs of virtually synchronous GCSs. We precisely specify the properties satisfied by our virtually synchronous multicast algorithm, the external membership service, and the underlying communication substrate. We then give a formal description of the virtually synchronous multicast algorithm. The algorithm is accompanied by a careful formal correctness proof. The safety properties are proved by using invariant assertions and simulation mappings; the liveness properties are proved by using invariant assertions and careful operational arguments. We found this level of rigor to be important: in the process of specifying and verifying the algorithm, we uncovered several ambiguities and errors.

Previously, formal approaches were used to specify the semantics of virtually synchronous GCSs and to model and verify their applications, for example, in [15, 22, 18, 33, 27]. Existing algorithms implementing VS are modeled in pseudocode and proven correct operationally. However, due to their size and complexity, such algorithms were not previously modeled using formal methods nor were they assertionally verified.

To manage the complexity of this project we have developed a formal inheritance-based methodology [30] for incrementally constructing specifications, algorithms, and proofs. In addition to making the project tractable, the use of this construct makes clear which parts of the algorithm implement which property. The modularity of this approach facilitates further modifications and alterations of the design. Our project and the inheritance-based construct are both developed in the framework of the I/O automaton formalism (see [37] and [36], Chap. 8).

3. Formal model and notation. In the I/O automaton model ([37] and [36], Chap. 8), a system component is described as a state-machine, called an *I/O automaton*. The transitions of this state-machine are associated with named actions, which are classified as either *input*, *output*, or *internal*. Input and output actions model the component's interaction with other components, while internal actions are externally unobservable.

Formally, an I/O automaton is defined as the following five-tuple: a signature (input, output, and internal actions), a set of states, a set of start states, a state-transition relation (a cross-product between states, actions, and states), and a partition of output and internal actions into *tasks*. Tasks are used for defining fairness conditions.

An action π is said to be *enabled* in a state s if the automaton has a transition of the form (s, π, s′); input actions are enabled in every state. An *execution* of an automaton is an alternating sequence of states and actions that begins with its start state and in which every action is enabled in the preceding state. An infinite execution is *fair* if, for each task, it contains either infinitely many actions from this task or infinitely many occurrences of states in which no action from this task is enabled; a finite execution is *fair* if no action is enabled in its final state. A *trace* is a subsequence of an execution solely consisting of the automaton's external actions. A *fair trace* is

a trace of a fair execution.

When reasoning about an automaton, we are interested in only its externally observable behavior as reflected in its traces. There are two types of trace properties: *safety* and *liveness*. Safety properties usually specify that some particular bad thing never happens. In this paper we specify safety properties using centralized, global, I/O automata that generate the legal sets of traces; for such automata we do not specify task partitions. Each external action in such a centralized automaton is tagged with a subscript which denotes the process at which this action occurs. An algorithm automaton *satisfies* a specification if all of its traces are also traces of the specification automaton. Refinement mappings are a commonly used technique for proving trace inclusion, in which one automaton (the algorithm) *simulates* the behavior of another automaton (the specification). Refinement mappings and other related proof techniques are reviewed in Appendix A. Liveness properties usually specify that some good thing eventually happens. An algorithm automaton satisfies a liveness property if the property holds in all of its *fair* traces.

The *composition operation* defines how automata interact via their input and output actions: It matches output and input actions with the same name in different component automata; when a component automaton performs a step involving an output action, so do all components that have this action as an input one. When reasoning about a certain system component, we compose it with abstract specification automata that specify the behavior of its environment.

I/O automata are conveniently presented using the *precondition-effect* style: In this style, typed state variables with initial values specify the set of states and the start states. A variable type is a set; if S is a set, the notation $S_\perp$ refers to the set $S \cup \{\perp\}$. Transitions are grouped by action name and are specified as a list of triples consisting of an action name possibly with parameters, a `pre` : block with preconditions on the states in which the action is enabled, and an `eff` : block which specifies how the pre-state is modified *atomically* to yield the poststate. The precondition-effect style is also known as a *guarded command* style: events have guards, or preconditions, and are triggered when the preconditions are enabled.

We have developed a novel formal notion of inheritance for automata [30]. A *child* automaton is specified as a modification of the parent automaton's code. When presenting a child we first specify a *signature extension* which consists of new actions, labeled new, and modified actions. A modified action is labeled with the name of the action which it modifies as follows: modifies `parent.action(parameters)`. We next specify the *state extension* consisting of new state variables added by the child. Finally, we describe the *transition restriction* which consists of new preconditions and effects added by the child to both new and modified actions. For modified actions, the preconditions and effects of the parent are appended to those added by the child. New effects added by the child are performed before the effects of the parent, all of them in a single atomic step. The child's effects are not allowed to modify state variables of the parent. This ensures that the set of traces of the child, when projected onto the parent's signature, is a subset of the parent's set of traces [30].

Inheritance allows us to reuse code and avoid redundancies. It also allows us to reuse proofs: Assume that an algorithm automaton `A` can simulate a specification automaton `S`, and let `A′` and `S′` be child automata of `A` and `S`, respectively. Then the proof extension theorem of [30] asserts that in order to prove that `A′` can simulate `S′`, it is sufficient to show that the restrictions added by `A′` are consistent with the restrictions `S′` places on `S` and that the new functionality of `A′` can simulate new

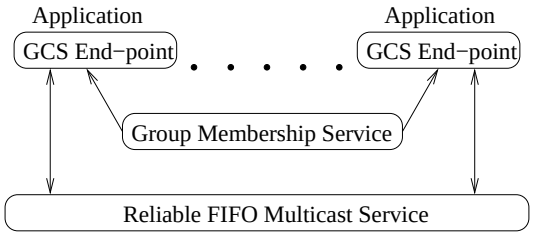

FIG. 4.1. *The client-server architecture: GCS end-points using an external membership service. Arrows represent interaction between GCS end-points and underlying services.*

functionality of $\mathtt{S}'$. Appendix A contains more details.

4. Client-server architecture and environment specification. Our service is designed to operate in an asynchronous message-passing environment. Processes and communication links may fail and may later recover, possibly causing network partitions and merges. For simplicity, we assume that processes recover with their running state intact; this is a plausible assumption as processes can keep their running state on stable storage. We do not explicitly model process crashes and recoveries because under this assumption a crashed process is indistinguishable from a slow one. In section 6.4, we argue that our algorithm also provides meaningful semantics when group communication processes lose their entire state upon a crash and recover with their state reset to an initial value.

Our GCS is implemented by a collection of GCS *end-points*, which are the GCS processes that run at the application clients' locations. GCS end-points handle clients' multicast requests and inform their clients of view changes.

The GCS architecture is depicted in Figure 4.1. All GCS end-points run the same algorithm. The algorithm relies on the underlying membership and multicast services to handle, respectively, formation of views and transmission of messages. The algorithm's task is to synchronize output of the two underlying services to implement the VS semantics.

Sections 4.1 and 4.2 below give precise specifications of the interface and semantics that the underlying membership and multicast services have to provide in order to be suitable for our algorithm. Services that satisfy these (or very similar) requirements have been previously used for GCSs, and efficient implementations of these services for WANs exist; see, for example, [31, 7].

4.1. The membership service specification. This section presents a formal specification of the membership services that are appropriate for our GCS design. For simplicity, here and in the rest of the paper, we assume that there is a single process group; multiple groups can be supported by treating each independently. We also omit part of the interface that handles processes' requests to join and leave groups.

Figure 4.2 contains an I/O automaton, called MEMB, that defines the interface and the safety properties of the membership service. The service interface is given by the automaton's signature.[3] Informally, it consists of the following two output

[3]When specifying a distributed system as a centralized automaton, we subscript each external action of the specification automaton with the location (or process) in the distributed system at which the action occurs.

AUTOMATON MEMB

Type:
Proc: Set of end-points.
StartId: Total-order; $\texttt{cid}_0$ is smallest.
ViewId: Partial-order; $\texttt{vid}_0$ is smallest.
View: ViewId × SetOf(Proc) × (Proc → StartId).
Def: $\texttt{v}_\texttt{p} = \langle \texttt{vid}_0, \{\texttt{p}\}, \{(\texttt{p} \rightarrow \texttt{cid}_0)\}\rangle$.

FIG. 4.2. *Membership service interface and safety specification.*

actions:

$\texttt{start}_\texttt{p}$(cid, set) notifies process p that the membership service is attempting to form a view with the members of set; cid is a local start identifier;

$\texttt{view}_\texttt{p}$(v) notifies process p that the membership service has succeeded in forming view v. A view v is a triple consisting of an identifier v.id, a set of members v.set, and a function v.startId that maps members of v to start identifiers. Two views are the same if they consist of identical triples.

Automaton MEMB maintains two state variables, memb_view[p] and start[p], for each client p. These variables contain, respectively, the last view and the last start message issued to client p; the variables are updated in the effects of the transitions. The safety properties satisfied by the MEMB automaton include two basic properties, which are provided by virtually all group membership services (for example, [13, 20, 5, 23, 9, 31, 40, 3]), as well as some new properties concerning the start notifications.

The two basic properties are *self-inclusion* and *local monotonicity*. Self-inclusion requires every view issued to a client p to include p as a member; this property is enforced with a precondition p ∈ v.set on the $\texttt{view}_\texttt{p}$(v) action. Local monotonicity requires that view identifiers delivered to p be monotonically increasing; this property is enforced with a precondition v.id > memb_view[p] on the $\texttt{view}_\texttt{p}$(v) action. Local monotonicity has two important consequences: the same view is not delivered more than once to the same client, and clients that receive the same two views receive them in the same order [16].

In addition, the MEMB automaton specifies that the membership service must issue at least one start notification to client p before issuing a new view v to p. Also, the start identifier v.startId(p) contained in the new view v must be the same as the identifier of the latest preceding start issued to p. These two requirements are enforced by the last two preconditions on $\texttt{view}_\texttt{p}$(v). In particular, the former one is achieved by requiring that a bigger start identifier than the one associated with p in the last view has been issued to p.

The MEMB specification allows the membership service to react to connectivity changes happening during view formation. Whenever the service wants to add new

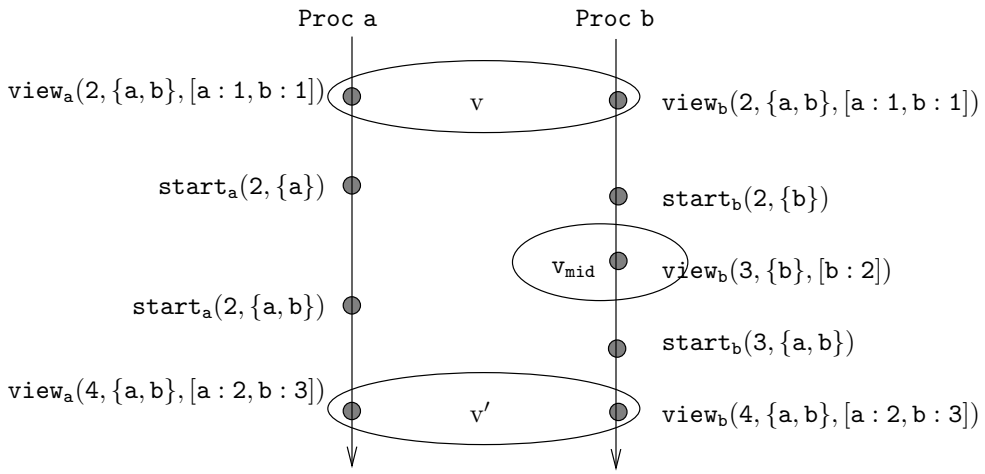

FIG. 4.3. *A sample execution of* MEMB.

members to the membership, it has to issue a new `start` notification to the clients: the second precondition on $\texttt{view}_{\texttt{p}}(\texttt{v})$ actions requires the membership `v.set` to be a subset of the tentative membership `set` included in the last `start` notification. In order to remove members from a forming view, the service does not need to issue a new `start` notification.

The first `start` notification issued to `p` after a view marks the beginning of a new view formation period. It includes a new local identifier `cid`, different from the ones that were previously sent to `p`: the first precondition on $\texttt{start}_{\texttt{p}}(\texttt{cid}, \texttt{set})$ requires `cid` to be strictly greater than `memb_view`[p].`startId`(p). Subsequent `start` notifications sent during an ongoing view formation may either reuse the last start identifier or issue a new one, as specified by the second precondition on `start` actions. We ensure uniqueness of local start identifiers by generating them in increasing order.

Notice that the MEMB automaton does not specify any relationship between views issued to different clients.

EXAMPLE 4.1. *Figure* 4.3 *presents a sample execution that shows the* MEMB *service delivering different sequences of views to two different clients,* a *and* b. *Arrows represent time passage at each client; gray dots represent events. First, both clients receive the same view* $\texttt{v} = \langle 2, \{\texttt{a}, \texttt{b}\}, [\texttt{a} : 1, \texttt{b} : 1]\rangle$*; we illustrate this with a circle around the view events at both clients. Then, client* b *receives a view* $\texttt{v}_{\texttt{mid}} = \langle 3, \{\texttt{b}\}, [\texttt{b} : 2]\rangle$ *by itself. Then, both clients receive another common view* $\texttt{v}' = \langle 4, \{\texttt{a}, \texttt{b}\}, [\texttt{a} : 2, \texttt{b} : 3]\rangle$*. Notice how the start identifiers included in the views correspond to the last start identifiers issued to the clients.*

We do *not* specify liveness properties for membership services. Instead, when we specify the liveness properties of our GCS in section 5.2, we *condition* them on the behavior of the membership service. For example, we state that if the same view is delivered to all the members and the members do not receive any subsequent membership events, then they eventually deliver this view to their application clients. Existing membership services do satisfy meaningful liveness properties. For example, [31] guarantees that, when the network stabilizes, all members receive the "correct" view and no other views thereafter. By combining our GCS liveness properties with such membership liveness properties, we can restate the liveness properties of our GCS

FIG. 4.4. *Reliable* FIFO *multicast service specification. Liveness-related code is italicized.*

conditionally on the network behavior.

The MEMB specification allows for simple and efficient distributed implementations that also satisfy meaningful liveness properties. The membership service of [31] is an example of such an implementation; our design was implemented by Tarashchanskiy [43] using this membership service. In this service, a small number of servers support a large number of clients, communicating with them asynchronously via FIFO ordered channels (TCP sockets). In case a server fails, clients can migrate to another server. Other existing membership algorithms (for example, [20, 5]) could also be easily extended to provide the interface and semantics specified here.

4.2. The reliable FIFO multicast service specification. The group communication end-points communicate with each other using an underlying multicast service that provides reliable FIFO communication between every pair of connected processes. Many existing group communication systems (for example, [26, 9, 20, 3]) implement VS over similar communication substrates. In our implementation [43], we use the service of [7].

Figure 4.4 presents an I/O automaton, CO_RFIFO, that specifies a multicast service appropriate for our GCS design. Portions of the code that define liveness properties are italicized.

Automaton CO_RFIFO maintains a FIFO queue $\texttt{channel}[\texttt{p}][\texttt{q}]$ for every pair of end-points. An input action $\texttt{send}_{\texttt{p}}(\texttt{set}, \texttt{m})$ models a multicast of message m from end-point p to the end-points listed in the set by appending m to the $\texttt{channel}[\texttt{p}][\texttt{q}]$ queues for every end-point q in set. The $\texttt{deliver}_{\texttt{p,q}}(\texttt{m})$ action removes the first message from $\texttt{channel}[\texttt{p}][\texttt{q}]$ and delivers it to q.

In addition, the interface of CO_RFIFO includes input actions of the type $\texttt{reliable}_{\texttt{p}}(\texttt{set})$; end-point p may use such actions to command the multicast service to maintain a reliable (gap-free) FIFO connection to the end-points listed in set. Whenever this action occurs, set is stored in a special variable $\texttt{reliable\_set}[\texttt{p}]$. For every process q not in $\texttt{reliable\_set}[\texttt{p}]$, the multicast service may lose an arbitrary suffix of the messages sent from p to q, as modeled by an internal action $\texttt{lose}(\texttt{p}, \texttt{q})$.

In order for the multicast service to be considered live, messages sent to live and connected processes must eventually reach their destinations. The CO_RFIFO specification enforces this property in the italicized portion of its code.

Recall from section 3 that an infinite fair execution of an automaton must contain either infinitely many events from each task $\mathtt{C}$ or infinitely many occurrences of states in which no action in $\mathtt{C}$ is enabled. Automaton CO_RFIFO defines the set $\mathtt{C}_{\mathtt{p},\mathtt{q}} = (\{\mathtt{deliver}_{\mathtt{p},\mathtt{q}}(\mathtt{m}) \mid \mathtt{m} \in \mathtt{Msg}\} \cup \mathtt{skip\_task}(\mathtt{p},\mathtt{q}) \cup \mathtt{lose}(\mathtt{p},\mathtt{q}))$ to be a task for each pair of end-points $\mathtt{p}$ and $\mathtt{q}$. This definition implies that $\mathtt{deliver}_{\mathtt{p},\mathtt{q}}$ actions must occur in an infinite fair execution of CO_RFIFO, provided the following three conditions hold: there are messages sent from $\mathtt{p}$ to $\mathtt{q}$—hence, $\mathtt{deliver}_{\mathtt{p},\mathtt{q}}$ is enabled; the client at $\mathtt{p}$ is interested in maintaining reliable connection to $\mathtt{q}$—hence, $\mathtt{lose}(\mathtt{p},\mathtt{q})$ is disabled; and $\mathtt{q}$ is believed to have a live connection to $\mathtt{p}$—hence, a special action $\mathtt{skip\_task}(\mathtt{p},\mathtt{q})$ is disabled, as explained below.

Action $\mathtt{skip\_task}(\mathtt{p},\mathtt{q})$ is defined only to provide an alternative to $\mathtt{deliver}_{\mathtt{p},\mathtt{q}}$ actions so that $\mathtt{deliver}_{\mathtt{p},\mathtt{q}}$ actions are not required to happen when $\mathtt{q}$ is believed to be disconnected from $\mathtt{p}$. $\mathtt{skip\_task}(\mathtt{p},\mathtt{q})$ is an internal action that has no effect on the state of CO_RFIFO and is enabled when $\mathtt{q}$ is believed to be disconnected from $\mathtt{p}$. Such belief is modeled using special $\mathtt{live}_{\mathtt{p}}(\mathtt{set})$ input actions. The $\mathtt{set}$ argument is assumed to represent a set of processes that are alive and connected to $\mathtt{p}$; when such an input happens, $\mathtt{set}$ is stored in a state variable $\mathtt{live\_set}[\mathtt{p}]$. The precondition on the $\mathtt{skip\_task}(\mathtt{p},\mathtt{q})$ action is $\mathtt{q} \notin \mathtt{live\_set}[\mathtt{p}]$.

An important implication of how tasks are defined in CO_RFIFO is that, if $\mathtt{q}$ remains in both $\mathtt{live\_set}[\mathtt{p}]$ and $\mathtt{reliable\_set}[\mathtt{p}]$ from some point on in a fair execution of CO_RFIFO, then all the messages that $\mathtt{p}$ sends to $\mathtt{q}$ from that point on are eventually delivered to $\mathtt{q}$.

5. Specifications of the group communication service. The next two subsections contain specifications of the safety and liveness properties satisfied by our GCS. The specifications capture a core set of properties that is commonly provided by GCSs and that have been shown to be useful for facilitating implementations of many distributed applications and other, stronger, group communication properties (see [16]). For example, [32, Chapter 10] illustrates the utility of our GCS system by describing a simple application that can be effectively built using GCS. The application implements a variant of a data service that allows a dynamic group of clients to access and modify a replicated data object.

5.1. Safety properties. We present the safety specification of our GCS incrementally as four automata: In section 5.1.1 we specify a simple GCS that synchronizes delivery of views and application messages to require *within-view delivery* of messages. In section 5.1.2 we extend the specification of section 5.1.1 to also require *virtually synchronous delivery*, the key property of VS (see section 1.1). In section 5.1.3 we specify the *transitional set* property, which complements virtually synchronous delivery. Finally, in section 5.1.4, we specify the *self-delivery* property, which requires the GCS to deliver to each client the client's own messages.

The incremental development of the safety specification is matched later when we develop the algorithm and its correctness proof in section 6 and Appendix B.

5.1.1. Within-view reliable FIFO multicast. In this section we specify a GCS that captures the following properties:

1. Views delivered to the application satisfy the self-inclusion and local monotonicity properties of the MEMB service; see section 4.1.

AUTOMATON WV_RFIFO : SPEC

eff: (∀ q) last_dlvrd[q][p] ← 0
current_view[p] ← v

FIG. 5.1. WV_RFIFO *service specification.*

2. Messages are delivered in the same view in which they were sent. This property is useful for many applications (see [23, 16, 42]) and appears in several systems and specifications (for example, [13, 44, 5, 38, 22, 28, 18]). A weaker property that requires each message to be delivered in the same view at every process that delivers it, but not necessarily the view in which it was sent, is typically implemented on top of an implementation of within-view delivery (see [16]).

3. Messages are delivered in gap-free FIFO order (within views). This is a basic property upon which one can build services with stronger ordering guarantees, such as causal order or total order. The totally ordered multicast algorithm of [14] is implemented atop a service with a similar specification.

Figure 5.1 presents automaton WV_RFIFO : SPEC that models this specification. The automaton uses centralized queues `msgs`[p][v] of application messages for each sender `p` and view `v`. It also maintains a variable `current_view`[p] that contains the last view delivered to each process `p` and a variable `last_dlvrd`[q][p], for every pair of processes `q` and `p`, containing the index in the `msgs`[q][`current_view`[p]] queue of the last message from `q` delivered to `p` in `p`'s current view.

Action $\text{view}_p(v)$ models the delivery of view `v` to process `p`; the precondition on this action enforces self-inclusion and local monotonicity. Action $\text{send}_p(m)$ models the multicast of message `m` from process `p` to the members of `p`'s current view by appending `m` to `msgs`[p][`current_view`[p]]. Action $\text{deliver}_p(q, m)$ models the delivery to process `p` of message `m` sent by process `q`. The gap-free FIFO ordered delivery of messages within-views is enforced by its precondition, which allows delivery of only the message indexed by `last_dlvrd`[q][p] + 1 in the `msgs`[q][`current_view`[p]] queue.

5.1.2. Virtually synchronous delivery. In this section we use the inheritance-based methodology to modify the WV_RFIFO : SPEC automaton to also enforce the *virtually synchronous delivery* property. The modified automaton, VSRFIFO : SPEC, is defined by the code contained in both Figures 5.1 and 5.2.

Figure 5.2 contains the code that enforces the *virtually synchronous delivery* property. Recall from section 1.1 that this property requires processes moving together from view `v` to view `v′` to deliver same set of messages while in view `v`. Since the parent specification, WV_RFIFO : SPEC, imposes gap-free FIFO delivery of messages, a message set can be represented by a set of indices, each pointing to the last message from each member of `v`; such representation of a set is called a *cut*.

AUTOMATON VS_RFIFO : SPEC MODIFIES WV_RFIFO : SPEC

Signature Extension:
Output: $\texttt{view}_p(v)$ modifies $\texttt{wv\_rfifo.view}_p(v)$
Internal: set_cut(v, v′, c), View v, View v′, $(\text{Proc} \to \text{Int})_\perp$ c new

State Extension:
For all View v, v′: $(\text{Proc} \to \text{Int})_\perp$ cut[v][v′], initially $\perp$

Transition Restriction:

OUTPUT $\textbf{view}_p(v)$
pre: cut[current_view[p]][v] $\neq \perp$
(∀ q) last_dlvrd[q][p]=cut[current_view[p]][v](q)

INTERNAL **set_cut**(v, v′, c)
pre: cut[v][v′] $= \perp$
eff: cut[v][v′] $\leftarrow$ c

FIG. 5.2. VS_RFIFO *service specification.*

The WV_RFIFO : SPEC automaton fixes a cut for processes that wish to move from some view v to some view v′: A new internal action $\texttt{set\_cut}(v, v', c)$ sets a new variable $\texttt{cut}[v][v']$ to a cut mapping c. For a given pair of views, v and v′, the cut is chosen only once, *nondeterministically.* Delivery of a view v to process p is allowed only if a cut for moving from p's current view into v has been set and if p has delivered all the messages identified in this cut. These conditions are enforced by the two new preconditions of the $\texttt{view}_p(v)$ action (see Figure 5.2). Since VSRFIFO : SPEC is a modification of WV_RFIFO : SPEC, the new preconditions work in conjunction with the preconditions in $\texttt{view}_p(v)$ of WV_RFIFO : SPEC.

The VSRFIFO : SPEC automaton, being a safety specification, does not require liveness properties to hold, for instance, that processes actually deliver messages specified by the cuts and hence are able to satisfy conditions for delivering new views. Such liveness specifications are stated in section 5.2.

5.1.3. Transitional set. While virtually synchronous delivery is a useful property, a process that moves from view v to view v′ cannot tell locally which of the processes in $v.\texttt{set} \cap v'.\texttt{set}$ move to view v′ directly from view v and which move to v′ from some other view. In order for the application to be able to exploit the virtually synchronous delivery property, application processes need to be informed which other processes move together with them from their current view into their new view. The set of processes that transition together from one view into the next is called a *transitional set* [16].

DEFINITION 5.1. *A transitional set from view* v *to view* v′ *is a subset of* $v.\texttt{set} \cap v'.\texttt{set}$ *that includes* (a) *all processes that receive view* v′ *while in view* v *and* (b) *no process that receive view* v′ *while in a view other than* v.

Note that the transitional set is not uniquely defined by Definition 5.1. If a process p in $v.\texttt{set} \cap v'.\texttt{set}$ does not receive view v′, Definition 5.1 does not specify whether or not p is included in the transitional sets of other processes that do receive view v′.

The notion of a transitional set was first introduced as part of a special transitional view in the EVS [38] model. In our formulation (as in [16]), transitional sets are delivered to the application along with views as an additional parameter T.

EXAMPLE 5.1. *Assume that Alice and Bob are using a virtually synchronous GCS that eventually reports the views produced by the* MEMB *service to Alice and Bob. Consider the scenario described in Example* 4.1*: both Alice and Bob receive views* v *and* v′ *with the membership* {*Alice, Bob*}*. Just from these views, Alice does not know whether Bob receives view* v′ *while in view* v *or while in some other view* v_{mid} *with the membership* {*Bob*}*. If the former holds, then Alice does not need to synchronize with Bob because virtually synchronous delivery guarantees that they have received the same messages while in view* v*; otherwise, she does. The transitional set*

AUTOMATON TRANS_SET : SPEC

OUTPUT **view_p(v)**
pre: last_dlvrd[p][p] = LastIndexOf(msgs[p][current_view[p]])

FIG. 5.4. WV_RFIFO+SELF *service specification.*

given to Alice together with view v' *provides this information.*

Figure 5.3 presents an automaton TS : SPEC that specifies delivery of transitional sets (Definition 5.1). There are two types of actions: output actions $\texttt{view}_p(v, T)$ deliver view v and transitional set T to process p; and internal actions $\texttt{set\_prev\_view}_p(v)$ declare that q intends to deliver view v while in its current view. The intentions are recorded in the variable prev_view[p][v], and the current views are recorded in the variable current_view[p].

Before process p can deliver a view v, each member q in the intersection of these views must execute $\texttt{set\_prev\_view}_q(v)$, as enforced by the second precondition. The transitional set T delivered by p with v is then computed to consist of those processes q in the intersection current_view[p].set ∩ v.set for which prev_view[q][v] is the same as current_view[p]; this is specified by the third precondition on $\texttt{view}_p(v, T)$.

5.1.4. Self-delivery. We now specify the *self-delivery* property, which requires that each client receives all the messages it sent in a given view before receiving a new view. We specify this property as a simple modification of the WV_RFIFO : SPEC automaton presented in section 5.1.1; the modified automaton is defined by the code contained in both Figures 5.1 and 5.4.

In order to enforce self-delivery, a new precondition on the $\texttt{view}_p(v)$ action requires the last_dlvrd[p][p] index to point to the last message sent by client p in its current view. Since the parent automaton, WV_RFIFO : SPEC, guarantees within-view gap-free FIFO delivery, this precondition implies that all of p's messages have in fact been delivered back to p.

In order for a GCS to be live and satisfy within-view delivery, self-delivery, and virtually synchronous delivery, the GCS must *block* its application from sending new messages during view formation periods; this is proved in [23]. Therefore, we introduce a block/block_ok synchronization when we extend our algorithm to support the self-

delivery property in section 6.3.

Our formulation of self-delivery as a safety property, when combined with the liveness property of section 5.2, implies the formulations in [16] and [38] of self-delivery as a liveness property. These formulations require a GCS to *eventually* deliver to each process its own messages.

5.2. Liveness property. In a fault-prone asynchronous model, it is not feasible to require that a GCS be live in every execution. The only way to specify useful liveness properties without strengthening the communication model is to make these properties *conditional* on the underlying network behavior (as specified, for example, in [22, 17, 16]). Since our GCS uses an external membership service, we condition the GCS liveness on the behavior of the membership service.

We define the liveness property for a restricted set of executions in which a component stabilizes from some point on forever thereafter.

PROPERTY 5.1 (view stability). *Let* GCS *be a group communication service whose interface with its clients consists of* `send`, `deliver`, *and* `view` *events as defined in the automaton signature in Figure* 5.1. *Furthermore, assume that the* GCS *uses a membership service* MEMB *described in section* 4.

A view $\mathtt{v}$ *eventually becomes* stable *in a given timed execution* $\alpha = \mathtt{s}_0, \pi_1, \mathtt{s}_1, \pi_2, \ldots$ *of the* GCS *service, in the sense that a* MEMB.$\mathtt{view}_\mathtt{p}(\mathtt{v})$ *event occurs in* α *for every* $\mathtt{p} \in \mathtt{v.set}$ *and is followed by neither* MEMB.$\mathtt{view}_\mathtt{p}$ *nor* MEMB.$\mathtt{start}_\mathtt{p}$ *events.*

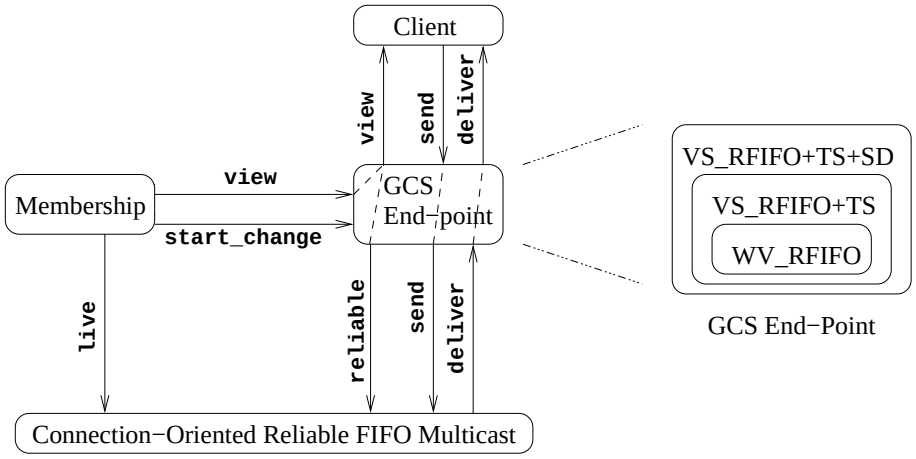
Given an execution that satisfies Property 5.1, the liveness property requires each end-point in the stable view to eventually deliver this last view and all the messages sent in this view to its client. Formally, we have the following property.

PROPERTY 5.2 (liveness). *Let* GCS *be a group communication service whose interface with its clients consists of* `send`, `deliver`, *and* `view` *events as defined in the automaton signature in Figure* 5.1. *Furthermore, assume that the* GCS *uses a membership service* MEMB *described in section* 4.

Let α *be a fair execution of* GCS *in which view* $\mathtt{v}$ *eventually becomes stable (Property* 5.1*). Then, at each* $\mathtt{p} \in \mathtt{v.set}$, GCS.$\mathtt{view}_\mathtt{p}(\mathtt{v})$ *eventually occurs. Moreover, for every* GCS.$\mathtt{send}_\mathtt{p}(\mathtt{m})$ *that occurs after* GCS.$\mathtt{view}_\mathtt{p}(\mathtt{v})$, *and for every* $\mathtt{q} \in \mathtt{v.set}$, GCS.$\mathtt{deliver}_\mathtt{q}(\mathtt{p}, \mathtt{m})$ *also occurs.*

It is important to note that although our liveness property requires the GCS to be live only in *certain* executions, any implementation that satisfies this property has to attempt to be live in *every* execution because it cannot test the external condition of the membership becoming stable. Also note that, even though membership stability is formally required to last forever, in practice it only has to hold "long enough" for the GCS to reconfigure, as explained in [21, 25]. However, we cannot explicitly introduce the bound on this time period in a fully asynchronous model, since it depends on external conditions such as message latency, process scheduling, and processing time.

6. The virtually synchronous group multicast algorithm. In this section we present an algorithm for a group communication service, GCS, that satisfies the specifications in section 5. The GCS is implemented by a collection of GCS end-points, each running the same algorithm. Figure 6.1(a) shows the interaction of a GCS end-point with its environment: a membership service MEMB and a reliable FIFO multicast service CO_RFIFO; these services are assumed to satisfy the specifications of section 4. The end-point interacts with its application client by accepting the client's send requests and by delivering application messages and views to the client. The end-point uses the CO_RFIFO service to send messages to other GCS end-points and to receive messages sent by other GCS end-points. When necessary, the end-point uses



(a) Interaction with Membership and Multicast Services **(b)** Inheritance Hierarchy

FIG. 6.1. *A GCS end-point and its environment.*

the `reliable` action to inform CO_RFIFO of the set of end-points to which CO_RFIFO must maintain reliable (gap-free) FIFO connections. The GCS end-point also receives `start` and `view` notifications from the membership service.

The algorithm running at each GCS end-point is constructed incrementally using the inheritance-based methodology of [30]. We proceed in three steps, at each step adding support for a new property (see Figure 6.1(b)):

1. In section 6.1, we present an algorithm WV_RFIFO_p for an end-point of the within-view reliable FIFO multicast service specified in section 5.1.1 and argue that this service satisfies safety specification WV_RFIFO : SPEC and liveness Property 5.2.

2. In section 6.2, we add support for the virtually synchronous delivery and transitional set properties specified in sections 5.1.2 and 5.1.3. We present a child VS_RFIFO+TS_p of WV_RFIFO_p and argue that the service built from VS_RFIFO+TS_p end-points satisfies safety specifications VSRFIFO : SPEC and TS : SPEC and liveness Property 5.2.

3. In section 6.3, we add support for the self-delivery property specified in section 5.1.4. The resulting automaton VS_RFIFO+TS+SD_p models a complete GCS end-point. Due to the use of inheritance, the service built from these end-points automatically satisfies safety specifications WV_RFIFO : SPEC, VSRFIFO : SPEC, and TS : SPEC. We argue that it also satisfies safety specification SELF : SPEC and liveness Property 5.2.

In the presented automata, each locally controlled action is defined to be a task by itself, which means that, if it becomes and stays enabled, it eventually gets executed.

When composing automata into a service, actions of the $\text{MEMB.start}_p(\texttt{id}, \texttt{set})$ type are linked with $\text{CO\_RFIFO.live}_p(\texttt{set})$, and actions of the $\text{MEMB.view}_p(\texttt{v})$ type are linked with $\text{CO\_RFIFO.live}_p(\texttt{v.set})$; the "link" operation can be formally expressed using the signature extension construct. When MEMB and CO_RFIFO actions are linked this way, the `live_set`[`p`] variable of CO_RFIFO matches the MEMB's perception of which end-points are alive and connected to `p`. (We assume that every permanently disconnected end-point is eventually excluded by either a `start` or a `view` notifica-

tion.) In the composed system, all output actions except the application interface are reclassified as internal.

For simplicity of the code, the presented automata do not include certain practical optimizations such as, for example, garbage collection; we point out some of the important ones in section 6.4.

6.1. Within-view reliable FIFO multicast algorithm. In this section we present the WV_RFIFO$_p$ algorithm running at an end-point p of a basic GCS, WV_RFIFO. The end-point algorithm is quite simple: It relies on the MEMB service to form and deliver views involving end-point p; the end-point forwards these views to its client. The algorithm also relies on the CO_RFIFO service to provide reliable gap-free FIFO multicast communication. When the end-point receives a message-send request from its client, it uses CO_RFIFO to send the message to other end-points in the client's current view. The end-point delivers to its client the messages received from other end-points via CO_RFIFO, provided the client's current view matches the views in which the messages were sent. The algorithm keeps track of the views in which messages are sent using the following technique: each time the end-point delivers a view v to its client, it sends a special view_msg message to the end-points in v.set informing them that the end-point's future messages will be sent in view v. Reliable delivery of messages is ensured by having CO_RFIFO maintain a reliable connection to every member of the end-point's view.

Figure 6.2 models the WV_RFIFO$_p$ algorithm as an automaton. The signature defines the interface through which end-point p interacts with its client and with the MEMB and CO_RFIFO services.

When a view v is received from MEMB via action MEMB.view$_p$(v), end-point p saves it in a variable memb_view and then delivers v to its client by executing action view$_p$(v). Variable current_view contains the last view delivered to the client. The precondition, v = memb_view $\neq$ current_view, on the view$_p$(v) action ensures that v is indeed the last view received from MEMB and that it has not already been delivered to the client. After end-point p delivers view v to its client, it sends a view_msg containing v to the rest of the members of current_view.set by using action CO_RFIFO.send$_p$(set, ⟨'**view_msg**', v⟩) with set = current_view.set − {p} and v = current_view. Variable view_msg[p] contains the last view sent as a view_msg. The first precondition on CO_RFIFO.send$_p$(set, ⟨'**view_msg**', v⟩), view_msg[p] $\neq$ current_view, ensures that each view_msg is sent only once, and the second precondition, current_view.set $\subseteq$ reliable_set, ensures that, prior to sending the view_msg, end-point p has requested CO_RFIFO to maintain reliable connection to every member of the client's view by executing action CO_RFIFO.reliable$_p$(set), which sets variable reliable_set to the value of set. When end-point p receives a view_msg from some end-point q via the CO_RFIFO.deliver$_{q,p}$(⟨'**view_msg**', v⟩) action, it stores v in a variable view_msg[q].

End-point p maintains a queue msgs[q][v] per each end-point q and view v; these queues are used for storing application messages received from other end-points via CO_RFIFO.deliver$_{q,p}$ and from the end-point's own client via send$_p$. When action send$_p$(m) occurs, message m is appended to msgs[p][current_view]. The end-point maintains the following indices that enforce message handling in the order of their appearances in the msgs queues:

- last_sent points to the last application message m on msgs[p][current_view] that was sent using CO_RFIFO.send$_p$(set, ⟨'**app_msg**', m⟩);
- last_rcvd[q], for each end-point q, points to the last message m on queue

FIG. 6.2. *Within-view reliable* FIFO *multicast end-point automaton.*

msgs[q][view_msg[q]] that was delivered to p by CO_RFIFO.deliver$_{q,p}$(⟨'**app_msg**', m⟩);

- last_dlvrd[q], for each end-point q, points to the last message m on queue msgs[q][current_view] that was delivered to p's client using CO_RFIFO.deliver$_p$(q, m).

The first precondition of CO_RFIFO.send$_p$(set, ⟨'**app_msg**', m⟩) ensures that a view_msg containing current_view has been already sent to everybody in set = current_view − {p}. The preconditions on sending view_msgs ensure that CO_RFIFO maintains a reliable connection to everyone in set at the time CO_RFIFO.send$_p$(set, ⟨'**app_msg**', m⟩) occurs.

Automaton WV_RFIFO$_p$ also implements auxiliary functionality that allows end-point p to forward an application message received from some end-point to some other end-points. Specifically, using CO_RFIFO.send$_p$(set, ⟨'**fwd_msg**', r, v, m, i⟩), end-point p can forward to some set of end-points the ith message, m, sent by the client at r in view v. In turn, when end-point p receives CO_RFIFO.deliver$_{q,p}$(⟨'**fwd_msg**', r, v, m, i⟩), it stores the forwarded message m in the ith location of the msgs[r][v] queue. The code of WV_RFIFO$_p$ does not specify a particular strategy for forwarding messages; the

strategy can be chosen nondeterministically. Such a strategy can be specified by more refined versions of the algorithm and/or by modifications of WV_RFIFO$_p$, as we do in the VS_RFIFO+TS$_p$ modification of the WV_RFIFO$_p$ automaton in section 6.2 below.

Leaving a certain level of nondeterminism at the parent automaton, with the intention of resolving it later at the child automaton, is a technique similar to the use of *abstract methods* or *pure virtual methods* in object-oriented methodology. We use the same technique in the CO_RFIFO.reliable$_p$(set) action when we require set to be a nondeterministic superset of current_view.set. The VS_RFIFO+TS$_p$ modification of WV_RFIFO$_p$ places additional preconditions on this action, thereby specifying precise values for the set argument.

The WV_RFIFO automaton resulting from the composition of all the end-point automata and the MEMB and CO_RFIFO automata models the WV_RFIFO service. The automaton satisfies the safety properties specified by WV_RFIFO : SPEC: it preserves the local monotonicity and self-inclusion properties of view deliveries guaranteed by the MEMB service; it also extends the gap-free FIFO ordered message delivery of CO_RFIFO with the within-view delivery property. The within-view delivery is achieved by delivering messages to the clients only if the views in which the messages were sent match the clients' current views.

Appendix B.1 contains a simulation from WV_RFIFO to WV_RFIFO : SPEC: Actions of automaton WV_RFIFO : SPEC involving view$_p$(v), send$_p$(m), and deliver$_p$(q, m) are simulated when WV_RFIFO takes the corresponding view$_p$(v), send$_p$(m), and deliver$_p$(q, m) actions. The steps of WV_RFIFO involving other actions correspond to empty steps of WV_RFIFO : SPEC. We define the following function R that maps every reachable state s of WV_RFIFO to a reachable state of WV_RFIFO : SPEC, where s[p].var denotes an instance of a variable var of end-point p in a state s:

```
R(s∈ReachableStates(WV_RFIFO)) = t∈ReachableStates(WV_RFIFO : SPEC), where
  for each Proc p, View v:       t.msgs[p][v]   =   s[p].msgs[p][v],
  for each Proc p, Proc q: t.last_dlvrd[p][q]   =   s[q].last_dlvrd[p],
  for each Proc p:          t.current_view[p]   =   s[p].current_view.
```

Lemma B.1 states that R is a refinement mapping from automaton WV_RFIFO to automaton WV_RFIFO : SPEC; the proof relies on a number of invariant assertions, stated and proved in Appendix B.1 as well.

The WV_RFIFO automaton also satisfies liveness (Property 5.2). Consider a fair execution in which each end-point p in v.set receives the same view v from the membership and no view events afterwards. Starting from the time the MEMB.view$_p$(v) action occurs, the view$_p$(v) action stays enabled; therefore it eventually happens due to the fairness of the execution. After view v is delivered to the clients, all messages sent in view v are also eventually delivered to the clients. This is due to the liveness property of CO_RFIFO, which guarantees that messages sent between live and connected end-points (as perceived by the membership service) are eventually delivered to their destinations. We prove these claims formally for the complete GCS algorithm in Appendix C.

6.2. Adding support for virtually synchronous delivery and transitional sets. The WV_RFIFO service of the previous section guarantees that each member p of a view v receives *some* prefix of the FIFO ordered stream of messages sent by every member q in v. In this section, we modify the WV_RFIFO$_p$ algorithm to yield an end-point VS_RFIFO+TS$_p$ of a service, VS_RFIFO+TS, that, in addition to the semantics provided by WV_RFIFO, guarantees that those members that transition from v into

the same view v' receive not just *some* but *the same* prefix of the message stream sent by each member q in v. This is the virtually synchronous delivery property, the key property of VS semantics (see section 5.1.2). Overall, the VS_RFIFO+TS service satisfies the VSRFIFO : SPEC and TS : SPEC safety specifications, as well as liveness Property 5.2; we prove these claims, respectively, in Appendixes B.2, B.3, and C.

In a nutshell, here is how VS_RFIFO+TS$_p$ computes transitional sets and enforces virtually synchronous delivery: When end-point p is notified via start$_p$(cid, set) of the MEMB's attempt to form a new view, p sends via CO_RFIFO a synchronization message tagged with cid to every end-point in set. The synchronization message includes p's current view v and a mapping cut, such that cut(q) is the index of the last message from each q in v.set that p commits to deliver in view v.

End-point p may receive subsequent start$_p$(cid, set) notifications from MEMB. When such a notification includes a new cid, p sends a new synchronization message, with a freshly made cut, to the proposed set; otherwise, when the cid is the same as the last one, p simply forwards the last synchronization message to the joining end-points, that is, to the end-points of the current set that were not listed in the previously proposed membership.

Once p receives via view$_p$(v') a new view v' from MEMB and a synchronization message tagged with v'.startId(q) from each end-point q in v.set ∩ v'.set, p computes a transitional set from v to v' and decides on which messages it needs to deliver to its client in view v before delivering view v'. A transitional set T from v to v' is computed to include every client q in v.set ∩ v'.set whose synchronization message tagged with v'.startId(q) contains p's current view v. For each client r in v.set, end-point p decides to deliver all the messages of r that appear in the cut of the synchronization message of any member q of T. Section 6.2.1 describes two message-forwarding strategies that ensure p's ability to actually deliver all the messages it decides to deliver. After p delivers all these messages to its client, it then delivers to its client the new view v' along with the transitional set T.

Virtually synchronous delivery follows from the fact that all end-points transitioning from view v to v' consider the same synchronization messages, compute the same set T, and hence use the same data to decide which messages to deliver in view v before delivering view v'. Set T satisfies Definition 5.1 of a transitional set from v to v' because (a) every end-point that computes T is itself included in T, and (b) no end-point q in T is allowed to deliver v' while in some view other than v because v'.startId(q) is linked through q's synchronization message to v.

FIG. 6.4. *Virtually synchronous reliable* FIFO *multicast: state extension and transition restriction.*

Figures 6.2, 6.3, and 6.4, together, contain the code of the VS_RFIFO+TS$_p$ automaton that models end-point p of the VS_RFIFO+TS service. Figures 6.3 and 6.4 specify how the WV_RFIFO$_p$ automaton of Figure 6.2 is modified to support virtually synchronous delivery and transitional sets. Figure 6.3 contains signature extension that defines the signatures of new and modified actions; Figure 6.4 contains the state extension and transition restriction defining, respectively, new state variables and new precondition/effect code. We now describe automaton VS_RFIFO+TS$_p$ in detail.

Upon receiving MEMB.start$_p$(cid, set), VS_RFIFO+TS$_p$ stores the cid and set

parameters in the `id` and `set` fields of a variable `start`. When `start` $\neq \perp$, it indicates that VS_RFIFO+TS$_p$ is engaged in a synchronization protocol, during which it exchanges synchronization messages tagged with `start.id` with the end-points in `start.set`; after VS_RFIFO+TS$_p$ delivers a view to its client it resets `start` to $\perp$.

Variable `sync_set` indicates the set of end-points to which a synchronization message tagged with the latest `start.id` has already been sent. When end-point `p` receives `start`$_p$(`cid`, `set`) with a new `cid`, `sync_set` is reset to $\emptyset$ to indicate that a new synchronization message needs to be sent to every end-point in `set`. However, if the `cid` is the same as the last one, `sync_set` is set to `sync_set` $\cap$ `set`. This way, the end-point will send its last synchronization message only to the joining end-points (i.e., those in `set` $-$ `sync_set`), and not to those to which the message was already sent. Notice that the disconnected end-points (i.e., those that are not in `set`) are removed from `sync_set`.

After VS_RFIFO+TS$_p$ receives a `start`$_p$(`cid`, `set`) input from MEMB, it executes an internal action, `set_cut`$_p$(). This action commits `p` to deliver to its client all the messages it has so far received from the members of its current view. For each member `q` of `current_view.set`, `cut`(`q`) is set to the length of the longest continuous prefix of messages in `msgs`[`q`][`current_view`].[4] Action `set_cut`$_p$() results in `p`'s current view being stored in `sync_msg`[`p`][`start.id`].`view`, the committed cut being stored in `sync_msg`[`p`][`start.id`].`cut`, and `sync_set` being set to {`p`}.

VS_RFIFO+TS$_p$ specifies precise preconditions on the CO_RFIFO.`reliable`$_p$(`set`) actions. When VS_RFIFO+TS$_p$ is not engaged in a synchronization protocol (i.e., when `start` $= \perp$), CO_RFIFO is asked to maintain reliable connection just to the end-points in `p`'s current view, `current_view.set`. When VS_RFIFO+TS$_p$ is engaged in a synchronization protocol, it requires CO_RFIFO to maintain reliable connection to the members of a forming view, `start.set`, as well as to those in `current_view.set`. Thus, CO_RFIFO avoids loss of messages sent to the disconnected end-points in case these end-points are later added to the forming view.

After setting the cut and telling CO_RFIFO to maintain reliable connection to everyone in `current_view.set` $\cup$ `start.set`, VS_RFIFO+TS$_p$ uses CO_RFIFO.`send`$_p$ to send the synchronization message `sync_msg`[`p`][`start.id`] tagged with `start.id` to the end-points in `start.set` $-$ `sync_set`, that is, to all those end-points in the proposed membership to which this synchronization message has not already been sent. Afterwards, `sync_set` is adjusted to `start.set`.

When end-point `p` receives synchronization messages from other end-points, via CO_RFIFO.`deliver`$_{q,p}$(⟨'**sync_msg**', `cid`, `v`, `cut`⟩), `p` saves ⟨`v`, `cut`⟩ in `sync_msg`[`q`][`cid`].

VS_RFIFO+TS$_p$ restricts delivery of application messages while it is engaged in a synchronization protocol (i.e., when `start` $\neq \perp$ and `sync_msg`[`p`][`start.id`] $\neq \perp$): Prior to receiving a new view from MEMB, only the messages identified in the cut of its own latest synchronization message, `sync_msg`[`p`][`start.id`].`cut`, can be delivered to the client. After MEMB.`view`$_p$(`v`) occurs, VS_RFIFO+TS$_p$ is allowed to deliver messages identified in the cut `sync_msg`[`q`][`v.startId`(`q`)].`cut` received from `q`, provided `q` is a member of the transitional set from `current_view` to `v`. An end-point `q` $\in$ `current_view.set` $\cap$ `v.set` is considered to be in the transitional set from `current_view` to `v` if `sync_msg`[`q`][`v.startId`(`q`)].`view` is the same as `p`'s `current_view`.

VS_RFIFO+TS$_p$ delivers a view `v` received from MEMB and a transitional set `T` to its client when `p` has received a synchronization message `sync_msg`[`q`][`v.startId`(`q`)]

[4] The longest continuous prefix can be different from the length of `msgs`[`q`][`current_view`] because forwarded messages may arrive out of order and introduce gaps in the `msgs` queues.

from every q in current_view.set ∩ v.set, has computed T, and has delivered all the application messages identified in the cuts of the members of T, as specified by the last three preconditions on $\texttt{view}_p(v, T)$. The first two preconditions ensure, respectively, that no new MEMB.$\texttt{start}_p$ notification was issued after MEMB.$\texttt{view}_p(v)$ and that p has sent its synchronization message to everybody in v.set. The third precondition specifies that p has sent to others all of its own messages indicated in its own cut. All these preconditions work in conjunction with those in WV_RFIFO.$\texttt{view}_p(v)$.

Recall from section 6.1 that WV_RFIFO_p allows for nondeterministic forwarding of other end-points' application mesages. VS_RFIFO+TS_p resolves this nondeterminism by placing two additional preconditions on CO_RFIFO.$\texttt{send}_p(\texttt{set}, \langle \text{'}\textbf{fwd\_msg}\text{'}, r, v, m, i\rangle)$: The first checks a variable forwarded_set to make sure that message m was not previously forwarded to anyone in set. The second tests that a certain predicate, called ForwardingStrategyPredicate(set, r, v, i), holds. This predicate is designed to ensure that all end-points in the transitional set T are able to deliver all the messages that each has committed to deliver in its synchronization message, in particular those sent by disconnected clients. End-points test ForwardingStrategyPredicate to decide whether they need to forward any messages to others.

6.2.1. Forwarding strategy predicate. We now provide two examples of ForwardingStrategyPredicates. With the first, multiple copies of the same message may be forwarded by different end-points. The second strategy reduces the number of forwarded copies of a message. Many other possible strategies exist. For example, a strategy can employ randomization to decide whether an end-point should forward a message in a certain time slice, and suppress forwarding of messages that have already been forwarded by others.

A simple strategy. With our first strategy, end-point p forwards message m only if p has committed to deliver m. In addition, if m was originally sent in view v, p forwards m to an end-point q only if p does not know of any view of q later than v and if the latest sync_msg from q sent in view v indicates that q has not received message m.

```
ForwardingStrategyPredicate(set, r, v, i) ≡
 (∃ cid) (sync_msg[p][cid].view = v  ∧  i ≤ sync_msg[p][cid].cut(r))
 ∧ set = { q |  view_msg[q] ≤ v  ∧  (∃ cid′) (sync_msg[q][cid′].view = v
               ∧ (∄ cid′′ > cid′) sync_msg[q][cid′′].view = v
               ∧ sync_msg[q][cid′].cut(r) < i) }.
```

If some end-point q is missing a certain message m, then m will be forwarded to q by some end-point p that has committed to deliver m, when p learns from q's synchronization message that q misses m.

Reducing the number of forwarded copies of a message. The second strategy relies on the computed transitional set T from view v to v′ to decide which message should be forwarded by which member of the transitional set. Assume that a member u of T misses a message m that was originally sent in v by a nonmember r of T, but that was committed to delivery by some other members of T. Among these members, ForwardingStrategyPredicate selects the one with the minimal process identifier to forward m to u; variations of this predicate may use a different deterministic rule for selecting a member, for example, accounting for network topology or communication costs. The selected end-point, p, forwards the message to u only if view v′ is the latest view known to p, as specified by the first conjunct below. Otherwise, v′ is an obsolete view, so there is no need to help u transition in to v′. The described strategy does not forward to $u \in T$ messages from the members of T because

u is guaranteed to receive these messages directly from their original senders (unless v′ becomes obsolete because further view changes occur).

```
ForwardingStrategyPredicate(set, r, v, i) ≡
  Let v′ = memb_view ∧                          // latest view known to {p}
  sync_msg[p][v′.startId(p)] ≠ ⊥ ∧               // already sent own sync_msg
  Let v = sync_msg[p][v′.startId(p)].view ∧
  (for all q ∈  v.set ∩ v′.set) sync_msg[q][v′.startId(q)] ≠ ⊥  ∧  // received right sync_msgs
  Let T = {q ∈ v.set ∩ v′.set | sync_msg[q][v′.startId(q)].view = v} ∧
  r ∉ T   ∧                              // only forward messages from end-point not in T
  set = {u ∈ T  | sync_msg[u][v′.startId(u)].cut(r) < i }  ∧
  p = min{u ∈ T  | sync_msg[u][v′.startId(u)].cut(r) ≥ i }.
```

If all end-points receive the same view from MEMB, only one copy of m will be forwarded to each u. In rare cases, however, when MEMB delivers different views to different end-points, more than one end-point may forward the same message m to the same end-point u.

Each end-point waits to receive a new view from MEMB and all the right synchronization messages before it forwards messages to others. Thus, compared to the first strategy, this strategy reduces the communication traffic at the cost of slower recovery of lost messages.

6.2.2. Correctness argument. The VS_RFIFO+TS automaton, resulting from the composition of all end-point automata and the MEMB and CO_RFIFO automata, satisfies the VSRFIFO : SPEC and TS : SPEC safety specifications, as well as liveness (Property 5.2), as we formally prove in Appendixes B.2, B.3, and C, respectively. Below we give highlights of these proofs.

VSRFIFO : SPEC is a modification of WV_RFIFO : SPEC. The proof that VS_RFIFO+TS satisfies VSRFIFO : SPEC reuses the proof that WV_RFIFO satisfies WV_RFIFO : SPEC and involves reasoning about only how VSRFIFO : SPEC modifies WV_RFIFO : SPEC. The proof extends refinement mapping R between WV_RFIFO and WV_RFIFO : SPEC with a mapping R_n. R_n maps the cut used by the end-points of VS_RFIFO+TS to move from a view v to a view v′ to the cut[v][v′] variable of VSRFIFO : SPEC. The proof depends on Invariant B.9 and Corollary B.1, which state that all end-points that move from a view v to a view v′ use the same synchronization messages, compute the same transitional set T, and therefore use the same cut.

The proof in Appendix B.3 shows that VS_RFIFO+TS satisfies TS : SPEC. The proof augments VS_RFIFO+TS_p with a *prophecy variable* that guesses, at the time end-point p receives a $\texttt{start}_p(\texttt{cid}, \texttt{set})$ notification from MEMB, possible future views that may contain cid in their startId(p) mappings. For each of these views v′, VS_RFIFO+TS simulates a $\texttt{set\_prev\_view}_p(v')$ action of TS : SPEC, thereby fixing the previous view of v′ to be p's current view v.

In a fair execution of VS_RFIFO+TS in which the same last view v′ is delivered to all its members and no start events subsequently occur, the three preconditions on the $\texttt{view}_p(v', T_p)$ delivery are eventually satisfied for every p ∈ v′.set:

1. Condition v′.startId(p) = start.id remains true since the execution has no subsequent start events at p.

2. End-point p eventually receives synchronization messages tagged with the "right" cid from every member of v.set ∩ v′.set because they keep taking steps towards reliably sending these synchronization messages to p (by low-level fairness of the code) and because CO_RFIFO eventually delivers these messages to p (by the liveness assumption on CO_RFIFO).

3. End-point p eventually receives and delivers all the messages committed to

AUTOMATON GCS_p = VS_RFIFO+TS+SD$_p$ MODIFIES VS_RFIFO+TS$_p$

Signature Extension:

Input: block_ok$_p$() new

eff: block_status ← unblocked

INPUT **block_ok$_p$**()
eff: block_status ← blocked

FIG. 6.5. GCS_p *end-point automaton.*

in the cuts of the members of the transitional set T_p because for each such message there is at least one end-point in T_p that has the message in its msgs buffer and that will reliably forward it to p (according to the ForwardingStrategyPredicate) if necessary. Also, p never delivers any messages beyond those committed to in the cuts of the members of T_p because of the precondition on application message delivery.

6.3. Adding support for self-delivery. As a final step in constructing the automaton that models an end-point of our group communication service, GCS_p, we add support for self-delivery to the VS_RFIFO+TS$_p$ automaton presented above. Self-delivery requires each end-point to deliver to its client all the messages the client sends in a view, before moving on to the next view.

In order to implement self-delivery, virtually synchronous delivery, and within-view delivery together in a live manner, each end-point must *block* its client from sending new messages while a view change is taking place (as proven in [23]). Therefore, we add to VS_RFIFO+TS$_p$ an output action block and an input action block_ok. We assume that the client at end-point p has the matching actions and that it eventually responds to every block request with a block_ok response and subsequently refrains from sending messages until a view is delivered to it. In section B.4, we formalize this requirement as an abstract client automaton.

The GCS_p automaton appears in Figure 6.5. After receiving the first start notification in a given view, end-point p issues a block request to its client and awaits receiving a block_ok response before executing set_cut$_p$(). As a result of set_cut$_p$(), p commits to deliver all the messages its client has sent in the current view. Therefore, p has to deliver all these messages before moving on to a new view, and self-delivery is satisfied. Due to the use of inheritance, the GCS automaton preserves all the safety properties satisfied by its parent. Since end-point p has its own messages on the msgs[p][p] queue and can deliver them to its client, liveness is also preserved. Thus, GCS satisfies all the properties we have specified in section 5.

6.4. Optimizations and extensions. Having formally presented the basic algorithm for an end-point of our virtually synchronous GCS, we now discuss several optimizations and extensions that can be added to the algorithm to make its implementation more practical. Specifically, we discuss ways to reduce the size and number of synchronization messages. (In general, the number of synchronization messages and the size of each message sent during a synchronization protocol can be linear in the number of members.) We also discuss garbage collection and ways to avoid the use of nonvolatile storage.

The first optimization that reduces the size of synchronization messages relies on the following observation: An end-point p does not need to send its current view and its cut to end-points that are not in current_view.set because p cannot be included in their transitional sets. However, these end-points still need to hear from p if p is in their current views. Therefore, end-point p could send a smaller synchronization message to the end-points in start.set − current_view.set, containing its start.id only (but neither a view nor a cut). This message would be interpreted as saying "I am not in your transitional set," and the recipients of this message would know not to include p in their transitional sets for views v' with v'.startId(p) = p's start.id. When using this optimization, p also does not need to include its current view in the synchronization messages sent to current_view.set − start.set, since the view information can be deduced from p's view_msg.

An additional optimization can be used if we strengthen the membership specification to require a MEMB.start with a new identifier to be sent every time MEMB changes its mind about the membership of a forming view. In this case, the latest MEMB.start has the same membership as the delivered MEMB.view. Therefore, the synchronization messages can be shortened to not include information about application messages delivered from end-points in start.set ∩ current_view.set: for an end-point p, end-points that have p in their transitional sets will deliver all the application messages that p sent before its synchronization message.

Other optimizations can reduce the total number of messages sent during synchronization protocol by all end-points. A simple way to do this is to transform the algorithm into a leader-based one, as in [44, 40]. A more scalable approach was suggested by Guo, Vogels, and van Renesse [26]. Their algorithm uses a two-level hierarchy for message dissemination in order to implement VS: end-points send synchronization messages to their designated leaders, which in turn exchange only the cumulative information among themselves. Also, the number of messages exchanged to synchronize multiple groups can be reduced, as suggested in [11, 39], by aggregating information pertaining to multiple groups into a single message.

Another optimization addresses the use of stable storage. Recall that in section 4 we assumed that end-points keep their running states on stable storage, and therefore, recover with their state intact. However, our group multicast service does provide meaningful semantics even when GCS end-points maintain their running state on volatile storage. When an end-point p recovers after a crash, it can start executing with its state reset to an initial value with current_view being the singleton view v_p. It needs to contact the MEMB service to be readmitted to its groups. The client would refrain from sending any messages in its recovered view until it receives a new view from its end-point. This view would satisfy local monotonicity and self-inclusion because these are the properties guaranteed by the MEMB service. The specification of virtually synchronous delivery should be changed so that recovery is interpreted as delivering a singleton view. The remaining safety properties are also preserved because they involve message delivery within a single view.

In a practical implementation of our service, some sort of garbage collection mechanism is required in order to keep the buffer sizes finite. The implementation of [43] discards messages from older views when moving to a new view and also when learning that they were already delivered to every client in the view. This implementation also discards older synchronization messages: an end-point holds on to only the latest synchronization message it has received from each end-point. This optimization does not violate liveness since discarded synchronization messages necessarily pertain to

obsolete views.

7. Conclusions. We have designed a novel group multicast service targeted for WANs. Our service implements a variant of the VS semantics that includes a collection of properties that have been shown useful for many distributed applications (see [16]). Many GCSs, for example, [44, 40, 9, 5, 19], support these and similar properties. Our design has been implemented [43] (in C++) as part of a novel architecture for scalable group communication in WANs using the datagram service of [7] and the Moshe membership algorithm [31].

The main contribution of this paper is a VS algorithm run by GCS end-points, in particular, its synchronization protocol, which enforces virtually synchronous delivery. This protocol is invoked when the underlying membership service begins to form a new view, and is run while the view is forming. The protocol involves a single message-exchange round during which members of the forming view send synchronization messages to each other. In contrast to previously suggested VS algorithms (e.g., [23, 5, 26, 3, 9]), our algorithm does not require end-points to preagree upon a globally unique identifier before sending synchronization messages and thus involves less communication. Performing less communication is especially important in WANs, where message latency tends to be high.

Furthermore, unlike the algorithms in [5, 26, 9, 40], our algorithm allows the membership service to change the membership of a forming view while the synchronization protocol is running; the protocol responds immediately to such membership changes.

We are not aware of any other algorithm for VS that does not preagree on common identifiers before sending synchronization messages and that always allows new members to join a forming view while the synchronization protocol is running. Our algorithm achieves these two features by virtue of a simple yet powerful idea: End-points tag their synchronization messages with start identifiers that are locally generated by the membership service; when the membership service forms a view and delivers it to the end-points, the view includes information about which start identifiers were given to which member. This information communicates to the end-points which synchronization messages they need to consider from each member. Since no preagreement upon a common identifier takes place, there is nothing that would inhibit the membership service and the VS algorithm from allowing new members to join the forming view; end-points just have to forward their last synchronization messages to the joiners.

As a second contribution of this paper, our design has demonstrated how to effectively decouple the algorithm for achieving VS from the algorithm for maintaining membership. As argued in [6, 31], such decoupling is important for providing efficient and scalable group communication services in WANs. In previous designs that implement VS atop an external membership service [11, 40], the membership service is not allowed to add new members to an already forming view, and the membership service waits to synchronize with all end-points of the formed view before delivering the view to any of the clients.

A distinct and important characteristic of our design is the high level of formality and rigor at which it has been carried out. This paper has provided precise descriptions of the GCS algorithm and the semantics it provides, as well as a formal proof of the algorithm's correctness—both safety and liveness. Previously, formal approaches based on I/O automata were used to specify the semantics of VS GCSs and to model and verify their applications, for example, in [15, 22, 18, 33, 27]. However,

due to their size and complexity, VS algorithms were not previously modeled using formal methods, nor were they assertionally verified. Our experience has taught us the importance of careful modeling and verification: in the process of proving our algorithm's correctness we have often uncovered subtleties and ambiguities that had to be resolved.

In order to manage the complexity of our design, we developed a new formal inheritance-based methodology [30]. The incremental way in which we constructed our algorithms and specifications also allowed us to construct the simulation proof incrementally. For example, in order to prove that VS_RFIFO+TS simulates VS_RFIFO+TS : SPEC, we extended the simulation relation from WV_RFIFO to WV_RFIFO : SPEC and reasoned solely about the extension, without repeating the reasoning about the parent components (see Appendix B.2). This reuse was justified by the proof extension theorem of [30] (see Appendix A.3). The use of incremental construction was the key to our success in formally modeling and reasoning about such a complex and sophisticated service. We hope that the methodology employed in this paper shall also be helpful to other researchers working on formal modeling of complex distributed systems.

Appendix A. Review of proof techniques. In this section we describe the main techniques used to prove correctness of I/O automata: invariant assertions, hierarchical proofs, refinement mappings, and history and prophecy variables. The material in this section is closely based on [36, pp. 216–228] and [35, pp. 3, 4, and 13]. In section A.3 we present a proof extension theorem of [30] that provides a formal framework for the reuse of simulation proofs based on refinement mappings.

A.1. Invariants. The most fundamental type of property to be proved about an automaton is an *invariant assertion*, or just *invariant* for short. An invariant assertion of an automaton A is defined as any property that is true in every single reachable state of A.

Invariants are typically proved by induction on the number of steps in an execution leading to the state in question. While proving an inductive step, we consider only *critical actions*, which affect the state variables appearing in the invariant.

A.2. Hierarchical proofs. One of the important proof strategies is based on a hierarchy of automata. This hierarchy represents a series of descriptions of a system or algorithm at different levels of abstraction. The process of moving through the series of abstractions, from the highest level to the lowest level, is known as *successive refinement*. The top level may be nothing more than a problem specification written in the form of an automaton. The next level is typically a very abstract representation of the system: it may be centralized rather than distributed, or have actions with large granularity, or have simple but inefficient data structures. Lower levels in the hierarchy look more and more like the actual system or algorithm that will be used in practice: they may be more distributed, have actions with small granularity, and contain optimizations. Because of all this extra detail, lower levels in the hierarchy are usually harder to understand than the higher levels. The best way to prove properties of the lower-level automata is by relating these automata to automata at higher levels in the hierarchy, rather than by carrying out direct proofs from scratch.

A.2.1. Refinement mappings. The simplest way to relate two automata, say A and S, is to present a *refinement mapping* R from the reachable states of A to the reachable state of S such that it satisfies the following two conditions:

1. If t_0 is an initial state of A, then $R(s_0)$ is an initial state of S.

2. If t and $R(t)$ are reachable states of A and S, respectively, and (t, π, t') is a step of A, then there exists an execution fragment of S beginning at state $R(t)$ and ending at state $R(t)'$, with its trace being the same as the trace of π and its final state $R(t)'$ being the same as $R(t')$.

The first condition asserts that any initial state of A has some corresponding initial state of S. The second condition asserts that any step of A has a corresponding sequence of steps of S. This corresponding sequence can consist of one step, many steps, or even no steps, as long as the correspondence between the states is preserved and the external behavior is the same.

The following theorem gives the key property of refinement mappings.

THEOREM A.1. *If there is a refinement mapping from A to S, then* `traces`*(A)* $\subseteq$ `traces`*(S).*

If automata A and S have the same external signature and the traces of A are the traces of S, then we say that A *implements* S *in the sense of trace inclusion*, which means that A never does anything that S couldn't do. Theorem A.1 implies that, in order to prove that one automaton implements another in the sense of trace inclusion, it is enough to produce a refinement mapping from the former to the latter.

A.2.2. History and prophecy variables. Sometimes, however, even when the traces of A are the traces of S, it is not possible to give a refinement mapping from A to S. This may happen due to the following two generic reasons:

1. The states of S may contain more information than the states of A.
2. S may make some premature choices, which A makes later.

The situation when A has been optimized not to retain certain information that S maintains can be resolved by augmenting the state of A with additional components, called *history variables* (because they keep track of additional information about the history of execution), subject to the following constraints:

1. Every initial state has at least one value for the history variables.
2. No existing step is disabled by the addition of predicates involving history variables.
3. A value assigned to an existing state component must not depend on the value of a history variable.

These constraints guarantee that the history variables simply record additional state information and do not otherwise affect the behavior exhibited by the automaton. If the automaton A_{HV} augmented with history variables can be shown to implement S by presenting a refinement mapping, it follows that the original automaton A without the history variables also implements S because they have the same traces.

The situation when S is making a premature choice, which A makes later, can be resolved by augmenting A with a different sort of auxiliary variable, *prophecy variable*, which can look into the future just as history variable looks into the past. A prophecy variable guesses in advance some nondeterministic choice that A is going to make later. The guess gives enough information to construct a refinement mapping to S (which is making the premature choice). For an added variable to be a prophecy variable, it must satisfy the following conditions:

1. Every state has at least one value for the prophecy variable.
2. No existing step is disabled *in the backward direction* by the new preconditions involving a prophecy variable. More precisely, for each step (t, π, t') there must be a state (t, p) and a p such that there is a step $((t, p), \pi, (t', p'))$.
3. A value assigned to an existing state component must not depend on the value of the prophecy variable.

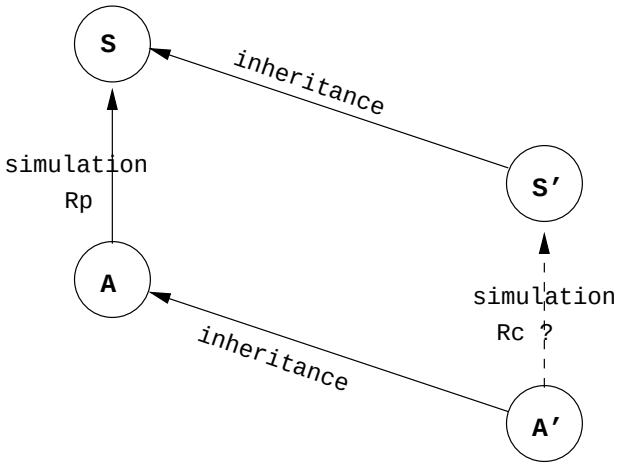

FIG. A.1. *Algorithm* A *simulates specification* S *with* R. *Can* R *be reused for building a refinement* R′ *from a child* A′ *of* A *to a child* S′ *of* S*?*

4. If t is an initial state of A and (t, p) is a state of the A augmented with the prophecy variable, then it must be its initial state.

If these conditions are satisfied, the automaton augmented with the prophecy variable will have the same (finite) traces as the automaton without it. Therefore, if we can exhibit a refinement mapping from A_{PV} to S, we know that the A implements S.

A.3. Inheritance and proof extension theorem. We now present a theorem from [30] which lays the foundation for incremental proof construction. Consider the example illustrated in Figure A.1, where a refinement mapping R from an algorithm A to a specification S is given, and we want to construct a refinement mapping R′ from a child A′ of an automaton A to a child S′ of a specification automaton S.

Theorem A.2 below implies that such a refinement R′ can be constructed by supplementing R with a mapping $\mathtt{R_n}$ from the states of A′ to the state extension introduced by S′. Mapping $\mathtt{R_n}$ has to map every initial state of A′ to some initial state extension of A′ and it has to satisfy a step condition similar to the one for refinement mapping (section A.2.1), but only involving the transition restriction of S′.

THEOREM A.2. *Let automaton* A′ *be a child of automaton* A. *Let automaton* S′ *be a child of automaton* S. *Let mapping* R *be a refinement from* A *to* S.

Let $\mathtt{R_n}$ *be a mapping from the states of* A′ *to the state extension introduced by* S′.

A mapping R′ *from the states of* A′ *to the states of* S′, *defined in terms of* R *and* $\mathtt{R_n}$ *as*

$$\mathtt{R'}(\langle \mathtt{t}, \mathtt{t_n} \rangle) = \langle \mathtt{R}(\mathtt{t}), \mathtt{R_n}(\langle \mathtt{t}, \mathtt{t_n} \rangle) \rangle,$$

is a refinement *from* A′ *to* S′ *if* R′ *satisfies the following two conditions:*

1. *If* t *is an initial state of* A′, *then* $\mathtt{R_n}(\mathtt{t})$ *is an initial state extension of* S′.
2. *If* $\langle \mathtt{t}, \mathtt{t_n} \rangle$ *is a reachable state of* A′, $\mathtt{s} = \langle \mathtt{R}(\mathtt{t}), \mathtt{R_n}(\langle \mathtt{t}, \mathtt{t_n} \rangle) \rangle$ *is a reachable state of* S′, *and* $(\langle \mathtt{t}, \mathtt{t_n} \rangle, \pi, \langle \mathtt{t}', \mathtt{t}'_\mathtt{n} \rangle)$ *is a step of* A′, *then there exists a finite sequence* α *of alternating states and actions of* S′, *beginning from* s *and ending at some state* s′, *satisfying the following conditions:*

1. α *projected onto states of* S *is an execution sequence of* S.

2. *Every step* $(\mathtt{s}_i, \sigma, \mathtt{s}_{i+1}) \in \alpha$ *is consistent with the transition restriction placed on* S *by* S′.
3. *The parent component of the final state* s′ *is* $\mathtt{R}(\mathtt{t}')$.
4. *The child component of the final state* s′ *is* $\mathtt{R}_n(\langle \mathtt{t}', \mathtt{t}'_n \rangle)$.
5. α *has the same trace as* π.

In practice, one would exploit this theorem as follows: The simulation proof between the parent automata already provides a corresponding execution sequence of the parent specification for every step of the parent algorithm. It is typically the case that the same execution sequence, padded with new state variables, corresponds to the same step at the child algorithm. Thus, conditions 1, 3, and 5 of Theorem A.2 hold for this sequence. The only conditions that have to be checked are 2, and 4, that is, that every step of this execution sequence is consistent with the transition restriction placed on S by S′ and that the values of the new state variables of S′ in the final state of this execution match those obtained when $\mathtt{R}_n$ is applied to the poststate of the child algorithm.

A.4. Safety versus liveness. Proving that one automaton implements another in the sense of trace inclusion constitutes only *partial correctness*, as it implies *safety* but not *liveness*. In other words, partial correctness ensures than "bad" things never happen, but it does not say anything about whether some "good" thing eventually happens.

In this paper, we use invariant assertions and simulation techniques to prove that our algorithms satisfy safety properties, which are stated as I/O automata. For liveness proofs, we use a combination of invariant assertions and carefully proven operational arguments.

Appendix B. Correctness proof: Safety properties. We now formally prove, using invariant assertions and simulations, that our algorithms satisfy the safety properties of section 5.1. Proofs done with invariant assertions and simulations are verifiable (even by a computer) because they involve reasoning only about single steps of the algorithm. A review of the proof techniques used in this section appears in Appendix A.

The safety proof is *modular*: we exploit the inheritance-based structure of our specifications and algorithms to reuse proofs. In section B.1 we prove correctness of the within-view reliable FIFO multicast service by showing a refinement mapping from WV_RFIFO to WV_RFIFO : SPEC. In section B.2 we extend this refinement mapping to map the new state added in VS_RFIFO+TS to that in VSRFIFO : SPEC. In section B.3 we prove that VS_RFIFO+TS also simulates TS : SPEC. Finally, in section B.4 we extend the refinement above to map the new state of GCS to that of SELF : SPEC. The proof extension theorem of [30] (also reviewed in Appendix A) implies that the GCS automaton satisfies WV_RFIFO : SPEC, VSRFIFO : SPEC, TS : SPEC, and SELF : SPEC.

B.1. Within-view reliable FIFO multicast. Intuitively, in order to simulate WV_RFIFO : SPEC with WV_RFIFO, we need to show that WV_RFIFO satisfies self-inclusion and local monotonicity for delivered views, and we need to show that the ith message delivered by q from p in view v is the ith message sent in view v by the client at p. In order to prove this, we need to show that the algorithm correctly associates messages with the views in which they were sent and with their indices in the sequences of messages sent in these views. We split the proof into three parts: section B.1.1 states key invariants but defers the proof of one of them to section B.1.3; section B.1.2 contains the simulation proof.

B.1.1. Key invariants. The following invariant captures the self-inclusion property.

INVARIANT B.1 (self-inclusion). *In every reachable state* `s` *of* WV_RFIFO*, for all* `Proc p`, $\texttt{p} \in \texttt{s[p].memb\_view.set}$ *and* $\texttt{p} \in \texttt{s[p].current\_view.set}$.

Proof of Invariant B.1. The proof immediately follows from the MEMB specification. □

The local monotonicity property follows directly from the precondition, $\texttt{v.id} > \texttt{memb\_view}$, of the MEMB.$\texttt{view}_\texttt{p}(\texttt{v})$ actions.

The following invariant relates application messages at different end-points' queues to the corresponding messages on the original senders' queues.

INVARIANT B.2 (message consistency). *In every reachable state* `s` *of* WV_RFIFO*, for all* `Proc p` *and* `Proc q`*, if* $\texttt{s[q].msgs[p][v][i]} = \texttt{m}$*, then* $\texttt{s[p].msgs[p][v][i]} = \texttt{m}$.

This proposition is vacuously true in the initial state because all message queues are empty. For the inductive step, we have to consider the CO_RFIFO.$\texttt{deliver}_{\texttt{q,p}}(\langle \text{`}\textbf{app\_msg}\text{'}, \texttt{m}\rangle)$ and CO_RFIFO.$\texttt{deliver}_{\texttt{q,p}}(\langle \text{`}\textbf{fwd\_msg}\text{'}, \texttt{r}, \texttt{v}, \texttt{m}, \texttt{i}\rangle)$ actions and have to argue that the message `m` that these actions deliver is placed in the right place in `q`'s `msgs` buffer. The proof of this invariant appears in section B.1.3 after the simulation proof.

B.1.2. Simulation.

LEMMA B.1. *The following function* `R` *is a* refinement mapping *from automaton* WV_RFIFO *to automaton* WV_RFIFO : SPEC *with respect to their reachable states.*

```
R(s∈ReachableStates(WV_RFIFO)) = t∈ReachableStates(WV_RFIFO : SPEC), where

  For each Proc p, View v:       t.msgs[p][v]   =   s[p].msgs[p][v]

  For each Proc p, Proc q: t.last_dlvrd[p][q]   =   s[q].last_dlvrd[p]

  For each Proc p:          t.current_view[p]   =   s[p].current_view
```

Proof of Lemma B.1.

Action correspondence. Automaton WV_RFIFO : SPEC has three types of actions. Actions $\texttt{view}_\texttt{p}(\texttt{v})$, $\texttt{send}_\texttt{p}(\texttt{m})$, and $\texttt{deliver}_\texttt{p}(\texttt{q}, \texttt{m})$ are simulated when WV_RFIFO takes the corresponding $\texttt{view}_\texttt{p}(\texttt{v})$, $\texttt{send}_\texttt{p}(\texttt{m})$, and $\texttt{deliver}_\texttt{p}(\texttt{q}, \texttt{m})$ actions. Steps of WV_RFIFO involving other actions correspond to empty steps of WV_RFIFO : SPEC.

Simulation proof. For the most part, the simulation proof is straightforward. Here, we present only the interesting steps.

The fact that the corresponding step of WV_RFIFO : SPEC is enabled when WV_RFIFO takes a step involving $\texttt{view}_\texttt{p}(\texttt{v})$ relies on $\texttt{p} \in \texttt{memb\_view.set}$ (Invariant B.1).

For the steps involving the $\texttt{deliver}_\texttt{p}(\texttt{q}, \texttt{m})$ action, in order to deduce that the corresponding step of WV_RFIFO : SPEC is enabled, we need to know that the message located at index $\texttt{s[p].last\_dlvrd[q]} + 1$ on the $\texttt{s[p].msgs[q][s[p].current\_view]}$ queue is the same message that end-point `q` has on its corresponding queue at the same index. This property is implied by Invariant B.2.

Steps that involve receiving original and forwarded application messages from the network simulate empty steps of WV_RFIFO : SPEC. Among these steps the only critical ones are those that deliver a message from `p` to `p` because they may affect $\texttt{s[p].msgs[p][p]}$ queue. Since end-points do not send messages to themselves, such steps may not happen. Indeed, action CO_RFIFO.$\texttt{send}_\texttt{p}(\texttt{set}, \langle \text{`}\textbf{app\_msg}\text{'}, \texttt{m}\rangle)$ has a precondition $\texttt{set} = \texttt{s[p].current\_view.set} - \{\texttt{p}\}$, and action CO_RFIFO.$\texttt{send}_\texttt{p}(\texttt{set}, \langle \text{`}\textbf{fwd\_msg}\text{'}, \texttt{r}, \texttt{v}, \texttt{m}, \texttt{i}\rangle)$ has a precondition $\texttt{p} \notin \texttt{set}$. □

From Lemma B.1 and Theorem A.1 we conclude the following.

THEOREM B.1. WV_RFIFO *implements* WV_RFIFO : SPEC *in the sense of trace inclusion.*

B.1.3. Auxiliary invariants. We now state and prove a number of auxiliary invariants necessary for the proof of the key message consistency invariant (Invariant B.2).

In any view, before an end-point sends a `view_msg` to others (and hence before it sends any application message to others), it tells CO_RFIFO to maintain reliable connection to every member of its current view. The following invariant captures this property.

INVARIANT B.3 (connection reliability). *In every reachable state* `s` *of* WV_RFIFO*, for all* `Proc p`*, if* `s[p].current_view = s[p].view_msg[p]`*, then* `s[p].current_view.set` $\subseteq$ `s[p].reliable_set`*.*

Proof of Invariant B.3. By induction on the length of the execution sequence, the proof follows directly from the code. □

After an end-point delivers a new view to its client, it sends a `view_msg` to other members of the view. The stream of `view_msg`s that an end-point sends to others is monotonic because the delivered views satisfy local monotonicity. The following invariant captures this property. It states that the subsequence of messages in transit from end-point `p` to end-point `q` solely consisting of the `view_msg`s is monotonically increasing. It also relates the current view of an end-point `p` to the view contained in the `p`'s latest `view_msg` to `q`.

INVARIANT B.4 (monotonicity of view messages). *Let* `s` *be a reachable state of* WV_RFIFO*. Consider the subsequence of messages in* `s.channel[p][q]` *of the* `ViewMsg` *type. Examine the sequence of views included in these view messages, and construct a new sequence* seq *of views by prepending this view sequence with the element* `s[q].view_msg[p]`*. For all* `Proc p`, `Proc q`*, the following propositions are true:*

1. *The sequence* seq *is (strictly) monotonically increasing.*
2. *If* `s[p].current_view` $\neq$ `s[p].view_msg[p]`*, then* `s[p].current_view` *is strictly greater then the last (largest) element of* seq*.*
3. *If* `s[p].current_view = s[p].view_msg[p]`*, and if* `q` $\in$ `s[p].current_view.set`*, then* `s[p].current_view` *is equal to the last (largest) element of* seq*.*

Proof of Invariant B.4. All three propositions are true in the initial state. We now consider steps involving the critical actions.

CO_RFIFO.`lose(p, q)`. The first two propositions remain true because this action throws away only the last message from the CO_RFIFO `s.channel[p][q]`. The third proposition is vacuously true because `q` $\notin$ `s[p].current_view.set`. If it were, the CO_RFIFO.`lose(p, q)` action would not be enabled because Invariant B.3 would imply that `s[p].current_view.set` is a subset of `s[p].reliable_set`, which would then imply that `q` $\in$ `s.reliable_set[p]` (because `s[p].reliable_set` = `s.reliable_set[p]`, as can be shown by straightforward induction).

$\texttt{view}_{\texttt{p}}$`(v)`. The first proposition is unaffected. The second proposition follows from the inductive hypothesis and the precondition `v.id` $>$ `s[p].current_view.id`. The third proposition is vacuously true because `s[p].current_view` $\neq$ `s[p].view_msg[p]` as follows from the precondition `v.id` $>$ `s[p].current_view.id` and the fact that, in every reachable state `s`, `s[p].current_view` $\geq$ `s[p].view_msg[p]` (as can be proved by straightforward induction).

CO_RFIFO.$\texttt{send}_{\texttt{p}}$`(set,` $\langle$`'view_msg', v`$\rangle$`)`. The first proposition is true in the poststate because of the inductive hypothesis of the second proposition. The second proposition is vacuously true in the poststate. The third proposition is true in the

poststate because of the effect of this action.

CO_RFIFO.$\texttt{deliver}_{\texttt{p,q}}(\langle$'**view_msg**', v$\rangle$). It is straightforward to see that all three propositions remain true in the poststate. □

History tags. In order to reason about original application messages traveling on CO_RFIFO channels, we need a way to reference, for each of these messages, the view in which it was originally sent and its index in the FIFO ordered sequence of messages sent in that view. To this end, we augment each original application message $\langle$'**app_msg**', m$\rangle$ with two *history tags*, Hv and Hi, that are set to current_view and last_sent + 1, respectively, when CO_RFIFO.$\texttt{send}_{\texttt{p}}(\texttt{set}, \langle$'**app_msg**', m$\rangle$) occurs. (See Appendix A for details on history variables.)

```
OUTPUT co_rfifo.send_p(set, ⟨'app_msg', m, Hv, Hi⟩)
pre: ...
     Hv = current_view
     Hi = last_sent + 1
 eff: ...
```

With the history tags, the interface between WV_RFIFO and CO_RFIFO for handling original application messages becomes CO_RFIFO.$\texttt{send}_{\texttt{p}}(\texttt{set}, \langle$'**app_msg**', m, Hv, Hi$\rangle$) and CO_RFIFO.$\texttt{deliver}_{\texttt{p,q}}(\langle$'**app_msg**', m, Hv, Hi$\rangle$).

The goal of the next three invariants is to show that, when end-point q receives an application message m tagged with a history view Hv and a history index Hi, the current value of q's view_msg[p] equals Hv and that of last_rcvd[p] + 1 equals Hi.

INVARIANT B.5 (history view consistency). *In every reachable state* s *of* WV_RFIFO*, for all* Procp, Procq*, the following holds. For all messages* $\langle$'**app_msg**', m, Hv, Hi$\rangle$ *on the* CO_RFIFO s.channel[p][q]*, view* Hv *equals either the view of the closest preceding view message on* s.channel[p][q] *if there is such, or* s[q].view_msg[p] *otherwise.*

Proof of Invariant B.5. The proof follows by induction. A step involving CO_RFIFO.$\texttt{send}_{\texttt{p}}(\texttt{set}, \langle$'**app_msg**', m, Hv, Hi$\rangle$) directly follows from part 3 of Invariant B.4. The proposition is not affected by steps involving CO_RFIFO.lose(p, q) because those may only remove the last messages from the CO_RFIFO s.channel[p][q]. The other steps are straightforward. □

The following invariant states that the value of s[p].last_sent equals the number of application messages that p sent in its current view and that are either still in transit on the CO_RFIFO s.channel[p][q] or are already received by q.

INVARIANT B.6. *In every reachable state* s *of* WV_RFIFO*, for all* Procp *and for all* Procq $\in$ s[p].current_view.set $-$ {p}*, the following is true.*

$$\begin{aligned}
&\texttt{s[p].last_sent} \\
&= \left|\{\texttt{msg} \in \texttt{s.channel[p][q]} \ : \ \texttt{msg} \in \texttt{AppMsg and msg.Hv} = \texttt{s[p].current_view}\}\right| \\
&+ \begin{cases} \texttt{s[q].last_rcvd[p]} & \textit{if } \texttt{s[q].view_msg[p]} = \texttt{s[p].current_view}, \\ 0 & \textit{otherwise.} \end{cases}
\end{aligned}$$

Proof of Invariant B.6. The proof follows by induction. Consider steps involving the following critical actions.

CO_RFIFO.lose(p, q). Assume that the last message on queue s.channel[p][q] is an application message msg with msg.Hv = s[p].current_view. If a step involving CO_RFIFO.lose(p, q) action could occur, then the proposition would be false. However, as we are going to argue now, q $\in$ s.reliable_set[p], so such a step cannot occur.

We can prove by induction that msg $\in$ s.channel[p][q] implies s[p].view_msg[p] = s[p].current_view. By Invariant B.3, s[p].current_view.set $\subseteq$ s[p].reliable_set.

Since $\mathtt{q} \in \mathtt{s}[\mathtt{p}].\mathtt{current\_view.set}$ and $\mathtt{s}[\mathtt{p}].\mathtt{reliable\_set} = \mathtt{s.reliable\_set}[\mathtt{p}]$, it follows that $\mathtt{q} \in \mathtt{s.reliable\_set}[\mathtt{p}]$.

$\mathtt{view}_\mathtt{p}(\mathtt{v})$. The proposition remains true for steps involving $\mathtt{view}_\mathtt{p}(\mathtt{v})$ action because its effect sets $\mathtt{s}'[\mathtt{p}].\mathtt{last\_sent}$ to 0 and because both summands of the right-hand side of the equation also become 0. Indeed, the first summand becomes 0 because CO_RFIFO channels never have messages tagged with views that are larger than the current views of the messages' senders (as can be shown by a simple inductive proof); the second summand becomes 0 because part 2 of Invariant B.4 implies that $\mathtt{s}'[\mathtt{q}].\mathtt{view\_msg}[\mathtt{p}] \neq \mathtt{s}'[\mathtt{p}].\mathtt{current\_view}$.

CO_RFIFO.$\mathtt{deliver}_{\mathtt{p},\mathtt{q}}(\langle \text{`}\mathbf{view\_msg}\text{'}, \mathtt{v}\rangle)$. The proposition remains true for steps involving this action because $\mathtt{s}[\mathtt{q}].\mathtt{view\_msg}[\mathtt{p}] \neq \mathtt{s}[\mathtt{p}].\mathtt{current\_view}$, as follows immediately from Invariant B.4.

CO_RFIFO.$\mathtt{send}_\mathtt{p}(\mathtt{set}, \langle \text{`}\mathbf{app\_msg}\text{'}, \mathtt{m}, \mathtt{Hv}, \mathtt{Hi}\rangle)$ and CO_RFIFO.$\mathtt{deliver}_{\mathtt{p},\mathtt{q}}$ $(\langle \text{`}\mathbf{app\_msg}\text{'}, \mathtt{m}, \mathtt{Hv}, \mathtt{Hi}\rangle)$. For steps involving these actions the truth of the proposition immediately follows from the effects of these actions, the inductive hypotheses, and Invariant B.5. □

The history index attached to an original application message m sent in a view Hv that is in transit on a CO_RFIFO channel to end-point q is equal to the number of such messages (including m) that precede m on that channel plus those (if any) that q has already received.

INVARIANT B.7 (history indices consistency). *In every reachable state* s *of* WV_RFIFO*, for all* Proc p *and* Proc q*, if* $\langle \text{`}\mathbf{app\_msg}\text{'}, \mathtt{m}, \mathtt{Hv}, \mathtt{Hi}\rangle = \mathtt{s.channel}[\mathtt{p}][\mathtt{q}][\mathtt{j}]$ *for some index* j*, then*

$$\mathtt{Hi} = \left|\{\mathtt{msg} \in \mathtt{s.channel}[\mathtt{p}][\mathtt{q}][..\mathtt{j}] \ : \ \mathtt{msg} \in \mathtt{AppMsg\ and\ msg.Hv} = \mathtt{Hv}\}\right| + \begin{cases} \mathtt{s}[\mathtt{q}].\mathtt{last\_rcvd}[\mathtt{p}] & \textit{if } \mathtt{s}[\mathtt{q}].\mathtt{view\_msg}[\mathtt{p}] = \mathtt{Hv}, \\ 0 & \textit{otherwise.} \end{cases}$$

Proof of Invariant B.7. In the initial state $\mathtt{s.channel}[\mathtt{p}][\mathtt{q}]$ is empty. For the inductive step, we consider steps involving the following critical actions.

CO_RFIFO.$\mathtt{lose}(\mathtt{p}, \mathtt{q})$. The proposition remains true since CO_RFIFO.$\mathtt{lose}(\mathtt{p}, \mathtt{q})$ discards only the last messages from the CO_RFIFO $\mathtt{s.channel}[\mathtt{p}][\mathtt{q}]$.

CO_RFIFO.$\mathtt{deliver}_{\mathtt{p},\mathtt{q}}(\langle \text{`}\mathbf{view\_msg}\text{'}, \mathtt{v}\rangle)$. We have to consider the effects on two types of application messages: those associated with view $\mathtt{s}[\mathtt{q}].\mathtt{view\_msg}[\mathtt{p}]$ and those associated with view Hv. Part 1 of Invariant B.4 and Invariant B.5 imply that there are no application messages with $\mathtt{msg.Hv} = \mathtt{s}[\mathtt{q}].\mathtt{view\_msg}[\mathtt{p}]$ on the CO_RFIFO $\mathtt{channel}[\mathtt{p}][\mathtt{q}]$. Thus, the proposition does not apply for such messages. For those messages that have $\mathtt{msg.Hv} = \mathtt{Hv}$, the proposition remains true because $\mathtt{s}'[\mathtt{q}].\mathtt{last\_rcvd}[\mathtt{p}]$ is set to 0 as a result of this action.

CO_RFIFO.$\mathtt{deliver}_{\mathtt{p},\mathtt{q}}(\langle \text{`}\mathbf{app\_msg}\text{'}, \mathtt{m}, \mathtt{Hv}, \mathtt{Hi}\rangle)$. This immediately follows from the effect of this action, the inductive hypothesis, and Invariant B.5.

CO_RFIFO.$\mathtt{send}_\mathtt{p}(\mathtt{set}, \langle \text{`}\mathbf{app\_msg}\text{'}, \mathtt{m}, \mathtt{Hv}, \mathtt{Hi}\rangle)$. The inductive step immediately follows from the inductive hypothesis and Invariant B.6. □

We now prove a generalization of Invariant B.2 which relates application messages either in transit on the CO_RFIFO channels or at end-points' queues to their corresponding messages on the senders' queues.

INVARIANT B.8 (general message consistency). *In every reachable state* s *of* WV_RFIFO*, for all* Procp *and* Procq*, the following are true.*

1. *If* $\langle \text{`}\mathbf{app\_msg}\text{'}, \mathtt{m}, \mathtt{Hv}, \mathtt{Hi}\rangle \in \mathtt{s.channel}[\mathtt{p}][\mathtt{q}]$*, then* $\mathtt{s}[\mathtt{p}].\mathtt{msgs}[\mathtt{p}][\mathtt{Hv}][\mathtt{Hi}] = \mathtt{m}$.
2. *If* $\langle \text{`}\mathbf{fwd\_msg}\text{'}, \mathtt{r}, \mathtt{m}, \mathtt{v}, \mathtt{i}\rangle \in \mathtt{s.channel}[\mathtt{p}][\mathtt{q}]$*, then* $\mathtt{s}[\mathtt{r}].\mathtt{msgs}[\mathtt{r}][\mathtt{v}][\mathtt{i}] = \mathtt{m}$.

3. *If* s[q].msgs[p][v][i] = m, *then* s[p].msgs[p][v][i] = m.

Proof of Invariant B.8. *Basis.* In the initial state all message queues are empty.

Inductive step. The following are the critical actions:

send$_p$(m),
co_rfifo.send$_p$(set, ⟨'**app_msg**', m, Hv, Hi⟩),
co_rfifo.deliver$_{q,p}$(⟨'**app_msg**', m, Hv, Hi⟩),
co_rfifo.send$_p$(set, ⟨'**fwd_msg**', r, v, m, i⟩),
co_rfifo.deliver$_{q,p}$(⟨'**fwd_msg**', r, v, m, i⟩).

For steps involving CO_RFIFO.deliver$_{q,p}$(⟨'**app_msg**', m, Hv, Hi⟩), we use Invariant B.5 and Invariant B.7, which, respectively, imply that history view Hv equals s[p].view_msg[q] and that history index Hi equals s[p].last_rcvd[q] + 1. Inductive steps involving each of the other actions are straightforward. □

Invariant B.2 is a private case of this invariant.

B.2. Virtual synchrony. We now show that automaton VS_RFIFO+TS simulates VSRFIFO : SPEC. We prove this by extending the refinement above using the proof extension theorem of [30] (see Appendix A for details).

B.2.1. Invariants. We prove that end-points that move together from one view to the next consider the same synchronization messages and thus compute the same transitional sets and use the same cuts from the members of the transitional set.

INVARIANT B.9. *In every reachable state* s *of* VS_RFIFO+TS, *for all* Procp, Procq, *and for every* StartIdcid, *if* s[q].sync_msg[p][cid] ≠ ⊥, *then* s[q].sync_msg[p][cid] = s[p].sync_msg[p][cid].

Proof of Invariant B.9. The proposition is true in the initial state s_0 as all s_0[q].sync_msg[p][cid] = ⊥. The inductive step involving a set_cut$_p$() action is trivial, for it only affects the case q = p. The inductive step involving a CO_RFIFO.deliver$_{p,q}$(⟨'**sync_msg**', cid, v, cut⟩) action follows immediately from the following proposition:

⟨'**sync_msg**', cid, v, cut⟩ ∈ s.channel[p][q] ⇒ s[p].sync_msg[p][cid] = ⟨v, cut⟩,

which can be proved by straightforward induction. Indeed, there are two critical actions: CO_RFIFO.send$_p$(set, ⟨'**sync_msg**', cid, v, cut⟩)—immediate from the code—and CO_RFIFO.deliver$_{p,p}$(⟨'**sync_msg**', cid, v, cut⟩)—this may not occur because end-points do not send synchronization messages to themselves. □

COROLLARY B.1. *End-points that move together from one view to the next use the same sets of synchronization messages to calculate transitional sets and message cuts.*

Proof. Consider two end-points that deliver view v′ while in view v. At the time of delivering view v′, each of these end-points has synchronization messages from all end-points in the intersection of these views (second precondition), and these synchronization messages are the same as those at their original end-points (Invariant B.9). Thus, the two end-points calculate the same transitional sets and use the same cuts from the members of this transitional set. □

B.2.2. Simulation. We augment VS_RFIFO+TS with a *global* history variable H_cut that keeps track of the cuts used for moving between views.

For each View v, v′: (Proc → Int)$_\perp$ H_cut[v][v′], initially ⊥

OUTPUT view$_p$(v, T) modifies wv_rfifo.view$_p$(v)
pre: ...

```
eff: ...
     (∀ q ∈ Proc)
       H_cut[current_view][v](q) ← max_{r∈T} (sync_msg[r][v.startId(r)].cut(q)).
```

Variable $\texttt{H\_cut}[\texttt{v}][\texttt{v}']$ is updated every time *any* end-point is delivering view $\texttt{v}'$ while in view $\texttt{v}$. Corollary B.1 implies that whenever this happens after $\texttt{H\_cut}[\texttt{v}][\texttt{v}']$ is set for the first time the value of $\texttt{H\_cut}[\texttt{v}][\texttt{v}']$ remains unchanged.

We now extend the refinement mapping $\texttt{R}()$ of Lemma B.1 with the new mapping $\texttt{R}_\texttt{n}()$:

$$\texttt{For each View v, View v}' : \texttt{R}_\texttt{n}(\texttt{s.H\_cut}[\texttt{v}][\texttt{v}']) = \texttt{cut}[\texttt{v}][\texttt{v}'].$$

We call the resulting mapping $\texttt{R}'()$. We exploit the proof extension theorem of [30] (see Appendix A) in order to prove that $\texttt{R}'()$ is a refinement mapping from VS_RFIFO+TS to VSRFIFO : SPEC.

LEMMA B.2. *Function* $\texttt{R}'()$ *defined above is a refinement mapping from automaton* VS_RFIFO+TS *to automaton* VSRFIFO : SPEC.

Proof of Lemma B.2. *Action correspondence.* The action correspondence is the same as that of WV_RFIFO, except for the steps of the type $(\texttt{s}, \texttt{view}_\texttt{p}(\texttt{v}', \texttt{T}), \texttt{s}')$ which involve VS_RFIFO+TS delivering views to the application clients. Among these steps, those that are the first to set variable $\texttt{H\_cut}[\texttt{v}][\texttt{v}']$ (when $\texttt{s.H\_cut}[\texttt{v}][\texttt{v}'] = \perp$) simulate two steps of VSRFIFO : SPEC: $\texttt{set\_cut}(\texttt{v}, \texttt{v}', \texttt{s}'.\texttt{H\_cut}[\texttt{v}][\texttt{v}'])$ followed by $\texttt{view}_\texttt{p}(\texttt{v}')$. The rest (when $\texttt{s.H\_cut}[\texttt{v}][\texttt{v}'] \neq \perp$) simulate single steps that involve just $\texttt{view}_\texttt{p}(\texttt{v}')$.

Simulation proof. First, we show that the refinement mapping of WV_RFIFO (presented in Lemma B.1) is still preserved after the modifications introduced by VSRFIFO : SPEC to WV_RFIFO : SPEC. Automaton VSRFIFO : SPEC adds the following preconditions to the $\texttt{view}_\texttt{p}(\texttt{v})$ actions of WV_RFIFO : SPEC:

$$\texttt{cut[current\_view[p]][v]} \neq \perp,$$
$$(\forall\ \texttt{q})\quad \texttt{last\_dlvrd[q][p]} = \texttt{cut[current\_view[p]][v](q)}.$$

Since $\texttt{set\_cut}(\texttt{current\_view}[\texttt{p}], \texttt{v}, \texttt{s}'.\texttt{H\_cut}[\texttt{current\_view}[\texttt{p}]][\texttt{v}])$ is simulated before action $\texttt{view}_\texttt{p}(\texttt{v})$, the first precondition holds. The second one follows immediately from the precondition on VS_RFIFO+TS.$\texttt{view}_\texttt{p}(\texttt{v}, \texttt{T})$ and the extended mapping $\texttt{R}'()$.

Second, we show that the mapping $\texttt{R}_\texttt{n}()$ used to extend $\texttt{R}()$ to $\texttt{R}'()$ is also a refinement. For those steps $(\texttt{s}, \texttt{view}_\texttt{p}(\texttt{v}', \texttt{T}), \texttt{s}')$ that are the first to set variable $\texttt{H\_cut}[\texttt{v}][\texttt{v}']$, the action correspondence implies that the mapping is preserved. For those steps that are not the first to set variable $\texttt{H\_cut}[\texttt{v}][\texttt{v}']$, the mapping is preserved because $\texttt{s}'.\texttt{H\_cut}[\texttt{v}][\texttt{v}'] = \texttt{s.H\_cut}[\texttt{v}][\texttt{v}']$, by Corollary B.1. □

From Lemmas B.1 and B.2 and from Theorem A.1, we conclude the following.

THEOREM B.2. VS_RFIFO+TS *implements* VSRFIFO : SPEC *in the sense of trace inclusion.*

B.3. Transitional set. We now show that VS_RFIFO+TS simulates TS : SPEC. The proofs makes use of *prophecy variables.* A simulation proof that uses prophecy variables implies only finite trace inclusion, but this is sufficient for proving safety properties (see Appendix A).

B.3.1. Invariants.

INVARIANT B.10. *In every reachable state* s *of* VS_RFIFO+TS*, for all* Proc p *and for all* StartId id*, if* $\texttt{id} > \texttt{s}[\text{MEMB}].\texttt{start}[\texttt{p}].\texttt{id}$*, then* $\texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{id}] = \perp$.

Proof of Invariant B.10. The proposition is true in the initial state. It remains true for the inductive step involving MEMB.$\texttt{start}_\texttt{p}(\texttt{id}, \texttt{set})$ because $\texttt{s}[\texttt{memb}].\texttt{start}[\texttt{p}].\texttt{id}$ is increased as a result of this action. For the step involving $\texttt{set\_cut}_\texttt{p}()$, the proposition remains true because $\texttt{s}[\texttt{p}].\texttt{start.id} = \texttt{s}[\text{MEMB}].\texttt{start}[\texttt{p}].\texttt{id}$, as implied by the following invariant, which can be proved by straightforward induction.

In every reachable state s of VS_RFIFO+TS, for all Procp, if $\texttt{s}[\texttt{p}].\texttt{start.id} \neq \perp$, then $\texttt{s}[\text{MEMB}].\texttt{start}[\texttt{p}].\texttt{id} = \texttt{s}[\texttt{p}].\texttt{start.id}$. This invariant holds in the initial state. Critical action MEMB.$\texttt{start}_\texttt{p}(\texttt{id}, \texttt{set})$ makes it true; critical action $\texttt{view}_\texttt{p}(\texttt{v}, \texttt{T})$ makes it vacuously true.

Finally, a step involving CO_RFIFO.$\texttt{deliver}_{\texttt{q},\texttt{p}}(\langle \text{`}\textbf{sync\_msg}\text{'}, \texttt{cid}, \texttt{v}, \texttt{cut}\rangle)$ does not affect the proposition because the case $\texttt{q} = \texttt{p}$ cannot happen since end-points do not send synchronization messages to themselves. □

LEMMA B.3. *For any step* $(\texttt{s}, \text{MEMB}.\texttt{start}_\texttt{p}(\texttt{id}, \texttt{set}), \texttt{s}')$ *of* VS_RFIFO+TS,

$$\texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{start.id}] = \perp.$$

Proof of Lemma B.3. The proof follows from the precondition $\texttt{id} > \texttt{s}[\text{MEMB}].\texttt{start}[\texttt{p}].\texttt{id}$ and Invariant B.10. □

INVARIANT B.11. *In every reachable state* s *of* VS_RFIFO+TS, *for all* Procp, *if* $\texttt{s}[\texttt{p}].\texttt{start} \neq \perp$ *and* $\texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{start.id}] \neq \perp$, *then*

$$\texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{start.id}].\texttt{view} = \texttt{s}[\texttt{p}].\texttt{current\_view}.$$

Proof of Invariant B.11. The proposition is vacuously true in the initial state. For the inductive step, consider the following critical actions:

MEMB.$\texttt{start}_\texttt{p}(\texttt{id}, \texttt{set})$. The proposition remains vacuously true because $\texttt{s}'[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{start.id}] = \texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{start.id}] = \perp$ (Lemma B.3).

$\texttt{set\_cut}_\texttt{p}()$. This follows immediately from the code.

CO_RFIFO.$\texttt{deliver}_{\texttt{q},\texttt{p}}(\langle \text{`}\textbf{sync\_msg}\text{'}, \texttt{cid}, \texttt{v}, \texttt{cut}\rangle)$. The proposition is unaffected because the case $\texttt{q} = \texttt{p}$ cannot happen since end-points do not send synchronization messages to themselves.

$\texttt{view}_\texttt{p}(\texttt{v})$. The proposition becomes vacuously true because $\texttt{s}'[\texttt{p}].\texttt{start} = \perp$. □

B.3.2. Simulation. We augment automaton VS_RFIFO+TS with a prophecy variable $\texttt{P\_legal\_views}(\texttt{p})(\texttt{id})$ for each Procp and each StartId id. At the time a start id is delivered to an end-point p, this variable is set to a *predicted* finite set of future views that are allowed to contain id as p's start id.

```
Prophecy Variable:
For each Proc p, StartId id: SetOf(View) P_legal_views(p)(id),
                                          initially arbitrary

INTERNAL  MEMB.start_p(id, set)  hidden parameter V, a finite set of views
pre: ...
     choose V such that for all v ∈ V: (p ∈ v.set) ∧ (v.startId(p) = id)
eff: ...
     P_legal_views(p)(id) ← V

OUTPUT  GCS.view_p(v, T)
pre: ...
     (for all q ∈ v.set) v ∈ P_legal_views(q)(v.startId(q))
eff: ...
```

The VS_RFIFO+TS automaton augmented with the prophecy variable has the same traces as those of the original automaton because it is straightforward to show that the following conditions required for adding a prophecy variable hold:

1. Every state has at least one value for $\texttt{P\_legal\_views(p)(id)}$.
2. No step is disabled in the *backward direction* by new preconditions involving P_legal_views.
3. Values assigned to state variables do not depend on the values of P_legal_views.
4. If $\texttt{s}_0$ is an initial state of VS_RFIFO+TS, and $\langle \texttt{s}_0, \texttt{P\_legal\_views} \rangle$ is a state of the automaton VS_RFIFO+TS augmented with the prophecy variable, then this state is an initial state.

INVARIANT B.12. *In every reachable state* s *of* VS_RFIFO+TS*, for all* Proc p*, if* $\texttt{s[p].start} \neq \perp$*, then, for all* View v $\in$ $\texttt{P\_legal\_views(p)(s[p].start.id)}$*, it follows that* $\texttt{p} \in \texttt{v.set}$ *and* $\texttt{v.startId(p)} = \texttt{s[p].start.id}$.

Proof of Invariant B.12. The proof follows by induction. The only critical actions are $\text{MEMB.}\texttt{start}_\texttt{p}(\texttt{id}, \texttt{set})$ and $\texttt{view}_\texttt{p}(\texttt{v}, \texttt{T})$. The proposition is true after the former and is vacuously true after the latter. □

LEMMA B.4. *The following function* TS() *is a* refinement mapping *from automaton* VS_RFIFO+TS *to automaton* TS : SPEC *with respect to their reachable states.*

$$\texttt{TS}(\texttt{s} \in \texttt{ReachableStates}(\text{VS\_RFIFO+TS})) = \texttt{t} \in \texttt{ReachableStates}(\text{TS : SPEC}), \texttt{where}$$

$$\texttt{For eachProcp : t.current\_view[p]} = \texttt{s[p].current\_view}$$

$$\texttt{For eachProcp, Viewv : t.prev\_view[p][v]}$$

$$= \begin{cases} \perp & \textit{if } \texttt{v} \notin \texttt{s.P\_legal\_views[p][v.startId(p)]}, \\ \texttt{s[p].sync\_msg[p][v.startId(p)].view} & \textit{otherwise} \end{cases}$$

Proof of Lemma B.4. *Action correspondence.* A step $(\texttt{s}, \texttt{set\_cut}_\texttt{p}(), \texttt{s}')$ of VS_RFIFO+TS simulates a sequence of steps of TS : SPEC. The sequence consists of steps that involve one $\texttt{set\_prev\_view}_\texttt{p}(\texttt{v}')$ action for each $\texttt{v}' \in \texttt{s.P\_legal\_views(p)}$ $(\texttt{s[p].start.id})$. A step $(\texttt{s}, \texttt{view}_\texttt{p}(\texttt{v}, \texttt{T}), \texttt{s}')$ of VS_RFIFO+TS simulates $(\texttt{TS(s)}, \texttt{view}_\texttt{p}(\texttt{v}, \texttt{T}), \texttt{TS}(\texttt{s}'))$ of TS : SPEC.

Simulation proof. Consider the following critical actions:

$\text{MEMB.}\texttt{start}_\texttt{p}(\texttt{id}, \texttt{set})$. A step involving this action simulates an empty step of TS : SPEC. The simulation holds because $\texttt{s}'\texttt{[p].sync\_msg[p][id]} = \texttt{s[p].sync\_msg[p][id]} = \perp$ (Lemma B.3).

$\texttt{set\_cut}_\texttt{p}()$. This simulates a sequence of steps of TS : SPEC involving one $\texttt{set\_prev\_view}_\texttt{p}(\texttt{v}')$ for each $\texttt{v}' \in \texttt{s.P\_legal\_views(p)(cid)}$, where $\texttt{cid} = \texttt{s[p].start.id}$. Each such step is enabled, as can be seen from the following derivation:

$$\begin{aligned} &\texttt{TS(s).prev\_view[p][v']} \\ &= \texttt{s[p].sync\_msg[p][v'.startId(p)].view} \text{ (Refinement mapping)} \\ &= \texttt{s[p].sync\_msg[p][cid].view} \text{ (Invariant B.12)} \\ &= \perp \text{ (precondition of } \texttt{set\_cut}_\texttt{p}()). \end{aligned}$$

In the poststate, $\texttt{s}'\texttt{[p].sync\_msg[p][cid].view}$ and all $\texttt{TS}(\texttt{s}')\texttt{.prev\_view[p][v']}$ are equal to $\texttt{s[p].current\_view}$; thus the simulation step holds.

$\text{CO\_RFIFO.}\texttt{deliver}_{\texttt{q,p}}(\langle \text{`}\textbf{sync\_msg}\text{'}, \texttt{cid}, \texttt{v}, \texttt{cut} \rangle)$. A step involving this action does not affect any of the variables of the refinement mapping and thus simulates an empty step of TS : SPEC. In particular, note that the case of $\texttt{q} = \texttt{p}$ may not happen because end-points do not send synchronization messages to themselves.

AUTOMATON CLIENT$_p$: SPEC

Signature:

Input: deliver$_p$(q, m), Proc q, AppMsg m
view$_p$(v), View v
block$_p$()

Output: send$_p$(m), AppMsg m
block_ok$_p$()

State: block_status ∈ {unblocked, requested, blocked}, initially unblocked

Transitions:

INPUT **block$_p$**()
eff: block_status ← requested

OUTPUT **block_ok$_p$**()
pre: block_status = requested
eff: block_status ← blocked

OUTPUT **send$_p$**(m)
pre: block_status ≠ blocked
eff: none

INPUT **deliver$_p$**(q, m)
eff: none

INPUT **view$_p$**(v)
eff: block_status ← unblocked

FIG. B.1. *Abstract specification of a blocking client at end-point* p.

view$_p$(v, T). A step involving this action simulates a step of TS : SPEC that involves view$_p$(v, T). The key thing is to show that it is enabled (since it is straightforward to see that, if it is, the refinement is preserved). Action view$_p$(v, T) of TS : SPEC has three preconditions. The fact that they are enabled directly follows from the inductive hypothesis, the code, the refinement mapping, and Invariants B.11 and B.12. □

From Lemma B.4 and Theorem A.1 we conclude the following.

THEOREM B.3. VS_RFIFO+TS *implements* TS : SPEC *in the sense of* finite *trace inclusion.*

B.4. Self-delivery. We now prove that the complete GCS end-point automaton simulates SELF : SPEC. In order to prove this, we need to formalize our assumptions about the behavior of the clients of a GCS end-point: we assume that a client eventually responds to every block request with a block_ok response and subsequently refrains from sending messages until a view is delivered to it. We formalize this requirement by specifying an abstract client automaton in Figure B.1. In this automaton, each locally controlled action is defined to be a task by itself, which means that it eventually happens if it becomes enabled unless it is subsequently disabled by another action.

B.4.1. Invariants. The following invariant states that GCS end-points and their clients have the same perception of what their block_status is.

INVARIANT B.13. *In every reachable state* s *of* GCS, *for all* Proc p, s[GCS$_p$].block_status = s[client$_p$].block_status.

Proof of Invariant B.13. The proof follows by trivial induction. □

INVARIANT B.14. *In every reachable state* s *of* GCS, *for all* Procp, *if* s[p].start ≠ ⊥ *and* s[p].block_status ≠ blocked, *then* s[p].sync_msg[p][s[p].start.id] = ⊥.

Proof of Invariant B.14. In the initial state s_0, s_0[p].start = ⊥; so the proposition is vacuously true. For the inductive step, consider the following critical actions:

MEMB.start$_p$(id, set). The proposition remains true because of Lemma B.3.

block$_p$(). The proposition is true in the poststate if it is true in the prestate.

block_ok$_p$(). The proposition becomes vacuously true because s′[p].block_status = blocked.

set_cut$_p$(). The proposition remains vacuously true because s[p].block_status = s′[p].block_status = blocked.

CO_RFIFO.deliver$_{q,p}$(⟨'**sync_msg**', cid, v, cut⟩). The proposition is unaffected because the case q = p cannot happen since end-points do not send synchronization

messages to themselves.

$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$. The proposition becomes vacuously true because $\texttt{s}'[\texttt{p}].\texttt{start} = \bot$. □

INVARIANT B.15. *In every reachable state* s *of* GCS*, for all* Procp*, if* $\texttt{s}[\texttt{p}].\texttt{start} \neq \bot$ *and* $\texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{start.id}] \neq \bot$*, then* $\texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{start.id}].\texttt{cut}[\texttt{p}] = \texttt{LastIndexOf}(\texttt{s}[\texttt{p}].\texttt{msgs}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{current\_view}])$.

Proof of Invariant B.15. In the initial state $\texttt{s}_0$, $\texttt{s}_0[\texttt{p}].\texttt{start} = \bot$, so the proposition is vacuously true. For the inductive step, consider the following critical actions:

$\texttt{send}_\texttt{p}(\texttt{m})$. The proposition is vacuously true because $\texttt{s}'[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{start.id}] = \bot$, as follows from the precondition $\texttt{s}[\texttt{client}_\texttt{p}].\texttt{block\_status} \neq \texttt{blocked}$ on this action at $\texttt{client}_\texttt{p}$, and from Invariants B.13 and B.14.

$\text{MEMB.}\texttt{start}_\texttt{p}(\texttt{id},\texttt{set})$. The proposition is vacuously true because $\texttt{s}'[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{id}] = \texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{id}]$, which by Lemma B.3 is $\bot$.

$\texttt{set\_cut}_\texttt{p}()$. This follows from $\texttt{p} \in \texttt{current\_view.set}$ (Invariant B.1) and the precondition $(\texttt{forall q} \in \texttt{current\_view.set})\ \texttt{cut}(\texttt{q}) = \texttt{LongestPrefixOf}(\texttt{msgs}[\texttt{q}][\texttt{v}])$.

$\text{CO\_RFIFO.}\texttt{deliver}_{\texttt{q},\texttt{p}}(\langle\text{`}\textbf{sync\_msg}\text{'}, \texttt{cid}, \texttt{v}, \texttt{cut}\rangle)$. The proposition is unaffected because the case $\texttt{q} = \texttt{p}$ cannot happen since, as can be proved by straightforward induction, end-points do not send synchronization messages to themselves.

$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$. The proposition becomes vacuously true because $\texttt{s}'[\texttt{p}].\texttt{start} = \bot$. □

B.4.2. Simulation. Lemma B.2 in section B.2 on page 117 establishes function $\texttt{R}'()$ as a refinement mapping from automaton VS_RFIFO+TS to automaton VSRFIFO : SPEC. We now argue that $\texttt{R}'()$ is also a refinement mapping from automaton GCS to automaton SELF : SPEC.

LEMMA B.5. *Refinement mapping* $\texttt{R}'()$ *from automaton* VS_RFIFO+TS *to automaton* VSRFIFO : SPEC *(given in Lemma* B.2*) is also a refinement mapping from automaton* GCS *to automaton* SELF : SPEC*, under the assumption that clients at each end-point* p *satisfy the* $\text{CLIENT}_\texttt{p}$: SPEC *specification for blocking clients.*

Proof. Automaton SELF : SPEC modifies automaton WV_RFIFO : SPEC by adding a precondition, $\texttt{last\_dlvrd}[\texttt{p}][\texttt{p}] = \texttt{LastIndexOf}(\texttt{msgs}[\texttt{p}][\texttt{current\_view}[\texttt{p}]])$, to the steps involving $\texttt{view}_\texttt{p}()$ actions. We have to show that this precondition is enabled when a step of GCS involving $\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ attempts to simulate a step of SELF : SPEC involving $\texttt{view}_\texttt{p}(\texttt{v})$. Indeed,

$$
\begin{aligned}
\texttt{s}[\texttt{p}].\texttt{last\_dlvrd}[\texttt{p}] &= \texttt{max}_{\texttt{r}\in\texttt{T}}\texttt{sync\_msg}[\texttt{r}][\texttt{v.startId}(\texttt{r})].\texttt{cut}[\texttt{p}] \text{ (a precondition)}\\
&= \texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{v.startId}(\texttt{p})].\texttt{cut}[\texttt{p}] \text{ (Invariant B.9.)}\\
&= \texttt{s}[\texttt{p}].\texttt{sync\_msg}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{start.id}].\texttt{cut}[\texttt{p}] \text{ (a precondition)}\\
&= \texttt{LastIndexOf}(\texttt{s}[\texttt{p}].\texttt{msgs}[\texttt{p}][\texttt{s}[\texttt{p}].\texttt{current\_view}]) \text{ (Invariant B.15).}
\end{aligned}
$$

Thus, $\texttt{R}'(\texttt{s}).\texttt{last\_dlvrd}[\texttt{p}][\texttt{p}] = \texttt{LastIndexOf}(\texttt{R}'(\texttt{s}).\texttt{msgs}[\texttt{p}][\texttt{R}'(\texttt{s}).\texttt{current\_view}[\texttt{p}]])$ and the precondition is satisfied. □

From Lemmas B.1, B.2, and B.5 and Theorem A.1 we conclude the following.

THEOREM B.4. *Automaton* GCS *implements automaton* SELF : SPEC *in the sense of trace inclusion, under the assumption that clients at each end-point* p *satisfy the* $\text{CLIENT}_\texttt{p}$: SPEC *specification for blocking clients.*

As a child of VS_RFIFO+TS, GCS also satisfies all the safety properties that VS_RFIFO+TS does, in particular TS : SPEC. Thus, from Theorems B.3 and B.4 we conclude the following.

THEOREM B.5. *Automaton* GCS *implements each of the* WV_RFIFO : SPEC*,*

VSRFIFO : SPEC, TS : SPEC, *and* SELF : SPEC *automata in the sense of trace inclusion, under the assumption that clients at each end-point* p *satisfy the* $\text{CLIENT}_{\mathtt{p}}$: SPEC *specification for blocking clients.*

Appendix C. Correctness proof: Liveness property. In this section we prove that fair executions of our group communication service GCS satisfy liveness property 5.2 of section 5.2. In order to show that a certain action eventually happens, we argue that the preconditions on this action eventually become and stay satisfied, and thus the action eventually occurs, by fairness of the execution. Subsection C.1 below presents a number of invariant that are used in the proof of liveness property 5.2 in subsection C.2.

C.1. Invariants. The following invariant captures the fact that, before an end-point computes who the members of its transitional set are, it does not deliver to its client application messages other than those committed by its own synchronization message. Afterwards, the end-point delivers only the messages committed to delivery by the members of the transitional set.

INVARIANT C.1. *In every reachable state* s *of* GCS*, for all* Proc p*, if* s[p].start $\neq \perp$ *and* s[p].sync_msg[p][s[p].start.id] $\neq \perp$*, then for all* Proc q $\in$ s[p].current_view.set*,*

1. *if* s[p].start.id $\neq$ s[p].memb_view.startId(p)*, then* s[p].last_dlvrd[q] $\leq$ s[p].sync_msg[p][s[p].start.id].cut[q]*;*
2. *otherwise, let* v = s[p].current_view*,* v′ = s[p].memb_view*, and let* T = {q $\in$ v′.set $\cap$ v.set | sync_msg[q][v′.startId(q)].view = v}*; then* s[p].last_dlvrd[q] $\leq max_{\mathtt{r}\in\mathtt{T}}$ s[p].sync_msg[r][v′.startId(r)].cut[q].

Proof of Invariant C.1. The proposition is true in the initial state $\mathtt{s}_0$, since $\mathtt{s}_0$[p].start = $\perp$. For the inductive step, consider the following critical actions:

$\mathtt{deliver}_{\mathtt{p}}(\mathtt{q},\mathtt{m})$. The proposition remains true because the precondition on this action mimics the statement of this proposition.

MEMB.$\mathtt{start}_{\mathtt{p}}(\mathtt{id},\mathtt{set})$. The proposition is vacuously true because s′[p].sync_msg[p][id] = s[p].sync_msg[p][id], which by Lemma B.3 is equal to $\perp$.

MEMB.$\mathtt{view}_{\mathtt{p}}(\mathtt{v})$. In the poststate, s[p].start.id = s[p].memb_view.startId(p), so we must consider the second proposition. Its truth follows from the inductive hypothesis and the fact that p $\in$ T, as implied by Invariant B.1.

$\mathtt{set\_cut}_{\mathtt{p}}()$. The proposition holds since index s[p].last_dlvrd[q] is bounded by LongestPrefixOf(s[p].msgs[q][s[p].current_view]) in every reachable state of the system for any Proc q $\in$ s[p].current_view.set (this fact can be straightforwardly proved by induction) and from the precondition (for all q $\in$ s[p].current_view.set) cut(q) = LongestPrefixOf(s[p].msgs[q][s[p].current_view]).

CO_RFIFO.$\mathtt{deliver}_{\mathtt{q},\mathtt{p}}(\langle$'**sync_msg**', cid, v, cut$\rangle)$. The proposition is unaffected because the case q = p is impossible since end-points do not send cuts to themselves.

$\mathtt{view}_{\mathtt{p}}(\mathtt{v},\mathtt{T})$. The proposition becomes vacuously true because s′[p].start = $\perp$. □

The following invariant states that if an end-point p has end-point q's cut committing certain messages sent by end-point r in view v, then end-point q has those messages buffered.

INVARIANT C.2. *In every reachable state* s *of* GCS*, for all* Proc p*,* Proc q*,* Proc r*, and* StartId cid*, if* s[p].sync_msg[q][cid] $\neq \perp$*, then, for every integer* i *between* 1 *and* s[p].sync_msg[q][cid].cut[r]*,* s[q].msgs[r][s[p].sync_msg[q][cid].view][i] $\neq \perp$.

Proof of Invariant C.2. The truth of the invariant follows from Invariant B.9 if we can prove that an end-point's cut commits the end-point to deliver only those messages that it already has on its msgs queue. Formally, this proposition means

that, in every reachable state s of GCS, for all Proc q, if s[q].start $\neq \perp$ and s[q].sync_msg[q][s[q].start.id] $\neq \perp$, then, for all Proc r and all Int i such that 1 $\leq$ i $\leq$ s[q].sync_msg[q][s[q].start.id].cut[r], s[q].msgs[r][s[q].current_view][i] $\neq \perp$. This proposition can be straightforwardly proved by induction: The only interesting action is $\texttt{set\_cut}_{\texttt{q}}()$. The truth of the proposition after this action is taken follows immediately from the precondition (for all r $\in$ s[q].current_view.set) cut(r) = LongestPrefixOf(s[q].msgs[r][s[q].current_view]). □

INVARIANT C.3. *In every reachable state* s *of* GCS*, for all* Proc p *and* Proc q*, if* q $\in$ s[p].sync_set*, then* (a) q $\in$ s[p].start.set *and* (b) q $\in$ s[p].reliable_set*.*

Proof of Invariant C.3. The proposition is vacuously true in the initial state, where s[p].sync_set is empty. The inductive steps for the critical actions $\text{MEMB.}\texttt{start}_{\texttt{p}}(\texttt{id}, \texttt{set})$, $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$, and $\text{CO\_RFIFO.}\texttt{send}_{\texttt{p}}(\texttt{set}, \langle \text{`}\textbf{sync\_msg}\text{'}, \texttt{cid}, \texttt{v}, \texttt{cut}\rangle)$ follow immediately from their code in Figure 6.4. The inductive step for the action $\text{CO\_RFIFO.}\texttt{reliable\_set}_{\texttt{p}}(\texttt{set})$ straightforwardly follows from the precondition-effect code in Figures 6.2 and 6.4. The inductive step for the critical action $\text{GCS.}\texttt{set\_cut}_{\texttt{p}}()$ follows from the code, which sets sync_set to {p}, and from the fact that p is always in its own reliable_set and start.set (provided start $\neq \perp$), which can be straightforwardly proved by induction. □

C.2. Liveness proof. The following lemma states that, in any execution of GCS, every $\text{GCS.}\texttt{view}_{\texttt{p}}$ event is preceded by the right $\text{MEMB.}\texttt{view}_{\texttt{p}}$ event, which itself is preceded by the right $\text{MEMB.}\texttt{start}_{\texttt{p}}$ event.

LEMMA C.1. *In every execution sequence* α *of* GCS*, the following are true:*

1. *For every* $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$ *event, there is a preceding* $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ *event. Moreover, neither a* $\text{MEMB.}\texttt{start}_{\texttt{p}}$ *nor a* $\text{MEMB.}\texttt{view}_{\texttt{p}}$ *event occurs between* $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ *and* $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$.
2. *For every* $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ *event, there is a preceding* $\text{MEMB.}\texttt{start}_{\texttt{p}}(\texttt{id}, \texttt{set})$ *event with* id = v.startId(p) *and* set $\supseteq$ v.set *such that neither a* $\text{MEMB.}\texttt{start}_{\texttt{p}}$*, nor a* $\text{MEMB.}\texttt{view}_{\texttt{p}}$ *nor a* $\text{GCS.}\texttt{view}_{\texttt{p}}$ *event occurs in* α *between* $\text{MEMB.}\texttt{start}_{\texttt{p}}(\texttt{id}, \texttt{set})$ *and* $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$.

Proof of Lemma C.1.

1. Assume that $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$ occurs in α. Two of the preconditions on $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$ are v = p.memb_view and v.startId(p) = p.start.id, which can only become satisfied as a result of a preceding $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ event, followed by no $\text{MEMB.}\texttt{start}_{\texttt{p}}$ and $\text{MEMB.}\texttt{view}_{\texttt{p}}$ events.
2. Assume that $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ occurs in α. Then a $\text{MEMB.}\texttt{start}_{\texttt{p}}(\texttt{id}, \texttt{set})$ event with id = v.startId(p) and set $\supseteq$ v.set must precede $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ because, by the MEMB specification, it is the only possible event that can cause the preconditions for $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$ to become true, and because these preconditions do not hold in the initial state of MEMB.
   There may be several $\text{MEMB.}\texttt{start}_{\texttt{p}}(\texttt{id}, \texttt{set})$ events with the same id and different set arguments. After the last such event, an occurrence of a different $\text{MEMB.}\texttt{start}_{\texttt{p}}$ event or a $\text{MEMB.}\texttt{view}_{\texttt{p}}$ event would violate one of the preconditions of $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$; thus, such events may not happen. As a corollary from this and part 1 of this lemma, a $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}', \texttt{T}')$ event cannot occur between the last $\text{MEMB.}\texttt{start}_{\texttt{p}}(\texttt{id}, \texttt{set})$ and $\text{MEMB.}\texttt{view}_{\texttt{p}}(\texttt{v})$. □

LEMMA C.2 (liveness). *Let* α *be a fair execution of a group communication service* GCS *in which view* v *becomes eventually stable as defined by Property* 5.1*. Then at each end-point* p $\in$ v.set*,* $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$*, with some* T*, eventually occurs. Furthermore, for every* $\text{GCS.}\texttt{send}_{\texttt{p}}(\texttt{m})$ *that occurs after* $\text{GCS.}\texttt{view}_{\texttt{p}}(\texttt{v}, \texttt{T})$ *and for every*

$\mathtt{q} \in \mathtt{v.set}$, GCS.$\mathtt{deliver_q(p, m)}$ *also occurs.*

Proof of Lemma C.2. Part I. We first prove that GCS.$\mathtt{view_p(v, T)}$ eventually occurs. Our task is to show that, for each $\mathtt{p} \in \mathtt{v.set}$ and some transitional set T, action GCS.$\mathtt{view_p(v, T)}$ becomes enabled at some point after p receives MEMB.$\mathtt{view_p(v)}$ and that it stays enabled forever thereafter unless it is executed. The fact that α is a fair execution of GCS then implies that GCS.$\mathtt{view_p(v, T)}$ is in fact executed.

In order for GCS.$\mathtt{view_p(v, T)}$ to become enabled, its preconditions (see Figures 6.2 and 6.4) must eventually become and stay satisfied until GCS.$\mathtt{view_p(v, T)}$ is executed. We now consider each of these preconditions:

$\mathtt{v} = \mathtt{p.memb\_view} \neq \mathtt{current\_view}$. This precondition ensures that view v that is attempted to be delivered to the client at p is the latest view produced by MEMB and has not yet been delivered to the client. The precondition becomes satisfied as a result of MEMB.$\mathtt{view_p(v)}$. Since in any reachable state of the system $\mathtt{MEMB.memb\_view} = \mathtt{p.memb\_view} \geq \mathtt{p.current\_view}$ (local monotonicity), this precondition remains satisfied forever, unless GCS.$\mathtt{view_p(v, T)}$ is executed. This is because, by our assumption, α does not contain any subsequent MEMB.$\mathtt{view_p(v')}$, and, hence, by the contrapositive of part 1 of Lemma C.1, it also does not contain any subsequent GCS.$\mathtt{view_p(v', T')}$ with $\mathtt{v'} \neq \mathtt{v}$.

$\mathtt{v.startId(p)} = \mathtt{p.start.id}$. This precondition prevents delivery of obsolete views: it ensures that the MEMB service has not issued a new start notification since the time it produced view v. If this condition is not already satisfied before the last MEMB.$\mathtt{start_p(id, set)}$ event with $\mathtt{id} = \mathtt{v.startId(p)}$ and $\mathtt{set} \supseteq \mathtt{v.set}$, then it becomes satisfied as a result of this event, which, by part 1 of Lemma C.1, must precede MEMB.$\mathtt{view_p(v)}$ in α.

This condition stays satisfied from the time of the last MEMB.$\mathtt{start_p(id, set)}$ at least until GCS.$\mathtt{view_p(v, T)}$ occurs because the only two types of actions, MEMB.$\mathtt{start_p(id', set')}$ and GCS.$\mathtt{view_p(v', T')}$ with $\mathtt{v'} \neq \mathtt{v}$, that may affect the value of p.start cannot occur in α after MEMB.$\mathtt{start_p(id, set)}$, as implied by the assumption on this lemma and Lemma C.1.

$\mathtt{v.set} - \mathtt{sync\_set} = \emptyset$. This precondition ensures that prior to delivering view v, end-point p sends out its synchronization message to every member of v.

Notice that if this precondition becomes satisfied any time after the occurrence of the last MEMB.$\mathtt{start_p(id, set)}$ event with $\mathtt{id} = \mathtt{v.startId(p)}$ and $\mathtt{set} \supseteq \mathtt{v.set}$, then it stays satisfied from then on until GCS.$\mathtt{view_p(v, T)}$ is executed. If the precondition is not already satisfied right after the MEMB.$\mathtt{start_p}$ action, it becomes satisfied as a result of CO_RFIFO.$\mathtt{send_p(set, \langle \text{`}\mathbf{sync\_msg}\text{'}, v.startId(p), v, cut\rangle)}$ with $\mathtt{set} = \mathtt{p.start.set} - \mathtt{p.sync\_set}$. This CO_RFIFO.$\mathtt{send_p}$ action must eventually occur in α because its two preconditions, $(\mathtt{p.sync\_msg[p][id]} \neq \perp)$ and $(\mathtt{set} \subseteq \mathtt{reliable\_set})$, eventually become satisfied, for the following reasons.

1. If the first precondition holds any time after the last MEMB.$\mathtt{start_p(id, set)}$ event with $\mathtt{id} = \mathtt{v.startId(p)}$ and $\mathtt{set} \supseteq \mathtt{v.set}$ occurs, then it stays satisfied from that point on. If it is not already satisfied right after the MEMB.$\mathtt{start_p}$ action, it becomes satisfied as a result of $\mathtt{set\_cut_p()}$. In order for $\mathtt{set\_cut_p()}$ to occur, its precondition, $\mathtt{block\_status} = \mathtt{blocked}$, has to becomes satisfied (see Figure 6.5). This occurs as a result of a $\mathtt{block\_ok_q()}$ input from the client at q. If block_status equals blocked at anytime after MEMB.$\mathtt{start_q(v.startId(q), set)}$, then it remains such until GCS.$\mathtt{view_q(v)}$ happens because $\mathtt{block_q()}$ is not enabled after that, and because GCS.$\mathtt{view_q(v)}$ is the only possible GCS view event (by the contrapositive of part 1 of Lemma C.1). To see that block_status does in fact become blocked, consider the

three possible values of block_status right after MEMB.start_q(v.startId(q), set) occurs:

1. block_status = blocked: We are done.
2. block_status = requested: By Invariant B.13, client.block_ok_q() is enabled. It stays enabled until it is executed because the actions, block_q() and GCS.view_q(), which would disable it, cannot occur. When it is executed, the precondition becomes satisfied.
3. block_status = unblocked: When MEMB.start_q(v.startId(q), set) occurs, block_q() becomes and stays enabled until it is executed. After that, block_status becomes requested and the same reasoning as in the previous case applies.

2. The second precondition, set $\subseteq$ reliable_set, becomes satisfied as a result of action CO_RFIFO.reliable_q(set) with set = current_view.set $\cup$ start.set. This action becomes enabled when q receives MEMB.start_q(v.startId(q), set), and therefore it eventually occurs. Afterwards, reliable_set remains unchanged because CO_RFIFO.reliable_q(set) remains disabled; this is because of the precondition reliable_set $\neq$ set and the fact that q's current_view and start remain unchanged.

When CO_RFIFO.send_p(set, ⟨'**sync_msg**', v.startId(p), v, cut⟩) occurs, p.sync_set is set to p.start.set. Since v.set is a subset of p.start.set, this implies that v.set − p.sync_set eventually becomes and stays $\emptyset$.

(for all q $\in$ v.set $\cap$ p.current_view.set) p.sync_msg[q][v.startId(q)] $\neq \perp$. This precondition ensures that p has received the right synchronization message from every q in v.set $\cap$ p.current_view.set. The argument above implies that q eventually sends to p a synchronization message tagged with v.startId(q) and, at the same time, adds p to q.sync_set, where p remains forever, unless GCS.view_p(v, T) with some T occurs. In order to conclude that CO_RFIFO eventually delivers this synchronization message to p, we argue that, from the time the last synchronization message from q to p is placed on CO_RFIFO.channel[q][p] and at least until it is delivered to p, end-point p is in both CO_RFIFO.reliable_set[q] and CO_RFIFO.live_set[q]. The former implies that CO_RFIFO does not lose any messages (in particular, this synchronization message) from q to p. In conjunction with α being a fair execution, the latter implies that CO_RFIFO eventually delivers every message (in particular, this synchronization message) on the channel from q to p.

1. From the time q sends to p the last synchronization message tagged with v.startId(q) until GCS.view_q(v, T) occurs, p is included in q.sync_set. Invariant C.3 implies that in that period p is included in CO_RFIFO.reliable_set[q]. After GCS.view_q(v, T) occurs, p is still included in CO_RFIFO.reliable_set[q], since p $\in$ v.set.

2. End-point p becomes a member of CO_RFIFO.live_set[q] at the time of MEMB.view_q(v), because MEMB.view_q(v) is linked to CO_RFIFO.live_set_q(v.set) and because p $\in$ v.set. This property remains true afterward because α does not contain any subsequent MEMB events at end-point q.

Thus, end-point p eventually receives the right synchronization messages from every q in v.set $\cap$ p.current_view.set.

last_sent $\geq$ sync_msg[p][v.startId(p)].cut(p). This precondition ensures that before delivering view v, p sends to others all of its own messages indicated in its own cut. This precondition eventually becomes satisfied because sending of application messages via CO_RFIFO.send_p, which increments p.last_sent, is enabled at least until p.last_sent reaches sync_msg[p][v.startId(p)].cut(p), as implied by Invariant C.2.

(for all q∈current_view.set) p.last_dlvrd[q]=$\max_{r\in T}$ p.sync_msg[r][v.startId(r)].cut[q]. This precondition verifies that p has delivered to its client exactly the application messages that it needs to deliver in order for virtually synchronous delivery to be satisfied. By Invariant C.1, the value of p.last_dlvrd[q] never exceeds $\max_{r\in T}$ {p.sync_msg[r][v.startId(r)].cut[q]} for any q. It is therefore left to show that p.last_dlvrd[q] does not remain smaller than $\max_{r\in T}$.

We have shown above that all the other preconditions for delivering view v by p eventually become and remain satisfied until the view is delivered. Consider the part of α after all of these preconditions hold. Let q be an end-point in current_view.set such that p.last_dlvrd[q] < $\max_{r\in T}$p.sync_msg[r][v.startId(r)].cut[q], and let i be p.last_dlvrd[q] + 1. We now argue that p.last_dlvrd[q] eventually becomes i, that is, that p eventually delivers the next message from q. An inductive application of this argument would imply that p.last_dlvrd[q] eventually reaches $\max_{r\in T}$ {p.sync_msg[r][v.startId(r)].cut[q]}.

All the preconditions (except perhaps p.msgs[q][p.current_view][i] $\neq \perp$) for delivering the ith message from q are eventually satisfied because they are the same as the preconditions for p delivering view v, which we have shown to be satisfied. Thus, if the ith message is already on p.msgs[q][p.current_view][i], then delivery of this message eventually occurs by fairness, resulting in p.last_dlvrd[q] being incremented; in this case, we are done.

Therefore, consider the case when p lacks the ith message, m, from q. There are two possibilities:

1. If end-point q is in p's transitional set T for view v, then we know the following:
   1. q's view prior to installing view v is the same as p's current view (by definition of T and Invariant B.11).
   2. q's reliable_set contains p starting before q sent any messages in that view and continuing for the rest of α.
   3. Invariant C.2 implies that q has this message and all the messages that precede it in q.msgs[q][p.current_view].
   4. End-point q is enabled to send these messages to p in FIFO order. The only event that could prevent q from sending these messages is GCS.view_q(v), as it would change the value of q.current_view. However, as we argued above, q must send all of the messages it committed in its cut before delivering view GCS.view_q(v). Self-delivery (Invariant B.15) implies that q's cut includes all of the messages q sent while in v. Thus, q would eventually send m to p.
   5. The fact that the connection between end-points q and p is live at least after MEMB.view_q(v) occurs implies that CO_RFIFO eventually delivers this message to p.
2. Otherwise, if end-point q is not in p's transitional set T for view v, we know by the fact that i is ≤ $\max_{r\in T}$ {p.sync_msg[r][v.startId(r)].cut[q]} that there exist some end-points in T whose synchronization messages commit to deliver the ith message from q in view p.current_view. Let r be an end-point with a smallest identifier among these end-points. Here is what we know:
   1. Invariant C.2 implies that r has this message on its r.msgs[r][p.current_view] queue.
   2. r's reliable_set contains p starting before r sent any messages in that view and continuing for the rest of α.
   3. Upon examination of each of the ForwardingStrategyPredicates in section 6.2.1,

we see that the preconditions for r forwarding the i'th message of q to a set including p eventually become and stay satisfied.

4. Since in both forwarding strategies there is only a finite number of messages from q sent in this view that can be forwarded, fairness implies that the i's message is eventually forwarded to p.
5. The fact that the connection between r and p is live at least after MEMB.$\texttt{view}_\texttt{q}(\texttt{v})$ occurs implies that CO_RFIFO eventually delivers this message to p.

Therefore, the ith message from q is eventually delivered to end-point p, and since, as a result of this, the preconditions on delivering this message to the client at p are satisfied, this delivery eventually occurs, and p.last_dlvrd[q] is incremented. By applying this argument inductively, we conclude that p.last_dlvrd[q] eventually reaches $\texttt{max}_{\texttt{r}\in\texttt{T}}$ p.sync_msg[r][v.startId(r)].cut[q] for every q in current_view.set.

We have shown that each precondition on p delivering GCS.$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ eventually becomes and stays satisfied. Fairness implies that GCS.$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ eventually occurs.

Part II. We now consider the second part of the lemma. The following argument proves that, after GCS.$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ occurs at p, for every subsequent GCS.$\texttt{send}_\texttt{p}(\texttt{m})$ event at p, there is a corresponding GCS.$\texttt{deliver}_\texttt{q}(\texttt{p},\texttt{m})$ event that occurs at every q ∈ v.set:

1. For the rest of α, after GCS.$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ occurs, CO_RFIFO.live_set[p] is equal to v.set. This is true because CO_RFIFO.live_set[p] is set to v.set when MEMB.$\texttt{view}_\texttt{p}(\texttt{v})$ occurs and remains unchanged thereafter because of the assumption that α does not contain any subsequent MEMB events at end-point p.
2. After GCS.$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ occurs and before any CO_RFIFO.$\texttt{send}_\texttt{p}$ event involving a ViewMsg or an AppMsg occurs, p eventually executes CO_RFIFO.$\texttt{reliable}_\texttt{p}(\texttt{v.set})$. Moreover, after that and forever thereafter, both p.reliable_set and CO_RFIFO.reliable_set[p] equal v.set. This is true because GCS.$\texttt{view}_\texttt{p}(\texttt{v},\texttt{T})$ sets p.start to $\perp$ and p.current_view.set to v.set, thus enabling CO_RFIFO.$\texttt{reliable}_\texttt{p}(\texttt{v.set})$. This action eventually happens because α is a fair execution and because for the rest of α there are no subsequent MEMB.$\texttt{start}_\texttt{p}$ and GCS.$\texttt{view}_\texttt{p}(\texttt{v}',\texttt{T}')$ events. Because of the latter reason, p.start and p.current_view.set remain unchanged. Therefore, CO_RFIFO.$\texttt{reliable}_\texttt{p}$ remains disabled and both variables CO_RFIFO.reliable_set[p] and p.reliable_set remain equal to v.set.
   From the above argument and from fairness, it follows that any kind of message that end-point p sends subsequently to q via CO_RFIFO will eventually reach end-point q.
3. Action CO_RFIFO.$\texttt{send}_\texttt{p}(\texttt{v.set} - \{\texttt{p}\}, \langle \text{`}\textbf{view\_msg}\text{'}, \texttt{v}\rangle)$ eventually occurs after action CO_RFIFO.$\texttt{reliable}_\texttt{p}(\texttt{v.set})$ occurs, as follows from the code in Figure 6.4. By the reasoning above, CO_RFIFO delivers this ViewMsg to every end-point q ∈ v.set − {p}, resulting in q.view_msg[p] being set to v for the remainder of α (Invariant B.4).
4. When GCS.$\texttt{send}_\texttt{p}(\texttt{m})$ event occurs at p, m is appended to p.msgs[p][v].
5. After sending the ViewMsg, for the rest of α, if p.msgs[p][v][p.last_sent + 1] contains a message (say m′), action CO_RFIFO.$\texttt{send}_\texttt{p}(\texttt{v.set} - \{\texttt{p}\}, \langle \text{`}\textbf{app\_msg}\text{'}, \texttt{m}'\rangle)$ is enabled, and hence eventually occurs by fairness. Since p.last_sent is incremented after each application message is sent using CO_RFIFO.$\texttt{send}_\texttt{p}$, any message on p.msgs[p][v] is eventually sent to v.set − {p}. As was argued above, these messages are eventually delivered to every end-point q ∈

$\mathtt{v.set} - \{\mathtt{p}\}$. Since $\mathtt{q.view\_msg[p]} = \mathtt{v}$ at the time $\mathtt{q}$ receives $\mathtt{m}'$, $\mathtt{q}$ puts $\mathtt{m}'$ in $\mathtt{q.msgs[p][v][q.last\_rcvd} + 1]$ (Invariant B.5) and increments $\mathtt{q.last\_rcvd}$. Therefore, all messages that end-point $\mathtt{p}$ sends in view $\mathtt{v}$ are eventually inserted with no gaps in the end-point $\mathtt{q}$'s queue, $\mathtt{q.msgs[p][v]}$, for every $\mathtt{q} \in \mathtt{v.set} - \{\mathtt{p}\}$.

6. Once $\text{GCS.}\mathtt{view}_{\mathtt{q}}(\mathtt{v}, \mathtt{T})$ happens (by part I of the proof of the lemma), end-point $\mathtt{q} \in \mathtt{v.set}$ is continuously enabled to deliver a message, $\mathtt{m}'$, from $\mathtt{q.msgs[p][v][q.last\_dlvrd} + 1]$; by fairness, such delivery eventually occurs, resulting in $\mathtt{q.last\_dlvrd[p]}$ being incremented. Therefore, every messages on $\mathtt{q.msgs[p][v]}$ is eventually delivered to the client at $\mathtt{p}$, including the case of $\mathtt{q} = \mathtt{p}$.

It follows from this argument that every $\text{GCS.}\mathtt{send}_{\mathtt{p}}(\mathtt{m})$ event at end-point $\mathtt{p}$ that occurs after $\text{GCS.}\mathtt{view}_{\mathtt{p}}(\mathtt{v}, \mathtt{T})$ in α is eventually followed by a $\text{GCS.}\mathtt{deliver}_{\mathtt{q}}(\mathtt{p}, \mathtt{m})$ at every $\mathtt{q} \in \mathtt{v.set}$. □

AN APPROXIMATE L^1-DIFFERENCE ALGORITHM FOR MASSIVE DATA STREAMS*

JOAN FEIGENBAUM†, SAMPATH KANNAN‡, MARTIN J. STRAUSS§, AND MAHESH VISWANATHAN¶

Abstract. Massive data sets are increasingly important in a wide range of applications, including observational sciences, product marketing, and the monitoring and operations of large systems. In network operations, raw data typically arrive in *streams*, and decisions must be made by algorithms that make one pass over each stream, throw much of the raw data away, and produce "synopses" or "sketches" for further processing. Moreover, network-generated massive data sets are often *distributed*: Several different, physically separated network elements may receive or generate data streams that, together, comprise one logical data set; to be of use in operations, the streams must be analyzed locally and their synopses sent to a central operations facility. The enormous scale, distributed nature, and one-pass processing requirement on the data sets of interest must be addressed with new algorithmic techniques.

We present one fundamental new technique here: a space-efficient, one-pass algorithm for approximating the L^1-difference $\sum_i |a_i - b_i|$ between two functions, when the function values a_i and b_i are given as data streams, and their order is chosen by an adversary. Our main technical innovation, which may be of interest outside the realm of massive data stream algorithmics, is a method of constructing families $\{V_j(s)\}$ of limited-independence random variables that are *range-summable*, by which we mean that $\sum_{j=0}^{c-1} V_j(s)$ is computable in time *polylog*(c) for all seeds s. Our L^1-difference algorithm can be viewed as a "sketching" algorithm, in the sense of [Broder et al., *J. Comput. System Sci.,* 60 (2000), pp. 630–659], and our technique performs better than that of Broder et al. when used to approximate the symmetric difference of two sets with small symmetric difference.

operations facility. The enormous scale, distributed nature, and one-pass processing requirement on the data sets of interest must be addressed with new algorithmic techniques.

We present one fundamental new technique here: a space-efficient, one-pass algorithm for approximating the L^1-difference $\sum_i |a_i - b_i|$ between two functions, when the function values a_i and b_i are given as data streams, and their order is chosen by an adversary. This algorithm fits naturally into a toolkit for Internet-traffic monitoring. For example, Cisco routers can now be instrumented with the NetFlow feature [CN98]. As packets travel through the router, the NetFlow software produces summary statistics on each *flow*.[1] Three of the fields in the flow records are source IP-address, destination IP-address, and total number of bytes of data in the flow. At the end of a day (or a week, or an hour, depending on what the appropriate monitoring interval is and how much local storage is available), the router (or, more accurately, a computer that has been "hooked up" to the router for monitoring purposes) can assemble a set of values $(x, f_t(x))$, where x is a source-destination pair, and $f_t(x)$ is the total number of bytes sent from the source to the destination during a time interval t. The L^1-difference between two such functions assembled during different intervals or at different routers is a good indication of the extent to which traffic patterns differ.

Our algorithm allows the routers and a central control and storage facility to compute L^1-differences efficiently under a variety of constraints. First, a router may want the L^1-difference between f_t and f_{t+1}. The router can store a small "sketch" of f_t, throw out all other information about f_t, and still be able to approximate $\|f_t - f_{t+1}\|_1$ from the sketch of f_t and (a sketch of) f_{t+1}.

The functions $f_t^{(i)}$ assembled at each of several remote routers R_i at time t may be sent to a central tape-storage facility C. As the data are written to tape, C may want to compute the L^1-difference between $f_t^{(1)}$ and $f_t^{(2)}$, but this computation presents several challenges. First, each router R_i should transmit its statistical data when R_i's load is low and the R_i-C paths have extra capacity; therefore, the data may arrive at C from the R_i's in an arbitrarily interleaved manner. Also, typically the x's for which $f(x) \neq 0$ constitute a small fraction of all x's; thus, R_i should only transmit $(x, f_t^{(i)}(x))$ when $f_t^{(i)}(x) \neq 0$. The set of transmitted x's is not predictable by C. Finally, because of the huge size of these streams,[2] the central facility will not want to buffer them in the course of writing them to tape (and cannot read from one part of the tape while writing to another), and telling R_i to pause is not always possible. Nevertheless, our algorithm supports approximating the L^1-difference between $f_t^{(1)}$ and $f_t^{(2)}$ at C, because it requires little work space, requires little time to process each incoming item, and can process in one pass all the values of both functions $\{(x, f_t^{(1)}(x))\} \cup \{(x, f_t^{(2)}(x))\}$ in any permutation.

Our L^1-difference algorithm achieves the following performance:

> Consider two data streams of length at most n, each representing the nonzero points on the graph of an integer-valued function on a domain of size n. Assume that the maximum value of either

[1] Roughly speaking, a "flow" is a semantically coherent sequence of packets sent by the source and reassembled and interpreted at the destination. Any precise definition of "flow" would have to depend on the application(s) that the source and destination processes were using to produce and interpret the packets. From the router's point of view, a flow is just a set of packets with the same source and destination IP-addresses whose arrival times at the routers are close enough, for a tunable definition of "close."

[2] In 1999, a WorldNet gateway router generated more that 10Gb of NetFlow data each day.

> function on this domain is M. Then a one-pass streaming algorithm can compute with probability $1-\delta$ an approximation A to the L^1-difference B of the two functions such that $|A-B| \le \epsilon B$, using total space $O(\log(Mn)\log(1/\delta)/\epsilon^2)$ and $O(\log^{O(1)}(Mn)\log(1/\delta)/\epsilon^2)$ time to process each item. The data streams may be interleaved in an arbitrary (adversarial) order. Here space usage is measured in number of bits and time in number of bit operations.

The main technical innovation used in this algorithm is a limited-independence random-variable construction that may prove useful in other contexts:

> A family $\{V_j(s)\}$ of uniform ± 1-valued random variables is called *range-summable* if $\sum_{j=0}^{c-1} V_j(s)$ can be computed in time *polylog*(c) for all seeds s. We construct range-summable families of random variables that are n^2-*bad* 4-*wise independent*.[3]

The property of n^2-bad 4-wise independence suffices for the time- and space-bounds on our algorithm. One can construct a truly 4-wise (in fact, 7-wise) independent range-summable family of random variables based on second-order Reed–Muller codes ([RS99]; for details about second-order Reed–Muller codes, see [MS77]), but the efficiency of the range summation seems to be significantly worse than it is in our construction.

The rest of this paper is organized as follows. In section 2, we give precise statements of our "streaming" model of computation and complexity measures for streaming and sketching algorithms. In section 3, we present our main technical results. Section 4 explains the relationship of our algorithm to other recent work, including that of Broder et al. [BCFM00] on sketching and that of Alon, Matias, and Szegedy [AMS99] and Alon et al. [AGMS99] on frequency moments.

2. Models of computation. Our model is closely related to that of Henzinger, Raghavan, and Rajagopalan [HRR98]. We also describe a related sketch model that has been used, e.g., in [BCFM00].

2.1. The streaming model. As in [HRR98], a *data stream* is a sequence of data items $\sigma_1, \sigma_2, \ldots, \sigma_n$ such that, on each *pass* through the stream, the items are read once in increasing order of their indices. We assume the items σ_i come from a set of size M, so that each σ_i has size $\log M$. In our computational model, we assume that the input stream consists of one or more data streams. We focus on two resources—the *work space* required in bits and the *time to process* each item in the stream. An algorithm will typically also require pre- and postprocessing time, but usually applications can afford more time for these tasks. For the algorithms in this paper, the pre- and postprocessing time is comparable to the per-item time and is not considered further.

DEFINITION 1. *The complexity class* PASST$(s(\delta,\epsilon,n,M), t(\delta,\epsilon,n,M))$ *(to be read as "probably approximately correct streaming space complexity* $O(s(\delta,\epsilon,n,M))$ *and time complexity* $O(t(\delta,\epsilon,n,M))$*") contains those functions* f *on domain* X^n*, where* $|X| = M$*, for which one can output a random variable* R *such that* $|R-f| < \epsilon f$ *with probability at least* $1-\delta$*, and computation of* R *can be done by making a single pass over an instance* $x \in X^n$*, presented in a stream, using total workspace* $O(s(\delta,\epsilon,n,M))$ *and taking time* $O(t(\delta,\epsilon,n,M))$ *to process each item.*

If $s = t$*, we also write* PASST(s) *for* PASST(s,t).

[3] The property of n^2-bad 4-wise independence is defined precisely in section 3 below.

We will also abuse notation and write $A \in \mathrm{PASST}(s,t)$ to indicate that an algorithm A for f witnesses that $f \in \mathrm{PASST}(s,t)$.

Thus f is a function of a single input that has n *elements* or *components*. We allow the input elements of f to be presented in any order in the stream; thus, an input item will be of the form "the jth input element value is a_j." For example, a fragment of the stream representing f might look like $\cdots(5,2)(3,7)(7,4)(2,6)\cdots$, and this is interpreted as $f(5)=2$, $f(3)=7$, etc. Note that the input to f is considered to be static—in a properly formed input stream, at most one item specifies the value of a_j. Thus the length of the input stream is n (items) for our algorithms.[4] Other variants of input streams are possible, in which input values may change (repeatedly) throughout the stream, or in which the input comes in a nonarbitrary order (e.g., in sorted order or random order). We do not consider these variations in this paper.

2.2. The sketch model. Sketches were used in [BCFM00] to check whether two documents are nearly duplicates. A sketch can also be regarded as a *synopsis data structure* [GM99].

Definition 2. *Let X be a set containing at most M items. The complexity class* $\mathrm{PAS}(s(\delta,\epsilon,n,M))$ *(to be read as "probably approximately correct sketch complexity $s(\delta,\epsilon,n,M)$") contains those functions $f : X^n \times X^n \to Z$ of two inputs for which there exists a set S of size $2^{O(s)}$, a randomized* sketch function $h : X^n \to S$, *and a randomized* reconstruction function $\rho : S \times S \to Z$ *such that, for all $x_1, x_2 \in X^n$, with probability at least $1-\delta$, $|\rho(h(x_1),h(x_2)) - f(x_1,x_2)| < \epsilon f(x_1,x_2)$.*

By "randomized function" of k inputs, we mean a function of $k+1$ variables. The first input is distinguished as the source of randomness. It is not necessary that, for all settings of the last k inputs and for most settings of the first input, the function outputs the same value.

Note that we can also define the sketch complexity of a function $f : X \times Y \to Z$ for $X \neq Y$. There may be two different sketch functions involved.

There are connections between the sketch model and the streaming model. Let XY denote the set of concatenations of $x \in X$ with $y \in Y$. It has been noted in [KN97] and elsewhere that a function on XY with low streaming complexity also has low one-round communication complexity (regarded as a function on $X \times Y$), because it suffices to communicate the memory contents of the hypothesized streaming algorithm after reading the X part of the input. Sometimes one can also produce a low-sketch-complexity algorithm from an algorithm with low streaming complexity. Our main result is an example.

Also, in practice, it may be useful for the sketch function h to have low streaming complexity. If the set X is large enough to warrant sketching, then it may also warrant processing by an efficient streaming algorithm.

Formally, we have the following.

Theorem 3. *If $f \in \mathrm{PAS}(s(\delta,\epsilon,n,M))$ via sketch function*

$$h \in \mathrm{PASST}(s(\delta,\epsilon,n,M), t(\delta,\epsilon,n,M)),$$

then $f \in \mathrm{PASST}(2s(\delta,\epsilon,2n,M), t(\delta,\epsilon,2n,M))$, where we identify $f : X^n \times X^n \to Z$ with $f : X^{2n} \to Z$ in the natural way.

[4] It turns out, however, that our algorithms will work if, by convention, we define a_j to be zero if *no* stream item specifies the value of a_j. Thus the length of the input stream may be considerably less than n. Our streaming algorithm for the L^1-distance between two vectors actually, at each point during the stream, can approximate the L^1-distance between the vectors seen thus far, regarding unseen inputs as zero.

We will state our time bounds in terms of field(D), the time necessary to perform a single arithmetic operation in a field of size 2^D. Naïve field-arithmetic algorithms guarantee that field(D) $= O(D^2)$.

3. The L^1-difference of functions.

3.1. Our approach. We consider the following problem. The input stream is a sequence of tuples of the form $(i, a_i, +1)$ or $(i, b_i, -1)$ such that, for each i in the universe $[n]$, there is at most one tuple of the form $(i, a_i, +1)$ and at most one tuple of the form $(i, b_i, -1)$, and a_i and b_i are nonnegative integers. If there is no tuple of the form $(i, a_i, +1)$, then define a_i to be zero for our analysis, and similarly for b_i. Also note that, in general, a small-space streaming algorithm cannot know for which i's the tuple $(i, a_i, +1)$ does not appear. The goal is to approximate the value of $F_1 = \sum |a_i - b_i|$ to within $\pm\epsilon F_1$, with probability at least $1 - \delta$.

Let M be an upper bound on a_i and b_i. We assume that n and M are known in advance; in section 3.7, we discuss small modifications that can be made when either of these is not known in advance.

We first present an intuitive exposition of the algorithm. Suppose that, for each type i, we can define a family of M ± 1-valued random variables $R_{i,j}, j = 0, 1, \ldots, (M-1)$, with independence properties to be specified later. When we encounter a tuple of the form $(i, a_i, +1)$, we add $\sum_{j=0}^{a_i - 1} R_{i,j}$ to a running sum z, and when we encounter a tuple of the form $(i, b_i, -1)$, we subtract $\sum_{j=0}^{b_i - 1} R_{i,j}$ from z. The overall effect on z is to cancel the first $\min(a_i, b_i)$ random variables leaving the sum of the remaining $|a_i - b_i|$ random variables. Finally, consider z^2. There are exactly $\sum_{i=1}^{n} |a_i - b_i|$ terms that are squares of random variables, and these terms contribute exactly the desired quantity F_1 to z^2. If the cross terms $R_{i,j} R_{k,l}$ with $\{i, j\} \neq \{k, l\}$ contribute very little, then z^2 is a good approximation to F_1.

Pairwise independence of the random variables in question will ensure that the expected contribution from these cross terms is 0, and 4-wise independence will ensure that the variance is small, thus ensuring that the cross terms contribute very little with high probability. Therefore, we would ideally like our random variables to be 4-wise independent. In addition, as seen above, we want to be able to compute sums of the form $\sum_{j=0}^{c} R_{i,j}$ efficiently. In order to compute these sums very efficiently, our construction produces random-variable families that deviate slightly from 4-wise independence.

We now develop a more formal treatment of the above. We start with the definition that captures the properties desired of the family of random variables corresponding to one type i. We will show how to construct random variables that satisfy this definition. Later, we extend this to show how to construct random-variable families to handle more than one type.

3.2. Construction of random variable families.

DEFINITION 4. *A family $\{V_j(s)\}$ of uniform ± 1-valued random variables with seed s (chosen at random from some set S of seeds) is called* range-summable, n^2-bad 4-wise independent *if the following properties are satisfied:*

1. *The family $\{V_j(s)\}$ is 3-wise independent, i.e., for all* distinct *j_1, j_2, j_3, for all $a, b, c \in \{+1, -1\}$,*

$$\Pr_s[V_{j_1}(s) = a | V_{j_2}(s) = b \wedge V_{j_3}(s) = c] = \Pr_s[V_{j_1}(s) = a].$$

2. *For all s, $\sum_{j=0}^{c-1} V_j(s)$ can be computed in time polylogarithmic in c.*

3. *For all $a < b$,*

$$E\left[\left(\sum_{j=a}^{b-1} V_j(s)\right)^4\right] = O((b-a)^2).$$

In property 3 *and in similar expressions throughout the rest of this paper, the expectation is computed over s.*

Note that even for 4-wise independent random variables, the sum in property 3 is $\Theta((b-a)^2)$ because of terms of the form $V_j^2(s)V_k^2(s)$. Thus, property 3 does not represent a significant weakening of 4-wise independence. On the other hand, we do not know of a construction using 4-wise independent random variables that matches ours in efficiency with regard to property 2.

We now describe our construction. This is the main technical innovation of our paper. It is also a significant point of departure from the work on frequency moments by Alon et al. [AMS99]. The relationship between our algorithm and the frequency-moment algorithms is explained in section 4.

We will construct a single family of M random variables $V_j(s)$, $0 \le j < M$, such that, for all $c \le M$, one can compute $\sum_{j=0}^{c-1} V_j(s)$ quickly. In the discussion that follows, $\oplus$ represents boolean exclusive-or, and $\vee$ represents boolean or. Logarithms in this paper are always to the base 2.

Suppose, without much loss of generality, that M is a power of 2. Let $H_{(\log M)}$ be the matrix with M columns and $\log M$ rows such that the jth column is the binary expansion of j. For example,

$$H_{(3)} = \begin{bmatrix} 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}.$$

Let $\hat{H}_{(\log M)}$ be formed from $H_{(\log M)}$ by adding a row of 1's at the top.

$$\hat{H}_{(3)} = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}.$$

We will index the $\log M + 1$ rows of $\hat{H}$ starting with -1 for the row of all 1's, then 0 for the row consisting of the 2^0-bits of the binary expansions, and continue consecutively up to the $(\log(M)-1)$st row. We will left multiply $\hat{H}$ by a seed s of length $\log M + 1$ and use the same indexing scheme for bits of s as for rows of $\hat{H}$. We will also refer to the last bit of s and the last row of $\hat{H}$, where "last" means $(\log M - 1)$st, as the "most significant."

Given a seed $s \in \{0,1\}^{\log M+1}$, let $s \cdot \hat{H}_j$ denote the inner product over $\mathbb{Z}_2$ of s with the jth column of $\hat{H}$. Let i_k denote the coefficient of 2^k in the binary expansion of i. Define $f(i)$ by[5]

$$f(i) = (i_0 \vee i_1) \oplus (i_2 \vee i_3) \oplus \cdots \oplus (i_{\log M-2} \vee i_{\log M-1}). \tag{3.1}$$

[5]Here and henceforth, we will actually assume that M is a power of 4 to simplify the exposition.

Thus, the sequence p of values $f(i)$, $i = 0, 1, 2, \ldots$, is

0111 1000 1000 1000 1000 0111 0111 0111 1000 0111 0111 0111 1000 0111 0111 0111 ...

and can be obtained as the string $p_{\log M}$ by starting with $p_0 = 0$ and putting $p_{k+2} = p_k\,\overline{p_k}\,\overline{p_k}\,\overline{p_k}$, where $\overline{\pi}$ denotes the bitwise negation of the pattern π. Finally, put $V_j(s) = (-1)^{(s\cdot\hat{H}_j)+f(j)}$.

PROPOSITION 5. *The quantity $\sum_{j=0}^{c-1} V_j(s)$ can be computed in time $O(\log(c))$.*

Proof. First assume that c is a power of 4. If $c < M$, then the first c columns of $\hat{H}_{\log M}$ have the form $\binom{\hat{H}_{\log c}}{0}$, and we can reduce our problem to one in which we truncate s to include only the first $1 + \log c$ bits. We may thus assume that $c = M$. Then $\hat{H}_{(\log M)}$ is given recursively by

$$\hat{H}_{(\log M)} = \begin{bmatrix} 1\cdots1 & 1\cdots1 & 1\cdots1 & 1\cdots1 \\ H_{(\log M-2)} & H_{(\log M-2)} & H_{(\log M-2)} & H_{(\log M-2)} \\ 0\cdots0 & 1\cdots1 & 0\cdots0 & 1\cdots1 \\ 0\cdots0 & 0\cdots0 & 1\cdots1 & 1\cdots1 \end{bmatrix}.$$

Also, note that the first M bits of p have the form

$$p_{\log M} = p_{\log M-2}\overline{p_{\log M-2}p_{\log M-2}p_{\log M-2}}.$$

Let s' be a string of length $\log M-2$ that is equal to s without the -1st bit and without the two most significant bits, and let f' denote the fraction of 1's in $s' \cdot H_{(\log M-2)}$. Also, for bits b_1, b_2, let $f_{b_1b_2}$ denote the fraction of 1's in

$$s \cdot \begin{bmatrix} 1\cdots1 \\ H_{(\log M-2)} \\ b_1\cdots b_1 \\ b_2\cdots b_2 \end{bmatrix}.$$

Then $f_{b_1b_2} = f'$ or $f_{b_1b_2} = 1 - f'$, depending on b_1, b_2, and the three bits of s dropped from s' (namely, -1, $\log M - 2$, and $\log M - 1$). Recursively compute f', and use the value to compute all the $f_{b_1b_2}$'s and, from that, the number of 1's in $\sum_{j=0}^{c-1} V_j(s)$. This procedure requires recursive calls of depth that is logarithmic in c.

Similarly, one can compute $\sum_{j=q4^r}^{(q+1)4^r-1} V_j(s)$.

Finally, if c is not a power of 4, write the interval $\{0, \ldots, (c-1)\} = [0, c)$ as the disjoint union of at most $O(\log(c))$ intervals, each of the form $[q4^r, (q+1)4^r)$. Use the above technique to compute the fraction of V's equal to 1 over each subinterval, and then combine. If one is careful to perform the procedure bottom up, the entire procedure requires just $\log(c)$ recursive calls, not $\log^2(c)$ calls. For example, suppose $c = 22$. Write $[0, 22)$ as $[0, 16) \cup [16, 20) \cup [20, 21) \cup [21, 22)$. A naïve way to proceed would be to perform recursive calls 3 deep to compute $\sum_{j=0}^{15} V_j(s)$, then calls 2 deep for $\sum_{j=16}^{19} V_j(s)$, then 1 deep for each of $V_{20}(s)$ and $V_{21}(s)$. It is better to proceed as follows: compute $V_{20}(s)$ directly (by taking the dot product of the first $O(\log(c))$ bits of s with the first $O(\log(c))$ rows of column 20 in $\hat{H}_{\log(M)}$, then adding $f(20)$); use this value to compute $V_{21}(s)$ and $V_{16}(s)$ (each of these computations requires looking at just $O(1)$ bits of s—in this case, $V_{21}(s)$ is the sum of $V_{20}(s)$ and the 2^0 bit of s, and $V_{16}(s)$ is the sum of $V_{20}(s)$ and the 2^2 bit of s); then use $V_{16}(s)$ to compute $\sum_{j=16}^{19} V_j(s)$; and finally use $\sum_{j=16}^{19} V_j(s)$ to compute $\sum_{j=0}^{3} V_j(s)$ and, from that,

$\sum_{j=0}^{15} V_j(s)$. For $j < c$, computing the value of a single $V_j(s)$ takes time $O(\log(c))$, and the overhead in each recursive call takes constant time. Thus, altogether, computing a range sum of V's requires time $O(\log(c))$. □

We now show that this construction yields a family of random variables that is n^2-bad 4-wise independent. The fact that $\{V_j(s)\}$ is three-wise independent is shown in [AS92].

PROPOSITION 6. *For all $a < b$, we have*

$$E\left[\left(\sum_{j=a}^{b-1} V_j(s)\right)^4\right] \leq 5(b-a)^2.$$

Proof. First, note that, for some tuples (j_1, j_2, j_3, j_4), columns j_1, j_2, j_3, and j_4 of $\hat{H}$ are independent. These tuples do not contribute to the expectation on the left of the inequality, because for each desired outcome (v_1, v_2, v_3, v_4), the sets

$$S_{(v_1,v_2,v_3,v_4)} = \{s : (V_{j_1}(s), V_{j_2}(s), V_{j_3}(s), V_{j_4}(s)) = (v_1, v_2, v_3, v_4)\}$$

have the same size by linear algebra.

Second, observe that, because any three columns of $\hat{H}$ are independent, if the columns $\hat{H}_{j_1}, \hat{H}_{j_2}, \hat{H}_{j_3}$, and $\hat{H}_{j_4}$ are dependent, then their mod 2 sum is zero. Thus a dependent tuple has one of 3 basic forms—all four columns are identical; there are two pairs of distinct columns; or all four columns are distinct. In the case of dependent tuples, the seed s is irrelevant to the product $V_{j_1}(s)V_{j_2}(s)V_{j_3}(s)V_{j_4}(s)$ because

$$V_{j_1}(s)V_{j_2}(s)V_{j_3}(s)V_{j_4}(s) \tag{3.2}$$
$$= (-1)^{(s\cdot\hat{H}_{j_1})+f(j_1)} \cdot (-1)^{(s\cdot\hat{H}_{j_2})+f(j_2)} \cdot (-1)^{(s\cdot\hat{H}_{j_3})+f(j_3)} \cdot (-1)^{(s\cdot\hat{H}_{j_4})+f(j_4)}$$
$$= (-1)^{f(j_1)+f(j_2)+f(j_3)+f(j_4)}. \tag{3.3}$$

Line (3.3) follows from the fact that the columns $\hat{H}_{j_1}, \hat{H}_{j_2}, \hat{H}_{j_3}$, and $\hat{H}_{j_4}$ sum to zero. Thus it is sufficient to show that

$$U(a,b) \triangleq \sum_{\substack{a\leq j_1,j_2,j_3,j_4<b \\ j_1\oplus j_2\oplus j_3\oplus j_4=0}} (-1)^{f(j_1)+f(j_2)+f(j_3)+f(j_4)} \leq K(b-a)^2$$

for some constant K. From Theorem 9 below, we can see that $K \leq 5$, and thus the proposition holds. □

We shall now provide upper bounds for the quantity $U(a,b)$ defined in the proof of Proposition 6. We will give two bounds for $U(a,b)$—a simply derived though poor bound (Theorem 8) and a more tediously obtained but much tighter bound (Theorem 9). Before presenting these bounds, we first prove a lemma that is used later in the proofs.

LEMMA 7. $U(4a, 4b) \leq 16U(a,b)$.

Proof. Let (j_1, j_2, j_3, j_4) be a dependent tuple in $[4a, 4b)^4$. Consider the two least significant bits of the j's. We will say that the tuple is *odd* if no two of its members have the same pair of least significant bits; otherwise, we will say that the tuple is *even*. There are 64 possibilities making the columns dependent, because we can choose two bits from each of the first three columns arbitrarily, and this forces a unique choice of the bits from the last column. Of these, $24 = 4!$ are odd and 40 are even. (The 40 even tuples arise from 4 tuples in which all columns have identical bits and 36 tuples

in which the 4 columns are paired in one of 6 ways, and the two pairs are given two distinct values out of the 4 possible in one of 6 ways.)

Note that a dependent tuple is odd if and only if there are an odd number of i's for which $(j_i)_0 \vee (j_i)_1 = 1$. Thus, if (j_1, j_2, j_3, j_4) is an odd dependent tuple and (j_1', j_2', j_3', j_4') is an even dependent tuple where j_i' agrees with j_i on all bits except possibly the two least significant, then the contributions of these two tuples to the $U(4a, 4b)$ cancel out. Therefore, given an odd tuple (j_1, j_2, j_3, j_4), pair it with (j_1', j_2', j_3', j_4') as above. Because $4a$ and $4b$ are multiples of 4, (j_1', j_2', j_3', j_4') will be in the correct range. If (j_1, j_2, j_3, j_4) is a tuple having one of the 16 other (even) configurations of the two least significant bits, attempt to pair it inductively with (j_1', j_2', j_3', j_4') such that j_i and j_i' have the same two least significant bits. Thus $U(4a, 4b) \leq 16U(a, b)$. □

We now give a simple argument that $U(a, b) \leq 27(b-a)^2$.

THEOREM 8. $U(a, b) \leq 27(b-a)^2$.

Proof. Given a and b, find r with $a, b \leq 4^r$. Let α be the smallest multiple of 4 that is at least a and let β be the largest multiple of 4 that is at most b. Then $U(a, b)$ is at most $U(\alpha, \beta)$ plus the number of tuples having at least one column in $[a, \alpha) \cup [\beta, b)$. We will handle the first term inductively; we now count the number of tuples having at least one column in $[a, \alpha) \cup [\beta, b)$. First, there are 4 ways to choose one of j_1, j_2, j_3, and j_4 to be in $[a, \alpha) \cup [\beta, b)$. (Having paid the factor 4, we now call this column j_1.) There are at most 6 ways to choose $j_1 \in [a, \alpha) \cup [\beta, b)$. There are at most $(b-a)^2$ ways to choose j_2 and j_3 in $[a, b)$. Finally, once j_1, j_2, and j_3 are fixed, there is at most one way to choose j_4 to make (j_1, j_2, j_3, j_4) dependent. (Note that j_2, j_3, and j_4 play symmetric roles.) This gives $24(b-a)^2$ tuples altogether. Thus we conclude that

$$\begin{aligned}
U(a,b) &\leq U(4\lceil a/4\rceil, 4\lfloor b/4\rfloor) + 24(b-a)^2 \\
&= 16U(\lceil a/4\rceil, \lfloor b/4\rfloor) + 24(b-a)^2 \\
&\leq 16U(4\lceil\lceil a/4\rceil/4\rceil, 4\lfloor\lfloor b/4\rfloor/4\rfloor) + 24(\lfloor b/4\rfloor - \lceil a/4\rceil)^2 + 24(b-a)^2 \\
&= 16^2 U(\lceil\lceil a/4\rceil/4\rceil, \lfloor\lfloor b/4\rfloor/4\rfloor) + 24(\lfloor b/4\rfloor - \lceil a/4\rceil)^2 + 24(b-a)^2 \\
&\vdots \\
&\leq 16^{\lfloor \log_4(b-a)\rfloor} + 24(b-a)^2\left[1 + 1/16 + 1/16^2 \cdots\right] \\
&\leq (b-a)^2 + 24(b-a)^2(16/15) \\
&\leq 27(b-a)^2,
\end{aligned}$$

as desired. □

We now give a more involved analysis that lets us improve the bound.

THEOREM 9. $U(a, b) \leq 5(b-a)^2$.

Proof. Define $A(a, b)$ to be $\frac{U(a,b)}{(b-a)^2}$. Note that it is sufficient to show that $\sup_{a,b} A(a, b) \leq 5$. We will give a recurrence for $A(a, b)$ and discuss a computer search over a, b with $b-a$ small that yields a bound better than immediately available from the recurrence.

We first assume that $b - a \geq 16$. Let a' be the smallest multiple of 4 that is at least a, and let b' be the greatest multiple of 4 that is at most b. (Because $b - a \geq 16$, it follows that $a \leq a' < b' \leq b$.) The number of unpaired tuples in $[a, b)^4$ is at most the number of unpaired tuples in $[a', b')^4$ plus the number of unpaired tuples having at least one column in $[a, a') \cup [b', b)$. The number of unpaired tuples in $[a', b')^4$ is $U(a', b') \leq 16U(a'/4, b'/4) = A(a'/4, b'/4)(b' - a')^2$. We now count the number of unpaired tuples having at least one column in $[a, a') \cup [b', b)$.

There are at most $36(b-a)$ tuples such that two of the columns are identical and in $[a,a') \cup [b',b)$, and the two other columns are identical. (The four columns may or may not all be equal. Note that a factor $\max\left(\binom{4}{1},\binom{4}{2}\right) = 6$ is needed to assign the four columns to the one or two values.) We now count the tuples whose columns are all different. Pick an assignment of roles for the columns, which contributes a factor 24. There are at most 6 ways to pick j_1 in $[a,a') \cup [b',b)$. Next we will consider the choices of the pair j_2 and j_3, which in turn will determine j_4 uniquely. We will argue that, for most pairs (j_2,j_3), by making local changes to j_2 and j_3, we can produce another tuple of columns (j_1,j_2',j_3',j_4) that cancels out with (j_1,j_2,j_3,j_4). The main difficulty will be to ensure that the columns j_2' and j_3' are in the correct range.

The local change strategy is as follows: Let k be the index of the least significant bit on which j_2 and j_3 disagree. Let k' be the index of the "mate" of k, i.e., the bit that is "or"ed with the kth bit in the computation of $f(j_2)$ or $f(j_3)$. The columns j_2' and j_3' will be obtained by toggling the k'th bit of j_2 and j_3, respectively. We have to check that the tuples (j_1,j_2,j_3,j_4) and (j_1,j_2',j_3',j_4) have opposite parity. To see this, assume without loss of generality that the kth bits of j_2 and j_3 are 0 and 1, respectively. Then the disjunction in expansion (3.1) corresponding to bits k and k' for each of $f(j_3')$ and $f(j_3)$ is 1, because of the 1 in bit k, but the k-k' disjunction for $f(j_2')$ and $f(j_2)$ differ, because the kth bits are zero, but the k'th bits differ. All the other disjunctions are the same in $f(j_2)$ as $f(j_2')$ and in $f(j_3)$ as $f(j_3')$. Note also that (j_1,j_2',j_3',j_4) is a dependent tuple whenever (j_1,j_2,j_3,j_4) is a dependent tuple.

Next we have to determine the conditions for j_2' and j_3' to be between a and b. We will consider the situation in which one of these columns falls below the lower bound a and appeal to symmetry for the situation in which one column is at least b.

For two columns x,y, let $eq(x,y) = \ell$ if the most significant bit in which they differ has index ℓ.

Because we have already paid a factor of 24 for the assignment of roles, choose roles such that $eq(a,j_2) \geq eq(a,j_3)$. Suppose all columns are r bits long. There are at most $2^{r-\ell}$ vectors j_2 for which $eq(a,j_2)$ is ℓ. For each such vector j_2, there are at most $\lceil (b-a)/2^{r-\ell-1} \rceil - 1 \leq (b-a)/2^{r-\ell-1}$ vectors j_3 distinct from j_2 that agree with j_2 on the least significant $r-\ell-1$ bits. (Such (j_2,j_3) pairs may require a toggling of the first ℓ bits that could cause j_2' or j_3' to drop below a.) Thus the total number of problem pairs with respect to the lower bound is at most $2(b-a)$ for each choice of ℓ. Over all choices of ℓ this number is at most $2(b-a)\log(b-a)$. By symmetry, the number of problem pairs with respect to b is also at most $2(b-a)\log(b-a)$. Thus there are at most $4(b-a)\log(b-a)$ ways to pick pairs j_2 and j_3 that do not cancel out. Combining with the 24 ways of assigning roles and the 6 ways of picking j_1 we find that there are at most $576(b-a)\log(b-a)$ tuples that do not get canceled. Thus, including the dependent tuples with repeated columns (at most $36(b-a)$), we get

$$\begin{aligned}
U(a,b) &\leq U(a',b') + 576(b-a)\log(b-a) + 36(b-a) \\
&\leq U(a',b') + 585(b-a)\log(b-a) \\
&\leq 16U(a'/4,b'/4) + 585(b-a)\log(b-a) \\
&= 16A(a'/4,b'/4)(b'/4-a'/4)^2 + 585(b-a)\log(b-a) \\
&= A(a'/4,b'/4)(b'-a')^2 + 585(b-a)\log(b-a) \\
&\leq A(a'/4,b'/4)(b-a)^2 + 585(b-a)\log(b-a),
\end{aligned}$$

and so

$$A(a,b) \leq A(\lceil a/4 \rceil, \lfloor b/4 \rfloor) + 585\frac{\log(b-a)}{(b-a)}.$$

Let

$$D_i = \sup_{4^i < (b-a) \le 4^{i+1}} A(a,b).$$

For each $C \ge 2$, we have the recurrence

$$D_i \le \begin{cases} D_{i-1} + 585 \cdot \frac{2i}{4^i}, & i \ge C, \\ M_C, & i < C, \end{cases} \tag{3.4}$$

where $M_C = \max(D_0, \ldots, D_{C-1})$ is a bound on $A(a,b)$ over $4^i < b - a \le 4^{i+1}$ for $i < C$, i.e., $b - a \le 4^C$. We want to find a minimal solution. We will discuss below how we establish M_C precisely using an exhaustive computer search.

Recurrence (3.4) has a solution

$$\begin{aligned} D_i &= M_C + 585 \sum_{j=C}^{i} \frac{2j}{4^j} \\ &\le M_C + 2 \cdot 585 \frac{C + 1/3}{3 \cdot 4^{C-1}}, \end{aligned}$$

where the empty sum is taken to be zero. If we put $C = 6$, we get

$$D_i \le M_6 + 2.413,$$

whence, for all a, b, $A(a,b) \le M_6 + 2.413$.

It remains to evaluate M_6. We first show that it is sufficient to consider a finite number of pairs $\{a, b\}$ even though the definition of M_6 requires it to be a supremum over an infinite number of pairs. We then use a computer search to find M_6.

CLAIM 10. *The value* $M_C = \max_{b-a \le 4^C = 2^{2C}} A(a,b)$ *is at most*

$$M'_C = \max_{\substack{a \le 2^{2C-1} \\ b \le a + 2^{2C}}} A(a,b).$$

Proof. Suppose (a,b) is a pair with $b - a \le 2^{2C}$ but $a > 2^{2C-1}$. We produce a', b' with $a' < a$ and $b' < b$ such that $b' - a' = b - a$ and $A(a',b') = A(a,b)$. The claim follows.

First, we show that if $a, b \le 2^r$, then $U(a,b) = U(2^r - b, 2^r - a)$. Given a tuple $(j_1, j_2, j_3, j_4) \in [a,b)^4$, write each j with r bits, padding with leading zeros if necessary. Form $j'_i = 2^r - 1 - j_i$ by negating all the bits in j_i. This procedure toggles the parity of the k-k' disjunct in the expansion of $f(j)$ when the k-k' bits are 00 or 11; for each k, in a dependent tuple, there are an even number of columns that are 00 or 11 in bits k and k' and an even number of columns that are 01 or 10 there. It follows that (j_1, j_2, j_3, j_4) and (j'_1, j'_2, j'_3, j'_4) have the same parity. Note also that this mapping is a bijection from $[a,b)$ to $[2^r - b, 2^r - a)$. From this we can conclude that $U(a,b) = U(2^r - b, 2^r - a)$. Similarly, if $a, b \le 3 \cdot 2^r$, then $U(a,b) = U(3 \cdot 2^r - b, 3 \cdot 2^r - a)$.

Finally:

- if $2^{2C-1} < a \le 2^{2C}$, then
  - if $2^{2C-1} < b \le 2^{2C}$, then put $(a', b') = (2^{2C} - b, 2^{2C} - a)$;
  - if $2^{2C} < b \le 3 \cdot 2^{2C-1}$, then put $(a', b') = (3 \cdot 2^{2C-1} - b, 3 \cdot 2^{2C-1} - a)$;

  - if $3 \cdot 2^{2C-1} < b$, then note that $b < a + 2^{2C} \leq 2^{2C+1}$. Put $(a', b') = (2^{2C+1} - b, 2^{2C+1} - a)$.
- if $2^{2C} < a$, then find $q > 2C$ with $2^q < a \leq 2^{q+1}$;
  - if $b \leq 2^{q+1}$, then $2^q < a < b \leq 2^{q+1}$. Put $(a', b') = (2^{q+1} - b, 2^{q+1} - a)$;
  - otherwise, $2^{q+1} < b \leq a + 2^{2C} \leq 2^{q+1} + 2^q = 3 \cdot 2^q$. Put $(a', b') = (3 \cdot 2^q - b, 3 \cdot 2^q - a)$.

In all cases, $a' < a$, $b' < b$, and $b' - a' = b - a$. □

Thus, if we are interested in M_6, i.e., (a, b) with $b - a \leq 4096$, we need only consider $a \leq 2048$. A computer search was done for $A(a, b)$ over $a \leq 2048$ and $b \leq a + 4096$, and the maximum is 2.55334. Thus $A(a, b) \leq 2.56 + 2.413 < 5$. □

3.3. The algorithm. Recall that for the overall algorithm, we will need to generate a family of random variables for each of the different types. It would be ideal to make these families n-wise independent, but that would require storing a seed for each of the n types, which is infeasible. Therefore, we will use short *master seeds* to generate n different seeds that are 4-wise independent and, from these, compute the n families of random variables that we will use to get an estimate of F_1. It will be necessary to repeat this process to achieve the specified values of ϵ and δ.

For each k, $1 \leq k \leq 3\log(1/\delta)$ and for each ℓ, $1 \leq \ell \leq 8A/\epsilon^2$ (where $A = 10$ will be justified later), choose a *master seed* $S_{k,\ell}$ and use $S_{k,\ell}$ to define a 4-wise independent family $\{s_{i,k,\ell}\}$ of n seeds, each of length $\log M + 1$. Each seed $s_{i,k,\ell}$ in turn defines a range-summable, n^2-bad 4-wise independent family $\{V_{i,j,k,\ell}\}$ of M uniform ± 1-valued random variables, where $V_{i,j,k,\ell} \stackrel{\Delta}{=} V_j(s_{i,k,\ell})$.

We can use any standard construction to define a family of seeds from a master seed. For example, we can use the construction based on BCH codes in [AS92]. Another construction is one in which the master seed is used to define the coefficients of a random degree-3 univariate polynomial over a sufficiently large finite field. We will describe and use this more elementary construction.

Let $D = \max(\log M + 1, \log n)$. Choose $F = GF_{2^D}$ as the finite field. Fix a representation for the elements of F as bit strings of length D. Choose a master seed $S_{k,\ell}$ of length $4D$ bits uniformly at random, and view these bits as coefficients a_3, a_2, a_1, a_0 of a degree-3 polynomial $a(x) \in F[x]$. Now define the ith seed, $s_{i,k,\ell} = a(i)$. It is immediate from basic algebra that these seeds are 4-wise independent and that the individual seeds can be computed in a constant number of field operations over the field F.

A final point of concern is whether the use of a master seed to generate individual seeds impacts the analysis of the last subsection. There we assumed that the seed for a single family of random variables was chosen uniformly at random among strings of a fixed length. In our construction here, when the master seed is chosen uniformly at random from strings of the correct length, each seed is also distributed uniformly at random, and hence the analysis of the previous subsection still applies.

A more formal, high-level description of the algorithm is given in Figure 1.

3.4. Correctness. The proof in this section that the algorithm described in Figure 1 is correct closely follows the one given in [AMS99] for the correctness of their algorithm (see section 4.3).

THEOREM 11. *The algorithm described in Figure* 1 *outputs a random variable* $W = \text{median}_k \text{avg}_\ell Z_{k,\ell}^2$ *such that* $|W - F_1| < \epsilon F_1$ *with probability at least* $1 - \delta$.

ALGORITHM L1($\langle (i, c_i, \theta_i) \rangle$).

```
Initialize:
    For k = 1 to 3 log(1/δ) do
        For ℓ = 1 to (8 · A)/ε² do
            //For any A ≥ 10 —see (3.8) and the end of section 3.2
            {  Z_{k,ℓ} = 0
            pick a master seed S_{k,ℓ} from the (k, ℓ)th sample space  }
            // This implicitly defines s_{i,k,ℓ} for 0 ≤ i < n and
            // in turn implicitly defines V_{i,j,k,ℓ} for 0 ≤ i < n and 0 ≤ j < M.

For each tuple (i, c_i, θ_i) in the input stream do
    For k = 1 to 3 log(1/δ) do
        For ℓ = 1 to (8 · A)/ε² do
            Z_{k,ℓ} +=  θ_i Σ_{j=0}^{c_i − 1} V_{i,j,k,ℓ}

Output median_k avg_ℓ Z²_{k,ℓ}.
```

FIG. 1. *High level L^1 algorithm.*

Proof. Note that for each $j < \min(a_i, b_i)$, both $V_{i,j,k,\ell}$ and $-V_{i,j,k,\ell}$ are added to $Z_{k\ell}$, and for $j \geq \max(a_i, b_i)$, neither $V_{i,j,k,\ell}$ nor $-V_{i,j,k,\ell}$ is added. Thus

$$Z_{k\ell} = \sum_i \sum_{\min(a_i,b_i) \leq j < \max(a_i,b_i)} \pm V_{i,j,k,\ell}.$$

We shall now compute $E[Z_{k\ell}^2]$ and $E[Z_{k\ell}^4]$ for each k, ℓ. We shall use the convention that $\sum_{a \leq i < b} = -\sum_{b \leq i < a}$ if $b < a$. For notational convenience, we let $V_{i,j}$ denote $V_{i,j,k,\ell}$ in the analysis below.

$$\begin{aligned}
E[Z_{k,\ell}^2] &= E\left[\left(\sum_i \sum_{j=a_i}^{b_i - 1} V_{i,j}\right)^2\right] \\
&= E\left[\left(\sum_{m=1}^{F_1} \pm V_m\right)^2\right] \qquad (3.5) \\
&= \sum_{m=1}^{F_1} E[(\pm V_m)^2] + 2 \sum_{1 \leq m < m' < F_1} E[(\pm V_m)(\pm V_{m'})] \\
&= \sum_{m=1}^{F_1} 1 \qquad (3.6) \\
&= F_1,
\end{aligned}$$

where, in line (3.5), we have relabeled the indices of V, and, in line (3.6), we have used the pairwise independence of V_m and $V_{m'}$ and the fact that the expectation of each of these random variables is 0.

Next, consider

$$E[Z_{k,\ell}^4] = E\left[\sum_{0\le i_1,i_2,i_3,i_4<n}\ \sum_{\substack{a_{i_1}\le j_1<b_{i_1}\\ a_{i_2}\le j_2<b_{i_2}\\ a_{i_3}\le j_3<b_{i_3}\\ a_{i_4}\le j_4<b_{i_4}}} V_{i_1,j_1}V_{i_2,j_2}V_{i_3,j_3}V_{i_4,j_4}\right].$$

By 3-wise independence and the fact that $E[V^t]=0$ for odd t, the only terms with nonvanishing expectation are of the form $V_{i,j}^4$ (of which there are F_1 terms), $V_{i,j}^2V_{i',j'}^2$ for $(i,j)\neq(i'j')$ (of which there are $\binom{4}{2}F_1(F_1-1)$ terms), and $V_{i_1,j_1}V_{i_2,j_2}V_{i_3,j_3}V_{i_4,j_4}$ for $(i_1,j_1),(i_2,j_2),(i_3,j_3),(i_4,j_4)$ all different. Suppose, in the third case, that i_1,i_2,i_3,i_4 are not all the same. Let $X=\prod_{i_m=i_1}V_{i_m,j_m}$ and $Y=\prod_{i_m\neq i_1}V_{i_m,j_m}$. Then $E[X]=0$ by 3-wise independence of the V's, and X and Y are independent by 4-wise independence of the seeds $s_{i,k,\ell}$. Therefore, if $(i_1,j_1),(i_2,j_2),(i_3,j_3),(i_4,j_4)$ are all different and i_1,i_2,i_3,i_4 are not all the same,

$$E[V_{i_1,j_1}V_{i_2,j_2}V_{i_3,j_3}V_{i_4,j_4}] = E[XY] = 0.$$

Thus we have

$$\begin{aligned} E[Z_{k,\ell}^4] &\le F_1 + 6F_1(F_1-1) + \sum_i E\left[\left(\sum_{j=a_i}^{b_i-1} V_{i,j}\right)^4\right] \\ &\le 6F_1^2 + \sum_i 5(b_i-a_i)^2 \qquad (3.7)\\ &\le 11F_1^2. \end{aligned}$$

In line (3.7), we used Proposition 6, which shows that our construction of random variables is n^2-bad 4-wise independent, with constant 5.

Thus

$$\mathrm{Var}(Z_{k,\ell}^2) = E[Z_{k,\ell}^4] - E^2[Z_{k,\ell}^2] \le A\cdot F_1^2 \qquad (3.8)$$

for $A=10$. Now, put $Y_k = \frac{\epsilon^2}{8\cdot A}\sum_{1\le\ell\le(8\cdot A)/\epsilon^2} Z_{k,\ell}^2$. Then $\mathrm{Var}(Y_k)\le\frac{\epsilon^2}{8}F_1^2$. By Chebyshev's inequality,

$$\begin{aligned} \Pr(|Y_k - F_1| > \epsilon F_1) &\le \frac{\mathrm{Var}(Y_k)}{\epsilon^2 F_1^2} \\ &\le 1/8. \end{aligned}$$

Put $W=\mathrm{median}_k Y_k$. Then $|W-F_1|>\epsilon F_1$ only if we have $|Y_k-F_1|>\epsilon F_1$ for at least half of the k's. Let $A_k=1$ if $|Y_k-F_1|>\epsilon F_1$ and $A_k=0$ otherwise; so, for all k, $E[A_k]\le 1/8$. Put $m=3\log(1/\delta)$ and $A=\sum_{k=1}^m A_k$; then $E[A]\le m/8$. By Chernoff's inequality, the probability that $A\ge m/2\ge(1+3)E[A]$ is at most

$$\begin{aligned} \left[\frac{e^3}{(1+3)^{(1+3)}}\right]^{m/8} &\approx 1.374^{-m} \\ &\le 2^{-m/3} \\ &\le \delta. \end{aligned}$$

The result follows. ∎

3.5. Cost.

THEOREM 12. *There is an implementation of Algorithm* L1 *(in Figure* 1*) that is in*

$$\text{PASST}\left(\log(Mn)\log(1/\delta)/\epsilon^2,\ \text{field}(\log(Mn))\log(1/\delta)/\epsilon^2\right).$$

Proof. The algorithm stores

- $\log(1/\delta)/\epsilon^2$ random variables $Z_{k,\ell}$ (called counters) whose values are at most Mn;
- master seeds, specifying the seeds and, through the seeds, the values of the ± 1-valued random variables $V_{i,j,k,\ell}$.

The space to store the counters is $O(\log(Mn)\log(1/\delta)/\epsilon^2)$. By our construction, for each k, ℓ, we need $O(\max(\log M, \log n)) = O(D)$ bits of master seed, and so we would need $O(D\log(1/\delta)/\epsilon^2)$ bits of storage to store all the master seeds. This is asymptotically the same as the space requirement for storing the counters.

We now consider the cost of processing a single item $(i, c_i, \pm 1)$. First, one has to produce the seeds $s_{i,k,\ell}$ from the master seeds $S_{k,\ell}$. For each i, this involves computing a degree-3 polynomial over $GF(2^D)$, which takes time $O(\text{field}(D))$. From $s_{i,k,\ell}$, we need to compute a range sum $\sum_{j=0}^{b-1} V_j(s_{i,k,\ell})$, which can be computed in $O(\log M)$. Thus, the overall time complexity is $O((\text{field}(D) + \log(M))\log(1/\delta)/\epsilon^2)$. Under the reasonable assumption that field arithmetic takes at least linear time, the first term dominates, and the complexity is as claimed above. ∎

3.6. Optimality. Our algorithm is quite efficient in the parameters n, M, and δ, but it requires space quadratic in $1/\epsilon$. We now show that for some nontrivial settings of M, for all large settings of n, and for all small settings of δ, any sketching algorithm that approximates the L^1-difference to within ϵ requires space close to $1/\epsilon$. Thus, our algorithm uses space within a polynomial of optimal.

THEOREM 13. *Fix $M = 2$. For sufficiently small δ, and for any (large) α and any (small) $\beta > 0$, the L^1-difference problem is not in* $\text{PAS}(\log^\alpha(n)/\epsilon^{1-\beta})$.

A similar result holds in the streaming model.

Proof. We reduce the set-disjointness problem to the L^1-difference problem.

Recall the set-disjointness problem of communication complexity [KN97]. Alice has a string x, $|x| = n$, and Bob has a string y, $|y| = n$, and they want to determine whether there exists a position i such that the ith bit of x and the ith bit of y are both 1. Any protocol for this problem, even a randomized protocol, requires $\Omega(n)$ bits of communication, even under the restriction that there is at most one bit i with $x_i = y_i = 1$. Finally, note that an efficient sketching or streaming algorithm directly yields a protocol with low communication complexity.

Suppose $L^1 \in \text{PAS}(\log^\alpha(n)/\epsilon^{1-\beta})$. Put $\epsilon = 1/(3n)$. Let (a, b) be an instance of set disjointness; so, for all i, $a_i, b_i \le M = 2$. Note that the symmetric difference of a and b as sets is the L^1-difference of a and b as functions. By hypothesis one can, with high probability, approximate the symmetric difference $|a\Delta b|$ to within $\epsilon|a\Delta b| < 1/2$ (whence one can, with high probability, compute $|a\Delta b|$ exactly) using space at most

$$\log^\alpha(n)/\epsilon^{1-\beta} = \log^\alpha(n)(3n)^{1-\beta},$$

i.e., at most $o(n)$. From the exact symmetric difference, one can compute the set intersection size as $(|a| + |b| - |a\Delta b|)/2$ with high probability. This is a contradiction. ∎

3.7. Algorithm for unknown parameters. If M is not known in advance, we won't know in advance how many random variables to construct (or, equivalently, how many bits are needed for each seed). Note that, because of the recursive construction of H and p, this is not a problem. If at any point we encounter a tuple (i_0, c, θ) with c bigger than the maximum C encountered before, we simply do the following. For each k, ℓ, we pick $(\log c - \log C)$ new random bits, which we associate with the master seed $S_{k,\ell}$. Use the new random bits to extend randomly (when needed) each of the n seeds $s_{i,k,\ell}$ to length $\lceil \log c \rceil + 1$. We also virtually form larger matrices $\hat{H}$ and pattern p without actually instantiating them.

It is also possible to run the algorithm with a constant factor space penalty if n is not known in advance. Initialize n to 2. Pick a field size appropriate for this n and for the known (or so far encountered) value of M. Let F_1 be this field and f_1 be its size. Start reading the stream, performing calculation in F_1. At an arbitrary point in the stream, suppose we are using a field F_c of size f_c.

If we now read a tuple (i, c_i, θ) where i is too big to handle in F_c, we compute the smallest q such that a degree q extension of F_c is sufficient to handle i, and for each k, ℓ, we prepare a new master seed in this extension which we denote by F_{c+1}. Note that $f_{c+1} = f_c^q$. In other words, for each k, ℓ, we generate at random the coefficients of a degree-3 polynomial in F_{c+1}. The new master seeds and field are to be used for all types which could not be handled in F_c but can be handled in F_{c+1}.

By keeping track of all field sizes we use and all master seeds for each of these field sizes, when we encounter a new type we can easily figure out the field size needed to handle this type using the correct seeds. The union of all seeds is still 4-wise independent. At the end, we will have a final value of n (the maximum type), and, along the way, in the worst case, we will have constructed master seeds for families of size $\nu, \nu^{1/2}, \nu^{1/4}, \nu^{1/8}, \ldots$, where $\nu^{1/2} < n \leq \nu$. For each k, ℓ, storing these master seeds and successive fields requires storage space $\log(\nu), \frac{1}{2}\log(\nu), \frac{1}{4}\log(\nu) \ldots$, and, thus, the storage for the master seeds is $O(\max(\log M, \log \nu)) = O(\max(\log M, \log n))$. The total space for all the master seeds and fields is $O((\max(\log M, \log n)) \log(1/\delta)/\epsilon^2)$. The space required for storing the counters remains $O(\log(Mn) \log(1/\delta)/\epsilon^2)$, and so the overall space is $O(\log(Mn) \log(1/\delta)/\epsilon^2)$. The average processing time per item increases by $o(1) \cdot \text{field}(\log(Mn))$, but preparing the last new collection of master seeds takes time $\log(\nu) \log(1/\delta)/\epsilon^2$, and this time represents an (acceptable) additive increase in the maximum per-item time. Note that the amortized per-item time is asymptotically the same as for the case when n is known in advance.

4. Related work.

4.1. Relationship with sketch algorithms. In [BCFM00], the authors consider the problem of detecting near-duplicate web pages. For their purpose and ours, a web page is a subset of a large universe, and two web pages A and B are near-duplicates if $r(A, B) = \frac{|A \cap B|}{|A \cup B|}$ is large. They present an algorithm that computes a small fixed-size "sketch" of each web page such that, with high probability, $r(A, B)$ can be approximated to within additive error given the two sketches. A central technique is based on the observation that, under a random injection h of the universe into the integers, the probability that the minimal element of $h(A \cup B)$ is in $h(A \cap B)$ is exactly $r(A, B)$. (In practice, the injections come from a small sample space; for the purpose of our comparison, we can consider truly random injections.) Some of the relevant techniques in [BCFM00] were used earlier in [C97, BGMZ97].

Our results on computing the L^1-difference between two functions can be viewed

TABLE 1
Relative-error approximability via sketches.

	$\|A\|$, $\|B\|$	$\|A \cap B\|$	$\|A \cup B\|$	$\|A \Delta B\|$
Here	trivial	iff large	yes	yes
[BCFM00]	trivial	iff large	yes	iff large

as a sketch algorithm. The sketch function h takes as input the graph of a single function and performs the algorithm of section 3, getting a set $\{Z_{k,\ell}\}$ of random variables. (Note that the same master seeds must be used for all sketches.) To reconstruct the L^1-difference from two sketches $\{Z_{k,\ell}\}, \{Z'_{k,\ell}\}$, compute $\rho(\{Z_{k,\ell}\}, \{Z'_{k,\ell}\}) = \text{median}_k \text{avg}_\ell (Z_{k,\ell} - Z'_{k,\ell})^2$.

THEOREM 14. *The L^1-difference of two functions from $\{0, \ldots, n-1\}$ to $\{0, \ldots, M-1\}$ is in*

$$\text{PAS}(\log(Mn) \log(1/\delta)/\epsilon^2).$$

In particular, the L^1-difference (or L^2-difference) of two characteristic functions χ_A and χ_B is the size of the symmetric difference $|A \Delta B|$; we've shown how to approximate it to within small relative error with high probability. The size of the sketch is $O(\log(Mn) \log(1/\delta)/\epsilon^2)$, the space bound of the streaming algorithm. Finally, note that computation of these sketches can be performed in the streaming model, which is sometimes an advantage both theoretically and in practice.

COROLLARY 15. *The symmetric difference between two sets from a universe of size n is in*

$$\text{PAS}(\log(n) \log(1/\delta)/\epsilon^2).$$

One can now ask which cells of the A-B Venn diagram can be approximated as functions of (A, B) in the sketch model using our techniques and using the techniques of [BCFM00]. First note that $|A|$, $|B|$, and $|A| + |B|$ are trivial in the sketch model. Next, an additive approximation of $r = r(A, B)$ yields an approximation of $(1+r)$ and, thus, of $1/(1+r)$ with small relative error; thus, $|A \cup B| = (|A| + |B|)/(1+r)$ can be approximated with small relative error using the techniques of [BCFM00] or with small relative error as $(|A| + |B| + |A \Delta B|)/2$ using our techniques. In general, one cannot approximate $|A \cap B|$ with small relative error, even using randomness [KN97], but, if $|A \cap B|$ is sufficiently large compared with $|A \cup B|$, the intersection can be approximated as $|A \cap B| = (|A| + |B|)r/(1+r)$ by [BCFM00] and as $|A \cap B| = (|A| + |B| - |A \Delta B|)/2$ by our methods. Finally, the techniques of [BCFM00] only approximate $1 - r$ additively, and, if $1 - r$ is smaller than the error ϵ of approximation (i.e., if $|A \Delta B| < \epsilon |A \cup B|$), then the techniques of [BCFM00], which approximate $|A \Delta B|$ as $|A \Delta B| = (|A| + |B|)\frac{1-r}{1+r}$, do not perform well,[6] but our technique approximates $|A \Delta B|$ with small relative error regardless of the size of $|A \Delta B|$.

This information is summarized in Table 1. Other cells in the Venn diagram reduce to these results, e.g., by complementing A or B. (Note that A and A-complement may have different sizes.)

[6] The results of [BCFM00] are the best possible in their original context, which is somewhat different from our context.

4.2. Approximating sizes of supports and the zeroth frequency moment. In this section, we briefly consider three variants.

Let

$$\begin{aligned} F_0^{\neq} &= |\{i : a_i \neq b_i\}|, \\ F_0^{\neq 0} &= |\{i : (a_i = 0 \wedge b_i \neq 0) \vee (a_i \neq 0 \wedge b_i = 0)\}|, \\ F_0^{20\%} &= |\{i : (a_i > 1.2b_i) \vee (b_i > 1.2a_i)\}|. \end{aligned}$$

Note that these are all generalizations of $F_0 = |\{i : a_i \neq 0\}|$, which was studied in [AMS99]. We will show that $F_0^{\neq}$ and $F_0^{\neq 0}$ can be approximated, but $F_0^{20\%}$ cannot be approximated. We do this by using reductions under which

$$\mathrm{PASST}(\log(M)\log(n)\log(1/\delta)/\epsilon^2)$$

is closed.

To approximate $F_0^{\neq}$, put

$$A_{i,x} = \begin{cases} 1 & a_i = x, \\ 0 & \text{otherwise} \end{cases}$$

and

$$B_{i,x} = \begin{cases} 1 & b_i = x, \\ 0 & \text{otherwise.} \end{cases}$$

Then $\frac{1}{2}\sum_{i,x} |A_{i,x} - B_{i,x}| = F_0^{\neq}$, where the sum is over $0 \leq i < n$ and $0 \leq x < M$. We can approximate this L^1-difference.

To approximate $F_0^{\neq 0}$, put

$$A_i = \begin{cases} 1 & a_i > 0, \\ 0 & \text{otherwise} \end{cases}$$

and

$$B_i = \begin{cases} 1 & b_i > 0, \\ 0 & \text{otherwise.} \end{cases}$$

Then $\sum_i |A_i - B_i| = F_0^{\neq 0}$. This is used in section 4.1.

Finally, consider $F_0^{20\%}$. We reduce the set-disjointness problem (restricted to inputs with intersection size at most one) to that of approximating $F_0^{20\%}$.

Let (x, y) be an instance of set disjointness, and put

$$a_i = \begin{cases} 11 & x_i = 1, \\ 13 & \text{otherwise} \end{cases}$$

and

$$b_i = \begin{cases} 15 & y_i = 1, \\ 13 & \text{otherwise.} \end{cases}$$

Then a_i and b_i differ by at least 20% exactly in the 11-15 case, i.e., exactly when $x_i = y_i = 1$.

If we could output a number X such that $|X - F_0^{20\%}| \leq \epsilon F_0^{20\%}$ for $\epsilon < 1$ with probability $1 - \delta$, then we would be able to distinguish the situation $F_0^{20\%} = 0$ from $F_0^{20\%} = 1$ and in turn distinguish $|x_i \cap y_i| = 0$ from $|x_i \cap y_i| = 1$, a contradiction.

Note that we cannot even output a random variable X satisfying the following apparently (but not actually) weaker condition:

$$F_0^{21\%}(1-\epsilon) \leq X \leq F_0^{20\%}(1+\epsilon),$$

with $F_0^{21\%} = |\{i : (a_i > 1.21b_i) \vee (b_i > 1.21a_i)\}|$, because, in fact,

$$\{i : (a_i > 1.21b_i) \vee (b_i > 1.21a_i)\} = \{i : (a_i > 1.20b_i) \vee (b_i > 1.20a_i)\},$$

so that $F_0^{21\%} = F_0^{20\%}$.

In summary, putting $F_0^\tau = |\{i : (a_i > (1+\tau)b_i) \vee (b_i > (1+\tau)a_i)\}|$, we obtain the following.

THEOREM 16. *We have*

1. $F_0^{\neq} \in \mathrm{PASST}(\log(Mn)\log(1/\delta)/\epsilon^2,\ \mathrm{field}(\log(Mn))\log(1/\delta)/\epsilon^2)$;
2. $F_0^{\neq 0} \in \mathrm{PASST}(\log(Mn)\log(1/\delta)/\epsilon^2,\ \mathrm{field}(\log(Mn))\log(1/\delta)/\epsilon^2)$;
3. *for all* $\tau \in (0,1)$, *all fixed* $\epsilon < 1$, $\delta < 1/4$, *and* $M > 1/\tau + 2$, *and, for any* $f = o(n)$, $F_0^\tau \notin \mathrm{PASST}(f(n))$.

Also,

1. $F_0^{\neq} \in \mathrm{PAS}(\log(Mn)\log(1/\delta)/\epsilon^2,\ \mathrm{field}(\log(Mn))\log(1/\delta)/\epsilon^2)$;
2. $F_0^{\neq 0} \in \mathrm{PAS}(\log(Mn)\log(1/\delta)/\epsilon^2,\ \mathrm{field}(\log(Mn))\log(1/\delta)/\epsilon^2)$;
3. *for all* $\tau \in (0,1)$, *all fixed* $\epsilon < 1$, $\delta < 1/4$, *and* $M > 1/\tau + 2$, *and, for any* $f = o(n)$, $F_0^\tau \notin \mathrm{PAS}(f(n))$.

4.3. Approximating the L^2-difference and the second frequency moment. In [AMS99], the authors consider the following problem. The input is a sequence of elements from $[n] = \{0, \ldots, n-1\}$. An element $i \in [n]$ may occur many times. We let a_i denote the number of times i occurs. As above, assume that, for all i, $|a_i| \leq M$.

The kth frequency moment F_k of the sequence is defined to be $\sum a_i^k$. Note that the first frequency moment $F_1 = \sum a_i$ is just the length of the stream and is therefore trivial to compute, but other frequency moments are nontrivial. Alon, Matias, and Szegedy [AMS99] give a variety of upper and lower bounds for frequency moments. In particular, for $F_2 = \sum a_i^2$, they show the following.

THEOREM 17 (see [AMS99]).

$$F_2 \in \mathrm{PASST}((\log(Mn))\log(1/\delta)/\epsilon^2,\ \mathrm{field}(\log(Mn))\log(1/\delta)/\epsilon^2).$$

We sketch the algorithm, without proof, in order to illustrate the previous work that is our point of departure. A full treatment of the correctness and work space of the algorithm of Theorem 17 may be found in [AMS99].

Proof (sketch). For each k, $1 \leq k \leq \Theta(\log(1/\delta))$, and for each ℓ, $1 \leq \ell \leq \Theta(1/\epsilon^2)$, let $\{v_{k\ell}[i]\}_i$ be a set of 4-wise independent ± 1-valued random variables. Output

$$\mathrm{median}_k \mathrm{avg}_\ell \left(\sum a_i v_{k\ell}[i]\right)^2. \qquad \square$$

Consider now a generalization of the input allowing signed examples, which were also considered by Alon et al. in [AGMS99]. That is, each item in the sequence consists of a type $i \in [n]$ and a sign $\pm$, and there may be many items of type i of each

sign. Denote by a_i the number of positive occurrences of i and by b_i the number of negative occurrences of i, and let L_k denote $\sum |a_i - b_i|^k$.

The following corollary was obtained independently by Alon et al. [AGMS99].

COROLLARY 18. $L_2 \in \text{PASST}(\log(Mn)\log(1/\delta)/\epsilon^2,\ \text{field}(\log(Mn))\log(1/\delta)/\epsilon^2)$.

Proof (sketch). With k, ℓ, and $v_{k\ell}[i]$ as above, output

$$\text{median}_k \text{avg}_\ell \left(\sum (a_i - b_i) v_{k\ell}[i]\right)^2. \qquad \square$$

The algorithm of Corollary 18 can be used to approximate the L^2-difference between the two functions a and b.

Note that for signed input examples, computing the frequency moment L_1 is nontrivial, modulo the special case of when $a_i \geq b_i$ for all i.

For any p, the problem of computing the pth frequency moment and that of computing the corresponding L^p-difference of functions differs only in the representation of the input stream. Given an L^p-instance stream $\langle (i, c_i, \theta_i) \rangle$, one can expand each item (i, c_i, θ_i) into c_i occurrences of (θ, i) to get a frequency moment instance. Therefore a frequency moment algorithm for signed examples can be used to compute the L^p-difference of functions, but note that, in general, one pays a high cost in processing time, even just to read the input—the input has been expanded exponentially. The algorithm of Corollary 18 avoids this cost, because it is efficient in both input representations. Thus, the L^2-difference is in

$$\text{PASST}((\log(Mn))\log(1/\delta)/\epsilon^2,\ \text{field}(\log(Mn))\log(1/\delta)/\epsilon^2).$$

4.4. Earlier work on probabilistic counting. In [FM83], the authors give a small-space randomized algorithm that approximates the number of distinct elements in a stream. Their algorithm assumed the existence of certain ideal hash functions. Later, [AMS99] improved this result by substituting a practically available family of hash functions. [AMS99] also gives a variety of other results on approximating the frequency moments. Many results of this kind, some old and some new, are described in [GM99].

Acknowledgments. We thank S. Muthukrishnan for helpful discussions. We also thank an anonymous referee for a very careful reading of the paper.

LIMIT LAWS FOR SUMS OF FUNCTIONS OF SUBTREES OF RANDOM BINARY SEARCH TREES*

LUC DEVROYE†

Abstract. We consider sums of functions of subtrees of a random binary search tree and obtain general laws of large numbers and central limit theorems. These sums correspond to random recurrences of the quicksort type, $X_n \stackrel{\mathcal{L}}{=} X_{I_n} + X'_{n-1-I_n} + Y_n$, $n \geq 1$, where I_n is uniformly distributed on $\{0, 1, \ldots, n-1\}$, Y_n is a given random variable, $X_k \stackrel{\mathcal{L}}{=} X'_k$ for all k, and, given I_n, X_{I_n} and X'_{n-1-I_n} are independent. Conditions are derived such that $(X_n - \mu n)/\sigma\sqrt{n} \stackrel{\mathcal{L}}{\to} \mathcal{N}(0,1)$, the normal distribution, for some finite constants μ and σ.

1. Introduction.

In this note, we consider a random binary search tree with n nodes obtained by inserting, in the standard manner, the values $\sigma_1, \ldots, \sigma_n$ of a random permutation of $\{1, \ldots, n\}$ into an initially empty tree. Equivalently, the search tree is obtained by inserting n independently and identically distributed (i.i.d.) uniform $[0,1]$ random variables $X_1, \ldots, X_n$. Most shape-related quantities of the tree have been well studied, including the expected depth and the exact distribution of the depth of X_n (Knuth (1973), Lynch (1965)), the limit theory for the depth (Mahmoud and Pittel (1984), Devroye (1988)), the first two moments of the internal path length (Sedgewick (1983)), the limit theory for the height of the tree (Pittel (1984), Devroye (1986), (1987)), and various connections with the theory of random permutations (Sedgewick (1983)) and the theory of records (Devroye (1988)). Surveys of known results can be found in Vitter and Flajolet (1990), Mahmoud (1992), and Gonnet (1984). Search trees are also useful in the analysis of quicksort. For recurrences of the quicksort type, we have $X_n \stackrel{\mathcal{L}}{=} X_{I_n} + X'_{n-1-I_n} + f(n)$, $n \geq 1$, $f(n) > 0$ for some $n > 0$, $f(0) = 0$, where I_n is uniformly distributed on $\{0, 1, \ldots, n-1\}$. X_n represents the number of comparisons in quicksort, and $f(n) = n - 1$. Other choices for $f(.)$ are of importance elsewhere. It is not hard to see that X_n is identical to the sum over all nodes u in a random binary search tree of $f(N(u))$, where $N(u)$ is the size of the subtree at u. The purpose of this note is to obtain central limit theorems for this class of random variables, regardless of the choice of f within a large class of functions.

In general, one might study the following class of tree parameters for random binary search trees: Let f be a mapping from the space of all permutations to the real line, and set

$$X_n = \sum_u f(S(u)),$$

where $S(u)$ is the random permutation associated with the subtree rooted at node u in the random binary search tree. More precisely, model a random binary search tree as follows. We let $U_1, \ldots, U_n$ be i.i.d. uniform $[0,1]$-valued random variables, and construct the unique binary search tree for $(1, U_1), \ldots, (n, U_n)$ with the property that

(i) it is a random binary search tree with respect to the first coordinates in the pairs, and

(ii) it is a heap with respect to the second coordinates, which can be regarded as time stamps, with increasing values as one travels from the root down any path.

A permutation is clearly described by any subset of $(1, U_1), \ldots, (n, U_n)$. It is this unique description we follow. For example, the root of the binary search tree contains that pair (i, U_i) with the smallest U_i value, the left subtree contains all pairs (j, U_j) with $j < i$, and the right subtree contains those pairs with $j > i$. Each node u can thus (recursively) be associated with a subset $S(u)$ of $(1, U_1), \ldots, (n, U_n)$. The pair that sticks with u is that with the smallest second component in $S(u)$.

With this embedding and representation, X_n is a sum over all nodes of a certain function of the permutation associated with each node. This definition is very broad. As each permutation uniquely determines subtree shape, a special case includes the functions of subtree shapes.

EXAMPLE 1 (the toll functions). *In the first class of applications, we let $N(u)$ be the size of the subtree rooted at u (thus, if u is the overall root, $N(u) = n$) and set $f(S(u)) = g(|S(u)|)$. Define*

$$X_n = \sum_u g(N(u)) \ .$$

Examples of such tree parameters abound:

A. *If $g(n) \equiv 1$ for $n > 0$, then $X_n = n$.*

B. *If $g(n) = \mathbb{1}_{[n=k]}$ for fixed $k > 0$, then X_n counts the number of subtrees of size k.*

C. *If $g(n) = \mathbb{1}_{[n=1]}$, then X_n counts the number of leaves.*

D. *If $g(n) = n - 1$ for $n > 1$, then X_n counts the number of comparisons in classical quicksort. Note, however, that $g(n)$ grows too rapidly for us to be able to apply the theorem below.*

E. *If $g(n) = \log_2 n$ for $n > 0$, then X_n is the logarithm base two of the product of all subtree sizes.*

F. *If $g(n) = \mathbb{1}_{[n=1]} - \mathbb{1}_{[n=2]}$ for $n > 0$, then X_n counts the number of nodes in the tree that have two children, one of which is a leaf.*

EXAMPLE 2 (tree patterns). *Fix a tree T. We write $S(u) \approx T$ if the subtree at u defined by the permutation $S(u)$ is equal to T, where equality of trees refers to shape only, not node labeling. Note that at least one, and possibly many permutations with $|S(u)| = |T|$, may give rise to T. If we set*

$$X_n = \sum_u \mathbb{1}_{[S(u) \approx T]},$$

then X_n counts the number of subtrees precisely equal to T. Note that these subtrees are necessarily disjoint. We are tempted to call them suffix tree patterns, as they hug the bottom of the binary search tree.

EXAMPLE 3 (prefix tree patterns). *Fix a tree T. We write $S(u) \supset T$ if the subtree at u defined by the permutation $S(u)$ consists of T (rooted now at u) and possibly other*

nodes obtained by replacing all external nodes of T by new subtrees. Define

$$X_n = \sum_u \mathbb{1}_{[S(u) \supset T]}.$$

For example, if T is a single node, then X_n counts the number of nodes, n. If T is a complete subtree of size $2^{k+1} - 1$ and height k, then X_n counts the number of occurrences of this complete subtree pattern (as if we try to count by sliding the complete tree to all nodes in turn to find a match). Matching complete subtrees can possibly overlap. If T consists of a single node and a right child, then X_n counts the number of nodes in the tree with just one right child.

EXAMPLE 4 (imbalance parameters). *If we set $f(S(u))$ equal to 1 if and only if the sizes of the left and right subtrees of u are equal, then X_n counts the number of nodes at which we achieve a complete balance.*

EXAMPLE 5 (local counters). *Following notation introduced by Devroye* (1991), *we may just elect to study indicator functions f with $f(S(u)) = 0$ if $|S(u))| > k$ for a fixed given k. In fact, the setting in Devroye* (1991) *is more general, as permutations are not necessarily restricted to those that correspond to nodes in the binary search tree.*

In this paper, we study X_n. First we derive its mean and variance. This is followed by a weak law of large numbers for X_n/n. Several interesting examples illustrate this universal law. A general central limit theorem with normal limit is obtained for X_n using Stein's method. Several specific laws are obtained for particular choices of f. For example, for toll functions g as in Example 1, with $g(n)$ growing at a rate inferior to $n^{1/3}$, a universal central limit theorem is established in Theorem 6.

2. Another representation of binary search trees. We replace the sum over all nodes u in a random tree in the definition of X_n by a sum over a deterministic set of index pairs, thereby greatly facilitating systematic analysis. We denote by $\sigma(i,k)$ to subset $(i,U_i),\ldots,(i+k-1,U_{i+k-1})$, so that $|\sigma(i,k)| = k$. We define $\sigma^*(i,k) = \sigma(i-1,k+1)$, with the convention that $(0,U_0) = (0,0)$ and $(n+1,U_{n+1}) = (n+1,0)$. Define the event

$$A_{i,k} = [\sigma(i,k) \text{ defines a subtree}] \ .$$

This event depends only on $\sigma^*(i,k)$, as $A_{i,k}$ happens if and only if among $U_{i-1},\ldots,U_{i+k}$, U_{i+k}, U_{i-1} and U_{i+k} are the two smallest values. We set $Y_{i,k} = \mathbb{1}_{[A_{i,k}]}$ and note that it is a function of $U_{i-1},\ldots,U_{i+k}$. Rewrite our tree parameter as follows:

$$X_n = \sum_u f(S(u)) = \sum_{i=1}^{n} \sum_{k=1}^{n-i+1} Y_{i,k} f(\sigma(i,k)) \ .$$

For example, in the toll function example with toll function g, this yields

$$X_n = \sum_u g(|S(u)|) = \sum_{i=1}^{n} \sum_{k=1}^{n-i+1} Y_{i,k} g(k) \ .$$

3. Mean and variance for toll functions. Let σ be a uniform random permutation of size k. Then define

$$\mu_k = \mathbb{E}\{f(\sigma)\} \ ,$$

$$\tau_k^2 = \mathbb{E}\{f^2(\sigma)\} \ ,$$

and

$$M_k = \sup_{\sigma:|\sigma|=k} |f(\sigma)| \ .$$

Note that $|\mu_k| \le \tau_k \le M_k$. In the toll function example, we have $\mu_k = g(k)$ and $\tau_k = M_k = |g(k)|$. We opt to develop the theory below in terms of these parameters. For some parts, such as the law of large numbers, the second moment approach may be avoided, but this comes at the expense of considerably more intricate computations and proofs.

LEMMA 1. *Assume $|\mu_k| < \infty$ for all k, $\mu_k = o(k)$, and*

$$\sum_{k=1}^{\infty} \frac{|\mu_k|}{k^2} < \infty \ .$$

Define

$$\mu = \sum_{k=1}^{\infty} \frac{2\mu_k}{(k+2)(k+1)} \ .$$

Then

$$\lim_{n\to\infty} \frac{\mathbb{E}\{X_n\}}{n} = \mu \ .$$

If also $|\mu_k| = O(\sqrt{k}/\log k)$, then $\mathbb{E}\{X_n\} - \mu n = o(\sqrt{n})$.

Proof. We have

$$\begin{aligned}\mathbb{E}\{X_n\} &= \sum_{i=1}^{n} \sum_{k=1}^{n-i+1} \mathbb{E}\{Y_{i,k}\}\mu_k \\ &= \sum_{i=2}^{n} \sum_{k=1}^{n-i} \frac{2}{(k+2)(k+1)}\mu_k + \sum_{k=1}^{n-1} \frac{1}{k+1}\mu_k + \sum_{i=1}^{n} \frac{1}{n-i+2}\mu_{n-i+1} + \mu_n,\end{aligned}$$

since

$$\mathbb{E}\{Y_{i,k}\} = \begin{cases} 1 & \text{if } i = 1 \text{ and } i+k = n+1; \\ 1/(k+1) & \text{if } i = 1 \text{ or } i+k = n+1 \text{ but not both}; \\ 2/(k+2)(k+1) & \text{otherwise.} \end{cases}$$

It is trivial to conclude the first part of Lemma 1. For the last part, we have

$$\begin{aligned}&|\mathbb{E}\{X_n - \mu n\}| \\ &\le \sum_{k=1}^{\infty} \frac{2}{(k+2)(k+1)}|\mu_k| + \sum_{i=2}^{n} \sum_{k=n-i+1}^{\infty} \frac{2}{(k+2)(k+1)}|\mu_k| + 2\sum_{k=1}^{n} \frac{|\mu_k|}{k+1} + |\mu_n| \\ &\le O(1) + \sum_{k=1}^{\infty} \frac{2\min(k,n)|\mu_k|}{(k+2)(k+1)} + 2\sum_{k=1}^{n} \frac{|\mu_k|}{k+1} + |\mu_n| \\ &\le O(1) + 4\sum_{k=1}^{n} \frac{|\mu_k|}{k+1} + n\sum_{k=n+1}^{\infty} \frac{|\mu_k|}{(k+2)(k+1)} + |\mu_n| \ . \qquad \square\end{aligned}$$

LEMMA 2. *Assume that $M_n < \infty$ for all n and that $f \geq 0$. Assume that for some $b \geq c \geq a > 0$, we have $\mu_n = O(n^a)$, $\tau_n = O(n^c)$, and $M_n = O(n^b)$. If $a + b < 2$, $c < 1$, then $\mathbb{V}\{X_n\} = o(n^2)$. If $a + b < 1$, $c < 1/2$, then $\mathbb{V}\{X_n\} = O(n)$. If f is a toll function and $M_n = O(n^b)$, then $\mathbb{V}\{X_n\} = o(n^2)$ if $b < 1$ and $\mathbb{V}\{X_n\} = O(n)$ if $b < 1/2$.*

Proof. Let Z_α, $\alpha \in A$, be a finite collection of random variables with finite second moments. Let E denote the collection of all pairs (α, β) from A^2 with $\alpha \neq \beta$ and Z_α not independent of Z_β. If $S = \sum_{\alpha \in A} Z_\alpha$, then

$$\mathbb{V}\{S\} = \sum_{\alpha \in A} \mathbb{V}\{Z_\alpha\} + \sum_{(\alpha,\beta) \in E} \left(\mathbb{E}\{Z_\alpha Z_\beta\} - \mathbb{E}\{Z_\alpha\}\mathbb{E}\{Z_\beta\}\right).$$

We apply this fact with A being the collection of all pairs (i, k), with $1 \leq i \leq n$ and $1 \leq k \leq n-i+1$. Let our collection of random variables be the products $Y_{i,k} f(\sigma(i, k))$, $(i, k) \in V$. Note that E consists only of pairs $((i, k), (j, \ell))$ from A^2 with $i + k \geq j - 1$ and $j + \ell \geq i$. This means that the intervals $[i, i + k - 1]$ and $[j, j + \ell - 1]$ correspond to an element of E if and only if they overlap or are disjoint and separated by exactly zero or one integer m. But to bound $\mathbb{V}\{X_n\}$ from above, since $f \geq 0$, we have

$$\mathbb{V}\{X_n\} \leq \sum_{(i,k) \in A} \mathbb{V}\{Y_{i,k} f(\sigma(i, k))\} + \sum_{((i,k),(j,\ell)) \in E} \mathbb{E}\{Y_{i,k} f(\sigma(i, k)) Y_{j,\ell} f(\sigma(j, \ell))\} = \text{I} + \text{II}.$$

By the independence of $Y_{i,k}$ and $f(\sigma(i, k))$, we have

$$\begin{aligned}
\mathbb{V}\{Y_{i,k} f(\sigma(i, k))\} &= \mathbb{V}\{Y_{i,k}\}\mathbb{E}\{f^2(\sigma(i, k))\} + (\mathbb{E}\{Y_{i,k}\})^2 \mathbb{V}\{f(\sigma(i, k))\} \\
&= \mathbb{V}\{Y_{i,k}\}\tau_k^2 + (\mathbb{E}\{Y_{i,k}\})^2(\tau_k^2 - \mu_k^2) \\
&\leq \mathbb{E}\{Y_{i,k}\}\tau_k^2,
\end{aligned}$$

and thus $\text{I} = O(n)$ if $\tau_n^2 = O(n)$, $\sum_{k=1}^n \tau_k^2/k = O(n)$, and $\sum_k \tau_k^2/k^2 < \infty$. These conditions hold if $c < 1/2$. We have $\text{I} = o(n^2)$ if $c < 1$.

In II, we have $Y_{i,k} Y_{j,\ell} = 0$ unless the intervals $[i, i + k - 1]$ and $[j, j + \ell - 1]$ are disjoint and precisely one integer apart or nested. For disjoint intervals, we note the independence of $Y_{i,k} Y_{j,\ell}$, $f(\sigma(i, k))$, and $f(\sigma(j, \ell))$, so that

$$\mathbb{E}\{Y_{i,k} f(\sigma(i, k)) Y_{j,\ell} f(\sigma(j, \ell))\} = \mathbb{E}\{Y_{i,k} Y_{j,\ell}\}\mu_k \mu_\ell \ .$$

If none of the intervals contains 1 or n, then a brief argument shows that

$$\mathbb{E}\{Y_{i,k} Y_{j,\ell}\} \leq \frac{4}{(k + \ell + 3)(k + 1)(\ell + 1)} \ .$$

If one interval covers 1 and the other n, then $k + \ell = n - 1$, and $\mathbb{E}\{Y_{i,k} Y_{j,\ell}\} = 1/n$. In the other cases, the expected value is bounded by $2/(k + \ell + 2)(k + 1)$ or $2/(k + \ell + 2)(\ell + 1)$, depending upon which interval covers 1 or n. Thus, the sum in II limited to disjoint intervals is bounded by

$$\begin{aligned}
&n \sum_{k=1}^n \sum_{\ell=1}^n \frac{4\mu_k \mu_\ell}{(k + \ell + 3)(k + 1)(\ell + 1)} + 1 + \sum_{k=1}^n \sum_{\ell=1}^n \frac{4\mu_k \mu_\ell}{(k + \ell + 2)(k + 1)} \\
&\leq 2n \sum_{k=1}^n \sum_{\ell=1}^k \frac{4\mu_k \mu_\ell}{(k + 3)(k + 1)(\ell + 1)} + 1 + 2 \sum_{k=1}^n \sum_{\ell=1}^k \frac{4\mu_k \mu_\ell}{(k + 2)(k + 1)} \ .
\end{aligned}$$

If $\mu_n = O(n^a)$ for $a > 0$, then it is easy to see that the three sums taken together are $O(n^{2a})$.

We next consider nested intervals. For properly nested intervals, with $[i, i+k-1]$ being the bigger one, we have

$$\begin{aligned}\mathbb{E}\{Y_{i,k} f(\sigma(i,k)) Y_{j,\ell} f(\sigma(j,\ell))\} &= \mathbb{E}\{Y_{i,k}\}\mathbb{E}\{f(\sigma(i,k)) Y_{j,\ell} f(\sigma(j,\ell))\} \\ &\le \frac{2M_k \mathbb{E}\{Y_{i,k}\}\mu_\ell}{(\ell+2)(\ell+1)} \ .\end{aligned}$$

Summed over all allowable pairs $(i,k),(j,\ell)$ with the outer interval not covering 1 or n, and noting that in all cases considered, $a < 1$, this yields a quantity not exceeding

$$\begin{aligned}n\sum_{k=1}^{n} k \sum_{\ell=1}^{k} \frac{4M_k\mu_\ell}{(\ell+2)(\ell+1)(k+2)(k+1)} &\le n\sum_{k=1}^{n} M_k O(k^{a-2}) \\ &= \begin{cases} O(n^{b+a}) & \text{if } b+a \neq 1 \ , \\ O(n\log n) & \text{if } b+a = 1. \end{cases}\end{aligned}$$

The contribution of the border effect is of the same order. This is $o(n^2)$ if $a+b<2$. It is $O(n)$ if $a+b \le 1$.

Finally, we consider nested intervals with $i = j$ and $\ell < k$. Then

$$\mathbb{E}\{Y_{i,k} f(\sigma(i,k)) Y_{j,\ell} f(\sigma(j,\ell))\} \le \mathbb{E}\{Y_{i,k}\} M_k \frac{\mu_\ell}{\ell+1} \ .$$

Summed over all appropriate (i,k,ℓ) such that the outer interval does not cover 1 or n, we obtain a bound of

$$n\sum_{k=1}^{n}\sum_{\ell=1}^{k} \frac{2M_k\mu_\ell}{(k+2)(k+1)(\ell+1)} = O(n^{a+b} + \mathbb{1}_{[a+b=1]} n\log n) \ .$$

The border cases do not alter this bound. Thus, the contribution to II for these nested intervals is $o(n^2)$ if $a+b<2$ and is $O(n)$ if $a+b<1$. □

4. A law of large numbers. The estimates of the previous section permit us to obtain a law of large numbers.

THEOREM 1. *Assume that $M_n < \infty$ for all n and that $f \ge 0$. Assume that for some $b \ge c \ge a > 0$, we have $\mu_n = O(n^a)$, $\tau_n = O(n^c)$, and $M_n = O(n^b)$. If $a+b<2$, $c<1$, then*

$$\frac{X_n}{n} \to \mu$$

in probability. If f is a toll function and $M_n = O(n^b)$, then $X_n/n \to \mu$ in probability when $b<1$.

Proof. Note that $a<1$. By Lemma 1, we have $\mathbb{E}\{X_n\}/n \to \mu$. Choose $\epsilon > 0$. By Chebyshev's inequality and Lemma 2,

$$\mathbb{P}\{|X_n - \mathbb{E}\{X_n\}| > \epsilon n\} \le \frac{\mathbb{V}\{X_n\}}{\epsilon^2 n^2} = o(1) \ .$$

Thus, $X_n/n - \mathbb{E}\{X_n\}/n \to 0$ in probability. □

Four examples will illustrate this result.

EXAMPLE 6. *We let f be the indicator function of anything, and note that the law of large numbers holds. For example, let $\mathcal{T}$ be a possibly infinite collection of possible tree patterns, and let X_n count the number of subtrees in a random binary search tree that match a tree from $\mathcal{T}$. Then, as shown below, the law of large numbers holds. There is inherent limitation to $\mathcal{T}$, which, in fact, might be the collection of all trees whose size is a perfect square and whose height is a prime number at the same time. Let X_n be the number of subtrees in a random binary search tree that match a given prefix tree pattern T, with $|T| = k$ fixed.*

THEOREM 2. *For any nonempty tree pattern collection $\mathcal{T}$, we have*

$$\frac{X_n}{n} \to \mu$$

in probability, and $\mathbb{E}\{X_n\}/n \to \mu$, where

$$\mu = \sum_{n=1}^{\infty} \frac{2\mu_n}{(n+2)(n+1)}$$

and μ_n is the probability that a random binary search tree of size n matches an element of $\mathcal{T}$.

Proof. Theorem 1 applies since f is an indicator function. By Lemma 1, we obtain the limit μ for $\mathbb{E}\{X_n\}/n$. □

Note that Theorem 2 remains valid if we replace the phrase "matches an element of $\mathcal{T}$" by the phrase "matches an element of $\mathcal{T}$ at its root," so that $\mathcal{T}$ is a collection of what we called earlier prefix tree patterns.

EXAMPLE 7. *Perhaps more instructive is the example of the sumheight $\mathcal{S}_n$, the sum of the heights of all subtrees in a random binary search tree on n nodes.*

THEOREM 3. *For a random binary search tree, the sumheight satisfies*

$$\frac{\mathcal{S}_n}{\mathbb{E}\{\mathcal{S}_n\}} \to 1$$

in probability. Here

$$\mathbb{E}\{\mathcal{S}_n\} \sim n \sum_{k=1}^{\infty} \frac{2h_k}{(k+2)(k+1)} \ ,$$

where h_k is the expected height of a random binary search tree on k nodes.

Proof. The statement about the expected height follows from Lemma 1 without work. As the height of a subtree of size k is at most $k-1$, we see that we may apply Theorem 1 with $M_k = k-1$. By well-known results (Robson (1979), Pittel (1984), Devroye (1986), (1987)), we have $\mathbb{E}\{H_n^2\} = O(\log^2 n)$, where H_n is the height of a random binary search tree. Thus, we may formally take a and c arbitrarily small but positive, and $b = 1$. □

EXAMPLE 8. *Define $L(u)$ to be the largest number of full levels below u, and let $C(u) = 2^{L(u)+1} - 1$ be the size of that largest full subtree rooted at u. Define*

$$X_n = \sum_u C(u) \ .$$

This parameter measures to some extent the amount of balance in the tree.

THEOREM 4. *For a random binary search tree,*

$$\frac{X_n}{n} \to \mu$$

in probability, and $\mathbb{E}\{X_n\}/n \to \mu$, *where*

$$\mu = \sum_{n=1}^{\infty} \frac{2\mu_n}{(n+2)(n+1)}$$

and μ_n *is the expected size of the largest complete subtree rooted at the root of a random binary search tree of size* n.

Proof. We verify that Theorem 1 and Lemma 1 may be applied with $a = 0.35$, $b = 1$, and $c = 0.35$. Indeed, if H_n is the number of full levels starting at a level below the root in a random binary search tree on n nodes, we know from Devroye (1986) that $L_n/\log n \to \gamma = 0.3711\cdots$ in probability and in the mean. This result does not suffice, as we need to show that $\mathbb{E}\{2^{L_n}\} = O(n^a)$ with $a = 0.35$. But using a representation for tree sizes in terms of products of independent uniform $[0,1]$ random variables $U_1, \ldots, U_n$ (Devroye (1986)) (the tree size for any node at distance k from the root is distributed as $\lfloor \cdots \lfloor \lfloor nU_1 \rfloor U_2 \rfloor \cdots U_k \rfloor$), we see that

$$\begin{aligned}
\mathbb{P}\{L_n \geq k\} &\leq \left(\mathbb{P}\{nU_1 \cdots U_k \geq 1\}\right)^{2^k} \\
&\leq \exp\left(-2^k \mathbb{P}\{ne^{-G_k} < 1\}\right) \\
&\leq \exp\left(-2^k \mathbb{P}\{G_k > \log n\}\right) \\
&\leq \exp\left(-2^k \int_{\log n}^{\infty} y^{k-1}/(k-1)!e^{-y}dy\right) \\
&\leq \exp\left(-2^k (\log n)^{k-1}/(k-1)!n\right) \\
&\leq \exp\left(-2^k (\log n)^{k-1}\sqrt{k}/(k/e)^k e\sqrt{2\pi}n\right) \\
&\qquad \text{(by Stirling's approximation)} \\
&\leq \exp\left(-(2e\log n/k)^k \sqrt{k}/e\sqrt{2\pi}n\log n\right) \\
&= \exp\left(-(2e^{1-1/c}/c)^{c\log n}\sqrt{c}/e\sqrt{2\pi\log n}\right) \\
&\qquad \text{(after setting } k = c\log n\text{)} \\
&\leq \exp\left(-n^{\log\sqrt{4/e}}/e\sqrt{4\pi\log n}\right) \\
&\qquad \text{(by the choice } c = 1/2\text{)}.
\end{aligned}$$

Clearly, then,

$$\mathbb{E}\{2^{L_n}\} \leq n\mathbb{P}\{L_n \geq (1/2)\log n\} + 2^{(1/2)\log n} = o(1) + n^{\log\sqrt{2}} = o(n^{0.35}) \ .$$

We also have $\mathbb{E}\{2^{2L_n}\} = o(n^{0.7})$ by the same argument. Thus, both the conditions of Lemma 1 and Theorem 1 are satisfied and the law of large numbers follows. □

EXAMPLE 9. *Consider* $X_n = \sum_u (N(u))^{0.999}$. *Recall that* $\sum_u N(u)$ *is the number of comparisons in quicksort, plus* n. *Thus,* X_n *is a discounted parameter with respect to the number of quicksort comparisons. Clearly, Theorem* 1 *applies with* $a = b = c = 0.999$, *and thus* $X_n/n \to \mu$ *in probability, and* $\mathbb{E}\{X_n\}/n$ *tends to the same constant* μ. *In a sense, this application is near the limit of the range for Theorem* 1. *For example,*

it is known that with $X_n = \sum_u (N(u))^{1+\epsilon}$*, there is no asymptotic concentration, and thus,* $X_n/g(n)$ *does not converge to a constant for any choice of* $g(n)$*. Also, for* $X_n = \sum_u (N(u))^1$*, the quicksort example, we have* $X_n/2n\log n \to 1$ *in probability (Sedgewick (*1983*)), so that once again Theorem* 1 *is not applicable. Therefore, in a vague sense, the conditions of Theorem* 1 *are nearly best possible, as the theorem applies to* $X_n = \sum_u (N(u))^{1-\epsilon}$ *with* $\epsilon \in (0, 1]$*.*

5. Dependency graph. We will require the notion of a dependency graph for a collection of random variables $(Z_\alpha)_{\alpha\in V}$, where V is a set of vertices. Let the edge set E be such that for all disjoint subsets A and B of V, either there is an edge of E between A and B or there is no edge, and in the latter case, $(Z_\alpha)_{\alpha\in A}$ and $(Z_\alpha)_{\alpha\in B}$ are mutually independent. Clearly, the complete graph is a dependency graph for any set of random variables, but this is useless. One usually takes the minimal graph (V, E) that has the above property, or one tries to keep $|E|$ as small as possible. Note that, necessarily, Z_α and Z_β are independent if $(\alpha, \beta) \notin E$, but to have a dependency graph requires much more than just checking pairwise independence. We call the neighborhood of $N(\alpha)$ of vertex $\alpha \in V$ the collection of vertices β such that $(\alpha, \beta) \in E$ or $\alpha = \beta$. We define the neighborhood $N(\alpha_1, \ldots, \alpha_r)$ as $\cup_{j=1}^r N(\alpha_j)$.

A. Now consider for V the pairs (i, k) with $1 \le i \le n$ and $1 \le k \le n - i + 1$. Let our collection of random variables be the permutations $\sigma(i, k)$, $(i, k) \in V$. Let us connect (i, k) to (j, ℓ) when $i + k \ge j - 1$ and $j + \ell \ge i$. This means that the intervals $(i, i + k - 1)$ and $(j, j + \ell - 1)$ correspond to an edge in E if and only if they overlap or are disjoint and separated by exactly zero or one integer m. We claim that (V, E) is a dependency graph. Indeed, if we consider disjoint subsets A and B of vertices with no edges between them, then these vertices correspond to intervals that are pairwise separated by at least two integers, and thus $(\sigma(i, k))_{(i,k)\in A}$ and $(\sigma(j, \ell))_{(j,\ell)\in B}$ are mutually independent.

B. Consider next the collection of random variables $Y_{i,k}g(k)$. For this collection, we can make a smaller dependency graph. Eliminate all edges from the graph of the previous paragraph if the intervals defined by the endpoints of the edges are properly nested. For example, if $i < j < j + \ell - 1 < i + k$, then the edge between (i, k) and (j, ℓ) is removed. The graph thus obtained is still a dependency graph. This observation repeatedly uses the fact that if one considers a sequence $Z_1, \ldots, Z_n$ of i.i.d. random variables with a uniform $[0, 1]$ distribution, then Z_1, Z_n and the permutation of $Z_2, \ldots, Z_{n-1}$ are all independent. Thus, for properly nested intervals as above, $Y_{i,k}g(k)$ is independent of $Y_{j,\ell}g(\ell)$.

C. A third dependency graph that will be useful is constructed as above when V is restricted to those pairs (i, k) with $1 \le i \le n$, $1 \le k \le n - i + 1$, and, additionally, $k \le K$. Typically, $K = o(n)$, so this will restrict the degree of each vertex in the dependency graph. For example, given any vertex (i, k) in this graph, its neighborhood $N((i, k))$ has cardinality bounded by $(2K+2)K$, because the starting point for a connected interval has at most $2K+2$ choices and the length at most K.

6. Stein's method. Stein's method (Stein (1972)) allows one to deduce a normal limit law for certain sums of random variables while computing only first and second order moments and verifying a certain dependence condition. Many variants have seen the light of day in recent years, and we will simply employ the following version derived in Janson, Łuczak, and Ruciński (2000, Theorem 6.33).

LEMMA 3. *Suppose that $(S_n)_1^\infty$ is a sequence of random variables such that $S_n = \sum_{\alpha \in V_n} Z_{n\alpha}$, where for each n, $\{Z_{n\alpha}\}_\alpha$ is a family of random variables with dependency graph (V_n, E_n). Let $N(.)$ denote the neighborhood of a vertex or vertices. Further suppose that there exist numbers M_n and Q_n such that*

$$\sum_{\alpha \in V_n} \mathbb{E}\{|Z_{n\alpha}|\} \le M_n$$

and for every $\alpha, \alpha' \in V_n$

$$\sum_{\beta \in N(\alpha, \alpha')} \mathbb{E}\{|Z_{n\beta}||Z_{n\alpha}, Z_{n\alpha'}\} \le Q_n \ .$$

Let $\sigma_n^2 = \mathbb{V}\{S_n\}$. Then

$$\frac{S_n - \mathbb{E}\{S_n\}}{\sqrt{\mathbb{V}\{S_n\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1)$$

if

$$\lim_{n \to \infty} \frac{M_n Q_n^2}{\sigma_n^3} = 0 \ .$$

Proof. We apply Lemma 3 with the basic collection of random variables $Y_{i,k} f(\sigma(i,k))$, $(i,k) \in V_n$, where V_n is the collection $\{(i,k) : 1 \le i \le n, 1 \le k \le \min(K, n-i+1)\}$. Let E_n be the edges in the dependency graph L_n defined by connecting (i,k) to (j,ℓ) if the respective intervals are overlapping or if the respective intervals are disjoint with zero or one integer separating them. We note that

$$\sum_{(i,k) \in V_n} \mathbb{E}\{Y_{i,k} g(k)\} \le (\nu + o(1))n$$

by computations not unlike those for the mean done earlier, where

$$\nu = \sum_{n=1}^{\infty} \frac{2g(n)}{(n+2)(n+1)} \ .$$

To apply Lemma 3, we note that we may thus take $M_n = O(n)$. We also note that $\sigma_n^2 = \Omega(n)$ by assumption. Define

$$Q_n = \sup_{(i,k),(j,\ell) \in V_n} \sum_{(p,r) \in N((i,k),(j,\ell))} \mathbb{E}\{Y_{p,r} g(r) | Y_{i,k} f(\sigma(i,k)), Y_{j,\ell} f(\sigma(j,\ell))\} \ .$$

Indeed, as g bounds $|f|$, this is all we need to bound. The technical condition in Lemma 3 is satisfied if $Q_n = o(n^{1/4})$. To compute an upper bound for Q_n, we bound as follows:

$$Q_n \le \sup_{(i,k),(j,\ell) \in V_n} |N((i,k),(j,\ell))| g(K).$$

Each of the intervals represented by (i,k) and (j,ℓ) has length at most K. Clearly, $(p,r) \in N((i,k),(j,\ell))$ means that both p and $p+r-1$ must be in these intervals or

within the $K+1$ neighbors of them. Each of p and r has thus at most $3K+2$ choices, so that $|N((i,k),(j,\ell))| \le (3K+2)^2$. Thus,

$$Q_n \le (3K+2)^2 g(K)$$

from which Lemma 3 follows without further work. □

A simple example counts the number of subtrees in a random binary search tree that match one of a given collection of tree patterns (these are "terminal matches" at the bottom of the tree), where each pattern is of size $\le K$, where K may depend upon n. As f is an indicator function, we may take $g \equiv 1$. Let X_n denote the number of matches.

LEMMA 4. *Let X_n be the number of matches of a tree pattern in a collection of tree patterns depending arbitrarily on n, as long as, within the collection, the maximal tree size is $K = K(n)$. If*

$$\lim_{n\to\infty} \frac{\mathbb{E}\{X_n\}K^2}{(\mathbb{V}\{X_n\})^{3/2}} = 0 \ ,$$

then

$$\frac{X_n - \mathbb{E}\{X_n\}}{\sqrt{\mathbb{V}\{X_n\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1) \ .$$

Proof. Follow the proof of Lemma 3, but do not use the estimate $\sigma_n^2 = \Omega(n)$. □

Note that the above result remains true even if the collection of patterns itself is a function of n, changing in cardinality and in membership with n, within the condition imposed on K. This result extends the central limit laws of Devroye (1991), where K had to remain fixed. Indeed, the technical condition of Lemma 4 becomes $\mathbb{V}\{X_n\}/\mathbb{E}^{2/3}\{X_n\} \to \infty$. Note in this respect that for K fixed, and the collection of tree patterns nonempty for all n, we have $\mathbb{V}\{X_n\} = \Theta(n)$ and $\mathbb{E}\{X_n\} = \Theta(n)$, facts that are easy to verify.

7. Sums of indicator functions. In this section, we take a simple example in which

$$X_n = \sum_u \mathbb{1}_{[S(u)\in A_n]} \ ,$$

where A_n is a nonempty collection of permutations of length k, with k possibly depending upon n. We denote $p_{n,k} = |A_n|/k!$, the probability that a randomly picked permutation of length k is in the collection A_n. Particular examples include sets A_n that correspond to a particular tree pattern, in which case X_n counts the number of occurrences of a given tree pattern of size k (a "terminal pattern") in a random binary search tree. The interest here is in the case of varying k. As we will see below, for a central limit law, k has to be severely restricted.

Our main result is the following theorem.

THEOREM 5. *We have*

$$\mathbb{E}\{X_n\} = \frac{2np_{n,k}}{(k+2)(k+1)} + O(1)$$

regardless of how k varies with n. If $k = o(\log n/\log\log n)$, then $\mathbb{E}\{X_n\} \to \infty$, $X_n/\mathbb{E}\{X_n\} \to 1$ in probability, and

$$\frac{X_n - \mathbb{E}\{X_n\}}{\sqrt{\mathbb{V}\{X_n\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1) \ .$$

Proof. Observe that

$$X_n = \sum_{i=1}^{n-k+1} Y_{i,k} Z_i \ ,$$

where $Z_i = \mathbb{1}_{[\sigma(i,k)\in A_n]}$. Thus,

$$\mathbb{E}\{X_n\} = \sum_{i=2}^{n-k} \frac{2}{(k+2)(k+1)}\mathbb{E}\{Z_1\} + 2 \times \frac{1}{k+1}\mathbb{E}\{Z_1\} = \frac{2(n-k-1)p_{n,k}}{(k+2)(k+1)} + \frac{2p_{n,k}}{k+1} \ .$$

This proves the first part of the theorem.

The computation of the variance is slightly more involved. However, it is simplified by considering the variance of

$$Y_n = \sum_{i=2}^{n-k} Y_{i,k} Z_i$$

and noting that $|X_n - Y_n| \le 2$. This eliminates the border effect. We note that $Y_{i,k}Y_{j,k} = 0$ if $i < j \le i + k$. Thus,

$$\begin{aligned}
\mathbb{E}\{Y_n^2\} &= \sum_{i=2}^{n-k} \mathbb{E}\{Y_{i,k}Z_i\} + 2 \sum_{2\le i<j\le n-k} \mathbb{E}\{Y_{i,k}Z_iY_{j,k}Z_j\} \\
&= \mathbb{E}\{Y_n\} + 2 \sum_{2\le i,i+k+1\le n-k} \mathbb{E}\{Y_{i,k}Z_iY_{i+k+1,k}Z_{i+k+1}\} \\
&\qquad + 2 \sum_{2\le i,i+k+1<j\le n-k} \mathbb{E}\{Y_{i,k}Z_i\}\mathbb{E}\{Y_{j,k}Z_j\} \\
&= (n-k-1)\beta + 2(n-2k-2)\alpha + (n-2k)^2\beta^2 + (10k+6-5n)\beta^2,
\end{aligned}$$

where $\alpha = \mathbb{E}\{Y_{2,k}Z_2Y_{3+k,k}Z_{3+k}\}$ and $\beta = \mathbb{E}\{Y_{2,k}Z_2\}$. Also,

$$(\mathbb{E}\{Y_n\})^2 = ((n-k-1)\beta)^2 \ .$$

Thus,

$$\begin{aligned}
\mathbb{V}\{Y_n\} &= 2(n-2k-2)\alpha + (n-k-1)\beta \\
&\qquad + \left((n-2k)^2 - (n-k-1)^2 + (10k+6-5n)\right)\beta^2 \\
&= n\left(2\alpha + \beta - (2k+3)\beta^2\right) + O(k\alpha + k\beta + k^2\beta^2) \ .
\end{aligned}$$

We note that $\beta = 2p_{n,k}/(k+2)(k+1)$. To compute α, let A, B, C be the minimal values among $U_1, \ldots, U_{k+1}$, U_{k+2}, and $U_{k+3}, \ldots, U_{2k+3}$, respectively. Clearly,

$$\alpha = p_{n,k}^2 \mathbb{E}\{Y_{2,k}Y_{3+k,k}\}.$$

Considering all six permutations of A, B, C separately, one may compute the latter expected value as

$$\frac{2}{2k+3}\frac{1}{2k+2}\frac{1}{k+1}+\frac{1}{2k+3}\frac{1}{k+1}\frac{1}{k+1}+\frac{2}{2k+3}\frac{1}{2k+2}\frac{1}{2k+1}$$
$$=\frac{5k+3}{(2k+3)(2k+1)(k+1)^2}.$$

Thus,

$$\alpha=\frac{(5k+3)p_{n,k}^2}{(2k+3)(2k+1)(k+1)^2}.$$

We have

$$\mathbb{V}\{Y_n\}$$
$$=n\left(p_{n,k}^2\frac{10k+6}{(2k+3)(2k+1)(k+1)^2}-p_{n,k}^2\frac{8k+12}{(k+2)^2(k+1)^2}+p_{n,k}\frac{2}{(k+2)(k+1)}\right)$$
$$+O(p_{n,k}/k).$$

Note that regardless of the value of $p_{n,k}$, the coefficient of n is strictly positive. Indeed, the coefficient is at least

$$p_{n,k}^2\left(\frac{(10k+6)(k+2)^2-(8k-8)(2k+3)(2k+1)+2(2k+3)(2k+1)(k+2)(k+1)}{(k+2)^2(k+1)^2(2k+3)(2k+1)}\right)$$
$$=p_{n,k}^2\left(\frac{8k^4+18k^3+4k^2-6k}{(k+2)^2(k+1)^2(2k+3)(2k+1)}\right).$$

Thus, there exist universal constants $c_1, c_2, c_3 > 0$ such that

$$\mathbb{V}\{Y_n\}\geq c_1 np_{n,k}^2/k^2-c_2p_{n,k}/k$$

and

$$\mathbb{V}\{Y_n\}\leq c_3 np_{n,k}/k^2\ .$$

We have $Y_n/\mathbb{E}\{Y_n\}\to 1$ in probability if $\mathbb{V}\{Y_n\}=o(\mathbb{E}^2\{Y_n\})$, i.e., if $k=o(\sqrt{np_{n,k}})$. Using $p_{n,k}\geq 1/k!$, we note that this condition holds if $k=o(\log n/\log\log n)$.

Finally, we turn to the normal limit law and note that

$$\frac{Y_n-\mathbb{E}\{Y_n\}}{\sqrt{\mathbb{V}\{Y_n\}}}\xrightarrow{\mathcal{L}}\mathcal{N}(0,1)$$

if (see Lemma 4)

$$\lim_{n\to\infty}\frac{k^2\mathbb{E}\{Y_n\}}{(\mathbb{V}\{Y_n\})^{3/2}}=0\ .$$

This holds if

$$\lim_{n\to\infty}\frac{np_{n,k}}{n^{3/2}p_{n,k}^3/k^3}=0$$

and $np_{n,k}/k\to\infty$. Both conditions are satisfied if $k=o(\log n/\log\log n)$. □

The limitation on k in Theorem 5 cannot be lifted without further conditions: indeed, if we consider as a tree pattern the tree that consists of a right branch of length k only, then $\mathbb{E}\{X_n\}\to 0$ if $k>(1+\epsilon)\log n/\log\log n$ for any given fixed $\epsilon>0$. As X_n is integer-valued, no meaningul limit laws can exist in such cases.

8. Notes on the variance. For toll functions, that is, functions f such that $f(\sigma) = g(|\sigma|)$ for some function g, we need the following lemma.

LEMMA 5. *Define* $X_n = \sum_u g(|S(u)|)$ *and* $X_{n,K} = \sum_u g(|S(u)|)\mathbb{1}_{[|S(u)|\le K]}$ *for a random binary search tree. The following statements are equivalent:*

A. $\mathbb{V}\{X_{n,K}\} = \Omega(n)$ *for any* K *with* $K \to \infty$ *as* $n \to \infty$.

B. $\mathbb{V}\{X_n\} = \Omega(n)$.

C. $\mathbb{V}\{X_k\} > 0$ *for some* $k > 0$.

D. *The function* g *is not constant on* $\{1, 2, \ldots\}$.

Proof. D implies C. Indeed, let k be the first integer at least equal to 2 such that

$$g(k) \neq g(k-1) = \cdots = g(1) \ .$$

For the integers up to k, we have the representation $g(x) = c + d\mathbb{1}_{[x=k]}$ with $d \neq 0$. We have $X_i = ic$, $i < k$, $X_k = kc + d$, and $X_{k+1} = f(k+1) + kc + dN_k$, where N_k is the number of nodes for which $|S(u)| = k$. Note that $N_k = 1$ with probability $2/(k+1)$ and 0 otherwise. Thus,

$$\mathbb{V}\{X_{k+1}\} = d^2 \times \frac{2(k-1)}{(k+1)^2} > 0 \ .$$

C implies A. For two random variables W, Y, we have $\mathbb{V}\{W\} = \mathbb{E}\{\mathbb{V}\{W|Y\}\} + \mathbb{V}\{\mathbb{E}\{W|Y\}\}$. Thus,

$$\mathbb{V}\{X_{n,K}\} \ge \mathbb{E}\{\mathbb{V}\{X_{n,K}|\mathcal{F}_k\}\},$$

where $\mathcal{F}_k$ is defined as follows. Identify in the permutation that defines the tree all nodes u for which $|S(u)| = k$. By construction, each $S(u)$ corresponds to an interval of the original random permutation (of length n). Let $\mathcal{F}_k$ be all elements of the original random permutation except those corresponding to the intervals representing $S(u)$ with $|S(u)| = k$. By the conditional independence of the various $S(u)$'s of size k (none can overlap), and defining $N_k = \sum_u \mathbb{1}_{[|S(u)|=k]}$, we have for n so large that $K \ge k$,

$$\begin{aligned}
\mathbb{V}\{X_{n,K}\} &\ge \mathbb{E}\left\{ \sum_{u:|S(u)|=k} \mathbb{V}\{X_{k,K}|\mathcal{F}_k\} \right\} \\
&= \mathbb{E}\left\{N_k \mathbb{V}\{X_{k,K}\}\right\} \\
&= \mathbb{E}\{N_k\}\mathbb{V}\{X_{k,K}\} \\
&= \mathbb{E}\{N_k\}\mathbb{V}\{X_k\} \\
&\sim \frac{2n\mathbb{V}\{X_k\}}{(k+2)(k+1)} \ .
\end{aligned}$$

Thus, the lower bound follows if $\mathbb{V}\{X_k\} > 0$ for some k.

A implies B. Just take $K = n$.

B implies D. If g is constant on the positive integers, then $\mathbb{V}\{X_k\} = 0$ for all k. □

For general functions f on the set of all permutations, it is always possible to have $X_n = 0$ (and thus $\mathbb{V}\{X_n\} = 0$) along a subsequence for n. Assume that all values for $f(\sigma)$ are given, with $|\sigma| < n$. Let σ be of size n. Define $f(\sigma)$ such that $X_n = \sum_u f(S(u)) = 0$. One can even construct examples in which f is integer-valued and $f(\sigma) = |\sigma| = n$ while, for smaller permutations σ', the values $f(\sigma')$ are quite

arbitrary as long as they are taken from $\{0, 1, 2, \ldots, |\sigma'|\}$. In the latter case, we have $X_n \equiv n$ for that particular n. So, faced with these pesky examples, we will develop the sequel with the condition $\mathbb{V}\{X_n\} = \Omega(n)$ thrown in. The reader should be warned that this condition needs rigorous verification in each application that does not deal with a toll function.

9. Sums of functions of sizes of subtrees. In this section, we consider two types of random variables,

$$X_n = \sum_u g(|S(u)|)$$

and

$$X_{n,K} = \sum_{u:|S(u)|\le K} g(|S(u)|) \ ,$$

where $K = K(n) \le n$ is a sequence of positive numbers. Define $G(n) = \max_{1\le i\le n} |g(i)|$.

LEMMA 6. *Assume that g is not constant on $\{1, 2, \ldots\}$. If $K \to \infty$, and $G(K)\log^2 K = o(n^{1/4})$, then*

$$\frac{X_{n,K} - \mathbb{E}\{X_{n,K}\}}{\sqrt{\mathbb{V}\{X_{n,K}\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1) \ .$$

Proof of Lemma 6. We apply Lemma 3 with the basic collection of random variables $Y_{i,k}g(k)$, $(i,k) \in V_n$, where V_n is the collection $\{(i,k) : 1 \le i \le n, 1 \le k \le \min(K, n-i+1)\}$. Let E_n be the edges in the dependency graph L_n defined by connecting (i,k) to (j,ℓ) if the respective intervals are overlapping without being properly nested, or if the respective intervals are disjoint with zero or one integers separating them. (Note that the dependency graph is thus considerably smaller than in the proof of Theorem 5.) We note that

$$\sum_{(i,k)\in V_n} \mathbb{E}\{Y_{i,k}|g(k)|\} \le (\nu + o(1))n$$

by computations not unlike those for the mean done earlier, where

$$\nu = \sum_{n=1}^{\infty} \frac{2|g(n)|}{(n+2)(n+1)} \ .$$

To apply Lemma 3, we note that we may thus take $M_n = O(n)$. We also note that $\sigma_n^2 = \Omega(n)$, by Lemma 5, since $K \to \infty$ and g is not constant on $\{1, 2, \ldots\}$. It thus suffices to show that $Q_n = o(n^{1/4})$. Note that conditioning on $Y_{i,k}g(k)$ is equivalent to conditioning on $Y_{i,k}$. Thus, we may bound Q_n by

$$Q_n \le G(K) \sup_{(i,k),(j,\ell)\in V_n} \sum_{(p,r)\in N((i,k),(j,\ell))} \mathbb{E}\{Y_{p,r}|Y_{i,k}, Y_{j,\ell}\} \ .$$

We show that sum above is uniformly bounded over all choices of $(i,k),(j,\ell)$ by $O(\log^2 K)$.

Consider the set $S = \{0, 1, \ldots, n, n+1\}$ and mark $0, n+1, i-1, i+k, j-1, j+\ell$ (where duplications may occur). The last four marked points are neighbors of

the intervals represented by (i,k) and (j,ℓ). Also mark all integers in S that are neighbors of these marked numbers. The total number of marked places does not exceed $3 \times 4 + 2 \times 2 = 16$. The set S, when traversed from small to large, can be described by consecutive intervals of marked and unmarked integers. The number of unmarked integer intervals is at most five. We call these intervals $H_1, \ldots, H_5$, from left to right, with some of these possibly empty. Set $H = \cup_i H_i$. Define $H^c = S - H$. Consider $Y_{p,r}$ for $r \le K$ fixed. Let $s = p + r - 1$ be the endpoint of the interval on which $Y_{p,r}$ sits. Note that $Y_{p,r}$ depends upon $\{U_i\}_{p-1 \le i \le s+1}$. We note four situations:

A. If $p, s \in H_i$ for a given i, then $Y_{p,r}$ clearly is independent of $Y_{i,k}, Y_{j,\ell}$. In fact, then, $(p,r) \notin N((i,k),(j,\ell))$.

B. If $p, s \in H^c$, then we bound $\mathbb{E}\{Y_{p,r}|Y_{i,k}, Y_{j,\ell}\}$ by one.

C. If p or s is in H^c and the other endpoint is in H_i, then we bound as follows:

$$\mathbb{E}\{Y_{p,r}|Y_{i,k}, Y_{j,\ell}\} \le \frac{1}{1 + |H_i \cap \{p, \ldots, s\}|}$$

because we can only be sure about the i.i.d. nature of the U_i's in $H_i \cap \{p, \ldots, s\}$ together with the two immediate neighbors of this set.

D. If $p \in H_i$, $s \in H_j$, $i < j$, then we argue as in case C twice, and obtain the following bound:

$$\mathbb{E}\{Y_{p,r}|Y_{i,k}, Y_{j,\ell}\} \le \frac{1}{1 + |H_i \cap \{p, \ldots, s\}|} \times \frac{1}{1 + |H_j \cap \{p, \ldots, s\}|} \ .$$

The above considerations permit us to obtain a bound for Q_n by summing over all $(p,r) \in N((i,k),(j,\ell))$. The sum for all cases A is zero. The sum for case B is at most $16^2 = 256$. The sum over all (p,r) as in C is at most

$$2 \times 16 \times 5 \times \sum_{r=1}^{K} \frac{1}{r+1} \le 160 \log(K+1) \ .$$

Finally, the sum over all (p,r) described by D is at most

$$\binom{5}{2} \left(\sum_{r=1}^{K} \frac{1}{r+1} \right)^2 \le 10 \log^2(K+1) \ .$$

The grand total is $O(\log^2 K)$, as required. This concludes the proof of Lemma 6. □

COROLLARY 1. *As $K \le n$, we deduce that for $G(n) = o(n^{1/4}/\log^2 n)$,*

$$\frac{X_n - \mathbb{E}\{X_n\}}{\sqrt{\mathbb{V}\{X_n\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1) \ .$$

This result will be slightly improved in Theorem 6 below.

COROLLARY 2. *A sufficient condition for Lemma 6 is $K = O(n^a)$ for some $0 \le a \le 1$, and $G(n) = o(n^{1/4a}/\log^2 n)$. Other sufficient conditions include either $K = O(1)$ or $K = O(\log n)$, $G(n) = O(\exp(\epsilon n))$ for all $\epsilon > 0$.*

THEOREM 6. *Assume that g is not constant on $\{1, 2, \ldots\}$. If $G(n) = o(n^{1/3}/\log^2 n)$, then*

$$\frac{X_n - \mathbb{E}\{X_n\}}{\sqrt{\mathbb{V}\{X_n\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1) \ .$$

Proof. Theorem 6 follows directly from Lemma 6 if we can prove the following facts with $K = \lfloor n^{3/4} \rfloor$:

A. For all $\epsilon > 0$, $\lim_{n\to\infty} \mathbb{P}\{X_n - X_{n,K} \geq \epsilon\sqrt{n}\} = 0$. A sufficient condition is $\mathbb{E}\{X_n - X_{n,K}\} = o(\sqrt{n})$.

B. $\liminf_{n\to\infty} \mathbb{V}\{X_n\}/n > 0$.

C. $\mathbb{V}\{X_{n,K}\} \sim \mathbb{V}\{X_n\}$.

For part A, note the following:

$$\begin{aligned}
|\mathbb{E}\{X_n - X_{n,K}\}| &= \left| \sum_{(i,k):1\leq i\leq n, K<k\leq n-i+1} \mathbb{E}\{Y_{i,k}\} g(k) \right| \\
&\leq G(n) + 2 \sum_{K<k\leq n-1} \mathbb{E}\{Y_{1,k}\} G(k) + \sum_{(i,k):2\leq i\leq n, K<k\leq n-i} \mathbb{E}\{Y_{i,k}\} G(k) \\
&\leq G(n) + 2 \sum_{K<k\leq n-1} \frac{G(k)}{k+1} + \sum_{(i,k):2\leq i\leq n, K<k\leq n-i} \frac{2G(k)}{(k+2)(k+1)} \\
&\leq o(n^{1/3}) + \sum_{k=K+1}^{n} \sum_{i=2}^{n-k} \frac{2G(k)}{(k+2)(k+1)} \\
&\leq o(n^{1/3}) + n \sum_{k=K+1}^{n} \frac{2G(k)}{(k+2)(k+1)} \\
&= o(n^{1/2})
\end{aligned}$$

by our choice of K.

Part B is immediate from Lemma 5.

For part C, set

$$X_n = X_{n,K} + W_{n,K}$$

and note that

$$\mathbb{V}\{X_n\} = \mathbb{V}\{X_{n,K}\} + \mathbb{V}\{W_{n,K}\} + 2\mathbb{E}\{(X_{n,K} - \mathbb{E}\{X_{n,K}\})(W_{n,K} - \mathbb{E}\{W_{n,K}\})\} \ .$$

We have from Lemmas 5 and 2, $\mathbb{V}\{X_{n,K}\} = \Theta(n)$. We will show that $\mathbb{V}\{W_{n,K}\} = o(n)$. By the Cauchy–Schwarz inequality,

$$\mathbb{E}\{(X_{n,K} - \mathbb{E}\{X_{n,K}\})(W_{n,K} - \mathbb{E}\{W_{n,K}\})\} = o\left(\sqrt{n}\sqrt{\mathbb{V}\{X_{n,K}\}}\right)$$

so that

$$\frac{\mathbb{V}\{X_n\}}{\mathbb{V}\{X_{n,K}\}} = 1 + o(1) + o\left(\frac{\sqrt{n}}{\sqrt{\mathbb{V}\{X_{n,K}\}}}\right) = 1 + o(1) \ .$$

We now show $\mathbb{V}\{W_{n,K}\} = o(n)$. Let $V_n = \{(i,k) : 1 \leq i \leq n, 1 \leq k \leq \min(K, n - i + 1)\}$ be the vertex set and let E_n be the edge set for the dependency graph for the random variables $Y_{i,k}g(k)$. That is, two pairs are connected by an edge if their intervals are not properly nested and are either overlapping or disjoint with at most one integer between them. Then

$$\mathbb{V}\{W_{n,K}\} = \sum_{(i,k)\in V_n} \mathbb{V}\{Y_{i,k}g(k)\} + \sum_{((i,k),(j,\ell))\in E_n} g(k)g(\ell) \left(\mathbb{E}\{Y_{i,k}Y_{j,\ell}\} - \mathbb{E}\{Y_{i,k}\}\mathbb{E}\{Y_{j,\ell}\}\right).$$

The first sum on the right-hand side is bounded by

$$\sum_{(i,k)\in V_n} g^2(k)\mathbb{E}\{Y_{i,k}\} = o(n^{2/3}) + n\sum_{k=K}^{\infty} g^2(k)/k^2 = o(n^{2/3}) + n \times o(K^{-1/3}) = o(n^{3/4}) \ .$$

Consider a fixed edge $((i,k),(j,\ell)) \in E_n$. Note that if the intervals for (i,k) and (j,ℓ) properly overlap without being nested, then $Y_{i,k}Y_{j,\ell} = 0$. The same is true if they are directly adjacent. So, if $((i,k),(j,\ell)) \in E_n$, the product $Y_{i,k}Y_{j,\ell}$ is nonzero only if they are nested and have one coinciding endpoint or if the intervals are separated by precisely one integer. Thus, for the latter intervals with, say, $1 < i \le i+k-1 = j-2 < j \le j+\ell-1 < n$,

$$\mathbb{E}\{Y_{i,k}Y_{j,\ell}\} \le \frac{2}{(\ell+2)(\ell+1)} \times \frac{1}{k+1} \ .$$

For the intervals aligned at i with, say, $1 < i = j \le i+k-1 < j+\ell-1 < n$, we have

$$\mathbb{E}\{Y_{i,k}Y_{j,\ell}\} \le \frac{2}{(\ell+2)(\ell+1)} \times \frac{1}{k+1} \ .$$

The last two bounds are also valid with ℓ and k interchanged. Thus,

$$\begin{aligned}
&\sum_{((i,k),(j,\ell))\in E_n} g(k)g(\ell)\mathbb{E}\{Y_{i,k}Y_{j,\ell}\} \\
&\qquad \le 4G(n) \sum_{(j,\ell)\in V_n} G(\ell)\mathbb{E}\{Y_{j,\ell}\} + \sum_{((i,k),(j,\ell))\in E_n} \frac{2G(k)G(\ell)}{\ell^2 k} \\
&\qquad \le o(n^{1/3}) \sum_{(j,\ell)\in V_n} G(\ell)\mathbb{E}\{Y_{j,\ell}\} + \sum_{((i,k),(i,\ell))\in E_n} \frac{2G(k)G(\ell)}{\ell^2 k} \\
&\qquad\quad + \sum_{((i,k),(i+k+1,\ell))\in E_n} \frac{2G(k)G(\ell)}{\ell^2 k} + \sum_{((j+\ell+1,k),(j,\ell))\in E_n} \frac{2G(k)G(\ell)}{\ell^2 k} \\
&\qquad = \mathrm{I} + \mathrm{II} + \mathrm{III} + \mathrm{IV}.
\end{aligned}$$

First of all,

$$\begin{aligned}
I &\le o(n^{1/3})n \sum_{\ell=K}^{n} \frac{2G(\ell)}{(\ell+2)(\ell+1)} + o(n^{1/3}) \sum_{\ell=K}^{n} \frac{G(\ell)}{\ell+1} \\
&\le \frac{o(n^{4/3}G(n))}{K+1} + o(n^{2/3}) \\
&= o(n^{11/12}).
\end{aligned}$$

Now, $\sum_{k\le\ell} G(k)/k = o(\ell^{1/3})$. Thus, using a symmetry argument,

$$\begin{aligned}
\mathrm{II} &= 2 \sum_{((i,k),(i,\ell))\in E_n, k<\ell} \frac{2G(k)G(\ell)}{\ell^2 k} \le O(n) \sum_{\ell=K}^{n} \frac{o(\ell^{1/3})G(\ell)}{\ell^2} \\
&= O(n) \times o(K^{-1/3}) = o(n^{3/4}).
\end{aligned}$$

Also,

$$\mathrm{III} \le O(n) \sum_{k=K}^{n} G(k)/k \times \sum_{\ell=K}^{n} G(\ell)/\ell^2 = O(n)o(n^{1/3})o(K^{-2/3}) = o(n^{5/6}).$$

Similarly, IV $= o(n^{5/6})$. We conclude that $\mathbb{V}\{W_{n,K}\} = o(n^{11/12})$, which is more than was needed. This concludes the proof of Theorem 6. □

REMARK. Using the contraction method and the method of moments, Hwang and Neininger (2001) showed that the central limit result of Theorem 6 holds with $G(n) = O(n^a)$, $a \leq 1/2$. Our result is weaker, but requires fewer analytic computations.

10. Bibliographic remarks. Central limit theorems for slightly dependent random variables have been obtained by Brown (1971), Dvoretzky (1972), McLeish (1974), Ibragimov (1975), Chen (1978), Hall and Heyde (1980), and Bradley (1981), to name just a few. Stein's method (our Lemma 3, essentially) is one of the central limit theorems that is better equipped to deal with cases of considerable dependence.

Stein's method offers short and intuitive proofs, but other methods may offer attractive alternatives. Hwang and Neininger (2001) are tackling the analysis of random variables of our type by the moment and contraction methods. The ranges of application of the results are not nested; in some situations, Stein's method is more useful, while in others the moment and contraction methods are preferable.

The limit law for L_n, the number of leaves in a random binary search tree, was obtained by Devroye (1991) (see also Mahmoud (1986)):

$$\frac{L_n - \mathbb{E}\{L_n\}}{\sqrt{\mathbb{V}\{L_n\}}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1) \ .$$

Equivalently, $(L_n - n/3)/\sqrt{n} \xrightarrow{\mathcal{L}} \mathcal{N}(0, 2/45)$. That paper deals with general sums $\sum_i f(\sigma(i,k))$ for k fixed and finite, without regarding the fact that permutations correspond to subtrees of the random binary search tree. As L_n corresponds in our setting to the toll function $\mathbb{1}_{[|\sigma|=1]}$, the above limit law follows easily from Lemma 4, Theorem 5, or Theorem 6. If W_n is the number of nodes with just a right subtree (which occurs at the ith node if and only if $U_i < U_{i+1}$), then it is easy to see that $f(\sigma(i,k)) = \mathbb{1}_{[U_i<U_{i+1}]}$ for all values of k, and this is clearly not covered by Lemma 4. A relatively easy extension would handle it, but we will not be concerned with that here. The result $(W_n - n/2)/\sqrt{n} \xrightarrow{\mathcal{L}} \mathcal{N}(0, 1/12)$ (Devroye (1991)) is thus not an immediate corollary of the present results.

Aldous (1991) showed that the number $V_{k,n}$ of subtrees of size precisely k in a random binary search tree is in probability asymptotic to $2/(k+2)(k+1)$. Devroye showed that $(V_{k,n} - 2n/(k+2)(k+1))/\sqrt{n}$ tends in law to a normal $(0, c_k)$ random variable where c_k is explicitly defined. The latter result also follows from the present paper if we take as toll function $f(\sigma) = \mathbb{1}_{[|\sigma|=k]}$.

Recently, there has been some interest in the logarithmic toll function $f(\sigma) = \log|\sigma|$ (Grabner and Prodinger (2001)) and the harmonic toll function $f(\sigma) = \sum_{i=1}^{|\sigma|} 1/i$ (Panholzer and Prodinger (2001)). The authors in these papers are mainly concerned with precise first and second moment asymptotics. Fill (1996) obtained the central limit theorem for the case $f(\sigma) = \log|\sigma|$. Clearly, these examples fall entirely within the conditions of Lemma 4 or Theorem 6, with some room to spare.

Flajolet, Gourdon, and Martinez (1997) obtained a normal limit law for the number of subtrees in a random binary search tree with fixed finite tree pattern. Clearly, this is a case in which (the indicator function) $f(\sigma)$ depends on σ in an intricate way, but $f = 0$ unless $|\sigma|$ equals the size of the tree pattern. The situation is covered by the law of large numbers of Theorem 2 and the central limit result of Theorem 5. Theorem 5 even allows tree patterns that change with n.

Acknowledgment. We appreciate the comments and improvements suggested to us by Hsien-Kuei Hwang, Ralph Neininger, and Ebrahim Mal-Alla.

APPROXIMATING THE DOMATIC NUMBER*

URIEL FEIGE†, MAGNÚS M. HALLDÓRSSON‡, GUY KORTSARZ§, AND ARAVIND SRINIVASAN¶

Abstract. A set of vertices in a graph is a dominating set if every vertex outside the set has a neighbor in the set. The domatic number problem is that of partitioning the vertices of a graph into the maximum number of disjoint dominating sets. Let n denote the number of vertices, δ the minimum degree, and Δ the maximum degree.

We show that every graph has a domatic partition with $(1 - o(1))(\delta + 1)/\ln n$ dominating sets and, moreover, that such a domatic partition can be found in polynomial-time. This implies a $(1 + o(1))\ln n$-approximation algorithm for domatic number, since the domatic number is always at most $\delta+1$. We also show this to be essentially best possible. Namely, extending the approximation hardness of set cover by combining multiprover protocols with zero-knowledge techniques, we show that for every $\epsilon > 0$, a $(1 - \epsilon)\ln n$-approximation implies that $NP \subseteq DTIME(n^{O(\log \log n)})$. This makes domatic number the first natural maximization problem (known to the authors) that is provably approximable to within polylogarithmic factors but no better.

We also show that every graph has a domatic partition with $(1 - o(1))(\delta + 1)/\ln \Delta$ dominating sets, where the "$o(1)$" term goes to zero as Δ increases. This can be turned into an efficient algorithm that produces a domatic partition of $\Omega(\delta/\ln \Delta)$ sets.

Key words. domatic number, domination, approximation algorithms, probabilistic analysis

1. Introduction.

A *dominating set* in a graph is a set of vertices such that every vertex in the graph either is in the set or has a neighbor in the set. A *domatic partition* is a partition of the vertices so that each part is a dominating set of the graph. The *domatic number* of a graph is the maximum number of dominating sets in a domatic partition of the graph or, equivalently, the maximum number of disjoint dominating sets.

The domatic partition problem is one of the classical NP-hard problems. It is also one of the few graph problems in Garey and Johnson [14] whose approximability status on general graphs has until now been a blank page, with no published upper or lower bounds found in a literature search. The purpose of this paper is to mend that situation and derive the optimal approximability within a lower order term.

The domatic partition problem arises in various situations of locating facilities in a network. Assume that a node in a network can access only resources located at

neighboring nodes (or at itself). Then if there is an essential type of resource that must be accessible from every node (a hospital, a printer, a file, etc.), copies of the resource need to be distributed over a dominating set of the network. If there are several essential types of resources, each one of them occupies a dominating set. If each node has bounded capacity, there is a limit to the number of resources that can be supported. In particular, if each node can only serve a single resource, the maximum number of resources supportable equals the domatic number of the graph [13]. We can show how the general case of larger, possibly nonuniform, capacities can be reduced to the unit case.

We review some elementary facts about dominating sets and domatic partitions in light of the novelty of the problem to many readers. Dominating sets satisfy a monotonicity property with regards to vertex additions: if D is a dominating set and $D' \supset D$, then D' is also a dominating set. This implies that if a graph contains k disjoint dominating sets, then its domatic number is at most k; those nodes not belonging to any of the k sets can be arbitrarily added to the sets to form a proper partition of the vertex-set. The domatic number can then be alternatively defined as the maximum number of disjoint dominating sets. Every graph G satisfies $D(G) \geq 1$, and unless G contains an isolated node, $D(G) \geq 2$. On the other hand, $D(G) \leq \delta + 1$, where δ is the minimum degree; the reason being that a node of minimum degree must have some neighbor (or itself) in each of the disjoint dominating sets.

Fujita [12] has studied several greedy algorithms and shown that their performance ratio is no better than $(\delta + 1)/2$ for values of δ up to $O(\sqrt{n})$. The only other lower bound on $D(G)$ given in a recent encyclopedic treatment of domination problems [17, 16] is $D(G) \geq \lceil n/(n - \delta(G)) \rceil$ [37], where n is the number of vertices. This lower bound is relevant only in very dense graphs, since it degenerates to $D(G) \geq 2$ when $\delta(G) \leq n/2$.

A number of results are known for special classes of graphs. A graph G is said to be *domatically full* if $D(G) = \delta(G) + 1$, the maximum possible. Determining if a d-regular graph is domatically full is NP-complete, for any $d \geq 3$ [32, 21]. Farber [8] showed nonconstructively that *strongly chordal* graphs are domatically full. This class contains the classes of interval graphs and path graphs. Rao and Rangan [35] then gave a linear-time algorithm for interval graphs, and Peng and Chang [30] for strongly chordal graphs. Farber's theorem turned out to be a special case of a result of Berge [5] for *balanced* hypergraphs, and Kaplan and Shamir [19] presented a simple algorithm. They also showed split graphs and bipartite graphs to be NP-hard. Efficient algorithms are known for partial k-trees, using generic methods [2]. Bonucelli [6] showed that circular-arc graphs are NP-hard, while Marathe, Hunt, and Ravi [26] gave a 4-approximation algorithm.

Let Δ denote the maximum degree of a given graph. Our main result is a tight bound on the approximability of the domatic number problem in general graphs. In particular, we give

(A) an algorithm that finds a domatic partition of size $(1 - o(1))(\delta + 1)/\ln n$, where the "$o(1)$" term goes to zero as n increases;
(B) an algorithm that finds a domatic partition of size at least $\delta/c \ln \Delta$, for some constant c;
(C) a nonconstructive argument showing that the domatic number is at least $(1 - o(1))(\delta + 1)/\ln \Delta$, where the "$o(1)$" term goes to zero as Δ increases. This shows that the *value* of the domatic number can be approximated within a factor of nearly $\ln \Delta$;

(D) a bound on the domatic number of random graphs, showing that for most graphs, the domatic number is at most $(1 + o(1))(\delta + 1)/\ln \Delta$, where the "$o(1)$" term goes to zero as n increases;

(E) a construction showing that for every $\epsilon > 0$, no polynomial-time algorithm can approximate the domatic number problem within a $(1 - \epsilon) \ln n$ factor, unless NP has slightly superpolynomial-time algorithms ($NP \subseteq DTIME(n^{\log \log n})$). It also yields a $(1 - o(1)) \ln \Delta$-hardness. These results hold even for bipartite graphs and split graphs.

The $(1 + o(1)) \ln n$-approximation algorithm is a simple randomized assignment (though care is needed not to lose a factor of two in the analysis) and is derandomized using the method of conditional probabilities. The results (B) and (C) above use the Lovász local lemma (LLL) [7] as their basic tool. Suitable application of the LLL to our randomized assignment algorithm above shows that the domatic number is at least $(1/3 - o(1))(\delta + 1)/\ln \Delta$; we then refine this using a "slow partitioning" scheme, leading to our result that the domatic number is at least $(1 - o(1))(\delta + 1)/\ln \Delta$. The $O(\ln \Delta)$-approximation algorithm is a constructive version of the LLL, following an approach of Beck [4].

The hardness construction builds on the proof of Feige [9] of similar hardness for the set cover and dominating set problems. In fact, the construction here generalizes the result of [9] in that it shows that it is hard to distinguish between the following two cases: when the minimum dominating set is large (and thus the domatic number small) or when there are many small disjoint dominating sets. This parallels the situation with the archetypical *minimum* partitioning problem, graph coloring, where Feige and Kilian [11] showed that it is hard to distinguish between the case when the maximum independent set is small and when the chromatic number is small. The construction of the current paper, in fact, draws additionally on the zero-knowledge techniques used in [11].

It is instructive to view our results in a larger context—that of the study of approximation algorithms in general. It has been empirically observed and further supported by classification of constraint satisfaction problems [20] that there seem to be no "natural" maximization problems approximable within polylogarithmic factors but no better. Our results provide (to the best of our knowledge) the first maximization problem with such a behavior, as the domatic number is a maximization problem approximable within logarithmic factors but no better.

Our algorithmic results give absolute ratios, namely bounds in terms of some basic parameters of the graph (minimum degree, number of vertices) rather than in terms of the size of the optimal solution. These are, in fact, the first nontrivial lower bounds on the size of an optimal domatic partition for arbitrary δ, Δ such that $\delta \geq \ln \Delta$:

$$D(G) \geq (1 - o(1)) \cdot \frac{\delta + 1}{\ln \Delta}. \tag{1}$$

As shown in section 2.5, this bound is best possible up to lower order terms, for a large range of values of $\delta = \delta(n)$ and $\Delta = \Delta(n)$.

In the past, most absolute ratios have been obtained by fairly simple greedy algorithms. Our algorithms are derandomizations of simple randomized algorithms, but their derandomized versions are not particularly natural, and natural greedy algorithms for the problem attain much worse results. It is also interesting that the hardness result gives a "gap location at 1": namely, it is equally hard to approximately partition graphs that are domatically full.

The rest of the paper is divided into positive results—algorithmic and existential—on domatic partitions in section 2 and hardness results in section 3.

2. Approximation algorithms and existential results. This section is devoted to positive results for domatic partitions. In section 2.1, we give an algorithmic proof of the bound $D(G) \geq (1 - o(1))(\delta + 1)/\ln n$ and also show that $D(G) \geq (1/3 - o(1))(\delta + 1)/\ln \Delta$. (The two usages of "$o(1)$" here, respectively, correspond to $n \to \infty$ and $\Delta \to \infty$.) This second result is made algorithmic in section 2.2, with a loss in the constant factor. The existential result that $D(G) \geq (1 - o(1))(\delta + 1)/\ln \Delta$ is then shown in section 2.3 and shown to be tight on random graphs in section 2.5. Section 2.4 is devoted to a short analysis of the natural greedy algorithm for domatic partition.

Notation. Let $N(v)$ denote the set of neighbors of a vertex v in the given graph G, and let $N^+(v) = \{v\} \cup N(v)$. Let $d(v) = |N(v)|$ denote the degree of v, and let $d^+(v) = |N^+(v)| = 1 + d(v)$. A *partial coloring* of G is an arbitrary coloring of an arbitrary subset of the vertices. Given a current partial coloring, define a Boolean variable $A_{v,c}$ to be true if there is no vertex of color c in $N^+(v)$ and to be false otherwise. Note that the events $A_{v,c}$ are "bad events" for us: if $A_{v,c}$ holds for some pair (v, c), then the coloring is not a domatic partition; conversely, if none of the events $A_{v,c}$ hold, then every vertex v "sees" every color in $N^+(v)$, and we will have a domatic partition. Thus, our focus will be on avoiding all of these bad events.

Define $[\ell]$ to be the set $\{1, 2, \ldots, \ell\}$. For an event X, $\mathcal{P}[X]$ denotes its probability and $\mathbf{E}[X]$ its expectation. Finally, let e denote the base of the natural logarithm.

2.1. Logarithmic bounds.

THEOREM 1. *Any graph admits a (polynomial-time constructible) domatic partition of size* $(\delta + 1)(1 - O(\log\log n/\log n))/\ln n$.

Proof. Independently give each vertex one of $\ell = (\delta + 1)/\ln(n \ln n)$ colors at random. For any vertex-color pair (v, c), $\mathcal{P}[A_{v,c}] = (1 - 1/\ell)^{d^+(v)} \leq e^{-d^+(v)/\ell} \leq 1/(n \ln n)$. Thus, summing over all (v, c) pairs, the expected total number of bad events $A_{v,c}$ is at most $\ell/\ln n$. Hence, the expected number of colors that form dominating sets is at least

$$\ell - \frac{\ell}{\ln n} = \frac{\delta + 1}{\ln n}\left(1 - \frac{\ln\ln n + 1}{\ln(n \ln n)}\right). \tag{2}$$

The color-classes that do not form dominating sets can all be merged into any one color-class that is a dominating set; thus, we get a domatic partition whose expected number of sets is at least as large as the right-hand side of (2).

This randomized argument can be derandomized using the method of conditional probabilities (cf. [1]). Arbitrarily number the vertices as $v_1, v_2, \ldots, v_n$, and color the vertices in this order (never recoloring a vertex) as follows. Color v_1 arbitrarily. Suppose the first $j \geq 1$ vertices have been colored with respective colors $c_1, c_2, \ldots, c_j$; vertex v_{j+1} is colored as follows. Let $d_{j+1}(v) = |N^+(v) \cap \{v_{j+1}, v_{j+2}, \ldots, v_n\}|$. Then, the conditional probability of the bad event $A_{v,c}$ is given by

$$\mathcal{P}[A_{v,c} | c_1, c_2, \ldots, c_j] = \begin{cases} 0 & \text{if } \exists v_z \leq j \text{ such that } v_z \in N^+(v) \text{ and } c_z = c, \\ (1 - 1/\ell)^{d_{j+1}(v)} & \text{otherwise.} \end{cases}$$

The weight of the current coloring is given by

$$g(c_1, c_2, \ldots, c_j) \doteq \sum_{v \in V} \sum_{c} \mathcal{P}[A_{v,c} | c_1, c_2, \ldots, c_j];$$

this is precisely the expected number of (v, c) pairs for which $A_{v,c}$ will hold after coloring all vertices, given the current coloring $c_1, \ldots, c_j$. In each step $j+1$, we choose a color for v_{j+1} so that the weight of the coloring does not increase. Such a color exists, since $g(c_1, c_2, \ldots, c_j)$ is a convex combination of the values $\{g(c_1, c_2, \ldots, c_j, c_{j+1}) : c_{j+1} \in [\ell]\}$:

$$g(c_1, c_2, \ldots, c_j) = (1/\ell) \cdot \sum_{c_{j+1} \in [\ell]} g(c_1, c_2, \ldots, c_j, c_{j+1}).$$

Then, the total number of colors that are not dominating sets is at most the weight of the final coloring, which we ensure is at most the expected number at the outset, or $\ell / \ln n$. □

We now refine this argument using the LLL to get better bounds when $\Delta \leq n^{1/3}$. We state the symmetric, simpler version of the LLL.

LEMMA 2 (LLL [7]). *Let $p < 1$, and let $\mathcal{E}_i$, $1 \leq i \leq k$, be k events such that $\mathcal{P}[\mathcal{E}_i] \leq p$ for all i. Suppose there is an integer d such that $e \cdot p \cdot (d+1) \leq 1$, and each event is independent of all but at most d other events. (More precisely, for each $\mathcal{E}_i$, there is a set T_i of at least $k - d - 1$ other events $\mathcal{E}_j$, such that the conditional probability of $\mathcal{E}_i$ given any Boolean combination of the events in T_i equals the unconditional probability of $\mathcal{E}_i$.) Then, $\mathcal{P}[\bigwedge_i \bar{\mathcal{E}}_i] > 0$.*

Independently color each vertex randomly with one of $\ell = \lfloor (\delta+1)/(3 \cdot \ln(3^{1/3} \cdot \Delta)) \rfloor$ colors. For each (v, c) pair, $\mathcal{P}[A_{v,c}] \leq (1 - 1/\ell)^{d^+(v)} \leq 1/(3 \cdot \Delta^3)$. We note that each event $A_{v,c}$ is independent of all but at most $\ell(1 + d(v) + d(v) \cdot (\Delta - 1))$ other such events, since vertices of distance at least 3 from v are completely irrelevant for v. More precisely, in the notation of Lemma 2, we can take $T_{v,c}$ to be the set of all events of the form (w, c'), where w is a vertex at a distance of at least 3 from v, and where c' is any color from $[\ell]$: conditioning on any Boolean combination of the events in $T_{v,c}$ does not influence the colors chosen by vertices in $N^+(v)$. The following lemma now directly follows from the LLL, using the fact that $\ell < \Delta$ and $d(v) \leq \Delta$: we set $d = \Delta^3 - 1$ and $p = 1/(3 \cdot \Delta^3)$ in using the LLL.

LEMMA 3. *Any graph admits a domatic partition of size $(1/3 - o(1))\delta / \ln \Delta$, where the "$o(1)$" term tends to zero as $\Delta \to \infty$.*

In section 2.3, we will refine the above approach by conducting a two-stage partitioning that attains the tight value of $1 - o(1)$ instead of the value $1/3 - o(1)$ of Lemma 3. However, the above direct approach will help us develop a simple algorithmic version of Lemma 3 in section 2.2. It also motivates the reason for developing the approach of section 2.3.

Remark. It is interesting to note that the Δ in the bound of Lemma 3 cannot be replaced by δ nor by $\overline{d}$, the average degree. Consider, for example, the bipartite graph with $3 \cdot \delta$ vertices on the left side and $\binom{3 \cdot \delta}{\delta}$ vertices on the right side, with each vertex on the right side connected to a particular subset of δ vertices in the left side. The domatic number of this graph is two. Indeed, say that there are 3 disjoint dominating sets. One of these sets, S, contains at least δ-vertices on the left side. There exists a vertex v on the right side all of whose neighbors are in S. Hence, the two remaining sets must both contain the vertex v, a contradiction.

A parameter that is intermediate between average and maximum degree is the *inductiveness* $\Delta^*(G) = \max_{H \subseteq G} \delta(H)$. It is most notable for giving a tighter upper bound on the chromatic number than the maximum degree, as $\chi(G) \leq \Delta^*(G) + 1 \leq \Delta(G) + 1$. The above construction shows, however, that Δ^* cannot replace Δ in the bound of Lemma 3 on the domatic number.

2.2. $O(\log \Delta)$-approximation algorithm. We use an algorithmic version of the LLL due to Beck [4] that derandomizes the probabilistic argument with some loss in the constants. We may assume without loss of generality that G is connected, since we can treat the connected components separately. Our algorithm has three phases assigning colors to successively larger fractions of the vertices. After the first phase, each vertex is either fully satisfied, seeing all colors within its neighborhood, or has at most one third of its neighbors colored. We show that the subgraph induced by nodes that are still active, i.e., either unsatisfied or not yet colored, consists with high probability of only small connected components of $O(\Delta^6 \log n)$ vertices each. After the second phase, more vertices are colored, with at most two thirds of the neighbors of yet unsatisfied vertices being colored. The connected components induced by active vertices are now of only $O(\Delta^7 \log\log n)$ size. Then, depending on the value of Δ, we can either solve each component by exhaustive search or apply Theorem 1 to obtain a full coloring where each vertex is satisfied.

2.2.1. The algorithm. The first phase proceeds as follows. Given a coloring of some of the vertices, call a vertex v *dangerous* iff

1. at least $\delta/3$ neighbors of v have been colored, and
2. not all the ℓ colors appear in the neighborhood of v.

Let $\ell = \delta/(c \ln \Delta)$ for a suitably large constant c. Order the vertices arbitrarily as $v_1, v_2, \ldots, v_n$ and process them in this order. When processing v_i, we do the following. If v_i or one of its neighbors is dangerous now, we *freeze* v_i; otherwise we independently assign it one of ℓ colors at random.

When the process ends, some vertices are colored and some are frozen, and some are dangerous and some are not. The vertices that are not dangerous belong to one of two categories:

Good: A good vertex sees all colors in its neighborhood.

Neutral: A neutral vertex v does not see all colors in its neighborhood but is not dangerous. This can happen only if more than $2/3$ of v's neighbors were frozen.

Thus, we have two orthogonal partitions: colored/frozen and good/neutral/dangerous.

Vertices that are both good and colored do not need to be considered further in the later phases. Call the other vertices *saved*, i.e., those that are dangerous, frozen, or neutral. As in [4], we are interested in the maximum size of a connected component of the subgraph induced by saved vertices, as this bounds the size of the independent subproblems in the next phase. We show in section 2.2.2 that with probability at least $1/2$, the largest connected component in the saved graph has size $O(\Delta^6 \log n)$; let us assume that this size bound holds.

Phase two of the algorithm is run separately on each connected component induced by the saved vertices. Note that each dangerous or neutral vertex v has at least $d(v) - \delta/3$ frozen (i.e., uncolored) neighbors in its connected component. Phase two differs from phase one in that some of the vertices are colored before we begin. We leave these colors untouched, because they may be useful for the vertices that were not saved. We only color the frozen vertices, and again define the notion of phase two dangerous, frozen, and neutral vertices. Since the number of vertices we are dealing with now in any connected component is $O(\Delta^6 \log n)$, we have essentially replaced n by $O(\Delta^6 \log n)$. Thus, analysis similar to that of phase one shows that the connected components of the newly saved vertices has size at most $N = O(\Delta^6(\log \Delta + \log\log n))$ with probability at least $1/2$.

In phase three, each dangerous/neutral vertex has at least $d(v)-2\delta/3 \geq \delta/3$ frozen neighbors in its connected component. If $\Delta > \log\log n$, we have a domatic partition of the frozen vertices to roughly $\delta/(3\ln N)$ parts via Theorem 1. As $\ln N = O(\log \Delta)$, this is good enough. If $\Delta \leq \log\log n$, then we can find a domatic partition of size $\Omega(\delta/\ln\Delta)$ whose existence is guaranteed by Theorem 3, using an exhaustive search. Since $\Delta \leq \log\log n$, this only takes time

$$N^{O(\delta/\ln\Delta)} \leq (\log\log n)^{O((\log\log n))} \leq poly(n).$$

This completes the description of the algorithm.

2.2.2. Analysis of the algorithm. We now show that with probability at least 1/2, the largest connected component in the saved graph in the first phase has size $O(\Delta^6 \log n)$. This will yield a proof of correctness of our algorithm.

Let $X(u)$ be the indicator random variable for vertex u becoming dangerous, and let $q = \ell(1-1/\ell)^{\delta/3}$.

LEMMA 4. *Let $U = \{u_1, u_2, \ldots, u_k\}$ be any set of vertices with pairwise distance at least 3. Then,* $\Pr[X(u_1) = X(u_2) = \cdots = X(u_k) = 1] \leq q^k$.

Proof. If a vertex v is a neighbor of the set U, then it has a unique neighbor in U since the elements of U have pairwise distance at least 3. Let $\vec{a} = (a_1, a_2, \ldots, a_k)$ be any sequence of k colors, and let S_i be the random variable denoting the set of the first i nonfrozen neighbors of U. Let $D_i(\vec{a})$ be the event that "for all $j = 1, 2, \ldots, k$, all neighbors of u_j in S_i avoid color a_j." Thus, $D_i(\vec{a})$ is the event that even after processing the first i nonfrozen neighbors of U, each u_j in U was missing a particular color a_j. We may assume without loss of generality that sets S_i exist for every i up to $\delta k/3$, because otherwise some vertex u in U does not have $\delta/3$ nonfrozen neighbors, and then u cannot be dangerous. Hence, $D_i(\vec{a})$ is defined for all $i \leq \delta k/3$. We have $\Pr[D_0(\vec{a})] = 1$. Now for every $i < \delta k/3$, $\Pr[D_{i+1}(\vec{a})] = \Pr[D_i(\vec{a})] \cdot (1-1/\ell)$, because the color of the $(i+1)$st nonfrozen neighbor of U is chosen at random independent of the previous colors and independent of which vertex it happens to be. Hence, $\Pr[D_i(\vec{a})] = (1-1/\ell)^i$; so, $\Pr[\exists \vec{a} :\ D_{\delta k/3}(\vec{a})] \leq \ell^k (1-1/\ell)^{\delta k/3} = q^k$.

If all the u_j are dangerous, then there is some $\vec{a}$ for which $D_{\delta k/3}(\vec{a})$ is true; this completes the proof. ∎

To prove that the largest connected component in the saved graph is "small enough" with reasonable probability, we now show that with reasonable probability the maximum number of vertices in a spanning tree of such a component is "small." This is done as follows. By a standard argument, a large connected component contains many vertices with a particular minimum pairwise distance. We first prove that the number of vertices with large pairwise mutual distance which are all saved is "small." This indirectly bounds the maximum number of vertices in a connected component as a function of Δ, which is enough for our purposes.

A set of vertices is said to be 7-*separated* if it is of mutual distance at least 7. A 7-separated set of k vertices is said to be a *bad k-set* if, additionally, it becomes connected if we connect all vertices of distance exactly 7. As shown next, the number of such sets in G is at most

$$n(4\Delta^7)^k. \tag{3}$$

Consider a spanning tree on the set where vertices of distance exactly 7 are connected. The number of distinct shapes of trees on k vertices is at most 4^{k-1}. Namely, such a tree can be uniquely represented by ordering the vertices in a lexicographic breadth-first order and attaching two flag bits to each nonroot vertex, whether it has the same

parent as the previous vertex in the order, and whether it has a child or not. For each shape of a tree, there are n possibilities of choosing the root and thereafter at most Δ^7 possibilities of choosing each new vertex since we already chose its parent in the tree.

Let $Y(u)$ be the indicator random variable for vertex u becoming saved. To complete our argument that no connected component of the saved vertices is "large," we show the following lemma.

LEMMA 5. *For any 7-separated set of vertices $v_1, v_2, \ldots, v_k$,*

$$\Pr[Y(v_1) = Y(v_2) = \cdots = Y(v_k) = 1] \leq (2.5\Delta q)^k,$$

where q is as defined prior to Lemma 4.

Proof. The following definition will be useful for this proof:

$$Z(u) \doteq X(u) + \left(\sum_{v \in N(u)} X(v) \right) + \frac{\sum_{v \in N(u)} \sum_{w \in N(v)} X(w)}{2d(u)/3}.$$

If vertex u is saved, then we have one of three cases: (i) u is dangerous and thus $X(u) = 1$; (ii) u has a dangerous neighbor and so $\sum_{v \in N(u)} X(v) \geq 1$; or (iii) u is neutral, so at least $2d(u)/3$ of its neighbors are frozen, and by the preceding argument it holds for each frozen neighbor v of u that $\sum_{w \in N(v)} X(w) \geq 1$. Therefore, we have the simple but useful observation that *if $Y(u) = 1$, then $Z(u) \geq 1$.*

By Markov's inequality,

$$\Pr[Y(v_1) = Y(v_2) = \cdots = Y(v_k) = 1] \leq \Pr\left[\prod_{i=1}^{k} Z(v_i) \geq 1 \right] \leq \mathbf{E}\left[\prod_{i=1}^{k} Z(v_i) \right]. \tag{4}$$

Now, because $Z(\cdot)$ is linear in the $X(\cdot)$ and using the linearity of expectation, we can expand $\mathbf{E}[\prod_i Z(v_i)]$ as a linear combination of the terms $\Pr[X(w_1) = X(w_2) = \cdots = X(w_k) = 1]$. The main observation is that since the v_i have pairwise distance at least 7, the w_i have pairwise distance at least 3. Thus, by Lemma 4, any such term has probability at most q^k. Thus we get

$$\mathbf{E}\left[\prod_i Z(v_i) \right] \leq \left(q + \Delta q + \frac{d(u)(\Delta - 1)q}{2d(u)/3} \right)^k \leq (2.5\Delta q)^k$$

by first replacing the probability of intersection of events by the product of probabilities and then unfolding and reversing the above expansion. ∎

Consider now a connected component in the subgraph of G of saved vertices. If its size is $k\Delta^6$ or more, then it must contain a bad k-set (which is obtained by repeating the procedure of putting a vertex in the bad k-set and removing all vertices of distance at most 6). Setting the constant c in the expression $\ell = \delta/(c \ln \Delta)$ large enough, we get that $q \leq \Delta^{-9}/10$. Set $k = \log(2n)/\log \Delta$, and recall (3) and Lemma 5. We get that the probability of existence of a connected component of the saved vertices with cardinality at least $k\Delta^6$ is at most $(2.5q\Delta)^k n(4\Delta^7)^k \leq 1/2$.

Finally, the above Las Vegas algorithm can be derandomized by the approach of *pessimistic estimators* [33], which is a generalization of the method of conditional probabilities. Briefly, we proceed as follows. As before, we process the vertices one-by-one. Suppose it is currently the turn of vertex v. If v is frozen, we skip over it.

Otherwise, we deterministically choose a color for it that minimizes the probability of emergence of a large connected component of the saved vertices using our bounds derived above. Since $k = \log(2n)/\log\Delta$, we see from (3) that the number of possible bad k-sets to be considered in our analysis above is bounded by a polynomial in n. Hence, we can write down a pessimistic estimator and choose, in deterministic polynomial-time, a color for vertex v that minimizes the pessimistic estimator.

2.3. Getting the right constant. Our next result improves the value $1/3-o(1)$ of Lemma 3 to the existentially best possible value of $1 - o(1)$.

THEOREM 6. *There is a constant $a > 0$ such that for large enough Δ_0, for every graph G with $\Delta \geq \Delta_0$, $D(G) \geq \lfloor \frac{\delta}{\ln\Delta + a\ln\ln\Delta} \rfloor$.*

We remark that if $\Delta < \Delta_0$, the theorem holds by setting a large enough. For the special case of $\Delta \leq 2$, the value of $D(G)$ is well known via a simple case analysis; there is also a linear-time algorithm for the domatic partition problem if $\Delta \leq 2$.

Proof. For the rest of section 2.3, any "$o(1)$" term will denote a function of Δ alone that goes to zero as Δ increases. We prove the theorem for a being any constant greater than 7, for all large enough Δ; this choice of a can be further improved, but we do not attempt this optimization here.

Preprocessing. We preprocess the graph as follows. As long as there is an edge that has both end-points with degree more than δ, remove such an edge from the graph. At the end of this process, the minimum degree remains at δ, and the maximum degree is at most Δ. We will now show a lower bound on the domatic number of this preprocessed version, which clearly will yield the same lower bound on the domatic number of the given graph. (This is because the preprocessing only removes edges from the given graph.) The useful property that now holds is that for each vertex u, either $d(u) = \delta$, or for all neighbors v of u, $d(v) = \delta$.

There are two cases, the first one being simpler.

Case I: $\delta \leq \ln^4\Delta$. We assume that $\delta > \ln\Delta + a\ln\ln\Delta$, since the theorem is trivially true otherwise. Define

$$\ell = \left\lfloor \frac{\delta}{\ln\Delta + a\ln\ln\Delta} \right\rfloor.$$

Color each vertex with a random color from $[\ell]$, independent of all other vertices. We will now use the LLL to show that $\mathcal{P}[\bigwedge_{u,c} \bar{A}_{u,c}] > 0$ in the same way as we did for Lemma 3. For each (u, c), we have

$$\Pr[A_{u,c}] = \left(1 - \frac{1}{\ell}\right)^{d^+(u)} \leq e^{-\ln(\Delta(\ln\Delta)^a)\cdot d^+(u)/\delta} \leq (\Delta(\ln\Delta)^a)^{-1}. \tag{5}$$

Let $N_2(u)$ denote the set of vertices at a distance of 0, 1, or 2 from u in G. As in our proof of Lemma 3, each event $A_{u,c}$ depends only on events $A_{v,c'}$ with $v \in N_2(u)$; so, it depends on at most $|N_2(u)| \cdot \ell$ other such events. Our preprocessing step above helps bound $|N_2(u)|$ for all u. If $d(u) = \delta$, then $|N_2(u)| \leq 1+\delta+\delta(\Delta-1)$. If $d(u) > \delta$, our preprocessing ensures that $d(v) = \delta$ for all neighbors v of u; so, $|N_2(u)| \leq 1 + \Delta + \Delta(\delta - 1)$. Thus, $|N_2(u)| \leq \delta\Delta + 1 \leq \Delta\ln^4\Delta + 1$ for all u, since $\delta \leq \ln^4\Delta$. So, each $A_{u,c}$ depends on at most $O(\ell\Delta\ln^4\Delta) = O(\Delta\ln^7\Delta)$ other such events. Recalling the LLL and (5), we see that $\mathcal{P}[\bigwedge_{u,c} \bar{A}_{u,c}] > 0$ as required, since $a > 7$.

Case II: $\delta > \ln^4\Delta$. Let $\epsilon = 1/(\ln\Delta)$; define $\ell_1 = \lfloor \epsilon^3\delta \rfloor$ and $\ell_2 = \lfloor \ln^2\Delta/(1 + b(\ln\ln\Delta)/\ln\Delta) \rfloor$, where b is any constant larger than 5. We will show the existence

of a domatic partition of size $\ell_1\ell_2$, i.e., a coloring of V using $\ell_1\ell_2$ colors, in such a way that for every vertex u there is at least one vertex of each color in $N^+(u)$. (Recall that $\delta > \ln^4 \Delta$. By choosing $b < 6$, for instance, we can ensure that $\ell_1\ell_2 \geq \delta/(\ln\Delta + 6\ln\ln\Delta)$ for all large enough Δ.) It will be convenient to view the colors as elements of $[\ell_1]\times[\ell_2]$. We will apply a two-stage coloring: the first coloring determines the first components of the vertex-colors, and the second coloring is for the second components. We can view the first coloring as a coarse partition, which the second coloring turns into a fine partition. The primary purpose of the first coloring is to reduce the dependencies sufficiently for our analysis of the second coloring.

The first partitioning is as follows. Color each vertex with a random color from $[\ell_1]$, independent of all other vertices. For each vertex u and each color c, define $X^+_{u,c}$ to be the subset of $N^+(u)$ that receives color c. We have $\mathbf{E}[|X^+_{u,c}|] = d^+(u)/\ell_1$. Let $B_{u,c}$ be the "bad" event that $\mid |X^+_{u,c}| - d^+(u)/\ell_1 \mid \geq 3\epsilon d^+(u)/\ell_1$. A Chernoff bound shows that

$$\Pr[B_{u,c}] \leq 2\cdot\exp(-(9/2-o(1))\cdot d^+(u)\epsilon^2/\ell_1) \leq \exp(-(9/2-o(1))\ln\Delta). \tag{6}$$

Once again, $B_{u,c}$ is independent of any Boolean combination of events of the form $B_{v,c'}$ for vertices v at a distance of 3 or more from u. Thus, each $B_{u,c}$ "depends" on $o(\Delta^3)$ other such events. Recalling (6), the LLL shows that $\Pr[\bigwedge_{u,c}\overline{B_{u,c}}] > 0$.

Fix a coloring $\chi_1 : V \to [\ell_1]$ which avoids all the events $B_{u,c}$. Choose a random color $\chi_2(u) \in [\ell_2]$ for each u, independent of all other vertices; the final color of u is the pair $(\chi_1(u), \chi_2(u))$. Let $\mathcal{B}_{u,c_1,c_2}$ be the bad event that there is no vertex of color (c_1, c_2) in $N^+(u)$. We now use the LLL to show that all these bad events can be avoided with positive probability.

For each vertex u and each $c \in [\ell_1]$, let $N^+_{u,c} = \{v \in N^+(u) :\ \chi_1(u) = c\}$, and define $d^+_{u,c} = |N^+_{u,c}|$. Since χ_1 avoids all the events $B_{u,c}$, we have

$$\forall (u,c),\ (1-3\epsilon)d^+(u)/\ell_1 \leq d^+_{u,c} \leq (1+3\epsilon)d^+(u)/\ell_1. \tag{7}$$

Fix an event $\mathcal{B}_{u,c_1,c_2}$. First,

$$\begin{aligned}\Pr[\mathcal{B}_{u,c_1,c_2}] = \left(1-\frac{1}{\ell_2}\right)^{d^+_{u,c_1}} &\leq e^{-(1-3\epsilon)d^+(u)/(\ell_1\ell_2)} \\ &\leq (\Delta(\ln\Delta)^b)^{-(1-3\epsilon)} \leq O((\Delta(\ln\Delta)^b)^{-1});\end{aligned} \tag{8}$$

the first inequality here follows from (7). Next, which other events does $\mathcal{B}_{u,c_1,c_2}$ depend on? Given $S \subseteq V$, let $N^+(S) \doteq \bigcup_{v\in S} N^+(v)$. Note that $\mathcal{B}_{u,c_1,c_2}$ simply says that all elements of N^+_{u,c_1} got a $\chi_2(\cdot)$ value different from c_2. Thus, we can check that $\mathcal{B}_{u,c_1,c_2}$ depends only on the events in

$$S(u,c_1,c_2) = \{\mathcal{B}_{v,c'_1,c'_2} :\ v \in N^+(N^+_{u,c_1}) \text{ and } c'_1 = c_1\}. \tag{9}$$

More precisely, we claim that $\mathcal{B}_{u,c_1,c_2}$ is independent of any Boolean function of the events lying outside $S(u,c_1,c_2)$; this can be verified by seeing that

$$N^+_{u,c_1} \cap \left(\bigcup_{(v,c'_1,c'_2):\ \mathcal{B}_{v,c'_1,c'_2}\notin S(u,c_1,c_2)} N^+_{v,c'_1}\right) = \emptyset.$$

We now bound $|S(u,c_1,c_2)|$ in order to apply the LLL; once again, our preprocessing step will be of help. If $d(u) = \delta$, then $|N^+(N^+_{u,c_1})| \leq \Delta|N^+_{u,c_1}|$; this is at most

$O(\delta\Delta/\ell_1)$, by (7). If $d(u) > \delta$, our preprocessing ensures that $|N^+(N^+_{u,c_1})| \leq \delta|N^+_{u,c_1}|$; so, from (7), we again get that $|N^+(N^+_{u,c_1})| \leq O(\delta\Delta/\ell_1)$. Thus, $|S(u,c_1,c_2)| \leq O(\delta\Delta\ell_2/\ell_1) = O(\Delta \ln^5 \Delta)$. We can now apply the LLL, using (8) and the facts that (i) $b > 5$ and (ii) each bad event $\mathcal{B}_{u,c_1,c_2}$ depends on at most $|S(u,c_1,c_2)|$ others. This completes the proof. □

To see why our two-stage coloring helps, note that the "dependence" $|S(u,c_1,c_2)|$ in the second coloring above is only $\Delta^{1+o(1)}$, as compared to the dependence of $\Delta^{3+o(1)}$ that we could get in the direct coloring approach underlying Lemma 3. The constraint "$v \in N^+(N^+_{u,c_1})$" in (9) saves us a factor of $\Delta^{1-o(1)}$, and the constraint "$c'_1 = c_1$" saves another factor of $\Delta^{1-o(1)}$. That the first-stage coloring eliminates many dependencies in this fashion is the main idea motivating this approach.

It is an open question if a domatic partition of the size guaranteed by Theorem 6 can be found in polynomial-time.

2.4. Greedy algorithm. One natural approach to the domatic partition problem is to try to greedily choose small dominating sets. The greedy algorithm iteratively pulls out dominating sets from the graph until the remainder is no longer dominating. The dominating sets are found by a standard $O(\log n)$-approximate greedy algorithm [18, 22].

LEMMA 7. *Suppose $D(G) = n/k$. Then, the greedy algorithm finds a domatic partition of $\Omega(n/(k^2 \log n))$ sets.*

Proof. We count how many disjoint dominating sets our algorithm finds before the set of vertices in them intersects at least half of the n/k vertex-disjoint dominating sets in the graph. During this period, there are at least $n/(2k)$ disjoint dominating sets; thus in each step there exists a dominating set of size at most $2k$, and we find one of size at most $2k \ln n$. Hence, in each step, a vertex from at most $2k \ln n$ different dominating sets is removed. It then requires at least $(n/2k)/(2k \ln n)$ steps to halve the original number of dominating sets in the graph. □

Since $D(G) \leq n$, the approximation ratio is maximized when $k \approx \sqrt{n/(4 \ln n)}$.

COROLLARY 8. *The performance ratio of the greedy domatic partition algorithm is $O(\sqrt{n \ln n})$.*

Fujita [12] has shown examples where the performance of this and some other greedy algorithms is $\Omega(\sqrt{n})$.

2.5. The domatic number of random graphs. We now show that the bound (1) is tight for a large range of values of $\delta = \delta(n)$, by studying $D(G)$ for suitable random graphs G. Suppose G is drawn from the random graph model $G(n,p)$; i.e., we take n labeled vertices, and put an edge with probability p independently between each pair of vertices. We will show that with probability $1 - o(1)$, $D(G) \leq (1 + o(1))\delta(G)/\ln \Delta(G)$. (Throughout this section, the "$o()$" and "$\omega()$" notation refers to n getting large.)

Choose any $p = p(n)$ such that $np = (\ln n)^{\omega(1)}$ and $p = o(1)$. It is easy to check via a Chernoff bound that with probability $1 - o(1)$, both δ and Δ will lie in the range $(1 \pm o(1))np$ for our random graph G. Fix any constant $\epsilon > 0$, and let $s = \lfloor (1-\epsilon)\ln(np)/p \rfloor$. We will show that with probability $1 - o(1)$, any dominating set in G will have size more than s. (Thus, with probability $1 - o(1)$, we will have $D(G) \leq n/(s+1)$, completing the proof.) For any given subset of the vertices S with $|S| = s$,

$$\Pr[S \text{ is a dominating set}] = (1 - (1-p)^s)^{n-s}$$

$$\begin{aligned}
&\leq (1 - e^{-(1+\Theta(p))sp})^{n-s} \\
&\leq (1 - (np)^{\epsilon-1-\Theta(p)})^{n-s} \\
&\leq e^{-(n-s)\cdot(np)^{\epsilon-1-\Theta(p)}} \\
&\leq e^{s-(1/p)\cdot(np)^{\epsilon-\Theta(p)}} \\
&= e^{s-(1/p)\cdot(np)^{\epsilon-o(1)}}.
\end{aligned}$$

Thus, the probability of existence of a dominating set of size s is at most

$$\begin{aligned}
\binom{n}{s} \cdot e^{s-(1/p)\cdot(np)^{\epsilon-o(1)}} \leq (n^s/s!) \cdot e^{s-(1/p)\cdot(np)^{\epsilon-o(1)}} &= (e^s/s!) \cdot e^{s\ln n-(1/p)\cdot(np)^{\epsilon-o(1)}} \\
&= o(1);
\end{aligned}$$

the bound $s \ln n = o((1/p) \cdot (np)^{\epsilon-o(1)})$ follows from the definition of s and from the fact that $np = (\ln n)^{\omega(1)}$.

3. Hardness of approximating the domatic number. We say that a problem is *hard to approximate within ratio* ρ if having a polynomial-time (randomized) ρ-approximation algorithm for it would violate some standard hardness assumption, such as P $\neq$ NP. The hardness assumption that we use in this paper is that NP does not have (randomized) algorithms that run in time $n^{O(\log\log n)}$; for brevity we shall just use the term *hard to approximate*.

We shall prove the following theorem.

THEOREM 9. *For every fixed $\epsilon > 0$, it is hard to approximate the domatic number within a ratio of $(1-\epsilon)\ln|V|$.*

For this purpose, it is helpful to work with a related but different problem.

DEFINITION 1. *A* one-sided dominating set *in a bipartite graph $G(V_1, V_2, E)$ is a set of vertices $U \subseteq V_1$ such that for every $v \in V_2$ there is some $u \in U$ with $(u, v) \in E$. Here it is assumed that the intended bipartition (V_1, V_2) is given explicitly as part of the input and that every vertex in V_2 has some neighbor in V_1. Observe that this problem merely is a reformulation of the well-known set cover problem.*

The one-sided domatic number *of a bipartite graph is the maximum number of mutually disjoint one-sided dominating sets that the graph contains.*

Observe that the dominating set and domatic number problems have a relation similar to the one of the coloring versus maximum independent problem. A coloring is a packing of independent sets while a domatic partition is a packing of dominating sets.

A related problem is the *set cover* problem, where a collection of subsets $\mathcal{S}$ of a base set U is given, and we are to find a minimum cardinality subcollection that contains all elements of U. The *set cover packing number* is then the maximum number of mutually disjoint set covers. It is well known that minimum dominating set, minimum one-sided dominating set, and minimum set cover are strongly related, and that $\ln n$ is the best approximation ratio for all of them within lower order terms (details in section 3.2). The one-sided domatic number problem can be shown to be equivalent to the set cover packing problem in terms of optimization. We are not aware of a similar relationship between one-sided domatic number and domatic number. However, we can give a reduction that yields the necessary result.

PROPOSITION 10. *Let $c > 1$ and consider bipartite graphs $G(V_1, V_2, E)$ with $|V_1|$ large enough (e.g., $|V_1| \geq 4^c$), $|V_2| > |V_1|^c$, and the following* promise*: for some $0 \leq \epsilon \leq 1 - 1/c$ and for r and q satisfying $rq > (1-\epsilon)|V_1|\ln|V_2|$ (r and q may depend on the size of G), either*

- *the size of the smallest one-sided dominating set in G is at least r, or*
- *the one-sided domatic number of G is at least q.*

Note that the two cases for the promise cannot both hold. If it is hard to distinguish which of the two cases holds, then it is hard to approximate the domatic number within a ratio of $(1 - 1/c - \epsilon) \ln |V|$.

The proof of Proposition 10 is given in section 3.2. The main result of the section is the following theorem, proved in section 3.5.

THEOREM 11. *For every $\epsilon > 0$ and every integer $c > 1$ the two cases of Proposition* 10 *cannot be distinguished in (random) polynomial-time unless NP has (randomized) algorithms that run in time $n^{O(\log \log n)}$.*

Theorem 9 now follows from Theorem 11 and Proposition 10.

Remark. Theorem 9 implies a $\ln \Delta$ hardness of approximation result, for $\Delta \simeq n^{\psi}$ for some $0 < \psi < 1$ which is close to 1. To obtain $\ln \Delta$ hardness of approximation results when Δ is much smaller compared to n, simply make many disjoint copies of the graph, increasing n without changing Δ or the domatic number.

3.1. Overview and intuition. Before presenting the proof of Theorem 11, let us provide some background on proving hardness of approximation results in general and how hardness of approximation results were proved for problems related to domatic number.

A convenient starting point for proving hardness of approximation results is the problem of Max 3SAT. The input to this problem is a 3CNF formula and the desired output is an assignment to the variables that satisfies as many clauses as possible. The well known PCP theorem of [3] implies (or in fact, is equivalent to) the following *gap*: for some $\epsilon > 0$ it is NP-hard to distinguish between 3CNF formulas that are satisfiable (which we call *yes* instances) and 3CNF formulas in which every assignment satisfies at most a $(1 - \epsilon)$-fraction of the clauses (which we call *no* instances). This hardness result can be extended to a restricted version of Max 3SAT in which the input 3CNF formula has the property that each variable appears in exactly 5 clauses. (The choice of 5 is arbitrary here. Any other constant greater than 5 would do as well.) We call this restricted version Max 3SAT-5.

As noted above, the set cover problem is strongly related to the dominating set problem, which in turn is related to the domatic number problem. Moreover, the one-sided domatic number problem is equivalent to the set cover packing problem. Hence our plan for proving Theorem 11 is to take known results regarding the hardness of approximation of set cover and modify their proof so that it shows hardness of approximation for the set cover packing problem as well (and hence also for one-sided domatic number). To see more explicitly what needs to be done, let us first review at a very high level the known result [9] that set cover (and one-sided dominating set) is hard to approximate within a factor of $(1 - \epsilon) \ln n$.

The proof in [9] reduces instances of Max 3SAT-5 to instances of one-sided dominating set. The reduction is slightly super polynomial (instances of size n are mapped to instances of size $n^{O(\log \log n)}$) and is a *gap reduction* in the following sense: *yes* instances give bipartite graphs that have small one-sided dominating sets and *no* instances give graphs all of whose one-sided dominating sets are much larger. To prove hardness of approximation for one-sided domatic number, the requirement for *no* instances does not change, as it already implies a small one-sided domatic number. However, we would like *yes* instances to give bipartite graphs that have not just one small one-sided dominating set but many disjoint small one-sided dominating sets, and hence a large one-sided domatic number.

To achieve this extra property, we invoke an idea used in [11] when proving hardness of approximation for the chromatic number problem. In our context, it suffices to change the starting point of the reduction from the problem Max 3SAT-5 to the problem Max-3-colorability-5. This is the problem of coloring a 5-regular graph with 3 colors so as to maximize the number of edges legally colored (see section 3.3). It also has a gap similar to that of Max 3SAT-5. The important property of Max 3-colorability-5 is that *yes* instances of it necessarily have many "disjoint" solutions. When these instances are reduced to instances of one-sided dominating set, the resulting bipartite graph has many disjoint small one-sided dominating sets. This implies a large one-sided domatic number, as required by Theorem 11.

Hence, to complete the proof of Theorem 11, we need to accomplish three things.

1. Introduce the problem of Max 3-colorability-5 and its properties. This is done in section 3.3.

2. Give the reduction from Max 3-colorability-5 to one-sided dominating set. This reduction closely follows the reduction of [9] from Max 3SAT-5 to set cover, except for one small extra step (vertices on one side of the bipartite graph are duplicated many times, an operation that was not performed in the reduction to set cover). This reduction is fairly complicated, but essentially all complications come from the reduction in [9].

3. Prove the properties of the reduction. This has two parts. One is to show that *yes* instances of Max 3-colorability-5 are reduced to bipartite graphs with high one-sided domatic number, which is done in Lemma 17. The other is to show that *no* instances are reduced to bipartite graphs with only large one-sided dominating sets. This part is not proved in this paper, because the proof in [9] that *no* instances of Max 3SAT-5 give instances with a large set cover, extends virtually without change to our adaptation of the reduction of [9].

Appendix B reviews some of the ingredients of the reduction used in [9] from Max 3SAT-5 to set cover and explains some modifications used in our context. Some of these ingredients are only used in the analysis of what happens on *no* instances, and hence do not come into any of the proofs in this paper. They are included only in the overview so as to give some indication of what led to the construction of the reduction. For more details, see [9].

3.2. Domination and one-sided domination. The three problems, minimum dominating set, one-sided dominating set, and set cover, are equivalent in the following sense (see e.g., [29]).

PROPOSITION 12 (see [29]). *There is a polynomial-time reduction between any of the three problems, dominating set, one-sided dominating set, and set cover, that preserves the value of the minimum solution.*

Proof. To reduce dominating set to set cover, let V (the set of vertices) become U (the ground set) and let the collection $\mathcal{S}$ include the sets $N^+(v)$ for every $v \in V$. To reduce set cover to one-sided dominating set, construct a bipartite graph $G(V_1, V_2, E)$ in which V_2 is the ground set U and the vertices of V_1 each represent a set in $\mathcal{S}$. Put an edge $(u, v) \in E$ if $v \in V_2$ corresponds to an item that is contained in the set that corresponds to the vertex $u \in V_1$. Finally, to reduce one-sided dominating set to dominating set make a clique out of all vertices of V_1 and let $V = V_1 \bigcup V_2$; it is not hard to see that these reductions reserve feasibility of solutions, and in addition it is not hard to see that the size of the minimum dominating set is preserved. □

For set cover, let $n = |U|$. It is known that minimum set cover can be approximated within a ratio of $\ln n$ [18, 22] and that, for every fixed $\epsilon > 0$, it is hard to

approximate it within a ratio of $(1-\epsilon)\ln n$ [9]. By Proposition 12, this implies a similar result for one-sided dominating set, with $n = |V_2|$. For dominating set, it is natural to take $n = |V|$. Then the approximation ratio of $\ln n$ trivially applies, but in order to transfer the $(1-\epsilon)\ln n$ hardness result from one-sided dominating set to dominating set using the reduction of Proposition 12 we also need that $\ln|V| \simeq \ln|V_2|$, which holds whenever $|V_1| \leq |V_2|^{1+\epsilon}$. It turns out that this is indeed the case in the construction of [9]. Hence it is known that up to low order terms, $\ln n$ is the best possible approximation ratio for all three problems.

A proof similar to that of Proposition 12 shows that there is a polynomial-time reduction from domatic number (whether one-sided or not) to set cover packing number that preserves the value of the maximum solution. Likewise, there is a polynomial-time reduction from set cover packing number to one-sided domatic number that preserves the value of the maximum solution. However, we are not aware of such a reduction from one-sided domatic number to domatic number. Instead, we use the following proposition.

PROPOSITION 13. *For every integer $k > 0$ (where k may be an arbitrary function bounded by a polynomial in the size of the input) there is a polynomial-time transformation mapping a bipartite graph (V_1, V_2, E) to a graph (V, E') with the following properties:*

- $|V| = |V_2| + k|V_1|$.
- *For the original graph, let q and r, respectively, denote the one-sided domatic number and the minimum cardinality of a one-sided dominating set; hence $q \leq |V_1|/r$. Let p denote the domatic number of the new graph. Then $kq \leq p \leq \min[|V|/r, 1 + 2k|V_1|/r]$.*

Proof. Let $G = (V_1, V_2, E)$ be a bipartite graph for which we are interested in computing the one-sided domatic number. Construct a graph $G'(V, E')$ as follows. $V_1' = \bigcup_{i=1}^{k} V_1^i$, where for every i, V_1^i is a copy of V_1. $V = V_1' \bigcup V_2$, which gives $|V| = |V_2| + k|V_1|$. For every $v \in V_2$, $1 \leq i \leq k$, and $u \in V_1^i$, place an edge $(u, v) \in E'$ iff there is an edge $(u, v) \in E$. In addition, all vertices of V_1' form a clique.

Observe that every one-sided dominating set in G corresponds in a natural way to k mutually disjoint dominating sets in G', one on each copy of V_1^i. Hence the optimal solution for G can be copied k times on G', giving $p \geq kq$. (If, in addition, V_1 has no isolated vertices, then V_2 can serve as one more dominating set disjoint from all the others, giving $p \geq kq + 1$.)

To upper bound p, let $D_1, \ldots, D_p$ be a maximum cardinality collection of disjoint dominating sets in G'. Similar to the proof of Proposition 12, we can see that we can change maximum dominating set D_j to maximum dominating set D_j' of no larger size, fully contained in V_1'. As D_j' must dominate V_2, we get that $|D_j| \geq |D_j'| \geq r$ for all j. Hence $p \leq |V|/r$.

We now turn to proving the second part of the upper bound, namely, $p \leq 1 + 2k|V_1|/r$. This gives a tighter bound when $|V_2| \gg k|V_1|$. Observe that $(D_i \bigcup D_j) \bigcap V_1'$ is a dominating set contained in V_1'. So suppose we pair up any $2\lfloor p/2 \rfloor$ of the D_i's into $\lfloor p/2 \rfloor$ pairs, each of which forms a dominating set of size at least r. Then, $r\lfloor p/2 \rfloor \leq k|V_1|$; so, $p \leq 1 + 2k|V_1|/r$. □

We are now ready to prove Proposition 10.

Proof. Perform the reduction of Proposition 13 with $k = |V_2|$. If the first case holds, then the domatic number of G' is at most $|V|/r$. If the second case holds, then the domatic number is at least $q|V_2|$. The ratio between these two values is $q|V_2|/(|V|/r) = qr|V_2|/|V|$. We use $|V_2|/|V| = 1/(|V_1| + 1)$ and $qr \geq (1-\epsilon)|V_1|\ln|V_2|$

to obtain that the ratio is at least $(1 - \epsilon - 1/|V_1|) \ln |V_2|$. Using $|V_2| > |V_1|^c$ and $|V_1| \geq 4^c$, we obtain that $\ln |V_2| \geq (1 - 1/(c + 1/2)) \ln |V|$. Now Proposition 10 follows assuming that $|V_1| \geq 2(c + 1)^2$. □

Remark. The graphs G' formed in the above reduction are *split graphs*, which are graphs whose vertex-set can be partitioned into a clique and an independent set. These graphs are both chordal and complements of chordal graphs, where a graph is chordal if it contains no cycle with four or more vertices as an induced subgraph. Thus, a $(1 - o(1)) \ln n$ hardness for domatic number holds also for split (and thus chordal and cochordal) graphs. Furthermore, one can get a similar result for bipartite graphs by the following modification. Instead of making a clique out of V_1, we add $(\delta+1)$ vertices and connect them to every node in V_1. This affects the domatic number by at most 1, and the approximability hardness follows.

3.3. The problem Max 3-colorability-5. We now introduce the NP-language that serves as the basis to our reduction.

DEFINITION 2. Max 3-colorability *is the problem of coloring the vertices of a graph with three colors so as to maximize the number of legally colored edges (edges whose endpoints are colored differently).*

An NP-witness for 3-colorability is an assignment of colors to the vertices such that each edge is legally colored. The witness can be checked in a probabilistic sense by sampling an edge at random and checking whether the colors of its two endpoints disagree. The actual names of the colors of the vertices play no role because the names of the three colors can be arbitrarily permuted without changing the legality of the 3-coloring. Hence every NP-witness gives rise to six different witnesses (depending on the permutation used for the names of the colors), and cycling over the six witnesses, every edge gets its six legal colorings. In our reductions to one-sided dominating set, we shall use this structure of the set of witnesses for 3-colorability in order to show that if the resulting bipartite graph has a small one-sided dominating set, then in fact it has many disjoint one-sided dominating sets. We note that the same structure was used in [15] to construct a zero-knowledge proof system for NP.

In order to prove a hardness result for Max 3-colorability-5, we rely on the hardness of Max 3-colorability and the use of expanders. Call a graph H with h vertices a (γ, κ)-*expander* if for any subset S of the vertices of H with $|S| \leq \gamma h$, the number of edges leaving S is at least $\kappa |S|$. For some constant $\kappa > 0$ and for any $\epsilon > 0$, there is an h_0 such that for all $h \geq h_0$, there is an explicitly constructible $(1/2, \kappa)$-expander with maximum degree at most 6 and with the number of vertices lying in the range $[h, h(1 + \epsilon)]$ [23]. Note that a $(1/2, \kappa)$-expander is necessarily also a $(2/3, \kappa/2)$-expander. In particular, this implies that for any given integer h, we can construct a $(2/3, \kappa')$-expander with maximum degree at most 6 and with the number of vertices being some $F(h)$ that satisfies $h \leq F(h) \leq 2h$ for some absolute constant $\kappa' > 0$. (We can proceed as follows. If $h \leq h_0$, where h_0 is a sufficiently large constant, just construct any connected h-vertex graph of maximum degree 6. If $h > h_0$, construct a $(1/2, \kappa)$-expander with maximum degree at most 6 and with the number of vertices lying in the range $[h, 2h]$, using [23].)

We will also need the following theorem of [31].

THEOREM 14 (see [31]). *For some explicit constant $\psi < 1$, it is NP-hard to distinguish between graphs that have a legal 3-coloring (that colors all edges legally), and graphs for which every 3-coloring legally colors at most a ψ-fraction of the edges.*

PROPOSITION 15. *For some explicit constant $\psi < 1$, it is NP-hard to distinguish between 5-regular graphs that have a legal 3-coloring, and 5-regular graphs for which*

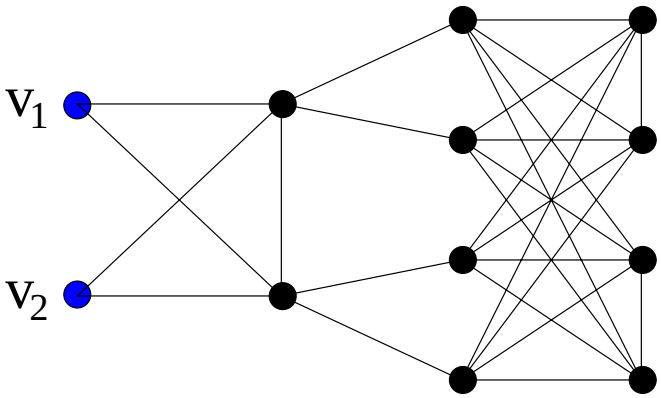

FIG. 1. *Equality gadget.*

every 3-coloring legally colors at most a ψ-fraction of the edges.

Proof. Given a graph $G(V, E)$, we show that it can be modified in polynomial-time to a graph $G'(V', E')$ such that (i) G' is 5-regular; (ii) $|E'| = O(|E|)$; (iii) G' is legally 3-colorable iff G is; and (iv) for some constant $c > 0$ and every $1 \leq k \leq |E'|$, every 3-coloring of G' that leaves k edges illegally colored can be transformed in polynomial-time to a 3-coloring of G that leaves at most ck illegally colored edges. We can then invoke Theorem 14.

First, we may assume that every vertex in G has degree at least three. Indeed, suppose we repeatedly remove any vertex of degree at most 2 until the remaining graph G'' has minimum degree at least 3. It is easy to see that, given any 3-coloring of the vertices of G'', we can add back the deleted vertices of G and color these added-back vertices in such a way that all the edges incident with them are legally colored. So, we assume that G has minimum degree at least 3.

Assume first that all vertices in G have degree at most 13. Then we replace each vertex v by a cluster of $d(v)$ vertices,[1] where each vertex handles one outgoing edge. (That is, if (v, u) is an edge in G, then the vertex representing u in v's cluster is made adjacent to the vertex representing v in u's cluster.) These $d(v)$ vertices are connected in a cycle by *equality gadgets*, shown in Figure 1. These equality gadgets are subgraphs that contain twelve vertices. Two of the vertices are special and have degree two, and all the rest have degree five. The equality gadget has the property that it is legally 3-colorable iff the special vertices receive the same color. The two cluster vertices serve as the special vertices. As each cluster vertex participates in two gadgets and also has one outgoing edge, its degree is 5. Hence G' is 5-regular. The number of edges added is at most $27 \sum_v d(v) \leq 54|E|$, and hence, $|E'| \leq 55|E|$. Every legal 3-coloring of G' colors all cluster vertices with the same color and hence naturally gives a legal 3-coloring of G. Similarly, a legal 3-coloring of G can be extended to a legal 3-coloring of G'. Any 3-coloring of G' in which cluster vertices receive different colors causes at least two edges of G' to be miscolored. Coloring the vertex corresponding to the cluster with an arbitrary color in G causes at most $d(v) \leq 13$ edges to be miscolored. Hence the number of illegally colored edges in G' is smaller than that of G by a factor of at most 13/2.

If G has a vertex of degree more than 13, we create a new graph G_1 as follows.

[1] Recall that $d(v)$ denotes the degree of vertex v [36].

Let $F(\cdot)$ and κ' be as in our discussion on expanders above. Similarly as [28], G_1 is the same as the G' constructed in the previous paragraph, except that for each vertex v, we create a $(2/3, \kappa')$-expander with $F(d(v))$ vertices and maximum degree at most 6 (instead of a cycle with $d(v)$ vertices) and do the above-seen operation of replacing the expander edges by equality gadgets. (Of the $F(d(v))$ vertices, $d(v)$ are "real" and represent the neighbors of v, and $F(d(v)) - d(v)$ are dummy vertices. As in the previous paragraph, if (v, u) is an edge in G, then the vertex representing u in v's cluster is made adjacent to the vertex representing v in u's cluster.) Note that G_1 has maximum degree at most $2 \times 6 + 1 = 13$ and has $O(\sum_v d(v)) = O(|E|)$ edges. Once again, a 3-coloring of G can be efficiently transformed into one for G_1 in which the number of miscolored edges remains the same. Conversely, suppose we have a 3-coloring χ_1 of G_1. Let X_1 be the number of original edges of G that are miscolored by χ_1 and let Y_1 be the number of edges in the equality gadgets miscolored by χ_1. We will produce the following coloring χ of G and then analyze χ. For each vertex v, choose a largest subcluster $C(v)$ of vertices (from its cluster of $F(d(v))$ vertices) that receive the same color in χ_1 and define $\chi(v)$ to be the color assigned to the vertices in $C(v)$ by χ_1. Call an edge (u, v) of G *bad* if it was properly colored by χ_1 in G_1 and was miscolored by χ in G. Let X be the number of bad edges. Then the number of edges miscolored by χ is at most $X_1 + X$. An edge (u, v) is bad only if "$u \notin C(v)$ or $v \notin C(u)$" holds. Thus, letting $x(v) = F(d(v)) - |C(v)| \leq 2F(d(v))/3$, we see that $X \leq \sum_v x(v)$. Since $x(v) \leq 2F(d(v))/3$ and recalling the property of $(2/3, \kappa')$-expansion, we can check that the number of edges in all the equality gadgets of v that are miscolored in χ_1 is $\Omega(x(v))$. Hence $Y_1 = \Omega(X)$. Armed with this property and the fact that G_1 has $O(|E|)$ edges and maximum degree 13, we transform G_1 into G' as described in the previous paragraph. □

3.4. Preliminaries. Our reduction closely follows that of [9]. The main differences are as follows: (i) The outcome of the reduction is one-sided dominating set, rather than set cover (which is the same thing termed differently). (ii) The starting point of the reduction is Max 3-colorability rather than Max 3SAT. As mentioned earlier, the purpose of this change is to have the reduction apply to one-sided domatic number rather than just one-sided dominating set. (iii) Every vertex in the V_1 side of the bipartite graph will be duplicated $2^{l/2}$ times, where l is a parameter of the reduction. This is a technical condition that seems to be required when we reason about the one-sided domatic number.

To describe the reduction, we recall two notions used in [9].

DEFINITION 3. *A* (k, l)-Hadamard code *is a set of* k *binary words of length* l*, where every codeword has Hamming weight* $l/2$ *and the Hamming distance between every two codewords is* $l/2$.

There is a simple construction of Hadamard codes when l is a power of 2 and $k \leq l$ (see, e.g., [25]).

DEFINITION 4. *A* partition system $B(m, L, k, d)$ *has the following properties:*

- *There is a ground set* B *of* m *points.*
- *There is a collection of* L *distinct* partitions $p_1, \ldots, p_L$.
- *For* $1 \leq i \leq L$*, partition* p_i *is a collection of* k *disjoint subsets whose union is* B.
- *Any cover of the* m *points by subsets that appear in pairwise different partitions requires at least* d *subsets.*

The following lemma is proved in [9].

LEMMA 16. *For every* $c \geq 0$ *and* m *sufficiently large there is a* partition system

$B(m, L, k, d)$ whose parameters satisfy the following:

- $L \simeq (\log m)^c$.
- *k can be chosen arbitrarily as long as* $k < \frac{\ln m}{3 \ln \ln m}$.
- $d = (1 - f(k))k \ln m$, *where* $f(k) \to 0$ *as* $k \to \infty$.

Moreover, a random collection of L partitions into k subsets with parameters chosen as above gives with high probability a partition system with $f(k) = 2/k$.

The randomized construction can be replaced by a deterministic construction (with a somewhat larger value for $f(k)$) using techniques developed in [27].

3.5. The construction. The input to the reduction is a 5-regular graph $G(V, E)$ for which we want to determine whether it is legally 3-colorable, or whether every 3-coloring of its vertices legally colors at most $\psi|E|$ edges. As noted in Proposition 15, for some explicit $\psi < 1$ this problem is NP-hard. The reduction uses the following parameters, which are chosen so that (k, l)-Hadamard codes exist and Lemma 16 holds:

- $k = l = c \log \log |V|$ for some sufficiently large constant c. We assume that l is a power of 2.
- $L = 3^l$, and $m = |V|^{\Theta(l)}$.

The output of the reduction is a bipartite graph $G'(V_1, V_2, E')$; when we say "color" below, we refer to a color-set of 3 colors. The left-hand side vertex-set V_2 is composed of $(2|E|)^l$ clusters of vertices, where each cluster contains m vertices. Each left-hand side cluster is labeled by a sequence of l edges in G and a sequence of l bits; for each i, the ith bit in the bit-sequence denotes one endpoint (vertex) of the ith edge in the edge-sequence. Hence, this sequence of bits can also be viewed as a sequence of vertices. The right-hand side vertex-set V_1 is composed of k disjoint *rays*, and each ray is labeled by a codeword of the (k, l)-Hadamard code. Each ray is composed of $|V|^{l/2}|E|^{l/2}$ clusters, where each cluster contains 6^l vertices. Each right-hand side cluster is labeled by a sequence of $l/2$ vertices in G and a sequence of $l/2$ edges in G. Equivalently, we may merge these two sequences to one sequence of length l, where the codeword of the ray containing the cluster is used as a selector function specifying the order in which vertices and edges are merged (a vertex when the corresponding bit in the codeword is 0, and an edge when the corresponding bit in the codeword is 1). This is called the merged label of a right-hand side cluster. Individual vertices of right-hand side clusters are further labeled by a sequence of $l/2$ colors (i.e., a ternary sequence), a sequence of $l/2$ pairs of distinct colors (i.e., a sequence in base 6), and a number between 1 and $2^{l/2}$. Simple counting shows that for each of the labeling schemes that we defined, the number of available labels is exactly equal to the number of objects that need to be labeled.

We say that a left-hand side cluster and a right-hand side cluster are *compatible* if their labels agree coordinate-wise in the following sense: for coordinate i, if the merged label of the right-hand side cluster has an edge, then this is the ith edge in the sequence of edges labeling the left-hand side cluster, and if the merged label has a vertex, then this is the ith vertex in the sequence of vertices labeling the left-hand side cluster. Edges in G' only connect compatible clusters (compatibility is necessary but not sufficient, as will be seen shortly). Note that each left-hand side cluster is compatible with exactly one cluster in each ray. Each right-hand side cluster is compatible with $5^{l/2}2^{l/2}$ left-hand side clusters; the term "5" here arises from the fact that G is 5-regular, and the term "2" follows from the fact that every edge has two end-points.

In order to describe the edge set E', we use the notion of a partition system. For each left-hand side cluster C_ℓ, we have $L = 3^l$ partitions with properties as in Definition 4. (Recall that C_ℓ has m elements as required by Definition 4.) Each partition is labeled by a sequence of l colors. This sequence of colors is interpreted as a sequence of colors for the sequence of vertices that label C_ℓ. Note that the same vertex of G may appear several times in the sequence of vertices that labels C_ℓ; we do not require the colors given to this vertex to be the same.

Consider an arbitrary vertex v in a cluster C_r that belongs to ray i. We now describe the set of neighbors that it has in a *compatible* left-hand side cluster C_ℓ. Recall that v is labeled by a sequence of $l/2$ colors and a sequence of $l/2$ pairs of distinct colors. These colors give in a natural way a coloring for the merged sequence of vertices and edges labeling C_r. The vertex v was also labeled by a number between 1 and $2^{l/2}$; this label is ignored when determining the set of neighbors of v (that is, C_r has $2^{l/2}$ identical copies of v).

The coloring of the merged sequence of C_r induces in a natural way a coloring for the sequence of vertices labeling C_ℓ. This coloring labels one particular partition p. Vertex v is connected to all vertices (points) of the ith part of partition p (recall that i is the ray to which C_r belongs). This completes the description of E'.

LEMMA 17. *If G is legally 3-colorable, then the one-sided domatic number of G' is 6^l.*

Proof. We first show that G' has a one-sided dominating set that includes exactly one vertex from every right-hand side cluster. Consider a sequence of l arbitrary legal 3-colorings of G (the same legal 3-coloring may appear multiple times in the sequence). Now consider an arbitrary right-hand side cluster. It is labeled by a length l merged sequence of vertices and edges. The sequence of legal 3-colorings induces a coloring on this merged sequence. The cluster contains exactly $2^{l/2}$ vertices whose label induces the same coloring. Select one of them arbitrarily to be included in the one-sided dominating set.

To show that indeed we have a one-sided dominating set, we need to show that every left-hand side vertex u is covered. Consider the cluster C_ℓ to which u belongs. It is labeled by a sequence of l edges and a sequence of l vertices. The sequence of legal 3-colorings induces a coloring for the sequence of vertices. This coloring agrees with the name of one partition p. Let i be the part of partition p to which u belongs. Consider the right-hand side cluster C_r that is compatible with C_ℓ and belongs to ray i. The vertex selected from C_r necessarily covers u.

We now show that the one-sided domatic number is at least 6^l (in fact, it is exactly 6^l). Consider an arbitrary legal 3-coloring of G. From it, we can derive 6^l distinct length l sequences of legal 3-colorings, where in each of the l coordinates we put one of the six permutations of the legal 3-coloring. Each of these sequences gives a one-sided dominating set as described above. We show that these one-sided dominating sets can be chosen to be distinct. This follows from the fact that for each sequence of legal 3-colorings and every right-hand side cluster, we can have $6^{l/2}3^{l/2}$ equivalence classes of $2^{l/2}$ vertices (who differ only in the number they are given in the third label) and $6^{l/2}3^{l/2}$ equivalence classes of $2^{l/2}$ sequences of colorings (who differ only in the way they color vertices not in the merged sequence of the right-hand side cluster). Preserving the structure of the equivalent classes, we can match the sequences of legal 3-colorings with the vertices of a right-hand side cluster. □

LEMMA 18. *If every 3-coloring of G legally colors at most $\psi|E|$ edges, then the smallest one-sided dominating set in G' is of cardinality at least $(1-o(1))|V_1| \ln m/6^l$.*

Proof. The proof is essentially identical to that of Lemma 7 in [9] and is omitted. □

By making m sufficiently large, we can have $|V_2| > |V_1|$ and $\ln m \simeq \ln |V_2|$, and the proof of Theorem 11 follows.

Appendix A. Multicoloring version. In the domatic multipartition problem, we are additionally given an integral weight $x : V \mapsto N$ indicating in how many dominating sets each vertex can appear. The domatic number problem has $x(v) = 1$ for each v; the *r-Conf* problem of [13] has $x(v) = r$ for each v.

We can reduce the multipartition problem to the ordinary partition problem. Given a graph G and weight vector x, form a graph G' as follows. G' has $x(v)$ copies of each vertex v connected as a clique. For each edge uv in G, the copies of u and v form a complete bipartite graph in G'. Any minimal dominating set in G' is also a dominating set in G, and taking one copy of each vertex of a dominating set in G also gives a dominating set in G'. Further, a domatic partition of G' is in one-to-one correspondence with a multipartition of G (within the weight constraints). Thus, the results obtained in this paper for the domatic number problem carry over to the domatic multipartition problem, replacing δ by $\min_v d(v)x(v)$ and n by $\sum_v x(v)$.

Appendix B. Overview of some ingredients from [9].

Parallel repetition of two-prover proof systems. There is a straightforward one-round two-prover proof system for Max 3-colorability-5 that has the following properties: on *yes* instances, the verifier always accepts, and on *no* instances (when at most a $(1 - \epsilon)$-fraction of the edges can be legally colored simultaneously) the verifier accepts with probability at most $1 - \epsilon/3$. Give a 5-regular graph G, the proof system proceeds as follows. The verifier sends to the first prover a random edge in G and to the second prover a random vertex from that edge. We call this vertex the *common* vertex. It is important that the first prover does not know which endpoint of the edge is the common vertex and that the second prover does not know which edge was received by the first prover. The first prover replies with two different colors (out of the three allowable colors) for the two vertices that are the endpoints of the edge. The second prover replies with a color for the common vertex. The verifier accepts only if the two provers give the same color to the common vertex. For a *yes* instance G the two provers can answer according to the global legal 3-coloring and ensure that the verifier accepts with probability 1. For a *no* instance G, regardless of the strategy of each prover (where a strategy is a function from questions to answers), the acceptance probability is at most $1 - \epsilon/2$, where probability is computed over the random choices of the verifier.

The l-fold parallel repetition of this one-round two-prover proof system is as follows. The verifier sends to the first prover a tuple of l random edges and to the second prover a tuple of l random vertices, one from each of these edges. Each prover replies with colors to all the vertices that it receives. The verifier accepts if on every one of the l common vertices, the two provers agree on the color that they give. It is not hard to see that on *yes* instances, the provers still have a strategy that makes the verifier accept with probability 1. The parallel repetition theorem [34] shows that on *no* instances, the verifier accepts with probability at most $(1 - \epsilon)^{cl}$, where c is a constant (that depends on ϵ).

Separating codes and *k*-provers. To eventually get $\simeq \ln n$ hardness of approximation results, two-prover proof systems are extended to k-prover systems in a special way. As in the two-prover proof system, the verifier selects l edges at random and a random vertex within each edge. This gives a total of $(2|E|)^l$ possible queries.

Each of the k provers is sent some subset of the l edges and l vertices using the following rule. A (k, l)-Hadamard code is a collection of k binary words of length l each, for which the Hamming distance between any pair of words is "large" (specifically, $l/2$). With each prover we associate one codeword from the Hadamard code. The verifier sends to each prover $l/2$ edges and $l/2$ vertices, selected according to the 1's and 0's in the codeword of the respective prover. Namely, if the ith bit in the code is 1, the next entry in the query is the respective ith edge (among the l edges in the tuple). If the ith entry is 0, the ith vertex in the vertex-tuple is sent. Considering separately two of the provers, the fact that their codewords have a large Hamming distance implies that in many coordinates one prover will receive an edge while the other prover will receive a vertex on this edge. This is similar to the scenario in the two-prover proof system. Intuitively, we may view the k-prover proof system as $\binom{k}{2}$ correlated two-prover proof systems going on in parallel. It is natural to have the verifier accept if all $\binom{k}{2}$ proof systems are accepting. The definition of acceptance used in [9] is more subtle and will not be discussed in this overview.

Next a bipartite graph $G'(V_1, V_2, E')$ is built based on this scenario. Specifically, the vertices in V_1 describe the provers/queries schema. The set V_1 corresponds to the provers and is partitioned into k "rays" V_1^j, $1 \le j \le k$, one ray for each prover. The sets V_1^k are further partitioned into disjoint subsets $V_1^j(Q)$, where Q ranges over all the $|V|^{l/2}|E|^{l/2}$ possible questions that a prover can receive. On each possible question, the prover must answer with a coloring of the $l/2$ edges and $l/2$ vertices received. Thus, the $V_1^j(Q)$ sets are further divided into all possible answers. Therefore, there are $3^{l/2} \cdot 6^{l/2}$ points inside $V_1^j(Q)$ in this final division; a point for each possible coloring of the $l/2$ vertices and $l/2$ edges. In addition, for technical reasons, each point (possible answer) of each prover is duplicated $2^{l/2}$ times.

Ground sets and random partitions. To determine the structure of V_2, some ideas essentially due to [24] (and extended in [9]) are used.

The set V_2 is partitioned into $(2|E|)^l$ *ground sets* C_ℓ, one ground set per each possible query. Each ground set contains m points for $m = |V|^{\Theta(l)}$. It is instructive to note the following asymmetry. Given a query, namely, a sequence of l edges and l corresponding endpoints for the edges, consider its corresponding ground set in V_2. There are exactly k sets $V_1^j(Q)$ that are compatible with this sequence, one per prover (since the question to the provers is completely determined by the Hadamard code). On the other hand, given a question cluster $V_1^j(Q)$, many possible query-base ground sets in V_2 could have caused this question. Indeed, since the question contains only $l/2$ edges and $l/2$ vertices, this partial information can be completed in $5^{l/2}2^{l/2}$ ways to give compatible l edges and l vertices. Each vertex sent to this prover has 5 neighbors and thus 5 ways of "completing" this vertex into a (compatible) edge. For each edge sent to this prover, there are 2 possibilities for which of the two vertices to put in the resulting query.

We use $L = 3^l$ random partitions of C_ℓ, each partitioning C_ℓ into k parts. Consider the l-tuple of vertices in a possible query (namely, the part of the query corresponding to the chosen vertices, one per each edge). Note that the number $L = 3^l$ of partitions of each ground set exactly equals the number of possible colorings 3^l of the vertices in that query. We can thus form a 1-1 correspondence between the 3^l partitionings and the 3-coloring (not necessarily a consistent one) of the l vertices in the query base. Each partition is now regarded as a coloring and vice versa. Recall that a point in the final subpartition cluster of V_1 corresponds to an answer to the coloring of the query of $l/2$ edge/vertex pairs. This corresponds to a coloring of the

l vertices of the cluster C_ℓ and hence gives a vertex coloring, and thus a partition of C_ℓ. The edges between the vertices of V_1 and V_2 are defined as follows. Each vertex (namely, coloring or answer) $v \in V_1^j(Q)$ is connected to the jth part of the partition corresponding to v (as v is a coloring, a partition is also associated with v).

Now, consider the graph G' resulting from a 3-colorable graph G. We can choose one point (answer) per each question-cluster in V_1, so as to cover each C_ℓ. Thus all the C_ℓ are covered using at most $k \cdot (2 \cdot E)^l$ vertices. This will happen if the provers use strategies which are all part of a global 3-coloring, and this gives a small dominating set. On the other hand, consider the resulting graph G' when only $1 - \epsilon$ of the edges of G can be simultaneously legally colored. Because of the parallel repetition which greatly increases the gap, the provers essentially cannot use a joint strategy. This means that each pair of answers $v_j \in V_1^j(Q), v_q \in V_1^q(Q)$ chosen corresponds to two different colorings. Hence a ground set C_ℓ is essentially covered via random sets each containing m/k random elements of C_ℓ. Thus, the number of elements needed in order to cover C_ℓ is roughly $k \ln m$. This gives a total of roughly $k \cdot (2 \cdot E)^l \ln |V'|$ minimum one-sided dominating sets for a logarithmic gap.

Zero-knowledge and the domatic number. Given the fact that a single "small" one-sided dominating set exists, we can permute the colors (as done in zero-knowledge protocols in order to "hide" information) to show the existence of "many" disjoint dominating sets, hence a "large" domatic number. Namely, once a 3-coloring of G exists, one gets 6 legal colorings for G. This implies a total of 6^l colorings (which can be completed into global coordinatewise-compatible colorings) of any l-tuple of vertices. The possibility for color permutation was the main reason for reducing from a coloring and not a satisfiability problem. Hence, we either get many small dominating sets which implies a large one-sided domatic number, or any dominating set is large, which gives a small one-sided domatic number.

MACHINE-INDEPENDENT CHARACTERIZATIONS AND COMPLETE PROBLEMS FOR DETERMINISTIC LINEAR TIME*

ETIENNE GRANDJEAN† AND THOMAS SCHWENTICK‡

Abstract. This article presents two algebraic characterizations and two related complete problems for the complexity class **DLIN** that was introduced in [E. Grandjean, Ann. Math. Artif. Intell., 16 (1996), pp. 183–236]. **DLIN** is essentially the class of all functions that can be computed in linear time on a Random Access Machine which uses only numbers of linear value during its computations.

The algebraic characterizations are in terms of recursion schemes that define unary functions. One of these schemes defines several functions simultaneously, while the other one defines only one function. From the algebraic characterizations, we derive two complete problems for **DLIN** under new, very strict, and machine-independent *affine* reductions.

Key words. linear time, model of computation, Random Access Machine, completeness, recursion schemes, affine reductions

1. Introduction.

In the definition of the main complexity classes like deterministic or nondeterministic polynomial time or polynomial space, the choice of the underlying machine model is not very crucial. The definition does not depend on whether one chooses 1-tape, multitape, or multidimensional Turing machines or RAMs. As long as the cost associated with a computation is reasonable, all definitions define the same classes—with the notable exception of the nonreasonable unit-cost model for RAMs that are allowed to multiply numbers. Linear time, on the other hand, is a much more delicate notion. For instance, as in algorithm design, it is very sensitive to the representation of inputs and to changes of the computational model. It is therefore a nontrivial task to define a robust notion of linear time. Some authors tried to circumvent this problem by considering so-called *quasi-linear time*, i.e., time $O(n\text{polylog}(n))$ [33, 23, 12]. On the other hand, there is even no general agreement on whether linear time on Turing machines is too weak or too powerful [31].

The underlying formalization of deterministic linear time for this article, the class **DLIN**, was defined and investigated by one of the authors in a series of articles [18, 17, 19]. Before we recall some details of this definition, let us first have a closer look at why deterministic linear time on Turing machines has little to do with linear time algorithms on, say, graphs. First, such algorithms rely usually on more sophisticated representations of the input graphs, such as adjacency lists. Such lists are basically pointer structures, and the algorithms usually make intensive use of pointer variables. As the movements of the heads of a Turing machine are only local, it is hard to see how such "pointer jumping" algorithms could be simulated on a Turing machine in linear time. On the other hand, RAMs are perfectly suited to perform such algorithms. The definition of the class **DLIN** for string problems is based on the idea of representing

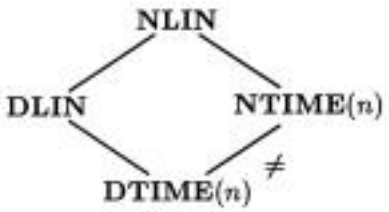

FIG. 1. *The known inclusions between the linear time classes considered.*

strings by pointer structures in analogy to efficient graph representations. In a first step, a string $w = w_1 \cdots w_n$ of length n is partitioned into $m := \lceil n/l \rceil$ pieces of length $l = \lceil \frac{1}{2} \log n \rceil$. Then such a partitioned string is encoded as a unary function $f : \{1, \ldots, m\} \to \{0, \ldots, m\}$ by defining $f(i)$ to be the number which is encoded[1] by the ith piece of the (partitioned) string w. A computation is linear time if it needs only a linear number of steps in m. The second characteristic feature of the model is that, during a computation, only numbers of value $O(m)$ are allowed. The model is quite robust with respect to arithmetic operations. We can choose addition and subtraction as the basic arithmetic operations. Allowing multiplication does not change the computational power. A complete definition is given in section 2. With **DLIN** and **NLIN** we denote the classes of problems that can be computed on such a deterministic (resp., nondeterministic) RAM in linear time. Both classes are quite robust and seem to be very reasonable formalizations of the intuitive notion of linear time.

Figure 1 shows the known inclusions between **DLIN**, **NLIN** and the linear time classes for (multitape) Turing machines, **DTIME**(n), and **NTIME**(n). The separation of **DTIME**(n) from **NTIME**(n) was shown in [30].

In [15, 16, 18, 21], it is shown that **NLIN**, the nondeterministic counterpart of **DLIN**, has a number of nice properties.

- **NLIN** contains all 21 **NP**-complete problems that were defined by Karp in his seminal paper on **NP**-completeness [25].
- **NLIN** coincides with the class of problems that can be characterized by logical formulas of the form $\exists f_1, \ldots, f_k$ for all x φ, where the f_i are unary function symbols and φ is a quantifier-free formula.
- There are natural complete sets for **NLIN** under **DTIME**(n)-reductions. These complete sets are derived from the mentioned logical characterizations. As **DTIME**$(n) \subset$ **NTIME**$(n) \subseteq$ **NLIN**, they are not in **DTIME**(n).
- **NLIN** coincides with the class of problems that can be solved in linear time on a nondeterministic Turing machine that is allowed to perform a constant number of string-sorting operations.

In a very recent paper [26], a logical characterization of **NTIME**(n) was given. Logical characterizations of deterministic linear time classes seem to be more difficult to come by. For **DLIN**, a decisive step was accomplished by one of the authors [34], who gave the first machine-independent characterization of this class and of related deterministic linear time classes.

In this article, we give algebraic characterizations of **DLIN**, from which we derive complete problems for this class under very strict reductions. These results significantly simplify and improve the characterizations that were given in [34]. We hope

[1] via the dyadic encoding which maps the string $0 \cdots 0$ to 0, $0 \cdots 01$ to 1, $0 \cdots 10$ to 2, and so on.

that these algebraic characterizations will lead to clean logical characterizations of **DLIN** which will eventually give us logical games as tools for lower bound proofs. For a discussion of the connections between linear time complexity classes and inexpressibility proofs in finite model theory, see [35].

It should be noted that there exist many characterizations of classical computational complexity classes in terms of algebraic recursion schemes in the literature, e.g., [4, 22, 23, 6, 2, 1, 14, 28, 3].

The article is organized as follows. In section 2, we give precise definitions of the underlying computational model and the class **DLIN**. Furthermore, we introduce the notion of *affine reductions*, a very strict type of reductions that are natural in the context of RAM computations. In section 3, we describe the algebraic recursion schemes that are used in the characterizations which are proved in section 4. In section 5, we exhibit complete problems for **DLIN**. We conclude with a summary of our results and possible ways they may be extended in section 6.

2. Preliminaries. For natural numbers $n > 0$, we write $[n]$ to denote the set $\{0, \ldots, n-1\}$. All arithmetic operations that we consider take only nonnegative integer values. In particular, we use the *underflow convention* that $a - b$ takes the value 0 if $a < b$.

2.1. RAM data structures. As mentioned in the introduction, the notion of linear time depends strongly on the computational model and the representation of the input. In this article, our model will be the RAM. The basic objects that a RAM manipulates in a single step are numbers, as opposed to Turing machines where the basic objects are characters of a finite alphabet. Therefore, it is reasonable to view the input and the output of a RAM as sequences of numbers, as opposed to sequences of characters, i.e., strings. It has turned out in previous work [17, 19] that one gets a robust model of linear time on RAMs if the running time, the number of registers, and the value of all numbers used during a computation, including the input numbers, are linearly bounded in the length of the input sequence, i.e., in the number of its numbers. A sequence $a_0, \ldots, a_{n-1}$ can be nicely represented by a function $f : [n] \to \mathbb{N}$, where f is defined by $f(i) = a_i$ for each $i \in [n]$. In general, we want to be able to consider inputs that consist of several sequences of numbers. This leads to our first basic definition. Let $\mathbf{t}$ be a set of function and constant symbols. A *RAM data structure s of type* $\mathbf{t}$ consists of

- a positive *size* $n \in \mathbb{N}$,
- a constant $C \in \mathbb{N}$ for each constant symbol C of $\mathbf{t}$, and
- a function $f : [n] \to \mathbb{N}$ for each function symbol f in $\mathbf{t}$.

We refer to constants C of s by $s.C$ and to functions f of s by $s.f$. We consider the size as a special constant symbol that appears in *every* type without mentioning it. Similarly, we consider the identity function $\mathbf{id}(x) = x$ as a function in any type t structure without mentioning it explicitly. We refer to the size of a structure s by $s.n$. In our notation, we usually do not distinguish between constant or function symbols and the actual values they take in a structure. As it is crucial for all of our considerations that the input numbers are linearly bounded in n, we pay special attention to the size of the values $s.f(i)$ and $s.C$ compared with $s.n$. If c is a natural number such that $s.f(i) \leq cs.n$ for each $i \in [n]$ and each $f \in \mathbf{t}$, and $s.C \leq cs.n$ for each $C \in \mathbf{t}$, then we say that s has *magnification bound* c or that s is *c-bounded* or $m(s) \leq c$. Intuitively, the magnification bound plays a similar role for RAM data structures as the size of the alphabet does for strings.

The restriction of the *size* of the numbers to be linearly bounded in n, while it may seem at first artificial, is an important part of our model. On one hand, we do not want arbitrary large values in our RAM registers, as, e.g., allowing linear increase in register length would result in exponential increase in the value represented. On the other hand, limiting the values strictly to n would result in at least technical awkwardness. For example, in the natural representation of graphs by adjacency lists, the numbers that occur are bounded by the number of vertices plus the number of edges.

Our convention does not prevent RAM algorithms from manipulating arbitrarily large words or integers at a higher level: e.g., as in real computers, where the word size is fixed, a large integer x can be represented in contiguous registers as a list of smaller integers $x_0, x_1, \ldots, x_k$, $x_i < b$, $x = x_0 + x_1 b + \cdots + x_k b^k$, i.e., in base b, and we take here $b = \theta(n)$.

For types $\mathbf{t}, \mathbf{t}'$ a $(\mathbf{t}, \mathbf{t}')$-*RAM function* Γ is a function which maps, for some constants $c(\Gamma), d(\Gamma)$, every RAM data structure of type $\mathbf{t}$ with magnification bound $c(\Gamma)$ to a RAM data structure of type $\mathbf{t}'$ with magnification bound $d(\Gamma)$. Γ is *linear* if $\Gamma(s).n = O(s.n)$.

A $\mathbf{t}$-*RAM decision problem* L is a set of RAM data structures of type $\mathbf{t}$ with magnification bound c for some constant c.

Our RAM data structures are minimally structured. They can encode more common data structures such as graphs, lists, lists of lists, etc. in a transparent way. We give two examples for such encodings that will be used in what follows.

Example 1. (a) Many data can be viewed at a lower level as mixed lists of nonnegative integers and special symbols, e.g., letters, parentheses, operators, equality signs, and so on, from a fixed alphabet Σ. For example, the system of equations

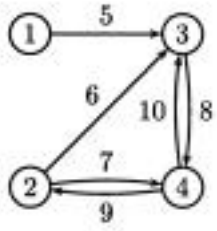
$$f_2(x) = 37 + f_0(x), \quad f_4(x) = f_1(x) - 51$$

can be represented by a list of 27 elements: $f, 2, (, x,), \ =, 37, \ldots, -, 51$. To distinguish numbers from other symbols, we represent each symbol of Σ by a number between 0 and $k-1$ and each number a by $a+k$, where k is the size of Σ. If, in the example above, the alphabet Σ has the 9 symbols $f, x, (,), \ = \ , \ + \ , \ - \ , \ \times \ , ;$, the system of equations can be represented by the RAM data structure s of type $\{g\}$, where $s.n = 27$ and $s.g(0) = 0$, $s.g(1) = 2 + 9 = 11$, $s.g(2) = 2, \ldots$, and $s.g(26) = 51 + 9 = 60$. Note that s has magnification bound 3.

(b) As a second example, we show how directed graphs can be represented by RAM data structures. The representation is an encoding of the adjacency list. Let G be a directed graph with vertex set V and edge set E. Let m and m' be the number of elements of V and E, respectively. We represent the vertices by the numbers $1, \ldots, m$ and the edges by the numbers $m+1, \ldots, m+m'$. If vertex 1 has out-degree l_1, then the numbers $m+1, \ldots \ .m+l_1$ represent the outgoing edges of vertex 1. The numbers $m+l_1+1, \ldots m+l_1+l_2$ represent the outgoing edges of vertex 2, and so forth.

The RAM data structure $s(G)$, which represents G, has type $\{m, m', f^-, f^+\}$, where m and m' are constant symbols and f^- and f^+ are function symbols. $s(G)$ is defined as follows.

- $s(G).n = m + m' + 1$.
- $s(G).m = m$.
- $s(G).m' = m'$.
- $s(G).f^-(i) = 0$ for all $i \in \{1, \ldots, m\}$.
- $s(G).f^+(i)$ is the first outgoing edge from vertex i for all $i \in \{1, \ldots, m\}$.



i	$f^-(i)$	$f^+(i)$
0	0	0
1	0	5
2	0	6
3	0	8
4	0	9
5	1	3
6	2	3
7	2	4
8	3	4
9	4	2
10	4	3

FIG. 2. *An example graph G and part of its representation.*

- For each number i which represents an outgoing edge of vertex j, we have $f^-(i) = j$, and $f^+(i)$ is the number of the target vertex of i.

As an illustration, consider the representation of the graph G, which is shown in Figure 2.

We have $s(G).n = 11$. The function values $s(G).f^-(i)$ and $s(G).f^+(i)$ for all $i \in [11]$ are given in Figure 2. Note that we do not make any assumption on the order in which the outgoing edges of a vertex are represented.

RAM data structures are very similar to finite structures as they appear in finite model theory [9]. A finite structure consists of a universe (the set of basic elements), constants, relations, and functions. There are the following main differences:

- We do not make use of relation symbols.
- All function symbols are *unary*.
- In a RAM data structure of size n, the "universe" is $[n]$. Unlike in finite structures, we allow that functions and constants take values outside the "universe"—but only in $[cn]$ for some constant c.

2.2. RAMs and linear time. In this section, we define precisely our model of computation and the complexity class **DLIN**.

A *simple* $\{+, -, \times\}$*-RAM* M is a RAM with two *accumulators* A, B, a *special register* N, and registers R_i for every $i \geq 0$. Its program is a sequence $I(1), \ldots, I(r)$ of instructions, each of which is of one of the following forms:

- $A := c$ for some constant $c \geq 0$,
- $A := A * B$, where $* \in \{+, -, \times\}$,
- $A := N$,
- $N := A$,
- $A := R_A$,
- $B := A$,
- $R_A := B$,
- IF $A = B$ THEN $I(i_0)$ ELSE $I(i_1)$,
- HALT.

The meaning of most of these instructions is straightforward. If the accumulator A contains a number l, then the execution of the instruction $A := R_A$ copies the contents of register R_l into A, whence the execution of $R_A := B$ copies the contents of B into R_l. We require the last instruction $I(r)$ of the program to be HALT. If before the execution of an instruction $A := A - B$ the content of A is smaller than that of B, then A is set to 0.

More generally, we define analogously simple Op-RAMs for any set Op of binary and/or unary operations.

Let $\mathbf{t}$ be a type that consists of the constant symbols $C_1, \ldots, C_l$ (besides n) and function symbols $f_1, \ldots, f_k$. We say that a RAM data structure of type $\mathbf{t}$ *corresponds to* register values of a RAM, or vice versa, if

- the special register N contains $s.n$,
- the registers $R_{(s.n)k}, \ldots, R_{(s.n)k+l-1}$ contain $s.C_1, \ldots, s.C_l$, and
- for each $i \in \{1, \ldots, k\}$, the consecutive registers $R_{(i-1)(s.n)}, \ldots, R_{i(s.n)-1}$ contain $s.f_i(0), \ldots, s.f_i(s.n-1)$, respectively.

At the beginning of a computation, on input s, the register values of the RAM correspond to s and A and B, and all registers R_i that are not determined by this correspondence have initial value 0.[2] The computation starts with instruction $I(1)$ and finishes when it executes a HALT statement. M computes the RAM function Γ if, for each $c(\Gamma)$-bounded input s, the computation terminates and, at the end of the computation, the register values correspond to $\Gamma(s)$.

Let **DLIN** denote the class of RAM functions Γ that can be computed in linear time $O(n)$ (i.e., using $O(n)$ instructions) on a simple $\{+, -, \times\}$-RAM which uses only numbers of value $O(n)$ for inputs of size n. We note that our convention that a RAM that works in time $O(n)$ should use only values $O(n)$ as register contents and addresses naturally implies that such a RAM also uses only a linear memory. This is a natural restriction as one expects that an algorithm which works in linear time $O(n)$ does not use space more than $O(n)$.

Although it is not decidable whether a given RAM M uses only linear values for RAM data structures with a given magnification bound c, by adding overflow test instructions after each instruction of M, every RAM M can be easily transformed into a RAM M' such that, for each $c > 0$, there is a $d > 0$ with the following two properties:

1. M' uses only values $< ds.n$ on c-bounded inputs s.
2. If M uses only values $< ds.n$ on c-bounded inputs s, then M' simulates the behavior of M.

We call such a RAM M' *safe* and will assume safety for all the RAMs that we consider in this article. In some of our proofs, we will make use of multimemory RAMs, i.e., RAMs with several sequences $R^1, \ldots, R^k$ of registers and instructions $A := R^j_A$ and $R^j_A := B$ for every $j \leq k$, with the obvious semantics. This does not change the power of RAMs significantly [17]. In particular, the class defined as **DLIN** does not change if one uses multimemory RAMs instead of RAMs. More generally, complexity classes on RAMs are robust. Many operations and different statements can be introduced without changing the class.

PROPOSITION 2.1. *A $\{+, -, \times, \div 2\}$-RAM[3] M working in time $O(n)$ and using only integers of value $O(n)$ can be simulated in time $O(n)$ on a $\{+\}$-RAM M', which again uses only integers of value $O(n)$.*

Proof. We are going to demonstrate how multiplication can be simulated on a multimemory $\{+\}$-RAM. The simulation of the other operations is similar and even simpler. More generally, it was proved in [17] that the proposition holds for any set of linear time turing computable (LTTC) operations, such as $-$, $\div 2$, shift, XOR, concatenation, etc., and for all time bounds $t(n) \geq n$ in place of $O(n)$.

[2] In our context, the initialization with 0 could also be done by the program itself, as only the first dn registers are used during the computation for some fixed d.

[3] Here $\div 2$ denotes the unary operation "division by 2."

Let c be a constant such that M uses, on inputs of size n, only numbers that are smaller than cn. The main idea is to use precomputed tables, in particular, a multiplication table for integers that are smaller than $b := \lceil \sqrt{cn} \rceil$. The simulation of M by M' proceeds in two stages.

Precomputation.

(1) Compute $b = \lceil \sqrt{cn} \rceil$.
(2) For each integer $i < cn$, compute and store in two tables $T_{\mathrm{mod}b}$ and $T_{\div b}$ the lower and the higher part of i, respectively. More precisely, let $T_{\mathrm{mod}b}[i] = i \bmod b$ and $T_{\div b}[i] = i \div b$.
(3) For each integer $i < b$, compute and store $T_{\times b}[i] = ib$.
(4) For every $i, j < b$, compute $T[ib + j] = ij$. T can be seen as a multiplication table for integers that are less than b.

Each of these tables can be computed by M' in time $O(s.n)$. As an example, the computation of T is based on the following induction:

$$T[ib + (j+1)] = \begin{cases} T[ib + j] + i & \text{if } j + 1 < b, \\ 0 & \text{otherwise.} \end{cases}$$

Main computation. M' works exactly as M does, except that each multiplication statement $A := A \times B$ is simulated in constant time by making use of the precomputed tables. Let x and y denote the numbers stored in A and B, respectively. As the product is not allowed to be as large as b^2, one of the factors, say, x, must be smaller than b. Hence

$$\begin{aligned} x \times y &= x \times (y \bmod b) + x \times b \times (y \div b) \\ &= T[T_{\times b}[x] + T_{\mathrm{mod}b}[y]] + T_{\times b}[T[T_{\times b}[x] + T_{\div b}[y]]]. \end{aligned}$$ □

2.3. Affine reductions. In order to study **DLIN**-complete problems and, more generally, to define a machine-independent reduction adapted for low complexity problems, we now introduce some simple algebraic notions and results about transformations of RAM data structures.

DEFINITION 2.2. *A* nondecreasing affine function*, for short* affine function*, is a function $A : \mathbb{N}^k \to \mathbb{N}$ of the form $A(x_1, \ldots, x_k) = a_0 + a_1 x_1 + \cdots + a_k x_k$, where the constants $a_1, \ldots, a_k$ are nonnegative integers and a_0 is any constant integer such that $a_0 \geq 0$ if $a_1 = a_2 = \cdots = a_k = 0$.*

DEFINITION 2.3. *Let T be a RAM function which maps RAM data structures of type $\mathbf{t}$ to RAM data structures of type $\mathbf{t}'$. T is an* affine transformation *if the following conditions hold.*

(1) *There are constants l, $d_1, \ldots, d_l$ and affine functions $\alpha_1, \ldots, \alpha_l$ such that, for each RAM data structure s of type $\mathbf{t}$, $T(s).n = \sum_{i=1}^{l} d_i \alpha_i(s.n)$.*
(2) *For each constant symbol $C' \neq n$ of $\mathbf{t}'$, there is an affine function $\beta_{C'}$ such that, for each RAM data structure s of type $\mathbf{t}$, $T(s).C' = \beta_{C'}(s.\overline{C})$, where $\overline{C}$ is the vector of all constant symbols of $\mathbf{t}$, including n.*
(3) *For each function symbol g of $\mathbf{t}'$, each $i \leq l$, and each $r < d_i$, there is a function symbol $f_{g,i,r}$ of $\mathbf{t}$, possibly the identity function symbol, and an affine function $A_{g,i,r}$ such that, for each $i \leq l$, $r < d_i$, for each s, and $x < \alpha_i(s.n)$,*

$$T(s).g\left(r + d_i x + \sum_{j<i} d_j \alpha_j(s.n)\right) = A_{g,i,r}(s.\overline{C}, s.f_{g,i,r}(x)),$$

where $\overline{C}$ is as above and $s.f_{g,i,r}(x)$ is interpreted as 0 whenever $x \geq s.n$.

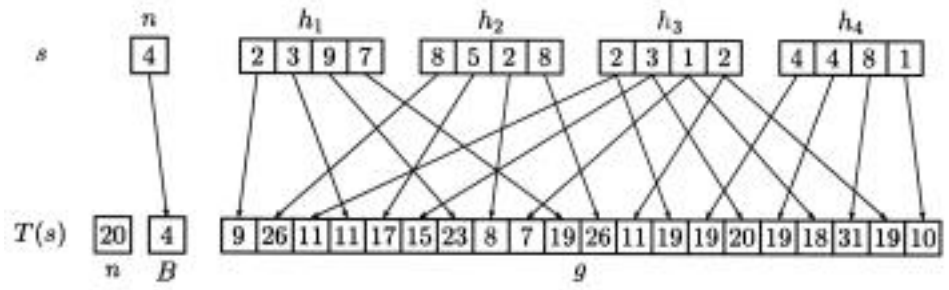


FIG. 3. *Example of an affine transformation.*

Note that each $T(s).g(y)$ depends on only one value $s.f_{g,i,r}(x)$. Also note that the size of the transformed input $T(s)$ is given by an affine function with respect to the size of s.

Intuitively, affine transformations allow linear transformations as well as "shuffle" and "concatenation" of the functions of the input structure. We illustrate the definition with a very simple example.

Example 2. Let $\mathbf{t}$ consist of the function symbols $h_1, \ldots, h_4$, and let $\mathbf{t}'$ consist of the function symbol g and the constant symbol B. We define an affine transformation from $\mathbf{t}$-structures to $\mathbf{t}'$-structures by choosing the following parameters.

- $l = 2$.
- $d_1 = 3$, $d_2 = 2$.
- $\alpha_1(n) = \alpha_2(n) = n$.
- $\beta_B(n) = n$.
- $f_{g,1,0} = h_1$, $f_{g,1,1} = h_2$, $f_{g,1,2} = h_3$.
- $f_{g,2,0} = h_3$, $f_{g,2,1} = h_4$.
- $A_{g,1,0}(n, y) = n + 2y + 1$.
- $A_{g,1,1}(n, y) = 3y + 2$.
- $A_{g,1,2}(n, y) = 4y + 3$.
- $A_{g,2,0}(n, y) = 3n + y + 5$.
- $A_{g,2,1}(n, y) = 3y + 7$.

Figure 3 shows s and $T(s)$ for an input structure s with $s.n = 4$. For example, $g(14) = 20$ because $14 = 0 + 2 \times \mathbf{1} + 3 \times 4$ and $A_{g,2,0}(4, f_{g,2,0}(\mathbf{1})) = 3 \times 4 + 3 + 5$. The function g in $T(s)$ can be seen as the concatenation of the shuffle of three linear transformations of h_1, h_2, h_3, respectively, and the shuffle of two linear transformations of h_3 and h_4, respectively.

Our transformations compose well as is shown by the result that follows. The proof is straightforward.

LEMMA 2.4. *If T and T' are affine transformations, then the composed transformation $T' \circ T$ is also affine.*

DEFINITION 2.5. *Let L, L' be two decision problems, i.e., sets of RAM data structures. An* affine reduction *from L to L' is an affine transformation T such that, for each RAM data structure s, we have $s \in L$ if and only if $T(s) \in L'$. If such a reduction exists, we write $L \leq_a L'$.*

Remark 1. The intention of the notion of affine reduction is two-fold. Affine reductions are

- *machine-independent* and
- at least as restrictive as the classical notions of reductions as indicated by the following proposition.

PROPOSITION 2.6. *An affine transformation can be computed by a deterministic Turing machine that works both in linear time and logarithmic space (when RAM data structures are represented by strings).*

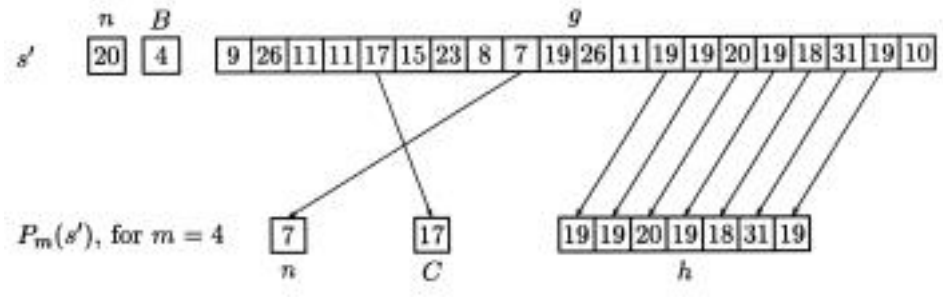

FIG. 4. *Example of an affine projection.*

Remark 2. In fact, affine reductions refine the very strict reset-log-lin reductions defined and used by [5].

In this article, we are mainly interested in RAM functions and not in decision problems. For a reduction between RAM functions, we need a means to extract a RAM data structure from another, possibly larger, RAM data structure. For this purpose, we define affine projections, which are much stricter than affine transformations.

DEFINITION 2.7. *Let* $\mathbf{t}$ *and* $\mathbf{t}'$ *be types of RAM data structures. An* affine projection P *is a transformation*

$$P : (m, s) \longrightarrow P_m(s),$$

where $m \in \mathbb{N}$ *and* s *and* $P_m(s)$ *are RAM data structures of respective types* $\mathbf{t}$ *and* $\mathbf{t}'$*, such that* $P_m(s)$ *is defined as follows.*

(1) *For each constant symbol* C *of* $\mathbf{t}'$*, and, in particular, for the symbol* n*, the values* $P_m(s).C$ *are determined in one of the following two ways.*
   - *Either there is a constant symbol* D_C *of* $\mathbf{t}$ *such that, for each* $\mathbf{t}$*-structure* s *and each* m*, it holds that* $P_m(s).C = s.D_C$*, or*
   - *there are a function symbol* f_C *of* $\mathbf{t}$ *and an affine function* $\alpha_C : \mathbb{N} \to \mathbb{N}$ *such that, for each* $\mathbf{t}$*-structure* s *and each* $m \in \mathbb{N}$*, it holds that* $P_m(s).C = s.f_C(\alpha_C(m))$*.*

(2) *For each function symbol* g *of* $\mathbf{t}'$*, there are a function symbol* f_g *of* $\mathbf{t}$ *and an affine function* $A_g : \mathbb{N}^2 \to \mathbb{N}$ *such that, for each* $\mathbf{t}$*-structure* s *and each* $m, a \in \mathbb{N}$*, it holds that* $P_m(s).g(a) = s.f_g(A_g(m, a))$*.*

In this definition, we again stick to the convention that $s.f(x) = 0$ whenever $x \geq s.n$.

Intuitively, the additional argument m in P corresponds to the input size, and each component of the output $P_m(s)$, e.g., $P_m(s).g(a) = s.f_g(A_g(m, a))$, is a copy of some component of the original output s, the address of which is given by some affine function.

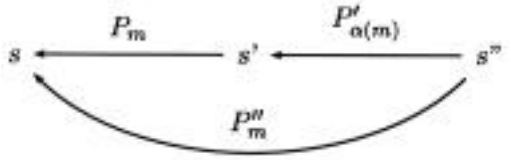
Example 3. We continue Example 2. Again let $\mathbf{t}'$ consist of the function symbol g and the constant symbol B, and let $\mathbf{t}$ have the constant symbol C and the function symbol h. In Figure 4, we illustrate $P_m(s')$ for $m = 4$ and the affine projection P, which is given by setting

- $f_n = g$ and $\alpha_n(m) = 2m$,
- $f_C = g$ and $\alpha_C(m) = m$, and
- $f_h = g$ and $A_h(m, a) = 3m + a$,

where $s' = T(s)$ is the transformed structure from Example 2. The reader should note how m is used to determine where the values for $P_m(s').n$, $P_m(s').C$, and $P_m(s').h$ can be found in $s'.g$.

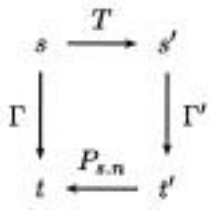
Affine projections compose well as is shown by the technical result that follows. The proof is straightforward.

LEMMA 2.8. *If P and P' are affine projections of appropriate types and $\alpha : \mathbb{N} \to \mathbb{N}$ is an affine function, then the mapping P'' defined by the commutative diagram*



i.e., such that $P''(m, s'') = P(m, P'(\alpha(m), s''))$, is also an affine projection.

DEFINITION 2.9. *Let Γ, Γ' be two RAM functions. An* affine reduction *ρ from Γ to Γ' is a pair (T, P), where T is an affine transformation and P is an affine projection such that the following diagram is commutative for all RAM structures s, s', t, t' of the appropriate types.*



In other words,

$$\Gamma(s) = P(s.n, \Gamma'(T(s)))$$

for each RAM data structure s.

If ρ is an affine reduction from Γ to Γ', then we write $\Gamma \to_\rho \Gamma'$. To express that there exists *an affine reduction from Γ to Γ', we write $\Gamma \leq_a \Gamma'$.*

Examples and properties of affine reductions. Affine reductions between RAM functions are a generalization of affine reductions between decision problems.

We note that the relation $\leq_a$ is reflexive and transitive.

- For each RAM function, we have $\Gamma \to_\rho \Gamma$ by the affine reduction $\rho = (T, P)$, where $T(s) = s$ and $P_m(t') = t'$.
- The transitivity follows from Lemmas 2.4 and 2.8.

Next, we are going to illustrate the notion of affine reductions by two more involved examples. First, we show that, for each $k > 3$, the classical reduction from k-satisfiability (-SAT) to 3-SAT can be turned into an affine reduction.

Example 4. Let $k \geq 3$ be fixed. The problem k-SAT is defined as follows.

Input. An integer p and n clauses $C_0, \ldots, C_{n-1}$ of k literals with variables from $v_0, \ldots, v_{p-1}$.

Question. Is $C_0 \wedge \cdots \wedge C_{n-1}$ satisfiable?

We represent an input for k-SAT by a RAM data structure s with one constant P and $2k$ functions $f_1, \ldots, f_k$ and $g_1, \ldots, g_k$. Here P represents the number of variables,

and, for each $i \leq s.n$ and each $j \leq k$, the jth literal of clause C_i is $v_{f_j(i)}$ if $g_j(i) = 1$ and $\neg v_{f_j(i)}$ if $g_j(i) = 0$.

The idea of the reduction is to transform a clause $(l_1^i \vee l_2^i \vee \cdots \vee l_k^i)$ into clauses $(\neg y_2^i \vee l_1^i \vee l_2^i)$, $(\neg y_3^i \vee y_2^i \vee l_3^i)$, $\ldots$, $(\neg y_{k-2}^i \vee y_{k-3}^i \vee l_{k-2}^i)$, and $(y_{k-2}^i \vee l_{k-1}^i \vee l_k^i)$, where the y_j^i, $i < n, 2 \leq j \leq k-2$, are new variables which intuitively represent the values of $l_1^i \vee \cdots \vee l_j^i$.

It is now easy to verify that this transformation is affine for the above representation of k-SAT instances. We encode the variables y_j^i by the single-indexed variables $v_{p+(k-2)i+j}$. The transformation T from k-SAT instances to 3-SAT instances can be defined as follows.

(1) $l = 1$, $d_1 = k-2$, and $T(s).n = (k-2)s.n$.
(2) $T(s).P = s.P + (k-1)s.n$.
(3)
- $T(s).f_1((k-2)x) = s.P + (k-2)x + 2$, $T(s).g_1((k-2)x) = 0$ (corresponding to the first literal $\neg y_2^i$ in the first clause that replaces a clause of s).
- More generally, $T(s).f_1(r+(k-2)x) = s.P+(k-2)x+(r+2)$, $T(s).g_1(r+(k-2)x) = 0$ for each r, $0 \leq r \leq k-4$.
- $T(s).f_1((k-3)+(k-2)x) = s.P + (k-2)x + (k-2)$, $T(s).g_1((k-3)+(k-2)x) = 1$ (corresponding to the first literal of the last clause).
- $T(s).f_2((k-2)x) = s.f_1(x)$, $T(s).g_2((k-2)x) = s.g_1(x)$ and $T(s).f_2((k-3)+(k-2)x) = s.f_{k-1}(x)$, $T(s).g_2((k-3)+(k-2)x) = s.g_{k-1}(x)$ (corresponding to the second literal of the first and last clause, respectively).
- $T(s).f_2(r+(k-2)x) = s.P+(k-2)x+(r+1)$, $T(s).g_2(r+(k-2)x) = 1$ for all r, $1 \leq r \leq k-4$.
- $T(s).f_3(r+(k-2)x) = s.f_{r+2}(x)$, $T(s).g_3(r+(k-2)x) = s.g_{r+2}(x)$ for all r, $0 \leq r \leq k-4$.
- $T(s).f_3((k-3)+(k-2)x) = s.f_k(x)$, $T(s).g_3((k-3)+(k-2)x) = s.g_k(x)$.

As a second example, we sketch why the problem CONTRACT is complete for the class **NLIN** under affine reductions. This problem was introduced in [18], where it was also shown to be complete for **NLIN** under **DTIME**(n)-reductions. For simplicity, we restrict ourselves in the following to RAM data structures with only one unary function f.

The problem CONTRACT is defined as follows.

Input. A set C of constants, a set V of variables, a set $\mathcal{F}$ of unary function symbols, and a set γ of triples (f, u, v), where $f \in \mathcal{F}$, $u, v \in C \cup V$.

Question. Is there a function VAL : $C \cup V \to C$ which is the identity on C such that the equations $f(\mathrm{VAL}(u)) = VAL(v)$, $(f, u, v) \in \gamma$, define partial functions for each $f \in \mathcal{F}$?

We think of the triples (f, u, v) of γ as equations $f(u) = v$.

The proof that CONTRACT is complete for **NLIN** under affine reductions makes use of the following normal form theorem of Olive [29].

THEOREM 2.10. *Every decision problem L in* **NLIN** *with one unary function symbol f is expressible by a formula of the form*

$$\exists \overline{f}\ \ \forall x \varphi(x, \overline{f}, f, succ, zero),$$

where φ is a quantifier-free formula of the form $\bigwedge_{i=1}^{k} \sigma_i(x) = \tau_i(x)$. Here $\overline{f}$ is a tuple of unary function symbols, succ and zero denote the successor function and the everywhere 0 function, respectively, and the σ_i and τ_i are terms over $f, \overline{f}, succ, zero$. More precisely, a 1-bounded structure s is in L if and only if $(s, succ, zero) \models \exists \overline{f}$

$\forall\, x\varphi(x)$, *where succ and zero are defined by* $succ(i) = i + 1$ *for all* $i < n - 1$, $succ(n - 1) = n - 1$, *and* $zero(i) = 0$ *for all* $i < n$.

From this theorem, it is easy to deduce the following corollary.

COROLLARY 2.11. *For any decision problem* L *in* **NLIN**, *it holds that* $L \leq_a$ *CONTRACT.*

We illustrate the proof of the corollary by the following example.

Example 5. Let L be expressible by the following sentence.

$$\exists g, h \quad \forall x f(g(x)) = h(x) \wedge h(\mathrm{succ}(x)) = \mathrm{zero}(g(x)).$$

First, for each structure s, $s \in L$ if and only if the following formula is satisfiable on the domain $[n]$.

$$(*) \qquad \mathrm{Diag}(\mathrm{succ}) \wedge \mathrm{Diag}(\mathrm{zero}) \wedge \mathrm{Diag}(f) \wedge \exists g, h \quad \forall x \varphi(x),$$

where

- $\varphi(x) \equiv f(g(x)) = h(x) \wedge h(\mathrm{succ}(x)) = \mathrm{zero}(g(x))$,
- $\mathrm{Diag}(\mathrm{succ}) \equiv (\bigwedge_{i<n-1} \mathrm{succ}(i) = i + 1) \wedge (\mathrm{succ}(n - 1) = n - 1)$,
- $\mathrm{Diag}(\mathrm{zero}) \equiv \bigwedge_{i<n} \mathrm{zero}(i) = 0$, and
- $\mathrm{Diag}(f) \equiv \bigwedge_{i<n} f(i) = s.f(i)$.

Second, we unfold the formula $\exists g, h\, \forall\, x\varphi(x)$, and hence we replace it by a formula $\bigwedge_{i<n} \varphi'(i)$. More precisely, let $(C, V, \mathcal{F}, \gamma)$ be the instance of CONTRACT which is given by $C = \{0, \ldots, n - 1\}$, $V = v_0, \ldots, v_{3n-1}$, $\mathcal{F} = \{f, g, h, \mathrm{succ}, \mathrm{zero}\}$, and the set γ is defined below. Intuitively, the variables $v_0, \ldots, v_{n-1}$ correspond to the terms $g(x)$, the variables $v_n, \ldots, v_{2n-1}$ correspond to the terms $h(x)$, and the variables $v_{2n}, \ldots, v_{3n-1}$ correspond to the terms $\mathrm{succ}(x)$.

The equations of γ are those which are given by Diag(succ), Diag(zero), and Diag(f) plus the following equations for every $i < n$:

- $g(i) = v_i$,
- $h(i) = v_{i+n}$,
- $f(v_i) = v_{i+n}$,
- $\mathrm{succ}(i) = v_{i+2n}$,
- $h(v_{i+2n}) = 0$.

Clearly, the above formula $(*)$ is satisfiable on $[n]$ if and only if γ is satisfiable on $C = [n]$. Hence $s \in L$ if and only if $(C, V, \mathcal{F}, \gamma) \in$ CONTRACT.

Moreover, this reduction from L to CONTRACT can be made affine. To this end, we represent instances $(C, V, \mathcal{F}, \gamma)$ by RAM data structures with constant symbols C, V, F and functions f_1, f_2, f_3. The symbols $s.C$, $s.V$, and $s.F$ represent the size of C, V, and $\mathcal{F}$, respectively, in a natural way. The value $s.n$ coincides with the number of triples in γ. The ith triple of γ is represented by $(s.f_1(i), s.f_2(i), s.f_3(i))$, where we view the elements of C to be numbered from 0 to $s.C - 1$, the elements of V from $s.C$ to $s.C + s.V - 1$, and the elements of $\mathcal{F}$ from 0 to $s.F - 1$.

It is straightforward to see that the above reduction can be made affine in this framework. For example, if the successor function symbol is numbered f_0 and we represent the successor function at the beginning of each instance s, then we get, for each $i < s.n - 1$, $s.f_1(i) = 0, s.f_2(i) = i, s.f_3(i) = i + 1$ (corresponding to the triple $(\mathrm{succ}, i, i + 1)$), and $s.f_1(s.n - 1) = 0, s.f_2(s.n - 1) = s.n - 1, s.f_3(s.n - 1) = s.n - 1$ (for $(\mathrm{succ}, s.n - 1, s.n - 1)$); in other words, we use the affine functions $\alpha_1(n) = n - 1$, $\alpha_2(n) = 1$ with the corresponding integers $d_1 = d_2 = 1$. For example, for $s.f_3$, we get the following values: $s.f_3(i) = i + 1$ for $i < \alpha_1(s.n) = s.n - 1$ and $s.f_3(i + \alpha_1(s.n)) = s.n - 1$ for $i < \alpha_2(s.n) = 1$ and hence for $i = 0$.

3. The algebraic framework. In this section, we are going to give two algebraic characterizations of **DLIN**. In subsection 3.1, we define simultaneous recursion schemes. These are recursion schemes that define several functions at once. From the structure containing these functions, the output data structure is extracted by an affine projection. In subsection 3.2, we introduce nonsimultaneous recursion schemes. These schemes allow more liberal operators, but they can define only a single function.

3.1. A linear simultaneous recursion scheme (LSRS). First, we define simultaneous recursion schemes. We allow two kinds of equations: standard equations that use arithmetical operations and a new kind that use two new operators, *Bounded Application* and *Equal-Predecessor*. Let us consider a function $f : [n] \to \mathbb{N}$. We define

Bounded Application.

$$f[x]_y := \begin{cases} f(x) & \text{if } x < y, \\ x & \text{otherwise.} \end{cases}$$

Equal-Predecessor.

$$f^{\leftarrow}(x) := \begin{cases} \max\{y < x : f(y) = f(x)\} & \text{if such a } y \text{ exists,} \\ x & \text{otherwise.} \end{cases}$$

It will turn out that the combination of these two operators captures the essence of random access read and write operations.

DEFINITION 3.1. *Let F be a set of unary function symbols, and let $f_1, \dots, f_k$ be unary function symbols that do not occur in F. For every $i \in \{0, \dots, k\}$, we write F_i for the set $F \cup \{f_1, \dots, f_i\}$. A* linear simultaneous recursion scheme (LSRS) *S for $f_1, \dots, f_k$ with respect to F is a sequence $E_1, \dots, E_k$ of equations, where each E_i is of one of the following two forms:*

- *(operation) $f_i(x) = g(x) * g'(x)$, where $g, g' \in F_{i-1}$ and $* \in \{+, -\}$,*
- *(recursion) $f_i(x) = g'[g^{\leftarrow}(x)]_x$, where $g \in F_{i-1}$ and $g' \in F_k$.*

Remark 3. We could choose other, more general, types of equations in the definition of LSRS, e.g., the following types:

- any operations that are computable in linear time on a Turing machine (see [17]) and also multiplication, which is not known to be computable in linear time;
- (bounded composition) $f_i(x) = g'[g(x)]_x$, where $g \in F_{i-1}$ and $g' \in F_k$;
- (bounded search)

$$f_i(x) = \begin{cases} \max\{y < x \mid g'(y) = g(x)\} & \text{if such a } y \text{ exists,} \\ x & \text{otherwise,} \end{cases}$$

  where $g \in F_{i-1}$ and $g' \in F_k$. (Note that the Equal-Predecessor is a bounded search with $g = g'$.)

It is a consequence of the results of this article that all of these schemes define the same class of functions, namely, **DLIN**. We have chosen the above definition mainly for two reasons:

- it is small in size, as it has only two types of equations;
- it will enable us to prove other characterizations of **DLIN** in a smooth way, e.g., a new recursion scheme without *simultaneous* recursion (see the linear recursion scheme (LRS) in 3.2).

LEMMA 3.2. *Let S be an LSRS for function symbols $f_1, \dots, f_k$ with respect to a set $F = \{f'_1, \dots, f'_l\}$ of function symbols. Then, for all integers m and functions*

$f'_1, \ldots, f'_l : [m] \to [m]$, there are unique functions $f_1, \ldots, f_k : [m] \to [m]$ which fulfill the equations of S with the overflow convention *that $f_i(a) = 0$ if the term defining $f_i(a)$ by an addition evaluates to a value $\geq m$.*

Proof. It is sufficient to observe that the computation of every term $f_i(x)$, $1 \leq i \leq k$, $x < m$, requires only the values of terms of the form $f_j(y)$, where the pair (y, j) precedes the pair (x, i) in the natural lexicographical order on pairs of natural numbers; so all terms can be computed in that order. □

Given a type $\mathbf{t}$, we write in the following $\mathbf{F_t}$ to denote the set $\{\mathbf{1}, \mathbf{n}, \mathbf{id}\} \cup \{\mathbf{f}_C \mid C \in \mathbf{t}\} \cup \{f \mid f \in \mathbf{t}\}$ of function symbols.

DEFINITION 3.3. *Let $\mathbf{t}_1, \mathbf{t}_2$ be types. Let Γ be a RAM function, which maps RAM data structures of type $\mathbf{t}_1$ to RAM data structures of type $\mathbf{t}_2$. Let S be an LSRS for $f_1, \ldots, f_k$ with respect to $\mathbf{F}_{\mathbf{t}_1}$. Γ is* linearly represented by *S if there are an integer c and an affine projection P such that, for each $c(\Gamma)$-bounded RAM data structure s, S defines functions $f_1, \ldots, f_k : [cs.n] \to [cs.n]$ with respect to the following functions $[cs.n] \to [cs.n]$:*

- *for every function symbol $f \in \mathbf{t}_1$,*

$$\mathbf{f}(i) = \begin{cases} s.f(i) & \text{if } i < s.n, \\ 0 & \text{else,} \end{cases}$$

- *$\mathbf{f}_C(i) = s.C$ for every constant symbol $C \in \mathbf{t}_1$,*
- *$\mathbf{1}(i) = 1$ for every i,*
- *$\mathbf{n}(i) = s.n$ for every i,*
- *$\mathbf{id}(i) = i$ for every i,*

and $P_{s.n}(s') = \Gamma(s)$, where s' is the RAM data structure of size $cs.n$ with the functions $f_1, \ldots, f_k$.

If a RAM function Γ is linearly represented by an LSRS, then we call Γ LSRS-definable*. We say that a RAM decision problem L of type $\mathbf{t}$ with magnification bound c is* LSRS-definable *if the following RAM function Γ, which maps RAM data structures of type $\mathbf{t}$ to 1-bounded RAM data structures of type $\{C\}$, is LSRS-definable. For each s, Γ is defined by*

- *$\Gamma(s).n = s.n$ and*
- $$\Gamma(s).C = \begin{cases} 1 & \text{if } s \in L, \\ 0 & \text{if } s \notin L. \end{cases}$$

Example 6. As an example, we consider an LSRS S for the RAM function Γ, which maps RAM data structures of type $\{f\}$ to RAM data structures of type $\{C\}$ such that, for each s, $\Gamma(s).n = s.n$ and $\Gamma(s).C = \max\{s.f(j) \mid j < s.n\}$.

S defines functions f_1, f_2, f_3, f_4 by the following equations:

$$\begin{aligned} f_1(x) &= f_3[\mathbf{1}^{\leftarrow}(x)]_x, \\ f_2(x) &= \mathbf{f}(x) - f_1(x), \\ f_3(x) &= f_1(x) + f_2(x), \\ f_4(x) &= \mathbf{n}(x) - \mathbf{1}(x). \end{aligned}$$

Note that $f_3[\mathbf{1}^{\leftarrow}(0)]_0 = 0$, by definition of Bounded Application and Equal-Predecessor, and that $f_3[\mathbf{1}^{\leftarrow}(i)]_i = f_3(i-1)$ for $i > 0$. S defines functions f_1, f_2, f_3 such that

- $f_1(i) = f_3(i-1)$,
- $f_2(i) = s.f(i) - f_2(i-1)$, and
- $f_3(i) = \max\{s.f(j) \mid j \leq i\}$ for each $i < s.n$.

To see this, recall, by our convention, that $b-a = 0$ if $b < a$, and, therefore, $a+(b-a) = \max\{a, b\}$ for all a, b. We get

$$\begin{aligned} f_3(i) &= f_1(i) + (s.f(i) - f_1(i)) \\ &= \max(f_1(i), s.f(i)) \\ &= \begin{cases} s.f(0) & \text{if } i = 0, \\ \max(f_3(i-1), s.f(i)) & \text{otherwise.} \end{cases} \end{aligned}$$

In particular, $f_3(s.n-1) = \max\{s.f(j) \mid j < s.n\} = \Gamma(s).C$. Hence S defines Γ with $c = 1$ and the affine projection P, which is given by $f_n = f_4$, $\alpha_n(m) = 0$, $f_C = f_3$, and $\alpha_C(m) = m - 1$.

It will be convenient to allow somewhat more relaxed recursion schemes. In particular, we allow, in the equation for any f'_i, instead of expressions $g(x) * g'(x)$, arbitrary arithmetical expressions using $-, +$, and functions $g \in F_{i-1}$, and we allow the use of *definition by cases*.

DEFINITION 3.4. *A function f_i is defined by cases if it is defined as*

$$f_i(x) = \begin{cases} g_1(x) & \text{if } g(x) \le h(x), \\ g_2(x) & \text{otherwise,} \end{cases}$$

where g, h, g_1, g_2 have to be in F_{i-1}.

LEMMA 3.5. *Any RAM function that is linearly represented by an LSRS using arbitrary arithmetic expressions and definition by cases can be linearly represented by an LSRS without definition by cases.*

Proof. A definition of a function f_i which uses a more complicated arithmetic expression can easily be replaced by a series of definitions of functions that use only terms of the form $g(x) * g'(x)$. Now we describe how definition by cases can be simulated. First, note that the convention that $a - b$ equals 0 whenever $a < b$ also implies, for all $a, b \in \mathbb{N}$, the following two statements.

- $a - (a - b) = \min(a, b)$,
- $1 - (a - b) = \begin{cases} 1 & \text{if } a \le b, \\ 0 & \text{otherwise.} \end{cases}$

Furthermore, if we restrict ourselves to the domain $[m]$ for some $m > 0$, it follows from our overflow convention for addition (cf. Lemma 3.2) that, for all $a, b, c \in [m]$,

$$\min(a, (m-1) + (1-c)) + \min(b, (m-1) + c) = \begin{cases} a & \text{if } c > 0, \\ b & \text{if } c = 0. \end{cases}$$

This allows us to simulate definitions by cases by using several new functions that are defined by using arithmetic operations ($+$ and $-$) only. □

Remark 4. It should be pointed out that the proof of Lemma 3.5 relies on the choice of the overflow convention. Although we view this choice as natural, we would like to mention other possibilities.

1. We could allow multiplication in LSRS. The simulation of definitions by cases could then simply be obtained by using

$$a \times c + b \times (1 - c) \begin{cases} a & \text{if } c = 1, \\ b & \text{if } c = 0. \end{cases}$$

It follows from Proposition 2.1 and Theorem 4.1 that this change would not increase the expressive power of LSRS.

2. Alternatively, definitions by cases could be simulated by allowing only multiplication with constants via

$$\min(a,(m-1)\times c)+\min(b,(m-1)\times(1-c))=\begin{cases}a & \text{if } c>0,\\ b & \text{if } c=0.\end{cases}$$

3. A further possibility would be to make use of *bounded composition* (cf. Remark 3) via

$$\min(a,g(c))+\min(b,g(1-c))=\begin{cases}a & \text{if } c>0,\\ b & \text{if } c=0,\end{cases}$$

where g is the easily definable function with $g(0)=0$ and $g(i)=m-1$ for all other i.

The next easy lemma states that the set of LSRS-definable RAM functions is closed under composition.

LEMMA 3.6. *Let Γ_1 be a RAM function which maps RAM data structures of type $\mathbf{t}_1$ to RAM data structures of type $\mathbf{t}_2$, and let Γ_2 be a RAM function which maps RAM data structures of type $\mathbf{t}_2$ to RAM data structures of type $\mathbf{t}_3$. If Γ_1 is LSRS-definable and Γ_2 is LSRS-definable, then $\Gamma_2\circ\Gamma_1$ is also LSRS-definable.*

It should be noted that the LSRS defined in this article is different from the LSRS of [34]. On one hand, it uses a smaller set of operations, on the other hand, the underlying domain of the defined functions is allowed to be linear in the size n of the input whereas that domain was exactly $[n]$ in [34].

3.2. A one-function one-equation linear recursion scheme. Is it possible to avoid simultaneous recursion in an LSRS, as asked in [34]? In this subsection, we give a positive answer to this question: each problem that is linearly representable by an LSRS can also be represented by a one-function one-equation recursion scheme, which we call LRS. The price to be paid is a slightly greater number of constructs for subterms of the LRS.

First, we define inductively what a *recursion term* $\sigma(x)$ with respect to a function symbol g and a type $\mathbf{t}$ is.

- 1, n, and x are recursion terms.
- C is a recursion term for each constant symbol C from $\mathbf{t}$.
- (Equal-Predecessor) $g^{\leftarrow}(x-\delta)$ is a recursion term for every integer $\delta>0$.
- (Bounded Application) If $\sigma(x)$ is a recursion term, then $g[\sigma(x)]_x$ is a recursion term.
- (Input application) If $\sigma(x)$ is a recursion term and f is a function symbol of $\mathbf{t}$, then $f(\sigma(x))$ is a recursion term.
- (Arithmetic operation) If $\sigma(x)$ and $\tau(x)$ are recursion terms, then, for each $*\in\{+,-\}$, $(\sigma(x)*\tau(x))$ is a recursion term.

Unnecessary brackets can be omitted.

DEFINITION 3.7. *A* linear recursion scheme (LRS) *with respect to g and $\mathbf{t}$ is an equation of the form $g(x)=\sigma(x)$ for some recursion term $\sigma(x)$ with respect to g and $\mathbf{t}$.*

Example 7.

$$g(x)=(g[g^{\leftarrow}(x-2)]_x+x)-f(x+C)$$

is an LRS with respect to g and the type $\mathbf{t}=\{f,C\}$.

LEMMA 3.8. *Let $\sigma(x)$ be a recursion term with respect to g and $\mathbf{t}$. Then, for all integers $m > 0$ and all structures s of type $\mathbf{t}$, there is a unique function $g : [m] \to [m]$, which satisfies the equation $g(a) = \sigma(a)$ for every $a < m$ with the following conventions:*

- *$\tau(a) = 0$ if, for a subterm τ of σ, $\tau(a)$ evaluates to a value which is not in $[m]$;*
- *$f(j) = s.f(j)$ for $j < s.n$, and $f(j) = 0$ for $j \geq s.n$, for every function symbol f of $\mathbf{t}$;*
- *$C = s.C$ for every constant symbol C of $\mathbf{t}$.*

We say that the function $g : [m] \to [m]$ is *defined by the LRS $g(x) = \sigma(x)$ in s*. We call $[m]$ the *range* of this definition.

Proof. For the proof, it is sufficient to verify that, for every a, the evaluation of $\sigma(a)$ needs only values $g(b)$ for numbers $b < a$. □

Remark 5. Note that $g(a) = \sigma(a)$ should also hold for $a = 0$; in this case, notice the interpretation of the possible subterms of the respective forms $g[\sigma(x)]_x$ and $g^{\leftarrow}(x - \delta)$ of respective values $\sigma(0)$ and $g^{\leftarrow}(0) = 0$.

DEFINITION 3.9. *Let E be an LRS given by $g(x) = \sigma(x)$. Let Γ be a RAM function. Γ is* linearly represented *by E if there is a constant c and an affine projection P, such that, for each $c(\Gamma)$-bounded RAM data structure s, E defines a function $g : [cs.n] \to [cs.n]$ in s, such that $P_{s.n}(s') = \Gamma(s)$, where s' is the RAM data structure of size $cs.n$ with the single function g.*

As in the case of LSRS, we can make use of definition by cases without changing the expressive power of LRS. The following lemma shows that simultaneous recursion schemes are no more powerful than nonsimultaneous schemes.

LEMMA 3.10. *Every RAM function that is linearly representable by an LSRS is also linearly representable by an LRS.*

Proof. Let Γ be a RAM function that is linearly represented by an LSRS S, which defines functions[4] $f_0, \ldots, f_{k-1}$ with respect to $\mathbf{F}_{\mathbf{t}_1}$, as in Definition 3.3, and let P be the corresponding affine projection. Let s be a $c(\Gamma)$-bounded RAM data structure of type $\mathbf{t}_1$. We write s' for the structure that is defined by S on s and s'' for $\Gamma(s) = P_{s.n}(s')$. To simplify notation in the following, we write n to denote $s.n$. Roughly, the idea is to first encode the functions $f_0, \ldots, f_{k-1} : [cn] \to [cn]$ by one function g. To ensure that the Equal-Predecessor operation works properly, the encodings of the different functions should have disjoint domain and disjoint range. This is done by using, for each $i < k$, only values that are congruent i modulo k to encode function f_i. As a tool for encoding and decoding operations, we additionally encode the function $(\div k)$ into g.

We are going to extend the domain of g in order to encode $\Gamma(s).f$, for each function symbol f of the output data structure, by function values of a contiguous interval.

More precisely, g will be defined on $[2kcn]$ such that

- for each $b < kcn$, it holds that $g(b) = b \div k$, and
- for every a and i, where $a < cn$ and $0 \leq i \leq k - 1$, it holds that

$$(*) \qquad g(kcn + ka + i) = kcn + kf_i(a) + i.$$

In other terms, for $b \geq kcn$ and $b \bmod k = j$, the value of $g(b)$ is $kcn + kf_j((b - kcn) \div k) + j$. We are going to define the value $g(b)$ for $b < 2kcn$ by case distinction on $b \bmod k$, as described in (1)–(3) below.

[4] We enumerate the functions from 0 to $k - 1$ to facilitate computations modulo k.

(1) Let the function symbols of $\mathbf{F}_{\mathbf{t}_1} = \{f \mid f \text{ function in } \mathbf{t}_1\} \cup \{f_C \mid C \in \mathbf{t}_1\} \cup \{\mathbf{1}, \mathbf{n}, \mathbf{id}\}$ be enumerated by $\{f^0, \ldots, f^{l-1}\}$. For the sake of uniformity, we modify S to limit the occurrence of these function symbols. First, the old function symbols $f_0, \ldots, f_{k-1}$ and all of their occurrences in S are replaced by $f_l, \ldots, f_{k+l-1}$, respectively. Next, we introduce l new functions $f_0, \ldots, f_{l-1}$ and l equations which define them. If f^i is from $\mathbf{t}_1$, the defining equation is simply $f_i(x) = f^i(x)$. If f^i is $\mathbf{id}$, then the equation is $f_i(x) = x$; if it is $\mathbf{1}, \mathbf{n}$, or f_C, then the equation is $f_i(x) = 1$, $f_i(x) = n$, or $f_i(x) = C$, respectively. We refer to these equations as *input equations*. Finally, we replace in S all occurrences of functions from $\mathbf{F}_{\mathbf{t}_1}$ by the respective function symbols f_i.
It is straightforward that the modified system with the above $k+l$ equations is equivalent to S, under the obvious semantics, although S is no longer an LSRS. From now on, we refer to the new system by S, and k denotes the number of equations of S. After these replacements, S no longer refers to any functions of $\mathbf{F}_{\mathbf{t}_1}$ except in the input equations.

(2) The equations of S are combined into one equation $g(y) = \sigma(y)$ as follows.[5] The term $\sigma(y)$ consists of a definition by cases, depending on the size of y and on $y \bmod k$. More precisely, we define a recursion term $\sigma_i(y)$ corresponding to f_i for every $i < k$ and define g by

$$g(y) = \begin{cases} 0 & \text{if } y \leq k-1, \\ g(y-k)+1 & \text{if } k \leq y < kcn, \\ \sigma_i(y) & \text{if } y \geq kcn \text{ and } y \bmod k = i. \end{cases}$$

Of course, the two first cases imply that $g(y) = y \div k$ for each $y < kcn$, as required. This allows us to express $y \bmod k$ (for $kcn \leq y < 2kcn$) as $(y - kcn) - kg(y - kcn) = (y - kcn) - \sum_{j=1}^{k} g(y - kcn)$.
The case distinction itself is done along the same lines as in the proof of Lemma 3.5 above.
Now we describe the construction of the recursion terms $\sigma_i(y)$.

- If E_i is an input equation, then $\sigma_i(y)$ is constructed as follows.
  - If the right-hand side is a constant C (possibly 1 or n), then $\sigma_i(y)$ is defined as $kcn + kC + i$.
  - If the right-hand side is x, then $\sigma_i(y)$ is defined as $kcn + kg(y - kcn) + i$.
  - If the right-hand side is $f^i(x)$, then $\sigma_i(y)$ is defined as $kcn + kf^i(g(y - kcn)) + i$.

  We justify why this definition of $\sigma_i(y)$ is correct. We do this for the third case; the other two cases are even simpler. Let $b = kcn + ka + i$ with $a < cn$. Then $g(b - kcn) = g(ka + i) = (ka + i) \div k = a$, and $\sigma_i(b) = kcn + kf^i(a) + i = kcn + kf_i(a) + i$, as required.
- If E_i is of the form $f_i(x) = f_j(x) - f_{j'}(x)$, then $\sigma_i(y)$ is defined by

$$\sigma_i(y) = (g(y - \delta) - kcn - j) - (g(y - \delta') - kcn - j') + kcn + i,$$

  where $\delta = i - j$, $\delta' = i - j'$, and, by definition of LSRS, $i > j, j'$. To verify the correctness of this expression, let $a \in [cn]$, $b = kcn + ka + i$, where $i < k$. If $g(b - \delta) = g(kcn + ka + j)$ equals $kcn + kf_j(a) + j$ and

[5] We choose y instead of x to distinguish the variable of the LRS from the variable of the LSRS.

$g(b-\delta') = g(kcn+ka+j')$ equals $kcn + kf_{j'}(a) + j'$, then

$$\begin{aligned}(g(b-\delta) - kcn - j) - (g(b-\delta') - kcn - j') + kcn + i \\ = (kf_j(a) - kf_{j'}(a)) + kcn + i \\ = k(f_j(a) - f_{j'}(a)) + kcn + i,\end{aligned}$$

as required.

- The case in which E_i is of the form $f_i(x) = f_j(x) + f_{j'}(x)$ is similar to the previous subtraction case. However, it requires an additional case distinction because of our convention that, in universe $[cn]$, the result of an addition is 0 in case of overflow, which is not the case in the enlarged universe $[2kcn]$ if a sum lies between kcn and $2kcn$. More precisely, $\sigma_i(y)$ is defined by

$$\sigma_i(y) = \begin{cases} \tau(y) + kcn + i & \text{if } \tau(y) < kcn, \\ kcn + i & \text{otherwise,} \end{cases}$$

where $\tau(y) = (g(y-\delta) - kcn - j) + (g(y-\delta') - kcn - j')$ with $\delta = i - j$ and $\delta' = i - j'$. The proof of the correctness of $\sigma_i(y)$ is similar to the previous subtraction case.

- If E_i is of the form $f_i(x) = f_{j'}[{f_j}^{\leftarrow}(x)]_x$, where $j < i$ and we assume without loss of generality that[6] $i \le j'$, then $\sigma_i(y)$ is defined by

$$\sigma_i(y) = g[g^{\leftarrow}(y-\delta) + \delta']_y - j' + i,$$

where again $\delta = i - j$ and $\delta' = j' - j$.

To justify this replacement, we have to ensure that the encoding of several functions into one function does not produce any side-effects when the Equal-Predecessor operator is applied. It is crucial here that, for each $i < k$, those function values of g which encode function values of f_i are congruent to i modulo k. To be more precise, let $b = kcn + ka + i$, with $a < cn$. Then $b - \delta = kcn + ka + i - (i - j) = kcn + ka + j$. Only two cases may arise.

(a) ${f_j}^{\leftarrow}(a) = a$. This means that, for no $a' < a$ does it hold that $f_j(a') = f_j(a)$. Hence there is no $a' < a$ such that $g(kcn + ka' + j) = g(kcn + ka' + j)$. The definition of g ensures that, for each $e \ge kcn$, $g(e) \bmod k = j$ if and only if $e \bmod k = j$ and that, for all $e, e' \in [2kcn]$, if $g(e) = g(e')$, either $e, e' < kcn$ or $e, e' \ge kcn$. Hence $g^{\leftarrow}(kcn+ka+j) = kcn+ka+j$, and $g^{\leftarrow}(b-\delta)+\delta' = kcn+ka+j' \ge kcn + ka + i = b$. Hence

$$\begin{aligned}\sigma_i(b) &= g[g^{\leftarrow}(b-\delta) + \delta']_b - j' + i \\ &= (kcn + ka + j') - j' + i \\ &= kcn + ka + i \\ &= kcn + kf_{j'}[{f_j}^{\leftarrow}(a)]_a + i \\ &= kcn + kf_i(a) + i \\ &= g(b),\end{aligned}$$

as required.

[6] If $i > j'$, then we first may add a new function f_l into S, with $l > i$, defined by the new equation $f_l(x) = f'_{j'}(x)$ and replace E_i by $f_i(x) = f_l[{f_j}^{\leftarrow}(x)]_x$.

(b) ${f_j}^{\leftarrow}(a) = a'$ for some $a' < a$. Then $g^{\leftarrow}(kcn+ka+j) = kcn+ka'+j$. In consequence,

$$g^{\leftarrow}(b-\delta)+\delta' = kcn+ka'+j' < kcn+ka+i = b.$$

Hence

$$\begin{aligned}\sigma_i(b) &= g[g^{\leftarrow}(b-\delta)+\delta']_b - j' + i\\ &= g(kcn+ka'+j') - j' + i\\ &= (kcn + kf_{j'}(a') + j') - j' + i\\ &= kcn + kf_{j'}(a') + i\\ &= kcn + kf_{j'}[{f_j}^{\leftarrow}(a)]_a + i\\ &= kcn + kf_i(a) + i\\ &= g(b),\end{aligned}$$

as required.

(3) Now we complete the LRS for g. For simplicity, we assume that $\mathbf{t}_2$ consists of the constant symbol n and only one function symbol h. Let $j < k$ and α be an affine function such that, for all structures s, it holds that $\Gamma(s).n = P_{s.n}(s').n = s'.f_j(\alpha(s.n))$, and let $i < k$ and A be an affine function such that, for all structures s and all $a < \Gamma(s).n$, it holds that $\Gamma(s).h(a) = P_{s.n}(s').h(a) = s'.f_i(A(s.n,a))$.
We have constructed g in such a way that all function values $f_i(a)$ are somehow available in g, but we have to deal with two problems. First, the $f_i(a)$ appear only in an encoded way; second, they do not form a contiguous interval but are scattered (modulo k). Hence, before we can extract the values by an appropriate affine projection, we have to decode the function values and bring them together into one interval. To accomplish this, we enlarge the domain of g to $[(2k+2)cn]$ and complete the definition of g as specified below.

$$g(y) = \begin{cases} \text{as before} & \text{if } y < 2kcn,\\ g[g[k(y-2kcn)+kcn+i]_y - kcn]_y & \text{if } 2kcn \le y < (2k+1)cn,\\ g[g[k(y-(2k+1)cn)+kcn+j]_y - kcn]_y & \text{if } (2k+1)cn \le y < (2k+2)cn.\end{cases}$$

It follows from equation $(*)$, the definition of g on $[kcn]$, and this definition that, for all $a < cn$, it holds that

$$\begin{aligned}g(2kcn+a) &= g[g[k(2kcn+a-2kcn)+kcn+i]_{2kcn+a} - kcn]_{2kcn+a}\\ &= g[g[ka+kcn+i]_{2kcn+a} - kcn]_{2kcn+a}\\ &= g[g(ka+kcn+i) - kcn]_{2kcn+a}\\ &= g[kcn + kf_i(a) + i - kcn]_{2kcn+a}\\ &= g[kf_i(a)+i]_{2kcn+a}\\ &= f_i(a).\end{aligned}$$

Analogously, we get that, for all $a < cn$, $g((2k+1)cn+a) = f_j(a)$. Now it is easy to define an affine projection P' which extracts $\Gamma(s)$ from the structure

s''' with the function g and the constant $s.n$ via $\Gamma(s).n = s'''.g(\alpha(s.n)+(2k+1)cs.n)$ and

$$\begin{aligned}\Gamma(s).h(a) &= P_{s.n}(s').h(a)\\ &= s'.f_i(A(s.n,a))\\ &= s'''.g(2kcs.n + A(s.n,a)).\end{aligned}$$ □

4. LRSs and linear time. In this section, we show that LSRS and LRS, which were defined in the previous section, exactly characterize the complexity class **DLIN**.

THEOREM 4.1. *Let Γ be a RAM function. Then the following assertions are equivalent.*

1. Γ *belongs to* **DLIN**.
2. Γ *is linearly represented by some LSRS.*
3. Γ *is linearly represented by some LRS.*

Since implication (2)$\Longrightarrow$(3) was proved in Lemma 3.10, it is sufficient to prove (1)$\Longrightarrow$(2) and (3)$\Longrightarrow$(1).

The proof of Lemma 4.2 below gives a slightly stronger result than implication (3)$\Longrightarrow$(1): with every LRS E, one can explicitly associate a "normalized" **DLIN** program which computes the RAM function Γ represented by E.

LEMMA 4.2. *If a RAM function Γ is linearly represented by an LRS E, then $\Gamma \in$* **DLIN**.

Proof. Let Γ be a RAM function which is linearly represented by the equation E, and let P be the corresponding affine projection. For simplicity, we assume that the type of the input structures of Γ consists of only one function symbol f_{in}. Recall that E consists of one equation of the form $g(x) = \sigma(x)$, where $\sigma(x)$ is a recursion term, and there is a constant c such that the output $s' = \Gamma(s)$ can be extracted from the function $g : [cs.n] \to [cs.n]$ and $s.n$. Instead of formally defining a RAM for Γ, we are going to give an algorithm that can easily be converted into a multimemory RAM, which in turn can be converted into a simple RAM (cf. section 2.2). Its data structure consists of variables p, x and, besides the input structure s and the output structure s', four one-dimensional arrays F_{in}, G, G_{inverse}, and EP. In p, we store the value $cs.n$, which bounds the domain and the range of the function g that is defined by E and s. Next we describe the intended meaning of F_{in}, G, G_{inverse}, and EP. For indices greater than or equal to $s.n$, F_{in} is 0; for smaller indices, it is determined by $s.f$. The main computation proceeds in p rounds, numbered from 0 to $p-1$. After round i of this computation, the following invariants should hold:

(a) for each $j < p$,

$$G[j] = \begin{cases} g(j) & \text{if } j \le i,\\ j & \text{if } i < j < p,\end{cases}$$

(b) $\text{EP}[j] = g^{\leftarrow}(j)$ for each $j \le i$, and

(c) for each $j < p$,

$$G_{\text{inverse}}[j] = \begin{cases} \max\{l \le i \mid g(l) = j\} & \text{if such an } l \text{ exists},\\ p & \text{otherwise.}\end{cases}$$

The computation of the values $G[i]$ is relatively straightforward. We associate with every recursion term $\sigma(x)$ a *programming term* $\sigma[x]$, which is recursively defined as follows:

- if $\sigma(x)$ is 1, n, x, then $\sigma[x]$ is 1, n, x, respectively;
- if $\sigma(x) = g^{\leftarrow}(x - \delta)$ for some δ, then $\sigma[x] = \mathrm{EP}[x - \delta]$;
- if $\sigma(x) = g[\tau(x)]_x$ for some subterm τ, then $\sigma[x] = G[\tau[x]]$;
- if $\sigma(x) = f_{\mathrm{in}}(\tau(x))$ for some subterm τ, then $\sigma[x] = F_{\mathrm{in}}[\tau[x]]$;
- if $\sigma(x) = \tau_1(x) * \tau_2(x)$ for subterms τ_1 and τ_2, then $\sigma[x] = \tau_1[x] * \tau_2[x]$.

In round i, we compute $G[i]$ by evaluating $\sigma[i]$. The only difficulty that arises is the evaluation of subterms of the form $g^{\leftarrow}(x-\delta)$, which would need more than a constant number of steps if it was done in a straightforward manner. Instead, we make use of the array EP, which contains, after round i, the value $g^{\leftarrow}(j)$ for each $j \le i$. G_{inverse} always holds a partial inverse of the function g on $\{0, \ldots, j\}$ and is used to compute EP.

The algorithm for Γ is as follows.

Input s
{ Initializations }
$p := cs.n$
EP[0] := 0
FOR $j := 0$ TO $s.n - 1$ DO
    $F_{\mathrm{in}}[j] := s.f(j)$
FOR $j := s.n$ TO $p - 1$ DO
    $F_{\mathrm{in}}[j] := 0$
FOR $j := 0$ TO $p - 1$ DO
    $G[j] := j$
    $G_{\mathrm{inverse}}[j] := p$
{ Main loop }
FOR $i := 0$ TO $p - 1$ DO
    $G[i] := \sigma[i]$
    $\mathrm{EP}[i] := \min(i, G_{\mathrm{inverse}}[G[i]])$
    $G_{\mathrm{inverse}}[G[i]] := i$
{ Output }
Compute the result s'' by applying the affine projection $P_{s.n}$
to the structure $s' = ([p], G)$

We show by induction on i that the above invariants (a)–(c) hold after each round i. Of course, they are satisfied after the initializations, i.e., before round 0. For the induction step, assume that (a)–(c) are satisfied *before* round i ($0 \le i \le p - 1$). We show that they also hold *after* round i and hence before round $i + 1$.

- $G[i] = g(i)$ holds because, by induction, we have $G[j] = g[j]_i$ for each $j \in [p]$ and $\mathrm{EP}[j] = g^{\leftarrow}(j)$ for each $j < i$; hence bounded application and equal predecessor are evaluated correctly.
- The assignment $\mathrm{EP}[i] := \min(i, G_{\mathrm{inverse}}[G[i]])$ implies that $\mathrm{EP}[i] = g^{\leftarrow}(i)$ by induction.
- It is also straightforward to observe that (c) is maintained by the assignment $G_{\mathrm{inverse}}[G[i]] := i$.

So (a)–(c), in particular (a), are invariants; this implies immediately that the program is correct.

The number of steps to evaluate a recursion term is linear in the size of the term. As the recursion term of E is fixed, we conclude that the computation of each $G[i]$ needs only a constant number of steps; therefore, the overall computation time of the program is $O(s.n)$.

It should be stressed that the structure of the resulting program is very simple, with essentially one main loop. □

It remains to prove the implication (1)$\Longrightarrow$(2) of Theorem 4.1.

LEMMA 4.3. *If a RAM function* Γ *is computed in time* $O(n)$ *on a simple* $\{+,-\}$*-RAM* M*, then* Γ *is linearly represented by some LSRS* S*.*

Proof. Let Γ be a RAM function. For simplicity, we assume that the type of the input as well as the type of the output consist of only one function symbol f. Let M be as in the statement of the lemma, and let $c > 0$ be such that M needs less than cn steps and uses numbers of size less than cn on $c(\Gamma)$-bounded inputs of size n.

The proof is similar to the one that was given to prove Theorem 3.1 (a) in [34]. Let us sketch the main ideas first. We are going to construct an LSRS that uses functions I, A, B, N, R_A, which are intended to describe the situation of the RAM *before* each step x, where

- $I(x)$ holds the current instruction number,
- $A(x)$, $B(x)$, and $N(x)$ hold the current values of registers A, B, N, respectively, and
- $R_A(x)$ holds the value of the register, the address of which is currently contained in register A.

For convenience, we also use functions I', A', B', R'_A, N', which describe the situation *after* a step of the RAM. By case distinctions on the value of $I(x)$, most of the simulation of the computation of M is straightforward. For example, if M executes a statement $A := A + B$, then the equations will force $A'(x) = A(x) + B(x)$. The main complication arises from the instruction $A := R_A$, which loads the content of the register, the number of which is contained in A (before the execution of the instruction), into A. Note that the functions that are defined by S do *not* explicitly encode the values of all registers of M at each time step t but only the content of the register to which A points. To get the right value for $R_A(t)$, the last time step before t at which A contained the value $A(t)$ (i.e., the current value) must be identified. If no such time step exists, we have to refer to the input. Recall that $s.f(i)$ is stored in $R(i)$ at the beginning of the computation. This is the point at which the recursion operation comes into play.

Compared with the proof of [34], we have to do some extra work here, as the recursion schemes in the present article have more restricted operations. In particular, in order to facilitate the simulation of $A := R_A$ instructions, we divide the domains of the functions into three main parts, $\{0, \dots, cn-1\}$, $\{cn, \dots, 2cn-1\}$, and $\{2cn, \dots, 3cn-1\}$. We use the first part to "store" $s.f$, the second part to actually simulate the computation of M, and the third part to extract the output function. In the third part, we use R_A for another purpose than that described before, namely, to encode the output.

We will take the liberty of using definition by cases (cf. Lemma 3.5) and some simple arithmetic operations that are not directly available in an LSRS. The translation into a pure LSRS is straightforward but involves the use of some more functions.

To simplify the presentation, we are going to describe the LSRS separately for the three parts of the domain. These definitions have then to be combined by using definition by cases.

The order of the function symbols is $I, A, B, N, R_A, I', A', B', N', R'_A$.

For $x < cn$, A and R_A are defined by

$$A(x) = x,$$
$$R'_A(x) = f(x).$$

TABLE 1
Equations of S for the middle part $\{cn, \ldots, 2cn-1\}$ of the domain.

$$I(x) = \begin{cases} 1 & \text{if } x = cn, \\ I'(x-1) & \text{otherwise,} \end{cases}$$

$$I'(x) = \begin{cases} i_0 & \text{if } I(x) \text{ is } \textbf{IF } \boldsymbol{A = B} \textbf{ THEN } \boldsymbol{I(i_0)} \textbf{ ELSE } \boldsymbol{I(i_1)} \text{ and } A(x) = B(x), \\ i_1 & \text{if } I(x) \text{ is } \textbf{IF } \boldsymbol{A = B} \textbf{ THEN } \boldsymbol{I(i_0)} \textbf{ ELSE } \boldsymbol{I(i_1)} \text{ and } A(x) \neq B(x), \\ I(x) & \text{if } I(x) \text{ is HALT,} \\ I(x)+1 & \text{otherwise,} \end{cases}$$

$$A(x) = \begin{cases} 0 & \text{if } x = cn, \\ A'(x-1) & \text{otherwise,} \end{cases}$$

$$A'(x) = \begin{cases} c & \text{if } I(x) \text{ is } \boldsymbol{A := c}, \\ A(x) * B(x) & \text{if } I(x) \text{ is } \boldsymbol{A := A * B}, \\ R_A(x) & \text{if } I(x) \text{ is } \boldsymbol{A := R_A}, \\ N(x) & \text{if } I(x) \text{ is } \boldsymbol{A := N}, \\ A(x) & \text{otherwise,} \end{cases}$$

$$B(x) = \begin{cases} 0 & \text{if } x = cn, \\ B'(x-1) & \text{otherwise,} \end{cases}$$

$$B'(x) = \begin{cases} A(x) & \text{if } I(x) \text{ is } \boldsymbol{B := A}, \\ B(x) & \text{otherwise,} \end{cases}$$

$$N(x) = \begin{cases} n & \text{if } x = cn, \\ N'(x-1) & \text{otherwise,} \end{cases}$$

$$N'(x) = \begin{cases} A(x) & \text{if } I(x) \text{ is } \boldsymbol{N := A}, \\ N(x) & \text{otherwise,} \end{cases}$$

$$R_A(x) = R'_A[A^{\leftarrow}(x)]_x,$$

$$R'_A(x) = \begin{cases} B(x) & \text{if } I(x) \text{ is } \boldsymbol{R_A := B}, \\ R_A(x) & \text{otherwise.} \end{cases}$$

All other functions can be defined arbitrarily in the first part of the domain; for concreteness, we define them all to equal 0. The initialization will enable the LSRS to smoothly recover the contents of the register R_A pointed to by A in the second part of the domain by means of the Equal-Predecessor operation.

Table 1 shows the equations of S that define the functions on the middle part $\{cn, \ldots, 2cn-1\}$ of the domain to simulate the computation of M. Note that cn encodes the initial instant of this computation.

We note that the functions I and I' take only a fixed number of values. In the conditions of the above definitions by cases, we use some abbreviations. As an example, "$I(x)$ is $\boldsymbol{A := c}$" is an abbreviation for "$I(x) = i_1$ or $I(x) = i_2$ or ... or $I(x) = i_q$," where the i_j are all numbers of instructions $\boldsymbol{A := c}$. The expression "$I(x)$ is $\textbf{IF } \boldsymbol{A = B} \textbf{ THEN } \boldsymbol{I(i_0)} \textbf{ ELSE } \boldsymbol{I(i_1)}$" has to be interpreted similarly, depending on the possible values of i_0 and i_1. Furthermore, as mentioned before, the constants that occur in the above scheme have to be replaced by additional functions in a pure LSRS. References to $x-1$ are made via recursion. For example, the equation $I(x) = I'(x-1)$ is an abbreviation of $I(x) = I'[\mathbf{1}^{\leftarrow}(x)]_x$. Remember that $\mathbf{1}(i) = 1$ for every i.

As mentioned before, we use R_A to extract the output values of the computation of M, given by the value n' of register N and the content of $R(0), \ldots, R(n'-1)$ at the end of the computation.[7] For $2cn \leq x < 3cn$, the LSRS consists of the equations

$$A(x) = x - 2cn,$$
$$R_A(x) = R'_A[A^{\leftarrow}(x)]_x.$$

All other functions h are defined by $h(x) = h(x-1)$.

It remains to be checked that the equations of S correctly define the intended functions which describe the computation of M and that S also induces the correct RAM output.

For this purpose, let s be a RAM data structure, $\mathbf{1}, \mathbf{n}, \mathbf{id}$, as before, and let I, A, B, N, R_A, I', A', B', N', and R'_A be functions that fulfill the equations of S. First, it is clear that, for all $a < cs.n$, the following hold:

$$A(a) = a,$$
$$R'_A(a) = s.f(a),$$
$$I(a) = B(a) = N(a) = R_A(a) = I'(a) = A'(a) = B'(a) = N'(a) = 0.$$

The values of the functions at $cs.n$ describe the situation of the RAM at the beginning of the computation with respect to the current instruction number and the contents of registers A, B, and N. Furthermore, the definition of A and R'_A on the first part of the domain mirrors the fact that, at the beginning of its computation, M has the value $s.f(i)$ in register $R(i)$.

The proof that the values of the defined functions at $cs.n+t$ encode the situation of M at time t, as intended, is an easy induction on t. The most difficult part is the correctness of function R_A. Note first that, as $A(a) < cs.n$, for every a, the initialization of the first part of the domain ensures that $A^{\leftarrow}(a) < a$ for every $a \in \{cn, \ldots, 2cn-1\}$. In fact, there are 2 cases.

- $cs.n \leq A^{\leftarrow}(a) < a$. In this case, there exists a b, with $cs.n \leq b < a$, such that $A(b) = A(a)$; hence the current R-register has been visited before in the computation of M, and $A^{\leftarrow}(a)$ is the last step for which this happened. Hence $R'_A(A^{\leftarrow}(a))$ gives the correct value of $R_A(a)$.
- $A^{\leftarrow}(a) < cs.n$. In this case, there is no b, with $cs.n \leq b < a$, such that $A(b) = A(a)$; hence the current R-register has not been visited before and should still hold the value $f(A(a))$. By the initialization, it follows that $A^{\leftarrow}(a) = A(a)$ and $R'_A(A(a)) = f(A(a))$, as required.

Finally, we have to show that S correctly defines the output $\Gamma(s)$. By definition of R_A and N on the last part of the universe, it follows analogously that, for each a, $R_A(2cs.n + a)$ contains the content of register $R(a)$ at the end of the computation. Furthermore, $N(3cs.n-1)$ has the value of register N at the end of the computation. Hence, with a suitable projection, $\Gamma(s)$ can be extracted from the functions that are defined by S.

Altogether, we have shown that S correctly defines $\Gamma(s)$. In other terms, Γ is linearly represented by S. □

This completes the proof of Theorem 4.1.

[7] Recall that M uses less than $cn-1$ steps. Therefore, as the first step is simulated at position cn, at position $2cn-2$ the simulation is finished, and we can use the position $2cn-1$ for other purposes, e.g., to encode the length of the output.

5. Complete problems for deterministic linear time. In this section, we are going to exhibit two problems that are related to the recursion schemes defined before and that are complete for **DLIN** under affine reductions. The first problem is an unfolded and nonuniform version of the LSRS algebra. It concerns the simultaneous definition of k functions $f_1, \ldots, f_k : [p] \to [p]$ for some $p > 0$. A *simultaneous function definition (SFD) instance* S consists of a positive integer p, a set $F = \{f_1, \ldots, f_k\}$ of k unary function symbols, and a system of kp equations

$$f_i(a) = (\sigma_i(a))$$

for each $i \in \{1, \ldots, k\}$ and $a \in [p]$, each of one of the following types:

(1) $f_i(a) = b$,

(2) $f_i(a) = h(g(b))$,

(3) $f_i(a) = g(b) * h(c)$,

(4) $f_i(a) = g^{\leftarrow}(b)$,

where $*$ is among $+, -$, b and c are integers in $[p]$, and g, h are in F.

A *valuation* for S is a mapping $V : [p] \times \{1, \ldots, k\} \to [p]$. A valuation is *suitable* if defining all functions f_i by $f_i(a) = V(a, i)$ makes all equations true. Given an SFD instance S and a suitable valuation V, we define the *dependency graph* $G(S, V)$ as follows. The vertices of $G(S, V)$ are all pairs (a, i), where $a \in [p]$ and $i \in \{1, \ldots, k\}$. The edges of (S, V) are defined as follows.

- If $f_i(a) = f_j(f_l(b))$ is an equation of S, then there are edges from (b, l) and $(V(b, l), j)$ to (a, i).
- If $f_i(a) = f_j(b) * f_l(c)$ is an equation of S, then there are edges from (b, j) and (c, l) to (a, i).
- If $f_i(a) = f_j{}^{\leftarrow}(b)$ is an equation of S, then there are edges from (l, j) to (a, i) for all $l \leq b$.

If there is an edge from (b, j) to (a, i), then we also say that $f_j(b)$ is an operand of $f_i(a)$. Note that only edges that correspond to equations of type (2) depend on V. All other edges are determined by S only.

It is not hard to see that an SFD instance S has a valuation V with an acyclic dependency graph if and only if the equations of S can be sorted into a list $E_1, \ldots, E_{kp}$ such that each operand of every equation E_i is defined in an equation E_j with $j < i$. Furthermore, as shown in Lemma 5.1, if this is the case, then the equations have a unique solution.

Example 8. If $k = 2$ and $p = 4$, the following set S of 8 $(= kp)$ sorted equations $E_1, \ldots, E_8$ of the form $f_j(a) = \sigma_j(a)$, $(j \in \{1, 2\}, a \in [p])$, clearly satisfy the required conditions:

- $f_1(2) = 1$;
- $f_2(0) = 3$;
- $f_2(3) = 1$;
- $f_1(0) = f_1(2) + f_2(3)$;
- $f_1(1) = f_2(0) - f_2(3)$;
- $f_1(3) = f_1(f_2(3))$;
- $f_2(1) = f_1{}^{\leftarrow}(3)$;
- $f_2(2) = f_2(1) - f_1(2)$.

Hence $f_1(0) = 1 + 1 = 2$, $f_1(1) = 2$, $f_1(3) = f_1(1) = 2$, $f_2(1) = 1$, (since $f_1(0) = f_1(1) = f_1(3) = 2$ and $f_1(2) = 1 \neq 2$), and $f_2(2) = 0$.

Problem "simultaneous function definition (SFD)".
Input. An SFD instance $S = (p, \{f_1, \dots, f_k\}, (\sigma_i(a))_{i \le k, a < p})$.
Question. Is there a suitable valuation V of S such that $G(S, V)$ is acyclic?
Output. If the answer is positive, the functions $f_1, \dots, f_k$.

In fact, we have defined two problems, one decision problem and one function. The formal representation of the inputs of this problem uses an encoding of a system of equations that is similar to the one that was explained in Example 1 (a). The output is a RAM data structure s' of type $\{C, f\}$ such that $s'.n = kp$, $s'.C = p$, and $s'.f((i-1)p + j) = f_i(j)$ for all $i \in \{1, \dots, k\}$, $j \in [p]$. In the following, unless otherwise stated, we always refer to SFD as a RAM function.

We stick to the convention that the value of an arithmetical expression $g(b) * h(c)$ is 0 in case of overflow, i.e., if its value is not in $[p]$.

Next, we show that the output of an SFD instance is well defined.

LEMMA 5.1. *For each SFD instance S, there is at most one valuation V such that $G(S, V)$ is acyclic.*

Proof. We define inductively a *height* $h(w)$ for vertices w of an acyclic dependency graph as follows. For vertices of in-degree 0, the height is 0. For all other vertices w, $h(w)$ is one plus the maximum height of all vertices u that have an edge to w. The acyclicity ensures that the height is well defined for each vertex. By induction on the height of the vertices, it is easy to show that any two suitable valuations with acyclic dependency graphs are equal. □

THEOREM 5.2. *SFD is complete for* **DLIN** *under affine reductions.*

Proof. We show that, (a) for every RAM function Γ in **DLIN**, we have $\Gamma \le_a$ SFD and (b) SFD is in **DLIN**.

(a) Let $\Gamma \in$ **DLIN** be a RAM function. For simplicity, we shall assume that the type of the input as well as the type of the output consist of only one function f. Let S_1 be the LSRS that linearly defines Γ, as it was constructed in the proof of Lemma 4.3. Given a RAM data structure s as input, we construct an SFD instance S_2 that defines the same functions as S_1. The main idea is to unfold S_1 so that we get one equation for each function of S_1 and each element of the universe $[3cs.n]$. We first describe the construction of a set of equations which allow arbitrary terms $f_i(a)$ and operators from $\{+, -\}$ on the right-hand side. By using more function symbols, this system can be transformed into a pure SFD instance. We describe later how these constructions can be done with affine functions.

The SFD instance S_2 uses all function symbols of the input structure s. Let l be the number of these function symbols. Furthermore, it uses all 10 function symbols of the functions that are defined in S_1. Let c be the constant of the proof of Lemma 4.3. The equations for the symbols of the input structure are simply assignments. For $a \ge s.n$, we assign 0. We construct equations for the three parts $\{0, \dots, cs.n - 1\}$, $\{cs.n, \dots, 2cs.n - 1\}$, and $\{2cs.n, \dots, 3cs.n - 1\}$ separately. For the definition of the second and the third part of R_A, we introduce one new function h, defined by $h(x) = A^{\leftarrow}(x)$. Hence the constructed SFD instance has $k = l + 11$ function symbols, $p = kcs.n$, and each $a \in [cs.n]$ gives rise to $3k$ equations (k equations for each of a, $cs.n + a$, and $2cs.n + a$). For most of the function symbols, the construction is straightforward. The treatment of definition by cases is along the lines of Lemma 3.5. For the second and the third part of R_A, we get two equations, $h(a) = A^{\leftarrow}(a)$ and $R_A(a) = R'_A(h(a))$. It is important to note that the semantics of these two equations together is, in its effect for R_A, the same as that of the original

equation $R_A(a) = R'_A[A^{\leftarrow}(a)]_a$, although the bounded application is replaced by a (nonbounded) composition of functions. This is because the construction of Lemma 4.3 ensures that, for all $a \geq cs.n$, $A^{\leftarrow}(a) < a$.

After transforming S_2 into a pure SFD instance S_3, we get a system of equations of the four allowed forms, such that, for each function symbol f and each of the three parts of the universe, all equations have the same form. The list of these equations is encoded into a RAM data structure with one function symbol g as described in Example 1 (a). Recall that numbers contribute only 1 to the length of the encoding of an equation.

As an example, assume that the sequence of $cs.n$ equations

$$f_3(a) = f_5(a) + f_9(a),$$

where $cs.n \leq a < 2cs.n$, defines f_3 on the middle part of the universe. Each equation has length 18. Let this sequence of equations be the ith such sequence in S_3. The sequence will be encoded by $18cs.n$ consecutive values of $T(s).g$ defined by the following equalities, where $D_i(n) = \sum_{j<i} d_j\alpha_j(n)$ and $b \in [cs.n]$:

- $T(s).g(18b + D_i(s.n)) = 0$, the encoding of the symbol f,
- $T(s).g(1 + 18b + D_i(s.n)) = 12$, the encoding of 3, as the size of the alphabet is 9,
- $T(s).g(2 + 18b + D_i(s.n)) = 2$, the encoding of the opening bracket,
- $T(s).g(3+18b+D_i(s.n)) = b+cs.n+9$, the encoding of the integer $a = b+cs.n$, and so on until finally
- $T(s).g(17 + 18b + D_i(s.n)) = 8$, the encoding of the semicolon.

So this ith part of S_3 clearly satisfies the affine requirements (see (3) in Definition 2.3) with $d_i = 18$ and $\alpha_i(n) = cn$. Moreover, as we saw before at the end of the proof of Lemma 4.3, the output transformation can be given by the affine projection

- $P_{s.n}(s').n = N(3cs.n - 1)$ for the size and
- $P_{s.n}(s').f(a) = R_A(a + 2cs.n)$ for the values.

More precisely, because of the output conventions of SFD, the output $\Gamma(s)$ (of type $\{f\}$) can be extracted from the output $s' = SFD(T(s))$ of type $\{C, f\}$, where $s.C = p = 3cs.n$, by the equalities

$$\begin{aligned}\Gamma(s).n &= P_{s.n}(s').n \\ &= f_i(3cs.n - 1) \qquad \text{if } N \text{ is numbered } f_i \\ &= s'.f(3(i-1)cs.n + (3cs.n - 1)),\end{aligned}$$

and, similarly, if R_A is numbered f_j, for each a,

$$\begin{aligned}\Gamma(s).f(a) &= P_{s.n}(s').f(a) \\ &= f_j(a + 2cs.n) \\ &= s'.f(3(j-1)cs.n + (a + 2cs.n)).\end{aligned}$$

(b) We are going to give a high-level description of an algorithm for SFD and argue that it can be easily transformed into a RAM which solves SFD in linear time.

Let an instance S of the SFD problem be given by p, a set $F = \{f_1, \ldots, f_k\}$, and a set $\{E_1, \ldots, E_{kp}\}$ of equations. The size of S is $\theta(kp)$. We have to show that S can be "evaluated" in $O(kp)$ steps.

We use the following arrays.

- For each $i \leq k$, we use an array E_i such that each $E_i[a]$ is the encoding of the equation which defines $f_i(a)$.

- For each $i \leq k$, we use an array F_i with the intention that, at the end, for each $a < p$, $F_i[a]$ should contain $f_i(a)$.
- For each $i \leq k$, we use a Boolean array Known_i such that $\text{Known}_i[a]$ is true only if $F_i[a]$ contains $f_i(a)$. Initially, all entries in these arrays are set to *false*.
- For each $i \leq k$, we use a variable MinUndef_i such that, at each moment of the computation, MinUndef_i is b if $\text{Known}_i[b]$ is *false*, but $\text{Known}_i[a]$ is *true* for all $a < b$. Initially, all MinUndef_i are 0.
- For each $i \leq k$, we use an array Inv_i such that $\text{Inv}_i[a]$ always contains the maximum $b < \text{MinUndef}_i$, such that $f_i(b) = a$, if such a b exists. Initially, all $\text{Inv}_i[a]$ are represented by p, i.e., a value outside $[p]$.
- For each $i \leq k$ and each $a < p$, we use a list $L_i[a]$ that contains pairs (j, b) such that $f_i(a)$ is an operand in the equation which defines $f_j(b)$, except if this equation is of the form (4).
- For each $i \leq k$ and each $a < p$, we use a list $L_i^{\leq}[a]$ that contains the list of all pairs (j, b) such that the equation $E_j[b]$ is $f_j(b) = f_i{}^{\leftarrow}(a)$. Note that the lists $L_i[a]$ and $L_i^{\leq}[a]$ can be directly computed from S in linear time.
- Furthermore, we use a queue Q, which consists of elements of the form (i, a, b), $a, b \in [p], i \leq k$, where each entry (i, a, b) indicates that $f_i(a) = b$, but this fact has not yet been incorporated to the whole data structure; i.e., in particular, $\text{Known}_i[a]$ is still *false*.

The algorithm is essentially a generalization of topological sorting, in fact a variant of the linear time algorithm for Horn-satisfiability [7].

For the initialization, the algorithm does the following. It first checks that the input is a correct SFD instance. This involves sorting the equations by i and a to check that there is exactly one equation for each i and a. A linear time algorithm for this purpose is described in [19]. Then all entries in Known are set to false, all entries in Inv to p, and all values MinUndef to 0. Furthermore, Q and all lists $L[i, a]$ and $L^{\leq}[i, a]$ are initially empty. For each $j \leq kp$, if equation E_j defines $f_i(a)$, then we set $E_i[a] := E_j$. For each equation of the form $f_i(a) = b$, we add (i, a, b) to Q. For each equation of the form $f_i(a) = f_h(f_j(b))$, we add (i, a) to $L[j, b]$. For each equation of the form $f_i(a) = f_j(b) * f_h(c)$, we add (i, a) to $L[j, b]$ and $L[h, c]$. For each equation of the form $f_i(a) = f_j{}^{\leftarrow}(b)$, we add (i, a) to $L^{\leq}[j, b]$.

The main computation of the algorithm is shown in Table 2.

Finally, it checks that all of the values of the functions $f_1, \ldots, f_k$, as represented by the array F_i, have been computed; i.e., $\text{MinUndef}_i = p$ for each $i \leq k$.

It remains to show that this algorithm is correct and works in linear time. The latter is easy to see. First, for each pair (i, a), at most one triple (i, a, b) is ever added to Q. Hence the outermost WHILE loop is executed at most kp times. Second, the use of MinUndef_i ensures that the innermost WHILE loop is also executed at most kp times. As the time for the initialization and the final tests is also linear, the overall running time is at most linear. The correctness of the algorithm can be shown by an induction on the height of the vertices of the dependency graph that corresponds to S and the valuation that is computed by the algorithm.

Note that the overall size of each of the multidimensional arrays is at most kp. Hence, e.g., the arrays F_i can be simulated[8] by a one-dimensional array F via $F_i[a] = F[ka+i]$. More generally, the algorithm uses only integers of value $O(kp)$, particularly in linear space. □

[8]Note that this RAM algorithm uses multiplication.

TABLE 2
Main part of the evaluation algorithm.

```
WHILE Q is not empty DO BEGIN
    Remove a triple (i, a, b) from Q
    F_i[a] := b; Known_i[a] := true
    For each pair (j, c) in L[i, a] DO BEGIN
        IF E_j[c] is f_j(c) = f_h(f_i(a)) THEN BEGIN
            Set E_j[c] := "f_j[c] = f_h(b)"
            IF Known_h[b] THEN add (j, c, F_h[b]) to Q
                ELSE add (j, c) to L[h, b]
        END
        IF E_j[c] is "f_j(c) = f_i(a) * f_h(d)" THEN
            Set E_j[c] := "f_j[c] = b * f_h(d)"
        IF E_j[c] is "f_j(c) = f_h(d) * f_i(a)" THEN
            Set E_j[c] := "f_j[c] = f_h(d) * b"
        IF E_j[c] is "f_j(c) = f_i(a)" THEN
            add (j, c, b) to Q
        IF E_j[c] is "f_j(c) = f_i(a) * d" THEN
            add (j, c, b * d) to Q
        IF E_j[c] is "f_j(c) = d * f_i(a)" THEN
            add (j, c, d * b) to Q
    END
    WHILE MinUndef_i = a and Known_i[a] DO BEGIN
        For each pair (j, c) in L^≤[i, a] DO
            add (j, c, min(a, Inv_i[F_i[a]])) to Q
        MinUndef_i := a + 1; Inv_i[F_i[a]] := a; a := a + 1
    END
END
```

The SFD function is strongly related to LSRS. Next we describe a problem that is related to LRS and that also turns out to be complete for **DLIN**.

An *inductive function definition (IFD) instance* S consists of a positive integer p and a list of p equations $E_0, \ldots, E_{p-1}$, where each E_a is of one of the following forms:

(i) $f(a) = c$ for some $c \in [p]$,
(ii) $f(a) = f(b) * f(c)$, where $* \in \{+, -\}$ and $b, c < a$,
(iii) $f(a) = f(f^{\leftarrow}(a-1) + 1)$.

Problem "inductive function definition (IFD)".
Input. An IFD instance $S = (p, E_0, \ldots, E_{p-1})$.
Output. The function $f : [p] \to [p]$, as defined by S.

As usual, we stick to the convention that the value of $f(b) * f(c)$ is 0 in case of overflow. As the equations are evaluated in the order in which they are given, and as this order agrees with the natural order on $[p]$, there is no ambiguity in the definition of f. However, it might happen that the output is undefined because $f(b) \neq a - 1$ for each $b < a - 1$, for an equation of type (iii), for some a. In this case, we define the output function to be constant 0.

THEOREM 5.3. *The RAM function IFD is complete for* **DLIN** *under affine reductions.*

Proof. Again we have to show that (a) for every RAM function Γ in **DLIN**, we have $\Gamma \leq_a$ IFD and (b) IFD is in **DLIN**.

Item (b) is much easier to show than in Theorem 5.2, as the equations are simply evaluated in the order in which they appear. This implies that the evaluation of equations of kind (iii) is similarly straightforward but simpler than that in the proof of Theorem 5.2.

It remains to show that IFD is complete for **DLIN**. This proof combines many of the techniques that we have described before in this article. Let $\Gamma \in \mathbf{DLIN}$ be a RAM function that is computed by a safe RAM (cf. section 2). Let S_1 be an LSRS for Γ, as constructed in the proof of Lemma 4.3, in which all definitions by cases, besides those which refer to the partition of the domain into three parts, are arithmetized as sketched in the proof of Lemma 3.5. Furthermore, we allow in S_1 right-hand sides like $I(x-1)$, which can be directly dealt with in the IFD by equations of type (ii). In particular, S_1 uses recursion only once, that is, in $R_A(x) = R'_A[A^{\leftarrow}(x)]_x$ for the middle part and the third part of the domain. Next we transform S_1 into an LRS S_2, similarly as in the proof of Lemma 3.10. The transformation here is much easier because, in S_1, only recursion with Equal-Predecessor over $A(x)$ is used. Let c be as in Lemma 4.3; i.e., all functions will be defined on the domain $[3cs.n]$ for input data structures s. Let c' be a constant such that the evaluation of S_1 always uses only numbers that are smaller than $c's.n$. We make use of an additional function A^+ with the intention that, for all a, $A^+(a) = A(a) + c'n$. Let k be chosen such that the functions of S_1 besides A, R_A, and R'_A can be numbered as $g_3, \ldots, g_{k-1}$. The function f that is defined by S_2 shall encode the functions of S_1 and A^+ in the following way. For each $a \in [3cs.n]$, we get

$$\begin{array}{cc}
f(2ka) = A(a) & f(2ka+k) = A(a) \\
f(2ka+1) = A^+(a) & f(2ka+k+1) = A^+(a) \\
f(2ka+2) = R_A(a) & f(2ka+k+2) = R'_A(a) \\
f(2ka+3) = g_3(a) & f(2ka+k+3) = g_3(a) \\
\vdots\ \vdots\ \vdots & \vdots\ \vdots\ \vdots \\
f(2ka+k-1) = g_{k-1}(a) & f(2ka+k+k-1) = g_{k-1}(a)
\end{array}$$

Now we unfold S_2 with respect to the input data structure s, as described in the following. For simplicity, we assume that s only has one function f'. First, S_3 gets $s.n$ equations $f(a) = s.f'(a)$, where the values $s.f'(a)$ are given by the input and are therefore constants for S_3. Then we have $s.n$ equations of the form $f(a) = c's.n$, where $c's.n$ is also a constant for S_3. The value $c's.n$ is needed in the next step to compute $A^+(x)$ from $A(x)$. Next we unfold S_2 with respect to $3cs.n$ analogously to the proof of Theorem 5.2. Note that all equations are "shifted" by $2s.n$, which can be easily adapted by the coefficients of the affine functions that are constructed. For all equations that do not use recursion, this unfolding is straightforward. Those equations that are obtained from the only recursion equation $R_A(x) = R'_A[A^{\leftarrow}(x)]_x$ of S_2 are encoded by equations of the form $f(2ka+2) = f(f^{\leftarrow}(2ka+1)+1)$. Note that we represented all function values besides those of R_A and R'_A twice in f to make this encoding possible with an equation of type (iii).

The definition of S_3 by affine functions can be done in a similar manner as sketched in the proof of Theorem 5.2. □

6. Conclusion. We have given two algebraic characterizations of **DLIN**. We feel that the existence of such machine-independent characterizations strengthens the intrinsic interest of this complexity class. Moreover, maybe they will help us to find nice logical characterizations of **DLIN** as was done for **NLIN** [20, 29, 8]. The goal of such logical characterizations would be to allow some of the techniques of finite model theory that have been developed to prove nonexpressibility results, to show nonlinear

lower bound results for concrete algorithmic problems. For surveys on this topic see, e.g., [10, 35].

Logical characterizations seem to be more difficult to obtain for deterministic linear time classes than for nondeterministic linear time classes. The known characterizations of deterministic polynomial time suggest two possible approaches. Following Graedel's characterization of **P** by existential second-order Horn logic [13], one could try to get a logical characterization of **DLIN** by restricting the formulas that are used in the characterization of **NLIN**. The other approach would be to use some kind of fixed point operator as in the work of Immerman and Vardi [24, 36]. Although the results of this article can be used to get logical characterizations by both approaches, the resulting logic is too complicated to be of any use.

We have defined a new very strict machine-independent reduction adapted for linear time classes defined by RAMs and at least as restrictive as the classical reductions like reset-log-lin [6], linear time and logarithmic space reductions, etc. Our affine transformation transforms a structure s into a new structure s', which is a kind of copy of s, with possible shuffle and repetitions; in particular, the value of each element $f'(y)$ of the transformed structure s' depends only on one value $f(x)$ of the original structure s.

Moreover, the class of affine transformations is closed under various operations: composition, concatenation, shuffle. Typically, the transformation of $s = ([n], f_0, \ldots, f_{k-1})$ into $s' = ([kn], f')$, where $f' : [kn] \to \mathbb{N}$ is defined by $f'(kx + r) = f_r(x)$ for $x < n$ and $r < k$, is affine.

It is easy to see that an affine reduction is highly parallelizable; more precisely, it is in $\mathbf{NC}^1$, i.e., computable on a uniform Boolean circuit of fan-in two and depth $O(logn)$.

We have shown that affine reductions are the right kind of reductions to define both **DLIN**-completeness and **NLIN**-completeness. We are convinced that they can be applied both in the context of tractable problems, e.g., linear reductions to HORN-SAT, and in the context of intractable problems, e.g., reducibility from SAT or 3-SAT.

Finally, we note that there is another kind of machine-independent reduction, namely, the logical reduction; it would be worthwhile to compare our affine reduction with the logical quantifier-free reduction used by [27] for linear reductions of some **NP**-complete problems, such as KERNEL, to and from problem SAT. We conjecture that an affine reduction between isomorphical invariant problems is also quantifier-free. The converse is unclear.

We have shown that the **NLIN**-complete problem CONTRACT is **NLIN**-complete not only via $\mathbf{DTIME}(n)$-reductions but also via affine reductions. We can also prove the respective statement, left as an exercise to the reader, for the more classical **NLIN**-complete problem reduction of incompletely specified automata (RISA) [11, 16]. We feel that our **DLIN**-complete problems SFD and IFD are still interesting even if they seem to be slightly less natural than CONTRACT and RISA because of the use of the Equal-Predecessor operator. More precisely, IFD appears to be a minimal problem in the following sense: it involves only one function; each one of the three forms (i)–(iii) of the equations of an IFD instance is or seems to be necessary. Of course, on the one hand, (i) $f(a) = c$ and (ii) $f(a) = f(b) * f(c)$ are required to initialize some values and compute new ones, but, on the other hand, (i)–(ii) do not seem to be sufficient unless any **DLIN** algorithm can be implemented in linear time on a write-once RAM, i.e., a RAM which may only write a value once in any register but is not allowed

to erase or rewrite it—an unlikely simulation; see [23] and [32]. Besides, note that IFD does not involve composition of functions; the "execution" of an equation (iii) $f(a) = f(f^{\leftarrow}(a-1)+1)$ has a flavor of "neighborhood copying": search the last $b < a-1$ such that $f(b) = f(a-1)$, and copy the neighbor value $f(b+1)$ into $f(a)$ so that the pairs $(f(b), f(b+1))$ and $(f(a-1), f(a))$ are equal.

If an affine transformation is regarded as a kind of copying process, then any **DLIN** (resp., **NLIN**) problem can be regarded as a subproblem of any **DLIN**-complete (resp., **NLIN**-complete) problem such as IFD (resp., RISA). That means that our above-mentioned linear-time algorithms for IFD and SFD are universal or most general programs with respect to the other linear-time programs, e.g., topological sorting, algorithms for Horn-satisfiability, or for graph planarity, and so forth.

The fact that SFD and IFD are **DLIN**-complete via affine reductions immediately implies that such a problem is at least as hard as any **DLIN** problem for many complexity measures: time and space on Turing machines, Boolean circuit or PRAM complexity, etc., as exemplified by the following equivalences.

PROPOSITION 6.1.

1. *SFD* $\in$ **DTIME**(n) *if and only if* **DLIN** = **DTIME**(n)*;*
2. $SFD \in$ **DSPACE**$(S(n))$ *if and only if* **DLIN** $\subseteq$ **DSPACE**$(S(n))$ *for any space constructible function* $S(n) \geq \log n$*;*
3. *SFD* $\in \mathbf{NC}^1$ *if and only if* **DLIN** $\subseteq \mathbf{NC}^1$*;*
4. *SFD* $\in$ **DTIME** $- PRAM(t(n))$ *if and only if* **DTIME** $- RAM(n)$ *(that is,* **DLIN***) is included in* **DTIME**$-PRAM(t(n))$ *for any honest function* $t(n) < n$*, where* **DTIME** $- PRAM(t(n))$ *denotes the set of problems computable in parallel time* $t(n)$ *on a PRAM which uses only numbers* $O(n)$*.*

It is very difficult to prove complexity lower bounds for natural combinatorial problems on general-purpose models of computation. The **NLIN**-complete problems are among the very few known exceptions: from the inclusions **DTIME**$(n) \subsetneq$ **NTIME**$(n) \subseteq$ **NLIN** [30, 16], one deduces, e.g., that RISA is not in **DTIME**(n). Note that RISA is in **DLIN** if and only if **DLIN** = **NLIN**. We have no idea on how to prove complexity lower bounds, e.g., on Turing machines, for problems such as HORN-SAT or GRAPH-PLANARITY, but we feel that it should be easier to prove that IFD and SFD cannot be reduced to such a problem; e.g., IFD $\leq_a$ HORN-SAT does not hold, and hence HORN-SAT is not complete for **DLIN**. Intuitively, IFD is not a subproblem of HORN-SAT.

Acknowledgments. We would like to thank Clemens Lautemann, Judy Goldsmith, Ken Regan, and Yuri Gurevich for many valuable hints and suggestions. We also thank an anonymous referee for many helpful comments.

IMPROVED APPROXIMATIONS OF CROSSINGS IN GRAPH DRAWINGS AND VLSI LAYOUT AREAS*

GUY EVEN†, SUDIPTO GUHA‡, AND BARUCH SCHIEBER§

Abstract. We give improved approximations for two classical embedding problems: (i) minimizing the number of crossings in a drawing on the plane of a bounded degree graph; and (ii) minimizing the VLSI layout area of a graph of maximum degree four. These improved algorithms can be applied to improve a variety of VLSI layout problems. Our results are as follows. (i) We compute a drawing on the plane of a bounded degree graph in which the sum of the numbers of vertices and crossings is $O(\log^3 n)$ times the optimal minimum sum. This is a logarithmic factor improvement relative to the best known result. (ii) We compute a VLSI layout of a graph of maximum degree four in a square grid whose area is $O(\log^4 n)$ times the minimum layout area. This is an $O(\log^2 n)$ improvement over the best known long-standing result.

Key words. approximation algorithm, crossing number, graph drawing, VLSI layout

1. Introduction.

In this paper, we study two related problems: (1) drawing a bounded degree graph on the plane with the fewest number of crossings of edges and (2) minimization of the VLSI layout area of a graph of maximum degree four in a grid with constant aspect ratio. Considerable attention has been devoted to these problems in the past (see, e.g., [L80, V81, BL84, U84, SSSV97, LR99]).

A *drawing of a graph on the plane* is an injection of the vertices of the graph to points in the plane and a mapping of the edges to simple continuous curves between the vertices' images. A curve may not contain an image of a vertex as an internal point, and three (or more) curves may intersect only at an image of a vertex. A *crossing* is an intersection of two curves at a point that is not an image of a vertex. The *size* of a drawing is the sum of the numbers of vertices and crossings in the drawing. The problem of determining the minimum size of a drawing of a graph on the plane is NP-complete [GJ83].

Bhatt and Leighton, in [BL84], apply a $B(n)$-approximate bisection procedure recursively to decompose a bounded degree graph with n vertices. They prove that this recursive decomposition induces a drawing of size $O(B^2(n)\log^2 n)$ times the minimum size drawing. Shahrokhi et al. [SSSV97] considered straight line drawings induced by decomposition trees and presented a simpler construction of a drawing of the same size as the one achieved in [BL84]. Leighton and Rao [LR99] showed that the above result can be realized with a $(\frac{1}{3}, \frac{2}{3})$-separator. Leighton and Rao also showed how

to find such a separator with size bounded by $\alpha(n) = O(\log n)$ times the optimal bisector. This implied an $O(\log^4 n)$- (or $O(\alpha^2(n) \log^2 n)$-) approximation algorithm for the drawing size of a bounded degree graph. The bound on the approximation factor in this algorithm relies only on the fact that an optimal drawing induces a planar graph which admits small vertex separators. The reason that the approximation algorithm applies only to bounded degree graphs is that, in bounded degree graphs, the vertex separators and the edge separators have roughly the same size. It appears that the ideas of [PSS96, SSSV97] may extend to arbitrary degree graphs. Motivated by graph layout problems, we focus on bounded degree graphs for results related to crossing numbers of graphs and on graphs of maximum degree four for results related to layouts.

A *VLSI layout* of a graph of maximum degree four is an embedding of the graph in a grid. The vertices of the graph are injected into the grid vertices, and the edges of the graph are mapped into edge disjoint paths in the grid. In fact, we consider the more restrictive "Manhattan" model of routing (in which layer assignment is trivial) and not the "knock-knee" model. Namely, an intersection of two paths (i.e., images of edges) at an internal grid vertex is allowed provided that one path traverses the grid vertex horizontally and the other path traverses the grid vertex vertically. The objective in the VLSI layout area problem is to minimize the area of the grid. Note that to be able to embed a graph in a grid, it must be of maximum degree four. From now on, we consider only graphs of maximum degree four for the VLSI layout problem.

Leiserson [L80] and Valiant [V81] showed that every planar graph can be embedded in a grid with constant aspect ratio of size $O(n \log^2 n)$. Bhatt and Leighton suggested embedding a graph of maximum degree four in two steps. First, draw it on the plane, and then apply the approximation algorithm for VLSI layouts of planar graphs to the planar graph resulting from the drawing by adding vertices in crossings. The optimal layout gives a feasible drawing of the same size; therefore, the $O(\log^4 n)$-approximation algorithm for drawing graphs on the plane combined with the $O(\log^2 n)$-approximation algorithm for VLSI layouts of planar graphs yield an $O(\log^6 n)$-approximation algorithm for the VLSI layout problem.

A *decomposition tree* of a graph $G = (V, E)$ is a tree with a mapping of the tree nodes to subsets of vertices as follows. The root is mapped to V; every two siblings are mapped to subsets that constitute a partitioning of the subset of V to which their parent is mapped; and leaves are mapped to subsets containing a single vertex. The cut associated with an internal tree node t is the set of edges between the subsets to which the children of t are mapped. Bhatt and Leighton, in [BL84], proposed a special type of decomposition trees called *bifurcators*. These decomposition trees are binary trees, and the cut sizes associated with their nodes decrease exponentially as a function of the depth of the node. Bhatt and Leighton [BL84] demonstrated that a $\sqrt{2}$-bifurcator can be used for a wide variety of problems in VLSI layouts: minimizing capacitive delay, producing fault tolerant layouts, layouts for graphs using prefabricated chips, regular layouts, and layouts minimizing wire crossing to name a few. (The detailed description of these applications is provided in [BL84].) Using the approximation of drawing size, in retrospect, Bhatt and Leighton provided an $O(\log^{2.5} n)$-approximation for the optimal $\sqrt{2}$-bifurcator.

Our results. In this paper, we provide improved approximation algorithms for the above problems. We first provide an $O(\log^3 n)$-approximation algorithm for the drawing size problem. As a consequence of this result, based on Bhatt and Leighton's results, we obtain an $O(\log^2 n)$-approximation for the optimal $\sqrt{2}$-bifurcator problem

and a corresponding improvement for all of its applications.

Our $O(\log^3 n)$-approximation for the drawing size problem combined with layout algorithms for planar graphs yield an $O(\log^5 n)$-approximation for the minimum VLSI layout area. Using further structural properties of the decomposition tree computed in our algorithm, we show that the VLSI layout area problem can be approximated to a factor of $O(\log^4 n)$.

In terms of the best approximation factor known for separators, our results can be stated as follows. Let $\alpha(n)$ denote the smallest known ratio of the separator size (that can be computed efficiently) to the optimal bisector size. We show an $O(\alpha^2(n) \log n)$-approximation of the minimum drawing size and an $O(\alpha^2(n) \log^2 n)$-approximation of the minimum VLSI layout area.

Our approximation algorithms construct a decomposition tree that can be viewed as an approximation of a decomposition tree $\widetilde{T}$ obtained by recursively bisecting the planar graph induced by an optimal drawing. Such a decomposition tree $\widetilde{T}$ induces a drawing of size $O(\log n)$ times the optimal drawing size. In addition, $\widetilde{T}$ can be used in Leiserson's embedding algorithm [L80] to compute a layout of area $O(\log^2 n)$ times the optimal layout area.

The decomposition tree that we compute mimics the useful properties of $\widetilde{T}$. In the problem of drawing a graph on the plane, we attach an estimator $\phi(t)$ to every tree node that estimates the optimal drawing size of the corresponding subgraph. The estimator quality is one-sided; it may not surpass (twice) the drawing size but might be much smaller than the drawing size. The estimators have the following two properties that approximate the properties of the drawing sizes of the subgraphs in $\widetilde{T}$: (a) the cut sizes are bounded by the square-root of the corresponding estimators up to a logarithmic error term; and (b) the estimators decrease exponentially as one goes down the tree. The main difficulty in constructing such an "approximated" decomposition tree with estimators is that the only tool we have is approximate separators. To overcome this difficulty, we apply a top-down approach with rebalancing to guarantee that the estimators decrease exponentially.

Our technique extends to a framework for computing decomposition trees with estimators of other superadditive functions. (Superadditive functions are functions in which the sum of the function values on disjoint subgraphs is no more than the value of the function on the whole graph.) Guha [G00] applied this technique to the fill-in function, yielding better approximations for chordal completion, operation count, and certain cases of elimination height and pathwidth.

For the grid embedding algorithm, we follow the paradigm suggested by Leiserson [L80]. First, we present a "weighted" version of Leiserson's algorithm that can be implemented when the separation properties of the decomposition tree are given relative to *weights* of subgraphs rather than *sizes* of subgraphs. A tempting approach is to use the decomposition tree computed for approximating the drawing size together with the estimators associated with its nodes as weights for the implementation of Leiserson's algorithm. However, this approach fails since the estimators are not adequate as weights. This is because they do not satisfy a superadditivity property. Therefore, we compute new node weights. These weights require a rebalancing of the decomposition tree before the weighted version of Leiserson's algorithm can be applied.

Organization. In section 2, we define the problems and describe the basic tools: decomposition trees, separators, etc. In section 3, we describe decomposition trees with estimators and show that they are useful for drawing graphs. In section 4, we present an algorithm for computing decomposition trees with estimators. In section 5,

an improved approximation of $\sqrt{2}$-bifurcators is presented. In section 6, we present an algorithm for approximating the minimum VLSI layout area.

2. Preliminaries.

Minimum drawing size of a graph. A *drawing* D of a graph G is a one-to-one mapping of the vertices to points on the plane. We call the image of a vertex its *position*. Every edge is mapped to a simple (non-self-intersecting) continuous curve connecting the positions of the end-points of the edge. A curve corresponding to an edge may not contain a position of a vertex as an interior point. A *crossing* is an intersection of the interiors of two curves corresponding to images of edges. (Note that a position of a vertex does not count as a crossing since a position of a vertex cannot be in the interior of a curve.) We do not allow more than two curves to intersect at every crossing. A *point* in a drawing is either a position of a vertex of the graph or a crossing. We denote the minimum number of points, over all drawings of G, by $\mathrm{MDS}(G)$. Note that $\mathrm{MDS}(G) = n + CR(G)$, where $CR(G)$ denotes the (minimum) crossing number of G, and n is the number of vertices in G.

The minimum drawing size of a graph satisfies the following *superadditivity* property.

PROPOSITION 1. *If the vertex set of G is partitioned into disjoint sets and the respective graphs induced by them are denoted by $\{G_i\}_i$, then* $\mathrm{MDS}(G) \geq \sum_i \mathrm{MDS}(G_i)$.

Minimum layout area of a graph. A *VLSI layout* of a graph of maximum degree four is an embedding of the graph in a grid. The embedding consists of an injection of the graph vertices to the grid vertices and a mapping of the graph edges into edge disjoint paths in the grid. The paths into which two edges are mapped may intersect at an internal grid vertex, provided that one edge is mapped to the two horizontal grid edges touching this vertex and the other edge is mapped to the vertical grid edges touching it. The *aspect ratio* of a (rectangular) grid is the ratio of its short dimension to its long one. Let $\textsc{Area}_\sigma(G)$ denote the minimum area required to embed a graph G in a host grid with aspect ratio σ. Let $\textsc{Area}(G) = \min_{\sigma>0} \textsc{Area}_\sigma(G)$. Using a "folding" argument, Leiserson [L80] showed that $\textsc{Area}_1(G) \leq 3 \cdot \textsc{Area}(G)$. It follows that considering only embeddings in squares has only a small effect on the minimum area.

Since every layout is also a drawing, and the area of the layout is an upper bound on the size of the drawing, the following property holds.

PROPOSITION 2. *For every graph of maximum degree four,* $\textsc{Area}(G) \geq \mathrm{MDS}(G)$.

Decomposition trees. A (binary) decomposition tree[1] T of $G = (V, E)$ is a rooted binary tree T, and a mapping of the tree nodes to subsets of vertices is as follows: The root is mapped to V; every two siblings are mapped to subsets that constitute a partition of the subset of V to which their parent is mapped; and leaves are mapped to subsets containing a single vertex. Let V_t denote the set of vertices to which the tree node t is mapped, and let $n_t = |V_t|$. Let $G_t = (V_t, E_t)$ denote the subgraph of G induced by V_t. To each internal tree node $t \in T$, we associate the cut between the vertex sets to which the two children of t are mapped. Formally, let $cut(V_1, V_2)$ denote the edges between vertices in V_1 and vertices in V_2. The cut corresponding to an internal node t is denoted by cut_t. This cut is defined by $cut_t = cut(V_{t_\ell}, V_{t_r})$, where t_ℓ and t_r are the children of t. For an edge $e = (u, v) \in E$, let $t(e)$ be the tree node for which $e \in cut_{t(e)}$. Note that $t(e)$ is the lowest tree node that is mapped to

[1]Decomposition trees may not be binary. However, in this paper, we consider only binary decomposition trees.

a set containing both u and v.

Drawings induced by decomposition trees. In [BL84], Bhatt and Leighton considered (recursive) drawings that are induced by decomposition trees. Shahrokhi et al. [SSSV97] described simple drawings that are induced by ordered decomposition trees.[2] Following Shahrokhi and Shi [SS00], we call this drawing a *linear drawing*. An ordered decomposition tree induces a permutation of the vertices by considering the order of the leaves in a preorder traversal. (Recall that each such leaf is mapped to a subset containing just one vertex in G.) Let $v_1, \ldots, v_n$ denote the vertices of G in this order. Map the vertices to points along a line (also called the *spine*), unit distances apart, according to their order. All of the edges are drawn on one side of the spine as half circles; namely, each edge $e = (v_i, v_j)$ is drawn as half a circle with diameter $|i - j|$ and end-points at v_i and v_j.

Shahrokhi et al. [SSSV97] count the number of crossings in such an induced drawing using the following observation.

LEMMA 3. *In a linear drawing, if the curves corresponding to edges $e = (v_i, v_j)$ and $e' = (v_k, v_\ell)$ cross, then either $t(e)$ is an ancestor of $t(e')$ or $t(e')$ is an ancestor of $t(e)$. (A node is considered both an ancestor and a descendant of itself.)*

Proof. Observe that, for each tree node t, the vertices in V_t are drawn contiguously along the spine. From the drawing it follows that whenever two edges $e = (v_i, v_j)$ and $e' = (v_k, v_\ell)$ cross, then either $k < i \leq \ell \leq j$ or $i \leq k \leq j < \ell$. The lemma follows. □

A crossing of the curves of e and e' is charged to edge e if $t(e)$ is an ancestor of $t(e')$ and to edge e' otherwise. From Lemma 3 it follows that a crossing of the curves of $e = (u, v)$ and e' is charged to e if $t(e')$ is either on the path connecting $t(e)$ to u in T or on the path connecting $t(e)$ to v. Recall that, for an internal tree node t, the number of edges e with $t(e) = t$ is $|cut_t|$. We get the following bound on the number of crossings charged to an edge e.

COROLLARY 4. *Let $P(u, v)$ denote the set of nodes in T on the path from the leaf mapped to u to the leaf mapped to v. The number of crossings in a linear drawing that are charged to the edge $e = (u, v)$ is bounded by $\sum_{t \in P(u,v)} |cut_t|$.*

Shahrokhi et al. [SSSV97] also suggested placing the vertices on a circle (or on the corners of a convex polygon) using the same order and drawing the edges with straight lines. The number of crossings in this drawing also satisfies Corollary 4.

Existence of special separators. In our algorithm, we need to compute a *simultaneous* edge separator. Such an edge separator is a cut that partitions a graph in a balanced way according to *two* measures—the number of vertices and their weights. Suppose that we are given a graph G with vertex weights $w(v)$. For a set of vertices S, let $w(S)$ denote the sum of the weights of vertices in the set S.

DEFINITION 1. *A cut $(S, V - S)$ is a $(\frac{1}{4}, \frac{3}{4})$*-separator with respect to the number of vertices *if* $\min\{|S|, |V - S|\} \geq \frac{1}{4}|V|$.

A cut $(S, V - S)$ is a $(\frac{1}{3}, \frac{2}{3})$-separator with respect to the vertex weights *if* $\min\{w(S), w(V - S)\} \geq \frac{1}{3}w(V)$.

A cut $(S, V - S)$ is a simultaneous (edge) separator *if it is a $(\frac{1}{4}, \frac{3}{4})$-separator with respect to the number of vertices and a $(\frac{1}{3}, \frac{2}{3})$-separator with respect to the vertex weights.*

The following lemma shows that a small simultaneous separator exists provided that vertex weights are not too big.

[2] An ordered tree is a tree in which the children of each internal node are ordered.

LEMMA 5. *If the maximum vertex weight is bounded by $\frac{2}{3}$ of the total weight, then there exists a cut of size $O(\sqrt{\mathrm{MDS}(G)})$ that is a simultaneous edge separator.*

Proof. First, for the sake of completeness, we prove the weighted version of the Planar Separator Theorem [LT79]. Namely, we show that there exists a cut of size $O(\sqrt{\mathrm{MDS}(G)})$ that separates G into subgraphs of weight between one third and two thirds of the total weight. Let $G = (V, E)$. Consider an optimal drawing of G, and let $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ denote the planar graph that is obtained by introducing vertices in the crossings of the optimal drawing. Assign zero weights to vertices in $\widetilde{V} - V$, and keep the weights of vertices in V unchanged. Note that $|\widetilde{V}| = \mathrm{MDS}(G)$. Construct an ordered decomposition tree of $\widetilde{G}$ by applying the Planar Separator Theorem recursively and setting the heavier subgraph as the left child in each step. Let $v_1, \ldots, v_n$ denote the order induced by a preorder traversal on the vertices in V. Define $S_i = \{v_1, \ldots, v_i\}$ and $S_0 = \phi$. Define ℓ as follows:

$$\ell = \min\{i : w(S_i) \geq w(V)/3\}.$$

Observe that $w(V)/3 \leq w(S_\ell) \leq 2w(V)/3$. If $\ell = 1$, then this follows from the fact that $w(v) \leq 2w(V)/3$ for every $v \in V$. If $\ell > 1$, then $w(v_\ell) \leq w(S_{\ell-1}) \leq w(V)/3$ because of the ordering rule, in which the heavier subgraph is set as the left child.

We now prove that the size of the cut $(S_\ell, V - S_\ell)$ is $O(\sqrt{\mathrm{MDS}(G)})$. Let $t_0, t_1, \ldots, t_k$ denote the path in the decomposition tree from the root to the leaf corresponding to v_ℓ. The size of the cut $(S_\ell, V - S_\ell)$ is bounded by $\sum_{i=0}^{k} |cut_{t_i}|$. The Planar Separator Theorem implies that (a) $|cut_{t_i}| \leq O(\sqrt{|\widetilde{V}_{t_i}|})$; and (b) $|\widetilde{V}_{t_i}| \leq (2/3)^i \cdot |\widetilde{V}|$ for every $i = 0, 1, \ldots, k$. This completes the proof of the weighted version of the Planar Separator Theorem. We note that since all of the vertices in $\widetilde{V}$ have constant degree, the weighted version of the Planar Separator Theorem follows from a general theorem of Gazit and Miller [GM90]. We detailed the proof for the sake of completeness and also since a similar construction is used later.

A simultaneous separator can be shown to exist as follows. Let $(S, V - S)$ denote a $(\frac{1}{3}, \frac{2}{3})$-separator with respect to the weights $w(v)$. If $|S|, |V| - |S| \geq \frac{1}{4}|V|$, we are done. Otherwise, without loss of generality, $|S| > \frac{3}{4}|V|$. Let $(S_1, S - S_1)$ denote a $(\frac{1}{3}, \frac{2}{3})$-separator of S with respect to the number of vertices. Without loss of generality, assume that $w(S_1) \leq w(S - S_1)$. In case $w(S - S_1) \geq \frac{1}{3}w(V)$, we are done since the partition into $S - S_1$ and $V - (S - S_1)$ is a good partition and the size of the cut is $O(\sqrt{\mathrm{MDS}(G)})$.

If $w(S - S_1) < \frac{1}{3}w(V)$, let $(S_2, V - S - S_2)$ denote a $(\frac{1}{3}, \frac{2}{3})$-separator of $V - S$ with respect to the weights. Without loss of generality, assume that $w(S_2) \leq w(V - S - S_2)$. We claim that the partition into $(S - S_1) \cup S_2$ and $(V - S - S_2) \cup S_1$ is a good partition. First, note that the size of the cut is $O(\sqrt{\mathrm{MDS}(G)})$. Clearly, it is a $(\frac{1}{4}, \frac{3}{4})$ partition with respect to the number of vertices since $|S_1|, |S - S_1| \geq \frac{1}{4}|V|$.

We show that $\frac{1}{3}w(V) \leq w(V - S - S_2) + w(S_1) \leq \frac{2}{3}w(V)$, and thus it is a $(\frac{1}{3}, \frac{2}{3})$ partition with respect to the weights. The lower bound is proved as follows:

$$\begin{aligned} w(V - S - S_2) + w(S_1) &\geq \frac{1}{2}w(V - S) + w(S_1) \\ &= \frac{1}{2} \cdot [(w(V) - w(S - S_1)) + w(S_1)]. \end{aligned}$$

Since $w(V) - w(S - S_1)$ is at least $\frac{2}{3}w(V)$, the lower bound follows. Also,

$$w(V - S - S_2) + w(S_1) \leq \frac{2}{3}w(V - S) + \frac{1}{2}w(S) \leq \frac{2}{3}w(V) - \frac{1}{6}w(S) \leq \frac{2}{3}w(V). \qquad \square$$

Computing simultaneous separators. The proof of Lemma 5 can be made into an efficient algorithm if one could efficiently compute balanced cuts with respect to vertex weights (or number of vertices). The size of the cuts needs to be $O(\sqrt{\mathrm{MDS}(G)})$. In this section, we present a weaker result; namely, the cut size is $O(\sqrt{\mathrm{MDS}(G)} \cdot \log n)$. This additional $O(\log n)$ factor is also added to the size of the simultaneous separator that we can compute efficiently. The algorithm is based on applying at most twice the Leighton–Rao bicriteria approximation algorithm for separators.

The Leighton–Rao separator algorithm [LR99] finds separators in unweighted graphs as well as weighted graphs. A cut $cut(U, V-U)$ is a b-balanced cut if the weights of U and $V-U$ are at most $1-b$ times the total weight. The Leighton–Rao algorithm receives two balance parameters $b \leq \frac{1}{2}$ and $b' \leq \min\{b, \frac{1}{3}\}$ and returns a b'-balanced cut the size of which is $O(\frac{\log n}{b-b'} \cdot \mathrm{SEP}_b)$, where SEP_b denotes the size of an optimal b-balanced cut.

We describe how to compute a b-balanced cut with respect to vertex weights provided that $b \leq \frac{1}{3}$. (Computing balanced cuts with respect to the number of vertices is simply the case of uniform weights.) The size of the cut is $O(\sqrt{\mathrm{MDS}(G)} \cdot \log n)$.

Set $b' = 1 - \sqrt{1-b}$, and apply the Leighton–Rao algorithm. The partitioning yields a b'-balanced cut $cut(U, V-U)$ with respect to vertex weights. If this cut happens to be also b-balanced, then we are done. Otherwise, assume U is the heavier part (i.e., $w(U) \geq w(V-U)$). Since $cut(U, V-U)$ is not b-balanced, it follows that $w(U) > (1-b)w(V)$. Apply the Leighton–Rao algorithm to U to obtain a b'-balanced cut $(U_1, U-U_1)$. Assume U_1 is the heavier part. Then the cut $cut(U_1, V-U_1)$ is b-balanced. The upper bound follows since $w(U_1) \leq (1-b')w(U) \leq (1-b')^2 w(V) = (1-b)w(V)$. The lower bound follows since $w(U_1) \geq \frac{1}{2}w(U) \geq \frac{1}{2}(1-b) \cdot w(V) \geq b \cdot w(V)$. (The last inequality holds since $b \leq \frac{1}{3}$.) Note that the sizes of both cuts are bounded by $O(\sqrt{\mathrm{MDS}(G)} \cdot \log n)$ since the sizes of the optimal b-balanced cuts of V and U are bounded by $\sqrt{\mathrm{MDS}(G)}$.

Another way to compute simultaneous separators with "relaxed" balance parameters uses the spreading metric based algorithm [ENRS99] for simultaneous separators.

Weight functions induced by cuts. The weight functions used in our decomposition algorithm are defined by cuts. We consider two subsets of vertices $A, B \subseteq V$ and call A the *home* set and B the *outside* set. The weight of $v \in A$ with respect to its *home* set A and the *outside* set B, denoted $W_{A,B}(v)$, is defined to be the number of edges connecting v with vertices in $B - A$. In other words, $W_{A,B}(v)$ equals the number of edges in $cut(A, B-A)$ incident to v. Note that $\sum_{v \in A} W_{A,B}(v) = |cut(A, B-A)|$. Since the graphs are of bounded degree, the weight function is bounded as well. We note that for some weight functions $W_{A,B}$, there may be a vertex v such that $W_{A,B}(v) > \frac{2}{3}\sum_{v \in A} W_{A,B}(v)$. Consequently, we cannot apply Lemma 5 to find a simultaneous separator in such cases. To keep the presentation simpler, we first assume that such cases of unbalanced weight functions do not happen and later note how to cope with them.

3. A decomposition tree for minimizing the drawing size.

3.1. Motivation. Following Bhatt and Leighton, the drawings that we obtain are induced by decomposition trees. Specifically, these drawings are linear drawings as defined by Shahrokhi et al. [SSSV97]. The definition of decomposition trees used for approximating the minimum drawing size is motivated by an "ideal" decomposition tree. Loosely speaking, this ideal decomposition tree is obtained by applying the Planar Separator Theorem recursively as in the proof of the weighted version

of the Planar Separator Theorem in Lemma 5. More formally, the ideal decomposition tree T_I is defined as follows. Let $\widetilde{G}$ denote a planar graph that is obtained by introducing vertices in the crossings of an optimal drawing of $G = (V, E)$. The decomposition tree $\widetilde{T}$ of $\widetilde{G}$ is obtained by recursively separating $\widetilde{G}$ using the Planar Separator Theorem. The decomposition tree $\widetilde{T}$ induces the decomposition tree T_I of G as follows: (a) For every $t \in \widetilde{T}$, define $V_t = \widetilde{V}_t \cap V$. (b) Prune the children, if any, of every tree node t for which $|V_t| = 1$.

The size of a linear drawing induced by an ideal decomposition tree T_I is analyzed as follows. For every internal tree node $t \in T_I$, $|cut(V_t, V - V_t)| \leq |cut(\widetilde{V}_t, \widetilde{V} - \widetilde{V}_t)|$. The Planar Separator Theorem implies that $|cut(\widetilde{V}_t, \widetilde{V} - \widetilde{V}_t)| = O(\sqrt{|\widetilde{V}_t|})$. By Corollary 4, in the linear drawing induced by T_I, an edge $e = (u, v)$ is charged for at most $\sum_{t \in P(u,v)} |cut(V_t, V - V_t)| = \sum_{t \in P(u,v)} O(\sqrt{|\widetilde{V}_t|})$ crossings. The recursive separation implies that $|\widetilde{V}_t|$ decreases exponentially as one goes down the tree; therefore, an edge $e = (u, v)$ is charged for $O(\sqrt{|\widetilde{V}_{t(e)}|})$ crossings. To bound the total charges, charge a tree node t for all of the edges e for which $t = t(e)$. Hence the charging of a tree node t is bounded by $O(|cut(\widetilde{V}_t, \widetilde{V} - \widetilde{V}_t)| \cdot \sqrt{|\widetilde{V}_t|}) = O(|\widetilde{V}_t|)$. The tree nodes in the same layer of $\widetilde{T}$ induce a partition of $\widetilde{G}$. It follows that the sum of $|\widetilde{V}_t|$ over all tree nodes t in the same layer is bounded by $O(|\widetilde{V}|) = O(\mathrm{MDS}(G))$. Since there are only a logarithmic number of layers in T_I, the size of the drawing induced by T_I is $O(\mathrm{MDS}(G) \cdot \log n)$.

Our goal is to define a decomposition tree that mimics the properties of an ideal decomposition tree. We attach to every tree node an estimator $\phi(t)$ that "behaves" like $\widetilde{V}_t$ so that we can adapt the analysis above for the drawing size that is actually computed. To be able to apply the same analysis, $\phi(t)$ should have the following properties:

1. $|cut_t| \leq \sqrt{\phi(t)}$.
2. $\phi(t)$ decreases exponentially along every path that goes down the tree.
3. $\phi(t) = O(\mathrm{MDS}(G_t))$.

Since we do not have an ideal separator procedure, we relax property 1 to $|cut_t| \leq \sqrt{\phi(t)} \cdot O(\log n)$. This degrades the approximation factor by an additional factor of $O(\log^2 n)$.

3.2. A decomposition tree with estimators.

Definition 2. *A decomposition tree T of a graph G together with a function $\phi(t)$ defined over the tree nodes is called* a decomposition tree with estimators *if the following properties are satisfied for every internal tree node $t \in T$:*

P1. $|cut_t| \leq c\sqrt{\phi(t)} \cdot \log n_t$ *for some constant c.*
P2. *For every child t' of t, $\phi(t') \leq \frac{2}{3}\phi(t)$.*
P3. $\phi(t) < 2 \cdot \mathrm{MDS}(G_t)$.

The following claim shows that a drawing induced by a decomposition tree with estimators is within $O(\log^3 n)$ factor from optimal.

Claim 6. *The size of a linear drawing of G that is induced by a decomposition tree T with estimators $\phi(\cdot)$ is $O(\mathrm{MDS}(G) \cdot \log^3 n)$.*

Proof. Consider an edge $e = (u, v)$. From Corollary 4 it follows that the number of crossings that are charged to e is bounded by $\sum_{t \in P(u,v)} |cut_t|$. Define $P(e, u)$ and $P(e, v)$ to be the paths in T from $t(e)$ to the leaves that are mapped to u and v,

respectively. It follows that

$$\sum_{t\in P(u,v)} |cut_t| \le \sum_{t\in P(e,u)} |cut_t| + \sum_{t\in P(e,v)} |cut_t|.$$

We bound each summand on the right-hand side as follows. Let $d(t,t')$ be the number of hops along the path from t to t'.

$$\begin{aligned}
\sum_{t\in P(e,u)} |cut_t| &\le \sum_{t\in P(e,u)} c\cdot\sqrt{\phi(t)}\cdot\log(n_t) && \text{(by property P1)}\\
&\le c\cdot\log n\cdot\sum_{t\in P(e,u)}\sqrt{\phi(t)}\\
&\le c\cdot\log n\cdot\sum_{t\in P(e,u)}\sqrt{\phi(t(e))\cdot\left(\tfrac{2}{3}\right)^{d(t(e),t)}} && \text{(by property P2)}\\
&= \log n\cdot O(\sqrt{\phi(t(e))})\\
&= O(\sqrt{\mathrm{MDS}(G_{t(e)})}\cdot\log n) && \text{(by property P3).}
\end{aligned}$$

By properties P1 and P3, for each tree node t, $|cut_t| = O(\sqrt{\mathrm{MDS}(G_t)}\cdot\log n)$; hence we can bound the total number of crossings charged to the edges in cut_t by $O(\log^2 n\cdot\mathrm{MDS}(G_t))$.

Fix some height in T, and consider all of the tree nodes $t_1,\ldots,t_r$ that are of this height. Notice that the sets V_{t_i} are disjoint and thus, by the superadditivity property (Proposition 1), $\mathrm{MDS}(G)\ge\sum_{i=1}^{r}\mathrm{MDS}(G_{t_i})$. It follows that the total number of crossings charged to the edges in $\cup_{i=1}^{r} cut_{t_i}$ is bounded by

$$\sum_i O(\log^2 n\cdot\mathrm{MDS}(G_{t_i}))\le O(\log^2 n\cdot\mathrm{MDS}(G)).$$

Observe that the tree T has height $O(\log n)$. This is because the estimator $\phi(\cdot)$ decreases exponentially along each path from the root to a leaf, and the estimator of the root of the tree is $O(m^2+n)$ since $\mathrm{MDS}(G)=O(m^2+n)$. It follows that the total number of crossing points is $O(\log^3 n\cdot\mathrm{MDS}(G))$. □

Remark. A better approximation algorithm for separators would yield a better approximation factor for the crossing number and the layout area. In particular, an $\alpha(n)$-approximation algorithm for separators would imply a tightened property P1, i.e., $cut_t\le c\sqrt{\phi(t)}\cdot\alpha(n_t)$, for every tree node t. This would imply an approximation factor of $O(\alpha^2(n)\cdot\log n)$ for the crossing number and $O(\alpha^2(n)\cdot\log^2 n)$ for the layout area (see section 6). This improves the corresponding results of Bhatt and Leighton (Theorems 17 and 19 in [BL84]) by a logarithmic factor and a log-square factor, respectively.

4. Constructing a decomposition tree with estimators. Our goal is to construct a decomposition tree T of G with estimators $\phi(t)$. The challenge in computing the tree is due to the requirements that (i) $\sqrt{\phi(t)}$ cannot be too small since we must be able to find a separator of size $c\sqrt{\phi(t)}\log n_t$ for some constant c; (ii) $\phi(t)$ must decay exponentially along every "downward" path; and (iii) $\phi(t)$ cannot be greater than (twice) $\mathrm{MDS}(G_t)$. The algorithm avoids an exponential search by using "failures" for pruning backtracking and for rebalancing.

Throughout the description, let $G = (V, E)$ denote the graph for which a decomposition tree is being computed. To simplify notation, we refer to induced subgraphs of G simply by their vertex sets.

Our algorithm is recursive. The input to the recursive procedures consists of the following inputs:

- a vertex subset V' (the goal is to compute a decomposition tree for the subgraph $G' = (V', E')$ induced by V');
- a "guess" g on the estimate $\phi(r')$ of the root of this tree;
- the second procedure also inputs a weight function on the vertices in V'. This weight function is either the trivial function I that assigns a unit weight to each vertex or the weight function $W_{V',B}$ with respect to the home set V' and an outside set B. To simplify notation, we sometimes omit the home set and the outside set and simply denote the nontrivial weight function by W.

Let decompose(V', g) denote our first recursive procedure. The procedure returns one of the following:

- "fail" if the guess is too small (i.e., $g < \mathrm{MDS}(V')$); or
- "success," in which case the procedure also returns a decomposition tree T' of G' with estimators $\phi(t)$. The estimator of the root r' of T' satisfies $\phi(r') \leq g$.

Since $n + \binom{m}{2}$ is an upper bound on $\mathrm{MDS}(G)$, the decomposition tree with estimators of the input graph $G = (V, E)$ is computed by calling decompose$(V, n + \binom{m}{2})$.

The procedure decompose(V', g) searches for an approximation of the smallest feasible guess in the range $[1, g]$. This search is performed by calling a second procedure test-decompose(V', g', I) for various values of g'. The output of procedure test-decompose is also either "fail" (when the guess is too small) or "success" (when the guess is large enough but might be too large). In case of success, test-decompose(V', g', I) returns a decomposition tree with "lax" estimators. The estimate $\phi(r')$ assigned to the root by the lax estimators might not satisfy property P3. That is, it outputs a success also in case the estimators $\phi(t)$ satisfy properties P1–P3 for all tree nodes but the root node, and the estimator for the root $\phi(r')$ satisfies P1 and P2 but $\phi(r') \geq 2 \cdot \mathrm{MDS}(V')$. The two procedures could be merged into a single procedure in which a range of guess values is input (the range is $[1, g]$ for decompose and $[g, g]$ for test-decompose), and a search takes place within the guess range for an approximation of the smallest feasible guess. However, the partition into two procedures seems to simplify the description.

The procedure decompose(V', g). This procedure calls successively test-decompose$(V', g/2^i, I)$ for $i = 0, 1, 2, \ldots$ until test-decompose returns "fail." We distinguish between two cases.

Case 1. The first call to test-decompose (with $i = 0$) returns "fail." In this case, decompose(V', g) returns "fail" as well.

Case 2. Some calls to test-decompose return "success." Let s be the index of the last success. In this case, decompose(V', g) returns "success" with the decomposition tree and estimators computed by test-decompose$(V', g/2^s, I)$.

The failure with $s+1$ in Case 2 is used to guarantee property P3 with respect to $\phi(r')$. In Lemma 8, we prove that if test-decompose(V', g', I) fails, then $\mathrm{MDS}(V') > g'$. Therefore, the failure with $s + 1$ implies that $g/2^s < 2 \cdot \mathrm{MDS}(V')$, and property P3 is satisfied.

The procedure test-decompose(V', g, W). This procedure has several steps.

Step 0. If V' contains a single vertex v, then return "fail" if $g < 1$ and "success"

if $g \geq 1$. In case of success, the decomposition tree is a single leaf t with $V_t = \{v\}$ and $\phi(t) = 1$. If G' contains more than one vertex, go to the next step.

Step 1. Find a simultaneous separator of V'. (Recall that such a separator is a $(\frac{1}{3}, \frac{2}{3})$-separator with respect to the weight and a $(\frac{1}{4}, \frac{3}{4})$-separator with respect to the cardinality.) Denote the two parts by V_1' and $V_2' = V' - V_1'$. Note that when the weight function is the trivial function I, a nonweighted $(\frac{1}{4}, \frac{3}{4})$-separator suffices.

Step 2. Let c_S be the constant such that by Lemma 5 there exists a simultaneous separator of V' of size $c_S \cdot \sqrt{\mathrm{MDS}(G')}$. If the size of the separator is greater than $c_S \cdot \sqrt{g} \cdot \log n'$, where $n' = |V'|$, then return "fail." Otherwise, go to the next step. The reason for the failure is that we are guaranteed to find a separator of size at most $c_S \cdot \sqrt{\mathrm{MDS}(V')} \log n'$, and thus we have a proof that $\mathrm{MDS}(V') > g$.

Step 3. Call decompose$(V_1', 2g/3)$ and decompose$(V_2', 2g/3)$.

Step 4. Distinguish between three cases depending on the outcome of Step 3.

Case 1. Both recursive calls returned a success. In this case, we have computed decomposition trees with estimators for V_1' and V_2' that satisfy properties P1–P3. We construct a decomposition tree for V' by connecting both subtrees to a root r'. Set the estimator $\phi(r')$ to be g, and return "success" with the resulting tree and estimators. Note that, in this case, $\phi(r')$ might be much larger than $\mathrm{MDS}(V')$.[3]

Case 2. Both recursive calls returned a failure. In this case, we return "fail." The failures imply that $\mathrm{MDS}(V_i') > 2g/3$ for $i = 1, 2$; hence by superadditivity $\mathrm{MDS}(V') > 4g/3$, which justifies the failure.

Case 3. One recursive call returned a success and the other a failure. Assume decompose$(V_1', 2g/3)$ succeeded and decompose$(V_2', 2g/3)$ failed. This is the most complicated case which may occur, even when g is a good guess, due to the lack of balance between $\mathrm{MDS}(V_1')$ and $\mathrm{MDS}(V_2')$. Such an imbalance can hamper satisfying P2 (i.e., the exponential decay of the estimators) along the branch from V' to V_2'. The algorithm attempts to rebalance the partitioning by recursing on V_2' and searching for a balanced cut $cut(U, V' - U)$, where $U \subseteq V_2'$. To avoid a significant increase in the cut size (compared with $cut(V_1', V_2')$), simultaneous separators are employed as follows.

Define a weight function W_2 as follows. If the procedure test-decompose was called with the trivial weight function I, then W_2 is the weight function defined with respect to the home set V_2' and the outside set V'. Otherwise, that is, if the procedure test-decompose was called with a nontrivial weight function W, then W_2 is the weight function defined with respect to the home set V_2' and the same outside set used for W. In this way, the outside set is always the first vertex set that failed in the current sequence of failures.

[3] In fact, $\phi(r')$ can be assigned a "tighter" value which could shorten the running time. Namely, set $\phi(r')$ to be the maximum of $\frac{3}{2} \cdot \phi(r_1')$, $\frac{3}{2} \cdot \phi(r_2')$, and $(\frac{|cut(V_1', V_2')|}{c_S \log n'})^2$, where r_i' is the root of the decomposition tree computed for V_i'. In this case, if $\phi(r') = (\frac{|cut(V_1', V_2')|}{c_S \log n'})^2$, then by Lemma 5 it follows that $\phi(r') \leq \mathrm{MDS}(V')$, which means that smaller guesses for V' are not needed. However, if $\phi(r') = \frac{3}{2} \cdot \phi(r_i')$, then, from superadditivity, we can only infer that $\mathrm{MDS}(V') \geq \mathrm{MDS}(V_1') + \mathrm{MDS}(V_2') \geq \frac{1}{2} \cdot (\phi(r_1') + \phi(r_2')) \geq \frac{1}{2} \cdot \frac{2}{3} \cdot \phi(r')$. Hence $\phi(r') \leq 3 \cdot \mathrm{MDS}(V')$, and one more guess of $\phi(r')/2$ would still be required for V'.

In Case 3, continue with the following substeps.

Step 4.1. Call test-decompose(V_2', g, W_2). If this call fails, then we have proof that $\mathrm{MDS}(V') \geq \mathrm{MDS}(V_2') > g$; therefore, return "fail."

Suppose that this call succeeded. Consider the recursion tree created by the call to test-decompose(V_2', g, W_2). Since this call succeeded, the two recursive calls of decompose with the parts of V_2' and guess $2g/3$ as inputs either both succeeded or at most one of them failed. In case one of the calls failed, we recursively call test-decompose on this "failed" part with a guess g. Since, by our assumption, the calling procedure test-decompose succeeded, test-decompose must succeed on this "failed" part with a guess g. Again, this implies that the two recursive calls of decompose with the subparts of this "failed" part and the guess $2g/3$ either both succeeded or at most one failed. It follows that the recursion tree has a chain of "failure" nodes, where each such failure node denotes a failure in a call to decompose with the corresponding subgraph and guess $2g/3$. We are guaranteed that the calls to decompose with the subgraphs that correspond to the siblings of these failed nodes succeeded. This sequence of "mixed" siblings must end with two siblings for which decompose succeeded on their corresponding subgraphs and $2g/3$.

Figure 1 depicts the recursion tree until two successful siblings are encountered. We use the following notation for the vertex sets inducing the subgraphs corresponding to the siblings in this sequence. Let $F_0 = V_2'$ and $S_0 = V_1'$ be the vertex sets of the first pair of mixed siblings. Suppose that the sequence of mixed pairs is of length $x \geq 1$. Then, for $1 \leq i < x$, the sets F_i (representing failure) and S_i (representing success) denote the partition of F_{i-1} computed in Step 1 of test-decompose$(F_{i-1}, g, W_{F_{i-1},V'})$. The set F_i is the one for which the call to decompose$(F_i, 2g/3)$ failed, and the set S_i is the one for which the call to decompose$(S_i, 2g/3)$ succeeded. This chain of failures ends with the vertex set F_{x-1} that is partitioned into two sets S_x and S_{x+1} for which both calls to decompose$(S_x, 2g/3)$ and decompose$(S_{x+1}, 2g/3)$ succeeded. Let $S = S_0 \cup S_1 \cup \cdots \cup S_{x-1}$.

Step 4.2. Call to decompose$(S \cup S_x, 2g/3)$ and decompose$(S \cup S_{x+1}, 2g/3)$. If both fail, then return "fail." Lemma 8 proves that these two failures imply that $\mathrm{MDS}(V') > g$.

Suppose that decompose$(S \cup S_x, 2g/3)$ succeeded. Recall the fact that decompose$(S_{x+1}, 2g/3)$ succeeded as well. Claim 7 proves that $|cut(S \cup S_x, S_{x+1})| \leq c \cdot \sqrt{g} \cdot \log n'$. Return "success" with the decomposition tree obtained by connecting the decomposition trees computed for $S \cup S_x$ and S_{x+1} with a common root r' and the estimators returned by the two recursive calls together with $\phi(r') = g$. (A tighter assignment of $\phi(r')$ is possible, as suggested in footnote 3.)

Correctness. The following claim proves that the rebalancing performed in Step 4.2 does not increase the cut by much so that property P1 holds.

CLAIM 7. *If* test-decompose(V', g, I) *reaches Step* 4.2*, then there exists a constant* c *such that*

$$|cut(S \cup S_x, S_{x+1})| \leq c \cdot \sqrt{g} \cdot \log n'.$$

Proof. We use the same notation as in the algorithm. Notice that $S \cup S_x =$

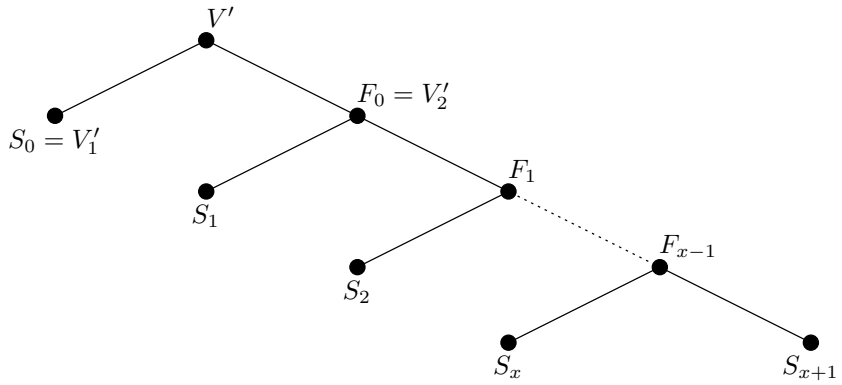

FIG. 1. *A recursion tree for which* (a) decompose$(F_i, 2g/3)$ *failed for* $i = 0, 1, \ldots, x-1$ *and* (b) decompose$(S_i, 2g/3)$ *succeeded for* $i = 0, 1, \ldots, x+1$.

$V' - S_{x+1}$, and

$$cut(S_{x+1}, V' - S_{x+1}) = cut(S_{x+1}, S_x) \cup cut(S_{x+1}, V' - F_{x-1}).$$

The success of test-decompose$(F_{x-1}, g, W_{F_{x-1},V'})$ implies that

$$|cut(S_{x+1}, S_x)| \leq c_S \cdot \sqrt{g} \cdot \log n'.$$

Since (S_{x+1}, S_x) is a $(\frac{1}{3}, \frac{2}{3})$-separator with respect to the weight function $W_{F_{x-1},V'}$ and since, for any subset $U \subseteq F_{x-1}$, the total weight $W_{F_{x-1},V'}$ over the vertices of U is $cut(U, V' - F_{x-1})$, we get

$$|cut(S_{x+1}, V' - F_{x-1})| \leq \frac{2}{3}|cut(F_{x-1}, V' - F_{x-1})|.$$

Continuing in the same manner, we get that, for $i = x-1, \ldots, 1$,

$$|cut(F_i, V' - F_i)| \leq |cut(F_i, S_i)| + \frac{2}{3}|cut(F_{i-1}, V' - F_{i-1})|.$$

For $i = 0, \ldots, x-1$, $|cut(F_i, S_i)| \leq c_S \cdot \sqrt{g} \cdot \log n'$. If we solve this recurrence relation, we get

$$|cut(S_{x+1}, V' - S_{x+1})| \leq \frac{1}{1 - \frac{2}{3}} \cdot c_S \cdot \sqrt{g} \cdot \log n'.$$

Setting $c = 3 \cdot c_S$ proves the claim. □

We now prove that failure of test-decompose(V', g, W) implies that $\mathrm{MDS}(V') > g$. This claim holds regardless of whether W is a trivial or nontrivial weight function. Notice that the guarantee is one-sided; a success might be obtained even if g is very small. (For example, consider a balanced binary tree as an input graph. All cuts have size 1, so g can be sublinear, i.e., $(\frac{3}{2})^{\log_2 n}$, but the drawing size is linear.)

LEMMA 8. *If the procedure* test-decompose(V', g, W) *fails, then* $g < \mathrm{MDS}(V')$.

Proof. The proof is by induction on $|V'|$. The induction basis is trivial (see Step 0). In the induction step, we consider the steps in which a failure can be decided upon. Assume that the lemma holds for all graphs with less than $|V'|$ vertices, and assume that $g \geq \mathrm{MDS}(V')$ and test-decompose(V', g, W) fails.

1. A failure in Step 2 contradicts the assumption because of the guarantee of the partitioning algorithm.
2. A failure in Case 2 in Step 4 contradicts the assumption as follows. By the induction hypothesis, failure of test-decompose$(V_i', 2g/3, I)$ implies $\mathrm{MDS}(V_i') > 2g/3$ for $i = 1, 2$. From the superadditivity property (Proposition 1) it follows that $\mathrm{MDS}(V') > 4g/3$, which is a contradiction.
3. A failure in Step 4.1 implies, by the induction hypothesis, that $\mathrm{MDS}(V_2') > g$. Since $\mathrm{MDS}(V') \geq \mathrm{MDS}(V_2')$, we reach a contradiction.
4. The harder case to prove is when a failure is decided upon in Step 4.2. Consider an optimal drawing D' of G', the subgraph of G induced by V'. Every point in D' is either a crossing point between two edges of G' or a vertex in V'. Let D_{x-1} denote the restriction of D' to a drawing of F_{x-1}. Recall that decompose$(F_{x-1}, 2g/3)$ failed. Therefore, by the induction hypothesis, $\mathrm{MDS}(F_{x-1}) > 2g/3$. Since D_{x-1} is a drawing of the subgraph induced by F_{x-1}, it follows that D_{x-1} contains more than $2g/3$ points.
   The points in D_{x-1} can be partitioned as follows: (a) points of the restriction of D_{x-1} to S_x, namely, vertices of S_x and crossings between edges of the subgraph induced by S_x; (b) points of the restriction of D to S_{x+1}; and (c) other crossings. Let P denote the points in D_{x-1} of type (b) or (c). By swapping S_x and S_{x+1} if needed, the number of points in P is at least half the number of points in D_{x-1} and hence greater than $g/3$.
   Let $D_{0..x}$ denote the restriction of D' to a drawing of $S \cup S_x$. The points in the drawing $D_{0..x}$ are contained in the points of the drawing D' that are not points in P. Since the number of points in P is more than $g/3$, we get that the number of points in $D_{0..x}$ is strictly less than $\mathrm{MDS}(G') - g/3$. By our assumption $g \geq \mathrm{MDS}(G')$, and thus the number of points in $D_{0..x}$ is strictly less than $2g/3$. Since $D_{0..x}$ is a drawing of $S \cup S_x$, $\mathrm{MDS}(S \cup S_x) < 2g/3$, and, by the induction hypothesis, decompose$(S \cup S_x, 2g/3, I)$ succeeds. Hence failure is not decided upon in Step 4.2, which is a contradiction. ∎

The following claim shows that the computed decomposition tree with estimators satisfies properties P1–P3.

LEMMA 9. *Let T' denote the decomposition tree with estimators $\phi(t)$ returned by a successful call to* decompose(G', g). *Then T and $\phi(t)$ satisfy properties* P1–P3 *with respect to G'.*

Proof. We extend the claim to decomposition trees computed by successful calls to test-decompose(G', g, W) with the relaxation that property P3 is not required for the root of T'.

The proof is by induction on $|V|$. It is obvious to show that the induction basis holds. The induction step proceeds as follows:

1. Property P1 is satisfied because cut_t is either a cut computed by the partitioning procedure (in which case the size of the cut is checked in Step 2) or a cut obtained by rebalancing in Step 4.2 (in which case Claim 7 guarantees that $|cut_t|$ satisfies property P1).
2. Property P2 is satisfied because, by the construction, if t' is a child of t, then $\phi(t') \leq \frac{2}{3}\phi(t)$.
3. Property P3 is satisfied by the induction hypothesis for all internal nodes of T. It holds for the root r' of T' since a success of decompose(G', g) implies a failure of test-decompose$(G', \phi(r')/2, I)$. By Lemma 8, this implies that $g/2 < \mathrm{MDS}(G')$, and property P3 follows. ∎

Polynomial running time. Let $F(n,g)$ and $G(n,g)$ denote the running times of decompose and test-decompose when the subgraph has n nodes and the guess equals g. Note that the weight function does not affect the running time. Let $p(n)$ denote a polynomial bounding the running time of the partitioning algorithm and the lines in test-decompose that do not call decompose and test-decompose. The functions $F(n,g)$ and $G(n,g)$ satisfy the following recurrences: (We make a relaxed upper bound in assuming that the functions $F(\cdot)$ and $G(\cdot)$ are monotone in both parameters.)

$$F(n,g) \leq \sum_{i=0}^{\lceil \log_2 g \rceil} G(n, g/2^i)$$

$$G(n,g) \leq p(n) + 2F\left(\frac{3}{4}n, \frac{2}{3}g\right) + G\left(\frac{3}{4}n, g\right) + 2F\left(n, \frac{2}{3}g\right).$$

The following claim proves that the running time of the decomposition algorithm is polynomial. Recall that g is always polynomial in n.

LEMMA 10. *There exist constants τ, γ, δ such that $F(n,g) \leq \tau \cdot p(n) \cdot n^{\gamma} \cdot g^{\delta}$.*

Proof idea. One may simply prove this by induction. The reason the proof works is that at each recursion step there are either (i) a constant number of recursive calls in which one of the parameters (the number of vertices or the guess value) decreases by a constant factor or (ii) a logarithmic number of recursive calls in which the guess parameters form a geometric sequence. For this reason, it was imperative that we went down a path with a geometrically decreasing number of vertices. It was also important that, in Step 4.2, once the chain of failures ends with two successful siblings, we were able to argue that the guess value should decrease by a constant factor.

Claim 6 and Lemmas 9 and 10 imply the following theorem. Note that the algorithm computes a linear drawing.

THEOREM 11. *There exists an $O(\log^3 n)$-approximation algorithm for the minimum drawing size of bounded degree graphs.*

Coping with skewed weight functions. As mentioned above, for some weight functions $W_{A,B}$, there may be a vertex v such that $W_{A,B}(v) > \frac{2}{3}\sum_{v \in A} W_{A,B}(v)$. We call such weight functions *skewed* weight functions. In the case of skewed weight functions, we cannot apply Lemma 5 to find a simultaneous separator. Below, we show how to handle such cases. First, we show that in such cases the total weight is bounded and then prove that, because of the bounded weight, any cut that is a $(\frac{1}{4}, \frac{3}{4})$-separator with respect to the number of vertices suffices.

CLAIM 12. *Let $G = (V,E)$ denote a graph with maximum degree Δ. For any two subsets of vertices $A, B \subseteq V$ and a vertex $v \in A$ such that $W_{A,B}(v) > \frac{2}{3}\sum_{v \in A} W_{A,B}(v)$, $|cut(A, B - A)| \leq \frac{3}{2} \cdot \Delta$.*

Proof. Recall that $\sum_{v \in A} W_{A,B}(v) = |cut(A, B - A)|$. The claim follows since by definition $W_{A,B}(v) \leq \Delta$. □

Simultaneous separators are computed in Steps 1 and 4.1 of test-decompose. Whenever the weight function is skewed and nontrivial, a simultaneous separator cannot be computed. Instead, a $(\frac{1}{4}, \frac{3}{4})$-separator with respect to the number of vertices is computed in such cases. To maintain the validity of the algorithm, we need to revise the proof of Lemma 7.

Proof of Lemma 7 (revised). We use the same notation as in the algorithm. Notice that $S \cup S_x = V' - S_{x+1}$, and

$$cut(S_{x+1}, V' - S_{x+1}) = cut(S_{x+1}, S_x) \cup cut(S_{x+1}, V' - F_{x-1}).$$

The success of test-decompose$(F_{x-1}, g, W_{F_{x-1},V'})$ implies that

$$|cut(S_{x+1}, S_x)| \leq c_S \cdot \sqrt{g} \cdot \log n'.$$

If $cut(S_{x+1}, S_x)$ is a simultaneous separator, then, since (S_{x+1}, S_x) is a $(\frac{1}{3}, \frac{2}{3})$-separator with respect to the weight function $W_{F_{x-1},V'}$ and since, for any subset $U \subseteq F_{x-1}$, the total weight $W_{F_{x-1},V'}$ over the vertices of U is $cut(U, V' - F_{x-1})$, we get

$$|cut(S_{x+1}, V' - F_{x-1})| \leq \frac{2}{3}|cut(F_{x-1}, V' - F_{x-1})|.$$

Suppose that $cut(S_{x+1}, S_x)$ is not a simultaneous separator but a $(\frac{1}{4}, \frac{3}{4})$-separator with respect to the number of vertices. This happens when the weight function $W_{F_{x-1},V'}$ is skewed. By Claim 12, we have in this case $|cut(S_{x+1}, V' - F_{x-1})| \leq \frac{3}{2}\Delta$ (where Δ is the degree bound).

Combining both cases, we have

$$\begin{aligned} |cut(S_{x+1}, V' - F_{x-1})| &\leq \max\left\{\frac{2}{3}|cut(F_{x-1}, V' - F_{x-1})|, \frac{3}{2}\Delta\right\} \\ &\leq \frac{2}{3}|cut(F_{x-1}, V' - F_{x-1})| + \frac{3}{2}\Delta. \end{aligned}$$

Continuing in the same manner, we get that, for $i = x - 1, \ldots, 1$,

$$|cut(F_i, V' - F_i)| \leq |cut(F_i, S_i)| + \frac{2}{3}|cut(F_{i-1}, V' - F_{i-1})| + \frac{3}{2}\Delta.$$

For $i = 0, \ldots, x - 1$, $|cut(F_i, S_i)| \leq c_S \cdot \sqrt{g} \cdot \log n'$. Solving this recurrence relation, we get

$$|cut(S_{x+1}, V' - S_{x+1})| \leq \frac{1}{1 - \frac{2}{3}}\left(c_S \cdot \sqrt{g} \cdot \log n' + \frac{3}{2}\Delta\right).$$

Setting $c = 3c_S + \frac{9}{2}\Delta$ proves the claim. ∎

5. Approximating $\sqrt{2}$-bifurcators. An (F, α)-bifurcator is a decomposition tree in which $|cut_t| \leq F \cdot \alpha^{-depth(t)}$ for every tree node t. An optimal α-bifurcator is an (F, α)-bifurcator with the minimum F. In our algorithm, we require that the bounds on the cut sizes decrease geometrically by $\frac{2}{3}$ relative to *every* node and not only the root. This property was required so that we could bound the sum of the cuts along a path from an internal tree node t to a leaf by $O(\phi(t))$. The following corollary is shown in [BL84, LR99].

COROLLARY 13. *Given an $O(\log^k n)$-approximation for the size of drawing on the plane, there exists an $O(\log^{(k+1)/2} n)$-approximation algorithm for finding the optimal $\sqrt{2}$-bifurcator.*

Theorem 11 implies an improvement of the approximation factor of $\sqrt{2}$-bifurcators by a $\sqrt{\log n}$ factor to $O(\log^2 n)$. As mentioned in the introduction, Bhatt and Leighton [BL84] demonstrated that $\sqrt{2}$-bifurcators are useful for minimizing capacitive delay, producing fault tolerant layouts (layouts using prefabricated chip and regular layouts), minimizing wire crossing in layouts, and more.

6. VLSI layouts. In this section, we present a VLSI layout algorithm for graphs of maximum degree four. The algorithm embeds a graph G in a square host grid of size $O(\text{AREA}(G) \cdot \log^4 n)$.

An $O(\log^5 n)$-approximate VLSI layout area can be derived by applying planar graph embedding algorithms on the drawing computed in section 4, the size of which is $O(\text{MDS} \cdot \log^3 n)$ [L80, V81]. This is an improvement by a logarithmic factor over the approximation factor of the VLSI layout algorithm of Bhatt and Leighton [BL84]. We show how an additional logarithmic factor can be saved.

6.1. Weighted version of Leiserson's algorithm. Leiserson's algorithm for computing layouts of graphs is based on the graphs satisfying a separator theorem. The separator theorem is stated in terms of the *number* of vertices. Namely, every n-vertex graph in a given family can be separated into two disjoint graphs, each containing at least a constant fraction of the vertices, by removing at most $f(n)$ edges. For example, in bounded degree planar graphs, the separator is guaranteed to be bounded by the square-root of the number of vertices, and the size of each part is bounded by $\frac{2}{3}$ of the original number of vertices. Planar graph embedding algorithms require $O(n \cdot \log^2 n)$ area.

We consider a "weighted" version of Leiserson's algorithm in which subgraphs are assigned weights. The input to the weighted version of Leiserson's algorithm consists of a graph and a decomposition tree with weights $Wt(t)$ defined over the tree nodes. Loosely, the cut size in every internal tree node is bounded by the square-root of the weight of the tree node, and the weight of each node is divided roughly equally between its two children. The weighted version of Leiserson's algorithm returns a VLSI layout of area $O(Wt(r) \cdot \log^2 Wt(r))$, where r denotes the root of T. If $Wt(r) = O(\text{MDS}(G) \cdot \log^2 n)$, then $\log Wt(r) = O(\log n)$, and, by Proposition 2, an approximation factor of $O(\log^4 n)$ follows for the VLSI layout.

The following four properties of the decomposition tree T and the tree node weights $Wt(t)$ are sufficient for the "success" of the weighted version of Leiserson's algorithm:

Nontriviality. For each leaf ℓ, $Wt(\ell) \geq 1$.

Superadditivity. For any two siblings t_ℓ and t_r in the tree, with a parent t,

$$Wt(t_\ell) + Wt(t_r) \leq Wt(t).$$

Balance. For any two siblings t_ℓ and t_r in the tree,

$$\max\{Wt(t_\ell), Wt(t_r)\} \leq 2 \cdot \min\{Wt(t_\ell), Wt(t_r)\}.$$

(Note that the above two conditions imply that both the weights $Wt(t_\ell)$ and $Wt(t_r)$ are at most $\frac{2}{3} Wt(t)$.)

Separator. For any internal tree node t, $|cut_t| = O(\sqrt{Wt(t)})$.

We outline the weighted version of Leiserson's algorithm. First, the algorithm defines a function $A(t)$ over the tree nodes that specifies the area allocated for embedding G_t. The function $A(t)$ is defined as follows:

$$A(t) = \begin{cases} 1 & \text{if } t \text{ is a leaf,} \\ \left(\sqrt{A(t_\ell) + A(t_r)} + \alpha \cdot |cut_t|\right)^2 & \text{otherwise,} \end{cases}$$

where t_ℓ and t_r denote the children of t and $\alpha = 2\sqrt{3}$.

Given a rectangle R_t with aspect ratio at least $\frac{1}{3}$ and area $A(t)$, the algorithm computes an embedding of G_t in R_t as follows. A subrectangle R'_t of area $A(t_\ell)+A(t_r)$ that is similar to R_t is allocated for embedding G_ℓ and G_r. The subrectangle R'_t is divided between G_{t_ℓ} and G_{t_r} in proportion to the weights $Wt(t_\ell)$ and $Wt(t_r)$. After G_{t_ℓ} and G_{t_r} are embedded in the subrectangles allocated for them, the edges of cut_t are embedded using the unused rows and columns of R_t. (At most two columns and two rows are used for embedding each edge in the cut.) In Claim 14, it is proved that there is a sufficient number of unused rows and columns left in R_t for routing the edges of cut_t.

We briefly point out why each of the properties is required: Nontriviality and superadditivity guarantee that the size of a rectangle allocated for a subgraph is not smaller than the size of the subgraph. Superadditivity also makes sure that the subrectangle allocated for the children of t is not larger than the rectangle allocated for t. The balance property makes sure that the division of the rectangle does not create subrectangles whose aspect ratios are below $\frac{1}{3}$. Hence, throughout the algorithm, the aspect ratios of the rectangles that serve as hosts for subgraphs are at least $\frac{1}{3}$. This also implies that the host grid for the whole graph can be a rectangle of aspect ratio $\frac{1}{3}$ rather than a square. The separator property is used to solve the recurrence and prove the bound on the required area.

The following claim shows that the weighted version of Leiserson's algorithm succeeds in embedding a graph of maximum degree four in a rectangle of area $A(t)$.

CLAIM 14. *Let T denote a decomposition tree with node weights $Wt(t)$ of a graph G of maximum degree four. Suppose that the node weights satisfy the nontriviality, superadditivity, and balance properties. If R is a rectangle whose aspect ratio is at least $\frac{1}{3}$ and whose area is at least $A(t)$, then the weighted version of Leiserson's algorithm succeeds in embedding G in R.*

Proof. The proof follows [L80, Thm. 6]. In particular, we rely on two observations in Leiserson's proof. One observation is that aspect ratios do not deteriorate. Namely, suppose we divide a rectangle R whose aspect ratio is at least $\frac{1}{3}$ into two subrectangles R_1 and R_2 by cutting it along the longer side. Suppose also that this cut is made between a third and two thirds of the side's length so that the area of the larger subrectangle is at most twice the area of the smaller subrectangle. Then the aspect ratios of R_1 and R_2 are also at least $\frac{1}{3}$. The second observation is that a new edge can be routed in a given embedding by introducing at most two rows and two columns. (This is called "slicing" in [L80].)

The proof is by induction on the height of the tree node. The induction basis obviously holds for leaves. Let R'_t denote the subrectangle of R_t allocated for G_{t_ℓ} and G_{t_r}. By definition, R'_t and R_t have the same aspect ratio. The area of R'_t equals $A(t_\ell) + A(t_\ell)$. (There is a "rounding" issue that we ignore to make the presentation simpler.) We need to show that there are at least $2 \cdot |cut_t|$ spare rows and columns in R_t for routing the edges of cut_t.

Let $L(R)$ and $W(R)$ denote the length and width of a rectangle R. (Assume $W(R_t) \leq L(R_t)$.) Denote the aspect ratio of a rectangle R by $\sigma(R)$, namely, $\sigma(R) = W(R)/L(R)$. The width of R_t satisfies

$$W(R_t) = \frac{area(R_t)}{L(R_t)} = \frac{area(R_t) \cdot \sigma(R_t)}{W(R_t)}.$$

Since $area(R_t) \geq A(t)$,

$$W(R_t) \geq \sqrt{A(t) \cdot \sigma(R_t)}.$$

Note that, since R_t and R'_t are similar, they have the same aspect ratio; hence

$$W(R'_t) = \sqrt{A(t_\ell) + A(t_r)}\sqrt{\sigma(R_t)}.$$

By the last two equations and the definition of $A(t)$, it follows that

$$\begin{aligned} W(R_t) &\geq \sqrt{\sigma(R_t) \cdot A(t)} \\ &= \sqrt{\sigma(R_t)} \cdot \left(\sqrt{A(t_\ell) + A(t_r)} + 2\sqrt{3} \cdot |cut_t| \right) \\ &= W(R'_t) + \sqrt{\sigma(R_t)} \cdot 2\sqrt{3} \cdot |cut_t|. \end{aligned}$$

Since $\sigma(R_t) \geq \frac{1}{3}$, it follows that $W(R_t) - W(R'_t) \geq 2 \cdot |cut_t|$. Hence there are enough spare rows. Since $L(R_t) - L(R'_t) = (W(R_t) - W(R'_t))/\sigma(R_t)$, there are also enough spare columns, and the claim follows. □

The following claim shows that if the decomposition tree satisfies all four properties, then $A(r) = O(Wt(r) \cdot \log^2 Wt(r))$, where r denotes the root of the decomposition tree.

Claim 15. *Let T denote a decomposition tree with node weights $Wt(t)$ of a graph G of maximum degree four. Suppose that the node weights satisfy the nontriviality, superadditivity, balance, and separator properties. There exists a constant c_A such that*

$$A(t) = c_A \cdot Wt(r) \cdot \log^2 Wt(r).$$

Proof. The proof follows [L80, section 5]. Recall that $\alpha = 2\sqrt{3}$, and let $\beta = \max_{t \in T}\{|cut_t|/\sqrt{Wt(t)}\}$. The separator property implies that β is a constant. Define the function $B(t)$ over the tree nodes as follows:

$$B(t) = \begin{cases} 1 & \text{if } t \text{ is a leaf,} \\ \max\{B(t_\ell), B(t_r)\} + \alpha \cdot \beta & \text{otherwise.} \end{cases}$$

We prove by induction that $A(t) \leq B^2(t) \cdot Wt(t)$. This obviously holds for leaves. The induction step is proved as follows:

$$\begin{aligned} \sqrt{A(t)} &= \sqrt{A(t_\ell) + A(t_r)} + \alpha \cdot |cut_t| \\ &\leq \sqrt{B^2(t_\ell) \cdot Wt(t_\ell) + B^2(t_r) \cdot Wt(t_r)} + \alpha\beta\sqrt{Wt(t)} \\ &\leq \max\{B(t_\ell), B(t_r)\} \cdot \sqrt{Wt(t)} + \alpha\beta\sqrt{Wt(t)} \\ &= B(t) \cdot \sqrt{Wt(t)}. \end{aligned}$$

The second inequality follows from the induction hypothesis and the definition of β. The third inequality follows from the superadditivity property.

The balance and superadditivity properties imply that the depth of T is at most $\log_{2/3} Wt(t)$, and hence it follows that $B(t) \leq \alpha\beta \log_{2/3} Wt(t)$, and the claim follows. □

Remark. If the balance property is relaxed so that $\max\{Wt(t_\ell), Wt(t_r)\} \leq (1 - \sigma) \cdot Wt(t)$, then the aspect ratios of the rectangles allocated in the algorithm are lower bounded by σ. The proof of Claim 14 required that $\alpha \geq 2/\sqrt{\sigma}$. In the proof of Claim 15, $A(t)$ is proportional to α^2. Therefore, the balance property can be relaxed at the cost of increasing $A(t)$.

6.2. Computing a weighted decomposition tree. Given a graph G, we show how to construct a decomposition tree T and a weight function $Wt(\cdot)$ that obeys the properties sufficient for the success of the weighted version of Leiserson's algorithm. Observe that recursively separating an optimal drawing of G generates a decomposition tree that satisfies these properties if the weight function equals the size of the subdrawing. We show how to compute an "approximation" of such a tree in which the weight of the root is $O(\mathrm{MDS}(G)\log^2 n)$.

At first glance, it is tempting to use the decomposition tree computed for the minimal drawing as the decomposition tree required here and to use the estimator function computed before as the required weight function. Two obstacles obstruct this approach: (a) The decomposition tree is not balanced since the ratio of estimators of two siblings is not bounded. (b) The decomposition tree may not obey the superadditivity property, as we may have two siblings with estimators that add up to more than the estimator of the parent (i.e., the estimators of each of the children of an internal node t can be $2\phi(t)/3$). Violating balance is solved by rebalancing, but violating superadditivity makes $\phi(t)$ a bad candidate for a weight function. Superadditivity is obtained by presenting a weight function that is computed bottom-up (to ensure superadditivity). Balance is obtained afterward by rebalancing the tree with respect to the weights in a top-down fashion.

6.2.1. The new weight function. Let T denote the decomposition tree of G with estimator $\phi(t)$ computed in section 4. Let $CW(t)$ be the maximum sum of cut sizes along a path from t to a leaf in the subtree rooted at t, where the maximum is taken over all such paths.

Definition 3. *The weight function $Wt(t)$ is defined as follows:*

$$Wt(t) = \begin{cases} 1 & \text{if } t \text{ is a leaf,} \\ \max\{\, Wt(t_\ell) + Wt(t_r), CW^2(t)\} & \text{otherwise.} \end{cases}$$

The following lemma bounds the weight of the root of T.

Lemma 16. *For some constant c_W, $Wt(t) \le c_W \cdot \mathrm{MDS}(G_t) \cdot \log^2(n_t + 1)$.*

Proof. The proof is by induction. The induction basis for the leaves is obvious. Consider an internal tree node t. If $Wt(t) = Wt(t_\ell) + Wt(t_r)$, then the claim follows by the superadditivity of the minimum drawing size.

If $Wt(t) = CW^2(t)$, note that the upper bounds on the sizes of the cuts along any path from t to any of its leaves decay exponentially and that the size of the first cut (and hence the sum of all of the cuts along a path from t to a leaf) is $O(\sqrt{\phi(t)}\log n_t) = O(\sqrt{\mathrm{MDS}(G_t)}\log n_t)$. The square of the sum of these cuts is $O(\mathrm{MDS}(G_t)\log^2 n_t)$. For an appropriately chosen c_W, the claim follows. ∎

The weight function $Wt(t)$ satisfies all of the properties required except for the balance property. We show how to achieve balance in the following subsection.

6.2.2. Rebalancing the tree. Rebalancing proceeds in two steps: First, the tree is rebalanced so that the weight of each node is at most two-thirds the weight of its parent. Second, weights are inflated, if necessary, so that balance is achieved.

Procedure rebalance($\mathcal{T}$). The rebalance($\mathcal{T}$) procedure balances the tree recursively and assigns weights $Wt_2(\cdot)$ to tree nodes. The weight of each node is at most two-thirds the weight of its parent. The input consists of a collection of trees (inclusive of the case of a single tree) denoted by $\mathcal{T}$, where the initial input consists of a single tree. The procedure outputs a decomposition tree over the union of the leaves of trees

in $\mathcal{T}$. The following notation is used: the weight of a tree, $Wt(T')$, is defined to be the weight of its root, $Wt(r')$. Given a collection $\mathcal{T}$ of trees, let $Wt(\mathcal{T}) = \sum_{T' \in \mathcal{T}} Wt(T')$.

The procedure rebalance($\mathcal{T}$). Assume $\mathcal{T} = \{T_1, \ldots, T_p\}$.

1. If there exists any j such that $\sum_{i=1}^{j} Wt(T_i)$ is between $\frac{1}{3}$ and $\frac{2}{3}$ of $Wt(\mathcal{T})$, we create the two collections $\mathcal{T}_1 = \{T_1, \ldots, T_j\}$ and $\mathcal{T}_2 = \{T_{j+1}, \ldots, T_k\}$. The separating cut is of size 0.
2. If there is no such j, then there exists a j such that $\sum_{i=1}^{j-1} Wt(T_i)$ and $\sum_{i=j+1}^{p} Wt(T_i)$ are both less than $\frac{1}{3} Wt(\mathcal{T})$. Starting at the root $r(T_j)$ of T_j, walk down the tree, following the heavier subtree until the first subtree T' whose weight is less than $\frac{2}{3} Wt(T_j)$ is reached. Let the subtrees hanging from the path from $r(T_j)$ to T' (other than T') be $T'_1, \ldots, T'_q$ (where T'_q denotes the sibling of T'). By Lemma 17, $\sum_{i=1}^{q} Wt(T'_i) < \frac{2}{3} Wt(T_j)$.
3. We have four collections:
$$\mathcal{T}_a = \{T_1, \ldots, T_{j-1}\}, \qquad \mathcal{T}_b = \{T_{j+1}, \ldots, T_p\},$$
$$\mathcal{T}_c = \{T'\}, \qquad \mathcal{T}_d = \{T'_1, \ldots, T'_q\}.$$
Let $MIN(a,b) \in \{a,b\}$ be the index of the collection with the smaller weight between collections $\mathcal{T}_a$ and $\mathcal{T}_b$. Recall that the weight of a collection $\mathcal{T}$ is the sum of the weights of the trees in $\mathcal{T}$. Similarly, $MAX(a,b) \in \{a,b\}$ is defined to be the index of the larger weighted collection. Define $MIN(c,d)$ and $MAX(c,d)$ similarly. Let
$$\mathcal{T}_1 = \mathcal{T}_{MIN(a,b)} \cup \mathcal{T}_{MAX(c,d)},$$
$$\mathcal{T}_2 = \mathcal{T}_{MAX(a,b)} \cup \mathcal{T}_{MIN(c,d)}.$$
4. Call rebalance($\mathcal{T}_1$) and rebalance($\mathcal{T}_2$), and let S_i denote the decomposition tree computed for $\mathcal{T}_i$. Let S be a decomposition tree for $\mathcal{T}$ obtained by connecting S_1 and S_2 to a root s. Set $Wt_2(s) = Wt(\mathcal{T})$.

Note that the weight function $Wt_2(\cdot)$ satisfies all of the properties except for balance. In particular: (a) The separator property holds since the size of a cut is either zero or is bounded by $CW(r(T_j))$, where $r(T_j)$ is the root of T_j, which is bounded by $\sqrt{Wt(T_j)}$. (b) The superadditivity property holds since either $\mathcal{T} = \mathcal{T}_1 \cup \mathcal{T}_2$ or T_j is partitioned into the collections $\mathcal{T}_c$ and $\mathcal{T}_d$, and $Wt(T_j) \geq Wt(\mathcal{T}_c) + Wt(\mathcal{T}_d)$. Note also that if a single tree is rebalanced, then the weight of the root after rebalancing equals the weight of the root before balancing. So Lemma 16 implies that the weight of the root s of the decomposition tree computed by rebalance($\{T\}$) satisfies

$$Wt_2(s) \leq c_W \cdot \mathrm{MDS}(G_t) \cdot \log^2(n+1).$$

The following lemmas prove that the weight of every node is at most two-thirds the weight of its parent.

LEMMA 17. *In step* 2 *above,* $\sum_{i=1}^{q} Wt(T'_i) < \frac{2}{3} Wt(T_j)$.

Proof. Consider two cases: (a) If $Wt(T') > Wt(T_j)/3$, then it follows by superadditivity. (b) If $Wt(T') \leq Wt(T_j)/3$, then $Wt(T'_q) \leq Wt(T_j)/3$ also. Since the weight of the parent of T' and T'_q is not less than $\frac{2}{3} Wt(T_j)$, we have $\sum_{i=1}^{q-1} Wt(T'_i) < Wt(T_j)/3$, and the claim follows. ∎

LEMMA 18. *In the decomposition tree returned by* rebalance($\mathcal{T}$)*, the weight of a nonroot node is at most two-thirds the weight of its parent.*

Proof. Since $Wt(\mathcal{T}_{MIN(a,b)}) \leq \frac{1}{2}(Wt(\mathcal{T}) - Wt(T_j))$ along with $Wt(\mathcal{T}_{MAX(c,d)}) < \frac{2}{3} Wt(T_j)$, we have $Wt(\mathcal{T}_1) < \frac{2}{3} Wt(\mathcal{T})$. For the bound on $Wt(\mathcal{T}_2)$, we distinguish two cases. (a) $Wt(T_j) \leq \frac{2}{3} Wt(\mathcal{T})$. In this case, since $Wt(\mathcal{T}_{MIN(c,d)}) \leq \frac{1}{2} Wt(T_j)$ and $Wt(\mathcal{T}_{MAX(a,b)}) < \frac{1}{3} Wt(\mathcal{T})$, we have $Wt(\mathcal{T}_2) < \frac{2}{3} Wt(\mathcal{T})$. (b) $Wt(T_j) > \frac{2}{3} Wt(\mathcal{T})$.

In this case, since $Wt(\mathcal{T}_{MAX(a,b)}) \leq Wt(\mathcal{T}) - Wt(T_j)$, we have $Wt(\mathcal{T}_2) \leq Wt(\mathcal{T}) - Wt(T_j) + \frac{1}{2} Wt(T_j) < \frac{2}{3} Wt(\mathcal{T})$. □

Inflating weights and achieving balance. The balance property is obtained by inflating weights using the following local transformation. For every nonroot internal tree node t, let t' denote its sibling. Define $Wt_3(t)$ as follows:

$$Wt_3(t) = \max\left\{ Wt_2(t), \frac{1}{2} Wt_2(t') \right\}.$$

After the inflation, all of the other properties are preserved. For example, the superadditivity property is preserved since, if $Wt_3(t_\ell) > Wt_2(t_\ell)$, then $Wt_3(t_\ell) + Wt_3(t_r) \leq \frac{3}{2} Wt_2(t_r) \leq \frac{3}{2} \cdot \frac{2}{3} Wt_2(t) = Wt_2(t) \leq Wt_3(t)$, where t denotes the parent of t_ℓ and t_r.

Having computed a decomposition tree with weights that satisfy all of the properties, we conclude with the following theorem.

THEOREM 19. *Every graph G of maximum degree four can be embedded in polynomial time in any grid of aspect ratio at least $\frac{1}{3}$ and area $O(\text{AREA}(G) \log^4 n)$.*

COMPUTATIONAL COMPLEXITY OF COMPACTION TO REFLEXIVE CYCLES*

NARAYAN VIKAS†

Abstract. In this paper, we solve a widely publicized open problem posed by Peter Winkler in 1988. The problem is to decide whether or not it is possible to partition the vertices of a graph into four distinct nonempty sets A, B, C, and D, such that there is no edge between the sets A and C, and between the sets B and D, and that there is at least one edge between any other pair of distinct sets. Winkler asked whether this problem is NP-complete. We show in this paper that it is NP-complete. We study the problem as the compaction problem for a reflexive 4-cycle. We also show in this paper that the compaction problem for a reflexive k-cycle is NP-complete for all $k \geq 4$.

Key words. computational complexity, graph, coloring, homomorphism, retraction, compaction

1. Introduction.

In this paper, we study the computational complexity of a special graph coloring problem, called the compaction problem. An extended abstract of this paper appears in [Vikas, 1999]. The coloring problem is a classic problem in graph theory. The graph homomorphism problem, also called the H-coloring problem, is a generalization of the coloring problem. The compaction problem is the graph homomorphism problem with additional constraints. The open problem of Peter Winkler described above can be viewed as a special case of the compaction problem. We explain the motivation for Winkler's problem after introducing the following definitions and problems.

Definitions. The pair of vertices of an edge in a graph are called the *endpoints* of the edge. An edge with the same endpoints in a graph is called a *loop*. A vertex v of a graph is said to have a loop if vv is an edge of the graph. A *reflexive graph* is a graph in which every vertex has a loop. An *irreflexive graph* is a graph which has no loops. Any graph, in general, is a *partially reflexive graph*, meaning that its individual vertices may or may not have loops. Thus reflexive and irreflexive graphs are special partially reflexive graphs. A bipartite graph is irreflexive by definition. When we do not mention the terms reflexive, irreflexive, or bipartite, the corresponding graph may be assumed to be a partially reflexive graph. For a graph G, we use $V(G)$ and $E(G)$ to denote its vertex set and edge set, respectively. A vertex u is said to be *adjacent* to a vertex v in a graph if uv is an edge of the graph; if u is adjacent to v then v is also adjacent to u. A graph in which every two distinct vertices are adjacent is called a *complete graph*. We denote an irreflexive complete graph with k vertices by K_k. A *path* of length $k-1$ is a graph containing k distinct vertices, say $v_0, v_1, v_2, \ldots, v_{k-1}$, such that $v_0v_1, v_1v_2, \ldots, v_{k-2}v_{k-1}$ are all the nonloop edges of the graph, $k \geq 1$; we may write such a path as $v_0v_1v_2 \ldots v_{k-1}$. A *cycle* of length k, called a *k-cycle*, is a graph containing k distinct vertices, say $v_0, v_1, v_2, \ldots, v_{k-1}$, such that $v_0v_1, v_1v_2, \ldots, v_{k-2}v_{k-1}, v_{k-1}v_0$ are all the nonloop edges of the graph, $k \geq 3$;

*Received by the editors January 12, 2001; accepted for publication June 22, 2001; published electronically January 3, 2003. An extended abstract of this paper appears in Proceedings of the Tenth Annual ACM-SIAM Symposium on Discrete Algorithms, Baltimore, MD, 1999.

we may write such a cycle as $v_0v_1v_2 \dots v_{k-1}v_0$. A *square* will be used as a synonym for a 4-cycle. For our purpose we shall denote a reflexive k-cycle by C_k.

Let G be a graph. A vertex v of G is said to be an *isolated vertex* of G if v is not adjacent to any other vertex v' of G, $v \neq v'$ (note that an isolated vertex may have a loop). A graph H is said to be a *subgraph* of G if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. If H is a subgraph of G such that H contains all the edges of G whose both endpoints are in $V(H)$ then H is called the subgraph of G *induced by* $V(H)$, and we say that H is an *induced subgraph* of G. Given an induced subgraph H of G, we denote by $G - H$ the subgraph obtained by deleting from G the vertices of H together with the edges incident with them; thus $G - H$ is a subgraph of G induced by $V(G) - V(H)$. A *chordal graph* is a graph which does not contain any induced cycle of length greater than three. A *chordal bipartite graph* is a bipartite graph which does not contain any induced cycle of length greater than four. A *clique* of G is a set $K \subseteq V(G)$ such that every two distinct vertices in K are adjacent in G, i.e., the subgraph of G induced by K is a complete graph. When a set S is an argument of a mapping f, we define $f(S) = \{f(s)|s \in S\}$. The *distance* between a pair of vertices u and v in G, denoted as $d_G(u, v)$ or $d_G(v, u)$, is the length of a shortest path from u to v in G if u and v are connected in G; we define $d_G(u, v)$ (and $d_G(v, u)$) to be infinite if u and v are disconnected in G. The *diameter* of G is the maximum distance between any two vertices in G. The distance between two sets X and Y of vertices in G, denoted as $d_G(X, Y)$ or $d_G(Y, X)$, is the minimum distance between any vertex of X and any vertex of Y in G, that is, $d_G(X, Y) = \min\{d_G(x, y)|x \in X, y \in Y\}$, where $\min A$ gives the minimum element in a set A. If a set has only one vertex, we may just write the vertex instead of the set. In the following, let G and H be graphs.

A *homomorphism* $f : G \to H$, of G to H, is a mapping f of the vertices of G to the vertices of H, such that if g and g' are adjacent vertices of G then $f(g)$ and $f(g')$ are adjacent vertices of H. If there exists a homomorphism of G to H then G is said to be *homomorphic* to H. Note that for any homomorphism $f : G \to H$, if a vertex v of G has a loop then the vertex $f(v)$ of H necessarily also has a loop. Also note that if G is irreflexive then G is k-colorable if and only if G is homomorphic to K_k. Thus the concept of a homomorphism generalizes the concept of a k-colorability.

A *compaction* $c : G \to H$, of G to H, is a homomorphism of G to H, such that for every vertex x of H there exists a vertex v of G with $c(v) = x$, and for every edge hh' of H, $h \neq h'$, there exists an edge gg' of G with $c(g) = h$ and $c(g') = h'$. Notice that the first part of the definition for a compaction (the requirement for every vertex x of H) follows from the second part unless H has isolated vertices. If there exists a compaction of G to H then G is said to *compact* to H. Given a compaction $c : G \to H$, if for a vertex v of G we have $c(v) = x$, where x is a vertex of H, then we say that the vertex v of G *covers the vertex* x of H under c; and if for an edge gg' of G we have $c(\{g, g'\}) = \{h, h'\}$, where hh' is an edge of H, then we say that the edge gg' of G *covers the edge* hh' of H under c (note that in the definition of compaction, it is not necessary that a loop of H be covered by any edge of G under c).

We note that the notion of a *homomorphic image* used in [Harary, 1969] (also cf. [Hell and Miller, 1979]) coincides with the notion of a compaction in the case of irreflexive graphs (i.e., when G and H are irreflexive in the above definition for compaction).

Now suppose that H is an induced subgraph of G. A *retraction* $r : G \to H$, of G to H, is a homomorphism of G to H such that $r(h) = h$ for every vertex h of H. If there exists a retraction of G to H then G is said to *retract to* H, and H is said to be

a *retract of* G. Note that every retraction $r : G \to H$ is necessarily also a compaction.

Homomorphism, compaction, and retraction problems. The problem of deciding the existence of a homomorphism to a fixed graph H, called the *homomorphism problem for* H, also known as the H-coloring problem, and denoted as *H-COL*, asks whether or not an input graph G is homomorphic to H. If H is a graph which has a vertex h with a loop then every graph G is homomorphic to H, as we will have the homomorphism $f : G \to H$, with $f(v) = h$, for all $v \in V(G)$. Thus the problem *H-COL* is interesting only if H is irreflexive. A complete complexity classification of *H-COL* has been given in [Hell and Nesetril, 1990]. Note that the classic k-colorability problem is a special case of the problem *H-COL* when H is K_k and the input graph G is irreflexive.

The problem of deciding the existence of a compaction to a fixed graph H, called the *compaction problem for* H, and denoted as *COMP-H*, is the following:

Instance: A graph G.

Question: Does G compact to H?

Note that Winkler's problem is the problem *COMP-*C_4. We also present results for the problem *COMP-*C_k for all $k \geq 4$. The problem *COMP-*C_k can be viewed as the problem to decide whether or not it is possible to partition the vertices of a graph into k distinct nonempty sets $A_0, A_1, \ldots, A_{k-1}$, such that there is at least one edge between the pair of sets A_i and $A_{(i+1) \bmod k}$, for all $i = 0, 1, 2, \ldots, k-1$, $k > 2$, and there is no edge between any other pair of distinct sets. When both G and H are input graphs (i.e., H is not fixed), and H is reflexive, the problem of deciding whether or not G compacts to H has been studied in [Karabeg and Karabeg, 1991, 1993]. Note that unlike the problem *H-COL*, the problem *COMP-H* is still interesting if H has a loop.

The problem of deciding the existence of a retraction to a fixed graph H, called the *retraction problem for* H, and denoted as *RET-H*, asks whether or not an input graph G, containing H as an induced subgraph, retracts to H. Retraction problems have been of continuing interest in graph theory for a long time and have been studied in various literature including [Hell, 1972], [Hell, 1974], [Nowakowski and Rival, 1979], [Pesch and Poguntke, 1985], [Bandelt, Dahlmann, and Schutte, 1987], [Hell and Rival, 1987], [Pesch, 1988], [Feder and Winkler, 1988], [Bandelt, Farber, and Hell, 1993], [Feder and Hell, 1998], [Feder, Hell, and Huang, 1999].

Note that the graph H for the problems *H-COL*, *COMP-H*, and *RET-H* is assumed to be fixed by default even if not explicitly mentioned.

Motivation. It has been proved in [Feder and Winkler, 1988] that *RET-*C_4 is NP-complete. This has also been proved independently by G. MacGillivray in 1988 (personal communication, cf. [Feder and Hell, 1998]). The transformation used in [Feder and Winkler, 1988] is from the satisfiability problem; this was proved there in order to show that *RET-H* is not polynomial time solvable for all graphs H unless P = NP. The transformation used by MacGillivray is from the 4-colorability problem.

It is not difficult to show that for every fixed graph H, if *RET-H* is solvable in polynomial time then *COMP-H* is also solvable in polynomial time. Is the converse true? This was also asked by Winkler in the context of reflexive graphs (personal communication, cf. [Feder and Winkler, 1988]), and this was the general problem that motivated Winkler. As mentioned above, *RET-*C_4 is NP-complete. It turns out that for any reflexive graph H, other than C_4, with at most four vertices, *RET-H* is polynomial time solvable. In other words, as mentioned in [Feder and Winkler, 1988], the unique smallest reflexive graph H for which *RET-H* is NP-complete is

C_4. Therefore, with respect to the preceding question, Winkler asked specifically the following question in 1988 (personal communication, cf. [Feder and Winkler, 1988]) which has been a popular open problem: Is *COMP-C_4* NP-complete? We show in this paper that *COMP-C_4* is NP-complete. To show this, we give a transformation from *RET-C_4* to *COMP-C_4*, using our technique explained below.

Our generic technique. We describe here a technique that we developed to use in our proofs. Let a graph G containing H as an induced subgraph be an instance of *RET-H*. When we give a transformation from *RET-H* to *COMP-H*, we apply the following technique. We construct in time polynomial in the size of G, a graph G' (containing G as an induced subgraph) such that the following statements (i), (ii), and (iii) are equivalent:

(i) G retracts to H.

(ii) G' retracts to H.

(iii) G' compacts to H.

Thus if *RET-H* is NP-complete, this shows that *COMP-H* is also NP-complete. It is this technique that we have used throughout, when giving a transformation from *RET-H* to *COMP-H*, for any graph H. Thus our technique turned out to be a generic one. We prove the equivalence of the above statements by showing that (i) is equivalent to (ii), and (ii) is equivalent to (iii).

Results. We now first mention the results known for *RET-C_k*. Feder extended the proof of NP-completeness of *RET-C_4* showing that *RET-C_k* is NP-complete for all $k \geq 4$ (personal communication through Hell, cf. [Feder and Hell, 1998]). This was also proved independently by G. MacGillivray in 1988 (personal communication). The transformation used by both Feder and MacGillivray is from the k-colorability problem. For the case of a reflexive 3-cycle, it is easily seen that *RET-C_3*, and hence *COMP-C_3*, are both polynomial time solvable. In fact, when H is a reflexive chordal graph (which includes C_3), the problem *RET-H* is shown to be polynomial time solvable in [Feder and Hell, 1998], and hence *COMP-H* is also polynomial time solvable.

In this paper, we show that *COMP-C_k* is NP-complete for all $k \geq 4$. We do this by giving a transformation from *RET-C_k* to *COMP-C_k*, using the technique described above, for all $k \geq 4$. For proving NP-completeness of *COMP-C_k*, for all $k \geq 4$, we provide four categories of construction depending on whether $k = 4m, 4m+1, 4m+2$, or $4m+3$, for some integer $m \geq 1$.

Since every retraction is also a compaction, the equivalence of (ii) and (iii) in the above technique implies that if G' compacts to H then there exists a compaction $c : G' \to H$ which is also a retraction. Hence, in our definition of compaction, if we require a compaction to also cover loops then the equivalence of (i), (ii), and (iii) in the above technique implies that if *RET-H* is NP-complete then *COMP-H* remains NP-complete under this varied definition of compaction also. Thus, with the above technique, our NP-completeness results for *COMP-H* in this paper also hold under this varied definition of compaction.

In the figures in this paper, we shall not be depicting any edge vh of G, with $v \in V(G - H)$ and $h \in V(H)$, where G is any graph containing H as an induced subgraph, i.e., G is an instance of *RET-H*. Also, in the figures in this paper, we shall not be depicting any loops. For the problem *COMP-H*, in the theorems in this paper, it is sufficient to remember that there is a loop on each vertex of the graph H. The presence or absence of a loop on any other vertex of any graph is immaterial for these theorems.

Although the NP-completeness of deciding the existence of a compaction to a reflexive square is a special case of the NP-completeness of deciding the existence of a compaction to a reflexive k-cycle, for all $k \geq 4$, we first present, in section 2, the proof for the case of a reflexive square which is easier to follow and will be helpful in understanding the proof for the case of a reflexive k-cycle, for all $k \geq 4$, which we present next in section 3. In section 4, we present our results for compaction to irreflexive cycles without including the proofs.

2. Compaction to a reflexive square. We prove the following theorem in this section.

THEOREM 2.1. *The problem of deciding the existence of a compaction to a reflexive square is NP-complete.*

Proof. Let H be the reflexive square in Figure 2.1.

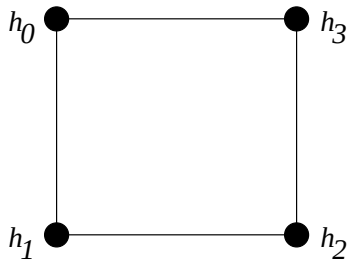

FIG. 2.1. H.

We shall prove that the problem of deciding the existence of a compaction to H, i.e., the problem *COMP-H*, is NP-complete. Clearly, *COMP-H* is in NP. We give a polynomial transformation from *RET-H* to *COMP-H*. As mentioned earlier, the problem *RET-H* is NP-complete. Let G be a graph with H as an induced subgraph of G, i.e., let G be an instance of *RET-H*. We construct in time polynomial in the size of G, a graph G' (containing G as an induced subgraph) such that the statements (i), (ii), and (iii) mentioned in our technique in section 1 are equivalent. Since *RET-H* is NP-complete, this shows that *COMP-H* is also NP-complete. We prove that (i) is equivalent to (ii), and (ii) is equivalent to (iii), in Lemma 2.1.1 and Lemma 2.1.2, respectively.

The construction of G' is as follows. For each vertex v in $V(G-H)$, we add to G three distinct new vertices: u_v adjacent to v, h_0, h_1; w_v adjacent to v, h_2, h_3, u_v; and y_v adjacent to h_0, h_2, u_v, w_v. See Figure 2.2. Note that there could be edges in G from v to some vertices of H but as mentioned earlier, in Figure 2.2 and all subsequent figures in this paper, we are not depicting these edges. Furthermore, we add the edges $u_v u_{v'}$ and $w_v w_{v'}$ for all $v, v' \in V(G-H), v \neq v'$.

Before completing the construction of G', we choose one fixed direction for every edge of $G-H$. By convention, this chosen direction will be implied by the order of the endpoints, when an edge is specified in this proof, i.e., when we mention an edge vv' of $G-H$ in this proof, we assume that the chosen direction is from v to v'. For every edge vv' in $E(G-H)$, $v \neq v'$, we add a new vertex $x_{vv'}$ adjacent to v, v', u_v, and $w_{v'}$. (Note how the choice of a direction for the edge vv' affects the adjacencies from $x_{vv'}$). See Figure 2.3.

This completes the construction of G'. For an edge $vv' \in E(G-H)$, the construction of G' is illustrated in Figure 2.4. We now prove the following two lemmas in order to prove the theorem.

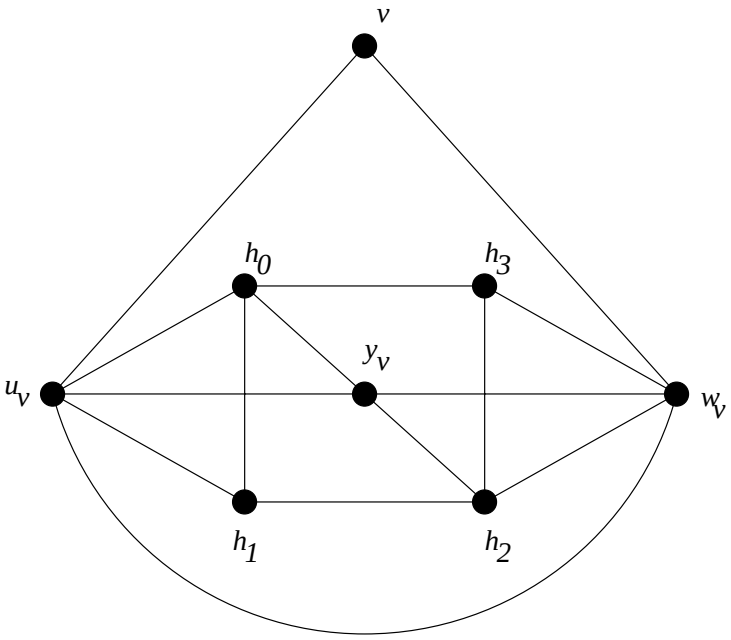

FIG. 2.2. *Construction of G' for a vertex v in $G - H$.*

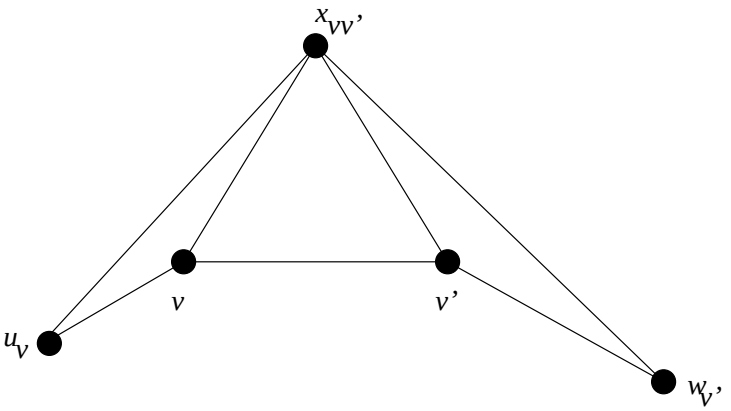

FIG. 2.3. *Construction of G' for an edge vv' in $G - H$.*

LEMMA 2.1.1. *G retracts to H if and only if G' retracts to H.*

Proof. If G' retracts to H then it is clear that G retracts to H since G is a subgraph of G'. Now suppose that $r : G \to H$ is a retraction. We define a retraction $r' : G' \to H$ as follows.

For each vertex v of the graph G, we define

$r'(v) = r(v)$.

For the vertices u_v, w_v, and y_v of G', with $v \in V(G - H)$, we define

$r'(u_v) = h_1$, $r'(w_v) = h_2$, and $r'(y_v) = h_1$, if $r(v) = h_1$ or h_2, and

$r'(u_v) = h_0$, $r'(w_v) = h_3$, and $r'(y_v) = h_3$, if $r(v) = h_0$ or h_3.

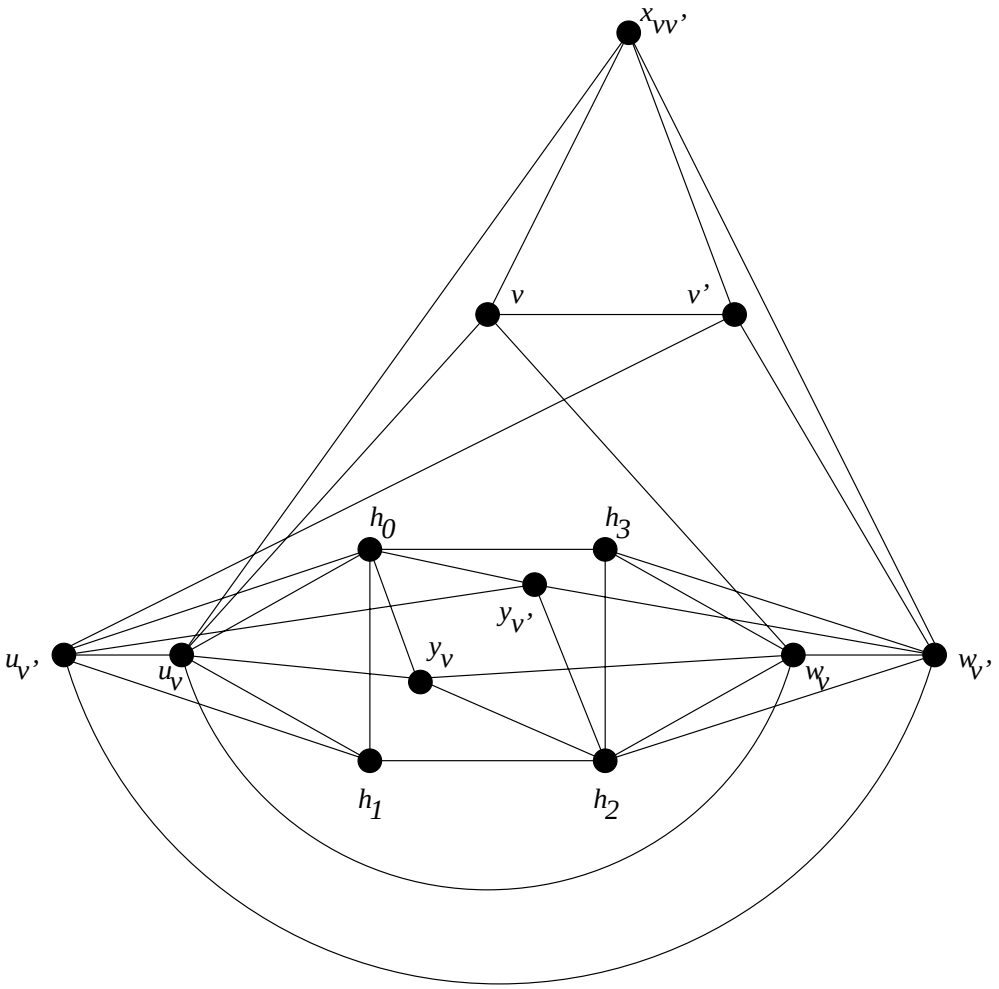

FIG. 2.4. *Construction of G', with $vv' \in E(G-H)$.*

For the vertex $x_{vv'}$ of G', with $vv' \in E(G-H)$, we define

$r'(x_{vv'}) = r(v)$, if $r(v) = h_2$ or h_3, and

$r'(x_{vv'}) = r(v')$, if $r(v) = h_0$ or h_1.

We now verify that $r' : G' \to H$ is indeed a homomorphism (and hence a retraction). We shall do this by considering all the edges ab of G' and proving that $r'(a)r'(b)$ is an edge of H.

Consider first an edge vv', with $vv' \in E(G)$. We have $r'(v)r'(v') = r(v)r(v')$. Hence $r'(v)r'(v')$ is an edge of H (as $r : G \to H$ is a homomorphism).

Next consider an edge $u_v u_{v'}$, with $v, v' \in V(G-H)$. We have that $r'(u_v)$ and $r'(u_{v'})$ are h_0 or h_1 depending on the values of $r(v)$ and $r(v')$, respectively. Hence $r'(u_v)r'(u_{v'})$ is always an edge of H. For the edges $u_v h_0$ and $u_v h_1$, with $v \in V(G-H)$, we argue similarly, since $r'(h_0) = r(h_0) = h_0$ and $r'(h_1) = r(h_1) = h_1$. In a similar way, we also argue for the edges $w_v w_{v'}, w_v h_2$, and $w_v h_3$, with $v, v' \in V(G-H)$.

Now consider an edge $u_v v$, with $v \in V(G-H)$. We have $r'(v) = r(v)$, and if $r(v) = h_1$ or h_2 then $r(u_v) = h_1$, otherwise $r(u_v) = h_0$. Thus $r'(u_v)r'(v)$ is always an

edge of H. Similarly, we argue for an edge $w_v v$, with $v \in V(G-H)$.

Take now an edge $y_v h_0$, with $v \in V(G-H)$. We have $r'(h_0) = r(h_0) = h_0$, and depending on the value of $r(v)$, $r'(y_v) = h_1$ or h_3. Thus $r'(y_v)r'(h_0)$ is always an edge of H. Similarly, we argue for an edge $y_v h_2$, with $v \in V(G-H)$.

Now consider an edge $u_v w_v$, with $v \in V(G-H)$. If $r(v) = h_1$ or h_2, we have $r'(u_v) = h_1$ and $r'(w_v) = h_2$. If $r(v) = h_0$ or h_3, we have $r'(u_v) = h_0$ and $r'(w_v) = h_3$. Thus $r'(u_v)r'(w_v)$ is always an edge of H.

Now take an edge $y_v u_v$, with $v \in V(G-H)$. If $r(v) = h_1$ or h_2, we have $r'(u_v) = h_1$ and $r'(y_v) = h_1$. If $r(v) = h_0$ or h_3, we have $r'(u_v) = h_0$ and $r'(y_v) = h_3$. Thus $r'(y_v)r'(u_v)$ is always an edge of H. Similarly, we argue for an edge $y_v w_v$, with $v \in V(G-H)$.

Consider now an edge $x_{vv'}v$, with $vv' \in E(G-H)$. We have $r'(x_{vv'}) = r(v)$ or $r(v')$, and $r'(v) = r(v)$. Since $r(v)r(v')$ must be an edge of H, $r'(x_{vv'})r'(v)$ is always an edge of H. Similarly, we argue for an edge $x_{vv'}v'$, with $vv' \in E(G-H)$.

Next consider an edge $x_{vv'}u_v$, with $vv' \in E(G-H)$. First suppose that $r(v) = h_2$ or h_3. Then $r'(x_{vv'}) = r(v)$. We have already proved that $r'(v)r'(u_v) = r(v)r'(u_v)$ is an edge of H. Hence $r'(x_{vv'})r'(u_v) = r(v)r'(u_v)$ is an edge of H. Now suppose that $r(v) = h_0$ or h_1. Then $r'(x_{vv'}) = r(v')$. If $r(v) = h_0$ then $r'(u_v) = h_0 = r(v)$ and $r'(x_{vv'})r'(u_v) = r(v')r(v)$ is an edge of H. If $r(v) = h_1$ then $r'(u_v) = h_1 = r(v)$ and $r'(x_{vv'})r'(u_v) = r(v')r(v)$ is again an edge of H. Thus we have proved that $r'(x_{vv'})r'(u_v)$ is always an edge of H.

Finally, consider an edge $x_{vv'}w_{v'}$, with $vv' \in E(G-H)$. First suppose that $r(v) = h_2$ or h_3. Then $r'(x_{vv'}) = r(v)$. We have $r'(w_{v'}) = h_2$ or h_3 depending on the value of $r(v')$. Thus $r(v)r'(w_{v'})$ is an edge of H, and hence $r'(x_{vv'})r'(w_{v'}) = r(v)r'(w_{v'})$ is an edge of H. Now suppose that $r(v) = h_0$ or h_1. Then $r'(x_{vv'}) = r(v')$. We have already proved that $r'(v')r'(w_{v'}) = r(v')r'(w_{v'})$ is an edge of H. Hence $r'(x_{vv'})r'(w_{v'}) = r(v')r'(w_{v'})$ is an edge of H. Thus we have proved that $r'(x_{vv'})r'(w_{v'})$ is always an edge of H.

Thus we have proved that $r' : G' \to H$ is a homomorphism. Since $r'(h) = r(h) = h$, for all $h \in V(H)$, $r' : G' \to H$ is a retraction, and the lemma is proved. □

LEMMA 2.1.2. *G' retracts to H if and only if G' compacts to H.*

Proof. If G' retracts to H then by definition G' compacts to H. Now suppose that $c : G' \to H$ is a compaction. We let $U = \{u_v | v \in V(G-H)\} \cup \{h_0, h_1\}$ and $W = \{w_v | v \in V(G-H)\} \cup \{h_2, h_3\}$. Note that U and W are cliques in G'.

Since U is a clique in G', $c(U)$ must be a clique in H. Thus $c(U)$ has either one or two vertices. Similarly, $c(W)$ has either one or two vertices. We shall prove that $c(U)$ and $c(W)$ both have two vertices.

Suppose that $c(U)$ has only one vertex. Without loss of generality, let $c(U) = \{h_0\}$. We can assume this, as due to symmetry of vertices in H, we can always redefine the compaction c so that $c(U) = \{h_0\}$. As every vertex of G' is adjacent to a vertex in U, no vertex a of G' can have $c(a) = h_2$. Thus $c(U)$ must have two vertices. Similarly, $c(W)$ must also have two vertices.

Thus both $c(U)$ and $c(W)$ are cliques of size two in H. Without loss of generality, suppose that $c(U) = \{h_0, h_1\}$ (due to symmetry). We first prove that $c(W) = \{h_2, h_3\}$. Let some edge ab of G' cover the edge h_2h_3 of H under c (indeed there exists such an edge in G', as $c : G' \to H$ is a compaction). Then both a and b are not in U, as $c(U) = \{h_0, h_1\}$. Thus a and b are among the vertices h_2, h_3; w_v, y_v, v, with $v \in V(G-H)$; and $x_{vv'}$, with $vv' \in E(G-H)$. Suppose that $c(W) \neq \{h_2, h_3\}$. Then no edge with both endpoints in W covers the edge h_2h_3 of H under c, and hence not

both a and b belong to W. Thus ab must be an edge among vw_v, y_vw_v, y_vh_2, with $v \in V(G-H)$; $vv', vx_{vv'}, v'x_{vv'}$, and $w_{v'}x_{vv'}$, with $vv' \in E(G-H)$. Further, if vh_2 or vh_3 is an edge of G, for some vertex $v \in V(G-H)$, then we need to include such an edge also for ab. We shall consider each of these possible edges for ab and show that they do not cover the edge h_2h_3 under c, i.e., $c(\{a,b\}) \neq \{h_2,h_3\}$, implying that $c(W) = \{h_2,h_3\}$.

Consider first an edge vw_v, with $v \in V(G-H)$. If $c(\{v,w_v\}) = \{h_2,h_3\}$ then it must be that $c(u_v) = h_2$ or h_3, as u_v is adjacent to v and w_v. This is a contradiction, as $c(u_v) = h_0$ or h_1 by assumption. A similar argument applies to an edge $vx_{vv'}$, with $vv' \in E(G-H)$; and an edge y_vw_v, with $v \in V(G-H)$.

Next consider an edge y_vh_2, with $v \in V(G-H)$. If $c(\{y_v,h_2\}) = \{h_2,h_3\}$ then $c(w_v) = h_2$ or h_3, as w_v is adjacent to y_v and h_2. Since $c(W) \neq \{h_2,h_3\}$, it must be that $c(w_v) = c(h_2)$. This implies that $c(\{y_v,w_v\}) = \{h_2,h_3\}$, which as noted above does not hold. Similarly, for the possible edges vh_2 and vh_3, with $v \in V(G-H)$, if $c(v,h_2) = \{h_2,h_3\}$ or $c(v,h_3) = \{h_2,h_3\}$ then we will have $c(v,w_v) = \{h_2,h_3\}$, which we have shown above is not possible.

Now consider an edge $vv' \in E(G-H)$. Suppose that $c(\{v,v'\}) = \{h_2,h_3\}$. Without loss of generality, let $c(v) = h_2$ and $c(v') = h_3$ (due to symmetry). Since u_v and $u_{v'}$ are adjacent to v and v', respectively, and $c(U) = \{h_0,h_1\}$, we have $c(u_v) = h_1$ and $c(u_{v'}) = h_0$. Since $c(w_v)$ must be adjacent to $c(v) = h_2$ and $c(u_v) = h_1$, we have $c(w_v) \in \{h_1,h_2\}$. Also, $c(w_{v'})$ must be adjacent to $c(u_{v'}) = h_0$ and $c(v') = h_3$. Hence $c(w_{v'}) \in \{h_0,h_3\}$. Since w_v is adjacent to $w_{v'}$ in G', and $c(W) \neq \{h_2,h_3\}$, this implies that $c(w_v) = h_1$ and $c(w_{v'}) = h_0$. Now $c(x_{vv'})$ must be adjacent to $c(w_{v'}) = h_0$, $c(u_v) = h_1$, $c(v) = h_2$, and $c(v') = h_3$, which is impossible.

Consider now an edge $v'x_{vv'}$, with $vv' \in E(G-H)$. If $c(\{v',x_{vv'}\}) = \{h_2,h_3\}$ then $c(v) = h_2$ or h_3, as v is adjacent to v' and $x_{vv'}$. This implies that either $c(\{v,v'\}) = \{h_2,h_3\}$ or $c(\{v,x_{vv'}\}) = \{h_2,h_3\}$, both of which we have already proved do not hold.

Finally, consider an edge $w_{v'}x_{vv'}$, with $vv' \in E(G-H)$. If $c(\{w_{v'},x_{vv'}\}) = \{h_2,h_3\}$ then $c(v') = h_2$ or h_3, as v' is adjacent to $w_{v'}$ and $x_{vv'}$. This implies that either $c(\{v',w_{v'}\}) = \{h_2,h_3\}$ or $c(\{v',x_{vv'}\}) = \{h_2,h_3\}$, both of which we have already proved do not hold.

This completes the proof that $c(W) = \{h_2,h_3\}$. We now prove that $c(h_0) \neq c(h_1)$. Suppose to the contrary that $c(h_0) = c(h_1)$. We know that $c(h_0), c(h_1) \in \{h_0,h_1\}$ (as $c(U) = \{h_0,h_1\}$). Without loss of generality, let $c(h_0) = c(h_1) = h_0$ (due to symmetry). Since $c(U) = \{h_0,h_1\}$, $c(u_v) = h_1$ for some vertex v of $G-H$. Since w_v and h_2 are adjacent to u_v and h_1, respectively, and $c(W) = \{h_2,h_3\}$, we have $c(w_v) = h_2$ and $c(h_2) = h_3$. Now $c(y_v)$ must be adjacent to $c(h_0) = h_0$, $c(u_v) = h_1$, $c(w_v) = h_2$, and $c(h_2) = h_3$, which is impossible.

Thus $c(h_0) \neq c(h_1)$, i.e., $c(\{h_0,h_1\}) = \{h_0,h_1\}$. Without loss of generality, suppose that $c(h_0) = h_0$ and $c(h_1) = h_1$ (due to symmetry). Since h_2 and h_3 are adjacent to h_1 and h_0, respectively, and $c(W) = \{h_2,h_3\}$, we have $c(h_2) = h_2$ and $c(h_3) = h_3$. Thus $c : G' \to H$ is a retraction, and the lemma is proved. □

We have thus proved Theorem 2.1. □

3. Compaction to a reflexive k-cycle. We prove the following theorem in this section.

THEOREM 3.1. *The problem of deciding the existence of a compaction to a reflexive k-cycle is NP-complete for all $k \geq 4$.*

Proof. Let H be the reflexive k-cycle $h_0h_1 \ldots h_{k-1}h_0$, with $k \geq 4$. See Figure 3.1.

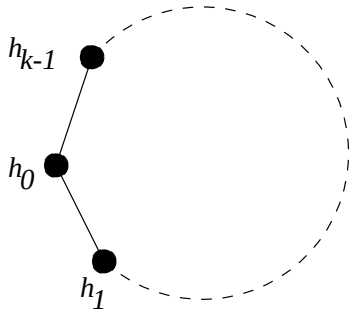

FIG. 3.1. H.

We shall prove that the problem of deciding the existence of a compaction to H, i.e., the problem *COMP-H*, is NP-complete. Clearly, the problem *COMP-H* is in NP. We give a polynomial transformation from the problem *RET-H* to *COMP-H*. As mentioned earlier, the problem *RET-H* is NP-complete. Let a graph G containing H as an induced subgraph be an instance of *RET-H*. We construct in time polynomial in the size of G, a graph G' (containing G as an induced subgraph) such that the statements (i), (ii), and (iii) mentioned in our technique in section 1 are equivalent. Since *RET-H* is NP-complete, this shows that *COMP-H* is also NP-complete. In analogy to the proof of Theorem 2.1 for a reflexive square, we prove that (i) is equivalent to (ii), and (ii) is equivalent to (iii), in two separate lemmas.

Assume that $k = 4m, 4m+1, 4m+2$, or $4m+3$, for some integer $m \geq 1$. Thus for any k we have $m = \lfloor k/4 \rfloor$. We also let $n = \lfloor k/2 \rfloor$. It may be helpful to note that $n - m = m + 1$ for $k = 4m + 2$ and $k = 4m + 3$, and $n - m = m$ for $k = 4m$ and $k = 4m + 1$. There are four categories of construction for G', depending on whether $k = 4m, 4m+1, 4m+2$, or $4m+3$. We include here a detailed proof of the theorem for $k = 4m + 2$ and $k = 4m + 3$. The proof for $k = 4m$ and $k = 4m + 1$ is similar to the proof for $k = 4m + 2$ and $k = 4m + 3$, respectively. Hence we will make remarks and refer to the cases $k = 4m + 2$ and $k = 4m + 3$ when proving the theorem for the cases $k = 4m$ and $k = 4m + 1$, respectively. We shall assume that all arithmetic operations are done modulo k unless otherwise convenient.

We prove the theorem in the cases $k = 4m + 2$, $k = 4m$, $k = 4m + 3$, and $k = 4m + 1$ in separate sections.

Proof of Theorem 3.1 in the case $k = 4m + 2$. The construction of G' is as follows. For each vertex v in $V(G - H)$, we add to G three vertex disjoint paths U_v, W_v, and Y_v, each containing $n - 1$ new vertices. Let $U_v = u_1^v u_2^v \dots u_{n-1}^v$, $W_v = w_1^v w_2^v \dots w_{n-1}^v$, and $Y_v = y_1^v y_2^v \dots y_{n-1}^v$, with $v \in V(G - H)$. We add the edges $u_1^v h_0$, $u_1^v h_1$, $v u_{n-1}^v$, $w_1^v h_n$, $w_1^v h_{n+1}$, $v w_{n-1}^v$, $u_{m+1}^v w_{m+1}^v$, $y_1^v h_0$, $y_{n-1}^v h_n$, $u_1^v y_1^v$, and $w_1^v y_{n-1}^v$, with $v \in V(G - H)$ (note that h_n is the vertex opposite to h_0 in H). For each $v \in V(G - H)$, we also add a new vertex a_v adjacent to u_m^v and w_m^v. For convenience, in the proof of the first lemma, we also use h_k to denote the vertex h_0. See Figure 3.2. Furthermore, we add the edges $u_1^v u_1^{v'}$ and $w_1^v w_1^{v'}$ for all $v, v' \in V(G - H)$, $v \neq v'$.

As for a reflexive square in Theorem 2.1, we choose one fixed direction for every edge of $G - H$, and when we mention an edge vv' of $G - H$ in this proof, we assume that the chosen direction is from v to v'. For every edge $vv' \in E(G - H)$, $v \neq v'$, we add a new vertex $x_{vv'}$ adjacent to v, v', u_{n-1}^v, and $w_{n-1}^{v'}$. See Figure 3.3.

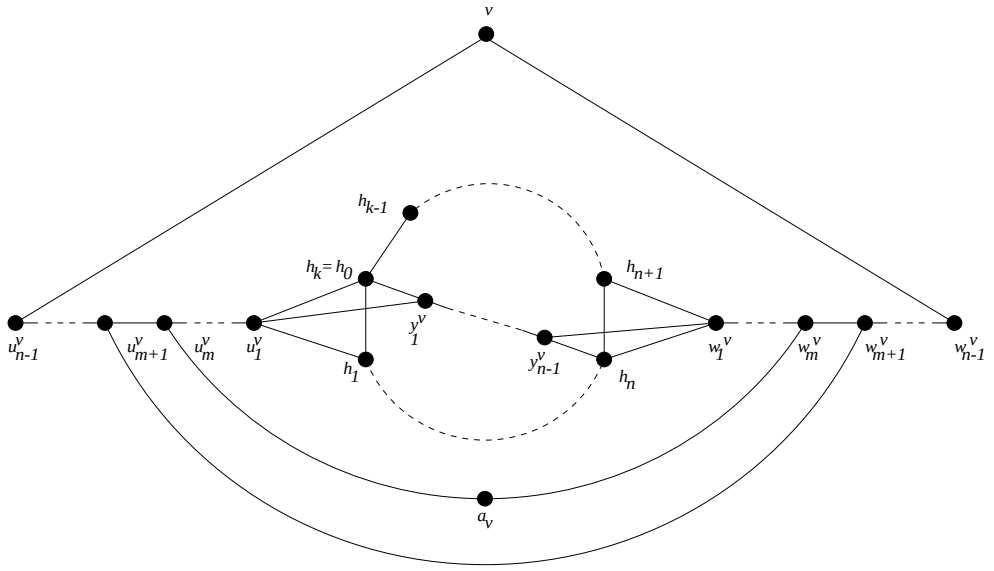

FIG. 3.2. *Construction of G' for a vertex v in $G - H$, with $k = 4m + 2$.*

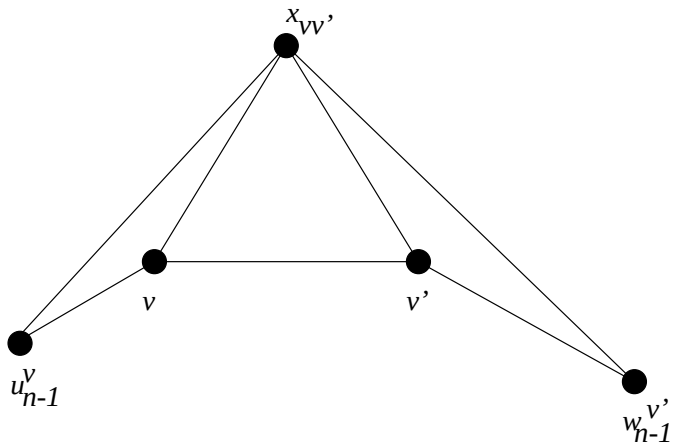

FIG. 3.3. *Construction of G' for an edge vv' in $G - H$.*

This completes the construction of G'. We now prove the following two lemmas in order to prove the theorem for $k = 4m + 2$.

LEMMA 3.1.1. *G retracts to H if and only if G' retracts to H.*

Proof. If G' retracts to H then clearly G retracts to H, as G is a subgraph of G'. Now suppose that $r : G \to H$ is a retraction. Below, we define a retraction $r' : G' \to H$. As we go along the definition of r', we shall be considering the edges ab of G', showing that $r'(a)r'(b)$ is indeed an edge of H (as required for $r' : G' \to H$ to be a homomorphism). Recall that the edges of G' are ab, $u_i^v u_{i+1}^v$, $w_i^v w_{i+1}^v$, $y_i^v y_{i+1}^v$, $u_1^v h_0$, $u_1^v h_1$, $w_1^v h_n$, $w_1^v h_{n+1}$, $v u_{n-1}^v$, $v w_{n-1}^v$, $u_{m+1}^v w_{m+1}^v$, $a_v u_m^v$, $a_v w_m^v$, $y_1^v h_0$, $y_{n-1}^v h_n$, $u_1^v y_1^v$, $w_1^v y_{n-1}^v$, $u_1^v u_1^{v'}$, $w_1^v w_1^{v'}$, $g x_{gg'}$, $g' x_{gg'}$, $x_{gg'} u_{n-1}^g$, and $x_{gg'} w_{n-1}^{g'}$, with $ab \in E(G)$, $v, v' \in V(G - H)$, $gg' \in E(G - H)$, $i = 1, 2, \ldots, n - 2$.

For each vertex v of the graph G, we define

$r'(v) = r(v)$.

Thus for an edge vv' of G', with $vv' \in E(G)$, we have that $r'(v)r'(v') = r(v)r(v')$ is an edge of H.

We now fix a vertex $v \in V(G - H)$ for defining r' for the vertices of U_v, W_v, and Y_v, and for the vertex a_v. Let $r(v) = h_j$. For the purpose of this lemma, as mentioned earlier, we use h_0 and h_k to denote the same vertex, and use the subscript 0 or k as convenient. We shall define r' for the said vertices when $1 \leq j \leq n$ and when $n + 1 \leq j \leq k$.

First assume that $1 \leq j \leq n$.

For the vertices of U_v, we define r' as follows.

If $j \leq m$ then we define

$r'(u_i^v) = h_i$ for all $i = 1, 2, \ldots, m$,

$r'(u_i^v) = h_{n-i}$ for all $i = m + 1, m + 2, \ldots, n - j$,

$r'(u_i^v) = h_j$ for all $i = n - j + 1, n - j + 2, \ldots, n - 1$.

Thus for the edges $u_1^v h_0$, $u_1^v h_1$, and vu_{n-1}^v of G', $r'(u_1^v)r'(h_0) = h_1h_0$, $r'(u_1^v)r'(h_1) = h_1h_1$, and $r'(v)r'(u_{n-1}^v) = h_jh_j$ are, respectively, the edges of H, when $j \leq m$. Clearly, for the edge $u_i^v u_{i+1}^v$ of G', $r'(u_i^v)r'(u_{i+1}^v)$ is an edge of H for all $i = 1, 2, \ldots, n - 2$.

If $j > m$ then we define

$r'(u_i^v) = h_i$ for all $i = 1, 2, \ldots, j - 1$,

$r'(u_i^v) = h_j$ for all $i = j, j + 1, \ldots, n - 1$.

Thus with $j > m$, we have $r'(u_{n-1}^v) = h_{j-1}$ if $j = n$, and $r'(u_{n-1}^v) = h_j$ if $j < n$. Hence for an edge vu_{n-1}^v of G', $r'(v)r'(u_{n-1}^v) = h_jr'(u_{n-1}^v)$ is an edge of H, when $j > m$. Also, for the edges ab of G' among $u_1^v h_0$, $u_1^v h_1$, and $u_i^v u_{i+1}^v$, for all $i = 1, 2, \ldots, n - 2$, clearly $r'(a)r'(b)$ is an edge of H, when $j > m$.

For the vertices of W_v, we define r' as follows.

If $j \geq n - m + 1$ then we define

$r'(w_i^v) = h_{n-i+1}$ for all $i = 1, 2, \ldots, m$,

$r'(w_i^v) = h_{i+1}$ for all $i = m + 1, m + 2, \ldots, j - 1$,

$r'(w_i^v) = h_j$ for all $i = j, j + 1, \ldots, n - 1$.

If $j < n - m + 1$ then we define

$r'(w_i^v) = h_{n-i+1}$ for all $i = 1, 2, \ldots, n - j$,

$r'(w_i^v) = h_j$ for all $i = n - j + 1, n - j + 2, \ldots, n - 1$.

As for the case of U_v, it can be verified that for the edges ab of G' among $w_1^v h_n$, $w_1^v h_{n+1}$, vw_{n-1}^v, and $w_i^v w_{i+1}^v$, for all $i = 1, 2, \ldots, n - 2$, $r'(a)r'(b)$ is always an edge of H.

Now we show that for an edge $u_{m+1}^v w_{m+1}^v$ of G', $r'(u_{m+1}^v)r'(w_{m+1}^v)$ is an edge of H. We note that $r'(w_{m+1}^v) = h_{m+2}$ if $j \geq n-m+1$, and $r'(w_{m+1}^v) = h_{n-m} = h_{m+1}$ if $j < n-m+1$. Also, we have $r'(u_{m+1}^v) = h_{n-m-1} = h_m$ if $j \leq m$, and $r'(u_{m+1}^v) = h_{m+1}$ if $j > m$. Thus, if $j < n - m + 1 = m + 2$ then $r'(u_{m+1}^v)r'(w_{m+1}^v) = r'(u_{m+1}^v)h_{m+1}$ is an edge of H (as $r'(u_{m+1}^v) = h_m$ or h_{m+1}). If $j \geq n - m + 1 = m + 2$ then $r'(u_{m+1}^v)r'(w_{m+1}^v) = h_{m+1}h_{m+2}$ is an edge of H. Thus under all possibilities, we have shown that $r'(u_{m+1}^v)r'(w_{m+1}^v)$ is an edge of H.

For the vertex a_v, we define

$r'(a_v) = h_{m+1}$.

Thus for the edges $a_v u_m^v$ and $a_v w_m^v$ of G', $r'(a_v)r'(u_m^v) = h_{m+1}h_m$ and $r'(a_v)r'(w_m^v) = h_{m+1}h_{n-m+1} = h_{m+1}h_{m+2}$ are, respectively, the edges of H.

For the vertices of Y_v, we define

$r'(y_i^v) = h_i$ for all $i = 1, 2, \ldots, n - 1$.

Thus for the edges $u_1^v y_1^v$ and $w_1^v y_{n-1}^v$ of G', $r'(u_1^v)r'(y_1^v) = h_1h_1$ and $r'(w_1^v)r'(y_{n-1}^v) = h_nh_{n-1}$ are, respectively, the edges of H. Also, for the edges ab of G' among $y_1^v h_0$, $y_{n-1}^v h_n$, and $y_i^v y_{i+1}^v$, for all $i = 1, 2, \ldots, n-2$, clearly $r'(a)r'(b)$ is an edge of H.

Now assume that $n+1 \leq j \leq k$.

Similar to the previous case, where $1 \leq j \leq n$, it can be verified that for the edges ab of G' considered in the previous case, $r'(a)r'(b)$ is indeed an edge of H in this case also, where $n+1 \leq j \leq k$.

For the vertices of U_v, we define r' as follows.

If $j \geq k-m+1$ then we define

$r'(u_i^v) = h_{k-i+1}$ for all $i = 1, 2, \ldots, m$,

$r'(u_i^v) = h_{n+i+1}$ for all $i = m+1, m+2, \ldots, j-n-1$,

$r'(u_i^v) = h_j$ for all $i = j-n, j-n+1, \ldots, n-1$.

If $j < k-m+1$ then we define

$r'(u_i^v) = h_{k-i+1}$ for all $i = 1, 2, \ldots, k-j$,

$r'(u_i^v) = h_j$ for all $i = k-j+1, k-j+2, \ldots, n-1$.

For the vertices of W_v, we define r' as follows.

If $j \leq n+m$ then we define

$r'(w_i^v) = h_{n+i}$ for all $i = 1, 2, \ldots, m$,

$r'(w_i^v) = h_{k-i}$ for all $i = m+1, m+2, \ldots, k-j$,

$r'(w_i^v) = h_j$ for all $i = k-j+1, k-j+2, \ldots, n-1$.

If $j > n+m$ then we define

$r'(w_i^v) = h_{n+i}$ for all $i = 1, 2, \ldots, j-n-1$,

$r'(w_i^v) = h_j$ for all $i = j-n, j-n+1, \ldots, n-1$.

For the vertex a_v, we define

$r'(a_v) = h_{k-m}$.

For the vertices of Y_v, we define

$r'(y_i^v) = h_{k-i}$ for all $i = 1, 2, \ldots, n-1$.

This completes the definition of r' for the vertices of U_v, W_v, and Y_v and for the vertex a_v.

Consider now the edges $u_1^v u_1^{v'}$ and $w_1^v w_1^{v'}$ of G', with $v, v' \in V(G-H)$. From the definition of r', we have that $r'(u_1^v)$ and $r'(u_1^{v'})$ are h_1 or h_0, and $r'(w_1^v)$ and $r'(w_1^{v'})$ are h_n or h_{n+1}. Thus $r'(u_1^v)r'(u_1^{v'})$ and $r'(w_1^v)r'(w_1^{v'})$ are always the edges of H.

For the vertex $x_{vv'}$, with $vv' \in E(G-H)$, we define

$r'(x_{vv'}) = r(v)$, if $r(v) \notin \{h_0, h_1\}$, and

$r'(x_{vv'}) = r(v')$, if $r(v) \in \{h_0, h_1\}$.

We now consider the edges of G' associated with $x_{vv'}$, with $vv' \in E(G-H)$. For the edges $vx_{vv'}$ and $v'x_{vv'}$ of G', we argue as for the case of a reflexive square in Lemma 2.1.1 that $r'(v)r'(x_{vv'})$ and $r'(v')r'(x_{vv'})$ are, respectively, the edges of H, with $vv' \in E(G-H)$.

Consider now an edge $x_{vv'}u_{n-1}^v$ of G', with $vv' \in E(G-H)$. First suppose that $r(v) \notin \{h_0, h_1\}$. Then $r'(x_{vv'}) = r(v)$. We have already proved that $r'(v)r'(u_{n-1}^v) = r(v)r'(u_{n-1}^v)$ is an edge of H. Hence $r'(x_{vv'})r'(u_{n-1}^v) = r(v)r'(u_{n-1}^v)$ is an edge of H. Now suppose that $r(v) \in \{h_0, h_1\}$. Then $r'(x_{vv'}) = r(v')$. If $r(v) = h_1$ then from our definition of r' we have $r'(u_{n-1}^v) = h_j = h_1 = r(v)$ (as $j = 1 \leq m$), and hence $r'(x_{vv'})r'(u_{n-1}^v) = r(v')r(v)$ is an edge of H. If $r(v) = h_0 (= h_k)$ then from the definition of r' we have $r'(u_{n-1}^v) = h_j = h_0 = r(v)$ (as $j = k \geq k-m+1$), and hence $r'(x_{vv'})r'(u_{n-1}^v) = r(v')r(v)$ is an edge of H. Thus we have proved, under all possibilities, that $r'(x_{vv'})r'(u_{n-1}^v)$ is an edge of H.

Now consider an edge $x_{vv'}w_{n-1}^{v'}$ of G', with $vv' \in E(G-H)$. First suppose that $r(v) \notin \{h_0, h_1\}$. Then $r'(x_{vv'}) = r(v)$. Now first let $r(v') = h_j$, with $1 \leq j \leq n$. Then from our definition of r' we have $r'(w_{n-1}^{v'}) = h_j = r(v')$ if $j > 1$, and $r'(w_{n-1}^{v'}) = h_{j+1} = h_2$ if $j = 1$. Hence if $j > 1$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)r(v')$ is an edge of H. If $j = 1$ then since $r(v)$ is adjacent to $r(v') = h_j = h_1$ and $r(v) \notin \{h_0, h_1\}$, it must be that $r(v) = h_2$. Thus if $j = 1$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)h_2 = h_2h_2$ is an edge of H. Now let $r(v') = h_j$, with $n+1 \leq j \leq k$. Then from the definition of r' we have $r'(w_{n-1}^{v'}) = h_j = r(v')$ if $j < k$, and $r'(w_{n-1}^{v'}) = h_{j-1} = h_{k-1}$ if $j = k$. Hence if $j < k$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)r(v')$ is an edge of H. If $j = k$ then since $r(v)$ is adjacent to $r(v') = h_j = h_k = h_0$ and $r(v) \notin \{h_0, h_1\}$, it must be that $r(v) = h_{k-1}$. Thus if $j = k$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)h_{k-1} = h_{k-1}h_{k-1}$ is an edge of H.

Now suppose that $r(v) \in \{h_0, h_1\}$. Then $r'(x_{vv'}) = r(v')$. We have already proved that $r'(v')r'(w_{n-1}^{v'}) = r(v')r'(w_{n-1}^{v'})$ is an edge of H. Hence $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v')r'(w_{n-1}^{v'})$ is an edge of H. Thus we have proved, under all possibilities, that $r'(x_{vv'})r'(w_{n-1}^{v'})$ is an edge of H.

This completes the proof that $r' : G' \to H$ is a homomorphism. Since $r'(h) = r(h) = h$, for all $h \in V(H)$, it follows that $r' : G' \to H$ is a retraction, and the lemma is proved. □

LEMMA 3.1.2. *G' retracts to H if and only if G' compacts to H.*

Proof. If G' retracts to H then by definition G' compacts to H. Now suppose that $c : G' \to H$ is a compaction. We shall prove that G' retracts to H. We let $U = \{u_1^v | v \in V(G-H)\} \cup \{h_0, h_1\}$ and $W = \{w_1^v | v \in V(G-H)\} \cup \{h_n, h_{n+1}\}$. Note that U and W are cliques in G'.

Since U is a clique in G', $c(U)$ must be a clique in H. Thus $c(U)$ has either one or two vertices. Similarly, $c(W)$ has either one or two vertices. We shall prove that $c(U)$ and $c(W)$ both have two vertices.

Suppose that $c(U)$ has only one vertex. Without loss of generality, let $c(U) = \{h_0\}$ (due to symmetry). We note that $d_{G'}(U, a) < n$ for all $a \in V(G')$. Hence we have $d_{G'}(U, a) < d_H(c(U) = \{h_0\}, h_n) = n$ for all $a \in V(G')$. This implies that $c(a) \neq h_n$ for all $a \in V(G')$. Thus $c(U)$ must have two vertices. We also note that $d_{G'}(W, a) < n$, for all $a \in V(G')$, and hence, similarly, $c(W)$ must also have two vertices.

Thus both $c(U)$ and $c(W)$ are cliques of size two in H. Without loss of generality, suppose that $c(U) = \{h_0, h_1\}$ (due to symmetry). We first prove that $c(W) = \{h_n, h_{n+1}\}$. Let some edge ab of G' cover the edge h_nh_{n+1} of H under c (indeed there exists such an edge in G'). We note that both h_n and h_{n+1} are at distance $n-1$ from $c(U)$ in H. Thus both a and b must be at distance greater than or equal to $n-1$ from U in G'. While there is no vertex at distance greater than $n-1$ from U in G', the only vertices that could possibly be at distance $n-1$ from U in G' are h_n, h_{n+1}, w_1^v, w_{n-1}^v, y_{n-1}^v, v, with $v \in V(G-H)$; and $x_{vv'}$, with $vv' \in E(G-H)$. Thus a and b are among these vertices. Upper bounds on distance to these vertices from U in G' may be obtained due to the following paths in G' (appropriate paths will apply to vertices in question). We are talking of upper bounds, as presence of an edge vh of G, with $v \in V(G-H)$, $h \in V(H)$, may result in a shorter path from U to a vertex mentioned above in G'. The paths are

$h_1h_2 \dots h_{n-1}h_n$, $h_0h_{k-1}h_{k-2} \dots h_{n+2}h_{n+1}$, $u_1^v u_2^v \dots u_m^v a_v w_m^v w_{m-1}^v \dots w_1^v$,
$u_1^v u_2^v \dots u_{m+1}^v w_{m+1}^v w_{m+2}^v \dots w_{n-1}^v$, $u_1^v y_1^v y_2^v \dots y_{n-1}^v$, $u_1^v u_2^v \dots u_{n-1}^v v$,
and $u_1^v u_2^v \dots u_{n-1}^v x_{vv'}$.

Suppose that $c(W) \neq \{h_n, h_{n+1}\}$. Then no edge with both endpoints in W covers

the edge h_nh_{n+1} of H under c, and hence not both a and b belong to W. Thus ab must be an edge among vw^v_{n-1}, $w^v_1y^v_{n-1}$, $y^v_{n-1}h_n$, with $v \in V(G-H)$; vv', $vx_{vv'}$, $v'x_{vv'}$, and $w^{v'}_{n-1}x_{vv'}$, with $vv' \in E(G-H)$; in order to meet the requirements of the edge ab, both vertices in each of these edges are assumed to achieve distance $n-1$ from U in G'. Further, if vh_n or vh_{n+1} is an edge of G, for some vertex $v \in V(G-H)$, then we need to include such an edge also for ab. We shall consider each of these possible edges for ab and show that they do not cover the edge h_nh_{n+1} under c (i.e., $c(\{a,b\}) \neq \{h_n, h_{n+1}\}$), implying that $c(W) = \{h_n, h_{n+1}\}$.

Consider first an edge vw^v_{n-1}, with $v \in V(G-H)$. Since $c(u^v_1) = h_0$ or h_1, either h_n or h_{n+1} is at distance n from $c(u^v_1)$ in H. Since both v and w^v_{n-1} are at distance $n-1$ from u^v_1, it is impossible that $c(\{v, w^v_{n-1}\}) = \{h_n, h_{n+1}\}$. A similar argument applies to an edge $vx_{vv'}$, with $vv' \in E(G-H)$; and an edge $w^v_1y^v_{n-1}$, with $v \in V(G-H)$.

Next consider an edge $y^v_{n-1}h_n$, with $v \in V(G-H)$. If $c(\{y^v_{n-1}, h_n\}) = \{h_n, h_{n+1}\}$ then $c(w^v_1) = h_n$ or h_{n+1}, as w^v_1 is adjacent to y^v_{n-1} and h_n. Since $c(W) \neq \{h_n, h_{n+1}\}$, it must be that $c(w^v_1) = c(h_n)$. This implies that $c(\{y^v_{n-1}, w^v_1\}) = \{h_n, h_{n+1}\}$ which, as noted above, is impossible.

Now consider an edge $vv' \in E(G-H)$. Suppose that $c(\{v,v'\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(v) = h_n$ and $c(v') = h_{n+1}$ (due to symmetry). We have $c(u^v_1), c(u^{v'}_1) \in \{h_0, h_1\}$. Since $d_{G'}(u^v_1, v) = n-1 < d_H(h_0, c(v) = h_n) = n$, this implies that $c(u^v_1) \neq h_0$, and hence $c(u^v_1) = h_1$. Since $d_{G'}(u^{v'}_1, v') = n-1 < d_H(h_1, c(v') = h_{n+1}) = n$, this implies that $c(u^{v'}_1) \neq h_1$, and hence $c(u^{v'}_1) = h_0$. We have the path $u^v_1u^v_2 \ldots u^v_{n-1}v$ of length $n-1$ in G'. Since $c(u^v_1) = h_1$ and $c(v) = h_n$, this implies that $c(u^v_i) = h_i$ for all $i = 1, 2, \ldots, n-1$. Thus we have $c(u^v_{n-1}) = h_{n-1}$. Since $c(w^v_{n-1})$ must be adjacent to $c(v) = h_n$, this implies that $c(w^v_{n-1}) \in \{h_{n-1}, h_n, h_{n+1}\}$. Since $d_{G'}(u^v_1, w^v_{n-1}) = n-1 < d_H(c(u^v_1) = h_1, h_{n+1}) = n$, this implies that $c(w^v_{n-1}) \neq h_{n+1}$, and hence $c(w^v_{n-1}) \in \{h_{n-1}, h_n\}$. Since $c(w^{v'}_{n-1})$ must be adjacent to $c(v') = h_{n+1}$, this implies that $c(w^{v'}_{n-1}) \in \{h_n, h_{n+1}, h_{n+2}\}$. Since $d_{G'}(u^{v'}_1, w^{v'}_{n-1}) = n-1 < d_H(c(u^{v'}_1) = h_0, h_n) = n$, this implies that $c(w^{v'}_{n-1}) \neq h_n$, and hence $c(w^{v'}_{n-1}) \in \{h_{n+1}, h_{n+2}\}$.

We now prove that $c(w^{v'}_{n-1}) \neq h_{n+1}$, which would leave us with the only choice that $c(w^{v'}_{n-1}) = h_{n+2}$. Suppose that $c(w^{v'}_{n-1}) = h_{n+1}$. We have the path $u^{v'}_1u^{v'}_2 \ldots u^{v'}_{m+1}w^{v'}_{m+1}w^{v'}_{m+2} \ldots w^{v'}_{n-1}$ of length $n-1$ in G'. Since $c(u^{v'}_1) = h_0$ and $c(w^{v'}_{n-1}) = h_{n+1}$, this implies that $c(u^{v'}_i) = h_{k-i+1}$ for all $i = 1, 2, \ldots, m+1$, and $c(w^{v'}_i) = h_{k-i}$ for all $i = m+1, m+2, \ldots, n-1$. Thus we have $c(u^{v'}_m) = h_{k-m+1}$ and $c(w^{v'}_{m+1}) = h_{k-m-1}$. Since $w^{v'}_m$ is adjacent to $w^{v'}_{m+1}$ and at distance two from $u^{v'}_m$ in G', this implies that $c(w^{v'}_m) = h_{k-m-1}$ or h_{k-m}. Since $w^{v'}_1$ is at distance $m-1$ from $w^{v'}_m$ in G', it follows that $c(w^{v'}_1) = h_s$, $n+1 \leq s \leq k-1$. We also have the path $u^v_1u^v_2 \ldots u^v_{m+1}w^v_{m+1}w^v_{m+2} \ldots w^v_{n-1}$ of length $n-1$ in G'. As shown above, we have $c(u^v_i) = h_i$, for all $i = 1, 2, \ldots, m+1$, and $c(w^v_{n-1}) = h_n$ or h_{n-1}. This implies that $c(w^v_i) = h_{i+1}$ or h_i for all $i = m+1, m+2, \ldots, n-1$. Thus we have $c(u^v_m) = h_m$ and $c(w^v_{m+1}) = h_{m+1}$ or h_{m+2}. Since w^v_m is adjacent to w^v_{m+1} and at distance two from u^v_m in G', this implies that $c(w^v_m) = h_m, h_{m+1}$, or h_{m+2}. Since w^v_1 is at distance $m-1$ from w^v_m in G', it follows that $c(w^v_1) = h_t$, $1 \leq t \leq n$. We have that $c(w^v_1)$ and $c(w^{v'}_1)$ must be adjacent in H. The only possible pair of values for t and s are n and $n+1$, respectively, for $c(w^v_1)$ to be adjacent to $c(w^{v'}_1)$. Thus $c(w^v_1) = h_n$ and $c(w^{v'}_1) = h_{n+1}$, which implies that $c(W) = \{h_n, h_{n+1}\}$ and we have a contradiction. Thus $c(w^{v'}_{n-1}) \neq h_{n+1}$, and hence $c(w^{v'}_{n-1}) = h_{n+2}$.

Now, $c(x_{vv'})$ must be adjacent to $c(u^v_{n-1}) = h_{n-1}$, $c(v) = h_n$, $c(v') = h_{n+1}$, and $c(w^{v'}_{n-1}) = h_{n+2}$, which is impossible.

Consider now an edge $v'x_{vv'}$, with $vv' \in E(G-H)$. If $c(\{v', x_{vv'}\}) = \{h_n, h_{n+1}\}$ then $c(v) = h_n$ or h_{n+1}, as v is adjacent to v' and $x_{vv'}$. This implies that either $c(\{v, v'\}) = \{h_n, h_{n+1}\}$ or $c(\{v, x_{vv'}\}) = \{h_n, h_{n+1}\}$, both of which we have already proved do not hold.

Now consider an edge $w^{v'}_{n-1}x_{vv'}$, with $vv' \in E(G-H)$. If $c(\{w^{v'}_{n-1}, x_{vv'}\}) = \{h_n, h_{n+1}\}$ then $c(v') = h_n$ or h_{n+1}, as v' is adjacent to $w^{v'}_{n-1}$ and $x_{vv'}$. This implies that either $c(\{v', w^{v'}_{n-1}\}) = \{h_n, h_{n+1}\}$ or $c(\{v', x_{vv'}\}) = \{h_n, h_{n+1}\}$, both of which we have already proved do not hold.

Finally, consider a possible edge vh_n, with $v \in V(G-H)$. Suppose that $c(\{v, h_n\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(v) = h_n$ and $c(h_n) = h_{n+1}$ (due to symmetry). Exactly, as in the case $vv' \in E(G-H)$ above, we establish that $c(w^v_1) = h_t$, $1 \le t \le n$. Since $c(w^v_1)$ must be adjacent to $c(h_n) = h_{n+1}$ in H, it follows that $c(w^v_1) = h_n$, and hence $h_n, h_{n+1} \in c(W)$, which is a contradiction. We argue similarly for a possible edge vh_{n+1}, with $v \in V(G-H)$.

This completes the proof that $c(W) = \{h_n, h_{n+1}\}$. We now prove that $c(h_0) \neq c(h_1)$. Suppose to the contrary that $c(h_0) = c(h_1)$. We have $c(h_0), c(h_1) \in \{h_0, h_1\}$, as $c(U) = \{h_0, h_1\}$. Without loss of generality, let $c(h_0) = c(h_1) = h_0$ (due to symmetry). Since $c(U) = \{h_0, h_1\}$, $c(u_v) = h_1$ for some vertex v of $G-H$. We have $c(w^v_1), c(h_n) \in \{h_n, h_{n+1}\}$, as $c(W) = \{h_n, h_{n+1}\}$. Since $d_{G'}(h_1, h_n) = n-1 < d_H(c(h_1) = h_0, h_n) = n$, this implies that $c(h_n) \neq h_n$, and hence $c(h_n) = h_{n+1}$. Since $d_{G'}(u^v_1, w^v_1) = n-1 < d_H(c(u^v_1) = h_1, h_{n+1}) = n$, this implies that $c(w^v_1) \neq h_{n+1}$, and hence $c(w^v_1) = h_n$. Now, $c(y^v_{n-1})$ must be adjacent to $c(h_n) = h_{n+1}$ and $c(w^v_1) = h_n$. Hence $c(y^v_{n-1}) \in \{h_n, h_{n+1}\}$. Also, $c(y^v_1)$ must be adjacent to $c(h_0) = h_0$ and $c(u^v_1) = h_1$. Hence $c(y^v_1) \in \{h_0, h_1\}$. We have $d_{G'}(y^v_1, y^v_{n-1}) = n-2 < d_H(\{h_0, h_1\}, \{h_n, h_{n+1}\}) = n-1$. Hence it is impossible that $c(y^v_1) \in \{h_0, h_1\}$ and $c(y^v_{n-1}) \in \{h_n, h_{n+1}\}$.

Thus $c(h_0) \neq c(h_1)$, i.e., $c(\{h_0, h_1\}) = \{h_0, h_1\}$. Without loss of generality, suppose that $c(h_0) = h_0$ and $c(h_1) = h_1$ (due to symmetry). We have $c(h_n), c(h_{n+1}) \in \{h_n, h_{n+1}\}$, as $c(W) = \{h_n, h_{n+1}\}$. Since $d_{G'}(h_1, h_n) = n-1 < d_H(c(h_1) = h_1, h_{n+1}) = n$, this implies that $c(h_n) \neq h_{n+1}$, and hence $c(h_n) = h_n$. Since $d_{G'}(h_0, h_{n+1}) = n-1 < d_H(c(h_0) = h_0, h_n) = n$, this implies that $c(h_{n+1}) \neq h_n$, and hence $c(h_{n+1}) = h_{n+1}$. We have the path $h_1h_2 \dots h_n$ of length $n-1$ in G'. Since $c(h_1) = h_1$ and $c(h_n) = h_n$, this implies that $c(h_i) = h_i$ for all $i = 1, 2, 3, \dots, n$. We also have the path $h_0h_{k-1}h_{k-2} \dots h_{n+1}$ of length $n-1$ in G'. Since $c(h_0) = h_0$ and $c(h_{n+1}) = h_{n+1}$, this implies that $c(h_i) = h_i$ for all $i = 0, n+1, n+2, n+3, \dots, k-1$. Thus we have $c(h_i) = h_i$ for all $i = 0, 1, 2, \dots, k-1$. Hence $c : G' \to H$ is a retraction and the lemma is proved. □

Proof of Theorem 3.1 in the case $k = 4m$. The construction of G' is as follows. For each vertex v in $V(G-H)$, we add to G three vertex disjoint paths U_v, W_v, and Y_v, each containing $n-1$ new vertices. Let $U_v = u^v_1u^v_2 \dots u^v_{n-1}$, $W_v = w^v_1w^v_2 \dots w^v_{n-1}$, and $Y_v = y^v_1y^v_2 \dots y^v_{n-1}$, with $v \in V(G-H)$. We add the edges $u^v_1h_0$, $u^v_1h_1$, vu^v_{n-1}, $w^v_1h_n$, $w^v_1h_{n+1}$, vw^v_{n-1}, $u^v_mw^v_m$, $y^v_1h_0$, $y^v_{n-1}h_n$, $u^v_1y^v_1$, and $w^v_1y^v_{n-1}$, with $v \in V(G-H)$. For convenience, in the proof of the first lemma, as for the case $k = 4m+2$, we also use h_k to denote the vertex h_0. See Figure 3.4. Furthermore, we add the edges $u^v_1u^{v'}_1$ and $w^v_1w^{v'}_1$ for all $v, v' \in V(G-H)$, $v \neq v'$.

The addition of a new vertex $x_{vv'}$ and the edges associated with it are same as for the case $k = 4m+2$, with $vv' \in E(G-H)$, $v \neq v'$. See Figure 3.3. This completes

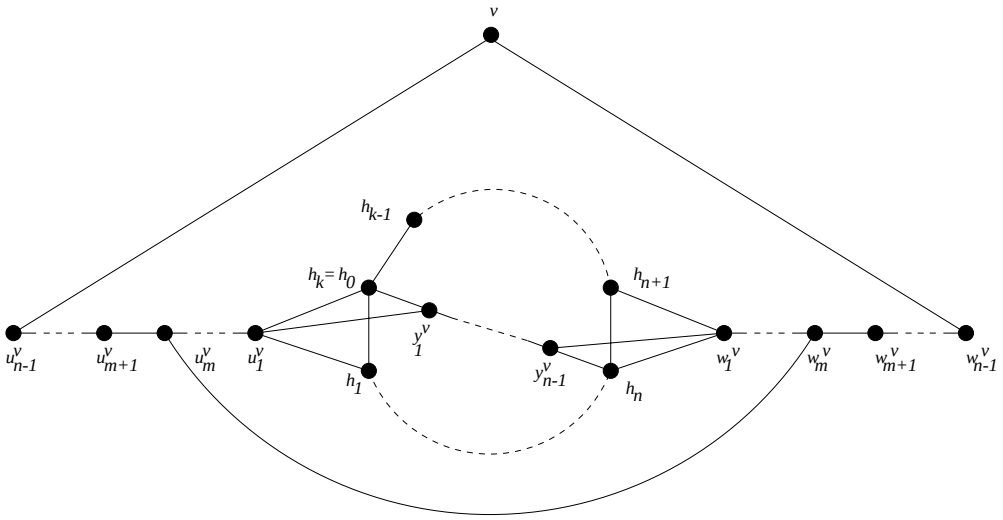

FIG. 3.4. *Construction of G' for a vertex v in $G - H$, with $k = 4m$.*

the construction of G'.

Note that the construction of G' is like for $k = 4m+2$ except that now we do not have the vertex a_v and the edge $u^v_{m+1}w^v_{m+1}$, with $v \in V(G-H)$. Instead we have the edge $u^v_m w^v_m$, with $v \in V(G-H)$. The two lemmas that we gave for the case when $k = 4m+2$ hold similarly for the case when $k = 4m$ with some variations in their proofs as noted below.

LEMMA 3.1.3. *G retracts to H if and only if G' retracts to H.*

Proof. If G' retracts to H then clearly G retracts to H, as G is a subgraph of G'. If $r : G \to H$ is a retraction then we define a retraction $r' : G' \to H$ exactly as we defined in the case $k = 4m+2$ in Lemma 3.1.1 except that now we do not need to define $r'(a_v)$, with $v \in V(G-H)$. As for the case $k = 4m+2$, it can be verified that for every edge ab of G', $r'(a)r'(b)$ is indeed an edge of H. Recall that the edges of G' are ab, $u^v_i u^v_{i+1}$, $w^v_i w^v_{i+1}$, $y^v_i y^v_{i+1}$, $u^v_1 h_0$, $u^v_1 h_1$, $w^v_1 h_n$, $w^v_1 h_{n+1}$, $v u^v_{n-1}$, $v w^v_{n-1}$, $u^v_m w^v_m$, $y^v_1 h_0$, $y^v_{n-1} h_n$, $u^v_1 y^v_1$, $w^v_1 y^v_{n-1}$, $u^v_1 u^{v'}_1$, $w^v_1 w^{v'}_1$, $g x_{gg'}$, $g' x_{gg'}$, $x_{gg'} u^g_{n-1}$, and $x_{gg'} w^{g'}_{n-1}$, with $ab \in E(G)$, $v, v' \in V(G-H)$, $gg' \in E(G-H)$, $i = 1, 2, \ldots, n-2$. □

LEMMA 3.1.4. *G' retracts to H if and only if G' compacts to H.*

Proof. If G' retracts to H then by definition G' compacts to H. Now suppose that $c : G' \to H$ is a compaction. We shall prove that G' retracts to H. We define cliques U and W, as we did for the case $k = 4m+2$ in Lemma 3.1.2, i.e., we let $U = \{u^v_1 | v \in V(G-H)\} \cup \{h_0, h_1\}$ and $W = \{w^v_1 | v \in V(G-H)\} \cup \{h_n, h_{n+1}\}$.

We note that $d_{G'}(U, a) < n$ and $d_{G'}(W, a) < n$ for all $a \in V(G')$. Thus, exactly as for the case $k = 4m+2$, we establish that both $c(U)$ and $c(W)$ are cliques of size two in H. Without loss of generality, suppose that $c(U) = \{h_0, h_1\}$ (due to symmetry). We first prove that $c(W) = \{h_n, h_{n+1}\}$. Let some edge ab of G' cover the edge $h_n h_{n+1}$ of H under c. As for the case $k = 4m+2$, we have that both a and b are at distance $n-1$ from U in G'. The only vertices that could possibly be at distance $n-1$ from U in G' are h_n, h_{n+1}, w^v_1, w^v_{n-1}, y^v_{n-1}, v, with $v \in V(G-H)$; and $x_{vv'}$, with $vv' \in E(G-H)$. Upper bounds on distance to these vertices from U in G' may be obtained due to the following paths in G':

$h_1h_2\dots h_{n-1}h_n$, $h_0h_{k-1}h_{k-2}\dots h_{n+2}h_{n+1}$, $u_1^vu_2^v\dots u_m^vw_m^vw_{m-1}^v\dots w_1^v$, $u_1^vu_2^v\dots u_m^vw_m^vw_{m+1}^v\dots w_{n-1}^v$, $u_1^vy_1^vy_2^v\dots y_{n-1}^v$, $u_1^vu_2^v\dots u_{n-1}^vv$, and $u_1^vu_2^v\dots u_{n-1}^vx_{vv'}$.

Notice that the paths to w_1^v and w_{n-1}^v from u_1^v, mentioned above, are different from the case $k=4m+2$.

Suppose that $c(W)\neq\{h_n,h_{n+1}\}$. Then, just as for the case $k=4m+2$, we conclude that ab must be an edge among vw_{n-1}^v, $w_1^vy_{n-1}^v$, $y_{n-1}^vh_n$, with $v\in V(G-H)$; vv', $vx_{vv'}$, $v'x_{vv'}$, and $w_{n-1}^{v'}x_{vv'}$, with $vv'\in E(G-H)$; in order to meet the requirements of the edge ab, both vertices in each of these edges are assumed to achieve distance $n-1$ from U in G'. Further, if vh_n or vh_{n+1} is an edge of G, for some vertex $v\in V(G-H)$, then we need to include such an edge also for ab. Note that the set of these possible edges for ab is the same as for the case $k=4m+2$. For all these possible edges of ab except $vv'\in E(G-H)$, the proof that these edges do not cover the edge h_nh_{n+1} under c (i.e., $c(\{a,b\})\neq\{h_n,h_{n+1}\}$) is exactly the same as for the case $k=4m+2$.

For an edge vv', we now make use of the paths $u_1^vu_2^v\dots u_m^vw_m^vw_{m+1}^v\dots w_{n-1}^v$ and $u_1^{v'}u_2^{v'}\dots u_m^{v'}w_m^{v'}w_{m+1}^{v'}\dots w_{n-1}^{v'}$ instead of the paths $u_1^vu_2^v\dots u_{m+1}^vw_{m+1}^vw_{m+2}^v\dots w_{n-1}^v$ and $u_1^{v'}u_2^{v'}\dots u_{m+1}^{v'}w_{m+1}^{v'}w_{m+2}^{v'}\dots w_{n-1}^{v'}$, respectively, with $vv'\in E(G-H)$. We consider this case and show its proof.

Let vv' be an edge of $G-H$. Suppose that $c(\{v,v'\})=\{h_n,h_{n+1}\}$. Without loss of generality, let $c(v)=h_n$ and $c(v')=h_{n+1}$ (due to symmetry). Exactly, as in the case $k=4m+2$, we prove that $c(u_i^v)=h_i$ for all $i=1,2,\dots,n-1$, $c(u_1^{v'})=h_0$, $c(w_{n-1}^v)\in\{h_{n-1},h_n\}$, and $c(w_{n-1}^{v'})\in\{h_{n+1},h_{n+2}\}$.

Now we prove that $c(w_{n-1}^{v'})\neq h_{n+1}$, which would leave us with the only choice that $c(w_{n-1}^{v'})=h_{n+2}$. Suppose that $c(w_{n-1}^{v'})=h_{n+1}$. We have the path $u_1^{v'}u_2^{v'}\dots u_m^{v'}w_m^{v'}w_{m+1}^{v'}\dots w_{n-1}^{v'}$ of length $n-1$ in G'. Since $c(u_1^{v'})=h_0$ and $c(w_{n-1}^{v'})=h_{n+1}$, this implies that $c(u_i^{v'})=h_{k-i+1}$ for all $i=1,2,\dots,m$, and $c(w_i^{v'})=h_{k-i}$ for all $i=m,m+1,\dots,n-1$. Thus we have $c(w_m^{v'})=h_{k-m}$. Since $w_1^{v'}$ is at distance $m-1$ from $w_m^{v'}$ in G', it follows that $c(w_1^{v'})=h_s$, $n+1\leq s\leq k-1$. We also have the path $u_1^vu_2^v\dots u_m^vw_m^vw_{m+1}^v\dots w_{n-1}^v$ of length $n-1$ in G'. Since $c(u_i^v)=h_i$, for all $i=1,2,\dots,m$, and $c(w_{n-1}^v)=h_n$ or h_{n-1}, this implies that $c(w_i^v)=h_{i+1}$ or h_i for all $i=m,m+1,\dots,n-1$. Thus we have $c(w_m^v)=h_m$ or h_{m+1}. Since w_1^v is at distance $m-1$ from w_m^v in G', it follows that $c(w_1^v)=h_t$, $1\leq t\leq n$. We have that $c(w_1^v)$ and $c(w_1^{v'})$ must be adjacent in H. The only possible pair of values for t and s are n and $n+1$, respectively, for $c(w_1^v)$ to be adjacent to $c(w_1^{v'})$. Thus $c(w_1^v)=h_n$ and $c(w_1^{v'})=h_{n+1}$, which implies that $c(W)=\{h_n,h_{n+1}\}$ and we have a contradiction. Thus $c(w_{n-1}^{v'})\neq h_{n+1}$, and hence $c(w_{n-1}^{v'})=h_{n+2}$.

Now, $c(x_{vv'})$ must be adjacent to $c(u_{n-1}^v)=h_{n-1}$, $c(v)=h_n$, $c(v')=h_{n+1}$, and $c(w_{n-1}^{v'})=h_{n+2}$, which is impossible. Hence $c(\{v,v'\})\neq\{h_n,h_{n+1}\}$.

Thus we have that $c(W)=\{h_n,h_{n+1}\}$. Exactly, as for the case $k=4m+2$, we prove that $c(h_0)\neq c(h_1)$. Without loss of generality, we let $c(h_0)=h_0$ and $c(h_1)=h_1$ (due to symmetry), and exactly as for the case $k=4m+2$, we establish that $c(h_i)=h_i$ for all $i=0,1,2,\dots,k-1$, i.e., $c:G'\to H$ is a retraction. □

Proof of Theorem 3.1 in the case $k=4m+3$. The construction of G' is as follows. For each vertex v in $G-H$, we add to G three vertex disjoint paths U_v, W_v, and Y_v, where U_v and W_v each contains $n-1$ new vertices, and Y_v contains n new vertices. Let $U_v=u_1^vu_2^v\dots u_{n-1}^v$, $W_v=w_1^vw_2^v\dots w_{n-1}^v$, and $Y_v=y_1^vy_2^v\dots y_n^v$,

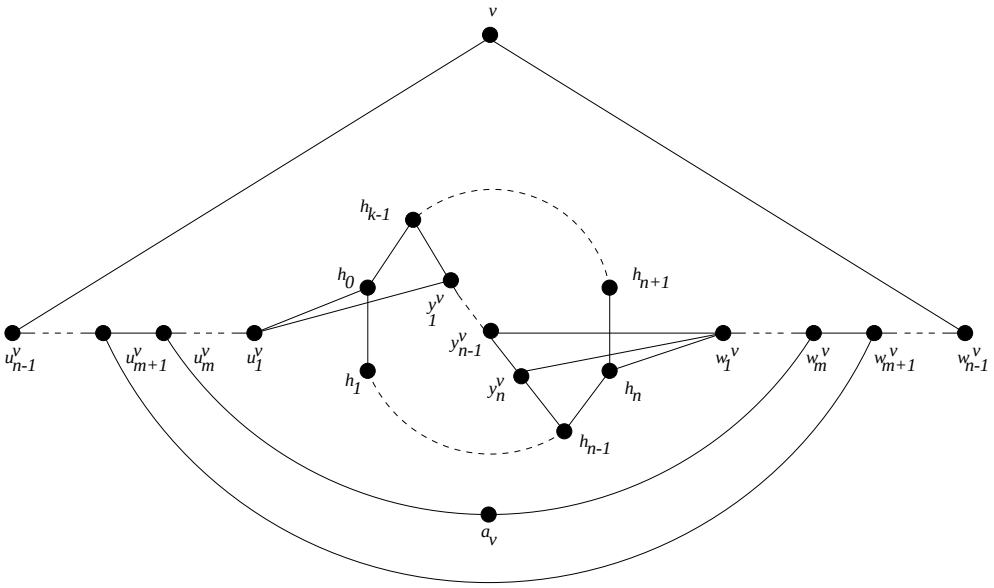

FIG. 3.5. *Construction of G' for a vertex v in $G - H$, with $k = 4m + 3$.*

with $v \in V(G - H)$. We add the edges $h_0u_1^v$, vu_{n-1}^v, $h_nw_1^v$, vw_{n-1}^v, $u_{m+1}^v w_{m+1}^v$, $h_{k-1}y_1^v$, $h_{n-1}y_n^v$, $u_1^v y_1^v$, $w_1^v y_n^v$, and $w_1^v y_{n-1}^v$, with $v \in V(G - H)$ (note that h_n is a vertex opposite to h_0 in H, and h_{n-1} is a vertex opposite to h_{k-1} in H). For each $v \in V(G - H)$, we also add a new vertex a_v adjacent to u_m^v and w_m^v. See Figure 3.5.

The addition of a new vertex $x_{vv'}$ and the edges associated with it are same as for the case $k = 4m + 2$, with $vv' \in E(G - H)$, $v \neq v'$. See Figure 3.3.

This completes the construction of G'. As for the case $k = 4m + 2$, we now prove the following two lemmas in order to prove the theorem for $k = 4m + 3$.

LEMMA 3.1.5. *G retracts to H if and only if G' retracts to H.*

Proof. If G' retracts to H then clearly G retracts to H, as G is a subgraph of G'. Now suppose that $r : G \to H$ is a retraction. Below, we define a retraction $r' : G' \to H$. Similar to the case $k = 4m + 2$, it can be verified that for the edges ab of G', $r'(a)r'(b)$ is indeed an edge of H. Recall that the edges of G' are (note the difference in the set of edges as compared to the case $k = 4m+2$) ab, $u_i^v u_{i+1}^v$, $w_i^v w_{i+1}^v$, $y_j^v y_{j+1}^v$, $u_1^v h_0$, $w_1^v h_n$, vu_{n-1}^v, vw_{n-1}^v, $u_{m+1}^v w_{m+1}^v$, $a_v u_m^v$, $a_v w_m^v$, $y_1^v h_{k-1}$, $y_n^v h_{n-1}$, $u_1^v y_1^v$, $w_1^v y_{n-1}^v$, $w_1^v y_n^v$, $gx_{gg'}$, $g'x_{gg'}$, $x_{gg'}u_{n-1}^g$, and $x_{gg'}w_{n-1}^{g'}$, with $ab \in E(G)$, $v \in V(G-H)$, $gg' \in E(G-H)$, $i = 1, 2, \ldots, n-2$, $j = 1, 2, \ldots, n-1$. We shall, however, include the verification for the edges $x_{vv'}u_{n-1}^v$ and $x_{vv'}w_{n-1}^{v'}$, with $vv' \in E(G - H)$, as it may be helpful.

For each vertex v of the graph G, we define

$$r'(v) = r(v).$$

Now we fix a vertex $v \in V(G - H)$ for defining r' for the vertices of U_v, W_v, and Y_v, and for the vertex a_v. Let $r(v) = h_j$. We shall define r' for the said vertices when $0 \leq j \leq n$, and when $n + 1 \leq j \leq k - 1$.

First assume that $0 \leq j \leq n$.
For the vertices of U_v, we define r' as follows.
If $j = 0$ then we define
$r'(u_i^v) = h_{i-1}$ for all $i = 1, 2, \ldots, m$,
$r'(u_i^v) = h_{n-i-1}$ for all $i = m+1, m+2, \ldots, n-1$.
If $1 \leq j \leq m$ then we define
$r'(u_i^v) = h_i$ for all $i = 1, 2, \ldots, m$,
$r'(u_i^v) = h_{n-i}$ for all $i = m+1, m+2, \ldots, n-j$,
$r'(u_i^v) = h_j$ for all $i = n-j+1, n-j+2, \ldots, n-1$.
If $j > m$ then we define
$r'(u_i^v) = h_i$ for all $i = 1, 2, \ldots, j-1$,
$r'(u_i^v) = h_j$ for all $i = j, j+1, \ldots, n-1$.
For the vertices of W_v, we define r' as follows.
If $j = n$ then we define
$r'(w_i^v) = h_{n-i}$ for all $i = 1, 2, \ldots, m-1$,
$r'(w_i^v) = h_{i+1}$ for all $i = m, m+1, m+2, \ldots, n-1$.
If $n - m \leq j \leq n-1$ then we define
$r'(w_i^v) = h_{n-i}$ for all $i = 1, 2, \ldots, m$,
$r'(w_i^v) = h_i$ for all $i = m+1, m+2, \ldots, j$,
$r'(w_i^v) = h_j$ for all $i = j+1, j+2, \ldots, n-1$.
If $j < n - m$ then we define
$r'(w_i^v) = h_{n-i}$ for all $i = 1, 2, \ldots, n-j-1$,
$r'(w_i^v) = h_j$ for all $i = n-j, n-j+1, \ldots, n-1$.
For the vertex a_v, we define r' as follows.
If $j = 0$ then we define
$r'(a_v) = h_m$.
If $j \neq 0$ then we define
$r'(a_v) = h_{m+1}$.
For the vertices of Y_v, we define
$r'(y_i^v) = h_{i-1}$ for all $i = 1, 2, \ldots, n$.
Now assume that $n + 1 \leq j \leq k - 1$.
For the vertices of U_v, we define r' as follows.
If $j \geq k - m$ then we define
$r'(u_i^v) = h_{k-i}$ for all $i = 1, 2, \ldots, m$,
$r'(u_i^v) = h_{n+i+1}$ for all $i = m+1, m+2, \ldots, j-n-1$,
$r'(u_i^v) = h_j$ for all $i = j-n, j-n+1, \ldots, n-1$.
If $j < k - m$ then we define
$r'(u_i^v) = h_{k-i}$ for all $i = 1, 2, \ldots, k-j-1$,
$r'(u_i^v) = h_j$ for all $i = k-j, k-j+1, \ldots, n-1$.
For the vertices of W_v, we define r' as follows.
If $j \leq n + m$ then we define
$r'(w_i^v) = h_{n+i}$ for all $i = 1, 2, \ldots, m$,
$r'(w_i^v) = h_{k-i-1}$ for all $i = m+1, m+2, \ldots, k-j-1$,
$r'(w_i^v) = h_j$ for all $i = k-j, k-j+1, \ldots, n-1$.
If $j > n + m$ then we define
$r'(w_i^v) = h_{n+i}$ for all $i = 1, 2, \ldots, j-n-1$,
$r'(w_i^v) = h_j$ for all $i = j-n, j-n+1, \ldots, n-1$.
For the vertex a_v, we define
$r'(a_v) = h_{k-m-1}$.

For the vertices of Y_v, we define

$r'(y_i^v) = h_{k-i-1}$ for all $i = 1, 2, \ldots, n$.

This completes the definition of r' for the vertices of U_v, W_v, and Y_v, and for the vertex a_v.

For the vertex $x_{vv'}$, with $vv' \in E(G - H)$, we define

$r'(x_{vv'}) = r(v)$, if $r(v) \notin \{h_0, h_{k-1}\}$, and

$r'(x_{vv'}) = r(v')$, if $r(v) \in \{h_0, h_{k-1}\}$.

We now consider the edges $x_{vv'}u_{n-1}^v$ and $x_{vv'}w_{n-1}^{v'}$ of G' and show that $r'(x_{vv'})r'(u_{n-1}^v)$ and $r'(x_{vv'})r'(w_{n-1}^{v'})$ are the edges of H, with $vv' \in E(G - H)$. It may be helpful to include the proof for these edges.

Consider first an edge $x_{vv'}u_{n-1}^v$ of G', with $vv' \in E(G - H)$. First suppose that $r(v) \notin \{h_0, h_{k-1}\}$. Then $r'(x_{vv'}) = r(v)$. We already have that $r'(v)r'(u_{n-1}^v) = r(v)r'(u_{n-1}^v)$ is an edge of H. Hence $r'(x_{vv'})r'(u_{n-1}^v) = r(v)r'(u_{n-1}^v)$ is an edge of H. Now suppose that $r(v) \in \{h_0, h_{k-1}\}$. Then $r'(x_{vv'}) = r(v')$. If $r(v) = h_0$ then from our definition of r' we have $r'(u_{n-1}^v) = h_0 = r(v)$ (as $j = 0$), and hence $r'(x_{vv'})r'(u_{n-1}^v) = r(v')r(v)$ is an edge of H. If $r(v) = h_{k-1}$ then from our definition of r' we have $r'(u_{n-1}^v) = h_j = h_{k-1} = r(v)$ (as $j = k - 1 \geq k - m$), and hence $r'(x_{vv'})r'(u_{n-1}^v) = r(v')r(v)$ is an edge of H. Thus we have proved, under all possibilities, that $r'(x_{vv'})r'(u_{n-1}^v)$ is an edge of H.

Now consider an edge $x_{vv'}w_{n-1}^{v'}$, with $vv' \in E(G-H)$. First suppose that $r(v) \notin \{h_0, h_{k-1}\}$. Then $r'(x_{vv'}) = r(v)$. Now first let $r(v') = h_j$, with $0 \leq j \leq n$. Then from our definition of r' we have $r'(w_{n-1}^{v'}) = h_j = r(v')$, if $j > 0$, and $r'(w_{n-1}^{v'}) = h_{j+1} = h_1$ if $j = 0$. Hence if $j > 0$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)r(v')$ is an edge of H. If $j = 0$ then since $r(v)$ is adjacent to $r(v') = h_j = h_0$ and $r(v) \notin \{h_0, h_{k-1}\}$, it must be that $r(v) = h_1$. Thus if $j = 0$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)h_1 = h_1h_1$ is an edge of H. Now let $r(v') = h_j$, with $n + 1 \leq j \leq k - 1$. Then from our definition of r' we have $r'(w_{n-1}^{v'}) = h_j = r(v')$, if $j < k - 1$, and $r'(w_{n-1}^{v'}) = h_{j-1} = h_{k-2}$, if $j = k - 1$. Hence if $j < k - 1$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)r(v')$ is an edge of H. If $j = k - 1$ then since $r(v)$ is adjacent to $r(v') = h_j = h_{k-1}$ and $r(v) \notin \{h_0, h_{k-1}\}$, it must be that $r(v) = h_{k-2}$. Thus if $j = k - 1$ then $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v)h_{k-2} = h_{k-2}h_{k-2}$ is an edge of H.

Now suppose that $r(v) \in \{h_0, h_{k-1}\}$. Then $r'(x_{vv'}) = r(v')$. We already have that $r'(v')r'(w_{n-1}^{v'}) = r(v')r'(w_{n-1}^{v'})$ is an edge of H. Hence $r'(x_{vv'})r'(w_{n-1}^{v'}) = r(v')r'(w_{n-1}^{v'})$ is an edge of H. Thus we have proved, under all possibilities, that $r'(x_{vv'})r'(w_{n-1}^{v'})$ is an edge of H.

Thus, as for $k = 4m + 2$, we conclude that $r' : G' \to H$ is a homomorphism and a retraction. □

LEMMA 3.1.6. *G' retracts to H if and only if G' compacts to H.*

Proof. If G' retracts to H then by definition G' compacts to H. Now suppose that $c : G' \to H$ is a compaction. We shall prove that G' retracts to H. We define the sets $U = \{u_1^v | v \in V(G - H)\} \cup \{h_1, h_0, h_{k-1}\}$ and $W = \{w_1^v | v \in V(G - H)\} \cup \{h_{n-1}, h_n, h_{n+1}\}$ (unlike the even k case, U and W are not cliques in G').

Since the subgraph of G' induced by the vertices in U is of diameter two (with h_0 adjacent to every vertex in U), the vertices of $c(U)$ induce a path of length at most two in H. Thus $c(U)$ has either one, two, or three vertices. Similarly, $c(W)$ has either one, two, or three vertices. We shall prove that both $c(U)$ and $c(W)$ have three vertices.

Suppose that $c(U)$ has only one or two vertices, i.e., $c(U)$ induces a path of length

at most one in H. Without loss of generality, let $c(U) = \{h_0\}$ or $c(U) = \{h_0, h_1\}$ (due to symmetry). We note that $d_{G'}(U, a) < n$ for all $a \in V(G')$. Hence we have $d_{G'}(U, a) < d_H(c(U), h_{n+1}) = n$ for all $a \in V(G')$. This implies that $c(a) \neq h_{n+1}$ for all $a \in V(G')$. Thus $c(U)$ must have three vertices. We also note that $d_{G'}(W, a) < n$, for all $a \in V(G')$, and hence, similarly, $c(W)$ must also have three vertices. We point out here that upper bounds on $d_{G'}(U, y)$ and $d_{G'}(W, y)$, for the vertices y of Y_v, with $v \in V(G - H)$, are obtained differently due to the following paths in G':
$u_1^v y_1^v y_2^v \dots y_{n-1}^v$, $h_1 h_2 \dots h_{n-1} y_n^v$, $w_1^v y_{n-1}^v y_{n-2}^v \dots y_1^v$, and $w_1^v y_n^v$.

Thus $c(U)$ and $c(W)$ both induce paths containing three vertices in H. Without loss of generality, suppose that $c(U) = \{h_1, h_0, h_{k-1}\}$ (due to symmetry). We first prove that $\{h_n, h_{n+1}\} \subset c(W)$, i.e., $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$ or $c(W) = \{h_n, h_{n+1}, h_{n+2}\}$. Let some edge ab of G' cover the edge $h_n h_{n+1}$ of H under c (clearly there exists such an edge in G'). We note that both h_n and h_{n+1} are at distance $n-1$ from $c(U)$ in H. Thus both a and b must be at distance greater than or equal to $n-1$ from U in G'. While there is no vertex at distance greater than $n-1$ from U in G', the only vertices that could possibly be at distance $n-1$ from U in G' are h_n, h_{n+1}, w_1^v, w_{n-1}^v, y_{n-1}^v, y_n^v, v, with $v \in V(G-H)$; and $x_{vv'}$, with $vv' \in E(G-H)$. Upper bounds on distance to these vertices from U in G' may be obtained due to the following paths in G' (appropriate paths will apply to vertices in question). We are mentioning upper bounds, as presence of an edge vh of G, with $v \in V(G - H)$, $h \in V(H)$, may result in a shorter path from U to a vertex mentioned above in G'. The paths are
$h_1 h_2 \dots h_n$, $h_{k-1} h_{k-2} \dots h_{n+1}$, $u_1^v u_2^v \dots u_m^v a_v w_m^v w_{m-1}^v \dots w_1^v$,
$u_1^v u_2^v \dots u_{m+1}^v w_{m+1}^v w_{m+2}^v \dots w_{n-1}^v$, $u_1^v y_1^v y_2^v \dots y_{n-1}^v$, $h_1 h_2 \dots h_{n-1} y_n^v$,
$u_1^v u_2^v \dots u_{n-1}^v v$, and $u_1^v u_2^v \dots u_{n-1}^v x_{vv'}$.

Suppose that $\{h_n, h_{n+1}\} \not\subset c(W)$. Then no edge with both endpoints in W covers the edge $h_n h_{n+1}$ of H under c, and hence not both a and b belong to W. Thus ab must be an edge among vw_{n-1}^v, $w_1^v y_n^v$, $w_1^v y_{n-1}^v$, $y_{n-1}^v y_n^v$, with $v \in V(G-H)$; vv', $vx_{vv'}$, $v'x_{vv'}$, and $w_{n-1}^{v'} x_{vv'}$, with $vv' \in E(G-H)$; in order to meet the requirements of the edge ab, both vertices in each of these edges are assumed to achieve distance $n-1$ from U in G'. Further, if vh_n or vh_{n+1} is an edge of G, for some vertex $v \in V(G-H)$, then we need to include such an edge also for ab. We shall consider each of these possible edges for ab and show that they do not cover the edge $h_n h_{n+1}$ under c (i.e., $c(\{a, b\}) \neq \{h_n, h_{n+1}\}$), implying that $\{h_n, h_{n+1}\} \subset c(W)$.

For the edges vw_{n-1}^v, $w_1^v y_{n-1}^v$, with $v \in V(G-H)$; and $vx_{vv'}$, with $vv' \in E(G-H)$, we argue exactly as in the case $k = 4m+2$ except that now $c(u_1^v) = h_{k-1}, h_0$, or h_1.

Consider now an edge $y_n^v w_1^v$, with $v \in V(G-H)$. Suppose that $c(\{y_n^v, w_1^v\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(y_n^v) = h_n$ and $c(w_1^v) = h_{n+1}$ (due to symmetry). We have $c(h_1) = h_1, h_0$, or h_{k-1}. Since $d_{G'}(h_1, y_n^v) = n-1 < d_H(\{h_0, h_{k-1}\}, c(y_n^v) = h_n) = n$, this implies that $c(h_1) \notin \{h_0, h_{k-1}\}$, and hence $c(h_1) = h_1$. We have the path $h_1 h_2 \dots h_{n-1} y_n^v$ of length $n-1$ in G'. Since $c(h_1) = h_1$ and $c(y_n^v) = h_n$, this implies that $c(h_i) = h_i$ for all $i = 1, 2, \dots, n-1$. Since $c(h_n)$ must be adjacent to $c(h_{n-1}) = h_{n-1}$ and $c(w_1^v) = h_{n+1}$, this implies that $c(h_n) = h_n$. Thus we have $c(w_1^v) = h_{n+1}$ and $c(h_n) = h_n$, implying that $\{h_n, h_{n+1}\} \subset c(W)$, which is a contradiction.

Now consider an edge $y_{n-1}^v y_n^v$, with $v \in V(G-H)$. Suppose that $c(\{y_{n-1}^v, y_n^v\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(y_{n-1}^v) = h_{n+1}$ and $c(y_n^v) = h_n$ (due to symmetry). We have $c(u_1^v) = h_1, h_0$, or h_{k-1}. Since $d_{G'}(u_1^v, y_{n-1}^v) = n-1 < d_H(\{h_0, h_1\}, c(y_{n-1}^v) = h_{n+1}) = n$, this implies that $c(u_1^v) \notin \{h_0, h_1\}$, and hence $c(u_1^v) = h_{k-1}$. Since $c(w_1^v)$ must be adjacent to $c(y_n^v) = h_n$, this implies that

$c(w_1^v) \in \{h_{n-1}, h_n, h_{n+1}\}$ (we are not making use of the fact that $c(w_1^v)$ is adjacent to y_{n-1}^v, for $k > 5$, to cover up the case for $k = 5$ also). Since $d_{G'}(u_1^v, w_1^v) = n-1 < d_H(c(u_1^v) = h_{k-1}, \{h_n, h_{n-1}\}) = n$, this implies that $c(w_1^v) \notin \{h_n, h_{n-1}\}$, and hence $c(w_1^v) = h_{n+1}$. Thus we have $c(y_n^v) = h_n$ and $c(w_1^v) = h_{n+1}$, which we have already proved is impossible.

Now consider an edge $vv' \in E(G-H)$. Suppose that $c(\{v, v'\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(v) = h_n$ and $c(v') = h_{n+1}$ (due to symmetry). We have $c(u_1^v), c(u_1^{v'}) \in \{h_1, h_0, h_{k-1}\}$. Since $d_{G'}(u_1^v, v) = n-1 < d_H(\{h_0, h_{k-1}\}, c(v) = h_n) = n$, this implies that $c(u_1^v) \notin \{h_0, h_{k-1}\}$, and hence $c(u_1^v) = h_1$. Since $d_{G'}(u_1^{v'}, v') = n-1 < d_H(\{h_0, h_1\}, c(v') = h_{n+1}) = n$, this implies that $c(u_1^{v'}) \notin \{h_0, h_1\}$, and hence $c(u_1^{v'}) = h_{k-1}$. We have the path $u_1^v u_2^v \dots u_{n-1}^v v$ of length $n-1$ in G'. Since $c(u_1^v) = h_1$ and $c(v) = h_n$, this implies that $c(u_i^v) = h_i$ for all $i = 1, 2, \dots, n-1$. Thus we have $c(u_{n-1}^v) = h_{n-1}$. Since $c(w_{n-1}^v)$ must be adjacent to $c(v) = h_n$, this implies that $c(w_{n-1}^v) \in \{h_{n-1}, h_n, h_{n+1}\}$. Since $d_{G'}(u_1^v, w_{n-1}^v) = n-1 < d_H(c(u_1^v) = h_1, h_{n+1}) = n$, this implies that $c(w_{n-1}^v) \neq h_{n+1}$, and hence $c(w_{n-1}^v) \in \{h_{n-1}, h_n\}$. Since $c(w_{n-1}^{v'})$ must be adjacent to $c(v') = h_{n+1}$, this implies that $c(w_{n-1}^{v'}) \in \{h_n, h_{n+1}, h_{n+2}\}$. Since $d_{G'}(u_1^{v'}, w_{n-1}^{v'}) = n-1 < d_H(c(u_1^{v'}) = h_{k-1}, h_n) = n$, this implies that $c(w_{n-1}^{v'}) \neq h_n$, and hence $c(w_{n-1}^{v'}) \in \{h_{n+1}, h_{n+2}\}$.

We now prove that $c(w_{n-1}^{v'}) \neq h_{n+1}$, which would leave us with the only choice that $c(w_{n-1}^{v'}) = h_{n+2}$. Suppose that $c(w_{n-1}^{v'}) = h_{n+1}$. We have the path $u_1^{v'} u_2^{v'} \dots u_{m+1}^{v'} w_{m+1}^{v'} w_{m+2}^{v'} \dots w_{n-1}^{v'}$ of length $n-1$ in G'. Since $c(u_1^{v'}) = h_{k-1}$ and $c(w_{n-1}^{v'}) = h_{n+1}$, this implies that $c(u_i^{v'}) = h_{k-i}$ for all $i = 1, 2, \dots, m+1$, and $c(w_i^{v'}) = h_{k-i-1}$ for all $i = m+1, m+2, \dots, n-1$. Thus we have $c(u_m^{v'}) = h_{k-m}$ and $c(w_{m+1}^{v'}) = h_{k-m-2}$. Since $w_m^{v'}$ is adjacent to $w_{m+1}^{v'}$ and at distance two from $u_m^{v'}$ in G', this implies that $c(w_m^{v'}) = h_{k-m-2}$ or h_{k-m-1}. Since $w_1^{v'}$ is at distance $m-1$ from $w_m^{v'}$ in G', it follows that $c(w_1^{v'}) = h_s$, $n+1 \leq s \leq k-2$. We also have the path $u_1^v u_2^v \dots u_{m+1}^v w_{m+1}^v w_{m+2}^v \dots w_{n-1}^v$ of length $n-1$ in G'. As shown above, we have $c(u_i^v) = h_i$, for all $i = 1, 2, \dots, m+1$, and $c(w_{n-1}^v) = h_n$ or h_{n-1}. This implies that $c(w_i^v) = h_{i+1}$ or h_i for all $i = m+1, m+2, \dots, n-1$. Thus we have $c(u_m^v) = h_m$ and $c(w_{m+1}^v) = h_{m+1}$ or h_{m+2}. Since w_m^v is adjacent to w_{m+1}^v and at distance two from u_m^v in G', this implies that $c(w_m^v) = h_m, h_{m+1}$, or h_{m+2}. Since w_1^v is at distance $m-1$ from w_m^v in G', it follows that $c(w_1^v) = h_t$, $1 \leq t \leq n$. We have that $c(w_1^v)$ and $c(w_1^{v'})$ must be adjacent in H. The only possible pair of values for t and s are n and $n+1$, respectively, for $c(w_1^v)$ to be adjacent to $c(w_1^{v'})$. Thus $c(w_1^v) = h_n$ and $c(w_1^{v'}) = h_{n+1}$, which implies that $h_n, h_{n+1} \in c(W)$ and we have a contradiction. Thus $c(w_{n-1}^{v'}) \neq h_{n+1}$, and hence $c(w_{n-1}^{v'}) = h_{n+2}$.

Now, $c(x_{vv'})$ must be adjacent to $c(u_{n-1}^v) = h_{n-1}$, $c(v) = h_n$, $c(v') = h_{n+1}$, and $c(w_{n-1}^{v'}) = h_{n+2}$, which is impossible.

For the edges $v'x_{vv'}$, $w_{n-1}^{v'}x_{vv'}$, with $vv' \in E(G-H)$; and a possible edge vh_n, with $v \in V(G-H)$, the arguments are exactly as in the case $k = 4m+2$.

Finally, consider a possible edge vh_{n+1}, with $v \in V(G-H)$. Suppose that $c(\{v, h_{n+1}\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(v) = h_n$ and $c(h_{n+1}) = h_{n+1}$ (due to symmetry). Exactly, as in the case $vv' \in E(G-H)$ above, we establish that $c(w_1^v) = h_t$, $1 \leq t \leq n$. Since w_1^v is at distance two from h_{n+1} in G', it follows that $c(w_1^v) = h_n$ or h_{n-1}. Clearly, $c(w_1^v) \neq h_n$, as otherwise we will have $h_n, h_{n+1} \in c(W)$. Thus $c(w_1^v) = h_{n-1}$. Since h_n is adjacent to w_1^v and h_{n+1}, this implies that $c(h_n) = h_n$, and hence $h_n, h_{n+1} \in c(W)$, which is a contradiction.

This completes the proof that $\{h_n, h_{n+1}\} \subset c(W)$. Thus $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$

or $c(W) = \{h_n, h_{n+1}, h_{n+2}\}$. Without loss of generality, suppose that $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$ (due to symmetry). This implies that $c(h_n) = h_n$, as h_n is adjacent to every vertex in W. We have $c(U) = \{h_1, h_0, h_{k-1}\}$ and h_0 is adjacent to every vertex in U. Hence $c(h_0) = h_0$. We have the path $h_0h_1 \dots h_n$ of length n in G'. Since $c(h_0) = h_0$ and $c(h_n) = h_n$, this implies that $c(h_i) = h_i$ for all $i = 0, 1, \dots, n$.

We now prove that $c(h_{k-1}) = h_{k-1}$. Suppose to the contrary that $c(h_{k-1}) \neq h_{k-1}$. Thus we have $c(h_{k-1}) = h_0$ or h_1, $c(h_0) = h_0$, and $c(h_1) = h_1$. Since $c(U) = \{h_1, h_0, h_{k-1}\}$, it must be that $c(u_1^v) = h_{k-1}$ for some vertex v of $G - H$. We have $c(w_1^v) \in \{h_{n-1}, h_n, h_{n+1}\}$, as $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$. Since $d_{G'}(u_1^v, w_1^v) = n - 1 < d_H(c(u_1^v) = h_{k-1}, \{h_n, h_{n-1}\}) = n$, this implies that $c(w_1^v) \notin \{h_n, h_{n-1}\}$, and hence $c(w_1^v) = h_{n+1}$. Now, $c(y_n^v)$ must be adjacent to $c(h_{n-1}) = h_{n-1}$ and $c(w_1^v) = h_{n+1}$. Hence $c(y_n^v) = h_n$. Since $c(y_1^v)$ must be adjacent to $c(u_1^v) = h_{k-1}$ and $c(h_{k-1}) = h_0$ or h_1, this implies that $c(y_1^v) \in \{h_0, h_{k-1}\}$. However, $d_{G'}(y_1^v, y_n^v) = n - 1 < d_H(\{h_0, h_{k-1}\}, c(y_n^v) = h_n) = n$, and hence it is impossible that $c(y_1^v) \in \{h_0, h_{k-1}\}$. Hence it must be that $c(h_{k-1}) = h_{k-1}$.

We have the path $h_{k-1}h_{k-2} \dots h_n$ of length n in G'. Since $c(h_{k-1}) = h_{k-1}$ and $c(h_n) = h_n$, this implies that $c(h_i) = h_i$ for all $i = n, n+1, \dots, k-1$. Thus we have $c(h_i) = h_i$ for all $i = 0, 1, 2, \dots, k-1$. Hence $c : G' \to H$ is a retraction, and the lemma is proved. □

Proof of Theorem 3.1 in the case $k = 4m + 1$. The construction of G' is as follows. For each vertex v in $G - H$, we add to G three vertex disjoint paths U_v, W_v, and Y_v, where U_v and W_v each contains $n - 1$ new vertices, and Y_v contains n new vertices. Let $U_v = u_1^v u_2^v \dots u_{n-1}^v$, $W_v = w_1^v w_2^v \dots w_{n-1}^v$, and $Y_v = y_1^v y_2^v \dots y_n^v$, with $v \in V(G - H)$. We add the edges $h_0u_1^v$, vu_{n-1}^v, $h_nw_1^v$, vw_{n-1}^v, $u_m^v w_m^v$, $h_{k-1}y_1^v$, $h_{n-1}y_n^v$, $u_1^v y_1^v$, and $w_1^v y_n^v$, with $v \in V(G - H)$. Further, if $k > 5$ then we also add the edge $w_1^v y_{n-1}^v$, with $v \in V(G - H)$. If $k = 5$ then for each $v \in V(G - H)$ we add a new vertex z_v adjacent to y_{n-1}^v, h_n, and u_1^v (note the similarity between the adjacencies of z_v and w_1^v). Thus there is a slight difference in the construction of G' for $k = 4m + 1 > 5$ and $k = 4m + 1 = 5$. See Figures 3.6 and 3.7.

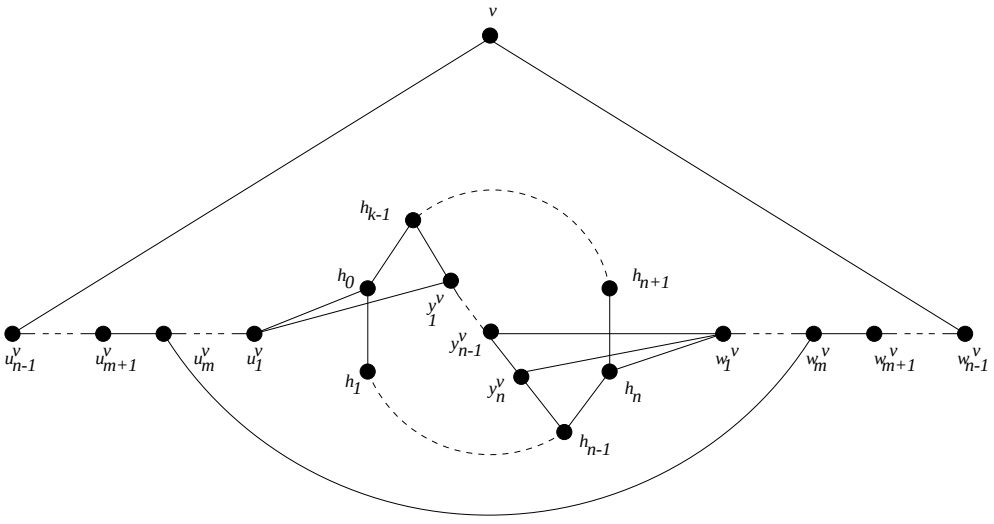

FIG. 3.6. *Construction of G' for a vertex v in $G - H$, with $k = 4m + 1 > 5$.*

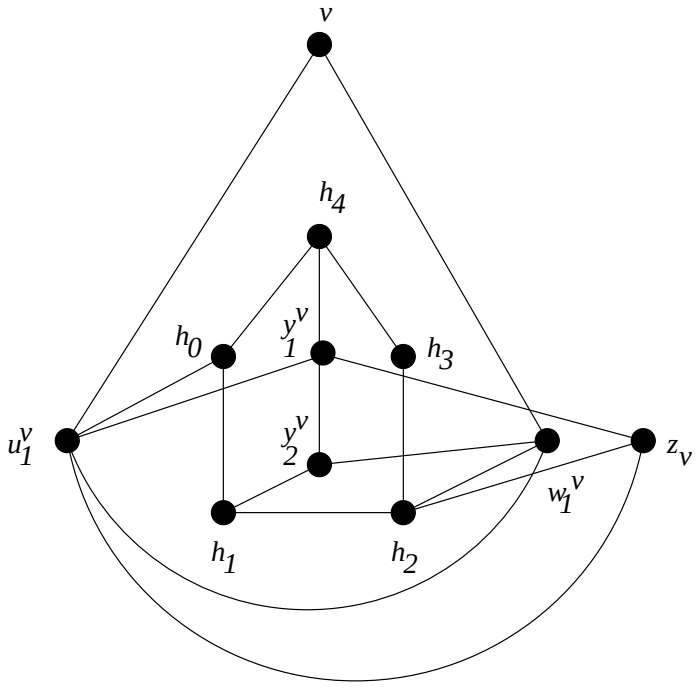

FIG. 3.7. *Construction of G' for a vertex v in $G - H$, with $k = 4m + 1 = 5$.*

The addition of a new vertex $x_{vv'}$ and the edges associated with it are same as for the case $k = 4m+2$, with $vv' \in E(G-H)$, $v \neq v'$. See Figure 3.3. This completes the construction of G'.

Note the similarity between the construction of G' for $k = 4m+1$ and $k = 4m+3$. The two lemmas that we gave for the case when $k = 4m + 3$ hold similarly for the case when $k = 4m + 1$ with some variations in their proofs as noted below.

LEMMA 3.1.7. *G retracts to H if and only if G' retracts to H.*

Proof. If G' retracts to H then clearly G retracts to H, as G is a subgraph of G'. If $r : G \to H$ is a retraction then we define a retraction $r' : G' \to H$ exactly as we defined in the case $k = 4m + 3$ in Lemma 3.1.5 except that now we do not need to define $r'(a_v)$, with $v \in V(G - H)$. For $k = 5$ however, we now need to define $r'(z_v)$, with $v \in V(G - H)$: in the case $0 \leq j \leq n$, we define $r'(z_v) = h_{n-1} = h_1$; and in the case $n + 1 \leq j \leq k - 1$, we define $r'(z_v) = h_{n+1} = h_3$. As for the case $k = 4m + 2$, it can be verified that for every edge ab of G', $r'(a)r'(b)$ is indeed an edge of H. Recall that the edges of G' are (note the difference in the set of edges as compared to the case $k = 4m$) ab, $u_i^v u_{i+1}^v$, $w_i^v w_{i+1}^v$, $y_j^v y_{j+1}^v$, $u_1^v h_0$, $w_1^v h_n$, $v u_{n-1}^v$, $v w_{n-1}^v$, $u_m^v w_m^v$, $y_1^v h_{k-1}$, $y_n^v h_{n-1}$, $u_1^v y_1^v$, $w_1^v y_n^v$, $g x_{gg'}$, $g' x_{gg'}$, $x_{gg'} u_{n-1}^g$, and $x_{gg'} w_{n-1}^{g'}$, with $ab \in E(G)$, $v \in V(G - H)$, $gg' \in E(G - H)$, $i = 1, 2, \ldots, n - 2$, $j = 1, 2, \ldots, n - 1$. Further, if $k > 5$ then G' also has the edge $w_1^v y_{n-1}^v$, with $v \in V(G - H)$. If $k = 5$ then G' also has the edges $z_v y_{n-1}^v$, $z_v h_n$, and $z_v u_1^v$, with $v \in V(G - H)$. □

LEMMA 3.1.8. *G' retracts to H if and only if G' compacts to H.*

Proof. If G' retracts to H then by definition G' compacts to H. Now suppose that $c : G' \to H$ is a compaction. We shall prove that G' retracts to H. For $k > 5$, we define the sets U and W as we did for the case $k = 4m + 3$ in Lemma 3.1.6, i.e., we let $U =$

$\{u_1^v | v \in V(G-H)\} \cup \{h_1, h_0, h_{k-1}\}$ and $W = \{w_1^v | v \in V(G-H)\} \cup \{h_{n-1}, h_n, h_{n+1}\}$. For $k = 5$, the set U is same as defined here but the set W now also contains z_v for all $v \in V(G-H)$, i.e., $W = \{w_1^v, z_v | v \in V(G-H)\} \cup \{h_{n-1}, h_n, h_{n+1}\}$.

We note that $d_{G'}(U, a) < n$ and $d_{G'}(W, a) < n$ for all $a \in V(G')$. We point out here that an upper bound on $d_{G'}(W, y)$, for the vertices y of Y_v, with $v \in V(G-H)$, is obtained differently in the cases $k > 5$ and $k = 5$ due to the following paths in G':
for $k > 5$: $w_1^v y_{n-1}^v y_{n-2}^v \dots y_1^v$, and $w_1^v y_n^v$;
for $k = 5$: $z_v y_{n-1}^v y_{n-2}^v \dots y_1^v = z_v y_1^v$, and $w_1^v y_n^v = w_1^v y_2^v$.

Thus, exactly as for the case $k = 4m+3$, we establish that both $c(U)$ and $c(W)$ induce paths containing three vertices in H. Without loss of generality, suppose that $c(U) = \{h_1, h_0, h_{k-1}\}$ (due to symmetry). We first prove that $\{h_n, h_{n+1}\} \subset c(W)$, i.e., $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$ or $c(W) = \{h_n, h_{n+1}, h_{n+2}\}$. Let some edge ab of G' cover the edge $h_n h_{n+1}$ of H under c. As for the case $k = 4m+3$, we have that both a and b are at distance $n-1$ from U in G'. The only vertices that could possibly be at distance $n-1$ from U in G' are h_n, h_{n+1}, w_1^v, w_{n-1}^v, y_{n-1}^v, y_n^v, v, with $v \in V(G-H)$; $x_{vv'}$, with $vv' \in E(G-H)$; and for $k = 5$, we also have z_v, with $v \in V(G-H)$. Upper bounds on distance to these vertices from U in G' may be obtained due to the following paths in G':
$h_1 h_2 \dots h_n$, $h_{k-1} h_{k-2} \dots h_{n+1}$, $u_1^v u_2^v \dots u_m^v w_m^v w_{m-1}^v \dots w_1^v$,
$u_1^v u_2^v \dots u_m^v w_m^v w_{m+1}^v \dots w_{n-1}^v$, $u_1^v y_1^v y_2^v \dots y_{n-1}^v$, $h_1 h_2 \dots h_{n-1} y_n^v$,
$u_1^v u_2^v \dots u_{n-1}^v v$, and $u_1^v u_2^v \dots u_{n-1}^v x_{vv'}$.
Notice that the paths to w_1^v and w_{n-1}^v from u_1^v, mentioned above, are different from the case $k = 4m+3$.

Suppose that $\{h_n, h_{n+1}\} \not\subset c(W)$. Then, just as for the case $k = 4m+3$, we conclude that ab must be an edge among $v w_{n-1}^v$, $w_1^v y_n^v$, $y_{n-1}^v y_n^v$, with $v \in V(G-H)$; vv', $v x_{vv'}$, $v' x_{vv'}$, $w_{n-1}^{v'} x_{vv'}$, with $vv' \in E(G-H)$; $w_1^v y_{n-1}^v$, when $k > 5$, with $v \in V(G-H)$; and $z_v y_{n-1}^v$, when $k = 5$, with $v \in V(G-H)$; in order to meet the requirements of the edge ab, both vertices in each of these edges are assumed to achieve distance $n-1$ from U in G'. Further, if $v h_n$ or $v h_{n+1}$ is an edge of G, for some vertex $v \in V(G-H)$, then we need to include such an edge also for ab. Note that the set of these possible edges for ab is the same as for the case $k = 4m+3$ except for a difference in the case $k = 5$. For all these possible edges of ab except $vv' \in E(G-H)$ and $z_v y_{n-1}^v$, when $k = 5$, with $v \in V(G-H)$, the proof that these edges do not cover the edge $h_n h_{n+1}$ under c (i.e., $c(\{a, b\}) \neq \{h_n, h_{n+1}\}$) is exactly the same as for the case $k = 4m+3$.

For an edge $z_v y_{n-1}^v$, when $k = 5$, we argue similarly as for an edge $v w_{n-1}^v$, with $v \in V(G-H)$, to show that it does not cover the edge $h_n h_{n+1}$ under c.

For an edge vv', we now make use of the paths $u_1^v u_2^v \dots u_m^v w_m^v w_{m+1}^v \dots w_{n-1}^v$ and $u_1^{v'} u_2^{v'} \dots u_m^{v'} w_m^{v'} w_{m+1}^{v'} \dots w_{n-1}^{v'}$ instead of the paths $u_1^v u_2^v \dots u_{m+1}^v w_{m+1}^v w_{m+2}^v \dots w_{n-1}^v$ and $u_1^{v'} u_2^{v'} \dots u_{m+1}^{v'} w_{m+1}^{v'} w_{m+2}^{v'} \dots w_{n-1}^{v'}$, respectively, with $vv' \in E(G-H)$. We consider this case and show its proof.

Let vv' be an edge of $G-H$. Suppose that $c(\{v, v'\}) = \{h_n, h_{n+1}\}$. Without loss of generality, let $c(v) = h_n$ and $c(v') = h_{n+1}$ (due to symmetry). Exactly, as in the case $k = 4m+3$, we prove that $c(u_i^v) = h_i$ for all $i = 1, 2, \dots, n-1$, $c(u_1^{v'}) = h_{k-1}$, $c(w_{n-1}^v) \in \{h_{n-1}, h_n\}$, and $c(w_{n-1}^{v'}) \in \{h_{n+1}, h_{n+2}\}$.

Now we prove that $c(w_{n-1}^{v'}) \neq h_{n+1}$, which would leave us with the only choice that $c(w_{n-1}^{v'}) = h_{n+2}$. Suppose that $c(w_{n-1}^{v'}) = h_{n+1}$. We have the path $u_1^{v'} u_2^{v'} \dots u_m^{v'} w_m^{v'} w_{m+1}^{v'} \dots w_{n-1}^{v'}$ of length $n-1$ in G'. Since $c(u_1^{v'}) = h_{k-1}$ and $c(w_{n-1}^{v'})$

$= h_{n+1}$, this implies that $c(u_i^{v'}) = h_{k-i}$ for all $i = 1, 2, \ldots, m$, and $c(w_i^{v'}) = h_{k-i-1}$ for all $i = m, m+1, \ldots, n-1$. Thus we have $c(w_m^{v'}) = h_{k-m-1}$. Since $w_1^{v'}$ is at distance $m-1$ from $w_m^{v'}$ in G', it follows that $c(w_1^{v'}) = h_s$, $n+1 \leq s \leq k-2$. We also have the path $u_1^v u_2^v \ldots u_m^v w_m^v w_{m+1}^v \ldots w_{n-1}^v$ of length $n-1$ in G'. Since $c(u_i^v) = h_i$ for all $i = 1, 2, \ldots, m+1$, and $c(w_{n-1}^v) = h_n$ or h_{n-1}, this implies that $c(w_i^v) = h_{i+1}$ or h_i, for all $i = m, m+1, \ldots, n-1$. Thus we have $c(w_m^v) = h_{m+1}$ or h_m. Since w_1^v is at distance $m-1$ from w_m^v in G', it follows that $c(w_1^v) = h_t$, $1 \leq t \leq n$. We have that $c(w_1^v)$ and $c(w_1^{v'})$ must be adjacent in H. The only possible pair of values for t and s are n and $n+1$, respectively, for $c(w_1^v)$ to be adjacent to $c(w_1^{v'})$. Thus $c(w_1^v) = h_n$ and $c(w_1^{v'}) = h_{n+1}$, which implies that $h_n, h_{n+1} \in c(W)$ and we have a contradiction. Thus $c(w_{n-1}^{v'}) \neq h_{n+1}$, and hence $c(w_{n-1}^{v'}) = h_{n+2}$.

Now, $c(x_{vv'})$ must be adjacent to $c(u_{n-1}^v) = h_{n-1}$, $c(v) = h_n$, $c(v') = h_{n+1}$, and $c(w_{n-1}^{v'}) = h_{n+2}$, which is impossible. Hence $c(\{v, v'\}) \neq \{h_n, h_{n+1}\}$.

Thus we have that $\{h_n, h_{n+1}\} \subset c(W)$. Hence $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$ or $c(W) = \{h_n, h_{n+1}, h_{n+2}\}$. Without loss of generality, suppose that $c(W) = \{h_{n-1}, h_n, h_{n+1}\}$ (due to symmetry). Exactly, as for the case $k = 4m+3$, we prove that $c(h_{k-1}) = h_{k-1}$ and establish that $c(h_i) = h_i$ for all $i = 0, 1, 2, \ldots, k-1$, i.e., $c : G' \to H$ is a retraction. □

We have thus proved Theorem 3.1. □

4. Compaction to an irreflexive *k*-cycle. In this section, we shall assume that C_k denotes an irreflexive k-cycle.

It follows from [Hell and Nesetril, 1990] that *RET-*C_k and *COMP-*C_k are both NP-complete for all odd $k \geq 3$. It is easy to see that *RET-*C_4, and hence *COMP-*C_4, are both polynomial time solvable. In fact, when H is a chordal bipartite graph (which includes C_4), the problem *RET-H* is polynomial time solvable [Bandelt, Dahlmann, and Schutte, 1987], and hence *COMP-H* is also polynomial time solvable. Feder showed that *RET-*C_k is NP-complete for all even $k \geq 6$ (personal communication through Hell, cf. [Feder, Hell, and Huang, 1999]). This was also proved independently by G. MacGillivray in 1988 (personal communication). The transformation used by both is from the $k/2$-colorability problem.

Determining the complexity of *COMP-*C_k, for any particular even $k \geq 6$, has been of interest since a long time to various people including Hell and Nesetril (personal communications). We show that *COMP-*C_k is NP-complete for all even $k \geq 6$. To show this, we give a transformation from *RET-*C_k to *COMP-*C_k, using the technique described in section 1 where we restrict the input graph to be bipartite for all even $k \geq 6$. For proving NP-completeness of *COMP-*C_k, for all even $k \geq 6$, we provide two categories of construction depending on whether $k = 4m+2$ for some integer $m \geq 1$, or $k = 4m$ for some integer $m \geq 2$.

Acknowledgments. The author would like to thank Professor Dr. Pavol Hell for his suggestions on improving the style of presentation for the work.

The author obtained the results for the open problem as a result of a direct encouragement from his father Professor Dr. Sukhdeo Narayan Prasad. The author would like to thank his father for his thoughtful encouragement with a remarkable effect.

BACKWARD CONSISTENCY AND SENSE OF DIRECTION IN ADVANCED DISTRIBUTED SYSTEMS*

P. FLOCCHINI†, A. RONCATO‡, AND N. SANTORO§

Abstract. Studies on the relationship between label consistency, computability, and complexity assume the existence of *local orientation*; this assumption is in fact at the basis of the *point-to-point* model and is realistic for systems where a communication link can connect only two entities. However, in systems which use more advanced communication and interconnection technology, such as *buses*, *optical* networks, and *wireless* communication media, and more importantly, in heterogeneous systems (such as the *Internet*) which include any combination of the above, local orientation *cannot* be assumed. This implies that the entire established body of results on the relationship between label consistency (e.g., *sense of direction*) and computability and complexity does not hold for systems with advanced communication technology.

In this paper we consider a new type of consistency which we shall call *backward consistency* and which, unlike sense of direction, can exist even without local orientation. Thus, unlike all previous forms of consistency, it can be found (or designed) in advanced distributed systems.

We study backward consistency both in terms of its relationship with the traditional properties of local orientation and (weak) sense of direction, and with respect to symmetries of the edge labelings and of the naming functions. We show that backward consistency is computationally equivalent to sense of direction; in other words, it is possible to take advantage of the computational power of sense of direction even in the absence of local orientation.

Key words. distributed computing, sense of direction, global consistency

1. Introduction.

A distributed system is a collection of computational entities communicating by exchanging messages. Depending on how the communication is achieved, different models exist. In the *point-to-point* model, the communication topology of the system is viewed as an edge-labeled undirected graph $(G = (V, E), \lambda)$ where nodes correspond to the system entities, edges represent pairs of neighboring entities (i.e., entities which can communicate directly), each node $x \in V$ has a local label (usually called port number) $\lambda_x(\langle x, y\rangle)$ associated to each of its incident edges $\langle x, y\rangle$, and $\lambda = \{\lambda_x : x \in V\}$ is the set of labeling functions.

In studies on computing in distributed systems, recurring challenging questions arise concerning the relationships between *local views* and *global consistency*, and concerning their impact on distributed computability and communication complexity. In these studies, *locality* is at the entity level: the local view of an entity x consists of just the labeling λ_x of its communication ports (or communication links, incident edges) and, sometimes, of the naming β_x used to refer to the other entities. A major goal of this investigation is to derive under what properties of λ and/or β it is possible to

infer global properties about the entire system. A practical aim is to determine if and how these properties can be usefully employed, e.g., to yield more efficient distributed computations. Examples of these studies include *compact routing,* which focuses on determining under what conditions the local port numbering provides global routing information for given global naming schemes (see [25] for a recent survey), and *sense of direction,* which analyzes the impact on communication complexity of local port labelings and local naming schemes (see [21] for a recent survey).

In particular, there is a large body of evidence on the positive impact on complexity of the set of global consistency constraints satisfied by labelings with sense of direction (e.g., see [18, 19, 22, 30, 32, 33, 41]). Properties of sense of direction have been studied, for example, in [5, 8, 10, 11, 17, 20, 23, 24, 26, 42]. Several levels of sense of direction have been considered and investigated, with researchers trying to identify the "smallest" amount of consistency really needed (e.g., to efficiently solve a specific problem).

All studies in the relevant literature, with very few exceptions, make the basic (but often unstated) fundamental assumption that the entities are able to distinguish among their incident links, i.e., the labelings λ_x are injective functions. Even if the links haven't yet been assigned a label, it is assumed that an entity is capable of such an assignment (e.g., [15, 27, 31]). This assumption, usually called *local orientation*, is in fact at the basis of the *point-to-point* model and is realistic for systems where a communication link can connect only two entities.

If we are to model systems which use more advanced communication and interconnection technology, such as *buses*, *optical* networks, and *wireless* communication media, and more importantly, in heterogeneous systems (such as the *Internet*) which include any combination of the above, local orientation *cannot* be assumed. This is because any direct connection between k entities will correspond, at each of those entities, to $k-1$ edges with the same label; hence, if $k > 2$ (e.g., a bus), λ is not injective. That is, unless the system is point-to-point (i.e., each connection is between only two entities) there are nodes that cannot distinguish between some of their incident edges. This implies that the entire established body of results on the relationship between consistency, computability, and complexity does not hold and, thus, cannot be applied outside the point-to-point model. In other words, very little is known on this subject for systems with advanced communication technology. (A vast body of knowledge does indeed exist on these systems, but not on these topics.)

There are a few exceptions: the early work on computing in complete graphs with "ambiguous" labelings [26, 40], the more recent studies on computability in anonymous "wireless" networks [14, 37], and the results on leader election and function evaluation in anonymous networks with different types of "port awareness" [9, 45]. Note that "ambiguous," "wireless," and "port aware" all denote the (possible) absence of local orientation.

In this paper we consider a new type of consistency which we shall call *backward consistency*. Backward consistency is strongly related to the classical "forward" consistency implied by sense of direction; however, unlike sense of direction, it can exist even without local orientation. Thus, unlike all previous forms of consistency, backward consistency can be found (or designed) in advanced distributed systems.

In the following, we study backward consistency both in terms of its relationship with the traditional properties of local orientation and (weak) sense of direction, and with respect to symmetries of the edge labelings and of the naming functions. In particular, we focus on the conditions under which a labeling can have simultaneously forward and backward consistency.

We then consider the power of backward consistency and prove that *backward consistency is computationally equivalent to sense of direction.* In other words, it is possible to take advantage of the computational power of sense of direction even in the absence of local orientation. This counterintuitive result somehow extends and generalizes the results of [1, 14] on the insensitivity of ring networks to local orientation. In addition to the theoretical result, we also provide a simple effective procedure to efficiently map protocols exploiting sense of direction into ones using "backward sense of direction."

In the following we consider the undirected case (i.e., bidirectional communication capabilities); this is done only for simplicity of exposition, as all results extend to and hold in the directed case as well.

2. Basic definitions and properties.

2.1. Labelings and sense of direction. In this section we first recall the basic definitions of consistency, symmetry, and sense of direction in labeled graphs; most of the terminology follows [20].

Let $G = (V, E)$ be a simple connected undirected graph, and let $E(x)$ denote the set of edges incident to node $x \in V$. Given $G = (V, E)$ and a set Σ of labels, a *local labeling function* of $x \in V$ is any function $\lambda_x : E(x) \to \Sigma$ which associates a label $l \in \Sigma$ to each edge $e \in E(x)$. A set $\lambda = \{\lambda_x : x \in V\}$ of local labeling functions will be called a *labeling* of G, and by (G, λ) we shall denote the corresponding *(edge-)labeled graph.* If all functions in λ are injective, we say that λ is a *local orientation.* Note that local orientation is assumed in the point-to-point model and in almost all literature on informative labelings, including those on unlabeled networks (e.g., [15, 27, 31]). A labeling λ is *symmetric* if there exists a bijection $\psi : \Sigma \to \Sigma$ such that for each $\langle x, y\rangle \in E$, $\lambda_y(\langle y, x\rangle) = \psi(\lambda_x(\langle x, y\rangle))$; ψ will be called the edge-symmetry function.

A *walk* π in G is a sequence of edges in which the endpoint of one edge is the starting point of the next edge. Let $P[x]$ denote the set of all walks starting from $x \in V$, and let $P[x, y]$ denote the set of walks starting from $x \in V$ and ending in $y \in V$. Let $\Lambda_x : P[x] \to \Sigma^+$ and $\Lambda = \{\Lambda_x : x \in V\}$ denote the extension of λ_x and λ, respectively, from edges to walks; let $\Lambda[x] = \{\Lambda_x(\pi) : \pi \in P[x]\}$, and let $\Lambda[x, y] = \{\Lambda_x(\pi) : \pi \in P[x, y]\}$.

Given an edge-symmetry function ψ, we shall denote by $\Psi : \Sigma^+ \to \Sigma^+$ its extension to strings; i.e., for $\alpha = a_1 \cdot a_2 \cdot \ldots \cdot a_p \in \Sigma^+$, $\Psi(\alpha) = \psi(a_p) \cdot \ldots \cdot \psi(a_1)$, where $\cdot$ denotes the concatenation operator.

Informally, a labeled graph (G, λ) has *sense of direction* when it is possible to understand, from the labels associated to the edges, whether different walks from any given node x end in the same node or in different ones.

A *coding* function of (G, λ) is any function $\mathbf{c}$ with domain Σ^+. It is said to be *consistent* if the following holds $\forall x, y, z \in V$, $\forall \pi_1 \in P[x, y]$, $\pi_2 \in P[x, z]$: $\mathbf{c}(\Lambda_x(\pi_1)) = \mathbf{c}(\Lambda_x(\pi_2))$ iff $y = z$. In other words, the labelings of the walks *originating* from the same node are mapped to the same value iff they end in the same node. Thus, we can define a consistent coding if the following holds $\forall x, y, z \in V$, $\forall \alpha \in \Lambda[x, y]$, $\beta \in \Lambda[x, z]$: $\mathbf{c}(\alpha) = \mathbf{c}(\beta)$ iff $y = z$. We shall denote by $\mathcal{N}(\mathbf{c})$ the codomain of $\mathbf{c}$.

DEFINITION 1 (weak sense of direction). *A labeled graph (G, λ) has* weak sense of direction $\mathbf{c}$ *iff* $\mathbf{c}$ *is a consistent coding function of (G, λ). Alternatively, we shall say that* $\mathbf{c}$ *is a weak sense of direction in (G, λ).*

We see immediately that consistency requires local orientation, as follows.

LEMMA 1. *Let (G, λ) have weak sense of direction* $\mathbf{c}$*. Then λ has local orientation.*

Proof. By contradiction, let there exist two distinct neighbors y, z of a node $x \in V$ such that $\lambda_x(\langle x, y\rangle) = \lambda_x(\langle x, z\rangle)$; thus, $\mathbf{c}(\lambda_x(\langle x, y\rangle)) = \mathbf{c}(\lambda_x(\langle x, z\rangle))$. On the other hand, by definition of the consistent coding function, $\mathbf{c}(\lambda_x(\langle x, y\rangle)) \neq \mathbf{c}(\lambda_x(\langle x, z\rangle))$, which leads to the contradiction. □

Given a coding function $\mathbf{c}$, a *decoding function* $\mathbf{d}$ for $\mathbf{c}$ is any function $\mathbf{d} : \Sigma \times \mathcal{N}(\mathbf{c}) \to \mathcal{N}(\mathbf{c})$ such that $\forall \langle x, y\rangle \in E(x)$, $\pi \in P[y, z]$: $\mathbf{d}(\lambda_x(\langle x, y\rangle), \mathbf{c}(\Lambda_y(\pi))) = \mathbf{c}(\lambda_x(\langle x, y\rangle) \cdot \Lambda_y(\pi))$, where $\cdot$ is the concatenation operator. Or alternatively, $\forall a \cdot w \in \Lambda[x, z]$, $a \in \Sigma$: $\mathbf{d}(a, \mathbf{c}(w)) = \mathbf{c}(a \cdot w)$.

DEFINITION 2 (sense of direction). *A labeled graph* (G, λ) *has* sense of direction $(\mathbf{c}, \mathbf{d})$ *iff* $\mathbf{c}$ *is a weak sense of direction and* $\mathbf{d}$ *is a decoding function for* $\mathbf{c}$. *Alternatively, we shall say that* $(\mathbf{c}, \mathbf{d})$ *is a sense of direction in* (G, λ).

Let $\mathcal{L}$, $\mathcal{W}$, and $\mathcal{D}$ denote the set of labeled graphs (G, λ) with local orientation, weak sense of direction, and sense of direction, respectively. The following relationship holds.

LEMMA 2 (see [11, 20]). $\mathcal{D} \subset \mathcal{W} \subset \mathcal{L}$.

The proof follows from the fact that local orientation is necessary but (obviously) not sufficient for consistency [20], and the fact that there exist labeled graphs with weak sense of direction but without sense of direction [11].

2.2. Backward consistency and sense of direction. In this section we introduce the notion of backward consistency.

DEFINITION 3. *A coding function* $\mathbf{c}$ *of* (G, λ) *is* backward consistent *if the following holds* $\forall x, y, z \in V$, $\forall \pi_1 \in P[x, z]$, $\pi_2 \in P[y, z]$: $\mathbf{c}(\Lambda_x(\pi_1)) = \mathbf{c}(\Lambda_y(\pi_2)) \Leftrightarrow x = y$.

In other words, sequences of labels of walks *terminating* in the same node are mapped to the same value iff they start from the same node.

Note that the difference between the consistency just defined and the traditional one is of "viewpoint." In the latter, the focus is *forward*, on the sequence of labels on walks leaving from a given node; in the former the focus is *backward,* on the sequences of labels on walks which terminate at a given node.

DEFINITION 4 (weak backward sense of direction). *A system* (G, λ) *has* weak backward sense of direction $\mathbf{c}$ *iff* $\mathbf{c}$ *is a backward consistent coding function. Alternatively, we shall say that* $\mathbf{c}$ *is a weak backward sense of direction in* (G, λ).

Given a coding function $\mathbf{c}$, a *backward decoding function* $\mathbf{b}$ for $\mathbf{c}$ is any function $\mathbf{b} : \mathcal{N}(\mathbf{c}) \times \Sigma \to \mathcal{N}(\mathbf{c})$ such that $\forall \pi \in P[x, y]$, $\mathbf{d}(\mathrm{a}, \mathbf{c}(\mathrm{w})) = \mathbf{c}(\mathrm{aw})$ $\langle y, z\rangle \in E(y)$, $\mathbf{b}(\mathbf{c}(\Lambda_x(\pi)), \lambda_y(\langle y, z\rangle)) = \mathbf{c}(\Lambda_x(\pi) \cdot \lambda_y(\langle y, z\rangle))$, where $\cdot$ is the concatenation operator. (Recall that $\mathcal{N}(\mathbf{c})$ denotes the codomain of $\mathbf{c}$.) We can now define backward sense of direction.

DEFINITION 5 (backward sense of direction). *A system* (G, λ) *has* backward sense of direction $(\mathbf{c}, \mathbf{b})$ *iff* $\mathbf{c}$ *is a weak backward sense of direction and* $\mathbf{b}$ *is a backward decoding function for* $\mathbf{c}$. *Alternatively, we shall say that* $(\mathbf{c}, \mathbf{b})$ *is a backward sense of direction in* (G, λ).

We shall denote by $\mathcal{W}^-$ and $\mathcal{D}^-$ the set of labeled graphs (G, λ) with backward weak sense of direction and backward sense of direction, respectively. In the following, when no ambiguity arises, we shall omit the reference to (G, λ).

3. Backward consistency.

3.1. Absence of local orientation. The first basic difference between forward and backward consistency is striking: Local orientation is *not* implied by the definition of backward sense of direction.

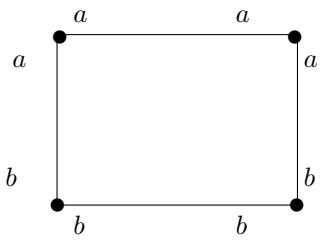

FIG. 1. $(\mathcal{D}^- - \mathcal{L}) \neq \emptyset$.

THEOREM 1 ($\mathcal{D}^- \not\subset \mathcal{L}$, $\mathcal{L} \not\subset \mathcal{D}^-$). *Local orientation is neither necessary nor sufficient for backward sense of direction.*

Proof. Consider the labeled graph (G, λ) of Figure 1. It is easy to verify that there exist both consistent backward coding and decoding functions in (G, λ). However, there is no local orientation. The fact that it is not sufficient is obvious (see, for example, the graph of Figure 4, which has local orientation but not backward sense of direction). □

Thus, in a system with backward sense of direction, nodes might not be able to distinguish among some of their incident edges. As the example in Figure 1 shows, in a system with backward sense of direction, this "blindness" can even be *complete* (i.e., it extends to all incident edges of a node) and, in the extreme case, *total* (i.e., it occurs at every node).

This phenomenon is not restricted to a few special graphs. On the contrary, *every* graph G can be labeled so as to have complete and total blindness and still have backward sense of direction.

THEOREM 2. *For any graph G there exists a labeling λ such that $\forall x \in V$, $\forall \langle x, y\rangle, \langle x, z\rangle \in E(x)$, $\lambda_x(\langle x, y\rangle) = \lambda_x(\langle x, z\rangle)$, but (G, λ) has backward sense of direction.*

Proof. Consider the labeling λ defined as follows: $\forall \langle x, y\rangle, \langle w, z\rangle \in E$, $\lambda_x(\langle x, y\rangle) = \lambda_w(\langle w, z\rangle)$ iff $x = w$ (see Figure 2). With this labeling, all the links starting from the same node x are labeled with the same label (hence, there is total and complete blindness). It is not difficult to show that the coding function $\mathbf{c}$ defined as $\mathbf{c}(a \cdot \alpha) = a$ $\forall\ a \in \Sigma, \alpha \in \Sigma^+$ is backward consistent and that the function $\mathbf{b}(\mathbf{c}(\alpha), a) = \mathbf{c}(\alpha)$ is a backward decoding for $\mathbf{c}$; hence, (G, λ) has backward sense of direction. □

Note that this is *not* the labeling used in Figure 1.

3.2. Backward local orientation. Systems with backward consistency may be without local orientation; however, they do have a property which is the "backward" analogue of local orientation. A labeling λ is a *backward local orientation* if the following holds $\forall z, \langle x, z\rangle, \langle y, z\rangle \in E(z)$: $\lambda_x(\langle x, z\rangle) \neq \lambda_y(\langle y, z\rangle)$. Let $\mathcal{L}^-$ denote the set of labeled graphs (G, λ) with backward local orientation.

First observe that backward local orientation is (obviously) *not sufficient* for backward consistency.

THEOREM 3 ($(\mathcal{L}^- - \mathcal{W}^-) \neq \emptyset$, $(\mathcal{L}^- - \mathcal{W}^-) - \mathcal{L} \neq \emptyset$). *Backward local orientation does not suffice for (either) backward consistency (or local orientation).*

Proof. Consider the labeled graph of Figure 3. Such a graph clearly has backward local orientation. By contradiction, let us assume that it has backward weak sense of direction. By definition of backward coding function we would have that, from node

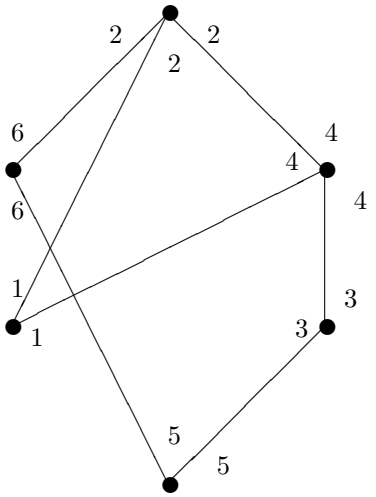

FIG. 2. *Total blindness.*

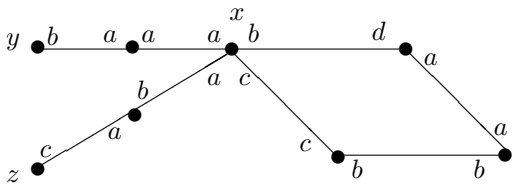

FIG. 3. $(\mathcal{L}^- - \mathcal{W}^-) - \mathcal{L} \neq \emptyset$.

x, $\mathbf{c}(b \cdot a) = \mathbf{c}(c \cdot b)$. However the labels $b \cdot a$ correspond to a path in $P[y, x]$ and $c \cdot b$ to a path in $P[z, x]$; thus, by definition of backward consistency, we must have the following: $\mathbf{c}(b \cdot a) \neq \mathbf{c}(c \cdot b)$. Since this graph does not have local orientation, this actually proves that $(\mathcal{L}^- - \mathcal{W}^-) - \mathcal{L} \neq \emptyset$. □

However, in a system with weak backward sense of direction, there is always backward local orientation.

THEOREM 4 ($\mathcal{W}^- \subset \mathcal{L}^-$). *If (G, λ) has weak backward sense of direction, then λ has backward local orientation.*

Proof. Let (G, λ) be a labeled graph without backward local orientation and with backward consistency. Then there exist two edges $\langle x, z\rangle$ and $\langle y, z\rangle$ such that $\lambda_x(\langle x, z\rangle) = \lambda_y(\langle y, z\rangle)$. But this contradicts the existence of a backward coding function $\mathbf{c}$, as by definition $\mathbf{c}(\lambda_x(\langle x, z\rangle)) = \mathbf{c}(\lambda_y(\langle y, z\rangle))$. □

Summarizing, (backward) local orientation is necessary but not sufficient for (backward) consistency. Thus, $\mathcal{W}^- \subset \mathcal{L}^-$.

Two questions naturally arise: Is the simultaneous presence of both local orientation and backward local orientation sufficient for consistency? Is it sufficient for backward consistency? The answer to these questions is negative, as we prove the stronger result that there exist labeled graphs having both forms of local orientation but without either form of consistency.

THEOREM 5 ($(\mathcal{L} \cap \mathcal{L}^-) - (\mathcal{W} \cup \mathcal{W}^-) \neq \emptyset$). *The simultaneous presence of local ori-*

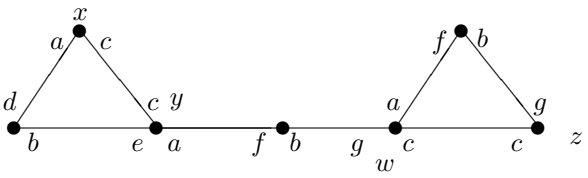

FIG. 4. $(\mathcal{L} \cap \mathcal{L}^-) - (\mathcal{W} \cup \mathcal{W}^-) \neq \emptyset$.

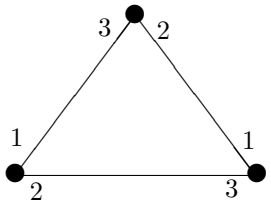

FIG. 5. $\mathcal{D} - \mathcal{L}^- \neq \emptyset$.

entation and backward local orientation does not imply either weak sense of direction or backward weak sense of direction.

Proof. Consider the labeled graph (G, λ) shown in Figure 4. The labeling clearly has both local orientation and backward local orientation. By contradiction, assume (G, λ) has weak sense of direction $\mathbf{c}$. By definition of consistent coding, at node x it must be $\mathbf{c}(a \cdot b) = \mathbf{c}(c)$; however, at node y it must be $\mathbf{c}(a \cdot b) \neq \mathbf{c}(c)$, yielding a contradiction. Assume now, again by contradiction, that (G, λ) has backward weak sense of direction $\mathbf{c}$. By definition of backward consistent coding, at node z it must be $\mathbf{c}(a \cdot b) = \mathbf{c}(c)$; however, at node w it must be $\mathbf{c}(a \cdot b) \neq \mathbf{c}(c)$, which is a contradiction. □

3.3. Orthogonality. In this section we will show that the concept of backward consistency is *orthogonal* to that of sense of direction; in particular, even the presence of sense of direction is not sufficient to guarantee the existence of a backward consistency.

THEOREM 6 ($\mathcal{D} \not\subset \mathcal{L}^-$, $\mathcal{L}^- \not\subset \mathcal{D}$). *Sense of direction is neither necessary nor sufficient for the existence of backward local orientation.*

Proof. Consider any graph with more than two nodes labeled with a *neighboring* labeling (e.g., see Figure 5); all such labeled graphs have sense of direction [20]: the coding function $\mathbf{c}$ is $\mathbf{c}(\alpha \cdot a) = a \ \forall a \in \Sigma, \alpha \in \Sigma^+$, and the decoding function is $\mathbf{d}(a, \mathbf{c}(\alpha)) = \mathbf{c}(\alpha)$. On the other hand, (G, λ) does not have backward local orientation. In other words, sense of direction is not sufficient for the existence of backward local orientation. The fact that it is also not necessary follows from Theorem 5. □

In other words, sense of direction cannot guarantee backward consistency because it cannot even guarantee backward local orientation. What if there is backward local orientation in addition to sense of direction? The answer is still negative, as shown in the following theorem.

THEOREM 7 ($(\mathcal{D} \cap \mathcal{L}^-) \not\subset \mathcal{W}^-$, $(\mathcal{D} \cap \mathcal{L}^-) \not\supset \mathcal{W}^-$). *Simultaneous presence of sense of direction and backward local orientation is neither necessary nor sufficient for the existence of a backward consistent coding function.*

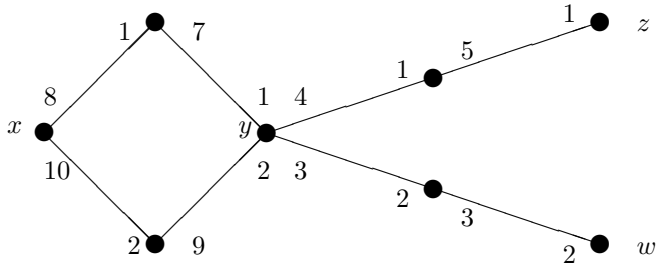

FIG. 6. $(\mathcal{D} \cap \mathcal{L}^-) \not\supset \mathcal{W}^-$.

Proof. $\not\subset$. To prove that it is not sufficient, consider the labeled graph (G, λ) of Figure 6. It is easy to verify that there exist both a consistent coding function and decoding function in (G, λ). By contradiction, assume that there exists a backward consistent coding function $\mathbf{c}$ in (G, λ). Then, by definition of backward consistency at node x we have that $\mathbf{c}(1 \cdot 1) = \mathbf{c}(2 \cdot 2)$. However, the sequence of labels $1 \cdot 1$ corresponds to a path in $P[z, y]$ and the sequence $2 \cdot 2$ to a path in $P[w, y]$; thus, by definition of backward consistency, $\mathbf{c}(1 \cdot 1) \neq \mathbf{c}(2 \cdot 2)$, yielding the contradiction.

$\not\supset$. Now we will prove that it is not necessary. By Theorem 4, backward consistency implies backward local orientation. However, from Theorem 6, it follows that backward consistency does not imply local orientation and, thus, does not imply sense of direction. This means that the simultaneous presence of sense of direction and backward local orientation is not necessary for backward consistency. □

The results of this section indicate that the presence of some additional property is necessary for one type of consistency to imply the other. We will show in the next section that *edge-symmetry* is one such property.

4. Symmetry and backward consistency. The results of the previous section indicate that the presence of some additional property is necessary for one type of consistency to imply the other. We will show that *edge-symmetry* is one such property.

Recall that a labeling λ is *symmetric* if there exists a bijection $\psi : \Sigma \to \Sigma$ such that for each $\langle x, y \rangle \in E$, $\lambda_y(\langle y, x \rangle) = \psi(\lambda_x(\langle x, y \rangle))$; ψ will be called the edge-symmetry function, and $\Psi : \Sigma^+ \to \Sigma^+$ is its extension to strings. Let $\mathcal{ES}$ denote the set of labeled graphs (G, λ) with λ symmetric.

Notice that all common labelings (e.g., "dimensional" in hypercubes, "compass" in meshes and tori, "left-right" in rings, "distance" in chordal rings, etc.) are symmetric.

4.1. Edge-symmetry and backward consistency. We will show that, while generally not true (as shown by Theorem 1), in systems with edge-symmetry, local orientation is necessary for backward consistency. In fact, we shall show that in systems with edge-symmetry, $\mathcal{L} = \mathcal{L}^-$.

THEOREM 8 ($\mathcal{ES} \cap \mathcal{L} = \mathcal{ES} \cap \mathcal{L}^-$). *Let (G, λ) be a system with edge-symmetry; then there is local orientation iff there is backward local orientation.*

Proof. Let (G, λ) be a system with edge-symmetry. $\subset$. By contradiction, suppose there is local orientation but no backward local orientation. Then there must exist two distinct edges $\langle x, z \rangle$, $\langle y, z \rangle$ such that $\lambda_x(\langle x, z \rangle) = \lambda_y(\langle y, z \rangle)$. However, by local orientation, we have that $\lambda_z(\langle z, x \rangle) \neq \lambda_z(\langle z, y \rangle)$, which contradicts the fact that there is edge-symmetry.

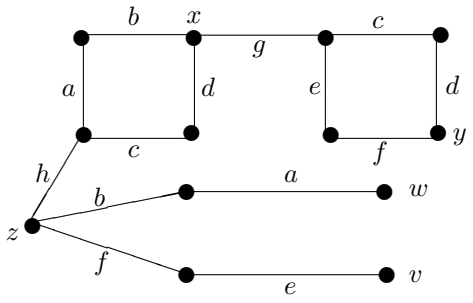

FIG. 7. $\mathcal{ES} \cap \mathcal{L} \cap \mathcal{L}^- \not\subset \mathcal{W}^-$.

$\supset$. By contradiction, suppose now that there is backward local orientation but no local orientation. Then there must exist two distinct edges $\langle x, y\rangle$, $\langle x, z\rangle$ such that $\lambda_x(\langle x, y\rangle) = \lambda_x(\langle x, z\rangle)$. However, by backward local orientation we must have $\lambda_y(\langle y, x\rangle) \neq \lambda_z(\langle z, y\rangle)$, contradicting edge-symmetry of the labeling. □

Thus, a system with edge-symmetry has either both types of local orientation or none; still, presence of both types and edge-symmetry are not sufficient for backward consistency.

THEOREM 9 ($\mathcal{ES} \cap \mathcal{L} \cap \mathcal{L}^- \not\subset \mathcal{W}^-$). *The simultaneous presence of local orientation and edge-symmetry is not sufficient for the existence of backward consistency.*

Proof. Consider the labeled graph of Figure 7. The labeling is a coloring, i.e., the edge-symmetry function is the identity function; moreover, it is a local orientation. By contradiction, assume that there exists a backward consistent coding function $\mathbf{c}$. By definition of backward consistency, at node x we have that $\mathbf{c}(a \cdot b) = \mathbf{c}(c \cdot d)$ and at node y, that $\mathbf{c}(c \cdot d) = \mathbf{c}(e \cdot f)$, which implies $\mathbf{c}(a \cdot b) = \mathbf{c}(e \cdot f)$. However, the sequence of labels $b \cdot a$ corresponds to a path in $P[w, z]$, and $f \cdot e$ corresponds to a path in $P[v, z]$; thus we have that $\mathbf{c}(a \cdot b) \neq \mathbf{c}(e \cdot f)$, which is a contradiction. □

We will now show that edge-symmetry in a system with (weak) sense of direction suffices for the system to have (weak) backward sense of direction.

LEMMA 3 (see [20]). $\forall \pi \in P[x, y]$, $\Lambda_x(\pi) = \Psi(\Lambda_y(\pi^R))$, *where* $\pi^R \in P[y, x]$ *is the reverse of walk* π.

THEOREM 10 ($\mathcal{ES} \cap \mathcal{W} \subset \mathcal{W}^-$, $\mathcal{ES} \cap \mathcal{D} \subset \mathcal{D}^-$). *Let* (G, λ) *be a system with edge-symmetry. If* (G, λ) *has weak sense of direction* $\mathbf{c}$*, then there exists a weak backward sense of direction* $\mathbf{c}_b$*. Furthermore, if* $\mathbf{c}$ *has a consistent decoding, there exists a consistent backward decoding of* $\mathbf{c}_b$*.*

Proof. Let (G, λ) have edge-symmetry and weak sense of direction $\mathbf{c}$. Let $\mathbf{c}_b$ be the coding function defined as follows: $\forall \pi \in P[x]$, $\mathbf{c}_b(\alpha) = \mathbf{c}(\Psi(\alpha))$, where $\alpha = \Lambda_x(\pi)$. We will now show that $\mathbf{c}_b$ is backward consistent.

Let $\pi_1 \in P[x, z]$, $\pi_2 \in P[y, z]$, $\alpha_1 = \Lambda_x(\pi_1)$, and $\alpha_2 = \Lambda_y(\pi_2)$. By Lemma 3, we have that $\alpha_1 = \Psi(\Lambda_z(\pi_1^R))$ and $\alpha_2 = \Psi(\Lambda_z(\pi_2^R))$. By definition of the consistent coding function, we have that $\mathbf{c}(\Psi(\Lambda_z(\pi_1^R))) = \mathbf{c}(\Psi(\Lambda_z(\pi_2^R)))$ iff $x = y$. By definition of $\mathbf{c}_b$, it follows that $\mathbf{c}_b(\Lambda_x(\pi_1)) = \mathbf{c}_b(\Lambda_y(\pi_2))$ iff $y = z$; that is, $\mathbf{c}_b$ is backward consistent.

Now let (G, λ) have edge-symmetry and sense of direction $(\mathbf{c}, \mathbf{d})$. Let $\mathbf{b}$ be the function defined as follows: $\forall \pi \in P[x, y]$, $\langle y, z\rangle \in E(y)$, $\mathbf{b}(\mathbf{c}_b(\alpha), \lambda_y(\langle y, z\rangle)) = \mathbf{d}(\psi(\lambda_y(\langle y, z\rangle)), \mathbf{c}_b(\alpha))$, where $\alpha = \Lambda_x(\pi)$. We will now show that $\mathbf{b}$ is a backward

FIG. 8. $\mathcal{W} \cap \mathcal{W}^- \not\subset \mathcal{ES}$.

FIG. 9. *Proof of Theorem* 13.

decoding. By definition of $\mathbf{c}_b$ we have that $\mathbf{d}(\psi(\lambda_y(\langle y,z\rangle)), \mathbf{c}_b(\alpha)) = \mathbf{d}(\psi(\lambda_y(\langle y,z\rangle)), \mathbf{c}(\Psi(\alpha)))$. By definition of the decoding function we have that $\mathbf{d}(\psi(\lambda_y(\langle y,z\rangle)), \mathbf{c}(\Psi(\alpha))) = \mathbf{c}(\psi(\lambda_y(\langle y,z\rangle))\cdot\Psi(\alpha))$. But, by definition of $\mathbf{c}$, we have that $\mathbf{c}(\psi(\lambda_y(\langle y,z\rangle))\cdot\Psi(\alpha)) = \mathbf{c}_b(\alpha\cdot\lambda_y(\langle y,z\rangle))$. Thus, it follows that $\mathbf{b}(\mathbf{c}_b(\alpha), \lambda_y(\langle y,z\rangle)) = \mathbf{c}_b(\alpha\cdot\lambda_y(\langle y,z\rangle))$, proving that $\mathbf{b}$ is a backward decoding of $\mathbf{c}_b$. □

Conversely, edge-symmetry in a system with (weak) backward sense of direction suffices for the system to have (weak) sense of direction.

THEOREM 11 ($(\mathcal{ES} \cap \mathcal{W}^-) \subset \mathcal{W}$, $(\mathcal{ES} \cap \mathcal{D}^-) \subset \mathcal{D}$). *Let (G,λ) be a system with edge-symmetry. If (G,λ) has weak backward sense of direction $\mathbf{c}_b$, then there exists a weak sense of direction $\mathbf{c}$. Furthermore, if $\mathbf{c}_b$ has a consistent backward decoding, there exists a consistent decoding of $\mathbf{c}$.*

From Theorems 10 and 11, it follows that systems with edge-symmetry have either both types of consistency or none. In other words, in systems with edge-symmetry, $\mathcal{W} = \mathcal{W}^-$ and $\mathcal{D} = \mathcal{D}^-$.

An immediate question is whether systems with edge-symmetry are the only ones with such a property.

THEOREM 12 ($\mathcal{W} \cap \mathcal{W}^- \not\subset \mathcal{ES}$). *Edge-symmetry is not necessary for a system to have both forward and backward consistency.*

Proof. Consider the graph of Figure 8. This graph does not have edge-symmetry; however, it is easy to verify that there exist both a forward consistent coding function $\mathbf{c}$, and a backward consistent coding function $\mathbf{c}_b$. □

4.2. Edge-symmetry and biconsistency. In the previous section we have seen that all systems with edge-symmetry have either both types of consistency or neither. For those that do have them, the corresponding coding functions are in general different.

The question we ask now is under what circumstances a single coding function suffices, that is, when a coding function is both forward and backward consistent. We shall call any such function *biconsistent*. Let $\mathcal{W}^{\pm}$ and $\mathcal{D}^{\pm}$ denote the set of labeled graphs (G,λ) with biconsistent weak sense of direction and biconsistent sense of direction, respectively. The first result is the following.

THEOREM 13. *Edge-symmetry is not sufficient for a (backward) consistent coding function to be biconsistent.*

Proof. Consider the labeled graph in Figure 9. This labeling has local orientation. Consider any coding function such that $\mathbf{c}(1) = \mathbf{c}(3)$, $\mathbf{c}(2) \neq \mathbf{c}(4)$, $\mathbf{c}(1,2) = \mathbf{c}(1432)$, $\mathbf{c}(3,4) = \mathbf{c}(3214)$, $\mathbf{c}(2,1) = \mathbf{c}(43)$, and $\forall \alpha,\beta \in \{1,2,3,4\}^*$, $\mathbf{c}(\alpha 12\beta) = \mathbf{c}(\alpha 21\beta) = \mathbf{c}(\alpha 34\beta) = \mathbf{c}(\alpha 43\beta) = \mathbf{c}(\alpha\beta)$.

It is easy to verify that such a coding function is consistent. However, $\mathbf{c}$ is not biconsistent. In fact, $\mathbf{c}(1) = \mathbf{c}(3)$, which violates the backward consistency in y. □

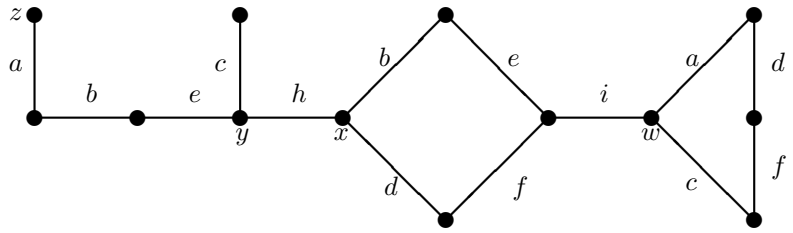

FIG. 10. $\mathcal{ES} \cap \mathcal{D}^- \not\subset \mathcal{ES} \cap \mathcal{D}$.

Even if not all the coding functions in a symmetric labeling are biconsistent, there exists at least one biconsistent coding function.

THEOREM 14 ($\mathcal{ES} \cap \mathcal{W} = \mathcal{ES} \cap \mathcal{W}^- = \mathcal{ES} \cap \mathcal{W}^{\pm}$). *In a system (G, λ) with edge-symmetry and (backward) weak sense of direction there exists also a biconsistent weak sense of direction.*

Proof. Let $\overline{\mathbf{c}}$ be a weak sense of direction in (G, λ) with edge-symmetry; we will show how to construct a weak sense of direction $\mathbf{c}$ which is biconsistent. We define the equivalence relation R between strings on the labeling alphabet in the following way: $\forall \alpha, \beta \in \Sigma^+ : \alpha R \beta \Leftrightarrow \exists x, y \in V, \pi_1, \pi_2 \in P[x, y] : \Lambda_x(\pi_1) = \alpha \wedge \Lambda_x(\pi_2) = \beta$. Let R^+ be the transitive closure of R. Let $c(\alpha) = [\alpha]_{R^+}$ (i.e., the equivalence class of the string α of the equivalence R^+).

CLAIM 1.

(i) *For all weak sense of direction* $\mathbf{c}', \alpha, \beta \in \Sigma^+ : \mathbf{c}(\alpha) = \mathbf{c}(\beta) \Rightarrow \mathbf{c}'(\alpha) = \mathbf{c}'(\beta)$.

(ii) $\forall \alpha, \beta : \mathbf{c}(\alpha) = \mathbf{c}(\beta) \Leftrightarrow \mathbf{c}(\psi(\alpha)) = \mathbf{c}(\psi(\beta))$.

(iii) $[\psi(\alpha)]_{R^+} = \psi([\alpha]_{R^+})$.

We now prove that $\mathbf{c}$ is a consistent coding function. Let $x, y, z \in V, \pi_1 \in P[x, y] \pi_2 \in P[x, z] : \Lambda_x(\pi_1) = \alpha \wedge \Lambda_x(\pi_2) = \beta$; then we have to prove that $\mathbf{c}(\alpha) = \mathbf{c}(\beta)$ iff $y = z$. By Claim 1(i), $\mathbf{c}(\alpha) = \mathbf{c}(\beta)$ implies $\overline{\mathbf{c}}(\alpha) = \overline{\mathbf{c}}(\beta)$, and by consistence of $\overline{\mathbf{c}}$ it follows that $y = z$. If $y = z$, then by definition of R it holds that $\alpha R \beta$, and then $[\alpha]_{R^+} = [\beta]_{R^+}$, that is, $\mathbf{c}(\alpha) = \mathbf{c}(\beta)$.

We now prove that $\mathbf{c}$ is a backward consistent coding function. By contradiction suppose that $\mathbf{c}$ is not consistent. Then there exists x, y, z and $\pi_1 \in P[x, z], \pi_2 \in P[y, z]$ for which $\mathbf{c}(\Lambda_x(\pi_1)) = \mathbf{c}(\Lambda(\pi_2)) \Leftrightarrow x = y$ is false. By Claim 1(i), this implies that there exists $x, y, z, \pi_1' \in P[z, x], \pi_2' \in P[z, y] : \Lambda_z(\pi_1') = \psi(\alpha)$, $\Lambda_z(\pi_2') = \psi(\beta)$, and $\mathbf{c}(\psi(\alpha)) = \mathbf{c}(\psi(\beta)) \Leftrightarrow x = y$ is false, contradicting the forward consistency of $\mathbf{c}$. □

The presence of biconsistency guaranteed by the above theorem is automatically true only for weak sense of direction. This property, unfortunately, does not extend to sense of direction, as the following theorem shows.

THEOREM 15 ($\mathcal{ES} \cap \mathcal{D} \not\subset \mathcal{W}^{\pm}$). *Sense of direction in a system with edge-symmetry is not sufficient for the existence of a biconsistent coding function.*

Proof. Consider the labeled graph of Figure 10. It is easy to verify that there exists a sense of direction for such a system. Let $(\mathbf{c}, \mathbf{d})$ be a sense of direction and suppose, by contradiction, that $\mathbf{c}$ is backward consistent.

By definition of the coding function at node x we have that $\mathbf{c}(df) = \mathbf{c}(be)$; it follows that $\mathbf{d}(a, \mathbf{c}(be)) = \mathbf{d}(a, \mathbf{c}(df)) = \mathbf{c}(c)$, which means that $\mathbf{c}(abe) = \mathbf{c}(c)$, contradicting the hypothesis of backward consistency at node y. □

As a consequence of the previous theorem we have that sense of direction in a system with edge-symmetry is not sufficient for the existence of a backward sense of direction (i.e., $\mathcal{ES} \cap \mathcal{D} \not\subset \mathcal{W}^{\pm}$).

Now we will study a sufficient property of a consistent function to be biconsistent. A weak sense of direction $\mathbf{c}$ has *name-symmetry* iff there exists a function $\mu : \mathcal{N}(\mathbf{c}) \to \mathcal{N}(\mathbf{c})$ such that $\forall \pi \in P[x,y]$, $\mu(\mathbf{c}(\Lambda_x(\pi))) = \mathbf{c}(\Lambda_y(\pi^R))$. A useful property is the following [22] lemma.

LEMMA 4 (see [22]). *Let λ be a symmetric labeling and let ψ be the corresponding function. A consistent coding function $\mathbf{c}$ has name-symmetry iff $\forall \pi_1 \in P[s,t], \pi_2 \in P[w,z]$, $\mathbf{c}(\Lambda_s(\pi_1)) = \mathbf{c}(\Lambda_w(\pi_2)) \Rightarrow \mathbf{c}(\Psi(\Lambda_s(\pi_1))) = \mathbf{c}(\Psi(\Lambda_w(\pi_2)))$.*

THEOREM 16. *In a system (G,λ) with edge-symmetry, any weak sense of direction with name-symmetry is also weak backward sense of direction.*

Proof. Let $\mathbf{c}$ be a weak sense of direction in (G,λ) with edge- and name-symmetry, and let ψ be the edge-symmetry function. By contradiction, suppose that c is not a consistent backward coding function; that is, suppose $\exists x,y,z$, $\pi_1 \in P[x,z]$, $\pi_2 \in P[y,z]$ with $x \neq y$ such that $\mathbf{c}(\Lambda_x(\pi_1)) = \mathbf{c}(\Lambda_y(\pi_2))$. Since there is name-symmetry, by Lemma 4, we have that $\mathbf{c}(\Psi(\Lambda_x(\pi_1))) = \mathbf{c}(\Psi(\Lambda_y(\pi_2)))$. But $\Lambda_z(\overline{\pi}_1) = \Psi(\Lambda_x(\pi_1))$, $\Lambda_z(\overline{\pi}_2) = \Psi(\Lambda_y(\pi_2))$ and $\overline{\pi}_1 \in P[z,x]$, $\overline{\pi}_2 \in P[z,y]$, which contradicts the consistency of $\mathbf{c}$ in z. □

In other words, in systems with edge-symmetry, any consistent coding function with name-symmetry is also backward consistent. We will now show that if any such coding function is decodable, then it is also backward decodable; that is, if there is sense of direction, there is also backward sense of direction with exactly the same coding function.

LEMMA 5. *Let $\mathbf{c}$ be a coding function with name-symmetry, and let μ be the name-symmetry function. For any $\alpha \in \Sigma^+$ corresponding to a path, $\mu(\mu(\mathbf{c}(\alpha))) = \mathbf{c}(\alpha)$.*

Proof. By definition of the name-symmetry function, we have $\mu(\mu(\mathbf{c}(\alpha))) = \mu(\mathbf{c}(\Psi(\alpha))) = \mathbf{c}(\Psi(\Psi(\alpha))) = \mathbf{c}(\alpha)$. □

THEOREM 17. *Let $(\mathbf{c},\mathbf{d})$ be a sense of direction in a system (G,λ) with edge- and name-symmetry. Then there exists a backward decoding $\mathbf{b}$ of $\mathbf{c}$; that is, $(\mathbf{c},\mathbf{b})$ is a backward sense of direction in (G,λ).*

Proof. Let ψ and μ be, respectively, the edge- and name-symmetry functions. Let $x,y \in V$, $\pi \in P[x,y]$, and $\omega = \Lambda_x(\pi)$. By definition of the name-symmetry function we have that $\mathbf{c}(\Psi(\omega)) = \mu(\mathbf{c}(\omega))$; it follows that $\mu(\mathbf{c}(\Psi(\omega))) = \mu(\mu(\mathbf{c}(\omega)))$. By Lemma 5, we have that

$$\mu(\mathbf{c}(\Psi(\omega))) = \mathbf{c}(\omega). \tag{4.1}$$

Consider now the following backward decoding function: $\forall \pi \in P[x,y]$, $\omega = \Lambda_x(\pi)$ and for $\langle y,z\rangle \in E(y) \wedge \lambda_y(\langle y,z\rangle) = a$, $\mathbf{b}(\mathbf{c}(\omega),a) = \mu(\mathbf{d}(\psi(a),\mu(\mathbf{c}(\omega))))$.

By definition of the name-symmetry function, it follows that $\mu(\mathbf{d}(\psi(a),\mu(\mathbf{c}(\omega)))) = \mu(\mathbf{d}(\psi(a),\mathbf{c}(\Psi(\omega)))) = \mu(\mathbf{c}(\Psi(w \cdot a)))$.

By (4.1), $\mu(\mathbf{c}(\Psi(w \cdot a))) = \mathbf{c}(\omega \cdot a)$. It follows that $\mathbf{b}(\mathbf{c}(\omega),a) = \mathbf{c}(\omega \cdot a)$, and thus $\mathbf{b}$ is consistent. □

5. Consistency landscape. The results of the previous sections can be seen, and have sometimes been stated, in terms of the "consistency landscape" (see Figure 11), i.e., of the relationship among the sets $\mathcal{L}, \mathcal{W}, \mathcal{D}, \mathcal{L}^-, \mathcal{W}^-, \mathcal{D}^-$.

In this section, we continue the analysis of the "consistency landscape."

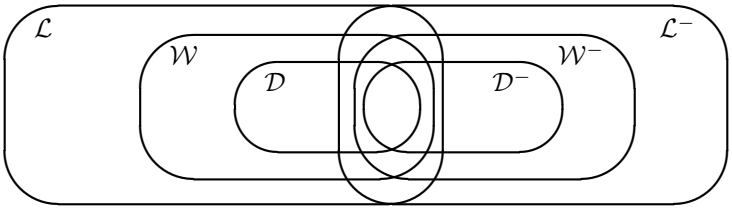

FIG. 11. *The consistency landscape.*

5.1. Transformations and constructions. In this section, we introduce two useful operations on labeled graphs. In the end, we shall derive general results on the structure of the consistency landscape.

The first operation, called "doubling," allows us to transform a labeling into a *symmetric* one. Hence, it allows us to transform a system with only one type of consistency into one which has both.

Given (G, λ), the *doubling* of λ is the mapping $\lambda_x^2((x, y))$, defined as follows: for all edges $\langle x, y\rangle$, $\lambda_x^2(\langle x, y\rangle) = (\lambda_x(\langle x, y\rangle), \lambda_y(\langle y, x\rangle))$. Its extension from edges to walks will be denoted by Λ^2.

The most important property of double labeling is that if (G, λ) has either form of consistency, then (G, λ^2) has both.

Given two strings of equal length $\alpha = a_0 a_1 \dots a_k \in \Sigma^+$ and $\beta = b_0 b_1 \dots b_k \in \Sigma^+$, let $\alpha \oplus \beta = (a_0, b_0)(a_1, b_1) \dots (a_k, b_k) \in (\Sigma^2)^+$ denote their product. Given a string $\alpha = a_0 a_1 \dots a_k \in \Sigma^+$, let $\alpha^R = a_k a_{k-1} \dots a_0$ denote the reverse string.

THEOREM 18 (double labeling). *If (G, λ) has either (weak) sense of direction or (weak) backward sense of direction, then (G, λ^2) has both (weak) sense of direction and (weak) backward sense of direction.*

Proof. Let $\mathbf{c}$ be a coding function in (G, λ). Consider the coding function $\mathbf{c}_2$ defined as follows: $\forall\, \alpha \oplus \beta \in (\Sigma^2)^+$, $\mathbf{c}_2(\alpha \oplus \beta) = \mathbf{c}(\alpha)$. Clearly, $\mathbf{c}_2$ is (resp., backward) consistent in (G, λ^2) iff $\mathbf{c}$ is (resp., backward) consistent in (G, λ).

Let $\mathbf{c}$, and hence $\mathbf{c}_2$, be (resp., backward) consistent. Given a function $\mathbf{d} : \Sigma \times \mathcal{N}(\mathbf{c}) \to \mathcal{N}(\mathbf{c})$, define the function $\mathbf{d}_2$ as follows: $\forall\ (a, b) \in \Sigma^2$ and $\alpha \oplus \beta \in (\Sigma^2)^+$, $\mathbf{d}_2((a, b), \mathbf{c}_2(\alpha \oplus \beta)) = \mathbf{d}(a, \mathbf{c}(\alpha))$. Clearly, $\mathbf{d}_2$ is a decoding of $\mathbf{c}_2$ iff $\mathbf{d}$ is a decoding of $\mathbf{c}$. Similarly, given $\mathbf{b} : \mathcal{N}(\mathbf{c}) \times \Sigma \to \mathcal{N}(\mathbf{c})$, the function $\mathbf{b}_2(\mathbf{c}_2(\alpha \oplus \beta), (a, b)) = \mathbf{d}(a, \mathbf{c}(\alpha))$ is a backward decoding of c_2 iff $\mathbf{b}$ is a backward decoding of $\mathbf{c}$.

In other words, (weak) sense of direction in (G, λ) implies (weak) sense of direction in (G, λ^2), and (weak) backward sense of direction in (G, λ) implies (weak) backward sense of direction in (G, λ^2).

Finally observe that λ^2 is symmetric; in fact, for every $\langle x, y\rangle \in E$, $\lambda_x^2(\langle x, y\rangle) = \lambda_y^2(\langle y, x\rangle)^R$. Thus, by Theorems 10 and 11, if (G, λ^2) has one type of consistency, it has both. □

The operation of doubling is important in that it allows us to transform a labeling into a *symmetric* one, and thus to extend the existing consistency to include also the other type.

The proof of Theorem 18 shows also how to employ the (resp., backward) coding and decoding of the original system to construct the analogous ones of the new system. However, it does not give any indication on the nature of the coding and decoding of the opposite type. As we will see later, such a nature is useful also for the other

transformation to be discussed in this section.

The purpose of the following lemmas is to show how to construct in the new systems the coding and decoding of the opposite type.

LEMMA 6. *Let* $\mathbf{c}$ *be a weak sense of direction in* (G,λ)*; then* $\mathbf{c}_b(\alpha \oplus \beta) = \mathbf{c}(\beta^R)$ *is a weak backward sense of direction in* (G,λ^2)*. Furthermore, if* $\mathbf{c}$ *has a decoding* $\mathbf{d}$*, then* $\mathbf{b}(\mathbf{c}_b(\alpha \oplus \beta),(a,b)) = \mathbf{d}(b,\mathbf{c}(\beta^R))$ *is a backward decoding of* $\mathbf{c}_b$*.*

Proof. Let $x,y,z \in V$, $\pi_1 \in P[x,z]$, $\pi_2 \in P[y,z]$. Let $\Lambda_x^2(\pi_1) = (a_0,a_0')\ (a_1,a_1')\ \dots\ (a_h,a_h')$, and $\Lambda_y^2(\pi_2) = (b_0,b_0')(b_1,b_1')\dots(b_k,b_k')$.

Let $x = y$. By definition of $\mathbf{c}_b$ we have that $\mathbf{c}_b(\Lambda_x^2(\pi_1)) = \mathbf{c}(a_h' \dots a_0') = \mathbf{c}(\Lambda_z(\overline{\pi_1})$. Since $x = y$, by definition of the consistency of $\mathbf{c}$ we have that $\mathbf{c}(\Lambda_z({\pi_1}^R)) = \mathbf{c}(\Lambda_z({\pi_2}^R)) = \mathbf{c}(b_k' \dots b_0')$. Since $\mathbf{c}(b_k' \dots b_0') = \mathbf{c}_b(\Lambda_y^2(\pi_2))$, it follows that $\mathbf{c}_b(\Lambda_x^2(\pi_1)) = \mathbf{c}_b(\Lambda_y^2(\pi_2))$.

Let $x \neq y$. By definition of $\mathbf{c}_b$ we have that $\mathbf{c}_b(\Lambda_x^2(\pi_1)) = \mathbf{c}(a_h' \dots a_0')$. Since $x \neq y$, by definition of the consistency of $\mathbf{c}$ we have that $\mathbf{c}(\Lambda_z({\pi_1}^R)) \neq \mathbf{c}(\Lambda_z({\pi_2}^R))$. But $\Lambda_z({\pi_1}^R) = (a_h' \dots a_0')$, and $\Lambda_z({\pi_2}^R) = b_k' \dots b_0'$. Since $\mathbf{c}(b_k' \dots b_0') = \mathbf{c}_b(\Lambda_y^2(\pi_2))$, it follows that $\mathbf{c}_b(\Lambda_x^2(\pi_1)) \neq \mathbf{c}_b(\Lambda_y(\pi_2))$.

We now show that the corresponding backward consistent decoding function is the following: $\forall \pi \in P[x,y]$, $\forall \langle y,z\rangle \in E(y)$, let $\Lambda_x^2(\pi) = (\alpha \oplus \beta))$ and $\lambda_y^2(\langle y,z\rangle) = (a,b)$; then $\mathbf{b}(\mathbf{c}_b(\alpha \oplus \beta),(a,b)) = \mathbf{d}(b,\mathbf{c}(\beta^R)$.

By definition of the consistent decoding function, $\mathbf{d}(b,\mathbf{c}(\beta^R) = \mathbf{c}(b \cdot \beta^R)$. By definition of $\mathbf{c}_b$ we have that $\mathbf{c}(b \cdot \beta^R) = \mathbf{c}_b((\alpha \oplus \beta) \cdot (a,b))$. Thus, it follows that $\mathbf{b}$ is consistent, i.e., $\mathbf{b}(\mathbf{c}_b(\alpha \oplus \beta),(a,b)) = \mathbf{c}_b((\alpha \oplus \beta) \cdot (a,b))$. □

Similarly, we have the following lemma.

LEMMA 7. *Let* $\mathbf{c}$ *be a weak backward sense of direction in* (G,λ)*. Then* $\mathbf{c}_f(\alpha \oplus \beta) = \mathbf{c}(\beta^R)$ *is a weak sense of direction in* (G,λ^2)*. Furthermore, if* $\mathbf{c}$ *has a backward decoding* $\mathbf{b}$*, then* $\mathbf{d}((a,b),\mathbf{c}_f(\alpha \oplus \beta)) = \mathbf{b}(\mathbf{c}(\beta^R),b)$ *is a decoding of* $\mathbf{c}_f$*.*

The second transformation is "reversal." Given a labeling λ of a graph G, the *reverse labeling* $\tilde{\lambda}$ of G is obtained in the following way: $\forall \langle x,y\rangle \in E$, $\tilde{\lambda}_x(\langle x,y\rangle) = \lambda_y(\langle y,x\rangle)$.

The reversal operation is related to doubling as follows, where $\mathbf{c}_b$, $\mathbf{c}_f$, $\mathbf{b}$, and $\mathbf{d}$ are as defined in Lemmas 6 and 7.

LEMMA 8. *Let* $\mathbf{c}$ *be a weak sense of direction in* (G,λ)*; then* $\mathbf{c}_b$ *is a weak backward sense of direction in* $(G,\tilde{\lambda})$*. Furthermore, if* $\mathbf{c}$ *has a decoding* $\mathbf{d}$*, then* $(\mathbf{c}_b,\mathbf{b})$ *is backward sense of direction in* $(G,\tilde{\lambda})$*.*

LEMMA 9. *Let* $\mathbf{c}$ *be a weak backward sense of direction in* (G,λ)*; then* $\mathbf{c}_f$ *is a weak sense of direction in* $(G,\tilde{\lambda})$*. Furthermore, if* $\mathbf{c}$ *has a backward decoding* $\mathbf{b}$*, then* $(\mathbf{c}_f,\mathbf{d})$ *is a sense of direction in* $(G,\tilde{\lambda})$*.*

Proof. It directly follows from Theorem 18 that the following coding function is consistent: $\forall \pi \in P[x_0]$, $\pi = \langle x_0,x_1\rangle \dots \langle x_{m-1},x_m\rangle$: $\mathbf{c}_b(\tilde{\Lambda}_x(\pi)) = \mathbf{c}(\tilde{\lambda}_{x_{m-1}}(\langle x_{m-1},x_m\rangle)\ \dots\ \tilde{\lambda}_{x_0}(\langle x_0,x_1\rangle))$. The corresponding backward decoding function is the following: $\forall \pi \in P[x_0]$, $\pi = (\langle x_0,x_1\rangle \dots \langle x_{m-1},x_m\rangle)$, $\forall \langle x_m,y\rangle \in E(x_m)$: $\mathbf{b}(\mathbf{c}_b(\tilde{\Lambda}_{x_0}(\pi)),\ \tilde{\lambda}_{x_m}(\langle x_m,y\rangle)) = \mathbf{d}(\tilde{\lambda}_{x_m}(\langle x_m,y\rangle),\ \mathbf{c}(\tilde{\lambda}_{x_{m-1}}(\langle x_{m-1},x_m\rangle)\ \dots\ \tilde{\lambda}_{x_0}(\langle x_0,x_1\rangle)))$. □

The above lemmas have a very important consequence, as follows.

THEOREM 19. (G,λ) *has (weak) backward sense of direction iff* $(G,\tilde{\lambda})$ *has (weak) sense of driection.*

This result implies that the structure of the "forward" consistency landscape and that of the backward consistent are mirror images. This fact will be instrumental in simplifying the proof of some of the results to be established in the remainder of this section.

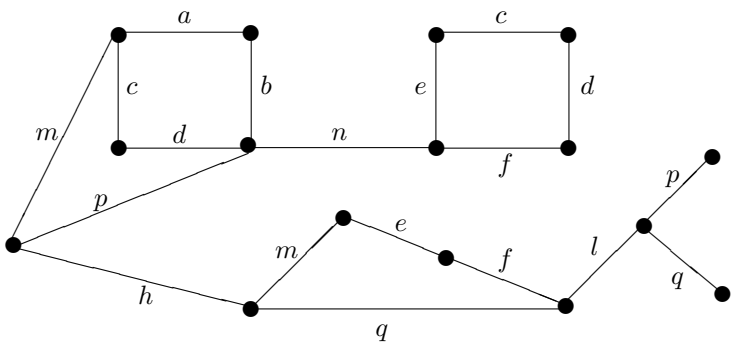

FIG. 12. $\mathbf{G}_w$.

5.2. Core. We now focus on the structure of the "core" of the consistency landscape; i.e., the set $\mathcal{W} \cap \mathcal{W}^-$.

The first result we establish is that backward sense of direction is a stronger form of consistency than weak backward sense of direction.

THEOREM 20 ($\mathcal{D}^- \subset \mathcal{W}^-$). *There are systems with backward consistency where no coding function is backward decodable.*

Proof. The proof follows from Lemmas 2 and 9. □

The next question we consider is whether the simultaneous presence of both consistencies suffices for the existence of either form of decoding. The answer is negative, as there exist systems with both weak sense of direction and weak backward sense of direction where no (backward) coding function is (backward) decodable. Let $\mathbf{G}_w$ be the labeled graph shown in Figure 12.

LEMMA 10 (see [11]). $\mathbf{G}_w \in \mathcal{W} - \mathcal{D}$.

THEOREM 21 ($(\mathcal{W} \cap \mathcal{W}^-) \not\subset (\mathcal{D} \cup \mathcal{D}^-)$). *Existence of both types of consistency is not sufficient for decodability of either type.*

Proof. By Lemma 10, graph G_w has weak sense of direction, but any coding function is not decodable. Such a labeled graph has edge-symmetry since the labeling is a coloring. Thus, by Theorem 10 we have that it also has backward weak sense of direction. However, no backward consistent coding function for G_w can be backward decodable; otherwise G_w would have backward sense of direction and, thus, by Theorem 11 would also have sense of direction contradicting Lemma 10. □

THEOREM 22 ($(\mathcal{D} \cap \mathcal{W}^-) \not\subset \mathcal{D}^-$, $\mathcal{D}^- \not\subset (\mathcal{W}^- \cap \mathcal{D})$). *Simultaneous presence of sense of direction and backward weak sense of direction is neither necessary nor sufficient for the existence of a backward decoding function.*

Proof. Not sufficient. It is easy to verify that the labeled graph of Figure 13 has sense of direction and weak backward sense of direction. However, no backward coding function is backward decodable. In fact, let $\mathbf{c}$ be a backward coding function; by definition, we have that $\mathbf{c}(dc) = \mathbf{c}(fe)$ and $\mathbf{c}(ba) = \mathbf{c}(dc)$; it follows that $\mathbf{c}(ba) = \mathbf{c}(fe)$. Let $\mathbf{b}$ be a backward decoding function; then we have that $\mathbf{b}(\mathbf{c}(ba), m) = \mathbf{c}(p) = \mathbf{b}(\mathbf{c}(fe), m)$. But $\mathbf{b}(\mathbf{c}(fe), m) = \mathbf{c}(q)$. It follows that $\mathbf{c}(q) = \mathbf{c}(p)$, which contradicts both forward and backward coding.

Not necessary. It follows from the fact that local orientation is not necessary for having a backward decoding function (see Theorem 1). □

Thus, by Theorem 19, the following holds.

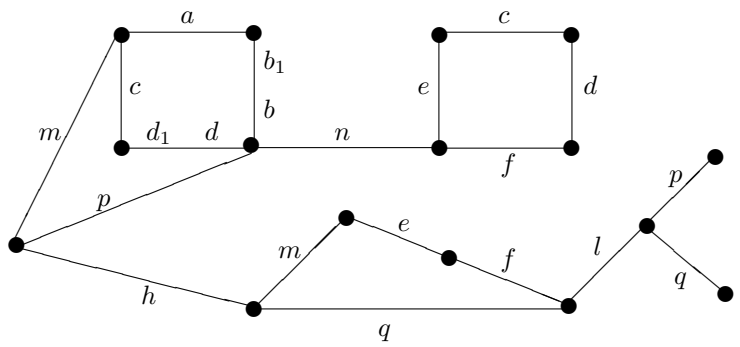

FIG. 13. $(\mathcal{D} \cap \mathcal{W}^-) - \mathcal{D}^- \neq \emptyset$.

THEOREM 23 ($(\mathcal{D}^- \cap \mathcal{W}) \not\subset \mathcal{D}$). *Simultaneous presence of backward sense of direction and weak sense of direction is not sufficient for the existence of a decoding function.*

5.3. Outer structure. In this section we focus on the outer structure of the consistency landscape: $(\mathcal{L} \cup \mathcal{L}^-) - (\mathcal{W} \cap \mathcal{W}^-)$.

We first introduce two useful properties.

Given two labeled graphs (G_1, λ_1) and (G_2, λ_2), the *melding* of (G_1, λ_1) and (G_2, λ_2) by $x_1 \in V_1, x_2 \in V_2$, denoted by $\mathbf{G_1}[x_1, x_2]\mathbf{G_2}$, is the union of the two graphs restricted by imposing $x_1 = x_2$.

THEOREM 24. *Let $\mathbf{G_1}$ and $\mathbf{G_2}$ be vertex- and label-disjoint labeled graphs with weak sense of direction. Then $\forall x_1 \in V_1, x_2 \in V_2$, $\mathbf{G} = \mathbf{G_1}[x_1, x_2]\mathbf{G_2}$ also has weak sense of direction. Furthermore, if $\mathbf{G_1}$ and $\mathbf{G_2}$ have sense of direction, (G, λ) also has sense of direction.*

Proof. By hypothesis the labeled graphs are label-disjoint, that is, $\Sigma_1 \cap \Sigma_2 = \emptyset$. By hypothesis there exists two coding function $\mathbf{c}_1$ and $\mathbf{c}_2$ such that $\mathbf{c}_1$ is a consistent coding function for G_1 and $\mathbf{c}_2$ for G_2. Without loss of generality we can also assume that $\mathcal{N}(\mathbf{c}_1) \cap \mathcal{N}(\mathbf{c}_2) = \emptyset$. (If this is not the case, take $\mathbf{c}'_1 = (0, \mathbf{c}_1)$ and $\mathbf{c}'_2 = (1, \mathbf{c}_2)$.) Let $i : (\Sigma_1 \cup \Sigma_2)^+ \to \{1, 2\}$ be a function such that $i(\alpha) = 1$ iff the last symbol of α belongs to Σ_1; otherwise, $i(\alpha) = 2$. Let $f : (\Sigma_1 \cup \Sigma_2)^+ \to \Sigma_1^+ \cup \Sigma_2^+$ be a function such that $f(\alpha) = \alpha \cap \Sigma_{i(\alpha)}$ (i.e., $f(\alpha)$ is the string of all the symbols of α belonging to the set $\Sigma_{i(\alpha)}$).

Let $p(x, \alpha) = x$ if $x \in G_{i(\alpha)}$, and $x_1 = x_2$ otherwise. Then it is easy to see that

$$(*) \qquad \forall \alpha \in \Lambda_G[x, y] \Rightarrow f(\alpha) \in \Lambda_{G_{i(\alpha)}}[p(x, \alpha), y].$$

Now let $\mathbf{c}$ be so defined: $\mathbf{c}(\alpha) = \mathbf{c}_{i(\alpha)}(f(\alpha))$. Now we will prove that $\mathbf{c}$ is consistent. By contradiction suppose that $\mathbf{c}$ is not consistent; then there exist $x, y, z \in V_G$ and $\alpha \in \Lambda_G[x, y], \beta \in \Lambda_G[x, z]$ such that either $\mathbf{c}(\alpha) = \mathbf{c}(\beta)$ but $y \neq z$, or $\mathbf{c}(\alpha) \neq \mathbf{c}(\beta)$ but $y = z$.

In the first case, since the codomains of $\mathbf{c}_1$ and $\mathbf{c}_2$ are disjoint, it follows that $\mathbf{c}_i(f(\alpha)) = \mathbf{c}_i(f(\beta))$ for some i such that $f(\alpha), f(\beta) \in \Sigma_i^+$. By (*) it follows that $f(\alpha) \in \Lambda_{G_i}[p(x, \alpha), y]$ and $f(\beta) \in \Lambda_{G_i}[p(x, \beta), z]$. Because of $i(\alpha) = i(\beta)$ it follows that $p(x, \alpha) = p(x, \beta)$. Thus, $f(\alpha) \in \Lambda_{G_i}[x', y]$ and $f(\beta) \in \Lambda_{G_i}[x', z]$. By consistency of c_i it follows that $y = z$, yielding a contradiction.

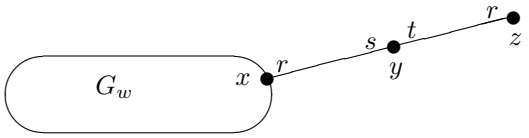

FIG. 14. $(\mathcal{W} - \mathcal{D}) - \mathcal{L}^- \neq \emptyset$.

In the second case, if $y = z$ and $y \in G_i$ for some i, by (*) and analogous deductions, we have that $f(\alpha), f(\beta) \in \Lambda_{G_i}[x', y]$ and, by consistency of $\mathbf{c}_i$, $\mathbf{c}_i(f(\alpha)) = \mathbf{c}_i(f(\beta))$; that is, $\mathbf{c}(\alpha) = \mathbf{c}(\beta)$, yielding a contradiction.

Thus, we have proved that $\mathbf{c}$ is consistent; that is, G has weak sense of direction.

Now we will prove that if G_1 and G_2 have sense of direction, then G also has sense of direction. Let $\mathbf{d}_1$ and $\mathbf{d}_2$ be the decoding functions, and let $\mathbf{d}$ be so defined:

$$\mathbf{d}(a, \mathbf{c}(w)) = \begin{cases} \mathbf{d}_1(a, \mathbf{c}(w)) & \text{if } a \in \Sigma_1 \wedge \mathbf{c}(w) \in \mathcal{N}(\mathbf{c}_1) \quad (1) \\ \mathbf{d}_2(a, \mathbf{c}(w)) & \text{if } a \in \Sigma_2 \wedge \mathbf{c}(w) \in \mathcal{N}(\mathbf{c}_2) \quad (2) \\ \mathbf{c}(w) & \text{if } a \in \Sigma_1 \wedge \mathbf{c}(w) \in \mathcal{N}(\mathbf{c}_2) \quad (3) \\ \mathbf{c}(w) & \text{if } a \in \Sigma_2 \wedge \mathbf{c}(w) \in \mathcal{N}(\mathbf{c}_1) \quad (4) \end{cases}.$$

We will show that $\mathbf{d}(a, \mathbf{c}(w)) = \mathbf{c}(aw)\ \forall\ aw \in \Lambda_G[x, z]$. We have to consider the four cases in the definition of $\mathbf{d}$.

(1) In this case $\mathbf{d}(a, \mathbf{c}(w)) = \mathbf{d}_1(a, \mathbf{c}(w))$, $a \in \Sigma_1$, and $\mathbf{c}(w) \in \mathcal{N}(\mathbf{c}_1)$. Thus, a is a label of an edge of G_1 and w is a label of a path ending in G_1. This means that $\mathbf{c}(w) = \mathbf{c}_1(f(w))$. Then, $\mathbf{d}_1(a, \mathbf{c}(w)) = \mathbf{d}_1(a, \mathbf{c}_1(f(w)))$. By property (*), it follows that $f(w)$ is the label of a path in G_1; since $x \in G_1$, $a \cdot f(w) = f(aw) \in \Lambda_{G_1}[x, z]$. By consistency of $\mathbf{d}_1$, we have $\mathbf{d}_1(a, \mathbf{c}_1(f(w))) = \mathbf{c}_1(a \cdot f(w)) = \mathbf{c}_1(f(aw)) = \mathbf{c}(aw)$.

(2) Symmetric to case (1).

(3) In this case, $\mathbf{d}(a, \mathbf{c}(w)) = \mathbf{c}(w)$, $a \in \Sigma_1$, and $\mathbf{c}(w) \in \mathcal{N}(\mathbf{c}_2)$. Thus, a is a label of an edge in G_1, while w is the labeling of a path ending in G_2. This implies that $f(aw) = f(w)$. Thus, $\mathbf{d}(a, \mathbf{c}(w)) = \mathbf{c}(w) = \mathbf{c}_2(f(w)) = \mathbf{c}_2(f(aw)) = \mathbf{c}(aw)$.

(4) Symmetric to case (3). □

THEOREM 25. $(\mathcal{W} - \mathcal{D}) \not\subset \mathcal{L}^-$.

Proof. Consider the labeled graph of Figure 14. Notice that such a graph is the melding in x of the graph G_w of Figure 12 and a line with two edges $\langle x, y\rangle$ and $\langle y, z\rangle$.

Since the labeled line has trivially weak sense of direction and since, by Lemma 10, the graph $\mathbf{G}_w$ of Figure 12 has weak sense of direction, it follows from Theorem 24 that the graph of Figure 14 has weak sense of direction as well.

On the other hand, by Lemma 10, the graph of Figure 12 does not have sense of direction, and, as a consequence, the graph of Figure 14 also does not have sense of direction. Moreover, this labeled graph does not have backward local orientation; in fact $\lambda_x(\langle x, y\rangle) = \lambda_z(\langle z, y\rangle)$. □

As a consequence, we have the following.

THEOREM 26. $(\mathcal{W}^- - \mathcal{D}^-) - \mathcal{L} \neq \emptyset$.

Proof. The proof follows from Theorems 19 and 25. □

THEOREM 27. $((\mathcal{W} - \mathcal{D}) \cap \mathcal{L}^-) - \mathcal{W}^- \neq \emptyset$.

Proof. Consider the labeled graph (G, λ) of Figure 15. Notice that it is the melding in x of Figure 12 and a labeled graph (G', λ'). It is easy to verify that (G', λ') has weak sense of direction, which implies that (G, λ) has weak sense of direction. However,

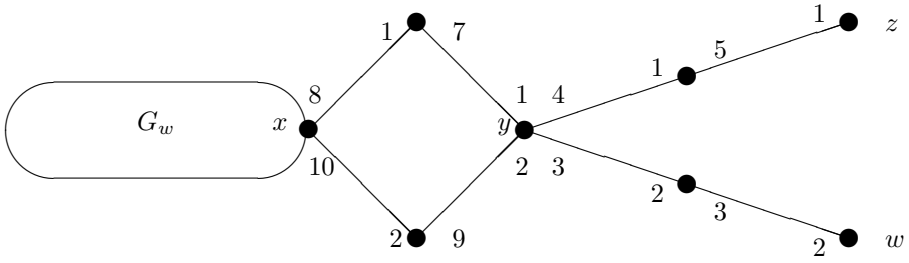

FIG. 15. $((\mathcal{W} - \mathcal{D}) \cap \mathcal{L}^-) - \mathcal{W}^- \neq \emptyset$.

since by Lemma 10 the graph G_w of Figure 12 does not have sense of direction, it follows that (G, λ) also does not have sense of direction. Clearly, there is backward local orientation. By contradiction, let us assume that there is weak backward sense of direction in (G, λ). By definition of backward consistency at node x we would have that $\mathbf{c}(1 \cdot 1) = \mathbf{c}(2 \cdot 2)$ (since these two sequences of labels correspond to two paths from y to x); however, $\mathbf{c}(1 \cdot 1) \neq \mathbf{c}(2 \cdot 2)$ (since they also correspond to two paths starting from different nodes (w and z) and terminating in the same node y). □

As a consequence, we have the following.

THEOREM 28. $((\mathcal{W}^- - \mathcal{D}^-) \cap \mathcal{L}) - \mathcal{W} \neq \emptyset$.

Proof. The proof follows from Theorems 19 and 27. □

6. Backward consistency and Σ. In this section we ask some questions about the relationship between the set of labels used in (G, λ) and the existence of backward consistency. In particular, we focus on the number $\kappa(G, \lambda) = |\Sigma|$ of labels used in (G, λ). A general bound on κ is the following, where $\deg(G)$ and $e(G)$ denote the maximum degree and the number of edges in G, respectively.

LEMMA 11. *If (G, λ) has backward consistency, then $d(G) \leq \kappa(G, \lambda) \leq 2e(G)$.*

6.1. Minimum backward sense of direction. If $\kappa(G, \lambda) = d(G)$, the labeling is said to be *minimum* and so is called any consistency property existing in (G, λ). So, consistency in minimally labeled systems is called *minimum (weak) sense of direction*; similarly we can define the backward analogues. Let $m\mathcal{C}$ denote the subclass of $\mathcal{C}$ of labeled graphs (G, λ) for which λ is a minimum labeling (e.g., $m\mathcal{W}$ is the class of labeled graphs with minimum weak sense of direction).

We now study the relationship between minimality and biconsistency in arbitrary topologies.

THEOREM 29. *Edge-symmetry in a minimum weak sense of direction is not sufficient for backward consistency.*

Proof. Consider the labeled graph of Figure 16.

For each $\alpha \in \{r, l, a\}^*$, let $\mu(\alpha) \in \{r, a\}^*$, the string obtained from α applying as many times as possible one of the following simplification rules: $rl \to \epsilon$, $lr \to \epsilon$, $aa \to \epsilon$, $rrr \to \epsilon$, $lll \to \epsilon$, $l \to rr$. The first three rules eliminate all the cycles of length 2, and the following two rules eliminate all the cycles of length 3. The last rule rewrites the l with two r's. Let $A = \{\alpha : \exists v \wedge \exists \pi \in P[v] : \Lambda_v(\pi) = \alpha\}$, and let $\mu(A) = \{\mu(\alpha) : \alpha \in A\}$. It can be proven that $\mu(A) = r^{2*}(\cdot a \cdot r^{2*})^?$, where r^{2*} means at most 2 repetitions of the symbol r (there can be 0 repetitions). $(x)^?$ means 0 or 1 repetition of x. Let a coding function c be defined as follows:

$$c(\alpha) = \begin{cases} (\mu(\alpha), 0) & \text{if } \mu(\alpha) \in r^{2*}, \\ (\beta, 1)) & \text{if } \mu(\alpha) = r^{2*}a\beta. \end{cases}$$

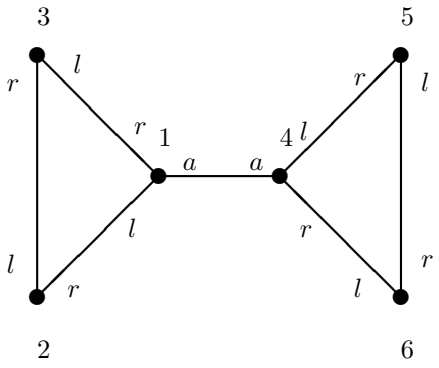

FIG. 16. *A minimum labeled graph with a consistent coding c that is not backward consistent.*

For each node v let $\overline{v}$ be the node on the same ring with degree 3 (e.g., $\overline{2} = \overline{3} = \overline{1} = 1$ and $\overline{4} = \overline{5} = \overline{6} = 4$). We can prove the following property.

CLAIM 2.

1. $\forall x, y, \pi \in P[x, y], (\mathbf{c}(\Lambda_x(\pi)) = \mathbf{c}(\gamma, 0) \Leftrightarrow \overline{x} = \overline{y} \wedge \exists \pi' \in P[x, y] \wedge \Lambda_x(\pi') = \gamma)$.
2. $\forall x, y, \pi \in P[x, y], (\mathbf{c}(\Lambda_x(\pi)) = \mathbf{c}(\gamma, 1) \Leftrightarrow \overline{x} \neq \overline{y} \wedge \exists \pi' \in P[\overline{y}, y] \wedge \Lambda_{\overline{y}}(\pi') = \gamma)$.

It is easy to see that $\mathbf{c}$ is a consistent coding function. But $\mathbf{c}$ is not backward consistent. We can see that ra is the label of the path from 6 to 1 passing from node 4, and a is the label of the path from 4 to 1. Thus $4 \neq 6$, but $\mathbf{c}(ra) = (\epsilon, 1) = \mathbf{c}(a)$. □

COROLLARY 1. *Edge-symmetry in a minimum (backward) weak sense of direction is not sufficient for biconsistency.*

Note that this also gives, as a corollary, a different proof of Theorem 13.

Now we will study the relationship between sense of direction and minimality in regular graphs. Let $\mathcal{R}$ denote the set of labeled regular graphs, that is, $\deg(v) = k$ for all nodes v.

First observe that the requirement of minimality does not make edge-symmetry necessary for either form of consistency.

LEMMA 12 ($\mathcal{R} \cap m\mathcal{W}^{(-)} \not\subset \mathcal{ES}$). *Edge-symmetry is not necessary for having minimum weak sense of direction or minimum weak backward sense of direction in regular graphs.*

Proof. The nonnecessity for minimum weak backward sense of direction can be seen by considering Figure 1, where the graph has minimum weak backward sense of direction but does not have edge-symmetry; the mirror image result follows by Theorem 19. □

However, for the simultaneous existence of both types of consistency, unlike the general case (see Theorem 12), edge-symmetry is necessary if minimality is required.

THEOREM 30 ($m\mathcal{W}^{\pm} \cap \mathcal{R} = m\mathcal{W} \cap \mathcal{ES} \cap \mathcal{R} = m\mathcal{W}^{-} \cap \mathcal{ES} \cap \mathcal{R}$). *In a regular labeled graph (G, λ) with edge-symmetry, any minimum weak sense of direction (minimum weak backward sense of direction) is also biconsistent.*

Proof. Let $\mathbf{c}$ be a consistent coding function for (G, λ). By contradiction, let us assume that $\mathbf{c}$ does not have backward consistency, which means that there exist two paths $\pi_1 \in P[x, z], \pi_2 \in P[y, z]$ such that either (i) $\mathbf{c}(\Lambda_x(\pi_1)) = \mathbf{c}(\Lambda_y(\pi_2))$ and $x \neq y$ or (ii) $\mathbf{c}(\Lambda_x(\pi_1)) \neq \mathbf{c}(\Lambda_y(\pi_2))$ and $x = y$.

Let us consider case (i). Since the graph is regular and the labeling minimum, there must exist a path $\pi_3 \in P[x]$ such that $\Lambda_x(\pi_3) = \Lambda_y(\pi_2)$. Thus, $\mathbf{c}(\Lambda_x(\pi_1)) =$

$\mathbf{c}(\Lambda_y(\pi_3))$, which implies that $\pi_3 \in P[x,z]$. This is a contradiction, because it violates local orientation in z.

Consider now case (ii). This case violates the definition of forward consistency in x.

The reverse is analogous. □

Thus, with edge-symmetry, the class of regular graphs with minimum weak backward sense of direction coincides with the class of edge-symmetric regular graphs with minimum weak sense of direction. Using the characterization of the latter class by [10, 23], we obtain the following.

THEOREM 31. *A regular labeled graph (G,λ) with edge-symmetry has minimum weak backward sense of direction iff it is a Cayley graph with Cayley labeling.*

In other words, if there is edge-symmetry, Cayley graphs with Cayley labelings are the only regular graphs with minimum backward sense of direction and/or minimum sense of direction.

COROLLARY 2 ($m\mathcal{W}^{\pm} \cap \mathcal{ES} \cap \mathcal{R} = m\mathcal{D}^{\pm} \cap \mathcal{ES} \cap \mathcal{R}$). *In a regular labeled graph with edge-symmetry, any minimum and biconsistent weak sense of direction is a sense of direction.*

The situation is quite different in the absence of edge-symmetry; in this case, at most one type of minimum consistency can exist.

LEMMA 13 ($m\mathcal{W} \cap m\mathcal{W}^{-} \subset \mathcal{ES}$). *Without edge-symmetry and restricted to regular graphs, $m\mathcal{W} \cap m\mathcal{W}^{-} = \emptyset$.*

Proof. The proof follows from Theorem 30. □

6.2. Number of labels and backward consistency. In this section we ask under what conditions a (large) value $\kappa(G,\lambda)$ is sufficient for backward consistency. The first obvious result is that $\kappa(G,\lambda) = 2e(G)$; then the system has both sense of direction and backward sense of direction without further conditions.

LEMMA 14. *If $\kappa(G,\lambda) = 2e(G)$, then (G,λ) has both sense of direction and backward sense of direction.*

Basically, this numerical requirement is equivalent to having all edges labeled with unique labels.

If we are interested only in backward sense of direction, we can actually relax this condition. In fact, it is sufficient that the labels used by each node are different from the ones used by the other nodes for the system to have backward sense of direction (but not necessarily sense of direction); see, for example, Figure 17. Let $\Sigma_x = \{\lambda_x(x,y) : y \in E(x)\}$.

THEOREM 32. *If, in (G,λ), $\Sigma_x \cap \Sigma_y = \emptyset \ \forall\ x \neq y$, then (G,λ) has backward sense of direction.*

Proof. For each $a \in \Sigma$, only one node x uses a: let $\sigma(a) = \Sigma_x$.

Consider the following backward coding function: $\forall \pi \in P[x_0]$, $\pi = \langle x_0, x_1\rangle \dots \langle x_{m-1}, x_m\rangle$, $\mathbf{c}(\Lambda_x(\pi)) = \sigma(\lambda_{x_0}(\langle x_0, x_1\rangle))$.

Let $\pi_1 \in P[x,z], \pi_2 \in P[y,z]$; $\pi_1 = \langle x, x_1\rangle \dots \langle x_h, z\rangle$, $\pi_2 = \langle y, y_1\rangle \dots \langle y_k, z\rangle$. We have that $\mathbf{c}(\Lambda_x(\pi_1)) = \sigma(\lambda_x(\langle x, x_1\rangle))$ and $\mathbf{c}(\Lambda_y(\pi_2)) = \sigma(\lambda_y(\langle y, y_1\rangle))$.

Consider the case $x = y$. By definition of σ, we have that $\sigma(\lambda_x(\langle x, x_1\rangle)) = \sigma(\lambda_y(\langle y, y_1\rangle))$; thus, $\mathbf{c}(\Lambda_x(\pi_1)) = \mathbf{c}(\Lambda_y(\pi_2))$.

Consider the case $x \neq y$. Since, by hypothesis, all the labels used by x are different from all the labels used by y, we have $\sigma(\lambda_x(\langle x, x_1\rangle)) \neq \sigma(\lambda_y(\langle y, y_1\rangle))$ and $\mathbf{c}(\Lambda_x(\pi_1)) \neq \mathbf{c}(\Lambda_y(\pi_2))$.

It is easy to see that the corresponding backward consistent decoding function is

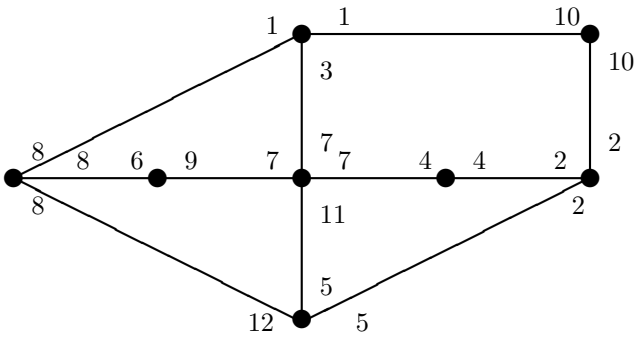

FIG. 17. $\Sigma_x \cap \Sigma_y = \emptyset$.

the following:

$$\forall \pi \in P[x_0], \pi = \langle x_0, x_1 \rangle \dots \langle x_{m-1}, x_m \rangle, \forall \langle x_m, y \rangle \in E(x_m),$$

$$\mathbf{b}(\mathbf{c}(\Lambda_{x_0}(\pi), \lambda_{x_m}(\langle x_m, y \rangle))) = \mathbf{c}(\Lambda_{x_0}(\pi)). \qquad \square$$

Analogously, when the labels used for the edges terminating in x are different from the ones used for edges terminating in any $y \neq x$, then the system has sense of direction. Let $\Sigma_x^- = \{\Sigma_y(y, x) : y \in E(x)\}$.

THEOREM 33. *If, in* (G, λ), $\Sigma_x^- \cap \Sigma_y^- = \emptyset \ \forall \ x \neq y$, *then* (G, λ) *has sense of direction.*

Notice that among the labelings satisfying the assumption of Theorem 32 are those yielding the systems with complete blindness discussed in Theorem 2; among the labelings satisfying the assumption of Theorem 33 are the so-called neighboring ones. In both cases the number of labels used is exactly $n(G)$.

7. Computational equivalence. From a computational viewpoint, *anonymous* systems are the least powerful distributed systems—and hence the ideal setting in which to study the capabilities of specific properties (e.g., [1, 2, 7, 16, 22, 35, 36, 38, 39, 43, 44]). The computational power of sense of direction in anonymous systems has been investigated for specific labeled graphs (e.g., meshes and tori [4, 34], hypercubes [28, 29], and Cayley graphs [27]). The general characterization has been given in [22]; as an indication of its capabilities, many unsolvable problems in anonymous networks (e.g., computing the XOR in a regular network without knowledge of the network size) can be solved if the system has sense of direction (and without breaking anonymity). To exist, and thus to be exploited, sense of direction requires the existence of constraints much stronger than local orientation.

What happens, from a computational point of view, if the system does not even guarantee local orientation? What can be computed if nodes cannot even distinguish among their links? There are several studies on computability in the absence of local orientation investigating these questions for specific topologies [14], specific problems [45], or classes of functions [9, 37]. As expected, these results indicate that the absence of local orientation dramatically reduces the computational power in almost all graphs (a noticeable exception is the ring [14]).

In this section we study the computational capability of the newly introduced backward consistency, which can exist even in the presence of complete and total blindness. We show the unexpected result that *backward consistency has the same computational capabilities as sense of direction*. In other words, not only does it overcome the handicap of not having local orientation, but it also actually empowers even a totally blind system with the additional capabilities of sense of direction.

7.1. Computability. A basic concept when computing on anonymous networks is the one of *view*, introduced in [44]. The *view* $T_{(G,\lambda)}(v)$ of a node v in a labeled graph (G,λ) is an infinite, labeled, rooted tree "downward locally isomorphic" to G, i.e., such that there exists a map from the vertices of the tree to the vertices of G which maps the root of the tree to v, the children of the root to the neighbors of v, and, recursively, the children of a node to the neighbors of that node. The labeling of the arcs are also downward preserved. When no ambiguity arises, we shall denote a view $T_{(G,\lambda)}(v)$ simply by $T(v)$.

Let $\mathcal{G}$ denote the set of labeled graphs. Given $\mathcal{C} \subseteq \mathcal{G}$ and a graph G, let $\mathcal{C}/G$ denote the restriction of $\mathcal{C}$ to G; e.g., $\mathcal{L}^-/G$ is the set of labeled graphs obtained by labeling G with backward local orientations.

A problem $\mathcal{P}$ is *solvable* in $\mathcal{C}/G$ if it is solvable in all labeled graphs $(G,\lambda) \in \mathcal{C}/G$. Given a topological knowledge K, a problem $\mathcal{P}$ is K-solvable in $\mathcal{C}/G$ if it is solvable in all $(G,\lambda) \in \mathcal{C}/G$, where all the nodes are empowered with a priori knowledge K.

We first report two results on the computational capabilities of sense of direction. The first result is that, from a computational point of view, there is no difference between weak sense of direction and sense of direction.

THEOREM 34 (see [22]). *$\forall G \forall \mathcal{P}$, $\mathcal{P}$ is solvable in $\mathcal{W}/G$ iff $\mathcal{P}$ is solvable in $\mathcal{D}/G$.*

The second result shows that, with sense of direction, no other knowledge is necessary.

THEOREM 35 (see [22]). *$\forall G \forall \mathcal{P} \forall K$, if $\mathcal{P}$ is K-solvable in $\mathcal{L}/G$, then $\mathcal{P}$ is solvable in $\mathcal{W}/G$.*

We will now focus on backward consistency and establish the equivalence result.

THEOREM 36. *$\forall G \forall \mathcal{P}$, $\mathcal{P}$ is solvable in $\mathcal{D}/G$ iff $\mathcal{P}$ is solvable in $\mathcal{D}^-/G$.*

Proof. To prove this theorem we will need several steps.

Given two labeled graphs $(G=(V,E),\lambda)$ and $(G'=(V',E'),\lambda')$, a *labeled graph isomorphism* is a bijection $\chi : V \to V'$ which preserves edges and edge labels; that is, $\langle u,v\rangle \in E \Leftrightarrow \langle \chi(u),\chi(v)\rangle \in E'$ and $\lambda(\langle u,v\rangle) = \lambda'(\langle \chi(u),\chi(v)\rangle)$.

The *complete topological awareness* of a node $x \in V$ in a labeled graph $(G = (V,E),\lambda)$ is knowledge of the isomorphic image $\psi(G,\lambda)$ of (G,λ) and of $\phi(x)$ for some labeled graph isomorphism ψ. The *complete topological knowledge* on a labeled graph $(G=(V,E),\lambda)$ (denoted by TK) is when every node $x \in V$ has complete topological awareness. Note that the isomorphism known by each node may be different.

The importance of TK becomes apparent with the following fact.

LEMMA 15 (see [22]). *$\forall G \forall \mathcal{P}$, $\mathcal{P}$ is TK-solvable in $\mathcal{L}/G$ iff $\mathcal{P}$ is solvable in $\mathcal{D}/G$.*

In other words, TK represents the maximum information obtainable with sense of direction. Hence, to prove the main theorem, we need only show that every node can construct TK with weak backward sense of direction. To do this, first observe the following.

LEMMA 16 (see [22]). *Let $\mathbf{c}$ be a consistent coding function of (G,λ). Then $\forall u \in V$, $T_{(G,\lambda)}/\mathbf{c} = \psi(G,\lambda)$ for some labeled graph isomorphism ψ.*

That is, consistency would allow each node to construct an isomorphic image of (G, λ) from each view. Since in its view a node knows its location (it is the root), it knows its location in the image. Therefore, to complete the proof, we have to show how to constructively empower each node with local orientation and a consistent coding.

If there is backward consistency in (G, λ), a local orientation with forward consistency can be easily constructed by employing the result of Lemma 9: if (G, λ) has backward consistency, then $(G, \tilde{\lambda})$ has local orientation and consistency. Since $\tilde{\lambda}$ is distributedly constructible (i.e., each node x can construct $\tilde{\lambda}_x$) by a simple round of communication), $T_{(G,\tilde{\lambda})}(u)$ is also constructible at every node.

Thus, we must only show how to construct at each node a consistent coding function $\mathbf{c}$ for $(G, \tilde{\lambda})$, given $\mathbf{b}$, λ_x, and $\tilde{\lambda}_x$. This is done by observing that, by Theorem 18, if (G, λ) has backward consistent coding $\mathbf{b}$, then we can construct a consistent coding $\mathbf{c}$ of (G, λ^2), and by Lemma 9, $\mathbf{c}$ is a consistent coding for $(G, \tilde{\lambda})$.

Summarizing, if (G, λ) has backward consistency $\mathbf{b}$, each node v can construct the view $T_{(G,\tilde{\lambda})}(v)$ and a consistent coding of $(G, \tilde{\lambda})$ which will empower it to construct both an isomorphic image of both (G, λ) and $\psi(v)$. This knowledge is equivalent to complete topological knowledge; since the class of problems solvable with TK is exactly the same solvable with sense of direction alone, it follows that backward sense of direction is computationally equivalent to sense of direction. □

7.2. Complexity. The result of Theorem 36 opens the problem of how to effectively use the computational power of backward consistency. The approach suggested by the proof of Theorem 36 is to use backward consistency to "simulate" sense of direction. While theoretically valid, this approach sidesteps the problem since it does not exploit backward consistency directly. Furthermore, the technique employed in the proof is not algorithmically reasonable, since it requires the construction of the views $T_{(G,\tilde{\lambda})}(v)$, a task with a formidable communication complexity.

While not solving the general problem, we will provide some complexity relief by pointing out how the simulation approach can be carried out simply and efficiently, without construction of the views.

Let A be an algorithm which solves problem $\mathcal{P}$ in any system with sense of direction. The simulation $S(A)$ of A in a system (G, λ) in which there is backward sense of direction is performed in two stages:

(1) *Preprocessing.* Each processor x computes the set $\Sigma_x(a) = \{b : \lambda_x(x, y) = a$ and $\lambda_y(y, x) = b\}$ for each of its labels $a \in \lambda_x(E(x))$. Notice that $\bigcup \Sigma(a) = \tilde{\lambda}_x(E(x))$.

(2) *Simulation.* Whenever, in algorithm A, a node x sends a message m on an edge labeled l, in the simulation $S(A)$ it will send a message (m, l) to the set of edges labeled by the (unique) label $p \in \lambda_x(E(x))$ such that $l \in \Sigma_x(p)$; whenever, in algorithm A, a node performs an action O upon reception of a message m from a link labeled l, in the simulation of A it will perform the same action O upon reception of message (m, l) from any of the edges labeled p, where p is the (unique) label such that $l \in \Sigma_x(p)$.

It is easy to see that algorithm $S(A)$ behaves on (G, λ) in exactly the same way as the algorithm A would behave on $(G, \tilde{\lambda})$ (the only difference being that $S(A)$ sends a pair $(m, label)$ every time A sends a message m). In fact, we have the following result.

THEOREM 37. *Algorithm $S(A)$ solves $\mathcal{P}$ in any system with backward sense of direction iff A solves $\mathcal{P}$ in any system with sense of direction.*

Proof. Let A solve P in any system with sense of direction. Since (G, λ) has

backward sense of direction, from Theorem 19, we have that $(G, \tilde{\lambda})$ is a system with sense of direction; and thus A solves P on $(G, \tilde{\lambda})$. But, by construction, algorithm S behaves on (G, λ) in exactly the same way as the algorithm A would behave on $(G, \tilde{\lambda})$, and the proof follows.

The reverse is analogous. □

Moreover, the number of message *transmissions* of $S(A)$ (denoted by $\mathcal{M}_T$) is the same as in the original algorithm A. The number of message *receptions* (denoted by $\mathcal{M}_R$) obviously depends on the cardinality of the sets $\Sigma_x(p)$. Given (G, λ), let $h(G, \lambda) = Max_{x \in V, a \in \Sigma}\{\Sigma_x(a)\}$; clearly, $h(G, \lambda) \leq d(G)$.

THEOREM 38.

(1) $\mathcal{M}_T(S(A), G, \lambda) = \mathcal{M}_T(A, G, \tilde{\lambda})$.

(2) $\mathcal{M}_R(S(A), G, \lambda) \leq h(G, \lambda)\mathcal{M}_R(A, G, \tilde{\lambda})$.

In other words, it is possible to use simulation with some level of efficiency. However, the real task is to develop protocols and techniques which exploit backward consistency directly (not just to simulate forward consistency).

8. Concluding remarks and open problems. Sense of direction, for its existence, requires the presence of many "low-level" subconditions, in particular local orientation. However, local orientation cannot be assumed if we are to model systems with more advanced communication and interconnection technology. In this paper we have shown the existence of another type of consistency—backward consistency—which is computationally equivalent to sense of direction but does not require local orientation; thus, it can be found (or designed) in advanced distributed systems.

The relationship between backward consistency and communication complexity is still virtually unknown. The study of how to effectively and efficiently exploit the power of backward consistency when solving problems is an open research area. Some results already exist for specific problems; see, for example, the protocols developed for multi-hop radio networks [3, 12].

Sense of direction and backward consistency are two among a large (and practically unknown) population of varying types of general consistency. An interesting aspect of the results presented here is that backward consistency and sense of direction are not comparable, but rather orthogonal. This fact raises the possibility of the existence of yet other types of consistency that are computationally equivalent to, but not comparable to, sense of direction.

There are interesting coincidences and analogies; for example, the discovery that the reverse of labeling with an important property (sense of direction) has another important property (backward consistency) finds its parallel in the context of interval routing, where it was recently discovered that the reversal of any interval-routing labeling is a broadcast labeling [13]. This coincidence reveals a new viewpoint from which to examine the problem: any operation on the labeling will transform the class of problem solvable in the resulting system (the result will obviously depend on the original type of consistency). The open questions then become, What operations on the labeling (such as reversal) preserve computability? Which will transform it? And into what will it be transformed?

BINARY SPACE PARTITIONS FOR LINE SEGMENTS WITH A LIMITED NUMBER OF DIRECTIONS*

CSABA D. TÓTH†

Abstract. We show that there is always a binary space partition (BSP) of size $O(n \log k)$ and an autopartition of size $O(nk)$ for n disjoint line segments in the plane, assuming that the segments have k distinct orientations. In particular, if k is a constant, these bounds imply that there is a linear-size BSP and autopartition. Our proof is constructive and can be turned into algorithms computing such a BSP or autopartition in $O(n^2)$ and $O(n^2 k)$ times.

Key words. binary space partition, line segments, computational geometry

1. Introduction.

The binary space partition (BSP) is a data structure introduced by the computer graphics community in the late seventies [17, 24, 26]. Originally it was designed to give an efficient visibility algorithm for polygonal scenes using the "painter's method." Currently applications of BSP range through hidden surface removal [18, 13], shadow generation [6], ray tracing [8, 25], solid modeling [19], surface approximation [20, 28], and robot motion planning [7, 4].

Informally, a BSP for n disjoint objects in the plane is a recursive dissection of the plane into convex regions such that each region is dissected in two by a segment or a line until every object (or part of an object) is in a distinct region. Ideally, every object should be in one convex region, but sometimes it is inevitable that some of the objects are dissected. The size of the BSP is defined as the number of regions in the resulting plane partition. The size of a BSP effects substantially the complexity of the algorithms using this data structure. Our concern, in general, is to find small BSPs for certain sets of objects. A special but important class of BSPs consists of *autopartitions* where every convex region is dissected along a flat of one of the objects within the region.

Previous and related works. The BSP was invented by Fuchs, Kedem, and Naylor [17], based on ideas of Schumacker et al. [24, 26]. Paterson and Yao [22] proved that there exists a BSP of size $O(n \log n)$ for a set of n disjoint line segments in the plane. The expected size of an autopartition, where cuts are made along the line segments in a random order, is $O(n \log n)$. The best-known lower bound, $\Omega(n \log n / \log \log n)$, for both BSP and autopartition follows from a recent construction described in [27]. De Berg, de Groot, and Overmars [11] have found linear upper bounds to the BSP for line segments where the ratio between the length of the longest and shortest segment is bounded by a constant.

Paterson and Yao [23, 21] exhibited BSPs of size $O(n^2)$ for rectangles in $\mathbb{R}^3$, matching the $\Omega(n^2)$ lower bound of a construction due to Eppstein. Agarwal et al. [2] constructed a BSP of size $n2^{O(\sqrt{\log n})}$ for n fat orthogonal rectangles in $\mathbb{R}^3$ in $n2^{O(\sqrt{\log n})}$ time. Dumitrescu, Mitchell, and Sharir [14] have proved that the size of the smallest BSP for n axis-parallel 2-dimensional rectangles in $\mathbb{R}^4$ is $\Theta(n^{5/3})$ in the worst case. De Berg [10] gave BSPs of size $O(n)$ for n "uncluttered" objects in $\mathbb{R}^d$ for every $d \in \mathbb{N}$ in $O(n \log n)$ time.

Main result. The construction of [27] shows that, in general, we cannot expect linear-size BSPs for sets of line segments in the plane. We may ask what is the smallest BSP if n segments have few different orientations compared to n, which is the case in many applications. Paterson and Yao [22] proved an $O(n)$ upper bound on the smallest BSP for orthogonal line segments. Dumitrescu, Mitchell, and Sharir [14] improved this upper bound to $2n-1$ and gave a worst-case lower bound of $2n-o(n)$. For more than two distinct directions (even for three different orientations) no better bound was known than $O(n \log n)$. We have the following.

THEOREM 1. *If L is a set of n disjoint line segments in the plane with at most k distinct directions, then there exists for L*

(i) *a BSP of size $O(n \log k)$, where every segment is cut at most $O(\log k)$ times;*

(ii) *an autopartition of size $O(nk)$, where every segment is cut at most $O(k)$ times.*

If k is a constant, Theorem 1 yields a linear upper bound, which is, up to a constant factor, optimal. Interestingly enough, the bound of Theorem 1(i) is also asymptotically tight for the lower bound construction of [27]: Here n line segments have $\exp(\Theta(\log n/\log\log n))$ different directions, and the minimum-size BSP is as big as $\Omega(n \log n/\log\log n) = \Omega(n \log k)$. For $k = n$, Theorem 1(i) returns the well-known bound of $O(n \log n)$ due to Paterson and Yao [22].

Our proof is constructive. The algorithm of constructing a BSP of size $O(n \log k)$ and an autopartition of size $O(nk)$ uses $O(n^2)$ and $O(n^2k)$ times, respectively. For $k = 2$, d'Amore and Franciosa [9] gave an $O(n \log n)$ time algorithm to find an autopartition of size at most $4n$.

Definitions. We define the BSP and the autopartition in the Euclidean plane only. It can be defined analogously in higher-dimensional Euclidean spaces (see, e.g., [12]). A *binary space partition tree* P for a set L of n disjoint line segments in the plane is a *rooted binary tree* defined as follows. Each node $u \in P$ corresponds to a convex region R_u. The root of P corresponds to $\mathbb{R}^2$ (or, equivalently, to the convex hull of all segments). If $\operatorname{int}(R_u)$ is disjoint from the segments, then u is a leaf of P. Otherwise R_u is partitioned into two convex regions R_v and R_w along a line, and the two children v and w correspond to R_v and R_w, respectively. A BSP is an *autopartition* if each R_u, where the interior of R_u intersects a segment of L, is dissected along a line spanned by one of the segments intersecting $\operatorname{int}(R_u)$.

The size of a BSP P is the number of its leaves. We denote by $\mathcal{R}(P)$ the set of regions corresponding to the leaves of P. The regions in $\mathcal{R}(P)$ give a convex decomposition of the plane. Note that many different BSPs and autopartitions exist for the same set L. The size of a BSP depends largely on the choice of the line that splits R_u at each interior node u. In fact, we consider a BSP for L as a recursive *algorithm* of building the tree from the root, where we choose a splitting line whenever there is a node u for which $\operatorname{int}(R_u)$ intersects a segment and split R_u into two regions R_v and R_w.

Proof technique and organization. Instead of the size of the BSP, we count

the number $c(P)$ of *cuts* on line segments during a BSP P, i.e., the events where a splitting line of an interior node $v \in P$ crosses a segment $\ell \in L$. The number of pieces of line segments is thus $n + c(P)$. The size of every BSP P described below is bounded by $O(n + c(P))$, since all our BSPs predominantly partition regions along fragments of the given line segments, and every fragment must be contained in one of the partitioning lines. Therefore, it is enough to show that there is a BSP (resp., autopartition) P with $c(P) = O(n \log k)$ (resp., $O(nk)$) for n disjoint line segments with k distinct directions.

We construct BSPs and autopartitions recursively. In the main loop, we apply a BSP for the segments which have an endpoint on the boundary of the convex hull $\mathrm{conv}(\bigcup L)$. Our Lemma 1 ensures that such a BSP *cut*s every line segment at most $O(\log k)$ and $O(k)$ times in the case of BSPs and autopartitions, respectively. Every fragment of segments cut during one iteration will have an endpoint on the boundary of a corresponding cell R_v, and we apply a BSP for those segments in the next iteration. In section 2, we describe the main loop of our algorithm and the proof of Theorem 1.

The proof of Lemma 1 can be found in sections 5 and 6. The two proofs (for the cases of BSP and autopartition) use recursion, too, and rely on simple partitioning algorithms on *convex sequences* and *cycles*. We discuss these concepts in detail in section 3.

2. Main theorem. First we introduce some notation. Fix a set L of disjoint line segments in the plane. We denote by $\mathrm{int}(C)$ and ∂C the interior and the boundary, respectively, of a planar set C. A *cell* is defined as a bounded closed convex region in the plane. We avoid considering unbounded convex regions by associating the root of every BSP to the convex hull $\mathrm{conv}(\bigcup L)$ of segments (instead of $\mathbb{R}^2$). Consequently, every node u of a BSP corresponds to a cell R_u.

For a cell C, let $L(C) = \{\ell \cap \mathrm{int}(C) : \ell \in L\} \setminus \{\emptyset\}$, that is, the set of fragments of line segments from L within the cell C. We use a simple observation throughout this paper: If there is a segment $\ell \in L(R_u)$ for some interior node u of the BSP such that ℓ connects two points on the boundary of the cell R_u, then we can split R_u along ℓ without creating any new cuts on segments. We apply such *free cuts* whenever possible. If a segment $\ell \in L$ is dissected into many pieces by consecutive cuts, we only have to care about two pieces, the two *endings* of ℓ, which are two disjoint line segments in two nonoverlapping regions of the current convex partition.

We may assume that no segment of $L(C)$ has two endpoints on the boundary of C, since otherwise a free cut could split C into two cells. We partition $L(C)$ into two disjoint subsets: Let $B(C)$ be the set of *boundary segments*, i.e., segments from $L(C)$ with exactly one endpoint on the boundary of C (and the other endpoint in $\mathrm{int}(C)$). Let $I(C)$ be the set of *interior segments*, i.e., segments from $L(C)$ which lie entirely in the interior of C.

Suppose without loss of generality (w.l.o.g.) that none of the segments of L is parallel to the x-axis of our coordinate system. Let $B^+(C) \subset B(C)$ (resp., $B^-(C) \subset B(C)$) be the set of all segments $\ell \in B(C)$ such that the extension of ℓ beyond the boundary ∂C is y-monotone increasing (resp., decreasing). Since the roles of $B^+(C)$ and $B^-(C)$ are symmetric, the claims we formulate below for $B^+(C)$ hold equally for $B^-(C)$, too.

The following lemma is the key to the proof of Theorem 1(i) and 1(ii). The proof of this lemma is postponed until the last two sections.

LEMMA 1. *Assume that we are given a nonempty set L of disjoint line segments in the plane with at most k distinct directions and a cell C.*

(i) *There exists a BSP P_C for $B^+(C)$ where every line segment of $B(C)$ is cut at most $3\lfloor \log_2 k \rfloor + 8$ times and every line segment of $I(C)$ is cut at most $6\lfloor \log_2 k \rfloor + 11$ times.*

(ii) *There exists a BSP P_C for $B^+(C)$ where every line segment of $B(C)$ is cut at most $4k + 4$ times and every line segment of $I(C)$ is cut at most $4k + 7$ times. Moreover, every region R_u corresponding to an internal node $u \in P_C$ is partitioned along a segment of $L(R_u)$.*

The last sentence of Lemma 1(ii) does not say that the BSP P_C is an autopartition for $B^+(C)$: Possibly P_C uses splitting lines spanned by segments of $L(C)$ which are actually not in $B^+(C)$. This constraint, however, will be used below to establish the existence of an autopartition for $L(C)$. A BSP P for $L(C)$ is now constructed by the following recursive algorithm.

Algorithm 1.

- *Put $i := 1$ and $\mathcal{R}_1 := \{\text{conv}(\bigcup L)\}$.*
- *While there is a $C \in \mathcal{R}_i$ such that $L(C)$ is nonempty, do*
  1. *If i is odd, then for every cell $C \in \mathcal{R}_i$ where $B^+(C)$ is nonempty, partition C applying Lemma 1 to $B^+(C)$.*
  2. *If i is even, then for every cell $C \in \mathcal{R}_i$ where $B^-(C)$ is nonempty, partition C applying* Lemma 1 *to $B^-(C)$.*
  3. *In every cell $C \in \mathcal{R}_i$ where $B(C)$ is empty but there is a segment $\ell \in I(C)$, dissect C along ℓ.*
  4. *Apply all possible free cuts in the resulting cells.*
  5. *Let $\mathcal{R}_{i+1}$ be the set of all resulting cells, and put $i := i + 1$.*

Proof of Theorem 1. Algorithm 1 performs a BSP for L. If every cell is dissected along a segment in the cell, then this BSP is an autopartition. From the point of view of one line segment $\ell \in L$, the algorithm appears as follows: ℓ is cut into pieces at some step i_ℓ. (There is the possibility of cutting along ℓ before it is cut otherwise. In this case ℓ is not cut at all by the procedure.) In step i_ℓ, ℓ may be cut several times, and its two endings fall into $B^+(D_1)$ and $B^-(D_2)$, where D_1 and D_2 are distinct cells of $\mathcal{R}_{i_\ell+1}$. Assume w.l.o.g. that i_ℓ is odd. In the even step $i_\ell + 1$, BSPs for $B^-(D_1)$ and $B^-(D_2)$ are called. In this step, both endings may also be cut several times. D_1 may be subdivided and the ending of the portion of ℓ within $B^+(D_1)$ belongs to some $B^+(E_1)$ for a $E_1 \subseteq D_1$, $E_1 \in \mathcal{R}_{i_\ell+2}$. In the odd step $i_\ell + 2$, a BSP for $B^+(E_1)$ is called, but ℓ may still be cut several times. Analogously, if i_ℓ is even, both endings may be cut at step $i_\ell + 1$, but only one of them can be cut in step $i_\ell + 2$. Thus, ℓ may be cut in at most three consecutive steps of Algorithm 1.

For part (i) of Theorem 1, we determine the maximal number of cuts during the "life cycle" of a segment ℓ from Lemma 1(i). In step i_ℓ, segment ℓ is cut at most $6\lfloor \log_2 k \rfloor + 11$ times. In step $i_\ell + 1$, either ending of the segment is cut at most $3\lfloor \log_2 k \rfloor + 8$ times. Finally in step $i_\ell + 2$, its one surviving ending might be cut at most $3\lfloor \log_2 k \rfloor + 8$ times. All in all, ℓ is cut at most $15\lfloor \log_2 k \rfloor + 35$ times during the algorithm.

For the proof of Theorem 1(ii), we use Lemma 1(ii). In step i_ℓ, segment ℓ is cut at most $4k + 7$ times. In step $i_\ell + 1$, either ending of the segment is cut at most $4k + 4$ times. Finally in step $i_\ell + 2$, its one surviving ending can be cut at most $4k + 4$ times. All in all, ℓ is cut at most $(4k + 7) + 3(4k + 4) = 16k + 19$ times during Algorithm 1. □

The constants in the upper bounds on the total number of cuts per segment can be slightly improved by a more careful analysis, namely, by applying the detailed

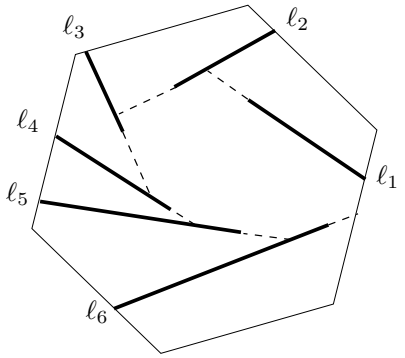

FIG. 1. *$P(\mathcal{S})$ for a convex sequence $\mathcal{S}$.*

versions of Lemma 1(i) and 1(ii) as they appear in sections 5 and 6.

3. Sequences, cycles, and convex cycles. In this section, we define a few simple BSP schemes using simple structures formed by boundary segments. These partition algorithms will serve as building blocks in the proofs of Lemma 1(i) and 1(ii) in the last two sections.

Let C be a cell and let L be a set of segments as above. For this section, consider a fixed set X, $X \subset B(C)$ of boundary segments. Recall that every segment $\ell \in X$ has one endpoint in $\mathrm{int}(C)$. Denote the other endpoint, $\ell \cap \partial C$, by $p(\ell)$. Extend ℓ towards the interior of C until it hits another segment of X or the boundary ∂C and denote the endpoint of the extension by $g(\ell)$. Notice that the extension of ℓ may cross segments of $L(C) \setminus X$ before hitting some other segment of X or ∂C; in other words, the function g depends on $X \subset B(C)$.

3.1. Sequences and cuts along sequences. We define a sequence as follows.

DEFINITION 1. *A* sequence *of X is a t-tuple $(\ell_1, \ell_2, \ldots, \ell_t)$, $t \in \mathbb{N}$, such that*
- *$\ell_1, \ell_2, \ldots, \ell_t \in X$,*
- *$g(\ell_i) \in \ell_{i+1}$ for $i = 1, 2, \ldots, t-1$, and*
- *$g(\ell_t) \in \partial C$.*

DEFINITION 2. *A sequence $(\ell_1, \ell_2, \ldots, \ell_t)$ is* convex *if the point $p(\ell_1)$ together with the points $g(\ell_i)$, $i = 1, 2, \ldots, t$, form a convex $(t+1)$-gon (see Figure 1).*

Consider a convex sequence $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$ in X. We obtain a BSP by recursively cutting along the segments of the sequence in reverse order starting from ℓ_t and proceeding to ℓ_1.

ALGORITHM 2 ($P(\mathcal{S})$).
- *Input: cell C, convex sequence $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$.*
- *For $j = 0, 1, 2, \ldots, t-1$, do*
  Partition every region D, $D \cap \ell_{t-j} \neq \emptyset$, along the line through ℓ_{t-j}.

PROPOSITION 2. *In $P(\mathcal{S})$, no segment of X is cut, and every segment of $L(C) \setminus X$ is cut at most twice.*

Proof. Since the segments of L are disjoint, the only portion of the partitioning lines $p(\ell_i)g(\ell_i)$, $i = t, t-1, \ldots, 1$, that may cut other segments is the extension of ℓ_i to $g(\ell_i)$. All these portions lie along sides of the convex polygon $p(\ell_1)g(\ell_1)g(\ell_2)\ldots g(\ell_t)$. A convex polygon crosses every line segment at most twice. ∎

Let $\mathcal{T}(P(\mathcal{S}))$ be the union of all the segments along which $P(\mathcal{S})$ made a dissection (i.e., the union of all extended segments $p(\ell_i)g(\ell_i)$, $i = 1, 2, \ldots, t$). Note that $\mathcal{T}(P(\mathcal{S}))$

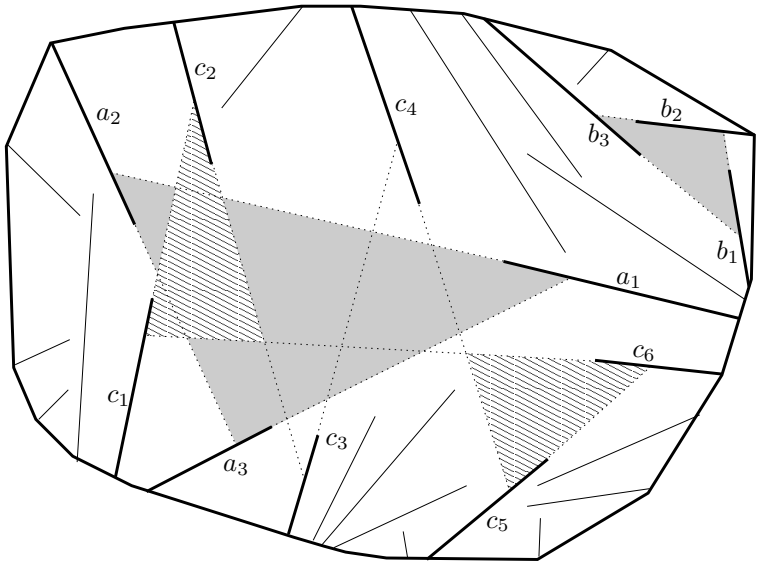

FIG. 2. *Three cycles* (a_1, a_2, a_3), (b_1, b_2, b_3), *and* $(c_1, c_2, c_3, c_4, c_5, c_6)$ *give rise to four convex cycles* (a_1, a_2, a_3), (b_1, b_2, b_3), (c_4, c_5, c_6), *and* (c_6, c_1, c_2). *Segments of cycles are depicted by bold lines. Segments of* $L(C) \setminus X$ *are not indicated.*

is a connected set.

3.2. Cycles and convex cycles.

DEFINITION 3. *A* cycle *of* X *is a* t*-tuple* $(\ell_1, \ell_2, \dots, \ell_t)$, $t \in \mathbb{N}$, *such that*

- $\ell_1, \ell_2, \dots, \ell_t \in X$,
- $g(\ell_i) \in \ell_{i+1}$ *for* $i = 1, 2, \dots, t-1$, *and*
- $g(\ell_t) \in \ell_1$.

Figure 2 exhibits three cycles. Every segment of X may appear in at most one cycle. The concept of *convex cycle*, defined below, is not a subclass of cycles: The extension of one segment in a convex cycle does not necessarily hit the next element of the cycle, but all segments are arranged along the sides of a convex polygon.

DEFINITION 4. *A* convex cycle *of* X *is a* t*-tuple* $(\ell_1, \ell_2, \dots, \ell_t)$ *such that*

- $\ell_1, \ell_2, \dots, \ell_t \in X$,
- $g(\ell_i) \in \ell_{i+1}$ *for* $i = 1, 2, \dots, t-1$,
- *the extension of* ℓ_t *hits the line through* ℓ_1 *at a point* $a \in C$ *but does not cross any segment of* X *until it reaches* a, *and*
- $g(\ell_1)g(\ell_2)\dots g(\ell_{t-1})a$ *forms a convex* t*-gon.*

In Figure 2, the cycles (a_1, a_2, a_3) and (b_1, b_2, b_3) are convex cycles. The third cycle $(c_1, c_2, c_3, c_4, c_5, c_6)$ is not a convex cycle but contains two convex cycles, (c_4, c_5, c_6) and (c_6, c_1, c_2), which are indicated by their striped interior convex regions.

PROPOSITION 3. *For any cycle* $(\ell_1, \ell_2, \dots, \ell_t)$, *there is* $q \in [1, t-2]$ *and* $r \in [q+2, t]$ *such that* $(\ell_q, \ell_{q+1}, \dots, \ell_r)$ *is a convex cycle.*

Proof. Consider the polygonal curve $\gamma = (p(\ell_1), g(\ell_1), g(\ell_2), \dots, g(\ell_t))$. If γ has no self-crossing, then $\mathcal{S}$ is a convex cycle.

Let $(p(\ell_1), g(\ell_1), g(\ell_2), \dots, g(\ell_{r-1}), w) \subset \gamma$ be the longest prefix curve without self-crossing. That is, w denotes the common point of two segments, say, $g(\ell_q)g(\ell_{q+1})$ and $g(\ell_{r-1})g(\ell_r)$, $q+1 < r-1$. We show that $(\ell_q, \ell_{q+1}, \dots, \ell_r)$ is a convex cycle.

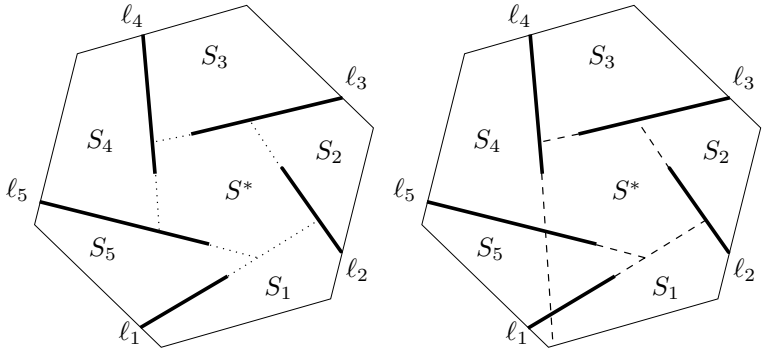

FIG. 3. *The notation on a convex cycle $\mathcal{S}$ (left) and $P^0(\mathcal{S}, 4)$ (right).*

$g(\ell_i) \in \ell_{i+1}$ for $i = q, q+1, \ldots, r-1$; the extension of ℓ_r hits the line through ℓ_q at point w; but it does not hit any segment of X before. Extend every segment ℓ_i for $i = 1, 2, \ldots, r-1$ to $g(\ell_i)$, and ℓ_r to w. We obtain a convex partition of C in which one face is $(g(\ell_q), g(\ell_{q+1}), \ldots, g(\ell_{r-1}), w)$; therefore it is a convex polygon. □

We observe here a useful property of set $B^+(C)$ with respect to cycles.

PROPOSITION 4. *$B^+(C)$ contains no cycle.*

Proof. Suppose, to the contrary, that $(\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$ is a convex cycle and, furthermore, $\ell_i \in B^+(C)$ for every $i = 1, 2, \ldots, t$. Let w be the vertex of the polygon $g(\ell_1)g(\ell_2)\ldots g(\ell_{t-1})a$ with the largest y-coordinate. Point w is the intersection of two lines through, say, ℓ_i and ℓ_{i+1}. Either the extension of ℓ_i or that of ℓ_{i+1} beyond the boundary ∂C is not y-monotone increasing, a contradiction. □

Consider a convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$ of X. Extend every ℓ_i for $i = 1, 2, \ldots, t-1$ to $g(\ell_i)$, and ℓ_t to a. The extended segments of S partition the cell C into $t+1$ convex regions $S^*, S_1, \ldots, S_t$. One of them, $S^* = g(\ell_1)g(\ell_2)\ldots g(\ell_{t-1})a$, lies completely in the interior of C (Figure 3, left).[1] Clearly, $\mathrm{int}(S^*)$ is disjoint from all segments of X. Every S_i, $i = 1, \ldots, t$, has a common boundary with C. We may choose the notation of S_i, $i = 1, 2, \ldots, t$, such that S_i is bounded by portions of the extension of segments ℓ_i and ℓ_{i+1}, and by ∂C.

3.3. Cuts along convex cycles. Consider a convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$. A BSP $P^0(\mathcal{S}, i)$, $i = 1, \ldots, t$, can be obtained in the following way (see Figure 3, right).

ALGORITHM 3 ($P^0(\mathcal{S}, i)$).

- *Input: cell C, index i, convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$.*
- *For $j = 0, 1, 2, \ldots, t-1$, do*
  Partition every region D, $D \cap \ell_{i-j} \neq \emptyset$, along the line through ℓ_{i-j}.

Denote by $\pi(\mathcal{S}, i)$ the set of regions S_i, $i = 1, 2, \ldots, t$, pierced by the line through $\ell_i \in \mathcal{S}$, and let $\bar{\pi}(\mathcal{S}, i) = \{S_1, S_2, \ldots, S_t\} \setminus \pi(\mathcal{S}, i)$. For instance, in Figure 3, $\pi(\mathcal{S}, 4) = \{S_1, S_5\}$.

Remark 1. For any convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$ and any index i, $1 \leq i \leq t$, we have $S_{i-1} \in \bar{\pi}(\mathcal{S}, i)$ and $S_i \in \bar{\pi}(\mathcal{S}, i)$.

PROPOSITION 5. *The regions of $\bar{\pi}(\mathcal{S}, i)$ are elements of the convex subdivision $\mathcal{R}(P^0(\mathcal{S}, i))$.*

[1] Here and in what follows, arithmetic on the indices of $\ell_1, \ell_2, \ldots, \ell_t$ and $S_1, S_2, \ldots, S_t$ is meant mod t, that is, $t+1$ stands for 1.

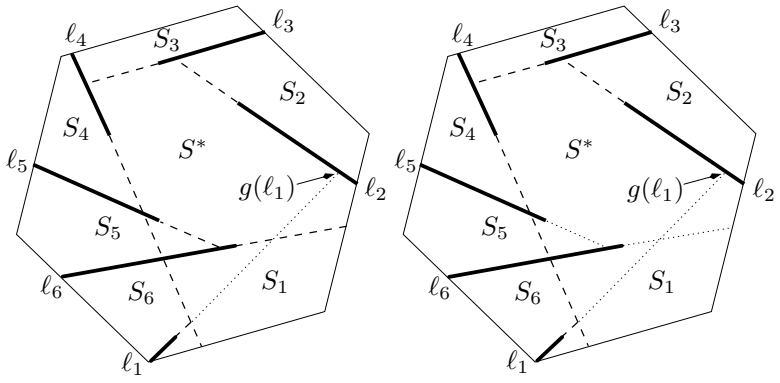

FIG. 4. $P^0(\mathcal{S}, 4)$ *(left) and* $P^1(\mathcal{S}, 4)$ *(right). Dissection lines are dashed.*

Proof. Every region S_j, $j = 1, 2, \ldots, t$, is determined by the cuts along ℓ_{j+1} and along ℓ_j to $g(\ell_j)$. Every segment ℓ_j of $\mathcal{S}$, except for ℓ_i, is extended to $g(\ell_j)$ only. If $S_j \in \bar{\pi}(\mathcal{S}, i)$, then the partitioning lines cut S_j out along its boundaries. □

PROPOSITION 6. *In the BSP* $P^0(\mathcal{S}, i)$*,*

- *every segment of the convex cycle* $\mathcal{S}$ *is cut at most once,*
- *no segment of* X *in a region of* $\pi(\mathcal{S}, i)$ *is cut,*
- *every segment of* X *in a region of* $\bar{\pi}(\mathcal{S}, i)$ *is cut at most twice, and*
- *every segment of* $L(C) \setminus X$ *is cut at most four times.*

Proof. A segment in the cycle $\mathcal{S}$ can only be cut by the line through ℓ_i. By Proposition 5, a segment lying in a region of $\pi(\mathcal{S}, i)$ cannot be cut. A segment entirely in a region of $\bar{\pi}(\mathcal{S}, i)$ can be cut by the line through ℓ_i. It can also be cut by the line through ℓ_t: If the line through ℓ_i separates ℓ_1 and $g(\ell_1)$, then the dissection along ℓ_t beyond the point a may cut again into the region S_1 (see, e.g., Figure 4, left). A segment $\ell \in L(C) \setminus X$ may be cut by the lines through ℓ_i and ℓ_t and by other dissecting lines located along the convex polygon S^*. □

In Algorithm 6 in section 6, we wish to have at most one cut on segments of X within the regions of $\bar{\pi}(\mathcal{S}, i)$; therefore, we need a slightly modified version of $P^0(\mathcal{S}, i)$, as follows.

ALGORITHM 4 ($P^1(\mathcal{S}, i)$).

- *Input: cell* C*, index* i*, convex cycle* $\mathcal{S} = (\ell_1, \ell_2, \ell_3, \ldots, \ell_t)$ *such that the line through* ℓ_i *does not cross the segment* ℓ_1 *but crosses the extended segment* $p(\ell_1)g(\ell_1)$*.*
- *For* $j = 0, 1, 2, \ldots, i-1$*, do*
  Partition every region D*,* $D \cap \ell_{i-j} \neq \emptyset$*, along the line through* ℓ_{i-j}*.*

The line through ℓ_i intersects the segments $\ell_{i+1}, \ell_{i+2}, \ldots, \ell_t$, because $p(\ell_{i+1})$, $p(\ell_{i+2}), \ldots, p(\ell_t)$, and $p(\ell_1)$ are all on the same side of ℓ_i. Therefore the portions of these segments between ∂C and the line through ℓ_i give rise to free cuts once the BSP $P^1(\mathcal{S}, i)$ is completed.

The two main differences between $P^0(\mathcal{S}, i)$ and $P^1(\mathcal{S}, i)$ are that (1) $P^0(\mathcal{S}, i)$ dissects along all segments of S while $P^1(\mathcal{S}, i)$ does not dissect along $\ell_{i+1}, \ell_{i+2}, \ldots, \ell_t$; (2) $P^0(\mathcal{S}, i)$ cuts segments within a region of $\bar{\pi}(\mathcal{S}, i)$ at most twice, but $P^1(\mathcal{S}, i)$ cuts them at most once.

PROPOSITION 7. *In the BSP* $P^1(\mathcal{S}, i)$*,*

- *every segment of the convex cycle* $\mathcal{S}$ *is cut at most once,*

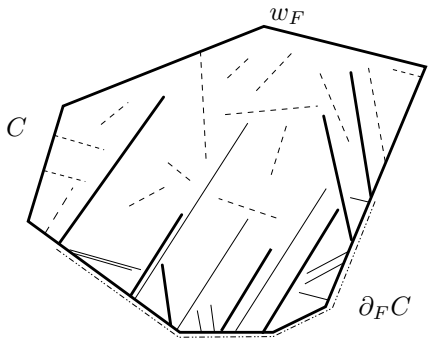

FIG. 5. *Segments of F are bold, segments of F^* are thin, and segments of $L(C) \setminus F^*$ are dashed.*

- *no segment of X in a region of $\pi(\mathcal{S}, i)$ is cut,*
- *every segment of X in a region of $\bar{\pi}(\mathcal{S}, i)$ is cut at most once, and*
- *every segment of $L(C) \setminus X$ is cut at most three times.*

4. More preparations. In sections 5 and 6, we describe two binary space partitioning algorithms for $B^+(C)$ to prove Lemma 1(i) and 1(ii). In intermediate steps of the partitionings in a subcell $D \subset C$, the set $B^+(D)$ may contain strictly more elements than $F = \{\ell \cap D : \ell \in B^+(C)\} \setminus \{\emptyset\}$ (i.e., the set of endings of segments of $B^+(C)$ in D): Although $F \subseteq B^+(D)$ holds, the endings of interior segments of C may also be in $B^+(D)$. In the algorithms below, we wish to treat endings of segments $I(C)$ similarly to segments of $I(D)$ up to a certain step, and later we wish to treat them as segments $B(D)$. We determine how to handle segments of $B(D) \setminus F$ by the set F^* defined below.

For any $F \subset B^+(C)$, we define F^* as follows. Let w_F be the vertex of C with the largest y-coordinate. Now let $\partial_F C \subset \partial C$ be the shortest polygonal path along the boundary ∂C of C containing all endpoints of F on ∂C, but not containing w_F. Let F^* be the set of segments in $B(C) \setminus F$ which have one endpoint in $\partial_F C$ (and the other endpoint in $\mathrm{int}(C)$). (See Figure 5.)

PROPOSITION 8. *Given $F \subset B^+(C)$, if $B(C) \setminus F^*$ contains no convex cycle, then there is a convex sequence $\mathcal{S} = (\ell_1, \ell_2, \dots, \ell_t)$, $t \in \mathbb{N}$, of $B(C) \setminus F^*$ such that $p(\ell_1) \in \partial C \setminus \partial_F C$ or $g(\ell_t) \in \partial C \setminus \partial_F C$.*

Proof. If there is a segment $\ell \in F$ such that $g(\ell)$ is in $\partial C \setminus \partial_F C$, then let $\mathcal{S} = (\ell)$. Assume that $g(\ell) \notin \partial C \setminus \partial_F C$ for any $\ell \in F$. Let $X = B(C) \setminus F^*$.

Let $p(r_1)$ and $p(s_1)$ be the first and last points of the curve $\partial_F C$ (with possibly $p(r_1) = p(s_1)$ if $|F| = 1$). Suppose w.l.o.g. that the y-coordinate of $p(s_1)$ is greater than or equal to that of $p(r_1)$. Consider the sequence $\mathcal{S} = (s_1, s_2, \dots, s_t)$ starting with s_1. Notice that if $s_i \in F$ for the indices $i = 1, 2, \dots, j$, then the y-coordinates of $p(s_1), g(s_1), g(s_2), \dots, g(s_j)$ are strictly increasing. If $g(s_j)$ is on the boundary of C (i.e., $t = j$), then it is in $\partial C \setminus \partial_F C$ by the choice of s_1. Therefore, the sequence starting with s_1 must contain a segment $s_q \in X \setminus F$, $j < q \le t$. Let s_q be the last segment of $\mathcal{S}$ from the set $X \setminus F$. Finally let $t' = t - q + 1$ and let $\mathcal{S}'$ be the post-fix sequence $(s_q, s_{q+1}, \dots, s_t)$ of $\mathcal{S}$.

We know that $p(s_q) \in \partial C \setminus \partial_F C$; now we show that $\mathcal{S}'$ is convex. Denote the elements of $\mathcal{S}'$ by $(\ell'_1, \ell'_2, \dots, \ell'_{t'})$. Every sequence of one or two segments is convex, so assume that $t' \ge 3$. For every segment $\ell \in B(C)$, we distinguish a left and a right side such that the closed curve on the boundary of C oriented in counterclockwise order

traverses ℓ from left to right. We may suppose w.l.o.g. that the extension of ℓ'_1 hits the left side of ℓ'_2. If the extension of every ℓ'_i, $i = 2, 3, \ldots, t'-1$, hits the left side of ℓ'_{i+1}, then S' is convex. Suppose, to the contrary, that $j \in \{2, 3, \ldots, t'-1\}$ is the first index such that ℓ'_j hits the right side of ℓ'_{j+1}. The polygonal curve $p(\ell'_j)g(\ell'_j)p(\ell'_{j+1})$ dissects C into two parts: C_1 and C_2. One part, say C_1, contains $\ell'_1 \in X \setminus F$ and all of the segments $\ell'_1, \ell'_2, \ldots, \ell'_{j-1}$, because X contains no convex cycle. Since both ℓ'_j and ℓ'_{j+1} are in F and $g(\ell'_{t'})$ lies in $\partial C_2 \cap \partial C$, the common boundary of C and C_1 belongs to $\partial_F C$. Therefore $p(\ell'_1) \in \partial_F C$, which in turn implies that ℓ'_1 is in F, a contradiction. □

PROPOSITION 9. *Given a cell C, a set of segments L, and a nonempty set $F \subset B^+(C)$, at least one of the following three statements holds.*

(a) *There is a convex sequence $\mathcal{S} = (\ell_1, \ell_2, \ldots, \ell_t)$, $t \in \mathbb{N}$, in $B(C) \setminus F^*$ such that $p(\ell_1) \in \partial C \setminus \partial_F C$ or $g(\ell_t) \in \partial C \setminus \partial_F C$.*

(b) *There is a convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ldots, \ell_t)$, $t \in \mathbb{N}$, in $B(C) \setminus F^*$, and there is an index i, $0 \le i \le t$, such that F has no element in regions of $\pi(\mathcal{S}, i)$.*

(c) *There is a convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ldots, \ell_t)$, $t \in \mathbb{N}$, in $B(C) \setminus F^*$ where $\ell_i, \ell_{i+1}, \ldots, \ell_j \in F$, $\ell_{j+1}, \ell_{j+2}, \ldots, \ell_{i-1} \notin F$, and the supporting line of ℓ_j intersects $p(\ell_{i-1})g(\ell_{i-1})$.*

Proof. If X contains no convex cycle, then (a) holds by Proposition 8. Suppose that X contains a convex cycle $\mathcal{S} = (\ell_1, \ell_2, \ldots, \ell_t)$.

If there is an index i such that every segment of F is either part of the cycle $\mathcal{S}$ or within one of two regions S_i and S_{i+1}, then (b) holds by Remark 1. Assume that segments of F are in at least three consecutive regions $S_{i-1}, S_i, S_{i+1}, \ldots, S_j$, where $j \neq i-1, i$. Consequently, $\ell_i, \ell_{i+1}, \ldots, \ell_j \in F$ and $\ell_{j+1}, \ell_{j+2}, \ldots, \ell_{i-1} \notin F$. Now, if the supporting line of ℓ_j does not intersect $p(\ell_{i-1})g(\ell_{i-1})$, then $\pi(\mathcal{S}, j) \subset \{S_{j+1}, S_{j+2}, \ldots, S_{i-2}\}$. Thus F has no element in regions of $\pi(\mathcal{S}, j)$ and (b) holds. Otherwise (c) holds. □

Proposition 9 states that at least one of (a), (b), and (c) holds, but it does not provide us with the convex sequence or convex cycle $\mathcal{S}$. It is easy to find an $\mathcal{S}$ by shooting a ray from an initial segment of X and iterating ray shooting queries until we hit the boundary of the cell or hit a previous (extended) segment. In the latter case, we identify a convex cycle, which necessarily satisfies (a) or (b). An algorithm finding any one convex sequence or cycle $\mathcal{S}$ may require a linear number of ray shooting queries among the segments of X, even if $\mathcal{S}$ consists of a small number of segments. Here, we do not elaborate on how to find an appropriate sequence or cycle $\mathcal{S}$, since in the main partition algorithms (Algorithms 5 and 6 below) we need to find an appropriate $\mathcal{S}$ possibly $\Omega(n)$ times, and we refer to a data structure appropriate for that many ray shooting queries at the end of section 5.

5. BSP for boundary segments. We demonstrate Lemma 1(i) in the following refined formulation (Lemma 10), which is necessary for the induction step in our proof.

DEFINITION 5. *We say that the directions of a subset of segments $F \subset B^+(C)$ are* consecutive *if the directions are consecutive in the linear order determined by the minimal angle α, $0 < \alpha < \pi$, made with the x-axis. (Recall that none of the segments of L are horizontal.)*

LEMMA 10. *Let L and C be as in Lemma 1. Consider a nonempty set $F \subset B^+(C)$ such that the directions in F belong to f consecutive directions. There is a BSP for F such that*

1. *every* $\ell \in B(C) \setminus F^*$ *is cut at most* $3\lfloor \log_2 f \rfloor + 3$ *times,*
2. *every* $\ell \in F^*$ *is cut at most* $3\lfloor \log_2 f \rfloor + 8$ *times,*
3. *every* $\ell \in I(C)$ *is cut at most* $6\lfloor \log_2 f \rfloor + 11$ *times.*

We prove Lemma 10 by giving an explicit partition algorithm (Algorithm 5) and showing that the number of cuts during that algorithm is within the bounds of Lemma 10. Throughout the remainder of this paper, we use the shorthand notation $F \cap D = \{\ell \cap \operatorname{int}(D) : \ell \in F\} \setminus \{\emptyset\}$ for the portions of the segments of $F \subset B^+(C)$ in a subcell $D \subset C$.

ALGORITHM 5. *Input:* $[C, L(C), F]$ *where* C *is a cell,* L *is a set of segments, and* $F \subset B^+(C)$, $F \neq \emptyset$.

(1) *Let* $X := B(C) \setminus F^*$.
(2) *Find a convex sequence or a convex cycle* $\mathcal{S}$ *as in Proposition* 9.
(3) *In the three cases of Proposition* 9 *proceed as follows:*
   (a) *Apply* $P(\mathcal{S})$ *for the convex sequence* $\mathcal{S}$.
   (b) *Apply* $P^0(\mathcal{S}, i)$ *for the convex cycle* $\mathcal{S}$.
   (c) *If the segments of* F *crossed by* $p(\ell_i)p(\ell_{i-1})$ *belong to at most* $\lfloor f/2 \rfloor$ *consecutive directions,*
      – *then dissect* C *along* $p(\ell_i)p(\ell_{i-1})$ *and apply* $P^0(\mathcal{S}, j)$;
      – *else dissect* C *along* $p(\ell_j)p(\ell_{i-1})$ *and apply* $P^0(\mathcal{S}, j-1)$.
(4) *Apply all possible free cuts.*
(5) *Call recursively Algorithm* 5 *for* $[D, L(D), F \cap D]$ *in every resulting cell* D *where* $F \cap D$ *is nonempty.*

In step (3)(c), the line segment $p(\ell_i)p(\ell_{i-1})$ dissects the region S_{i-1} and the line segment $p(\ell_j)p(\ell_{i-1})$ dissects the regions $S_j, S_{j+1}, \ldots, S_{i-2}$. The line through ℓ_j separates $p(\ell_{i-1})$ from $g(\ell_{i-1})$ and from the region S^*. This implies that the segment $p(\ell_j)p(\ell_{i-1})$ does not intersect S^* but crosses all the segments $\ell_{j+1}, \ell_{j+2}, \ldots, \ell_{i-1}$. Therefore $\mathcal{S}$ remains a convex cycle after a dissection along either $p(\ell_i)p(\ell_{i-1})$ or $p(\ell_j)p(\ell_{i-1})$, so $P^0(\mathcal{S}, j)$ and $P^0(\mathcal{S}, i)$ are defined.

Proof of Lemma 10. We proceed by induction on $|L(C)|$. Our lemma clearly holds for $|L(C)| = 1$. Suppose that it holds for every $|L'(C')| < |L(C)|$. Put $X = B(C) \setminus F^*$. We show that Algorithm 5 provides a required BSP.

Notice that segments are cut only in step (3) of Algorithm 5. The free cuts in step (4) do not increase the number of cuts on segments. We use one common argument for cases (a) and (b); while for case (c) we use another argument. In the first two cases, the partition $P(\mathcal{S})$ (and, resp., $P^0(\mathcal{S}, i)$) has, as we show below for both cases, the following two properties:

(α) If a segment $\ell \in X$ is cut, then it is cut at most twice and is either part of $\mathcal{S}$ or its ending is in a subcell D of $\mathcal{R}(P(\mathcal{S}))$ (or, resp., $\mathcal{R}(P^0(\mathcal{S}, i))$) in which $F \cap D$ is empty.
(β) If a segment $\ell \in I(C) \cup F^*$ is cut, then it is cut at most four times and its ending(s) are in sets $B(D) \setminus (F \cap D)^*$ in the corresponding subcell(s) D of $\mathcal{R}(P(\mathcal{S}))$ (or, resp., $\mathcal{R}(P^0(\mathcal{S}, i))$).

We prove properties (α) and (β) below, but let us first show that they establish our lemma: If a segment of X is cut, then it is cut at most twice and its ending is cut no more in the induction step by (α). If a segment of F^* is cut, then it is cut at most four times and its ending will be cut, by (β) and by induction, at most $3\lfloor \log_2 f \rfloor + 3$ more times, which totals to at most $3\lfloor \log_2 f \rfloor + 7$ cuts. If a segment of $I(C)$ is cut, then it is cut at most four times and either of its endings will be cut, by (β) and by induction, at most $3\lfloor \log_2 f \rfloor + 3$ more times, which totals to at most $6\lfloor \log_2 f \rfloor + 10$

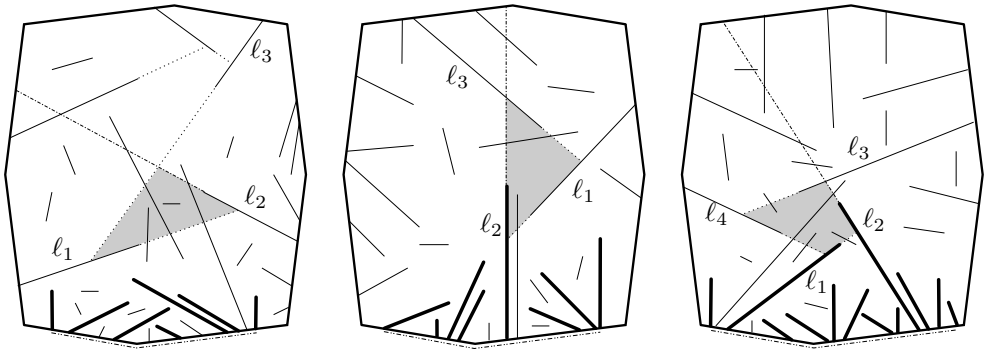

FIG. 6. *Case* (b) *in Algorithm* 5 *with* $i = 2$. *Segments of* F *are bold.*

cuts.

Case (a). By Proposition 2, no segment of $X = B(C) \setminus F^*$ is cut, so (α) follows. We need to prove (β). (α) implies that in any subcell $D \in \mathcal{R}(P(\mathcal{S}))$ the common point of an $\ell \in F \cap D$ and ∂D is necessarily on $\partial_F C$. Furthermore, a common point of an $\ell \in I(C) \cup F^*$ cut by $P(\mathcal{S})$ and ∂D is on $\mathcal{T}(P(\mathcal{S}))$. Therefore to prove (β), it is enough to show that $\partial_F C \cap \partial D$ is a connected curve for every subcell $D \in \mathcal{R}(P(\mathcal{S}))$. But $\partial_F C \cap \partial D$ is necessarily connected, since $\mathcal{T}(P(\mathcal{S}))$ is connected and contains at least one point (i.e., $p(\ell_1)$ or $g(\ell_t)$) from $\partial C \setminus \partial_F C$.

Case (b). Every segment of F either is part of the convex cycle $\mathcal{S}$ or lies in a cell S_j, $S_j \in \bar{\pi}(\mathcal{S}, i)$, of $\mathcal{R}(P^0(\mathcal{S}, i))$. Therefore, by Propositions 5 and 6, a segment of F can be cut (at most once) only if it is in the cycle $\mathcal{S}$. By Proposition 5, if any $\ell' \in B(C) \setminus (F \cup F^*)$ is cut, then its ending must lie in some region S_j, $j \in \pi(\mathcal{S}, I)$. This proves (α). Finally, as in case (a), (β) follows from the fact that $\mathcal{T}(P^0(\mathcal{S}, i))$ is connected and, by Proposition 4, contains at least one point from $\partial C \setminus \partial_F C$. (See Figure 6 for illustrations.)

Case (c). Observe that the sets of directions of segments of F which cross the segments $p(\ell_i)p(\ell_{i-1})$ and $p(\ell_j)p(\ell_{i-1})$, respectively, are disjoint: Segments of $B^+(C)$ cannot cross both $p(\ell_i)p(\ell_{i-1})$ and $p(\ell_j)p(\ell_{i-1})$. Indeed, the directions[2] of rays along segments of X crossing both $p(\ell_i)p(\ell_{i-1})$ and $p(\ell_j)p(\ell_{i-1})$ are between the directions of $\overrightarrow{p(\ell_{i-1})p(\ell_i)}$ and $\overrightarrow{p(\ell_{i-1})p(\ell_j)}$. The opposite of these directions lies between $\overrightarrow{p(\ell_i)p(\ell_{i-1})}$ and $\overrightarrow{p(\ell_j)p(\ell_{i-1})}$, which is a proper subset of the directions between $\overrightarrow{\ell_i}$ and $\overrightarrow{\ell_j}$. Recall that the directions between the directions of $\overrightarrow{\ell_i}$ and $\overrightarrow{\ell_j}$ are among the consecutive directions of $F \subset B^+(C)$. Therefore segments of X with opposite directions must belong to $B^-(C)$. (See Figure 7 for an illustration.)

In step (3)(c) of Algorithm 5, if the segments of F crossed by $p(\ell_i)p(\ell_{i-1})$ belong to at most $\lfloor f/2 \rfloor$ consecutive directions, then C is dissected along $p(\ell_i)p(\ell_{i-1})$; if the segments of F crossed by $p(\ell_j)p(\ell_{i-1})$ belong to at most $\lfloor f/2 \rfloor$ consecutive directions, then C is dissected along $p(\ell_j)p(\ell_{i-1})$. Suppose w.l.o.g. that the first case is called and our algorithm dissects C along $p(\ell_i)p(\ell_{i-1})$ and applies $P^0(\mathcal{S}, j)$. Let $\mathcal{R}(Q)$ denote the set of the resulting subcells. Instead of properties (α) and (β), we have the following two properties:

(γ) If a segment of X is cut, then it is cut at most three times and either is part

[2]The direction $\alpha \in [0°, 180°)$ of a line corresponds to two opposite directions, α and $\alpha + 180°$, of rays.

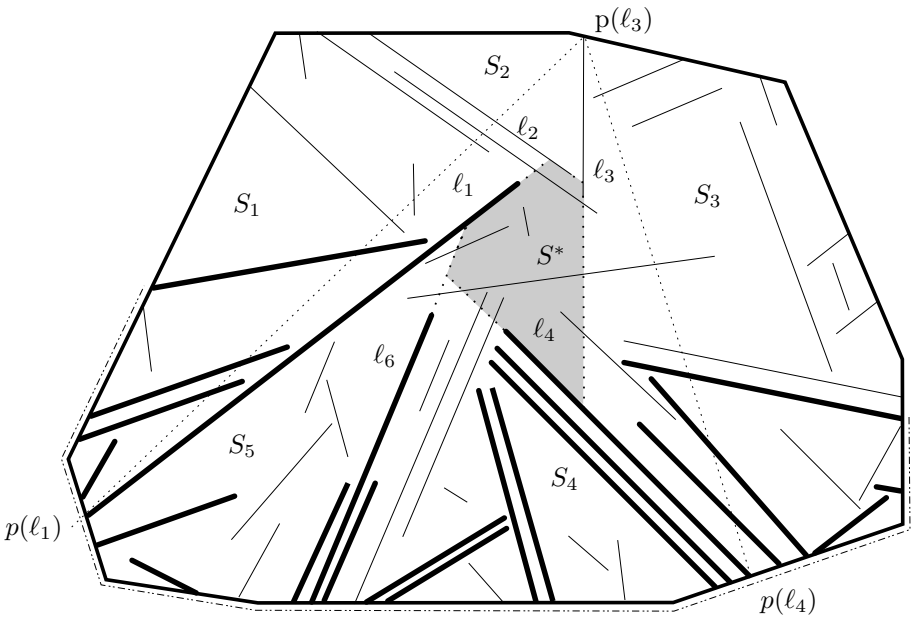

FIG. 7. *Example for case* (c), *with a convex cycle highlighted and with* $i = 4$ *and* $j = 1$.

of $\mathcal{S}$ or its ending is in a subcell $D \in \mathcal{R}(Q)$ in which $F \cap D$ belongs to at most $\lfloor f/2 \rfloor$ consecutive directions.

(δ) A segment of $F^* \cup I(C)$ can be cut in two possible ways:
– Either it is cut at most five times and each of its endings is in some $B(D) \setminus (F \cap D)^*$, $D \in \mathcal{R}(Q)$; or
– it is cut at most three times and one of its ending is in $(F \cap D)^*$, $D \in \mathcal{R}(Q)$, where segments of $F \cap D$ belong to at most $\lfloor f/2 \rfloor$ consecutive directions, and a second ending (for segments of $I(C)$) is in $B(D') \setminus (F \cap D')^*$, $D' \in \mathcal{R}(Q)$.

Let us first show that (γ) and (δ) establish our lemma: If a segment of X is cut, then it is cut at most three times. If $f > 1$, then its ending is further cut by induction at most $3\lfloor \log_2(f/2) \rfloor + 3$ more times, which totals to $3\lfloor \log_2 f \rfloor + 3$ cuts. If a segment of F^* is cut, then either it is cut at most five times and its ending is cut by induction at most $3\lfloor \log_2 f \rfloor + 3$ more times (this totals to $3\lfloor \log_2 f \rfloor + 8$ cuts) or it is cut at most three times and its ending is cut by induction at most $3\lfloor \log_2(f/2) \rfloor + 8$ more times (this totals to $3\lfloor \log_2 f \rfloor + 8$ cuts). If a segment of $I(C)$ is cut, then either it is cut at most five times and both its endings are cut at most $3\lfloor \log_2 f \rfloor + 3$ more times (this totals to $6\lfloor \log_2 f \rfloor + 11$ cuts) or it is cut at most three times and one ending is cut at most $3\lfloor \log_2 f \rfloor + 3$ more times and the other is cut at most $3\lfloor \log_2(f/2) \rfloor + 8$ times (this totals to $6\lfloor \log_2 f \rfloor + 11$ cuts, too).

Now we show (γ). Elements of X can be cut once by $p(\ell_{i-1})p(\ell_i)$ and at most twice by $P(\mathcal{S}, j)$. In particular, every segment of the convex cycle $\mathcal{S}$ can be cut at most twice only, and no segment ending remains. If a segment of $X \setminus \mathcal{S}$ is cut by $p(\ell_{i-1})p(\ell_i)$, then its ending is necessarily in a cell $D \in \mathcal{R}(Q)$ where all segments of $F \cap D$ are cut by $p(\ell_{i-1})p(\ell_i)$; therefore $F \cap D$ belongs to at most $\lfloor f/2 \rfloor$ consecutive directions. According to Proposition 6, $P^0(\mathcal{S}, j)$ can further dissect segments of X which lie in regions of $\pi(\mathcal{S}, j)$. Since only $S_{i-1} \in \pi(\mathcal{S}, j)$ contains segments of F, the BSP $P^0(\mathcal{S}, j)$ can dissect segments of X already cut by $p(\ell_{i-1})p(\ell_i)$. (Similarly if $P^0(\mathcal{S}, j-1)$ is

applied, we may assure that $g(\ell_{j-1}) \in p(\ell_{i-1})p(\ell_j)$; hence the line through ℓ_{j-1} cuts segments of F whose directions belong to $\lfloor f/2 \rfloor$ consecutive directions.)

For (δ), notice that an ending of a segment $\ell \in F^* \cup I(C)$ is in $(F \cap D)^*$ for some subcell $D \in \mathcal{R}(Q)$ only if its endpoint on ∂D is between two endpoints of two endings from $F \cap D$ which are cut by $p(\ell_{i-1})p(\ell_i)$ or by $P^0(\mathcal{S}, j)$. If this happens, then ℓ is cut at most once by $p(\ell_{i-1})p(\ell_i)$ and at most twice more only by $P^0(\mathcal{S}, j)$, and the second ending of an $\ell \in I(C)$ belongs to $B(E) \setminus ((F \cap E) \cup (F \cap E)^*)$ for an $E \in \mathcal{R}(Q)$. Otherwise $\ell \in F^* \cup I(C)$ can be cut five times: once by $p(\ell_{i-1})p(\ell_i)$ and four times by $P^0(\mathcal{S}, j)$, but the ending(s) do not belong to $(F \cap D)^*$ in the corresponding subcell(s) $D \in \mathcal{R}(Q)$. □

Our proof can easily be turned into an $O(n^2)$ time and $O(n^2)$ space algorithm. We expect that this complexity is not optimal. Our algorithm takes $O(n^2)$ time because finding a convex cycle $\mathcal{S} \subset X$ can use up to a linear number of ray shooting queries (even if $\mathcal{S}$ consists of a constant number of segments), and we cannot use the information from this computation in the induction steps, as many new elements are inserted into X for the subproblems. Each time a new segment ending ℓ is inserted into X, not only do we need to compute the segment its extension hits, but we also need to make updates on every segment of X whose extension now hits ℓ with respect to X. Computing the dissections alone could be done in $O(n^{4/3+2\varepsilon}k^{2/3+\varepsilon})$ time by ray shooting techniques of, e.g., Agarwal [1] and Agarwal and Matoušek [3]. It can offer a space-time trade-off, but the updates on the structure of X would require $O(n^3)$ queries.

Once we allow for an $O(n^2)$ time and space algorithm, the full arrangement of the n lines through the line segments is at hand. It can be computed in $O(n^2)$ time and space by the incremental algorithm of Chazelle, Guibas, and Lee [5] (see also [16, 15]). This data structure allows us to insert new lines (in particular, new elements of X and the dissecting lines which are not supporting lines of any segment) into the arrangement in linear time.

Using the notation introduced in the beginning of this section, we show the life cycle of a segment $\ell \in L$, as follows. A segment can, at first, be in $I(C)$. If ℓ is cut into pieces, then the two endings are in $B^+(C_1)$ and $B^-(C_2)$ (either in some set F^* or in $B(C) \setminus F^*$). Next, the two endings move independently into X and eventually to F. We can keep track of these events for each segment ending, and there is only a constant number of events for each segment.

We first compute the arrangement of the n supporting lines of the segments of L in $O(n^2)$ time. Then we compute the convex hull $\text{conv}(\bigcup L)$, the cell corresponding to the root of our BSP tree. We build a BSP by our Algorithm 1 while maintaining the sets $L(C)$, $I(C)$, $B^+(C)$, and $B^-(C)$ for each cell corresponding to a leaf of our current BSP tree. The total cost of maintaining $L(C)$ for all leaves is $O(n^2)$, since the cell containing a segment endpoint can be dissected at most linearly many times. In each round of Algorithm 1, we need to recompute X and the function $g(\ell)$ for every segment $\ell \in X$: For each segment ending we can find the hitting point of its extension in linear time using the full arrangement. A segment ending can occur in X in at most two more rounds of Algorithm 1. In the arrangement of the segments, we label each edge maintaining the information whether it is

- a portion of a segment in $L(C)$, and in particular belongs to $I(C)$, $B^+(C)$, or $B^-(C)$;
- part of a segment ending in F, F^*, or X;
- part of the boundary of a cell C; and

– part of an extension of a segment of X to another segment of X or to ∂C.

Thus we can maintain a pointer from each segment ending in X to the point hit by its extension at another element of X or at ∂C. When a segment of $\ell \in I(C)$ is cut and its ending is inserted into X in step (1) of Algorithm 5, we can update the information on the extensions of elements of X in linear time: at each intersection of ℓ with an extension of a previous segment $\ell' \in X$, we simply update the pointer of ℓ' to ℓ and delete the labels of the edges on the line through ℓ' beyond the intersection with ℓ. The total time complexity of maintaining hitting relations within X amounts to $O(n^2)$. Relying on these pointers, we find either a convex cycle or a convex sequence complying with one of the three cases of Proposition 9 in linear time (that is, we can find a sequence or cycle $\mathcal{S}_C$ in each cell $C \in \mathcal{R}_i$ in $O(|L(C)|)$ time, which totals to $O(n)$ time for all cells of the current partition). In either case, we dissect a cell C into subcells along the convex cycle or convex sequence and eliminate at least one segment ending from X. The total time spent on searching cycles is therefore $O(n^2)$, too.

The space complexity can be reduced to $O(n)$ by allowing $O(n^2 \log n)$ time. For each segment $\ell \in L$ we maintain the information if it is in the interior of any cell of the current partition or if ℓ is already dissected and its two endings belong to $B^+(C_1)$ and $B^-(C_2)$ and the middle of ℓ is the boundary of some cells of the current partition. Once a segment ℓ is dissected, we also maintain the two extensions of the endings to another segment of X or to the boundary of a cell. This involves a ray shooting query for the first time. We invest $O(n \log n)$ time into every ray shooting query: We spend $O(n)$ time on computing the intersection with all other supporting lines of segments and cutting lines and $O(n \log n)$ time on sorting the intersections. When a segment ending ℓ is inserted into X, we can update the information on the extensions of other segments of X (which might hit ℓ from now on) in $O(n \log n)$ time, too, based on the sorted list of intersections of ℓ with extensions of other segments in X. Similarly, we use $O(n \log n)$ time for a dissection along a segment. As each segment ending implies one ray shooting, one insertion into X, and one cutting, the total time amounts to $O(n^2 \log n)$.

6. Autopartition for boundary segments. In this section , we formulate and prove a stronger version of Lemma 1(ii). The proof follows the scheme of section 5.

LEMMA 11. *Let C and L be as in Lemma 1. Consider a nonempty set $F \subset B^+(C)$ such that the directions in F belong to f consecutive directions. There is a BSP P for F such that*

1. *every segment of* F *is cut at most* $2f$ *times,*
2. *every segment of* F^* *is cut at most* $4f+4$ *times,*
3. *every segment of* $I(C)$ *is cut at most* $4f+7$ *times,*
4. *every segment of* $B(C) \setminus (F \cup F^*)$ *is cut at most once.*
5. *In particular, if an ending of a segment $\ell \in F^*$ or $\ell \in I(C)$ is in a common subcell with an ending of segment of $B(C) \setminus (F \cup F^*)$, then ℓ is cut at most 5 or 7 times, respectively.*
6. *Every region corresponding to an internal node $v \in P$ is dissected along a segment of $L(R_v)$.*

We prove Lemma 11 by giving an explicit partition algorithm (Algorithm 6), which is a modified version of our Algorithm 5. Specifically, Algorithm 6 has new elements only in step (3)(c). The proof of Lemma 11 is based on the same case distinction as the proof of Lemma 10. The only difference is in the argument for case (c), where we are bound to use dissections along segments of $L(C)$. For the proof of Lemma 10, we applied induction to sets $F \cap D$ in the subcells of C. When segments

of $F \cap D$ were cut in step (3)(c), we ensured that their endings belonged to at most $\lfloor f/2 \rfloor$ consecutive directions. If we had to use autopartitions, we were unable to find a scheme which halved the number of consecutive directions. We can only ensure that if the segments of $F \cap D$ are cut in one loop, then the number of their consecutive directions decreases by a constant.

ALGORITHM 6. *Input:* $[C, L(C), F]$ *where* C *is a cell,* L *is a set of segments, and* $F \subset B^+(C)$, $F \neq \emptyset$.

(1) *Let* $X := B(C) \setminus F^*$.
(2) *Find a convex sequence or a convex cycle* $\mathcal{S}$ *as in Proposition* 9.
(3) *In the three cases of Proposition* 9 *proceed as follows:*
  (a) *Apply* $P(\mathcal{S})$ *for the convex sequence* $\mathcal{S}$.
  (b) *Apply* $P^0(\mathcal{S}, i)$ *for the convex cycle* $\mathcal{S}$.
  (c) (i) *If the line through* ℓ_{i-1} *does not cross the segment* ℓ_1 *but crosses the extended segment* $p(\ell_1)g(\ell_1)$, *then apply* $P^1(\mathcal{S}, i-1)$; *else apply* $P^0(\mathcal{S}, i-1)$.
    (ii) *Apply all possible free cuts.*
    (iii) *In every resulting cell* D, *let* $F_x(D)$ *denote the segments of* $F \cap D$ *whose endpoint lies on* $\partial_F C$.
    (iv) *Call recursively Algorithm* 6 *for* $[D, L(D), F_x(D)]$ *in every cell where* $F_x(D) \neq \emptyset$.
(4) *Apply all possible free cuts.*
(5) *Call recursively Algorithm* 6 *for* $[D, L(D), F(D)]$ *in every resulting cell* D *where* $F(D)$ *is nonempty.*

Proof of Lemma 11. We proceed by induction on $|L(C)|$. Our lemma clearly holds for $|L(C)| = 1$. Suppose that it holds for every $|L'(C')| < |L(C)|$. For cases (a) and (b), we can repeat the argument of Lemma 10 with the parameters in 1–4 of our Lemma 11. We only need to remark that properties 5 and 6 of Lemma 11 hold by induction.

Let us recall the setting in case (c): We assume that we are given a cell C, a set of segments L, and a subset $F \subset B^+(C)$ of the boundary segments, and that $X = B(C) \setminus F^*$. We assume, furthermore, that there is a convex cycle $\mathcal{S} \subset X$ and that there are at least two common segments of $\mathcal{S}$ and F. We denote the common segments by $\ell_i, \ell_{i+1}, \ldots, \ell_j$ appearing in this (cyclic) order in $\mathcal{S}$. The supporting line of ℓ_j intersects $p(\ell_{i-1})g(\ell_{i-1})$, which implies that the direction of the line ℓ_{i-1} is between the consecutive directions of F between ℓ_i and ℓ_j. (See Figure 8.)

In step (3)(c)(i) of Algorithm 6 a BSP $P(\mathcal{S}, i-1)$ is applied. Let s denote the line through ℓ_{i-1}. Line s may cut the regions in $\pi(\mathcal{S}, i-1)$, and $\pi(\mathcal{S}, i-1) \subseteq \{S_i, S_{i+1}, \ldots, S_{j-1}\}$. By Proposition 1, it cannot cut any segment of $B(C) \setminus (F \cup F^*)$.

In every subcell $D \in \mathcal{R}(P(\mathcal{S}, i-1))$, we partition the endings of the segments in $F \cap D$ into two sets: Let $F_s(D)$ be the subset of endings of segments cut by s, and let $F_x(D)$ be the subset of segments not cut by s. Observe that segments in $F_s(D)$ have at most $f-1$ consecutive directions: The direction of s cannot occur in $F_s(D)$. Observe, furthermore, that $F_s(D)^*$ and $F_x(D)^*$ are disjoint in every subcell $D \in \mathcal{R}(P(\mathcal{S}, i-1))$. Elements of $F_x(D)^*$ all belong to F^*. Elements of $F_s(D)^*$ are endings of segments from F^* or $I(C)$ cut by the line s.

In step (3)(c)(iv) of Algorithm 6, we obtain a BSP P_D for $F_x(D)$ in each subcell $D \in \mathcal{R}(P(\mathcal{S}, i-1))$. These BSPs jointly partition C into a collection $\mathcal{E}$ of subcells. In step (5) of Algorithm 6, a BSP for $(F \cap D) \cap E$ (or, for short, $F \cap E$) is applied in each subcell $E \in \mathcal{E}$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$. Notice that $F \cap E = F_s(D) \cap E$ since a

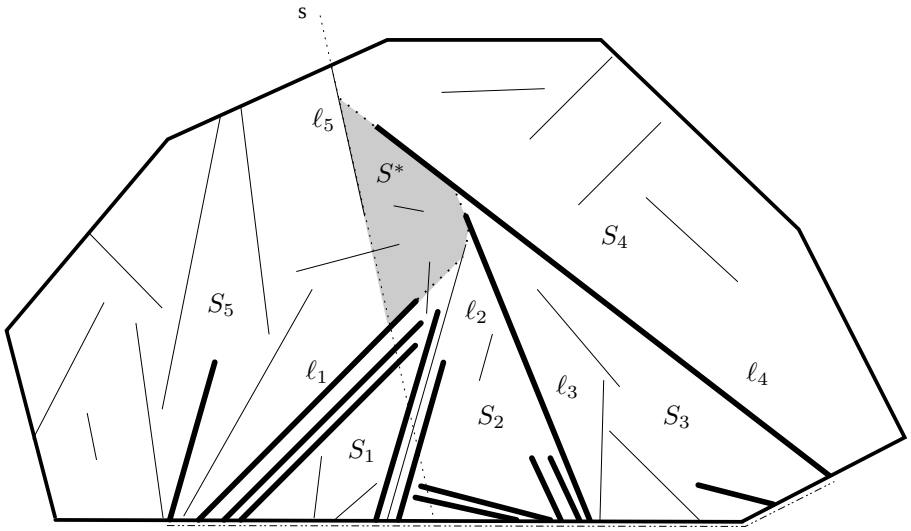

FIG. 8. *Example for case* (c), *with a convex cycle highlighted and with* $i = 1$ *and* $j = 4$.

BSP for $(F_x \cap D)$ was already applied. For brevity, we refer to the three partitioning schemes as $P(\mathcal{S}, i-1)$, P_x, and P_s. (The last two recursive calls can be carried out in parallel in the nonoverlapping subcells.)

We check one by one statements 1–5 of our lemma. Statement 6 follows automatically.

1. If a segment $\ell^1 \in F$ is not cut by s, then it belongs to $F_x(D)$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$ and is cut at most $2f$ times by induction. If $\ell^1 \in F$ is cut by s, then P_x (called in step (3)(c)(iv) for $F_x(D)$ in a subcell $D \in \mathcal{R}(P(\mathcal{S}, i-1))$) cuts it at most once more, and P_s (by induction to $F_s(E)$, $E \subset D$) cuts it at most $2(f-1)$ times.

2. A segment $\ell^2 \in F^*$ is cut at most 4 times by $P(\mathcal{S}, i-1)$ by Propositions 6 and 7. If the ending of ℓ^2 is in $F_s(D)^*$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$, then it is cut at most once by P_x and at most $4(f-1)+4$ times by P_s. This totals to $4f+4$ cuts. If the ending of ℓ^2 is in $F_x(D)^*$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$, then it was not cut by $P(\mathcal{S}, i-1)$ and it is cut at most $4f+4$ times by P_x. It can be cut once more by P_s, but then by Lemma 11(5) it was cut at most 5 times by P_x; this totals to at most 6 cuts. Otherwise if $\ell^2 \in F^*$ is cut by $P(\mathcal{S}, i-1)$ and its ending is in $B(D) \setminus (F_x(D) \cup F_x(D)^*)$ for some $D \in \mathcal{R}(P(\mathcal{S}, i-1))$ and in $B(E) \setminus ((F_s \cap E) \cup (F_s \cap E)^*)$, $E \subseteq D$, then it is cut at most 4 times by $P(\mathcal{S}, i-1)$, at most once by P_x, and at most once by P_s, that is, at most 6 times in total.

3. A segment $\ell^3 \in I(C)$ is cut at most 4 times by $P(\mathcal{S}, i-1)$. Note that if ℓ^3 is cut by s, then at most one of its endings may be in $F_s(D)^*$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$. If one ending is actually in $F_s(D)^*$, then this ending is cut at most once by P_x and at most $4(f-1)+4$ times by P_s, while the other ending is cut at most once by both P_x and P_s. This implies at most $4f+7$ cuts on ℓ^3. If neither ending is in $F_s(D)^*$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$, then P_x and P_s cuts either ending at most once each, which totals to at most 8 cuts on ℓ^3. If ℓ^3 is not cut by $P(\mathcal{S}, i-1)$ and, therefore, belongs to $I(D)$, $D \in \mathcal{R}(P(\mathcal{S}, i-1))$, then P_x cuts it at most $4f+7$ times. The subsequent BSP P_s can cut either of its endings at most once more, but in that case, by Lemma 11(5), it was cut at most 7 times by P_x; thus we obtain a total of at most 9 cuts.

4. A segment $\ell^4 \in B(C) \setminus (F \cup F^*)$ is cut by s only if ℓ^4 is part of $\mathcal{S}$. Moreover it cannot be in any of the regions $\pi(\mathcal{S}, i-1) \subseteq \{S_i, S_{i+1}, \ldots, S_{j-1}\}$, which are possibly cut by s. Therefore P_x cuts ℓ^4 at most once, but P_s cannot cut the ending of ℓ^4.

5. Observe that the BSP P_s for $F_s \cap E$ was applied only in subcells $E \in \mathbf{E}$ where $F_s \cap E$ is nonempty, that is, only in subcells of $\mathcal{R}(P(\mathcal{S}, i-1))$ which lie along the extension of segment ℓ_{i-1} beyond $g(\ell_{i-1})$. If a segment $\ell^5 \in F^* \cup I(C)$ is cut by $P(\mathcal{S}, i-1)$ (at most 4 times) and one of its endings lies in a cell $D_1 \in \mathcal{R}(P(\mathcal{S}, i-1))$ which has no common boundary with (the relative interior of) $\partial_F C$, then this ending is necessarily in $B(D_1) \setminus (F_x(D_1) \cup F_x(D_1)^*)$ and is cut at most once by P_x. P_s does not cut this ending, since $F_s \cap E = \emptyset$ for all such $E \subseteq D_1$. If, furthermore, $\ell^5 \in I(C)$ and its other ending lies in some $D_2 \in \mathcal{R}(P(\mathcal{S}, i-1))$, then it is in $B(D_2) \setminus (F_x(D_2) \cup F_x(D_2)^*)$ and then in $B(E) \setminus ((F_s \cap E) \cup (F_s \cap E)^*)$, $E \subseteq D_2$; hence is cut at most once by P_x and at most once by P_s. The total number of cuts is therefore 5 and 7 if $\ell \in F^*$ and $\ell \in I(C)$, respectively. □

It is straightforward to turn this proof into an $O(n^2 k)$ time and $O(n^2)$ space algorithm using the arrangement of the supporting lines of all segments, or into an $O(n^2 k \log n)$ time and $O(n)$ space algorithm by maintaining, as in section 5, only constant information per segment. The crucial difference, compared to the algorithms at the end of section 5, is that a segment ending can be inserted into X and deleted from it $O(k)$ times: in case 5 of the previous proof, a segment ending can be in $B(D) \setminus (F_x(D) \cup F_x(D)^*) \subset X$ then in $(F_s(D) \cap E)^* \not\subset X$. Each time, when we apply induction with a smaller value of the parameter f, some of the segment endings can be deleted from X, and we need to recompute the relations between elements of X.

Acknowledgments. I am grateful to Günter Rote, Emo Welzl, and the anonymous referee for their many useful remarks and suggestions that allowed me to improve this paper.

ARC-DISJOINT PATHS IN EXPANDER DIGRAPHS*

TOM BOHMAN† AND ALAN FRIEZE†

Abstract. Given a digraph $D = (V, A)$ and a set of κ pairs of vertices in V, we are interested in finding, for each pair (x_i, y_i), a directed path connecting x_i to y_i such that the set of κ paths so found is arc-disjoint. For arbitrary graphs the problem is $\mathcal{NP}$-complete, even for $\kappa = 2$.

We present a polynomial time randomized algorithm for finding arc-disjoint paths in an r-regular expander digraph D. We show that if D has sufficiently strong expansion properties and the degree r is sufficiently large, then *all* sets of $\kappa = \Omega(n/\log n)$ pairs of vertices can be joined. This is within a constant factor of best possible.

1. Introduction. Given a (graph) digraph $D = (V, A)$ with n vertices and a set of κ pairs of vertices in V, we are interested in finding, for each pair (x_i, y_i), an (undirected) directed path connecting x_i to y_i, such that the set of κ paths so found is (edge) arc-disjoint. This is a classical problem in graph theory. See Frank [7] for a survey and Chapter 9.2 of the recent book on digraphs by Bang-Jensen and Gutin [2].

For undirected graphs, the related decision problem is in $\mathcal{P}$ for fixed κ (see Robertson and Seymour [22]) but is $\mathcal{NP}$-complete if κ is part of the input. For digraphs the situation is seemingly much worse. Fortune, Hopcroft, and Wyllie [6] showed that the related decision problem is $\mathcal{NP}$-complete, even when $\kappa = 2$.

For undirected graphs there have been positive results in the case of expanders. Peleg and Upfal [21] presented a polynomial time algorithm for the case where D is a (sufficiently strong) bounded degree expander graph and $\kappa \leq n^{\epsilon}$ for a small constant ϵ that depends on the expansion property of the graph. This result has been improved and extended by Broder, Frieze, and Upfal [4, 5], Frieze [8, 9], Leighton and Rao [17], and Leighton, Rao, and Srinivasan [18, 19]. In particular Frieze [9] showed that if D has sufficiently strong *edge* expansion properties and r is sufficiently large, then *all* sets of $\kappa = \Omega(n/\log n)$ pairs of vertices can be joined. This is within a constant factor of a simple upper bound. The purpose of this paper is to extend this result to digraphs.

In this paper we discuss r-regular digraphs. A digraph D is r-regular if every vertex has in-degree and out-degree r. Let d_μ be the median distance between pairs of vertices in the digraph D which has m arcs. Clearly, there exists a collection of $O(m/d_\mu)$ pairs of vertices that cannot be connected by arc-disjoint paths because such a collection of paths would require more arcs than all the arcs available. In the case of an r-regular expander, this absolute upper bound on κ is $O(n/\log n)$ (assuming r is independent of n). We show that if D has sufficiently strong *arc* expansion

properties and r is sufficiently large, then *all* sets of $\kappa = \Omega(n/\log n)$ pairs of vertices can be joined. This is therefore within a constant factor of the optimum. The precise definition of "sufficiently strong" is given after the theorem.

THEOREM 1. *Let $D = (V, A)$ be an n-vertex, r-regular digraph. Suppose that D is a sufficiently strong arc expander. Then there exist $\epsilon_1, \epsilon_2 > 0$ such that D has the following property: For all sets of pairs of vertices $\{(x_i, y_i) \mid i = 1, \ldots, \kappa\}$ satisfying*

(i) $\kappa = \lceil \epsilon_1 rn/\log n \rceil$, *and*

(ii) *for each vertex v, $|\{i : x_i = v\}|, |\{i : y_i = v\}| \le \epsilon_2 r$,*

there exist arc-disjoint paths in D, each of length $O(\log n)$, joining x_i to y_i for each $i = 1, 2, \ldots, \kappa$. Furthermore, there is a polynomial time randomized algorithm for constructing these paths. The constants ϵ_1, ϵ_2 depend only on certain expansion parameters α, β, γ defined below. They do not depend on n or r. (For example, conditions (2) *with $\epsilon = \alpha$,* (3), (9), *and* (12) *suffice.)*

Remark 1. The algorithm is similar to the algorithm of [9]. The difficulty in moving from graphs to digraphs has been with that part of the algorithm for graphs which was based on the rapid mixing of a random walk on expanders. Random walks on digraphs are not necessarily time reversible, and the steady state can be hard to determine. We therefore abandoned this approach and replaced it with a different random choice of path (in part, this random choice for digraphs uses the multicommodity flow results of Leighton and Rao [16]).

It will be observed that this new algorithm can substitute for that given in [9].

Remark 2. If D has sufficiently strong *vertex* expansion properties, then we can take $\kappa = \lceil \epsilon_1 rn/\log_r n \rceil$; see Remark 4 below.

Remark 3. It is perhaps worth remarking that regularity is not crucial to the result. One can easily extend the results to digraphs where in- and out-degrees are constrained to be in the interval $[r, ar]$, where $a \ge 1$ is an absolute constant. All we need is for r to be sufficiently large. The crucial property is strong expansion.

1.1. Preliminaries. In this section we state the definitions for the expanders we work with here, make some preliminary observations about such expanders, and precisely define the notion of "sufficiently strong" expansion needed for Theorem 1. We begin with some notational conventions.

Let $D = (V, A)$ be a digraph and let $n = |V|$. For $S, T \subseteq V$ let $A_D^+(S, T)$ be the set of arcs with tail in S and head in T; that is,

$$A^+(S,T) = A_D^+(S,T) = \{(u,v) \in A \mid u \in S, v \in T\} \quad \text{and} \quad d^+(S,T) = |A^+(S,T)|.$$

We define $A^-(S, T)$ similarly (i.e., $A^-(S, T) = A^+(T, S)$). We set

$$A^+(S) = \{(u,v) \in A \mid u \in S, v \notin S\} \quad \text{and} \quad d^+(S) = |A^+(S)|.$$

So, for example, we have $A^+(S) = A^+(S, V \setminus S)$. We define $A^-(S)$ and $d^-(S)$ analogously. Throughout the paper, when $\star$ is used as a subscript or superscript, it stands for $+$ or $-$. We abbreviate $A^\star(\{v\}, T)$ to $A^\star(v, T)$. Thus, for $v \in V$, $d_D^+(v)$ and $d_D^-(v)$ denote the out-degree and in-degree of v in D.

We now have the notation necessary to introduce expansion. We define expanders in terms of arc expansion (a weaker property than vertex expansion). For $S \subseteq V$ let $\Phi_S^\star = d^\star(S)/|S|$. The (arc) expansion $\Phi = \Phi(D)$ of D is defined by

$$\Phi = \min_{\substack{S \subseteq V \\ |S| \le n/2}} \min\{\Phi_S^+, \Phi_S^-\}.$$

A digraph $D = (V, A)$ is a θ-expander if for every set $S \subseteq V$, $|S| \leq n/2$, we have $d^\star(S) \geq \theta|S|$; in other words, D is a θ-expander if $\Phi(D) \geq \theta$. An r-regular digraph $D = (V, A)$ is called an (α, β, γ)-expander if for every set $S \subseteq V$,

$$d^\star(S) \geq \begin{cases} (1-\alpha)r|S| & \text{if } |S| \leq \gamma n, \\ \beta r|S| & \text{if } \gamma n < |S| \leq n/2. \end{cases}$$

We naturally assume that $\beta < 1 - \alpha$. By "sufficiently strong" in Theorem 1 we mean that β, γ are arbitrary and α is sufficiently small; in particular, we assume that conditions (2) with $\epsilon = \alpha$, (3), (9), and (12) hold. We also assume throughout that r and n are sufficiently large (but r is *not* a function of n). We have made no real attempt to optimize constants. Such digraphs exist; in particular, random regular digraphs are usually (α, β, γ)-expanders. (See [4] for the corresponding notion in undirected graphs.)

We conclude this section with some preliminary observations about expanders. Since $|A^\star(S, S)| + d^\star(S) = r|S|$ we see that, putting $in(S) = |A^+(S, S)| = |A^-(S, S)|$, in an (α, β, γ)-expander

$$in(S) \leq \alpha r|S| \qquad \text{when } |S| \leq \gamma n. \tag{1}$$

For a digraph $\Delta = (V', A')$ and a set $S \subseteq V'$ we define its out-neighbor set $N^+_\Delta(S)$ as

$$N^+_\Delta(S) = \{w \notin S : \exists v \in S \text{ such that } (v, w) \in A'\}.$$

Similarly, the in-neighbor set of S, $N^-_\Delta(S)$, is given by

$$N^-_\Delta(S) = \{w \notin S : \exists v \in S \text{ such that } (w, v) \in A'\}.$$

LEMMA 1. *Suppose that $D = (V, A)$ is an (α, β, γ)-expander and that $D' = (V', A')$ is a subdigraph of D of expansion at least θr where $\theta > \alpha$. Suppose $S \subseteq V'$. If $|S| \leq \frac{\gamma\alpha}{\theta} n$, then*

$$|N^\star_{D'}(S)| \geq \frac{\theta - \alpha}{\alpha}|S|.$$

Proof. Suppose that $|S| \leq \frac{\gamma\alpha}{\theta} n$ and $T = N^\star_{D'}(S)$ satisfies $|T| < \frac{\theta-\alpha}{\alpha}|S|$. Then

$$|S \cup T| < \left(1 + \frac{\theta - \alpha}{\alpha}\right)|S| = \frac{\theta}{\alpha}|S| \leq \gamma n.$$

But $S \cup T$ contains at least

$$\theta r|S| > \theta r \left(1 + \frac{\theta - \alpha}{\alpha}\right)^{-1} |S \cup T| = \alpha r|S \cup T|$$

arcs, which contradicts (1). ∎

2. The algorithm. The input to our algorithm is a sufficiently strong (α, β, γ)-expander digraph D and a set of pairs of vertices $\{(x_i, y_i) \mid i = 1, \ldots, \kappa\}$ satisfying the premises of Theorem 1. The output is a set of κ arc-disjoint paths, $P_1, \ldots, P_\kappa$, such that P_i connects x_i to y_i.

The algorithm has three phases. We begin in Phase 0 by splitting our graph into 13 arc-disjoint expanders $D_i = (V, A_i)$, $1 \leq i \leq 13$. These graphs will be used for

various purposes in Phases 1 and 2, and each path we construct will be a union of paths in the D_i's. Phase 1 consists mainly of applications of GenPaths, an algorithm that uses the expander property to naively connect pairs of vertices with paths of length $O(\log n)$ one at a time, deleting the arcs from a path as soon as it is used. Of course, this deletion of arcs may quickly destroy the expander property. To compensate for this problem, GenPaths "shrinks" the expanders in which it finds paths. The real work of GenPaths is in keeping as many vertices as possible "connected" to these shrinking expanders. Those pairs of vertices that are not connected with paths in Phase 1 (i.e., those pairs that contain a vertex whose connection with one of the "shrinking expanders" is lost) are handled in Phase 2. There are $O(\frac{n}{\log^4 n})$ such pairs. Loosely speaking, Phase 2 uses the multicommodity flow algorithm of Leighton and Rao to give a distribution on paths connecting the remaining pairs such that **whp** paths chosen at random with respect to this distribution are arc-disjoint.

2.1. Phase 0. We need an algorithm for splitting an (α, β, γ)-expander digraph into 13 expander digraphs. Algorithms for splitting undirected graphs are given in [4] and [10]. They are easily adapted to digraphs, and we outline an adaptation of the algorithm of [10] in Appendix A. In the appendix we prove the following.

Theorem 2. *Suppose we have*

$$\frac{r}{\log r} \geq 91\epsilon^{-2} \quad \text{and} \quad \beta \geq 65\epsilon^{-2}r^{-1}\log 2er \tag{2}$$

and that D is an r-regular (α, β, γ)-expander, r constant. Then there is a randomized polynomial time algorithm which, with probability at least $1 - \delta$, constructs $A_1, A_2, \ldots, A_{13}$ such that the arc expansion Φ_i of $D_i = (V, A_i)$ satisfies

$$\Phi_i \geq (1-\epsilon)\frac{\Phi}{13} - (\alpha + 2\epsilon)\, r$$

for $i = 1, 2, \ldots, 13$.

This theorem is useful only if Φ is at least a constant multiple of r and α is sufficiently small. This is the case discussed in this paper. The algorithm runs in $O(n^2 \ln n \log \delta^{-1})$ expected time. There is not enough time to verify that the algorithm succeeds. Instead, we simply assume it has and repeat the split if we fail to find the required paths.

We apply the algorithm of Theorem 2 with $\alpha = \epsilon$ and assume that

$$\beta > 156\alpha. \tag{3}$$

Setting

$$\beta_0 = \frac{\beta}{13} - 4\alpha > 8\alpha > 0, \tag{4}$$

each D_i satisfies

$$\Phi_i = \Phi(D_i) \geq \beta_0 r, \qquad \text{and} \tag{5}$$

$$\beta_0 r \leq d_i^\star(v) < r \qquad \text{for all } v \in V. \tag{6}$$

2.2. Phase 1. Phase 1 uses expanders D_1 through D_6. The centerpiece of Phase 1 is the algorithm GenPaths, which connects a large collection of *random*

pairs of vertices in an expander with arc-disjoint paths. Since the pairs x_i, y_i are arbitrary, GenPaths cannot be applied to them directly; we must reduce the problem of connecting the x_i's to the y_i's to the problem of connecting random pairs.

In order to produce random pairs we introduce three random sets of κ vertices: $\tilde{X}$, $\tilde{Y}$, and Z. In the initialization step of Phase 1, a network-flow technique is used to find a collection of arc-disjoint paths $\mathcal{P}^1 = \{P_i^1 : i = 1, \dots, \kappa\}$ from $X = \{x_1, \dots, x_\kappa\}$ to $\tilde{X}$ in expander D_1 such that the path P_i^1 starts at x_i for $i = 1, \dots, \kappa$. It is important to note that we have no control over which element of $\tilde{X}$ is at the end of the path P_i^1 (but there will be one path ending at x for each $x \in \tilde{X}$). This network-flow technique is also used in the initialization step of Phase 1 to find a collection of arc-disjoint paths $\mathcal{P}^6 = \{P_i^6 : i = 1, \dots, \kappa\}$ from $\tilde{Y}$ to $Y = \{y_1, \dots, y_\kappa\}$ in D_6 such that the endpoint of the path P_i^6 is y_i. After the initialization step, we take a random ordering of $\tilde{X}$: $\tilde{X} = \{\tilde{x}_1, \dots, \tilde{x}_\kappa\}$. Furthermore, we order $\tilde{Y}$ so as to respect the pairing of $\tilde{X}$ and $\tilde{Y}$ that is inherited from the collections $\mathcal{P}^1$ and $\mathcal{P}^6$; that is, we set $\tilde{Y} = \{\tilde{y}_1, \dots, \tilde{y}_\kappa\}$ so that if the endpoint of P_i^1 is $\tilde{x}_j$, then $\tilde{y}_j$ is the starting point of P_i^6. Thus, it remains to find a collection of arc-disjoint paths connecting the pairs $\{(\tilde{x}_i, \tilde{y}_i) : i = 1, \dots, \kappa\}$. Unfortunately this sequence of pairs of vertices is *not* truly random. This is a consequence of the fact that the pairing between $\tilde{X}$ and $\tilde{Y}$ is determined by a deterministic process (i.e., knowledge of some of the *pairs* from this collection may bias the distribution on the unknown pairs). We overcome this problem by introducing the third random set $Z = \{z_1, \dots, z_\kappa\}$. The sequences $\{(\tilde{x}_i, z_i) : i = 1, \dots, \kappa\}$ and $\{(z_i, \tilde{y}_i) : i = 1, \dots, \kappa\}$ are perfectly random sequences of pairs of vertices (as long as we view them separately). It remains to connect these two sequences of pairs of vertices with arc-disjoint paths. This is the work of the algorithm GenPaths.

The input to GenPaths is a pair of expanders, D_a and D_b, and a collection of pairs of vertices $\{(v_i, u_i) : i = 1, \dots, \kappa\}$ that is generated uniformly at random. The output of GenPaths is a collection of arc-disjoint paths from v_i to u_i for $i = 1, \dots, \kappa$ that use only the arcs from D_a and D_b. We apply GenPaths twice. For the first application we set $D_a = D_2$, $D_b = D_3$, and $\{(v_i, u_i) : i = 1, \dots, \kappa\} = \{(\tilde{x}_i, z_i) : i = 1, \dots, \kappa\}$. In the second application we set $D_a = D_4$, $D_b = D_5$, and $\{(v_i, u_i) : i = 1, \dots, \kappa\} = \{(z_i, \tilde{y}_i) : i = 1, \dots, \kappa\}$. Now, the expander D_a is used to connect the v_i's to the u_i's with *short* paths one at a time. In order to be sure that such paths exist we must be working with an expander. Therefore we delete some vertices in the course of the algorithm; in other words, this expander shrinks as the algorithm progresses. D_b is used to keep as many vertices as possible connected to the "shrinking expander" contained in D_a. We should note that these connections also require that D_b be an expander. So, D_b also "shrinks" in the course of the algorithm. The subroutines Remove and ConnectBack are used by GenPaths.

2.2.1. Initialization. Let $\tilde{X}, \tilde{Y}$ be two randomly chosen κ-subsets of V. We begin by replacing the problem of finding paths from x_i to y_i by that of finding paths from a_i to b_i, where $a_i \in \tilde{X}$ and $b_i \in \tilde{Y}$. Let X denote the set $\{x_1, x_2, \dots, x_\kappa\}$ and $Y = \{y_1, y_2, \dots, y_\kappa\}$. We connect X to $\tilde{X}$ via arc-disjoint paths in the digraph D_1 using a network flow. We construct our network as follows:

- Each directed arc of D_1 gets capacity 1.
- Each $v \in V$ becomes a source of capacity $|\{i : x_i = v\}|$, and each member of $\tilde{X}$ becomes a sink of capacity 1.

Then we find a flow from X to $\tilde{X}$ that satisfies all demands. We can find such a maximum flow with integer values, and this decomposes naturally into $|X|$ arc-disjoint

paths (together perhaps with some cycles). We connect $\tilde{Y}$ to Y by arc-disjoint paths in a similar manner using D_6

We now have a collection of arc-disjoint paths $\mathcal{P}^1 = \{P_i^1 : i = 1, \ldots, \kappa\}$ such that the starting point of P_i^1 is x_i for $i = 1, \ldots, \kappa$ and each member of $\tilde{X}$ is the endpoint of exactly one path from $\mathcal{P}^1$. Furthermore, we have a collection of arc-disjoint paths $\mathcal{P}^6 = \{P_i^6 : i = 1, \ldots, \kappa\}$ such that each member of $\tilde{Y}$ is the starting point of exactly one path from $\mathcal{P}^6$ and the endpoint of path P_i^6 is y_i for $i = 1, \ldots, \kappa$.

2.2.2. Algorithm GenPaths. The aim of GenPaths is to join v_i and u_i for $i = 1, 2, \ldots, \kappa$ by a *short* (i.e., of length $O(\log n)$) path in D_a. After constructing a path, we remove its arcs. It is important to ensure that short paths exist. Of course, this would not be a problem if we could ensure that D_a remained an expander throughout. We have to be satisfied with identifying a *dynamically changing large* subgraph $\Delta_a = (V_a, F_a)$ of D_a which is an expander. Initially $\Delta_a = D_a$, and V_a loses vertices as GenPaths progresses. We ensure that Δ_a remains an expander by keeping the degrees of vertices in the Δ_a close to their degree in D_a. This may involve deleting some (low degree) vertices after the construction of a path. We use the routine Remove to do this.

If the proposed start vertex v of a walk on Δ_a does not lie in V_a, then we try to *connect it back* to V_a by a path in D_b. The terminal endpoint of this walk is denoted by v'. We use a subroutine ConnectBack for this purpose. Similarly, the proposed end vertex u might not lie in V_a. In this case we use ConnectBack to find a path from some $u' \in V_a$ to u in D_b. We do not expect to succeed all the time and our failures are kept in a set L for treatment in Phase 2. The arcs in the paths generated by ConnectBack are deleted from D_b. Since ConnectBack requires that D_b is an expander we will also be working with a second "shrinking expander" $\Delta_b = (V_b, F_b)$ contained in D_b. This shrinking expander will also be maintained by use of the subroutine Remove.

In the end, the path from v_i to u_i will be a concatenation of up to three separate paths. There will always be a path Q_i from D_a, and there may also be a short walk (or walks) from D_b provided by ConnectBack (these are denoted $W_i^{CB\rightarrow}$ and $W_i^{CB\leftarrow}$, respectively).

1. **Algorithm** GenPaths
2. **begin**
3. $\Delta_t \leftarrow D_t$, $t = a, b$.
4. **for** $i = 1$ **to** κ **do**
5. **Execute** Remove(Δ_a)
6. **Execute** ConnectBack($V_a, v_i, \rightarrow, v_i', i, W_i^{CB\rightarrow}$)
7. **Execute** ConnectBack($V_a, u_i, \leftarrow, u_i', i, W_i^{CB\leftarrow}$)
8. **if** $i \notin L$ **then**
9. Construct a shortest path Q_i from v_i' to u_i' in Δ_a.
10. $P_i \leftarrow (W_i^{CB\rightarrow}, Q_i, W_i^{CB\leftarrow})$
11. $\Delta_a \leftarrow \Delta_a \setminus E(P_i)$
12. **fi**
13. **od**
14. **end** GenPaths

2.2.3. Subroutine Remove. The purpose of Remove is to delete vertices that might prevent a digraph from being an expander. In the course of GenPaths we apply REMOVE to Δ_a and Δ_b. In other words, this simple algorithm iteratively removes those vertices whose in-/out-degree is less than the original in-/out-degree

minus $\beta_0 r/2$. To be precise, at the end of the algorithm we have a graph $\Delta_t = (V_t, F_t)$, where $t \in \{a, b\}$ such that

$$v \in V_t \quad \text{implies} \quad d^\star_{\Delta_t}(v) \geq d^\star_{D_t}(v) - \beta_0 r/2 \geq \beta_0 r/2. \tag{7}$$

The final inequality in (7) follows from (6). It follows immediately from (7) that for $S \subseteq V_t$ we have

$$d^\star_{\Delta_t}(S) \geq d^\star_{D_t}(S) - \beta_0 r|S|/2 \geq (\Phi_t - \beta_0 r/2)|S|.$$

This implies that, provided neither V_a nor V_b become empty (an issue which we take up in the next section), both Δ_a and Δ_b are expanders throughout Phase 1:

$$\Phi_{\Delta_t} \geq \Phi_t - \beta_0 r/2 \geq \beta_0 r/2 \qquad \text{for } t = a, b. \tag{8}$$

1. **Algorithm** REMOVE(Δ_t)
2. **begin**
3. $B \leftarrow \{v \in V_t : \ d^+_{\Delta_t}(v) < d^+_{D_t}(v) - \beta_0 r/2 \ \text{ or } \ d^-_{\Delta_t}(v) < d^-_{D_t}(v) - \beta_0 r/2\}$.
4. **if** $B \neq \emptyset$ **then**
5. $A \leftarrow V_t \setminus B$
6. $d \leftarrow \max\{ \max\{d^+_{D_t}(v) - d^+_{\Delta_t}(v, A) \ , \ d^-_{D_t}(v) - d^-_{\Delta_t}(v, A)\} : \ v \in A\}$.
7. **while** $d > \beta_0 r/2$ **do**
8. $C \leftarrow \{w \in A : \max\{d^+_{D_t}(w) - d^+_{\Delta_t}(w, A) \ , \ d^-_{D_t}(w) - d^-_{\Delta_t}(w, A)\} \ \geq \beta_0 r/2\}$
9. $B \leftarrow B \cup C$
10. $A \leftarrow A \setminus C$
11. $d \leftarrow \max\{ \max\{d^+_{D_t}(v) - d^+_{\Delta_t}(v, A) \ , \ d^-_{D_t}(v) - d^-_{\Delta_t}(v, A)\} : \ v \in A\}$.
12. **od**
13. $V_t \leftarrow A$
14. **fi**
15. **end** REMOVE

2.2.4. Subroutine ConnectBack. The purpose of ConnectBack is to connect a vertex z to V_a by means of a short walk in D_b. The direction of this walk is determined by the input dir. If dir $= \rightarrow$, then a path from z to V_a is required, and if dir $= \leftarrow$, then a path from V_a to z is needed. If $z \in V_a$ already, then ConnectBack does nothing but relabel z as z'. Since $|V \setminus V_a|$ can be of order n (this is discussed below), we must maintain the expander property of Δ_b in order to find short connecting paths. Thus we apply Remove to Δ_b in the course of ConnectBack. Now, those pairs that contain a vertex that lies in $V \setminus (V_a \cup V_b)$ are passed to Phase 2 in the set L. Thus, the long-term success of ConnectBack hinges on keeping $V \setminus (V_a \cup V_b)$ small. In fact, this can be viewed as the key point in all of GenPaths.

We keep V_b large by ensuring that the paths we use in Δ_b are spread out; in other words, we avoid using too many paths through any one vertex. This is achieved **whp**; recall that the pairs of vertices $\{(v_i, u_i) : i = 1, \ldots, \kappa\}$ that are the input to GenPaths are assumed to be generated uniformly at random. When a path is needed (i.e., when $z \notin V_a$) ConnectBack constructs a collection $\mathcal{W}^{\text{dir}}$ of walks in Δ_b. This collection has the following properties:

1. If dir $= \rightarrow$, then every walk in $\mathcal{W}^{\text{dir}} = \mathcal{W}^{\rightarrow}$ is a walk from a distinct vertex in $V_b \setminus V_a$ to V_a.
2. If dir $= \leftarrow$, then every walk in $\mathcal{W}^{\text{dir}} = \mathcal{W}^{\leftarrow}$ is a walk from V_a to a distinct vertex in $V_b \setminus V_a$.

3. No path in $\mathcal{W}^{\text{dir}}$ is longer than $22 \log\log n$.
4. No vertex of D_b lies on more than $240(\log\log n)^2$ paths.

The set of start vertices of the walks in $\mathcal{W}^{\rightarrow}$ is denoted $S^{\rightarrow}_{CB}$, and the set of terminal vertices of the walks in $\mathcal{W}^{\leftarrow}$ is denoted $S^{\leftarrow}_{CB}$. Clearly, $S^{\text{dir}}_{CB} \subseteq V_b \setminus V_a$. The collection of walks will have the following additional property:

5. $|V \setminus (V_a \cup S^{\text{dir}}_{CB})| \leq \frac{n}{(\ln n)^4}$.

In other words, condition 3 says that the paths in $\mathcal{W}^{\text{dir}}$ are short, condition 4 says that the paths are "spread out" and condition 5 says that very few vertices are left out of the collection.

We emphasize that $\mathcal{W}^{\text{dir}}$ is constructed without use of any information about z. Therefore, z (which was a random vertex to begin with) can be viewed as a vertex chosen uniformly at random *after* the collection $\mathcal{W}^{\text{dir}}$ is constructed. Heuristically, we can think of $\mathcal{W}^{\rightarrow}$ and $\mathcal{W}^{\leftarrow}$ as collections of connecting paths that are updated whenever Δ_a or Δ_b "shrink," but we only "look" at these collections when we need them.

If $z \in S^{\text{dir}}_{CB}$, then we connect z back to V_a by way of the unique path in $\mathcal{W}^{\text{dir}}$that begins at z (if dir $= \rightarrow$) or ends at z (if dir $= \leftarrow$). If z does not lie in S^{dir}_{CB}, we put i into L (note that we have either $z = \tilde{x}_i$ or $z = \tilde{y}_i$). Arc-disjoint paths for the pairs $(\tilde{x}_i, \tilde{y}_i), i \in L$ are found in Phase 2.

A network-flow technique for the construction of the collection of paths $\mathcal{W}^{\text{dir}}$ follows from the proof of Lemma 3, which is given in section 2.3.3.

```
1.  subroutine ConnectBack(V_a, z, dir, z', i, W_CB)
2.  begin
3.     if z ∈ V_a
4.        then z' ← z
5.        else
6.           Execute Remove(Δ_b)
7.           Construct W^dir (see Lemma 3 for algorithm).
8.           if z ∉ S^dir_CB
9.              then L ← L ∪ {i}
10.             else
11.                W_CB ← the unique path in W^dir with start/terminal vertex z
12.                z' ← terminal/start vertex of W_CB
13.                Δ_b ← Δ_b \ W_CB
14.          fi
15.    fi
16. end ConnectBack
```

2.3. Analysis of Phase 1. There are three facts concerning Phase 1 that remain to be shown: that the flow needed in the initialization exists, that V_3 stays large, and that at the end of Phase 1 **whp** we have $L = O(\frac{n}{(\log n)^4})$.

2.3.1. Initialization. In this subsection we show that if (5) holds and r is sufficiently large, then we can find arc-disjoint paths from $\{x_1, \ldots, x_\kappa\}$ to $\tilde{X}$ in D_1 and arc-disjoint paths from $\tilde{Y}$ to $\{y_1, \ldots, y_\kappa\}$ in D_6 for *any* choice of $x_1, \ldots, y_\kappa$ consistent with the premises of Theorem 1, and for every choice for $\tilde{X}, \tilde{Y}$. We assume that we have

$$8\alpha > \epsilon_2 > r^{-1}. \tag{9}$$

For $S \subseteq V$, let

$$\alpha(S) = \sum_{v \in S} |\{i : x_i = v\}| \qquad \text{and} \qquad \xi(S) = |S \cap \tilde{X}|.$$

It follows from a theorem of Gale [12] (see Bondy and Murty [3, Theorem 11.8]) that if

$$d^+_{D_1}(S) \geq \xi(\bar{S}) - \alpha(\bar{S}) \quad \text{for all } S \subseteq V, \tag{10}$$

then there exists a flow in the network defined on D_1 such that exactly one unit of flow travels through each vertex in $\tilde{X}$, and the amount of flow traveling through each vertex $v \in \{x_1, \ldots, x_\kappa\}$ is $|\{i : x_i = v\}|$. In other words, (10) implies a successful run of Phase 2.

Now, if $|S| \leq n/2$, then, applying (4), (5), and (9), we have

$$d^+_{D_1}(S) \geq |S|\Phi_1 \geq |S|\beta_0 r \geq 8\alpha r|S| \geq \epsilon_2 r|S| \geq \alpha(S) - \xi(S) = \xi(\bar{S}) - \alpha(\bar{S}).$$

On the other hand, if $|S| > n/2$, then we have

$$d^+_{D_1}(S) = d^-_{D_1}(\bar{S}) \geq |\bar{S}|\Phi_1 \geq |\bar{S}|\beta_0 r \geq \epsilon_2 r|\bar{S}| \geq \xi(\bar{S}) - \alpha(\bar{S}).$$

Therefore, Phase 1 succeeds with respect to $X, \tilde{X}$. The same argument applies to $Y, \tilde{Y}$. To ensure these paths are of length $O(\log n)$ we can solve a minimum cost maximum flow problem as indicated in Kleinberg and Rubinfeld [13].

2.3.2. On the size of V_a.

LEMMA 2. *Throughout* GENPATHS *we have*

$$|V_a| \geq (1 - \gamma_0)n,$$

where

$$\gamma_0 = \frac{\beta_0 \gamma}{10}.$$

Proof. It follows from (8) that Δ_a is a $(\beta_0 r/2)$-expander throughout the execution of Phase 1. It follows from Lemma 1 that the diameter of Δ_a is always at most

$$\tau = \left\lceil 2\log_3 n + \frac{2}{\alpha\gamma} \right\rceil. \tag{11}$$

Indeed, consider breadth-first search from some $v \in V_a$. Let $L_t, t \geq 0$, be the vertices at distance t from v. Lemma 1 implies that the cardinalities of the L_t grow at a rate at least 3 until they reach size $(2\gamma\alpha/\beta_0)n$. The same will be true for breadth-first search to a target vertex w. This accounts for the first term in (11). Once L_t reaches $(2\gamma\alpha/\beta_0)n$, we use the fact that going to the next level involves finding $\beta_0 r|L_t|/2$ "new arcs," at least until size $n/2$ is reached. This accounts for the second term in (11).

Thus the total number of arcs in the paths that are removed from D_a is at most $\kappa\tau$. Let B be the set of vertices that are removed from Δ_a in the course of Phase 1, and let B_1 be the set of vertices in B incident with at least $\beta_0 r/4$ of the paths that are generated in D_a. We have

$$|B_1| \leq \frac{4\kappa\tau}{\beta_0 r} \leq \frac{\gamma_0 n}{2},$$

provided

$$\epsilon_1 \leq \frac{\beta_0^2 \gamma}{160}, \tag{12}$$

where ϵ_1 is as in the statement of Theorem 1. Let $B_2 = B \setminus B_1$ (i.e., those vertices removed from Δ_a that lie on less than $\beta_0 r/4$ of the paths generated in D_a).

Assume for the sake of contradiction that $|B_2| > |B_1|$. Let B_3 be the *first* $|B_1|$ vertices of B_2 to join B. Note that the vertices in B_3 have a large degree to $B_1 \cup B_3$ (otherwise these vertices would remain in V_a). Applying (4) we have

$$in_{D_a}(B_1 \cup B_3) \geq \frac{\beta_0 r}{4}|B_3| = \frac{\beta_0 r}{8}|B_1 \cup B_3| > \alpha r |B_1 \cup B_3|.$$

This contradicts (1).

Therefore, $|B| = |B_1| + |B_2| \leq 2|B_1| \leq \gamma_0 n$. □

2.3.3. Analysis of ConnectBack. Of course, the first order of business here is to show how the collection of paths $\mathcal{W}^{\mathrm{dir}}$ is generated.

Lemma 3. *Suppose that $D = (V, A)$ is an (α, β, γ)-expander and that $D' = (V', A')$ is a subdigraph of D of expansion at least θr where $\theta > 6\alpha$. Suppose that $S \subseteq V'$ and that $|S| \geq (1 - \frac{\gamma\alpha}{\theta})n$, and let $T = V' \setminus S$. Then there exists $T^\star \subseteq T$ such that D' contains a collection of walks $\mathcal{W}^{\mathrm{dir}} = \{W_v : v \in T^\star\}$ such that*

1. *for* $\mathrm{dir} = \rightarrow / \leftarrow$, *$v$ is the start/terminal vertex of W_v for all $v \in T^\star$;*
2. *the terminal/start vertex of each W_v is in S;*
3. *each W_v is of length at most $22 \log\log n$;*
4. *no vertex of D' lies on more than $240(\log\log n)^2$ paths; and*
5. *$|T \setminus T^\star| \leq \frac{n}{(\log n)^4}$.*

Proof. Assume without loss of generality that $\mathrm{dir} = \rightarrow$. For $i = 1, 2, \ldots,$ let

$$T_i = \{v \in T : \ dist_{D'}(v, S) = i\},$$

and set $T_0 = S$. Since $N^+_{D'}(\cup_{k \geq i} T_k) \subseteq T_{i-1}$, it follows from Lemma 1 that we have

$$|T_{i-1}| \geq \zeta |T_i| \qquad \text{for } i \geq 1, \tag{13}$$

where $\zeta = \frac{\theta - \alpha}{\alpha} > 5$. Setting $i_0 = \lceil 11 \log\log n \rceil$ and $\hat{T} = \bigcup_{i \geq i_0} T_i$, it follows from (13) that we have

$$|\hat{T}| \leq \frac{n}{2(\log n)^4}. \tag{14}$$

Fix $1 \leq i < i_0$. We define a flow network $\mathcal{N}_i$. The vertex set of $\mathcal{N}_i$ is $\{s, t\} \cup \bigcup_{j=1}^{j_0}(C_j \cup C'_j)$, where C_1 and C'_1 are disjoint copies of T_i for $2 \leq j \leq i$, C_j and C'_j are disjoint copies of $\bigcup_{\ell \geq i+1-j} T_\ell$ and, for $i < j \leq j_0 = 2i_0$, C_j and C'_j are disjoint copies of V'. The vertices s and t will be the source and sink, respectively, for the flow we introduce to $\mathcal{N}_i$. A vertex v in V' may appear many times in the vertex set of $\mathcal{N}_i$; a copy of v in C_j is denoted v_j, and a copy of v in C'_j is denoted v'_j. For ease of notation, we let ϕ be the map that takes the vertices of $\mathcal{N}_i$ to their corresponding vertices in V'. The arc-set of $\mathcal{N}_i$ is defined as follows. There is an arc from s to each vertex of C_1. Each $v \in S$ gives rise to arcs $(v'_j, t), i < j \leq j_0$. If $v'_j \in C'_j$ and $w_{j+1} \in C_{j+1}$ are such that (v, w) is an arc of D', then (v'_j, w_{j+1}) is an arc of $\mathcal{N}_i$. All arcs described so far have infinite capacity. In addition there are arcs (v_j, v'_j) of unit capacity defining a perfect matching between C_j and C'_j for $1 \leq j \leq j_0$.

CLAIM 1. *$\mathcal{N}_i$ contains an $s-t$ flow of value at least $|T_i| - \frac{n}{(\log n)^5}$.*

We first show the lemma follows from Claim 1. The flow given by Claim 1 defines paths in D' from all but at most $\frac{n}{(\log n)^5}$ vertices of T_i to S, each of length at most j_0. No vertex of V' can be on more than j_0 paths since each visit to v uses a (v_j, v'_j) arc for some j. Repeating this construction for $i = 1, 2, \dots, i_0$ we find paths for all but a set $\tilde{T}$ of at most $i_0 \frac{n}{(\log n)^5} \le \frac{n}{2(\log n)^4}$ vertices, and no vertex can be on more than $i_0 j_0$ paths. Putting $T^\star = T \setminus (\hat{T} \cup \tilde{T})$ and using (14) gives us the lemma.

It only remains to prove Claim 1. Of course, we do this via the max-flow min-cut theorem. Consider a cut $Z \dot\cup \bar{Z}$ of $\mathcal{N}_i$, where the vertex set Z contains s but not t. Let $A_j = Z \cap C_j$, $B_j = C_j \setminus A_j$, $A'_j = Z \cap C'_j$, and $B'_j = C'_j \setminus A'_j$ for $j = 1, 2, \dots, j_0$. Assume for the sake of contradiction that the capacity of this cut is less than $|C_1| - \frac{n}{(\log n)^5}$. It follows from this assumption that the cut contains no infinite capacity arcs and therefore

(15)
$$A_1 = C_1, \qquad \phi(A_{j+1}) \supseteq N^+_{D'}(\phi(A'_j)) \quad \text{for all } j, \qquad \phi(A'_j) \cap S = \emptyset \quad \text{for all } j.$$

The capacity of the cut is

$$|B'_1| + \sum_{j=2}^{j_0} |\phi(A_j) \cap \phi(B'_j)|. \tag{16}$$

The third condition of (15) implies that for all j, $|A'_j| < \frac{\gamma\alpha}{\theta} n$. It then follows from Lemma 1 and the second condition of (15) that we have $|A_{j+1}| \ge \zeta |A'_j|$. This implies that for all j we have either

$$|A'_{j+1}| \ge \frac{1}{2}|A_{j+1}| \ge \frac{\zeta}{2}|A'_j| \tag{17}$$

or

$$|\phi(A_{j+1}) \cap \phi(B'_{j+1})| \ge \frac{1}{2}|A_{j+1}| \ge \frac{\zeta}{2}|A'_j|. \tag{18}$$

Now, if $|A'_1| \le \frac{n}{(\log n)^5}$, then $|B'_1| \ge |C_1| - \frac{n}{(\log n)^5}$, which contradicts our initial assumption. On the other hand, if $|A'_1| > \frac{n}{(\log n)^5}$, then, since $(\frac{\zeta}{2})^{j_0 - 1} > (\log n)^5$, condition (17) cannot always hold. Let $j_1 \ge 1$ be the first j for which (18) holds. We have

$$|\phi(A_{j_1+1}) \cap \phi(B'_{j_1+1})| \ge (\zeta/2)^{j_1} |A'_1| \ge |A'_1|.$$

The capacity of the cut is at least $|B'_1| + |A'_1| = |C_1|$. This is a contradiction. □

To get the collection of paths needed for CONNECTBACK we apply Lemma 3 with $D' = \Delta_b, V' = V_b, S = V_a \cap V_b$. So, for example, we have $S^{\mathrm{dir}}_{CB} = T^\star$. It remains to show that **whp** we have $|L| \le \frac{n}{(\log n)^4}$.

Note that Lemma 3 can be applied only if $V_a \cap V_b$ is large. However, by applying the proof of Lemma 2 and the fact that the paths generated by CONNECTBACK are short (length at most $22 \log\log n$) we see that $|V_b| = n - O(n \log\log n / \log n)$ throughout, and this is sufficient. (Furthermore, the assumption that $\theta > 6\alpha$ in Lemma 3 is justified, since it follows from this observation that the expansion of Δ_b is always at least $3\beta_0 r/4$.) However, we shall see that V_b is **whp** larger than this.

This is where we use the fact that the paths in $\mathcal{W}^{\mathrm{dir}}$ are spread out (i.e., the fact that there are at most $240(\log\log n)^2$ paths in $\mathcal{W}^{\mathrm{dir}}$ through any one vertex).

It follows from this fact that the probability that an arbitrary vertex w is on the path $W_i^{CB\mathrm{dir}}$ is at most $240(\log\log n)^2/n$. It follows that we have

$$\begin{aligned}\mathbf{Pr}\left(\left|\left\{i : w \in W_i^{CB\rightarrow}\right\}\right| + \left|\left\{i : w \in W_i^{CB\leftarrow}\right\}\right| \geq 20\right)&\\ \leq \mathbf{Pr}(B(2\kappa, 240(\log\log n)^2/n) \geq 20)&\\ \leq \binom{2\kappa}{20}\left(\frac{240(\log\log n)^2}{n}\right)^{20}&\\ = o((\log n)^{-19}).&\end{aligned} \tag{19}$$

Let B be the set of vertices which are removed from Δ_b by applications of Remove. Let X_1 be the set of vertices in B that are on at least 20 of the paths $W_i^{CB\rightarrow}, W_i^{CB\leftarrow}$. Note that X_1 contains the set B_1 introduced in the proof of Lemma 2 (B_1 is the collection of vertices taken out of V_b by Remove that are on many of the paths). It follows from (19) and Markov's inequality that **whp** we have $|X_1| \leq n/(\log n)^{18}$. Now, B (which contains $V \setminus V_b$ at every step) consists of B_1 together with extra vertices deleted by Remove. In total this will be at most $2|B_1|$ vertices removed by the argument of Lemma 2, following (12). Thus, $|B| \leq 2|B_1| \leq 2|X_1|$. Therefore

$$|B| \leq \frac{n}{(\log n)^{18}} \tag{20}$$

whp.

Now, a failure (i.e., the index i joining the set L) can occur in one of two ways. On one hand we have a failure if either v_i or u_i does not lie in $V_a \cup V_b$, and on the other hand a failure results when $u_i \in V_b \setminus (V_a \cup S_{CB}^{\rightarrow})$ or $v_i \in V_b \setminus (V_a \cup S_{CB}^{\leftarrow})$. It follows from (20) that the total number of failures of the first type is **whp** at most $\frac{n}{(\log n)^{18}}$. For failures of the second type we note that $v_1, \ldots, v_\kappa$ form a random sequence of size $o(n)$. The probability that a particular vertex gives a failure of the second kind is at most

$$\frac{|S_{CB}^{\mathrm{dir}}|}{n} = O\left(\frac{1}{(\log n)^4}\right).$$

Applying the Chernoff bound for the tails of the binomial, we see that **whp** the total number of failures of the second kind is $O(n/(\log n)^4)$.

Remark 4. Suppose D has the following vertex expansion property for small sets: $S \subseteq V$, $|S| \leq \frac{\gamma}{r}n$ implies that $|N_D^\star(S)| \geq (1-\alpha)r|S|$. The algorithm of Theorem 4 can be modified to split D so that each subgraph D_i and small S satisfies $|N_{D_i}^\star(S)| \geq \frac{1-30\alpha}{13}r|S|$. Then the shortest paths in Δ_a will be of length $O(\log_r n)$ and the claim in Remark 2 will follow.

2.4. Phase 2. The set of pairs $\{(\tilde{x}_i, \tilde{y}_i) : i \in L\}$ have not yet been connected by paths. We have seen that **whp** the number of such pairs, $|L|$, is at most $O(n/(\log n)^4)$. These pairs are dealt with by the algorithm described below which uses digraphs D_7–D_{13}.

The heart of the algorithm is a randomized method (based on a multicommodity flow result of Leighton and Rao [16]) for connecting pairs of vertices with arc-disjoint paths which works **whp** when the collection of pairs is generated uniformly at random. So, as in Phase 1, some preliminary steps must be taken in order to reduce the problem

of connecting an arbitrary set of pairs of vertices with arc-disjoint paths to the problem of connecting a random collection of pairs with arc-disjoint paths. We proceed directly to a description of the algorithm. Let $m = |L|$ and $\lambda = \lceil \log n \rceil$.

We begin by "amplifying" each start vertex $\tilde{x}_i, i \in L$, and each end vertex $\tilde{y}_i, i \in L$, to a collection of λ vertices. This process occurs in steps (a) and (b).

(a) In this step, we choose a collection of vertices $w_j, 1 \le j \le 2m$, and a collection of sets of vertices $W_j, 1 \le j \le 2m$, such that for $1 \le j \le 2m$,
   (i) $w_j \in W_j$;
   (ii) $|W_j| = \lambda$;
   (iii) the sets W_j are pairwise disjoint; and
   (iv) D_9 contains an arborescence with vertex set W_j and root w_j; for $1 \le j \le m$ this arborescence is directed away from the root, and for $m+1 \le j \le 2m$ this arborescence is directed toward the root.

   Following [17], we find these arborescences by partitioning large arborescences of D_9. We begin with a rooted spanning arborescence T with the property that all arcs are directed away from the root. We generate $W_1, \dots, W_m$ greedily from D_9, removing an arborescence from T once it is used. Of course, this process will divide T into a number of components. However, since the maximum degree of D_9 is r, the number of components produced in this process is at most $r\lambda m = O(\frac{nr}{(\log n)^3})$. Since any tree having at least λ vertices contains a subtree having exactly λ vertices, we will always be able to find the needed arborescences. We then apply REMOVE to D_9 less the vertex set $\cup_{i=1}^m W_i$ to produce an expander D_9'. It follows from the proof of Lemma 2 that D_9' has $n - o(n)$ vertices. We repeat the process described above (this time using D_9' and an arborescense directed toward the roots) to produce $W_{m+1}, \dots, W_{2m}$.

(b) Let $S_X = \{\tilde{x}_i : i \in L\}$ and $S_Y = \{\tilde{y}_i : i \in L\}$ denote the sets of vertices that need to be joined. Use a network flow algorithm (analogous to what is given in the initialization step of Phase 1) in D_7 to connect in an arbitrary manner the vertices of S_X to $W_X = \{w_1, \dots, w_m\}$ by m arc-disjoint paths. Using the same network flow algorithm in D_8, connect in an arbitrary manner the vertices of $W_Y = \{w_{m+1}, \dots, w_{2m}\}$ to S_Y by m arc-disjoint paths. The expansion properties of D_7 and D_8 ensure that such paths always exist (as we saw in the initialization step of Phase 1).

Let $\hat{x}_k$ (resp., $\hat{y}_k$) denote the vertex in W_X that was connected to the endpoint $\tilde{x}_k$ (resp., $\tilde{y}_k$). Our problem is now to find arc-disjoint paths joining $\hat{x}_k$ to $\hat{y}_k$ for $1 \le k \le m$. If w_t has been renamed as $\hat{x}_k$ (resp., $\hat{y}_k$), then rename the elements of W_t as $\hat{x}_{k,\ell}$ (resp., $\hat{y}_{k,\ell}$), $1 \le \ell \le \lambda$.

(c) Choose $\xi_j, 1 \le j \le \lambda m$, and $\eta_j, 1 \le j \le \lambda m$, uniformly at random from V without replacement. Using a network-flow algorithm (as in (b)) connect $\{\hat{x}_{k,\ell} : 1 \le k \le m, 1 \le \ell \le \lambda\}$ to $\{\xi_j : 1 \le j \le \lambda m\}$ by arc-disjoint paths in D_{10}. Similarly, connect $\{\eta_j : 1 \le j \le \lambda m\}$ to $\{\hat{y}_{k,\ell} : 1 \le k \le m, 1 \le \ell \le \lambda\}$ by arc-disjoint paths in D_{13}. Rename the other endpoint of the path starting at $\hat{x}_{k,\ell}$ (resp., ending at $\hat{y}_{k,\ell}$) as $x^*_{k,\ell}$ (resp., $y^*_{k,\ell}$).

(d) Choose $z^*_{k,\ell}, 1 \le k \le m, 1 \le \ell \le \lambda$, uniformly at random from V with replacement. (We sample without replacement in (c) to ensure that all vertices have demands 0 or 1 in the flow algorithm. Here it is convenient to sample with replacement so that these choices are independent.) Now, it is important to note that the pairs $x^*_{k,\ell}, z^*_{k,\ell}$ and the pairs $z^*_{k,\ell}, y^*_{k,\ell}$ are (when viewed

separately) perfectly random. We are using the same "trick" that we used in Phase 1 for replacing the problem of connecting arbitrary pairs to the problem of connecting random pairs.

The paths between pairs of the form $x^*_{k,\ell}, z^*_{k,\ell}$ and between pairs of the form $z^*_{k,\ell}, y^*_{k,\ell}$ are generated at random. Using the multicommodity flow algorithm of Leighton and Rao [16] find a collection of paths $P_{u,v;\theta}, u \neq v \in V, 1 \leq \theta \leq \nu_{u,v}$, where each $P_{u,v;\theta}$ is a path in D_{11} from u to v. These are the flow paths given by Theorem 18 in [16] ($\nu_{u,v}$ is simply the number of flow paths we have for the pairs u, v). Let $\mathcal{P}_{u,v} = \{P_{u,v;\theta} : 1 \leq \theta \leq \nu_{u,v}\}$. For each $P_{u,v;\theta}$ we will have a flow value $f_{u,v;\theta} > 0$, and we let $F_{u,v} = \sum_{\theta=1}^{\nu_{u,v}} f_{u,v;\theta}$. Theorem 18 promises the following:

(P1) For all arcs e of D_{11},

$$\sum_{(u,v,\theta):\, e \in P_{u,v;\theta}} f_{u,v;\theta} \leq 1.$$

(P2)

$$F_{u,v} \geq \frac{c_2}{n \log n}$$

for some absolute constant $c_2 > 0$.

(P3) The length of each path $P_{u,v;\theta}$ is at most $\lambda_1 = c_1 \log_r n$ for some absolute constant $c_1 > 0$.

For $u, v \in V$, let $P_{u,v}$ be the probability distribution over $\mathcal{P}_{u,v}$ where $P_{u,v}(P_{u,v;\theta}) = f(u,v,\theta)/F(u,v)$. Then for each k, ℓ choose $W'_{k,\ell}$ randomly from $\mathcal{P}_{x^*_{k,\ell}, z^*_{k,\ell}}$ using the distribution $P_{x^*_{k,\ell}, z^*_{k,\ell}}$ to select the path.

Let B'_k denote the *bundle* of paths $\{W'_{k,\ell}, 1 \leq \ell \leq \lambda\}$. Carry out the same construction in D_{12} and construct a bundle of paths $B''_k = \{W''_{k,\ell}, 1 \leq \ell \leq \lambda\}$, where $W''_{k,\ell}$ is a path from $z^*_{k,\ell}$ to $y^*_{k,\ell}$.

Let $\pi_0 = \max_e \mathbf{Pr}(e \in P)$, where P is a path chosen by (i) randomly choosing endpoints u, v and then (ii) choosing $P \in \mathcal{P}_{u,v}$ according to the distribution $P_{u,v}$. We have

$$\pi_0 = \max_e \sum_{P_{u,v;\theta} \ni e} \frac{1}{n^2} \cdot \frac{f(u,v,\theta)}{F(u,v)} \leq \frac{1}{n^2} \frac{n \log n}{c_2} = \frac{\log n}{c_2 n}.$$

We say that $W'_{k,\ell}$ is *bad* if there exists $k' \neq k$ such that $W'_{k,\ell}$ shares an arc with a walk in a bundle $B'_{k'}$.

Now, suppose the bundles in the set $\{B_j : j \neq k\}$ are *fixed*. The collection of paths involved in these bundles gives at most $m\lambda\lambda_1$ arcs. Thus, the probability that $W_{k,l}$ is bad, conditioning on what happens outside the bundle B_k, is at most

$$\pi_0 m \lambda \lambda_1 = O\left(\frac{1}{\log n}\right).$$

We say that index k is bad if either B'_k or B''_k contains more than $\lambda/3$ bad walks. If index k is not bad, then we can find a walk from $x^*_{k,\ell}$ to $y^*_{k,\ell}$ through $x^*_{k,\ell}$ for some ℓ which is arc-disjoint from all other walks. This gives a walk

$$x_k - \tilde{x}_k - \hat{x}_k - \hat{x}_{k,\ell} - x^*_{k,\ell} - z^*_{k,\ell} - y^*_{k,\ell} - \hat{y}_{k,\ell} - \hat{y}_k - \tilde{y}_k - y_k,$$

which is arc-disjoint from all other such walks.
The probability that index k is bad is at most

$$2\,\mathbf{Pr}(B(\lambda, O((\log n)^{-1})) \geq \lambda/3) = O(n^{-2}).$$

So with probability 1-o(1) there are no bad indices. □

Appendix A. Splitting an expander digraph. We prove two results on splitting D into $D_1 \cup \cdots \cup D_k$, where $D_i = (V, A_i)$. The first is nonconstructive and shows what might be achieved. The second is constructive and uses the first. The split produced by the second is not as good as that indicated by the first result. We use a subscript i to denote graph-theoretic constructs related to D_i. Thus $d_i^+(v)$ is the out-degree of v in D_i. Left unsubscripted, such things refer to D. Thus $d^-(v) = r$.

In section B we prove the following.

THEOREM 3. *Let $k \geq 2$ be a positive integer and let $\epsilon > 0$ be a small positive real number. Suppose that the r-regular digraph $D = (V, A)$ has edge expansion Φ and that we have*

$$\frac{r}{\ln r} \geq 7k\epsilon^{-2} \qquad \text{and} \qquad \Phi \geq 5\epsilon^{-2}k \ln 2er.$$

Then there exists a partition $A = A_1 \cup A_2 \cup \cdots \cup A_k$ such that for $1 \leq i \leq k$

$$\Phi_i \geq (1-\epsilon)\frac{\Phi}{k} \qquad \text{and} \qquad (1-\epsilon)\frac{r}{k} \leq \delta^*(D_i) \leq \Delta^*(D_i) \leq (1+\epsilon)\frac{r}{k}.$$

We then use this in Appendix C in the proof of Theorem 4.

THEOREM 4. *Suppose that the conditions of Theorem 3 hold, and suppose further that D is an (α, β, γ)-expander. Then there is a randomized polynomial time algorithm (running time $O(n^2 \ln n \ln \delta^{-1})$) which with probability at least $1-\delta$ constructs $A_1, A_2, \ldots, A_k$ such that*

$$\Phi_i \geq (1-\epsilon)\frac{\Phi}{k} - (\alpha+\epsilon)\, r$$

for $i = 1, 2, \ldots, k$.

Note that this theorem is useful only if $\Phi \geq cr$ for some c satisfying $c \gg \alpha$. For random r-regular digraphs we can take γ to be a small constant and $\alpha = O(\gamma + \frac{1}{\sqrt{r}})$. Also note that there is not enough time to verify that the algorithm succeeds. Instead, we assume it has and repeat the split if we fail to find the required paths.

Appendix B. Existence result. We prove Theorem 3. We will use the general version of the Lovász local lemma. For each $a \in A$ we randomly choose an integer $i \in [k]$ and then place a in A_i. We must show that there is a positive probability of choosing a partition which satisfies the conditions of the theorem.

We begin with some definitions and preliminary observations. Let $G = (V, E)$ be the $2r$-regular (multi-)graph obtained by ignoring orientation in D. If $S \subseteq V$, then $G[S]$ is the subgraph of G induced by S. We say that S is *connected* if $G[S]$ is.

CLAIM 2. *For $v \in V$ there are at most $(2er)^{s-1}$ sets S such that* (i) *$v \in S$,* (ii) *$|S| = s$, and* (iii) *S is connected.*

Proof of Claim 2. The number of such sets is bounded by the number of distinct s-vertex trees which are rooted at v. This in turn is bounded by the number of distinct $2r$-ary rooted trees with s vertices. This is equal to $\binom{2rs}{s}/((2r-1)s+1)$; see Knuth [15]. □

In both this section and what follows will use the following Chernoff bounds for the tails of the binomial distribution $B(n,p)$:

$$\mathbf{Pr}(B(n,p) \geq (1+\epsilon)np) \leq e^{-\epsilon^2 np/3}, \tag{21}$$

$$\mathbf{Pr}(B(n,p) \leq (1-\epsilon)np) \leq e^{-\epsilon^2 np/2}, \tag{22}$$

where $0 \leq \epsilon \leq 1$.

For our application of the Lovász local lemma, we define the following *bad* events:

(a) For $v \in V$, $i \in [k]$, and $* \in \{+,-\}$, $A_{v,i,*} = A_{\{v\},i,*}$ is the event that

$$d_i^*(v) \notin [(1-\epsilon)r/k, (1+\epsilon)r/k].$$

(b) For $S \subseteq V$, $2 \leq |S| \leq n/2$, S connected, $i \in [k]$, and $* \in \{+,-\}$, $A_{S,i,*}$ is the event that

$$|d_i^*(S)| < (1-\epsilon)|d^*(S)|/k.$$

In showing that Φ_i is sufficiently large we can restrict our attention to S for which S is connected. Indeed, for $S \subseteq V$ let $C_1, C_2, \ldots, C_t$ be the components of $G[S]$. Then for $* \in \{+,-\}$,

$$\Phi_{S,i}^* \geq \min_{1 \leq s \leq t} \frac{d_i^*(C_s)}{|C_s|}.$$

Using the Chernoff bounds given above, we obtain

$$\mathbf{Pr}(A_{v,i,*}) \leq 2e^{-\epsilon^2 r/(3k)} \leq 2e^{-(7\ln r)/3} < \frac{1}{r^2}$$

and

$$\mathbf{Pr}(A_{S,i,*}) \leq \exp\left\{-\frac{\epsilon^2 d^*(S)}{2k}\right\} \leq e^{-2|S|\ln r} = \frac{1}{r^{2|S|}}.$$

Now, for $S \subseteq V$, $1 \leq |S| \leq n/2$, and S connected, let

$$x_{S,i,*} = \left(\frac{2}{r^2}\right)^{|S|}.$$

We show that for $*, \# \in \{+,-\}$,

$$\mathbf{Pr}(A_{S,i,*}) < x_{S,i,*} \prod_{(S,i,*) \sim (T,j,\#)} (1 - x_{T,j,\#}), \tag{23}$$

where $(S,i,*) \sim (T,j,\#)$ denotes adjacency of $A_{S,i,*}$ and $A_{T,j,\#}$ in the dependency graph of bad events (i.e., we have $(S,i,*) \sim (T,j,\#)$ if and only if $A^*(S) \cap A^{\#}(T) \neq \emptyset$). The theorem then follows from the general version of the local lemma; see, for example, Alon and Spencer [1].

It follows from Claim 2 that if $|S| = s$, then there are at most $ks(2er)^t$ events $A_{T,j,\#}$ with $|T| = t$ such that $(S,i,*) \sim (T,j,\#)$. Thus, using $1 - x \geq e^{-2x}$ for

$0 \le x \le 1/2$, we have

$$\begin{aligned} x_{S,i,*} \prod_{(S,i,*)\sim(T,j,\#)} (1 - x_{T,j,\#}) &\ge \left(\frac{2}{r^2}\right)^s \prod_{t\ge 1} \left(1 - \left(\frac{2}{r^2}\right)^t\right)^{ks(2er)^t} \\ &\ge \left(\frac{2}{r^2}\right)^s \exp\left\{-2ks \sum_{t\ge 1} \left(\frac{4e}{r}\right)^t\right\} \\ &= \left(\frac{2}{r^2}\right)^s \exp\left\{-\frac{8kes}{r-4e}\right\} \\ &> \frac{1}{r^{2s}}, \end{aligned}$$

since for small values of ϵ, the fact that $r/\ln r \ge 7k\epsilon^{-2}$ implies

$$r > 4e + \frac{8ke}{\ln 2}.$$

Thus (23) holds, proving the theorem. □

Appendix C. Splitting algorithm. In this section, we prove Theorem 4.

Idea. We produce the split in a series of rounds that gives a series of vertex sets $V = B_1 \supseteq B_2 \supseteq \cdots \supseteq B_t$. In round i we fix the "destination" of a fixed arc if it has at least one endpoint in B_i but no endpoint in B_{i+1}. This is done in such a way that if $S \subseteq B_j \setminus B_{j+1}$, then $d_i^+(S), d_i^-(S)$ are large enough, and further that every vertex in $B_j \setminus B_{j+1}$ has few neighbors in B_{j+1}. We will see that this latter condition accounts for the $-(\alpha + 2\epsilon)\, r$ term in the theorem.

Assume that we have $B \subseteq V$. Initially, $B = V$. We randomly color the arcs of D *which are incident with* B with k colors. Note that if $s_0 = 5k\epsilon^{-2}\Phi^{-1}\ln n$,

$$\begin{aligned} &\mathbf{Pr}\left(\exists S \subseteq B, i \in [k] \text{ s.t. } |S| > s_0, S \text{ is connected and } \Phi_{i,S} \le (1-\epsilon)\,\frac{\Phi}{k}\right) \\ &\qquad \le 2kn \sum_{s\ge s_0} (2er)^{s-1} e^{-\epsilon^2 s\Phi/(2k)} \le 4kn(2er)^{s_0} e^{-\epsilon^2 s_0\Phi/(2k)} = O(kn^{-1/5}). \end{aligned}$$

So, in a sense the large sets take care of themselves. Now consider the smaller sets. Let

$$X_0 = \left\{v : \exists S \subseteq B, |S| \le s_0, S \text{ is connected}, v \in S \text{ and } i \in [k] \text{ s.t. } \Phi_{i,S} \le (1-\epsilon)\,\frac{\Phi}{k}\right\}.$$

X_0 can be constructed in $O(n(er)^{s_0}) = O(n^2)$ time.

$$\mathbf{E}(|X_0|) \le |B| \sum_{s=1}^{s_0} (2er)^{s-1} e^{-\epsilon^2 s\Phi/(2k)} \le \frac{|B|}{2er}$$

since $\Phi \ge 5\epsilon^{-2}k\ln 2er$.

Therefore by Markov's inequality,

$$\mathbf{Pr}\left(|X_0| \ge \frac{|B|}{er}\right) \le \frac{1}{2}.$$

We repeat the above coloring until we find that $|X_0| \le \frac{|B|}{er}$. Now recursively define $X_j = X_{j-1} \cup \{v_j\}$, where $d^+(v_j, X_{j-1}) \ge (\alpha+\epsilon)r$ or $d^-(v_j, X_{j-1}) \ge (\alpha+\epsilon)r$ if such a v_j exists. Here we use the strong expansion properties of an (α, β, γ)-expander: $|S| \le \gamma n$ implies that S contains at most

$$(r|S| - d^*(S)) \le \alpha r|S|$$

arcs. Note that X_j has at least $(\alpha+\epsilon)rj$ arcs and at most $j + \frac{|B|}{er}$ vertices. Thus this process stops before j reaches $\frac{\alpha|B|}{\epsilon er}$, unless $|X_j|$ exceeds γn first. However, this latter possibility cannot happen because $|X_0| + \frac{\alpha|B|}{\epsilon er} \le (1+\frac{\alpha}{\epsilon})\frac{1}{er}|B| \le \gamma|B| \le \gamma n$, since $\gamma, \epsilon > r^{-\frac{1}{2}}, \alpha < 1$ implies $\gamma > (1+\frac{\alpha}{\epsilon})\frac{1}{er}$.

So if X denotes X_j when v_{j+1} cannot be found, then

$$|X| \le \gamma|B|.$$

We will repeat the construction with B replaced by X. Let $V = B_1 \supseteq B_2 \supseteq \cdots \supseteq B_t$ be the sequence of sets constructed. B_t will be the first set of size at most $r^{-1}\ln n$. Since $\gamma < \frac{1}{2}$, we have $t \le \log_2 n$. Thus the expected number of recolorings needed is at most $2\log_2 n$ and is $\le 3\log_2 n$ **whp**. We can "brute force" color the arcs incident with B_t so that every subset S of B_t satisfies $\Phi_{i,S} \ge (1-\epsilon)\frac{\Phi}{k}$. We use Theorem 3 to justify the success of this. The sequence of sets $B_1, B_2, \ldots, B_t$ satisfies the following:

- $|B_j| \le \gamma^j n$;
- $S \subseteq B_j \setminus B_{j+1}$ implies $\Phi_{i,S} \ge (1-\epsilon)\frac{\Phi}{k}$;
- $v \in B_j \setminus B_{j+1}$ implies v has at most $(\alpha+\epsilon)r$ out-neighbors and at most $(\alpha+\epsilon)r$ in-neighbors in B_{j+1}.

So if $S \subseteq V$ and $S_j = S \cap (B_j \setminus B_{j+1})$,

$$\begin{aligned} d_i^*(S) &\ge \sum_{j=1}^{t-1}(d_i^*(S_j) - d_i^*(S_j, B_{j+1})) + d_i^*(S_t) \\ &\ge \sum_{j=1}^{t-1}\left((1-\epsilon)\frac{\Phi}{k} - (\alpha+\epsilon)r\right)|S_j| + (1-\epsilon)\frac{\Phi}{k}|S_t| \\ &\ge \left((1-\epsilon)\frac{\Phi}{k} - (\alpha+\epsilon)\,r\right)|S|. \qquad \square \end{aligned}$$

THE PROBABLE VALUE OF THE LOVÁSZ–SCHRIJVER RELAXATIONS FOR MAXIMUM INDEPENDENT SET*

URIEL FEIGE† AND ROBERT KRAUTHGAMER‡

Abstract. Lovász and Schrijver [*SIAM J. Optim.*, 1 (1991), pp. 166–190] devised a lift-and-project method that produces a sequence of convex relaxations for the problem of finding in a graph an independent set (or a clique) of maximum size. Each relaxation in the sequence is tighter than the one before it, while the first relaxation is already at least as strong as the Lovász theta function [*IEEE Trans. Inform. Theory*, 25 (1979), pp. 1–7]. We show that on a random graph $G_{n,1/2}$, the value of the rth relaxation in the sequence is roughly $\sqrt{n/2^r}$, almost surely. It follows that for those relaxations known to be efficiently computable, namely, for $r = O(1)$, the value of the relaxation is comparable to the theta function. Furthermore, a perfectly tight relaxation is almost surely obtained only at the $r = \Theta(\log n)$ relaxation in the sequence.

1. Introduction.

Let $G(V, E)$ be a graph on n vertices. An *independent set* (also known as a *stable set*) in G is a subset of vertices no two of which are connected by an edge. The *maximum independent set* problem requires one to find an independent set of maximum size in an input graph G. The *independence number* (also known as a *stability number*) of G, denoted $\alpha(G)$, is the maximum size of an independent set in G.

A *clique* in G is a subset of vertices every two of which are connected by an edge. The *maximum clique* problem requires one to find a clique of maximum size in an input graph G. The *clique number* of G, denoted $\omega(G)$, is the maximum size of a clique in G. A clique in G forms an independent set in the edge complement graph $\overline{G}$, so $\omega(G) = \alpha(\overline{G})$. It follows that the maximum clique problem and the maximum independent set problem are equivalent in many respects, including the context presented here. For consistency with related literature, we refer to one problem in some parts and to the other problem in others.

The maximum independent set problem is fundamental in the area of combinatorial optimization and is closely related, in addition to the maximum clique problem, to the *vertex cover* problem (the vertex complement of an independent set) and the *chromatic number* problem (minimum cover by independent sets). The maximum independent set problem (or even finding $\alpha(G)$) is one of the first problems shown to be NP-hard in [16].

A common way to cope with the NP-hardness of a problem is to devise algorithms

that give approximate solutions. An *efficient* (i.e., polynomial time) algorithm is said to have an *approximation ratio* $\rho > 1$ for the maximum independent set problem if for every input graph, the ratio between $\alpha(G)$ and the size of the independent set returned by the algorithm is at most $\rho = \rho(n)$. It is known through work culminating in [12] that for any fixed $\epsilon > 0$, it is impossible to approximate the independence number $\alpha(G)$ within a ratio of $n^{1-\epsilon}$, unless NP has randomized polynomial time algorithms (NP = ZPP). The best approximation algorithm that is known for $\alpha(G)$, due to [4], has approximation ratio $O(n/\log^2 n)$.

The intractability of the maximum independent set problem in the worst case suggests studying the performance of algorithms on average instances. A possible rigorous description of average instances is by probabilistic models; see, e.g., [8] for a survey on average-case analysis of graph algorithms on random graphs.

The problem of finding a maximum independent set on a random graph appears to be difficult. Let $G_{n,1/2}$ denote the random graph on n labeled vertices obtained by connecting each pair of vertices by an edge independently with probability 1/2. It is known that the independence number of $G_{n,1/2}$ is roughly $2\log_2 n$, almost surely, i.e., with probability that approaches 1 as n tends to infinity; see, e.g., [3]. Several simple and natural algorithms (e.g., the greedy one) find an independent set of size roughly $\log_2 n$, almost surely. However, no algorithm is known to find efficiently an independent set of size significantly larger than $\log_2 n$; see, e.g., [17, 8]. Finding independent sets of size $\frac{3}{2}\log_2 n$ in random graphs was even suggested as a hard computational problem on which to base cryptographic applications; see [14].

Lovász theta function. A well-known relaxation of the maximum independent set problem is the *theta* function of a graph, denoted $\vartheta(G)$, introduced by Lovász [21] (see also [11, Chapter 9] and Knuth's survey [18]). The theta function can be formulated as a semidefinite program and thus can be computed, up to arbitrary precision, in polynomial time; see, e.g., [11]. We may consider the theta function also as a relaxation of the maximum clique problem by formally referring to $\vartheta(\bar{G})$.

In terms of approximation ratio, the theta function appears to have little to offer. The ratio between $\vartheta(G)$ and the independence number $\alpha(G)$ can be as large as $n^{1-o(1)}$, as shown in [6].

Also, on the average there is a large gap between the Lovász theta function $\vartheta(G)$ and the independence number $\alpha(G)$. While the independence number of a random graph $G_{n,1/2}$ is almost surely roughly $2\log_2 n$, it was shown by Juhász [15] that the value of the theta function is almost surely $\Theta(\sqrt{n})$.

The hidden clique problem. Jerrum [13] and Kučera [20] suggested independently the following *hidden clique problem*. A random graph $G_{n,1/2}$ is chosen and a clique of size k is randomly placed in the graph. We wish to find in this graph a maximum clique. Jerrum showed that the Metropolis process almost surely does not find the clique when $k = o(\sqrt{n})$. Kučera observed that when $k > c\sqrt{n \log n}$ for an appropriate constant c, the vertices of the planted clique would almost surely be the ones with the largest degrees in G, and hence it is easy to recognize them efficiently. Alon, Krivelevich, and Sudakov [1] showed an algorithm that almost surely finds the planted clique whenever $k \geq \Omega(\sqrt{n})$. Their algorithm is based on spectral properties of the graph, namely, it uses the eigenvector that corresponds to the second largest eigenvalue of the adjacency matrix of the graph. (See also [24].)

Feige and Krauthgamer [7] devised another algorithm that is based on the semidefinite programming relaxation provided by the Lovász theta function. Their algorithm works for the same planted clique size k as the algorithm of [1], but it has the ad-

vantage of being more robust; it works also in a semirandom model in which an adversary can remove edges that are outside the planted clique. Another advantage of their algorithm is that it certifies almost surely the optimality of its solution.

The approach of [7] was motivated by Juhász' result [15] that the theta function of a random graph $G_{n,1/2}$ is $\Theta(\sqrt{n})$, almost surely. It follows that the maximum clique relaxation $\vartheta(\bar{G})$ is also almost surely $\Theta(\sqrt{n})$ for a random graph $G_{n,1/2}$. When a clique of size $k \geq c\sqrt{n}$ for a sufficiently large constant $c > 0$ is planted in a random graph, the theta function (being a relaxation) must increase to at least k. Furthermore, it is plausible that such a noticeable increase in the theta function will allow us to find the planted clique. Indeed, it is shown in [7] that on the hidden clique graph $G_{n,1/2,k}$, the theta function almost surely gives exactly k, the planted clique size, in which case it allows us to find the planted clique (with some extra work). In contrast, when a clique of size $k = o(\sqrt{n})$ is planted in a random graph, the monotonicity properties of the theta function (see, e.g., [18, sections 18–19]) guarantee that its value can only increase, but not by more than k. It follows that on the hidden clique graph $G_{n,1/2,k}$, the value of the theta function is also almost surely $\Theta(\sqrt{n})$, and it is therefore possible that the planted clique has no noticeable effect on the theta function.

A possible direction for extending the approach of [7] to a planted clique of smaller size $k = o(\sqrt{n})$ is to use relaxations that are stronger than the Lovász theta function. In particular, it is desirable to find a relaxation whose value on a random graph $G_{n,1/2}$ is almost surely $o(\sqrt{n})$.

The general Lovász–Schrijver technique. Lovász and Schrijver [23] propose a general technique for obtaining stronger and stronger relaxations of 0-1 integer programming problems. Specifically, they devise several procedures called *matrix-cut operators* that produce from a convex (e.g., linear programming) relaxation $P \subseteq [0,1]^n$ of the problem a convex set that is an improved relaxation for the 0-1 (i.e., integral) vectors in P. That is, the resulting convex set is contained in P and contains all the 0-1 vectors in P. The matrix-cut operators follow a *lift-and-project* approach; they lift the convex relaxation P into a higher (quadratic) dimension by introducing new variables and new constraints, and then project it back into the original space.

The two main matrix-cut operators of Lovász and Schrijver [23] are denoted by N and N_+. The difference between the two operators is that the lifting of the latter involves, in addition, a positive semidefinite constraint. That is, if P is a linear programming relaxation, then $N(P)$ is also a linear programming relaxation, while $N_+(P)$ is a semidefinite programming relaxation.

The matrix-cut operators can be applied iteratively, say $r \geq 0$ times, and the iterated operators are denoted N^r and N_+^r. The *N-rank of a convex relaxation P* is defined as the number of iterations of the N operator that are needed to obtain the convex hull of the 0-1 vectors of P (i.e., a perfectly tight relaxation). The *N_+-rank* is defined similarly. Lovász and Schrijver [23] show that the N-rank of a relaxation is always at most the dimension d (e.g., number of variables in a linear program). The N_+ operator is a strengthening of the N operator, and hence the N_+-rank is also always at most d. Goemans and Tunçel [10] and Cook and Dash [5] show independently that there exist relaxations whose N_+-rank meets the upper bound d.

Furthermore, Lovász and Schrijver [23] show that the N and N_+ operators have the following important algorithmic property. If it is possible to efficiently optimize (linear objective functions) over a relaxation P, then it is also possible to efficiently optimize over the relaxation obtained by applying the operator on P. It follows that for every *fixed* $r \geq 0$, the iterated operators N^r and N_+^r also satisfy this property.

Strong relaxations for maximum independent set. To obtain relaxations of the maximum independent set problem, Lovász and Schrijver [23] apply their general technique of matrix-cut operators on a classical linear programming relaxation FRAC of the problem. The relaxation FRAC is a linear program of polynomial size, and hence for every fixed $r \geq 0$, one can efficiently optimize over $N_+^r(\text{FRAC})$. In contrast, the dimension d (i.e., number of variables) of FRAC is the number of vertices n in the graph, and so optimizing over $N^n(\text{FRAC})$ is NP-hard.

Lovász and Schrijver [23] show that the semidefinite programming relaxation $N_+(\text{FRAC})$ is at least as strong as the Lovász theta function. It follows, for example, that for any graph on which the theta function is not tight, the relaxation $N_+^r(\text{FRAC})$ for $r \geq 2$ is stronger than the theta function.

The *N-rank of a graph* is defined as the N-rank of the relaxation FRAC. The *N_+-rank* is defined similarly. It follows that for graphs with bounded N_+-rank, the maximum independent set problem can be solved in polynomial time. This family includes, for example, all perfect graphs, since the above connection with the theta function implies that their N_+-rank is at most 1.

Stephen and Tunçel [25] study the case where the n-vertex graph G is the line graph of a graph H on h vertices. They show that the N_+-rank of G is at most $\lfloor h/2 \rfloor$, and that this bound is met if H is a complete graph on an odd number of vertices, in which case $n = \binom{h}{2}$, and so the N_+-rank of G is $\Omega(\sqrt{n})$. Note that independent sets in G correspond to matchings in H, and that a maximum weight matching can be found efficiently; it follows that there are graphs with unbounded (and rather large) N_+-rank, in which the maximum (weighted) independent set problem can be solved in polynomial time.

Our results. We examine the asymptotic behavior on the random graph $G_{n,1/2}$ of the relaxations of Lovász and Schrijver [23] for the maximum independent set problem. In particular, we show that the typical value of the semidefinite programming relaxation $N_+^r(\text{FRAC})$ on a random graph is roughly $\sqrt{n/2^r}$ for $r = o(\log n)$. We note that this characterization answers (up to a constant factor) a question of Knuth [18, section 37, Problem P6].

THEOREM 1.1. *For every fixed $\delta > 0$ and $r = o(\log n)$, the value of the relaxation $N_+^r(\text{FRAC})$ on a random graph $G_{n,1/2}$ is at least $\sqrt{n/(2+\delta)^{r+1}}$ and at most $4\sqrt{n/(2-\delta)^{r+1}}$, almost surely.*

Recall that the strongest relaxations of Lovász and Schrijver [23] whose value is known to be efficiently computable are $N_+^r(\text{FRAC})$ for $r = O(1)$. Theorem 1.1 shows that on a random graph, the typical value of these relaxations is smaller than that of the theta function by no more than a constant factor. In the hidden clique problem, the planted clique size k that a heuristic can handle can be improved by an arbitrarily large constant factor using a method of [1], and therefore it appears that the improvement offered by these stronger relaxations can be achieved by other methods.

We use Theorem 1.1 to characterize, up to a constant factor, the typical N_+-rank of a random graph $G_{n,1/2}$.

THEOREM 1.2. *The N_+-rank of a random graph $G_{n,1/2}$ is almost surely $\Theta(\log n)$.*

Our results for the N_+ operator extend to a slightly stronger variant of the matrix-cut operators of Lovász and Schrijver [23]. This operator, denoted $N_{\text{FR}+}$, is specialized for the maximum independent set problem and retains the important algorithmic property of N_+, namely, an efficient optimization over P implies an efficient optimization over $N_{\text{FR}+}(P)$.

Organization. Section 2 is a technical description of the matrix-cut operators of Lovász and Schrijver [23] (including our variant $N_{\mathrm{FR}+}$). We present the formal definitions in section 2.1 and state in section 2.2 some basic useful properties (whose proof is deferred to Appendix A.1).

Section 3 describes our results on matrix-cuts in a random graph. Specifically, a lower bound on the value of the relaxation $N_+^r(\mathrm{FRAC})$ is shown in section 3.1 and an upper bound is shown in section 3.2.

The appendix proves several useful properties of the matrix-cut operators. In section A.1 we give some basic properties that are needed for our main results, and in section A.2 we give bounds on the ranks of the different matrix-cut operators. Most of the results on the N and N_+ operators were previously published in [23, 5, 10] and are included here for completeness. The results on the $N_{\mathrm{FR}+}$ operator were not published previously (to the best of our knowledge).

Preliminaries. Throughout, we omit the graph $G(V, E)$ if it is clear from the context. We let n denote the number of vertices in the graph G and assume, without loss of generality, that $V = \{1, \ldots, n\}$. For a vertex i in the graph, let $\Gamma(i)$ denote the set of the vertices that are adjacent to i in the graph, i.e., $\Gamma(i) := \{j \in V : ij \in E\}$, and let $\Gamma(S)$ denote the set of vertices in V that are adjacent to at least one vertex of S, i.e., $\Gamma(S) := \cup_{i \in S} \Gamma(i)$.

An $n \times n$ (real) matrix Y is *positive semidefinite* if Y is symmetric and $x^T Y x \geq 0$ for all $x \in \mathbb{R}^n$. It is well known that a symmetric matrix Y is positive semidefinite if and only if all the eigenvalues of Y are nonnegative.

A *Gram matrix representation* of an $n \times n$ matrix Y is a set of real-valued vectors $\{v_1, \ldots, v_n\}$ such that $Y_{ij} = v_i^T v_j$ for all i, j (i.e., $Y = B^T B$ for a corresponding matrix B). It is well known that a matrix Y is positive semidefinite if and only if it has a Gram matrix representation.

2. The Lovász–Schrijver matrix-cut operators. In this section we describe the so-called matrix-cut operators that were proposed by Lovász and Schrijver [23]. Given a convex set (e.g., a polytope) P, the matrix-cut operators consider P as a relaxation of the convex hull of its 0-1 vectors and produce another relaxation that is tighter than P. In other words, these operators produce a convex set that is sandwiched (in terms of containment) between P and (the convex hull of) the 0-1 vectors in P. Furthermore, the produced relaxation is strictly tighter than P, unless P is already tight. Our description and notation mostly follow that of Lovász and Schrijver [23] (but also those of [5, 10]). An alternative formulation of the matrix-cut operators is given by Lovász in [22].

Section 2.1 reviews the definitions of the Lovász–Schrijver matrix-cut operators. In section 2.2 we state some of their known properties (that we need), focusing on the application of these operators to the stable set problem. For completeness (and to aid readers who are unfamiliar with these operators), we give the proofs of these properties in the appendix, where these and relevant known results and examples are repeated and extended to a more general setting that includes the $N_{\mathrm{FR}+}$ operator.

Throughout, let e_j be the jth unit vector, let $\mathbf{0}$ be the vector of all zeros, and let $\mathbf{1} = \sum_j e_j$ be the vector of all ones. The sizes (dimensions) of $\mathbf{0}, \mathbf{1}$, and e_j will be clear from the context. Recall that a set is called a *cone* if it is closed under multiplication by a nonnegative number. A *convex cone* is thus a set that is closed under a nonnegative linear (i.e., *conic*) combination. (Throughout, we will consider convex cones rather than polytopes.) A *polyhedral cone* is a cone that is also a polyhedron; equivalently, a polyhedral cone is a set that can be defined by $\{x : Ax \geq 0\}$ for some matrix A.

2.1. Definitions.

Homogenization. It will be convenient to deal with homogenous systems of inequalities. We therefore embed the n-dimensional space $\mathbb{R}^n$ in $\mathbb{R}^{n+1}$ as the hyperplane $x_0 = 1$ (throughout, the 0th variable plays a special role) and work with convex cones in $\mathbb{R}^{n+1}$, as follows.

Since we deal with 0-1 programming on n variables, our basic example is a polytope P that is contained in $[0,1]^n$ (the convex hull of the n-dimensional hypercube $\{0,1\}^n$). To homogenize P using the new variable x_0, first embed P in the hyperplane $x_0 = 1$ of $\mathbb{R}^{n+1}$ and then generate from it a convex cone. That is, if

$$P = \{x \in \mathbb{R}^n : Ax \le b,\ \mathbf{0} \le x \le \mathbf{1}\}, \tag{1}$$

then the convex cone obtained by homogenization is

$$K := \left\{ \begin{pmatrix} x_0 \\ x \end{pmatrix} \in \mathbb{R}^{n+1} : Ax \le x_0 b,\ 0 \le x \le x_0 \mathbf{1} \right\}. \tag{2}$$

Note that such K can be described as the intersection of finitely many halfspaces defined by linear constraints $u^t x \ge 0$ (here $x \in \mathbb{R}^{n+1}$), and hence it is a polyhedral cone.

We denote by $Q \subset \mathbb{R}^{n+1}$ the convex cone that is obtained from the polytope $[0,1]^n$ via the homogenization procedure (1)–(2). Namely,

$$Q := \left\{ (x_0, x_1, \ldots, x_n)^T : 0 \le x_i \le x_0 \text{ for all } 1 \le i \le n \right\}. \tag{3}$$

Note that Q is a polyhedral cone that can be described by $2n$ linear inequalities.

Throughout, let $K \subseteq Q$ be a (closed) convex cone. We denote by K_I the convex cone that is generated by all 0-1 vectors in K. Observe that within the hyperplane $x_0 = 1$, K_I is exactly the *integral hull* (i.e., convex hull of the integral vectors) of K. For example, $Q_I = Q$.

The *polar cone* of K, denoted K^*, is the convex cone defined by

$$K^* := \{u \in \mathbb{R}^{n+1} : x^T u \ge 0 \text{ for all } x \in K\}.$$

Observe that a vector $u \in K^*$ corresponds to a linear constraint $u^T x \ge 0$ that is *valid* for K (i.e., satisfied by all vectors $x \in K$). The polar cone K^* is thus the collection of valid linear constraints for K. For example, Q is defined in (3) by $2n$ linear constraints, and hence Q^* is spanned by the vectors e_i and $f_i = e_0 - e_i$ for $i = 1, \ldots, n$.

Fractional stable sets. We will be mostly interested in the stable set problem. Let $G(V,E)$ be a graph with no isolated vertices and $|V| = n$. Then the stable sets of G correspond to the 0-1 solutions of the system of linear inequalities

$$x_i \ge 0 \quad \text{for all } i \in V \qquad (\textit{nonnegativity constraints}) \tag{4}$$

and

$$x_i + x_j \le 1 \quad \text{for all } ij \in E \qquad (\textit{edge constraints}). \tag{5}$$

Let $\mathrm{STAB}(G) \subset \mathbb{R}^n$ denote the convex hull of the 0-1 solutions of the system (4)–(5). Let $\mathrm{FRAC}(G) \subset \mathbb{R}^n$ (for "fractional stable sets") denote the solution set of the system (4)–(5) (i.e., without integrality restriction). Clearly, $\mathrm{STAB}(G) \subseteq \mathrm{FRAC}(G)$.

Let $\mathrm{FR}(G) \subset \mathbb{R}^{n+1}$ be the polyhedral cone that is obtained from the polytope $\mathrm{FRAC}(G)$ via the homogenization procedure (1)–(2). That is, $\mathrm{FR}(G)$ is the solution set of the following homogenous system of linear inequalities for the stable set problem:

$$x_i \geq 0 \quad \text{for each } i \in V, \tag{6}$$

$$x_0 - x_i - x_j \geq 0 \quad \text{for each } ij \in E. \tag{7}$$

Let $\mathrm{ST}(G)$ be the polyhedral cone that is obtained from the polytope $\mathrm{STAB}(G)$ via the homogenization procedure (1)–(2). It is straightforward that $(\mathrm{FR}(G))_I = \mathrm{ST}(G)$.

Throughout, we omit the graph G when it is clear from the context, denoting $\mathrm{STAB}(G)$ by STAB, etc. It can be seen that the polar cone FR^* is spanned by the vectors e_i for $i = 1, \ldots, n$ and the vectors $f_{ij} = e_0 - e_i - e_j$ for $ij \in E$. Note that $\mathrm{FR} \subseteq Q$ and hence $\mathrm{FR}^* \supseteq Q^*$.

Matrix-cut operators. Let $K_1, K_2 \subseteq Q$ be closed convex cones in $\mathbb{R}^{n+1}$ (e.g., $K_1 = \mathrm{FR}(G)$ and $K_2 = Q$). Consider the cone $K_1 \cap K_2$. For each $u \in K_1^*$ the constraint $u^T x \geq 0$ is valid for K_1, and for each $v \in K_2^*$ the constraint $v^T x \geq 0$ is valid for K_2. It follows that the quadratic inequality $(u^T x)(x^T v) \geq 0$ is valid for $K_1 \cap K_2$. Furthermore,

$$K_1 \cap K_2 = \left\{x : u^T x x^T v \geq 0 \text{ for all } u \in K_1^*, v \in K_2^*, x_0 \geq 0\right\}$$

because any original inequality, say $u^T x \geq 0$ for K_1, can be recovered by adding the two quadratic inequalities obtained by $e_i, f_i \in Q^* \subseteq K_2^*$, giving $u^T x \cdot x_0 = u^T x x^T (e_i + f_i) \geq 0$.

Furthermore, all 0-1 vectors in $K_1 \cap K_2$ satisfy $x_i^2 = x_i$. Therefore, if x is a 0-1 vector in $K_1 \cap K_2$ and with $x_0 = 1$, then setting $Y = xx^T$ we have the following:

(a) Y is symmetric.
(b) $Ye_0 = \mathrm{diag}(Y)$, i.e., $Y_{ii} = Y_{i0}$ for all $1 \leq i \leq n$.
(c) $u^T Y v \geq 0$ for all $u \in K_1^*$ and $v \in K_2^*$.
(d) Y is positive semidefinite.

Note that (c) can be written as

(c′) $YK_2^* \subseteq K_1$.

Lovász and Schrijver [23] proposed the following lift-and-project procedure. Given K_1, K_2, consider the derived cones

$$M(K_1, K_2) := \{Y \in \mathbb{R}^{(n+1)\times(n+1)} : Y \text{ satisfies (a)–(c)}\},$$

$$M_+(K_1, K_2) := \{Y \in \mathbb{R}^{(n+1)\times(n+1)} : Y \text{ satisfies (a)–(d)}\}$$

and define the projections of these liftings on $\mathbb{R}^{n+1}$:

$$N(K_1, K_2) := \{Ye_0 : Y \in M(K_1, K_2)\},$$

$$N_+(K_1, K_2) := \{Ye_0 : Y \in M_+(K_1, K_2)\}.$$

It follows from the above discussion that

$$(K_1 \cap K_2)_I \subseteq N_+(K_1, K_2) \subseteq N(K_1, K_2) \subseteq K_1 \cap K_2. \tag{8}$$

Relevant variants of the operators. We shorten notation to better handle two important special cases. When $K_2 = Q$ we omit K_2, i.e., $N(K) := N(K, Q)$ and $N_+(K) := N_+(K, Q)$. In this case, we have that (c′) is equivalent to the following:

(c″) Every column of Y is in K_1; the difference of the first column and any other column of Y is in K_1.

Note that we have from (8) that

$$K_I \subseteq N_+(K) \subseteq N(K) \subseteq K. \tag{9}$$

For the stable set problem, we may take $K_2 = \mathrm{FR}$, denoting it in the subscript, i.e., $N_{\mathrm{FR}}(K) := N(K, FR)$ and $N_{\mathrm{FR}+}(K) := N_+(K, FR)$. In this case, we have that (c′) is equivalent to the following:

(c‴) $Ye_i \in K_1$ for all $i \geq 1$, and $Yf_{ij} \in K_1$ for all $ij \in E$.

We assume throughout that $K \subseteq \mathrm{FR}$, and then we have from (8) that

$$K_I \subseteq N_{\mathrm{FR}+}(K) \subseteq N_{\mathrm{FR}}(K) \subseteq K. \tag{10}$$

It follows from the definition that using $K_2 = \mathrm{FR}$ is at least as strong as using $K_2 = Q$ in the same operator, i.e., $N_{\mathrm{FR}}(K) \subseteq N(K)$ and $N_{\mathrm{FR}_+}(K) \subseteq N_+(K)$. We therefore have that

$$K_I \subseteq N_{\mathrm{FR}+}(K) \subseteq N_{\mathrm{FR}}(K) \subseteq N(K) \subseteq K, \tag{11}$$

$$K_I \subseteq N_{\mathrm{FR}+}(K) \subseteq N_+(K) \subseteq N(K) \subseteq K. \tag{12}$$

It can also be seen that $N_{\mathrm{FR}}(K) \not\subseteq N_+(K)$ (e.g., when G is a clique on 5 vertices and taking $K = \mathrm{FR}$; see Appendix A.2), but it is not clear (to us) whether $N_+(K) \subseteq N_{\mathrm{FR}}(K)$. The strength of these operators is further discussed in Appendix A.2.

Iterated operators. Define the iterated operator $N^r(K)$ recursively by $N^0(K) = K$ and $N^r(K) = N(N^{r-1}(K))$ for $r \geq 1$. For other operators, the iterated operator is defined similarly.

The following theorem of Lovász and Schrijver [23] proves that even without the positive semidefiniteness constraint (d), it suffices to apply n iterations in order to get from a convex cone $K \subseteq Q$ the cone K_I. It follows that applying the N operator on $K \neq K_I$ produces a relaxation of K_I that is strictly tighter than K.

THEOREM 2.1 (Lovász and Schrijver [23]). *Let $K \subseteq Q$ be a convex cone in $\mathbb{R}^{n+1}$. Then $N^n(K) = K_I$.*

It is often easier to work in the original n-dimensional space (without homogenization), so in the case that K is the cone obtained from a polytope (or a convex set) P in $[0,1]^n$ via the homogenization procedure (1)–(2), define

$$N(P) := \left\{ x \in \mathbb{R}^n : \begin{pmatrix} 1 \\ x \end{pmatrix} \in N(K) \right\},$$

and similarly for the other operators (including the iterated ones).

For the stable set problem, K will be one of the cones obtained from $\mathrm{FR}(G)$ by an iterated operator, e.g., $N^r(\mathrm{FR}(G))$. Going back to the original n-dimensional space we shall abbreviate $N^r(G) := N^r(\mathrm{FRAC}(G))$, and similarly for the other operators. We then have from Theorem 2.1 that $N^n(G) = \mathrm{STAB}(G)$.

Ranks. The *N-rank of an inequality* $u^T x \geq 0$ that is valid for K_I is the smallest nonnegative integer r such that $u^T x \geq 0$ is valid for $N^r(K)$. (Note that the rank is relative to K.) For N_+, N_{FR}, and $N_{\mathrm{FR}+}$ the rank is defined similarly. Theorem 2.1 implies that the rank of any valid inequality is at most n (the dimension).

The *N-rank of a cone* K is the smallest nonnegative integer r such that $N^r(K) = K_I$, and similarly for the other operators. By Theorem 2.1, the N-rank of K is at most n (the dimension).

The N-rank of a graph G is the N-rank of $\mathrm{FR}(G)$, and similarly for the other operators. For example, for a bipartite graph, STAB = FRAC, and hence the N-rank of a bipartite graph is 0. We discuss bounds on the rank in Appendix A.2.

2.2. Useful properties.

Algorithmic aspects. Lovász and Schrijver [23] give sufficient conditions for efficient *weak* (i.e., up to arbitrary precision) optimization (of linear objective functions) over $N(K)$, $N_+(K)$, $N_{\mathrm{FR}}(K)$, and $N_{\mathrm{FR}+}(K)$. Technically, the matrix-cut operators have the following algorithmic property.

THEOREM 2.2 (Lovász and Schrijver [23]). *A polynomial time weak separation oracle for K gives a polynomial time weak separation oracle for $N^r(K), N_+^r(K), N_{\mathrm{FR}}^r(K)$, and $N_{\mathrm{FR}+}^r(K)$ for any fixed constant r.*

By the equivalence between weak (i.e., up to arbitrary precision) optimization and weak separation (see [11]), Theorem 2.2 implies a weak optimization of any linear objective function over these relaxations of K_I.

Lovász and Schrijver [23] suspect that Theorem 2.2 does not extend to $N(K, K)$. They remark, however, that if K is given by an explicit system of polynomially many linear inequalities, then Theorem 2.2 does extend to $N(K, K)$.

For the stable set problem, the cone $K = \mathrm{FR}$ is given by an explicit linear program of polynomial size, so one can solve the separation problem for it in polynomial time. We thus obtain the following theorem.

THEOREM 2.3. *For every fixed $r \geq 0$, the weak optimization problem for $N^r(G)$ can be solved in polynomial time, and similarly for $N_+^r, N_{\mathrm{FR}}^r, N_{\mathrm{FR}+}^r$.*

Down-monotonicity. A nonempty convex set $P \subseteq [0,1]^n$ is called *down-monotone* (in $[0,1]^n$) if for every $x \in P$, every $y \in [0,1]^n$ with $y \leq x$ is also in P (see, e.g., [11, p. 11]). Similarly, a convex cone $\{\mathbf{0}\} \neq K \subseteq Q$ is called *down-monotone* if for every $x \in K$, every $y \in Q$ with $y \leq x$ and $y_0 = x_0$ is also in K.

The next lemma shows that the relaxations of the stable set problem that are produced by iterated matrix-cut operators are down-monotone. Its proof appears in Appendix A.1.

LEMMA 2.4. *$N^r(G)$ is down-monotone for every $r \geq 0$, and similarly for N_+^r, N_{FR}^r, $N_{\mathrm{FR}+}^r$.*

Removing vertices from the graph. Recall that $V = \{1, \ldots, n\}$. For a vector $x \in \mathbb{R}^n$ and a subset $W \subset V$, we denote by x_W the restriction of x to the coordinates of W.

The next lemma characterizes the relaxations of the stable set problem that are produced by iterated matrix-cut operators when one of the coordinates is fixed (i.e., $x_i = 0$ or $x_i = x_0$). Its proof appears in Appendix A.1.

LEMMA 2.5. *Let $x \in \mathbb{R}^n$ and assume that i satisfies $x_i = 1$ and $x_j = 0$ for all $j \in \Gamma(i)$. Then for all $r \geq 0$, $x \in N^r(G)$ if and only if $x_{V-\Gamma(i)-i} \in N^r(G - \Gamma(i) - i)$, and similarly for N_+^r, N_{FR}^r, and $N_{\mathrm{FR}+}^r$.*

Vertex deletion and contraction. Let $a^T x \le b$ be an inequality valid for STAB(G). For a subset $W \subset V$, we denote by a_W the restriction of a to the coordinates of W. For every $i \in V$, if $a^T x \le b$ is valid for STAB(G), then $a^T_{V-i} x \le b$ is valid for STAB($G-i$) and $a^T_{V-\Gamma(v)-i} x \le b - a_i$ is valid for STAB($G - \Gamma(i) - i$). Following the terminology of Lovász and Schrijver [23], we say that these inequalities arise from $a^T x \le b$ by the *deletion* and *contraction* of vertex i, respectively. Note that if $a^T x \le b$ is an inequality such that for some i, both the deletion and the contraction of i yield inequalities valid for the corresponding graphs, then $a^T x \le b$ is valid for G.

Upper bounds on the N_+-rank. Lovász and Schrijver [23] prove the following bounds for the N_+ operator.

LEMMA 2.6 (Lovász and Schrijver [23]). *If $a^T x \le b$ is an inequality valid for* STAB(G) *such that for all $i \in V$ with $a_i > 0$ the contraction of i gives an inequality with N_+-rank at most r, then $a^T x \le b$ has N_+-rank at most $r+1$.*

LEMMA 2.7 (Lovász and Schrijver [23]). *The N_+-rank of a graph G is at most its stability number $\alpha(G)$.*

3. The Lovász–Schrijver relaxations in a random graph. In this section we show that the N_+-rank of a random graph $G_{n,1/2}$ is almost surely $\Theta(\log n)$. In particular, we analyze the asymptotic behavior of $\max\{\mathbf{1}^T x : x \in N_+^r(G)\}$ for $r = o(\log n)$. Loosely speaking, we show that the value of this relaxation is almost surely roughly $\sqrt{n/2^r}$. The precise formulations of our lower bound and upper bound on $\max\{\mathbf{1}^T x : x \in N_+^r(G)\}$ appear below. Our analysis extends the proof of Juhász [15] that shows that the theta function of a random graph is almost surely $\Theta(\sqrt{n})$.

THEOREM 3.1. *For any $c > \sqrt{2}$ there exists an $\epsilon' > 0$ such that if $0 \le r \le \epsilon' \log n$, then almost surely* $\max\{\mathbf{1}^T x : x \in N_+^r(G_{n,1/2})\} \ge \sqrt{n}/c^{r+1}$, *and similarly for $N^r_{\mathrm{FR}+}$.*

The proof of Theorem 3.1 appears in section 3.1. Technically, we show that $N_+^r(G_{n,1/2})$ almost surely contains the "uniform" solution $(1/c^{r+1}\sqrt{n})\mathbf{1}$ and hence obtain a lower bound on the probable value of the relaxation.

To show that the above lower bound is nearly tight, we next give an upper bound on the value of the relaxation. Its proof appears in section 3.2.

THEOREM 3.2. *For any $d < \sqrt{2}$ there exists an $\epsilon' > 0$ such that if $1 \le r \le \epsilon' \log n$, then almost surely* $\max\{\mathbf{1}^T x : x \in N_+^r(G_{n,1/2})\} \le 4\sqrt{n}/d^{r+1}$, *and similarly for $N^r_{\mathrm{FR}+}$.*

It is straightforward that Theorem 1.1 follows from Theorems 3.1 and 3.2 by taking $c = \sqrt{2+\delta}$ and $d = \sqrt{2-\delta}$.

The N_+-rank of a random graph $G_{n,1/2}$. Using Theorem 3.1 and Lemma 2.7 we can now show that the N_+-rank of a random graph is almost surely $\Theta(\log n)$, proving Theorem 1.2. For comparison, it follows from Corollary A.24 that the N-rank of a random graph is almost surely at least $\Omega(n/\log n)$.

Proof of Theorem 1.2. Let G be a random graph from the distribution $G_{n,1/2}$, and let us first show a lower bound on the N_+-rank. It is well known that, almost surely, the maximum size of a stable set in G is roughly $2\log_2 n$, i.e.,

$$\max\{\mathbf{1}^T x : x \in \mathrm{STAB}\} \le O(\log n).$$

We have from Theorem 3.1 with $r = \epsilon' \log n$ that, almost surely,

$$\max\{\mathbf{1}^T x : x \in N_+^r(\mathrm{FRAC})\} \ge n^{\Omega(1)}.$$

It follows that $N_+^r(\mathrm{FRAC}) \ne \mathrm{STAB}$, and hence the N_+-rank of FRAC (and therefore of G) is larger than $r = \epsilon' \log n = \Omega(\log n)$.

The upper bound on the N_+-rank of G follows from Lemma 2.7. Indeed, the stability number of a random graph $G_{n,1/2}$ is almost surely roughly $2\log_2 n$, and hence the N_+-rank of G is almost surely $O(\log n)$, as claimed. □

3.1. Lower bound on the value of $N_+^r(G_{n,1/2})$. We prove Theorem 3.1 by showing that $N_+^r(G_{n,1/2})$ almost surely contains the "uniform" solution $(1/c^{r+1}\sqrt{n})\mathbf{1}$. First we exhibit in Lemma 3.3 certain conditions that are sufficient for such a uniform solution to be feasible in $N_+^r(G)$. We then show in Lemma 3.4 that these conditions are almost surely satisfied by a random graph $G_{n,1/2}$.

We will say that two vertices are *nonadjacent* if they are not adjacent and they are not equal (i.e., they are adjacent in the complement graph). We make no attempt to optimize constants.

LEMMA 3.3. *Let G be a graph on n vertices, let $c = \sqrt{2}(1+\epsilon)^{10}$ for $0 < \epsilon < 1/5$, and let $r \geq 0$. Assume that for every $S \subset V$ with $|S| \leq r$, the graph $G' = G - S - \Gamma(S)$ satisfies the following (letting n' denote the number of vertices in G'):*

(i) *All eigenvalues of the adjacency matrix of $\overline{G'}$ are at least $-(1+\epsilon)\sqrt{n'}$.*

(ii) *The degree of every vertex in $\overline{G'}$ is between $\frac{1}{1+\epsilon}\frac{n'}{2}$ and $(1+\epsilon)\frac{n'}{2}$.*

If $c^{r+1} \leq \epsilon\sqrt{n}$, then $(1/c^{r+1}\sqrt{n})\mathbf{1} \in N_+^r(G)$, and similarly for $N_{\mathrm{FR}+}^r(G)$.

Proof. Proceed by induction on r. For the base case $r = 0$, observe that $(1/c^{r+1}\sqrt{n})\mathbf{1}$ (and even $(1/2)\mathbf{1}$) satisfies the nonnegativity and edge constraints and therefore is in $\mathrm{FR}(G)$ by definition.

For the inductive step, assume that it holds for $r \geq 0$, and let us show that it holds for $r+1$. Let G be a graph with (i) and (ii) holding for any $|S| \leq r+1$, and $c^{r+2} \leq \epsilon\sqrt{n}$. We can choose, in particular, $|S| = 0$ and have that (i) and (ii) hold for the graph G itself. To ease notation, define

$$\mu := (1+\epsilon)^5(c^{r+1}/\sqrt{2})\sqrt{n}. \tag{13}$$

Let A be the $n \times n$ adjacency matrix of $\overline{G}$, i.e., $A_{ij} = 0$ whenever $(i,j) \in E$ or $i = j$, and $A_{ij} = 1$ otherwise. We know from (i) that all eigenvalues of A are at least $-(1+\epsilon)\sqrt{n} \geq -\mu$. Hence, the matrix $B = A + \mu I$ is positive semidefinite, and there exist vectors $z_1, \ldots, z_n$ such that $B_{ij} = z_i^T z_j$. Therefore

$$\|z_i\|^2 = B_{ii} = \mu \quad \text{for all } i \geq 1. \tag{14}$$

Let $z_0 = \sum_{i=1}^n z_i$. Then

$$\|z_0\|^2 = \left(\sum_{i>0} z_i\right)^T \left(\sum_{j>0} z_j\right) = \sum_{i,j>0} B_{ij} = \sum_{i>0}\sum_{j>0} B_{ij}.$$

To estimate $\sum_{j>0} B_{ij} = \sum_{j>0} A_{ij} + \mu$ for $i > 0$, observe that we have from (ii) that

$$\frac{1}{1+\epsilon}\frac{n}{2} \leq \sum_{j>0} A_{ij} \leq (1+\epsilon)\frac{n}{2},$$

while $\mu \leq (c^{r+2}/2)\sqrt{n} \leq \epsilon n/2$. Hence,

$$\frac{1}{1+\epsilon}\frac{n}{2} \leq \sum_{j>0} B_{ij} \leq (1+\epsilon)^2\frac{n}{2}, \tag{15}$$

and we conclude that

$$\frac{1}{1+\epsilon}\frac{n^2}{2} \le \|z_0\|^2 \le (1+\epsilon)^2\frac{n^2}{2}. \tag{16}$$

For every $i \ge 0$ let v_i be the unit length vectors in the direction of the vector z_i, i.e., $v_i = z_i/\|z_i\|$, and let $x_i = (v_i^T v_0)^2$. Observe that $x_0 = (v_0^T v_0)^2 = 1$.

We claim that $x = (x_1, \ldots, x_n)^T$ is in $N_+^{r+1}(G)$. Let us first show how the proof of Lemma 3.3 follows from this claim. Indeed, from (ii) we have that

$$v_i^T v_0 = \left(\frac{z_i}{\|z_i\|}\right)^T \left(\frac{\sum_{j>0} z_j}{\|z_0\|}\right) = \frac{\sum_{j>0} B_{ij}}{\sqrt{\mu}\|z_0\|}.$$

Together with (15) and (16) we can estimate $x_i = (v_i^T v_0)^2$ by

$$\frac{1}{(1+\epsilon)^4}\cdot\frac{1}{2\mu} \le x_i \le (1+\epsilon)^5\frac{1}{2\mu}, \tag{17}$$

and from (13) we have that

$$x_i \ge \frac{1}{2(1+\epsilon)^4}\cdot\frac{\sqrt{2}}{(1+\epsilon)^5 c^{r+1}\sqrt{n}} \ge \frac{1}{c^{r+2}\sqrt{n}};$$

thus $(1/c^{r+2}\sqrt{n})\mathbf{1} \le x \in N_+^{r+1}(G)$. By the monotonicity guaranteed in Lemma 2.4 we have $(1/c^{r+2}\sqrt{n})\mathbf{1} \in N_+^{r+1}(G)$, which indeed proves the inductive step.

We now prove the claim $x \in N_+^{r+1}(G)$ by presenting a matrix $Y \in M_+(N_+^r(G))$ whose 0th column corresponds to x. Indeed, let Y be the $(n+1)\times(n+1)$ matrix defined by $Y_{ij} = (v_i^T v_j)\sqrt{x_i x_j}$ for all $i, j \ge 0$. By definition, $Y_{i0} = (v_i^T v_0)\sqrt{x_i} = x_i$ for $i \ge 0$, and in particular $Y_{00} = x_0 = 1$. We will show that Y satisfies (a), (b), (c$''$), and (d). Three of them are straightforward:

(a) Y is symmetric by definition.
(b) $Y_{ii} = \|v_i\|^2 x_i = x_i$ and hence $Y_{ii} = x_i = Y_{i0}$.
(d) Y is positive semidefinite because it can be represented by the vectors $\{\sqrt{x_i}v_i\}$, i.e., $Y_{ij} = (\sqrt{x_i}v_i)^T(\sqrt{x_j}v_j)$ for all $i, j \ge 0$.

Before proving (c$''$), observe that for $i, j > 0$ we have

$$Y_{ij} = \left(\frac{z_i}{\|z_i\|}\right)^T \left(\frac{z_j}{\|z_j\|}\right)\sqrt{x_i x_j} = (1/\mu)B_{ij}\sqrt{x_i x_j},$$

and B_{ij} is either μ, 0, or 1. So for $i, j > 0$ we have

$$Y_{ij} = \begin{cases} x_i & \text{if } i = j, \\ 0 & \text{if } i \ne j \text{ and } ij \in E, \\ (1/\mu)\sqrt{x_i x_j} & \text{if } i \ne j \text{ and } ij \notin E, \end{cases}$$

and the estimate of (17) gives that $x_i \sim 1/2\mu$ and $\sqrt{x_i x_j} \sim 1/2\mu$. Hence,

$$Y = \left[\begin{array}{cccc} 1 & x_1 & \cdots & x_n \\ x_1 & x_1 & 0 & \frac{\sqrt{x_i x_j}}{\mu} \\ \vdots & & \ddots & \\ x_n & 0 & \frac{\sqrt{x_i x_j}}{\mu} & x_n \end{array}\right] \sim \left[\begin{array}{cccc} 1 & \frac{1}{2\mu} & \cdots & \frac{1}{2\mu} \\ \frac{1}{2\mu} & \frac{1}{2\mu} & 0 & \frac{1}{2\mu^2} \\ \vdots & & \ddots & \\ \frac{1}{2\mu} & 0 & \frac{1}{2\mu^2} & \frac{1}{2\mu} \end{array}\right].$$

Consider Ye_i, the ith column of Y, for $i > 0$, and scale it by a factor of $1/x_i$ so that its 0th entry will be 1. We get a fractional solution where vertex i has value 1, its adjacent vertices have value 0, and its nonadjacent vertices j have value $(1/\mu)\sqrt{x_j/x_i} \sim 1/\mu$. Let G' be the subgraph of G induced on the latter vertices (i.e., those nonadjacent to i), and let n' denote the number of vertices in G'. Then by Lemma 2.5, we have that the fractional solution Ye_i is in $N_+^r(G)$ if and only if its restriction to G' is in $N_+^r(G')$. Each coordinate in the fractional solution restricted to G' is bounded by

$$\frac{1}{\mu}\sqrt{\frac{x_j}{x_i}} \leq \frac{1}{\mu}(1+\epsilon)^{9/2} \leq \frac{\sqrt{2}}{c^{r+1}\sqrt{n(1+\epsilon)}} \leq \frac{1}{c^{r+1}\sqrt{n'}},$$

where the first inequality is due to (17), the second is due to (13), and the third follows from $n' \leq (1+\epsilon)\frac{n}{2}$, which we have from (ii). The fractional solution restricted to G' is thus dominated by the uniform solution $(1/c^{r+1}\sqrt{n'})\mathbf{1}$, which belongs to $N_+^r(G')$ by applying the induction hypothesis to G'. (Note that G' satisfies (i) and (ii) for any $0 \leq |S| \leq r$ by definition, and that we have $c^{r+1} \leq \epsilon\sqrt{n}/c \leq \epsilon\sqrt{n'}$.) From the monotonicity guaranteed by Lemma 2.4, we conclude that also the fractional solution restricted to G' is in $N_+^r(G')$, and therefore $Ye_i \in N_+^r(G)$.

Consider Yf_i, the difference between column 0 and column i of Y, for $i > 0$. Its 0th entry is $1 - x_i \sim 1 - 1/2\mu$, its ith entry is 0, and any other jth entry is at most roughly $1/2\mu$. Observe that

$$x_i \leq \frac{(1+\epsilon)^5}{2\mu} \leq \frac{1}{\sqrt{2n}} \leq 1 - \frac{1}{\sqrt{2}}, \tag{18}$$

where the first inequality is due to (17), the second is due to (13), and the third is due to $\sqrt{n} \geq 5\epsilon\sqrt{n} \geq 5c^{r+2} > 10$. Scaling the vector Yf_i by a factor $1/(1-x_i)$ so that its 0th entry is 1, we obtain a fractional solution in which the value of the jth entry is at most

$$\frac{x_j}{1-x_i} \leq \frac{(1+\epsilon)^5/2\mu}{1/\sqrt{2}} = \frac{1}{c^{r+1}\sqrt{n}}.$$

The fractional solution is thus dominated by $(1/c^{r+1}\sqrt{n})\mathbf{1}$, which by the induction hypothesis belongs to $N_+^r(G)$. (Note that G satisfies the requirements for r). From the monotonicity guaranteed by Lemma 2.4 (as all entries of Yf_i are nonnegative), we conclude that $Yf_i \in N_+^r(G)$.

We therefore have that (c″) holds, which completes the proof of the inductive step for $N_+^r(G)$.

Finally, let us show that the proof extends also to $N_{\mathrm{FR}+}^r(G)$. We need to consider also Yf_{ij} for $ij \in E$. The 0th entry of this vector is $1 - x_i - x_j \sim 1 - 2/2\mu$, the ith and jth entries are 0, and any other kth entry is either roughly $1/2\mu$ if k is adjacent to both i, j, or roughly $1/2\mu - 2/2\mu^2 \sim 1/2\mu$ if k is nonadjacent to both i, j, or roughly $1/2\mu - 1/2\mu^2 \sim 1/2\mu$ if k is adjacent to exactly one of i, j. Similar to (18) we have that

$$x_i + x_j \leq 2 \cdot \frac{1}{\sqrt{2n}} \leq 1 - \frac{1}{\sqrt{2}}.$$

Scaling this vector (by a small factor) so that the 0th entry is 1, we obtain a fractional

solution in which the value of the kth entry is at most

$$\frac{x_k}{1-x_i-x_j} \le \frac{(1+\epsilon)^5/2\mu}{1/\sqrt{2}} = \frac{1}{c^{r+1}\sqrt{n}}.$$

The fractional solution is thus dominated by $(1/c^{r+1}\sqrt{n})\mathbf{1}$, which by the induction hypothesis belongs to $N_+^r(G)$. From the monotonicity guaranteed by Lemma 2.4 (as all entries of Yf_{ij} are nonnegative), we conclude that $Yf_{ij} \in N_+^r(G)$. □

LEMMA 3.4. *Let $\epsilon > 0$. Then there exists an $\epsilon' > 0$ that depends only on ϵ such that for any $r \le \epsilon' \log n$, a random graph $G_{n,1/2}$ almost surely satisfies all the requirements of Lemma* 3.3.

Proof. Observe that a sufficiently small $\epsilon' > 0$ that depends on ϵ guarantees that $c^{r+1} \le \epsilon\sqrt{n}$ (we can assume, without loss of generality, that $\epsilon < 1/5$).

Consider a particular choice of S of size $s \le r$, and its corresponding graph $G'(V', E')$ (the subgraph of G induced on the vertices that are nonadjacent to all the vertices of S). The number of vertices in G', which we denote by $n' = |V'|$, has binomial distribution $B(n-s, 1/2^s)$. Since $s \le \log n \le n/4$, we have by Chernoff bound that

$$\mathbb{P}\left[n' \le n/2^{s+1}\right] \le 2^{-\delta_1 n/2^s} \tag{19}$$

for some fixed $\delta_1 > 0$.

G' is a random graph (with edge probability $1/2$) on n' vertices. Therefore, the adjacency matrix of $\overline{G'}$ is a random symmetric matrix, and we can use results on the concentration of its eigenvalues. In particular, we have from Krivelevich and Vu [19] (who improve the concentration shown by Füredi and Komlós [9]; see also [2]) that

$$\mathbb{P}\left[G' \text{ does not satisfy (i)}\right] \le 2^{-\delta_2 n'} \tag{20}$$

for some $\delta_2 > 0$ that depends on ϵ.

Since G' is a random graph, the degree of a particular vertex in $\overline{G'}$ has binomial distribution $B(n'-1, 1/2)$. By Chernoff bound and the union bound on the n' vertices we have that

$$\mathbb{P}\left[G' \text{ does not satisfy (ii)}\right] \le n' 2^{-\delta_3 n'} \tag{21}$$

for some fixed $\delta_3 > 0$ that depends on ϵ.

Using the union bound on the events of (20) and (21) we can bound the probability that G' does not satisfy (i) or (ii). In order to obtain a bound in terms of n (rather than n'), we add to the union bound also the event of (19) and have that for some fixed $\delta > 0$ that depends on ϵ,

$$\mathbb{P}\left[G' \text{ does not satisfy (i) or (ii)}\right] \le n 2^{-\delta n/2^s}.$$

Taking the union bound on all possible sets S of size at most r, the probability that the requirements of Lemma 3.3 do not hold is at most

$$\sum_{s=0}^{r} \binom{n}{s} n 2^{-\delta n/2^s} \le r n^{r+1} 2^{-\delta n/2^r} \le n^{r+2} 2^{-\delta n/2^r} \ll 1$$

when $r \le \epsilon' \log n$ for a sufficiently small $\epsilon' > 0$ that depends on ϵ, and hence these requirements hold almost surely. □

The proof of Theorem 3.1 follows from Lemmas 3.3 and 3.4.

3.2. Upper bound on the value of $N_+^r(G_{n,1/2})$. We prove Theorem 3.2 by showing that the inequality $\mathbf{1}^T x \le 4\sqrt{n}/d^{r+1}$ is almost surely valid for $N_+^r(G)$. First we exhibit in Lemma 3.5 certain conditions that are sufficient for this inequality to be valid for $N_+^r(G)$. We then show in Lemma 3.6 that these conditions are almost surely satisfied by a random graph $G_{n,1/2}$.

The Lovász theta function of a graph is defined as $\vartheta(G) := \max\{\mathbf{1}^T x : x \in TH(G)\}$, where $TH(G)$ is the solution set of the nonnegativity constraints (4) and the so-called orthogonality constraints (see [21, 11] for a definition). Lovász and Schrijver [23] show that the orthogonality constraints have N_+-rank at most 1, and hence $N_+(G) \subseteq TH(G)$.

LEMMA 3.5. *Let G be a graph on n vertices, let $d = \sqrt{2}(1-\epsilon)$ for $0 < \epsilon < 1$, and let $r \ge 1$. Assume that for every $S \subset V$ with $|S| \le r$, the graph $G' = G - S - \Gamma(S)$ satisfies the following (letting n' denote the number of vertices in G'):*

(i) $\vartheta(G') \le 2(1+\epsilon)\sqrt{n'}$.

(ii) *The degree of every vertex in $\overline{G'}$ is between $\frac{1}{1+\epsilon}\frac{n'}{2}$ and $(1+\epsilon)\frac{n'}{2}$.*

If $d^{r+1} \le \epsilon^2\sqrt{n}$, then $\max\{\mathbf{1}^T x : x \in N_+^r(G)\} \le 4\sqrt{n}/d^{r+1}$, and similarly for $N_{\mathrm{FR}+}^r$.

Proof. Proceed by induction on r. For the base case $r = 1$, we can choose $|S| = 0$ and then (i) and (ii) hold for the graph G itself. In particular, we have that

$$\max\{\mathbf{1}^T x : x \in N_+(G)\} \le \vartheta(G) \le 2(1+\epsilon)\sqrt{n} < 4\sqrt{n}/d^2.$$

For the inductive step, assume that it holds for $r \ge 1$, and let us show that it holds for $r+1$. In other words, given a graph G with (i) and (ii) holding for any $|S| \le r+1$, we will prove that the inequality $\mathbf{1}^T x \le 4\sqrt{n}/d^{r+2}$ is valid for $N_+^{r+1}(G)$. By Lemma 2.6 we know that it suffices to prove that for every vertex v, the inequality that arises from the contraction of v, i.e., $\mathbf{1}^T x \le 4\sqrt{n}/d^{r+2} - 1$, is valid for $N_+^r(G - \Gamma(v) - v)$.

By the induction hypothesis for $G' = G - \Gamma(v) - v$ we have that $\max\{\mathbf{1}^T x : x \in N_+^r(G')\} \le 4\sqrt{n'}/d^{r+1}$, i.e., the inequality $\mathbf{1}^T x \le 4\sqrt{n'}/d^{r+1}$ is valid for $N_+^r(G')$. Since (ii) holds also for G itself, we have that $n' \le (1+\epsilon)\frac{n}{2}$, and hence

$$\frac{4\sqrt{n'}}{d^{r+1}} \le \frac{4\sqrt{n}}{d^{r+1}}\frac{\sqrt{1+\epsilon}}{\sqrt{2}} = \frac{4\sqrt{n}}{d^{r+2}}\sqrt{1+\epsilon}(1-\epsilon) \le \frac{4\sqrt{n}(1-\epsilon^2)}{d^{r+2}} \le \frac{4\sqrt{n}}{d^{r+2}} - 1,$$

where the last inequality follows from $d^{r+2} \le 4\epsilon^2\sqrt{n}$. Therefore we have that for $N_+^r(G')$ the inequality $\mathbf{1}^T x \le 4\sqrt{n'}/d^{r+1} \le 4\sqrt{n}/d^{r+2} - 1$ holds, which completes the proof of the inductive step.

Finally, the proof immediately extends to the $N_{\mathrm{FR}+}^r$ operator since $N_{\mathrm{FR}+}^r(G) \subseteq N_+^r(G)$. ∎

LEMMA 3.6. *Let $\epsilon > 0$. Then there exists an $\epsilon' > 0$ that depends only on ϵ such that for any $r \le \epsilon' \log n$, a random graph $G_{n,1/2}$ almost surely satisfies all the requirements of Lemma* 3.5.

Proof. The proof is similar to that of Lemma 3.4, but with the different requirement (i). Juhász [15] shows that $\vartheta(G')$ is at most $(2 + o(1))\sqrt{n'}$, almost surely, by using the result of Füredi and Komlós [9] on the concentration of eigenvalues of random symmetric matrices. By using the stronger concentration result of Krivelevich and Vu [19] (see also [2]), we have that the analogue of (20) holds, and the proof follows. ∎

The proof of Theorem 3.2 follows from Lemmas 3.5 and 3.6.

Appendix. Properties of the matrix-cut operators.

A.1. Basic properties. We collect some properties of the matrix-cut operators defined in section 2.1. In particular, we prove Lemmas 2.4 and 2.5 (which are used in section 3.1).

Monotonicity. It is straightforward that the matrix-cut operators are monotone with respect to containment of K_1 and K_2, as follows.

LEMMA A.1. *Let $K_1' \subseteq K_1$ and $K_2 \subseteq K_2'$. Then $N(K_1', K_2') \subseteq N(K_1, K_2)$, and similarly for N_+.*

For the stable set problem it follows that the matrix-cut operators are monotone with respect to adding/removing edges.

COROLLARY A.2. *Let G' be a graph that is obtained from another graph G by adding edges. Then $N^r(G') \subseteq N^r(G)$, and similarly for N_+^r, N_{FR}^r, $N_{\mathrm{FR}+}^r$.*

Proof. Observe that $\mathrm{FR}(G') \subseteq \mathrm{FR}(G)$. The proof follows from Lemma A.1. ∎

Down-monotonicity. The next lemma shows that down-monotonicity (see section 2.2 for a definition) is preserved by the matrix-cut operators. It extends a similar result that is given for $N(\cdot)$ and $N_+(\cdot)$ by Goemans and Tunçel [10, Theorem 5.1] (under the name lower-comprehensive) and by Cook and Dash [5, Lemma 2.6] (under the name anti-blocking type).

LEMMA A.3. *Let $K_1, K_2 \subseteq Q$ be down-monotone convex cones. Then $N(K_1, K_2)$ is down-monotone, and similarly for N_+.*

Proof. Let $x \in N(K_1, K_2)$ and $0 \le x' \le x$ with $x_0' = x_0$. It suffices to prove that $x' \in N(K_1, K_2)$ when x, x' differ only in a single coordinate, say $i = 1$, since we can repeat the same argument for each coordinate. Furthermore, for a single coordinate $i = 1$ it suffices to prove the case $x_1' = 0$, since $N(K_1, K_2)$ is convex, and so convex combinations of x' and x give any desired value in coordinate $i = 1$.

Since $x \in N(K_1, K_2)$, there exists a matrix $Y \in M(K_1, K_2)$ with $x = Ye_0$. Define the matrix Y' by

$$Y'_{ij} = \begin{cases} 0 & \text{if } i = 1 \text{ or } j = 1, \\ Y_{ij} & \text{otherwise.} \end{cases}$$

We claim that $Y' \in M(K_1, K_2)$. Indeed, Y' clearly satisfies (a) and (b). To prove (c), let $u \in K_1^*, v \in K_2^*$, and from Proposition A.4 below we have that $u - u_1 x_1 \in K_1^*$ and $v - v_1 x_1 \in K_2^*$, and hence

$$u^T Y' v = (u - u_1 x_1)^T Y (v - v_1 x_1) \ge 0.$$

Observe that $x' = Y' e_0$, and therefore $x' \in N(K_1, K_2)$, as required.

For the proof of N_+ we need to show that (d) also holds, and indeed from the Gram matrix representation of Y we can obtain a Gram matrix representation of Y' by replacing the vector that corresponds to coordinate $i = 1$ with the all-zeros vector $\mathbf{0}$. ∎

PROPOSITION A.4. *Let $K \subseteq Q$ be down-monotone and let $v \in K^*$. Then $v - v_i e_i \in K^*$ for all $i \ge 1$.*

Proof. By the down-monotonicity of K, for every $x \in K$ we have that $x - x_i e_i \in K$, and hence $(v - v_i e_i)^T x = \sum_{j \ne i} v_j x_j = v^T (x - x_i e_i) \ge 0$. ∎

We can now prove Lemma 2.4, i.e., show that $N^r(G)$ is down-monotone for every $r \ge 0$, and similarly for N_+^r, N_{FR}^r, $N_{\mathrm{FR}+}^r$.

Proof of Lemma 2.4. Observe that Q is down-monotone by its definition (3), and that FRAC is down-monotone by its definition (6)–(7). By Lemma A.3 the matrix-cut operators preserve down-monotonicity and the proof follows. ∎

Flipping and renaming coordinates. The operators $N, N_+, N_{\mathrm{FR}}, N_{\mathrm{FR}+}$ are invariant under various operations, including *renaming coordinates* (i.e., permuting the order of coordinates), and *flipping coordinates* $x_i \to (x_0 - x_i)$ for any subset of the coordinates $\{1, 2, \ldots, n\}$. More formally, we present the following lemma.

LEMMA A.5 (Lovász and Schrijver [23]). *Let A be a linear transformation mapping Q onto itself. Then $N(AK_1, AK_2) = AN(K_1, K_2)$, and similarly for N_+. Hence $N(AK) = AN(K)$, and similarly for N_+.*

By flipping coordinates, one can extend Lemma A.3. For example, it follows that the N and N_+ operators preserve up-monotonicity; see Cook and Dash [5, section 2] (as the blocking property) and Goemans and Tunçel [10, section 5] (as the "convex corner" property).

Intersection with faces. A *face* of Q is the intersection of Q with hyperplanes of the form $\{x : x_i = 0\}$ or $\{x : x_i = x_0\}$. The intersection of K with a face of Q consists of all $x \in K$ with one or more of their coordinates *fixed* to 0 or x_0 (recall that x_0 corresponds to 1 in the nonhomogenous case).

The following lemma proves equivalence between fixing some coordinates before applying a matrix-cut operator (e.g., in K) and afterwards (e.g., in $N(K)$). It extends a similar result that is given by Goemans and Tunçel [10] for $N(\cdot)$ and $N_+(\cdot)$.

LEMMA A.6. *If F is a face of Q, then $N(K_1 \cap F, K_2) = N(K_1, K_2) \cap F$ and similarly for N_+.*

Proof. The direction "$\subseteq$" follows from Lemma A.1, since $N(K_1 \cap F, K_2) \subseteq N(K_1, K_2)$ and $N(K_1 \cap F, K_2) \subseteq N(F, K_2) \subseteq F$, and similarly for N_+.

For the converse direction "$\supseteq$" with the N operator, let $x \in N(K_1, K_2) \cap F$. Then there exists a matrix $Y \in M(K_1, K_2)$ with $Ye_0 = x$. Let H be any one of the hyperplanes of the form $\{x : x_i = 0\}$ or $\{x : x_i = x_0\}$ that define F. Since $e_j, f_j \in Q^* \subseteq K_2^*$ for all j, we have that $Ye_j \in K_1 \subseteq Q$ and $Yf_j \in K_1 \subseteq Q$, while their sum satisfies $Ye_j + Yf_j = Ye_0 = x \in F \subset H$. Since H defines a face of Q, then by definition of a face we have that Ye_j (and also Yf_j) must belong to H.[1] But every $v \in \mathbb{R}^{n+1}$ is a linear combination of $\{e_0, e_1, \ldots, e_n\}$ and $Ye_j \in H$ for all $j \geq 0$, and so $Yv \in H$ for every v, including all $v \in K_2^*$.

For every $v \in K_2^*$ we have that Yv belongs to $K_1 \subseteq Q$ by the definition of Y. We saw above that Yv also belongs to all hyperplanes H that define F, and we conclude that Yv belongs also to F. Hence, $Yv \in K_1 \cap F$ for all $v \in K_2^*$, implying that $Y \in M(K_1 \cap F, K_2)$ and $x \in N(K_1 \cap F, K_2)$. The proof for N_+ is similar, since Y is also known to be positive semidefinite. □

We remark that the above proof of Lemma A.6 extends to the case where F is a face of K_1, as shown by Cook and Dash [5, Lemma 2.2] for $N(\cdot)$ and $N_+(\cdot)$. For the special cases $K_2 = Q$ and $K_2 = \mathrm{FR}$ we obtain the following.

COROLLARY A.7. *If F is a face of Q (or a face of K), then $N(K \cap F) = N(K) \cap F$, and similarly for N_+, N_{FR}, $N_{\mathrm{FR}+}$.*

Deleting fixed coordinates. Suppose that K is contained in a face of Q. Then some of the coordinates are fixed (i.e., $x_i = 0$ or $x_i = x_0$), and it may be desirable to delete these coordinates and reduce the dimension. Formally, a *deletion* operation of indices subset $I \subset \{1, \ldots, n\}$ is the function $f : \mathbb{R}^{n+1} \to \mathbb{R}^{n+1-|I|}$, where $f(x)$ is the vector x restricted to the coordinates not in I, i.e., $f(x) = (x_i)_{i \notin I}$.

[1] In other words, suppose that the hyperplane H is defined by the equality $u^T x = 0$ (with $u = e_i$ or $u = f_i$) and that the inequality $u^T x \geq 0$ is valid for Q (i.e., Q is entirely contained in one side of H). We then have that $u^T(Ye_j), u^T(Yf_j) \geq 0$, while their sum is $u^T x = 0$, implying that $u^T(Ye_j) = u^T(Yf_j) = 0$.

For the stable set problem it is straightforward that the effect of fixing and deleting a coordinate of $\mathrm{FR}(G)$ is as follows.

LEMMA A.8. *Let $F = Q \cap \{x : x_i = 0\}$, and let f be the deletion operation of coordinate i. Then $f(\mathrm{FR}(G) \cap F) = \mathrm{FR}(G - i)$.*

LEMMA A.9. *Let $F = Q \cap \{x : x_i = x_0\}$, and let f be the deletion operation of coordinate i. Then $f(\mathrm{FR}(G) \cap F) = \mathrm{FR}(G - i) \cap \{x : \forall j \in \Gamma(i), x_j = 0\}$.*

We show below that deleting fixed coordinates of K before applying a matrix-cut operator (e.g., in K) is equivalent to deleting them afterwards (e.g., in $N(K)$). This extends similar results that are given for $N(\cdot)$ and $N_+(\cdot)$ by Cook and Dash [5] (see also [25]). Technically, they consider an embedding operation (that introduces new coordinates that are fixed to either 0 or x_0), which is just the inverse of the deletion operation.

We first handle the basic case of one coordinate that is fixed to 0 (Lemma A.10), then extend the result to an arbitrary face F and to an arbitrary K_2 (Lemma A.11), and finally specialize it to the cases $K_2 = Q$ and $K_2 = \mathrm{FR}$ (Corollary A.12).

LEMMA A.10. *Let $F = Q \cap \{x : x_n = 0\}$ and let f be the deletion operation of coordinate n. If $K_1, K_2 \subseteq F$ are convex cones, then $f(N(K_1, K_2)) = N(f(K_1), f(K_2))$,*[2] *and similarly for N_+.*

Proof. The deletion operation f is a linear transformation from $\mathbb{R}^{n+1}$ to $\mathbb{R}^n$ and thus can be described as an $n \times (n+1)$ matrix A. Note that columns 0 to $n-1$ of A form an identity matrix, and column n of A is all zeros. We first claim that $AK^* = (AK)^*$ for $K = K_1$ and for $K = K_2$. Indeed, by definition, $u \in AK^*$ if there exists $r \in \mathbb{R}$ with $\binom{u}{r} \in K^*$. Note that $\binom{u}{r} \in K^*$ holds either for all values of r or for no value of r, since $K \subset \{x : x_n = 0\}$. Therefore,

$$AK^* = \left\{ u : \exists r \in \mathbb{R} \text{ with } \begin{pmatrix} u \\ r \end{pmatrix} \in K^* \right\} = \left\{ u : \begin{pmatrix} u \\ 0 \end{pmatrix} \in K^* \right\}.$$

We also have that

$$(AK)^* = \{u : u^T(Ax) \geq 0 \ \ \forall x \in K\} = \{u : A^T u \in K^*\}.$$

Since $A^T u = \binom{u}{0}$, we obtain $AK^* = (AK)^*$.

Let us now prove that $M(AK_1, AK_2) = AM(K_1, K_2)A^T$. For the direction "$\subseteq$", let $Y \in M(AK_1, AK_2)$. Then by (c), for every $u \in K_1^*, v \in K_2^*$ we have that $u^T A^T Y A v \geq 0$. We therefore have that

$$\begin{pmatrix} Y & \mathbf{0} \\ \mathbf{0}^T & 0 \end{pmatrix} = A^T Y A \in M(K_1, K_2).$$

Multiplying by A from the left and by A^T from the right, we obtain (since AA^T is the identity matrix) that $Y \in AM(K_1, K_2)A^T$.

For the converse direction "$\supseteq$", let $Y \in AM(K_1, K_2)A^T$. Since $K_1 \subseteq \{x : x_n = 0\}$, every matrix in $M(K_1, K_2)$ has only zeros in row n, and by the symmetry (a) it has only zeros also in column n. Hence,

$$A^T Y A = \begin{pmatrix} Y & \mathbf{0} \\ \mathbf{0}^T & 0 \end{pmatrix} \in M(K_1, K_2).$$

[2] Note that the application of N in the right-hand side is in a smaller dimension than in the left-hand side.

By (c), for every $u \in K_1^*, v \in K_2^*$ it holds that $u^T A^T Y A v \geq 0$, and hence $Y \in M(AK_1, AK_2)$.

Now since $A^T e_0$ is just e_0 (in a larger dimension), we conclude that

$$N(AK_1, AK_2) = AM(K_1, K_2)A^T e_0 = AM(K_1, K_2)e_0 = AN(K_1, K_2).$$

The proof for the N_+ operator is similar since Y is positive semidefinite if and only if $A^T Y A$ is (observe that Y has a Gram matrix representation if and only if $A^T Y A$ has such a representation). □

LEMMA A.11. *Let $F = Q \cap \{x : \forall i \in I_0, x_i = 0\} \cap \{x : \forall i \in I_1, x_i = x_0\}$, and let f be the deletion operation of the coordinates $I_0 \cup I_1$. If $K_1 \subseteq F$ and $K_2 \subseteq Q$ are convex cones, then $f(N(K_1, K_2)) = N(f(K_1), f(K_2 \cap F))$, and similarly for N_+.*

Proof. K_1 and $K_2 \cap F$ are both contained in F, so we can repeatedly apply Lemma A.10 to them and delete the coordinates of $I_0 \cup I_1$. (Note that by using Lemma A.5 we can extend Lemma A.10 also to deleting coordinates that are fixed to x_0.) It follows that $f(N(K_1, K_2 \cap F)) = N(f(K_1), f(K_2 \cap F))$.

By Lemma A.6 we have that $N(K_1, K_2 \cap F) = N(K_1, K_2) \cap F$, and since $N(K_1, K_2) \subseteq K_1 \subseteq F$, we have that $N(K_1, K_2 \cap F) = N(K_1, K_2)$. The proof follows. □

COROLLARY A.12. *Let $F = Q \cap \{x : \forall i \in I_0, x_i = 0\} \cap \{x : \forall i \in I_1, x_i = x_0\}$, and let f be the deletion operation of the coordinate $I_0 \cup I_1$. If $K \subseteq F$ is a convex cone, then $f(N(K)) = N(f(K))$,[3] and similarly for N_+, N_{FR}, and $N_{\mathrm{FR}+}$.*

Proof. For the N operator we have from Lemma A.11 that

$$f(N(K)) = N(f(K), f(Q \cap F)),$$

and $f(Q \cap F)$ is just Q in the smaller dimension, so $f(N(K)) = N(f(K))$. The proof for the N_+ operator is similar.

For the N_{FR} operator we have from Lemma A.11 that

$$f(N_{\mathrm{FR}}(K)) = N(f(K), f(\mathrm{FR}(G) \cap F)),$$

and it follows from Lemmas A.8 and A.9 that $f(\mathrm{FR}(G) \cap F) = \mathrm{FR}(G - I_0 - I_1) \cap H$, where $H = \{x : x_i = 0 \ \forall i \in \Gamma(I_1) - I_0 - I_1\}$. We therefore have that

$$f(N_{\mathrm{FR}}(K)) = N(f(K), \mathrm{FR}(G - I_0 - I_1) \cap H).$$

Note that $f(K) \subset H$ since $K \subseteq F \cap \mathrm{FR}(G) \subseteq H$, and so by Lemma A.6 we have that $f(N_{\mathrm{FR}}(K)) = N_{\mathrm{FR}}(f(K))$, as required. The proof for $N_{\mathrm{FR}+}(K)$ is similar. □

Removing vertices from the graph. For the stable set problem, the properties collected so far, and in particular Corollary A.12, give a useful characterization to whether $x \in N^r(G)$ in the case that x has a fixed coordinate (i.e., $x_i = 0$ or $x_i = x_0$).

Recall that $V = \{1, \ldots, n\}$. For a vector $x \in \mathbb{R}^n$ and a subset $W \subset V$, we denote by x_W the restriction of x to the coordinates of W. We can now prove Lemma 2.5, showing that if $x \in \mathbb{R}^n$ with $x_i = 1$ and $x_j = 0$ for all $j \in \Gamma(i)$, then for all $r \geq 0$, $x \in N^r(G)$ if and only if $x_{V - \Gamma(i) - i} \in N^r(G - \Gamma(i) - i)$, and similarly for N_+^r, N_{FR}^r, and $N_{\mathrm{FR}+}^r$.

Proof of Lemma 2.5. It is clear that x belongs to the face F of Q that is defined by the hyperplanes $\{x : x_i = x_0\}$ and $\{x : x_j = 0\}$ for all $j \in \Gamma(i)$. Then $x \in N^r(G)$ if and only if $x \in N^r(G) \cap F$, which is equivalent, by Corollary A.7, to

[3] Note that the application of N in the right-hand side is in a smaller dimension than in the left-hand side.

$x \in N^r(\mathrm{FR}(G) \cap F)$. Let f be the deletion operation of the coordinates $\Gamma(i) \cup \{i\}$, and then we have equivalently that $f(x) \in f(N^r(\mathrm{FR}(G) \cap F))$. By Corollary A.12, the latter is equivalent to $f(x) \in N^r(f(\mathrm{FR}(G) \cap F))$. By Lemmas A.8 and A.9, we have that $f(\mathrm{FR}(G) \cap F) = \mathrm{FR}(G - \Gamma(i) - i)$, and the proof follows. The proof for N_+^r, N_{FR}^r, and $N_{\mathrm{FR}+}^r$ is similar. □

LEMMA A.13. *Let $x \in \mathbb{R}^n$ be a vector and assume that $x_i = 0$ for some i. Then $x \in N^r(G)$ if and only if $x_{V-i} \in N^r(G-i)$, and similarly for N_+^r, N_{FR}^r, and $N_{\mathrm{FR}+}^r$.*

Proof. It is clear that x belongs to the face F of Q that is defined by the hyperplane $x_i = 0$. Then $x \in N^r(G)$ if and only if $x \in N^r(G) \cap F$, which is equivalent, by Corollary A.7, to $x \in N^r(\mathrm{FR}(G) \cap F)$. Let f be the deletion operation of the coordinate i, and then we have equivalently that $f(x) \in f(N^r(\mathrm{FR}(G) \cap F))$. By Corollary A.12, the latter is equivalent to $f(x) \in N^r(f(\mathrm{FR}(G) \cap F))$. By Lemma A.8 we have that $f(\mathrm{FR}(G) \cap F) = \mathrm{FR}(G - i)$, and the proof follows. The proof for N_+^r, N_{FR}^r, and $N_{\mathrm{FR}+}^r$ is similar. □

A.2. Bounds on the rank. We describe some general methods to obtain upper and lower bounds on the N-rank and N_+-rank of valid inequalities and extend them to the N_{FR}-rank. We also illustrate the use of these methods on a few valid constraints for the stable set problem (see Table 1).

The N-rank of an inequality valid for $\mathrm{STAB}(G)$ depends only on the subgraph induced by those vertices with a nonzero coefficient, and similarly for N_+, N_{FR}, and $N_{\mathrm{FR}+}$. Indeed, if a vertex i has a zero coefficient, then the inequality being valid for $N^r(G)$ is equivalent, by Lemma 2.4, to the inequality being valid for $N^r(G) \cap \{x : x_i = 0\}$, which in turn is equivalent, by Lemma A.13, to the inequality being valid for $N^r(G - i)$.

Upper bounds on the N-rank. Lovász and Schrijver [23] give an upper bound on $N(K)$, which allows us to upper bound the N-rank of an inequality, as follows.

The *sum* of two sets $K', K'' \subseteq \mathbb{R}^{n+1}$ is defined as $K' + K'' := \{x' + x'' : x \in K', x'' \in K''\}$. Note that if K', K'' are convex cones in Q, then $K'+K''$ is also a convex cone in Q. Furthermore, if K', K'' are obtained via the homogenization procedure (1)–(2) from polytopes $P', P'' \subseteq \mathbb{R}^n$, respectively, then $K' + K''$ corresponds to all convex combinations of a point from P' and a point from P'' (recall that x_0 needs to be scaled to 1).

LEMMA A.14 (Lovász and Schrijver [23]). *For all $1 \le i \le n$,*

$$N(K) \subseteq \Big(K \cap \{x : x_i = 0\}\Big) + \Big(K \cap \{x : x_i = x_0\}\Big).$$

Proof. If $x \in N(K)$, then there exists $Y \in M(K)$ with $x = Ye_0 = Ye_i + Yf_i$ for any $i \le i \le n$. Clearly, $Ye_i \in K \cap \{x : x_i = x_0\}$ and $Yf_i \in K \cap \{x : x_i = 0\}$, and the proof follows. □

COROLLARY A.15. *If an inequality is valid for both $K \cap \{x : x_i = 0\}$ and $K \cap \{x : x_i = x_0\}$, then it is valid for $N(K)$.*

Goemans and Tunçel [10] note that repeatedly using Lemma A.14 and Corollary A.7 gives that, for all $I \subseteq \{1, \dots, n\}$ with $|I| = r$,

$$N^r(K) \subseteq \sum_{I_0 \subseteq I} \Big(K \cap \{x : \forall i \in I_0, x_i = 0\} \cap \{x : \forall i \in I \setminus I_0, x_i = x_0\}\Big).$$

In particular, this shows that the N-rank of any cone K is at most n, proving Theorem 2.1.

For the stable set problem, Corollary A.15 can be rephrased as follows (using Lemmas 2.5 and A.13).

LEMMA A.16 (Lovász and Schrijver [23]). *Let P be a convex set with* STAB $\subseteq P \subseteq$ FRAC. *If $a^T x \leq b$ is an inequality such that for some $i \in V$, both the deletion and contraction of i give an inequality valid for P, then $a^T x \leq b$ is valid for $N(P)$.*

For example, if C induces a chordless odd cycle in G, the *odd hole constraint*

$$\sum_{i \in C} x_i \leq \frac{|C| - 1}{2} \tag{22}$$

has N-rank at most (and actually exactly) 1, because both the contraction and the deletion of any vertex result in an inequality that is valid for FRAC. (In fact, Lovász and Schrijver [23] prove that N(FRAC) is exactly the relaxation that is obtained by adding to FRAC all the odd hole constraints.)

Lovász and Schrijver [23] also give the following upper bound on the N-rank of a graph. The proof follows by applying Lemma A.16 repeatedly for $n - \alpha(G) - 1$ vertices outside a maximum stable set in the graph, since the graph induced on the other vertices must be bipartite.

COROLLARY A.17 (Lovász and Schrijver [23]). *The N-rank of a graph G with stability number $\alpha(G)$ is at most $n - \alpha(G) - 1$.*

It follows that the N-rank of any graph G is at most $n-2$. Note that the N-rank of FR is at most $n - 2$, while the N-rank of a general cone K is at most (and can actually be) n.

We next analyze the N-rank of a few more examples, due to Lovász and Schrijver [23]. By Corollary A.17, if B is a clique in G, the *clique constraint*

$$\sum_{i \in B} x_i \leq 1 \tag{23}$$

has N-rank at most (and actually exactly) $|B| - 2$. Note that the class of all clique constraints strengthens the class of all edge constraints (5).

If D induces a chordless odd cycle in $\overline{G}$ (the edge complement of G), the *odd antihole constraint*

$$\sum_{i \in D} x_i \leq 2 \tag{24}$$

has N-rank at most (and actually exactly) $(|D| - 3)/2$, because the contraction of a vertex results in an inequality trivially valid for FRAC, and the deletion of a vertex results in an inequality that is the sum of two clique constraints, each of size $(|D|-1)/2$ and hence of N-rank $(|D| - 5)/2$.

If W induces an odd wheel in G with center $i_0 \in W$, the *odd wheel constraint*

$$\sum_{i \in W \setminus \{i_0\}} x_i + \frac{|W| - 2}{2} x_{i_0} \leq \frac{|W| - 2}{2} \tag{25}$$

has N-rank at most (and actually exactly) 2, since the contraction of the center vertex results in a trivial inequality, and the deletion of the center vertex results in the odd hole constraint.

Upper bounds on the $N_{\rm FR}$-rank. The methods for obtaining upper bounds on the N-rank can be extended (with modifications) to upper bounds on the $N_{\rm FR}$-rank, as follows.

LEMMA A.18. *For all $ij \in E$,*

$$N(K) \subseteq \Big(K \cap \{x : x_i = x_j = 0\}\Big) + \Big(K \cap \{x : x_j = x_0\}\Big) + \Big(K \cap \{x : x_i = x_0\}\Big).$$

Proof. If $x \in N_{\rm FR}(K)$, then there exists $Y \in M(K)$ with $x = Ye_0 = Ye_i + Ye_j + Yf_{ij}$ for any $ij \in E$. Clearly, $Ye_i \in K \cap \{x : x_i = x_0\}$, $Ye_j \in K \cap \{x : x_j = x_0\}$, and $Yf_{ij} \in K \cap \{x : x_i = x_j = 0\}$, and the proof follows. □

COROLLARY A.19. *Let $ij \in E$. If an inequality is valid for $K \cap \{x : x_i = x_0\}$, for $K \cap \{x : x_j = x_0\}$, and for $K \cap \{x : x_i = x_j = 0\}$, then it is valid for $N_{\rm FR}(K)$.*

Corollary A.19 can be rephrased as follows (using Lemmas 2.5 and A.13).

LEMMA A.20. *Let P be a convex set with* STAB $\subseteq P \subseteq$ FRAC. *If $a^T x \le b$ is an inequality such that for some $ij \in E$, the contraction of i, the contraction of j, and the deletion of $\{i, j\}$ give an inequality valid for P, then $a^T x \le b$ is valid for $N(P)$.*

The following upper bound on the $N_{\rm FR}$-rank of a graph follows by applying Lemma A.20 repeatedly on edges, so that the removal of their endpoints results in a bipartite graph (e.g., a matching that is maximal with respect to containment).

COROLLARY A.21. *Suppose that a graph G contains a set of β edges, the removal of whose endpoints results in a bipartite graph. Then the $N_{\rm FR}$-rank of G is at most β.*

It follows that the $N_{\rm FR}$-rank of a graph G is at most $(n-2)/2$ if n is even and $(n-1)/2$ if n is odd; in general it is at most $\lfloor (n-1)/2 \rfloor$. In particular, the $N_{\rm FR}$-rank of the clique constraint (23) is at most $\lfloor (|B|-1)/2 \rfloor$.

We can apply these bounds to the other examples. The $N_{\rm FR}$-rank of the odd hole constraint (22) is at most (and thus exactly) 1, since the $N_{\rm FR}$ operator is at least as strong as N. The $N_{\rm FR}$-rank of the odd antihole constraint (24) is at most $\lfloor (|D|+1)/4 \rfloor$, because the contraction of a vertex results in an inequality trivially valid for FRAC, and the deletion of two vertices results in an inequality that is the sum of two clique constraints, each of size at most $(|D|-1)/2$ and hence of $N_{\rm FR}$-rank $\lfloor (|D|-3)/4 \rfloor$.[4] The $N_{\rm FR}$-rank of the wheel constraint (25) is at most (and thus exactly) 1, since the contraction of the center vertex results in a trivial inequality, the contraction of a noncenter vertex results in an inequality that is valid for FRAC, and the deletion of these two vertices also results in an inequality that is valid for FRAC.

Lower bounds on the N-rank. Lovász and Schrijver [23] show that certain uniform fractional stable sets belong to $N^r(G)$, regardless of the graph G. For example, for $r = 0$ it is straightforward that $(1/2)\mathbf{1} \in$ FRAC(G). The following lemma allows us to extend this to larger r, with the uniform solution being smaller, depending on r.

LEMMA A.22 (Lovász and Schrijver [23]). *Assume that P is down-monotone and contains* STAB(G). *If $(1/r)\mathbf{1} \in P$ for $r > 0$, then $1/(r+1)\mathbf{1} \in N(P)$.*

Proof. Let K be the convex cone obtained from P via the homogenization procedure (1)–(2). Define the matrix $Y \in \mathbb{R}^{(n+1)\times(n+1)}$ by

$$Y_{ij} = \begin{cases} 1 & \text{if } i = j = 0, \\ 1/(r+1) & \text{if } (i = 0, j > 0) \text{ or } (i > 0, j = 0) \text{ or } (i = j > 0), \\ 0 & \text{otherwise.} \end{cases}$$

[4] In fact, direct calculations show that the $N_{\rm FR}$-rank of the odd antihole constraint (24) with $|D| = 7$ is at most 1.

To see that $Y \in M(K,Q)$ observe that (a), (b) clearly hold, and let us now show that (c$''$) holds:

$$Ye_i = \frac{1}{t+1}(e_0 + e_i) \in \mathrm{ST}(G) \subseteq K$$

and

$$Yf_i = \frac{r}{r+1}e_0 + \sum_{j\neq 0,i} \frac{1}{r+1}e_j = \frac{r}{r+1}\left(e_0 + \sum_{j\neq 0,i}\frac{1}{r}e_j\right).$$

By the induction hypothesis we have that

$$\sum_{j\neq 0,i}\frac{1}{r}e_j \leq \sum_{j\neq 0}\frac{1}{r}e_j \in P,$$

and the down-monotonicity of P implies that $Yf_i \in K$, and thus (c$''$) holds. We conclude that $Ye_0 \in N(K)$, i.e., $1/(r+1)\mathbf{1} \in N(P)$. □

COROLLARY A.23 (Lovász and Schrijver [23]). *$1/(r+2)\mathbf{1} \in N^r(G)$ for all $r \geq 0$.*

Proof. Proceed by induction on r. We mentioned above that the case $r = 0$ is trivial. The inductive step follows from Lemma A.22, since $N^r(\mathrm{FRAC}(G))$ clearly contains $\mathrm{STAB}(G)$ and is down-monotone by Lemma 2.4. □

COROLLARY A.24 (Lovász and Schrijver [23]). *The N-rank of a graph G with stability number $\alpha(G)$ is at least $n/\alpha(G) - 2$.*

Proof. Let r be the N-rank of G, and hence $N^r(G) = \mathrm{STAB}(G)$. By Corollary A.23 we have that $1/(r+2)\mathbf{1} \in N^r(G)$. The inequality $\mathbf{1}^T x \leq \alpha$ is valid for $\mathrm{STAB}(G) = N^r(G)$, and in particular for $1/(r+2)\mathbf{1}$, implying that $n/(r+2) \leq \alpha(G)$, and the proof follows. □

For example, the stability number of a clique B is 1, so the N-rank of B is at least, and hence exactly, $|B| - 2$. In fact, the above proof shows that the N-rank of the clique constraint (23) is at least, and hence exactly, $|B| - 2$. The stability number of an odd antihole D is 2, so the N-rank of D is at least $|D|/2 - 2$, and since $|D|$ is odd, it must be at least $(|D| - 3)/2$. In fact, this shows that the N-rank of the odd antihole constraint (24) is at least, and hence exactly, $(|D| - 3)/2$. Corollary A.23 also yields a lower bound on the N-rank of the wheel constraint (25). Indeed, let r be the N-rank of this constraint. Then we have that this constraint is valid for $N^r(G)$ and, in particular, for $1/(r+2)\mathbf{1} \in N^r(G)$. Thus,

$$\frac{1}{r+2}\left(|W| - 1 + \frac{|W|-2}{2}\right) \leq \frac{|W|-2}{2},$$

which gives us that $\frac{2(|W|-1)}{|W|-2} + 1 \leq r + 2$ and thus $r \geq 1 + \frac{2}{|W|-2}$. Since the N-rank of the wheel constraint is an integer, it must be at least, and hence exactly, 2.

Lower bounds on the N_{FR}-rank. The methods for obtaining lower bounds on the N-rank can be extended (with modifications) to lower bounds on the N_{FR}-rank, as follows.

LEMMA A.25. *Assume that P be down-monotone and contains $\mathrm{STAB}(G)$. If $(1/r)\mathbf{1} \in P$ for $r > 0$, then $1/(r+2)\mathbf{1} \in N_{\mathrm{FR}}(P)$.*

Proof. Define the matrix $Y \in \mathbb{R}^{(n+1)\times(n+1)}$ by

$$Y_{ij} = \begin{cases} 1 & \text{if } i = j = 0, \\ 1/(r+2) & \text{if } (i = 0, j > 0) \text{ or } (i > 0, j = 0) \text{ or } (i = j > 0), \\ 0 & \text{otherwise.} \end{cases}$$

To see that $Y \in M(K, FR)$ observe that (a), (b) clearly hold, and let us now show that (c$''$) holds:

$$Ye_i = \frac{1}{r+2}(e_0 + e_i) \in \mathrm{ST}(G) \subseteq K$$

and for $ij \in E$

$$Yf_{ij} = \frac{r}{r+2}e_0 + \sum_{l \neq 0,i,j} \frac{1}{r+2}e_l = \frac{r}{r+2}\left(e_0 + \sum_{l \neq 0,i,j} \frac{1}{r}e_l\right).$$

By the induction hypothesis we have that

$$\sum_{l \neq 0,i,j} \frac{1}{r}e_l \leq \sum_{l \neq 0} \frac{1}{r}e_l \in P,$$

and the down-monotonicity of P implies that $Yf_{ij} \in K$, and thus (c$''$) holds. We conclude that $Ye_0 \in N_{\mathrm{FR}}(K)$, i.e., $1/(r+2)\mathbf{1} \in N_{\mathrm{FR}}(P)$. □

COROLLARY A.26. *$1/(2r+2)\mathbf{1} \in N^r_{\mathrm{FR}}(G)$ for all $r \geq 0$.*

Proof. Proceed by induction on r. We mentioned above that the case $r = 0$ is trivial. The inductive step follows from Lemma A.25, since $N^r_{\mathrm{FR}}(\mathrm{FRAC}(G))$ clearly contains $\mathrm{STAB}(G)$ and is down-monotone by Lemma 2.4. □

COROLLARY A.27. *The N_{FR}-rank of a graph G with stability number $\alpha(G)$ is at least $n/(2\alpha(G)) - 1$.*

Proof. Let r be the N-rank of G, and hence $N^r(G) = \mathrm{STAB}(G)$. By Corollary A.26 we have that $1/(r+2)\mathbf{1} \in N^r(G)$. The inequality $\mathbf{1}^T x \leq \alpha(G)$ is valid for $\mathrm{STAB}(G) = N^r(G)$, and in particular for $1/(r+2)\mathbf{1}$, implying that $n/(2r+2) \leq \alpha(G)$, and the proof follows. □

For example, the N_{FR}-rank of a clique B is at least $|B|/2 - 1$ (since the stability number of B is 1), and it must be an integer, so we have that it is at least $\lfloor (|B|-1)/2 \rfloor$. In fact, the above proof shows that the N_{FR}-rank of the clique constraint (23) is at least, and hence exactly, $\lfloor (|B|-1)/2 \rfloor$. The N_{FR}-rank of an odd antihole D is at least $|D|/4 - 1$ (since the stability number of D is 2), and it must be an integer (while $|D|$ is odd), so we have that it is at least $\lfloor |D|/4 \rfloor$. In fact, this shows that the N-rank of the odd antihole constraint (24) is at least $\lfloor |D|/4 \rfloor$.

Upper bounds on the N_+-rank. Lovász and Schrijver [23] give also a sufficient condition for an inequality to be valid for $N_+(K)$. The following lemma considers an inequality $u^T x \geq 0$ with $u_0 \geq 0$ and $u_i \leq 0$ for $i \geq 1$. It can be extended to an arbitrary inequality $u^T x \geq 0$ by flipping the relevant coordinates according to Lemma A.5.

LEMMA A.28 (Lovász and Schrijver [23]). *If for all i with $u_i < 0$, $u^T x \geq 0$ is valid for $K \cap \{x : x_i = x_0\}$, then $u^T x \geq 0$ is valid for $N_+(K)$.*

By applying this to the stable set problem we obtain Lemma 2.6. Indeed, considering the original n-dimensional space, the inequalities $a^T x \leq b$ (with $a \in \mathbb{R}^n$) that are valid for $\mathrm{STAB}(G)$ are nontrivial only when $b > 0$ and $a \geq 0$, and then we can use Lemma A.28.

For example, the clique, odd hole, odd wheel, and odd antihole constraints all have N_+-rank at most (and thus exactly) 1. Lovász and Schrijver [23] show also that the so-called orthogonality constraints (see [21, 11] for a definition) are valid for $N_+(\mathrm{FRAC})$ by definition, and hence their N_+-rank is also 1.

One simple way to derive facet-defining valid inequalities from other facet-defining inequalities is *cloning* a clique at a vertex i. That is, replacing the vertex i by a clique and replacing every edge incident to i by corresponding edges that are incident to all the clique vertices and substituting the variable of i in the inequality with the sum of the variables of the clique vertices. In general, it is not clear how cloning influences the N_+-rank of an inequality. However, Goemans and Tunçel [10] note that Lemma 2.6 implies that cloning at the center vertex of an odd wheel inequality still has N_+-rank 1, and that cloning at one or several vertices of an odd wheel, odd hole, or odd antihole inequality has N_+-rank at most 2. Indeed, fixing any variable (of the corresponding subgraph) to 1, the resulting inequality can be seen to be a linear combination of clique inequalities and hence valid for $N_+(\text{FRAC})$.

COROLLARY A.29 (Lovász and Schrijver [23]). *If $G - \Gamma(i) - i$ has N_+-rank at most r for every $i \in V$, then the N_+-rank of G is at most $r + 1$.*

It follows, for example, that the N_+-rank of a clique, an odd antihole, or an odd wheel is at most (and hence exactly) 1. It also follows (as stated in Lemma 2.7) that the N_+-rank of a graph G is at most its stability number $\alpha(G)$. This bound is tight for a clique.

Lower bounds on the N_+-rank. Lovász and Schrijver [23] give no general method to lower bound the N_+-rank. The approach taken by Stephen and Tunçel [25], Goemans and Tunçel [10], and Cook and Dash [5] is to obtain an analogue of Corollary A.23 that holds for a specific cone K. That is, they show that $N_+^r(K)$ contains a "uniform" solution that does not belong to K_I, and thus obtain that the N_+-rank of K must be larger than r. Our analysis in section 3 also follows this approach.

We note that Goemans and Tunçel [10] give a sufficient condition for $N_+(K) = N(K)$ to hold, but this condition does not appear to be applicable to the stable set problem.

The ranks of the constraints exemplified above are listed in Table 1.

TABLE 1
The ranks of some example constraints.

Constraint	N-rank	N_{FR}-rank	N_+-rank	$N_{\text{FR}+}$-rank
odd hole (22)	1	1	1	1
clique (23)	$\lvert B\rvert - 2$	$\lfloor(\lvert B\rvert - 1)/2\rfloor$	1	1
antihole (24)	$(\lvert D\rvert - 3)/2$	$\lfloor\lvert D\rvert/4\rfloor \le \text{rank} \le \lfloor(\lvert D\rvert + 1)/4\rfloor$	1	1
wheel (25)	2	1	1	1

STABILITY OF ADAPTIVE AND NONADAPTIVE PACKET ROUTING POLICIES IN ADVERSARIAL QUEUEING NETWORKS*

DAVID GAMARNIK†

Abstract. We investigate the stability of packet routing policies in adversarial queueing networks. We provide a simple classification of networks which are stable under any greedy scheduling policy. We show that a network is stable if and only if the underlying undirected connected graph contains at most two edges. We also propose a simple and distributed policy which is stable in an arbitrary adversarial queueing network even for the critical value of the arrival rate $r = 1$. Finally, a simple and checkable network flow-type load condition is formulated for adaptive adversarial queueing networks, and a policy is proposed which achieves stability under this new load condition. This load condition is a relaxation of the integral network flow-type condition considered previously in the literature.

Key words. congestion, scheduling, multicommodity flow

1. Introduction.

The focus of this paper is the stability of adversarial queueing systems. Such queueing models have attracted much attention recently as a convenient tool for modeling packet injection and routing in a communication network. An adversarial assumption on the nature of the incoming traffic substitutes more traditional stochastic arrival assumptions. Two types of queueing networks are usually considered: circuit switch and packet switch networks (also referred to as adaptive and nonadaptive packet routing networks). In the first model, an adversary injects packets for processing, specifying the paths that the packets have to follow. The scheduler needs to decide which packets to process when several packets are competing for the same edge. Such models have been introduced by Borodin et al. in [6] and considered subsequently in several papers [3], [9], [11], [17].

In packet switch networks, an adversary injects packets and specifies only their origin and destination. The scheduler is free to choose a path along which the packets are processed. This model has been considered only recently by Aiello et al. [1]. In both models, the goal of the scheduler is to keep the queue lengths of packets competing for the same edge as small as possible. While constructing schedules which guarantee minimal queue length is a computationally intractable problem (even static circuit switch and packet switch scheduling problems are NP-complete), researchers have focused on schedules which at least guarantee bounded queue lengths at all times, i.e., stability.

1.1. Stability of nonadaptive packet routing schedules.

A natural necessary condition for stability exists in circuit switch-type networks. A positive integer w (called burstiness) exists such that, for any edge e and any time interval $[t_1, t_2)$, the total number of packets that are injected and contain edge e on their paths should not be bigger than $t_2 - t_1 + w$ (assuming each edge processes packets with unit speed).

If the load condition is systematically violated, the queue lengths will build up no matter what schedule is used. The focus of the research has been understanding when the load condition is also sufficient for stability. It was proven that acyclic and unidirectional ring queueing networks are stable whenever the load condition is met and an arbitrary greedy schedule is implemented [3], [6], [16]. Meanwhile, certain natural policies were shown to be unstable even if the load condition holds. Andrews [2] and Andrews et al. [3] showed that First-In-First-Out (FIFO) and Nearest-To-Go (NTG) policies can be unstable. The instability of FIFO policies was also shown before by Bramson [7] for nonadversarial (stochastic) queueing networks. Borodin et al. [6] showed that NTG policy can be unstable in certain networks even if the arrival rate of the packets is bounded by an arbitrarily small constant r. On the other hand, Furthest-To-Go policy is stable in all networks (Andrews et al. [3]) whenever the maximal arrival rate r is strictly smaller than one. Goel [11] provided a complete algorithmic characterization of directed graphs which are stable for all greedy scheduling rules. Such characterization can be adapted to undirected graphs in which packets competing for an edge from opposite sides can simultaneously cross the edge. Our assumption throughout the paper will be that only one packet can cross any given edge at a time from either end, and all the graphs are assumed to be undirected. Obtaining a complete algorithmic classification of stable networks for every policy seems to be an unachievable task. It is shown in Gamarnik [10] that checking stability for a class of *generalized priority* policies is an algorithmically undecidable problem. Whether undecidability holds for more common policies like FIFO or priority policies remains to be seen.

1.2. The stability of adaptive packet routing schedules. The stability of adaptive packet routing schedules in adversarial queueing networks has only recently been analyzed by Aiello et al. [1]. This model does not have a natural load condition for stability, as opposed to nonadaptive queueing models. There is no explicit load on edges implied by the incoming traffic; rather, the load depends on the routing policy used. Aiello et al. thus introduced the following assumption. Suppose, for some positive integer w and some positive real $r < 1$, that an adversary can associate with each incoming packet a path in such a way that, in every time interval $[t, t+w)$, every edge has been assigned to no more than rw paths. In other words the adversary should be able to reformulate the problem in the nonadaptive sense, described above, without revealing the underlying assigned paths. It was shown in [1] that a stable distributed routing policy exists under the assumption above. Also, the schedule does not assume the knowledge of the arrival rate r and interval w, and the total number of packets in the network is bounded by $O(m^{5/2}n^{5/2}w/(1-r))$, where m and n are the numbers of edges and nodes in the graph, respectively.

1.3. Results. A number of questions remain outstanding, some of which are listed in Borodin et al. [6]. It is not clear whether a ring-type queueing network allowing traffic in both directions is stable under any greedy scheduling rule. More generally, which networks are stable under all greedy scheduling rules (universally stable)? This question was resolved by Goel [11] for directed graph queueing networks but remains outstanding for undirected graphs in which each edge can be crossed by only one packet at a time from either end. We provide in this paper a very simple answer to this problem. A connected undirected graph is universally stable if and only if it contains at most two edges. We establish this result by proving universal stability for a simple graph with two edges, G_1, and constructing unstable greedy schedules for graphs G_2, G_3, G_4 (see Figure 1). We will show specifically that such an

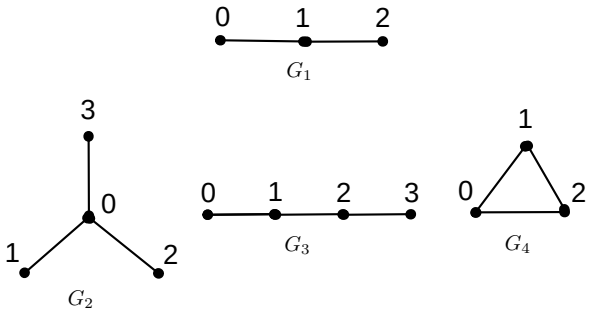

FIG. 1. *Graphs* G_1, G_2, G_3, G_4.

unstable greedy policy exists when the maximal arrival rate r satisfies $r^3 + r^4 > 1$ for the graph G_2 and satisfies $r^4 + r^5 > 1$ for the graphs G_3, G_4.

These schedules are very similar to the ones constructed by Goel [11] and Andrews et al. [3]. Clearly, any connected undirected graph with more than two edges contains one of the graphs G_2, G_3, G_4 as a subgraph and as a result is unstable. In particular, the ring-type queueing network either is graph G_4 or contains G_3 as a subgraph and, as a result, is not universally stable. We then propose a very simple distributed Nearest-To-Origin (NTO) priority policy and prove that this policy is stable in all adversarial queueing networks even for the critical arrival rate $r = 1$. This answers positively the question posed in [6] on the existence of a stable scheduling policy under a critical arrival rate $r = 1$.

For the case of adaptive packet routing models, we consider a more relaxed load condition than the one used in [1]. We assume that, for the packets that arrive during any time interval of the length w, the corresponding static multicommodity flow problem has a feasible *fractional* solution with maximal congestion (to be defined) not bigger than rw, where $r < 1$. That is, we relax the integrality requirement in the multicommodity flow-type constraint on the arriving traffic considered in [1]. We construct a simple discrete review-type policy based on the static packet routing problem and prove that this policy is stable under this relaxed load condition. The algorithm is based on an algorithm proposed in [5] for the static packet routing problem, which achieves asymptotic optimality as the network load diverges to infinity.

The advantage of the relaxed assumption above is clear—the load condition can be checked efficiently by solving a corresponding fractional multicommodity flow problem, whereas the integral multicommodity flow problem is NP-complete. Specifically, if the maximal arrival rate for any pair of origin-destination nodes (i, j) is r_{ij}, then there exists a stable packet routing protocol if the fractional multicommodity flow problem with parameters r_{ij} has a feasible solution with maximal congestion smaller than one. Our scheduling rule, however, would not assume the knowledge of the rates r_{ij}. We will also show that if, for any feasible solution, the maximal congestion is bigger than one, then no stable policy exists. We do not know whether a stable policy exists when the smallest maximal congestion is equal to one.

The disadvantage of our schedule compared to the one of Aiello et al. is that it occasionally needs information about the queue lengths in the entire network and thus is not distributed. Our bounds on maximal queue lengths are also inferior to the ones in [1].

We conclude with some open questions and directions for further research.

2. Definitions and assumptions. A nonadaptive adversarial queueing network is given as a graph (V, E). An adversary injects packets for processing. Each arriving packet has a prespecified path it has to follow. Once the end of the path is reached, the packet leaves the network. Each packet takes a unit time to cross a single edge, and only one packet in either direction can cross any given edge at a time. Packet processing occurs at integer time epochs $t = 0, 1, 2, \ldots$, although packet arrival can occur at an arbitrary real time. Packets that wait to cross some edge e accumulate into a queue at the vertex of e until chosen to cross. We introduce some additional notation in order to formally describe the dynamics. Let $\mathcal{P}$ be the set of all simple paths in the network (the set of paths that can be requested by packets).

For each path $P \in \mathcal{P}$, let $\{e_0^P, e_1^P, \ldots, e_{k(P)}^P\}$ be the set of consecutive edges in P. Let $A_P(t_1, t_2)$ denote the total number of packets injected during the time interval $[t_1, t_2)$ that request path P. For each $P \in \mathcal{P}$ and $e \in P$, let $D_{(e,P)}(t_1, t_2)$ be the total number of packets following path P that crossed edge e during the time interval $[t_1, t_2)$. In particular, $D_{(e,P)}(t, t+1)$ takes value 0 or 1 for each $t = 0, 1, 2, \ldots$. The values of $D_{(e,P)}(t, t+1)$ depend on the rule by which packets competing for the same edge are prioritized—the scheduling rule. Some examples of scheduling rules include First-In-First-Out (FIFO), in which packets are prioritized according to their arrival time into edge e, Longest-In-System, in which packets are prioritized according to their arrival time into the network, Shortest-In-System, Furthest-To-Go (FTG), and many others. Note that, whichever policy is used, the following restriction applies. For any edge e and time t,

$$\sum_{P:e\in P} D_{(e,P)}(t, t+1) \le 1.$$

In other words, at most one packet can cross an edge e during the time interval $[t, t+1)$. Finally, let $A_P(t) = A_P(0, t)$ and $D_{(e,P)}(t) = D_{(e,P)}(0, t)$, and let $Q_{(e,P)}(t)$ be the total number of packets following path P that are waiting to cross edge e at time t. The dynamics of the network is described as follows. For each $t = 0, 1, 2, \ldots$ and each path $P \in \mathcal{P}$,

$$Q_{(e_0^P,P)}(t) = Q_{(e_0^P,P)}(0) + A_P(t) - D_{(e_0^P,P)}(t) \tag{1}$$

and

$$Q_{(e_i^P,P)}(t) = Q_{(e_i^P,P)}(0) + D_{(e_{i-1}^P,P)}(t) - D_{(e_i^P,P)}(t) \tag{2}$$

for all $i = 1, 2, \ldots, k(P)$. We let $Q(t) = \sum_{e,P} Q_{(e,P)}(t)$ denote the total number of packets in the network at time t.

The packets are injected into the system by an adversary in a restricted manner. There exist a positive real number r, called the arrival rate, and a positive integer w with the following property. For each edge e, the total number of packets, injected during any interval $[t_1, t_2)$, whose assigned paths contain e is at most $r(t_2 - t_1) + w$. Formally, for each $e \in E$ and $t_1 < t_2$,

$$\sum_{P:e\in P} A_P(t_1, t_2) \le r(t_2 - t_1) + w. \tag{3}$$

This is the load assumption considered in [3], [6], [9], [11] and is a generalization of the path-specific arrival rate assumption considered earlier by Cruz [8].

The goal of the stability analysis is to understand the conditions under which the total number of packets in the network stays bounded, i.e., the conditions under which the network is stable. Specifically, we are interested in when a particular scheduling policy is stable and which networks are stable under an arbitrary greedy scheduling policy.

DEFINITION 1. *A scheduling policy in an adversarial queueing network* (V, E, r, w) *is defined to be greedy if, whenever there is a positive number of packets waiting to cross any given edge* e *at time* t*, at least one of these packets will cross* e *during interval* $[t, t+1)$*. Formally, for each* $e \in E$ *and* $t = 0, 1, 2, \ldots,$

$$\sum_{P:e\in P} Q_{(e,P)}(t) > 0$$

implies

$$\sum_{P:e\in P} D_{(e,P)}(t, t+1) = 1. \tag{4}$$

DEFINITION 2. *A scheduling policy in an adversarial queueing network* (V, E, r, w) *is defined to be stable if, under this policy, the total number of packets in the network stays bounded for all times. Namely,*

$$\sup_{t\in\Re_+} Q(t) < \infty.$$

A scheduling policy is defined to be universally stable if it is stable in all graphs. A (directed or undirected) graph (V, E) *is defined to be universally stable if every greedy policy in it is stable for all* $r < 1$ *and all nonnegative* w*.*

The necessary condition for stability is

$$r \le 1. \tag{5}$$

If this condition is violated, then an adversary can inject packets so that no scheduling rule will be able to keep the number of packets bounded.

An adaptive packet routing model is similar to the model above. An undirected graph (V, E) is given. An adversary injects packets but now specifies only their origin-destination pair $(i, j) \in V^2$. The goal of the scheduler is to select the paths for packets as well as to prioritize packets competing for the same edge. The total number of packets in the network again needs to be bounded. Immediately the following question arises: What is the analogue of the condition (5)? Aiello et al. [1] considered the following condition. A certain integer w and a real value $r < 1$ are fixed. It is assumed that the packets that arrived during any time interval $[t, t+w)$ can be associated with paths in the graph (V, E) in such a way that any edge e belongs to no more than rw paths. This condition can be reformulated using the integral multicommodity flow problem as follows. For a given graph (V, E) and a set of positive integers n_{ij}, $i, j \in V$, consider the following integer programming problem (we represent edges as pairs of nodes $(k, l) \in E$):

$$\begin{aligned} &\text{Minimize } C_{\max} \\ &\text{Subject to} \\ &\sum_{k:(i,k)\in E} x_{ik}^{ij} = n_{ij}, \qquad (i, j) \in V^2, \end{aligned} \tag{6}$$

$$\sum_{k:(k,j)\in E} x_{kj}^{ij} = n_{ij}, \qquad (i,j) \in V^2, \tag{7}$$

$$\sum_{l:(l,k)\in E} x_{lk}^{ij} = \sum_{l:(k,l)\in E} x_{kl}^{ij}, \ (i,j) \in V^2, \ k \neq i,j, \tag{8}$$

$$C_{kl} = \sum_{(i,j)\in V^2} x_{kl}^{ij}, \qquad (k,l) \in E, \tag{9}$$

$$C_{kl} \leq C_{\max}, \qquad (k,l) \in E, \tag{10}$$

$$x_{kl}^{ij}, C_{kl} \geq 0, \tag{11}$$

$$x_{ij}^{kl} \in Z_+. \tag{12}$$

Here x_{kl}^{ij} represents the number of packets going from node i to node j that pass through the edge (k,l). Equations (6)–(8) represent the conservation of flow. C_{kl} represents the total amount of integral flow assigned to any edge $(k,l) \in E$, and $C_{\max}$ represents the maximal amount of flow assigned to any edge $e \in E$.

It is not hard to prove that the load condition considered by Aiello et al. is equivalent to the following condition. Let $A_{ij}(t, t+w)$ denote the number of packets that arrived during the time interval $[t, t+w)$ and have an origin-destination pair (i,j). The condition is that, for any time t, the integral multicommodity flow problem above with input $n_{ij} = A_{ij}(t, t+w)$ has a solution $C_{\max}$ satisfying

$$C_{\max} \leq rw. \tag{13}$$

DEFINITION 3. *An adversarial queueing network is said to be of the type* (r, w, IMF) *(IMF stands for integral multicommodity flow) if the condition* (13) *is satisfied for any time* t*, where* $C_{\max}$ *is the optimal value of the integral multicommodity flow problem* (6)–(12) *on the input* $n_{ij} = A_{ij}(t, t+w)$*.*

An algorithm was constructed in [1] which achieves stability under the load condition (r, w, IMF) for networks of type (r, w, IMF) with $r < 1$. In this paper, we consider queueing networks of the type (r, w, FMF) (FMF stands for fractional multicommodity flow), where the load condition above is still assumed to be satisfied, but the solution to the multicommodity flow problem above need not be integral (constraint (12) is removed).

DEFINITION 4. *An adversarial queueing network is said to be of the type* (r, w, FMF) *if the condition* (13) *is satisfied for any time* t*, where* $C_{\max}$ *is the optimal value to the fractional multicommodity flow problem* (6)–(11) *on the input* $n_{ij} = A_{ij}(t, t+w)$*.*

Clearly our load condition is weaker. Since it uses a linear programming formulation, the condition is also efficiently checkable. We construct in section 4 a stable scheduling policy under this relaxed load condition whenever $r < 1$.

3. Universally stable graphs and universally stable policies. In the first part of this section, we focus on universal stability of undirected graphs. An exact characterization of directed stable graphs is given in [11]. Two directed graphs were constructed which are not universally stable. It is then proven that a directed graph is universally stable if and only if it does not contain one of these two graphs as a minor (for a definition of a graph minor, see [14]). This leads to an efficient algorithm for checking whether a given graph is stable.

In this section, we show that, for undirected graphs, the classification is even simpler. A graph with one edge and a graph G_1 with two edges are the only connected

undirected universally stable graphs. Note that the stability of unconnected graphs can be resolved by considering their connected components.

THEOREM 1. *A connected undirected graph is universally stable if and only if it has at most two edges.*

Remark. We conjecture that the graph with two edges is stable also for the critical arrival rate $r = 1$, but we do not have a proof.

Proof. We omit a trivial case of a graph with only one edge. We prove the stability of the graph G_1 by a simple reduction to a unidirectional ring network with two nodes. An adversarial queueing network (V, E, r, w) is called a unidirectional ring network if it is of the form $V = \{v_1, v_2, \ldots, v_n\}$, $E = \{e_1, e_2, \ldots, e_n\}$, $e_k = (v_k, v_{k+1})$, $k = 1, 2, \ldots, n-1$, $e_n = (v_n, v_1)$, and if every path P contains edges in increasing order modulo n. Namely, $P = \{e_j, e_{j+1}, \ldots, e_{j+k(P)}\}$ for some e_j, where the convention is to identify edge e_{n+i} with e_i. Thus a unidirectional ring is a circular form graph with all the packets moving in one direction. It was shown in [3] that the unidirectional ring is universally stable for all $r < 1$ and the total number of packets in the network at any moment is not bigger than $n^2 w/(1-r)$ (assuming initially that there are no packets in the network). We now show that, from the stability point of view, our graph G_1 is equivalent to the unidirectional ring with two nodes $V = \{v_1, v_2\}$ and two edges $E = \{e_{\text{lower}}, e_{\text{upper}}\}$ connecting nodes v_1 and v_2. Any packet in G_1 going from 0 to 1 or from 1 to 0 we associate with a packet going along the edge e_{lower} in the directions $v_1 \to v_2$. Any packet in G_1 going from 1 to 2 or from 2 to 1 we associate with a packet going along the edge e_{upper} in the directions $v_2 \to v_1$. We associate packets going along nodes $0, 1, 2$ or $2, 1, 0$ similarly. It is easy to see that this correspondence makes the two systems equivalent. In particular, graph G_1 is stable, and, if the initial number of packets is zero, then the maximal number of packets at any time is not more than $4w/(1-r)$.

We now prove the second part of the theorem. We will show that in any connected graph with more than two edges there exists an unstable greedy scheduling policy whenever $r > .86$. Clearly it suffices to prove the existence of such policies only for graphs G_2,G_3, G_4 on Figure 1.

Consider the graph G_2 first. The arrival pattern and the scheduling policy are described in several stages. Suppose initially that there are c packets waiting to cross the edge $(1, 0)$, where c is a sufficiently large number. During the time interval $[0, c)$, we process these c packets and generate rc packets requesting the path $1, 0, 2$. These packets do not move until time c. During the time interval $[c, c+rc)$, we process these rc packets and generate r^2c packets requesting path $2, 0, 3$ and r^2c packets requesting $0, 1$. These packets also do not move until the time $c + rc$. During the next time interval of the length r^2c, we generate r^3c packets requesting $1, 0, 3$ and r^3c packets requesting $2, 0$. The latter packets are processed before the previously generated $2, 0, 3$ packets. As a result, at time $c + rc + r^2c$, we obtain r^3c packets requesting $1, 0, 3$ and r^3c packets requesting $2, 0, 3$ (the latter generated in the previous round). During the next r^3c time units, we process entirely packets on the path $1, 0, 3$, process packets on the path $2, 0, 3$ along the edge $(2, 0)$, and generate r^4c packets requesting path $0, 3$. In the end, we obtain $r^3c + r^4c$ packets requesting edge $(0, 3)$. If $r^3 + r^4 > 1$ (which holds for $r > .82$), we end up with more than c packets requesting the path $0, 3$. Repeating the schedule for $c' = (r^3 + r^4)c$ packets starting from the edge $(0, 3)$, we obtain an unstable schedule. This completes the proof for the graph G_2.

The proof for the graph G_3 is very similar. Suppose initially that we have c packets requesting path $2, 1$. Process these packets, and generate rc packets requesting $2, 0$ during the time interval $[0, c)$. Process the new packets, and generate r^2c packets

requesting paths $1,2,3$ and $0,1$. Process these packets, and generate r^3c packets requesting $3,2,1$ and $0,1$. During the next r^3c time units, process all $0,1$ packets, and generate r^4c packets requesting $0,1,2$. Also during this time interval, generate and process r^4c packets requesting $3,2$, give them priority over previously generated $3,2,1$ packets, and in the remaining time process these $3,2,1$ packets. We obtain in the end r^4c packets requesting $0,1,2$ and r^4c packets requesting $3,2,1$. Note that all these packets require edge $(1,2)$. Process all the $0,1,2$ packets, process $3,2,1$ packets through their first edge $(3,2)$, and generate r^5c packets requesting $2,1$. As a result, we obtain $r^4c + r^5c$ packets requesting edge $2,1$. If $r^4 + r^5 > 1$, that is, $r > .86$, then we end up with more than c packets requesting edge $2,1$. It follows that the scheduling rule is unstable. The construction of the unstable policy in the graph G_4 is identical to the one of G_3, where we identify node v_3 of G_3 with v_0 of G_4. This completes the proof of the theorem. □

In the remainder of this section, we address the question of universal stability of specific policies. We propose a simple NTO policy and prove that it is stable in all graphs even for the critical arrival rate $r = 1$. The NTO policy gives priority to packets which have crossed the smallest amount of edges. Namely, if two packets following paths $P, P' \in \mathcal{P}$ compete for the same edge $e = e_i^P = e_j^{P'}$ and $i < j$, then the packet following P should be processed first. If $i = j$, then the packets are prioritized arbitrarily.

THEOREM 2. *NTO policy is stable in any network for $r = 1$.*

Proof. Let $Q_e(0)$ denote the total initial number of packets waiting to cross an edge e. Also let $Q_k(t)$ denote the total number of packets at time t which are within exactly k steps from the origin. That is,

$$Q_k(t) = \sum_{P \in \mathcal{P}} Q_{(e_k^P, P)}(t).$$

Let us call these packets layer k packets. We will show by induction by k that $Q_k(t)$ is bounded by a constant for all t.

Base step $k = 0$. Fix an edge e and a time t. Let $t_0 \in [0,t]$ be the largest time at which no packets of layer 0 (packets that have not crossed any edge yet) were waiting at e. If no such time exists, set $t_0 = 0$. The total number of layer 0 packets in e at time t_0 is then at most $Q_e(0)$. During the time interval $[t_0, t)$, at most $r(t - t_0) + w = t - t_0 + w$ layer 0 (external) packets that want to cross e have arrived. Also, by the choice of t_0, edge e was processing packets constantly during the time interval $[t_0, t)$. Since NTO policy is used, layer 0 packets have priority over all other packets. It follows that total number of layer 0 packets at the edge e at time t satisfies

$$\sum_{P: e_0^P = e} Q_{(e_0^P, P)}(t) \le Q_e(0) + t - t_0 + w - (t - t_0) = Q_e(0) + w.$$

As a result, $Q_0(t) \le \sum_e Q_e(0) + w|E|$ for all t. We denote $\sum_e Q_e(0) + w|E|$ by B_0.

Induction step. Suppose, for some constants B_j, $j = 0, 1, \ldots, k-1$, $Q_j(t) \le B_j$ for all $j \le k-1$ and for all times t. We will show that, for some constant B_k, $Q_k(t) \le B_k$ for all t. Again, fix an edge e and an arbitrary time t. Again let $t_0 \le t$ denote the largest time instance such that there were no layer k packets waiting to cross e. Then edge e was always processing packets during the time interval $[t_0, t)$ (packets in layer k or lower). The layer k packets that wait to cross e at time t then are composed only of packets which were in layers $j \le k-1$ at time t_0 or packets that

arrived externally during the time interval $[t_0, t)$ and have edge e as their kth edge on the requested path. The first group of packets has a size bounded by $\sum_{j=0}^{k-1} B_j$, by the induction assumption. The second is bounded by $\sum_{P:e_k^P=e} A_P(t_0, t)$. We now estimate the number of layer k packets that crossed e during the time interval $[t_0, t)$. Since NTO policy is used, these packets were not processed only when there were packets in layers up to $k-1$ that wanted to cross e. The number of such packets is bounded by $\sum_{j=0}^{k-1} B_j$, i.e., the total possible number of packets in layers up to $k-1$ at time t_0, plus $\sum_{j=0}^{k-1} \sum_{P:e_j^P=e} A_P(t_0, t)$, which is the number of new packets that arrived in $[t_0, t)$ and cross e within $k-1$ steps. We conclude that at least

$$\max\left\{0, t - t_0 - \sum_{j=0}^{k-1} B_j - \sum_{j=0}^{k-1} \sum_{P:e_j^P=e} A_P(t_0, t)\right\}$$

packets of layer k crossed e during the time interval $[t_0, t)$. We obtain

$$\sum_{P:e_k^P=e} Q_k(t) \le \sum_{j=0}^{k-1} B_j + \sum_{P:e_k^P=e} A_P(t_0, t) - \left(t - t_0 - \sum_{j=0}^{k-1} B_j - \sum_{j=0}^{k-1} \sum_{P:e_j^P=e} A_P(t_0, t)\right)$$

$$\le 2\sum_{j=0}^{k-1} B_j + w,$$

where the last inequality follows from (3) and $r = 1$. Thus the total number of layer k packets is bounded by $B_k = 2|E|(\sum_{j=0}^{k-1} B_j) + w|E|$. This completes the induction step. □

After this paper was written, it was pointed out to the author by Kleinberg [12] that a similar analysis shows the stability of FTG policy (which gives priority to packets closest to their destination) when $r = 1$. During the course of the proof, we obtained the following bound on the total number of packets in the network at time t:

$$|Q(t)| \le (2|E|)^{p_{\max}+1}(B_0 + w),$$

where B_0 is the initial number of packets in the network and $p_{\max}$ is the maximal length $|P|$ of paths $P \in \mathcal{P}$. Unfortunately, the bound is exponential in the network parameters. It is shown in [4] that both NTO and FTG lead to exponentially large queue sizes in certain networks. It is also shown that no bound better than $2^{\sqrt{\max|V|,|E|}}$ is possible for a whole class of distributed deterministic policies including NTG and FTG.

Note that, unlike the $r < 1$ case, stability under the $r = 1$ condition does not necessarily imply that all the packets are delivered within a finite time. Indeed, consider the graph G_1 operating under NTG policy. Assume that initially there are several packets requesting path $0, 1, 2$. Assume that at each integer moment $t = 1, 2, \ldots$ an adversary injects a packet following $1, 2$. These packets have priority over the initial packets and block them from processing forever. Thus the delivery time for the initial packets is infinity. Whether there exists a policy with bounded delivery time for every packet when $r = 1$ is an open question.

4. Stable scheduling policies in adaptive adversarial queueing networks. In this section, we focus on adaptive packet routing policies in adversarial queueing networks. We have an undirected graph (V, E) and parameters $r, w > 0$. An adversary generates packets and specifies only their origin-destination. The network flow load assumption (r, w, FMF), described in section 2, is assumed to be satisfied by an adversary traffic. The goal is to construct a policy which is stable under the (r, w, FMF) assumption, when $r < 1$, and show that no stable policy exists against any adversary traffic when $r > 1$. For the case in which $r < 1$, we consider a corresponding static packet routing problem on a fixed input n_{ij}, which is formulated as follows. Suppose, for each $i, j \in V$, that we are given n_{ij} packets which are required to go from node i to node j via some path selected by the scheduler. Each edge can process only one packet at one time unit. The objective is to find a routing schedule which would minimize the time until all the packets reach their destination (makespan time). This static version of the packet routing problem with the makespan objective has been considered before by Srinivasan and Teo [15] and Bertsimas and Gamarnik [5]. We use here an asymptotically optimal scheduling algorithm developed in [5] (the Packet Routing Synchronization Algorithm or PRSA) for this static packet routing problem. The following result was proven in [5].

THEOREM 3. *Let n_{ij} denote the number of packets that are present in the network at time 0 and have nodes $i, j \in V$ as their origin-destination pair. Let $C_{\max}$ be the optimal solution to the (fractional) multicommodity problem with input n_{ij}, $i, j \in V$. Then there exists a packet routing scheduling algorithm which brings all the packets to their destination (has makespan time) in not more than*

$$C_{\max} + O(|V|^3|E|\sqrt{C_{\max}}) \tag{14}$$

time units. Moreover, the algorithm is such that, after time $T = C_{\max} + |V|\sqrt{C_{\max}}$, not more than $2|V||E|\sqrt{C_{\max}} + |V|^2|E|$ packets are still present in the network.

Since $C_{\max}$ is a lower bound on any feasible makespan time, the schedule is asymptotically optimal when the total initial number of packets $\sum_{ij} n_{ij}$ diverges to infinity. We now use this scheduling algorithm to construct a stable policy in a network (V, E) which satisfies the load condition (r, w, FMF). The routing policy is of *Discrete Review* type and is described as follows. We assume that $T_0 = 0$. The number of packets of type (i, j) at time t is denoted by $Q_{ij}(t)$.

Discrete Review Algorithm. For $k = 0, 1, 2, \ldots$, let $C^k_{\max}$ denote the optimal value to the multicommodity flow problem with the input $n_{ij} = Q_{ij}(T_k)$. Set $T_{k+1} = T_k + C^k_{\max} + |V|\sqrt{C^k_{\max}}$. Implement the PRSA at time T_k to the input $n_{ij} = Q_{ij}(T_k)$ for the first $C^k_{\max} + |V|\sqrt{C^k_{\max}}$ time units, ignoring packets arriving after time T_k.

In other words, the Discrete Review Algorithm looks at times T_k, $k = 0, 1, 2, \ldots$, at the entire network and solves the corresponding static packet routing problem, ignoring packets that arrive after T_k. Intuitively, since the PRSA has makespan time close to the maximal congestion when the loads are high, then, by the (r, w, FMF) assumption, $C^{k+1}_{\max}/C^k_{\max} \approx r < 1$, and the Discrete Review policy is stable. The following result is obtained.

THEOREM 4. *Suppose an adversarial queueing network (V, E) satisfies the (r, w, FMF) load condition. If $r < 1$, then the Discrete Review routing schedule is stable. Moreover,*

$$\limsup_{t\to\infty} \sum_{ij} Q_{ij}(t) = O\left(\frac{|V|^4|E|^3 + w^2|E|}{(1-r)^2}\right). \tag{15}$$

If $r > 1$, then no stable routing policy exists.

Proof. First we prove the stability of the Discrete Review routing schedule. We show that, for any k,

$$C_{\max}^{k+1} \le r(C_{\max}^{k} + |V|\sqrt{C_{\max}^{k}}) + w + |V|^2|E|\sqrt{C_{\max}^{k}}. \tag{16}$$

In fact, the total number of type (i,j) packets in the network at time T_{k+1} consists of two types of packets. We have $A_{ij}(T_k, T_{k+1})$ packets that arrived during the time interval $[T_k, T_{k+1})$ and packets that arrived before time T_k and still have not been processed. Denote the latter packets by $\hat{Q}_{ij}(T_k)$. From Theorem 3, since $T_{k+1} - T_k = C_{\max}^{k} + |V|\sqrt{C_{\max}^{k}}$, we have

$$\sum_{ij} \hat{Q}_{ij}(T_k) \le 2|V||E|\sqrt{C_{\max}^{k}} + |V|^2|E| \le |V|^2|E|\sqrt{C_{\max}^{k}} \tag{17}$$

(as long as $|V|, C_{\max} \ge 4$, which we assume to hold). Since our network is of (r, w, FMF) type, the optimal value of the multicommodity flow problem on the input $n_{ij} = A_{ij}(T_k, T_{k+1})$ is at most

$$r\left(\left\lceil \frac{T_{k+1} - T_k}{w} \right\rceil w\right) \le r(T_{k+1} - T_k) + w.$$

The optimal value of the multicommodity flow problem on the input $n_{ij} = \hat{Q}_{ij}(T_k)$ is upper bounded by $\sum_{ij} \hat{Q}_{ij}(T_k)$. We obtain that the optimal value $C_{\max}^{k+1}$ of the multicommodity flow problem on the input $n_{ij} = Q_{ij}(T_{k+1}) = A_{ij}(T_k, T_{k+1}) + \hat{Q}_{ij}(T_k)$ satisfies

$$C_{\max}^{k+1} \le r(T_{k+1} - T_k) + w + |V|^2|E|\sqrt{C_{\max}^{k}} = r(C_{\max}^{k} + |V|\sqrt{C_{\max}^{k}}) + w + |V|^2|E|\sqrt{C_{\max}^{k}}.$$

This proves (16). From (16) we obtain

$$\limsup_{k\to\infty} C_{\max}^{k} \le r \limsup_{k\to\infty} C_{\max}^{k} + (r|V| + |V|^2|E|) \limsup_{k\to\infty} \sqrt{C_{\max}^{k}} + w$$

$$\le r \limsup_{k\to\infty} C_{\max}^{k} + (r + |V|^2|E| + w)\sqrt{\limsup_{k\to\infty} C_{\max}^{k}}$$

or

$$\limsup_{k\to\infty} C_{\max}^{k} \le \frac{(r + |V|^2|E| + w)^2}{(1-r)^2}. \tag{18}$$

We finally argue that, for any $t = 0, 1, 2, \ldots$, the total number of packets in the network at time t, for large t, is at most $2|E|C_{\max}^{k_t}$, where k_t satisfies $T_{k_t} \le t < T_{k_t+1}$. We split all the packets in the network at time t into two groups: those that arrived before time T_{k_t} and those that arrived after time T_{k_t}. The first group has a size at most $\sum_{ij} Q_{ij}(T_{k_t})$, which is at most $|E|C_{\max}^{k_t}$ since $C_{\max}^{k_t}$ is a feasible solution to the multicommodity problem on the input $n_{ij} = Q_{ij}(T_{k_t})$. The second group has a size at most $\sum_{ij} Q_{ij}(T_{k_t+1})$ since none of these packets are processed before time T_{k_t+1}. Therefore, the second group has a size at most $|E|C_{\max}^{k_t+1}$. We apply (18) and conclude the proof of the theorem.

We now prove that if $r > 1$, then no stable routing policy exists. For that we need to exhibit a certain adversarial arrival pattern with arrival rate r for which stability cannot be achieved. Select $\delta > 0$, a small positive value, and construct a set of rates r_{ij} such that the optimal value r_0 of the multicommodity flow problem on the input $n_{ij} = r_{ij}$ satisfies $r_0 = r/(1+\delta)$. This can be achieved as follows: select values r'_{ij} very small arbitrarily, and increase them proportionally by t, $r_{ij} = r'_{ij}t$ until the objective value becomes r_0. We now construct an arrival pattern. For each pair (i,j), inject a type (i,j) packet every $1/r_{ij}$ time units. Select an integer $w > 0$ so that $r_{ij}w > 1/\delta$ for every r_{ij}. Then, for every time t,

$$A_{ij}(t, t+w) \le \left\lceil \frac{w}{1/r_{ij}} \right\rceil \le r_{ij}w + 1 = r_{ij}w + \frac{1}{r_{ij}w} r_{ij}w \le r_{ij}(1+\delta)w.$$

Since the optimal value of the multicommodity flow problem on the input $r_{ij}(1+\delta)$ is $r_0(1+\delta) = r$, the network is of the (r, w, FMF) type. In the proof of Corollary 1, we show that, for this arrival pattern, if the objective value $r_0 = r/(1+\delta) > 1$, then no stable policy can exist. By choosing δ sufficiently small, we obtain the result. □

The Discrete Review Algorithm is one way of turning a schedule for a static packet routing problem into a schedule for a dynamic packet routing problem. There are schedules other than the PRSA which achieve a certain degree of closeness to the optimal makespan time. For example, a routing schedule was constructed in [15] with makespan time $cC_{\max}$, where $C_{\max}$ is the optimal maximal congestion (solution to the multicommodity flow problem), and c is some (large) constant independent of the data of the problem. Note that this schedule, if implemented in the Discrete Review manner, does not necessarily lead to a stable policy if $r > 1/c$. The asymptotic optimality of the routing schedule (which is achieved by the PRSA) is essential for stability.

The result above can be used to decide what the necessary and sufficient conditions are for stability in adversarial queueing networks when the arrival rate for each pair of origin-destination is bounded by a constant.

COROLLARY 1. *Given an adversarial queueing network (V, E), suppose that there exist constants r_{ij}, $i, j \in V$, and a positive integer $w > 0$ such that the total number of packets injected during any interval $[t_1, t_2)$ with origin-destination pair (i, j) is not bigger than $r_{ij}(t_2 - t_1) + w$. If the multicommodity flow problem on the input r_{ij}, $i, j \in V$, has an optimal solution satisfying $C_{\max} < 1$, then there exists a stable packet routing schedule. If the optimal solution satisfies $C_{\max} > 1$, then a stable schedule cannot exist.*

Proof. Suppose $C_{\max} < 1$ for the multicommodity flow problem on the input $n_{ij} = r_{ij}$. Select a positive integer

$$W > \frac{2|V|^2 w}{1 - C_{\max}}.$$

By assumption, for any time t,

$$A_{ij}(t, t+W) \le r_{ij}W + w.$$

Also, by assumption, the optimal value of the multicommodity flow problem on the input $n_{ij} = r_{ij}W$ is at most $C_{\max}W$. The optimal value of the multicommodity flow problem on the input $n_{ij} = w$ is trivially at most $|V|^2 w$. Therefore, the optimal value of the multicommodity flow problem on the input $n_{ij} = r_{ij}W + w$ is at most

$$C_{\max}W + |V|^2 w = C_{\max}W + \frac{|V|^2 w}{W} W \le C_{\max}W + \frac{1 - C_{\max}}{2} W = \frac{1 + C_{\max}}{2} W.$$

We set $r = (1 + C_{\max})/2 < 1$. Then our queueing network is of the type (r, W, FMF). We apply Theorem 4 and complete the proof of the first part.

Suppose now that the optimal solution to the multicommodity flow problem on the input $n_{ij} = r_{ij}$ satisfies $C_{\max} > 1$. Let an adversary inject a type (i, j) packet every $1/r_{ij}$ time unit. Then, for every type (i, j),

$$A_{ij}(t_1, t_2) \le \left\lceil \frac{t_2 - t_1}{1/r_{ij}} \right\rceil \le r_{ij}(t_2 - t_1) + 1 \le r_{ij}(t_2 - t_1) + w.$$

So this arrival pattern satisfies the conditions of the theorem. Suppose, for the purposes of contradiction, that there exists a stable routing policy. For every type (i, j) and every edge $(k, l) \in E$, let $D_{kl}^{ij}(t_1, t_2)$ denote the number of type (i, j) packets that crossed the edge (k, l) during the time interval $[t_1, t_2)$, when this stable policy is implemented. Let also $Q_k^{ij}(t)$ denote the number of type (i, j) packets that are queued at the node k at time t. Then

$$Q_i^{ij}(t) = Q_i^{ij}(0) + A_{ij}(0, t) - \sum_{k:(i,k)\in E} D_{ik}^{ij}(0, t). \tag{19}$$

Also, for each $k \neq i, j$,

$$Q_k^{ij}(t) = \sum_{l:(l,k)\in E} D_{lk}^{ij}(0, t) - \sum_{l:(k,l)\in E} D_{kl}^{ij}(0, t). \tag{20}$$

By assumption, $Q_j^{ij}(t) = 0$ and $D_{jl}^{ij}(0, t) = 0$ for all l such that $(j, l) \in E$. Since the policy implemented is stable, then there exists $B > 0$ such that, for all k and all times t, $Q_k^{ij}(t) \le B$. In particular,

$$Q_k^{ij}(t)/t \to 0 \tag{21}$$

when $t \to \infty$. Note that, for each $(k, l) \in E$,

$$\sum_{i,j} D_{kl}^{ij}(0, t)/t \le 1 \tag{22}$$

since each edge processes at most one packet at a time. Therefore, there exists a sequence $t_1 < t_2 < \cdots < t_s < \cdots$ along which all the limits

$$x_{kl}^{ij} \equiv \lim_{s\to\infty} \frac{D_{kl}^{ij}(0, t_s)}{t_s}$$

exist. Note also that

$$\lim_{t\to\infty} \frac{A_{ij}(0, t)}{t} = r_{ij}.$$

From (19)–(21), it follows that x_{kl}^{ij}, $i, j \in V$, $(k, l) \in E$ is a feasible solution to the multicommodity flow problem on the input $n_{ij} = r_{ij}$. However, from (22) it follows that, for each edge $(k, l) \in E$,

$$\sum_{i,j} x_{kl}^{ij} \le 1.$$

In particular, the maximal congestion $C_{\max}$ corresponding to this feasible solution satisfies $C_{\max} \leq 1$. This contradicts the assumption. □

It is not clear whether a stable packet routing schedule exists for the critical case $C_{\max} = 1$, analogous to the NTO policy proposed in section 3. The existence of such a policy might depend on the integrality of a feasible solution to the multicommodity flow problem (6)–(12).

Note that the bound given by Theorem 4 is weaker than the bound

$$O\left(\frac{|V|^{5/2}|E|^{5/2}w}{1-r}\right) \tag{23}$$

obtained in [1] for networks of type (r, w, IMF). Also, the schedule constructed in [1] is distributed, whereas our schedule needs information about the entire network at times T_k. This raises the question of whether the schedule in [1] is applicable for the network of type (r, w, FMF). This turns out to be possible but at the cost of a somewhat inferior performance. Consider[1] an optimal fractional solution (maximal congestion) $C_{\max}$ to the multicommodity problem on the input $n_{ij} = A_{ij}(t, t+w)$. Using Raghavan's and Thomson's randomized algorithm (see [13]), one can construct an integral solution to the multicommodity flow problem with expected maximal congestion satisfying $C^{\text{int}}_{\max} \leq C_{\max} + C_{\max} \cdot O(\sqrt{\frac{\log|E|}{C_{\max}}})$. Suppose now that

$$w > O\left(\frac{\log|E|r}{(1-r)^2}\right). \tag{24}$$

Then $C_{\max} \leq rw$ implies $C^{\text{int}}_{\max} \leq rw + \sqrt{rw}O(\sqrt{\log|E|}) < w$. Thus, if (24) holds, then the network is of the type (r', w, IMF) for $r' \equiv C^{\text{int}}_{\max}/w$. Unfortunately, the bound (24) combined with (23) implies the bound

$$O\left(\frac{|V|^{5/2}|E|^{5/2}\log|E|r}{(1-r)^2(1-r')}\right),$$

which is at best (using $r \leq r'$) $O(\frac{1}{(1-r)^3})$ when $r \approx 1$. This is inferior to our bound $O(\frac{1}{(1-r)^2})$ in Theorem 4 when $r \approx 1$. (Recall that our bound does not require (24).)

Observe that we used the second part of Theorem 3 in the construction of the Discrete Review Algorithm. We could also use the first part (routing entirely the packets present in the system at time T_k) at the price of somewhat larger upper bounds, although this scheme has the following advantage. In this form of implementation, the path of each packet is predetermined at time T_k for packets present in their origination node at time T_k. Thus the path information can be recorded in the header of the packet, and no path recalculation is needed while the packet is on its route.

5. Conclusion. We have provided in this paper a simple classification of undirected graphs which are universally stable: a connected undirected graph is universally stable if and only if it has at most two edges. We have also proved that a simple distributed policy, NTO, achieves stability in all the graphs under the critical arrival rate $r = 1$. A multicommodity flow-type load condition was formulated for adaptive adversarial queueing networks, and a stable policy was constructed whenever this load condition was met.

[1]The author wishes to thank Ashish Goel for pointing out this argument.

A number of interesting questions remain outstanding. It is not clear which graphs are universally stable for a given value of $r < 1$. Given that a network could be unstable for an arbitrarily small r (see [6]), such a classification could be quite nontrivial. Deciding the stability of specific policies is not well understood in general and might become an impossible problem in light of the undecidability results in [10].

Acknowledgments. The author wishes to thank Ashish Goel, Matthew Andrews, and several anonymous referees for many fruitful suggestions and corrections.

MANY TO ONE EMBEDDINGS FROM GRIDS INTO CYLINDERS, TORI, AND HYPERCUBES*

JOHN ELLIS†, STIRLING CHOW†, AND DENNIS MANKE†

Abstract. We describe novel methods for embedding 2-dimensional grid graphs into cylinders (one way wrap-around grids), tori, and hypercubes, where the guest grid G is larger than the host graph H, implying a many to one embedding.

We call $\lceil \mid G \mid / \mid H \mid \rceil$ the optimal load, denoted l. We consider optimal embeddings with respect to dilation (the stretching of guest edges) and load; i.e., edges are mapped to edges or onto one node, and the number of grid nodes mapped onto any hypercube node is not greater than l.

We show, by construction, that, for loads of at least 4, optimal embeddings into the hypercube always exist subject only to modest restrictions on the relative dimensions of guest and host. If the problem instances are grouped by grid height, the restrictions imply that only some finite number of instances in each group may not be solvable by the given methods.

The essence of the method is a mapping from grids into cylinders of height at least one half of but not greater than the grid height, and so it can also be used to construct embeddings into cylinders and tori.

Previous work has gone so far as to show that if the optimal load l is a power of 2, then dilation 1, load $l + 1$ embeddings into the hypercube can be constructed. Optimal results for loads 2 and 3 are not known.

Key words. graph embedding, many to one, grid, cylinder, torus, hypercube

1. Introduction.

The study of embeddings from one family of graphs to another has received substantial attention over many years. Besides the inherent mathematical interest of these problems, motivation for the study comes from the many concerns of computer science that can be effectively modelled by this graph theoretical abstraction. In this paper, we describe some results on many to one embeddings from 2-dimensional grids into smaller cylinders, tori, and hypercubes. Plausible applications for our results include the simulation of large grid-like networks of processors by smaller networks in the form of cylinders, tori, or hypercubes and the efficient implementation of a parallel algorithm conceived of as running on a grid of unlimited size but executed on some fixed sized network in those same families. In these applications the embedding parameters *load*, *dilation*, and *congestion*, defined in the next section, strongly influence the effectiveness of the simulation.

Several papers have discussed grid to grid and grid to hypercube embeddings. [6, 7, 9, 15] describe one to one embeddings from 2-dimensional grids into other 2-dimensional grids of smaller aspect ratio, with dilation 2. Likewise, [12] considers efficient embeddings from grids into grids.

One to one embeddings from 2-dimensional grids into hypercubes are considered in [13], and those from 3-dimensional grids into hypercubes are considered in [3] and [11].

It is well known (see, for example, [8] and Lemma 3.1) that not all 2-dimensional grids are subgraphs of the minimum sized hypercube sufficient to contain the grid. In [2], it is shown that all 2-dimensional grids can be one to one embedded into the smallest possible hypercube with dilation two. This result can also be obtained by an entirely different route, namely, by using the grid to grid embeddings just cited to reduce the width of the grid down to the next power of two; i.e., embed the guest grid into a grid that is a subgraph of the hypercube. This is the approach taken in [1].

What happens when the guest grid is arbitrarily larger than the host graph, i.e., one considers many to one embeddings, is by no means completely understood. Do dilation one embeddings with an optimal load always exist, at least into the hypercube if not for the simpler families?

Many to one embeddings from 2-dimensional grids into smaller 2-dimensional grids are considered in [14]. There it is shown that dilation one with optimal load plus one is always obtainable as long as the host is smaller than the guest in both dimensions. In [10], many to one embeddings from both 2- and 3-dimensional grids into hypercubes are considered. For 2-dimensional grids, the main result (Theorem 1) states the following (and we paraphrase): *If the optimal load is* 2^k *for some integer* k*, then an embedding exists with dilation one and load* $2^k + 1$.

Our main result shows that dilation one optimal load solutions can always be constructed for embeddings from the 2-dimensional grid into the hypercube for all loads greater than three, with only a modest restriction on the relative dimensions of the guest and host. The restriction may be interpreted as saying that, in each group of problem instances of a given grid height, only a finite number might not be solved by our methods.

The technique is based on a mapping into the torus, so similar results also apply to the torus, under some restrictions on the relation between grid and torus dimensions.

For cylinders, the absence of horizontal wrap-around edges seems to prevent the technique from achieving optimal load in those instances where the host is only just big enough to contain the guest.

We leave open the conjecture that instances of the grid to hypercube embedding problem always have optimal load and dilation 1 solutions for all loads greater than or equal to 2 and irrespective of the relative dimensions of the guest and host.

2. Definitions. A *graph embedding* is a mapping from the nodes of the guest graph to the nodes of the host graph, together with a mapping from guest edges to paths in the host. In general, the node mapping can be one to one or many to one, but here we are concerned only with many to one embeddings. The *dilation* of a guest edge is the length of the path which is the image of that edge in the host. Because, in a many to one mapping, nodes incident to an edge could be mapped to the same host node, it is possible that the dilation of an edge is zero. The dilation of an entire embedding is the largest dilation over all edges in the guest.

Here we consider only instances where the number of nodes in the guest graph, denoted $\mid G \mid$, is greater than the number of nodes in the host, $\mid H \mid$. For any many to one mapping, the maximum over all host nodes of the number of guest nodes mapped to the host node is called the *load* of the mapping. We call the ratio $\lceil \mid G \mid / \mid H \mid \rceil$, denoted l, the *optimal load*. Throughout the paper, we assume that $l \geq 2$.

The *congestion* of an embedding is the maximum over all host edges of the number of guest edges mapped to a path that includes the host edge.

We are interested only in what we call *optimal* embeddings, which are those with dilation 1 and for which no more than l guest nodes are mapped onto any host node.

Restricting the dilation to 1 means that we consider only embeddings that map edges to edges or map both ends of a guest edge onto the same host node. Hence we have no need in this presentation to explicitly define the guest edge to host path mapping.

The family of guest graphs which we consider consists of the 2-dimensional grids. A 2-dimensional grid of height h and width w is the graph comprising the node set $\{(x, y) \mid 0 \leq x < h, 0 \leq y < w\}$ and the edge set $\{\{(u, v), (x, y)\} \mid \mid u - x \mid + \mid v - y \mid = 1\}$. We will refer to these guest graphs as (h, w)-*grids*.

The families of host graphs considered are as follows:

1. Cylinders, which we picture as (h, w)-grids with wrap-around edges in the vertical dimension, are the graphs comprising the node set $\{(x, y) \mid 0 \leq x < h, 0 \leq y < w\}$ and the edge set $\{\{(u, v), (x, y)\} \mid \mid u - x \mid + \mid v - y \mid = 1\} \bigcup \{(0, v), (h - 1, v)\}$. We will refer to these host graphs as (h, w)-*cylinders*.

2. Tori, which we picture as (h, w)-grids with wrap-around edges in both dimensions, are the graphs comprising the node set $\{(x, y) \mid 0 \leq x < h, 0 \leq y < w\}$ and the edge set $\{\{(u, v), (x, y)\} \mid \mid u - x \mid + \mid v - y \mid = 1\} \bigcup \{(0, v), (h - 1, v)\} \bigcup \{(u, 0), (u, w - 1)\}$. We will refer to these host graphs as (h, w)-*tori*.

3. Hypercubes of dimension d, denoted Q_d, are the graphs with vertex set $\{n \mid 0 \leq n \leq 2^n - 1\}$ and edge set $\{\{x, y\} \mid$ the binary representations of x and y differ in exactly one bit position$\}$.

3. An example. Figure 3.1 defines our notation for naming the nodes of the guest and host graphs. We begin with a small example by way of introducing both our notation and our method. In this example, the host is a cylinder.

It is well known (see, for example, [8]) that not all 2-dimensional grids G are subgraphs of H, where H is the smallest hypercube such that $|G| \leq |H|$. The distinction between those that are and are not is defined in the following lemma.

LEMMA 3.1. *The (h, w)-grid is a subgraph of Q_d iff $\lceil \log_2 h \rceil + \lceil \log_2 w \rceil \leq d$.*

So, for example, the $(5, 6)$-grid is not a subgraph of Q_5. We also use another well-known property of the hypercube Q_d; again, see [8].

LEMMA 3.2. *If $p + q \leq d$, then the $(2^p, 2^q)$-torus is a subgraph of Q_d.*

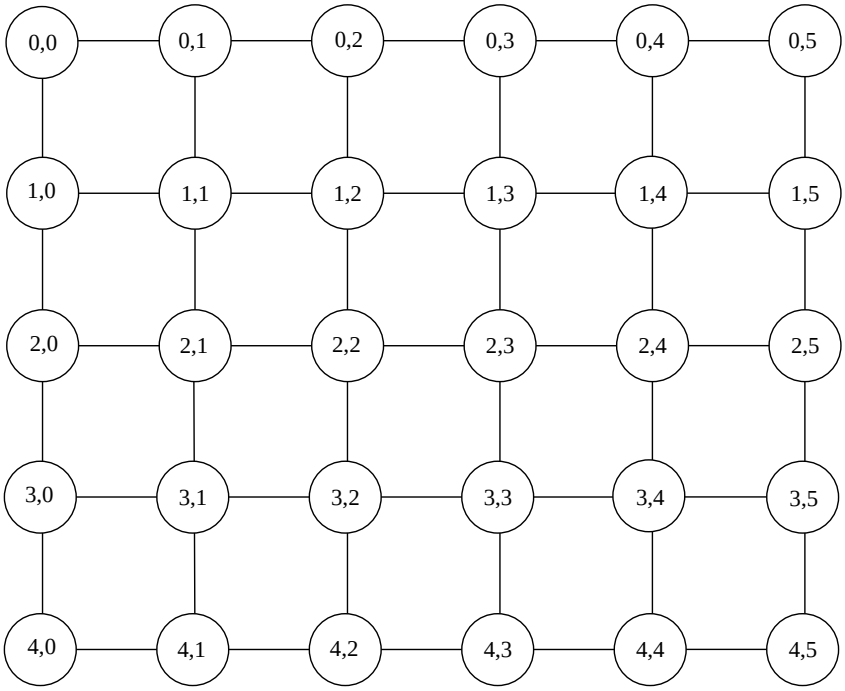
Consequently, the $(4, 8)$-cylinder is a subgraph of Q_5. Hence there is no dilation 1 load 1 embedding from the $(5, 6)$-grid into the $(4, 8)$-cylinder because such an embedding would imply the existence of a dilation 1 embedding from the (5,6)-grid into Q_5, contradicting Lemma 3.1.

However, there is a load 2 dilation 1 embedding into the $(4, 4)$-cylinder. A solution, illustrated in Figure 3.2, demonstrates the way we will illustrate all such embeddings. If the guest is an (h, w)-grid, the diagram shows an $h \times w$ array of integers. Let the top leftmost element in the array shown in the figure be indexed (0,0). Then any element (i, j) in the array represents a node (i, j) in the guest grid, as illustrated in Figure 3.1. The value of array element (i, j) defines which host row is to be the image of grid node (i, j). The host column number is defined by the numbers beneath the bottom row, where adjacent host columns are distinguished by the presence or absence of shading. For example, Figure 3.2 tells us that node (4,3) of the guest is mapped to row 2, column 1 of the host.

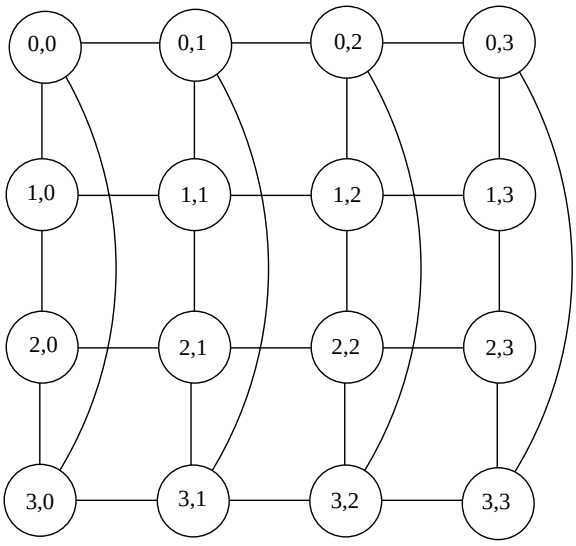
Remembering that there exist wrap-around edges between rows 0 and 3 in the host cylinder, one can verify that the diagram defines a legitimate load 2 embedding in which edges are mapped to edges by noticing the following:

1. Each host node appears no more than twice.

2. Elements in the array that are vertically or horizontally adjacent, i.e., representing adjacent guest nodes, are designated either adjacent row numbers in the same



a) A (5,6)-grid



b) A (4,4)-cylinder

FIG. 3.1. *Node-naming conventions.*

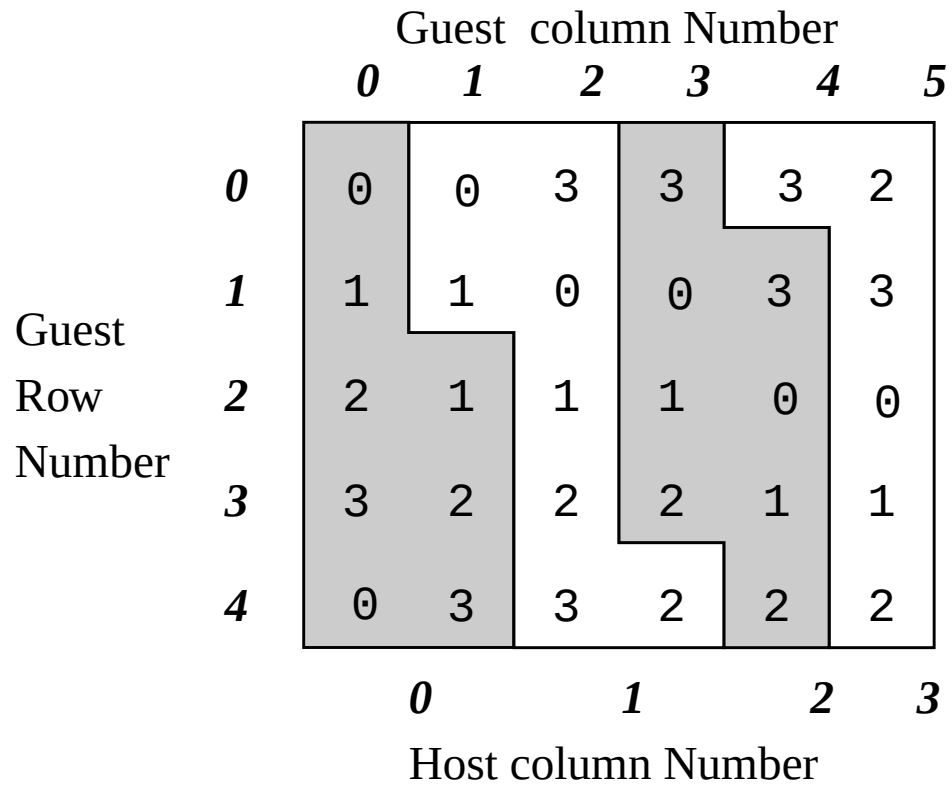


FIG. 3.2. *Embedding a* $(5,6)$*-grid into a* $(4,4)$*-cylinder with load* 2.

host column or identical row numbers in adjacent host columns.

Our way of visualizing embeddings is an alternative to that often used in previous work, where one draws the host and indicates for each host node which guest nodes are mapped onto it. It is interesting to note that the solutions suggested by these different views are quite distinct and that the pattern underlying one type of solution may not be at all apparent in the alternative visualization.

4. The partial mapping.

4.1. Informal description of the partial mapping. Our embedding is based on a single, simple guest node to host node mapping. This mapping does not immediately give us the final embedding because it is only a partial mapping from the guest (h,w)-grid. This partial mapping does not define an image for guest nodes in the bottom left and top right corners in the diagrams. The final total mapping is constructed from the partial mapping by methods to be described in later sections. In this section, we describe and define the partial mapping and investigate some of its properties.

The partial mappings are illustrated in the same way as in the earlier example, Figure 3.2. Consider Figure 4.1, which defines a load 2 dilation 1 mapping from the nodes of a subgraph of a $(13,20)$-grid to the nodes of an (8,13)-cylinder.

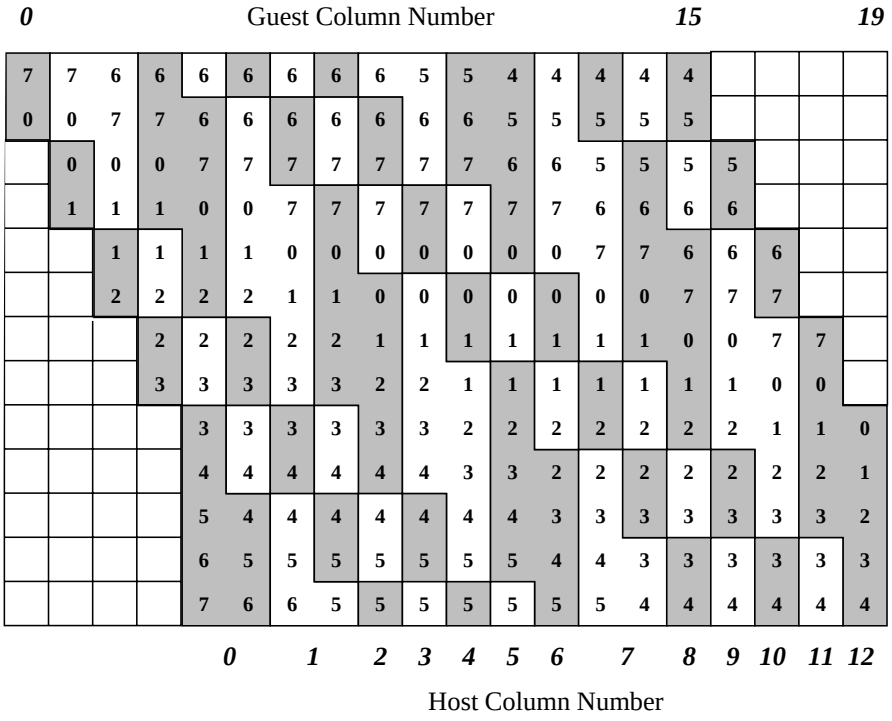

FIG. 4.1. *A height* 13 *load* 2 *partial mapping.*

4.2. Formal definition of the partial mapping. The partial mapping maps nodes from a grid of height h_g onto the nodes of a cylinder of height h_h, where $h_g/2 < h_h < h_g$, with load l. To completely define the mapping, we need a fourth parameter, which we call a *profile*. Let $\mathbf{p} = p_1 p_2 \cdots p_k$ denote a string of k integers.

DEFINITION 4.1. *The string* $\boldsymbol{p}$ *is a* (k, n)*-profile if* $\sum_{i=1}^{k} p_i = n$*, and, for all* i*,* $p_i \geq 2$*.*

Informally, the profile associated with a given mapping is the sequence of "step" heights on the left or right of a host column in a mapping diagram. We will refer to these step sequences as left and right column profiles when the context makes the meaning clear. To map a height h_g guest into a height h_h host, we need an $(h_g - h_h, h_g)$-profile. Of course, for any h_g, h_h pair, there are many profiles satisfying the definition. For example, the (5,13)-profile used to generate Figure 4.1 and which is the left profile of host column 0 is 2 2 2 2 5.

For each $(h_g, h_h, l, \mathbf{p})$ 4-tuple, we define a mapping, i.e., we define a function $F(h_g, h_h, l, \mathbf{p})$, whose value is the required node to node mapping.

For each column i of the host, $F(h_g, h_h, l, \mathbf{p})$ defines the set C_i of triples (r, c, v), where $0 \leq r < h_g$. The existence of the triple (r, c, v) in C_i indicates that node (r, c) of the guest is to be mapped to node (v, i) of the host; i.e., the contents of C_i define completely which guest nodes are mapped onto which row nodes of column i in the host. Note that i is unbounded, meaning that we can apply the mapping to any width host of the given height.

Before presenting a formal definition of the partial mapping, Definition 4.2 below, we give an informal description. Figure 4.1 can be used as an example. Let $k = h_g - h_h$ so that we use a profile $\mathbf{p} = p_1 p_2 \cdots p_k$.

1. Starting at the top of guest column 0, mark off p_1 rows in that column. In column 1, mark off the p_2 rows immediately following the marked rows in column 0. Continue in this fashion until the last p_k rows are marked in column $k-1$. By the definition of $\mathbf{p}$, h_g rows have been marked in the first k columns of the guest grid.

2. Consider the sequence of integers 0 through $h_h - 1$. Skipping the top row in each marked column segment, write the first $p_1 - 1$ numbers in the sequence in the remaining $p_1 - 1$ rows of column 0, the next $p_2 - 1$ numbers in the sequence in the remaining $p_2 - 1$ rows of column 1, and so on to the last $p_k - 1$ numbers in the sequence in the remaining $p_k - 1$ rows of column $k-1$. At this point, we have computed C_0^0 as defined in item 1 (i) of Definition 4.2.

3. Repeat $l-1$ times: run down the right-hand edge of the current pattern, and, for each of the most recent additions of the numbers 0 through $h_h - 1$, copy that number into the next location one column to the right and one row down from the current position. If moving down runs off the bottom of the pattern, place the number in the next vacant location in row 0. At this point, we have completed the computation of C_0, i.e., the mapping into the first host column, as defined in item 1 (ii) of Definition 4.2.

4. To create C_1 from C_0, i.e., host column 1 from host column 0, or, in general, C_{i+1} from C_i, all numbers are incremented by one, and the pattern is cyclically rotated downward by l rows. In the cyclic rotation, items that run off the bottom are returned to the top rows, but the column number is decreased by k every time the new row number passes through a multiple of h_g. This process is defined in item 2 of Definition 4.2.

Here is the algebraic definition, which is used to prove claims about the properties of the mapping and could be used as the basis for an algorithm to generate it.

DEFINITION 4.2 (the partial mapping). *The C_i corresponding to the 4-tuple $(h_g, h_h, l, \mathbf{p})$, where $\mathbf{p}$ is a (k,n)-profile, are defined recursively as follows:*

1. $C_0 = \bigcup_{j=0}^{l-1} C_0^j$, *where the following hold:*

(i) *Let $d_1 = 0$ and for all $i, 2 \le i \le k$, let $d_i = d_{i-1} + p_i - 1$. Then for all $i, 1 \le i \le k$; for all $z, d_i \le z < d_i + p_i - 1, (z+i, i-1, z) \in C_0^0$.*

(ii) *For all $j, 1 \le j \le l-1, (r,c,v) \in C_0^{j-1}$ implies $((r+1) \bmod h_g, c+1-\lfloor (r+1)/h_g \rfloor k, v) \in C_0^j$.*

2. *For all $i, 1 \le i$, $(r,c,v) \in C_{i-1}$ implies $((r+l) \bmod h_g, c+l-\lfloor (r+l)/h_g \rfloor k, (v+1) \bmod h_h) \in C_i$, where "mod" denotes the remainder after integer division.*

The reader will find that C_0, generated with $l = 2$, $h_g = 13$, and $h_h = 8$, and profile 2 2 2 2 5 yield host column 0 in Figure 4.1 and that C_1 defines host column 1 and so on. This definition can be used as the basis for an algorithm which computes the mapping using a number of arithmetic and other primitive operations linear in the size of the guest.

4.3. Properties of the partial mapping. The following properties of the mappings are evident from the diagrams and are straightforward to prove.

The mapping properties.

1. Every node in the host is the image of exactly l guest nodes; i.e., the load is optimal (taking the size of the domain of the mapping to be the numerator).

2. If two nodes are adjacent in the guest and both have images defined by the mapping, then their images are adjacent in the host; i.e., the dilation of the mapping is one.

3. Each edge in a host column appears no more than $2l-1$ times, and each edge in a host row appears no more than l times; i.e., the congestion of the mapping

is $\leq 2l-1$.

4. The left and right column profiles are rotated through l rows from one host column to the next.

The first statement follows directly from rule 1 (ii) in the definition of the mapping. The second can be demonstrated by an inductive argument based on noting that, within a column, adjacent array elements are given adjacent row numbers and that, across column boundaries, adjacent elements are given identical row numbers. The third statement follows from the fact that adjacent consecutive row numbers within a host column correspond to column edges and there are no more than $2l-1$ such adjacencies per edge. Host row edges correspond to adjacent numbers across host column boundaries. Along a boundary, each row number can appear no more than l times. The fourth statement follows directly from rule 2 in the definition of the mapping.

The partial mapping has two significant periodicity properties. For example, notice that in Figure 4.1 the left profile of host column 0 and the right profile of host column 12 (which is identical to the left profile of host column 13) are identical.

DEFINITION 4.3. *The* structural periodicity *of the mapping is the smallest integer, p_s, such that $\exists \delta_s$ for all $i(r,c,v) \in C_i$ implies $(r, c+\delta_s, (v+p_s) \bmod h_h) \in C_{i+p_s}$.*

Note also that the values in host column 13 (the next column in the mapping but not shown in the diagram) would not be identical to those in column 0. However, C_0 would be identical, in both profiles and content, to C_{104} ($104 = 8 \times 13$) were the mapping to be continued that far.

DEFINITION 4.4. *The* numerical periodicity *of the mapping is the smallest integer, p_n, such that $\exists \delta_n$ for all $i(r,c,v) \in C_i$ implies $(r, c+\delta_n, v) \in C_{i+p_n}$.*

The following lemmas show how these periodicities are related to the parameters that define the mapping. We refer to the greatest common divisor and to the lowest common multiple of two positive integers i and j as $gcd(i,j)$ and $lcm(i,j)$, respectively, and we use $i \mid j$ to mean i divides j.

LEMMA 4.5. *The structural periodicity of the pattern is given by $p_s = h_g/gcd(l,h_g)$, and the constant δ_s is given by $\delta_s = lh_h/gcd(l,h_g)$.*

Proof. Suppose the operation defined in rule 2 of the initial mapping definition is repeated $p_s = h_g/gcd(l,h_g)$ times on a triple (r,c,v), producing the triple (r',c',v').

Then the following hold:

1. $r' = (r+lp_s) \bmod h_g = (r+lh_g/gcd(l,h_g)) \bmod h_g = r$.

2. Let $k = h_g - h_h$. The column number c will be incremented, by l, p_s times and decremented, by k, the number of times the value of r, incremented by l at each iteration, passes through a multiple of h_g, namely, $\lfloor (r+lp_s)h_g \rfloor$ times. Noting that $\lfloor r/h_g + (l/h_g)(h_g/gcd(l,h_g)) \rfloor = l/gcd(l,h_g)$, we have

$$\begin{aligned} c' &= c + lh_g/gcd(l,h_g) - lk/gcd(l,h_g) \\ &= c + l(h_g-k)/gcd(l,h_g) \\ &= c + lh_h/gcd(l,h_g). \end{aligned}$$

3. $v' = (v+p_s) \bmod h_h$.

4. $h_g/gcd(l,h_g)$ is the smallest integer z with the required properties because z must satisfy $r = (r+lz) \bmod h_g$. Then it must be that $h_g \mid lz$, i.e., $l = ax$, $z = by$, where $xy = h_g$ for some integers a,b,x,y. Since z is minimal, it must be that $x = gcd(l,h_g)$. Hence $z = by = bh_g/x = bh_g/gcd(l,h_g) \geq h_g/gcd(l,h_g)$. ∎

LEMMA 4.6. *The numerical periodicity of the pattern is given by*

$$p_n = lcm(h_h, h_g/gcd(l,h_g)).$$

Proof. We require that $r' = r$, which implies that $p_n = ap_s$ for some integer a. Also, we must have $v' = v$, and hence $ap_s \bmod h_h = 0$. Hence $ap_s = lcm(h_h, p_s) = lcm(h_h, h_g/gcd(l, h_g))$. □

Note that both periodicities are independent of the profile **p** used to initiate the mapping.

For some of our constructions, we need a lower bound on what we will call the *column thickness* of a mapping.

DEFINITION 4.7. *The* column thickness *of a mapping is the minimum over all rows of the number of grid columns in the row mapped to the same host column.*

LEMMA 4.8. *The thickness of a partial mapping is* $\geq \lfloor l/2 \rfloor$.

Proof. The thickness of C_0 is $\geq \lfloor l/2 \rfloor$ because $C_0^0 \cup C_0^1$ includes every row at least once. Hence every two repetitions of rule 1 (ii) of the mapping definition adds at least one to the thickness. The later columns are formed by the rotation of C_0, which does not change its shape. □

5. Embedding into cylinders. So far we have described only partial mappings from guest grid nodes to the host cylinder nodes, but our goal is to define a total mapping for (h, w)-grids. Obviously, a partial mapping can yield a total mapping for any (h, w)-grid whose nodes fall within the domain of the partial mapping. By a *partially mapped* guest column, we mean one for which one or more but not all column nodes have an image defined by the mapping. For example, in Figure 4.1, we can obtain a load 2, dilation 1 embedding of the $(13, 12)$-grid into an $(8, 13)$-cylinder by discarding the partially mapped columns.

In this section, we improve on that by showing that we can "square up" at least one end of the mapping diagram. This squaring up method works for one particular family of profiles. Let $k = h_g - h_h$. The (k, h_g)-profile we need is a sequence of $k - 1$ twos followed by $h_g - 2(k - 1)$. Let us call these *cylindrical* profiles. Figure 4.1 was initiated by such a profile.

A guest node will be said to be *uncovered* if it is not in the domain of the partial mapping. In the mapping diagrams, the uncovered nodes that we consider now are those making up the bottom left corner. We will refer to this set of uncovered nodes as the *corner*.

LEMMA 5.1. *There are* $(k-1)h_h$ *nodes in the corner of a partial mapping initiated by a cylindrical profile.*

Proof. We deduce from the definition of the partial mapping, rule 1 (i), that there are $k - 1$ partially mapped columns, that the leftmost such column is of height $h_g - 2$, and that the rightmost column is of height $h_g - 2k + 2$, decreasing by 2 at each column. A simple summation yields the following: the number of uncovered nodes $= (k - 1)(h_g - k) = (k - 1)h_h$. □

The remainder of the paper is presented in terms of mapping diagrams. We do not attempt to specify the mappings algebraically. The following process creates a corner mapping diagram which maintains the necessary mapping properties for any load l.

1. Take $(k - 1)$ height h_h columns, numbered 0 through $k - 2$. Assign the first l columns to host column 0, the next l to host column 1, and so on until all are given some designation. The columns will now be divided into $\lceil (k - 1)/l \rceil$ groups, with l columns per group, except perhaps for the last group, which will contain $(k-1) \bmod l$ columns. Number the rows of column 0 from 0 downward to $h_h - 1$ (or any rotation thereof). See Figure 5.1 (a), where an appropriate rotation is chosen to match Figure 4.1.

2. For columns 1 through $k-2$, the following hold.

(i) If the guest node and its left neighbor are assigned to the same host column, assign a row number one less (cyclically) than its left neighbor.

(ii) If the column and its left neighbor are assigned to different (adjacent) host columns, assign a row number identical to that of its left neighbor.

See Figure 5.1 (b).

3. Repeat the following *shift* process $k-2$ times: Consider a 45 degree diagonal drawn from above the top leftmost element, down to the right edge of the current profile. Shift everything above this diagonal one place up and one place to the left. See Figure 5.1 (c) through (e).

We observe the following.

1. The diagram covers $h_h(k-1)$ nodes, i.e., the number originally uncovered, and distributes them with load $\leq l$ across $\lceil (k-1)/l \rceil$ host columns.

2. After steps 1 and 2, mapping properties 2 and 3 hold.

3. Mapping properties 2 and 3 are preserved at each step of the shifting process. This can be seen by noting the following.

(i) Any diagonal shift involving elements originally related in the way defined by steps 1 and 2 preserves the properties. Consider two horizontally adjacent elements, *left* and *right*, on either side of the diagonal which defined the shift. Shifting puts *right* above *left*, and the element which was below and to the right of *right* becomes the right neighbor of *left*. In each of the only two possible cases (i.e., *left* and *right* are assigned either to the same or to adjacent host columns) the row numbering defined in steps 1 and 2 ensures that mapping properties are preserved.

(ii) All diagonal shifts are on elements related as defined in steps 1 and 2, as the diagonal moves up through previously undisturbed elements.

4. Height $h_g - 2$ is achieved.

5. The right profile of the result is a cylindrical profile.

Finally, we note that once a corner has been built in this way, we can continue the mapping in the usual way. It is necessary only to note whether those uncovered elements adjacent to elements covered by the corner building process should be assigned to the same host column or to the next one.

Case 1. $l \mid (k-1)$, i.e., the number of host columns used in the corner is a multiple of the load. In this case, the mapping that follows the corner begins with a new host column. Then the mapping definition 1 (i) is initiated not by a profile but by the numbers already defined by the corner. Then definition 1 (ii) is applied without change.

Case 2. Not $(l \mid (k-1))$, i.e., the available repetitions of the current host column, as determined by the load, have not been completely used. Again, rule 1 (i) is modified so that C_0^i, for some i, is defined not by a profile but by the numbers defined by the corner construction. C_0^{i+1} through C_0^{l-1} are defined as usual by rule 1 (ii).

Figure 5.1 shows the construction of a corner for the problem instance $h_h = 8$, $h_g = 13$, and load 2. Here we need four columns to fill the corner, i.e., two host columns, each appearing twice.

Figure 5.2 shows a similar example—the construction of a corner for the same problem instance but with load 3. Now we need two host columns, one appearing three times and the other once. As the mapping continues, it will first use two copies of this latter host column.

In general, we know how to square up the other end of the mapping only in certain

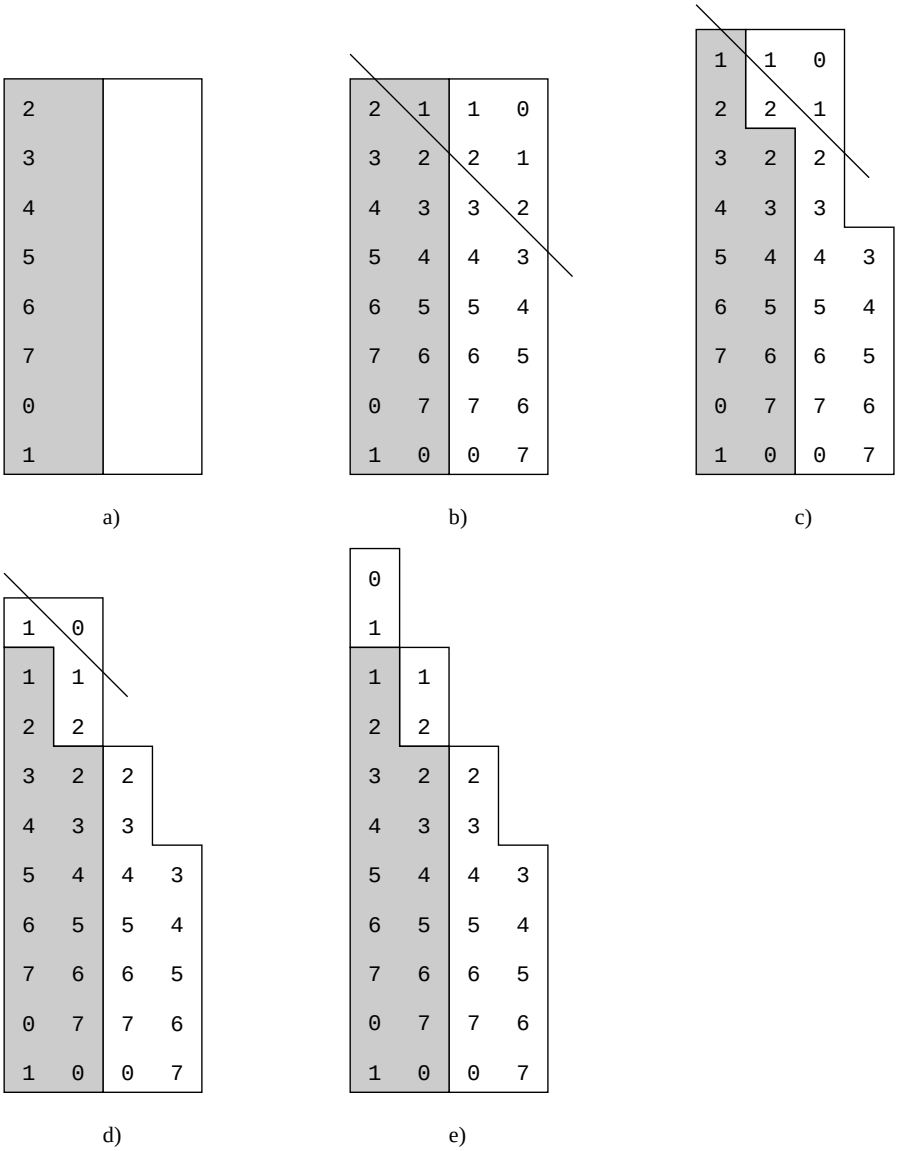

FIG. 5.1. *Creating a corner:* $h_g = 13$, $h_h = 8$, *load* 2.

special cases. We can, however, put an upper bound on how many extra host columns we may have to use to make up for the uncovered nodes in the top right corner of the mapping. We need to consider the *skew* of the mapping.

DEFINITION 5.2. *Let the mapping be defined for host columns* 0 *through* i. *The* skew *of a mapping is the number of guest columns that are partially mapped and that contain some element mapped to host column* i.

LEMMA 5.3. *The skew of any partial mapping is* $\leq h_g - h_h$.

Proof. By definition of the mapping, rule 1 (i), there are $h_g - h_h - 1$ partially mapped guest columns containing some element mapped to host column 0. As the mapping progresses across host columns, the profile can be split by the wrap-

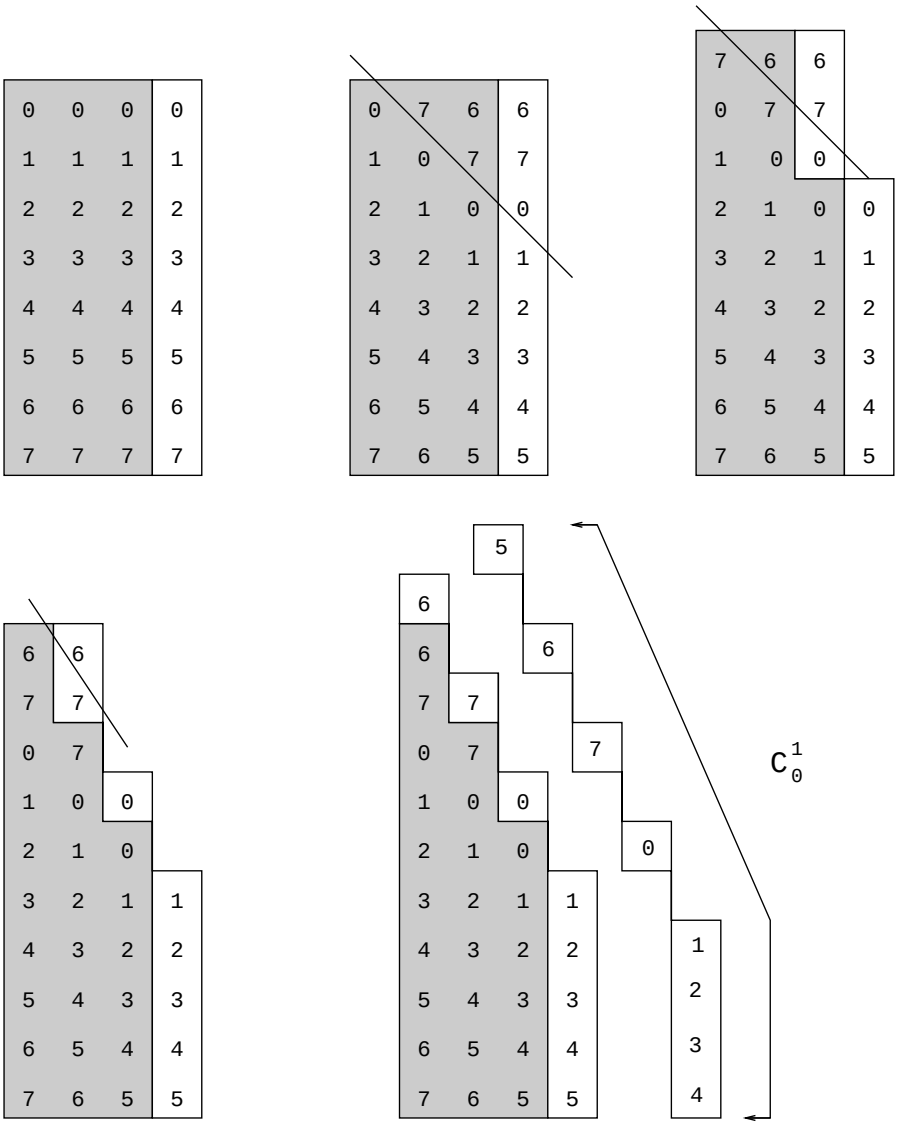

FIG. 5.2. *Creating a corner:* $h_g = 13$, $h_h = 8$, *load* 3.

around at only one place, which can increase the skew by no more than one over the minimum. □

Let w_c denote the smallest integer such that $h_g w_g \leq l h_h w_c$; i.e., w_c is the smallest width of a host of height h_h that can accommodate the given guest at the given load. Let k denote $h_g - h_h$.

THEOREM 5.4. *If* $h_g/2 < h_h < h_g$, *then the* (h_g, w_g)*-grid is embeddable in the* (h_h, w_h)*-cylinder, where* $w_h = (w_c + \lceil k/\lfloor l/2 \rfloor \rceil)$ *with dilation* 1 *and load* l.

Proof. We can square up the left end of the mapping as just demonstrated. The skew is an upper bound on the number of partially mapped columns at either end. Hence, by Lemma 5.3, the skew of the mapping at the right end is not greater than k. By Lemma 4.8, each host column covers at least $\lfloor l/2 \rfloor$ nodes from every row of the

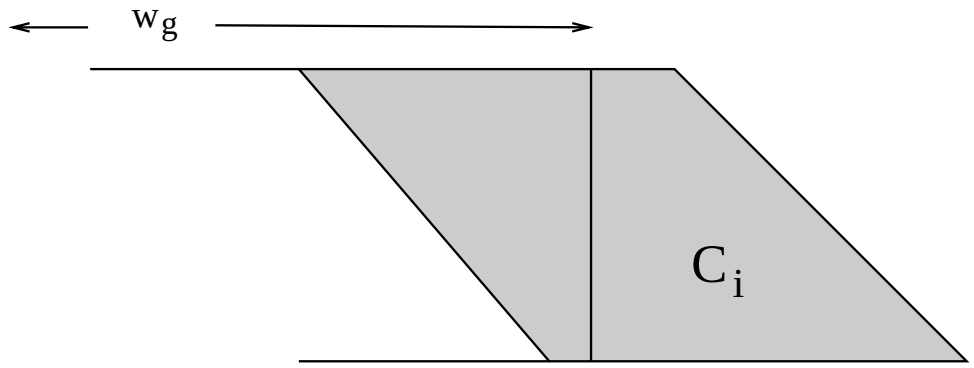

FIG. 5.3. *A high load can yield an optimal embedding.*

grid. Hence we need no more than $\lceil k/\lfloor l/2 \rfloor \rceil$ extra host columns to make up for the skew. □

We can also note that, if the load is sufficiently high, guest column w_g may be completely mapped, without the addition of extra host columns beyond column w_c. Such a situation is illustrated in Figure 5.3, where host column C_i is necessary but not completely used.

THEOREM 5.5. *If $lh_hw_h - h_gw_g \geq kh_h$ and $h_g/2 < h_h < h_g$, then the (h_g, w_g)-grid is embeddable in the (h_h, w_h)-cylinder with dilation* 1 *and load l.*

Proof. The skew is the number of partially mapped columns. The leftmost of these is of height $\leq h_g - 1$, and the next is of height $\leq h - 3$, etc., for $\leq k$ columns. Summing this series shows that the number of guest nodes in the partially filled columns is $\leq k(h_g - k) = kh_h$. Hence we need to add no extra host columns as long as $lh_hw_c - h_gw_g \geq kh_h$. □

6. Embedding into tori.

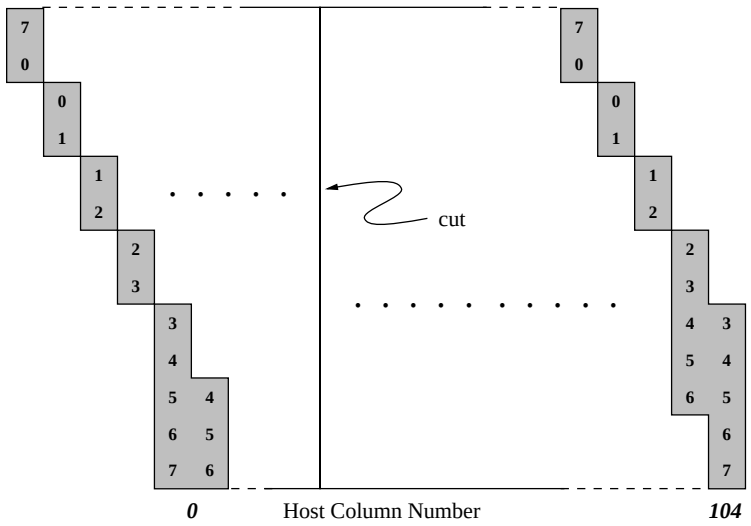
6.1. The problem. We now consider the "hardest" instances of the problem of embedding an (h_g, w_g)-grid into an (h_h, w_h)-torus, namely, those where w_g is maximal with respect to preserving $h_gw_g \leq lh_hw_h$. We will derive certain restrictions on the load and on the guest and host dimensions under which optimal solutions can be constructed.

To obtain these solutions, we match up the ends of a partial mapping. Consider first those special cases in which w_g is a multiple of the numerical periodicity (Definition 4.4 and Lemma 4.6). By definition, the host row numbers and profiles at the left and right ends of the partial mapping match. Hence we can cut the mapping vertically anywhere outside of the partially mapped columns, transpose the left and right portions of the mapping, and so produce a total mapping for the guest grid.

For example, consider Figure 6.1. In the illustration, a continuation of the example shown in Figure 4.1, $h_g = 13$, $h_h = 8$, and $l = 2$. Hence, by Lemma 4.6, the numerical periodicity is $p_n = 104$. So the figure is illustrating an embedding of the (13,128)-grid into the (8,104)-cylinder with load 2.

Of course, except in these very special cases, neither the row numbers nor the profiles at the ends of the mapping will match. We now show how to solve both of these problems.

6.2. Toroidal profiles. For embeddings into tori, we must initiate the partial mapping with a unique profile. We will refer to them here as *toroidal profiles*. In



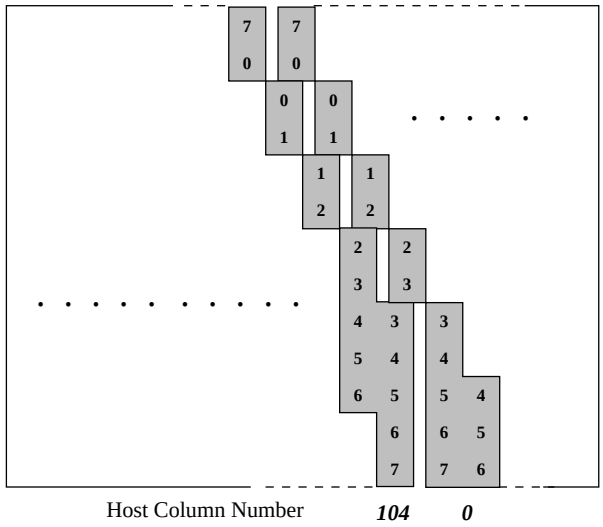


FIG. 6.1. *Matching up the ends of a partial mapping.*

[4, 5], where their existence and properties are demonstrated, they are called *Euclidean strings* because they are generated by an extension to Euclid's greatest common divisor algorithm. In this section, we show how to generate these special profiles and state their properties without repeating the proofs.

Let $\mathbf{p} = p_1 p_2 \cdots p_k$ denote a string of k nonnegative integers. Let $\rho(\mathbf{p})$ denote a left rotation of $\mathbf{p}$ by one position, i.e., $\rho(\mathbf{p}) = p_2 \cdots p_k p_1$, and let $\rho^d(\mathbf{p})$ denote a left rotation through d positions. Let $\sigma_i(\mathbf{p})$ be the string obtained from $\mathbf{p}$ by replacing p_i by $p_i + 1$ and $p_{(i+1) \bmod k}$ by $p_{(i+1) \bmod k} - 1$.

DEFINITION 6.1. *The string* $\boldsymbol{p}$ *is a* toroidal (k,n)-profile *if* $\sum_{i=1}^{k} p_i = n$, *and there exist integers* d *and* i *such that* $\sigma_i(\mathbf{p}) = \rho^d(\mathbf{p})$.

```
function profile (k, n : integer) : string;
if (k = 1) and (n = 1) then profile := 1
else if n > k then profile := expand(profile(k, n − k))
else profile := increment(profile(k − n, n));
```

FIG. 6.2. *Computing a profile.*

```
procedure parameters (k, n : integer);
if (k = 1) and (n = 1) then i := 0; j := 0; c := 0; d := 1
else if k < n then parameters (k, n − k); j := i + j; c := c + d  else parameters (k − n, n); i :=
i + j + 1; d := c + d;
```

FIG. 6.3. *Computing the profile parameters.*

In [4, 5], the following lemma is established.

LEMMA 6.2. *A toroidal (k, n)-profile exists iff $gcd(k, n) = 1$, where gcd denotes the greatest common divisor. If it exists, then it is unique.*

Suppose 1^r denotes a string of r ones, and suppose the function expand($\mathbf{p}$) replaces every element r in $\mathbf{p}$ by the string 01^r and the function increment($\mathbf{p}$) replaces every number r in $\mathbf{p}$ by $r + 1$. Then Figure 6.2 describes, in pseudocode, a procedure that computes a (k, n)-profile when k and n are relatively prime.

For the application of profiles to the computation of our embedding, we also need to compute the following parameters. We note that, since the profile is unique, all of these parameters are well defined.

1. i and d, as in the definition of profile,
2. j, the sum of elements p_1 through p_i,
3. c, the sum of the d elements to the left (cyclically) of and including p_i.

Figure 6.3 shows a pseudocode procedure which computes these parameters, assuming that all the variables are global. Figure 6.4 shows the computation of a string and its associated parameters for particular values of k and n.

We will refer to the parameters c and d as the *cost* and *displacement* of a profile, respectively, and we let $c_{k,n}$ and $d_{k,n}$ denote the cost and the displacement, respectively, of a toroidal (k, n)-profile.

LEMMA 6.3. *If $n + k \geq 2$, then $d_{k,n}n = c_{k,n}k + 1$.*

Proof. We argue by induction on $n + k$. For the basis, we note that, if $n + k = 2$, then $(n = 1)$ and $(k = 1)$, and hence the initialization defined by the algorithm satisfies the lemma.

We note that n and k are not equal because $gcd(n, k) = 1$. For the induction, suppose first that $n > k$. By the inductive hypothesis, $d_{k,n-k}(n - k) = c_{k,n-k}k + 1$. Hence $d_{k,n-k}n = d_{k,n-k}(n - k) + d_{k,n-k}k = (c_{k,n-k} + d_{k,n-k})k + 1$. However, when $n > k$, the algorithm sets $d_{k,n-k} = d_{k,n}$ and $c_{k,n-k} + d_{k,n-k} = c_{k,n}$. Hence $d_{k,n}n = c_{k,n}k + 1$.

Suppose $n < k$. By the inductive hypothesis, $d_{k-n,n}n = c_{k-n,n}(k - n) + 1$. Hence $(d_{k-n,n} + c_{k-n,n})n = c_{k-n,n}k + 1$. However, when $n < k$, the algorithm sets $d_{k-n,n} + c_{k-n,n} = d_{k,n}$ and $c_{k-n,n} = c_{k,n}$. Hence $d_{k,n}n = c_{k,n}k + 1$. ∎

So $d_{k,n}$ and $-c_{k,n}$ are in fact the constants computed by the standard extended Euclidean algorithm. Lemma 6.3 yields the following corollary.

COROLLARY 6.4. *$c_{k,n}$ is the multiplicative inverse of $(n - k)$ modulo k, i.e., $c_{k,n}(n - k) \equiv 1 \bmod n$.*

Proof. By Lemma 6.3, $d_{k,n}n = c_{k,n}k + 1$, implying $-c_{k,n}k = -d_{k,n}n + 1$. Hence $c_{k,n}(n-k) = c_{k,n}n-c_{k,n}k = c_{k,n}n-d_{k,n}n+1 = (c_{k,n}-d_{k,n})n+1$. Hence $c_{k,n}(n-k) \equiv$

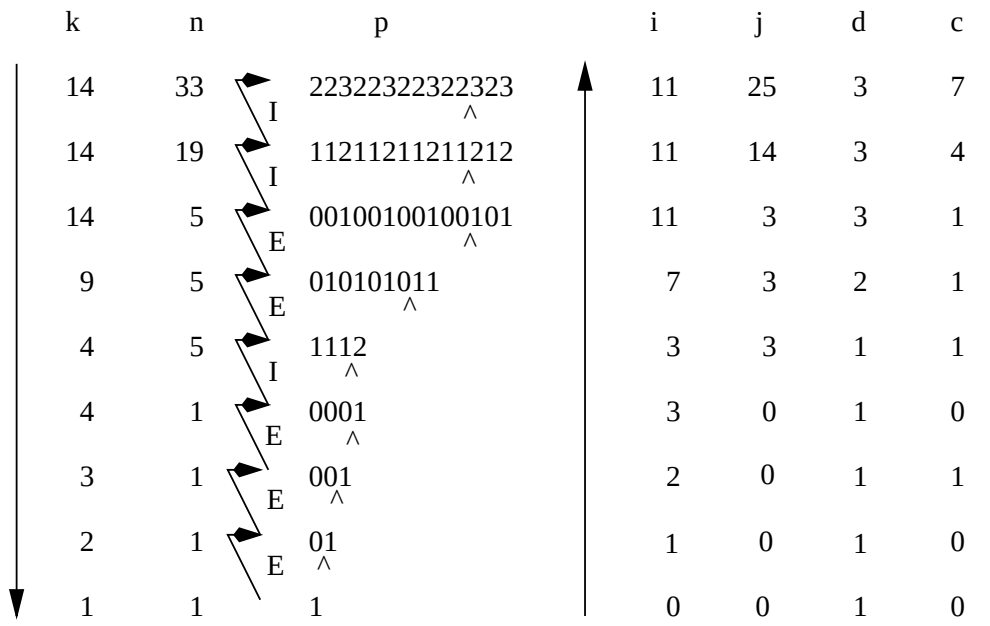

FIG. 6.4. *An example of computing a profile and its parameters.*

1 mod n. □

It is also shown in [4, 5] that all of the elements in a profile are of the form i or $i+1$ for some integer i. We will be using $(h_g - h_h, h_g)$-profiles, and so, since $h_h > h_g/2$, all of the profile elements will be ≥ 2.

6.3. Matching profiles. We are considering those problem instances in which $0 \leq l|H| - |G| < h_g$, the case in which the difference is zero being trivial. So we need a way of dropping between 1 and $h_g - 1$ host nodes from the mapping while simultaneously guaranteeing that the left profile of host column 0 is identical to the right profile of the last column.

Consider the running example, where $h_g = 13$ and $h_h = 8$. The application of the toroidal profile generator (see Figures 6.2 and 6.3) yields the profile 2 3 2-3 3, where swapping the hyphenated pair yields a rotation of the original string. In our application, the profile elements define the height of the steps in the left or right profiles of the host columns.

Suppose our mapping is based on a toroidal profile, and suppose we remove el-

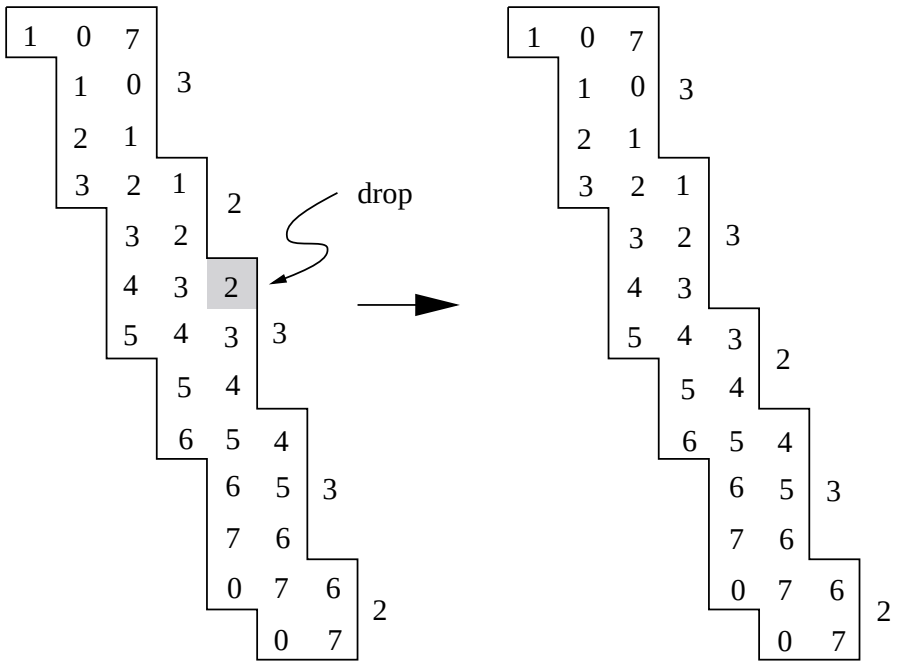

FIG. 6.5. *Dropping an element while preserving the profile.*

ement $(i+1)$ from the mapping in the right profile of some host column, where i is the profile parameter in Definition 6.1. Removing an element decreases the height of the step containing that element and increases the height of the step above. However, because the profile is toroidal, the resulting profile is a rotation of the original. Because the profile is preserved, except for a rotation, the operation can be repeated as many times as necessary. This is illustrated in Figure 6.5.

We deduce that we can drop $(l|H| - |G|) < h_g$ elements and be assured that the right profile of the rightmost host column is a rotation of the left profile of column 0. It remains only to show that not only are these two profiles rotations of each other, but they are identical. For the moment, let us assume that we apply the drop process to distinct host columns.

LEMMA 6.5. *If the drop operation is applied to $l|H| - |G|$ distinct host columns, the right profile of the rightmost host column is identical to the left profile of host column* 0.

Proof. Every host column rotates the profile l rows in what we will call the forward direction. Therefore, the profile shift s in the forward direction relative to its initial position is given by

$$s = (l(w_h \bmod p_s)) \bmod h_g, \tag{6.1}$$

where p_s denotes the structural periodicity. By Lemma 4.5, $p_s = h_g/gcd(l, h_g)$, and so we derive from (6.1)

$$s = (lw_h) \bmod h_g. \tag{6.2}$$

Let $\delta = lw_hh_h - w_gh_g$. Suppose we apply the drop process δ times. Each application shifts the profile c rows backward, where c is the cost of the profile. So the repeated

application shifts the profile $s' = \delta c \bmod h_g$ rows. However,

$$\delta c \bmod h_g = c(lw_h h_h - w_g h_g) \bmod h_g, \tag{6.3}$$

and so

$$s' = lw_h \bmod h_g = s \tag{6.4}$$

because $ch_h \bmod h_g = 1$ by Corollary 6.4. □

Hence the profile shift caused by the excess host columns is exactly compensated for by the repeated application of the drop process. Finally, we note that all of the drop operations can be applied to one host column, without removing all of the elements from that column from any one row.

LEMMA 6.6. *If $(l|H| - |G|) < h_g$ drop operations are applied to one host column and the load $l \geq 4$, the resulting width of the column is at least one.*

Proof. By Corollary 6.4, $ch_h \bmod h_g = 1$. It follows that c and h_g are relatively prime. Hence, since $\delta = (l|H| - |G|) < h_g$, if up to δ elements are dropped, they are all taken from different rows, so the width of the column is decreased by no more than one. By Lemma 4.8, the width of a column in the partial mapping is at least $\lfloor l/2 \rfloor$; hence, if $l \geq 4$, the resulting width is at least $\lfloor l/2 \rfloor - 1 = 1$. □

6.4. Matching row numbers. We describe a perturbation of the partial mapping which has the effect of incrementing all the host row numbers by one or two in all the columns following the perturbation. The perturbation can be applied to any instance of the problem for which the load is at least 4.

Let us suppose we are perturbing host column i. C_i is composed of C_i^0 through C_i^{l-1}. The perturbation simply adds one or two to all the host row values in C_i^2 and to those in C_i^3. If $l > 4$, then the mapping follows in the usual way after C_i^3. It is clear that the perturbation is still yielding dilation 1. In fact, at the junction where the perturbation occurs, adjacent guest nodes are mapped to the same host node; i.e., for those edges the dilation is zero. It is also clear that, since only the values in the mapping are changed, the profiles are not changed.

Figures 6.6 and 6.7 illustrate the process with a load 4 example, following from our running example. In these figures, the shading distinguishes C_i^0 and C_i^1 from C_i^2 and C_i^3.

Suppose we need to increment the row numbers by more than one. The process just described can be repeated on C_i^4 and C_i^5, etc., within a host column. Each column, therefore, can be used to obtain an increment of up to $2\lfloor (l-2)/2 \rfloor$. We observe that the row values never need to be incremented by more than $h_h - 1$ and that we can adjust by incrementing either by one or two. We have then justified the following lemma.

LEMMA 6.7. *If $\lceil (h_h - 1)/2 \rceil \leq w_h \lfloor (l-2)/2 \rfloor$ and the right profile of the last column in the mapping is identical to the left profile of column 0, then we can adjust row values so that they are equal in these two profiles.*

6.5. The solution. The computation of the total mapping can then proceed as follows.

1. Compute a toroidal $(h_g - h_h, h_g)$-profile together with the associated parameters using Figures 6.2 and 6.3.

2. Use this profile to initiate the computation of a partial mapping using Definition 4.1.

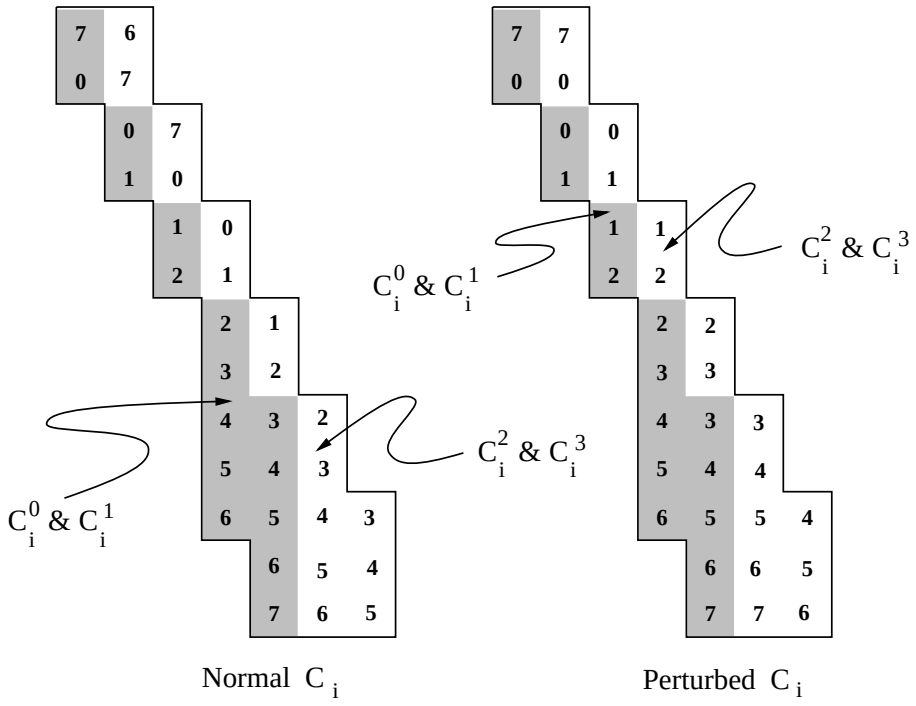

FIG. 6.6. *The perturbation that increments row numbers by one.*

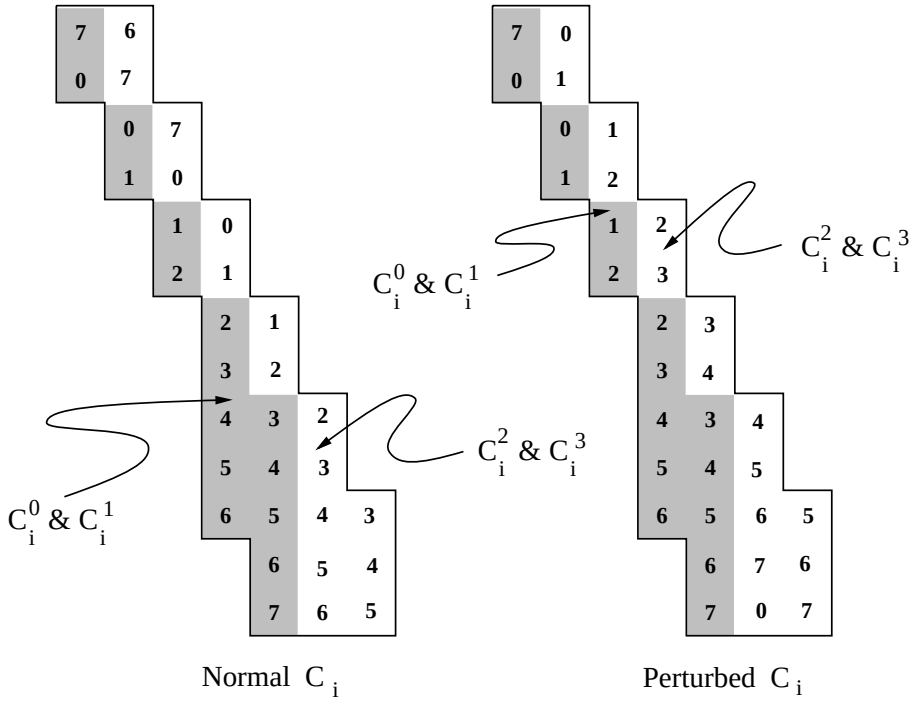

FIG. 6.7. *The perturbation that increments row numbers by two.*

3. Compute δ, the difference between available host nodes and the number of guest nodes, and apply the drop process δ times to (say) the right profile of the rightmost host column.

4. Compute the row number incrementation required, and apply the incrementation perturbation.

5. Cut the modified partial mapping vertically at any point outside of the partially mapped columns, and transpose the left and right portions produced by the cut.

The conditions under which this process is effective are summarized in the following theorem.

THEOREM 6.8. *If*

1. $h_g/2 < h_h < h_g$,
2. h_g *and* $(h_g - h_h)$ *are relatively prime,*
3. *the optimal load is at least* 4, *and*
4. $w_h(\lfloor (l-2)/2 \rfloor) \geq \lceil (h_h - 1)/2 \rceil + 1$,

then the (h_g, w_g)*-grid can be embedded in the* (h_h, w_h)*-torus with optimal load and dilation* 1.

Proof. The first item is a necessary condition for the construction of the partial mapping. The second is sufficient for a suitable profile to exist for the initiation of the mapping. The restriction on the load is sufficient for the increment operation and allows the drop operation to be repeated on one column.

The last item ensures that there is sufficient width within which to carry out both the row incrementation and the drop operations. Each host column i is composed of $\lfloor (l-2)/2 \rfloor$ pairs C_i^k, C_i^{k+1}, where $k \geq 2$. We may not assume that we can apply the increment operation on a pair that has already been the subject of the drop operation. As many as $\lfloor (h_h - 1)/2 \rfloor$ increment operations may be necessary. Consequently, we have sufficient host width if $w_h(\lfloor (l-2)/2 \rfloor) \geq \lfloor (h_h - 1)/2 \rfloor + 1$. □

7. Embedding into hypercubes. The previous section has shown that we can construct optimal embeddings into the torus under some restrictions on the load and dimensions of the guest and host. Because we can always find a torus of suitable height within a hypercube host, we obtain a much simpler result.

Consider the restrictions listed in Theorem 6.8 when applied to the embedding of the (h_g, w_g)-grid into the hypercube Q_d of dimension d.

1. By Lemma 3.2, there is a toroidal subgraph of the hypercube with height h_h in the range $h_g/2$ to h_g, namely, $h_h = 2^{\lfloor \log_2 h_g \rfloor}$, which is the next power of 2 less than h_g. Then also w_h is a power of two, namely, $2^{d - \lfloor \log_2 h_g \rfloor}$.

2. If h_g is an odd number, then h_g and h_h are relatively prime since h_h is now a power of two.

3. We retain the condition on the optimal load, namely, $l = \lceil h_g w_g / 2^d \rceil \geq 4$.

4. The last restriction cannot be dispensed with, but see the corollaries below. It can be simplified slightly by noting that h_h is a power of 2, yielding

$$w_h(\lfloor (l-2)/2 \rfloor) \geq h_h/2 + 1,$$

where h_h and w_h are now as defined in the first item.

Let h_h and w_h be the dimensions of the host torus as defined above as functions of the guest grid and host hypercube dimensions h_g, h_h, and d. Then the following theorems follow from Theorem 6.8.

THEOREM 7.1. *If*

1. h_g *is odd,*

2. *the optimal load* $l \geq 4$*, and*
3. $w_h(\lfloor (l-2)/2 \rfloor) \geq h_h/2 + 1$,

then the (h_g, w_g)*-grid can be embedded into* Q_d *with optimal load and dilation* 1.

We cannot guarantee that all instances of the problem present sufficient width to permit the necessary incrementation and drop operations. For example, the problem instance

$$h_g = 11, w_g = 14, h_h = 8, w_h = 4, l = 5$$

does not satisfy the third constraint of Theorem 7.1. Some slightly stronger but simpler forms of that constraint show more clearly that it is excluding only a small portion of problem instances.

COROLLARY 7.2. *If* h_g *is odd and the optimal load* $l \geq 4$ *and* $w_h \geq h_h$*, then the* (h_g, w_g)*-grid can be embedded into* Q_d *with optimal load and dilation* 1.

Proof. If $w_h \geq h_h$, then the third constraint of Theorem 7.1 is satisfied. ∎

COROLLARY 7.3. *If* h_g *is odd and either* $((l = 4$ *or* $l \geq 6)$ *and* $w_g \geq 2h_g)$ *or* $(l = 5$ *and* $w_g \geq 5h_g/2)$*, then the* (h_g, w_g)*-grid can be embedded into* Q_d *with optimal load and dilation* 1.

Proof. Since, by definition of the problem, $lh_hw_h \geq h_gw_g$ and $w_g \geq h_g > h_h$, if $w_g \geq 2h_g$, we deduce that $lw_h > 2h_h \geq 2h_h + 1$. However, $\lfloor l/2 \rfloor - 1 \geq l/4$ for $l = 4$ and $l \geq 6$, thus satisfying the third constraint. For load 5, the same algebra shows that $w_g \geq 5h_g/2$ suffices. ∎

The theorem implies that, if we group the problem instances by h_g, there are no more than a finite number of instances of the problem in each group that may not be solved by our method. Finally, we note that instances where h_g is even either are trivial if h_g is a power of two or can be reduced to instances where h_g is odd.

THEOREM 7.4. *If* h_g *is of the form* $a2^k$ *for some odd integer* a *and positive integer* k *and either* $k \leq d$ *and there is an optimal embedding from the* (a, w_g)*-grid into the hypercube of degree* $d - k$ *or* $k > d$*, then the* (h_g, w_g)*-grid can be embedded into the hypercube of degree* d *with optimal load and dilation* 1.

Proof. If $k \leq d$, we note that it must be that $2^k | (l2^d - a2^k w_g)$. Hence we can solve the subproblem of embedding the (a, w_g)-grid into Q_{d-k} with load l and then construct a solution to the original problem by simple duplication of the host.

If $k > d$, then $|Q_d| < h_g$ and $|Q_d| \mid h_g$. Hence an embedding can be constructed by simple duplication of the host. ∎

THEOREM 7.5. *If* h_g *is a power of two, then an optimal embedding always exists into any hypercube.*

Proof. If $h_g = 2^k$ and $d \leq k$, then the host is not bigger than one column of the guest. Hence a simple duplication technique can cover the guest with copies of the host.

If $h_g = 2^k$ and $d > k$, then we consider the $(2^k, 2^{d-k})$-grid, which is a subgraph of the host. A simple duplication technique can then cover the guest with copies of the host. ∎

Theorems 7.1, 7.4, and 7.5 cover all possibilities for the form of h_g and constitute the main result of this paper. Corollaries 7.2 and 7.3 slightly simplify the third condition.

8. Conclusions. We have described a novel grid to hypercube embedding construction which is simple and optimal with respect to load and dilation for all except perhaps finitely many instances for each grid height, when the load is at least four.

The method also yields optimal embeddings into the torus, under constraints on the relative heights of the torus and grid. For embeddings into the cylinder, the same constraints are necessary, and we may have to extend the cylinder somewhat beyond the minimum necessary to accommodate the grid.

Open problems include the removal of the restrictions on load 4 and above hypercube embeddings and the question as to whether optimal load dilation 1 hypercube embeddings exist for loads 2 and 3. It may also be possible to push the results we have obtained here further for cylindrical and toroidal hosts.

Acknowledgment. We are indebted to the referees for thorough readings and for their many valuable suggestions and corrections.

COMMON-FACE EMBEDDINGS OF PLANAR GRAPHS*

ZHI-ZHONG CHEN†, XIN HE‡, AND MING-YANG KAO§

Abstract. Given a planar graph $\mathcal{G}$ and a sequence $\mathcal{C}_1, \ldots, \mathcal{C}_q$, where each $\mathcal{C}_i$ is a family of vertex subsets of $\mathcal{G}$, we wish to find a plane embedding of $\mathcal{G}$, if any exists, such that, for each $i \in \{1, \ldots, q\}$, there is a face F_i in the embedding whose boundary contains at least one vertex from each set in $\mathcal{C}_i$. This problem has applications in the recovery of topological information from geographical data and the design of constrained layouts in VLSI. Let I be the input size, i.e., the total number of vertices and edges in $\mathcal{G}$ and the families $\mathcal{C}_i$, counting multiplicity. We show that this problem is NP-complete in general. We also show that it is solvable in $O(I \log I)$ time for the special case in which, for each input family $\mathcal{C}_i$, each set in $\mathcal{C}_i$ induces a connected subgraph of the input graph $\mathcal{G}$. Note that the classical problem of simply finding a planar embedding is a further special case of this case with $q = 0$. Therefore, the processing of the additional constraints $\mathcal{C}_1, \ldots, \mathcal{C}_q$ incurs only a logarithmic factor of overhead.

Key words. planar graph, planar embedding, topological inference

1. Introduction.

It is a fundamental problem in mathematics (see, e.g., [13, 17, 18, 19, 20, 29]) to embed a graph into a given surface while optimizing certain objectives required by applications. (Throughout this paper, a graph may have multiple edges and self-loops, but a simple graph has neither.) A graph is *planar* if it can be embedded on the plane so that any pair of edges intersect only at their endpoints; a *plane* graph is a planar graph together with such an embedding. A classical variant of the problem is to test whether a given graph is planar and, in case it is, to find a planar embedding. This planarity problem can be solved in linear time sequentially [4, 5, 19] and efficiently in parallel [26].

In this paper, we initiate the study of the following new planarity problem. Let $\mathcal{G}$ be a planar graph. Let $\mathcal{M}$ be a sequence $\mathcal{C}_1, \ldots, \mathcal{C}_q$, where each $\mathcal{C}_i$ is a family of vertex subsets of $\mathcal{G}$. A plane embedding Φ of $\mathcal{G}$ *satisfies* $\mathcal{C}_i$ if the boundary of some face in Φ contains at least one vertex from each set in $\mathcal{C}_i$. Φ *satisfies* $\mathcal{M}$ if it satisfies all $\mathcal{C}_i$. $\mathcal{G}$ *satisfies* $\mathcal{M}$ if $\mathcal{G}$ has an embedding that satisfies $\mathcal{M}$.

PROBLEM 1 (the common-face embedding (CFE) problem).

- *Input*: A planar graph $\mathcal{G}$ and a sequence $\mathcal{M}$ of families of vertex subsets of $\mathcal{G}$.
- *Question*: Does $\mathcal{G}$ satisfy $\mathcal{M}$?

Let I be the input size, i.e., the total number of vertices and edges in $\mathcal{G}$ and the families $\mathcal{C}_i$, counting multiplicity. We first show that the CFE problem is NP-complete in general. Then, for the special case in which each vertex subset in each $\mathcal{C}_i$

induces a connected subgraph of $\mathcal{G}$, we give an $O(I \log I)$-time algorithm which finds a plane embedding satisfying $\mathcal{M}$, if any exists. Note that the classical problem of simply finding a planar embedding is a further special case of this special case with $q = 0$. Therefore, the processing of the additional constraints $\mathcal{C}_1, \ldots, \mathcal{C}_q$ incurs only a logarithmic factor of overhead.

The CFE problem arises naturally from topological inference [6]. For instance, in the conference version of this paper [7], a less general and less efficient variant of our algorithm for the special case was employed to design fast algorithms for reconstructing maps from scrambled partial data in geometric information systems [7]. In this application [8, 9, 10, 15, 23, 24], each vertex subset in $\mathcal{M}$ describes a recognizable geographical feature, and each face in a planar embedding represents a geographical region. Each family in $\mathcal{M}$ is a set of features that are known to be near each other, i.e., surrounding the same region (on the boundary of the same face). Similarly, our algorithm for the special case can compute a constrained layout of VLSI modules [14], where each vertex subset consists of the ports of a module, and each subset family specifies a set of modules that are required to be close to each other [7].

To the best of our knowledge, the conference version of this paper is the first to investigate the CFE problem [7]. A related problem has been studied in the context of speeding up the computation of Steiner trees and minimum-concave-cost network flows [11, 25, 3]. Given a planar graph $G = (V, E)$ and a set of special vertices $S \subseteq V$, the pair (G, S) is called *k-planar* if all the vertices in S are on the boundaries of at most k faces of a planar embedding of G. Bienstock and Monma [3] showed that testing k-planarity is NP-complete if k is part of the input but takes linear time for any fixed k.

The remainder of this paper is organized as follows. Section 2 proves the NP-completeness result and formally states the main theorem on the CFE algorithm (Theorem 2.2). Sections 3 through 6 prove the main theorem by detailing the algorithm for the key cases in which $\mathcal{G}$ is (1) triconnected, (2) disconnected, (3) connected, or (4) biconnected, respectively. The triconnected case is the base case in that the other cases are eventually reduced to it. For this reason, this case is analyzed before the other cases. Section 7 concludes this paper with some directions for further research.

2. Basics and the main results.

2.1. Basic definitions. Let G be a graph. $|G|$ denotes the *size* of G, i.e., the total number of vertices and edges in G. $\mathcal{V}(G)$ denotes the vertex set of G. If G is a plane graph, then $\mathcal{F}(G)$ denotes the set of faces of G.

A set U is *G-local* if $U \subseteq \mathcal{V}(G)$. A family $\mathcal{C}$ of sets is *G-local* if every set in $\mathcal{C}$ is G-local.

For a subset U of $\mathcal{V}(G)$, the *subgraph of G induced by U* is the graph (U, E_U), where E_U consists of all edges e of G whose endpoints both belong to U; $G - U$ denotes the subgraph of G induced by $\mathcal{V}(G) - U$.

A *cut* vertex of G is one whose removal increases the number of connected components in G; a *block* of G is a maximal subgraph of G with no cut vertex. Let $\Psi(G)$ denote the forest whose vertices are the cut vertices and the blocks of G and whose edges are those $\{v, B\}$ such that v is a cut vertex of G, B is a block of G, and $v \in \mathcal{V}(B)$. Note that $\Psi(G)$ is a tree if G is connected. A *block vertex* of $\Psi(G)$ is a vertex of $\Psi(G)$ that is a block of G.

Let w be a cut vertex of G. Let $W_1, \ldots, W_k$ be the vertex sets of the connected components of $G - \{w\}$. Let G_i be the subgraph of G induced by $\{w\} \cup W_i$.

$G_1, \ldots, G_k$ are called the *augmented components* of G induced by w.

G is *biconnected* if it is connected and has at least two vertices but no cut vertex. G is triconnected if it is biconnected and has at least three vertices and the removal of any two vertices does not disconnect it.

The *size* of a set S, denoted by $|S|$, is the number of elements in S. The *size* of a family $\mathcal{C}$ of sets, denoted by $|\mathcal{C}|$, is $\sum_S |S|$, where S ranges over all sets in $\mathcal{C}$. The *size* of a sequence $\mathcal{M}$ of families of sets, denoted by $|\mathcal{M}|$, is $\sum_{\mathcal{C}} |\mathcal{C}|$, where $\mathcal{C}$ ranges over all families in $\mathcal{M}$.

2.2. An NP-completeness result.

THEOREM 2.1. *The CFE problem is NP-complete.*

Proof. We reduce the SATISFIABILITY problem [14] to the CFE problem. Let ϕ be a CNF formula over variables $x_1, \ldots, x_n$ with $n \geq 2$. Let $C_1, \ldots, C_m$ be the clauses of ϕ, each regarded as the set of literals in it. We construct a simple biconnected planar graph $\mathcal{G} = (V_1 \cup V_2, E)$ as follows. $V_1 = \{x_1, \ldots, x_n\} \cup \{\bar{x}_1, \ldots, \bar{x}_n\} \cup \{c_1, \ldots, c_m\}$. $V_2 = \{u_0, \ldots, u_n\}$. For each x_i, $\mathcal{G}$ contains edges $\{u_{i-1}, x_i\}$, $\{x_i, u_i\}$, $\{u_{i-1}, \bar{x}_i\}$, $\{\bar{x}_i, u_i\}$. The only other edges of $\mathcal{G}$ are $\{u_0, c_1\}$, $\{c_1, c_2\}$, $\{c_2, c_3\}$, $\ldots$, $\{c_{m-1}, c_m\}$, $\{c_m, u_n\}$, $\{u_n, u_0\}$. Let $\mathcal{M}$ be the sequence $\{\{c_1\}, C_1\}, \ldots, \{\{c_m\}, C_m\}$. Observe that, in every plane embedding Φ of $\mathcal{G}$, the cycle $c_1, \ldots, c_m, u_n, u_0$ forms the boundary of some face F. Moreover, for each $i = 1, \ldots, n$, exactly one of x_i and $\bar{x}_i$ is on the boundary of the face other than F whose boundary contains the path $c_1, \ldots, c_m$. Also, for every set $S \subseteq \{x_1, \ldots, x_n\} \cup \{\bar{x}_1, \ldots, \bar{x}_n\}$ with $|S \cap \{x_i, \bar{x}_i\}| = 1$ for all $i = 1, \ldots, n$, $\mathcal{G}$ has a plane embedding where the boundary of some face contains the path $c_1, \ldots, c_m$ and the vertices in S. Therefore, ϕ is satisfiable if and only if $\mathcal{G}$ satisfies $\mathcal{M}$. □

2.3. The main theorem. Although the input to the CFE problem is a planar graph $\mathcal{G}$, it is easy to see that $\mathcal{G}$ satisfies a given sequence $\mathcal{M}$ if and only if its underlying simple graph (i.e., the simple graph obtained from $\mathcal{G}$ by deleting multiple edges and self-loops) satisfies the same $\mathcal{M}$. Thus, throughout the rest of this paper, unless explicitly stated otherwise, $\mathcal{G}$ and $\mathcal{M}$ always denote the input simple graph and the input sequence to our algorithm for the CFE problem, respectively. Also, I always denotes $|\mathcal{G}| + |\mathcal{M}|$, i.e., the size of the input to our algorithm.

The next theorem is the main theorem of this paper. In light of this theorem, the remainder of the paper assumes that every vertex subset of $\mathcal{G}$ in $\mathcal{M}$ induces a connected subgraph of $\mathcal{G}$.

THEOREM 2.2. *If every vertex subset in $\mathcal{M}$ induces a connected subgraph of $\mathcal{G}$, then the CFE problem can be solved in $O(I \log I)$ time.*

Proof. We consider three special cases:

- *Case* M1. $\mathcal{G}$ is connected.
- *Case* M2. $\mathcal{G}$ is biconnected.
- *Case* M3. $\mathcal{G}$ is triconnected.

In section 3, Theorem 3.8 solves Case M3 of the CFE problem faster than the desired time bound. In section 4, Theorem 4.3 reduces this theorem to Case M1. In section 5, Theorem 5.3 reduces Case M1 to Case M2. In section 6, Theorem 6.1 uses Theorem 3.8 to solve Case M2 of the CFE problem within the desired running time. This theorem follows from Theorems 4.3, 5.3, and 6.1. □

As mentioned in section 1, Case M3 is the base case, meaning that the other cases are eventually reduced to it. So the next section describes an algorithm for this case.

3. Solving Case M3, where $\mathcal{G}$ is triconnected. Throughout this section, we assume that $\mathcal{G}$ is triconnected. Then $\mathcal{G}$ has a unique combinatorial embedding up to the choice of the exterior face [21, 30]. Thus the CFE problem reduces in linear time to that of finding all the faces in the embedding whose boundaries intersect every set in some $\mathcal{C}_i$. The naive algorithm takes $\Theta(|\mathcal{G}||\mathcal{M}|)$ time. We solve the latter problem more efficiently by recursively solving Problem 2 defined below.

Throughout this section, for technical convenience, the vertices of a plane graph are indexed by distinct positive integers. The faces are indexed by positive integers or -1. The faces indexed by positive integers have distinct indices and are called the *positive* faces. Those indexed by -1 are the *negative* faces.

Let $\mathcal{H}$ be a plane graph. A *vf-set* of $\mathcal{H}$ is a set of vertices and positive faces in $\mathcal{H}$. A *vf-family* of $\mathcal{H}$ is a family of vf-sets of $\mathcal{H}$. A *vf-sequence* of $\mathcal{H}$ is a sequence of vf-families of $\mathcal{H}$. For a vf-family $\mathcal{D} = \{S_1, \ldots, S_d\}$ of $\mathcal{H}$, we define $\Lambda_{\mathrm{f}}(\mathcal{H}, \mathcal{D})$ and $\mathrm{ACF}(\mathcal{H}, \mathcal{D})$ as follows:

1. $\Lambda_{\mathrm{v}}(\mathcal{H}, \mathcal{D}) = \cap_{i=1}^{d} S_i \cap \mathcal{V}(\mathcal{H})$.
2. $\Lambda_{\mathrm{f}}(\mathcal{H}, \mathcal{D})$ is the set of positive faces F of $\mathcal{H}$ such that, for each $S_i \in \mathcal{D}$, F is a face in S_i or its boundary intersects $S_i - \Lambda_{\mathrm{v}}(\mathcal{H}, \mathcal{D})$.
3. $\mathrm{ACF}(\mathcal{H}, \mathcal{D}) = \Lambda_{\mathrm{v}}(\mathcal{H}, \mathcal{D}) \cup \Lambda_{\mathrm{f}}(\mathcal{H}, \mathcal{D})$.

PROBLEM 2 (the all-common-face (ACF) problem).

- *Input*: A plane graph $\mathcal{H}$ and a vf-sequence $\mathcal{N}$ of $\mathcal{H}$.
- *Output*: $\mathrm{ACF}(\mathcal{H}, \mathcal{D}_1), \ldots, \mathrm{ACF}(\mathcal{H}, \mathcal{D}_q)$, where $\mathcal{D}_1, \ldots, \mathcal{D}_q$ are the vf-families in $\mathcal{N}$.

Throughout the rest of this section, $\mathcal{H}$ and $\mathcal{N}$ always denote the input graph and the input sequence to our algorithm for the ACF problem, respectively.

To solve the ACF problem recursively, $\mathcal{H}$ need not be simple or triconnected. Furthermore, those faces that are indexed by -1 are ruled out as final output during recursions. To solve the problem efficiently, each vertex in $\Lambda_{\mathrm{v}}(\mathcal{H}, \mathcal{D}_i)$ is meant as a succinct representation of all the faces whose boundaries contain that vertex. Similarly, the positive faces in the input $\mathcal{D}_i$ and the output are represented by their indices.

The next observation relates the CFE problem and the ACF problem.

OBSERVATION 3.1. *Let the faces of $\mathcal{G}$ be indexed by positive integers. Then the output to the CFE problem is "yes" if and only if, for all $\mathcal{C}_i$, $\mathrm{ACF}(\mathcal{G}, \mathcal{C}_i) \neq \emptyset$.*

Section 3.1 proves a counting lemma useful for analyzing the time complexity of our algorithms for the ACF problem. Section 3.2 provides a technique for simplifying $\mathcal{H}$ during recursions. Section 3.3 uses this technique to recursively solve the ACF problem without increasing the total size of the subproblems.

3.1. A counting lemma.

LEMMA 3.2.

1. *Let v_1 and v_2 be distinct vertices in $\mathcal{G}$. Let F_1 and F_2 be distinct faces in $\mathcal{G}$. Then both v_1 and v_2 are on the boundaries of both F_1 and F_2 if and only if v_1 and v_2 form a boundary edge of both F_1 and F_2.*
2. *Given a set U of vertices in $\mathcal{G}$, there are $O(|U|)$ faces in $\mathcal{G}$ whose boundaries each contain at least two vertices in U.*
3. *Given a set $\mathcal{P}$ of faces in $\mathcal{G}$, there are $O(|\mathcal{P}|)$ vertices in $\mathcal{G}$ which are each on the boundaries of at least two faces in $\mathcal{P}$.*

Proof. We prove the statements separately as follows.

Statement 1. This statement immediately follows from the condition that $\mathcal{G}$ is triconnected with no multiple edges.

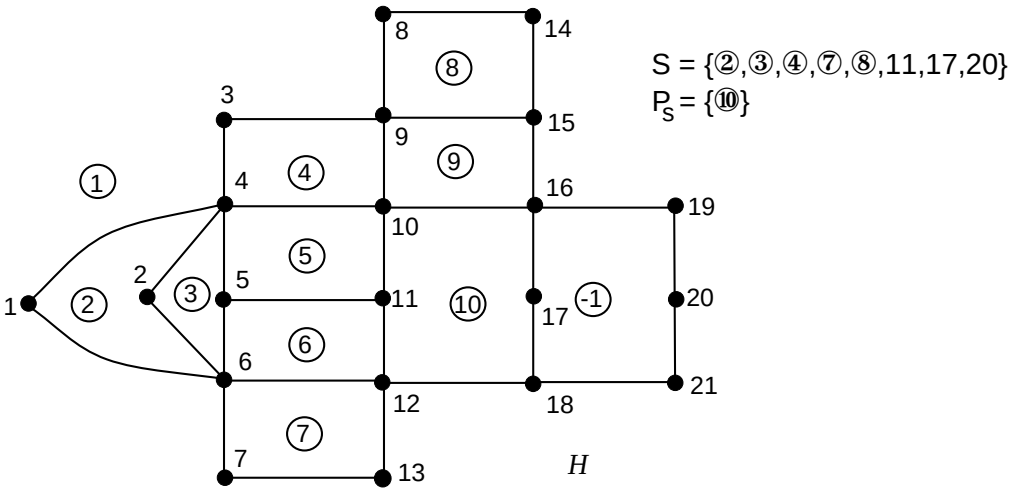

FIG. 3.1. *This is an example of a graph $\mathcal{H}$, a vf-set S, and $\mathcal{P}_S$, where a number in a circle is the index of the corresponding face.*

Statement 2. Since $\mathcal{G}$ has no multiple edges, $\mathcal{G}$ contains $O(|U|)$ edges between distinct vertices in U. Then this statement follows from statement 1 and the fact that an edge in a simple plane graph can be a boundary edge of at most two faces.

Statement 3. If $\mathcal{G}$ has at most three vertices, the statement holds trivially. Otherwise, the statement follows from statement 2 and the fact that the dual of $\mathcal{G}$ is also a simple triconnected plane graph [22]. □

COROLLARY 3.3. *If $\mathcal{H}$ is simple and triconnected, then the output of the ACF problem has size $O(|\mathcal{N}|)$.*

Proof. This corollary follows from Lemma 3.2(2). □

3.2. Simplifying $\mathcal{H}$ over a vf-set. To solve the ACF problem efficiently, we simplify the input graph $\mathcal{H}$ by removing unnecessary edges and vertices as follows.

For a vf-set S of $\mathcal{H}$, the plane graph $\mathcal{H}\diamondsuit S$ of $\mathcal{H}$ constructed as follows is said to *simplify* $\mathcal{H}$ over S. An example is illustrated in Figures 3.1, 3.2, and 3.3.

Let $\mathcal{P}_S$ be the set of the positive faces in $\mathcal{H}$ whose boundaries each contain at least two distinct vertices in $S \cap \mathcal{V}(\mathcal{H})$. Let $\mathcal{H}_S$ be the plane subgraph of $\mathcal{H}$ (1) whose vertices are those in $S \cap \mathcal{V}(\mathcal{H})$ and the boundary vertices of the faces in $(S \cap \mathcal{F}(\mathcal{H})) \cup \mathcal{P}_S$ and (2) whose edges are the boundary edges of the faces in $(S \cap \mathcal{F}(\mathcal{H})) \cup \mathcal{P}_S$. Note that $\mathcal{H}_S$ inherits a plane embedding from $\mathcal{H}$.

Let U_3 be the set of vertices which are of degree at least 3 in $\mathcal{H}_S$; note that each vertex in U_3 appears on the boundaries of at least two faces in $(S \cap \mathcal{F}(\mathcal{H})) \cup \mathcal{P}_S$. A *compressible* path P in $\mathcal{H}_S$ is a maximal path, which may be a cycle, such that (1) every internal vertex of P appears only once in it, and (2) no internal vertex of P is in $S \cup U_3$. Note that, by the choice of U_3, every internal vertex of a compressible path is of degree 2 in $\mathcal{H}_S$. We use this property to further simplify $\mathcal{H}_S$. Let $\mathcal{H}\diamondsuit S$ be the plane graph obtained from $\mathcal{H}_S$ by replacing each compressible path with an edge between its endpoints. This edge is embedded by the same curve in the plane as the path is. For technical consistency, if a compressible path forms a cycle and its endpoint is not in $S \cup U_3$, then we replace it with a self-loop for the vertex of the cycle with the smallest index.

Each vertex in $\mathcal{H}\diamondsuit S$ is given the same index as in $\mathcal{H}$. Note that the closure of

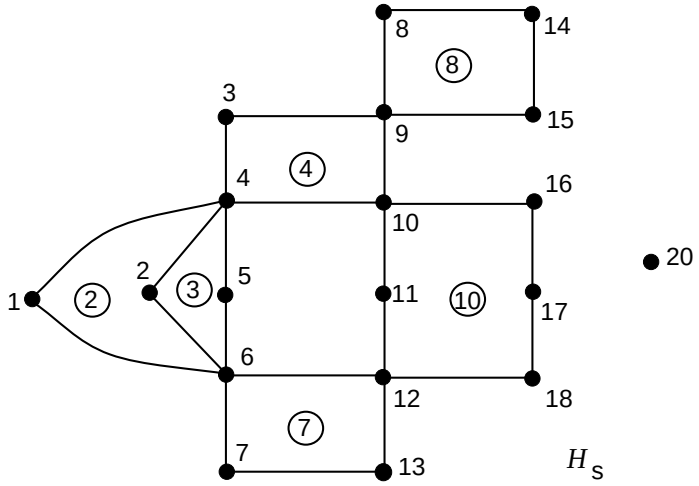

FIG. 3.2. *This is the graph $\mathcal{H}_S$ for the example of $\mathcal{H}$ and S in Figure* 3.1.

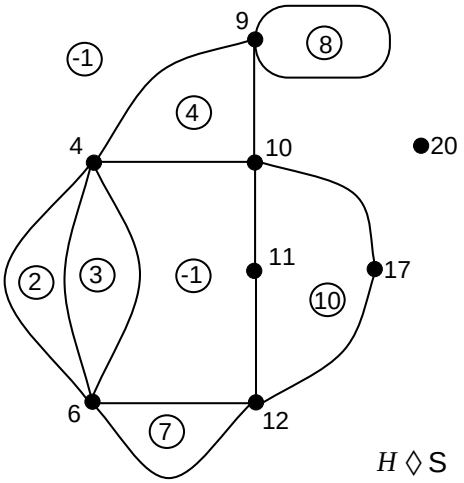

FIG. 3.3. *This is the graph $\mathcal{H}\diamondsuit S$ for the example of $\mathcal{H}$ and S in Figure* 3.1.

the interior of each face of $\mathcal{H}\diamondsuit S$ is the union of those of several faces or just one in $\mathcal{H}$. Let F be a face in $\mathcal{H}\diamondsuit S$, and let F' be one in $\mathcal{H}$. Let σ (respectively, σ') denote the closure of the interior of F (respectively, F'). If $\sigma = \sigma'$, then F and F' are regarded as the same face, and F is assigned the same index in $\mathcal{H}\diamondsuit S$ as F' is in $\mathcal{H}$. For technical conciseness, these two faces are identified with each other. If σ is the union of the closures of the interiors of two or more faces in $\mathcal{H}$, F is not the same as any face in $\mathcal{H}$ and is indexed by -1. This completes the definition of $\mathcal{H}\diamondsuit S$.

LEMMA 3.4.

1. *Given $\mathcal{H}$ and S, we can compute $\mathcal{H}\diamondsuit S$ in $O(|\mathcal{H}| + |S|)$ time.*
2. *Let S' be a vf-set of $\mathcal{H}\diamondsuit S$. If $S' \subseteq S$, then $\mathcal{H}\diamondsuit S' = (\mathcal{H}\diamondsuit S)\diamondsuit S'$.*
3. *If $\mathcal{H}$ simplifies $\mathcal{G}$ over a vf-set S^* with $S \subseteq S^*$, then $|\mathcal{H}\diamondsuit S| = O(|S|)$.*

Proof. Statements 1 and 2 are straightforward. To prove statement 3, it suffices to prove $|\mathcal{G}\diamondsuit S| = O(|S|)$ since by statement 2, $\mathcal{H}\diamondsuit S = \mathcal{G}\diamondsuit S$.

To bound the number of vertices in $\mathcal{G}\diamondsuit S$, let $\mathcal{P}_S$ and U_3 be as specified in the definition of $\mathcal{G}\diamondsuit S$. Let U_1 be the set of vertices v in $\mathcal{G}\diamondsuit S$ such that v appears on the boundary of exactly one face in $(S \cap \mathcal{F}(\mathcal{G})) \cup \mathcal{P}_S$. Then $(S \cap \mathcal{V}(\mathcal{G})) \cup U_3 \cup U_1$ consists of all the vertices in $\mathcal{G}\diamondsuit S$. Note that $|U_1| \leq |(S \cap \mathcal{F}(\mathcal{G})) \cup \mathcal{P}_S|$. Also, by Lemma 3.2(3), $|U_3| = O(|(S \cap \mathcal{F}(\mathcal{G})) \cup \mathcal{P}_S|)$. Consequently, since by Lemma 3.2(2) $|\mathcal{P}_S| = O(|(S \cap \mathcal{V}(\mathcal{G}))|)$, $|(S \cap \mathcal{V}(\mathcal{G})) \cup U_3 \cup U_1| = O(|S|)$ as desired.

To bound the number of edges in $\mathcal{G}\diamondsuit S$, we first examine the multiple edges. Let u and v be adjacent vertices in $\mathcal{G}\diamondsuit S$. Let $X_{u,v}$ be the set of faces in $(S\cap\mathcal{F}(\mathcal{G}))\cup\mathcal{P}_S$ whose boundaries contain both u and v. Then $|X_{u,v}| \geq 1$. By Lemma 3.2(1), $|X_{u,v}| \leq 2$. If $X_{u,v} = \{F\}$, then the two boundary paths of F between u and v may degenerate into at most two multiple edges between u and v in $\mathcal{G}\diamondsuit S$. If $X_{u,v} = \{F_1, F_2\}$, then by the triconnectivity of $\mathcal{G}$, F_1 and F_2 share exactly one common boundary edge e, which is also an edge in $\mathcal{G}\diamondsuit S$. Let C_i be the boundary of F_i without e. C_1 and C_2 may degenerate into at most two multiple edges between u and v in $\mathcal{G}\diamondsuit S$. In summary, there are at most three multiple edges between two vertices in $\mathcal{G}\diamondsuit S$. Similarly, only the boundary of a face in $S \cap \mathcal{F}(\mathcal{G})$ can degenerate into a self-loop in $\mathcal{G}\diamondsuit S$; so $\mathcal{G}\diamondsuit S$ has only $O(|S|)$ self-loops. By Euler's formula, $\mathcal{G}\diamondsuit S$ has $O(|S|)$ edges as desired. ∎

3.3. Algorithms for the ACF problem. Throughout this subsection, let $\mathcal{D}_1, \ldots, \mathcal{D}_q$ be the vf-families in $\mathcal{N}$. To solve the ACF problem recursively, we use simplification to reduce the number of $\mathcal{D}_i$ and the number of sets in each $\mathcal{D}_i$.

For brevity, we define several notations. For a vf-family $\mathcal{D}$ of $\mathcal{H}$, let $\mathcal{H}\diamondsuit\mathcal{D} = \mathcal{H}\diamondsuit(\cup_{S\in\mathcal{D}}S)$. For a vf-sequence $\mathcal{N}'$: $\mathcal{D}'_1, \ldots, \mathcal{D}'_p$ of $\mathcal{H}$, let $\mathcal{H}\diamondsuit\mathcal{N}' = \mathcal{H}\diamondsuit(\mathcal{D}'_1\cup\cdots\cup\mathcal{D}'_p)$. For a vf-set S^* of $\mathcal{H}$ and a vf-family $\mathcal{D}$ of $\mathcal{H}$, we say $\mathcal{D} \leq S^*$ if $S \subseteq S^*$ for all $S \in \mathcal{D}$. For a vf-set S^* of $\mathcal{H}$, we say $\mathcal{N} \leq S^*$ if $\mathcal{D}_i \leq S^*$ for all $\mathcal{D}_i$, $1 \leq i \leq q$.

Lemmas 3.5 and 3.6 below reduce to 1 the number of $\mathcal{D}_i$ in $\mathcal{N}$ in the ACF problem.

LEMMA 3.5. *Assume $q \geq 2$. Let $\mathcal{N}_\ell = \mathcal{D}_1, \ldots, \mathcal{D}_{\lceil q/2\rceil}$ and $\mathcal{N}_r = \mathcal{D}_{\lceil q/2\rceil+1}, \ldots, \mathcal{D}_q$. Let $\mathcal{H}_\ell = \mathcal{H}\diamondsuit\mathcal{N}_\ell$ and $\mathcal{H}_r = \mathcal{H}\diamondsuit\mathcal{N}_r$.*

1. *Given $\mathcal{H}$ and $\mathcal{N}$, we can compute $\mathcal{H}_\ell$ and $\mathcal{H}_r$ in $O(|\mathcal{H}| + |\mathcal{N}|)$ total time.*
2. *For $1 \leq i \leq \lceil q/2\rceil$, $\mathcal{H}\diamondsuit\mathcal{D}_i = \mathcal{H}_\ell\diamondsuit\mathcal{D}_i$. Similarly, for $\lceil q/2\rceil + 1 \leq i \leq q$, $\mathcal{H}\diamondsuit\mathcal{D}_i = \mathcal{H}_r\diamondsuit\mathcal{D}_i$.*
3. *If $\mathcal{H}$ simplifies $\mathcal{G}$ over a vf-set S^* with $\mathcal{N} \leq S^*$, then $|\mathcal{H}_\ell| = O(|\mathcal{N}_\ell|)$ and $|\mathcal{H}_r| = O(|\mathcal{N}_r|)$.*

Proof. The three statements follow from those of Lemma 3.4, respectively. ∎

LEMMA 3.6. *Assume $q \geq 1$. Let $\mathcal{H}_i = \mathcal{H}\diamondsuit\mathcal{D}_i$.*

1. *$\mathrm{ACF}(\mathcal{H}, \mathcal{D}_i) = \mathrm{ACF}(\mathcal{H}_i, \mathcal{D}_i)$.*
2. *If $\mathcal{H}$ simplifies $\mathcal{G}$ over a vf-set S^* with $\mathcal{N} \leq S^*$, then $|\mathcal{H}_i| = O(|\mathcal{D}_i|)$.*
3. *If $\mathcal{H}$ simplifies $\mathcal{G}$ over a vf-set S^* with $\mathcal{N} \leq S^*$, then, given $\mathcal{H}$ and $\mathcal{N}$, we can compute all $\mathcal{H}_i$ in $O(|\mathcal{H}| + |\mathcal{N}|\log(q+1))$ total time.*

Proof. We prove the statements separately as follows.

Statement 1. The proof is straightforward. Note that a positive face in $\mathcal{H}_i$ is also a positive face in $\mathcal{H}$ and that a negative face in $\mathcal{H}_i$ combines one or more faces not in $\mathrm{ACF}(\mathcal{H}, \mathcal{D}_i)$.

Statement 2. The proof follows from Lemma 3.4(3).

Statement 3. The graphs $\mathcal{H}_i$ can be computed by applying Lemma 3.5 recursively with $O(\log(q+1))$ iterations. By Lemma 3.5(1), the first iteration takes $O(|\mathcal{H}|+|\mathcal{N}|)$ time. By Lemmas 3.5(3) and 3.5(1), each subsequent iteration takes $O(|\mathcal{N}|)$ time. By Lemma 3.4(2), the constant coefficient in the $O(|\mathcal{N}|)$ term does not accumulate over recursions. ∎

Lemma 3.7 below solves the ACF problem with only one $\mathcal{D}_i$ in $\mathcal{N}$.

LEMMA 3.7. *Let $\mathcal{D} = \{S_1, \ldots, S_d\}$ be a vf-family of $\mathcal{H}$ where $d \geq 1$. Let $\mathcal{D}'_\ell = \{S_1, \ldots, S_{\lceil d/2 \rceil}\}$ and $\mathcal{D}'_r = \{S_{\lceil d/2 \rceil + 1}, \ldots, S_d\}$. Let $\mathcal{H}_\ell = \mathcal{H} \diamondsuit \mathcal{D}'_\ell$ and $\mathcal{H}_r = \mathcal{H} \diamondsuit \mathcal{D}'_r$. Let $\mathcal{D}'' = \{\mathrm{ACF}(\mathcal{H}_\ell, \mathcal{D}'_\ell), \mathrm{ACF}(\mathcal{H}_r, \mathcal{D}'_r)\}$.*

1. *$\mathrm{ACF}(\mathcal{H}, \mathcal{D}) = \mathrm{ACF}(\mathcal{H}, \mathcal{D}'')$.*
2. *If $\mathcal{H}$ simplifies $\mathcal{G}$ over a vf-set S^* with $\mathcal{D} \leq S^*$, then, given $\mathcal{H}$ and $\mathcal{D}$, $\mathrm{ACF}(\mathcal{H}, \mathcal{D})$ can be computed in $O(|\mathcal{H}| + |\mathcal{D}| \log(d+1))$ time.*

Proof. The statements are proved separately as follows.

Statement 1. Note that $\mathrm{ACF}(\mathcal{H}, \mathcal{D}) = \mathrm{ACF}(\mathcal{H}, \{\mathrm{ACF}(\mathcal{H}, \mathcal{D}'_\ell), \mathrm{ACF}(\mathcal{H}, \mathcal{D}'_r)\})$ by a straightforward case analysis. Then, as in Lemma 3.6(1), $\mathrm{ACF}(\mathcal{H}, \mathcal{D}'_\ell) = \mathrm{ACF}(\mathcal{H}_\ell, \mathcal{D}'_\ell)$ and $\mathrm{ACF}(\mathcal{H}, \mathcal{D}'_r) = \mathrm{ACF}(\mathcal{H}_r, \mathcal{D}'_r)$.

Statement 2. We compute $\mathrm{ACF}(\mathcal{H}, \mathcal{D})$ recursively using statement 1. If $d = 1$, then $\mathrm{ACF}(\mathcal{H}, \mathcal{D}) = S_1$. If $d = 2$, then $\mathrm{ACF}(\mathcal{H}, \mathcal{D})$ can be computed in $O(|\mathcal{H}|)$ time in a straightforward manner. For $d > 2$, there are three stages:

1. Compute $\mathcal{H}_\ell$ and $\mathcal{H}_r$ in $O(|\mathcal{H}| + |D|)$ time in a straightforward manner.
2. Recursively compute $\mathrm{ACF}(\mathcal{H}_\ell, \mathcal{D}'_\ell)$ and $\mathrm{ACF}(\mathcal{H}_r, \mathcal{D}'_r)$.
3. Compute $\mathrm{ACF}(\mathcal{H}, \mathcal{D}'')$ in $O(|\mathcal{H}|)$ time in a straightforward manner, which is $\mathrm{ACF}(\mathcal{H}, \mathcal{D})$ by statement 1.

This recursive computation has $\log d + O(1)$ iterations. The recursion at the top level takes $O(|\mathcal{H}| + |\mathcal{D}|)$ time. Every subsequent level takes $O(|\mathcal{D}|)$ time since by Lemma 3.4(3) $O(|\mathcal{H}_\ell|) = O(|\mathcal{D}'_\ell|)$ and $O(|\mathcal{H}_r|) = O(|\mathcal{D}'_r|)$. Note that by Lemma 3.4(2), the constant coefficient in the $O(|\mathcal{D}|)$ term does not accumulate over recursions. ∎

The next theorem is the main result of this section.

THEOREM 3.8.

1. *Let d be the maximum number of vf-sets in any $\mathcal{D}_i$ in $\mathcal{N}$. If $\mathcal{H}$ simplifies $\mathcal{G}$ over a vf-set S^* with $\mathcal{N} \leq S^*$, then the ACF problem can be solved in $O(|\mathcal{H}| + |\mathcal{N}| \log(d+q))$ time.*
2. *Let d be the maximum number of vertex sets in any $\mathcal{C}_i$ in $\mathcal{M}$. Case* M3 *of the CFE problem can be solved in $O(|\mathcal{G}| + |\mathcal{M}| \log(d+q))$ time.*

Proof. Statement 1 follows from Lemmas 3.6 and 3.7. Statement 2 follows from Observation 3.1, statement 1, and the fact that $\mathcal{G}$ has a unique combinatorial embedding computable in linear time [21, 30]. ∎

In section 6.4, the algorithm for Case M2 of the CFE problem calls Theorem 3.8(2) to solve subproblems in which some $S \in \mathcal{C}_i$ may consist of a single edge $\{u, v\}$. For such subproblems, we replace S by $\{u\}$ and $\{v\}$ and then apply Theorem 3.8(2).

4. Reducing Theorem 2.2 to Case M1, where $\mathcal{G}$ is connected. Let $\mathcal{G}_1, \ldots, \mathcal{G}_k$ be the connected components of $\mathcal{G}$. Let $\mathcal{C}_1, \ldots, \mathcal{C}_q$ be the families in $\mathcal{M}$. A family $\mathcal{C}_h$ in $\mathcal{M}$ is *global* if, for every $i \in \{1, \ldots, k\}$, $\mathcal{C}_h$ is not $\mathcal{G}_i$-local. Let H be an edge-labeled graph defined as follows. The vertices of H are $1, \ldots, k$. For each global $\mathcal{C}_h$, H contains a cycle C possibly of length 2, where (1) the vertices of C are those $i \in \{1, \ldots, k\}$ such that some set in $\mathcal{C}_h$ is $\mathcal{G}_i$-local and (2) the edges of C are all labeled h. See Figures 4.1(1) through 4.1(3) for examples of $\mathcal{G}$, $\mathcal{M}$, and H.

OBSERVATION 4.1. *Let $H_1, \ldots, H_\ell$ be the connected components of H. For each H_j, let $\mathcal{G}'_j$ be the subgraph of $\mathcal{G}$ formed by all $\mathcal{G}_i$ with $i \in \mathcal{V}(H_j)$. Let $\mathcal{M}'_j$ be the sequence of all $\mathcal{G}'_j$-local families in $\mathcal{M}$. Then $\mathcal{G}$ satisfies $\mathcal{M}$ if and only if every $\mathcal{G}'_j$ satisfies $\mathcal{M}'_j$.*

By Observation 4.1, we may assume that H is connected. Let $B_1, \ldots, B_p$ be the blocks of H. Then, for each global $\mathcal{C}_h$, exactly one B_j contains all the edges labeled h. For every B_j, let $\mathcal{U}_j = \cup_h \mathcal{C}_h$, where h ranges over all labels on the edges of B_j. For

FIG. 4.1. (1) *This is a simple disconnected graph $\mathcal{G}$ with six connected components $\mathcal{G}_1$ through $\mathcal{G}_6$, where $\mathcal{V}(\mathcal{G}_1) = \{1, \ldots, 8\}$, $\mathcal{V}(\mathcal{G}_2) = \{9, \ldots, 13\}$, $\mathcal{V}(\mathcal{G}_3) = \{21, 22\}$, $\mathcal{V}(\mathcal{G}_4) = \{16, \ldots, 20\}$, $\mathcal{V}(\mathcal{G}_5) = \{23, \ldots, 25\}$, and $\mathcal{V}(\mathcal{G}_6) = \{14, 15\}$.* (2) *This is a sequence $\mathcal{M}$ of families of vertex subsets of $\mathcal{G}$, where $\mathcal{C}_6$ and $\mathcal{C}_7$ are $\mathcal{G}_1$-local but the rest of the families are global.* (3) *This is the graph H constructed from $\mathcal{G}$ and $\mathcal{M}$.* (4) *These are the sequences constructed for $\mathcal{G}_1$ through $\mathcal{G}_6$.*

each $\mathcal{G}_i$, let $\mathcal{M}_i$ be the sequence consisting of the $\mathcal{G}_i$-local families in $\mathcal{M}$ as well as the families $\mathcal{U}_{j,i} = \{U \in \mathcal{U}_j \mid U \text{ is } \mathcal{G}_i\text{-local}\}$ for all B_j with $i \in \mathcal{V}(B_j)$. See Figure 4.1(4) for an example of $\mathcal{M}_1, \ldots, \mathcal{M}_6$ constructed from $\mathcal{G}$, $\mathcal{M}$, and H in Figures 4.1(1) through 4.1(3).

LEMMA 4.2. *$\mathcal{G}$ satisfies $\mathcal{M}$ if and only if every $\mathcal{G}_i$ satisfies $\mathcal{M}_i$.*

Proof. The two directions are proved as follows.

($\Longrightarrow$) Let Φ be an embedding of $\mathcal{G}$ satisfying $\mathcal{M}$. Let Φ_i be the restriction of Φ to $\mathcal{G}_i$. For each $\mathcal{G}_i$, our goal is to prove that Φ_i satisfies $\mathcal{M}_i$. First, Φ_i satisfies each $\mathcal{G}_i$-local family in $\mathcal{M}$. Let B_j be a block of H with $i \in B_j$. We next prove that Φ_i satisfies $\mathcal{U}_{j,i}$. Let $i, i_1, \ldots, i_\ell$ be the vertices of B_j. We claim that $\mathcal{G}$ has no cycle C such that at least one but not all of $\mathcal{G}_i$, $\mathcal{G}_{i_1}, \ldots, \mathcal{G}_{i_\ell}$ are inside C in Φ. To prove by contradiction, assume that such a C exists. Then some $\mathcal{G}_x$ with $1 \le x \le k$ contains C. However, by the construction of H, no connected component of $H - \{x\}$ contains all of i, $i_1, \ldots, i_\ell$, contradicting the fact that B_j is a block of H. Thus the claim holds. Therefore, the boundary of some face F in Φ intersects each of $\mathcal{G}_i, \mathcal{G}_{i_1}, \ldots, \mathcal{G}_{i_\ell}$. Since F must be unique, the boundary of F intersects every set in $\mathcal{C}_h$ for every $\mathcal{C}_h$ in $\mathcal{M}$ such that the sets in $\mathcal{C}_h$ fall into two or more of $\mathcal{G}_i$, $\mathcal{G}_{i_1}$, ..., $\mathcal{G}_{i_\ell}$. Hence the boundary of F intersects every set in $\mathcal{U}_j$. Consequently, Φ_i satisfies $\mathcal{U}_{j,i}$.

($\Longleftarrow$) Let Φ_i be an embedding of $\mathcal{G}_i$ satisfying $\mathcal{M}_i$. We construct an embedding

of $\mathcal{G}$ satisfying $\mathcal{M}$ as follows. First, consider a block B_j of H. Let $i_1, \ldots, i_\ell$ be the vertices of B_j. Let $\mathcal{G}'_j$ be the subgraph of $\mathcal{G}$ formed by $\mathcal{G}_{i_1}, \ldots, \mathcal{G}_{i_\ell}$. Let $\mathcal{M}'_j$ be the sequence consisting of $\mathcal{U}_j$ and the $\mathcal{G}_{i_x}$-local families in $\mathcal{M}$ for $x = 1, \ldots, \ell$. We can assume that the boundary of the exterior face of Φ_{i_x} intersects every set in $\mathcal{U}_{j,i_x}$. By identifying the exterior faces of $\Phi_{i_1}, \ldots, \Phi_{i_\ell}$, we can combine the embeddings into an embedding Φ'_j of $\mathcal{G}'_j$ satisfying $\mathcal{M}'_j$. Next, we utilize $T = \Psi(H)$ to combine $\Phi'_1, \ldots, \Phi'_p$ into a single embedding of $\mathcal{G}$. First, root T at a block of H. For a leaf B_{j_1} in T, let $\mathcal{G}_i$ and B_{j_2} be the parent and grandparent of B_{j_1} in T, respectively. Let $\mathcal{L}_{i,1}$ (respectively, $\mathcal{L}_{i,2}$) be the restriction of Φ'_{j_1} (respectively, Φ'_{j_2}) to $\mathcal{G}_i$. Note that Φ_i, $\mathcal{L}_{i,1}$, and $\mathcal{L}_{i,2}$ are topologically equivalent up to the choice of their exterior face. Thus Φ'_{j_1} (respectively, Φ'_{j_2}) can be obtained as follows: For every vertex $i' \neq i$ of B_{j_1} (respectively, B_{j_2}), put a suitable embedding $\mathcal{L}_{i'}$ of $\mathcal{G}_{i'}$ that is topologically equivalent to $\Phi_{i'}$ into a suitable face $F_{i'}$ of Φ_i. This gives an embedding of those $\mathcal{G}_x \in \{\mathcal{G}_1, \ldots, \mathcal{G}_k\}$ with $x \in \mathcal{V}(B_{j_1}) \cup \mathcal{V}(B_{j_2})$. We replace Φ'_{j_2} with this embedding, replace B_{j_2} with the union of B_{j_1} and B_{j_2}, and delete B_{j_1} from T. Afterward, if $\mathcal{G}_i$ becomes a leaf of T, then we further delete it from T. We repeat this process until T is a single vertex, at which time we obtain an embedding of $\mathcal{G}$ satisfying $\mathcal{M}$. □

THEOREM 4.3. *Theorem* 2.2 *holds if it holds for Case* M1.

Proof. The proof follows from Lemma 4.2 and the fact that H and the sequences $\mathcal{M}_i$ above can be constructed from $\mathcal{G}$ and $\mathcal{M}$ in $O(I)$ time. □

5. Reducing Case M1 to Case M2, where $\mathcal{G}$ is biconnected. This section assumes Case M1, where $\mathcal{G}$ is connected. We also assume that $\mathcal{G}$ has at least two vertices; otherwise, the problem is trivial.

Section 5.1 shows how to eliminate one cut vertex from $\mathcal{G}$; iterating this elimination until $\mathcal{G}$ has no cut vertex gives us a reduction from Case M1 to Case M2. However, this reduction is not efficient. Section 5.2 describes a more efficient reduction based on a direct elimination of all cut vertices from $\mathcal{G}$. Throughout the rest of this section, let $\mathcal{C}_1, \ldots, \mathcal{C}_q$ be the families in $\mathcal{M}$.

5.1. Eliminating one cut vertex. Let w be a cut vertex of $\mathcal{G}$. Let $\mathcal{G}_1, \ldots, \mathcal{G}_k$ be the augmented components of $\mathcal{G}$ induced by w. For each $\mathcal{C}_h$ in $\mathcal{M}$, let $U_{h,1}, \ldots, U_{h,t_h}$ be the sets in $\mathcal{C}_h$ containing w; possibly $t_h = 0$. $\mathcal{C}_h$ is *w-global* if, for all $i \in \{1, \ldots, k\}$, $\mathcal{C}_h - \{U_{h,1}, \ldots, U_{h,t_h}\}$ is not $\mathcal{G}_i$-local; otherwise, $\mathcal{C}_h$ is *w-local*.

OBSERVATION 5.1.

1. *Assume that $\mathcal{C}_h - \{U_{h,1}, \ldots, U_{h,t_h}\}$ is $\mathcal{G}_i$-local for some $\mathcal{G}_i$. Then $\mathcal{G}$ satisfies $\mathcal{M}$ if and only if $\mathcal{G}$ satisfies $\mathcal{M}$ with $\mathcal{C}_h$ replaced by $(\mathcal{C}_h - \{U_{h,1}, \ldots, U_{h,t_h}\}) \cup \{U_{h,1} \cap \mathcal{V}(\mathcal{G}_i), \ldots, U_{h,t_h} \cap \mathcal{V}(\mathcal{G}_i)\}$.*
2. *Assume that $\mathcal{C}_h$ is w-global. Then $\mathcal{G}$ satisfies $\mathcal{M}$ if and only if $\mathcal{G}$ satisfies $\mathcal{M}$ with $\mathcal{C}_h$ replaced by $\mathcal{C}_h - \{U_{h,1}, \ldots, U_{h,t_h}\}$.*

By Observation 5.1, we may assume that (1) each set in a w-global family in $\mathcal{M}$ does not contain w and (2) each set in a family in $\mathcal{M}$ is $\mathcal{G}_i$-local for some $\mathcal{G}_i$. Let H be an edge-labeled graph constructed as follows. The vertices of H are $1, \ldots, k$. For each w-global family $\mathcal{C}_h$, H has a cycle C possibly of length 2, where (1) the vertices of C are those $i \in \{1, \ldots, k\}$ such that at least one set in $\mathcal{C}_h$ is $\mathcal{G}_i$-local and (2) the edges of C are all labeled h. See Figures 5.1(1) through 5.1(3) for examples of $\mathcal{G}$, $\mathcal{M}$, and H.

Note that Observation 4.1 still holds for this H and the augmented components $\mathcal{G}_1, \ldots, \mathcal{G}_k$. Thus we may assume that H is connected. Let $B_1, \ldots, B_p$ be the blocks of H. Clearly, for each w-global family $\mathcal{C}_h \in \mathcal{M}$, exactly one block of H contains all the edges labeled h. For each B_j, let $\mathcal{U}_j = \cup_h \mathcal{C}_h \cup \{\{w\}\}$, where h ranges over

FIG. 5.1. (1) *This is a simple connected graph $\mathcal{G}$ with a cut vertex* 2. *It induces four augmented components $\mathcal{G}_1$ through $\mathcal{G}_4$ with $\mathcal{V}(\mathcal{G}_1) = \{1, 2\}$, $\mathcal{V}(\mathcal{G}_2) = \{2, \ldots, 6\}$, $\mathcal{V}(\mathcal{G}_3) = \{2, 7, \ldots, 10\}$, and $\mathcal{V}(\mathcal{G}_4) = \{2, 11, \ldots, 21\}$.* (2) *This is a sequence $\mathcal{M}$ of families of vertex subsets of $\mathcal{G}$, where only $\mathcal{C}_2$ through $\mathcal{C}_5$ are* 2*-global.* (3) *This is the graph H constructed from $\mathcal{G}$ and $\mathcal{M}$.* (4) *These are the sequences constructed for $\mathcal{G}_1$ through $\mathcal{G}_4$, respectively.*

all labels on the edges of B_j. For each $\mathcal{G}_i$, let $\mathcal{M}_i$ be the sequence consisting of the $\mathcal{G}_i$-local families in $\mathcal{M}$ as well as the families $\mathcal{U}_{j,i} = \{U \in \mathcal{U}_j \mid U \text{ is } \mathcal{G}_i\text{-local}\}$ for all B_j with $i \in \mathcal{V}(B_j)$. See Figure 5.1(4) for an example of $\mathcal{M}_1, \ldots, \mathcal{M}_4$ constructed from $\mathcal{G}$, $\mathcal{M}$, and H in Figures 5.1(1) through 5.1(3).

LEMMA 5.2. *$\mathcal{G}$ satisfies $\mathcal{M}$ if and only if every $\mathcal{G}_i$ satisfies $\mathcal{M}_i$.*

Proof. The two directions are proved as follows.

($\Longrightarrow$) The proof is the same as that of Lemma 4.2 except that the claim therein now implies that the boundary of some face F in Φ intersects each of $\mathcal{G}_i - \{w\}, \mathcal{G}_{i_1} - \{w\}, \ldots, \mathcal{G}_{i_\ell} - \{w\}$.

($\Longleftarrow$) The proof is the same as that of Lemma 4.2 except that Φ'_{j_1} (respectively, Φ'_{j_2}) now can be obtained as follows: For each vertex $i' \neq i$ of B_{j_1} (respectively, B_{j_2}), put a suitable embedding $\mathcal{L}_{i'}$ of $\mathcal{G}_{i'}$ that is topologically equivalent to $\Phi_{i'}$ into a suitable face $F_{i'}$ of Φ_i, and then identify the two occurrences of w. □

5.2. Eliminating all cut vertices. Let $T = \Psi(\mathcal{G})$. Root T at a block vertex, and perform a postorder traversal of T. For each vertex γ of T, let $\text{post}(\gamma)$ be the postorder number of γ in the postorder traversal of T.

Let $W = \{w_1, \ldots, w_\ell\}$ be the set of cut vertices of $\mathcal{G}$ where $\text{post}(w_1) < \cdots < \text{post}(w_\ell)$. For each $v \in \mathcal{V}(\mathcal{G}) - W$, let $\text{post}(v) = \text{post}(B)$, where B is the unique block of $\mathcal{G}$ with $v \in \mathcal{V}(B)$. We may assume $\mathcal{V}(\mathcal{G}) = \{1, \ldots, n\}$. For each $v \in \mathcal{V}(\mathcal{G})$, the *rank*

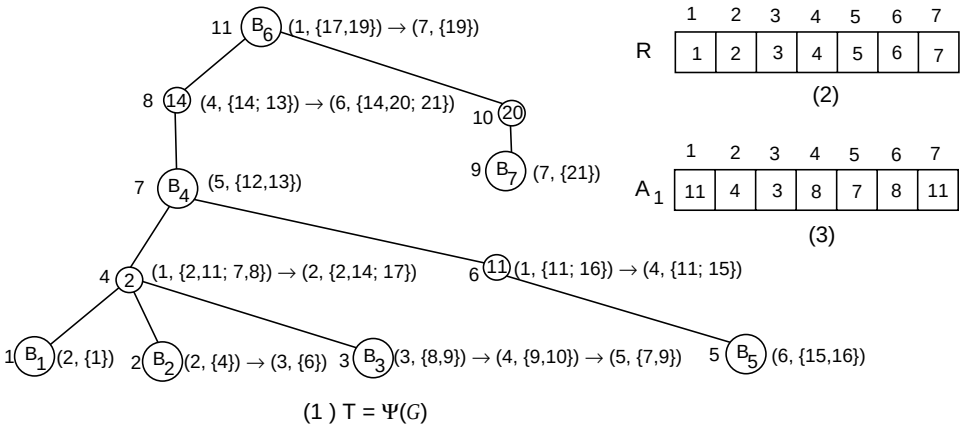

FIG. 5.2. (1) *This is* $\Psi(\mathcal{G})$, *where* $\mathcal{G}$ *is the simple graph in Figure* 5.1(1). *Here,* $\mathcal{V}(B_1) = \{1, 2\}$, $\mathcal{V}(B_2) = \{2, \ldots, 6\}$, $\mathcal{V}(B_3) = \{2, 7, \ldots, 10\}$, $\mathcal{V}(B_4) = \{2, 11, \ldots, 14\}$, $\mathcal{V}(B_5) = \{11, 15, 16\}$, $\mathcal{V}(B_6) = \{14, 17, \ldots, 20\}$, *and* $\mathcal{V}(B_7) = \{20, 21\}$. *The number to the left of each vertex* γ *of* $\Psi(\mathcal{G})$ *is* $\text{post}(\gamma)$, *and the list to the right is* $L(\gamma)$ *before processing the first cut vertex of* $\mathcal{G}$. *For visibility, each set* U *in a pair in* $L(\gamma)$ *with* $U \cap W \neq \emptyset$ *is divided into two parts via a semicolon; the first part consists of vertices in* $U \cap W$ *in the increasing order of their postorder numbers.* (2) *These are the representatives in the union-find data structure before processing the first cut vertex of* $\mathcal{G}$. (3) *This is the array* A_1 *before processing the first cut vertex of* $\mathcal{G}$.

of v, denoted by $\text{rank}(v)$, is $(\text{post}(v), v)$. The rank of a vertex u is *lower* than that of another vertex v if (1) $\text{post}(u) < \text{post}(v)$ or (2) $\text{post}(u) = \text{post}(v)$ and $u < v$. For each $w_i \in W$, let $B_{i,1}, \ldots, B_{i,k_i}$ be the children of w_i in T. Let $B_{i,0}$ be the parent of vertex w_i in T.

THEOREM 5.3. *Theorem* 2.2 *holds for Case* M1 *if it holds for Case* M2.

Proof. It suffices to construct a sequence $\mathcal{M}[B]$ for each block B of $\mathcal{G}$, with a total size of $O(I)$ in $O(I \log I)$ total time over all the blocks of $\mathcal{G}$, such that $\mathcal{G}$ satisfies $\mathcal{M}$ if and only if every B satisfies $\mathcal{M}[B]$. To construct $\mathcal{M}[B]$ based on Observation 5.1 and Lemma 5.2, we process $w_1, \ldots, w_\ell$ one at a time. During the processing of w_i, we construct $\mathcal{M}[B_{i,j}]$ for all $j = 1, \ldots, k_i$. Then, we delete w_i, $B_{i,1}, \ldots, B_{i,k_i}$ from T. After processing w_ℓ, we are left with the root $B_{\ell,0}$ for which we then construct $\mathcal{M}[B_{\ell,0}]$.

We use the following data structures. See Figure 5.2 for an example of some of the data structures before processing the first cut vertex of $\mathcal{G}$.

1. During the construction, some families in $\mathcal{M}$ may be united, and we use a union-find data structure to maintain a collection of disjoint dynamic subsets of $\Delta = \{1, \ldots, q\}$. (Recall that q is the number of families in $\mathcal{M}$.) Each subset of Δ in the data structure is identified by a *representative* member of the subset. For each $h \in \Delta$, let $R(h)$ be the representative of the subset containing h. Initially, each $h \in \Delta$ forms a singleton subset, and thus $R(h) = h$.
2. Each set U in a family in $\mathcal{M}$ is implemented as a pair $(\mathcal{W}[U], \mathcal{S}[U])$, where $\mathcal{W}[U]$ is a linked list, and $\mathcal{S}[U]$ is a splay tree [28]. Initially, $\mathcal{W}[U]$ consists of the vertices in $U \cap W$ in the increasing order of their postorder numbers. $\mathcal{S}[U]$ is initialized by inserting the ranks of the vertices in $U - W$ into an empty splay tree. A splay tree supports the following operations in amortized logarithmic time per operation: (1) insert a rank, and (2) delete the ranks in a given range.

3. A linked list $L[B]$ for each block B of $\mathcal{G}$. Initially, each $L[B]$ consists of all pairs (h, U) such that $h \in \Delta$, $U \in \mathcal{C}_h$, U is B-local, and $U \cap W = \emptyset$.
4. A linked list $L[w_i]$ for each $w_i \in W$. Initially, each $L[w_i]$ consists of all pairs (h, U) such that $h \in \Delta$, $U \in \mathcal{C}_h$, $w_i \in U$, and $i = \min\{j \mid w_j \in U \cap W\}$.
5. An array $A_1[1 \ldots q]$ of integers. Initially, for each $h \in \Delta$, $A_1[h] = \max_\gamma \text{post}(\gamma)$, where γ ranges over all vertices of T such that $L[\gamma]$ contains a pair $(h, *)$ with $* =$ "don't care."
6. An array $A_2[1 \ldots q]$ of integers. Initially, for each $h \in \Delta$, $A_2[h] = 0$.
7. An array $J[1 \ldots q]$ of linked lists of integers. Initially, for each $h \in \Delta$, $J[h]$ is empty.
8. A temporary array $Y[1 \ldots q]$ of integers.

We maintain the following invariants immediately before processing each w_i. In particular, we initialize the above data structures so that the invariants hold before w_1 is processed. It takes $O(I)$ total time to initialize the data structures except the splay trees.

1. For each vertex γ of T and each pair $(h, U) \in L[\gamma]$, (1) $\mathcal{W}[U]$ consists of the vertices in $U \cap \{w_i, \ldots, w_\ell\}$ in the increasing order of their postorder numbers, (2) the rank of each vertex of $U - \{w_i, \ldots, w_\ell\}$ is stored in $\mathcal{S}[U]$, and (3) for every $w_j \in U \cap \{w_1, \ldots, w_{i-1}\}$, $\text{post}(w_j)$ and $\text{rank}(w_j)$ have been updated as $\text{post}(B_{j,0})$ and $(\text{post}(B_{j,0}), w_j)$, respectively.
2. For each block vertex B of T and each $(h, U) \in L[B]$, it holds that $h \in \Delta$, U is B-local, and $U \cap \{w_i, \ldots, w_\ell\} = \emptyset$.
3. For each $j \in \{i, \ldots, \ell\}$ and each $(h, U) \in L[w_j]$, it holds that $h \in \Delta$, $w_j \in U$, and $j = \min\{x \mid i \le x \le \ell \text{ and } w_x \in U\}$.
4. For each $h \in \Delta$ with $R(h) = h$, let $\mathcal{C}'_h = \{U \mid \text{there is a vertex } \gamma \text{ of } T \text{ such that } L[\gamma] \text{ contains a pair } (h', U) \text{ with } R(h') = h\}$. Let $\mathcal{M}'$ be the sequence of all families $\mathcal{C}'_h$ such that $h \in \Delta$ and $R(h) = h$. Let $\mathcal{G}'$ be the subgraph of $\mathcal{G}$ induced by $\cup_B \mathcal{V}(B)$, where B ranges over all the block vertices of T. Then $\mathcal{G}$ satisfies $\mathcal{M}$ if and only if (1) $\mathcal{G}'$ satisfies $\mathcal{M}'$ and (2) for each block B of $\mathcal{G}$ that has been deleted from T, B satisfies $\mathcal{M}[B]$.
5. For each $h \in \Delta$ with $R(h) = h$, $A_1[h] = \max_\gamma \text{post}(\gamma)$, where γ ranges over all vertices of T such that $L[\gamma]$ contains a pair $(h', *)$ with $R(h') = h$.
6. For each $h \in \Delta$, $A_2[h] = 0$ and $J[h]$ is empty.

We process w_i as follows in Stages W1 through W4. See Figure 5.3 for an example of some of the data structures after processing the first cut vertex of $\mathcal{G}$.

• Stage W1 checks whether each related family is w_i-global as follows.

1. Compute $X = \{h \in \Delta \mid R(h) = h, \text{ and for some } j \in \{1, \ldots, k_i\}, L[B_{i,j}] \text{ contains a pair } (h', *) \text{ with } R(h') = h\}$. (*Remark.* For each $h \in \Delta - X$ with $R(h) = h$, the family $\mathcal{C}'_h - \{U \mid w_i \in U\}$ is Q_i-local, where Q_i is the augmented component of $\mathcal{G}'$ induced by w_i that is not among $B_{i,1}, \ldots, B_{i,k_i}$. See the fourth invariant for $\mathcal{C}'_h$ and $\mathcal{G}'$.)
2. For each $h \in X$, set $Y[h]$ to be the number of integers $j \in \{1, \ldots, k_i\}$ such that $L[B_{i,j}]$ contains a pair $(h', *)$ with $R(h') = h$. (*Remark.* For $h \in X$, $Y[h] \ge 1$.)
3. For each $h \in X$, perform the following:
   (a) If $Y[h] = 1$ and $A_1[h] \le \text{post}(w_i)$, then set $A_2[h] = j$, where j is the unique integer in $\{1, \ldots, k_i\}$ such that $L[B_{i,j}]$ contains a pair $(h', *)$ with $R(h') = h$. (*Remark.* $\mathcal{C}'_h - \{U \mid w_i \in U\}$ is $B_{i,j}$-local.)
   (b) Otherwise, set $A_2[h] = -1$. (*Remark.* $\mathcal{C}'_h - \{U \mid w_i \in U\}$ is w_i-global.)

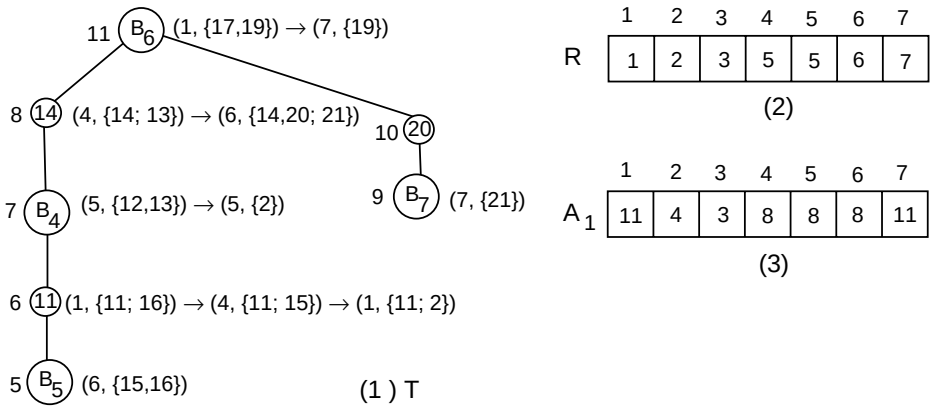

FIG. 5.3. *This is the data structure after processing the first cut vertex (i.e., the vertex* 2*) of the graph in Figure* 5.3(1).

• Stage W2 modifies each U with $w_i \in U$ in each w_i-local family based on Observation 5.1(1) as follows.

1. For each $(h, U) \in L[w_i]$ with $A_2[R(h)] \geq 1$, let $j = A_2[R(h)]$, delete all vertices outside $\mathcal{V}(B_{i,j})$ from U, and then insert (h, U) into $L[B_{i,j}]$. Here, deleting all vertices outside $\mathcal{V}(B_{i,j})$ from U is done as follows: Delete w_i from $\mathcal{W}[U]$, delete all the ranks in the range $[-\infty \ldots (\text{post}(B_{i,j}), 0)]$ and all the ranks in the range $[(\text{post}(B_{i,j}), n+1) \ldots \infty]$ from $\mathcal{S}[U]$, and insert $(\text{post}(B_{i,j}), w_i)$ into $\mathcal{S}[U]$.
2. For each $(h, U) \in L[w_i]$ with $A_2[R(h)] = 0$, perform the following. (*Remark.* $\mathcal{C}'_h - \{U \mid w_i \in U\}$ is Q_i-local. See the remark in step 1 of Stage W1 for Q_i.)
   (a) Delete all vertices v with $\text{post}(v) < \text{post}(w_i)$ from U as follows: Delete w_i from $\mathcal{W}[U]$, delete all the ranks in the range $[-\infty \ldots \text{rank}(w_i)]$ from $\mathcal{S}[U]$, and insert $(\text{post}(B_{i,0}), w_i)$ into $\mathcal{S}[U]$.
   (b) If $\mathcal{W}[U] = \emptyset$, i.e., U has no cut vertex, then insert (h, U) into $L[B_{i,0}]$, and set $A_1[R(h)] = \max\{\text{post}(B_{i,0}), A_1[R(h)]\}$.
   (c) If $\mathcal{W}[U] \neq \emptyset$, then find the first vertex w_j in $\mathcal{W}[U]$, insert (h, U) into $L[w_j]$, and set $A_1[R(h)] = \max\{\text{post}(w_j), A_1[R(h)]\}$. (*Remark.* $j > i$.)

• Stage W3 modifies each w_i-global family based on Observation 5.1(2) as follows.

1. For each $h \in X$ with $A_2[h] = -1$, set $J[h] = \{j \in \{1, \ldots, k_i\} \mid L[B_{i,j}]$ contains a pair $(h', *)$ with $R(h') = h\}$.
2. For each $h \in X$ with $A_2[h] = -1$ and $A_1[h] > \text{post}(w_i)$, insert 0 into $J[h]$.
3. Set $\text{post}(w_i) = \text{post}(B_{i,0})$ and $\text{rank}(w_i) = (\text{post}(B_{i,0}), w_i)$.
4. Construct an edge-labeled graph H_i as follows. The vertices of H_i are 0, 1, $\ldots$, k_i. For each $h \in X$ with $A_2[h] = -1$, H_i has a cycle possibly of length 2 whose vertices are the integers in $J[h]$ and whose edges are all labeled h.
5. For each block $\mathcal{B}$ of H_i, find the labels $h_1, \ldots, h_t$ on the edges in $\mathcal{B}$, and unite those subsets in the union-find data structure that have $h_1, \ldots, h_t$ as their representative, respectively; afterward, for the representative h_r of the resulting subset, further perform the following:
   (a) Insert $(h_r, \{w_i\})$ into all lists $L[B_{i,j}]$ such that $j \in \mathcal{V}(\mathcal{B})$.
   (b) If $0 \in \mathcal{V}(\mathcal{B})$, then set $A_1[h_r] = \max\{\text{post}(B_{i,0}), A_1[h_1], \ldots, A_1[h_t]\}$.

• Stage W4 constructs the sequences $\mathcal{M}[B_{i,j}]$ for $1 \leq j \leq k_i$ and updates the

data structures as follows.

1. For each j and each (h, U) in $L[B_{i,j}]$, replace (h, U) by $(R(h), U)$.
2. For each j, set $\mathcal{M}[B_{i,j}]$ to be the sequence of the families $\mathcal{C}''_h = \{U \mid (h, U) \in L[B_{i,j}]\}$, where h ranges over those integers that are in a pair in $L[B_{i,j}]$.
3. Delete w_i and its children from T.
4. For each $h \in X$, set $A_2[h] = 0$ and $J[h] = \emptyset$.

By Observation 5.1 and Lemma 5.2, after the processing of w_i, the invariants hold for $i + 1$.

After processing w_ℓ, we construct $\mathcal{M}[B_{\ell,0}]$ as follows: Replace each pair (h, U) in $L[B_{\ell,0}]$ by $(R(h), U)$, and then set $\mathcal{M}[B_{\ell,0}]$ to be the sequence of the families $\mathcal{C}''_h = \{U \mid (h, U) \in L[B_{\ell,0}]\}$, where h ranges over those integers that are in a pair in $L[B_{\ell,0}]$.

By the invariants, Observation 5.1, and Lemma 5.2, $\mathcal{G}$ satisfies $\mathcal{M}$ if and only if every block B of $\mathcal{G}$ satisfies $\mathcal{M}[B]$. As for the time complexity, we make the following observations:

1. When processing w_i, we create at most n_i new sets all equal to $\{w_i\}$, where n_i is the maximum number of blocks in a simple graph with $k_i + 1$ vertices. Since $n_i = O(k_i + 1)$ and $k_i + 1$ does not exceed the degree of w_i in $\mathcal{G}$, the total number of newly created sets is $O(|\mathcal{G}|)$.
2. If a set U does not intersect $\{w_i, \ldots, w_\ell\}$ immediately before the processing of w_i, then there is at most one $w_j \in \{w_i, \ldots, w_\ell\}$ such that some vertices of U are touched during the processing of w_j.
3. If w_i is in U immediately before the processing of w_i, then we either (1) touch at most $1 + |\{v \in U \mid \text{post}(v) \le \text{post}(w_i)\}|$ vertices of U during the processing of w_i, or (2) touch no vertex of U during the processing of each $w_j \in \{w_{i+1}, \ldots, w_\ell\}$.

There are at most q unions and $O(I)$ finds, and at most $|\mathcal{G}|$ insertions into each splay tree. By the above observations, the total time spent on the union-find data structure is $O(I \log I)$, that on the splay trees is $O(I \log |\mathcal{G}|)$, and that on the remaining computation is $O(I)$, all within the desired time. □

6. Case M2, where $\mathcal{G}$ is biconnected. This section assumes that $\mathcal{G}$ is biconnected. Let $\mathcal{C}_1, \ldots, \mathcal{C}_q$ be the families in $\mathcal{M}$. For each $i \in \{1, \ldots, q\}$, let $\mathcal{C}_i = \{U_{i,1}, \ldots, U_{i,r_i}\}$.

THEOREM 6.1. *Theorem* 2.2 *holds for Case* M2.

To prove Theorem 6.1, we review a decomposition of $\mathcal{G}$ in section 6.1, outline the basic ideas of our CFE algorithm in section 6.2, detail the algorithm in section 6.3, and analyze it in section 6.4.

6.1. SPQR decompositions. A *planar st-graph* G is a directed acyclic plane graph such that G has exactly one source s and exactly one sink t, and both vertices are on the exterior face. These two vertices are the *poles* of G. A *split pair* of G is either a pair of adjacent vertices or a pair of vertices whose removal disconnects the graph obtained from G by adding the edge (s, t). A *split component* of a split pair $\{u, v\}$ is either an edge (u, v) or a maximal subgraph C of G such that C is a planar uv-graph and $\{u, v\}$ is not a split pair of C. A split pair $\{u, v\}$ of G is *maximal* if there is no other split pair $\{u', v'\}$ in G such that a split component of $\{u', v'\}$ contains both u and v.

The *decomposition tree* T of G is a rooted ordered tree recursively defined in four cases as follows. The nodes of T are of four types: S, P, Q, and R. Each node μ of T has an associated planar st-graph $\text{ske}(\mu)$, called the *skeleton* of μ. Also, μ is

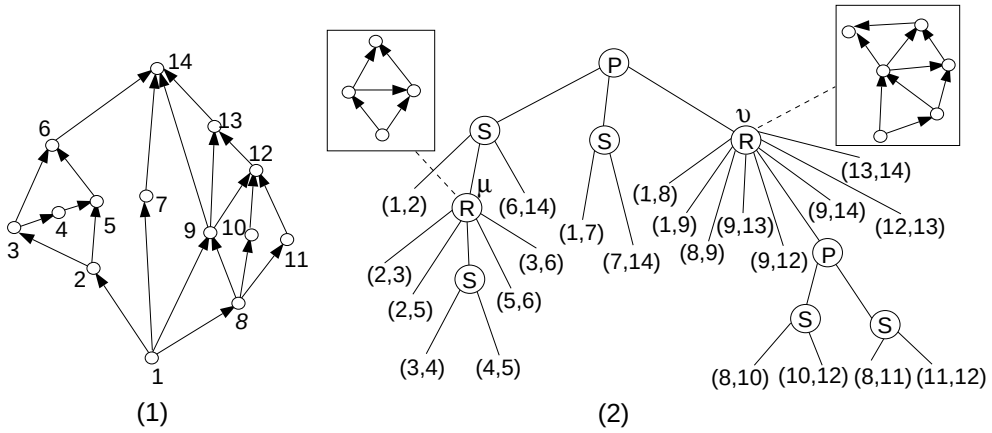

FIG. 6.1. *The tree in* (2) *is the decomposition tree of the graph in* (1).

associated with an edge in the skeleton of the parent ϕ of μ, called the *virtual edge* of μ in ske(ϕ).

Case Q. G is a single edge from s to t. Then T is a Q-node whose skeleton is G.

Case S. G is not biconnected. Let $c_1, \ldots, c_{k-1}$ with $k \geq 2$ be the cut vertices of G. Since G is a planar st-graph, each c_i is in exactly two blocks G_i and G_{i+1} with $s \in G_1$ and $t \in G_k$. Then T's root is an S-node μ, and ske(μ) consists of the chain $e_1, \ldots, e_k$, where the edge e_i goes from c_{i-1} to c_i, $c_0 = s$, and $c_k = t$.

Case P. $\{s, t\}$ is a split pair of G with k split components, where $k \geq 2$. Then T's root is a P-node μ, and ske(μ) consists of k parallel edges $e_1, \ldots, e_k$ from s to t.

Case R. Otherwise. Let $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ with $k \geq 1$ be the maximal split pairs of G. Let G_i be the union of the split components of $\{s_i, t_i\}$. Then T's root is an R-node μ, and ske(μ) is the simple graph obtained from G by replacing each G_i with an edge e_i from s_i to t_i. Note that adding the edge (s, t) to ske(μ) yields a simple triconnected graph.

Figure 6.1 illustrates the decomposition tree of G as well as the skeletons of μ and ν. In the last three cases, μ has children $\chi_1, \ldots, \chi_k$, in this order, such that each χ_i is the root of the decomposition tree of G_i. The virtual edge of χ_i is the edge e_i in ske(μ). G_i is called the *pertinent graph* pert(χ_i) of χ_i as well as the *expansion graph* of e_i. Note that G is the pertinent graph of T's root. Also, no child of an S-node is an S-node, and no child of a P-node is a P-node.

The *allocation nodes* of a vertex v of G are the nodes of T whose skeleton contains v; note that v has at least one allocation node.

LEMMA 6.2 (see [2]).

1. *T has $O(|G|)$ nodes and can be constructed in $O(|G|)$ time. The total number of edges of the skeletons stored at the nodes of T is $O(|G|)$.*
2. *The pertinent graphs of the children of μ can share only vertices of* ske(μ).
3. *If v is in* ske(μ), *then v is also in the pertinent graph of all ancestors of μ.*
4. *If v is a pole of* ske(μ), *then v is also in the skeleton of the parent of μ. If v is in* ske(μ) *but is not a pole of* ske(μ), *then v is not in the skeleton of any ancestor of μ.*
5. *The least common ancestor μ of the allocation nodes of v itself is an allocation node of v, called the* proper allocation node *of v. Also, if $v \notin \{s, t\}$, then μ is the only allocation node of v such that v is not a pole of* ske(μ).

6. *If $v \neq s, t$, then the proper allocation node of v is an R-node or S-node.*

For each non-S-node μ in T, $\text{pert}(\mu)$ is called a *block* of G [2], which differs from that in sections 4 and 5. For a block $B = \text{pert}(\mu)$, let $\text{node}(B) = \mu$. For an ancestor ϕ of $\text{node}(B)$, the *representative* of B in $\text{ske}(\phi)$ is the edge in $\text{ske}(\phi)$ whose expansion graph contains B.

Let μ be an R-node or P-node in T with children $\chi_1, \ldots, \chi_b$. For each $k \in \{1, \ldots, b\}$, let e_k be the virtual edge of χ_k in $\text{ske}(\mu)$. If χ_k is an S-node, $\text{pert}(\chi_k)$ is a chain consisting of two or more blocks. If χ_k is an R-node or P-node, $\text{pert}(\chi_k)$ is a single block. For each $k \in \{1, \ldots, b\}$, we say that the blocks in $\text{pert}(\chi_k)$ are *on edge* e_k. The *minor blocks* of $\text{pert}(\mu)$ are the blocks on e_1,... , the blocks on e_b.

6.2. Basic ideas. An *st-orientation* of a planar graph is an orientation of its edges together with an embedding such that the resulting digraph is a planar st-graph.

LEMMA 6.3 (see [1, 2]). *If an n-vertex simple planar graph has an st-orientation, then every embedding, where s and t are on the exterior face, of this graph can be obtained from this orientation through a sequence of $O(n)$ following operations:*

1. *Flip an R-node's skeleton around its poles.*
2. *Permute a P-node's children (and consequently their skeletons with respect to their common poles).*

Let $\{s, t\}$ be an edge of $\mathcal{G}$. Since $\mathcal{G}$ is a simple biconnected graph, we convert $\mathcal{G}$ to a planar st-graph in $O(n)$ time [12] for technical convenience. For the remainder of section 6, let T be the decomposition tree of $\mathcal{G}$.

The CFE algorithm processes the nodes of T in a bottom-up manner. It first processes the leaf nodes of T. When processing a node μ, for each $\mathcal{C}_i$ such that $\text{pert}(\mu)$ is the smallest block that intersects every set in $\mathcal{C}_i$, the algorithm looks for an embedding of $\text{pert}(\mu)$ that satisfies $\mathcal{C}_i$. If this is impossible, the algorithm outputs "no" and stops; otherwise, it continues on to process the next node of T. We note, in passing, that Theorem 3.8(2) is used when processing R-nodes.

Let μ be a node of T. T_μ denotes the subtree of T rooted at μ, and $\text{dep}(\mu)$ denotes the distance from T's root to μ. We need the following definitions:

1. $U_{i,j}$ is *contained* in $\text{pert}(\mu)$ if the vertices of $U_{i,j}$ are all in $\text{pert}(\mu)$; $U_{i,j}$ is *strictly contained* in $\text{pert}(\mu)$ if, in addition, no pole of $\text{pert}(\mu)$ is in $U_{i,j}$.
2. Let $\text{done}(U_{i,j})$ be the deepest node μ in T such that $U_{i,j}$ is strictly contained in $\text{pert}(\mu)$, if such a node exists. If no such μ exists, then $U_{i,j}$ contains a pole of $\mathcal{G}$, and let $\text{done}(U_{i,j})$ be T's root.
3. A family $\mathcal{C}_i$ *straddles* $\text{pert}(\mu)$ if at least one set in $\mathcal{C}_i$ is strictly contained in $\text{pert}(\mu)$ and at least one set in $\mathcal{C}_i$ has no vertex in $\text{pert}(\mu)$.
4. Let $\text{done}(\mathcal{C}_i)$ be the deepest node μ in T such that, for every $U_{i,j} \in \mathcal{C}_i$, at least one vertex of $U_{i,j}$ is in $\text{pert}(\mu)$.
5. Let $\text{sub}(\mu) = \{U_{i,j} \mid \text{done}(U_{i,j}) = \mu\}$ and $\text{fam}(\mu) = \{\mathcal{C}_i \mid \text{done}(\mathcal{C}_i) = \mu\}$.
6. If μ is a P-node or R-node, let $\text{xfam}(\mu) = \text{fam}(\mu) \cup (\cup_{\chi_k} \text{fam}(\chi_k))$ and $\text{xsub}(\mu) = \text{sub}(\mu) \cup (\cup_{\chi_k} \text{sub}(\chi_k))$, where χ_k ranges over all S-children of μ.

In a fixed embedding of a block B, the poles of B divide the boundary of its exterior face into two paths $\text{side}_1(B)$ and $\text{side}_2(B)$, called the two *sides* of B. $U_{i,j}$ is *two-sided* for B if both $\text{side}_1(B)$ and $\text{side}_2(B)$ intersect $U_{i,j}$. In particular, $U_{i,j}$ is two-sided for B if it contains a pole of B. $U_{i,j}$ is *side*-1 (respectively, *side*-2) for B if only $\text{side}_1(B)$ (respectively, $\text{side}_2(B)$) intersects $U_{i,j}$. Assume that B is a minor block of $\text{pert}(\mu)$ for some μ. Let e_k be the representative of B in $\text{ske}(\mu)$. In a fixed embedding of $\text{ske}(\mu)$, e_k separates two faces F and F'. When embedding $\text{pert}(\mu)$, we

can embed $\text{side}_1(B)$ toward either F or F', referred to as the two *orientations* of B in $\text{pert}(\mu)$.

A family $\mathcal{C}_i$ is *side*-0 (respectively, *side*-1 or *side*-2) *exterior-forcing* for B if $\text{done}(\mathcal{C}_i)$ is an ancestor of $\text{node}(B)$ in T and some $U_{i,j} \in \mathcal{C}_i$ strictly contained in B is two-sided (respectively, side-1 or side-2) for B. For $p = 0, 1, 2$, define the following.

1. $\text{ext}_p(B) = \min\{\text{dep}(\text{done}(\mathcal{C}_i)) \mid \mathcal{C}_i, 1 \le i \le q, \text{ is side-}p \text{ exterior-forcing for } B\}$ if at least one family in $\mathcal{M}$ is side-p exterior-forcing for B;
2. $\text{ext}_p(B) = \infty$ otherwise.

Assume $\text{ext}_p(B) \neq \infty$. Let $\mu = \text{node}(B), \phi_1, \phi_2, \ldots, \phi_h$ be the path in T from μ to ϕ_h, where $\text{dep}(\phi_h) = \text{ext}_p(B)$. For each $\ell \in \{1, \ldots, h-1\}$, the representative of B in $\text{ske}(\phi_\ell)$ must be an exterior edge in any satisfying embedding of $\text{ske}(\phi_\ell)$. In addition, if $p = 1$ or 2, $\text{side}_p(B)$ must be embedded toward the exterior face of the embedding of $\text{pert}(\phi_\ell)$.

Since (s, t) is an edge of $\mathcal{G}$, the root ρ of T is a P-node and has a child Q-node ϕ representing (s, t). A subtle difference between ρ and each nonroot node of T is that the two sides of $\mathcal{G} = \text{pert}(\rho)$ are actually on the same face. To eliminate this difference, we delete ϕ from T; afterward, if ρ has only one child, we further delete ρ from T. From here onward, T denotes this modified tree.

6.3. The CFE algorithm. The CFE algorithm processes T from the bottom up. A *ready* node μ of T is either (1) a leaf node or (2) a P-node or R-node such that the non-S-children of μ and the children of every S-child of μ all have been processed. The CFE algorithm processes the ready nodes of T in an arbitrary order. An S-node is processed when its parent is processed. We detail how to process μ as follows.

For the case where μ is a leaf node of T, note that $\text{pert}(\mu)$ is a single edge of $\mathcal{G}$. Since no $U_{i,j}$ is strictly contained in $\text{pert}(\mu)$, $\text{sub}(\mu) = \emptyset$. Also, each $\mathcal{C}_i \in \text{fam}(\mu)$ is satisfied by every embedding of $\mathcal{G}$. Therefore, we simply set $\text{ext}_p(\text{pert}(\mu)) = \infty$ for $p = 0, 1, 2$.

We next consider the case where μ is a non-leaf-ready node. Before μ is processed, an embedding of every minor block of $\text{pert}(\mu)$ is already fixed, except for a possible flip around its poles. Moreover, for each minor block B of $\text{pert}(\mu)$ and each $p \in \{0, 1, 2\}$, $\text{ext}_p(B)$ is known. When processing μ, the CFE algorithm checks whether some embedding Φ_μ of $\text{pert}(\mu)$ satisfies the following two conditions:

1. Φ_μ satisfies every $\mathcal{C}_i$ in $\text{xfam}(\mu)$.
2. For each $\mathcal{C}_i$ straddling $\text{pert}(\mu)$ and each $U_{i,j} \in \mathcal{C}_i$ strictly contained in $\text{pert}(\mu)$, at least one vertex of $U_{i,j}$ is embedded on the exterior face of Φ_μ. (*Remark.* This ensures the existence of an embedding of $\text{pert}(\text{done}(\mathcal{C}_i))$ satisfying $\mathcal{C}_i$ later.)

If no such Φ_μ exists, then $\mathcal{G}$ cannot satisfy $\mathcal{M}$, and the CFE algorithm outputs "no" and stops. Otherwise, it finds such a Φ_μ and fixes it except for a possible flip around its poles. It also computes $\text{ext}_p(\text{pert}(\mu))$ for $p = 0, 1, 2$.

To detail how to process μ, we classify the sets $U_{i,j}$ that intersect $\text{pert}(\mu)$ into four types and define a set $\text{img}(U_{i,j}, \mu)$ for each type as follows.

Type 1. $U_{i,j}$ contains at least one pole of $\text{ske}(\mu)$. Then $\text{done}(U_{i,j})$ is an ancestor of μ. Let $\text{img}(U_{i,j}, \mu) = \{v \in U_{i,j} \mid v \text{ is a vertex in } \text{ske}(\mu)\}$.

Type 2. $U_{i,j}$ contains at least one vertex but no pole of $\text{ske}(\mu)$. Then $\text{done}(U_{i,j}) = \mu$. Let $\text{img}(U_{i,j}, \mu)$ as in the case of type 1.

Type 3. $U_{i,j}$ is strictly contained in $\text{pert}(\chi)$ for some S-node child χ of μ, and $U_{i,j}$ contains at least one vertex in $\text{ske}(\chi)$. Then $\text{done}(U_{i,j}) = \chi$. Let $\text{img}(U_{i,j}, \mu)$ consist

of the virtual edge of χ in ske(μ).

Type 4. $U_{i,j}$ is strictly contained in a minor block B of pert(μ). Then done($U_{i,j}$) is node(B) or its descendent. Let img($U_{i,j}, \mu$) consist of the representative of B in ske(μ).

Each element of img($U_{i,j}, \mu$) is called an *image* of $U_{i,j}$ in ske(μ). The remainder of section 6.3 details how to process μ.

6.3.1. Processing an S-child of μ. When processing μ, for each S-child χ of μ, we need to find an embedding of pert(χ) satisfying certain conditions. We call this process the *S-procedure* and describe it below.

Let χ be an S-child of μ. Then ske(χ) is a path. Let $e_1, \ldots, e_b$ be the edges in ske(χ). For each $k \in \{1, \ldots, b\}$, let B_k be the expansion graph of e_k. Before the S-procedure is called on χ, the following requirements are met.

1. For each $k \in \{1, \ldots, b\}$, an embedding of B_k has been fixed, except for a possible flip around its poles.
2. For some integers $k \in \{1, \ldots, b\}$ and $p \in \{1, 2\}$, side$_p(B_k)$ is required to face either the left or the right side of ske(χ).

Our only choice for embedding pert(χ) is to flip $B_1, \ldots, B_b$ around their poles. We need to check whether, for some combination of flippings of $B_1, \ldots, B_b$, (1) the resulting embedding satisfies every $\mathcal{C}_i \in$ fam(χ) and (2) the second requirement above is met.

The S-procedure consists of the following five stages.

• Stage S1 constructs an auxiliary graph $D = (V_D, E_D)$ with $V_D = \{k_p \mid 1 \le k \le b,\ p = 1, 2\}$ as follows. For each $\mathcal{C}_i \in$ fam(χ), insert an arbitrary path P_i into D to connect all $k_p \in V_D$ such that, for some type-4 $U_{i,j} \in \mathcal{C}_i$, (a) img($U_{i,j}, \chi$) = $\{e_k\}$, and (b) $U_{i,j}$ is side-p for B_k. To avoid confusion, we call the elements of V_D *points* and the connected components of D *clusters*. Those points $k_p \in V_D$ such that side$_p(B_k)$ is required to face the left side of ske(χ) are called *L-points*. *R-points* are defined similarly. Note that, for each cluster C of D, all side$_p(B_k)$, where k_p ranges over all the points in C, must be embedded toward the same side of ske(χ). Also, each type-3 $U_{i,j}$ in $\mathcal{C}_i$ contains a vertex in ske(χ) which is on both sides of ske(χ). For this reason, such sets were not considered when constructing D.

• Stage S2 checks whether there is a cluster of D containing both an L-point and an R-point. If such a cluster exists, then S2 outputs "no" and stops. Suppose that no such cluster exists. If a cluster C contains an L-point (respectively, R-point), we call C an *L-cluster* (respectively, *R-cluster*).

• Stage S3 constructs another auxiliary graph $RD = (V_{RD}, E_{RD})$ from D as follows. The vertices of RD are the clusters of D. For each $k \in \{1, \ldots, b\}$, there is an edge $\{C_1, C_2\}$ in RD, where C_1 (respectively, C_2) is the cluster of D containing point k_1 (respectively, k_2). Note that RD may have self-loops.

• Stage S4 checks whether RD is bipartite. If it is not, then S4 outputs "no" and stops. Otherwise, for each connected component K of RD, the clusters in K can be uniquely partitioned into two independent subsets $V_{K,1}$ and $V_{K,2}$ of clusters. If $V_{K,1}$ or $V_{K,2}$ contains both an L-cluster and an R-cluster, S4 outputs "no" and stops. Otherwise, V_{RD} can be partitioned into two independent subsets V^L_{RD} and V^R_{RD} of clusters such that all L-clusters are in V^L_{RD} and all R-clusters are in V^R_{RD}. Let $V^L_D = \{k_p \mid k_p$ is in a cluster in $V^L_{RD}\}$ and $V^R_D = \{k_p \mid k_p$ is in a cluster in $V^R_{RD}\}$.

• Stage S5 embeds side$_p(B_k)$ toward the left side of ske(χ) for each $k_p \in V^L_D$.

Example 1. In Figure 6.2, pert(χ) has eight blocks $B_1, \ldots, B_8$. The left side of each B_k is side$_1(B_k)$. Also, fam(χ) = $\{\mathcal{C}_1, \ldots, \mathcal{C}_6\}$. An integer i in a small square on

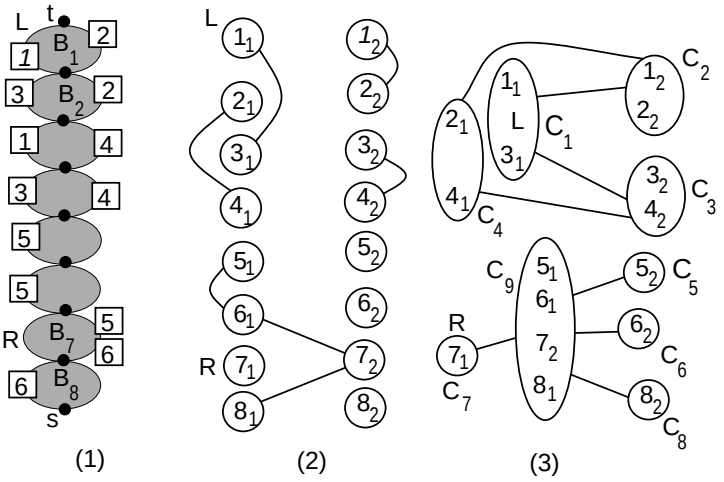

FIG. 6.2. *The graph in* (1) *is* pert(χ) *for an S-node* χ*, the graph in* (2) *is* D*, and that in* (3) *is* RD.

side$_p(B_k)$ for $p = 1$ or 2 indicates that k_p is on P_i. For example, the points on P_5 are 5_1, 6_1, and 7_2. The letter L is marked on side$_1(B_1)$, indicating that side$_1(B_1)$ must face left. The letter R is marked on side$_1(B_7)$, indicating that side$_1(B_7)$ must face right. D is shown in Figure 6.2(2). 1_1 is an L-point, while 7_1 is an R-point. RD is shown in Figure 6.2(3). C_1 is an L-cluster and C_7 is an R-cluster. RD is bipartite, and V_{RD} can be partitioned into $V^L_{RD} = \{C_1, C_4, C_9\}$ and $V^R_{RD} = \{C_2, C_3, C_5, C_6, C_7, C_8\}$. Thus $V^L_D = \{1_1, 2_1, 3_1, 4_1, 5_1, 6_1, 7_2, 8_1\}$ and $V^R_D = \{1_2, 2_2, 3_2, 4_2, 5_2, 6_2, 7_1, 8_2\}$. Flipping B_7 in Figure 6.2(1) gives a satisfying embedding of pert(χ). If 8_2 were also on P_5, there would be an edge $\{7_2, 8_2\}$ in D, which would cause C_9 and C_8 to be merged in RD with a self-loop attached to it. In that case, RD would not be bipartite, and the CFE algorithm would output "no."

6.3.2. μ is an R-node. In this case, adding the edge (s, t) to ske(μ) yields a simple triconnected graph. Thus the unique embedding of ske(μ) with both s and t on the exterior face is ske(μ) itself. Let $\chi_1, \ldots, \chi_b$ be the children of μ in T. For each $k \in \{1, \ldots, b\}$, let $B_{k,1}, \ldots, B_{k,s_k}$ be the minor blocks of pert(μ) in pert(χ_k). Note that $s_k = 1$ when χ_k is an R-node or P-node. To process μ, the CFE algorithm proceeds in five stages.

• Stage R1 first computes $\mathcal{C}'_i = \{\text{img}(U_{i,j}, \mu) \mid U_{i,j} \in \mathcal{C}_i\}$ for every $\mathcal{C}_i \in \text{fam}(\mu)$. Let $\mathcal{M}'(\mu)$ be the sequence of all $\mathcal{C}'_i$ with $\mathcal{C}_i \in \text{fam}(\mu)$. Then R1 calls Theorem 3.8(2) to solve the CFE problem on input ske(μ) and $\mathcal{M}'(\mu)$. If the output is "no," R1 outputs "no" and stops. Otherwise, for each $\mathcal{C}'_i$ in $\mathcal{M}'(\mu)$, there is a face F_i in ske(μ) whose boundary intersects each img$(U_{i,j}, \mu) \in \mathcal{C}'_i$. Note that F_i must be unique or else done($\mathcal{C}_i$) would be a descendent of μ, contradicting the fact that $\mathcal{C}_i \in \text{fam}(\mu)$.

• Stage R2 computes the minor block $B_{k,l}$ of pert(μ) strictly containing $U_{i,j}$ for each $\mathcal{C}_i \in \text{fam}(\mu)$ and each type-4 $U_{i,j} \in \mathcal{C}_i$. If $U_{i,j}$ is two-sided for $B_{k,l}$, either side of $B_{k,l}$ may be embedded toward the face F_i; otherwise, for some $p \in \{1, 2\}$, $U_{i,j}$ is side-p for $B_{k,l}$, and it requires that side$_p(B_{k,l})$ be embedded toward F_i.

• Stage R3 makes sure that, for every $\mathcal{C}_i$ straddling pert(μ) and for every $U_{i,j} \in \mathcal{C}_i$ strictly contained in pert(μ), a vertex in $U_{i,j}$ is embedded on the exterior face of pert(μ). This is done by checking whether the following statements are all false.

1. There are an exterior edge e_k of $\mathrm{ske}(\mu)$ and a minor block $B_{k,l}$ of $\mathrm{pert}(\mu)$ on e_k with $\max_{p\in\{1,2\}} \mathrm{ext}_p(B_{k,l}) < \mathrm{dep}(\mu)$; thus both $\mathrm{side}_1(B_{k,l})$ and $\mathrm{side}_2(B_{k,l})$ must be embedded toward the exterior face of $\mathrm{ske}(\mu)$.
2. There are an interior edge e_k of $\mathrm{ske}(\mu)$ and a minor block $B_{k,l}$ of $\mathrm{pert}(\mu)$ on e_k with $\min_{p\in\{0,1,2\}} \mathrm{ext}_p(B_{k,l}) < \mathrm{dep}(\mu)$; thus at least one of $\mathrm{side}_1(B_{k,l})$ and $\mathrm{side}_2(B_{k,l})$ must be embedded toward the exterior face of $\mathrm{ske}(\mu)$.
3. There is a $U_{i,j} \in \mathrm{sub}(\mu)$ with $\mathrm{dep}(\mathrm{done}(\mathcal{C}_i)) < \mathrm{dep}(\mu)$ (i.e., $\mathcal{C}_i$ straddles $\mathrm{pert}(\mu)$), and neither side of $\mathrm{ske}(\mu)$ contains an image in $\mathrm{img}(U_{i,j}, \mu)$.
4. There are an S-child χ_k of μ and a $U_{i,j} \in \mathrm{sub}(\chi_k)$ such that $\mathrm{dep}(\mathrm{done}(\mathcal{C}_i)) < \mathrm{dep}(\mu)$ and the virtual edge e_k of χ_k is an interior edge in $\mathrm{ske}(\mu)$.

If at least one statement above holds, R3 outputs "no" and stops. Otherwise, for each minor block $B_{k,l}$ of $\mathrm{pert}(\mu)$ such that $\mathrm{ext}_p(B_{k,l}) < \mathrm{dep}(\mu)$ for some $p \in \{1,2\}$, it requires that $\mathrm{side}_p(B_{k,l})$ be embedded toward the exterior face of $\mathrm{ske}(\mu)$. Note that, since statement 2 above is false, the representative e_k of $B_{k,l}$ in $\mathrm{ske}(\mu)$ must be an exterior edge of $\mathrm{ske}(\mu)$.

• Stage R4 first checks whether, for some minor block $B_{k,l}$ of $\mathrm{pert}(\mu)$, the orientation requirements imposed on $B_{k,l}$ in Stages R2 or R3 are in conflict. If they are, R4 outputs "no" and stops. Otherwise, for each R-child or P-child χ_k of μ, the minor block $\mathrm{pert}(\chi_k)$ can be oriented according to the requirements imposed on it or arbitrarily if no requirement was imposed on it. Afterward, for each S-child χ_k of μ, it calls the S-procedure on input χ_k together with the orientation requirements that were imposed on the minor blocks in $\mathrm{pert}(\chi_k)$ in Stages R2 or R3. If the S-procedure on a χ_k outputs "no," R4 outputs "no" and stops because $\mathrm{pert}(\chi_k)$ cannot be successfully embedded; otherwise, it has found a satisfying embedding of $\mathrm{pert}(\mu)$.

• Stage R5 computes $\mathrm{ext}_p(\mathrm{pert}(\mu))$ for $p = 0, 1, 2$ as follows. Let $\mathrm{xsub}'(\mu) = \{U_{i,j} \in \mathrm{xsub}(\mu) \mid \mathrm{dep}(\mathrm{done}(\mathcal{C}_i)) < \mathrm{dep}(\mu)\}$; i.e., $\mathrm{xsub}'(\mu)$ consists of all $U_{i,j} \in \mathrm{xsub}(\mu)$ such that $\mathcal{C}_i$ straddles $\mathrm{pert}(\mu)$. Partition $\mathrm{xsub}'(\mu)$ into A_0, A_1, A_2, where A_0 (respectively, A_1 or A_2) consists of all $U_{i,j} \in \mathrm{xsub}'(\mu)$ such that $U_{i,j}$ is two-sided (respectively, side-1 or side-2) for $\mathrm{pert}(\mu)$. For $i \in \{1,2\}$, let $\beta_i = \min_{p,B_{k,l}} \mathrm{ext}_p(B_{k,l})$, where p ranges over all integers in $\{0,1,2\}$ and $B_{k,l}$ ranges over all minor blocks on an edge of $\mathrm{side}_i(\mathrm{ske}(\mu))$. Then set

$$\mathrm{ext}_0(\mathrm{pert}(\mu)) = \min_{U_{i,j}\in A_0} \mathrm{dep}(\mathrm{done}(\mathcal{C}_i));$$

$$\mathrm{ext}_1(\mathrm{pert}(\mu)) = \min\left\{\beta_1, \min_{U_{i,j}\in A_1} \mathrm{dep}(\mathrm{done}(\mathcal{C}_i))\right\};$$

$$\mathrm{ext}_2(\mathrm{pert}(\mu)) = \min\left\{\beta_2, \min_{U_{i,j}\in A_2} \mathrm{dep}(\mathrm{done}(\mathcal{C}_i))\right\}.$$

This completes the processing of μ.

Example 2. In Figure 6.3, the circles denote the vertices in $\mathrm{ske}(\mu)$, where s and t are the poles of $\mathrm{pert}(\mu)$. An integer i in a small square at a side of a block $B_{k,l}$ indicates that a set in $\mathcal{C}_i$ has a vertex on that side of $B_{k,l}$. Also, $\mathrm{fam}(\mu) = \{\mathcal{C}_1, \mathcal{C}_2\}$. $\mathcal{C}_1 = \{U_{1,1}, \ldots, U_{1,4}\}$. $U_{1,1}$ is of type 3 and $\mathrm{img}(U_{1,1}, \mu) = \{e_3\}$. $U_{1,2}$ and $U_{1,3}$ are of type 4, $\mathrm{img}(U_{1,2}, \mu) = \{e_2\}$, and $\mathrm{img}(U_{1,3}, \mu) = \{e_4\}$. $U_{1,2}$ is two-sided for $B_{2,1}$. $U_{1,4}$ is of type 2 and $\mathrm{img}(U_{1,4}, \mu) = \{d\}$. $\mathcal{C}_2$ consists of $U_{2,1}$ and $U_{2,2}$, which are of type 4. $\mathrm{img}(U_{2,1}, \mu) = \{e_1\}$ and $\mathrm{img}(U_{2,2}, \mu) = \{e_2\}$. $\mathcal{C}_3$ is the only family straddling $\mathrm{pert}(\mu)$. $U_{3,1}$, $U_{3,2}$, and $U_{3,3}$ are the sets in $\mathcal{C}_3$ that intersect $\mathrm{pert}(\mu)$; the other sets in $\mathcal{C}_3$ are not shown in this figure. $U_{3,1}$ is of type 4 and $\mathrm{img}(U_{3,1}, \mu) = \{e_1\}$. $U_{3,2}$ is of type 2 and is two-sided for $\mathrm{pert}(\mu)$; $\mathrm{img}(U_{3,2}, \mu) = \{a, b, c\}$. Since $U_{3,3}$ is not strictly

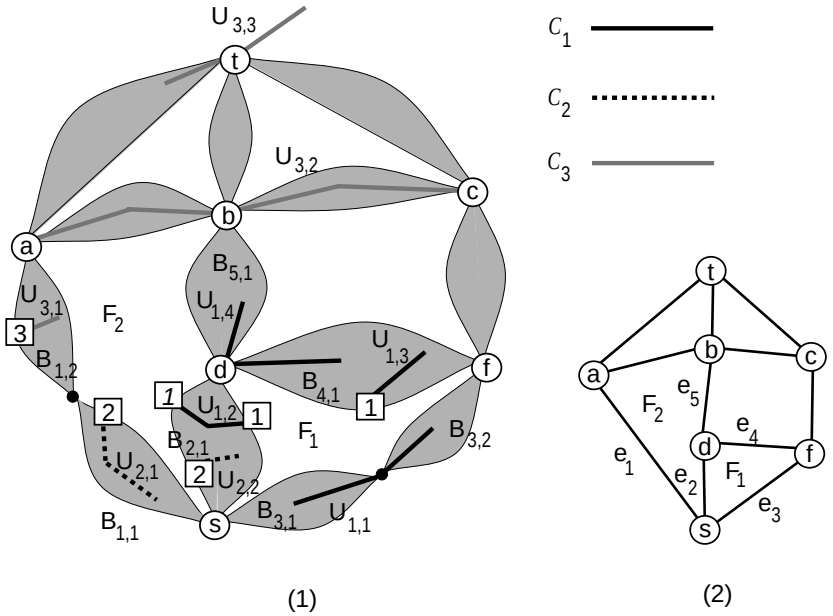

FIG. 6.3. *The graph in* (1) *is* pert(μ) *for an R-node* μ*, and the graph in* (2) *is* ske(μ).

contained in pert(μ), it is not tested during the processing of μ. Note that pert(μ) has a satisfying embedding as shown. For $i = 1, 2$, the boundary of F_i intersects each set in $\mathcal{C}_i$. The exterior face of pert(μ) contains an image of every set in $\mathcal{C}_3$ strictly contained in pert(μ). The side of $B_{4,1}$ on which 1 is marked must be embedded toward F_1. In contrast, whichever side of $B_{2,1}$ is embedded toward F_1, the boundary of F_1 intersects $U_{1,2}$. In the embedding of pert(μ), $\mathcal{C}_3$ is side-1 (respectively, side-0) exterior-forcing for pert(μ) because of $U_{3,1}$ (respectively, $U_{3,2}$).

6.3.3. μ is a P-node. In this case, ske(μ) consists of parallel edges $e_1, e_2, \ldots, e_b$ between its two poles with $b \geq 2$. Let $\chi_1, \ldots, \chi_b$ be the children of μ in T. For each $k \in \{1, \ldots, b\}$, let $B_{k,1}, \ldots, B_{k,s_k}$ be the minor blocks of pert(μ) in pert(χ_k). When embedding ske(μ), edges e_1 through e_b can be embedded in any order. The CFE algorithm first finds a proper embedding of ske(μ) in three stages.

• Stage P1 constructs an auxiliary graph $H = (V_H, E_H)$ with $V_H = \{e_1, \ldots, e_b\}$ by performing the following steps in turn for every $\mathcal{C}_i \in \text{fam}(\mu)$:

1. Compute $S_i = \cup_{U_{i,j}} \text{img}(U_{i,j}, \mu)$, where $U_{i,j}$ ranges over all type-3 or type-4 sets in $\mathcal{C}_i$. Let m_i be the number of edges in S_i. Then $m_i \geq 2$; otherwise, $\mathcal{C}_i$ would be in fam(χ_k) for some $k \in \{1, \ldots, b\}$.
2. If $m_i \geq 3$, then output "no" and stop since pert(μ) does not satisfy $\mathcal{C}_i$.
3. Insert edge $\{e_k, e_{k'}\}$ to H, where e_k and $e_{k'}$ are the two edges in S_i.

Note that, for each $\mathcal{C}_i \in \text{fam}(\mu)$, no set in $\mathcal{C}_i$ is of type 2, and each type-1 set in $\mathcal{C}_i$ contains a pole of pert(μ), which is on every face of all embeddings of ske(μ). For this reason, neither type-1 nor type-2 set in $\mathcal{C}_i$ is considered in the construction of H.

• Stage P2 checks whether both statements below are false in order to ensure that, for every $\mathcal{C}_i$ straddling pert(μ) and every $U_{i,j} \in \mathcal{C}_i$ strictly contained in pert(μ), a vertex in $U_{i,j}$ is embedded on the exterior face of pert(μ).

1. There is a minor block $B_{k,l}$ of pert(μ) with $\max_{p \in \{1,2\}} \text{ext}_p(B_{k,l}) < \text{dep}(\mu)$.

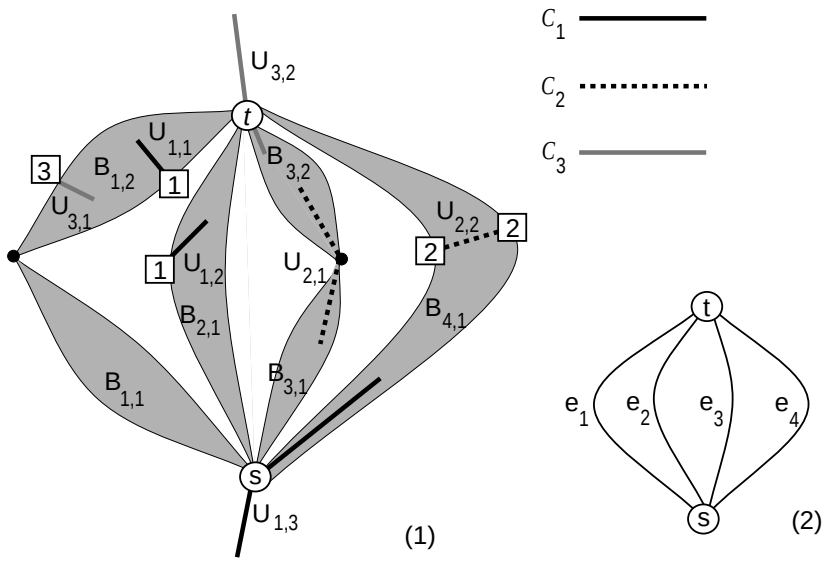

FIG. 6.4. *The graph in* (1) *is* $\mathrm{pert}(\mu)$ *for a P-node* μ*, and that in* (2) *is* $\mathrm{ske}(\mu)$.

2. There are at least three edges e_k in $\mathrm{ske}(\mu)$ such that (1) there is a minor block $B_{k,l}$ on e_k with $\min_{p\in\{0,1,2\}} \mathrm{ext}_p(B_{k,l}) < \mathrm{dep}(\mu)$ or (2) χ_k is an S-node and there exists $U_{i,j}$ in $\mathrm{sub}(\chi_k)$ with $\mathrm{dep}(\mathrm{done}(\mathcal{C}_i)) < \mathrm{dep}(\mu)$.

If statements 1 or 2 hold, P2 outputs "no" and stops. Otherwise, it marks each $e_k \in V_H$ for which statement 2(1) or 2(2) holds. Note that at most two $e_k \in V_H$ are marked, and each marked $e_k \in V_H$ must be an exterior edge in any satisfying embedding of $\mathrm{ske}(\mu)$.

• Stage P3 outputs "no" and stops if an $e_k \in V_H$ has degree at least 3 in H or a marked $e_k \in V_H$ has degree 2 in H. Otherwise, P3 finds and fixes an embedding of $\mathrm{ske}(\mu)$, where (1) each marked $e_k \in V_H$ is in the exterior face and (2) for every $\{e_k, e_{k'}\} \in E_H$, e_k and $e_{k'}$ form the boundary of a face. For each $\mathcal{C}_i \in \mathrm{fam}(\mu)$, let F_i be the face in the fixed embedding of $\mathrm{ske}(\mu)$ whose boundary is formed by the two edges in S_i. Note that, for each $U_{i,j} \in \mathcal{C}_i$, the boundary of F_i intersects $\mathrm{img}(U_{i,j}, \mu)$.

Next, the CFE algorithm tries to embed $\mathrm{pert}(\mu)$ based on the embedding of $\mathrm{ske}(\mu)$ fixed in Stage P3 through the same stages as Stages R2 through R5 in section 6.3.2 except that, in the stage corresponding to R5, $A_0 = \emptyset$ and the algorithm sets $\mathrm{ext}_0(\mathrm{pert}(\mu)) = \infty$. This completes the processing of μ.

Example 3. In Figure 6.4, $\mathrm{fam}(\mu) = \{\mathcal{C}_1, \mathcal{C}_2\}$. $\mathcal{C}_1 = \{U_{1,1}, U_{1,2}, U_{1,3}\}$. Both $U_{1,1}$ and $U_{1,2}$ are of type 4; $\mathrm{img}(U_{1,1}, \mu) = \{e_1\}$ and $\mathrm{img}(U_{1,2}, \mu) = \{e_2\}$. $U_{1,3}$ is of type 1 and need not be tested during the processing of μ. $\mathcal{C}_2 = \{U_{2,1}, U_{2,2}\}$. $U_{2,1}$ is of type 3 and $\mathrm{img}(U_{2,1}, \mu) = \{e_3\}$. $U_{2,2}$ is of type 4 and $\mathrm{img}(U_{2,2}, \mu) = \{e_4\}$. $\mathcal{C}_3$ is the only family straddling $\mathrm{pert}(\mu)$. $\{U_{3,1}$ and $U_{3,2}\}$ are the sets in $\mathcal{C}_3$ that intersect $\mathrm{pert}(\mu)$; the other sets in $\mathcal{C}_3$ are not shown in this figure. Since $U_{3,2}$ contains the pole t of $\mathrm{pert}(\mu)$, it is not tested during the processing of μ. $U_{3,1}$ is of type 4 and $\mathrm{img}(U_{3,1}, \mu) = \{e_1\}$. $V_H = \{e_1, e_2, e_3, e_4\}$ and $E_H = \{\{e_1, e_2\}, \{e_3, e_4\}\}$. Only e_1 is marked in graph H. Figure 6.4(2) shows an embedding of $\mathrm{ske}(\mu)$ that might be found and fixed in Stage P3. This embedding of $\mathrm{ske}(\mu)$ results in a satisfying embedding of $\mathrm{pert}(\mu)$ as shown. If either $\mathcal{C}_1$ had another set strictly contained in block $B_{4,1}$ or $\mathcal{C}_3$ had another set

strictly contained in $B_{2,1}$, then pert(μ) has no satisfying embedding.

This completes the description of the CFE algorithm. Its correctness follows from the above discussion and Lemma 6.3.

6.4. Implementation and analysis. We implement the CFE algorithm as follows. The nodes of T are identified by their preorder numbers. At each node $\mu \in T$, we store dep(μ) and the preorder number of the largest node in T_μ. Let $\chi_1, \ldots, \chi_b$ be the children of μ. The nodes in $T_{\chi_1}, \ldots, T_{\chi_b}$ form an ordered partition of the nodes in $T_\mu - \{\mu\}$. For a node ν, we can check whether ν is in T_μ in $O(1)$ time. If $\nu \in T_\mu$, we can find the subtree T_{χ_k} containing ν in $O(\log |\mathcal{G}|)$ time by a binary search of the children of μ. We equip T with a data structure which can be constructed in linear time and which outputs a least common ancestor query in $O(1)$ time [16, 27].

We also store ske(μ) at μ. Each μ has a pointer to its virtual edge in its parent's skeleton. For each nonpole vertex of ske(μ), we mark μ as its proper allocation node. This takes $O(|\mathcal{G}|)$ total time by Lemma 6.2(1). Each edge e of $\mathcal{G}$ has a pointer to the leaf node in T that represents e.

LEMMA 6.4. *Given $\mathcal{G}$, $\mathcal{M}$, and T, we can compute* fam(μ), sub(μ), done($\mathcal{C}_i$), *and* done($U_{i,j}$) *for all nodes μ of T, all $\mathcal{C}_i$ in $\mathcal{M}$, and all $U_{i,j}$ in $\mathcal{C}_i$ in $O(I)$ total time.*

Proof. For each vertex v of $\mathcal{G}$, let low(v) be the deepest allocation node of v in T. In $O(|\mathcal{G}|)$ time, we can compute low(v) for all vertices v of $\mathcal{G}$. For a set $U_{i,j} \in \mathcal{C}_i$, if a pole of $\mathcal{G}$ is in $U_{i,j}$, then done($U_{i,j}$) is the root of T; otherwise, done($U_{i,j}$) is the least common ancestor of all low(v) with $v \in U_{i,j}$. So done($U_{i,j}$) can be computed in $O(|U_{i,j}|)$ time. Let low($U_{i,j}$) be the deepest one among all low(v) with $v \in U_{i,j}$. We can compute low($U_{i,j}$) in $O(|U_{i,j}|)$ time. Since done($\mathcal{C}_i$) is the least common ancestor of all low($U_{i,j}$) with $U_{i,j} \in \mathcal{C}_i$, it can be computed in $O(|\mathcal{C}_i|)$ time. Thus, in $O(I)$ total time, we can compute done($U_{i,j}$) and done($\mathcal{C}_i$) for all $\mathcal{C}_i$ in $\mathcal{M}$ and all $U_{i,j}$ in $\mathcal{C}_i$. Afterward, in $O(I)$ total time, we can compute fam(μ) and sub(μ) for all nodes μ of T. □

After processing μ, the CFE algorithm records the following information:

1. the embedding of ske(μ);
2. ext$_p$(pert(μ)) for $p = 0$, 1, and 2;
3. the edges and vertices on side$_1$(ske(μ)) and side$_2$(ske(μ)), respectively;
4. an integer $p = 0$, 1, or 2 for each $U_{i,j} \in$ xsub(μ), indicating whether $U_{i,j}$ is two-sided, side-1, or side-2 for pert(μ), respectively.

The CFE algorithm processes a P-node or R-node μ with the five operations below.

Operation 1 uses $O(|U_{i,j}| + \log |\mathcal{G}|)$ time to determine the type of a given $U_{i,j}$ in xfam(μ) and finds img($U_{i,j}, \mu$) as follows. Let $\nu =$ done($U_{i,j}$).

Case 1. dep(ν) $\leq$ dep(μ). Then $U_{i,j}$ is of type 1 or 2 for pert(μ). $U_{i,j}$ is of type 1 if and only if it contains a pole of pert(μ). Also, img($U_{i,j}, \mu$) consists of all $v \in U_{i,j}$ which are also in ske(μ). Note that $v \in$ ske(μ) if and only if μ is the proper allocation node of v or v is a pole of pert(μ).

Case 2. dep(ν) = dep(μ) + 1, and ν is an S-node. Then $U_{i,j}$ is of type 3 for pert(μ). Also, img($U_{i,j}, \mu$) consists of the virtual edge of ν in ske(μ).

Case 3. Otherwise. Then $U_{i,j}$ is of type 4 for pert(μ). Also, img($U_{i,j}, \mu$) is the virtual edge of χ_k in ske(μ), where χ_k is the child of μ such that ν is in the subtree T_{χ_k}.

Operation 2 checks in $O(|U_{i,j}|)$ time whether a given $U_{i,j} \in$ xsub(μ) has a vertex on either side of pert(μ) after an embedding of pert(μ) is fixed. If $U_{i,j} \in$ sub(μ), we check whether a vertex in img($U_{i,j}, \mu$) is on either side of ske(μ). If $U_{i,j} \in$ sub(χ_k)

for an S-child χ_k of μ, we check whether the virtual edge e_k of χ_k is on either side of $\text{ske}(\mu)$.

Operation 3 uses $O(1)$ time to check whether a given $U_{i,j} \in \text{xsub}(\mu)$ is in $\text{xsub}'(\mu)$ by checking whether $\text{dep}(\text{done}(\mathcal{C}_i)) < \text{dep}(\mu)$.

Operation 4 checks whether a given $U_{i,j}$ is strictly contained in $\text{pert}(\mu)$ and, if so, further computes the minor block B of $\text{pert}(\mu)$ strictly containing $U_{i,j}$ in $O(|U_{i,j}| + \log|\mathcal{G}|)$ total time. For the first task, we check whether (1) $\nu = \text{done}(U_{i,j})$ is a descendent of μ, or (2) $\nu = \mu$ and $U_{i,j}$ contains no pole of $\text{pert}(\mu)$. For the second task, we first find the child χ_k of μ such that T_{χ_k} contains ν. If χ_k is not an S-node, $\text{pert}(\chi_k)$ is B; otherwise, B is $\text{pert}(\eta)$, where η is the child of χ_k such that T_η contains ν.

Operation 5 checks in $O(\log|\mathcal{G}|)$ time whether a given type-4 $U_{i,j}$ for $\text{pert}(\mu)$ is side-1, side-2, or two-sided for the minor block $B_{k,l}$ in $\text{pert}(\mu)$ strictly containing $U_{i,j}$. Let $\eta = \text{node}(B_{k,l})$ and $\nu = \text{done}(U_{i,j})$. Note that η has been processed. If $\eta = \nu$, this operation takes $O(1)$ time using the information stored for η. If ν is a descendent of η, the representative e of ν in $\text{ske}(\eta)$ can be found in $O(\log|\mathcal{G}|)$ time. Then it takes $O(\log|\mathcal{G}|)$ time to check whether e is on $\text{side}_1(\text{ske}(\eta))$ or $\text{side}_2(\text{ske}(\eta))$ using the information stored for η.

LEMMA 6.5.

1. $\{\text{xfam}(\mu) \mid \mu$ *is a P-node or R-node*$\}$ *is a partition of* $\{\mathcal{C}_1, \ldots, \mathcal{C}_q\}$.
2. $\{\text{xsub}(\mu) \mid \mu$ *is a P-node or R-node*$\}$ *is a partition of* $\mathcal{C}_1 \cup \cdots \cup \mathcal{C}_q$.
3. *Each input family* $\mathcal{C}_i$ *is processed exactly once.*
4. *Each input* $U_{i,j}$ *is processed at most twice, and the total time spent on processing* $U_{i,j}$ *is* $O(|U_{i,j}| + \log|\mathcal{G}|)$.

Proof. Statements 1 and 2 are straightforward. Statement 3 holds since each $\mathcal{C}_i$ is processed only when the node μ with $\mathcal{C}_i \in \text{xfam}(\mu)$ is processed. Each $U_{i,j}$ is processed once when the node μ with $U_{i,j} \in \text{xsub}(\mu)$ is processed and once when the node ϕ with $\mathcal{C}_i \in \text{xfam}(\phi)$ is processed. When $U_{i,j}$ is processed, we perform some of operations 1 through 5 on it. Since an operation takes $O(|U_{i,j}| + \log|\mathcal{G}|)$ time, statement 4 holds. □

We now bound the time of processing an R-node or P-node μ. Let $\text{xske}(\mu)$ be obtained from $\text{ske}(\mu)$ by replacing the virtual edge of each S-child χ_k of μ with $\text{ske}(\chi_k)$. Let n_μ be the number of vertices in $\text{xske}(\mu)$. Let $N_\mu = \sum_{\mathcal{C}_i \in \text{xfam}(\mu)} |\mathcal{C}_i|$. Recall that μ is processed using some of the following operations:

1. Process the sets $U_{i,j}$ in the families $\mathcal{C}_i \in \text{xfam}(\mu)$.
2. Call Theorem 3.8(2) on input $\text{ske}(\mu)$ and $\mathcal{M}'(\mu)$.
3. Call the S-procedure on χ_k for the S-children χ_k of μ.
4. Compute $\text{ext}_p(\text{pert}(\mu))$ for $p = 0$, 1, and 2.
5. Construct auxiliary graphs D, RD, and H, and operate on them.

Note that each $K \in \{D, RD, H\}$ is constructed and operated on in $O(|K|)$ total time. Since $\sum_K |K| \leq n_\mu$, where K ranges over all auxiliary graphs constructed during the processing of μ, it takes $O(n_\mu)$ total time to process the auxiliary graphs for μ. Therefore, the above operations take $O((n_\mu + N_\mu)\log I)$ time in total. By summing over all P-nodes and R-nodes μ of T, and by Theorem 3.8, Lemma 6.2(1), and Lemma 6.5, the CFE algorithm runs in the desired total time, completing the proof of Theorem 6.1.

7. Directions for further research. We have proved that the CFE problem can be solved in $O(I \log I)$ time for the special case where, for each input family $\mathcal{C}_i$, each set in $\mathcal{C}_i$ induces a connected subgraph of the input graph $\mathcal{G}$. One direction

for further research would be to reduce the running time to linear. Such a result might lead to substantial simplification of the SPQR tree decomposition or an entirely different data structure. Another worthy direction would be to solve more general cases in similar time bounds. Beyond these technical open problems, it would be of significance to find further applications of the CFE problem in addition to VLSI layout and topological inference as well as to identify novel and fundamental constrained planar embeddings.

Acknowledgments. We wish to thank the anonymous referees for many helpful suggestions.

ACCELERATED SOLUTION OF MULTIVARIATE POLYNOMIAL SYSTEMS OF EQUATIONS*

B. MOURRAIN†, V. Y. PAN‡, AND O. RUATTA†

Abstract. We propose new Las Vegas randomized algorithms for the solution of a square nondegenerate system of equations, with well-separated roots. The algorithms use $\mathcal{O}(\delta\, 3^n D^2 \log(D)\log(b))$ arithmetic operations (in addition to the operations required to compute the normal form of the boundary monomials modulo the ideal) to approximate all real roots of the system as well as all roots lying in a fixed n-dimensional box or disc. Here D is an upper bound on the number of all complex roots of the system (e.g., Bezout or Bernshtein bound), δ is the number of real roots or the roots lying in the box or disc, and $\epsilon = 2^{-b}$ is the required upper bound on the output errors. For computing the normal form modulo the ideal, the efficient practical algorithms of [B. Mourrain and P. Trébuchet, in *Proceedings of the International Symposium on Symbolic and Algebraic Computation,* ACM, New York, 2000, pp. 231–238] or [J. C. Faugère, *J. Pure Appl. Algebra,* 139 (1999), pp. 61–88] can be applied. We also yield the bound $\mathcal{O}(3^n D^2 \log(D))$ on the complexity of counting the numbers of all roots in a fixed box (disc) and all real roots. For a large class of inputs and typically in practical computations, the factor δ is much smaller than D, $\delta = o(D)$. This improves by the order of magnitude the known complexity estimates of the order of at least $3^n D^4 + D^3 \log(b)$ or D^4, which so far are the record estimates even for the approximation of a single root of a system and for each of the cited counting problems, respectively. Our progress relies on proposing several novel techniques. In particular, we exploit the structure of matrices associated to a given polynomial system and relate it to the associated linear operators, dual space of linear forms, and normal forms of polynomials in the quotient algebra; furthermore, our techniques support the new nontrivial extension of the matrix sign and quadratic inverse power iterations to the case of multivariate polynomial systems, where we emulate the recursive splitting of a univariate polynomial into factors of smaller degree.

Key words. multivariate polynomials, systems of equations, quotient algebras, dual spaces, quasi-Toeplitz matrices, quasi-Hankel matrices, matrix sign iteration, quadratic power iteration

1. Introduction.

The classical problem of solving a multivariate polynomial system of equations is presently the subject of intensive research and one of the central practical and theoretical problems in the area of algebraic computation (see [21], [5], [32], [15].) It has major applications, for instance, to robotics, computer modelling and graphics, molecular biology, and computational algebraic geometry.

The oldest approach to the solution is the elimination method, reducing the problem to the computation of the associated resultant or its multiples. This classical method evolved in the old works by Bezout, Dixon, and Macaulay (see, e.g., [21], [45]) but later remained largely ignored by the researchers and algorithm designers until it was resurrected first by Chistov and Grigoriev [8], who designed a deterministic solution algorithm, then in a randomized approach by Canny [4], and later by

Giusti and Heintz [18] and has since become a very popular approach. One of the major further steps was the reduction of the solution of a multivariate polynomial system to matrix operations, in particular, by rational transformation of the original problem into a matrix eigenproblem (cf. [1], [16], [15], [27], [25], [10]).

The approach has been explored and extended by many researchers, has been exploited in the practice of algebraic computing, and has also supported the record asymptotic upper bound $\mathcal{O}^*(D^4)$ on the arithmetic computational complexity of the solution of a nondegenerate polynomial system having a finite number of roots [40]. Here and hereafter, $\mathcal{O}^*(s)$ stands for $\mathcal{O}(s \log^c s)$, c denoting a constant independent of s, and D is an upper bound on the number of roots of the given polynomial system. (For D, one may choose either the Bezout bound, $\prod_i d_i$, d_i denoting the maximum degree in the ith variable in all monomials of the system, or the Bernshtein bound, which is much smaller for sparse systems and equals the mixed volume of the associated Newton polytope, defined by the exponents of the monomials.) Even for many subproblems and related problems, no known algorithms support any better bound than $\mathcal{O}(D^4)$. This includes approximation of all real roots of a polynomial system (which is highly important due to applications to robotic and computer graphics), all its roots lying in a fixed n-dimensional box or disc, counting all roots in such a box or disc or all real roots, and even approximation of a single root. Some progress was achieved in [30], where a single root was approximated in $\mathcal{O}^*(3^n D^2)$ time, but under a strong restriction on the input polynomials.

Against this background, our new algorithms support the computational cost estimate of $\mathcal{O}^*(3^n D^2)$ for all of the subproblems listed above, that is, for both of the counting problems, the computation of a single root, all real roots, and all roots in a fixed box or disc. More precisely, our bound is $\mathcal{O}^*(\delta\, 3^n D^2)$ in the latter two cases, where δ is the number of real roots or roots in the selected box or disc, respectively. In practical applications, such a number is typically much less than D. The number of real roots grows as $\sqrt{D}$ for a large class of input systems [41]. See also the sparse case [24]. Thus, for all listed problems, we improve the known complexity estimates by an order of magnitude.

We have a reservation from a theoretical point of view; that is, our main algorithm relies on the known effective algorithms for the computation of the normal form of monomials on the boundary of the monomial basis (see section 4). These algorithms exploit structured matrices and in practice appear to run faster than our subsequent computations (see [17], [33]), but their known theoretical cost bounds are greater than the order of $e^{3n} D^3$ (see [22]).

Our paper addresses the problem of the asymptotic acceleration of the resolution stage, where the structure of the quotient algebra $\mathcal{A}$ (associated with the polynomial system) is already described by using the minimal number of parameters, that is, via the normal form of the monomials on the boundary of the basis. From a purely theoretical point of view, we have an alternative approach that avoids the normal-form algorithms at the price of using the order of $\mathcal{O}(12^n\, D^2)$ additional arithmetic operations [31]. This should be technically interesting because no other known approach yields this bound, but in this paper, we prefer to stay with our present, practically promising version, referring the reader to [31] on the cited theoretical approach. Our practically promising solution relies on fast computation of normal forms of polynomials modulo the ideal, based on the algorithm of [33]. Some limited amount of experimental evidence to the efficiency of this algorithm has been reported in [33], and further experimentation is ongoing.

Our algorithms approximate the roots numerically, and in terms of the required upper bound 2^{-b} (b is the bit precision) on the output errors of the computed solution, we obtain the running time estimate $\mathcal{O}(\log b)$ due to quadratic convergence of our algorithms. Within a constant factor, such an estimate matches the lower bound of [39] and enables us to yield a high output precision at relatively low cost; this gives us a substantial practical advantage versus the algorithms that reach only $\mathcal{O}(b)$ because the solution of a polynomial system is usually needed with a high precision. We achieve this by using the matrix sign iteration and the inverse quadratic iteration, both of which converge at a quadratic rate right from the start. All techniques and results can be extended to the case of sparse input polynomials (see Remark 3.16). In this case, the computation cost bounds become $\mathcal{O}(D\,C_{PolMult})$, where $C_{PolMult}$ is the cost of polynomial multiplication, which is small when the polynomials are sparse. (This cost depends on the degree of the polynomials and not only on an upper bound D on the number of roots.)

The factor 3^n is a substantial deficiency, of course, but it is still much less than D for the large and important class of input polynomials of degree higher than 3.

Our results require some other restrictions. First, we consider systems with simple roots or well-separated roots. In the presence of a cluster, a specific analysis is needed [43] and deserves additional work, which is not in the scope of this paper. Second, we need the existence of a nondegenerate linear form, which implies that the quotient algebra $\mathcal{A}$ is a Gorenstein algebra [12], [14]. This is the case in which the solution set is 0-dimensional and is defined by n equations. If we have more than n equations defining a 0-dimensional variety, we may take their n-random linear combination (see, e.g., [13]), which yields the required Gorenstein property, but this may introduce extra solutions that we will have to remove at the end. Finally, for approximation, our algorithms converge quadratically (using $\mathcal{O}(\log(b))$ steps) but require certain nondegeneracy assumptions (such as uniqueness of the minimum of the value of $|h(\zeta)|$, where ζ is a root and $h(x)$ is a polynomial). The latter assumptions can be ensured with a high probability by a random linear transformation of the variables. Even if these assumptions are barely satisfied, the slowdown of the convergence is not dramatic because the convergence is quadratic right from the start.

Similarly, we apply randomization to regularize the computations at the counting stages and for the auxiliary computation of the nondegenerate linear form in the dual space $\widehat{\mathcal{A}}$. Then again, nondegeneracy is ensured probabilistically and is verified in the subsequent computation. (That is, we stay under the Las Vegas probabilistic model, where failure may occur, with a small probability, but otherwise the correctness of the output is ensured.)

Some of our techniques should be of independent interest. In particular, we extend the theory of structured matrices to the ones associated to multivariate polynomials and show correlation among computations with such matrices and dual spaces of linear forms. We show some new nontrivial applications of the normal forms of polynomials of the quotient algebra. Furthermore, we establish new reduction from multivariate polynomial computations to some fundamental operations of linear algebra (such as the matrix sign iteration, the quadratic inverse power iteration, and the computation of Schur's complements).

Our progress has some technical similarity to the acceleration of the solution of linear systems of equations via fast matrix multiplication (in particular, we also rely on faster multiplication in the quotient algebra defined by the input polynomials) but even more so to the recent progress in the univariate polynomial rootfinding

via recursive splitting of the input polynomial into factors (cf. [6], [34], [36], [37]). Although recursive splitting into factors may be hard to even comprehend in the case of multivariate polynomial systems, this is exactly the basic step of our novel recursive process, which finally reduces our original problem to ones of small sizes. Of course, we could not achieve splitting in the original space of the variables, but we yield it in terms of idempotent elements of the associated quotient algebra (such elements represent the roots), and for this purpose we have to apply all of our advanced techniques. This approach generalizes the methods of [6] and [36] to the multivariate case. The only missing technical point of our extension of the univariate splitting construction of [36] is the balancing of the splitting, which was the most recent and elusive step in the univariate case (cf. [36], [37]). It is a major challenge to advance our approach to achieve balancing in our recursive splitting process even in the worst case (possibly by using the geometry of discriminant varieties) and, consequently, to approximate all of the roots of any specific polynomial system in $\mathcal{O}^*(3^n D^2 \log b)$ arithmetic time. Another goal is the computations in the dual space, as well as with structured matrices. The latter subject is of independent interest as well [44], [32].

Let us conclude this section with a high-level description of our approach. Our solution of polynomial systems consists of the following stages:

1. Compute a basic nondegenerate linear form on the quotient algebra $\mathcal{A}$ associated to a given system of polynomial equations.

2. Compute nontrivial idempotent elements of $\mathcal{A}$.

3. Recover the roots of the given polynomial system from the associated idempotents.

The quotient algebra $\mathcal{A}$ and the dual space of linear forms on it are defined and initially studied in section 2. Stage 1 is elaborated in section 4. Idempotents are computed by iterative algorithms of section 6. Section 7 shows how to recover or to count the roots efficiently when the idempotents are available. The computations are performed in the quotient algebra, and they are reduced to operations in the dual space by using the associated structured (quasi-Toeplitz and quasi-Hankel) matrices. In section 3, we define the classes of such matrices, show their correlation to polynomial computations, and exploit it to operate with such matrices faster. In section 5, we show how the combined power of the latter techniques and the ones developed for working in the dual space enable us to rapidly perform the basic operations in the quotient algebra and, consequently, the computations of sections 6 and 7.

Stage 1 contributes $O(3^n D^2 \log D)$ ops to the overall complexity bound, assuming that the normal form of the monomials on the boundary of a basis is known. The computation of a nontrivial idempotent at stage 2 has cost $O(3^n D^2 \log D \log b)$, which dominates the cost of the subsequent root counting or their recovery from the idempotents. The overall complexity depends on the number of idempotents that one has to compute, which in turn depends on the number δ of roots of interest. So far, we cannot utilize here the effective tools of balanced splitting, available in the similar situation for the univariate polynomial rootfinding. Thus, in the worst case, in each step we split out only a single root from the set of all roots, and then we need δ idempotents.

2. Definitions and preliminaries. Hereafter, $R = \mathbb{C}[x_1, \dots, x_n]$ is the ring of multivariate polynomials in the variables $x_1, \dots, x_n$, with coefficients in the complex field $\mathbb{C}$. $\mathbb{Z}$ is the set of integers, $\mathbb{N}$ is its subset of nonnegative integers, and $L = \mathbb{C}[x_1^{\pm}, \dots, x_n^{\pm}]$ is the set of Laurent polynomials with monomial exponents in $\mathbb{Z}^n$. For any $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{Z}^n$, $\mathbf{x}^{\mathbf{a}}$ is the monomial $\mathbf{x}^{\mathbf{a}} = x_1^{a_1} \cdots x_n^{a_n}$. $\lfloor E \rceil$ is the cardinality

(that is, the number of elements) of a finite subset E of $\mathbb{Z}^n$. "ops" will stand for "arithmetic operations" in the underlying coefficient ring or field.

2.1. Quotient algebra. To motivate and to demonstrate our study, we will next consider the univariate case, where we have a fixed polynomial $f \in \mathbb{C}[x]$ of degree d with d simple roots: $f(x) = f_d \prod_{i=1}^{d}(x-\zeta_i)$. The quotient algebra of residue polynomials modulo f, denoted by $\mathcal{A} = \mathbb{C}[x]/(f)$, is a vector space of dimension d. Its basis is $(1, x, \ldots, x^{d-1})$. Consider the Lagrange polynomials

$$\mathbf{e}_i = \prod_{j \neq i} \frac{x-\zeta_j}{\zeta_i - \zeta_j}.$$

One immediately sees that $\sum_i \mathbf{e}_i = 1$ and $\mathbf{e}_i\mathbf{e}_j \equiv \mathbf{e}_i(\mathbf{e}_i - 1) \equiv 0$ (for these two polynomials vanish at the roots of f). In other words, the Lagrange polynomials $\mathbf{e}_i$ are orthogonal idempotents in $\mathcal{A}$, and we have $\mathcal{A} = \sum_i \mathbb{C}\,\mathbf{e}_i$. Moreover, for any polynomial $a \in \mathcal{A}$, we also have $(a - a(\zeta_i))\mathbf{e}_i \equiv 0$, so that $\mathbf{e}_i$ is an eigenvector for the operator of multiplication by a in $\mathcal{A}$, for the eigenvalue $a(\zeta_i)$. These multiplication operators have a diagonal form in the basis $(\mathbf{e}_i)$ of $\mathcal{A}$. According to a basic property of Lagrange polynomials, we have $a \equiv \sum_i a(\zeta_i)\,\mathbf{e}_i(x)$ for any $a \in \mathcal{A}$. Therefore, the dual basis of $(\mathbf{e}_i)$ (formed by the coefficients of the $\mathbf{e}_i$ in this decomposition) consists of the linear forms associating to a its values at the points ζ_i. We will extend this approach to the case of multivariate polynomial systems, which, of course, will require substantial further elaboration and algebraic formalism. We refer the reader to [26], [27], [32], [42] for further details.

Let $f_1, \ldots, f_m$ be m polynomials of R, defining the polynomial system $f_1(x) = 0, \ldots, f_m(x) = 0$. Let I be the ideal generated by these polynomials, that is, the set of polynomial combinations $\sum_i f_i q_i$ of these elements. $\mathcal{A} = R/I$ denotes the quotient ring (algebra) defined in R by I, and $\equiv$ denotes the equality in $\mathcal{A}$. We consider the case in which the quotient algebra $\mathcal{A} = R/I$ *is of finite dimension* D *over* $\mathbb{C}$. This implies that the set of roots or solutions $\mathcal{Z}(I) = \{\zeta \in \mathbb{C}^n; f_1(\zeta) = \cdots = f_m(\zeta) = 0\}$ is finite: $\mathcal{Z}(I) = \{\zeta_1, \ldots, \zeta_d\}$ with $d \leq D$. Then we have a decomposition of the form

$$\mathcal{A} = \mathcal{A}_1 \oplus \cdots \oplus \mathcal{A}_d, \tag{1}$$

where $\mathcal{A}_i$ is a local algebra, for the maximal ideal $\mathbf{m}_{\zeta_i}$ defining the root ζ_i. From decomposition (1), we deduce that there exist orthogonal idempotents $\mathbf{e}_1, \ldots, \mathbf{e}_d$ satisfying

$$\mathbf{e}_1 + \cdots + \mathbf{e}_d \equiv 1 \text{ and } \mathbf{e}_i\,\mathbf{e}_j \equiv \begin{cases} 0 & \text{if } i \neq j, \\ \mathbf{e}_i & \text{if } i = j. \end{cases}$$

If $I = Q_1 \cap \cdots \cap Q_d$ is the minimal primary decomposition of I, we have $\mathbf{e}_i\mathcal{A} \sim R/Q_i$, where $\mathcal{A}_i = \mathbf{e}_i\,\mathcal{A}$ is a local algebra, for the maximal ideal $\mathbf{m}_{\zeta_i}$ defining the root ζ_i. Thus, to any root $\zeta \in \mathcal{Z}$, we associate an idempotent $\mathbf{e}_\zeta$.

2.2. Dual space. Let $\widehat{R}$ denote the dual of the $\mathbb{C}$-vector space R, that is, the space of linear forms

$$\begin{aligned} \Lambda : R &\to \mathbb{C}, \\ p &\mapsto \Lambda(p). \end{aligned}$$

(R will be the primal space for $\widehat{R}$.) Let us recall two celebrated examples, that is, the *evaluation at a fixed point* ζ,

$$\begin{aligned} \mathbf{1}_\zeta \,:\, & R \to \mathbb{C}, \\ & p \mapsto p(\zeta), \end{aligned}$$

and the map

$$\begin{aligned} (\mathbf{d}^{\mathbf{a}} = (\mathbf{d}_1)^{a_1} \cdots (\mathbf{d}_n)^{a_n}) : R &\to \mathbb{C} \\ p &\mapsto \frac{1}{\prod_{i=1}^n a_i!}\, (d_{x_1})^{a_1} \cdots (d_{x_n})^{a_n}\, (p)(0), \end{aligned} \tag{2}$$

where $\mathbf{a} = (a_1, \ldots, a_n)$ is any vector from $\mathbb{N}^n$ and d_{x_i} is the partial derivative with respect to the variable x_i. For any $\mathbf{b} = (b_1, \ldots, b_n) \in \mathbb{N}^n$, we have

$$\mathbf{d}^{\mathbf{a}}(\mathbf{x}^{\mathbf{b}}) = \begin{cases} 1 & \text{if } \forall i, a_i = b_i, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, $(\mathbf{d}^{\mathbf{a}})_{\mathbf{a}\in\mathbb{N}^n}$ is the dual basis of the primal monomial basis. Thus we decompose any linear form $\Lambda \in \widehat{R}$ as

$$\Lambda = \sum_{\mathbf{a}\in\mathbb{N}^n} \Lambda(\mathbf{x}^{\mathbf{a}})\, \mathbf{d}^{\mathbf{a}}. \tag{3}$$

Hereafter, *we will identify* $\widehat{R}$ *with* $\mathbb{C}[[\mathbf{d}_1, \ldots, \mathbf{d}_n]]$. The map $\Lambda \to \sum_{\mathbf{a}\in\mathbb{N}^n} \Lambda(\mathbf{x}^{\mathbf{a}})\, \mathbf{d}^{\mathbf{a}}$ defines a one-to-one correspondence between the set of linear forms Λ and the set $\mathbb{C}[[\mathbf{d}_1, \ldots \mathbf{d}_n]] = \mathbb{C}[[\mathbf{d}]] = \{\sum_{\mathbf{a}\in\mathbb{N}^n} \lambda_{\mathbf{a}} \mathbf{d}_1^{a_1} \cdots \mathbf{d}_n^{a_n}\}$ of polynomials in the variables $\mathbf{d}_1, \ldots, \mathbf{d}_n$.

The evaluation at 0 corresponds to the constant 1 under this definition. It will also be denoted by $\delta_0 = \mathbf{d}^0$.

We will denote by $\widehat{\mathcal{A}}$ and also by $I^\perp$ the subspace of $\widehat{R}$ made of those linear forms that vanish on the ideal I.

We now define multiplication of a linear form by a polynomial ($\widehat{R}$ is an R-module) as follows. For any $p \in R$ and $\Lambda \in \widehat{R}$, we write

$$\begin{aligned} p \star \Lambda : R &\to \mathbb{C}, \\ q &\mapsto \Lambda(p\, q). \end{aligned}$$

For any pair of elements $p \in R$ and $a \in \mathbb{N},\ a > 1$, we have

$$(d_{x_i})^a\, (x_i\, p)(0) = a\, (d_{x_i})^{a-1}\, p(0).$$

Consequently, for any pair $(p, \mathbf{a})$, $p \in R$, $\mathbf{a} = (a_1, \ldots, a_n) \in \mathbb{N}^n$ (where $a_i \neq 0$ for a fixed i), we obtain

$$\begin{aligned} x_i \star \mathbf{d}^{\mathbf{a}}(p) &= \mathbf{d}^{\mathbf{a}}(x_i\, p) \\ &= \mathbf{d}_1^{a_1} \cdots \mathbf{d}_{i-1}^{a_{i-1}} \mathbf{d}_i^{a_i - 1} \mathbf{d}_{i+1}^{a_{i+1}} \cdots \mathbf{d}_n^{a_n}(p); \end{aligned}$$

that is, x_i acts as the *inverse* of $\mathbf{d}_i$ in $\mathbb{C}[[\mathbf{d}]]$. For this reason, such a representation is referred to as the *inverse systems* (see, for instance, [23]). If $a_i = 0$, then $x_i \star \mathbf{d}^{\mathbf{a}}(p) = 0$, which allows us to redefine the product $p \star \Lambda$ as follows.

PROPOSITION 2.1. *For any pair $p, q \in R$ and any $\Lambda(\mathbf{d}) \in \mathbb{C}[[\mathbf{d}]]$, we have*

$$p \star \Lambda(q) = \Lambda(p\,q) = \pi_+(p(\mathbf{d}^{-1})\,\Lambda(\mathbf{d}))(q),$$

where π_+ is the projection mapping Laurent series onto the space generated by the monomials in $\mathbf{d}$ with positive exponents.

This yields the following algorithm.

ALGORITHM 2.2. *For any polynomial $p \in \langle \mathbf{x}^\alpha \rangle_{\alpha \in E}$ and a vector $[\Lambda(\mathbf{x}^\beta)]_{\beta \in E+F}$, compute the vector $[p \star \Lambda(\mathbf{x}^\beta)]_{\beta \in F}$ as follows:*

- *Write $\tilde{\Lambda}(\mathbf{d}) = \sum_{\beta \in E+F} \Lambda(\mathbf{x}^\beta)\,\mathbf{d}^\beta$.*
- *Compute the product $\rho(\mathbf{d}) = p(\mathbf{d}^{-1})\tilde{\Lambda}(\mathbf{d})$ in $\mathbb{C}[\mathbf{d}, \mathbf{d}^{-1}]$.*
- *Keep the coefficients ρ_α of $\mathbf{d}^\alpha$ for $\alpha \in F$.*

3. Quasi-Toeplitz and quasi-Hankel matrices. In this section, we describe the structure of the matrices and some tools that we will use for our algorithm design.

Let us recall first the known arithmetic complexity bounds for polynomial multiplication (see [2, pp. 56–64]), which is the basic step of our subsequent algorithms. Let $C_{PolMult}(E, F)$ denote the number of ops (that is, of arithmetic operations) required for the multiplication of a polynomial with support in E by a polynomial with support in F.

THEOREM 3.1. *Let $E + F = \{\alpha^i = (\alpha_1^{(i)}, \ldots, \alpha_n^{(i)}),\ i = 1, \ldots, N\}$ with $|\alpha^{(i)}| = \sum_j \alpha_j^{(i)} = d_i$ for $i = 1, \ldots, N$ and $d = \max_i(d_i)$. Let $C_{K;Eval}(G)$ ops suffice to evaluate a polynomial with a support G on a set of K points. Then we have*

$$C_{PolMut}(E, F) = \mathcal{O}\left(C_{N;Eval}(E) + C_{N;Eval}(F) + N\left(\log^2(N) + \log(d)\right)\right).$$

Proof. Apply the evaluation-interpolation techniques to multiply the two polynomials (cf. [2]). That is, first evaluate the input polynomials on a fixed set of N points, then multiply pairwise the computed values to obtain the values of the product on the same set, and finally interpolate from these values and compute the coefficients of the product by applying the (sparse) polynomial interpolation algorithm (cf. [2]). By summarizing the computational cost estimates, we obtain the theorem. □

For special sets E and F, we have better bounds.

THEOREM 3.2. *Let $E_d = [0, \ldots, d-1] \subset \mathbb{N}$. Then*

$$C_{PolMult}(E_d, E_d) = \mathcal{O}(d \log(d)).$$

THEOREM 3.3. *Let $E_{\mathbf{c}} = \{(\alpha_1, \ldots, \alpha_n)\ ;\ 0 \le \alpha_i \le c_i - 1\}$, $E_{\mathtt{d}} = \{(\beta_1, \ldots, \beta_n)\ ;\ 0 \le \beta_i \le d_i - 1\}$, $c = \max\{c_1, \ldots, c_n\}$, and $d = \max\{d_1, \ldots, d_n\}$. Then we have*

$$C_{PolMult}(E_{\mathbf{c}}, E_{\mathtt{d}}) = \mathcal{O}(M \log(M)),$$

where $M = f^n$ and $f = c + d + 1$.

THEOREM 3.4. *Let $E_{f,n}$ be the set of exponents having total degree at most f in n variables. Then*

$$C_{PolMult}(E_{c,n}, E_{d,n}) = \mathcal{O}(T \log^2(T)),$$

where $T = \binom{n+c+d}{n}$ is the number of monomials of degree at most $c+d$ in n variables.

REMARK 3.5. *Theorems 3.1 and 3.3 correspond, respectively, to lattice points in a product of intervals and in the scaled standard simplex and can be extended to the computations over any ring of constants (rather than over the complex field) at*

the expense of increasing their complexity bounds by at most the factors of $\log\log(N)$ *or* $\log\log(M)$*, respectively* [2]. *Theorem* 3.4 *can be extended similarly to any field of constants having characteristic* 0.

Next, by following [32], [31], we will extend the definitions of Toeplitz and Hankel matrices to the multivariate case. As we will see, these structures are omnipresent when we solve polynomial systems.

DEFINITION 3.6. *Let* E *and* F *be two finite subsets of* $\mathbb{N}^n$*, and let* $M = (m_{\alpha,\beta})_{\alpha\in E,\beta\in F}$ *be a matrix whose rows are indexed by the elements of* E *and columns by the elements of* F*. Let* $\mathtt{i}$ *denote the* i*th basis coordinate vector of* $\mathbb{N}^n$*.*

- $M = [m_{\alpha,\beta}]_{\alpha\in E,\beta\in F}$ *is an* (E,F) quasi-Toeplitz *matrix if and only if, for all* $\alpha \in E, \beta \in F$*, the entries* $m_{\alpha,\beta} = t_{\alpha-\beta}$ *depend only on* $\alpha - \beta$*, that is, if and only if, for* $i = 1,\dots,n$*, we have* $m_{\alpha+\mathtt{i},\beta+\mathtt{i}} = m_{\alpha,\beta}$*, provided that* $\alpha, \alpha+\mathtt{i} \in E; \beta, \beta+\mathtt{i} \in F$*; such a matrix* M *is associated with the polynomial* $T_M(\mathbf{x}) = \sum_{\mathbf{u}\in E+F} t_{\mathbf{u}}\,\mathbf{x}^{\mathbf{u}}$.
- M *is an* (E,F) quasi-Hankel *matrix if and only if, for all* $\alpha \in E, \beta \in F$*, the entries* $m_{\alpha,\beta} = h_{\alpha+\beta}$ *depend only on* $\alpha+\beta$*, that is, if and only if, for* $i = 1,\dots,n$*, we have* $m_{\alpha-\mathtt{i},\beta+\mathtt{i}} = m_{\alpha,\beta}$ *provided that* $\alpha, \alpha-i \in E; \beta, \beta+\mathtt{i} \in F$*; such a matrix* M *is associated with the Laurent polynomial* $H_M(\mathbf{d}) = \sum_{\mathbf{u}\in E-F} h_{\mathbf{u}}\mathbf{d}^{\mathbf{u}}$.

For $E = [0,\dots,m-1]$ and $F = [0,\dots,n-1]$ (resp., $F = [-n+1,\dots,0]$), Definition 3.6 turns into the usual definition of Toeplitz (resp., Hankel) matrices (see [2]). Quasi-Toeplitz matrices have also been studied under the name of multilevel Toeplitz matrices (see, e.g., [44]) in the restricted special case, where the sets E and F are rectangular (i.e., a product of intervals). For our study of polynomial systems of equations, using the latter restricted case is not sufficient, and our more general definitions are required.

The definitions can be extended immediately to all subsets E, F of $\mathbb{Z}^n$ if we work with the Laurent polynomials.

The classes of quasi-Toeplitz and quasi-Hankel matrices can be transformed into each other by means of multiplication by the reflection matrix, having ones on its antidiagonal and zeros elsewhere.

DEFINITION 3.7. *Let* $\pi_E : L \to L$ *be the projection map such that* $\pi_E(\mathbf{x}^\alpha) = \mathbf{x}^\alpha$ *if* $\alpha \in E$ *and* $\pi_E(\mathbf{x}^\alpha) = 0$ *otherwise. Also let* $\pi_E : \mathbb{C}[[\mathbf{d}]] \to \mathbb{C}[[\mathbf{d}]]$ *denote the projection map such that* $\pi_E(\mathbf{d}^\alpha) = \mathbf{d}^\alpha$ *if* $\alpha \in E$ *and* $\pi_E(\mathbf{d}^\alpha) = 0$ *otherwise.*

We can describe the quasi-Toeplitz and quasi-Hankel operators in terms of polynomial multiplication (see [30], [29]), and the next proposition reduces multiplication of an (E,F) quasi-Toeplitz (resp., quasi-Hankel) matrix by a vector $\mathbf{v} = [v_\beta] \in \mathbb{C}^F$ to (Laurent's) polynomial multiplication.

PROPOSITION 3.8. *The matrix* M *is an* (E,F) *quasi-Toeplitz (resp., an* (E,F) *quasi-Hankel) matrix if and only if it is the matrix of the operator* $\pi_E \circ \mu_{T_M} \circ \pi_F$ *(resp.,* $\pi_E \circ \mu_{H_M} \circ \pi_F$*), where, for any* $p \in L$*,* $\mu_p : q \mapsto p\,q$ *is the operator of multiplication by* p *in* L*.*

Proof (see [29]). We will give a proof only for an (E,F) quasi-Toeplitz matrix $M = (M_{\alpha,\beta})_{\alpha\in E,\beta\in F}$. (The proof is similar for a quasi-Hankel matrix.) The associated polynomial is $T_M(\mathbf{x}) = \sum_{\mathbf{u}\in E+F} t_{\mathbf{u}}\mathbf{x}^{\mathbf{u}}$. For any vector $\mathbf{v} = [v_\beta] \in \mathbb{C}^F$, let $v(\mathbf{x})$ denote

the polynomial $\sum_{\beta\in F} v_\beta \mathbf{x}^\beta$. Then

$$T_M(\mathbf{x})\, v(\mathbf{x}) = \sum_{\mathbf{u}\in E+F,\beta\in F} \mathbf{x}^{\mathbf{u}+\beta}\, t_{\mathbf{u}}\, v_\beta$$
$$= \sum_{\alpha=\mathbf{u}+\beta\in E+2\,F} \mathbf{x}^\alpha \left(\sum_{\beta\in F} t_{\alpha-\beta}\, v_\beta\right),$$

where we assume that $t_{\mathbf{u}} = 0$ if $\mathbf{u} \notin E + F$. Therefore, for $\alpha \in E$, the coefficient of $\mathbf{x}^\alpha$ equals

$$\sum_{\beta\in F} t_{\alpha-\beta}\, v_\beta = \sum_{\beta\in F} M_{\alpha,\beta}\, v_\beta,$$

which is precisely the coefficient α of $M\mathbf{v}$. □

ALGORITHM 3.9. *Multiplication of the (E, F) quasi-Toeplitz (resp., quasi-Hankel) matrix $M = (M_{\alpha,\beta})_{\alpha\in E,\beta\in F}$ by a vector $\mathbf{v} = [v_\beta] \in \mathbb{C}^F$:*

- *multiply the polynomials $T_M = \sum_{\mathbf{u}\in E+F} t_{\mathbf{u}}\, \mathbf{x}^{\mathbf{u}}$ (resp., $H_M(\mathbf{d}) = \sum_{\mathbf{u}\in E-F} h_{\mathbf{u}}\mathbf{d}^{\mathbf{u}}$) by $v(\mathbf{x}) = \sum_{\beta\in F} v_\beta \mathbf{x}^\beta$ (resp., $v(\mathbf{d}^{-1}) = \sum_{\beta\in F} v_\beta \mathbf{d}^{-\beta}$),*
- *and output the projection of the product on $\mathbf{x}^E$ (resp., $\mathbf{d}^E$).*

DEFINITION 3.10. *$C_{PolMult}(E, F)$ denotes the number of ops required to multiply a polynomial with a support in E by a polynomial with a support in F.*

Clearly, Algorithm 3.9 uses $C_{PolMult}(E+F, F)$ (resp., $C_{PolMult}(E-F, -F)$) ops.

PROPOSITION 3.11.

(a) *An (E, F) quasi-Hankel (resp., an (E, F) quasi-Toeplitz) matrix M can be multiplied by a vector by using $\mathcal{O}(N \log^2(N) + N \log(d) + C_{M,N})$ ops, where $d = \deg H_M$ (resp., $\deg T_M$) , $N = \lfloor E - 2\,F \rceil$ (resp., $\lfloor E + 2F \rceil$), and $C_{M,N}$ denotes the cost of the evaluation of all monomials of the polynomial H_M (resp., T_M) on a fixed set of N points.*

(b) *In particular, the ops bound becomes $\mathcal{O}(M \log(M))$, where $E + F = E_{\mathbf{c}}, F = E_{\mathbf{d}}$ and $E_{\mathbf{c}}, E_{\mathbf{d}}$ and $M = (c + d + 1)^n$ are defined as in Theorem 3.3, whereas*

(c) *the bound turns into $\mathcal{O}(T \log^2(T))$, where $E + F = E_{c,n}, F = E_{d,n}$ and $E_{c,n}, E_{d,n}$, and $T = \binom{n+c+d}{n}$ are defined as in Theorem 3.4.*

Proof. Reduce the problem to computing the product of the two polynomials $H_M(\mathbf{x})$ (resp., $T_M(\mathbf{x})$) and $V(\mathbf{x})$, and then apply Theorems 3.1–3.4. □

Applying these results, we can bound the number of ops in Algorithm 2.2 as follows.

PROPOSITION 3.12. *For any polynomial $p \in R$ with support in E and any vector $[\Lambda(\mathbf{x}^\alpha)]_{\alpha\in E+F}$ (with $\Lambda \in \widehat{R}$), the vector $[p \star \Lambda(\mathbf{x}^\beta)]_{\beta\in F}$ can be computed in $\mathcal{O}(\lfloor E + F \rceil \log^2(\lfloor E + F \rceil))$ ops.*

Once we have a fast matrix-by-vector multiplication, a nonsingular linear system of equations can also be solved quickly by means of the conjugate gradient algorithm, which is based on the following theorem [19, section 10.2].

THEOREM 3.13. *Let $W\,\mathbf{v} = \mathbf{w}$ be a nonsingular linear system of N equations. Then N multiplications of each of the matrices W and W^T by vectors and $\mathcal{O}(N^2)$ additional ops suffice to compute the solution $\mathbf{v}$ to this linear system.*

Note that W^T is a quasi-Toeplitz (resp., quasi-Hankel) matrix if W is, and then both matrices can be multiplied by a vector quickly (see Proposition 3.11). Therefore, in the cases of quasi-Toeplitz and quasi-Hankel matrices W, Theorem 3.13 yields a

fast algorithm for solving the linear system $W\,\mathbf{v} = \mathbf{w}$. We will also need the following related result.

THEOREM 3.14 (see [32]). *Let W be an $N \times N$ real symmetric or Hermitian matrix. Let S be a fixed finite set of complex numbers. Then there is a randomized algorithm that selects N random parameters from the set S independently of each other (under uniform probability distribution on S) and either fails with a probability of at most $\frac{(N+1)N}{2\lfloor S\rceil}$ or performs $\mathcal{O}(N)$ multiplications of the matrix W by vectors and $\mathcal{O}(N^2\log(N))$ other ops to compute the rank and the signature of W.*

Hereafter, random selection of elements of a set S as in Theorem 3.14 will be called *sampling*.

Proof. To support the claimed estimate, we first tridiagonalize the matrix W by the Lanczos randomized algorithm [2, pp. 118–119], which involves an initial vector of dimension N and fails with a probability of $\frac{(N+1)N}{2\lfloor S\rceil}$ if the N coordinates of the vector have been sampled at random from the set S. The above bound on the failure probability and the cost bound of $\mathcal{O}(N)$ multiplications of the matrix W by vectors and $\mathcal{O}(N^2\log(N))$ other ops of this stage have been proved in [38]. Then, in $\mathcal{O}(N)$ ops, we compute the Sturm sequence of the N values of the determinants of all of the $k \times k$ northwestern (leading principal) submatrices of W for $k = 1, \dots, N$ and obtain the numbers N_+ and N_- of positive and negative eigenvalues of W from the Sturm sequence (cf., e.g., [3]). These two numbers immediately define the rank and the signature of W. ∎

Combining Proposition 3.11 with Theorems 3.13 and 3.14 gives us the next corollary.

COROLLARY 3.15. *For an $N \times N$ quasi-Toeplitz or quasi-Hankel matrix W, the estimates of Theorems* 3.13 *and* 3.14 *turn into $O(N^2\log(N))$ ops if the matrix has a maximal (c,d) support where $c+d=N$. They turn into $\mathcal{O}(N^2\log^2(N))$ ops if the matrix has a total degree (c,d) support where $c+d=O(N)$ and into $\mathcal{O}((\log^2(N)+\log(d))N^2+C_{W,N})$ otherwise, where d and $C_{W,N}$ are defined as in Proposition* 3.11 (a) *for $M=W$.*

REMARK 3.16. *Hereafter, we will refer to the matrices of case* (b) *in Proposition* 3.11 *as the matrices with support of the maximal degree (c,d) and to the matrices of case* (c) *as the ones with support of the total degree (c,d). Furthermore, stating our estimates for the arithmetic complexity of computations, we will assume that the input polynomials have the maximal degree (c,d) support. That is, we will rely on Theorem* 3.3 *and Proposition* 3.11 (b)*, and we will express the estimates in terms of the cardinality of the supports E and/or F or in terms of an upper bound D on the number of common roots of the input polynomials. The estimates can be easily extended to the other cases based on Theorem* 3.1 *or* 3.4 *and Proposition* 3.11 (a) *or* (c) *instead of Theorem* 3.3 *and Proposition* 3.11 (b)*. In the latter case (Theorem* 3.4 *and Proposition* 3.11 (c)*), the cost estimates increase by the factors* $\log(D)$, $\log(\lfloor E\rceil)$, *or* $\log(\lfloor F\rceil)$, *respectively. In case Theorems* 3.1 *and Proposition* 3.11 (a) *are used, the estimates are expressed in terms of the bounds $C_{PolMult}(G,H)$ or $C_{M,N}$ for appropriate sets G and H, matrix M, and integer N. The latter case covers sparse input polynomials for which the respective bounds $C_{PolMult}(G,H)$ and $C_{M,N}$ are smaller than for the general (or dense) input, although they are not expressed solely in terms of the cardinality D. (They also depend on the degree of the monomials or the cardinality of the supports of the input polynomial system.)*

4. Computation of a nondegenerate linear form. In this section, we will compute a nondegenerate linear form on $\mathcal{A}$ provided that we are given a basis $(\mathbf{x}^\alpha)_{\alpha\in E}$ of $\mathcal{A}$ and the normal form of the elements on the boundary of this basis. This is the case, for instance, when we have computed a Gröbner basis of our ideal I for any monomial ordering [9] or when we apply any other normal-form algorithm [28], [33].

DEFINITION 4.1.

- *Let $v_i = (\delta_{i,1}, \dots, \delta_{i,n}) \in \mathbb{N}^n$, where $\delta_{i,j}$ is the Kronecker symbol.*
- *For all $A \subset \mathbb{N}^n$, $\Omega(A) = \{\alpha \in \mathbb{N}^n : \alpha \in A \text{ or } \exists i \in \{1, \dots, n\}, \alpha - v_i \in A\}$.*
- *N_α for $\alpha \in \Omega(E)$ is the normal form of the monomial $\mathbf{x}^\alpha \bmod I$, i.e., the canonical representative of its class modulo the ideal I. $N_\alpha = \mathbf{x}^\alpha$ if $\alpha \in E$, and*

$$N_\alpha = \sum_{\beta\in E} n_{\alpha,\beta}\mathbf{x}^\beta$$

if $\alpha \in \Omega(E) - E$.

Our goal is to obtain the coefficients $\tau(\mathbf{x}^\alpha)$ for $\alpha \in E+E+E$, where $\tau \in \widehat{\mathcal{A}} = I^\perp$ is a generic linear form. We will compute them, by induction, under the following hypothesis.

HYPOTHESIS 4.2.

- *$(x^\alpha)_{\alpha\in E}$ is stable under derivation, that is, $\alpha = \alpha' + v_i \in E$ implies that $\alpha' \in E$.*
- *N_α, the normal form of $\mathbf{x}^\alpha$, is available for every $\alpha \in \Omega(E)$.*
- *The values $\tau_\alpha = \tau(x^\alpha)$ are available for all $\alpha \in E$, where τ is not degenerate $\in \widehat{\mathcal{A}} = I^\perp$.*

For the third part, we can remark that a random choice of $\tau(\mathbf{x}^\alpha)$ will imply with a high probability that τ does not degenerate. Our procedure is based on the following property.

PROPOSITION 4.3. *For each $\alpha \in \Omega(E)$, we have $\tau_\alpha = \tau(N_\alpha) = \sum_{\beta\in E} n_{\alpha,\beta}\tau_\beta$. This value can be computed by applying $\mathcal{O}(D)$ ops, where $D = \lfloor E \rceil$. More generally, for all $\gamma \in E$ we have the following inductive relation:*

$$\tau_{\alpha+\gamma} = \sum_{\beta\in E} n_{\alpha,\beta}\tau_{\beta+\gamma}.$$

Now assume that we have computed all of the values τ_β for $\beta \in \Omega(E)$, and let $\alpha = \alpha_0 + v_i \in \Omega(\Omega(E))$ with $\alpha_0 \in \Omega(E)$. Then

$$\tau(\mathbf{x}^\alpha) = \tau(x_i N_{\alpha_0}) = \sum_{\beta\in E} n_{\alpha_0,\beta}\tau\left(x_i\mathbf{x}^\beta\right).$$

We know all of the $n_{\alpha_0,\beta}$ and all of the $\tau\left(x_i\mathbf{x}^\beta\right)$ because $\beta + v_i \in \Omega(E)$. Therefore, we obtain $\tau_\alpha = \sum_{\beta\in E} n_{\alpha_0,\beta}\tau_{\beta+v_i}$ by computing a scalar product. Recursively, this leads us to the following inductive definition of the "levels" Ω_i.

DEFINITION 4.4. *Write $\Omega_0 = E$, $\Omega_1 = \Omega(E)$ and $\Omega_i = \Omega(\Omega_{i-1}) \cap (E + E + E)$, $i = 2, 3, \dots$, and write $h = \max\{|\alpha| : \alpha \in E\}$ so that $E + E + E = \Omega_{2h}$.*

PROPOSITION 4.5. *For every $\alpha \in \Omega_i$, there is $\alpha' \in \mathbb{N}^n$ and $\alpha_1 \in \Omega_1 - \Omega_0$ such that $\alpha = \alpha_1 + \alpha'$ with $|\alpha'| \le i - 1$ and for all $\beta \in E$ we have $\beta + \alpha' \in \Omega_{i-1}$.*

Proof. Assume that $i > 0$. Let $\alpha \in \Omega_i \subset E + E + E$. Then α can be decomposed as follows: $\alpha = \gamma_0 + \gamma_1 + \gamma_2$ with $\gamma_0, \gamma_1, \gamma_2 \in E$ and $|\gamma_1 + \gamma_2| = i$. As $i > 1$, there exists $\alpha' = \gamma_1 + \gamma_2 - v_j \in \mathbb{N}^n$, and because $(\mathbf{x}^\alpha)_{\alpha\in E}$ is stable by Hypothesis 4.2, we have

$\alpha' \in E + E$. It follows that $\alpha = \alpha_1 + \alpha'$, where $\alpha_1 = \gamma_0 + v_j \in \Omega_1$ and $|\alpha'| \leq i - 1$. Therefore, for all $\beta \in E$, $\beta + \alpha' \in \Omega_{i-1}$, which completes the proof. ∎

Assume now that we have already computed all of the values τ_β for $\beta \in \Omega_{i-1}$. Then, according to Proposition 4.5, for any $\alpha \in \Omega_i$, we have $\alpha = \alpha_1 + \alpha'$, with $\alpha_1 \in \Omega_1$ and $|\alpha'| \leq i - 1$. Thus, if $\alpha_1 \in \Omega_1 - \Omega_0$, we have

$$\tau(\mathbf{x}^\alpha) = \tau(\mathbf{x}^{\alpha_1}\, \mathbf{x}^{\alpha'}) = \sum_{\beta \in E} n_{\alpha_1,\beta} \tau(\mathbf{x}^{\beta+\alpha'})$$

with $\beta + \alpha' \in \Omega_{i-1}$; otherwise, if $\alpha_1 \in \Omega_0$, we have $\alpha = \alpha_1 + \alpha' \in \Omega_{i-1}$. In other words, we can compute by induction the values of τ on Ω_i from its values on Ω_{i-1}. This yields the following recursive algorithm for the computation of $\tau(\mathbf{x}^\alpha)$ with $\alpha \in E + E + E$.

ALGORITHM 4.6. *Compute the first coefficients of the series associated with a linear form τ of $I^\perp$ as follows:*

1. *For i from 1 to $2h$ do for each $\alpha = \alpha_0 + \alpha_1 \in \Omega_i$ with α_0 and α_1 as in Proposition 4.5 compute $\tau_\alpha = \sum_{\beta \in E} n_{\alpha_1,\beta} \tau_{\alpha_0+\beta}$*
   End for
2. *Compute and output the polynomial $S = \sum_{\alpha \in E+E+E} \tau_\alpha \mathtt{d}^\alpha$.*

PROPOSITION 4.7. *The arithmetic complexity of Algorithm 4.6 is $\mathcal{O}\left(3^n D^2\right)$.*

Proof. For each element $\alpha \in E + E + E$, we compute τ_α in $\mathcal{O}(D)$ arithmetic operations, and there are at most $\mathcal{O}(3^n D)$ elements in $E + E + E$, which gives us the claimed arithmetic complexity estimate. ∎

5. Arithmetic in the algebra $\mathcal{A}$. Our algorithms in the next sections perform computations in $\mathcal{A}$ efficiently based on the knowledge of a certain linear form on $\mathcal{A}$ (such as the one computed in the previous section), which induces a nondegenerate inner product. More precisely, we assume that the following items are available.

Basic set of items:

- *a linear form $\tau \in \widehat{\mathcal{A}} = I^\perp$, such that the bilinear form $\tau(a\, b)$ from $\mathcal{A} \times \mathcal{A}$ to $\mathbb{C}$ is nondegenerate,*
- *a monomial basis $(\mathbf{x}^\alpha)_{\alpha \in E}$ of $\mathcal{A}$,*
- *the coefficients $(\tau(\mathbf{x}^\alpha))_{\alpha \in F}$, where $F = E + E + E$.*

The number of elements in E is the dimension D of $\mathcal{A}$ over $\mathbb{C}$. We describe basic operations in the quotient ring $\mathcal{A}$ in terms of the following quasi-Hankel matrix.

DEFINITION 5.1. *For any Λ in $\widehat{\mathcal{A}}$ and for any subset F of $\mathbb{N}^n$, let $\mathtt{H}_\Lambda^F$ denote the quasi-Hankel matrix, $\mathtt{H}_\Lambda^F = (\Lambda(\mathbf{x}^{\alpha+\beta}))_{\alpha,\beta \in F}$.*

By default we will assume we are dealing with the maximal degree support whenever we state our arithmetic complexity estimates (see Remark 3.16).

PROPOSITION 5.2. *The matrix $\mathtt{H}_\Lambda^F$ can be multiplied by a vector by using $\mathcal{O}(3^n \lfloor F \rceil \log(3^n \lfloor F \rceil))$ ops.*

Proof. Apply Proposition 3.11 (b) to the (F, F) quasi-Hankel matrix $\mathtt{H}_\Lambda^F$, and observe that $\lfloor F + F + F \rceil = 3^n \lfloor F \rceil$. ∎

Combining Corollary 3.15 and Proposition 5.2 implies the following result.

PROPOSITION 5.3. *Check if the linear system $\mathtt{H}_\Lambda^F \mathbf{u} = \mathbf{v}$ has a unique solution, and, if so, computing the solution requires $\mathcal{O}(3^n \lfloor F \rceil^2 \log(3^n \lfloor F \rceil))$ ops. The same cost estimate applies to the computation of the rank of the matrix $\mathtt{H}_\Lambda^F$, which involves randomization with $\lceil F \rceil$ random parameters and has a failure probability of at most $(\lfloor F \rceil + 1) \lfloor F \rfloor / (2 \lfloor S \rceil)$ provided that the parameters have been sampled from a fixed finite set S.*

5.1. Dual basis. As τ defines a nondegenerate bilinear form, there exists a set of polynomials $(\mathbf{w}_\alpha)_{\alpha\in E}$ such that $\tau(\mathbf{x}^\alpha\,\mathbf{w}_\beta)=\delta_{\alpha,\beta}$, $\delta_{\alpha,\beta}$ being Kronecker's symbol, $\delta_{\alpha,\alpha}=1$, and $\delta_{\alpha,\beta}=0$ if $\alpha\neq\beta$. The set $(\mathbf{w}_\alpha)_{\alpha\in E}$ is called the *dual basis* of $(\mathbf{x}^\alpha)_{\alpha\in E}$ for τ.

PROPOSITION 5.4 (projection formula). *For any $p\in R$, we have*

$$p\equiv\sum_{\alpha\in E}\tau(p\,\mathbf{w}_\alpha)\mathbf{x}^\alpha\equiv\sum_{\alpha\in E}\tau(p\,\mathbf{x}^\alpha)\mathbf{w}_\alpha. \tag{4}$$

Proof. See [7], [11]. □

DEFINITION 5.5. *For any $p\in\mathcal{A}$, denote by $[p]_{\mathbf{x}}$ and $[p]_{\mathbf{w}}$ the coordinate vectors of p in the bases $(\mathbf{x}^\alpha)_{\alpha\in E}$ and $(\mathbf{w}_\alpha)_{\alpha\in E}$, respectively.*

Let $\mathbf{w}_\alpha=\sum_{\beta\in E}w_{\beta,\alpha}\,\mathbf{x}^\beta$, and let $\mathtt{W}_\tau=(w_{\alpha,\beta})_{\alpha,\beta\in E}$ be the coefficient matrix. By the definition of the dual basis,

$$\tau(\mathbf{w}_\alpha\,\mathbf{x}^\gamma)=\sum_{\beta\in E}w_{\alpha,\beta}\,\tau(\mathbf{x}^{\beta+\gamma}) \tag{5}$$

is 1 if $\alpha=\gamma$ and 0 elsewhere. In terms of matrices, (5) implies that

$$\mathtt{H}_\tau\,\mathtt{W}_\tau=\mathbb{I}_D, \tag{6}$$

where $\mathtt{H}_\tau=\mathtt{H}_\tau^E=(\tau(\mathbf{x}^{\beta+\gamma}))_{\beta,\gamma\in E}$. From the definition of $\mathtt{W}_\tau$ and (6), we deduce that

$$[p]_{\mathbf{x}}=\mathtt{W}_\tau\,[p]_{\mathbf{w}},\ [p]_{\mathbf{w}}=\mathtt{H}_\tau\,[p]_{\mathbf{x}}. \tag{7}$$

The next result follows from Proposition 5.3.

PROPOSITION 5.6. *For any $p\in\mathcal{A}$, the coordinates $[p]_{\mathbf{x}}$ of p in the monomial basis can be computed from its coordinates $[p]_{\mathbf{w}}$ in the dual basis by using $\mathcal{O}(3^nD^2\,\log(3^nD))$ ops.*

5.2. Product in $\mathcal{A}$. We apply projection formula (4) and, for any $f\in R$, deduce that $f\equiv\sum_{\alpha\in E}\tau(f\,\mathbf{x}^\alpha)\,\mathbf{w}_\alpha=\sum_{\alpha\in E}f\star\tau(\mathbf{x}^\alpha)\,\mathbf{w}_\alpha$ in $\mathcal{A}$. Furthermore, by expressing the linear form $f\star\tau$ as a formal power series, we obtain $f\star\tau=\sum_{\alpha\in\mathbb{N}^n}\,f\star\tau(\mathbf{x}^\alpha)\,\mathbf{d}^\alpha$ so that the coefficients of $(\mathbf{d}^\alpha)_{\alpha\in E}$ in the expansion of $f\star\tau$ are the coefficients $[f]_{\mathbf{w}}$ of f in the dual basis $(\mathbf{w}_\alpha)_{\alpha\in E}$.

Similarly, for any $f,g\in\mathcal{A}$, the coefficients of $(\mathbf{d}^\alpha)_{\alpha\in E}$ in $fg\star\tau$ are the coefficients $[fg]_{\mathbf{w}}$ of $f\,g$ in the dual basis $(\mathbf{w}_\alpha)_{\alpha\in E}$. This leads to the following algorithm for computing the product in $\mathcal{A}$.

ALGORITHM 5.7. *For any pair $f,g\in\langle\mathbf{x}^\alpha\rangle_{\alpha\in E}$, compute the product fg in the basis $\langle\mathbf{x}^\alpha\rangle_{\alpha\in E}$ of $\mathcal{A}$ as follows:*

1. *Compute the coefficients of $(\mathbf{d}^\alpha)_{\alpha\in E}$ in the product $f\,g\star\tau$.*
2. *Obtain the coefficients $[f\,g]_{\mathbf{w}}$ from the first coefficients of $fg\star\tau$.*
3. *Solve in $\mathbf{u}$ the linear system $[f\,g]_{\mathbf{w}}=\mathtt{H}_\tau\,\mathbf{u}$.*

Output the vector $\mathbf{u}$, which is the coordinate vector $[f\,g]_{\mathbf{x}}$ of $f\,g$ in the monomial basis of $\mathcal{A}$.

PROPOSITION 5.8. *The product $f\,g$ can be computed in $\mathcal{O}(3^nD^2\log(3^nD))$ ops.*

Proof. $f\,g\star\tau$ is the product of polynomials with supports in $-E$ or $E+E+E$. Such a product can be computed in $\mathcal{O}(3^nD\log^2(3^nD))$ ops (see Proposition 3.11 and Remark 3.16 and observe that $\lfloor E+E+E\rceil=\mathcal{O}\,(3^n\lfloor E\rceil)$). The complexity of the third step is bounded according to Proposition 5.3 (with $F=E$). □

5.3. Inversion in $\mathcal{A}$. The projection formula of Proposition 5.4 implies that $f\,\mathbf{x}^\alpha = \sum_{\beta\in E} f \star \tau(\mathbf{x}^{\alpha+\beta})\,\mathbf{w}_\beta$, which means that $[f\,\mathbf{x}^\alpha]_{\mathbf{w}}$ is the coordinate vector $[f \star \tau(\mathbf{x}^{\alpha+\beta})]_{\beta\in E}$, that is, the column of the matrix $\mathtt{H}_{f\star\tau}$ indexed by α. In other words, $[f\,\mathbf{x}^\alpha]_{\mathbf{w}} = \mathtt{H}_{f\star\tau}\,[\mathbf{x}^\alpha]_{\mathbf{x}}$. By linearity, for any $g \in \mathcal{A}$, we have

$$[f\,g]_{\mathbf{w}} = \mathtt{H}_{f\star\tau}[g]_{\mathbf{x}} = \mathtt{H}_\tau\,[f\,g]_{\mathbf{x}},$$

according to (7). Thus, if $fg = 1$, that is, if $g = f^{-1}$, we have $\mathtt{H}_{f\star\tau}[g]_{\mathbf{x}} = \mathtt{H}_\tau\,[1]_{\mathbf{x}}$. This leads to the following algorithm for computing the inverses (reciprocals) in $\mathcal{A}$.

ALGORITHM 5.9. *For any $f \in \langle \mathbf{x}^\alpha\rangle_{\alpha\in E}$, verify whether there exists the inverse (reciprocal) of $f \in \mathcal{A}$, and, if so, compute it.*

1. *Compute* $\mathbf{v} = \mathtt{H}_\tau\,[1]_{\mathbf{x}}$.
2. *Solve in* $\mathbf{u}$ *the linear system* $\mathtt{H}_{f\star\tau}\mathbf{u} = \mathbf{v}$ *or output* FAILURE *if the matrix* $\mathtt{H}_\tau$ *is not invertible.*

Output the vector $\mathbf{u}$*, which is the coordinate vector* $[f^{-1}]_{\mathbf{x}}$ *of* f^{-1} *in the monomial basis of* $\mathcal{A}$.

By combining Propositions 5.2 and 5.3 and Remark 3.16, we obtain the following proposition.

PROPOSITION 5.10. *The inverse (reciprocal)* f^{-1} *of an element* f *of* $\mathcal{A}$ *can be computed by using* $\mathcal{O}(3^n D^2 \log(3^n D))$ *ops.*

6. Iterative methods. Our algorithms for the root approximation will essentially amount to computing nontrivial idempotents in the quotient algebra $\mathcal{A}$ by iterative processes with the subsequent simple recovery of the roots from the idempotents. The algorithms work in $\mathbb{C}^D$, and we will write $\mathbf{i} = \sqrt{-1}$. More rudimentary univariate versions of such algorithms were studied in [6]. We will use the basic operations in the quotient algebra $\mathcal{A}$ in order to devise two iterative methods, which will converge to nontrivial idempotents. We will first consider an iteration associated to a slight modification of the so-called *Joukovski* map (see [20], [6]): $z \mapsto \frac{1}{2}(z + \frac{1}{z})$ and its variant $z \mapsto \frac{1}{2}(z - \frac{1}{z})$. The two attractive fixed points of this map are 1 and -1; for its variant, they turn into $\mathbf{i}$ and $-\mathbf{i}$.

ALGORITHM 6.1. *Sign iteration. Choose* $u_0 = h \in \langle \mathbf{x}^\alpha\rangle_{\alpha\in E}$*, and recursively compute* $u_{k+1} \equiv \frac{1}{2}(u_k - \frac{1}{u_k}) \in \mathcal{A},\ k = 0, 1, \dots$.

By applying Proposition 5.10 and Remark 3.16, we obtain the following result.

PROPOSITION 6.2. *Each iteration of Algorithm* 6.1 *requires* $\mathcal{O}(3^n D^2 \log(3^n D))$ *ops.*

Proof. Apply Proposition 5.3 and Remark 3.16 to estimate the arithmetic cost of the computation of the inverse (reciprocal) of an element of $\mathcal{A}$. To yield the claimed cost bound of Proposition 6.2, it remains to compute a linear combination of u_n and u_n^{-1} in $\mathcal{O}(D)$ ops by direct operations on vectors of size D. ∎

Hereafter, $\Re(h)$ and $\Im(h)$ denote the real and the imaginary parts of a complex number h, respectively. Recall that we write ζ to denote the common roots $\zeta \in \mathcal{Z}(I)$ of given polynomials $f_1, \dots, f_m$.

REMARK 6.3. *In Proposition* 6.4*, we will assume that* $J(h(\zeta)) \neq 0$ *for all* $\zeta \in \mathcal{Z}(I)$ *and, in Proposition* 6.6*, that* $|h(\zeta)|$ *is minimized for a unique root* $\zeta \in \mathcal{Z}(I)$*. These assumptions are satisfied for a generic system of polynomials or a generic polynomial* h.

PROPOSITION 6.4. *The sequence* $(u_0, u_1, \dots)$ *of Algorithm* 6.1 *converges quadratically to* $\sigma = \sum_{\Im(h(\zeta))>0} \mathbf{e}_\zeta - \sum_{\Im(h(\zeta))<0} \mathbf{e}_\zeta$*, and we have*

$$\|u_n - \sigma\| \le K \times \rho^{2^n}$$

(for some constant K), where

$$\rho^+ = \max_{\Im(h(\zeta))>0, \zeta\in\mathcal{Z}(I)} \left|\frac{h(\zeta)-\mathbf{i}}{h(\zeta)+\mathbf{i}}\right|,$$

$$\rho^- = \max_{\Im(h(\zeta))<0, \zeta\in\mathcal{Z}(I)} \left|\frac{h(\zeta)+\mathbf{i}}{h(\zeta)-\mathbf{i}}\right|,$$

$\mathbf{i}=\sqrt{-1}$, *and* $\rho=\max\{\rho^+,\rho^-\}$.

Proof. Apply the classical convergence analysis of the Joukovski map (see [20]) to the matrices of multiplication by u_n in $\mathcal{A}$, whose eigenvalues are $\{u_n(\zeta), \zeta\in\mathcal{Z}(I)\}$. □

Let

$$\mathbf{e}^+ = \sum_{\Im(h(\zeta))>0} \mathbf{e}_\zeta = \frac{1}{2}(1+\sigma), \quad \mathbf{e}^- = \sum_{\Im(h(\zeta))\le 0} \mathbf{e}_\zeta = \frac{1}{2}(1-\sigma)$$

denote the two sums of the idempotents associated to the roots $\zeta\in\mathcal{Z}$ such that $\Im(h(\zeta))>0$ and $\Im(h(\zeta))<0$, respectively.

If $h(\mathbf{x})$ is a linear function in $\mathbf{x}$, then each of the idempotents $\mathbf{e}^+$ and $\mathbf{e}^-$ is associated with all of the roots lying in a fixed half-space of $\mathbb{C}^n$ defined by the inequalities $\Im(h(\zeta))>0$ or $\Im(h(\zeta))<0$. Conversely, an appropriate linear function $h(\mathbf{x})$ defines the idempotents $\mathbf{e}^+$ and $\mathbf{e}^-$ associated with any fixed half-space of $\mathbb{C}^n$. Furthermore, for any fixed polytope in $\mathbb{C}^n$ defined as the intersection of half-spaces, we may compute the family of the associated idempotents whose product will be associated with the polytope. In particular, any bounded box is the intersection of $4n$ half-spaces, and the associated idempotent can be computed in $4n$ applications of Algorithm 6.1. Let us specify the case in which the polytope is the almost flat unbounded box approximating the real manifold $R^n=\{\mathbf{x}:\Im(x_i)=0, i=1,\dots,n\}$. In this case, the choices of $h=x_i-\epsilon$ and $h=x_i+\epsilon$ allow us to approximate the two idempotents

$$\mathbf{e}^-_{i,\epsilon} = \sum_{\Im(\zeta_i)<\epsilon} \mathbf{e}_\zeta, \quad \mathbf{e}^+_{i,\epsilon} = \sum_{\Im(\zeta_i)>-\epsilon} \mathbf{e}_\zeta.$$

Their product can be computed in $\mathcal{O}(3^nD^2\log(3^nD))$ ops to yield $\mathbf{r}_{i,\epsilon}=\sum_{|\Im(\zeta_i)|<\epsilon}\mathbf{e}_\zeta$, and the product $\mathbf{r}_\epsilon\equiv\mathbf{r}_{1,\epsilon}\cdots\mathbf{r}_{n,\epsilon}$ can be computed in $\mathcal{O}(3^nD^2\log(3^nD))$ ops to yield the sum of the fundamental idempotents whose associated roots of the polynomial system are nearly real.

ALGORITHM 6.5. *Computing the sum of the fundamental (nearly real) idempotents.*

- *For i from 1 to n do*
  $u_0=x_i\pm\epsilon$; $u_1:\equiv\frac{1}{2}(u_0-\frac{1}{u_0})$ in $\mathcal{A}$; $k:=1$;
  while $\|u_k-u_{k-1}\|<2^{-b}$ do $\{\ u_{k+1}:=\frac{1}{2}(u_k-\frac{1}{u_k})$; $k:=k+1\ \}$
  Compute $\mathbf{e}^\pm_{i,e}$ and $\mathbf{r}_{i,\epsilon}$.
- *Compute and output the product $\mathbf{r}_\epsilon\equiv\mathbf{r}_{1,\epsilon}\cdots\mathbf{r}_{n,\epsilon}$ in $\mathcal{A}$.*

According to Propositions 6.2 and 6.4 and Remark 3.16, we have the following proposition.

PROPOSITION 6.6. *An approximation of $\mathbf{r}_\epsilon$ (within the error bound $\epsilon=2^{-b}$) can be computed in $\mathcal{O}(\mu\,3^nD^2\ \log(3^nD))$ ops, where*

$$\mu=\mu(b,\rho)=\log|b/\log(\rho)| \tag{8}$$

and

$$\rho = \max_i\{ \quad \max_{\Im(\zeta_i)>0,\zeta\in\mathcal{Z}(I)} |\tfrac{\zeta_i-\mathbf{i}}{\zeta_i+\mathbf{i}}|, \quad \max_{\Im(\zeta_i)<0,\zeta\in\mathcal{Z}(I)} |\tfrac{\zeta_i+\mathbf{i}}{\zeta_i-\mathbf{i}}| \quad \}. \tag{9}$$

The second iterative method is the quadratic power method.

ALGORITHM 6.7. *Quadratic power iteration. Choose* $u_0 = h \in \langle \mathbf{x}^\alpha \rangle_{\alpha\in E}$, *and recursively compute* $u_{n+1} \equiv u_n^2 \in \mathcal{A}$, $n = 0, 1, \ldots$.

Each step of this iteration requires at most $\mathcal{O}\left(3^n D^2 \log\left(3^n D\right)\right)$ ops, and we have the following property.

PROPOSITION 6.8. *An approximation (within the error bound* $\epsilon = 2^{-b}$*) of the idempotent* $\mathbf{e}_\zeta$ *such that a unique simple root* ζ *minimizes* $|h|$ *on* $\mathcal{Z}(I)$ *can be computed in* $\mathcal{O}\left(\nu 3^n D^2 \log\left(3^n D\right)\right)$ *ops, where*

$$\nu = \nu\left(b, \gamma\right) = \log\left(b/|\log\left(\gamma\right)|\right), \tag{10}$$

$$\gamma = \left|\frac{h(\zeta)}{h(\zeta')}\right|, \tag{11}$$

and $|h(\zeta')|$ *is the second smallest value of* $|h|$ *over* $\mathcal{Z}(I)$.

Proof. We rely on the convergence analysis of the quadratic power method applied to the matrices of multiplication by u_n in $\mathcal{A}$, whose eigenvalues are $\{u_n(\zeta), \zeta \in \mathcal{Z}(I)\}$. ∎

7. Counting and approximating the roots and the real roots. In this section, we will apply the techniques and algorithms of the previous sections to the problems of counting and approximation of the roots of the system $\mathbf{p} = \mathbf{0}$.

In the algorithms for counting roots, we will use the randomization required to apply Theorem 3.13. The resulting randomized algorithms and the computational complexity estimates for counting (excluding the preprocessing stage of subsection 7.5) will apply to any 0-dimensional polynomial system.

In the approximation algorithms, we do not need randomization except for the ensurance of the assumption of Propositions 6.4 (cf. Remark 6.3), but the estimates for the computational cost depend on the parameters ρ and γ of the two latter propositions (cf. (8), (11)) and remain meaningful unless these parameters are extremely close to 1.

7.1. Counting the roots and the real roots.

THEOREM 7.1 (see [29]). *The number of the roots (resp., real roots) of the system* $\mathbf{p} = \mathbf{0}$ *is given by the rank (resp., the signature) of the quasi-Hankel matrix* H_τ^E.

Theorem 7.1, Corollary 3.15, and Remark 3.16 together imply the following result.

COROLLARY 7.2. *The numbers of the roots and of the real roots of the polynomial system* $\mathbf{p} = \mathbf{0}$ *can be computed by a randomized algorithm that generates* D *random parameters and, in addition, performs* $O(3^n D^2 \log(3^n D))$ *ops. If the random parameters are sampled from a fixed finite set* S, *then the algorithm may fail with a probability at most* $\left(3^n D + 1\right) 3^n D / \left(2\lfloor S \rceil\right)$.

7.2. Approximation of a root. Application of Algorithm 6.7 in $\mathcal{A}$ yields the following theorem.

THEOREM 7.3. *The idempotent corresponding to a root* ζ *that maximizes the absolute values* $|h(\zeta)|$ *of a fixed polynomial* $h(\mathbf{x})$ *can be approximated (within an error bound* $\epsilon = 2^{-b}$*) by using* $O(3^n D^2 \nu \log(3^n D))$ *ops, where* ν *is defined in* (10) *and* (11).

The latter cost bound dominates the cost of the subsequent transition from the idempotent to a root.

THEOREM 7.4. *The n coordinates of a simple root ζ can be determined from the idempotent $\mathbf{e}_\zeta$ in $\mathcal{O}(3^n D^2 \log(3^n D))$ ops. This bound increases by the factor of n if the root is multiple.*

Proof. We compute $J\mathbf{e}_\zeta$ in $\mathcal{A}$ (where J is the Jacobian of the n equations) by Algorithm 5.7. According to [29], [32], in the case of a simple root, we have

$$\mathtt{H}_\tau^E\,[J\,\mathbf{e}_\zeta]_{\mathbf{x}} = \lambda\,[\zeta^\alpha]_{\alpha\in E}, \quad \lambda \in \mathbb{C}.$$

This vector is computed at the arithmetic cost within the complexity bound of Proposition 5.2 (cf. [32]), and this immediately gives us the coordinates of the root ζ if $\mathbf{x}^E$ contains $1, x_1, \dots, x_n$, which is generically the case. If the root is not simple, then, according to the relation

$$x_i\,J\,\mathbf{e}_\zeta \equiv \zeta_i\,J\,\mathbf{e}_\zeta$$

(see [29], [32], [11]), we recover the coordinates of ζ by computing $n+1$ products in $\mathcal{A}$ (by Algorithm 5.7). □

7.3. Approximation of a selected root. In view of Theorem 7.4, it is sufficient to approximate the idempotents associated to the roots.

Suppose that we seek a root of the system $\mathbf{p} = \mathbf{0}$ whose coordinate x_1 is the closest to a given value $u \in \mathbb{C}$. Let us assume that u is not a projection of any root of the system $\mathbf{p} = \mathbf{0}$ so that $x_1 - u$ has the inverse (reciprocal) in $\mathcal{A}$. Let $h(\mathbf{x})$ denote such an inverse (reciprocal). We have $h\,(\mathbf{x})(x_1 - u) \equiv 1$ and $h(\zeta) = \frac{1}{\zeta_1 - u}$. Therefore, a root whose coordinate x_1 is the closest to u_1 is a root for which $|h(\zeta)|$ is the largest. Consequently, iterative squaring of $h = h(\mathbf{x})$ shall converge to this root.

The polynomial h can be computed by using $O(3^n D^2 \nu \log(3^n D))$ ops for ν of (10) and (11) (see [32, section 3.3.4]).

One may compute several roots of the polynomial system by applying the latter computation (successively or concurrently) to several initial values u.

7.4. Counting nearly real roots and the roots in a polytope. As long as we have (a close approximation to) the idempotent $\mathbf{r}$ associated with a fixed polytope, we may restrict our counting and approximation algorithms to such a polytope simply by moving from the basic nondegenerate linear form τ to the form $\mathbf{r} \star \tau$ (by using $O(3^n D^2 \log(3^n D))$ ops). Let us specify this in the case in which the polytope is the nearly flat box approximating the real space $\mathbb{R}^n$ (cf. Algorithm 6.5 and Proposition 6.6).

Let $\mathcal{A}_\epsilon^{\mathbb{R}} = \mathbf{r}_\epsilon \mathcal{A}$ denote the subalgebra of $\mathcal{A}$ corresponding to the (nearly) real idempotents for a fixed $\epsilon = 2^{-b}$.

We may restrict our computation on $\mathcal{A}_\epsilon^{\mathbb{R}}$ by computing the linear form $\tau' = \mathbf{r}_\epsilon \star \tau$ (in $\mathcal{O}(3^n D^2 \log(D))$ ops, according to Proposition 3.12), and we have the following properties.

PROPOSITION 7.5.

- *The linear form $\tau' = \mathbf{r}_\epsilon \star \tau$ defines a nondegenerate inner product on $\mathcal{A}_\epsilon^{\mathbb{R}}$.*
- *The number of nearly real roots (counted with their multiplicities) is the rank of the matrix $H^E_{\mathbf{r}_\epsilon \star \tau} = (\mathbf{r}_\epsilon \star \tau(\mathbf{x}^{\beta+\gamma}))_{\beta,\gamma \in F}$.*
- *Let E' be a subset of E such that the submatrix $H^{E'}_{\tau'}$ is of the maximal rank. Then E' is a basis of $\mathcal{A}_\epsilon$.*

Proof. See [32]. □

We thus require an algorithm for computing the rank of $H_{\tau'}^{E}$ (see [35] on fast computation of the rank). Assuming (8) and (9), we deduce the following result from Theorem 3.14.

PROPOSITION 7.6. *The number of all nearly real roots can be computed by using* $\mathcal{O}(\mu\, 3^n\, D^2 \log(3^n D))$ *ops (for* μ *of* (8) *and* (9)*).*

7.5. Approximation of nearly real roots and the roots in a box.. To compute a nearly real root as well as a root lying in a fixed box in $\mathbb{C}^n$ maximizing a given function $|h|$, we may apply Algorithm 6.7 in $\mathcal{A}$ (or $\mathcal{A}_{\epsilon}^{\mathbb{R}}$) and Proposition 6.8 and obtain the following theorem.

THEOREM 7.7. *A nearly real root (as well as a root lying in a fixed box) that maximizes a function* $|h|$ *can be computed (up to an error* $\epsilon = 2^{-b}$*) by using* $\mathcal{O}((\mu+\nu)\ 3^n D^2 \log(3^n D))$ *ops for* μ *and* ν *of* (8)–(11)*.*

This process can be extended to compute the other roots via deflation. That is, we replace $\mathbf{r}_\epsilon$ by $\mathbf{r}'_\epsilon = \mathbf{r}_\epsilon - \mathbf{e}_\zeta$, compute $\tau'' = \mathbf{r}'_\epsilon \star \tau$, and apply the same iteration to compute the next (real) root, where $|h|$ takes on its second smallest value over $\mathcal{Z}(I)$. We can also restrict our computation to a fixed box by using the algorithm of subsection 7.4 to compute the sum of the idempotents corresponding to the roots lying inside the box. The complexity of each step is bounded in Theorem 7.7, leading to the following result for δ (real) roots in a given box.

THEOREM 7.8. *The* δ *(real) roots* ζ *lying in a given box can be computed (up to an error* $\epsilon = 2^{-b}$*) by using* $\mathcal{O}((\mu+\nu)\, n 3^n \delta\, D^2\, \log(D)\log(b))$ *ops for* μ *and* ν *of* (8)–(11)*.*

NEW BOUNDS FOR VARIABLE-SIZED ONLINE BIN PACKING*

STEVEN S. SEIDEN†, ROB VAN STEE‡, AND LEAH EPSTEIN§

The remaining authors would like to dedicate this paper to the memory of our friend Steve Seiden, who was killed in an accident on June 11, 2002

Abstract. In the variable-sized online bin packing problem, one has to assign items to bins one by one. The bins are drawn from some fixed set of sizes, and the goal is to minimize the sum of the sizes of the bins used. We present new algorithms for this problem and show upper bounds for them which improve on the best previous upper bounds. We also show the first general lower bounds for this problem. The case in which bins of two sizes, 1 and $\alpha \in (0, 1)$, are used is studied in detail. This investigation leads us to the discovery of several interesting fractal-like curves.

Key words. bin packing, online algorithms

1. Introduction.

In this paper, we investigate the bin packing problem, one of the oldest and most thoroughly studied problems in computer science [3, 5]. In particular, we investigate a natural generalization of the classical online bin packing problem known as online variable-sized bin packing. We show improved upper bounds and the first lower bounds for this problem and in the process encounter several strange fractal-like curves.

Problem definition. In the *classical bin packing* problem, we receive a sequence σ of *pieces* $p_1, p_2, \ldots, p_N$. Each piece has a fixed *size* in $(0, 1]$. In a slight abuse of notation, we use p_i to indicate both the ith piece and its size. We have an infinite number of *bins* each with *capacity* 1. Each piece must be assigned to a bin. Further, the sum of the sizes of the pieces assigned to any bin may not exceed its capacity. A bin is *empty* if no piece is assigned to it; otherwise, it is *used*. The goal is to minimize the number of bins used.

The *variable-sized bin packing* problem differs from the classical one in that the bins do not all have the same capacity. There are an infinite number of bins of each capacity $\alpha_1 < \alpha_2 < \cdots < \alpha_m = 1$. The goal now is to minimize the sum of the capacities of the bins used.

In the *online* versions of these problems, each piece must be assigned in turn, without knowledge of the next pieces. Since it is impossible in general to produce the best possible solution when computation occurs online, we consider approximation

algorithms. Basically, we want to find an algorithm which incurs cost which is within a constant factor of the minimum possible cost, no matter what the input is. This constant factor is known as the asymptotic performance ratio.

A bin packing algorithm uses *bounded space* if it has only a constant number of bins available to accept items at any point during processing. These bins are called *open* bins. Bins which have already accepted some items, but which the algorithm no longer considers for packing, are *closed* bins. While bounded space algorithms are sometimes desirable, it is often the case that unbounded space algorithms can achieve lower performance ratios.

We define the asymptotic performance ratio more precisely. For a given input sequence σ, let $\text{cost}_{\mathcal{A}}(\sigma)$ be the sum of the capacities of the bins used by algorithm $\mathcal{A}$ on σ. Let $\text{cost}(\sigma)$ be the minimum possible cost to pack pieces in σ. The *asymptotic performance ratio* for an algorithm $\mathcal{A}$ is defined to be

$$R_{\mathcal{A}}^{\infty} = \limsup_{n\to\infty} \max_{\sigma} \left\{ \frac{\text{cost}_{\mathcal{A}}(\sigma)}{\text{cost}(\sigma)} \;\middle|\; \text{cost}(\sigma) = n \right\}.$$

The *optimal asymptotic performance ratio* is defined to be

$$R_{\text{OPT}}^{\infty} = \inf_{\mathcal{A}} R_{\mathcal{A}}^{\infty}.$$

Our goal is to find an algorithm with asymptotic performance ratio close to R_{OPT}^{∞}.

Previous results. The online bin packing problem was first investigated by Johnson [9, 10]. He showed that the NEXT FIT algorithm has performance ratio 2. Subsequently, it was shown by Johnson et al. that the FIRST FIT algorithm has performance ratio $\frac{17}{10}$ [11]. Yao showed that REVISED FIRST FIT has performance ratio $\frac{5}{3}$ and further showed that no online algorithm has performance ratio less than $\frac{3}{2}$ [21]. Brown [1] and Liang [14] independently improved this lower bound to 1.53635. This was subsequently improved by van Vliet to 1.54014 [19]. Chandra [2] shows that the preceding lower bounds also apply to randomized algorithms.

Define

$$u_{i+1} = u_i(u_i - 1) + 1, \qquad u_1 = 2,$$

and

$$h_{\infty} = \sum_{i=1}^{\infty} \frac{1}{u_i - 1} \approx 1.69103.$$

Lee and Lee showed that the HARMONIC algorithm, which uses bounded space, achieves a performance ratio arbitrarily close to h_{∞} [13]. They further showed that no bounded space online algorithm achieves a performance ratio less than h_{∞} [13]. A sequence of further results has brought the upper bound down to 1.58889 [13, 15, 16, 17].

The variable-sized bin packing problem was first investigated by Friesen and Langston [7, 8]. Kinnersley and Langston gave an online algorithm with performance ratio $\frac{7}{4}$ [12]. Csirik proposed the VARIABLE HARMONIC algorithm and showed that it has performance ratio at most h_{∞} [4]. This algorithm is based on the HARMONIC algorithm of Lee and Lee [13]. Like HARMONIC, it uses bounded space. Csirik also showed that if the algorithm has two bin sizes 1 and $\alpha < 1$ and if it is allowed to pick α, then a performance ratio of $\frac{7}{5}$ is possible [4]. Seiden has recently shown that VARIABLE HARMONIC is an optimal bounded-space algorithm [18].

The related problem of variable-sized bin covering has been solved by Woeginger and Zhang [20] and extended by Epstein [6].

Our results. In this paper, we present new algorithms for the variable-sized online bin packing problem. By combining the upper bounds for these algorithms, we improve the upper bound for this problem from 1.69103 to 1.63597. Our technique extends the general packing algorithm analysis technique developed by Seiden [17]. We also show the first lower bounds for variable-sized online bin packing. We focus on the case in which there are two bin sizes. However, our techniques are applicable to the general case. We think that our results are particularly interesting because of the unusual fractal-like curves that arise in the investigation of our algorithms and lower bounds.

2. Upper bounds. To begin, we present two different online algorithms for variable-sized bin packing.

We focus in on the case in which there are two bin sizes, $\alpha_1 < 1$ and $\alpha_2 = 1$, and examine how the performance ratios of our algorithms change as a function of α_1. Since it is understood that $m = 2$, we abbreviate α_1 using α. Both of our algorithms are combinations of the HARMONIC and REFINED HARMONIC algorithms. Both have a real parameter $\mu \in (\frac{1}{3}, \frac{1}{2})$. We call these algorithms VRH1(μ) and VRH2(μ). VRH1(μ) is defined for all $\alpha \in (0, 1)$, but VRH2(μ) is defined only for

$$\alpha > \max\left\{\frac{1}{2(1-\mu)}, \frac{1}{3\mu}\right\}. \tag{2.1}$$

First, we describe VRH1(μ). Define $n_1 = 50$, $n_2 = \lfloor n_1\alpha \rfloor$, $\epsilon = 1/n_1$, and

$$T = \left\{\frac{1}{i} \;\middle|\; 1 \le i \le n_1\right\} \cup \left\{\frac{\alpha}{i} \;\middle|\; 1 \le i \le n_2\right\} \cup \{\mu, 1-\mu\}.$$

Define $n = |T|$. Note that it may be that $n < n_1 + n_2 + 2$ since T is not a multiset. Rename the members of T as $t_1 = 1 > t_2 > t_3 > \cdots > t_n = \epsilon$. For convenience, define $t_{n+1} = 0$. The interval I_j is defined to be $(t_{j+1}, t_j]$ for $j = 1, \ldots, n+1$. Note that these intervals are disjoint and that they cover $(0, 1]$. A piece of size s has *type* j if $s \in I_j$. Define the *class* of an interval I_j to be α if $t_j = \alpha/k$ for some positive integer k; otherwise, the class is 1.

The basic idea of VRH1 is as follows: When each piece arrives, we determine the interval I_j to which it belongs. If this is a class 1 interval, we pack the item in a size 1 bin using a variant of REFINED HARMONIC. If it is a class α interval, we pack the item in a size α bin using a variant of HARMONIC.

VRH1 packs bins in *groups*. All the bins in a group are packed in a similar fashion. The groups are determined by the set T. We define

$$g = \begin{cases} 3 & \text{if } \alpha > 1-\mu, \\ 2 & \text{otherwise.} \end{cases} \qquad h = \begin{cases} 6 & \text{if } \alpha/2 > \mu, \\ 5 & \text{if } \alpha > \mu \text{ and } \alpha/2 \le \mu, \\ 4 & \text{otherwise.} \end{cases}$$

Note that these functions are defined so that $t_g = 1 - \mu$ and $t_h = \mu$. The groups are named $(g, h), 1, \ldots, g-1, g+1, g+2, \ldots, n$.

Bins in group $j \in \{1, 2, \ldots, n\} \setminus \{g\}$ contain only type j pieces.

Bins in group (g, h) all have capacity 1. Closed bins contain one type g piece and one type h piece.

        For each item p:
            j ← type of p.
            If j = n then pack p using NEXT FIT in a group n bin.
            Else, if j = g then PUT(p, (g, h)).
            Else, if j = h:
                x ← x + 1.
                If y < ⌊τx⌋:
                    y ← y + 1.
                    PUT(p, (g, h)).
                Else PUT(p, h).
            Else PUT(p, j).
```

```
PUT(p, G)
        If there is no open bin in G then allocate a new bin b.
        Else, let b be an arbitrary open bin in G.
        Pack p in b.
```

FIG. 2.1. *The* VRH1(μ) *algorithm and the* PUT *subroutine.*

Bins in group n all have capacity 1 and are packed using the NEXT FIT algorithm. There is always one open bin in group n. When a type n piece arrives, if the piece fits in the open bin, it is placed there. If not, the open bin is closed, the piece is placed in a newly allocated open group n bin.

For group $j \in \{1, 2, \ldots, n-1\} \setminus \{g\}$, the capacity of bins in the group depends on the class of I_j. If I_j has class 1, then each bin has capacity 1, and each closed bin contains $\lfloor 1/t_j \rfloor$ items of type j. Note that t_j is the reciprocal of an integer for $j \neq h$, and therefore $\lfloor 1/t_j \rfloor = 1/t_j$. If I_j has class α, then each bin has capacity α, and each closed bin contains $\lfloor \alpha/t_j \rfloor$ items of type j. Similarly to before, t_j/α is the reciprocal of an integer, and therefore $\lfloor \alpha/t_j \rfloor = \alpha/t_j$. For each of these groups, there is at most one open bin.

The algorithm has a real parameter $\tau \in [0, 1]$, which for now we fix to be $\frac{1}{7}$. Essentially, a proportion τ of the type h items are reserved for placement with type g items.

A precise definition of VRH1 appears in Figure 2.1. The algorithm uses the subroutine PUT(p, G), where p is an item and G is a group.

We analyze VRH1 using the technique of *weighting systems* introduced in [17]. A weighting system is a tuple $(\mathbb{R}^\ell, \mathbf{w}, \xi)$, where $\mathbb{R}^\ell$ is a real vector space, $\mathbf{w}$ is a *weighting function*, and ξ is a *consolidation function*. We shall simply describe the weighting system for VRH1 and assure the reader that our definitions meet the requirements put forth in [17].

For VRH1, we use $\ell = 3$ and define $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$ to be orthogonal unit basis vectors.

The weighting function is

$$\mathbf{w}(x) = \begin{cases} \mathbf{b} & \text{if } x \in I_g, \\ (1-\tau)\dfrac{\mathbf{a}}{2} + \tau\,\mathbf{c} & \text{if } x \in I_h, \\ \dfrac{\mathbf{a}\,x}{1-\epsilon} & \text{if } x \in I_n, \\ \mathbf{a}\,t_i & \text{otherwise.} \end{cases}$$

The consolidation function is $\xi(x\,\mathbf{a} + y\,\mathbf{b} + z\,\mathbf{c}) = x + \max\{y, z\}$. The following lemma allows us to upper bound the performance of VRH1 using the preceding weighting system.

LEMMA 2.1. *For all input sequences σ,*

$$\text{cost}_{\text{VRH1}}(\sigma) \le \xi\left(\sum_{i=1}^{n} \mathbf{w}(p_i)\right) + O(1).$$

Proof. We count the cost for bins in each group.

First, consider bins in group n. Each of these is packed using NEXT FIT and contains only pieces of size at most ϵ. By the definition of NEXT FIT, each closed bin contains items of total size at least $1-\epsilon$, and there is at most one open bin. Therefore, the number of bins used is at most

$$\frac{1}{1-\epsilon}\sum_{p_i \in I_n} p_i + 1 = \mathbf{a} \cdot \sum_{p_i \in I_n} \mathbf{w}(p_i) + O(1).$$

Now consider group j with $j \notin \{h, (g,h), n\}$. There is at most one open bin in this group. The capacity x of each bin is equal to the class of I_j. The number of items in each closed bin is $\lfloor x/t_j \rfloor$. Since $j \notin \{h, (g,h), n\}$, we have $\lfloor x/t_j \rfloor = x/t_j$. Putting these facts together, the cost is at most

$$\sum_{p_i \in I_j} \frac{x}{\lfloor x/t_j \rfloor} + 1 = \sum_{p_i \in I_j} t_j + 1 = \mathbf{a} \cdot \sum_{p_i \in I_j} \mathbf{w}(p_i) + O(1).$$

Next, consider group h. Let k be the number of type h items in σ. The algorithm clearly maintains the invariant that $\lfloor \tau k \rfloor$ of these items go to group (g,h). The remainder are packed two to a bin in capacity 1 bins. At most one bin in group h is open. The total is at most

$$\frac{k - \lfloor \tau k \rfloor}{2} + 1 = \sum_{p_i \in I_h} \frac{1-\tau}{2} + O(1) = \mathbf{a} \cdot \sum_{p_i \in I_h} \mathbf{w}(p_i) + O(1).$$

Finally, consider group (g,h). Let f be the number of type g items in σ. The number of bins is

$$\max\{f, \lfloor \tau k \rfloor\} = \max\{f, \tau k\} + O(1) = \max\left\{\mathbf{b} \cdot \sum_{p_i \in I_g} \mathbf{w}(p_i),\ \mathbf{c} \cdot \sum_{p_i \in I_h} \mathbf{w}(p_i)\right\} + O(1).$$

Putting all these results together, the total cost is at most

$$\mathbf{a} \cdot \sum_{i=1}^{n} \mathbf{w}(p_i) + \max\left\{\mathbf{b} \cdot \sum_{i=1}^{n} \mathbf{w}(p_i),\ \mathbf{c} \cdot \sum_{i=1}^{n} \mathbf{w}(p_i)\right\} + O(1) = \xi\left(\sum_{i=1}^{n} \mathbf{w}(p_i)\right) + O(1). \qquad \square$$

From [17], we also have the following lemma.

LEMMA 2.2. *For any input σ on which* VRH1 *achieves a performance ratio of c, there exists an input σ' where* VRH1 *achieves a performance ratio of at least c and*

1. *every bin in an optimal solution is full, and*
2. *every bin in some optimal solution is packed identically.*

Given these two lemmas, the problem of upper bounding the performance ratio of VRH1 is reduced to that of finding the single packing of an optimal bin with maximal weight/size ratio. We consider the following integer program: Maximize $\xi(\mathbf{x})/\beta$ subject to

$$\mathbf{x} = \mathbf{w}(y) + \sum_{j=1}^{n-1} q_j \mathbf{w}(t_j); \tag{2.2}$$

$$y = \beta - \sum_{j=1}^{n-1} q_j \, t_{j+1}, \tag{2.3}$$

$$y > 0, \tag{2.4}$$

$$q_j \in \mathbb{N} \qquad \text{for } 1 \le j \le n-1, \tag{2.5}$$

$$\beta \in \{1, \alpha\}, \tag{2.6}$$

over variables $\mathbf{x}, y, \beta, q_1, \ldots, q_{n-1}$. Intuitively, q_j is the number of type j pieces in an optimal bin. y is an upper bound on space available for type n pieces. Note that strict inequality is required in (2.4) because a type j piece is strictly larger than t_{j+1}. Call this integer linear program $\mathcal{P}$. The value of $\mathcal{P}$ upper bounds the asymptotic performance ratio of VRH1.

The value of $\mathcal{P}$ is easily determined using a branch and bound procedure very similar to those in [17, 18]. Define

$$\psi_i = \max\left\{(\mathbf{a}+\mathbf{b}+\mathbf{c})\cdot\mathbf{w}(t_i),\ \frac{1}{1-\epsilon}\right\} \qquad \text{for } 1 \le i \le n-1; \qquad \psi_n = \frac{1}{1-\epsilon}.$$

Intuitively, ψ_i is the maximum contribution to the objective function for a type i item relative to its size. We define π so that

$$\psi_{\pi(1)} \ge \psi_{\pi(2)} \ge \cdots \ge \psi_{\pi(n)}.$$

The procedure is displayed in Figure 2.2. The heart of the procedure is the subroutine TRYALL, which basically finds the maximum weight which can be packed into a bin of size β. Using π, we try first to include items which contribute the most to the objective relative to their size. This is a heuristic. The variables $\mathbf{v}$ and y keep track of the weight and total size of items included so far. The variable j indicates that the current item type is $\pi(j)$. In the For loop at the end of TRYALL, we try each possible number of type $\pi(j)$ items, starting with the largest possible number. First packing as many items as possible is a heuristic which seems to speed up computation. The current maximum is stored in x. When we enter TRYALL, we first compute an upper bound given the packing so far, which is stored in z. When $j = n$, this upper bound is exactly the objective value. If $z \le x$, we do not have to consider any packing reachable from the current one, and we drop straight through. In the main routine, we simply initialize x, call TRYALL for the two bin sizes, and return x.

Now we describe VRH2(μ). Redefine

$$T = \left\{\frac{1}{i} \;\middle|\; 1 \le i \le n_1\right\} \cup \left\{\frac{\alpha}{i} \;\middle|\; 1 \le i \le n_2\right\} \cup \{\alpha\mu,\ \alpha(1-\mu)\}.$$

```
x ← 1.
TRYALL(1, 0, 1, 1).
TRYALL(1, 0, α, α).
Return x.
```

```
TRYALL(j, v, y, β)
    z ← (ξ(v) + y ψ_{π(j)}) /β.
    If z > x then:
    If j = n then:
        x ← z.
    Else:
        For i ← ⌈y/t_{π(j)+1}⌉ − 1, ..., 0:
            TRYALL(j + 1, v + i w(t_{π(j)}), y − i t_{π(j)+1}, β).
```

FIG. 2.2. *The algorithm for computing $\mathcal{P}$ along with subroutine* TRYALL.

Define n_1, n_2, ϵ, and n as for VRH1. Again, rename the members of T as $t_1 = 1 > t_2 > t_3 > \cdots > t_n = \epsilon$. Equation (2.1) guarantees that $1/2 < \alpha(1-\mu) < \alpha < 1$ and $1/3 < \alpha\mu < \alpha/2 < 1/2$, so we have $g = 3$ and $h = 6$. The only difference from VRH1 is that (g, h) bins have capacity α. Otherwise, the two algorithms are identical. We therefore omit a detailed description and analysis of VRH2.

We display the upper bound on the performance ratio achieved using the best of VRH1(μ), VRH2(μ), and VARIABLE HARMONIC in Figure 4.3. This upper bound is achieved by optimizing μ for each choice of α. Our upper bound is at most $\frac{373}{228} < 1.63597$ for all α, which is the performance ratio of REFINED HARMONIC in the classic bin packing context.

3. Lower bounds. We now consider the question of lower bounds. Prior to this work, no general lower bounds for variable-sized online bin packing were known.

Our method follows that of Brown [1], Liang [14], and van Vliet [19]. We give some unknown online bin packing algorithm $\mathcal{A}$ one of k possible different inputs. These inputs are defined as follows: Let $\varrho = s_1, s_2, \ldots, s_k$ be a sequence of *item sizes* such that $0 < s_1 < s_2 < \cdots < s_k \leq 1$. Let ϵ be a small positive constant. We define σ_0 to be the empty input. Input σ_i consists of σ_{i-1} followed by n items of size $s_i + \epsilon$. Algorithm $\mathcal{A}$ is given σ_i for some $i \in \{1, \ldots, k\}$.

A *pattern* with respect to ϱ is a tuple $p = \langle \text{size}(p), p_1, \ldots, p_k \rangle$, where size($p$) is a positive real number and p_i, $1 \leq i \leq k$, are nonnegative integers such that

$$\sum_{i=1}^{k} p_i \, s_i < \text{size}(p).$$

Intuitively, a pattern describes the contents of some bin of capacity size(p). Define $\mathcal{P}(\varrho, \beta)$ to be the set of all patterns p with respect to ϱ with size(p) = β. Further define

$$\mathcal{P}(\varrho) = \bigcup_{i=1}^{m} \mathcal{P}(\varrho, \alpha_i).$$

Note that $\mathcal{P}(\varrho)$ is necessarily finite. Given an input sequence of items, an algorithm is defined by the numbers and types of items it places in each of the bins it uses.

Specifically, any algorithm is defined by a function $\Phi : \mathcal{P}(\varrho) \mapsto \mathbb{R}_{\geq 0}$. The algorithm uses $\Phi(p)$ bins containing items as described by the pattern p. We define $\phi(p) = \Phi(p)/n$.

Consider the function Φ that determines the packing used by online algorithm $\mathcal{A}$ for σ_k. Since $\mathcal{A}$ is online, the packings it uses for $\sigma_1, \ldots, \sigma_{k-1}$ are completely determined by Φ. We assign to each pattern a *class*, which is defined as

$$\text{class}(p) = \min\{i \mid p_i \neq 0\}.$$

Intuitively, the class tells us the first sequence σ_i, which results in some item being placed into a bin packed according to this pattern. That is, if the algorithm packs some bins according to a pattern which has class i, then these bins will contain one or more items after σ_i. Define

$$\mathcal{P}_i(\varrho) = \{p \in \mathcal{P}(\varrho) \mid \text{class}(p) \leq i\}.$$

Then, if $\mathcal{A}$ is determined by Φ, its cost for σ_i is simply

$$n \sum_{p \in \mathcal{P}_i(\varrho)} \text{size}(p)\phi(p).$$

Since the algorithm must pack every item, we have the following constraints:

$$n \sum_{p \in \mathcal{P}(\varrho)} \phi(p)\, p_i \geq n \qquad \text{for } 1 \leq i \leq k.$$

For a fixed n, define $\chi_i(n)$ to be the optimal offline cost for packing the items in σ_i. The following lemma gives us a method of computing the optimal offline cost for each sequence.

LEMMA 3.1. *For $1 \leq i \leq k$, $\chi^* = \lim_{n\to\infty} \chi_i(n)/n$ exists and is the value of the following linear program: Minimize*

$$\sum_{p \in \mathcal{P}_i(\varrho)} \text{size}(p)\phi(p) \tag{3.1}$$

subject to

$$1 \quad \leq \quad \sum_{p \in \mathcal{P}(\varrho)} \phi(p)\, p_j \qquad \text{for } 1 \leq j \leq i \tag{3.2}$$

over variables χ_i and $\phi(p)$, $p \in \mathcal{P}(\varrho)$.

Proof. Clearly, the linear program always has a finite value between $\sum_{j=1}^{i} s_j$ and i. For any fixed n, the optimal offline solution is determined by some ϕ. It must satisfy the constraints of the linear program, and the objective value is exactly the cost incurred. Therefore, the linear program lower bounds the optimal offline cost. The linear program is a relaxation in that it allows a fractional number of bins of any pattern, whereas a legitimate solution must have an integral number. Rounding the relaxed solution up to get a legitimate one, the change in the objective value is at most $|\mathcal{P}(\varrho)|/n$. □

Given the construction of a sequence, we need to evaluate

$$c = \min_{\mathcal{A}} \max_{i=1,\ldots,k} \limsup_{n\to\infty} \frac{\text{cost}_{\mathcal{A}}(\sigma_i)}{\chi_i(n)}.$$

As $n \to \infty$, we can replace $\chi_i(n)/n$ by χ_i^*. Once we have the values $\chi_1^*, \ldots, \chi_k^*$, we can readily compute a lower bound for our online algorithm.

LEMMA 3.2. *The optimal value of the linear program: Minimize c subject to*

$$\begin{aligned} c &\geq \frac{1}{\chi_i^*} \sum_{p \in \mathcal{P}_i(\varrho)} \text{size}(p)\phi(p) \qquad \text{for } 1 \leq i \leq k, \\ 1 &\leq \sum_{p \in \mathcal{P}(\varrho)} \phi(p)\, p_i \qquad \text{for } 1 \leq i \leq k \end{aligned} \tag{3.3}$$

over variables c and $\phi(p)$, $p \in \mathcal{P}(\varrho)$, is a lower bound on the asymptotic performance ratio of any online bin packing algorithm.

Proof. For any fixed n, any algorithm $\mathcal{A}$ has some Φ which must satisfy the second constraint. Further, Φ should assign an integral number of bins to each pattern. However, this integrality constraint is relaxed, and $\sum_{p \in \mathcal{P}_i(\varrho)} \text{size}(p)\phi(p)$ is $1/n$ times the cost to $\mathcal{A}$ for σ_i as $n \to \infty$. The value of c is just the maximum of the performance ratios achieved on $\sigma_1, \ldots, \sigma_k$. ∎

Although this is essentially the result we seek, a number of issues are left to be resolved.

The first is that these linear programs have a variable for each possible pattern. The number of such patterns is potentially quite large, and we would like to reduce the linear program size if possible. We show that this goal is indeed achievable. We say that a pattern p of class i is *dominant* if

$$s_i + \sum_{j=1}^{k} p_j\, s_j > \text{size}(p).$$

Let p be a nondominant pattern with class i. There exists a unique dominant pattern q of class i such that $p_j = q_j$ for all $i \neq j$. We call q the *dominator* of p with respect to class i.

LEMMA 3.3. *In computing the values of the linear programs in Lemmas* 3.1 *and* 3.2*, it suffices to consider only dominant patterns.*

Proof. We transform a linear program solution by applying the following operation to each nondominant pattern p of class i: Let $x = \phi(p)$ in the original solution. We set $\phi(p) = 0$ and increment $\phi(q)$ by x, where q is the dominator of p with respect to i. The new solution remains feasible, and its objective value has not changed. Further, the value of $\phi(p)$ is zero for every nondominant p; therefore, these variables can be safely deleted. ∎

Given a sequence of item sizes ϱ, we can compute a lower bound $L_m(\varrho, \alpha_1, \ldots, \alpha_{m-1})$ using the following algorithm:

1. Enumerate the dominant patterns.
2. For $1 \leq i \leq k$, compute χ_i via the linear program given in Lemma 3.1.
3. Compute and return the value of the linear program given in Lemma 3.2.

Step 1 is most easily accomplished via a simple recursive function. Our concern in the remainder of the paper shall be to study the behavior of $L_m(\varrho, \alpha_1, \ldots, \alpha_{m-1})$ as a function of ϱ and $\alpha_1, \ldots, \alpha_{m-1}$.

4. Lower bound sequences. Up to this point, we have assumed that we were given some fixed item sequence ϱ. We consider now the question of choosing ϱ. We again focus on the case in which there are two bin sizes and examine properties of $L_2(\varrho, \alpha_1)$. We again abbreviate α_1 using α and L_2 using L.

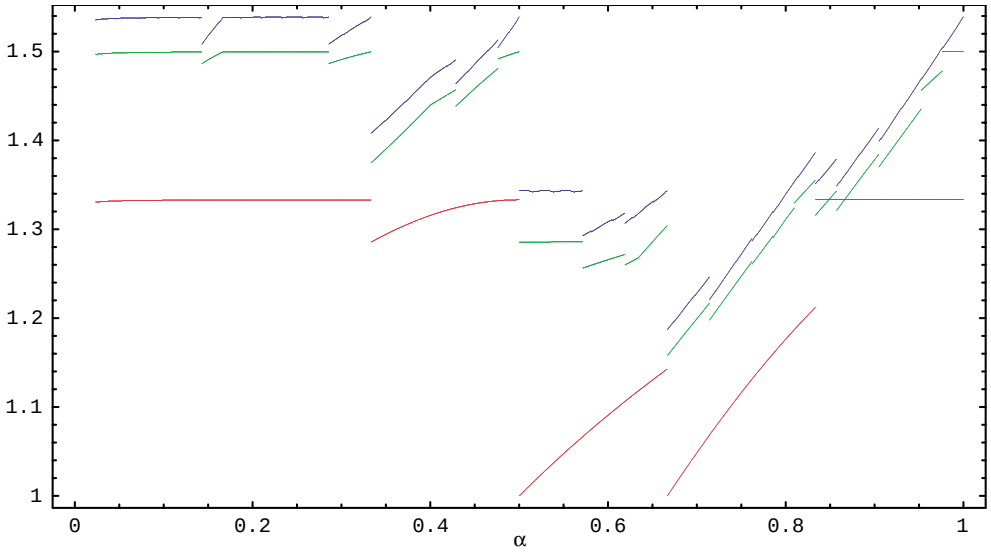

FIG. 4.1. *The evolution of the curves given by the greedy item sequence. The lowest curve is* $\frac{1}{2}, \frac{1}{3}$; *the middle curve is* $\frac{1}{2}, \frac{1}{3}, \frac{1}{7}$; *the highest curve is* $\frac{1}{2}, \frac{1}{3}, \frac{1}{7}, \frac{1}{43}$.

To begin, we define the idea of a *greedy* sequence. Let ϵ denote the empty sequence, and let $\wedge$ denote the sequence concatenation operator. The greedy sequence $\Gamma_\tau(\beta)$ for capacity β with cutoff τ is defined by

$$\gamma(\beta) = \frac{1}{\lfloor \frac{1}{\beta} \rfloor + 1}, \qquad \Gamma_\tau(\beta) = \begin{cases} \epsilon & \text{if } \beta < \tau, \\ \gamma(\beta) \wedge \Gamma_\tau(\beta - \gamma(\beta)) & \text{otherwise.} \end{cases}$$

The sequence defines the item sizes which would be used if we packed a bin of capacity β using the following procedure: At each step, we determine the remaining capacity in our bin. We choose as the next item the largest reciprocal of an integer which fits without using the remaining capacity completely. We stop when the remaining capacity is smaller than τ. Note that, for $\tau = 0$, we get the infinite sequence. We shall use Γ as a shorthand for Γ_0.

The recurrence u_i described in section 1, which is found in connection with bounded-space bin packing [13], gives rise to the sequence

$$\frac{1}{u_i} = \frac{1}{2}, \frac{1}{3}, \frac{1}{7}, \frac{1}{43}, \frac{1}{1807}, \ldots.$$

This turns out to be the infinite greedy sequence $\Gamma(1)$. Somewhat surprisingly, it is also the sequence used by Brown [1], Liang [14], and van Vliet [19] in the construction of their lower bounds. In essence, they analytically determine the value of $L_1(\Gamma_\tau(1))$. Liang and Brown lower bound the value, while van Vliet determines it exactly.

This well-known sequence is our first candidate. Actually, we use the first k item sizes in it, and we resort them so that the algorithm is confronted with items from smallest to largest. In general, this resorting seems to be a good heuristic since the algorithm has the most decisions to make about how the smallest items are packed but, on the other hand, has the least information about which further items will be received. The results are shown in Figure 4.1.

Examining Figure 4.1, one immediately notices that $L(\Gamma_\tau(1), \alpha)$ exhibits some very strange behavior. The curve is highly discontinuous. Suppose we have a finite sequence ϱ, where each item size is a continuous function of $\alpha \in (0,1)$. Tuple p is a *potential pattern* if there exists an $\alpha \in (0,1)$ such that p is a pattern. The set of breakpoints of p with respect to ϱ is defined to be

$$B(p,\varrho) = \left\{ \alpha \in (0,1) \;\middle|\; \sum_{i=1}^{k} p_i\, s_i = \text{size}(p) \right\}.$$

Let $\mathcal{P}^*$ be the set of all potential patterns. The set of all breakpoints is

$$B(\varrho) = \bigcup_{p \in \mathcal{P}^*} B(p,\varrho).$$

Intuitively, at each breakpoint, some combinatorial change occurs, and the curve may jump. In the intervals between breakpoints, the curve behaves nicely as summarized by the following lemma.

LEMMA 4.1. *Let ϱ be a finite item sequence with each item size a continuous function of $\alpha \in (0,1)$. In any interval $I = (\ell, h)$ which does not contain a breakpoint, $L(\varrho,\alpha)$ is continuous. Furthermore, for all $\alpha \in I$,*

$$L(\varrho,\alpha) \geq \min\left\{ \frac{\ell+h}{2h}, \frac{2\ell}{\ell+h} \right\} L\left(\varrho, \tfrac{1}{2}(\ell+h)\right).$$

This lemma follows as a corollary from the following lemma.

LEMMA 4.2. *Let ϱ be a finite item sequence with each item size a continuous function of $\alpha \in (0,1)$. Let I be any interval which does not contain a breakpoint, and let α be any point in I. The following two results hold:*

1. *If $\delta > 0$ is such that $\alpha + \delta \in I$, then*

$$L(\varrho,\alpha+\delta) \geq \left(1 - \frac{\delta}{\alpha+\delta}\right) L(\varrho,\alpha).$$

2. *If $\delta > 0$ is such that $\alpha - \delta \in I$, then*

$$L(\varrho,\alpha-\delta) \geq \left(1 - \frac{\delta}{\alpha}\right) L(\varrho,\alpha).$$

Proof. We first prove statement 1. Denote by $\chi_i^*(x)$ the value of χ_i^* at $\alpha = x$. For $1 \leq i \leq k$, we have

$$\chi_i^*(\alpha+\delta) \leq \frac{\alpha+\delta}{\alpha} \chi_i^*(\alpha).$$

To see this, note that any feasible Φ at α is also feasible at $\alpha+\delta$ since both points are within I and (3.2) does not change within this interval. Each term in (3.1) increases by at most $(\alpha+\delta)/\alpha$. Now consider the linear program of Lemma 3.2. Consider some arbitrary feasible solution ϕ at α. At $\alpha+\delta$, this solution is still feasible (except that possibly c must increase). In the sum $1/\chi_i^* \sum_{p \in \mathcal{P}_i(\varrho)} \text{size}(p)\phi(p)$, the factor $1/\chi_i^*$ decreases by at most $\alpha/(\alpha+\delta)$, and size(p) cannot decrease.

Now consider statement 2. The arguments are quite similar. For $1 \leq i \leq k$, we have

$$\chi_i^*(\alpha-\delta) \leq \chi_i^*(\alpha).$$

Again, a feasible solution remains feasible. Further, its objective value (3.1) cannot increase. Considering the linear program of Lemma 3.2, we find that, for each feasible solution, each sum $1/\chi_i^* \sum_{p\in\mathcal{P}_i(\varrho)} \text{size}(p)\phi(p)$ decreases by a factor of at most $(\alpha-\delta)/\alpha$. □

Considering Figure 4.1 again, there are sharp drops in the lower bound near the points $\frac{1}{3}$, $\frac{1}{2}$, and $\frac{2}{3}$. It is not hard to see why the bound drops so sharply at those points. For instance, if α is just larger than $\frac{1}{2}+\epsilon$, then the largest items in $\Gamma(1)$ can each be put in their own bin of size α. If $\alpha \geq \frac{2}{3}+2\epsilon$, two items of size $\frac{1}{3}+\epsilon$ can be put pairwise in bins of size α. In short, in such cases, the online algorithm can pack some of the largest elements in the list with very little wasted space—hence the low resulting bound.

This observation leads us to try other sequences in which the last items cannot be packed well. A first candidate is the sequence $\alpha, \Gamma(1-\alpha)$. As expected, this sequence performs much better than $\Gamma(1)$ in the areas described above.

It is possible to find further improvements for certain values of α. For instance, the sequence $\alpha/2, \Gamma(1-\alpha/2)$ also works well in some places, and we used other sequences as well. We give two examples in Figure 4.2.

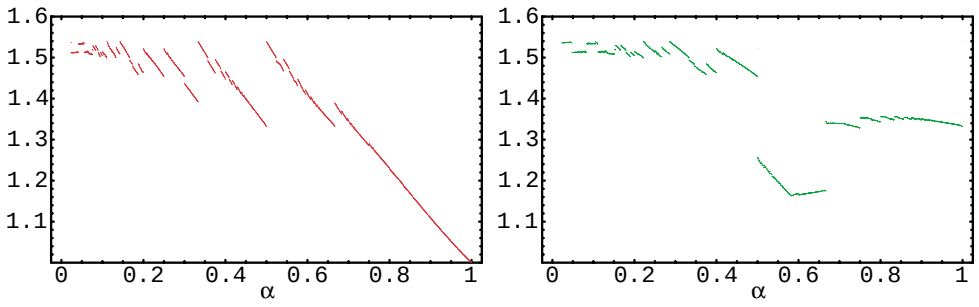

FIG. 4.2. *Two lower bound sequences for* $\tau = 1/1000$: *On the left is* $\alpha, \Gamma_\tau(1-\alpha)$, *and on the right is* $\frac{\alpha}{2}, \Gamma_\tau(1-\frac{\alpha}{2})$.

As a general guideline for finding sequences, items should not fit too well in either bin size. If an item has size x, then $\min\{1 - \lfloor \frac{1}{x} \rfloor x,\ \alpha - \lfloor \frac{\alpha}{x} \rfloor x\}$ should be as large as possible. In areas where a certain item in a sequence fits very well, that item should be adjusted (e.g., use an item $1/(j+1)$ instead of the item $1/j$), or a completely different sequence should be used. (This helps explain why the algorithms have a low competitive ratio for α close to 0.7: in that area, this minimum is never very large.)

Furthermore, as in the classical bin packing problem, sequences that are bad for the online algorithm should have very different optimal solutions for each prefix sequence. Finally, the item sizes should not increase too quickly or too slowly: If items are very small, the smallest items do not affect the online performance much, while if items are close in size, the sequence is easy because the optimal solutions for the prefixes are alike.

In addition to the three sequences already described, namely, the greedy sequence, $\alpha, \Gamma(1-\alpha)$, and $\alpha/2, \Gamma(1-\alpha/2)$, we have found that the following sequences yield good results in restricted areas: $\alpha, \frac{1}{3}, \frac{1}{7}, \frac{1}{43}$; $\frac{1}{2}, \frac{1}{4}, \frac{1}{5}, \frac{1}{21}$; and $\frac{1}{2}, \frac{\alpha}{2}, \frac{1}{9}, \Gamma_\tau(\frac{7}{18} - \frac{\alpha}{2})$.

Using Lemma 4.2, we obtain the following main theorem of this section.

THEOREM 4.3. *Any online algorithm for the variable-sized bin packing problem with* $m = 2$ *has asymptotic performance ratio at least* $495176908800/370749511199 > 1.33561$.

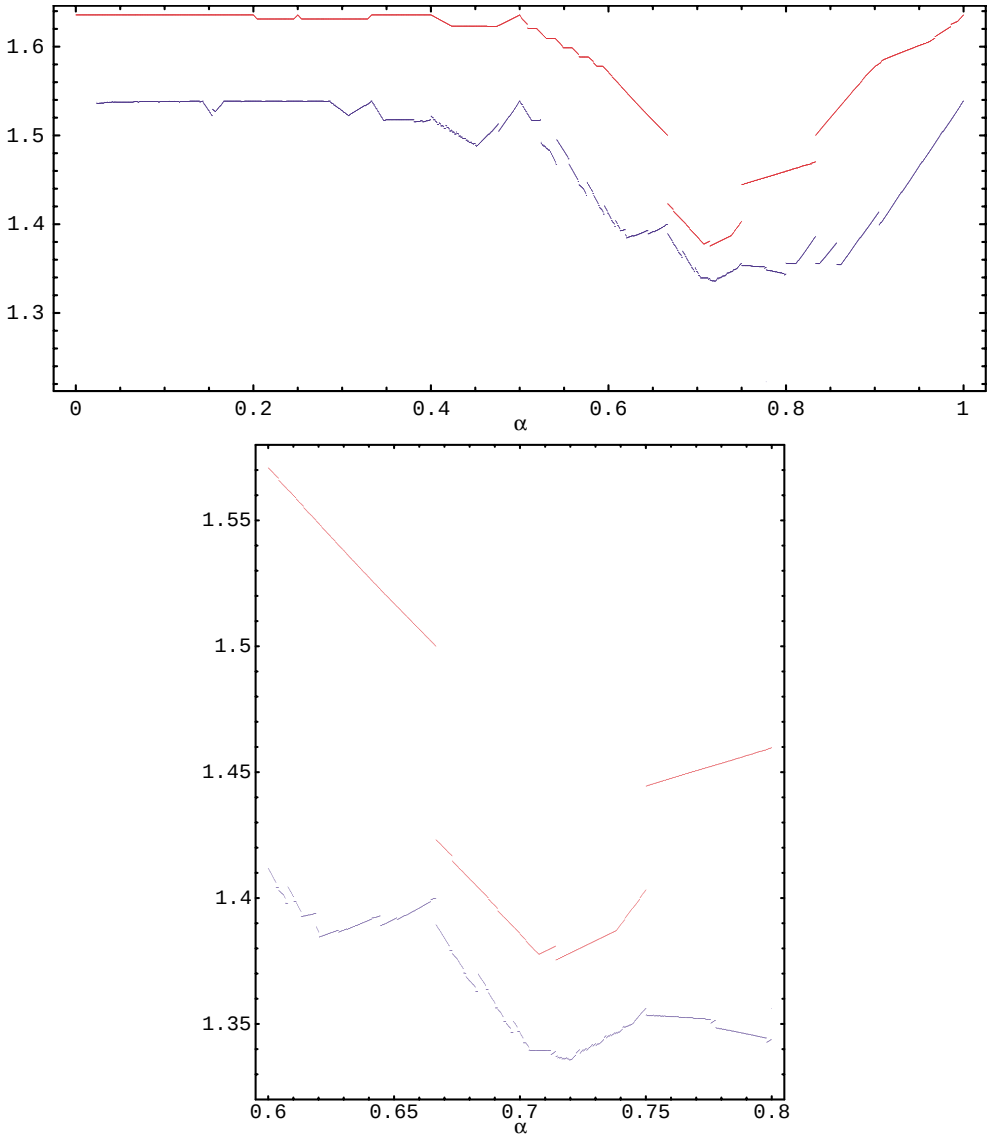

FIG. 4.3. *The best upper and lower bounds for variable-sized online bin packing. The bottom figure is a closeup of* $[.6, .8]$. *The upper bound is best of the* VRH1, VRH2, *and* VARIABLE HARMONIC *algorithms.*

Proof. First, note that, for $\alpha \in (0, 1/43]$, the sequence $\frac{1}{2}, \frac{1}{3}, \frac{1}{7}, \frac{1}{43}$ yields a lower bound of $217/141 > 1.53900$ as in the classic problem: Bins of size α are of no use.

We use the sequences described in the preceding paragraphs. For each sequence ϱ, we compute a lower bound on $(1/43, 1)$ using the following procedure.

Define $\varepsilon = 1/10000$. We break the interval $(0, 1)$ into subintervals using the lattice points $\varepsilon, 2\varepsilon, \ldots, 1 - \varepsilon$. To simplify the determination of breakpoints, we use a constant sequence for each subinterval. This constant sequence is fixed at the upper limit of the interval. That is, throughout the interval $[\ell\varepsilon, \ell\varepsilon + \varepsilon)$, we use the sequence $\varrho|_{\alpha=\ell\varepsilon+\varepsilon}$. Since the sequence is constant, a lower bound on the performance ratio of any online bin packing algorithm with $\alpha \in [\ell\varepsilon, \ell\varepsilon + \varepsilon)$ can be determined by the following algorithm:

1. $\varrho' \leftarrow \varrho|_{\alpha=\ell\varepsilon+\varepsilon}$.
2. Initialize $B \leftarrow \{\ell\varepsilon, \ell\varepsilon + \varepsilon\}$.
3. Enumerate all the patterns for ϱ' at $\alpha = \ell\varepsilon + \varepsilon$.
4. For each pattern:
   (a) $z \leftarrow \sum_{i=1}^{k} p_i\, s_i$.
   (b) If $z \in (\ell\varepsilon, \ell\varepsilon + \varepsilon)$, then $B \leftarrow B \cup \{z\}$.
5. Sort B to get $b_1, b_2, \ldots, b_j$.
6. Calculate and return the value:

$$\min_{1 \le i < j} \min \left\{ \frac{b_i + b_{i+1}}{2b_{i+1}},\ \frac{2b_i}{b_i + b_{i+1}} \right\} L\left(\varrho',\, \tfrac{1}{2}(b_i + b_{i+1})\right).$$

We implemented this algorithm in `Mathematica` and used it to find lower bounds for each of the aforementioned sequences. The results are shown in Figures 4.2 and 4.3. The lowest lower bound is 495176908800/370749511199 in the interval $[0.7196, 0.7197)$. □

5. Conclusions. We have shown new algorithms and lower bounds for variable-sized online bin packing with two bin sizes. By combining these algorithms with Variable Harmonic, choosing for each size α of the second bin the best algorithm for that size, we find an algorithm with asymptotic performance ratio of at most $\frac{373}{228} < 1.63597$ for all α. The best previous upper bound was $h_\infty \approx 1.69103$.

The largest gap between the performance of the algorithm and the lower bound is 0.18193 achieved for $\alpha = 0.9071$. The smallest gap is 0.03371 achieved for $\alpha = 0.6667$. Note that, for $\alpha \le \frac{1}{2}$, there is not much differing from the classical problem: having the extra bin size does not help the online algorithm much. To be more precise, it helps about as much as it helps the offline algorithm.

Our work raises the following questions: Is there a value of α where it is possible to design a better algorithm and show a matching lower bound? Or, can a lower bound be shown anywhere that matches an existing algorithm? Note that at the moment there is also a small gap between the competitive ratio of the best algorithm and the lower bound in the classical bin packing problem.

Another interesting open problem is analyzing variable-sized bin packing with an arbitrary number of bin sizes.

ON LOCAL SEARCH AND PLACEMENT OF METERS IN NETWORKS*

SAMIR KHULLER†, RANDEEP BHATIA‡, AND ROBERT PLESS§

Abstract. This work is motivated by the problem of placing pressure-meters in fluid networks. The problem is formally defined in graph-theoretic terms as follows. Given a graph, find a cotree (complement of a tree) incident upon the minimum number of vertices. We show that this problem is NP-hard and MAX SNP-hard. We design an algorithm with an approximation factor of $2 + \epsilon$ for this problem for any fixed $\epsilon > 0$. This approximation bound comes from the analysis of a local search heuristic, a common practical optimization technique that does not often allow formal worst-case analysis. The algorithm is made very efficient by finding restrictive definitions of the local neighborhoods to be searched. We also exhibit a polynomial time approximation scheme for this problem when the input is restricted to planar graphs.

Key words. local search, approximation algorithms, feedback sets, pressure-meters

1. Introduction.

To measure flow through edges of a fluid network, one can install flow-meters on all edges. However, *one does not need to install flow-meters on all the edges in the network.* By installing flow-meters on edges of any cotree[1] [16] (see Figure 1.1), we can *infer* the flow on edges of the spanning tree due to flow conservation [21]. This requires that we install exactly $|E| - (|V| - 1)$ flow-meters, where $|E|$ is the number of edges and $|V|$ is the number of vertices, since every cotree has $|E| - (|V| - 1)$ edges in a connected network. Since "the cost of flow meters is several times the cost of pressure meters" [21], another option is to install pressure-meters at nodes of the network. A pressure-meter measures fluid pressure at a node of the network, and one can *compute* the flow on an edge by measuring the pressure reading on both of the incident nodes (see [19, 20]). One option would be to place a pressure-meter at each node of the network. However, this is not essential. Since we need only to compute the flow on edges of a cotree, we are looking for a cotree that is incident on as few vertices as possible (to minimize cost). If we place pressure-meters at the nodes incident on the edges of the cotree, we can compute the flow on all cotree edges and infer the flow on the remaining edges of the network. In Figure 1.2, we show a network. Assume that we know the inflow and outflow from the network. By measuring the pressure reading at the marked vertices, we can compute the flow on the edges that are shown. Using this information, we can infer the flow on the remaining edges of the network.

[1] A cotree in a connected graph is a subset of edges that is the complement of a spanning tree.

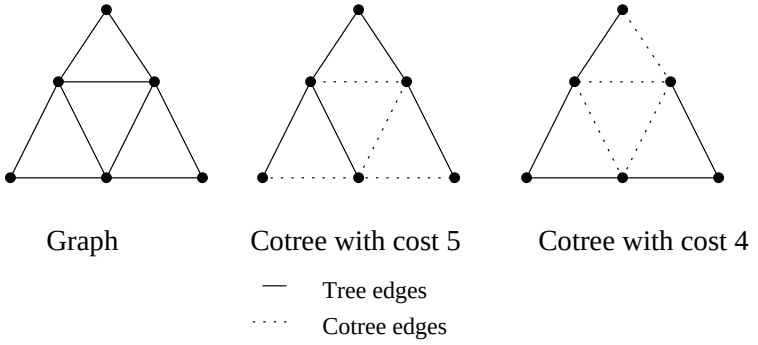

FIG. 1.1. *A simple example to show two different cotrees.*

We can also express this problem in "standard" optimization nomenclature as follows: A feedback edge set (FES) is a subset of edges in a graph whose deletion from the graph makes the graph acyclic. In other words, each cycle in the graph is required to have at least one edge from the FES. In graph-theoretic terms, minimizing the number of pressure-meters leads to the following optimization problem. The minimum vertex feedback edge set (VFES) problem is defined as follows: Given an undirected graph, find an FES incident upon the minimum number of vertices. We show that this problem is NP-hard and MAX SNP-hard and develop an approximation algorithm for it that is fast and practical and that delivers solutions that are guaranteed to have cost at most $2 + \epsilon$ times optimal (for any fixed $\epsilon > 0$).

The complement problem to the minimum VFES problem is the *full degree spanning tree* (FDST) problem [18, 21, 11, 10], namely that of computing a spanning tree T in a connected graph $G = (V, E)$ so as to *maximize* the number of vertices of *full* degree. These are vertices whose degree in the tree T is the same as their degree in the graph G. In other words, the vertices that are incident to the edges in $E \setminus T$ are exactly the vertices that do not have full degree in T. Thus, if K is the maximum number of full degree vertices in some spanning tree T in G, then $|V| - K$ is the cost of the minimum VFES. The *savings* of this solution, compared to installing pressure-meters at every vertex, is exactly the number of full degree vertices in a spanning tree since these vertices have zero degree in the corresponding FES and we do not have to install pressure-meters at these vertices. Hence maximizing the number of vertices of full degree maximizes savings. One pressure-meter is installed at each vertex that does not have full degree; by using these meters, we can compute the flow on each edge in the cotree and then infer the flow on each edge in the tree due to flow conservation.

The FDST problem was recently studied by Pothof and Schut [21], Broersma et al. [11], and Bhatia et al. [10]. The problem was introduced by Pothof and Schut [21], who gave a simple heuristic for it. In [10], it was shown that, for the case of general graphs, an approximation factor of $\Theta(\sqrt{n})$ can be obtained using a very simple algorithm called the *Greedy Star-Insertion Algorithm*. Using Håstad's result on the hardness of approximating clique, it was also shown that, if there is a polynomial time approximation algorithm for the FDST problem with a factor of $O(n^{\frac{1}{2}-\epsilon})$, then $NP = coR$ [10]. For the case of planar graphs, a polynomial time approximation scheme (PTAS) was presented [10]. Independently, Broersma et al. [11] developed a PTAS for planar graphs and showed that, for special classes of graphs such as bounded treewidth graphs and cocomparability graphs, the problem can be solved optimally

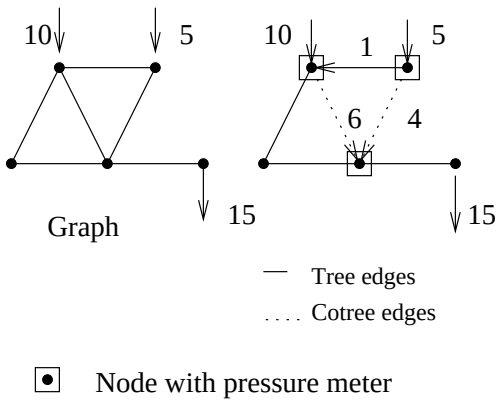

FIG. 1.2. *Figure to illustrate pressure-meters.*

in polynomial time.

Local search is widely used as a general approach to tackle hard optimization problems. Typically, each instance of the optimization problem is associated with a set of feasible solutions, together with a cost function, and the objective is to find a solution of minimum cost. To derive a local search algorithm, one superimposes a "local search neighborhood"; i.e., for each solution, we define a neighborhood of solutions that are "close" to it. We start with some initial solution. The algorithm iteratively checks to see whether or not we can "move" from the current solution to another solution in its neighborhood with lower cost, and if so, we move to the lower cost solution until we reach a locally optimal solution, a solution whose cost is as low as any other in its local search neighborhood.

Even though local search is a powerful practical tool for optimization, there are not many problems for which local search leads to good worst-case approximation factors. In fact, often, when it does lend itself to worst-case analysis, the bounds that we obtain are significantly worse than the worst-case approximation bounds that we can obtain by other methods. However, since local search is a powerful optimization method and relatively simple to implement, it is interesting to analyze local search algorithms as they enhance our understanding of the problems we are studying. For example, for the traveling salesman problem (with triangle inequality), an analysis of the local search method done by Chandra, Karloff, and Tovey [12] shows an approximation factor of $4\sqrt{n}$ for 2-exchange, with improvements for Euclidean instances.

A feedback vertex set (FVS) is a subset of vertices in the graph whose deletion from the graph makes the graph acyclic. In other words, each cycle in the graph is required to have at least one vertex from the FVS. Minimum vertex feedback set problems are NP-hard, and approximation algorithms for them have been widely studied. The first constant approximation algorithm for unweighted FVSs was given by Bar-Yehuda et al. [5]. They also gave a constant approximation algorithm for the weighted case for planar graphs and an $O(\log n)$ approximation algorithm for general graphs. For planar graphs, there is a constant factor approximation algorithm due to Goemans and Williamson [15] and recently a PTAS due to Kleinberg and Kumar [17]. For general graphs (weighted case), a 2 approximation algorithm was developed by Becker and Geiger [6] and Bafna, Berman, and Fujito [3] (see also Chudak et al. [13]).

On the other hand, for undirected graphs, the FES problem has largely been ignored since an FES is the complement of a spanning tree (cotree) and both the

maximization and minimization versions can be solved in polynomial time. However, in our problem, we need to find an FES so as to *minimize the number of vertices incident on the edges* in the FES. We show that this problem is NP-hard as well as MAX SNP-hard. Approximation algorithms for feedback arc problems on directed graphs were given by Even et al. [14].

We study the minimum VFES problem and show that the local search method applied to this problem yields a good approximation algorithm. The local search neighborhood for a given FES is defined by a constant k that allows us to "move" to any other FES that differs from the first one on fewer than k edges. The main difficulty with making this approach practical is that we need to examine all possible changes, and this is not practical even for small values of k. The naive upper bound on the size of the neighborhood we have to search for an improvement is $O(m^k n^k)$, where m is the number of edges in the graph and n is the number of vertices. However, quite surprisingly, we are able to show that we can refine the search so that we do not need to search the entire neighborhood for a better solution. We can implement each step of the local search in time $O(n^2 + nf(k))$, where $f(k)$ is a function only of k and not of the size of the graph. This makes the local search practical. Moreover, we can show that the cost of the solution produced by local search is at most $2 + \frac{1}{k}$ times the cost of the optimal solution. (In fact, we found that even for $k = 2$ this led to a very fast algorithm that we tested on several random planar and nonplanar graphs generated using the Stanford Graphbase and LEDA [9]. In these instances, the algorithm found the optimal solution in each case.)

2. Main results. We show that the minimum VFES problem is NP-hard and MAX SNP-hard. We show that taking *any* minimal FES already yields a 3 approximation to the VFES problem. We then show that a local search method gives an approximation factor of $2 + \epsilon$ for any fixed $\epsilon > 0$ for the minimum VFES problem. However, the running time of this algorithm is $O(n^{O(1/\epsilon)})$. Since this algorithm is not practical, we develop a restricted local search algorithm that restricts the local search neighborhood, which yields a significantly improved running time of $O(n^3 + n^2 f(\frac{1}{\epsilon}))$, and actually yields a practical algorithm with the same approximation guarantee. (Here f is an exponential function but has no dependence on n.) We also show that, for planar graphs, we can design a PTAS. In other words, for any fixed $\epsilon > 0$, we obtain a $1 + \epsilon$ approximation in polynomial time.

3. Hardness results.

THEOREM 3.1. *The minimum VFES problem is MAX SNP-hard and NP-hard.*

Proof. In Lemma 3.2, we show that there is a polynomial time reduction from the independent set problem to the complement of the minimum VFES problem, namely, the FDST problem, such that there is an independent set of size I in a graph G with n nodes and m edges, if and only if there is an FDST solution of size $I + 1$ in a graph H with $N = m + n + 3$ nodes. This implies that G has a vertex cover of size VC if and only if H has a solution to the minimum VFES problem of size $N - (n - VC + 1) = m + VC + 2$.

The vertex cover problem is MAX SNP-hard for graphs in which all degrees are bounded by 3 [1]. Let G be one such graph. Then any vertex cover of G has size $VC \geq m/3$. Let VC^* be the size of the optimal vertex cover of G, and let OPT be the size of the optimal solution to the minimum VFES problem on H. Similarly, let VC and $VFES$ be the size of a vertex cover of G and the size of the corresponding

minimum VFES on H respectively. Then it follows (assuming $m > 0$) that

$$OPT \leq m + VC^* + 2 \leq 4VC^* + 2 \leq 6VC^*.$$

Also,

$$|VFES - OPT| = |m + VC + 2 - (m + VC^* + 2)| = |VC - VC^*|.$$

Thus a $1+\epsilon$ approximation algorithm for the minimum VFES can be used to construct a $1+6\epsilon$ approximation algorithm for the bounded degree vertex cover problem. Hence the minimum VFES problem is MAX SNP-hard. □

The following lemma is based on the NP-completeness proof of the FDST problem [10].

LEMMA 3.2. *There is a polynomial time reduction from the independent set problem on a graph G with n nodes and m edges to the FDST problem on a graph H with $m + n + 3$ nodes such that there is an independent set of size I in G if and only if there is an FDST of size $I + 1$ in H.*

Proof. Given a graph G, an input instance of the independent set problem (we will assume without loss of generality that G has at least two edges, has no isolated vertices, and has a maximum independent set of size at least 3), we create an instance of the FDST problem as follows. Graph H can be viewed as a four-layer graph whose edges connect only vertices in adjacent layers. Hence H is bipartite. Layer one consists of just one vertex a. Layer two has one vertex for every vertex of G, and every vertex in the second layer is connected to a. Layer three has one vertex for every edge of G, and if (u, v) is an edge in G, then the corresponding vertex in the third layer is connected to the vertices in layer two, corresponding to the vertices u and v of G. Finally, layer four has two vertices b and c, which are both connected to every vertex in the third layer.

Let T be a feasible solution to the FDST problem for graph H. First, note that if any two vertices have at least two common neighbors in H, then they both cannot have full degree in T. Hence only one vertex from among $\{b, c\}$ might have full degree in T. This is because G has at least two edges, and hence b and c have at least two common neighbors. Similarly, at most one vertex in the third layer of H has full degree in T. This is because both b and c are in the neighborhood of every vertex in the third layer of H. If vertex a has full degree in T, then none of the vertices in the third layer of H have full degree in T. Vertex a and any vertex in layer three have two common neighbors in layer two. Finally, note that all vertices in the second layer with full degree in T must form an independent set in G.

The above implies that, if G has an independent set of size I, then there is a feasible solution of size $I + 1$ to the FDST problem for the graph H. In this solution, vertex a and the vertices in the independent set have full degree. Similarly, if there is a feasible solution to the FDST problem for the graph H of size $I+1$, then if b or c have full degree (only one of them can be a full degree vertex), then no pair of vertices in the second layer can have full degree. To see this, suppose that there are two vertices in the second layer that have full degree. Note that each one of them has neighbors in layer three since there are no isolated vertices in G. They also have edges to a. By the assumption that one of b or c has full degree, this would thus imply the presence of a cycle in the solution to the FDST, which is a contradiction. We cannot pick more than one full degree vertex in layer three in any case, and we also can only pick vertex a or a vertex in layer three of full degree but not both. Therefore, we will be able to pick at most three vertices of full degree. Hence at least I vertices in layer two

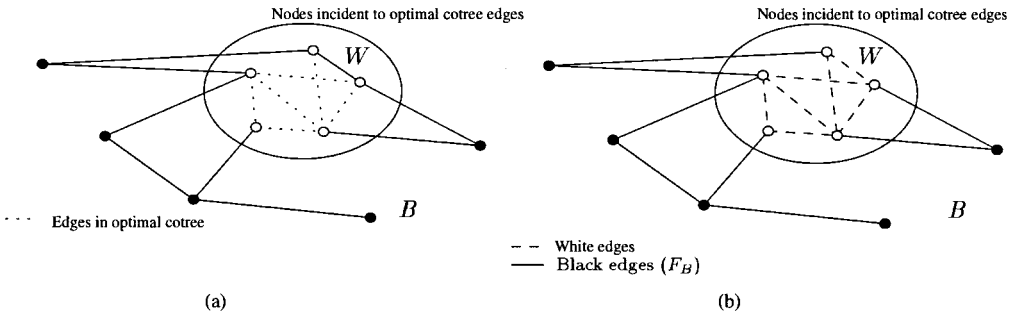

FIG. 4.1. *Example showing black and white vertices.*

have full degree in this feasible solution and therefore G has an independent set of size I. □

4. The minimum VFES problem. In this section, we consider the minimum VFES problem, namely, to find an FES incident on the minimum number of vertices. Any minimal FES is also a cotree.

We show that iteratively deleting any edge from a cycle in the graph $G = (V, E)$ yields an approximation algorithm with a performance ratio of 3. We then improve the solution by applying a "local-improvement" strategy and prove that this is a $2+\epsilon$ approximation for any fixed $\epsilon > 0$. We will also assume that our input graph is connected.

Let S be any subset of edges. Let $V(S)$ be the subset of vertices in G incident on edges in S. Let C_{OPT} be the edges of a minimum VFES (cotree). Let W (white vertices) be $V(C_{OPT})$. Let B (black vertices) be the set of remaining vertices, $V \setminus W$. Edges of G incident to at least one black vertex are colored black and all remaining edges are colored white. (See Figure 4.1(a) for a minimum cotree and Figure 4.1(b) for the colors of edges.) The set of black edges induces a forest F_B in G. We refer to the set of white edges as E_W.

We first prove the following theorem about minimal FESs.

THEOREM 4.1. *Any minimal FES gives a* 3 *approximation to the VFES problem.*

Proof. Let S be a minimal FES. Let $S_w = S \cap E_W$ and $S_b = S \setminus S_w$. We prove that $|V(S)| \leq 3|V(C_{OPT})| - 2$ as follows. Since $|V(E_W)| = |W| = |V(C_{OPT})|$, we have $|V(S_w)| \leq |V(C_{OPT})|$. The proof of the following inequality is given in Lemma 4.2:

$$|S_b| \leq |V(C_{OPT})| - 1.$$

Since the number of vertices that can be incident on any set of edges is at most twice the number of edges, we conclude that

$$|V(S_b)| \leq 2(|V(C_{OPT})| - 1).$$

Thus $|V(S)| \leq |V(S_w)| + |V(S_b)| \leq 3|V(C_{OPT})| - 2$. □

LEMMA 4.2. *Let S be a minimal FES and S_b the set of black edges in this set; then*

$$|S_b| \leq |V(C_{OPT})| - 1.$$

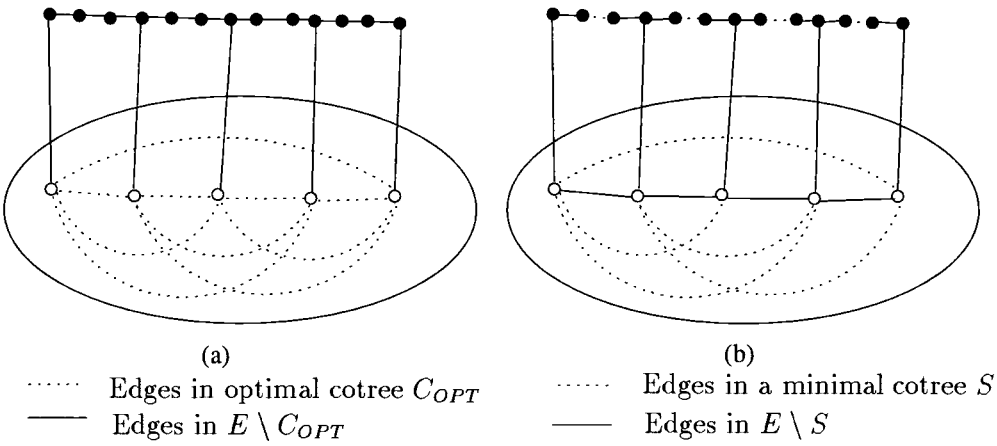

FIG. 4.2. *Example to show that factor* 3 *bound is tight.*

Proof. Recall that the black edges form a forest F_B. Any black edge $e \in S_b$ is essential to a minimal FES. In other words, the introduction of edge e into $E \setminus S$ would create a cycle C_e. C_e contains only edges in $E \setminus S$, except for edge e. Since every cycle in G has at least one white edge, C_e must also have two white vertices incident to this white edge. Walking around the cycle from e in both directions, we stop when we first encounter a white vertex. (We will stop at two distinct white vertices.) Consider $F_B \setminus S_b$; edge e connects two components, each of which must contain at least one white vertex. If $|S_b| \geq |V(C_{OPT})|$, then there are at least $|V(C_{OPT})| + 1$ distinct components in $F_B \setminus S_b$. In the forest F_B, there are exactly $|V(C_{OPT})|$ white vertices; thus one edge in S_b connects two components such that one component contains no white vertex, which is a contradiction. □

It is possible to make examples that show that this bound is tight (see Figure 4.2). If there are k vertices in the optimal cotree, then a minimal solution may have up to $k + 2(k-1)$ vertices.

4.1. Local improvement. We can apply the following local-improvement strategy to our minimal FES S. Let k be $\lceil \frac{1}{\epsilon} \rceil$. We will show that we can prove an approximation bound of $2 + \frac{1}{k}$ using a simple local search algorithm. Replace a set of at most $k-1$ edges from S to get another FES with lower cost (cost is the number of vertices incident to the edges in the FES). Keep doing this until no reduction in cost is possible. This new solution will be referred to as S^k. This can be done for any fixed $k > 0$. (For $k = 1$, this is simply any minimal FES.)

We call this the k-Local-Improvement Algorithm.

k-Local Improvement(G)—

1. Pick an arbitrary cotree S (of size $|E| - (|V| - 1)$).
2. **while** there exists a cotree S' such that
   $|V(S')| < |V(S)|$ and $|S \bigcap S'| > |S| - k$ **do**
3. $S \leftarrow S'$.
4. $S^k \leftarrow S$.
5. **end**

We can partition the solution S^k obtained by the algorithm into two sets as

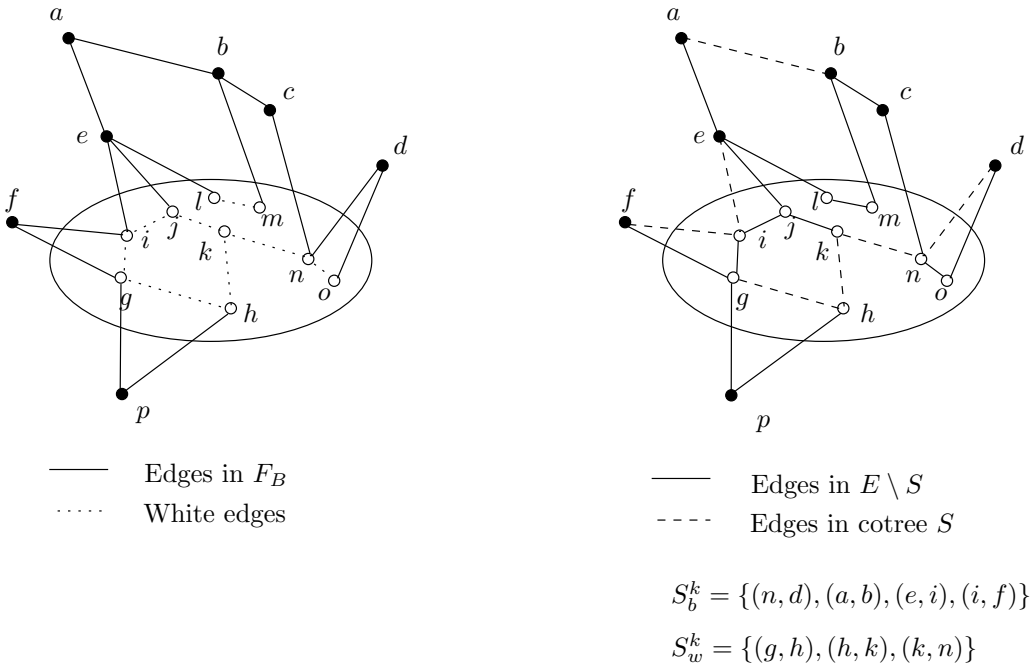

FIG. 4.3. *Figure to show full and nonfull black components.*

before—white edges S_w^k and black edges S_b^k. The edges in S_b^k form a collection of connected components. Let $\mathcal{C} = \{C_i | C_i \text{ is a component of black edges from } S_b^k\}$.

For each black component C_i that shares at least one white vertex with S_w^k, $|V_b(C_i)| \leq |E(C_i)|$, where $V_b(C_i)$ denotes the black vertices of C_i. A black component that does not share any vertices with S_w^k is called a *full black component*. In Figure 4.3, we show three black components: $\{a, b\}$, $\{e, f, i\}$, and $\{d, n\}$. The first two components are full black components. The third component shares a white vertex (n) with an edge in S_w^k.

A full black component may have all black vertices or may have white vertices in $W \setminus V(S_w^k)$. We call a full black component C_i *small* if it has at most $k-1$ edges. The other full black components in $\mathcal{C}$ are referred to as *large*. $\mathcal{C}_{\text{small}}$ is the set of small full black components. $\mathcal{C}_{\text{large}}$ is the set of large full black components. The remaining components are referred to as $\mathcal{C}_{\text{nonfull}}$.

The proof of the main theorem relies on a lemma bounding the number of small full black components $|\mathcal{C}_{\text{small}}|$ by $|W| - |V(S_w^k)|$ (Lemma 4.6). We will prove this lemma next.

Root each black tree in F_B at an arbitrary black vertex, and orient all edges away from the root (see Figure 4.4). Let C_i be a small (full) black component in S^k rooted at r_i.

Number the vertices in C_i as $u_1^i, \ldots, u_{p_i+1}^i$. Let e be the (oriented) edge (u_j^i, u_k^i). Let Shadow(i, e) be the set of white vertices reachable from u_k^i by following a directed path of zero or more black edges that are in $F_B \setminus S^k$. The vertices in Shadow(i, e) are descendants of u_k^i in the rooted black forest F_B.

Let Shadow$(C_i) = \cup_{e \in C_i}$Shadow(i, e). Note that Shadow(C_i) is the set of white vertices that are reachable from vertices in $C_i - \{r_i\}$ by following a directed path of

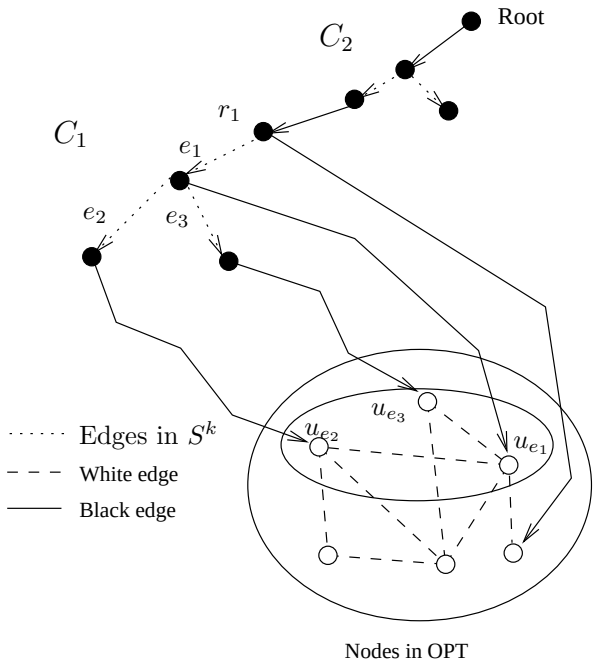

FIG. 4.4. *Example showing black components.*

black edges that are in $F_B \setminus S^k$.

LEMMA 4.3. *For any full black component C_i and $e \in C_i$, we have Shadow$(i, e) \neq \emptyset$.*

Proof. Consider an (oriented) edge $e = (u_j^i, u_k^i) \in C_i$. If $u_k^i \in W$, then clearly Shadow$(i, e) \neq \emptyset$. Now assume that $u_k^i \in B$. If we add edge e to $E \setminus S^k$, we get a cycle C_e with a white edge on it connecting two white vertices. Note that all the edges in F_B incident on u_k^i except for the edge from the parent u_j^i are oriented away from u_k^i. Consider the first white vertex on the path in C_e from node u_k^i to u_j^i avoiding e; we take edges from $F_B \setminus S^k$ before reaching this white vertex. Thus there is a directed path of zero or more black edges from u_k^i using edges from $F_B \setminus S^k$ to some white vertex. □

LEMMA 4.4. *For each pair of black components C_i and C_j, Shadow(C_i) and Shadow(C_j) are disjoint.*

Proof. Suppose (for the sake of contradiction) that $w \in \text{Shadow}(C_i) \bigcap \text{Shadow}(C_j)$. By the definition of Shadow, $\exists u \in C_i - \{r_i\}$ (and $\exists v \in C_j - \{r_j\}$) such that there is a directed path of black edges in $F_B \setminus S^k$ from u (and v) to w. Since w is a descendant of both u and v in the black tree F_B, one of $\{u, v\}$ is a descendant of the other. Assume that u is an ancestor of v. The unique path from u to w in F_B includes the tree path from u to v and the path from v to w. Since the edge joining v to its parent is in C_j and in S^k, at least one edge along this path is not in the set $F_B \setminus S^k$, and thus w is not in the shadow of u. □

Consider a small (full) black component C_i with $p_i (< k)$ edges.

LEMMA 4.5. *For each small (full) black component C_i, Shadow(C_i) contains at least one vertex in $W \setminus V(S_w^k)$.*

Proof. Assume for the sake of contradiction that all the vertices in Shadow(C_i) are

in $V(S_w^k)$. This means that each of these nodes is incident to at least one white edge in S^k. Adding a new edge to the cotree that is incident on a vertex in Shadow(C_i) can only increase the cost of the solution by at most one since one end point of such an edge is already incident to some white edge in the cotree. Let T_{S^k} be the tree corresponding to $E \setminus S^k$. We call R_i a *replacement set* for C_i if $T_{S^k} \cup C_i \setminus R_i$ is a spanning tree in G. We now show that we can find a valid replacement set R_i for C_i of cost at most p_i. By this replacement, we will obtain a strictly better solution since C_i is incident to $p_i + 1$ vertices, and R_i has cost p_i. This exchange involves a set of at most $k-1$ edges, contradicting the assumption that we have a solution that cannot be locally improved.

We now show how to find the set R_i. Note that the solution S^k is minimal, and the introduction of any edge from S^k into the tree formed by $E \setminus S^k$ will create a cycle.

Initially, $R_i = \emptyset$ and $T = T_{S^k}$. As we add edges from C_i to T, we will delete edges from T to maintain a tree. These deleted edges will be added to R_i to form the replacement set for C_i. We process the edges of C_i as we encounter them in a preorder traversal of C_i from r_i. Assume that we are processing the edge $e = (u_j^i, u_k^i) \in C_i$ (oriented downward (away from the root)). If we add the edge e to T, we get a cycle C_e. We follow the path in C_e starting from u_k^i and going away from u_k^i and stop at the first white edge (u_e, v_e). By Lemma 4.3, such an edge will be encountered. If $u_e \in C_i$, then this cannot be a full black component since $u_e \in V(S_w^k)$, and we obtain a contradiction. Since $u_e \in$ Shadow(i, e), it is in $V(S_w^k)$ and does not cost anything. The edge (u_e, v_e) is the replacement edge for e and costs at most one. We add e to T and remove (u_e, v_e) from T and add (u_e, v_e) to R_i. We repeat this until we find all the replacement edges for C_i. ∎

LEMMA 4.6. *The number of small (full) black components in S^k is at most $|W| - |V(S_w^k)|$.*

Proof. We charge each small black component C_i to a vertex in $W \setminus V(S_w^k)$ that also belongs to Shadow(C_i). Since the shadows are disjoint (Lemma 4.4), each node in $W \setminus V(S_w^k)$ is charged at most once, and the lemma follows. ∎

THEOREM 4.7. *The k-Local-Improvement Algorithm obtains a solution that is at most $2 + \frac{1}{k}$ times the optimal solution. This algorithm runs in polynomial time for any fixed $k > 0$.*

Proof. We bound the number of small full black components $|\mathcal{C}_{\text{small}}|$ by $|W| - |V(S_w^k)|$ (Lemma 4.6). For each large full black component C_i, the number of vertices $|V(C_i)| = |E(C_i)| + 1 \leq |E(C_i)| + \frac{E(C_i)}{k} \leq \frac{k+1}{k}|E(C_i)|$.

For each black component with at least one white vertex also in $V(S_w^k)$, we have $|V_b(C_i)| \leq |E(C_i)|$.

$$
\begin{aligned}
|V(S_b^k) \setminus V(S_w^k)| &= \sum_{C_i \in \mathcal{C}_{\text{small}}} |V(C_i)| + \sum_{C_i \in \mathcal{C}_{\text{large}}} |V(C_i)| + \sum_{C_i \in \mathcal{C}_{\text{nonfull}}} |V_b(C_i)| \\
&\leq \sum_{C_i \in \mathcal{C}_{\text{small}}} (|E(C_i)| + 1) + \sum_{C_i \in \mathcal{C}_{\text{large}}} \frac{k+1}{k} |E(C_i)| + \sum_{C_i \in \mathcal{C}_{\text{nonfull}}} |E(C_i)| \\
&\leq |\mathcal{C}_{\text{small}}| + \sum_{C_i \in \mathcal{C}_{\text{small}}} |E(C_i)| + \sum_{C_i \in \mathcal{C}_{\text{large}}} \frac{k+1}{k} |E(C_i)| \\
&\qquad + \sum_{C_i \in \mathcal{C}_{\text{nonfull}}} |E(C_i)|.
\end{aligned}
$$

By Lemma 4.6, we get

$$
|V(S_b^k) \setminus V(S_w^k)| \leq |W| - |V(S_w^k)| + \sum_{C_i \in \mathcal{C}} \frac{k+1}{k} |E(C_i)|.
$$

Note that

$$
|V(S^k)| = |V(S_w^k)| + |V(S_b^k) \setminus V(S_w^k)|.
$$

Using the bound on $|V(S_b^k) \setminus V(S_w^k)|$ obtained above, we get

$$
|V(S^k)| \leq |V(S_w^k)| + |W| - |V(S_w^k)| + \frac{k+1}{k} \sum_{C_i \in \mathcal{C}} |E(C_i)|.
$$

By Lemma 4.2, since S_b^k is also a subset of a minimal cotree, we can bound $\sum_{C_i \in \mathcal{C}} |E(C_i)|$ by $|V(C_{OPT})| - 1$.

$$
\begin{aligned}
|V(S^k)| &\leq |W| + \frac{k+1}{k}(|V(C_{OPT})| - 1) \\
&= |V(C_{OPT})| + \frac{k+1}{k}(|V(C_{OPT})| - 1).
\end{aligned}
$$

This gives us a $2 + \frac{1}{k}$ approximation to VFES.

A naive bound on the running time of the algorithm can be computed as follows. There are at most n iterations since in each iteration our cost decreases by at least one. To implement an iteration, we have to try subsets of at most $k-1$ edges from our cotree and try to replace them by another subset of the same size such that we obtain a cotree with lower cost. An easy bound on the running time for a single iteration is $O(m^{k-1}n^k)$. □

Since this algorithm is not very practical, we show how to modify the algorithm to obtain an efficient implementation.

4.2. Restricted local improvement. We show that we can obtain the $2 + \frac{1}{k}$ bound by modifying the algorithm to improve only "small trees." In other words, once we have a cotree S (corresponding to tree T), we can consider its connected components and try to reduce $|V(S)|$ by eliminating only small trees (of size $< k$) from S. We check to see if we can delete the edges of a small tree T_s from S (this will create cycles in $T \cup T_s$) and then find a set of edges to add to S so that we again

get a cotree. If this replacement reduces the cost of the cotree, we perform this step. Keep doing this until either no small trees are left or we cannot get a reduction in the number of vertices that are incident to the edges in the cotree.

THEOREM 4.8. *The Restricted-Local-Improvement Algorithm obtains a solution that is at most* $2 + \frac{1}{k}$ *times the optimal solution.*

Proof. The proof of this theorem is essentially the same as the proof of the k-Local-Improvement Algorithm. Basically, we observe that the only place where we actually use any specific property of the k-Local-Improvement Algorithm is in the proof of Lemma 4.5. This proof assumes only that components of the solution that are trees are chosen as candidates to be eliminated during the local search. Hence the same bound as in Theorem 4.7 follows. □

This method can be implemented in $O(n^{k+2})$ time as follows: We show that each iteration can be implemented in $O(n^{k+1})$ time, and there are at most n iterations. There are only $O(n)$ possible "small trees" to eliminate. For each small tree, we have to find a valid replacement set—this takes $O(n^k)$ time since there are $O(n^{k-1})$ possible replacement steps, and checking each one takes $O(n)$ time. Thus this gives a bound of $O(n^{k+1})$ for each iteration. The cost is measured as the number of vertices incident to the set of edges in our subset of edges. The initial cost of the cotree is at most n, the number of vertices. Since in each iteration this cost decreases by at least one, we have at most n iterations (there could be far fewer in practice) giving the overall bound of $O(n^{k+2})$.

The key difficulty is in implementing the replacement step efficiently. The naive implementation takes $O(n^{k+1})$ time as we just observed. We now give an algorithm whose complexity (per iteration) is $O(n^2 + nf(k))$, where $f(k)$ is an exponential function in k. The key point is that this algorithm is practical, whereas the previous one is not practical. This improvement is obtained by showing that we need only to "search" for an improvement by restricting our search space to a very small number of possibilities. This gives an overall bound of $O(n^3 + n^2 f(k))$ for the entire algorithm.

We now focus on the implementation of a single iteration of the algorithm. Suppose we have a current cotree S, and let T be the tree $E \setminus S$. Let T_s be a tree with $\ell \leq k-1$ edges in the graph (V, S). Our goal is to try to find a "replacement" set of ℓ edges R such that $(S \setminus T_s) \cup R$ is a cotree or, equivalently, $(T \cup T_s) \setminus R$ is a tree. If the cost of $(S \setminus T_s) \cup R$ is lower than the cost of S, we obtain a local improvement (reduction in cost).

Each edge $e \in T_s$ induces a cycle in T. Path $P(T, e)$ is obtained by removing e from this cycle. Let $\mathcal{T}$ be the subtree of T defined by taking the union of the ℓ paths $P(T, e)$ for each $e \in T_s$. Clearly, $R \subseteq \mathcal{T}$. Figure 4.5 shows the tree T along with a tree $T_s \subseteq S$ (of three edges in this case) and the corresponding paths $P(T, e)$. Our goal is to find a replacement set R of lower cost. Observe that, since we need to "destroy" the ℓ cycles that are created when we add the ℓ edges of T_s to T, we are restricted to picking edges from $\mathcal{T}$ to obtain the set R. We now show that, even though $\mathcal{T}$ can be large, we can find a subtree $\mathcal{T}'$ of size $O(\ell)$ such that if a replacement set R of lower cost exists, then a replacement set of edges chosen from $\mathcal{T}'$ can be found.

We now define tree $\mathcal{T}'$. Consider $T_s \cup \mathcal{T}$. Mark the vertices of T_s as "special" and all the vertices in $\mathcal{T} \setminus T_s$ with degree three or more in the tree $\mathcal{T}$ as "special." (Special vertices are shown as the circled vertices in Figure 4.5.) We can now think of $\mathcal{T}$ as a "tree-like" structure on "special" vertices, where we have paths connecting the "special" vertices. If T_s has ℓ edges, then there are at most 2ℓ special vertices, and thus there are at most $2\ell - 1$ "paths" in $\mathcal{T}$ connecting the special vertices. (This

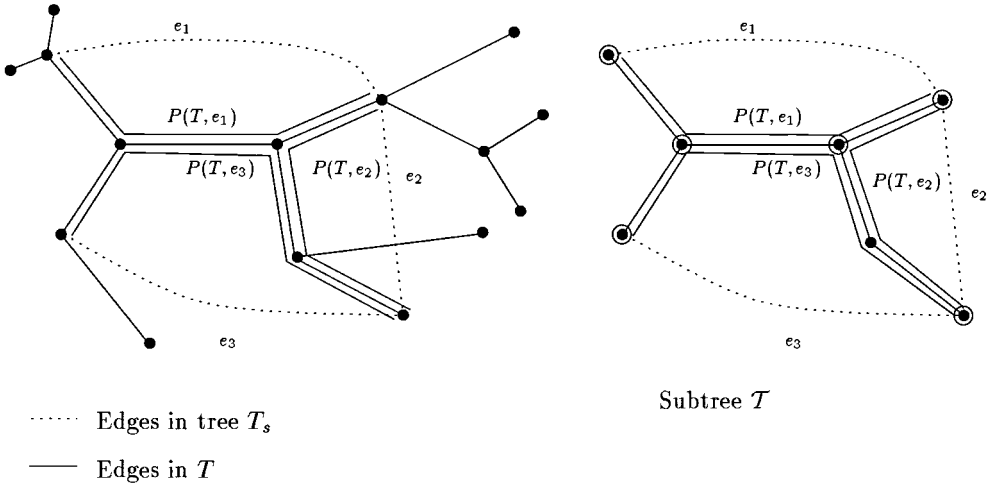

FIG. 4.5. *Figure to show* $\mathcal{T}$.

will be proven formally in Lemma 4.10.) If any "path" between two special vertices has five or more edges, then we will "shrink" this to a path of length at most four. (This will be shown later.) This will ensure that each path has a constant number of edges, and thus the size of the entire tree $\mathcal{T}'$ is $O(\ell)$. Each "path" between two special vertices is also referred to as a "link."

The cost of the ℓ edges in T_s is exactly $\ell + 1$. The vertices in $V(S \setminus T_s)$ are called *marked*. All other vertices are *unmarked*. Our goal is to pick a replacement set R of cost at most ℓ. Our replacement set of edges is incident on marked and unmarked vertices, but only the unmarked vertices cost 1, while the marked vertices cost 0 since these nodes are already incident on edges in $S \setminus T_s$. To do this, we will enumerate over subsets of size ℓ from $\mathcal{T}'$. For each candidate set, we will check if it is a valid replacement set and compute the cost of the new cotree. If the cost of the new cotree is lower, we perform the replacement. It should now be clear that the function f is the number of ways of choosing ℓ edges from the $2\ell - 1$ links so that they form a valid replacement set.

LEMMA 4.9. *If a replacement set R of cost lower than the cost of T_s exists, then there exists a replacement set of edges chosen from $\mathcal{T}'$ of the same cost as R.*

Proof. We first make some observations about the replacement set R. In the replacement set R, at most one edge can be chosen from each link. Let the path $P = [v_0, \ldots, v_k]$ (see Figure 4.6) be the path corresponding to a link. If $k \leq 4$, we do not change the link. (This link has at most four edges.) If $k > 4$, we will define a new compressed link for $\mathcal{T}'$ based on the subset of marked vertices on path P. If there is a replacement set R in $\mathcal{T}$, then picking the corresponding edge from $\mathcal{T}'$ yields a replacement set of the same cost.

If there is no marked vertex on P and R chooses an edge from P, then, without loss of generality, R picks an edge incident to v_0 or v_k. We can compress this path to a path with two edges.

If there exists a pair of adjacent marked vertices on P and R picks an edge from P, then, without loss of generality, we may assume that R picks the edge between a pair of marked vertices. This can be shown by arguing that, if R does not pick an

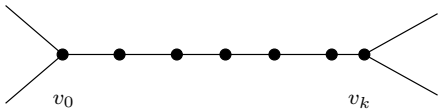

FIG. 4.6. *A long path that will be compressed.*

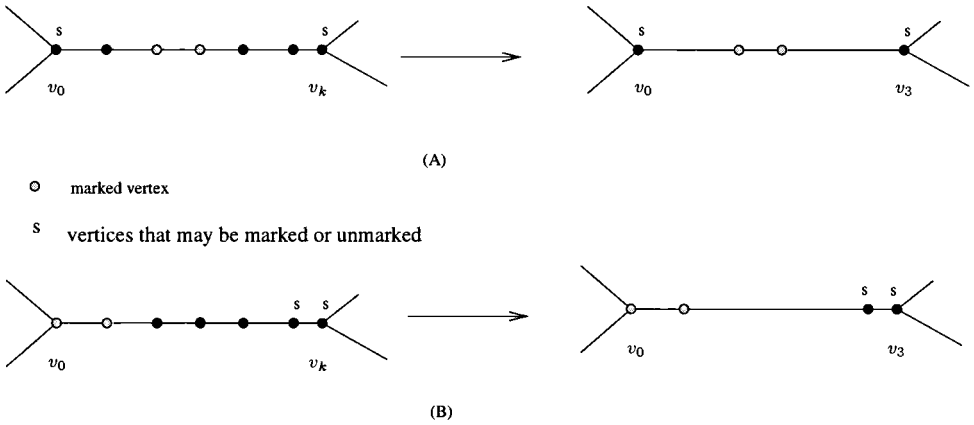

FIG. 4.7. *Compressing a link when there is an adjacent pair of marked vertices.*

adjacent pair of marked vertices, then we can change R to another valid replacement set which uses the adjacent marked pair without increasing its cost. See Figure 4.7 to see the "compression" of a long path to a short path. In case (A), the marked pair is an internal pair on the path, and, in case (B), it is an end pair on the path. In either case, we perform the transformation as shown in Figure 4.7. We leave it to the reader to see that a replacement set of edges in $\mathcal{T}$ can be translated to a replacement set of edges in $\mathcal{T}'$ with no increase in cost.

If there exists at least one marked vertex on P but no adjacent pair of marked vertices and R chooses an edge from P, then, without loss of generality, R picks an edge that is incident on a marked vertex. In each case, it can be verified that we preserve the cost of the set R in $\mathcal{T}$ when we consider the corresponding replacement set R' in $\mathcal{T}'$. Figure 4.8 shows how we compress the link. In each case, it can be verified that we preserve the cost of the set R in $\mathcal{T}$ when we consider the corresponding replacement set R' in $\mathcal{T}'$. We consider all cases based on the status of the vertices marked "s." We do not show the symmetric cases and the cases when an adjacent marked pair exists. The proof for each case is left to the reader. □

LEMMA 4.10. *The size of $\mathcal{T}'$ is $O(\ell)$.*

Proof. In $\mathcal{T}'$ there are at most 2ℓ special vertices. This can easily be proven by induction on the number of edges in T_s. If T_s has one edge, then it creates exactly two marked vertices. Consider T_s, and delete an edge incident to a leaf vertex of T_s. This has $\ell - 1$ edges and thus $2(\ell - 1)$ special vertices. When we add the leaf edge, we create one more special vertex (the leaf vertex) and possibly one more vertex whose degree becomes three.

Thus in $\mathcal{T}$ there are at most $2\ell - 1$ "links," where a "link" is a maximal sequence of degree two vertices. Each link is a sequence of at most four edges, hence the number of edges in $\mathcal{T}'$ is at most $4(2\ell - 1)$, which is $O(\ell)$. □

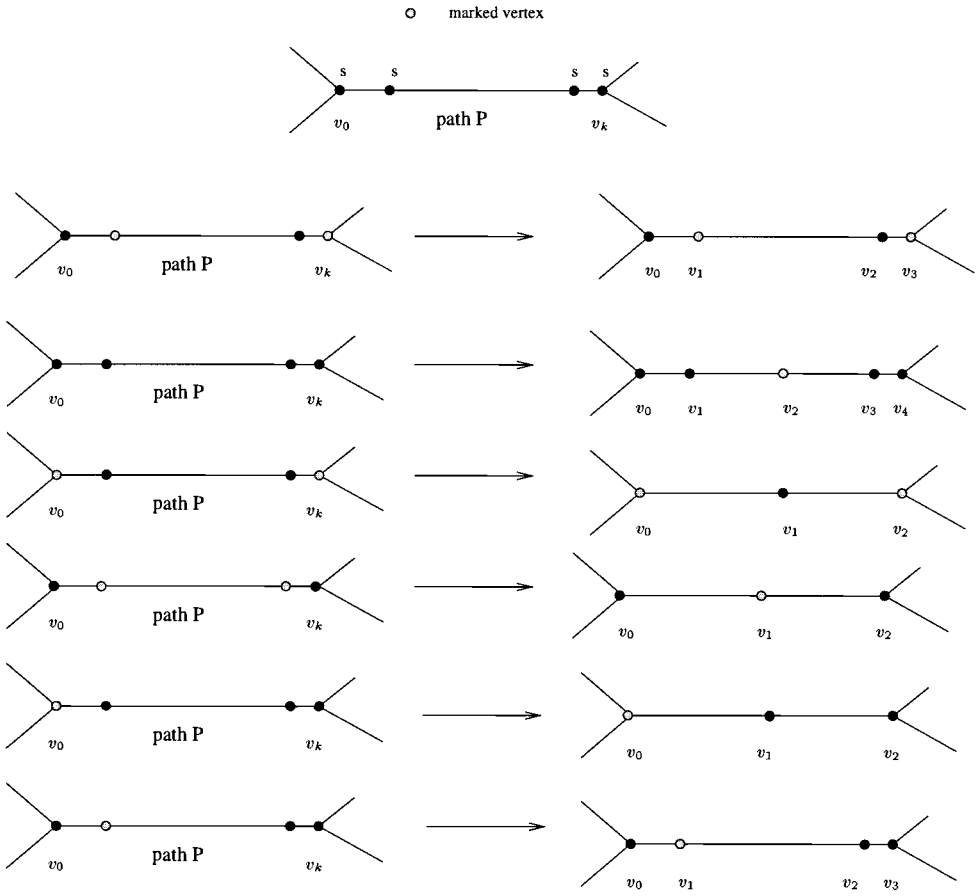

FIG. 4.8. *Compressing a link when there is no adjacent pair of marked vertices.*

5. Planar graphs. In this section, we give a $(1 + \epsilon)$ approximation for the VFES problem for any fixed $\epsilon > 0$ (also referred to as a PTAS). A PTAS for the VFES problem requires two steps. First, we preprocess the graph to compute its 2-edge connected components. We can work with each 2-edge connected component separately since the edges that are cut-edges (bridges) cannot be on any cycle. We then preprocess the graph to eliminate adjacent pairs of degree two vertices and then prove that, in the resulting graph, the optimal solution has size $\Omega(n')$, where n' is the number of vertices, after the elimination of adjacent pairs of vertices with degree two. We then explain the necessary modifications to Baker's schema for generating a PTAS by using optimal solutions for k-outerplanar graphs [4]. Baker's schema requires an optimal solution to a version of the VFES problem when restricted to k-outerplanar graphs; this is assumed to be available as a subroutine here and is presented explicitly in section 6.

We first show that the optimal solution has size $\Omega(n')$. Observe that a maximal

sequence of degree two vertices can be contracted into a sequence containing only one degree two vertex without changing the cost of the optimal solution. We then prove that the number of edges in the graph is at least $\frac{6}{5}n'$, and hence any FES must have at least $\frac{n'}{5}$ edges.

LEMMA 5.1. *If G is a 2-edge connected graph with n' vertices and has no adjacent vertices of degree 2, then the number of edges is at least $\frac{6}{5}n'$.*

Proof. Let n_i be the number of vertices of degree i. Since the graph is 2-edge connected, $n_1 = 0$. (Each vertex has degree at least 2.) Since there is no edge between two vertices of degree 2, we have $|E| \geq 2n_2$. If $n_2 \geq \frac{3}{5}n'$, then we immediately obtain $|E| \geq \frac{6}{5}n'$. Hence we assume that $n_2 \leq \frac{3}{5}n'$. Note that $2|E| = \sum_{i=2}^{n-1} in_i$. Hence $|E| = \sum_{i=2}^{n-1} \frac{i}{2}n_i$. Since $\sum_{i=3}^{n-1} n_i = n' - n_2$, $|E| \geq n_2 + \sum_{i=3}^{n-1} \frac{3}{2}n_i = n_2 + \frac{3}{2}(n' - n_2)$. We obtain $|E| \geq \frac{3}{2}n' - \frac{1}{2}n_2 \geq \frac{6}{5}n'$. ∎

Baker gives a framework which constructs a PTAS using optimal solutions for k-outerplanar graphs—planar graphs where all nodes have a path of length less than or equal to k to a node on the outermost face [4].

Fix a planar embedding of the graph. Let $d(v)$ equal the shortest path length from v to any node on the outer face of G. This scheme creates a collection of k decompositions of the planar graph G into a set of k-outerplanar graphs. For each value of $i = 0 \ldots (k-1)$, we generate the ith decomposition as follows: delete edges that connect nodes with label $d(v) - 1$ and $d(v)$, where $d(v)$ is congruent to $i (\mathrm{mod}\ k)$. For example, for $i = 0$, we delete edges connecting nodes with $d(v)$ value $k - 1$ and k, $2k - 1$ and $2k$, etc. After we delete these edges, we are left with a graph G_i, which is a collection of connected components that are each k-outerplanar. We obtain the optimal solution for G_i by running a linear time algorithm for each connected component (see section 6). This optimal VFES for the graph G_i can be extended to become an FES for the input graph G by including a subset of the edges deleted earlier, with an additional cost less than or equal to the number of nodes with label $d(v) - 1$ and $d(v)$, where $d(v)$ is congruent to $i (\mathrm{mod}\ k)$. Define the set of nodes with these labels to be R_i; then the cost of our solution is at most $|OPT| + |R_i|$.

A given partition of G into a collection of k-outerplanar graphs G_i will have a solution of size at most $|OPT| + |R_i|$, where R_i is the set of "boundary" nodes in G_i. If, for all $i, |R_i| > \frac{2n'}{k}$, then $\sum_{i\text{even}} |R_i| > n'$, which is a contradiction. Therefore, for some i, we obtain a solution of size at most $|OPT| + \frac{2n'}{k}$.

By Lemma 5.1, the optimal FES must have at least $\frac{n'}{5}$ edges. Since the graph is planar, these edges must be incident on $\Omega(n')$ vertices; $|OPT| \geq cn'$ for some constant c. Our solution cost is at most $OPT + \frac{2OPT}{kc} \leq OPT(1 + \frac{2}{kc})$. By setting $k = \frac{2}{c\epsilon}$, we get a bound of $(1 + \epsilon)OPT$.

6. *k*-outerplanar and treewidth-bounded graphs. In this section, we give a linear time algorithm for treewidth-bounded graphs. (If the graph has treewidth k, then the time required for the algorithm to run will be exponential in k but linear in the size of the graph.) Bodlaender [7] proves that any k-outerplanar graph has treewidth at most $3k - 1$. Since our graph G_i consists of a collection of connected components, each of treewidth $3k - 1$, we can run this algorithm on each component separately and take the union of the solutions we obtain. These algorithms rely on a tree-decomposition of a graph, which we define for completeness.

DEFINITION 6.1. *Let $G = (V, E)$ be a graph. A* tree-decomposition *of G is a pair $(\{X_i \mid i \in I\}, T = (I, F))$, where $\{X_i \mid i \in I\}$ is a family of subsets of V and $T = (I, F)$ is a tree with the following properties:*

1. $\bigcup_{i \in I} X_i = V$.
2. *For every edge* $e = (v, w) \in E$, *there is a subset* X_i, $i \in I$, *with* $v \in X_i$ *and* $w \in X_i$.
3. *For all* $i, j, k \in I$, *if* j *lies on the path from* i *to* k *in* T, *then* $X_i \bigcap X_k \subseteq X_j$.

The treewidth *of a tree-decomposition* $(\{X_i \mid i \in I\}, T)$ *is* $\max_{i \in I}\{|X_i| - 1\}$. *The* treewidth *of a graph is the smallest value* k *such that the graph has a tree-decomposition with treewidth* k.

Many problems are known to have linear time algorithms on graphs with constant treewidth, and there are frameworks for automatically generating a linear time algorithm, given a problem specification in a particular format [2, 8]. The VFES problem can be expressed in the formalism of Borie, Parker, and Tovey [8] as follows: given input graph $G = (V, E)$, find $\min |V_1| [Forest(V, E \setminus E'), Inc(E', V_1)]$, which states that we want to minimize the set of nodes incident upon a set of edges whose removal makes the graph a forest. $Forest(V, E \setminus E')$ and $Inc(E', V_1)$ are predicates that specify that the edges induced by the set $E \setminus E'$ form a forest and V_1 is the set of vertices incident on the edges in E'.

LOWER BOUNDS FOR MATRIX PRODUCT IN BOUNDED DEPTH CIRCUITS WITH ARBITRARY GATES*

RAN RAZ† AND AMIR SHPILKA‡

Abstract. We prove superlinear lower bounds for the number of edges in constant depth circuits with n inputs and up to n outputs. Our lower bounds are proved for all types of constant depth circuits, e.g., constant depth arithmetic circuits and constant depth Boolean circuits with arbitrary gates. The bounds apply for several explicit functions and, most importantly, for matrix product. In particular, we obtain the following results:

1. We show that the number of edges in any constant depth arithmetic circuit for *matrix product* (over any field) is superlinear in m^2 (where $m \times m$ is the size of each matrix). That is, the lower bound is superlinear in the number of input variables. Moreover, if the circuit is bilinear, the result applies also for the case in which the circuit gets any product of two linear functions for free.
2. We show that the number of edges in any constant depth arithmetic circuit for the trace of the product of three matrices (over fields with characteristic 0) is superlinear in m^2. (Note that the trace is a *single-output* function.)
3. We give explicit examples for n Boolean functions $f_1, \ldots, f_n$, such that any constant depth *Boolean circuit with arbitrary gates* for $f_1, \ldots, f_n$ has a superlinear number of edges. The lower bound is also proved for *circuits with arbitrary gates over any finite field*. The bound applies for matrix product over finite fields as well as for several other explicit functions.

Key words. bounded depth circuits, matrix products, lower bounds, superconcentrators

1. Introduction.

Exponential lower bounds are well known for constant depth Boolean circuits over the base $\{\text{AND}, \text{OR}, \text{NOT}\}$ [Ajt83, FSS81, Yao85, Hås86]. However, for many other types of constant depth circuits, almost nothing is known. In this work, we prove superlinear lower bounds for the number of edges in constant depth circuits with n inputs and up to n outputs. Our lower bounds are proved for all models of Boolean and arithmetic circuits and, in particular, for Boolean circuits with arbitrary gates. The bounds apply for several explicit functions and, in particular, for matrix product.

In general, our lower bound for circuits of depth $d \geq 2$ is $\Omega(n \cdot \lambda_d(n))$, where $\lambda_d(n)$ is a slowly growing function. Our main method is a graph theoretic argument that analyzes certain superconcentration properties of the circuit as a graph. Hence the same lower bounds are obtained for all types of circuits. Our results and proof methods are related to the works of [DDPW83, Pud94], where lower bounds of $\Omega(n \cdot \lambda_d(n))$ were proved for the size of superconcentrators. Pudlak used similar methods to prove lower bounds of $\Omega(n \cdot \lambda_d(n))$ for the number of edges in constant depth arithmetic circuits with n inputs and up to n outputs over fields with characteristic 0 [Pud94]. Pudlak's results hold for the parallel prefix problem as well as for other explicit functions.

In all that follows, the size of a circuit means the number of edges in it.

1.1. Matrix product. Matrix product is among the most studied computational problems. Surprising upper bounds of $O(m^{2+\epsilon})$ (where $\epsilon < 1$ and $m \times m$ is the size of each matrix) were obtained by Strassen in [Str69] and improved in many other works (see [Gat88] for a survey). The only known lower bound, however, is a lower bound of $2.5 \cdot m^2$ for the number of products needed [Bsh89, Bla99]. In particular, the following problem is still open: Can matrix product be computed by circuits of size $O(m^2)$? Nontrivial size-depth tradeoffs for matrix product are also unknown. In particular, the following problem is still open: Can matrix product be computed by circuits of size $O(m^2)$ and logarithmic depth? In this work, we prove that matrix product cannot be computed by circuits of size $O(m^2)$ and constant depth.

The standard computational model for matrix product is by arithmetic circuits over some field F. Usually, it is assumed that the circuits are bilinear; that is, product gates are applied only on two linear functions, where the first function is linear in the variables of the first matrix and the second function is linear in the variables of the second matrix. Such an assumption can be made without loss of generality if the field F is of characteristic 0. For fields of characteristic different than 0, the nonbilinear case is also interesting. Note, however, that all known upper bounds for matrix product (over any field) are by bilinear circuits.

In the bilinear case, our lower bound proof also works if the circuit gets any product of two linear functions for free. That is, the lower bound is proven for the number of edges above the product gates. We prove that if the circuit is of depth 1 above these products (i.e., total depth 3), it is of size $\Omega(m^3)$. For $d \geq 2$, we prove that if the circuit is of depth d above the products (i.e., total depth $d+2$), it is of size $\Omega(m^2 \cdot \lambda_d(m))$. In the general (nonbilinear) case for fields of characteristic different than 0, our lower bound is $\Omega(m^3)$ for circuits of depth 1 and $\Omega(m^2 \cdot \lambda_d(m))$ for circuits of depth $d \geq 2$. The last lower bound is a special case of a more general lower bound for circuits with arbitrary gates over finite fields. That lower bound is discussed in subsection 1.2.

1.2. Circuits with arbitrary gates. In a *Boolean circuit with arbitrary gates*, we allow each gate (of fanin k) to compute an arbitrary function $g : \{0,1\}^k \to \{0,1\}$. In this work, we give explicit examples for (up to) n Boolean functions $f_1, \ldots, f_n$, such that any constant depth Boolean circuit with arbitrary gates for $f_1, \ldots, f_n$ is of superlinear size. (As before, the bound for depth $d \geq 2$ is $\Omega(n \cdot \lambda_d(n))$.) The bound holds for matrix product over $GF(2)$ (where the dimension of each matrix is $m = \sqrt{n/2}$) as well as for matrix product over other finite fields (where, say, each field element is represented by its bits). The bound also holds for the parallel prefix problem and for other problems from [Pud94].

Previously, Impagliazzo, Paturi, and Saks [IPS97] had considered the case of circuits with arbitrary monotone gates and negations (including the case of threshold circuits). In this model, they proved superlinear lower bounds for constant depth circuits for a single Boolean function, parity. In contrast, our bounds apply to circuits with completely general gates but give only lower bounds for multiple output functions.

The above results for Boolean circuits with arbitrary gates can be generalized to circuits over larger domains. Let F be some fixed finite set (e.g., some fixed finite field), and assume that the input variables range over F (or over a subset of F). A *circuit with arbitrary gates over* F allows each gate (of fanin k) to compute an arbitrary function $g : F^k \to F$. By a reduction to the Boolean case, we get explicit examples for (up to) n functions $f_1, \ldots, f_n$, such that any constant depth circuit with

arbitrary gates over F for $f_1, \ldots, f_n$ is of superlinear size. (As before, the bound for depth $d \geq 2$ is $\Omega(n \cdot \lambda_d(n))$.) In particular, this gives lower bounds for circuits with arbitrary gates over any finite field F. The bound holds for matrix product over F as well as for many other functions.

1.3. Arithmetic circuits. In *arithmetic circuits*, the allowed gates are product and addition over a field F. Constants in the field are also allowed. Arithmetic circuits compute polynomials in the ring $F[x_1, \ldots, x_n]$ (where $x_1, \ldots, x_n$ are the input variables for the circuit), and we would like to give explicit examples for polynomials that are hard to compute. Note that for finite fields the representation of a function $f : F^n \to F$ as a polynomial is not unique (since for every i we have the equation $x_i^p = x_i$, where $p \neq 0$ is the characteristic of the field). Usually, it is required only that the circuit compute the given polynomials as functions; that is, the circuit may compute other polynomials that represent the same functions.

Lower bounds for the size of arithmetic circuits for explicit polynomials are known only if we allow polynomials with large degree or large coefficients (see, e.g., [Str73, BS82]). However, if we limit the degree and the coefficients to be of size $O(1)$, then no nontrivial lower bound is known. For constant depth arithmetic circuits, exponential lower bounds are known for fields F with characteristic $p = 2$ [Razb87, Smo87]. For other finite characteristics, exponential lower bounds are known only for depth 3 [GK98, GR98] (and, for depth larger than 3, no nontrivial lower bound was known). For characteristic 0, the best lower bounds for depth 3 are the almost quadratic bounds of $\Omega(n^{2-\epsilon})$ [SW99].

In this work, we get (for any field F) explicit examples for (up to) n polynomials $f_1, \ldots, f_n$ such that any constant depth arithmetic circuit (over F) for $f_1, \ldots, f_n$ is of superlinear size. One such example is matrix product (over F). For finite fields (and hence also for any field with characteristic different than 0), this follows by the general lower bound for circuits with arbitrary gates over F, as discussed in subsection 1.2. For fields with characteristic 0, this follows from the bilinear lower bound for matrix product, as discussed in subsection 1.1. Similar bounds for fields with characteristic 0 were previously proved by Pudlak [Pud94]. Pudlak gives explicit examples for n linear functions $f_1, \ldots, f_n$ such that any constant depth arithmetic circuit with linear gates (i.e., products are not allowed) for $f_1, \ldots, f_n$ is of superlinear size. (Over fields with characteristic 0, the assumption that all the gates in the circuit are linear can be made without loss of generality.)

For fields with characteristic 0, our results (as well as Pudlak's results) also give explicit examples for *one* polynomial $h = f_1 \cdot y_1 + \cdots + f_n \cdot y_n$ (in the input variables $x_1, \ldots, x_n, y_1, \ldots, y_n$) such that any constant depth arithmetic circuit for h is of superlinear size. This follows easily by the result of [BS82] and was noted to us by Toni Pitassi and Avi Wigderson.

1.4. Methods and related work. Our main lemma gives an analysis of the structure of a constant depth circuit as a graph. Let G be a directed acyclic graph. Denote by V_G the set of all nodes of G. Denote by I_G the set of all nodes of indegree 0 (inputs) and by O_G the set of all nodes of outdegree 0 (outputs). The depth of G is the length of the longest directed path in G. Roughly speaking, the main lemma shows that if G is of depth d and has fewer than $n \cdot \lambda_d(n)$ edges (where, for each $1 \leq d$, $\lambda_d(n)$ is a slowly growing function of n), then one can remove from G a set of $\epsilon \cdot n$ inputs and $\epsilon \cdot n$ outputs (for some small constant ϵ) and a small number of intermediate nodes, such that, in the new graph, the total number of directed paths from I_G to O_G is small.

LEMMA 1.1. *For any $0 < \epsilon < 1/400$ and any directed acyclic graph G of depth d, with more than n vertices and less than $\epsilon \cdot n \cdot \lambda_d(n)$ edges, the following is satisfied.*

For some k, such that $\sqrt{n} \leq k = o(n)$, there exist subsets $I \subset I_G$, $O \subset O_G$, and $V \subset V_G$, such that $|I|, |O| \leq 5\epsilon \cdot d \cdot n$, $|V| = k$, and the total number of directed paths from $I_G \setminus I$ to $O_G \setminus O$ that do not pass through nodes in V is at most $\epsilon \cdot n^2/k$.

Lemma 1.1 is restated (in a slightly more general form) as Corollary 3.12.

The main lemma is used to transform any circuit of depth d and size less than $\epsilon n \lambda_d(n)$ into a new circuit of depth 1 (and relatively small size). This is done by removing from the original circuit $5\epsilon dn$ inputs, $5\epsilon dn$ outputs, and a small number of intermediate nodes. The lower bounds then follow by a *rigidity argument* in the spirit of Valiant's approach [Val77].

As mentioned before, similar methods were previously used to prove lower bounds for superconcentrators [DDPW83, Pud94] and for constant depth arithmetic circuits over fields with characteristic 0 [Pud94]. In particular, methods similar to our main lemma are implicit in [Pud94] (although the presentation there is different). Versions of these methods appeared already in [DDPW83]. One can think of Lemma 1.1 also as a generalization of the lower bounds for superconcentrators given in [DDPW83, Pud94]. In fact, all these lower bounds follow easily by a reduction to Lemma 1.1. Our proof for Lemma 1.1 relies on [Pud94].

1.5. Organization of the paper. In section 2, we give the definition of the functions $\lambda_d(n)$ and prove some simple properties of these functions. In section 3, we give the proof of Lemma 1.1. In section 4, we prove our results for bilinear arithmetic circuits. In section 5, we prove our results for Boolean circuits with arbitrary gates and for circuits with arbitrary gates over finite fields.

2. Slowly growing functions. In this section, we define the functions $\lambda_d(n)$ and we prove some easy properties of them. We start with a definition of the "star" operator.

DEFINITION 2.1. *For a function f, define $f^{(i)}$ to be the composition of f with itself i times; i.e., $f^{(i)} = f \circ f \circ \cdots \circ f$ i times, $f^{(1)} = f$.*

For a function $f : N \to N$ such that $f(n) < n$ for $n > 0$, define

$$f^*(n) = \min\{\ i \mid \text{ such that } \ f^{(i)}(n) \leq 1\}.$$

We will need the following properties of f^* (taken from [Pud94]).

CLAIM 2.2 (see [Pud94]). *Suppose $f(n) \leq \lfloor \sqrt{n} \rfloor$. For every $n \geq 0$, we have*

1. $\frac{f^{(i)}(n)}{f^{(i+1)}(n)} \geq f^{(i+1)}(n)$ *for every $i > 0$ (provided that the denominator is not 0),*
2. $f^{(i)}(n) \geq \frac{f^*(n)}{2}$ *for every $i \leq \frac{f^*(n)}{2}$.*

The proof is taken from [Pud94] as well.

Proof.

1.

$$\frac{f^{(i)}(n)}{f^{(i+1)}(n)} \geq \frac{f^{(i)}(n)}{\lfloor \sqrt{f^{(i)}(n)} \rfloor} \geq \sqrt{f^{(i)}(n)} \geq f^{(i+1)}(n).$$

2. From (1) it follows that, if $f^{(i+1)}(n) > 1$, then $f^{(i)}(n) > f^{(i+1)}(n)$. Therefore,

$$f(n) > f^{(2)}(n) > \cdots > f^{(f^*(n))}(n).$$

Since the values of f are integers, the result follows. □

Our lower bounds will be expressed in terms of the following set of slowly growing functions.

DEFINITION 2.3. *Let*

$$\lambda_1(n) = \lfloor \sqrt{n} \rfloor,$$

$$\lambda_2(n) = \lceil \log n \rceil,$$

$$\lambda_d(n) = \lambda^*_{d-2}(n).$$

Some easy-to-verify properties of these functions are the following.

CLAIM 2.4.

1. *Each $\lambda_i(n)$ is a monotone increasing function tending to infinity with n.*
2. *For $i \geq 2$, $\lambda_{2i}(n) = \Theta(\lambda_{2i+1}(n))$.*
3. *For $i \geq 2$ and n large enough, $\lambda_i(n) \leq \lfloor \sqrt{\frac{n}{2}} \rfloor$.*

Proof.

1. The fact that λ_i is increasing is immediate from the fact that λ_1 and λ_2 are.
2. Notice that $\lambda_3(n) = \Theta(\log \log n)$. Since $\log \log n = \log^{(2)}(n)$, we have $\lambda_4(n) = \Theta(\lambda_5(n))$. Using induction, we get the desired result.
3. Clearly $\lambda_2(n), \lambda_3(n) \leq \sqrt{\frac{n}{2}}$ for n large enough. Assume that $\lambda_j(n) \leq \sqrt{\frac{n}{2}}$. We have

$$\sqrt{\frac{n}{2}} \geq \lambda_j(n) \geq (\lambda_j^{(2)}(n))^2 \geq \frac{1}{4}(\lambda_{j+2}(n))^2;$$

hence

$$\lambda_{j+2}(n) \leq (8n)^{\frac{1}{4}} \leq \sqrt{\frac{n}{2}}$$

for n large enough. ∎

3. Superconcentration properties of graphs. In this section, we prove our main lemma on graphs and several stronger versions of it. The lemma will be used to analyze the structure of a constant depth circuit as a graph. For simplicity, we prove here the lemma for leveled graphs. The general case follows easily by a reduction to the leveled case. Let $G = (V_G, E_G)$ be a leveled graph of depth d. The number of levels in G is hence $d+1$, and all edges in the graph are between vertices of adjacent levels. In all the following, we allow all graphs to be multigraphs.

We will use the following notation: We denote by $L_0, \ldots, L_d$ the levels of G; that is, L_i is the set of vertices at level i. The set of vertices L_0 is also denoted by I_G (and we call these vertices *inputs*). The set of vertices L_d is also denoted by O_G (and we call these vertices *outputs*).

Let $U \subset V_G$ be a set of vertices. We denote by $E(U)$ the set of edges that touch vertices in U. We denote by $\Gamma(U)$ the set of neighbors of U. We denote by $maxdeg(U)$ the maximal degree of a vertex in U. For subsets $I \subset I_G$, $O \subset O_G$, $V \subset V_G$, we denote by $P_G[I, O, V]$ the total number of paths of length d between I and O that do not pass through vertices in V.

Since our results are expressed as functions of the λ_d's, all our results hold whenever n is large enough. So, from now on, we assume that n is large enough.

3.1. Depth 2. We will prove the main lemma for graphs of depth 2. We will start by proving a stronger lemma (Lemma 3.1). The main lemma (for depth 2) will then follow as Corollary 3.3. These lemmas are not needed for the proofs for higher depth. Nevertheless, the methods used here give some hints for the proofs needed for the general case.

LEMMA 3.1. *Let $\epsilon > 0$, and let $1 \le k \le n$. Let G be a leveled graph of depth 2 with at most $\epsilon n \lambda_2(\frac{n}{k})$ edges. Assume that $|L_1| \ge k$. Then there exists a set $V \subset L_1$ of size $k \le |V| \le \sqrt{kn}$ such that*

$$P_G[I_G, O_G, V] \le \frac{100\epsilon^2 n^2}{|V|}.$$

For the proof of Lemma 3.1, we will need Lemma 3.2. For the proof of Lemma 3.2, the reader is referred to [Pud94, Lemma 4].

LEMMA 3.2 (see [Pud94]). *Let $c_1 \ge c_2 \ge \cdots \ge c_t \ge 0$ be a sequence of real numbers, and let p, q be two integers such that $1 \le p \le q \le t$. If, for every $p \le l \le q$,*

$$\sum_{i=l}^{t} {c_i}^2 \ge \frac{1}{l},$$

then

$$\sum_{i=1}^{t} c_i \ge \frac{1}{2} \log\left(\frac{q}{p}\right).$$

Proof of Lemma 3.1. Denote $m = |L_1|$. Let $v_1, v_2, \ldots, v_m$ be the vertices of L_1, ordered according to their degree, from highest to lowest. That is, for every i, $deg(v_i) \ge deg(v_{i+1})$. For every $k \le l \le \sqrt{nk}$, denote $V_l = \{v_1, \ldots, v_l\}$. Then, for every such l,

$$P_G[I_G, O_G, V_l] \le \sum_{i=l+1}^{m} (deg(v_i))^2.$$

Let $c_i = \frac{deg(v_i)}{10\epsilon n}$. Then

$$\sum_{i=1}^{m} c_i = \frac{1}{10\epsilon n} \sum_{i=1}^{m} deg(v_i) = \frac{1}{5\epsilon n}|E_G| \le \frac{1}{5}\left\lceil \log\left(\frac{n}{k}\right)\right\rceil < \frac{1}{2}\log\left(\frac{\sqrt{n}}{\sqrt{k}}\right) = \frac{1}{2}\log\left(\frac{\sqrt{nk}}{k}\right).$$

Therefore, by Lemma 3.2, for some $k \le l \le \sqrt{nk}$,

$$\sum_{i=l}^{m} {c_i}^2 < \frac{1}{l}.$$

Hence

$$P_G[I_G, O_G, V_l] \le \sum_{i=l}^{m} (deg(v_i))^2 = (100\epsilon^2 n^2) \sum_{i=l}^{m} c_i^2 \le \frac{100\epsilon^2 n^2}{l} = \frac{100\epsilon^2 n^2}{|V_l|}. \qquad \square$$

As a corollary, we obtain our main lemma for $d = 2$.

COROLLARY 3.3. *Let G be a leveled graph of depth 2 with at most $\epsilon n \lambda_2(n)$ edges for some $0 < \epsilon < 1/400$. Assume that $|L_1| \geq \sqrt{n}$. Then there exists a set $V \subset L_1$ of size $\sqrt{n} \leq |V| \leq n^{\frac{3}{4}}$ such that*

$$P_G[I_G, O_G, V] \leq \frac{\epsilon n^2}{|V|}.$$

Proof. Note that

$$\epsilon n \lambda_2(n) \leq 2\epsilon n \lambda_2\left(\frac{n}{\sqrt{n}}\right).$$

By Lemma 3.1 with $k = \sqrt{n}$, there is a set $V \subset L_1$ of size $\sqrt{n} \leq |V| \leq n^{\frac{3}{4}}$ such that

$$P_G[I_G, O_G, V] \leq \frac{100(2\epsilon)^2 n^2}{|V|} \leq \frac{\epsilon n^2}{|V|}. \qquad \square$$

3.2. Reducing the depth by 2. Roughly speaking, the main lemma shows that, if G has a small number of edges, then one can remove from G a small set J of inputs and outputs and a small set V of other vertices, such that the total number of paths of length d from $I_G \setminus J$ to $O_G \setminus J$ that do not pass through vertices in V is small (i.e., $P_G[\, I_G \setminus J, O_G \setminus J, V]$ is small).

The proof is by induction on the depth, and it uses a specific way to reduce the depth by 2: Given a partition (A, B, C) of $L_1 \cup L_{d-1}$, we will eliminate $L_1 \cup L_{d-1}$ by

1. removing A,
2. removing all neighbors of B among $I_G \cup O_G$, and
3. adding an edge between vertices from I_G and L_2 that are connected through C (and the same with L_{d-2} and O_G) and then removing C.

This leads us to the following definition.

DEFINITION 3.4. *Let G be a leveled graph of depth $d \geq 3$. Let (A, B, C) be a partition of $L_1 \cup L_{d-1}$. The graph $\hat{G}$ of depth $d-2$ is defined in the following way: The inputs of $\hat{G}$ are*

$$I_{\hat{G}} = I_G \setminus \Gamma(B).$$

The outputs of $\hat{G}$ are

$$O_{\hat{G}} = O_G \setminus \Gamma(B).$$

The $d-1$ levels of $\hat{G}$ are

$$I_{\hat{G}}, L_2, \ldots, L_{d-2}, O_{\hat{G}}$$

(note that, for $d = 3$, the levels of $\hat{G}$ are just $I_{\hat{G}}, O_{\hat{G}}$). The edges between the levels $L_2, \ldots, L_{d-2}$ are the same as they are in G. The other edges are defined in the following way:

- *For $d > 3$, we have to define the edges between $I_{\hat{G}}$ and L_2 and between L_{d-2} and $O_{\hat{G}}$. For every v, c, w such that $v \in I_{\hat{G}}$, $c \in C$, $w \in L_2$, and there are edges $(v, c), (c, w)$ in G, we add the edge (v, w) to $\hat{G}$ (i.e., we replace every such path of length 2 with an edge). In the same way, for every v, c, w such that $v \in L_{d-2}$, $c \in C$, $w \in O_{\hat{G}}$, and there are edges $(v, c), (c, w)$ in G, we add the edge (v, w) to $\hat{G}$.*

- *For $d = 3$, we have to define the edges between $I_{\hat{G}}$ and $O_{\hat{G}}$. This case is slightly different because we do not have a level between L_1 and L_2 to absorb the new edges. So instead, for every path of length 3 (v, c_1, c_2, w), such that $v \in I_{\hat{G}}$, $w \in O_{\hat{G}}$, and $c_1, c_2 \in C$, we put an edge (v, w) in $\hat{G}$.*

Clearly $\hat{G}$ is a function of G, A, B, C. For convenience, we will use the notation $\hat{G}$ instead of $\hat{G}(G, A, B, C)$.

Obviously, $\hat{G}$ is a multigraph of depth $d-2$. In the construction of $\hat{G}$, we replaced each path of length 2 through C (or a path of length 3 in the case in which $d = 3$) with an edge. Therefore, we have the following easy corollary. The corollary shows that the number of relevant paths in the graph $\hat{G}$ is the same as it is in the graph G after removing the sets A and $\Gamma(B)$. Hence, in order to count the paths in G, it is enough to count the corresponding paths in $\hat{G}$. This easy observation makes the use of induction possible.

PROPOSITION 3.5. *Let $G, A, B, C, \hat{G}$ be as in Definition* 3.4. *Then the following hold:*

1. $P_G[\, I_G \setminus \Gamma(B),\, O_G \setminus \Gamma(B),\, A] = P_{\hat{G}}[I_{\hat{G}}, O_{\hat{G}}, \emptyset]$.
2. *More generally, for any set of vertices $\hat{V} \subset L_2 \cup \cdots \cup L_{d-2}$ and any set of inputs and outputs $\hat{J} \subset I_{\hat{G}} \cup O_{\hat{G}}$,*

$$P_G[\, I_G \setminus (\hat{J} \cup \Gamma(B)),\, O_G \setminus (\hat{J} \cup \Gamma(B)),\, \hat{V} \cup A] = P_{\hat{G}}[\, I_{\hat{G}} \setminus \hat{J},\, O_{\hat{G}} \setminus \hat{J},\, \hat{V}].$$

As mentioned above, we will prove the main lemma by induction. In each step, we reduce the depth by 2 by removing a set A of intermediate vertices and a set $\Gamma(B)$ of inputs and outputs. The final set V will be the union of the sets A from all steps of the induction, and the final set J will be the union of the sets $\Gamma(B)$ from all these steps.

In each step of the induction, we assume that the graph G has a relatively small number of edges. We would like to make sure that $\hat{G}$ also has a small number of edges. The next lemma shows that, given certain bounds for $|A|$, $maxdeg(C)$, and $|E_G|$, one can bound the number of edges in $\hat{G}$. The idea of the proof is that the only edges that we add to $\hat{G}$ are related to paths through C. Therefore (roughly), we can bound $|E_{\hat{G}}|$ by $|E_G| \cdot maxdeg(C)$. Note that we assume here the bound

$$|E_G| \leq \epsilon n \lambda_d \left(\frac{n}{k}\right)$$

for some $k \geq 1$. This is more general than the original assumption $|E_G| \leq \epsilon n \lambda_d(n)$. The reason that we need a more general assumption is that the graph G may be a graph that was obtained after several steps of reduction (rather than the original graph). Roughly, the parameter k corresponds to the number of intermediate vertices that were already removed from the original graph (the set V in the statement of the lemma). Since we think of the set A as being removed from the graph as well (and being added to the set V), the bound that we want for $|E_{\hat{G}}|$ is

$$|E_{\hat{G}}| \leq \epsilon n \lambda_{d-2} \left(\frac{n}{k + |A|}\right).$$

LEMMA 3.6. *Let $G, A, B, C, \hat{G}$ be as in Definition* 3.4. *Let $0 < \epsilon < 1/3$ and $1 \leq k \leq \epsilon^2 n$. Assume that*

$$|E_G| \leq \epsilon n \lambda_d \left(\frac{n}{k}\right)$$

and that, for some integer $1 \leq i \leq \frac{\lambda_d(\frac{n}{k})}{2} - 3$*, we have*

1. $|A| \leq \frac{2\epsilon n}{\lambda^{(i)}_{d-2}(\frac{n}{k})}$ *and*
2. $maxdeg(C) \leq \lambda^{(i+3)}_{d-2}(\frac{n}{k})$.

Then

$$|E_{\hat{G}}| \leq \epsilon n \lambda_{d-2}\left(\frac{n}{k+|A|}\right).$$

The proof is by a straightforward calculation using Claims 2.2 and 2.4.

Proof. Since $k \leq \epsilon^2 n$, we have

$$k\lambda^{(i)}_{d-2}\left(\frac{n}{k}\right) \leq k\lambda_1\left(\frac{n}{k}\right) \leq k\sqrt{\frac{n}{k}} < \epsilon n;$$

therefore,

$$k + |A| \leq k + \frac{2\epsilon n}{\lambda^{(i)}_{d-2}(\frac{n}{k})} = \frac{k\lambda^{(i)}_{d-2}(\frac{n}{k}) + 2\epsilon n}{\lambda^{(i)}_{d-2}(\frac{n}{k})} < \frac{3\epsilon n}{\lambda^{(i)}_{d-2}(\frac{n}{k})} < \frac{n}{\lambda^{(i)}_{d-2}(\frac{n}{k})}.$$

We now have two different cases that follow from the construction in Definition 3.4:

1. $d > 3$. From the construction of $\hat{G}$, we get that the degree of each vertex in $L_2 \cup L_{d-2}$ has increased by a factor of $maxdeg(C)$ at most. Therefore, we have

$$|E_{\hat{G}}| \leq |E_G| \cdot maxdeg(C) \leq \epsilon n \lambda_d\left(\frac{n}{k}\right) \lambda^{(i+3)}_{d-2}\left(\frac{n}{k}\right)$$

$$\leq 2\epsilon n \left(\lambda^{(i+3)}_{d-2}\left(\frac{n}{k}\right)\right)^2 \leq \epsilon n \lambda^{(i+2)}_{d-2}\left(\frac{n}{k}\right) \leq \epsilon n \lambda^{(2)}_{d-2}\left(\frac{n}{k+|A|}\right)$$

$$< \epsilon n \lambda_{d-2}\left(\frac{n}{k+|A|}\right)$$

(where all inequalities are due to Claims 2.2 and 2.4 and the bound that we proved on $k + |A|$).

2. $d = 3$. Since we dropped $L_1 \cup L_2$, the set of inputs and outputs now absorbs both the edges of $C \cap L_1$ and the edges of $C \cap L_2$, so we have

$$|E_{\hat{G}}| \leq |E_G| \cdot maxdeg(C)^2 \leq \epsilon n \lambda_d\left(\frac{n}{k}\right)\left(\lambda^{(i+3)}_{d-2}\left(\frac{n}{k}\right)\right)^2$$

$$\leq \frac{1}{2}\epsilon n \lambda_d\left(\frac{n}{k}\right) \lambda^{(i+2)}_{d-2}\left(\frac{n}{k}\right) \leq \frac{1}{2}\epsilon n \lambda^{(i+1)}_{d-2}\left(\frac{n}{k}\right)$$

$$\leq \frac{1}{2}\epsilon n \lambda_{d-2}\left(\frac{n}{k+|A|}\right)$$

(where, as before, all inequalities are due to Claims 2.2 and 2.4 and the bound that we proved on $k + |A|$). ∎

So far, we have presented the construction of $\hat{G}$ from G, given an arbitrary partition (A, B, C). In order to maintain the bound on the number of edges of $\hat{G}$, we need A, C to satisfy the conditions of Lemma 3.6. Also, we need $\Gamma(B)$ to be not too large in order to make sure that the total number of inputs and outputs removed in the process is small. The next lemma shows how to partition $L_1 \cup L_{d-1}$ into suitable sets (A, B, C). The way it is done is by first ordering the vertices in $L_1 \cup L_{d-1}$ according to their degrees (from highest to lowest) and then finding appropriate numbers $r_1 > r_2$, such that A will be the set of vertices with degree larger than r_1, B will be the set of vertices with degree larger than r_2 and at most r_1, and C will be the set of vertices with degree at most r_2.

LEMMA 3.7. *Let G be a leveled graph of depth $d \geq 3$, such that $|E_G| \leq \epsilon n \lambda_d(r)$ for large enough r (more accurately, we need $\lambda_d(r) > 72$). Then there exist a partition (A, B, C) of $L_1 \cup L_{d-1}$ and $1 \leq i \leq \lambda_d(r)/2 - 3$ with the following properties:*

1. $|A| \leq \frac{2\epsilon n}{\lambda_{d-2}^{(i)}(r)}$,
2. $|\Gamma(B)| \leq 9\epsilon n$,
3. $maxdeg(C) \leq \lambda_{d-2}^{(i+3)}(r)$.

Proof. Denote

$$W_0 = \{v \in L_1 \cup L_{d-1} \mid \ deg(v) > \lambda_{d-2}(r)\}$$

and, for $i \geq 1$,

$$W_i = \{v \in L_1 \cup L_{d-1} \mid \ \lambda_{d-2}^{(i)}(r) \geq deg(v) > \lambda_{d-2}^{(i+1)}(r)\}.$$

CLAIM 3.8. *For every $1 \leq i \leq \lambda_d(r)/2 - 3$,*

$$|W_0 \cup W_1 \cup \cdots \cup W_{i-1}| \leq \frac{2\epsilon n}{\lambda_{d-2}^{(i+1)}(r)}.$$

Proof. The proof follows from the fact that the degree of each vertex in $W_0 \cup W_1 \cup \cdots \cup W_{i-1}$ is at least $\lambda_{d-2}^{(i)}(r)$. If the claim were not true, we would have had

$$|E_G| \geq |E(W_0 \cup W_1 \cup \cdots \cup W_{i-1})|\lambda_{d-2}^{(i)}(r) \geq \frac{2\epsilon n}{\lambda_{d-2}^{(i+1)}(r)}\lambda_{d-2}^{(i)}(r)$$

$$\geq 2\epsilon n \lambda_{d-2}^{(i+1)}(r) \geq \epsilon n \lambda_d(r),$$

in contradiction. ∎

CLAIM 3.9. *For some $0 \leq i \leq \lambda_d(r)/2 - 4$,*

$$|E(W_i \cup W_{i+1} \cup W_{i+2} \cup W_{i+3})| \leq 9\epsilon n.$$

Proof. The proof follows from the bound on $|E_G|$. Since $|E_G| \leq \epsilon n \lambda_d(r)$, we must have

$$\sum_{i=0}^{\frac{\lambda_d(r)/2-4}{4}} |E(W_{4i} \cup W_{4i+1} \cup W_{4i+2} \cup W_{4i+3})| \leq \epsilon n \lambda_d(r).$$

If each of the sets $E(W_{4i} \cup W_{4i+1} \cup W_{4i+2} \cup W_{4i+3})$ were of size larger than $9\epsilon n$, then we would have had

$$|E_G| \geq 9\epsilon n \frac{\lambda_d(r)/2 - 4}{4} > \epsilon n \lambda_d(r)$$

(for large enough r), in contradiction. ∎

Fix i' to be such that Claim 3.9 is satisfied for i'. The proof of the lemma now follows for $i = i' + 1$ by taking

1. $A = W_0 \cup W_1 \cup \cdots \cup W_{i'-1}$,
2. $B = W_{i'} \cup W_{i'+1} \cup W_{i'+2} \cup W_{i'+3}$,
3. $C = (L_1 \cup L_{d-1}) \setminus (A \cup B)$. ∎

3.3. Depth 3. The induction that we are about to perform on the depth will end with a graph of depth 2 or 3 (without loss of generality, 3). We will now give the proof of the main lemma for the special case in which $d = 3$. As mentioned before, we need a more general lemma that assumes a more general bound for the number of edges in the graph.

The proof for $d = 3$ already gives the main idea of the proof for the general case. First, we partition $L_1 \cup L_2$ into three sets (A, B, C) as described before. The partition (A, B, C) will satisfy the following: The first set A is small, the second set B is not connected to many inputs and outputs, and each vertex in the third set C has small degree. We then reduce the depth of the graph to 1, using Definition 3.4. Thus we get a graph, $\hat{G}$, with the same number of input-output paths, between $I_{\hat{G}}$ and $O_{\hat{G}}$. Since $\hat{G}$ is a graph of depth 1, the number of such paths is simply the number of edges. The last step would be to calculate the number of edges in $\hat{G}$, which is done using Lemma 3.6.

LEMMA 3.10. *Let* $0 < \epsilon < 1/3$. *Let* $0 < \beta$ *and* $0 < \alpha$ *satisfy*

$$\alpha < \epsilon^2 \text{ and } \frac{4\epsilon}{\lambda_3(\frac{1}{\alpha})} < \beta.$$

Let G *be a leveled graph of depth* 3 *with at most* $\epsilon n \lambda_3(\frac{n}{k})$ *edges for some* $1 \le k \le \alpha n$. *Then there exists a partition* (A, B, C) *of* $L_1 \cup L_2$ *such that*

1. $|A| < \beta n$,
2. $|\Gamma(B)| \le 9\epsilon n$,
3. $P_G[\, I_G \setminus \Gamma(B),\, O_G \setminus \Gamma(B),\, A] \le \epsilon n \lambda_1(\frac{n}{k+|A|})$.

Proof. By Lemma 3.7, we can partition $L_1 \cup L_2$ into three sets (A, B, C) such that, for some $1 \le i \le \lambda_3(\frac{n}{k})/2 - 3$, we have

1. $|A| \le \frac{2\epsilon n}{\lambda_1^{(i)}(\frac{n}{k})} \le \frac{2\epsilon n}{\lambda_1^{(i)}(\frac{1}{\alpha})} \le \frac{4\epsilon n}{\lambda_3(\frac{1}{\alpha})} < \beta n$,
2. $|\Gamma(B)| \le 9\epsilon n$,
3. $maxdeg(C) \le \lambda_1^{(i+3)}(\frac{n}{k})$.

Let $\hat{G}$ be as in Definition 3.4 (with respect to (A, B, C)). By Proposition 3.5,

$$P_G[\, I_G \setminus \Gamma(B),\, O_G \setminus \Gamma(B),\, A] = P_{\hat{G}}[I_{\hat{G}}, O_{\hat{G}}, \emptyset].$$

Since $\hat{G}$ is of depth 1, the right-hand side equals $|E_{\hat{G}}|$. By Lemma 3.6,

$$|E_{\hat{G}}| \le \epsilon n \lambda_1 \left(\frac{n}{k + |A|} \right).$$

Hence

$$P_G[\, I_G \setminus \Gamma(B),\, O_G \setminus \Gamma(B),\, A] \le \epsilon n \lambda_1 \left(\frac{n}{k + |A|} \right). \quad ∎$$

3.4. Higher depth. We are now ready to state and prove our main lemma. As mentioned above, we actually prove a stronger lemma that will be needed for the induction. The main lemma will then follow as an easy corollary. First, note that the functions $\lambda_d(n)$ satisfy $\lambda_{2i}(n) = \Theta(\lambda_{2i+1}(n))$ for $2 \leq i$. Hence we can assume without loss of generality that the depth d is odd; otherwise, we can just increase the depth by 1. (We could not prove better results for the even levels because of the constructions given in [DDPW83].)

LEMMA 3.11. *Let $0 < \epsilon < 1/3$. For any odd integer $3 \leq d$ and $0 < \beta < 1$, there exists $0 < \alpha = \alpha(d, \beta)$ such that, if $1 \leq k \leq \alpha n$ and G is a leveled graph of depth d, with at most $\epsilon n \lambda_d(\frac{n}{k})$ edges, then there exist a set V of vertices and a set J of inputs and outputs such that*

1. $|V| \leq \beta n$,
2. $|J| \leq 5\epsilon d n$,
3. $P_G[\, I_G \setminus J,\, O_G \setminus J,\, V] \leq \epsilon n \lambda_1(\frac{n}{k+|V|})$.

Proof. The proof is by induction on d. The base case $d = 3$ was proved in Lemma 3.10. So assume that, for any $0 < \beta < 1$ and any integer $0 < l$, $\alpha(d - 2l, \beta)$ exists. Let α satisfy the following:

$$\alpha + \frac{4\epsilon}{\lambda_d(\frac{1}{\alpha})} < \alpha\left(d - 2, \frac{\beta}{2}\right) \text{ and}$$

$$\frac{\beta}{2} + \frac{4\epsilon}{\lambda_d(\frac{1}{\alpha})} < \beta.$$

Clearly such an α exists. Take $\alpha(d, \beta) = \alpha$. Let G be a leveled graph of depth d, with at most $\epsilon n \lambda_d(\frac{n}{k})$ edges, for $1 \leq k \leq \alpha n$. Let (A, B, C) be the partition of $L_1 \cup L_{d-1}$ from Lemma 3.7. Let $\hat{G}$ be the depth $d-2$ graph defined in Definition 3.4 (with respect to (A, B, C)). Then, by Lemma 3.6,

$$|E_{\hat{G}}| \leq \epsilon n \lambda_{d-2}\left(\frac{n}{k + |A|}\right).$$

Also, for some

$$1 \leq i \leq \frac{1}{2}\lambda_{d-2}\left(\frac{n}{k}\right) - 3,$$

we have that

$$|A| \leq \frac{2\epsilon n}{\lambda^{(i)}_{d-2}(\frac{n}{k})} \leq \frac{2\epsilon n}{\lambda^{(i)}_{d-2}(\frac{1}{\alpha})} \leq \frac{4\epsilon n}{\lambda_d(\frac{1}{\alpha})}.$$

Therefore,

$$k + |A| \leq \alpha n + \frac{4\epsilon n}{\lambda_d(\frac{1}{\alpha})} \leq \alpha\left(d - 2, \frac{\beta}{2}\right) \cdot n.$$

Hence the inductive assumption holds for $\hat{G}$ with parameters $d - 2$ and $\frac{\beta}{2}$. We get that, for $\hat{G}$, there exist a set $\hat{V}$ of vertices and a set $\hat{J}$ of inputs and outputs such that

1. $|\hat{V}| \leq \frac{\beta}{2} n$,

2. $|\hat{J}| \leq 5\epsilon(d-2)n$,
3. $P_{\hat{G}}[\, I_{\hat{G}} \setminus \hat{J},\, O_{\hat{G}} \setminus \hat{J},\, \hat{V}] \leq \epsilon n \lambda_1(\frac{n}{k+|A|+|\hat{V}|})$.

Define $V = \hat{V} \cup A$ and $J = \hat{J} \cup \Gamma(B)$. We have that

$$|V| = |\hat{V}| + |A| \leq \frac{\beta}{2} n + \frac{4\epsilon n}{\lambda_d(\frac{1}{\alpha})} \leq \beta n.$$

Since $|\hat{J}| \leq 5\epsilon(d-2)n$ and $|\Gamma(B)| \leq 9\epsilon n$, we have that $|J| \leq 5\epsilon d n$.

Finally, by Proposition 3.5,

$$P_G[\, I_G \setminus J,\, O_G \setminus J,\, V] = P_{\hat{G}}[\, I_{\hat{G}} \setminus \hat{J},\, O_{\hat{G}} \setminus \hat{J},\, \hat{V}]$$

$$\leq \epsilon n \lambda_1 \left(\frac{n}{k + |A| + |\hat{V}|} \right) = \epsilon n \lambda_1 \left(\frac{n}{k + |V|} \right). \qquad \square$$

Our main lemma is now stated as the following corollary. Note that the requirement $\epsilon < 1/400$ is needed only for the case in which $d = 2$. (A weaker requirement is needed for $d > 2$.)

COROLLARY 3.12. *Let $0 < \beta < 1$. Let G be a leveled graph of constant depth $d \geq 2$, with more than n vertices and less than $\epsilon n \lambda_d(n)$ edges, for some $0 < \epsilon < 1/400$ and n sufficiently large. Then there exist a set V of vertices and a set J of inputs and outputs such that*

1. $\sqrt{n} \leq |V| \leq \beta n$,
2. $|J| \leq 5\epsilon d n$,
3. $P_G[\, I_G \setminus J,\, O_G \setminus J,\, V] \leq \epsilon \frac{n^2}{|V|}$.

Proof. First note that (as mentioned above) Lemma 3.11 is correct also for even depth if we just require ϵ to be slightly smaller (a factor of 2 or 3 is enough). Since here we require $\epsilon < 1/400$, we can apply Lemma 3.11 for any depth larger than 2.

We apply Lemma 3.11 with $k = 1$. If $|V| \geq \sqrt{n}$, we are done. Otherwise, just add arbitrary vertices to V. Call the resulting set V'. We have

$$P_G[\, I_G \setminus J,\, O_G \setminus J,\, V'] \leq P_G[\, I_G \setminus J,\, O_G \setminus J,\, V]$$

$$\leq \epsilon n \lambda_1 \left(\frac{n}{1 + |V|} \right) \leq \epsilon n \sqrt{\frac{n}{1 + |V|}} = \epsilon \frac{n^2}{\sqrt{n(1 + |V|)}} \leq \epsilon \frac{n^2}{|V'|}.$$

This completes the proof for depth higher than 2. For $d = 2$, the corollary was already stated as Corollary 3.3. $\square$

3.5. Graphs for matrix product. As mentioned in the introduction, the main function that we concentrate on in this work is matrix product. A circuit for matrix product has $2m^2$ inputs and m^2 outputs, where m is the dimension of each matrix. Therefore, we will assume here that our graph has $2m^2$ inputs and m^2 outputs and that the outputs are ordered as a matrix. We will refer to such a graph as a graph for matrix product. For convenience, we will prove a lemma that will be specific for such graphs. The proof will follow easily by Corollary 3.12.

Denote by O_i the outputs in the ith column of the output matrix. Denote by $[m]$ the set $\{1, \ldots, m\}$. We think of $[m]$ as the set of all output columns. For a subset $D \subset [m]$, denote by O_D the outputs in all the columns in D. That is, $O_D = \cup_{i \in D} O_i$.

Roughly, our lemma will state that, after removing from the graph a small set I of inputs, a small set O of outputs, and a set V of size k of intermediate nodes, one can find a set D of $10k/m$ output columns such that there are no paths between the inputs and the outputs in O_D. For simplicity, we will not state the lemma for a general constant ϵ, and we will just fix some constant that will be good enough.

LEMMA 3.13. *Let G be a leveled graph for matrix product, of constant depth $d \geq 2$, with less than $\epsilon m^2 \lambda_d(m^2)$ edges, for $\epsilon = 1/(1000 \cdot d)$. Then, for any $0 < \beta < 1$, there exist sets $V \subset V_G$, $D \subset [m]$, $O \subset O_D$, $I \subset I_G$ such that the following hold:*

1. $m \leq |V| \leq \beta m^2$.
2. $|D| \geq \frac{10|V|}{m}$.
3. *For every $i \in D$, $|O_i \cap O| < \frac{1}{10}m$.*
4. $|I| < \frac{1}{10}m^2$.
5. $P_G[\, I_G \setminus I,\, O_D \setminus O,\, V] = 0$.

Proof. Let V, J be the sets guaranteed by Corollary 3.12 with $n = m^2$. Define $\tilde{I} = J \cap I_G$ and $\tilde{O} = J \cap O_G$, and let $k = |V|$. Then

1. $m \leq |V| = k \leq \beta n$ (hence requirement 1 is satisfied),
2. $|\tilde{I}|, |\tilde{O}| \leq (1/200) \cdot m^2$,
3. $P_G[\, I_G \setminus \tilde{I},\, O_G \setminus \tilde{O},\, V] \leq \epsilon \frac{m^4}{k}$.

Denote by $\tilde{D}$ the set of all $i \in [m]$ such that $|O_i \cap \tilde{O}| < (1/100) \cdot m$. Then, by the bound we have on $|\tilde{O}|$, we know that

$$|\tilde{D}| \geq (1/2) \cdot m.$$

For every $i \in \tilde{D}$, let $P(i)$ be the total number of paths between outputs in $O_i \setminus \tilde{O}$ and inputs in $I_G \setminus \tilde{I}$ that do not pass through V. Denote by D the set of $\lceil 10k/m \rceil$ indices i with the smallest $P(i)$. (Then, by the definition of D, requirement 2 is satisfied.) Denote $O = \tilde{O} \cap O_D$. (Then, by the fact that $D \subset \tilde{D}$, requirement 3 is satisfied.) Since

$$\sum_{i \in \tilde{D}} P(i) \leq P_G[\, I_G \setminus \tilde{I},\, O_G \setminus \tilde{O},\, V] \leq \epsilon \frac{m^4}{k},$$

we have

$$\sum_{i \in D} P(i) \leq \frac{|D|}{|\tilde{D}|} \sum_{i \in \tilde{D}} P(i) \leq \frac{\lceil 10k/m \rceil}{m/2} \cdot \epsilon \frac{m^4}{k} < (1/50) \cdot m^2.$$

Hence, if we denote by $\hat{I}$ the set of all inputs that are connected by a path (that do not pass through V) to some output in $O_D \setminus O$, we have

$$|\hat{I}| < (1/50) \cdot m^2.$$

Denote $I = \tilde{I} \cup \hat{I}$. (Then, by the bounds we have on $|\tilde{I}|, |\hat{I}|$, requirement 4 is satisfied.) By the definition of $\hat{I}$, all paths between $O_D \setminus O$ and $I_G \setminus I$ pass through V. (Hence requirement 5 is satisfied.) ∎

4. Arithmetic model. In this section, we present our results for bilinear arithmetic circuits. An arithmetic circuit is a directed acyclic graph as follows. Nodes of indegree 0 are called inputs and are labeled with input variables. Nodes of outdegree 0 are called outputs. Each edge is labeled with a constant from the field, and each node other than an input is labeled with one of the following operations: $\{+, \cdot\}$. (In the

first case the node is a plus gate and in the second case a product gate.) The computation is done in the following way: An input just computes the value of the variable that labels it. Then, if $v_1, \ldots, v_k$ are the vertices that fan into v, then we multiply the result of each v_i by the value of the edge that connects it to v. If v is a plus gate, we sum all the results; otherwise, v is a product gate, and we multiply all the results. Obviously, each node in the circuit computes a polynomial in the input variables.

In this section, we prove lower bounds on the size of circuits computing the product of two $m \times m$ matrices. The input is of size $n = 2m^2$, and it consists of two $m \times m$ matrices X, Y. The output is the matrix $Z = X \cdot Y$; i.e., there are m^2 outputs, and the (i, j)th output is

$$z_{i,j} = \sum_{k=1}^{m} x_{i,k} \cdot y_{k,j}.$$

Each output $z_{i,j}$ is hence a bilinear form in X and Y.

Since the product of two matrices is a bilinear form, it is natural to consider bilinear arithmetic circuits for it. A bilinear arithmetic circuit is an arithmetic circuit with the additional restriction that a product gate is allowed only to compute the product of two linear functions—one in the variables of X and the other in the variables of Y. Thus bilinear circuits have the following structure: First, there are many plus gates computing linear forms in X and linear forms in Y. Then there is one level of product gates which compute bilinear forms, and, finally, there are many plus gates that eventually compute the outputs. We will now define the *size* and *depth* of the circuit.

DEFINITION 4.1. *For a bilinear circuit C, we denote by $s(C)$ (the* size *of C) the number of edges between the product gates and the outputs. We denote by $d(C)$ (the* depth *of C) the length of the longest directed path from a product gate to an output.*

Note that these definitions ignore all gates and edges below the product gates (i.e., between the inputs and the products). That is, we allow the circuit to get for free any number of linear functions in the variables of X, and any number of linear functions in the variables of Y. We count only the size and depth above the product gates.

The requirement that the circuit is bilinear seems restrictive. It is easy to show, however, that over fields of characteristic 0, the bilinearity assumption does not change (up to a constant factor) the size and the depth of the circuit. More accurately, by paying a constant factor in the size and in the depth, we can transform any arithmetic circuit computing a bilinear form into an equivalent bilinear circuit. Roughly, this is done in the following way: Since the circuit computes polynomials of degree two, it does not really need to keep track of any monomial of higher degree. Therefore, we need only keep track of monomials of degree one or two, and we can do that by replacing each gate by a constant number of new gates (at most 5 new gates) that satisfy the bilinearity assumption. Thus we have the following proposition.

PROPOSITION 4.2. *If a set of bilinear forms is computed by an arithmetic circuit of depth d and size s over a field of characteristic 0, then there is a bilinear circuit of depth $3d$ and size $5s$ over the same field computing the same set of bilinear forms.*

Over finite fields, the bilinearity assumption may be restrictive. We prove lower bounds for the general case of arithmetic circuits over finite fields in section 5. It is also worth noting that all known algorithms for matrix product are by bilinear arithmetic circuits.

Our main tool in proving our lower bounds is Lemma 3.13. Since that lemma is stated for leveled graphs, we would like our circuit to be leveled. We hence assume that our circuit is a leveled bilinear arithmetic circuit. Since we consider leveled circuits, the depth of the circuit is just the number of levels above the product gates. Our main result in this section is the following lower bound.

THEOREM 4.3. *Any leveled bilinear arithmetic circuit C of depth d, for the product of two $m \times m$ matrices, is of size*

$$s(C) = \begin{cases} \Omega(m^3), & d = 1, \\ \Omega(\frac{1}{d} m^2 \lambda_d(m^2)), & d > 1. \end{cases}$$

In order to prove lower bounds for a nonleveled bilinear circuit, we just level it. We can do that by increasing its size by a factor of d. We can then use the lower bounds for leveled circuits. We hence have the following corollary.

COROLLARY 4.4. *Any bilinear arithmetic circuit C of depth d, for the product of two $m \times m$ matrices, is of size*

$$s(C) = \begin{cases} \Omega(m^3), & d = 1, \\ \Omega(\frac{1}{d^2} m^2 \lambda_d(m^2)), & d > 1. \end{cases}$$

In particular, this gives the following size-depth tradeoff: there is no linear size and constant depth bilinear arithmetic circuit for the product of two matrices. Note that the theorem is valid for any field. It just needs the bilinearity assumption.

After proving the main theorem, we will use the result of Baur and Strassen [BS82] to prove a lower bound on the size of bounded depth arithmetic circuits for the trace of the product of three matrices:

$$\sum_{i,j,k=1}^{m} x_{i,j} \cdot y_{j,k} \cdot z_{k,i},$$

which is a function with a single output.

Let us start with bilinear circuits of depth 1. The structure of such circuits is very simple. First, they compute linear forms. Then there is one level of product gates computing bilinear forms. Finally, there is one level of m^2 plus gates computing the outputs. For the proof, we will use the following notation:

$$O_j = \{z_{i,j} \mid i \in \{1, \ldots, m\}\};$$

i.e., O_j denotes the set of outputs of the jth column of the output matrix.

THEOREM 4.5. *Any leveled bilinear circuit C of depth 1, for the product of two $m \times m$ matrices, is of size*

$$s(C) = \Omega(m^3).$$

Proof. Since the circuit is of depth 1, the outputs come right after the product gates. Each output is computed by a plus gate that adds the results of the product gates that are connected to it. We will show that there are at least m^2 edges connected to each output column O_j. Hence, since there are m output columns, the result follows.

Assume, for a contradiction, that an output column O_j is connected to $r < m^2$ product gates. Denote the functions computed by these gates by $M_1, \ldots, M_r$. For

each M_k, denote by $L_{k,1}(X), L_{k,2}(Y)$ the two linear functions that it multiplies. That is,

$$M_k(X,Y) = L_{k,1}(X) \cdot L_{k,2}(Y).$$

Since $r < m^2$, we can find a substitution for the matrix X such that the following hold:

1. $X \neq 0$.
2. For every $1 \leq k \leq r$, $L_{k,1}(X) = 0$.

Hence, for every $1 \leq k \leq r$,

$$M_k(X,Y) = 0.$$

Therefore, $O_j = 0$, no matter what Y is. On the other hand, $X \neq 0$, and hence we can find a substitution for the matrix Y such that no column of $X \cdot Y$ is all zero (a contradiction). □

The main idea of the proof for depth 1 was the following: if there is a small number of edges in the circuit, then one can find a substitution for the matrix X such that a large number of outputs are forced to be 0 (no matter what Y is). The main idea of the proof for larger depth is the following: First, apply Lemma 3.13 to transform the circuit into a circuit of depth 1. This is done by removing from the circuit a certain number of inputs, outputs, and intermediate gates. Then use the argument for depth 1. However, since we remove from the circuit a certain number of nodes, we will need a more general argument. Roughly, we will need to generalize the proof for depth 1 to the case in which X and Y are restricted to certain subspaces of matrices. We will show that even if X and Y are restricted to (not too small) subspaces, their product still cannot be computed by a small circuit of depth 1. We will use the following notation.

DEFINITION 4.6. *For a matrix X, denote by $(X)_j$ the jth column of X. For a linear subspace of matrices $\mathcal{A}$, denote*

$$(\mathcal{A})_j = \{(X)_j \mid \ X \in \mathcal{A}\}.$$

Since $\mathcal{A}$ is a linear subspace, so is $(\mathcal{A})_j$.

We clearly have the following proposition.

PROPOSITION 4.7. *For any linear subspace of matrices $\mathcal{A}$,*

$$\dim(\mathcal{A}) \leq \sum_{j=1}^{m} \dim((\mathcal{A})_j).$$

We will also need the following lemma. Roughly, the lemma claims that if X is a matrix of large rank and $\mathcal{B}$ is a subspace of matrices of high dimension, then for many columns j, $\dim(\{(X \cdot Y)_j \mid Y \in \mathcal{B}\})$ is high.

LEMMA 4.8. *Let X be an $m \times m$ matrix of rank $\geq \frac{2}{3}m$. Let $\mathcal{B}$ be a linear subspace of $m \times m$ matrices such that $\dim(\mathcal{B}) \geq m^2 - k$. Then, for any subset of columns D of size $|D| \geq \frac{10k}{m}$, there exists a column $j \in D$ such that*

$$\dim(\{(X \cdot Y)_j \mid \ Y \in \mathcal{B}\}) \geq \frac{m}{2}.$$

Proof. Let D be a subset of columns such that $|D| \geq \frac{10k}{m}$. We first show that there is a column $j \in D$ such that $\dim((\mathcal{B})_j) \geq \frac{9}{10}m$. If this were not the case, then

by Proposition 4.7 we would have had

$$m^2 - k \leq \dim(\mathcal{B}) \leq |D| \left(\frac{9}{10} m - 1 \right) + (m - |D|)m = m^2 - \frac{m}{10}|D| - |D| < m^2 - k.$$

Let $j \in D$ be such that $\dim((\mathcal{B})_j) \geq \frac{9}{10}m$. Since $\operatorname{rank}(X) \geq \frac{2}{3}m$, we have

$$\dim(\{(X \cdot Y)_j \mid \ Y \in \mathcal{B}\}) = \dim(\{X \cdot v \mid \ v \in (\mathcal{B})_j\}) \geq \operatorname{rank}(X) - (m - \dim((\mathcal{B})_j))$$

$$\geq \frac{2}{3}m - \frac{1}{10}m > \frac{m}{2}. \qquad \square$$

In the proof for depth 1, we had $X \neq 0$. Since, in the proof for higher depth, Y will be restricted to a subspace of matrices, we will need X to satisfy a stronger condition. Namely, we need X to be of high rank. However, X itself will also be restricted to a subspace of matrices. Therefore, we want to show that in any subspace (of matrices) of high dimension, there is a matrix of high rank.

LEMMA 4.9. *In any subspace of $m \times m$ matrices of dimension larger than $(2mr - r^2 + m)$, there is a matrix of rank at least r.*

Proof. We have two different proofs. The first is for finite fields, and the second is for fields of characteristic 0. We wish to compare the number of matrices with rank at most r to the number of matrices in our linear subspace. If we prove that the number of matrices in the linear subspace is larger, then it must contain a matrix of rank larger than r.

- Assume that F is a finite field. Denote $|F| = q$. The number of elements in a subspace of dimension larger than $(2mr - r^2 + m)$ is larger than $q^{2mr - r^2 + m}$. We will now count the number of $m \times m$ matrices with rank at most r. Note that, for every such matrix, there are r rows such that every row in the matrix is in their linear span. There are $\binom{m}{r}$ possible ways to choose these r rows. There are q^{mr} possible ways to choose the r vectors for these rows. Every other row is in the linear span of these r rows, so it can be one of q^r vectors. Therefore, the number of matrices of rank at most r is bounded from above by

$$\binom{m}{r} q^{mr} (q^r)^{m-r} < q^{2mr - r^2 + m}.$$

- Assume that F is a field of characteristic 0. Instead of counting, we will consider the dimension of the variety of matrices with rank at most r. The same argument as above shows that this variety is included in the union of $\binom{m}{r}$ varieties, each of dimension at most $mr + r(m - r)$. (As before, mr is for the freedom of choice of the first r vectors, and $r(m - r)$ is for spanning the other $m - r$ rows.) Therefore, the dimension is $2mr - r^2 < 2mr - r^2 + m$. $\square$

Before giving the formal proof for Theorem 4.3, let us first give a sketch of this proof. Let C be a leveled bilinear arithmetic circuit of depth d for the product of two $m \times m$ matrices. Let G be the leveled graph of depth d, corresponding to the graph of the circuit between the product gates and the outputs (i.e., the product gates are the inputs of the graph, the outputs are the outputs of the graph, and the levels of the circuit between the product gates and the outputs are the levels of the graph). We would like to prove that

$$s(C) \geq \Omega \left(\frac{1}{d} m^2 \lambda_d(m^2) \right).$$

Assume for a contradiction that $s(C) < \frac{1}{1000d} m^2 \lambda_d(m^2)$ or, in other words,

$$|E_G| < \frac{1}{1000d} m^2 \lambda_d(m^2).$$

By Lemma 3.13, we can find a set of columns D and three sets of vertices V, I, O in the graph G such that the following hold:

- $m \leq |V| = k \leq \frac{1}{10} m^2$.
- I is a small set of inputs.
- D is a set of $\lceil \frac{10k}{m} \rceil$ output columns.
- For every $i \in D$, $|O_i \cap O|$ is small (where O_i is the ith output column).
- All the paths from $O_D \setminus O$ to the inputs pass through V or reach I.

We will derive a contradiction in four steps:

1. Since I is a small set of product gates, we can find a subspace of matrices $\mathcal{A}$ such that, for every matrix X in $\mathcal{A}$, all the gates in I output 0. The matrix X will be restricted to the subspace $\mathcal{A}$.
2. Note that once a matrix X is fixed, the nodes of V just compute linear functions in the variables of Y. Therefore, for every matrix $X \in \mathcal{A}$, we can find a subspace of matrices $\mathcal{B}_X$ such that, for every pair ($X \in \mathcal{A}$, $Y \in \mathcal{B}_X$), all the gates in V output zero. Since V is a small set, the dimension of $\mathcal{B}_X$ is high. The matrix Y will be restricted to the subspace $\mathcal{B}_X$.
3. The subspace $\mathcal{A}$ is of high dimension, and for every X the subspace $\mathcal{B}_X$ is of high dimension. Therefore, we can find $X \in \mathcal{A}$ such that $\dim((X \cdot \mathcal{B}_X)_j)$ is large for some $j \in D$. (This will follow from Lemmas 4.8 and 4.9.)
4. Since we restrict $X \in \mathcal{A}$ and $Y \in \mathcal{B}_X$, all the gates in V and I output zero. Therefore, $X \cdot Y$ is computed by a circuit with no paths between $O_D \setminus O$ and $I_G \setminus I$. Hence all the outputs in $O_D \setminus O$ must give zero. Because of the third step, this is a contradiction.

Let us now give the formal proof.

Proof of Theorem 4.3. We already gave the proof for $d = 1$, so assume $d > 1$. Assume for a contradiction that we have a leveled bilinear arithmetic circuit C of depth d for the product of two $m \times m$ matrices such that

$$s(C) < \frac{1}{1000d} m^2 \lambda_d(m^2).$$

Let G be the leveled graph of depth d between the product gates and the outputs of C (as explained above).

As before, denote by O_j the jth output column. As before, for a set $D \subset [m]$, we denote $O_D = \cup_{i \in D} O_i$. By Lemma 3.13, there exist sets $V \subset V_G$, $D \subset [m]$, $O \subset O_D$, and $I \subset I_G$ such that the following hold:

1. $m \leq |V| \leq \frac{1}{10} m^2$.
2. $|D| \geq \frac{10|V|}{m}$.
3. For every $i \in D$, $|O_i \cap O| < \frac{1}{10} m$.
4. $|I| < \frac{1}{10} m^2$.
5. $P_G[\, I_G \setminus I,\, O_D \setminus O,\, V] = 0$.

Denote $k = |V|$. Hence we have a set of outputs O_D consisting of at least $\frac{10k}{m}$ output columns such that each of the output columns in O_D has a small intersection with O, and there are no paths between $O_D \setminus O$ and $I_G \setminus I$ that do not pass through V.

In the circuit C, the set I is just a set of product gates. Since

$$|I| < \frac{1}{10} m^2,$$

we can find a subspace of matrices $\mathcal{A}$ of dimension

$$\dim(\mathcal{A}) \geq m^2 - |I| > \frac{9}{10}m^2$$

such that, for every $X \in \mathcal{A}$, all the product gates in I give zero.

Assume that a matrix X is fixed. All the functions computed by the vertices of V are now linear functions in the variables of Y. Therefore, for every matrix X, there is a subspace of matrices $\mathcal{B}_X$ such that, for every $Y \in \mathcal{B}_X$, all the gates in V give zero, and such that

$$\dim(\mathcal{B}_X) \geq m^2 - |V| = m^2 - k.$$

Since

$$\dim(\mathcal{A}) \geq \frac{9}{10}m^2,$$

by Lemma 4.9 we can find a matrix $X \in \mathcal{A}$ such that $\operatorname{rank}(X) \geq \frac{2}{3}m$. We fix this X. Since $|D| \geq \frac{10k}{m}$ and $\dim(\mathcal{B}_X) \geq m^2 - k$, we can apply Lemma 4.8 to get a column $j \in D$ such that

$$\dim((X \cdot \mathcal{B}_X)_j) \geq \frac{m}{2}.$$

On the other hand, for $X \in \mathcal{A}$ and $Y \in \mathcal{B}_X$, all the product gates in I and all the gates in V output zero. Since all the paths to $O_D \setminus O$ pass through V or I, we get that, for every $X \in \mathcal{A}$ and $Y \in \mathcal{B}_X$, all the outputs in $O_D \setminus O$ must give zero. Therefore, for every $j \in D$,

$$\dim((X \cdot \mathcal{B}_X)_j) \leq |O_j \cap O| < \frac{m}{10}$$

(a contradiction). □

Theorem 4.3 gives a superlinear lower bound for a multioutput function. The following theorem of [BS82] (it is an immediate corollary of the results presented there) shows that we can also obtain a superlinear lower bound for a single-output function.

THEOREM 4.10 (see [BS82]). *Suppose that $f(x_1, \ldots, x_n)$ is computed by an arithmetic circuit of size s and depth d over a field of characteristic 0; then there is an arithmetic circuit of size $3s$ and depth $2d$ that computes $f, \frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$.*

(Note that in this theorem the size and depth of a circuit are just the usual size and depth; i.e., the size is the number of edges, and the depth is the length of the longest directed path.)

Consider the function

$$f(X, Y, Z) = \sum_{i=1}^{m}\sum_{j=1}^{m}\sum_{k=1}^{m} x_{i,j}y_{j,k}z_{k,i} = \operatorname{trace}(X \cdot Y \cdot Z),$$

where X, Y, Z are $m \times m$ matrices. Notice that

$$\frac{\partial f}{\partial z_{k,i}} = \sum_{j=1}^{m} x_{i,j}y_{j,k} = (X \cdot Y)_{i,k}.$$

Therefore, the partial derivatives of f with respect to the $Z_{k,i}$'s are the outputs of the product of two matrices. If we take into account the price that we have to pay when transforming a circuit into a bilinear leveled one, we get the following theorem.

THEOREM 4.11. *Every arithmetic circuit C of depth d that computes the trace of the product of three $m \times m$ matrices over a field of characteristic 0 is of size*

$$\Omega\left(\frac{1}{d^2} m^2 \lambda_{6d}(m^2)\right).$$

We can also generalize this result for circuits over finite fields, but we must make another assumption: the circuit computes

$$\sum_{i=1}^{m}\sum_{j=1}^{m}\sum_{k=1}^{m} x_{i,j} \cdot y_{j,k} \cdot z_{k,i}$$

as a polynomial and not as a function. As mentioned in the introduction, over finite fields there are many polynomials that represent the same function. For example, $x^p - x = 0$ over a field with p elements. Therefore, we demand that the circuit computes this exact polynomial. In this case, we can apply the theorem of Baur and Strassen as before and get the same lower bound as in the case of characteristic 0.

5. Circuits with arbitrary gates. In this section, we prove lower bounds for circuits with arbitrary gates over finite fields. Since the proofs are similar for all finite fields, we will detail only the proofs for the field $GF(2)$, that is, the Boolean case. The proofs for other fields are only sketched.

A Boolean circuit with arbitrary gates is a directed acyclic graph as follows. Nodes of indegree 0 are called inputs and are labeled with input variables. Nodes of outdegree 0 are called outputs. All nodes other than the inputs are labeled with arbitrary Boolean functions. That is, if v is a node of indegree k, then v is labeled with some function

$$g_v : \{0,1\}^k \to \{0,1\}.^1$$

The inputs to the circuit are Boolean variables, and each node in the circuit computes in a natural way a Boolean function in the original input variables. The size of a circuit C is denoted by $size(C)$ and is defined to be the number of edges in it. The depth of a circuit is defined to be the length of the longest directed path from an input to an output in the circuit. Note that the standard definition of a Boolean circuit requires $g_v \in \{\vee, \wedge, \neg\}$. Our definition is more general and allows g_v to be any function.

The model of Boolean circuits with arbitrary gates includes all other models of Boolean circuits, e.g., standard Boolean circuits, Boolean circuits with threshold gates, Boolean circuits with $MODP$ gates, etc. For some of these models, almost nothing is known. For example, for constant depth threshold circuits, only slightly superlinear lower bounds are known [IPS97]. (Exponential lower bounds are known for depth 2 [HMPST87].)

We will mainly concentrate on matrix product over $GF(2)$. Our main result in this section is the following lower bound.

[1] Since g_v is not necessarily a symmetric function, we need to order the inputs to v so we know which input is the first variable of g_v, etc.

THEOREM 5.1. *Any leveled Boolean circuit with arbitrary gates, C, of depth d, for the product of two $m \times m$ Boolean matrices over $GF(2)$, is of size*

$$size(C) = \begin{cases} \Omega(m^3), & d = 1, \\ \Omega(\frac{1}{d} m^2 \lambda_d(m^2)), & d > 1. \end{cases}$$

As before, in order to prove lower bounds for a nonleveled circuit, we just level it. We can do that by increasing its size by a factor of d. We can then use the lower bounds for leveled circuits. We hence have the following corollary.

COROLLARY 5.2. *Any Boolean circuit with arbitrary gates, C, of depth d, for the product of two $m \times m$ Boolean matrices over $GF(2)$, is of size*

$$size(C) = \begin{cases} \Omega(m^3), & d = 1, \\ \Omega(\frac{1}{d^2} m^2 \lambda_d(m^2)), & d > 1. \end{cases}$$

Our proof for these lower bounds is quite general and can be applied to many other functions. In particular, the lower bound applies also for the following functions:

1. The product of two $m \times m$ matrices over $GF(p)$, where each element of the field is represented by $\lceil \log p \rceil$ bits.
2. All the functions considered in [Pud94], e.g., the parallel prefix linear transformation over $GF(2)$.

As mentioned above, we define a similar model of circuits with arbitrary gates over any finite field. We prove similar lower bounds for this model for any finite field. In particular, for the field $GF(p)$, we prove a lower bound for the product of two $m \times m$ matrices, where the inputs take values in the field.

Let us start with a short sketch of the proof of Theorem 5.1. As before, the proof is based on Lemma 3.13. In all that follows, we use the notation of subsection 3.5. We will apply Lemma 3.13 on the circuit C. By Lemma 3.13, there is a set of columns $D \subset [m]$ and small sets of vertices I, O, V such that I is a set of inputs, O is a set of outputs, V is a set of intermediate gates, and

$$P_G[\, I_G \setminus I,\ O_D \setminus O,\ V] = 0$$

(where O_D is the set of outputs corresponding to the set of columns D). The values of the outputs in $O_D \setminus O$ are hence determined by the outputs of the gates in V and by the values of the inputs in I. Therefore, for any fixed assignment for the inputs in I, the total number of possible values that the outputs in $O_D \setminus O$ can take is at most $2^{|V|}$ (which is the total number of values that the gates in V can output). Since V is a small set, $2^{|V|}$ is a relatively small number, and we conclude that, for any fixed assignment for the inputs in I, the outputs in $O_D \setminus O$ can get only a small number of values. We will derive a contradiction by finding a fixed assignment for the inputs in I such that the outputs in $O_D \setminus O$ can get many values.

Let us describe our assignment for I. First, we fix Y to be a matrix in which any minor of size $\frac{m}{2} \times |D|$ is of high rank. Therefore, there will be many vectors in the image of any such minor. After fixing Y, we set to zero all the inputs in I that come from the matrix X. That is, we allow X to be any matrix in which this certain set of entries is zero (the entries that appear in I). Since I is a relatively small set, there are many such matrices. More accurately, the set of all such matrices forms a linear subspace of dimension $\geq m^2 - |I|$. The last step will be to show that, after fixing Y as above and after fixing to 0 all the inputs in I that come from X, there are still many possibilities for the product $X \cdot Y$. In particular, we will get that the number of possible values for the outputs in $O_D \setminus O$ is larger than $2^{|V|}$.

Thus the first step is to show that there is a matrix Y, in which any minor of size $\frac{m}{2} \times |D|$ is of high rank. Note that it is not hard to prove that there exists a matrix Y, in which any such minor is of maximal rank. For our proof, however, it will be enough to have the weaker requirement that any such minor is of high rank.

DEFINITION 5.3. *Let $Y = (y_{i,j})$ be an $m \times m$ matrix. For sets $\alpha, \beta \subset [m]$, denote*

$$(Y)_{\alpha,\beta} = (y_{i,j}) \text{ such that } i \in \alpha,\ j \in \beta;$$

i.e., $(Y)_{\alpha,\beta}$ is the minor of Y with the set of rows α and the set of columns β.

CLAIM 5.4. *For any $m > 40$ and $l \leq \frac{m}{2}$, there exists an $m \times m$ matrix Y (over $GF(2)$) such that, for any $\alpha, \beta \subset [m]$, with $|\alpha| = \lceil \frac{m}{2} \rceil$ and $|\beta| = l$,*

$$\operatorname{rank}((Y)_{\alpha,\beta}) \geq \frac{l}{2}.$$

Proof. We assume for convenience that m, l are even numbers. We will show that a random matrix Y satisfies the requirement of the lemma (with high probability). Let us first calculate the probability that a certain minor of size $\frac{m}{2} \times l$ is of rank $\leq \frac{l}{2}$. As in the proof of Lemma 4.9, the number of $\frac{m}{2} \times l$ matrices of rank $\leq \frac{l}{2}$ is at most

$$\binom{l}{\frac{l}{2}} \cdot 2^{\frac{m}{2} \cdot \frac{l}{2}} \cdot 2^{\frac{l}{2} \cdot (l - \frac{l}{2})} < 2^{\frac{1}{4}ml + \frac{1}{4}l^2 + l}.$$

Therefore, the probability that a certain minor of size $\frac{m}{2} \times l$ is of rank $\leq \frac{l}{2}$ is at most

$$2^{\frac{1}{4}ml + \frac{1}{4}l^2 + l} \cdot 2^{-\frac{m}{2}l} = 2^{-(\frac{1}{4}ml - \frac{1}{4}l^2 - l)}.$$

Hence, if Y is a random matrix, the probability that some $\frac{m}{2} \times l$ minor is of rank $\leq \frac{l}{2}$ is at most

$$\binom{m}{\frac{m}{2}} \cdot \binom{m}{l} \cdot 2^{-(\frac{1}{4}ml - \frac{1}{4}l^2 - l)} \leq 2^{-(\frac{1}{4}ml - \frac{1}{4}l^2 - l - 2m)} < 1.$$

Consequently, there is an $m \times m$ matrix Y, in which every $\frac{m}{2} \times l$ minor is of rank $> \frac{l}{2}$. ∎

For a set of coordinates $\beta \subset [m]$ and an m-vector v, denote by v_β the restriction of v to β; i.e.,

$$v_\beta = (v_i)_{i \in \beta}.$$

For a set of coordinates $\alpha \subset [m]$, denote by $\mathcal{V}_\alpha$ the subspace of all vectors that have the value 0 in all the coordinates outside α; i.e.,

$$\mathcal{V}_\alpha = \{v \in \{0,1\}^m \mid \forall i \in [m] \setminus \alpha,\ v_i = 0\}.$$

We will now prove that, if Y is the matrix guaranteed by Claim 5.4 for $l = |\beta|$, then for every vector space $\mathcal{V}_\alpha$ of high dimension, there are many different vectors in the set

$$\{(v \cdot Y)_\beta \mid v \in \mathcal{V}_\alpha\}.$$

CLAIM 5.5. *Let $\beta \subset [m]$ be such that $|\beta| \leq \frac{m}{2}$. Let $\alpha \subset [m]$ be such that $|\alpha| = \lceil \frac{m}{2} \rceil$. Let Y be an $m \times m$ matrix that satisfies the requirement of Claim 5.4 for*

$l = |\beta|$. Then the number of different vectors of the form $(v \cdot Y)_\beta$, where $v \in \mathcal{V}_\alpha$, is at least $2^{\frac{|\beta|}{2}}$.

Proof. Since Y satisfies the requirement of Claim 5.4 for $l = |\beta|$, the minor $(Y)_{\alpha,\beta}$ is of rank at least $|\beta|/2$. Hence the image of this minor is of dimension at least $|\beta|/2$. The image of this minor is just the set of all vectors of the form $(v \cdot Y)_\beta$, where $v \in \mathcal{V}_\alpha$. Hence this set is of size at least $2^{\frac{|\beta|}{2}}$. □

We are now ready to give the proof of Theorem 5.1.

Proof of Theorem 5.1. For $d = 1$, the proof is trivial by the observation that every output column depends on all the variables in X. For larger depth, assume for a contradiction that $size(C) < (1/1000d) \cdot m^2 \lambda_d(m^2)$. Let G be the graph of the circuit. By Lemma 3.13, there exist sets $V \subset V_G$, $D \subset [m]$, $O \subset O_D$, $I \subset I_G$, such that the following hold:

1. $m \leq |V| = k \leq \frac{1}{30}m^2$.
2. $|D| = \lceil \frac{10k}{m} \rceil < \frac{m}{2}$.
3. For every $i \in D$, $|O_i \cap O| < \frac{1}{10}m$.
4. $|I| < \frac{1}{10}m^2$.
5. $P_G[\, I_G \setminus I,\, O_D \setminus O,\, V] = 0$.

Since $P_G[\, I_G \setminus I,\, O_D \setminus O,\, V] = 0$, the values of the outputs in $O_D \setminus O$ are determined by the outputs of the gates in V and by the inputs in I.

Fix Y to be a matrix in which every $\lceil \frac{m}{2} \rceil \times |D|$ minor is of rank higher than $\frac{|D|}{2}$. (By Claim 5.4, there exists such a matrix.) Denote by I_X the set of inputs in I that are variables of X. Obviously,

$$|I_X| \leq |I| < \frac{1}{10}m^2.$$

Fix all the input variables in I_X to be 0. Since all the inputs in I are now fixed, the values of the outputs in $O_D \setminus O$ are determined by the outputs of the gates in V. Since there are at most 2^k possible values for the outputs of the gates in V, we conclude that, after fixing Y and I_X as above, the outputs in $O_D \setminus O$ can get at most 2^k different values.

On the other hand, we fixed only less than $\frac{1}{10}m^2$ of the entries of X. Therefore, the number of rows of X, in which we fixed at most $\frac{m}{2}$ entries, is at least $\frac{8}{10}m$. For each one of these rows, we can apply Claim 5.5 (with $\beta = D$) and conclude that the outputs in the corresponding row in O_D can get at least $2^{\frac{|D|}{2}}$ possible values. Since the value of each of these $\frac{8}{10}m$ rows of X is independent of the values of the other rows, we conclude that the total number of different values that the outputs in O_D can get is at least

$$2^{\frac{|D|}{2} \cdot \frac{8}{10}m} = 2^{\frac{4}{10} \cdot |D| \cdot m}.$$

Since, for every $i \in D$, $|O_i \cap O| < \frac{1}{10}m$, we get that

$$|O| < \frac{1}{10} \cdot |D| \cdot m.$$

Hence the outputs in O can get at most

$$2^{\frac{1}{10} \cdot |D| \cdot m}$$

different values. Therefore, the outputs in $O_D \setminus O$ can get at least

$$2^{\frac{4}{10} \cdot |D| \cdot m} \,/\, 2^{\frac{1}{10} \cdot |D| \cdot m} = 2^{\frac{3}{10} \cdot |D| \cdot m} \geq 2^{3k}$$

different values (a contradiction). □

As mentioned above, we can also obtain similar lower bounds for circuits with arbitrary gates over any finite field. A circuit with arbitrary gates over a finite field $GF(p)$ is defined similarly to a circuit with arbitrary gates over $GF(2)$. The only difference is that the inputs take values in $GF(p)$, and every gate of indegree k is labeled with an arbitrary function from $GF(p)^k$ to $GF(p)$. Note that, in particular, this model includes the model of arithmetic circuits over $GF(p)$.

THEOREM 5.6. *Any circuit C with arbitrary gates over $GF(p)$, where p is constant, of depth d for the product of two $m \times m$ matrices over $GF(p)$ is of size*

$$size(C) = \begin{cases} \Omega(m^3), & d = 1, \\ \Omega(\frac{1}{d^2} m^2 \lambda_d(m^2)), & d > 1. \end{cases}$$

The proof is similar to the proof of Theorem 5.1 with some minor modifications: We prove a version of Claim 5.4 to get a matrix with the same properties over $GF(p)$. Then we prove a version of Claim 5.5 for $GF(p)$. (Both proofs are similar to the original proofs.) We then repeat the proof of Theorem 5.1 to get Theorem 5.6. (We have to make some minor changes; e.g., the outputs of the gates in V can get $p^{|V|}$ different values (rather than $2^{|V|}$), etc.)

We can also prove similar lower bounds for Boolean circuits with arbitrary gates for the product of two $m \times m$ matrices over the field $GF(p)$, where each element of the field is represented by $\lceil \log p \rceil$ bits. (Note that the input to the circuit is of size $2m^2 \lceil \log p \rceil$.) One way of proving this lower bound is by a reduction to Theorem 5.6. Just observe that $\{0, 1\} \subset GF(p)$, and hence any Boolean circuit (with arbitrary gates) can be viewed as a circuit with arbitrary gates over $GF(p)$. Another way of proving this lower bound is by proving a version of Lemma 3.13 with different parameters (because of the $\lceil \log p \rceil$ factor), and then we can repeat the proof of Theorem 5.1 with minor modifications.

THEOREM 5.7. *Any Boolean circuit with arbitrary gates, C, of depth d, for the product of two $m \times m$ matrices over $GF(p)$ (p is constant), is of size*

$$size(C) = \begin{cases} \Omega(m^3), & d = 1, \\ \Omega(\frac{1}{d^2} m^2 \lambda_d(m^2)), & d > 1. \end{cases}$$

Acknowledgments. We would like to thank Toni Pitassi and Avi Wigderson for helpful conversation.

NEW RESULTS ON MONOTONE DUALIZATION AND GENERATING HYPERGRAPH TRANSVERSALS*

THOMAS EITER†, GEORG GOTTLOB†, AND KAZUHISA MAKINO‡

Abstract. We consider the problem of dualizing a monotone CNF (equivalently, computing all minimal transversals of a hypergraph) whose associated decision problem is a prominent open problem in NP-completeness. We present a number of new polynomial time, respectively, output-polynomial time results for significant cases, which largely advance the tractability frontier and improve on previous results. Furthermore, we show that duality of two monotone CNFs can be disproved with limited nondeterminism. More precisely, this is feasible in polynomial time with $O(\log^2 n/\log\log n)$ suitably guessed bits. This result sheds new light on the complexity of this important problem.

Key words. dualization, hypergraphs, transversal computation, output-polynomial algorithms, combinatorial enumeration, treewidth, hypergraph acyclicity, limited nondeterminism

1. Introduction.

Recall that the prime conjunctive normal form (CNF) of a monotone Boolean function f is the unique formula $\varphi = \bigwedge_{c\in S} c$ in conjunctive normal form, where S is the set of all prime implicates of f, i.e., minimal clauses c which are logical consequences of f. In this paper, we consider the following problem.

Problem DUALIZATION
Input: The prime CNF φ of a monotone Boolean function $f = f(x_1, \ldots, x_m)$.
Output: The prime CNF ψ of its dual $f^a d = \overline{f}(\overline{x}_1, \ldots, \overline{x}_m)$.

It is well known that DUALIZATION is equivalent to the TRANSVERSAL COMPUTATION problem, which requests to compute the set of all minimal transversals (i.e., minimal hitting sets) of a given hypergraph $\mathcal{H}$, in other words, the *transversal hypergraph* $Tr(\mathcal{H})$ of $\mathcal{H}$. Actually, these problems can be viewed as the same problem if the clauses in a monotone CNF φ are identified with the sets of variables they contain. DUALIZATION is a search problem; the associated decision problem DUAL is to decide whether two given monotone prime CNFs φ and ψ represent a pair (f, g) of dual Boolean functions. Analogously, the decision problem TRANS-HYP associated with TRANSVERSAL COMPUTATION is deciding, given hypergraphs $\mathcal{H}$ and $\mathcal{G}$, whether $\mathcal{G} = Tr(\mathcal{H})$.

DUALIZATION and several problems which are like transversal computation known to be computationally equivalent to problem DUALIZATION (see [15]) are of interest

in various areas such as database theory (e.g., [39, 50]), machine learning and data mining (e.g., [7, 8, 10, 25]), game theory (e.g., [26, 43, 44]), artificial intelligence (e.g., [21, 30, 32, 45]), mathematical programming (e.g., [5]), and distributed systems (e.g., [18, 27]), to mention a few.

While the output CNF ψ can be exponential in the size of φ, it is currently not known whether ψ can be computed in *output-polynomial* (or *polynomial total*) *time*, i.e., in time polynomial in the combined size of φ *and* ψ. Any such algorithm for DUALIZATION (or for TRANSVERSAL COMPUTATION) would significantly advance the state of the art of several problems in the above application areas. Similarly, the complexity of DUAL (equivalently, TRANS-HYP) has been open for more than 20 years now (cf. [3, 15, 28, 29, 34]).

Note that DUALIZATION is solvable in polynomial total time on a class $\mathcal{C}$ of hypergraphs iff DUAL is in PTIME for all pairs $(\mathcal{H}, \mathcal{G})$, where $\mathcal{H} \in \mathcal{C}$ [3]. DUAL is known to be in co-NP, and the best currently known upper time-bound is quasi-polynomial time [17, 19, 48]. Determining the complexities of DUALIZATION and DUAL, and of equivalent problems such as the transversal problems, is a prominent open problem. This is witnessed by the fact that these problems are cited in a rapidly growing body of literature and have been referenced in various survey papers and complexity theory retrospectives, e.g., [28, 35, 40].

Given the importance of monotone dualization and equivalent problems for many application areas, and given the long-standing failure to settle the complexity of these problems, emphasis was put on finding tractable cases of DUAL and corresponding polynomial total time cases of DUALIZATION. In fact, several relevant tractable classes were found by various authors; see, e.g., [4, 6, 9, 12, 10, 14, 15, 20, 37, 38, 42, 41] and references therein. Moreover, classes of formulas were identified on which DUALIZATION is not just polynomial total time, but where the conjuncts of the dual formula can be enumerated with *incremental polynomial delay*, i.e., with delay polynomial in the size of the input plus the size of all conjuncts so far computed, or even with *polynomial delay*, i.e., with delay polynomial in the input size only. On the other hand, there are also results which show that certain well-known algorithms for DUALIZATION are not polynomial total time. For example, [15, 42] pointed out that a well-known sequential algorithm, in which the clauses c_i of a CNF $\varphi = c_1 \wedge \cdots \wedge c_m$ are processed in order $i = 1, \ldots, m$, is not polynomial total time in general. Most recently, [47] showed that this holds even if an optimal ordering of the clauses is assumed (i.e., they may be arbitrarily arranged for free).

Main goal. The main goal of this paper is to present important new polynomial total time cases of DUALIZATION and, correspondingly, PTIME solvable subclasses of DUAL which significantly improve previously considered classes. Toward this aim, we first present a new algorithm DUALIZE and prove its correctness. DUALIZE can be regarded as a generalization of a related algorithm proposed by Johnson, Yannakakis, and Papadimitriou [29]. Like other dualization algorithms, DUALIZE reduces the original problem by self-reduction to smaller instances. However, the subdivision into subproblems proceeds according to a particular order, which is induced by an arbitrary fixed ordering of the variables. This, in turn, allows us to derive some bounds on intermediate computation steps which imply that DUALIZE, when applied to a variety of input classes, outputs the conjuncts of ψ with polynomial delay or incremental polynomial delay. In particular, we show positive results for the following input classes.

Degenerate CNFs. We generalize the notion of k-degenerate graphs [51] to hypergraphs and define *k-degenerate monotone CNFs*, respectively, *hypergraphs*. A mono-

tone CNF is *k-degenerate* if there exists a variable ordering $x_1, \ldots, x_n$ such that, for $i = 1, 2, \ldots, n$, the number of clauses which contain x_i and, apart from it, only variables from $x_1, \ldots, x_{i-1}$ is at most k. We prove that, for any constant k, DUALIZE works with polynomial delay on k-degenerate CNFs. Moreover, it works in output-polynomial time on $O(\log n)$-degenerate CNFs.

Read-k CNFs. A CNF is *read-k* if each variable appears at most k times in it. We show that, for read-k CNFs, problem DUALIZATION is solvable with polynomial delay if k is constant and in total polynomial time if $k = O(\log \|\varphi\|)$. Our result for constant k significantly improves upon the previous best-known algorithm [10], which has a higher complexity bound, is not polynomial delay, and outputs the clauses of ψ in no specific order. The result for $k = O(\log \|\varphi\|)$ is a nontrivial generalization of the result in [10], which was posed as an open problem [13].

Acyclic CNFs. There are several notions of hypergraph, respectively, monotone CNF acyclicity [16], where the most general and well-known is α-acyclicity. As shown in [15], DUALIZATION is polynomial total time for β-acyclic CNFs; β-acyclicity is the hereditary version of α-acyclicity and far less general. A similar result for α-acyclic prime CNFs was left open. (For nonprime α-acyclic CNFs, this is trivially as hard as the general case.) In this paper, we give a positive answer and show that, for α-acyclic (prime) φ, DUALIZATION is solvable with polynomial delay.

Formulas of bounded treewidth. The *treewidth* [46] of a graph expresses its degree of cyclicity. Treewidth is an extremely general notion, and bounded treewidth generalizes almost all other notions of near-acyclicity. Following [11], we define the treewidth of a hypergraph, respectively, monotone CNF φ, as the treewidth of its associated (bipartite) variable-clause incidence graph. We show that DUALIZATION is solvable with polynomial delay (exponential in k) if the treewidth of φ is bounded by a constant k and in polynomial total time if the treewidth is $O(\log \log \|\varphi\|)$.

Recursive applications of DUALIZE *and k-CNFs.* We show that if DUALIZE is applied recursively and the recursion depth is bounded by a constant, then DUALIZATION is solved in polynomial total time. We apply this to provide a simpler proof of the known result [6, 15] that monotone k-CNFs (where each conjunct contains at most k variables) can be dualized in output-polynomial time.

After deriving the above results, we turn our attention in section 5 to the fundamental computational nature of problems DUAL and TRANS-HYP in terms of complexity theory.

Limited nondeterminism. In a landmark paper, Fredman and Khachiyan [17] proved that problem DUAL can be solved in quasi-polynomial time. More precisely, they first gave an Algorithm A solving the problem in $n^{O(\log^2 n)}$ time and then a more complicated Algorithm B whose runtime is bounded by $n^{4\chi(n)+O(1)}$, where $\chi(n)$ is defined by $\chi(n)^{\chi(n)} = n$. As noted in [17], $\chi(n) \sim \log n / \log \log n = o(\log n)$; therefore, duality checking is feasible in $n^{o(\log n)}$ time. This is the best upper bound for problem DUAL so far and shows that the problem is most likely not NP-complete.

A natural question is whether DUAL lies in some lower complexity class based on other resources than just runtime. In the present paper, we advance the complexity status of this problem by showing that its complement is feasible with *limited nondeterminism*, i.e, by a nondeterministic polynomial time algorithm that makes only a polylogarithmic number of guesses. For a survey on complexity classes with limited nondeterminism and for several references, see [22]. We first show by using a simple but effective technique, which succinctly describes computation paths, that testing nonduality is feasible in polynomial time with $O(\log^3 n)$ nondeterministic steps. We then observe that this approach can be improved to obtain a bound of

$O(\chi(n) \cdot \log n) = O(\log^2 n / \log\log n)$ nondeterministic steps. *This result is surprising because most researchers dealing with the complexity of* DUAL *and* TRANS-HYP *believed so far that these problems are completely unrelated to limited nondeterminism.*

We believe that the results presented in this paper are significant, and we are confident that they will be proven useful in various contexts. First, we hope that the various polynomial/output-polynomial cases of the problems which we identify will lead to better and more general methods in various application areas (as we show, e.g., in learning and data mining [10]) and that, based on the algorithm DUALIZE or some future modifications, further relevant tractable classes will be identified. Second, we hope that our discovery on limited nondeterminism will provide a new momentum to complexity research on DUAL and TRANS-HYP and will push toward settling these long-standing open problems.

The rest of this paper is structured as follows. The next section provides some preliminaries and introduces notation. In section 3, we present our Algorithm DUALIZE for dualizing a given monotone prime CNF. After that, we exploit this algorithm in section 4 to derive a number of polynomial instance classes of the problems DUALIZATION and DUAL. In section 5, we then show that DUAL can be solved with limited nondeterminism.

2. Preliminaries and notation. A *Boolean function* (in short, *function*) is a mapping $f : \{0,1\}^n \to \{0,1\}$, where $v \in \{0,1\}^n$ is called a *Boolean vector* (in short, *vector*). As usual, we write $g \leq f$ if f and g satisfy $g(v) \leq f(v)$ for all $v \in \{0,1\}^n$, and $g < f$ if $g \leq f$ and $g \neq f$. A function f is *monotone* (or *positive*) if $v \leq w$ (i.e., $v_i \leq w_i$ for all i) implies $f(v) \leq f(w)$ for all $v, w \in \{0,1\}^n$. Boolean variables $x_1, x_2, \ldots, x_n$ and their complements $\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n$ are called *literals*. A *clause* (resp., *term*) is a disjunction (resp., conjunction) of literals containing at most one of x_i and $\bar{x}_i$ for each variable. A clause c (resp., term t) is an *implicate* (resp., *implicant*) of a function f if $f \leq c$ (resp., $t \leq f$); moreover, it is *prime* if there is no implicate $c' < c$ (resp., no implicant $t' > t$) of f and *monotone* if it consists only of positive literals. We denote by $PI(f)$ the set of all prime implicants of f.

A *conjunctive normal form* (CNF) (resp., disjunctive normal form (DNF)) is a conjunction of clauses (resp., disjunction of terms); it is *prime* (resp., *monotone*) if all its members are prime (resp., *monotone*). For any CNF (resp., DNF) ρ, we denote by $|\rho|$ the number of clauses (resp., terms) in it. Furthermore, for any formula φ, we denote by $V(\varphi)$ the set of variables that occur in φ and by $\|\varphi\|$ its *length*, i.e., the number of literals in it. We occasionally view CNFs φ also as sets of clauses, and clauses as sets of literals, and use respective notation (e.g., $c \in \varphi$, $\bar{x}_1 \in c$, etc.).

As is well known, a function f is monotone iff it has a monotone CNF. Furthermore, all prime implicants and prime implicates of a monotone f are monotone, and it has a unique prime CNF, given by the conjunction of all its prime implicates. For example, the monotone f such that $f(v) = 1$ iff $v \in \{(1100), (1110), (1101), (0111), (1111)\}$ has the unique prime CNF $\varphi = x_2(x_1 \vee x_3)(x_1 \vee x_4)$.

Recall that the *dual* of a function f, denoted f^d, is defined by $f^d(x) = \overline{f}(\overline{x})$, where $\overline{f}$ and $\overline{x}$ are the complements of f and x, respectively. By definition, we have $(f^d)^d = f$. From De Morgan's law, we obtain a formula for f^d from any one of f by exchanging $\vee$ and $\wedge$ as well as the constants 0 and 1. For example, if f is given by $\varphi = x_1x_2 \vee \bar{x}_1(\bar{x}_3 \vee x_4)$, then f^d is represented by $\psi = (x_1 \vee x_2)(\bar{x}_1 \vee \bar{x}_3x_4)$. For a monotone function f, let $\psi = \bigwedge_{c \in C}(\bigvee_{x_i \in c} x_i)$ be the prime CNF of f^d. Then, by De Morgan's law, f has the (unique) prime DNF $\rho = \bigvee_{c \in C}(\bigwedge_{x_i \in c} x_i)$; in the previous example, $\rho = x_1x_2 \vee x_2x_3x_4$. Thus we will regard DUALIZATION also as the problem

of computing the prime DNF of f from the prime CNF of f.

3. Ordered transversal generation. In what follows, let f be a monotone function, and let

$$\varphi = \bigwedge_{i=1}^{m} c_i \tag{1}$$

be a monotone CNF of it, where we assume without loss of generality that all variables x_j $(j = 1, 2, \ldots, n)$ appear in φ. Let φ_i $(i = 0, 1, \ldots, n)$ be the CNF obtained from φ by fixing variables $x_j = 1$ for all j with $j \geq i+1$. By definition, we have $\varphi_0 = 1$ (truth) and $\varphi_n = \varphi$. For example, consider $\varphi = (x_1 \vee x_2)(x_1 \vee x_3)(x_2 \vee x_3 \vee x_4)(x_1 \vee x_4)$. Then we have $\varphi_0 = \varphi_1 = 1$, $\varphi_2 = (x_1 \vee x_2)$, $\varphi_3 = (x_1 \vee x_2)(x_1 \vee x_3)$, and $\varphi_4 = \varphi$. Similarly, for a monotone DNF

$$\psi = \bigvee_{t=1}^{k} t_i \tag{2}$$

of f, we denote by ψ_i the DNF obtained from ψ by fixing variables $x_j = 1$ for all j with $j \geq i + 1$. Clearly, we have $\varphi_i \equiv \psi_i$; i.e., φ_i and ψ_i represent the same function denoted by f_i.

PROPOSITION 3.1. *Let φ and ψ be any CNF and DNF for f, respectively. Then, for all $i \geq 0$,* (a) $\|\varphi_i\| \leq \|\varphi\|$ *and* $|\varphi_i| \leq |\varphi|$, *and* (b) $\|\psi_i\| \leq \|\psi\|$ *and* $|\psi_i| \leq |\psi|$.

Denote by Δ^i $(i = 1, 2, \ldots, n)$ the CNF consisting of all the clauses in φ_i but not in φ_{i-1}. For the above example, we have $\Delta^1 = 1$, $\Delta^2 = (x_1 \vee x_2)$, $\Delta^3 = (x_1 \vee x_3)$, and $\Delta^4 = (x_2 \vee x_3 \vee x_4)(x_1 \vee x_4)$. Note that $\varphi_i = \varphi_{i-1} \wedge \Delta^i$; hence, for all $i = 1, 2, \ldots, n$, we have

$$\psi_i \equiv \psi_{i-1} \wedge \Delta^i \equiv \bigvee_{t \in PI(f_{i-1})} (t \wedge \Delta^i). \tag{3}$$

Remark 3.1. Let Γ^i denote the prime DNF for Δ^i. For k-degenerate monotone CNFs, the inequalities $|\psi_i| \leq |\psi|$ and $|\Gamma^i| \leq n^k$ readily imply in light of (3) that such CNFs can be dualized in output-polynomial time by simply multiplying the clauses in all Δ^i and combining them in the order specified by their highest-rank variables. However, we shall present a faster algorithm.

Let $\Delta^i[t]$ for $i = 1, \ldots, n$ denote the CNF consisting of all the clauses c such that c contains no literal in t_{i-1} and $c \vee x_i$ appears in Δ^i. For example, if $t = x_2x_3x_4$ and $\Delta^4 = (x_2 \vee x_3 \vee x_4)(x_1 \vee x_4)$, then $\Delta^4[t] = x_1$. It follows from (3) that, for all $i = 1, 2, \ldots, n$,

$$\psi_i \equiv \bigvee_{t \in PI(f_{i-1})} \big((t \wedge \Delta^i[t]) \ \vee \ (t \wedge x_i)\big). \tag{4}$$

In what follows, let φ and ψ be the prime CNF and prime DNF of f, respectively.

LEMMA 3.2. *For every term $t \in PI(f_{i-1})$, let $g_{i,t}$ be the function represented by $\Delta^i[t]$. Then $|PI(g_{i,t})| \leq |\psi_i| \leq |\psi|$.*

Proof. Let $V = \{x_1, x_2, \ldots, x_n\}$, and let $s \in PI(g_{i,t})$. Then, by (4), $t \wedge s$ is an implicant of ψ_i. Hence some $t^s \in PI(f_i)$ exists such that $t^s \geq t \wedge s$. Note that $V(t) \cap V(\Delta^i[t]) = \emptyset$, t and $\Delta^i[t]$ have no variable in common, and hence we have $V(s) \subseteq V(t^s)\,(\subseteq V(s) \cup V(t))$, since otherwise there exists a clause c in $\Delta^i[t]$ such

that $V(c) \cap V(t^s) = \emptyset$, which is a contradiction. Thus $V(t^s) \cap V(\Delta^i[t]) = V(s)$. For any $s' \in PI(g_{i,t})$ such that $s \neq s'$, let $t^s, t^{s'} \in PI(f_i)$ such that $t^s \geq t \wedge s$ and $t^{s'} \geq t \wedge s'$, respectively. By the above discussion, we have $t^s \neq t^{s'}$. This completes the proof. □

We now describe our Algorithm DUALIZE for generating $PI(f)$. It is inspired by a similar graph algorithm of Johnson, Yannakakis, and Papadimitriou [29] and can be regarded as a generalization.

Algorithm DUALIZE

Input: The prime CNF φ of a monotone function f.
Output: The prime DNF ψ of f, i.e., all prime implicants of f.

Step 1:

compute the smallest prime implicant t_{min} of f and set $Q := \{ t_{min} \}$;

Step 2:

while $Q \neq \emptyset$ **do begin**
  remove the smallest t from Q and output t;
  for each i with $x_i \in V(t)$ and $\Delta^i[t] \neq 1$ **do begin**
    compute the prime DNF $\rho_{(t,i)}$ of the function represented by $\Delta^i[t]$;
    for each term t' in $\rho_{(t,i)}$ **do begin**
      if $t_{i-1} \wedge t'$ is a prime implicant of f_i **then begin**
        compute the smallest prime implicant t^* of f such that $t_i^* = t_{i-1} \wedge t'$;
        $Q := Q \cup \{t^*\}$
      end{if}
    end{for}
  end{for}
end{while}

Here, we say that term s is *smaller* than term t if $\sum_{x_j \in V(s)} 2^{n-j} < \sum_{x_j \in V(t)} 2^{n-j}$; i.e., as vector, s is lexicographically smaller than t.

THEOREM 3.3. *Algorithm* DUALIZE *correctly outputs all* $t \in PI(f)$ *in increasing order.*

Proof. First note that the term t^* inserted in Q when t is output is larger than t. Indeed, t' $(\neq 1)$ and t_{i-1} are disjoint and $V(t') \subseteq \{x_1, \ldots, x_{i-1}\}$. Hence every term in Q is larger than all terms already output, and the output sequence is increasing. We show by induction that, if t is the smallest prime implicant of f that was not output yet, then t is already in Q. This clearly proves the result.

Clearly, the above statement is true if $t = t_{min}$. Assume now that $t \neq t_{min}$ is the smallest among the prime implicants not output yet. Let i be the largest index such that t_i is not a prime implicant of f_i. This i is well defined since otherwise $t = t_{min}$ must hold, which is a contradiction. Now we have (1) $i < n$ and (2) $i+1 \notin V(t)$, where (1) holds because t_n $(= t)$ is a prime implicant of f_n $(= f)$ and (2) follows from the maximality of i. Let $s \in PI(f_i)$ such that $V(s) \subseteq V(t_i)$, and let $K = V(t_i) - V(s)$. Then $K \neq \emptyset$ holds, and since $x_{i+1} \notin V(t)$, the term $t' = \bigwedge_{x_j \in K} x_j$ is a prime implicant of $\Delta^{i+1}[s]$. There exists $s' \in PI(f)$ such that $s'_i = s$ and $x_{i+1} \in V(s')$ since $s \wedge x_{i+1} \in PI(f_{i+1})$. Note that $\Delta^{i+1}[s] \neq 0$. Moreover, since s' is smaller than t, by induction s' has already been output. Therefore, $t' = \bigwedge_{x_j \in K} x_j$ has been considered in the inner for-loop of the algorithm. Since $s'_i \wedge t'$ $(= t_i = t_{i+1})$ is a prime implicant of f_{i+1}, the algorithm has added the smallest prime implicant t^* of f such that $t^*_{i+1} = t_{i+1}$. We finally claim that $t^* = t$. Otherwise, let k be the first index

in which t^* and t differ. Then $k > i+1$, $x_k \in V(t)$, and $x_k \notin V(t^*)$. However, this implies $t_k \notin PI(f_k)$, contradicting the maximality of i. □

Remark 3.2. (1) The decomposition rule (4) was already used in [34]. (2) In Step 1, we could generate any prime implicant t of f and choose then a lexicographic term ordering inherited from a dynamically generated variable ordering. In Step 2, it is sufficient that any monotone DNF $\tau_{(t,i)}$ of the function represented by $\Delta^i[t]$ is computed, rather than its prime DNF $\rho_{(t,i)}$. This might make the algorithm faster.

Let us consider the time complexity of Algorithm DUALIZE. We store Q as a binary tree, where each leaf represents a term t and the left (resp., right) son of a node at depth $j-1 \geq 0$, where the root has depth 0 and encodes $x_j \in V(t)$ (resp., $x_j \notin V(t)$). In Step 1, we can compute t_{min} in $O(\|\varphi\|)$ time and initialize Q in $O(n)$ time.

As for Step 2, let $T_{(t,i)}$ be the time required to compute the prime DNF $\rho_{(t,i)}$ from $\Delta^i[t]$. By analyzing its substeps, we can see that each iteration of Step 2 requires $\sum_{x_i \in V(t)}(T_{(t,i)} + |\rho_{(t,i)}| \cdot O(\|\varphi\|))$ time.

Indeed, we can update Q (i.e., remove the smallest term and add t^*) in $O(n)$ time. For each t and i, we can construct $\Delta^i[t]$ in $O(\|\varphi\|)$ time. Moreover, we can check whether $t_{i-1} \wedge t'$ is a prime implicant of f_i, and, if so, we can compute the smallest prime implicant t^* of f such that $t_i^* = t_{i-1} \wedge t'$ in $O(\|\varphi\|)$ time; note that t^* is the smallest prime implicant of the function obtained from f by fixing $x_j = 1$ if $x_j \in V(t_i \wedge t')$ and 0 if $x_j \notin V(t_i \wedge t')$ for $j \leq i$.

Hence we have the following result.

THEOREM 3.4. *The output delay of Algorithm* DUALIZE *is bounded by*

$$\max_{t \in PI(f)} \left(\sum_{x_i \in V(t)} (T_{(t,i)} + |\rho_{(t,i)}| \cdot O(\|\varphi\|)) \right) \tag{5}$$

time, and DUALIZE *needs in total time*

$$\sum_{t \in PI(f)} \sum_{x_i \in V(t)} (T_{(t,i)} + |\rho_{(t,i)}| \cdot O(\|\varphi\|)). \tag{6}$$

If the $T_{(t,i)}$ are bounded by a polynomial in the input length, then DUALIZE becomes a polynomial delay algorithm since $|\rho_{(t,i)}| \leq T_{(t,i)}$ holds for all $t \in PI(f)$ and $x_i \in V(t)$. On the other hand, if they are bounded by a polynomial in the combined input and output length, then DUALIZE is a polynomial total time algorithm, where $|\rho_{(t,i)}| \leq |\psi|$ holds from Lemma 3.2. Using results from [3], we can construct from DUALIZE an incremental polynomial time algorithm for DUALIZATION, which, however, might not output $PI(f)$ in increasing order. Summarizing, we have the following corollary.

COROLLARY 3.5. *Let* $T = \max\{T_{(t,i)} \mid t \in PI(f), x_i \in V(t)\}$. *Then,*

(i) *if* T *is bounded by a polynomial in* n *and* $\|\varphi\|$, *then* DUALIZE *is an* $O(n\|\varphi\|T)$ *polynomial delay algorithm;*

(ii) *if* T *is bounded by a polynomial in* n, $\|\varphi\|$, *and* $\|\psi\|$, *then* DUALIZE *is an* $O(n \cdot |\psi| \cdot (T + |\psi| \cdot \|\varphi\|))$ *polynomial total time algorithm; moreover,* DUALIZATION *is solvable in incremental polynomial time.*

In the next section, we identify sufficient conditions for the boundedness of T and fruitfully apply them to solve open problems and improve previous results.

4. Polynomial classes.

4.1. Degenerate CNFs. We first consider the case of small $\Delta^i[t]$. Generalizing a notion for graphs (i.e., monotone 2-CNFs) [51], we call a monotone CNF φ *k-degenerate* if there exists a variable ordering $x_1, \ldots, x_n$ in which $|\Delta^i| \leq k$ for all $i = 1, 2, \ldots, n$. We call a variable ordering $x_1, \ldots, x_n$ *smallest last* as in [51] if x_i is chosen in the order $i = n, n-1, \ldots, 1$, such that $|\Delta^i|$ is smallest for all variables that were not chosen. Clearly, a smallest last ordering gives the least k such that φ is k-degenerate. Therefore, we can check for every integer $k \geq 1$ whether φ is k-degenerate in $O(\|\varphi\|)$ time. If this holds, then we have $|\rho_{(t,i)}| \leq n^k$ and $T_{(t,i)} = O(kn^{k+1})$ for every $t \in PI(f)$ and $i \in V(t)$ (for $T_{(t,i)}$, apply the distributive law to $\Delta^i[t]$, and remove terms t, where some $x_j \in V(t)$ has no $c \in \Delta^i[t]$ such that $V(t) \cap V(c) = \{x_j\}$). Thus Theorem 3.4 implies the following.

THEOREM 4.1. *For k-degenerate CNFs φ,* DUALIZATION *is solvable with $O(\|\varphi\| \cdot n^{k+1})$ polynomial delay if $k \geq 1$ is constant.*

Applying the result of [36] that log-clause CNF is dualizable in incremental polynomial time, we obtain a polynomiality result also for nonconstant degeneracy.

THEOREM 4.2. *For $O(\log \|\varphi\|)$-degenerate CNFs φ, problem* DUALIZATION *is solvable in polynomial total time.*

In the following, we discuss several natural subclasses of degenerate CNFs.

4.1.1. Read-bounded CNFs. A monotone CNF φ is called *read-k* if each variable appears in φ at most k times. Clearly, read-k CNFs are k-degenerate, and in fact φ is read-k iff it is k-degenerate under every variable ordering. By applying Theorems 4.1 and 4.2, we obtain the following result.

COROLLARY 4.3. *For read-k CNFs φ, problem* DUALIZATION *is solvable*

(i) *with $O(\|\varphi\| \cdot n^{k+1})$ polynomial delay if k is constant and*

(ii) *in polynomial total time if $k = O(\log \|\varphi\|)$.*

Note that Corollary 4.3.(i) trivially implies that DUALIZATION is solvable in $O(|\psi| \cdot n^{k+2})$ time for constant k since $\|\varphi\| \leq kn$. This improves upon the previous best known algorithm [10], which is only $O(|\psi| \cdot n^{k+3})$ time, not polynomial delay, and outputs $PI(f)$ in no specific order. Corollary 4.3 (ii) is a nontrivial generalization of the result in [10], which was posed as an open problem [13].

4.1.2. Acyclic CNFs. Like in graphs, acyclicity is appealing in hypergraphs, respectively, monotone CNFs, from a theoretical as well as a practical point of view. However, there are many notions of acyclicity for hypergraphs (cf. [16]) since different generalizations from graphs are possible. We refer to α-, β-, γ-, and *Berge*-acyclicity as stated in [16], for which the following proper inclusion hierarchy is known:

$$\text{Berge-acyclic} \subseteq \gamma\text{-acyclic} \subseteq \beta\text{-acyclic} \subseteq \alpha\text{-acyclic}.$$

The notion of α-acyclicity came up in relational database theory. A monotone CNF φ is *α-acyclic* iff $\varphi = 1$ or is reducible by the Graham–Yu–Ozsoyoglu-reduction (GYO-reduction) [24, 52], i.e., repeated application of one of the following two rules to 0 (i.e., the empty clause):

(1) If variable x_i occurs in only one clause c, remove x_i from c.

(2) If distinct clauses c and c' satisfy $V(c) \subseteq V(c')$, remove c from φ.

Note that α-acyclicity of a monotone CNF φ can be checked, and a suitable GYO-reduction can be output, in $O(\|\varphi\|)$ time [49]. A monotone CNF φ is *β-acyclic* iff every CNF consisting of clauses in φ is α-acyclic. As shown in [15], the prime implicants of a monotone f represented by a β-acyclic CNF φ can be enumerated (and thus

DUALIZATION solved) in $p(\|\varphi\|) \cdot |\psi|$ time, where p is a polynomial in $\|\varphi\|$. However, the time complexity of DUALIZATION for the more general α-acyclic prime CNFs was left as an open problem. We now show that it is solvable with polynomial delay by showing that α-acyclic CNFs are 1-degenerate.

Let $\varphi \neq 1$ be a prime CNF. Let $a = a_1, a_2, \ldots, a_q$ be a GYO-reduction for φ, where $a_\ell = x_i$ if the ℓth operation removes x_i from c and where $a_\ell = c$ if it removes c from φ. Consider the unique variable ordering $b_1, b_2, \ldots, b_n$ such that b_i occurs after b_j in a for all $i < j$. For example, let $\varphi = c_1c_2c_3c_4$, where $c_1 = (x_1 \vee x_2 \vee x_3)$, $c_2 = (x_1 \vee x_3 \vee x_5)$, $c_3 = (x_1 \vee x_5 \vee x_6)$, and $c_4 = (x_3 \vee x_4 \vee x_5)$. Then φ is α-acyclic since it has the GYO-reduction

$$a_1 = x_2,\ a_2 = c_1,\ a_3 = x_4,\ a_4 = x_6,\ a_5 = c_4,\ a_6 = c_3,\ a_7 = x_1,\ a_8 = x_3,\ a_9 = x_5.$$

From this sequence, we obtain the variable ordering

$$b_1 = x_5,\ b_2 = x_3,\ b_3 = x_1,\ b_4 = x_6,\ b_5 = x_4,\ b_6 = x_2.$$

As easily checked, this ordering shows that φ is 1-degenerate. Under this ordering, we have $\Delta^1 = \Delta^2 = 1$, $\Delta^3 = (x_1 \vee x_3 \vee x_5)$, $\Delta^4 = (x_1 \vee x_5 \vee x_6)$, $\Delta^5 = (x_3 \vee x_4 \vee x_5)$, and $\Delta^6 = (x_1 \vee x_2 \vee x_3)$. This is not accidental.

LEMMA 4.4. *Every α-acyclic prime CNF is 1-degenerate.*

Note that the converse is not true; i.e., there exists a 1-degenerate CNF that is not α-acyclic. For example, $\varphi = (x_1 \vee x_2 \vee x_3)(x_1 \vee x_2 \vee x_4)(x_2 \vee x_3 \vee x_4 \vee x_5)$ is such a CNF. Lemma 4.4 and Theorem 4.1 imply the following result.

COROLLARY 4.5. *For α-acyclic CNFs φ, problem* DUALIZATION *is solvable with $O(\|\varphi\| \cdot n^2)$ delay.*

Observe that, for a prime α-acyclic φ, we have $|\varphi| \leq n$. Thus, if we slightly modify Algorithm DUALIZE to check $\Delta^i = 1$ in advance (which can be done in linear time in a preprocessing phase) such that such Δ^i need not be considered in Step 2, then the resulting algorithm has $O(n \cdot |\varphi| \cdot \|\varphi\|)$ delay. Observe that the algorithm in [15] solves, minorly adapted for enumerative output, DUALIZATION for β-acyclic CNFs with $O(n \cdot |\varphi| \cdot \|\varphi\|)$ delay. Thus the above modification of DUALIZE is of the same order.

4.1.3. CNFs with bounded treewidth. A *tree decomposition (of type* I*)* of a monotone CNF φ is a tree $T = (W, E)$, where each node $w \in W$ is labeled with a set $X(w) \subseteq V(\varphi)$ under the following conditions:

1. $\bigcup_{w \in W} X(w) = V(\varphi)$;
2. for every clause c in φ, there exists some $w \in W$ such that $V(c) \subseteq X(w)$; and
3. for any variable $x_i \in V$, the set of nodes $\{w \in W \mid x_i \in X(w)\}$ induces a (connected) subtree of T.

The *width* of T is $\max_{w \in W} |X(w)| - 1$, and the *treewidth* of φ, denoted by $Tw_1(\varphi)$, is the minimum width over all its tree decompositions.

Note that the usual definition of treewidth for a graph [46] results in the case in which φ is a 2-CNF. Similarly to acyclicity, there are several notions of treewidth for hypergraphs, respectively, monotone CNFs. For example, tree decomposition of type II of CNF $\varphi = \bigwedge_{c \in C} c$ is defined as type-I tree decomposition of its incident 2-CNF (i.e., graph) $G(\varphi)$ [11, 23]. That is, for each clause $c \in \varphi$, we introduce a new variable y_c and construct $G(\varphi) = \bigwedge_{x_i \in c \in \varphi}(x_i \vee y_c)$. (Here, $x_i \in c$ denotes that x_i appears in c.) Let $Tw_2(\varphi)$ denote the type-II treewidth of φ.

PROPOSITION 4.6. *For every monotone CNF φ, it holds that $Tw_2(\varphi) \leq Tw_1(\varphi) + 2^{Tw_1(\varphi)+1}$.*

Proof. Let $T = (W, E)$, $X : W \to 2^V$ be any tree decomposition of φ having width $Tw_1(\varphi)$. Introduce for all $c \in \varphi$ new variables y_c, and add y_c to every $X(w)$ such that $V(c) \subseteq X(w)$. Clearly, the result is a type-I tree decomposition of $G(\varphi)$ and thus a type-II tree decomposition of φ. Since at most $2^{|X(w)|}$ many y_c are added to $X(w)$ and $|X(w)| - 1 \leq Tw_1(\varphi)$ for every $w \in W$, the result follows. □

This means that if $Tw_1(\varphi)$ is bounded by some constant, then so is $Tw_2(\varphi)$. Moreover, $Tw_1(\varphi) = k$ implies that φ is a k-CNF; we discuss k-CNFs in section 4.2 and consider only $Tw_2(\varphi)$ here. The following proposition states some relationships between type-II treewidth and other restrictions of CNFs from above.

PROPOSITION 4.7. *The following properties hold for type-*II *treewidth.*

(i) *There is a family of monotone prime CNFs φ such that $Tw_2(\varphi)$ is bounded by a constant, but φ is not k-CNF for any constant k.*

(ii) *There is a family of monotone prime CNFs φ such that $Tw_2(\varphi)$ is bounded by a constant, but φ does not have bounded read.*

(iii) *There is a family of α-acyclic prime CNFs φ such that $Tw_2(\varphi)$ is not bounded by any constant. (This is a contrast to the graph case that a graph is acyclic if and only if its treewidth is* 1*.)*

Proof. (i) For example, $\varphi = (\bigvee_{x_i \in V} x_i)$ has $Tw_2(\varphi) = 1$, since it has a tree decomposition $T = (W, E)$ with $X : W \to 2^V$ defined by $W = \{1, 2, \ldots, n\}$, $E = \{(w, w+1),\ w = 1, 2, \ldots, n-1\}$, and $X(w) = \{x_w, y_c\}$, $w \in W$, where $c = (\bigvee_{x_i \in V} x_i)$. However, it is not an $(n-1)$-CNF (but an n-CNF). On the other hand, by Lemma 4.8, we can see that there is a family of monotone prime CNFs φ such that $Tw_2(\varphi)$ is not bounded by any constant, but φ is k-CNF for some constant k.

(ii) For example, let φ be a CNF containing $n-1$ clauses $c_i = (x_1 \vee x_i)$, $i = 2, 3, \ldots, n$. Then φ has $Tw_2(\varphi) = 1$, since it has a tree decomposition $T = (W, E)$ with $X : W \to 2^V$ defined by $W = \{(c_i, x_1), (c_i, x_i),\ i = 2, 3, \ldots, n\}$, $E = \{((c_i, x_1), (c_{i+1}, x_1)),\ i = 2, 3, \ldots, n-1\} \cup \{((c_i, x_1), (c_i, x_i)),\ i = 2, 3, \ldots, n\}$, and $X((c_i, x_k)) = \{y_{c_i}, x_k\}$, $(c_i, x_k) \in W$. However, it is not read-$(n-2)$ (but read-$(n-1)$).

(iii) For example, let φ be a CNF on $V = \{x_1, x_2, \ldots, x_{2n}\}$ containing n clauses $c_i = (x_i \vee \bigvee_{j \geq n+1} x_j)$ for $i = 1, \ldots, n$. Then φ is α-acyclic. We claim that $Tw_2(\varphi) \geq n-1$. Let us assume that there exists a tree $T = (W, E)$ with $X : E \to 2^V$ that shows $Tw_2(\varphi) \leq n-2$, where T is regarded as a rooted tree. Let $T_i = (W_i, E_i)$ be the subtree of T induced by $W_i = \{w \in W \mid y_{c_i} \in X(w)\}$, and let r_i be its root. Consider the case in which W_i and W_j are disjoint for some i and j. Suppose that r_j is an ancestor of r_i. Since $|X(r_i)| \leq Tw_2(\varphi) + 1 \leq n-1$, there exists a node $x_{n+k} \in V$ such that $1 \leq k \leq n$ and $x_{n+k} \notin X(r_i)$. However, since the incident graph of φ contains two edges (x_{n+k}, y_{c_i}) and (x_{n+k}, y_{c_j}), we have $x_{n+k} \in \bigcup_{w \in W_i - \{r_i\}} X(w)$ and $x_{n+k} \in \bigcup_{w \in W_j} X(w)$. This is a contradiction to the condition that $\{w \in W \mid x_{n+k} \in X(w)\}$ is connected. Similarly, we can prove our claim when T_i and T_j are disjoint, but r_j is not an ancestor of r_i.

We thus consider the case in which $W_i \cap W_j \neq \emptyset$ holds for any i and j. Since the T_i's are trees, the family of W_i, $i = 1, 2, \ldots, n$, satisfies the well-known Helly property; i.e., there exists a node w in $\bigcap_{i=1}^{n} W_i$. $X(w)$ must contain all y_{c_i}'s. This implies $|X(w)| \geq n$, which is a contradiction. □

As we show now, bounded treewidth implies bounded degeneracy.

LEMMA 4.8. *Let φ be any monotone CNF with $Tw_2(\varphi) = k$. Then φ is 2^k-degenerate.*

Proof. Let $T = (W, E)$ with $X : W \to 2^V$ show $Tw_2(\varphi) = k$. From this, we reversely construct a variable ordering $a = a_1, \ldots, a_n$ on $V = V(\varphi)$ such that

$|\Delta^i| \leq 2^k$ for all i.

Set $i := n$. Choose any leaf w^* of T, and let $p(w^*)$ be a node in W adjacent to w^*. If $X(w^*) \setminus X(p(w^*)) \subseteq \{y_c \mid c \in \varphi\}$, then remove w^* from T. On the other hand, if $(X(w^*) \setminus X(p(w^*))) \cap V = \{x_{j_1}, \ldots, x_{j_\ell}\}$, where $\ell \geq 1$ (in this case, only $X(w^*)$ contains $x_{j_1}, \ldots, x_{j_\ell}$), then define $a_{i+1-h} = x_{j_h}$ for $h = 1, \ldots, \ell$, and update $i := n - \ell$, $X(w^*) := X(w^*) \setminus \{x_{j_1}, \ldots, x_{j_\ell}\}$, and $X(w) := X(w) \setminus \{y_c \mid c \in \varphi, V(c) \cap \{x_{j_1}, \ldots, x_{j_\ell}\} \neq \emptyset\}$ for every $w \in W$. Let a be completed by repeating this process.

We claim that a shows that $|\Delta^i| \leq 2^k$ for all $i = 1, \ldots, n$. To see this, let w^* be chosen during this process, and assume that $a_i \in X(w^*) \setminus X(p(w^*))$. Then, by induction on the (reverse) construction of a, we obtain that, for each clause $c \in \Delta^i$, we must have either (a) $y_c \in X(w^*)$ or (b) $V(c) \subseteq X(w^*)$. The latter case may arise if in previous steps of the process some descendant $d(w^*)$ of w^* was removed which contains y_c such that y_c does not occur in w^*; however, in this case $V(c) \subseteq X(w)$ must be true on every node on the path from $d(w^*)$ to w^*.

Now let $q = |X(w^*) \setminus V|$. Since $|X(w^*) \setminus \{a_i\}| \leq k$, we have

$$|\Delta^i| \;\leq\; q + 2^{k-q} \;\leq\; 2^k.$$

This proves the claim. □

COROLLARY 4.9. *For CNFs φ with $Tw_2(\varphi) \leq k$,* DUALIZATION *is solvable* (i) *with $O(\|\varphi\| \cdot n^{2^k+1})$ polynomial delay if k is constant and* (ii) *in polynomial total time if $k = O(\log\log\|\varphi\|)$.*

4.2. Recursive application of Algorithm DUALIZE. Algorithm DUALIZE computes in Step 2 the prime DNF $\rho_{(t,i)}$ of the function represented by $\Delta^i[t]$. Since $\Delta[t]$ is the prime CNF of some monotone function, we can recursively apply DUALIZE to $\Delta^i[t]$ for computing $\rho_{(t,i)}$. Let us call this variant R-DUALIZE. Then we have the following result.

THEOREM 4.10. *If its recursion depth is d,* R-DUALIZE *solves* DUALIZATION *in $O(n^{d-1} \cdot |\psi|^{d-1} \cdot \|\varphi\|)$ time.*

Proof. If $d = 1$, then $\Delta^i[t_{min}] = 1$ holds for t_{min} and every $i \geq 1$. This means that $PI(f) = \{t_{min}\}$ and φ is a 1-CNF (i.e., each clause in φ contains exactly one variable). Thus, in this case, R-DUALIZE needs $O(n)$ time. Recall that Algorithm DUALIZE needs, by (6), time $\sum_{t \in PI(f)} \sum_{x_i \in V(t)} (T_{(t,i)} + |\rho_{(t,i)}| \cdot O(\|\varphi\|))$. If $d = 2$, then $T_{(t,i)} = O(n)$ and $|\rho_{(t,i)}| \leq 1$. Therefore, R-DUALIZE needs time $O(n \cdot |\psi| \cdot \|\varphi\|)$. For $d \geq 3$, Corollary 3.5.(ii) implies that R-DUALIZE needs $O(n^{d-1} \cdot |\psi|^{d-1} \cdot \|\varphi\|)$ time. □

Recall that a CNF φ is called *k-CNF* if each clause in φ has at most k literals. Clearly, if we apply Algorithm R-DUALIZE to a monotone k-CNF φ, the recursion depth of R-DUALIZE is at most k. Thus we obtain the following result; it re-establishes, with different means, the main positive result of [6, 15].

COROLLARY 4.11. R-DUALIZE *solves* DUALIZATION *in $O(n^{k-1} \cdot |\psi|^{k-1} \cdot \|\varphi\|)$ time, i.e., in polynomial total time for monotone k-CNFs φ where k is constant.*

5. Limited nondeterminism. In the previous section, we discussed polynomial cases of monotone dualization. In this section, we now turn to the issue of the precise complexity of this problem. For this purpose, we consider the decision problem DUAL, i.e., decide whether given monotone prime CNFs φ and ψ represent dual Boolean functions instead of the search problem DUALIZATION.

It appears that problem DUAL can be solved with limited nondeterminism, i.e., with polylog many guessed bits by a polynomial time nondeterministic Turing machine. This result might bring new insight toward settling the complexity of the problem.

We adopt Kintala and Fischer's terminology [33] and write $g(n)$-P for the class of sets accepted by a nondeterministic Turing machine in polynomial time making at most $g(n)$ nondeterministic steps on every input of length n. For every integer $k \geq 1$, define $\beta_k\mathrm{P} = \bigcup_c (c \log^k n)$-P. The $\beta\mathrm{P}$ *Hierarchy* consists of the classes

$$\mathrm{P} = \beta_1\mathrm{P} \subseteq \beta_2\mathrm{P} \subseteq \cdots \subseteq \bigcup_k \beta_k\mathrm{P} = \beta\mathrm{P}$$

and lies between P and NP. The β_kP classes appear to be rather robust; they are closed under polynomial time and logspace many-one reductions and have complete problems (cf. [22]). The complement class of β_kP is denoted by co-β_kP.

We start in section 5.1 by recalling Algorithm A of [17], reformulated for CNFs and by analyzing A's behavior. The proof that A can be converted to an algorithm that uses $\log^3 n$ nondeterministic bit guesses, and that DUAL is thus in co-β_3P, is rather easy and should give the reader a sense of how our new method of analysis works. In section 5.2, we use basically the same technique for analyzing the more involved Algorithm B of [17]. Using a modification of this algorithm, we show that DUAL is in co-β_2P. We also prove the stronger result that the complement of DUAL can be solved in polynomial time with only $O(\chi(n) \cdot \log(n))$ nondeterministic steps (= bit guesses). Finally, section 5.3 shows that membership in co-β_2P can alternatively be obtained by combining the results of [17] with a theorem of Beigel and Fu [2].

5.1. Analysis of Algorithm A of Fredman and Khachiyan. The first algorithm in [17] for recognizing dual monotone pairs is as follows.

Algorithm A (reformulated for CNFs[1]).

Input: Monotone CNFs φ, ψ representing monotone f, g s.t. $V(c) \cap V(c') \neq \emptyset$ for all $c \in \varphi$, $c' \in \psi$.

Output: `yes` if $f = g^d$, and otherwise a vector w of form $w = (w_1, \ldots, w_m)$ such that $f(w) \neq g^d(w)$.

Step 1:

Delete all redundant (i.e., nonminimal) clauses from φ and ψ.

Step 2:

Check that (1) $V(\phi) = V(\psi)$, (2) $\max_{c \in \varphi} |c| \leq |\psi|$, (3) $\max_{c' \in \psi} |c'| \leq |\varphi|$, and (4) $\Sigma_{c \in \varphi} 2^{-|c|} + \Sigma_{c' \in \psi} 2^{-|c'|} \geq 1$. If any of conditions (1)–(4) fails, $f \neq g^d$ and a witness w is found in polynomial time (cf. [17]).

Step 3:

If $|\varphi| \cdot |\psi| \leq 1$, test duality in $O(1)$ time.

Step 4:

If $|\varphi| \cdot |\psi| \geq 2$, find the lowest index variable x_i which occurs in φ or ψ with frequency $\geq 1/\log(|\varphi| + |\psi|)$.

Let

$$\varphi_0 = \{c - \{x_i\} \mid x_i \in c,\, c \in \varphi\}, \quad \varphi_1 = \{c \mid x_i \notin c,\, c \in \varphi\},$$

[1] In [17], duality is tested for DNFs, while our problem DUAL speaks about CNFs; this is insignificant since DNFs are trivially translated to CNFs for this task and vice versa (cf. section 2).

$\psi_0 = \{c' - \{x_i\} \mid x_i \in c',\ c' \in \psi\},\ \psi_1 = \{c' \mid x_i \notin c',\ c' \in \psi\}.$

Call Algorithm A on the two pairs of forms

(A.1) $(\varphi_1, \psi_0 \wedge \psi_1)$ and (A.2) $(\psi_1, \varphi_0 \wedge \varphi_1)$.

If both calls return `yes`, then return `yes` (as $f = g^d$); otherwise, we obtain w such that $f(w) \neq g^d(w)$ in polynomial time (cf. [17]).

We observe that, as noted in [17], the binary length of any standard encoding of the input φ, ψ to Algorithm A is polynomially related to $|\varphi| + |\psi|$ if Step 3 is reached. Thus, for our purpose, we consider $|\varphi| + |\psi|$ to be the input size.

Let φ^*, ψ^* be the original input for A. For any pair (φ, ψ) of CNFs, define its *volume* by $v = |\varphi| \cdot |\psi|$, and let $\epsilon = 1/\log n$, where $n = |\varphi^*| + |\psi^*|$. As shown in [17], Step 4 of Algorithm A divides the current (sub)problem of volume $v = |\varphi| \cdot |\psi|$ by self-reduction into subproblems (A.1) and (A.2) of respective volumes, assuming without loss of generality that x_i frequently occurs in φ (otherwise, swap φ and ψ):

$$|\varphi_1| \cdot |\psi_0 \wedge \psi_1| \leq (1 - \epsilon) \cdot v, \tag{7}$$

$$|\varphi_0 \wedge \varphi_1| \cdot |\psi_1| \leq |\varphi| \cdot (|\psi| - 1) \leq v - 1. \tag{8}$$

Let $T = T(\varphi, \psi)$ be the recursion tree generated by A on input (φ, ψ). In T, each node u is labeled with the respective monotone pair, denoted by $I(u)$; thus, if r is the root of T, then $I(r) = (\varphi, \psi)$. The *volume* $v(u)$ of node u is defined as the volume of its label $I(u)$.

Any node u is a leaf of T if Algorithm A stops on input $I(u) = (\varphi, \psi)$ during Steps 1–3; otherwise, u has a left child u_l and a right child u_r corresponding to (A.1) and (A.2), i.e., labeled $(\varphi_1, \psi_0 \wedge \psi_1)$ and $(\psi_1, \varphi_0 \wedge \varphi_1)$, respectively. Without loss of generality, u_l is the "high frequency move" by the splitting variable.

We observe that every node u in T is determined by a *unique path* from the root to u in T and thus by a unique sequence $seq(u)$ of right and left moves starting from the root of T and ending at u. The following key lemma bounds the number of moves of each type for certain inputs.

LEMMA 5.1. *Suppose* $|\varphi^*| + |\psi^*| \leq |\varphi^*| \cdot |\psi^*|$. *Then for any node* a *in* T, $seq(a)$ *contains at most* v^* *right moves and at most* $\log^2 v^*$ *left moves, where* $v^* = |\varphi^*| \cdot |\psi^*|$.

Proof. By (7) and (8), each move decreases the volume of a node label. Thus the length of $seq(u)$, and in particular the number of right moves, is bounded by v^*. To obtain the better bound for the left moves, we will use the following well-known inequality:

$$(1 - 1/y)^y \leq 1/e \qquad \text{for } y \geq 1. \tag{9}$$

In fact, the sequence $(1 - 1/y_i)^{y_i}$ for any $1 \leq y_1 < y_2 < \cdots$ monotonically converges to $1/e$ from below. By (7), the volume $v(u)$ of any node u such that $seq(u)$ contains $\log^2 v^*$ left moves is bounded as follows:

$$v(u) \leq v^* \cdot (1 - \epsilon)^{\log^2 v^*} = v^* \cdot (1 - 1/\log n)^{\log^2 v^*}.$$

Since $n = |\varphi^*| + |\psi^*| \leq |\varphi^*| \cdot |\psi^*| = v^*$ and because of (9), it follows that

$$\begin{aligned} v(u) &\leq v^* \cdot \left((1 - 1/\log v^*)^{\log v^*}\right)^{\log v^*} \\ &\leq v^* \cdot (1/e)^{\log v^*} = v^*/(e^{\log v^*}) < v^*/(2^{\log v^*}) = 1. \end{aligned}$$

Thus u must be a leaf in T. Hence, for every u in T, $seq(u)$ contains at most $\log^2 v^*$ left moves. □

THEOREM 5.2. *Problem* DUAL *is in* co-β_3P.

Proof. Instances such that either $c \cap c' = \emptyset$ for some $c \in \varphi^*$ and $c' \in \psi^*$, the sequence $seq(u)$ is empty, or $|\varphi^*| + |\psi^*| > |\varphi^*| \cdot |\psi^*|$ are easily recognized and solved in deterministic polynomial time. In the remaining cases, if $f \neq g^d$, then there exists a leaf u in T labeled by a nondual pair (φ', ψ'). If $seq(u)$ is known, we can compute, by simulating Algorithm A on the branch described by $seq(u)$, the entire path $u_0, u_1, \ldots, u_l = u$ from the root u_0 to u with all labels $I(u_0) = (\varphi^*, \psi^*)$, $I(u_1), \ldots, I(u_l)$ and check that $I(u_l)$ is nondual in Steps 2 and 3 of Algorithm A in polynomial time. Since the binary length of any standard encoding of (φ^*, ψ^*) is polynomially related to $n = |\varphi^*| + |\psi^*|$ if $seq(u)$ is nonempty, to prove the result, it is sufficient to show that $seq(u)$ can be constructed in polynomial time from $O(\log^3 v^*)$ suitably guessed bits. To see this, let us represent every $seq(u)$ as a sequence $seq^*(u) = [\ell_0, \ell_1, \ell_2, \ldots, \ell_k]$, where ℓ_0 is the number of leading right moves and ℓ_i is the number of consecutive right moves after the ith left move in $seq(u)$ for $i = 1, \ldots, k$. For example, if $seq(u) = [\mathtt{r}, \mathtt{r}, \mathtt{l}, \mathtt{r}, \mathtt{r}, \mathtt{r}, \mathtt{l}]$, then $seq^*(u) = [2, 3, 0]$. By Lemma 5.1, $seq^*(u)$ has length at most $\log^2 v^* + 1$. Thus $seq^*(u)$ occupies in binary only $O(\log^3 v)$ bits; moreover, $seq(u)$ is trivially computed from $seq^*(u)$ in polynomial time. □

5.2. Analysis of Algorithm B of Fredman and Khachiyan. The aim of the above proof was to exhibit a new method of algorithm analysis that allows us to show with very simple means that duality can be polynomially checked with limited nondeterminism. By applying the same method of analysis to the slightly more involved Algorithm B of [17] (which runs in $n^{4\chi(n)+O(1)}$ time, and thus in $n^{o(\log n)}$ time), we can sharpen the above result by proving that deciding whether monotone CNFs φ and ψ are nondual is feasible in polynomial time with $O(\chi(n) \cdot \log n)$ nondeterministic steps; consequently, the problem DUAL is in co-β_2P.

Like Algorithm A, Algorithm B uses a recursive self-reduction method that decomposes its input, a pair (φ, ψ) of monotone CNFs, into smaller input instances for recursive calls. Analogously, the algorithm is thus best described via its *recursion tree* T, whose root represents the input instance (φ^*, ψ^*) (of size n), whose intermediate nodes represent smaller instances, and whose leaves represent those instances that can be solved in polynomial time. Like for Algorithm A, the nodes u in T are labeled with the respective instances $I(u) = (\varphi, \psi)$ of monotone pairs. Whenever there is a branching from a node u to children, then $I(u)$ is a pair of dual monotone CNFs iff $I(u')$ for *each* child u' of u in T is a pair of dual monotone CNFs. Therefore, the original input (φ^*, ψ^*) is a dual monotone pair iff all leaves of T are labeled with dual monotone pairs.

Rather than describing Algorithm B in full detail, we confine ourselves here to recalling those features which are relevant for our analysis. In particular, we will describe some essential features of its recursion tree T.

For each variable x_i occurring in φ, the *frequency* ϵ_i^φ *of* x_i *with respect to* φ is defined as $\epsilon_i^\varphi = \frac{|\{c \in \varphi : x_i \in c\}|}{|\varphi|}$, i.e., as the number of clauses of φ containing x_i divided by the total number of clauses in φ. Moreover, for each $v \geq 1$, let $\chi(v)$ be defined by $\chi(v)^{\chi(v)} = v$.

Let $v^* = |\varphi^*||\psi^*|$ denote the volume of the input (= root) instance (φ^*, ψ^*). For the rest of this section, we assume that $|\varphi^*| + |\psi^*| \leq |\varphi^*| \cdot |\psi^*|$. In fact, in any instance which violates this inequality, either φ^* or ψ^* has at most one clause; in this case,

DUAL is trivially solvable in polynomial time.

Algorithm B first constructs the root r of T and then recursively expands the nodes of T. For each node u with label $I(u) = (\varphi, \psi)$, Algorithm B does the following.

The algorithm first performs a polynomial time computation, which we shall refer to as LCHECK(φ, ψ) here, as follows. LCHECK(φ, ψ) first eliminates all redundant (i.e., nonminimal) clauses from φ and ψ and then tests whether at least one of the following conditions is violated:

1. $V(\varphi) = V(\psi)$;
2. $\max_{c \in \varphi} |c| \leq |\psi|$ and $\max_{c \in \psi} |c| \leq |\varphi|$;
3. $\min(\, |\varphi|, |\psi|\,) > 2$.

If LCHECK$(\varphi, \psi) = \mathit{true}$, then u is a leaf of T (i.e., not further expanded); whether $I(\varphi, \psi)$ is a dual monotone pair is then decided by some procedure TEST(φ, ψ) in polynomial time. In case TEST(φ, ψ) returns *false*, the original input (φ^*, ψ^*) is not a dual monotone pair, and Algorithm B returns *false*. Moreover, in this case a counterexample w to the duality of φ^* and ψ^* is computable in polynomial time from the path leading from the root r of T to u.

If LCHECK(φ, ψ) returns *false*, Algorithm B chooses in polynomial time some appropriate variable x_i such that $\epsilon_i^{\varphi} > 0$ and $\epsilon_i^{\psi} > 0$ and creates two or more children of u by deterministically choosing one of three alternative decomposition rules, (i), (ii), or (iii). Each rule decomposes $I(u) = (\varphi, \psi)$ into smaller instances, whose respective volumes are summarized as follows. Let, as for Algorithm A, $\varphi_0 = \{c - \{x_i\} \mid x_i \in c,\, c \in \varphi\}$, $\varphi_1 = \{c \mid x_i \notin c,\, c \in \varphi\}$, $\psi_0 = \{c' - \{x_i\} \mid x_i \in c',\, c' \in \psi\}$, and $\psi_1 = \{c' \mid x_i \notin c',\, c' \in \psi\}$. Furthermore, define $\epsilon(v) = 1/\chi(v)$ for any $v > 0$.

Rule (i) If $\epsilon_i^{\varphi} \leq \epsilon(v(u))$, then $I(u)$ is decomposed into:

- (a) one instance $(\varphi_1, \psi_0 \wedge \psi_1)$ of volume $\leq (1 - \epsilon_i^{\varphi}) \cdot v(u)$;
- (b) $|\psi_0|$ instances $I_1, \ldots, I_{|\psi_0|}$ of volume $\leq \epsilon_i^{\varphi} \cdot v(u)$ each. Each such instance I_j corresponds to one clause of ψ_0 and can thus be identified as the jth clause of ψ_0 with an index $j \leq |\psi_0| < n$ (recall that n denotes the size of the original input).

Rule (ii) If $\epsilon_i^{\varphi} > \epsilon(v(u)) \geq \epsilon_i^{\psi}$, then $I(u)$ is decomposed into:

- (a) one instance $(\psi_1, \varphi_0 \wedge \varphi_1)$ of volume $\leq (1 - \epsilon_i^{\psi}) \cdot v(u)$;
- (b) $|\varphi_0|$ instances $I_1, \ldots, I_{|\varphi_0|}$ of volume $\leq \epsilon_i^{\psi} \cdot v(u)$ each. Each such instance I_j corresponds to one clause of φ_0 and can be identified by an index $j \leq |\varphi_0| < v^*$.

Rule (iii) If both $\epsilon_i^{\varphi} > \epsilon(v(u))$ and $\epsilon_i^{\psi} > \epsilon(v(u))$, then I is decomposed into:

- (c_0) one instance of volume $\leq (1 - \epsilon_i^{\varphi}) \cdot v(u)$, and
- (c_1) one instance of volume $\leq (1 - \epsilon_i^{\psi}) \cdot v(u)$.

Algorithm B returns *true* iff TEST$(I(u))$ returns *true* for each leaf u of the recursion tree. This concludes the description of Algorithm B.

For each node u and child u' of u in T, we label the arc (u, u') with the precise type of rule that was used to generate u' from u. The possible labels are thus (i.a), (i.b), (ii.a), (ii.b), (iii.c_0), and (iii.c_1). We call (i.a) and (ii.a) *a-labels*, (i.b) and (ii.b) *b-labels*, and (iii.c_0) and (iii.c_1) *c-labels*. Any arc with a *b*-label is in addition labeled with the index j of the respective instance I_j in the decomposition, which we refer to as the *j-label* of the arc.

DEFINITION 5.1. *For any node u of the tree T, let seq(u) denote the sequence of all edge-labels on the path from the root r of T to u.*

Clearly, if *seq*(u) is known, then the entire path from r to u including all node-labels (in particular, the one of u) can be computed in polynomial time. Indeed,

the depth of the tree is at most v^*, and adding a child to a node of T according to Algorithm B is feasible in polynomial time.

The following lemma bounds the number of various labels which may occur in $seq(u)$.

LEMMA 5.3. *For each node u in T, $seq(u)$ contains at most*

(i) v^* *many a-labels,*
(ii) $\log v^*$ *many b-labels, and*
(iii) $\log^2 v^*$ *many c-labels.*

Proof. (i) Let us consider rule (i.a) first. Given that $\epsilon_i^{\varphi} > 0$, x_i effectively occurs in some clause of φ. Thus $|\varphi_1| < |\varphi|$. Moreover, by definition of ψ_0 and ψ_1, $|\psi_0 \wedge \psi_1| \leq |\psi|$. Thus we have $|\varphi_1| \cdot |\psi_0 \wedge \psi_1| < |\varphi| \cdot |\psi|$. It follows that whenever rule (i.a) is applied, the volume decreases (at least by 1). The same holds for rule (ii.a) by a symmetric argument. Since no rule ever increases the volume, there are at most v^* applications of an a-rule.

(ii) Assume that rule (i.b) is applied to generate a child t' of node t. By condition 3 of LCHECK, $v(t) > 4$. Therefore, $\chi(v(t)) > 2$, and thus $\epsilon_i^{\varphi} \leq \epsilon(v(t)) < 1/2$. It follows that $v(t') < v(t)/2$. The same holds if t' results from t via rule (ii.b). Because no rule ever increases the volume, any node generated after (among others) $\log v^*$ applications of a b-rule has volume ≤ 1 and is thus a leaf in T.

(iii) If a c-rule is applied to generate a child t' of a node t, and since $\epsilon(v(t)) > \epsilon(v^*) > 1/\log v^*$, the volume of $v(t)$ decreases at least by factor $(1 - 1/\log v^*)$. Thus the volume of any node u which results from t after $\log v^*$ applications of a c-rule satisfies $v(u) \leq v(t)(1 - 1/\log v^*)^{\log v^*} \leq v(t)/e$ by (9); i.e., the volume has decreased by more than half. Thus any node u resulting from the root of T after $\log^2 v^*$ applications of a c-rule satisfies $v(u) \leq v^* \cdot (\frac{1}{2})^{\log v^*} = 1$; that is, u is a leaf in T. □

THEOREM 5.4. *Deciding whether monotone CNFs φ and ψ are nondual is feasible in polynomial time with $O(\log^2 n)$ nondeterministic steps, where $n = |\varphi| + |\psi|$.*

Proof. As in the proof of Theorem 5.2, we use a compact representation $seq^*(u)$ of $seq(u)$. However, here the definition of seq^* is somewhat more involved.

1. $seq^*(u)$ contains all b-labels of $seq(u)$, which are the anchor elements of $seq^*(u)$. Every b-label is immediately followed by its associated j-label, i.e., the label specifying which of the (many) b-children is chosen. We call a b-label and its associated j-label a *bj-block*.

2. At the beginning of $seq^*(u)$, as well as after each bj-block, there is an *ac-block*. The first ac-block in $seq^*(u)$ represents the sequence of all a- and c-labels in $seq(u)$ preceding the first b-label in $seq(u)$, and the ith ac-block in $seq^*(u)$, $i > 1$, represents the sequence of the a- and c-labels (uninterrupted by any other label) following the $(i-1)$st bj-block in $seq(u)$.

Each ac-block consists of an α-block followed by a γ-block, where

(i) the α-block contains, in binary, the *number* of a-labels in the ac-block, and
(ii) the γ-block contains all c-labels (single bits) in the ac-block, in the order they appear.

For example, if $s =$ "$(i.a), (ii.a), c_0, (ii.a), c_1, c_0, (i.a)$" is a maximal ac-subsequence in $seq(u)$, then its corresponding ac-block in $seq^*(u)$ is "$10, c_0, c_1, c_0$," where $10\,(= 4)$ is the α-block (stating that there are four a-labels) and "c_0, c_1, c_0" is the γ-block enumerating the c-labels in s in their correct order.

The following facts are now the key to the result.

FACT A. *Given ϕ^*, ψ^*, and a string s, it is possible to compute in polynomial time the path $r = u_0, u_1, \ldots, u_l = u$ from the root r of T to the unique node u in T*

such that $s = seq^*(u)$ and all labels $I(u_i)$, or to tell that no such node u exists (i.e., $s \neq seq^*(u)$ for every node u in T).

This can be done by a simple procedure, which incrementally constructs u_0, u_1, etc. as follows.

Create the root node $r = u_0$, and set $I(u_0) = (\phi^*, \psi^*)$ and $t := 0$. Generate the next node u_{t+1} and label it, while processing the main blocks (*ac*-blocks and *bj*-blocks) in s in order as follows.

ac-block. Suppose the α-block of the current *ac*-block has value n_α and the γ-block contains labels $\gamma_1, \ldots, \gamma_k$. Set up counters $p := 0$ and $q := 0$, and while $p < n_\alpha$ or $q < k$, do the following.

If LCHECK$(I(u_t)) = true$, then flag an error and halt, as $s \neq seq^*(u)$ for every node u in T. Otherwise, determine the rule type $\tau \in \{(\mathrm{i}), (\mathrm{ii}), (\mathrm{iii})\}$ used by Algorithm B to (deterministically) decompose $I(u_t)$.

1. If $\tau \in \{(\mathrm{i}), (\mathrm{ii})\}$ and $p < n_\alpha$, then assign $I(u_{t+1})$ the a-child of $I(u_t)$ according to Algorithm B, and increment p and t by 1.
2. If $\tau = (\mathrm{iii})$ and $q < k$, then increment q by 1, assign $I(u_{t+1})$ the γ_q-child of $I(u_t)$ according to Algorithm B, and increment t by 1.
3. In all other cases (i.e., either $\tau \in \{(\mathrm{i}), (\mathrm{ii})\}$ and $p \geq n_\alpha$ or $\tau = (\mathrm{iii})$ and $q \geq k$), flag an error and halt, since $s \neq seq^*(u)$ for every node u in T.

bj-block. Determine the rule type $\tau \in \{(\mathrm{i}), (\mathrm{ii}), (\mathrm{iii})\}$ used by Algorithm B to (deterministically) decompose $I(u_t)$. If $\tau = (\mathrm{iii})$, then flag an error and halt since $s \neq seq^*(u)$ for every node u in T. Otherwise, assign $I(u_{t+1})$ the j'th $(\tau.\mathbf{b})$-child of $I(u_t)$ according to rule $(\tau.\mathbf{b})$ of Algorithm B, where j' is the j-label of the current *bj*-block.

Clearly, this procedure outputs in polynomial time the desired labeled path from r to u or flags an error if $s \neq seq^*(u)$ for every node u in T.

Let us now bound the size of $seq^*(u)$ in terms of the original input size v^*.

FACT B. *For any u in T, the size of $seq^*(u)$ is $O(\log^2 v^*)$.*

By Lemma 5.3 (ii), there are $< \log v^*$ *bj*-blocks. As already noted, each *bj*-block has size $O(\log v^*)$; thus the total size of all *bj*-blocks is $O(\log^2 v^*)$. Next, there are at most $\log v^*$ many *ac*-blocks and thus α-blocks. Each α-block encodes a number of $< v^*$ a-rule applications (see Lemma 5.3.(i)) and thus uses at most $\log v^*$ bits. The total size of all α-blocks is thus at most $\log^2 v^*$. Finally, by Lemma 5.3 (iii), the total size of all γ-blocks is at most $\log^2 v^*$. Overall, this means that $seq^*(u)$ has size $O(\log^2 v^*)$.

To prove that Algorithm B rejects input (φ^*, ψ^*), it is thus sufficient to guess $seq^*(u)$ for some leaf u in T, to compute in polynomial time the corresponding path $r = u_0, u_1, \ldots, u_l = u$, and to verify that LCHECK$(I(u)) = true$ but TEST$(I(u)) = false$. Therefore, nonduality of ϕ^* and ψ^* can be decided in polynomial time with $O(\log^2 v^*)$ bit guesses. Given that $v^* \leq n^2$, the number of guesses is $O(\log^2 n^2) = O(\log^2 n)$. □

The following result is an immediate consequence of this theorem.

COROLLARY 5.5. *Problem* DUAL *is in* co-β_2P *and solvable in deterministic $n^{O(\log n)}$ time, where $n = |\varphi| + |\psi|$.*

(Note that yes-instances of DUAL must have size polynomial in n since dual monotone pairs (φ, ψ) must satisfy conditions (2) and (3) in Step 2 of Algorithm A.) We remark that the proofs of Lemma 5.3 and Theorem 5.4 did not stress the fact that $\epsilon(v) = 1/\chi(v)$; the proofs go through for $\epsilon(v) = 1/\log v$ as well. Thus the use of the χ-function is not essential for deriving Theorem 5.4.

However, a tighter analysis of the size of $seq^*(u)$ stressing $\chi(v)$ yields a better bound for the number of nondeterministic steps. In fact, we show in the next result that $O(\chi(n) \cdot \log n)$ bit guesses are sufficient. Note that $\chi(n) = o(\log n)$; thus the result is an effective improvement. Moreover, it also shows that DUAL is most likely not complete for co-β_2P.

THEOREM 5.6. *Deciding whether monotone CNFs φ and ψ are nondual is feasible in polynomial time with $O(\chi(n) \cdot \log n)$ nondeterministic steps, where $n = |\varphi| + |\psi|$.*

Proof. In the proof of Theorem 5.4, our estimates of the components of $seq^*(u)$ were rather crude. With more effort, we establish the following.

FACT C. *For any u in T, the size of $seq^*(u)$ is $O(\chi(v^*) \cdot \log(v^*))$.*

Assume node u' in T is a child of u generated via a b-rule. The j-label of the arc (u, u') serves to identify one clause of $I(u)$. Clearly, there are no more than $v(u)$ such clauses. Thus $\log v(u)$ bits suffice to represent any j-label.

Observe that if u is a node of T, then any path π from u to a node w in T contains at most $v(u)$ nodes since the volume always decreases by at least 1 in each decomposition step. Thus the number of a-labeled arcs in π is bounded by $v(u)$ and not just by v^* $(= v(r))$.

For each node u and descendant w of u in T, let

$$f(u, w) = \sum_{u' \in B(u,w)} \log v(u'),$$

where $B(u, w)$ is the set of all nodes t on the path from u to w such that the arc from t to its successor on the path is b-labeled.

By what we have observed, the total size of all encodings of j-labels in $seq^*(u)$ is at most $f(v^*, u)$, and the size of all α-blocks in $seq^*(u)$ is at most $\log(v^*)+f(v^*, u)$, where the first term takes care of the first α-block and the second of all other α-blocks. Therefore, the total size of all α-blocks and all bj-blocks in $seq^*(u)$ is $O(f(v^*, u)+\log(v^*))$.

We now show that, for each node u and descendant w of u in T, it holds that

$$f(u, w) \leq \log(v(u)) \cdot \chi(v(u)).$$

The proof is by induction on the number $|B(u, w)|$ of b-labeled arcs on the path π from u to w. If $|B(u, w)| = 0$, then obviously $f(u, w) = 0 \leq v(u)$.

Assume the claim holds for $|B(u', w)| \leq i$, and consider $|B(u, w)| = i + 1$. Let t be the first node on π contained in $B(u, w)$, and let t' be its child on π. Clearly, $f(u, w) = f(t, w)$, and thus we obtain

$$\begin{aligned}
f(u, w) &= \log(v(t)) + f(t', w) \\
&\leq \log(v(t)) + \log(v(t')) \cdot \chi(v(t')) && \text{(induction hypothesis)} \\
&\leq \log(v(t)) + (\log(v(t)) - \log(\chi(v(t)))) \cdot \chi(v(t)) \\
&&& \text{(as } v(t') \leq \tfrac{v(t)}{\chi(v(t))},\ \chi(v(t')) \leq \chi(v(t))\text{)} \\
&= \log(v(t)) \cdot \chi(v(t)) && \text{(as } \log(\chi(y)) \cdot \chi(y) = \log y \text{ for all } y\text{).}
\end{aligned}$$

Thus $f(u, w) \leq \log(v(u)) \cdot \chi(v(u))$. This concludes the induction and proves the claim.

Finally, we show that the total size of all γ blocks in $seq^*(u)$, i.e., the number of all c-labels in $seq(u)$, is bounded by $\chi(v^*) \cdot \log(v^*) < \log^2 v^*$. Indeed, assume a c-rule is applied to generate a child t' of any node t, and let $v = v(t)$, $v' = v(t')$. Since

$\epsilon_i^{\varphi} > \epsilon(v)$ and $\epsilon_i^{\psi} > \epsilon(v)$, we have $v' < (1 - \epsilon(v)) \cdot v$. Since $\chi(v^*) > \chi(v)$, we have $\epsilon(v) = 1/\chi(v) > 1/\chi(v^*)$, and thus

$$v' < \left(1 - \frac{1}{\chi(v^*)}\right) \cdot v.$$

Hence any node in T resulting after $\chi(v^*) \cdot \log(v^*)$ applications of a c-rule has volume at most

$$v^* \cdot \left(1 - \frac{1}{\chi(v^*)}\right)^{\chi(v^*)\cdot \log v^*} = v^* \cdot \left[\left(1 - \frac{1}{\chi(v^*)}\right)^{\chi(v^*)}\right]^{\log v^*} \leq v^* \cdot \left(\frac{1}{e}\right)^{\log v^*} \leq 1$$

(cf. also (9)). Consequently, along each branch in T there must be no more than $\chi(v^*) \cdot \log v^*$ applications of a c-rule. In summary, the total sizes of all α-blocks, all γ-blocks, and all encodings of j-labels in $seq^*(u)$ are all bounded by $\chi(v^*) \cdot \log v^*$. This proves Fact C.

As a consequence, nonduality of a monotone pair (φ^*, ψ^*) can be recognized in polynomial time with $O(\chi(v^*) \cdot \log v^*)$ many bit guesses. As already observed in the last lines of [17], we have $\chi(v^*) < 2\chi(n)$. Furthermore, $v^* \leq n^2$; thus $\log v^* \leq 2 \log n$. Hence nonduality of (φ^*, ψ^*) can be recognized in polynomial time with $O(\chi(n) \cdot \log(n))$ bit guesses. □

COROLLARY 5.7. *Problem* DUAL *is solvable in deterministic* $n^{O(\chi(n))}$ *time, where* $n = |\varphi| + |\psi|$.

Remark 5.1. Note that the sequence $seq(u)$ describing a path from the root of T to a "failure leaf" with label $I(u) = (\varphi', \psi')$ describes a choice of values for all variables in $V(\varphi \wedge \psi) \setminus V(\varphi' \wedge \psi')$. By completing it with values for $V(\varphi' \wedge \psi')$ that show nonduality of (φ', ψ'), which is possible in polynomial time, we obtain in polynomial time from $seq(u)$ a vector w such that $f(w) \neq g^d(w)$. It also follows from the proof of Theorem 5.6 that a witness w for $f \neq g^d$ (if one exists) can be found in polynomial time with $O(\chi(n) \cdot \log n)$ nondeterministic steps.

5.3. Application of Beigel and Fu's results. While our independently developed methods substantially differ from those in [1, 2], membership of problem DUAL in co-β_2P may also be obtained by exploiting Beigel and Fu's Theorem 8 in [1] (or, equivalently, Theorem 11 in [2]). They show how to convert certain recursive algorithms that use disjunctive self-reductions, have runtime bounded by $f(n)$, and fulfill certain additional conditions into polynomial algorithms using $\log(f(n))$ nondeterministic steps (cf. [2, Section 5]).

Let us first introduce the main relevant definitions of [1]. Let $\|y\|$ denote the size of a problem instance y.

DEFINITION 5.2 (see [1]). *A partial order* $\prec$ *(on problem instances) is polynomially well founded if there exists a polynomial bounded function* p *such that*

- $y_m \prec \cdots \prec y_1 \Rightarrow m \leq p(\|y_1\|)$ *and*
- $y_m \prec \cdots \prec y_1 \Rightarrow \|y_m\| \leq p(\|y_1\|)$.

For technical simplicity, [1] considers only languages (of problem instances) containing the empty string, Λ.

DEFINITION 5.3 (see [1]). *A disjunctive self-reduction (for short, d-self-reduction) for a language* L *is a pair* $\langle h, \prec \rangle$ *of a polynomial time computable function* $h(x) = \{x_1, \ldots, x_m\}$ *and a polynomially well-founded partial order* $\prec$ *on problem instances such that*

1. Λ *is the only minimal element under* $\prec$*;*

2. *for all* $x \neq \Lambda$, $x \in L \equiv h(x) \cap L \neq \emptyset$;
3. *for all* x, $x_i \in h(x) \Rightarrow x_i \prec x$.

DEFINITION 5.4 (see [1]). *Let* $\langle h, \prec \rangle$ *be a d-self-reduction, and let* x *be a problem instance.*

1. $T_{h,\prec}(x)$ *is the unordered rooted tree that satisfies the following rules:* (1) *the root is* x; (2) *for each* y, *the set of children of* y *is* $h(y)$.
2. $|T_{h,\prec}(x)|$ *is the number of leaves in* $T_{h,\prec}(x)$.

DEFINITION 5.5 (see [1]). *Let* T *be a polynomial time computable function. A language* L *is in* $\mathrm{REC}(T(x))$ *if there is a d-self-reduction* $\langle h, \prec \rangle$ *for* L *such that, for all* x,

1. $|T_{h,\prec}(x)| \leq T(x)$, *and*
2. $T(x) \geq \sum_{x_i \in h(x)} T(x_i)$.

Let $T(x)$-P denote the set of all (languages of) problems whose yes-instances x are recognizable in polynomial time with $T(x)$ nondeterministic bit guesses.

THEOREM 5.8 (see [1]). $\mathrm{REC}(T(x)) \subseteq \lceil \log T(x) \rceil$-P.

We now show that Theorem 5.8, together with Fredman's and Khachiyan's proof of the deterministic complexity of Algorithm B, can be used to prove that problem DUAL is in co-β_2P.

Let L denote the set of all nondual monotone pairs (φ, ψ) plus Λ. Let us identify each monotone pair (φ, ψ) which satisfies LCHECK(φ, ψ) but does not satisfy TEST(φ, ψ) with the "bottom element" Λ. Thus, if a node in the recursion tree T has a child labeled with such a pair, then the label is simply replaced by Λ.

Let us define the order $\prec$ on monotone pairs plus Λ as follows: $J \prec I$ if $I \neq J$ and either $J = \Lambda$ or J labels a node of the recursion tree generated by Algorithm B on input I. It is easy to see that both conditions of Definition 5.2 apply; therefore, $\prec$ is polynomially well founded. In fact, we may define the polynomial p by the identity function; since the sizes of the instances in the recursion tree strictly decrease on each path in T, the two conditions hold.

Define h as the function which associates with each monotone pair $I = (\varphi, \psi)$ those instances that label all children of the root by Algorithm B on input I. Clearly h satisfies all three conditions of Definition 5.3, and hence $\langle h, \prec \rangle$ is a d-self-reduction for L.

Let T be the function which to each instance I associates $v(I)^{\log v(I)}$. (Recall that $v(I)$ denotes the volume of I.) It is now sufficient to check that conditions 1 and 2 of Definition 5.5 are satisfied and to ensure that Theorem 5.8 can be applied.

That item 1 of Definition 5.5 is satisfied follows immediately from Lemma 5 in [17], which states that the maximum number of recursive calls of Algorithm B on any input I of volume v is bounded by $v^{\chi(v)}$ $(\leq v^{\log v})$. Retain, however, that the proof of this lemma is noticeably more involved than our proof of the membership of DUAL in co-β_2P.

To verify item 2 of Definition 5.5, it is sufficient to prove that for a volume $v > 4$ of any input instance to Algorithm B, it holds that

$$v^{\log v} \geq (v-1)^{\log(v-1)} + \frac{v}{3} \cdot \left(\frac{v}{2}\right)^{\log \frac{v}{2}}, \quad \text{and} \tag{10}$$

$$v^{\log v} \geq 2(\alpha \cdot v)^{\log(\alpha \cdot v)}, \quad \text{where } \alpha = 1 - 1/\log v; \tag{11}$$

here, (10) arises from the rules (i), (ii), and (11) from rule (iii). As for (10), the child of u from (i.a), respectively, (ii.a), has volume at most $v - 1$, and there are at most $v/3$ many children from (i.b), respectively, (ii.b), since $\min(|\varphi|, |\psi|) > 2$ (recall that

$v = |\varphi| \cdot |\psi|$); furthermore, each such child has volume $\leq \epsilon(v) \cdot v \leq \frac{1}{2}v$. In the case of (11), the volume of each child of u is bounded by $(1 - \epsilon(v)) \cdot v \leq (1 - 1/\log v) \cdot v$; note also that $v^{\log v}$ monotonically increases for $v > 4$. To see (10), we have

$$\begin{aligned}(v-1)^{\log(v-1)} + \tfrac{v}{3} \cdot (\tfrac{v}{2})^{\log \frac{v}{2}} &\leq (v-1)^{\log v} + \tfrac{v}{3} \cdot \tfrac{v^{\log v - 1}}{2^{\log v - 1}} \\ &= v^{\log v} \cdot (1 - \tfrac{1}{v})^{\log v} + \tfrac{2 \cdot v^{\log v}}{3 \cdot v} \\ &\leq v^{\log v} \cdot (1 - \tfrac{1}{v} + \tfrac{2}{3 \cdot v}) \\ &= v^{\log v} \cdot (1 - \tfrac{1}{3 \cdot v}) \\ &< v^{\log v};\end{aligned}$$

to show (11), note that

$$\begin{aligned}2(\alpha \cdot v)^{\log(\alpha \cdot v)} &= 2\alpha^{\log v + \log \alpha} \cdot v^{\log v + \log \alpha} \\ &\leq 2(\tfrac{1}{e} \cdot \alpha^{\log \alpha}) \cdot v^{\log v + \log \alpha} \qquad (\alpha^{\log v} \leq 1/e \text{ by (9)}) \\ &= \tfrac{2}{e} \cdot (\alpha \cdot v)^{\log \alpha} \cdot v^{\log v} \\ &\leq \tfrac{2}{e} \cdot v^{\log v} \qquad ((\alpha \cdot v)^{\log \alpha} \leq 1, \text{ i.e., } \log \alpha \cdot (\log \alpha + \log v) \leq 0, \\ &\qquad\qquad \text{since } -1 < \log \alpha \leq 0 \text{ and } \log v > 2) \\ &< v^{\log v}.\end{aligned}$$

We can thus apply Theorem 5.8 and conclude that the complement of DUAL is in $\lceil \log T(x) \rceil$-P and thus also in β_2P.

The advantage of Beigel and Fu's method is its very abstract formulation. The method has two disadvantages, however, that are related to the two items of Definition 5.5.

The first item requires that $T(x)$ is at least the number of leaves in the tree for x. In order to show this, one must basically prove a deterministic time bound for the considered algorithm (or at least a bound of the number of recursive calls for each instance, which is often tantamount to a time bound). The method does not suggest how to do this but presupposes that such a bound exists. (In the present case, this was done by Fredman and Khachiyan in a nontrivial proof.) The second item requires proving that the T-value of any node x in the recursion tree is at least the sum of the T-values of its children. This may be hard to show in many cases and does not necessarily hold for every upper bound T.

Our method instead does not require an a priori time bound but directly constructs a nondeterministic algorithm from the original deterministic algorithm, which lends itself to a simple analysis that directly leads to the desired nondeterministic time bound. The deterministic time bound follows as an immediate corollary. It turns out (as exemplified by the very simple proof of Theorem 5.4) that the analysis involved in our method can be simpler than an analysis according to previous techniques.

6. Conclusion. We have presented several new cases of the monotone dualization problem which are solvable in output polynomial time. These cases generalize some previously known output polynomial cases. Furthermore, we have shown by rather simple means that nondual monotone pairs (φ, ψ) can be recognized, using a nondeterministic variant of Fredman and Khachiyan's Algorithm B [17] in polynomial time with $O(\log^2 n)$ many bit guesses, which places problem DUAL in the class co-β_2P. In fact, a refined analysis revealed that this is feasible in polynomial time with $O(\chi(n) \cdot \log n) = O(\log^2 n / \log \log n)$ many bit guesses.

While our results document progress on DUAL and DUALIZATION and reveal novel properties of these problems, the question of whether dualization of monotone pairs (φ, ψ) is feasible in polynomial time remains open. It would be interesting to see whether the amount of guessed bits can be further significantly decreased, e.g., to $O(\log \log n \cdot \log n)$ many bits.

Note added in proof. Independently, Dimitris J. Kavvadias and Elias C. Stavropoulos have shown that DUALIZATION can be solved with limited nondeterminism using $O(\log^2 n)$ deterministic steps in polynomial time (see [31]).

Acknowledgments. Georg Gottlob thanks José Balcázar for inviting him to an interesting workshop in Bellaterra, Barcelona, Spain and thanks Leonard Pitt for giving an elucidating lecture on the dualization problem there. The authors appreciate the review comments which helped to improve the paper.

COMPUTING THE MEDIAN WITH UNCERTAINTY*

TOMÁS FEDER†, RAJEEV MOTWANI‡, RINA PANIGRAHY§, CHRIS OLSTON¶, AND JENNIFER WIDOM¶

Abstract. We consider a new model for computing with uncertainty. It is desired to compute a function $f(X_1, \ldots, X_n)$, where $X_1, \ldots, X_n$ are unknown but guaranteed to lie in specified intervals $I_1, \ldots, I_n$. It is possible to query the precise value of any X_j at a cost c_j. The goal is to pin down the value of f to within a precision δ at a minimum possible cost. We focus on the selection function f which returns the value of the kth smallest argument. We present optimal offline and online algorithms for this problem.

1. Introduction.

Consider the following model for computing with uncertainty. We wish to compute a function $f(X_1, \ldots, X_n)$ over n real-valued arguments. The values of the variables $X_1, \ldots, X_n$ are not known in advance; however, we are provided with real intervals $I_1, \ldots, I_n$ along with a guarantee that, for each j, $X_j \in I_j$. Furthermore, it is possible to query the true value x_j of each X_j at a cost c_j. The goal is to pin down the value of f into an interval of size $\delta \geq 0$. Thus we are faced with the following optimization problem: *Given a function f, precision parameter δ, real intervals $I_1, \ldots, I_n$, and query costs $c_1, \ldots, c_n$, pin down the value of f to an interval of size δ using a set of queries of minimum total cost.* Note that there are two natural versions of this problem: in the *online* version, the sequence of queries is chosen *adaptively* in that each successive query is answered before the next one is chosen; and, in the *offline* version, where the entire set of queries must be specified completely before the answers are provided, it must be guaranteed that f can be pinned down as desired regardless of the results of the queries.

This model is motivated by the work of Olston and Widom [4] on query processing over replicated databases, where local cached copies of databases are used to support quick processing of queries at client sites. Each data value cached at a client has a corresponding master copy maintained by a remote database where all the updates take place. The frequency of updates makes it infeasible to maintain consistency between the cached copies and master copies, and the data values in the cache are likely to become stale and drift from the master values. However, the clients store for

each cached data value an interval that is guaranteed to contain the master value. In processing an aggregation query at a client cache, it is desired to compute a function f defined over the data values to within a specified precision δ. For each data value X_j, it is possible to query the master copy for the exact value, incurring a cost, rather than use the interval I_j at the cached copy. In some cases, the cost to query the master copy of any data value is the same, but in other cases, the master copies are spread across multiple remote databases, each with a different access cost that is typically predictable and static. In general, querying the master copy of each data value X_j incurs a potentially different static cost c_j. The goal then is to compute the result of an aggregation query to within the desired precision at the minimum possible total cost. Systems considerations sometimes make it desirable to perform all queries to the master copy en masse, motivating the offline version of the problem.

Olston and Widom [4] considered functions f which are simple aggregation functions, including

$$\begin{aligned} \mathrm{SUM}\left(f(X_1,\ldots,X_n) = \sum_{j=1,n} X_j\right),\\ \mathrm{MIN}(f(X_1,\ldots,X_n) = \min_{j=1,n} X_j), \text{ and}\\ \mathrm{MAX}(f(X_1,\ldots,X_n) = \max_{j=1,n} X_j). \end{aligned}$$

It was observed that the SUM problem is isomorphic to the knapsack problem [2]: Consider the set of X_j's that are *not* queried; clearly, the sum of the corresponding interval sizes must be at most δ, and the objective function is equivalent to maximizing the corresponding costs. The case of the selection function, i.e., where the function f returns the value of its kth smallest argument, and particularly the median, was left open.

In this paper, we resolve the complexity of the problem of computing the median (and, in general, the kth smallest element) under the model of computing with uncertainty, in both the offline and the online settings. We begin by expressing the offline selection problem in terms of an integer linear program (section 3). Not only is this integer program's structure critical to the development of our offline algorithms, but it also helps provide a useful lower bound for the online selection problem. Based on these insights, we provide a polynomial-time algorithm for the offline case with unit costs and a general offline algorithm with running time exponential in k (section 4). Then we apply this tool to the development of an optimal online algorithm and provide a tight relationship between the performance of the optimal online and offline algorithms (section 5). We extend our results to obtaining a polynomial-time algorithm for the general offline case based on the use of linear programming (section 6). We also present a simple approximation algorithm that does not rely on linear programming. Finally, we define a class of problems called *interval problems* and show that this is equivalent to the offline median problem and includes weighted bipartite matching as a special case (section 7). It also turns out that our offline selection problem can be expressed as a min-cost network flow problem (section 7). Finally, we demonstrate that a mild generalization of our selection problem is NP-hard.

2. Preliminaries. An instance of the *selection problem* consists of n intervals $I_1, I_2, \ldots, I_n$, an associated real cost $c_j \geq 0$ for each interval $I_j = [l(I_j), r(I_j)]$, an integer $1 \leq k \leq \lceil \frac{n}{2} \rceil$, and a value $\delta \geq 0$. Each interval I_j has an unknown point p_j. The aim is to estimate the value of the kth smallest p_j with precision δ. An algorithm

can query an interval I_j, paying cost c_j, and obtain the point p_j. The interval I_j is then replaced with the interval $I'_j = [p_j, p_j]$. At any point in time, for the current intervals I_j, the kth smallest point can be pinned down into an interval $[l, r]$.

LEMMA 2.1. *Given the intervals I_j, the kth smallest point must lie in the interval $[l, r]$, where l is the kth smallest $l(I_j)$, and r is the $(n-k+1)$th largest $r(I_j)$.*

Note that this is the smallest interval to which the kth smallest point can be pinned, in the absence of any other information.

When the algorithm terminates, we must have $r - l \leq \delta$. We seek an algorithm that minimizes the worst-case total cost to achieve this bound. In the unit-cost case, all $c_j = 1$, and the aim is to minimize the number of intervals queried. Two special cases of interest seek the smallest element, with $k = 1$, or the median of the elements, with n odd and $k = \lceil \frac{n}{2} \rceil$. The special case in which $k = 1$ has been addressed in [4] and turns out to have linear complexity. There are two variants of the problem we are interested in. In the online version of the problem that was stated above, we can use the points returned by previous queries to decide which interval to query next. We are also interested in the offline problem, where the algorithm must decide which intervals to query at the same time and guarantee that, regardless of the points obtained in these queries, the estimate $[l, r]$ will have $r - l \leq \delta$.

3. An integer programming formulation. We shall express the offline problem as an integer linear program. The structure of this integer program is critical to the development of our algorithms; also, we obtain from the constraints of this integer program a lower bound on the worst-case online cost. The integer program has a variable $x_j \in \{0, 1\}$ that expresses whether the interval I_j is queried. The aim is then to minimize $\sum c_j x_j$. To describe the constraints, we introduce some terminology. Consider an interval $O = [l(O), r(O)]$ of size $|O| = r(O) - l(O) > \delta$. Let a be the number of I_j with $l(I_j) \leq l(O)$, and let b be the number of I_j with $r(I_j) \geq r(O)$. If $a \geq k$ and $b \geq n - k + 1$, then we say that O is an *obstruction*. We shall show that, for all obstructions O, the offline algorithm must satisfy $\sum x_j \geq a + b - n$, where the sum is over the x_j such that I_j contains O. That is, at least $a + b - n$ intervals containing O must be queried in order to guarantee the bound δ on the final estimate.

To obtain a finite number of constraints, we introduce some additional terminology. A *proper obstruction* is an obstruction O such that, for some input intervals $I_j, I_{j'}$, we have $l(O) = l(I_j)$ and $r(O) = r(I_{j'})$. A *minimal proper obstruction* is a proper obstruction that does not contain any other proper obstructions. The integer program is then to minimize $\sum c_j x_j$, with $x_j \in \{0, 1\}$, subject to the constraint that for each minimal proper obstruction O_i, $\sum x_j \geq a_i + b_i - n$, where the sum is over the x_j such that I_j contains O_i. Notice that there are at most k minimal proper obstructions, since $r(O_i)$ must be one of the k smallest $r(I_j)$.

It will sometimes be convenient, for an obstruction O, to write $a + b - n = d - e$, where d is the number of I_j containing O, and e is the number of I_j inside O, that is, with $l(I_j) > l(O)$ and $r(I_j) < r(O)$. To see why this equality holds, write it as $n = a + b - d + e$; that is, the n intervals can be counted as a intervals with $l(I_j) \leq l(O)$ and b intervals with $r(I_j) \geq r(O)$, subtracting the d intervals that satisfy both conditions and adding the e intervals that satisfy neither condition.

For the online problem, we let V be the maximum over all minimal proper obstructions O_i of the minimum of $\sum c_j x_j$ with $\sum x_j = a_i + b_i - n$, where the sums are over the x_j with I_j containing O_i. That is, for each minimal proper obstruction O_i, we determine the sum of the $(a_i + b_i - n)$ smallest costs of intervals containing O_i and find the worst such O_i.

PROPOSITION 3.1. *The integer program solves the offline selection problem. The quantity V is a lower bound on the maximum total cost for the online selection problem.*

Proof. Say that a choice of queried intervals I_j *clears* an obstruction O if, regardless of the points p_j returned for the queried intervals, the interval O will no longer be an obstruction after the queried I_j are replaced by $I'_j = [p_j, p_j]$. We show that O is cleared if and only if $\sum x_j \geq a + b - n$, where the sum is over the intervals I_j containing O.

If $\sum x_j \leq a + b - n - 1 = (a - k) + (b - (n - k + 1))$, then for each I_j queried not containing O, we can return $p_j = l(I_j)$ if $r(I_j) < r(O)$ and return $p_j = r(I_j)$ otherwise, with $l(I_j) > l(O)$. Clearly, this choice of p_j does not decrease the values a, b for O. For the I_j queried containing O, we can return $p_j = l(I_j)$ for at most $b - (n - k + 1)$ of them and return $p_j = r(I_j)$ for at most $a - k$ of them. Then O will still be an obstruction, since there will be still at least k intervals with $l(I'_j) \leq l(O)$, and at least $n - k + 1$ intervals with $r(I'_j) \geq r(O)$. That is, the obstruction is not cleared.

For the converse, suppose $\sum x_j \geq a + b - n = (a - k) + (b - (n - k + 1)) + 1$. Then in each queried interval I_j containing O, either a decreases by 1 if $p_j > l(O)$ or b decreases by 1 if $p_j < r(O)$. Thus, in the end, we will have either $a' < k$ or $b' < n - k + 1$, so O will no longer be an obstruction. That is, the obstruction is cleared. This completes the proof of the equivalence.

A choice of intervals to be queried solves the offline problem if and only if it clears all obstructions. We show that it is sufficient to consider minimal proper obstructions. For an obstruction O, the smallest proper obstruction O' containing it has $a' = a$, $b' = b$, and the intervals I_j containing O are the same as those containing O'. Therefore, the linear constraints for O and O' are the same, and it is sufficient to consider proper obstructions. If an obstruction is cleared, then every obstruction containing it is also cleared, so it is sufficient to consider minimal proper obstructions. This completes the proof of the characterization of the offline problem as an integer program.

We prove the lower bound V for the online problem. Let O be an obstruction giving the value V. In the proof that if $\sum x_j \leq a + b - n - 1$, then the obstruction is not cleared, we could have chosen the points returned for the queries one by one, as the queried intervals are chosen, that is, in an online fashion. Therefore, we must have $\sum x_j \geq a + b - n$, paying for the $a + b - n$ intervals of least cost containing O. ∎

4. Offline problem with unit costs. We now show how to solve the offline problem efficiently, in the unit-cost case, using the integer program described above. List the minimal proper obstructions in order, letting $O_1 < O_2$ if $l(O_1) < l(O_2)$ and $r(O_1) < r(O_2)$. For the leftmost minimal proper obstruction O_1, since all the intervals I_j containing it have the same cost, we can greedily select I_j with $r(I_j)$ as large as possible, so as to cover as many O_j as possible with it, until we have chosen $a_1 + b_1 - n$ intervals containing O_1. We then move on to O_2, with O_1 already covered, and choose additional intervals to cover O_2 as needed, again with their right endpoint as far to the right as possible, until we have chosen at least $a_2 + b_2 - n$ intervals to cover O_2. We proceed in this fashion, satisfying the constraints on minimal proper obstructions in order, from left to right.

THEOREM 4.1. *In the unit-cost case, the integer program that characterizes the offline selection problem can be solved in polynomial time by a greedy algorithm.*

This approach does not seem to work in the general offline case with arbitrary

costs, since longer intervals might have a larger cost, so that it is not clearly an advantage to choose them. However, we can obtain an exponential-time algorithm as follows. Let r be the $(n-k+1)$th largest $r(I_j)$. At most $k-1$ intervals I_j have $r(I_j) < r$. Call these the special intervals, and choose which ones will be queried in all possible ways, that is, 2^{k-1} ways. All obstructions have $r(O) \leq r$, so we can again examine the minimal proper obstructions in order from left to right, covering them with intervals I_j of least possible cost which are not special, using as many intervals as needed. The right endpoint of intervals that are not special does not matter, since it is at least r.

This gives an algorithm with a time bound of $2^k poly(n)$. A tighter time bound follows from observing that there are at most k minimal proper obstructions O_i, and by writing $a_i + b_i - n = d_i - e_i$, we observe that the number e_i of intervals inside O_i is at most $k-1$, so at most $k-1$ intervals containing O_i will not be queried. We can then just identify the at most $k-1$ intervals of largest cost that are not special and have O_i as the first minimal proper obstruction they cover. That is, after $poly(n)$ preprocessing time, each of the 2^{k-1} cases involves at most k obstructions and k^2 identified intervals, so it uses $poly(k)$ time.

THEOREM 4.2. *With arbitrary costs, the integer program that characterizes the offline selection problem can be solved in time* $poly(n) + 2^k poly(k)$.

A different approach will later enable us to obtain a polynomial-time algorithm for the general offline case.

5. The online problem. We now turn to the online problem and consider an algorithm for the general case with arbitrary costs. The greedy algorithm is as follows. Determine the interval $[l, r]$, where l is the kth smallest $l(I_j)$ and r is the $(n-k+1)$th largest $r(I_j)$. If $r - l \leq \delta$, then we are done. Otherwise, $[l, r]$ is an obstruction O. Query the I_j containing O of least cost. Once the point p_j is obtained, replace I_j by $I'_j = [p_j, p_j]$, and go back to the beginning of the algorithm.

Consider an execution of the greedy algorithm. Let O_1, O_2,..., O_s be the sequence of obstructions obtained, with O_t containing O_{t+1}. For the last obstruction O_s, let H be the set of the $a_s + b_s - n$ intervals of least cost containing O_s. Clearly, the total cost of H is at most V, the lower bound established in section 6. We show that the interval queried at stage t with $1 \leq t \leq s$ is in H, completing the proof.

The proof is by induction on t. Since the intervals in H clear the obstruction O_s, they also clear the obstruction O_t which contains O_s. In fact, the intervals in H containing O_t clear the obstruction O_t because only containing intervals matter in clearing an obstruction. By inductive hypothesis, the $t-1$ intervals previously queried are in H. However, these $t-1$ intervals have not cleared O_t. Therefore, H must have some interval containing O_t other than the $t-1$ intervals previously queried, and such an interval in H of least cost c will be queried. In the case in which there are also intervals of cost c not in H (that is, c is the largest cost in H), then an interval of cost c not in H may be queried; however, in that case, we can change H by switching this interval for the interval of cost c containing O_t in H without increasing the total cost of H.

THEOREM 5.1. *With arbitrary costs, the greedy polynomial online selection algorithm achieves the cost* V *of Proposition* 3.1, *and is therefore optimal.*

We will now compare the performance of the offline algorithm with the worst-case performance of the online algorithm, both in the unit-cost case and in the general case with arbitrary costs. For the unit-cost case, we will transform the problem as follows.

Let P be an instance of the problem. Suppose P contains two intervals I_1 and I_2

with I_2 inside I_1, that is, $l(I_1) < l(I_2)$ and $r(I_2) < r(I_1)$. We construct a new instance P' by replacing these two intervals by $I_1' = [l(I_1), r(I_2)]$ and $I_2' = [l(I_2), r(I_1)]$. We repeatedly perform this transformation until we obtain an instance $\widehat{P}$ with no interval inside another interval.

We first look at the offline problem. Consider the optimal solution for P'. If both I_1' and I_2' are queried in this solution, obtain a candidate solution for P by querying both I_1 and I_2. If only one of I_1' or I_2' is queried, then query only I_1. If neither I_1' nor I_2' is queried, then query neither I_1 nor I_2.

Since P and P' have the same left and right endpoints of intervals, the minimal proper obstructions O are the same for P and P' and have the same value of $a+b-n$. Suppose O is such an obstruction. If both I_1' and I_2' contain O, then both I_1 and I_2 contain O; and if only one of I_1' and I_2' contain O, then I_1 contains O. Therefore, the candidate solution for P is indeed a solution with the same cost (number of queried intervals) as the solution for P'.

Consider now the online problem. Here, the worst-case performance is given by the minimal proper obstruction O with the largest value $a + b - n$. This value, as we said before, is the same for P and P'.

PROPOSITION 5.2. *Consider the unit-cost case. For the offline selection problem, the performance on $\widehat{P}$ is at least as bad as the performance on P. For the online selection problem, the worst-case performance is the same for $\widehat{P}$ as for P.*

We can now compare the performance of the optimal offline algorithm with the worst-case performance of the optimal online algorithm.

THEOREM 5.3. *The worst-case performance ratio between offline and online selection algorithms is $\frac{2k-1}{k} < 2$ in the unit-cost case. Therefore, both algorithms have the same performance for the smallest element problem, while the ratio for the median problem is $\frac{2n}{n+1}$. In the case of arbitrary costs, the worst-case ratio equals k.*

Proof. We begin with the unit-cost case. By the preceding proposition, it is sufficient to consider an instance $\widehat{P}$ with no interval inside another interval. The intervals can then be ordered from left to right, breaking ties between identical intervals arbitrarily, and letting otherwise $I_1 < I_2$ if $l(I_1) \le l(I_2)$ and $r(I_1) < r(I_2)$ or if $l(I_1) < l(I_2)$ and $r(I_1) \le r(I_2)$.

Let $I_1, I_2, \ldots, I_n$ be the intervals in this order. Consider the interval I_k. Clearly I_k is also the largest obstruction, and so all minimal proper obstructions are contained in it. We can assume $|I_k| > \delta$; otherwise, no queries are needed. Since no interval is inside an obstruction, all intervals containing an obstruction will be queried. Let I_{k-s} be the first I_j with $j \le k$ such that $r(I_j) - l(I_k) > \delta$. Similarly, let I_{k+t} be the last I_j with $j \ge k$ such that $r(I_k) - l(I_j) > \delta$. Clearly $0 \le s \le k-1$ and $0 \le t \le n-k$.

The intervals preceding I_{k-s} do not contain any obstruction and will therefore not be queried by either algorithm. Similarly, the intervals following I_{k+t} will not be queried by either algorithm. The intervals from I_{k-s} to I_{k+t} contain at least one obstruction and will therefore be queried by the offline algorithm. Therefore, the offline algorithm makes $s + t + 1$ queries.

For the online algorithm, it is sufficient to consider the minimal proper obstruction with the largest number of intervals containing it. The first minimal proper obstruction is contained at least in the intervals from I_{k-s} to I_k. The last minimal proper obstruction is contained at least in the intervals from I_k to I_{k+t}. Thus the online algorithm makes at least $\max(s,t)+1$ queries in the worst case, and this quantity is the worst case when the I_j with $j < k$ do not intersect the I_j with $j > k$.

The ratio $\frac{s+t+1}{\max(s,t)+1}$ with $0 \le s \le k-1$ and $0 \le t \le n-k$ is maximized at

$s = t = k - 1$, and it then equals $\frac{2k-1}{k}$.

Consider next the case of arbitrary costs. Since the performance of the online algorithm is given by the worst constraint for a single minimal proper obstruction and there are at most k such obstructions, the ratio is at most k. An example that achieves k has $n = 2k - 1$ and consists of k disjoint intervals I_j of unit-cost plus $k - 1$ intervals I'_j of zero cost, with the I'_j containing all the I_j. The offline algorithm will have to query all the intervals, incurring cost k with the intervals I_j. The online algorithm queries the I'_j first and, depending on the resulting answers, determines which single I_j to query, with total cost 1. □

6. Offline problem with arbitrary costs. The earlier algorithm for the offline selection problem with arbitrary costs has complexity exponential in k. We now provide a polynomial-time algorithm for this problem, but this algorithm is noncombinatorial and relies on linear programming.

The polytope of the offline selection problem is defined by replacing in the integer program the conditions $x_j \in \{0, 1\}$ with linear constraints $0 \leq x_j \leq 1$, with the remaining linear constraints being the same.

THEOREM 6.1. *The vertices of the polytope of the offline selection problem are all integer vertices (i.e., 0–1 vertices). Therefore, with arbitrary costs, the problem can be solved in polynomial time by linear programming.*

Proof. Consider a vertex x of the polytope. If some x_j is either 0 or 1 for x, then use this value in the constraints where x_j occurs. We are thus left with some h variables with $0 < x_j < 1$. Since x is a vertex of the polytope, there must be some h constraints satisfied with equality that define x uniquely. The corresponding h-by-h square matrix M is a 0–1 matrix M, with the property that, for every column of M, the value 1 occurs in consecutive rows, since a variable x_j occurs in consecutive linear constraints. We show that the determinant of such a matrix M is either 0, 1, or -1. Therefore, the solution must be an integer; that is, all x_j for the vertex x are either 0 or 1, completing the proof of optimality.

Assume M has a nonzero determinant. Then some column must have a 1 in the first row. Consider the column with a 1 in the first row that has the least number r of 1's; say it is the first column. Then the 1's in the first column occur in rows $1, 2, \ldots, r$. After subtracting the first row from rows $2, \ldots, r$, we can remove the first row and the first column and argue inductively for the resulting submatrix M'. Notice that the only columns affected by the subtraction are the columns that have a 1 in the first row. These columns, however, have a 1 in rows $1, 2, \ldots, r$ by the choice of the first column. For such a column, after the subtraction, the 1's in rows $2, \ldots, r$ become 0's, and after the first row is removed, the remaining 1's in the column will be in consecutive rows. Therefore, the matrix M' has the property of consecutive 1's in each column, and the induction goes through.

A linear programming algorithm that finds a vertex of the polytope minimizing the objective function $\sum c_j x_j$ thus solves the problem. □

Unfortunately, a linear programming algorithm is not very practical for the applications at hand. It therefore becomes interesting to seek a combinatorial algorithm that is polynomial-time. As shown in the next section, the weighted bipartite matching problem is a special case of our offline selection problem, and therefore we cannot really hope for a simple combinatorial algorithm. In practice, it might be better to use the following approximation algorithm.

THEOREM 6.2. *The offline selection problem with arbitrary costs has a* $2 \log_2 k$*-approximation polynomial-time algorithm.*

Proof. Construct a binary tree whose leaves are the minimal proper obstructions $O_1, O_2, \ldots, O_{k'}$ in left to right order, with $k' \leq k$. Place an interval at a node q if the minimal proper obstructions it contains, $O_s, O_{s+1}, \ldots, O_t$, are precisely the leaves below node q.

Unfortunately, not all intervals correspond to a single node; we argue that in general, the minimal proper obstructions covered by an interval can be decomposed into at most $2\log_2 k$ groups, with each group corresponding to a single node q. To show this, let P_i be the set of nodes on the path from the root to the leaf O_i, and consider in particular P_{s-1} and P_{t+1}, which are taken to be empty if $s = 1$ or $t = k'$, respectively. Then the nodes selected are precisely the nodes q not on P_{s-1} such that q is the right child of a node on $P_{s-1} - P_{t+1}$ plus the nodes q not on P_{t+1} such that q is the left child of node on $P_{t+1} - P_{s-1}$. If the binary tree is chosen to be balanced, the bound of $2\log_2 k$ on the number of nodes q selected follows. (By carefully choosing the binary tree, the bound can be improved by an asymptotic factor of 2.)

The algorithm then represents each interval by at most $2\log_2 k$ intervals at nodes q, each with the same cost as the original interval. This may increase the cost of an optimal solution by a factor of $2\log_2 k$. The algorithm then solves the problem with each interval at a single node q in polynomial time.

The algorithm computes at each node q, starting at the leaves O_i and moving up to the root, how to select intervals at node q so as to leave a requirement of r intervals having to be chosen at nodes higher than q, on the path from the root to q, for all possible values r, which we call the *demand* at node q. Initially, at a leaf O_i, before choosing which intervals to select at O_i, we have $r = a_i + b_i - n$. Suppose a node q has inherited demands of r' and r'' from its children and wishes to achieve demand $r \leq \max(r', r'')$ to pass on to its parent. (At a leaf, there is a single inherited demand r' as described above.) Then we must select the $\max(r', r'') - r$ intervals of least cost at q. For a given r, we carry out the calculation of total cost with the possible choices of r', r'', and select the one that gives the least total cost for the intervals chosen at q and its descendants, for the demand r under consideration. At the root, we force $r = 0$, since no demand can be satisfied at nodes higher than the root. ∎

7. Interval problems and weighted bipartite matching. We now examine the expressive power of the offline selection problem. Specifically, we define the notion of an "interval problem," show that it is equivalent to the offline median problem, and show that it includes weighted bipartite matching as a special case. It turns out that every interval problem can be expressed as a min-cost network flow problem [3]. This allows us to apply combinatorial algorithms for min-cost flow to our selection problem. We will also show that a mild generalization of the interval problem is in fact NP-hard.

DEFINITION 7.1. *Define an* interval problem *to be to minimize* $\sum c_j x_j$ *with* $x_j \in \{0, 1\}$ *subject to* k *constraints* $\sum_{S_i} x_j \geq f_i$, *with the property that each* x_j *occurs in consecutive constraints.*

We know that the offline selection problem is an interval problem. We now show the converse. The median problem will have $\delta = 1 - \frac{1}{2(k+1)}$ and k minimal proper obstructions $O_i = [i-1, i]$ for $1 \leq i \leq k$. If a variable x_j occurs in constraints $s, s+1, \ldots, t$, then we represent it by the interval $I_j = [s-1, t]$. We must also have $f_i = a_i + b_i - n = d_i - e_i$, with $a_i, b_i \geq \lceil \frac{n}{2} \rceil$. In order to have $f_i = d_i - e_i$, where d_i is the number of variables in the constraint and e_i is the number of intervals inside O_i, we put e_i single-point intervals $I_j = [p_j, p_j]$ inside O_i at $i - \frac{i}{k+1}$. To make O_i a proper obstruction, we add a zero-cost interval $I_j = O_i$. To ensure that $a_i, b_i \geq \lceil \frac{n}{2} \rceil$,

we add a sufficiently large number of zero-cost intervals $I_j = [0, k]$. It is then clear that the O_i will be the minimal proper obstructions and will give the corresponding constraint when the zero-cost intervals that were added are selected.

PROPOSITION 7.2. *Every interval problem is an offline median problem.*

We may sometimes want to force a constraint $\sum_{S_i} x_j \geq f_i$ to hold with equality. To achieve this, we choose a large $L > \sum c_j$ and add $L \sum_{S_i} x_j$ to the objective function. If the constraint can be satisfied with equality, this will be forced by the minimization, making the added term equal to Lf_i. The same L can be used to force several different constraints to hold with equality, when this is feasible.

It turns out that every interval problem can be expressed as a min-cost network flow problem and vice versa [3]. We now prove a simpler statement.

THEOREM 7.3. *The interval problem can express the weighted bipartite matching problem.*

Proof. The case in which all constraints must hold with equality can express the minimum cost bipartite perfect matching problem. To see this, consider a bipartite graph G, with k vertices on each side and costs on the edges, that has a perfect matching; we seek a minimum cost perfect matching. Let $1, 2, \ldots, k$ be the k vertices on the left, and let $1', 2', \ldots, k'$ be the k vertices on the right. The corresponding interval problem will have $2k$ constraints corresponding to these vertices, in the order $1, 2, \ldots, k, k', \ldots, 2', 1'$. An edge from i to j' will correspond to a variable occurring in the constraints from i to j' in this order. To force exactly one of the edges incident to vertex 1 to be selected, we use the bound $f_1 = 1$ for the first constraint, with equality. To force exactly one additional edge incident to vertex 2 to be selected, we use the bound $f_2 = 2$ for the second constraint, with equality. In general, we have $f_i = f_{i'} = i$, with equality. This completes the representation. □

Consequently, the weighted bipartite matching problem is a special case of the weighted offline median problem. We use this expressiveness of the weighted offline median problem to show that a slight generalization is computationally hard.

The *median problem with multiplicities* is the median problem with the additional provision that some specified intervals, when queried, return two points instead of just one. This is like having, in the median problem, pairs of identical intervals that must be simultaneously queried or not queried.

THEOREM 7.4. *The weighted offline median problem with multiplicities is NP-complete.*

Proof. The problem corresponds as before to a general interval problem, except that now, for some of the variables, the quantity $2x_j$ instead of x_j appears in the constraints. We can again force equality to hold in the constraints by using appropriate costs. The special case of bipartite matching from before now generalizes to a bipartite flow problem. In this problem, vertices on the left have a given supply amount, vertices on the right have a given demand amount, and vertices on the left are joined to vertices on the right by edges of capacity 1 or 2. The supplies and demands must be satisfied by sending flow across the edges but in such a way that the flow across an edge is either zero or the full capacity of the edge.

We show that this bipartite flow problem is NP-complete. The reduction is from 3SAT. In fact, we assume that every variable x in the 3SAT instance occurs at most twice as a positive literal x and at most twice as a negative literal $\overline{x}$. Every 3SAT instance can be made to satisfy this assumption by replacing every variable with several variables forced to be equal by a cycle of implications; the implications in the cycle account for one positive and one negative occurrence, so each variable in the

cycle can be used again, once as positive and once as negative.

To express such a 3SAT instance as a bipartite flow problem, we put a vertex on the right for each literal x or $\overline{x}$, with demand 2. We put a vertex on the left for each clause, with supply 1, and with three capacity 1 edges joining it to the literals occurring in the clause on the right. Thus the supply 1 must be sent to one of the three literals occurring in the clause, which we can take to be a satisfying literal for the clause. Notice that the demand bound of 2 will hold, since no literal occurs in more than two clauses. We must ensure that complementary literals are not both chosen as satisfying literals. To achieve this, we put a vertex on the left for each variable x, with supply 2, and with capacity 2 edges joining it to both literals x and $\overline{x}$. Thus only one of the two literals will have demand left to be chosen by the clauses on the left. Thus the supply on the left can be sent while satisfying the demand bounds on the right if and only if the instance has a solution. It then remains to force the demands of 2 to be met exactly, and this is done by providing additional $2v - w$ units of supply to be sent along capacity 1 edges to any vertex on the right, where v is the number of variables and w is the number of clauses. This completes the proof of NP-completeness. □

It is natural to consider the related problem, where, when an interval I_j is queried, instead of returning a single point p_j in I_j, we obtain a subinterval of I_j of length at most δ'. If the new parameter δ' satisfies $\delta' \leq \delta$, where δ is the parameter for the required precision as before, then all the results obtained above go through (unit-cost or arbitrary cost, online or offline), since an obstruction O has length greater than δ, so that an interval containing it will no longer contain it after the interval length is reduced to at most δ'. On the other hand, if $\delta' > \delta$, then the problem has no solution (unless no queries are needed), since queried intervals I_j can be answered so as to still contain a sufficiently small obstruction O.

Acknowledgment. We would like to thank Suresh Venkatasubramanian for several helpful discussions.

ACCELERATION OF EUCLIDEAN ALGORITHM AND RATIONAL NUMBER RECONSTRUCTION*

XINMAO WANG† AND VICTOR Y. PAN‡

Abstract. We accelerate the known algorithms for computing a selected entry of the extended Euclidean algorithm for integers and, consequently, for the modular and numerical rational number reconstruction problems. The acceleration is from quadratic to nearly linear time, matching the known complexity bound for the integer gcd, which our algorithm computes as a special case.

Key words. extended Euclidean algorithm, rational number reconstruction

1. Introduction.

A customary approach in computer algebra is to perform computations with rational numbers modulo a large integer q (a prime, prime power, or product of several selected primes) and then to reconstruct the rational output from its value modulo q [GG99]. In particular, the *modular rational number reconstruction* is the final stage of the solution of a nonsingular linear system of n equations by means of p-adic lifting [MC79], [D82], [P02] (see [GG99], [S86], [UP83], [Z93], [HW60] for other important applications).

PROBLEM 1.1 (modular rational number reconstruction). *Compute a pair of integers (η, δ) from three positive integers m, n, k such that*

$$|\eta| < k < m, \quad 1 \le \delta \le m/k, \quad \eta = n\delta \bmod m. \tag{1.1}$$

PROBLEM 1.1a. *Compute all coprime solutions (η, δ) to Problem* 1.1.

There always exists a solution to Problem 1.1. There are at most two solutions to Problem 1.1a, and at most one of them satisfies $|\eta| < k/2$ [GG99, Theorem 5.26]. To ensure unique correct reconstruction of η and δ, having some upper bounds on $|\eta|$ and δ (e.g., Hadamard's bound applies to the coordinates of the rational solution to a linear system of equations), we may double the available bound k on $|\eta|$, compute one solution to (1.1), and either output it if $|\eta| < k/2$ or otherwise compute and output the other solution.

A related problem of *numerical rational number reconstruction* or *rational roundoff* is the problem of computing the best rational approximation s/t to a given rational n/m such that $1 \le t \le k$.

PROBLEM 1.2 (rational roundoff). *Compute all rational numbers s/t from three positive integers m, n, k such that*

$$1 \le t \le k, \quad |s/t - n/m| \text{ is minimal.} \tag{1.2}$$

Problem 1.2 is closely related to computing *Diophantine approximations* to a real number [HW60], [H82], [GG99] and extends the following problem.

PROBLEM 1.2a (see [UP83]). *Given a rational number $\alpha = m/n$ and a natural number k, find a rational number p/q such that $1 \le q \le k$ and $|\alpha - p/q| < 1/(2k^2)$.*

Problem 1.2a may have no solution, but the solution is unique if it exists. In section 5, we show that the solution to Problem 1.2 is also unique.

Dirichlet [D1842] showed that, for any real numbers α and $0 < \epsilon \le 1$, there exist integers p and q such that $|\alpha - p/q| < \epsilon/q$ and $1 \le q \le \epsilon^{-1}$. In particular, let p_i/q_i be the ith *convergent* of α (i.e., the ith term in the continued fraction approximation for α); then $|\alpha - p_i/q_i| \le 1/(q_i q_{i+1}) < 1/q_i^2$ [HW60], [H82]. Furthermore, Hurwitz [H1891] showed that at least one of the two consecutive convergents of α satisfies $|\alpha - p/q| < 1/(2q^2)$, and at least one of the three consecutive convergents of α satisfies $|\alpha - p/q| < 1/(\sqrt{5}q^2)$. On the other hand, Legendre [L1798] showed that if $|\alpha - p/q| < 1/(2q^2)$, then p/q is a convergent of α. Therefore, Problems 1.2 and 1.2a are reduced to computing the convergents of α.

The common approach to the solution of the problems of modular and numerical rational number reconstruction is by applying the extended Euclidean algorithm to m and n [HW60]. Hereafter, we refer to this algorithm as the *EEA* and we seek faster solution algorithms based on accelerating the EEA. The algorithm produces a sequence of triples (r_j, s_j, t_j), $j = 1, \dots, l$ (notation used in [GG99]; see our Remark 2.10). In our case, we need only the triples $(r_{j-1}, s_{j-1}, t_{j-1})$ and (r_j, s_j, t_j) for a specially selected j. Extension from computing these triples to the solution to Problems 1.1 and 1.1a is shown in full detail in [GG99, Theorem 5.26]. We show an alternative approach, which is more directly related to our modification of the EEA. We also extend the known reduction of the Diophantine approximation to the EEA to solve Problem 1.2. Our main result, however, is the acceleration of the EEA and consequently the solution of all the listed problems. The known algorithms compute the desired pair of the EEA triples and thus solve Problems 1.1, 1.1a, 1.2, and 1.2a by using

$$f(d) = O(d^2)$$

bit operations, where $d = \lfloor \log_2 m \rfloor$, $m \ge n$. We speed up the computation by the factor of almost d; that is, we decrease the above bit cost bound to the level

$$\rho(d) = O(\mu(d) \log d), \tag{1.3}$$

provided that $\mu(d)$ bit operations are sufficient to multiply two integers modulo $2^d + 1$, and (see [SS71]) we have

$$\mu(d) = O((d \log d) \log \log d). \tag{1.4}$$

A similar acceleration is known for the Euclidean algorithm applied to polynomials [M73], [AHU74], [BGY80], but in the integer case a well-known additional difficulty is due to the carries. Among the known methods, only the Knuth–Schönhage algorithm [S71] has settled the problem for integers but only in the special case in which $j = l$ and the triple (r_l, s_l, t_l) terminates the Euclidean algorithm, that is, where r_l is the gcd. In our work, we were motivated by the following excerpt from [GG99, p. 305] on the EEA for integers:

> *The method also works for integers, although there are some complications due to the carries,*

and by the recent comments of expert Joachim von zur Gathen on the state of the art which he sent by email to one of the present authors:

> *Yes, I suppose rational number reconstruction can be done in time* $O(m(n)\log n)$ *for* n*-bit numbers and a given upper bound on the denominator. This is alluded to in* [GG99]*, as you observed. But we do not give a proof, and I do not know any rigorous proof in the literature. I can imagine roughly what needs to be done, but it will be quite messy.*

In the next sections, we clear the cited mess and come out with a desired algorithm, which solves the gcd problem as a special case (see Remark 4.3(ii)). Our construction relies on computing a matrix sequence $\{Q_i,\ i = 0, 1, \dots\}$, which represents the quotients and cofactors computed in the EEA, rather than on computing just the remainder sequence $\{r_i,\ i = 0, 1, \dots\}$. This enables a simpler control over the growth of the magnitude of the entries of the Q_i than we would have had over the decrease of the r_i.

We organize our paper as follows. After some preliminaries in the next section, we prove our technical results on the EEA in section 3. In section 4, we present our main algorithm. In section 5, we apply it to accelerate the modular and numerical rational number reconstruction. Our proof of our main result is substantially simpler than in the proceedings version [PW02].

2. Some basic results. Hereafter, we write log to replace $\log_2$ unless specified otherwise.

DEFINITION 2.1. *$\mathbb{Z}$ is the ring of integers. $\lfloor x\rfloor$ and $\lceil x\rceil$ are two integers closest to a real number x such that $\lfloor x\rfloor \le x \le \lceil x\rceil$. $\{x\} = x - \lfloor x\rfloor$. $|A| = \max_{i,j} |a_{i,j}|$ for any real matrix $A = (a_{i,j})_{i,j}$. $m \bmod n$ is defined to be $m - n\lfloor m/n\rfloor$ for $m, n \in \mathbb{Z}$, and $n > 0$.*

ALGORITHM 2.2 (Euclidean algorithm).

INPUT: *A pair of natural numbers (m, n), $m \ge n$.*

OUTPUT: $\gcd(m, n)$.

COMPUTATION: *Write $r_0 = m$, $r_1 = n$. Compute*

$$r_{i+1} = r_{i-1} \bmod r_i$$

for $i = 1, 2, \dots, l$ until $r_{l+1} = 0$. Output r_l.

DEFINITION 2.3. *Let $\binom{r_{i-1}}{r_i} = P_i \binom{r_i}{r_{i+1}}$, where*

$$P_i = \begin{pmatrix} q_i & 1 \\ 1 & 0 \end{pmatrix}, \quad q_i = \lfloor r_{i-1}/r_i\rfloor, \quad i = 1, 2, \dots, l, \tag{2.1}$$

$$Q_i = \begin{pmatrix} a_i & b_i \\ c_i & d_i \end{pmatrix} = P_1 P_2 \cdots P_i, \quad i = 1, 2, \dots, l, \tag{2.2}$$

$$Q_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad Q_{l+1} = \begin{pmatrix} \infty & \infty \\ \infty & \infty \end{pmatrix}.$$

The sequence $\{r_i\}_{i=0}^{l}$ is called the remainder sequence*, and the sequence $\{Q_i\}_{i=0}^{l}$ is called the* matrix sequence*. The* extended Euclidean algorithm (EEA) *outputs both sequences $\{r_i\}_{i=0}^{l}$ and $\{Q_i\}_{i=0}^{l}$ (see Remark* 2.10*).*

For a given pair (m, n) and the sequence $\{Q_i\}$, we can immediately compute the sequence $\{r_i\}$ because

$$\det P_i = -1, \quad \det Q_i = (-1)^i, \tag{2.3}$$

$$\begin{pmatrix} m \\ n \end{pmatrix} = Q_i \begin{pmatrix} r_i \\ r_{i+1} \end{pmatrix}, \quad Q_i^{-1} = (-1)^i \begin{pmatrix} d_i & -b_i \\ -c_i & a_i \end{pmatrix} \tag{2.4}$$

for all $i = 1, 2, \dots, l$.

Our main task is to solve the following problem.

PROBLEM 2.4 (selected output of the EEA).

INPUT: *Integers m, n, h such that $m \geq n \geq 1$, $h \geq 0$.*

OUTPUT: *The unique Q_i such that $|Q_i| \leq 2^h < |Q_{i+1}|$.*

In the remaining part of this section, we state some simple auxiliary properties of the remainders r_i and the matrices Q_i.

THEOREM 2.5. *$r_i > r_{i+1} > 0$, $r_i \geq r_{i+1} + r_{i+2}$ for $i = 0, 1, \dots, l-1$.*

THEOREM 2.6 (cf. Definition 2.3 for a_i, b_i, c_i, q_i).

(i) *$b_i = a_{i-1}$, $d_i = c_{i-1}$ for $i = 1, 2, \dots, l$.*

(ii) *$a_i = a_{i-1}q_i + a_{i-2} > a_{i-1}$, $c_i = c_{i-1}q_i + c_{i-2} > c_{i-1}$ for $i = 2, 3, \dots, l$.*

(iii) *$a_{i-2} = a_i \bmod a_{i-1}$, $c_{i-2} = c_i \bmod c_{i-1}$ for $i = 3, 4, \dots, l$.*

(iv) *$a_0 > c_0$, $a_1 \geq c_1$, $a_i > c_i$ for $i = 2, 3, \dots, l$.*

COROLLARY 2.7. *Q_{i-1} can be computed from Q_i by Theorem* 2.6 (i), (iii).

COROLLARY 2.8.

(i) *$|Q_i| = a_i$ for $i = 0, 1, \dots, l$.*

(ii) *$|Q_i| \geq |Q_{i-1}| + |Q_{i-2}|$ for $i = 2, 3, \dots, l$.*

COROLLARY 2.9. *$m/2 < r_i|Q_i| \leq m$ for $i = 0, 1, \dots, l$.*

Remark 2.10. Note an equivalent customary representation of the EEA's output by the sequences $\{r_i\}$, $\{s_i\}$, $\{t_i\}$ (with the notation in [GG99]), where $s_i = (-1)^i d_i$, $t_i = (-1)^{i-1} b_i$.

Remark 2.11. By Corollary 2.9, we have $|Q_i| \leq m$ for $i \leq l$, so it is sufficient to consider Problem 2.4 for $h \leq d + 1$, $d = \lfloor \log m \rfloor$.

Remark 2.12. The remainder r_i defined by (2.4) for the solution Q_i of Problem 2.4 equals the gcd of m and n if and only if $Q_{i+1} = \left(\begin{smallmatrix} \infty & \infty \\ \infty & \infty \end{smallmatrix}\right)$, which is always the case for $h = d + 1$.

3. The EEA for a modified input. To accelerate the solution of Problem 2.4, we apply the divide-and-conquer techniques. Roughly, the idea is to solve Problem 2.4 in two steps. In each step, Problem 2.4 is solved for h replaced by $\lfloor h/2 \rfloor$, and the output of the first step is used as the input of the second step. We are going to show that

(i) this leads to the same desired output, and

(ii) the computational cost of the reduction to the pair of half-size problems is small.

A basic observation is that the matrix sequence $\{Q_i\}$ depends only on the quotient m/n. That is, for another input values m^* and n^* such that $m^*/n^* = m/n$, the Euclidean algorithm computes the same matrices $Q_i^* = Q_i$ for all i. A relatively small perturbation of the quotient m/n should not affect the first several terms of the sequence $\{Q_i\}$, using which is enough to solve the problem for smaller h. That is, we may replace m and n by smaller integers m^* and n^* provided that $m^*/n^* \approx m/n$. For the input values m^* and n^*, we denote by $\{r_i^*\}$ the remainder sequence and by $\{Q_i^*\}$ the matrix sequence. Next, we specify some bounds on the allowed perturbations of m/n for which $Q_i = Q_i^*$ and then state our main theorem.

THEOREM 3.1. *Suppose* $m^* = \lfloor m/\lambda \rfloor$ *and* $n^* = \lfloor n/\lambda \rfloor$ *for a positive integer* λ. *For any given integer* i, *if*

$$r^*_{i+2} \geq |Q^*_{i+1}| \quad or \quad r_{i+2} \geq \lambda |Q_{i+1}|,$$

then $Q_i = Q^*_i$.

Proof. (i) Suppose $r^*_{i+2} \geq |Q^*_{i+1}|$. Write $\binom{u_j}{v_j} = Q^{*-1}_j \binom{m}{n}$ for $j = 0, 1, \ldots, i+1$. Then we have

$$\begin{pmatrix} u_{j+1} \\ v_{j+1} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & -q^*_{j+1} \end{pmatrix} \begin{pmatrix} u_j \\ v_j \end{pmatrix}.$$

Therefore, $u_{j+1} = v_j$ for $j = 0, 1, \ldots, i$. Furthermore, extending (2.4) to (m^*, n^*), we obtain that

$$\begin{pmatrix} r^*_j \\ r^*_{j+1} \end{pmatrix} = Q^{*-1}_j \begin{pmatrix} m^* \\ n^* \end{pmatrix},$$

$$\begin{pmatrix} u_j \\ v_j \end{pmatrix} = \begin{pmatrix} r^*_j \\ r^*_{j+1} \end{pmatrix} \lambda + Q^{*-1}_j \begin{pmatrix} m - m^*\lambda \\ n - n^*\lambda \end{pmatrix}.$$

By (2.4) we also know that, in each row of Q^{*-1}_j, one of the entries is nonnegative, and another is nonpositive, and their absolute values are bounded by $|Q^*_{j-1}|$ in the first row and by $|Q^*_j|$ in the second row. Therefore, we have

$$v_j > (r^*_{j+1} - |Q^*_j|)\lambda$$

and

$$u_j - v_j > (r^*_j - |Q^*_{j-1}|)\lambda - (r^*_{j+1} + |Q^*_j|)\lambda \geq (r^*_{j+2} - |Q^*_{j+1}|)\lambda.$$

So, by assumption, $u_j > v_j > 0$ for $j = 1, 2, \ldots, i$. Now we have $u_0 = m$, $u_1 = n$, $u_{j+1} = u_{j-1} \bmod u_j$ for $j = 1, 2, \ldots, i$. So $u_j = r_j$ and $Q_j = Q^*_j$ for $j = 0, 1, \ldots, i$.

(ii) Suppose $r_{i+2} \geq \lambda |Q_{i+1}|$. Write $\binom{x_j}{y_j} = Q^{-1}_j \binom{m^*}{n^*}$ for $j = 0, 1, \ldots, i+1$. Then we have

$$\begin{pmatrix} x_{j+1} \\ y_{j+1} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & -q_{j+1} \end{pmatrix} \begin{pmatrix} x_j \\ y_j \end{pmatrix}.$$

Therefore, $x_{j+1} = y_j$ for $j = 0, 1, \ldots, i$. Furthermore, by (2.4), we extend the above expression for x_j and y_j as follows:

$$\begin{pmatrix} x_j \\ y_j \end{pmatrix} = \begin{pmatrix} r_j \\ r_{j+1} \end{pmatrix} \lambda^{-1} - Q^{-1}_j \begin{pmatrix} m/\lambda - m^* \\ n/\lambda - n^* \end{pmatrix}.$$

Now, similarly as in part (i), we deduce that $y_j > r_{j+1}\lambda^{-1} - |Q_j|$ and $x_j - y_j > (r_j\lambda^{-1} - |Q_{j-1}|) - (r_{j+1}\lambda^{-1} + |Q_j|) \geq (r_{j+2}\lambda^{-1} - |Q_{j+1}|)$. So, by assumption, $x_j > y_j > 0$ for $j = 1, 2, \ldots, i$. Now we have $x_0 = m^*$, $x_1 = n^*$, $x_{j+1} = x_{j-1} \bmod x_j$ for $j = 1, 2, \ldots, i$. So $x_j = r^*_j$ and $Q_j = Q^*_j$ for $j = 0, 1, \ldots, i$. □

COROLLARY 3.2. *Suppose* $m^* = \lfloor m/\lambda \rfloor$, $n^* = \lfloor n/\lambda \rfloor$ *for a positive integer* λ. *For any given integer* i, *if*

$$m^* \geq 2|Q^*_{i+2}| \cdot |Q^*_{i+1}| \quad or \quad m \geq 2\lambda |Q_{i+2}| \cdot |Q_{i+1}|,$$

then $Q_i = Q_i^*$.

Proof. Combine the assumed bound on m^* and m with the first inequality of Corollary 2.9 extended also to m^*, r_i^*, Q_i^*, and arrive at the bounds on r_{i+2}^* and r_{i+2} in Theorem 3.1. ∎

THEOREM 3.3 (main theorem). *Suppose* $m^* = \lfloor m/\lambda \rfloor$, $n^* = \lfloor n/\lambda \rfloor$ *for a positive integer* λ, *and* K *is a given positive integer such that* $m^* \geq 2K^2$. *If* $|Q_i^*| \leq K < |Q_{i+1}^*|$, *then* $Q_j = Q_j^*$ *for all* $j \leq i-2$ *and* $|Q_j| \leq K < |Q_{j+1}|$ *for some* j *such that* $i-2 \leq j \leq i+2$.

Proof. By Corollary 3.2, we have $Q_j = Q_j^*$ for $j \leq i-2$. If $|Q_{i+3}| > K$, then we are done. Otherwise, we have $m \geq \lambda m^* \geq 2\lambda K^2 \geq 2\lambda |Q_{i+3}|^2$. By applying Corollary 3.2 again, we obtain $Q_{i+1} = Q_{i+1}^*$, $Q_i = Q_i$. ∎

4. Our main algorithm.

ALGORITHM 4.1 (selected output of the EEA).

INPUT: *A triple of integers* (m, n, h) *such that* $m \geq n > 0, h \geq 0$.

OUTPUT: *The unique matrix* Q_k *such that* $|Q_k| \leq 2^h < |Q_{k+1}|$.

COMPUTATION: *Let* $d = \lfloor \log m \rfloor$.

1. *When* $h \leq \lfloor d/2 \rfloor - 1$, *let* $\lambda = 2^{d-2h-1}$, $m^* = \lfloor m/\lambda \rfloor$, *and* $n^* = \lfloor n/\lambda \rfloor$; *then* $2^{2h+1} \leq m^* \leq m/2$. *We first apply the algorithm to the input* (m^*, n^*, h) *and have the output* Q_i^*. *Theorem* 3.3 *for* $K = 2^h$ *implies that* $Q_{i-2} = Q_{i-2}^*$ *and* $|Q_k| \leq 2^h < |Q_{k+1}|$ *for some* $i-2 \leq k \leq i+2$. *We may compute* $Q_{i-2} = Q_{i-2}^*$ *from* Q_i^* *(cf. Corollary* 2.7*) and then find* Q_k *in a few Euclidean steps.*
2. *When* $\lfloor d/2 \rfloor \leq h \leq d-1$, *we first apply the algorithm to find* $|Q_i| \leq 2^{\lfloor h/2 \rfloor} < |Q_{i+1}|$. *Next we apply the algorithm again for the input* $(r_i, r_{i+1}, \lfloor h/2 \rfloor)$ *and have the output* $\tilde{Q}_j$. *Now we have* $Q_{i+j} = Q_i \tilde{Q}_j$, $|Q_{i+j}| < 2^{h+1}$, *and* $|Q_{i+j+2}| > 2^{h-1}$. *Then* $|Q_k| \leq 2^h < |Q_{k+1}|$ *for some* $i+j-2 \leq k \leq i+j+2$, *and we may find* Q_k *in a few Euclidean steps.*
3. *When* $h \geq d$, *we first apply the algorithm to find* $|Q_i| \leq 2^{d-1} < |Q_{i+1}|$. *Then* $|Q_k| \leq 2^h < |Q_{k+1}|$ *for some* $i \leq k \leq i+4$, *and we may find* Q_k *in a few Euclidean steps.*

THEOREM 4.2. *Let* $f(d, h)$ *be the bit cost of performing Algorithm* 4.1 *for the input* (m, n, h), *where* $d = \lfloor \log m \rfloor$. *Then we have*

$$f(d, h) = O(\mu(d) \log h)$$

for μ *in* (1.4).

Proof. By inspection of the algorithm, we have

$$f(d,h) = \begin{cases} f(2h+1, h) + O(\mu(d)) & \text{if } h \leq \lfloor \frac{d}{2} \rfloor - 1, \\ f(d, \lfloor \frac{h}{2} \rfloor) + f(d - \lfloor \frac{h}{2} \rfloor, \lfloor \frac{h}{2} \rfloor) + O(\mu(d)) & \\ & \text{if } \lfloor \frac{d}{2} \rfloor \leq h \leq d-1, \\ f(d, d-1) + O(\mu(d)) & \text{if } h \geq d. \end{cases}$$

Let us write $F(h) = f(2h+1, h)$. Then

$$F(h) = 2F(\lfloor h/2 \rfloor) + O(\mu(2h)),$$

and we obtain that

$$F(h) = O(\mu(2h) \log h).$$

By recursively combining this bound with the above expressions for $f(d,h)$, we obtain

$$f(d,h)=\sum_{i=1}^{1+\lfloor \log h\rfloor}(F(\lfloor h/2^i\rfloor)+O(\mu(d)))=O(\mu(d)\log h). \qquad \square$$

Remark 4.3.

(i) We may easily extend Algorithm 4.1 to compute the matrix Q_i (at the bit cost $O(\mu(d)\log\log K)$), such that $|Q_i|\le K<|Q_{i+1}|$ for any real $K\ge 1$, not just for $K=2^h$.

(ii) Due to Remark 2.12, we may also easily extend Algorithm 4.1 to find the remainder r_i (at the bit cost $O(\mu(d)\log\log(m/K))$, such that $r_i\ge K>r_{i+1}$ for any real $1\le K\le m$. By choosing $K=1$, we compute $r_i=\gcd(m,n)$.

5. Applications to rational number reconstruction. Let us next extend Algorithm 4.1 to solve Problems 1.1, 1.1a, 1.2, and 1.2a of rational number reconstruction.

Solution of Problems 1.1 *and* 1.1a. Note that (cf. (2.4))

$$\begin{pmatrix} r_i\\ r_{i+1}\end{pmatrix}=Q_i^{-1}\begin{pmatrix} m\\ n\end{pmatrix}=(-1)^i\begin{pmatrix} d_i & -b_i\\ -c_i & a_i\end{pmatrix}\begin{pmatrix} m\\ n\end{pmatrix}.$$

Therefore,

$$(-1)^i r_{i+1}=na_i \bmod m \text{ for all } i.$$

Let i be such that $a_i\le m/k<a_{i+1}$.

1. Since $a_i\le m/k$ and $r_{i+1}\le \frac{m}{a_{i+1}}<k$, we obtain a solution $\big((-1)^i r_{i+1},\ a_i\big)$ to Problem 1.1.
2. Suppose Problem 1.1a has a solution (η,δ) such that $\eta/\delta=(-1)^i r_{i+1}/a_i$; then $(\eta,\delta)=\big((-1)^i r_{i+1},\ a_i\big)$ and $\gcd(r_{i+1},a_i)=1$. Indeed, a_i divides δ because $\frac{n\delta-\eta}{m}=\frac{c_i\delta}{a_i}\in\mathbb{Z}$ and $\gcd(a_i,c_i)=1$.
3. Suppose Problem 1.1a has a solution such that $\eta/\delta\ne(-1)^i r_{i+1}/a_i$. Then the solution is unique. (Indeed, it follows from $a_i\eta-(-1)^i r_{i+1}\delta=0 \bmod m$ that $a_i(-1)^{i-1}\eta+r_{i+1}\delta=m$ and $(-1)^{i-1}\eta\ge 0$. Furthermore, if there are two such solutions (η_1,δ_1) and (η_2,δ_2), then $\eta_1\delta_2-\eta_2\delta_1=0 \bmod m$. So $\eta_1\delta_2-\delta_1\eta_2$ equals $0, m$, or $-m$. Combine $(-1)^{i-1}\eta_1\ge 0$ and $(-1)^{i-1}\eta_2\ge 0$ to deduce that only $\eta_1\delta_2-\eta_2\delta_1=0$ can hold.) Since $m=a_i r_i+r_{i+1}a_{i-1}$ by (2.4), we have $((-1)^{i-1}\eta-r_i)a_i=(a_{i-1}-\delta)r_{i+1}$. Therefore, $(\eta,\delta)=\big((-1)^{i-1}(r_i-tr_{i+1}),\ a_{i-1}+ta_i\big)$ for a real t. Note that $a_{i-1}+ta_i\in\mathbb{Z}$, $\frac{n\delta-\eta}{m}=c_{i-1}+tc_i\in\mathbb{Z}$, and $\gcd(a_i,c_i)=1$, and so $t\in\mathbb{Z}$. If $r_i<k$, then $(\eta,\delta)=\big((-1)^{i-1}r_i,\ a_{i-1}\big)$ defines the unique solution. If $r_i\ge k$, then by applying the inequalities $|\eta|<k$ and $\delta\le m/k$, we obtain $\frac{r_i-k}{r_{i+1}}<t\le\frac{m/k-a_{i-1}}{a_i}$. Therefore, the unique solution must be defined by the unique integer t in the interval $\big(\frac{r_i-k}{r_{i+1}},\frac{m/k-a_{i-1}}{a_i}\big]$. $\square$

COROLLARY 5.1. *Problems* 1.1 *and* 1.1a *of modular rational number reconstruction can be solved by using* $\rho(d)$ *bit operations for* ρ *in* (1.3).

Solution of Problems 1.2 *and* 1.2a. Recall that c_i/a_i is the ith continued fraction approximation of n/m, and $|\frac{c_i}{a_i}-\frac{n}{m}|<|\frac{s}{t}-\frac{n}{m}|$ for all i,s,t, where $1\le t<a_i$ (see [HW60, Theorem 181]). In particular, $|\frac{c_i}{a_i}-\frac{n}{m}|<|\frac{c_{i-1}}{a_{i-1}}-\frac{n}{m}|$ for all i. Let i be such that $a_i\le k<a_{i+1}$. Suppose

$$|\tfrac{s}{t}-\tfrac{n}{m}|\le|\tfrac{c_i}{a_i}-\tfrac{n}{m}|,\quad a_i<t\le k.$$

Then

$$\begin{aligned} & |\tfrac{c_i}{a_i} - \tfrac{s}{t}| \le 2|\tfrac{c_i}{a_i} - \tfrac{n}{m}| = \tfrac{2r_{i+1}}{a_i m} < \tfrac{2}{a_i k} \\ \Longrightarrow \quad & |c_i t - a_i s| < \tfrac{2t}{k} \le 2 \\ \Longrightarrow \quad & |c_i t - a_i s| = 1 = |c_i a_{i-1} - a_i c_{i-1}| \\ \Longrightarrow \quad & (s,t) = (c_i,\ a_i)\tau \pm (c_{i-1},\ a_{i-1}) \end{aligned}$$

for a real τ. Since $t > a_i > a_{i-1}$ and $tc_{i-1} - sa_{i-1} = (a_i c_{i-1} - c_i a_{i-1})\tau = (-1)^i\tau$, τ is a positive integer. Furthermore, observe that $\frac{c_i}{a_i} - \frac{n}{m} = \frac{(-1)^{i+1} r_{i+1}}{a_i m}$ and $\frac{c_{i-1}}{a_{i-1}} - \frac{n}{m} = \frac{(-1)^i r_i}{a_{i-1} m}$ have opposite signs, and recall that $|\frac{s}{t} - \frac{n}{m}| \le |\frac{c_i}{a_i} - \frac{n}{m}| < |\frac{c_{i-1}}{a_{i-1}} - \frac{n}{m}|$, so $(s,t) = \tau(c_i,\ a_i) + (c_{i-1},\ a_{i-1})$. Therefore, (s,t) is the unique solution to Problem 1.2 for $\tau = \lfloor \frac{k - a_{i-1}}{a_i} \rfloor$. □

COROLLARY 5.2. *Problems* 1.2 *and* 1.2a *of rational roundoff can be solved by using* $\rho(d)$ *bit operations for* ρ *in* (1.3).

Acknowledgment. We are grateful to Joachim von zur Gathen for his expert advice on the state of the art of the bit complexity of rational number reconstruction and for his helpful comments on the original draft of our paper.

REARRANGEABILITY OF $(2n-1)$-STAGE SHUFFLE-EXCHANGE NETWORKS*

HASAN ÇAM†

Abstract. Rearrangeable networks can realize each and every permutation in one pass through the network. Shuffle-exchange networks provide an efficient interconnection scheme for implementing various types of parallel processes. Whether $(2n-1)$-stage shuffle-exchange networks with $N=2^n$ inputs/outputs are rearrangeable has remained an open question for approximately three decades. This question has been answered affirmatively in this paper. An important corollary of the main result is the proof that two passes through an Omega network are sufficient and necessary to implement any permutation. In obtaining the main results of this paper, *frames* that look like grids with horizontal links of different lengths are shown to be remarkable tools for identifying and characterizing the binary matrix representations of permutations.

Key words. shuffle-exchange network, rearrangeable network, permutations, balanced matrices, frames

1. Introduction.

An interconnection network (IN) with $N=2^n$ inputs/outputs is called a rearrangeable network if it realizes each and every one of $N!$ permutations in a single pass [9]. It is known that the lower bound for the number of stages of a symmetrical multistage IN with 2×2 switching boxes (SBs) to be rearrangeable is $2n-1$ [10]. The validity of this lower bound for shuffle-exchange (SE) networks can be established by showing the existence of a permutation which cannot be performed with less than $2n-1$ stages [2]. The question of whether or not a $(2n-1)$-stage SE network is rearrangeable has remained open for three decades [3, 4, 7, 8, 12, 13, 16, 18, 19, 21, 25, 26, 27]. This paper proves that a $(2n-1)$-stage SE network with 2×2 SBs is rearrangeable.

SE networks, initially proposed by Stone [7], provide an efficient interconnection scheme for implementing various types of parallel processes [7, 1, 6, 11, 14, 20]. These networks are constructed of repeated copies of an SE stage which consists of a "perfect shuffle" interconnection pattern followed by a column of 2×2 SBs [7, 8]. The most used SE network is the Omega network consisting of n SE stages. For about three decades, several researchers have been interested in the number of SE stages needed to realize all $N!$ permutations. The algorithm proposed by Stone [7] can be used to realize any permutation on an SE network with n^2 stages. Siegel [12] also described an algorithm for realizing any permutation on a single SE stage in $2n^2$ passes. Parker [8] showed that three passes through the Omega network are sufficient to generate any permutation, and two passes are necessary. Wu and Feng [18] have shown that a $(3n-1)$-stage SE network implements all $N!$ permutations. The upper bound of $(3n-1)$ stages was later reduced to $(3n-3)$ stages by different researchers (Huang and Tripathi [19] and Babu and Raghavendra [16]). Using a constructive approach, Raghavendra and Varma [3] showed that an SE network of five stages with $N=8$ inputs/outputs is

†Computer Science and Engineering Department, Arizona State University, Tempe, AZ 85287 (hasan.cam@asu.edu).

rearrangeable. This has also been proven by Linial and Tarsi [4], who provided the best previously known upper bound of $3n-4$ stages. The rearrangeability of a $(2n-1)$-stage SE network was first conjectured by Beneš, and the conjecture was published in 1975 [26, 27]. Raghavendra [21] surveyed the latest status of the rearrangeability conjecture of SE networks, along with some claims of unsuccessful proofs made earlier. Raghavendra [21] also stated that they have shown the rearrangeability of a seven-stage SE network with 16 inputs by running a program that exhaustively checks all 16! permutations. Kim, Yoon, and Maeng [25] have recently refuted the claim made by Feng and Seo [24] for proving the rearrangeability conjecture.

To prove the rearrangeability of a $(2n-1)$-stage SE network, this paper first identifies the permutations realized by the reverse baseline (RB) network, called $RB_{1:n}$, using "frames," which look like grids with horizontal links of different lengths [22]. Then it is proven that a composite network, called $RB_{1:(n-1)}SE_{1:n}$ (consisting of an $(n-1)$-stage RB network followed by an n-stage SE network), is rearrangeable. Finally, the functional equivalence of $RB_{1:(n-1)}SE_{1:n}$ and the $(2n-1)$-stage SE network is shown.

The remainder of this paper is organized as follows. The basic terminology and definitions used throughout the paper are introduced in section 2. Basic concepts and some preliminary results concerning the relationship between frames, balanced matrices, and some INs are presented in section 3. The objective of section 4 is to show the rearrangeability of $RB_{1:(n-1)}SE_{1:n}$. The proof that SE networks with at least $2n-1$ stages are rearrangeable is presented in section 5. Section 6 is dedicated to conclusions. The appendix contains some proofs that are omitted earlier.

2. Basic definitions. Throughout this paper, matrices are denoted by single capital letters, and columns of a matrix are represented by the lower case of the letter denoting that matrix. Matrix A having N rows and k columns is denoted by $A_{N\times k}$. However, the columns of a matrix are numbered starting with 1. The rows of any matrix are labeled in ascending order starting with 0, unless otherwise specified. The N rows of $A_{N\times k}$ can form $N/2$ pairs such that the row contents of each pair can be swapped/unswapped independent of the other pairs, without swapping the labels (i.e., the order of row labels in $A_{N\times k}$ is never changed). To refer to a set of specific columns of a matrix, the notation $A_{x:y}$ is used to denote the submatrix that contains those columns of A whose indices are $x,\ x+1,\dots,y$, where $1\le x\le y$; if x happens to be greater than y, then $A_{x:y}$ refers to a nil matrix. Unless specifically stated, the number of the rows of a matrix $A_{x:y}$ is assumed to be equal to N and N=2^n. $A_{N\times k}(i)$ refers to row i of the matrix $A_{N\times k}$, where $0\le i\le N-1$. A *permutation* on a set X is a bijection of X onto itself. A permutation f permutes the ordered list $0,\ 1,\dots,\ N-1$ into $f(0),\ f(1),\dots,f(N-1)$.

Definition 2.1 (permutation matrix, identity permutation matrix, reverse permutation matrix). *A permutation h is represented by an $N\times n$ binary matrix called a permutation matrix, H, such that its ith row, $H_{N\times n}(i)$, is the binary representation of the integer $h(i)$. The identity permutation matrix, denoted by $I_{N\times n}$, is the matrix whose ith row is the binary representation of i (this is called a "standard matrix" in* [15]*). The reverse permutation matrix, denoted $R_{N\times n}$, is the matrix whose jth column is the $(n+1-j)$th column of $I_{N\times n}$.*

As an example, the identity permutation matrix $I_{8\times 3}$, the reverse permutation matrix $R_{8\times 3}$, and a permutation matrix $H_{8\times 3}$ are shown below. There is a one-to-one correspondence between permutations and permutation matrices. For instance, $R_{8\times 3}$ represents the permutation $r = (0)(1\ 4)(2)(3\ 6)(5)(7)$ in cyclic notation, where we

transpose 1 and 4, transpose 3 and 6, and keep everything else fixed.

$$I_{8\times 3} = \begin{array}{c} \\ 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array}\!\!\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \\ 1 & 1 & 1 \end{bmatrix} \qquad R_{8\times 3} = \begin{array}{c} \\ 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array}\!\!\begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \qquad H_{8\times 3} = \begin{array}{c} \\ 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array}\!\!\begin{bmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix}$$

If the binary representation of an integer i has the form $i_1 i_2 \dots i_n$, then the *shuffle* operation cyclically shifts its bits one place left, that is, $shuffle(i_1 i_2 \dots i_n) = i_2 i_3 \dots i_n i_1$. Given that the input and output addresses of an interconnection pattern with $N = 2^n$ inputs/outputs ports have the form $i_1 i_2 \dots i_n$, the *perfect shuffle* connection performs the transformation $shuffle(i_1 i_2 \dots i_n) = i_2 i_3 \dots i_n i_1$, whereas the *inverse perfect shuffle* connection performs the transformation $inverse - shuffle(i_1 i_2 \dots i_n) = i_n i_1 i_2 \dots i_{n-1}$. Let γ and γ_0 denote a general permutation and the identity permutation, respectively. Also, for $1 \le k \le n$, let γ_k denote the permutation obtained by applying the *shuffle* operation to γ_{k-1}; that is, $\gamma_k = shuffle\ (\gamma_{k-1})$. Note that γ_n also becomes the identity permutation, and γ_{n-1} is the inverse-shuffle permutation.

A k-stage IN consists of k columns of SBs, each followed and preceded by links which form interconnection patterns. A column of IN contains $N/2$ SBs with two inputs/outputs, each of which can be set both straight and cross. Figure 2.1 shows two networks considered in this paper, namely, the RB and the four-stage SE. Network stages are numbered in ascending order starting with 1 for the leftmost stage. The inputs of the leftmost stage (i.e., first stage) of any IN are labeled in ascending order from 0 to $N-1$. The inputs of the other stages of any IN except the inverse shuffle-exchange (ISE) network are also labeled from 0 to $N-1$. The inputs of ISE_k (i.e., stage k of the ISE) are labeled by the permutation γ_{k-1} described above for all i, $0 \le i \le N-1$. Specifically, the input i of ISE_k is labeled by $\gamma_{k-1}(i)$. These input labels can also be obtained as follows: (1) the inputs of the first stage ISE_1 are numbered from 0 to $N-1$ in ascending order, (2) all SBs are set straight, and (3) the input labels of the first stage are propagated through the ISE network to determine the input labels of SBs in the other stages. For instance, for $N = 16$, the inputs of ISE_2 are numbered by 0,2,4,6,8,10,12,14,1,3,5,9,11,13, and 15 from top to bottom; similarly, the inputs of ISE_3 are numbered by 0,4,8,12,1,5,9,13,2,6,10,14,3,7,11, and 15.

DEFINITION 2.2 (RB network). *An n-stage reverse baseline (RB) network is the same as the network formed by the last n stages of the Beneš network with N inputs/outputs. Specifically, for $1 \le i \le n$, stage i of the RB network consists of a pile of 2^{n-i} copies of the SE stage with 2^i inputs/outputs. (An SE stage consists of a shuffle interconnection pattern followed by a column of 2×2 SBs.) Figure* 2.1(a) *illustrates an RB network with* 16 *inputs/outputs.*

DEFINITION 2.3 (SE and ISE networks). *A shuffle-exchange (SE) network with N inputs/outputs is constructed of repeated copies of a "perfect shuffle" connection followed by a column of 2×2 SBs, where the shuffle connection implements the perfect shuffle permutation. An inverse shuffle-exchange (ISE) network is constructed of repeated copies of an ISE stage consisting of a column of 2×2 SBs followed by an*

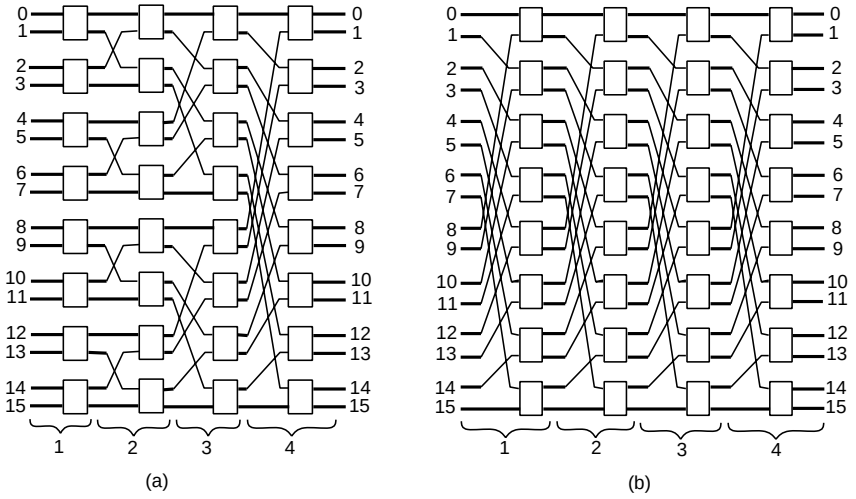

FIG. 2.1. (a) *An RB network with* 16 *inputs/outputs.* (b) *An SE network with* 16 *inputs/outputs.*

"inverse perfect shuffle" connection implementing the inverse shuffle permutation. Informally, we would obtain the ISE network if data flowed from right to left in the SE network. Figure 2.1(b) *illustrates an SE network.*

DEFINITION 2.4 (stages of RB and SE networks). *With one exception, a stage in the RB and SE networks consists of a connection pattern and the following column of SBs. The exception is the rightmost stage (i.e., the output stage), which consists of the last column of SBs and both the preceding and succeeding connection patterns. Stages are labeled from left to right in ascending order starting with* 1. *The interconnection pattern of an SE stage is called a shuffle (or perfect shuffle) interconnection pattern that implements the shuffle permutation. The interconnection pattern of stage* i *in the RB network consists of a pile of* 2^{n-i} *copies of shuffle interconnection patterns with* 2^i *inputs/outputs. See Figure* 2.1 *for the stages.*

An IN with N *inputs/outputs and* k *stages is denoted by both* $IN_{N\times k}$ *and* $IN_{1:k}$ *for* $k \geq 1$. *The subnetwork that consists of the stages* x *through* y *of* $IN_{1:k}$ *is denoted by* $IN_{x:y}$, *where* $1 \leq x \leq y \leq k$. *The notation used for networks is different from that used for matrices because matrices are always denoted by single letters, as opposed to the double letters used for INs. In this paper, if the name of an IN has more than one word, then it is denoted by the upper case form of the first letters of those words.*

DEFINITION 2.5 (RB, SE, ISE, composite IN). *The symbols* RB, SE, *and* ISE *in this paper refer to the network's reverse baseline, shuffle-exchange, and inverse shuffle-exchange, respectively. If an IN is a cascade of different INs, then it is called a composite IN and is denoted by the concatenation of symbols that represent the* IN*s in the order they are cascaded.*

As an example for a composite network, the notation $RB_{1:n}SE_{1:m}$, $m \geq 1$, denotes the network consisting of $RB_{1:n}$ followed by $SE_{1:m}$. The concept of balanced matrices was introduced by Linial and Tarsi [4]. Next, we express their definition using permutations.

DEFINITION 2.6 (balanced matrix). *Let* $N = 2^n$, $n \geq 1$, $k \geq 1$, *and* $1 \leq m \leq n$. *A matrix* $A_{N\times k}$ *containing* 0*'s and* 1*'s is balanced only if, for every set of* m

consecutive columns, every m-bit binary number appears 2^{n-m} *times in the rows. This implies that, for* $k \geq n$, *each and every n consecutive column forms the binary representation of a permutation on the set* $\{0, 1, \ldots, N-1\}$.

As an example, two balanced matrices D and E are shown below. However, notice that the matrix $[D\ E]$ is not balanced because not all three consecutive columns of $[D\ E]$ form the binary representation of a permutation on $\{0, 1, \ldots, 7\}$. For instance, "001" is repeated on rows 1 and 2 of columns 2, 3, and 4 in $[D\ E]$.

$$D = [d_1\ d_2\ d_3] = \begin{array}{c} 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} \qquad E = [e_1\ e_2] = \begin{array}{c} 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{array} \begin{bmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 1 & 1 \\ 0 & 1 \\ 0 & 1 \\ 0 & 0 \\ 0 & 0 \end{bmatrix}$$

A subset M of edges in a graph G is called independent or a *matching* if no two edges of M have a vertex in common. A matching M is said to be a *perfect matching* if it covers all vertices of G. For more extended discussion of these basic concepts, the reader is referred to [5].

DEFINITION 2.7 (perfect matching graph of a balanced matrix of order $N \times (n-1)$). *Let A be a balanced matrix of order* $2^n \times (n-1)$ *for* $n \geq 2$. *The* perfect matching graph of A, *denoted by* PG_A, *on* 2^n *vertices is a graph whose vertices have degree one and vertices* V_i *and* V_j *are joined by an edge if the* i*th and* j*th rows of A are identical.*

Note that the perfect matching graph of $A_{N\times(n-1)}$ is unique because each $(n-1)$-bit row is repeated twice in $A_{N\times(n-1)}$. As an example, consider the balanced matrix E given in the above example. Its perfect matching graph is unique and has four edges such that each of the following four sets contains the two vertices of an edge: $\{V_0,\ V_1\}$, $\{V_2,\ V_3\}$, $\{V_4,\ V_5\}$, and $\{V_6,\ V_7\}$. The perfect matching graph corresponding to the first two columns of the above balanced matrix D also has four edges such that each of the following four sets contains the two vertices of an edge: $\{V_0,\ V_4\}$, $\{V_1,\ V_6\}$, $\{V_2,\ V_5\}$, and $\{V_3,\ V_7\}$.

DEFINITION 2.8 (2-labeling). *The* 2-labeling *(or* 2*-coloring) of a graph refers to the assignment of integers* 0 *and* 1 *to its vertices such that no two adjacent vertices are assigned the same integer. The integers* 0 *and* 1 *that are assigned to two adjacent vertices are called* 2*-labels.*

DEFINITION 2.9 (agree). *A balanced matrix* $B_{N\times j}$, $j \geq 1$, *is said to agree with a balanced matrix* $A_{N\times i}$, $i \geq 1$, *if the matrix* $[A_{N\times i}\ B_{N\times j}]$ *is balanced.*

LEMMA 2.10. *Given a balanced matrix* $A_{N\times(n-1)}$, $n \geq 2$, *there exist* $2^{N/2}$ *binary column vectors, say, x's, each having* $N/2$ 0*'s and* $N/2$ 1*'s such that* $[A_{N\times(n-1)}\ x]$ *is balanced for each x.*

Proof. The unique perfect matching graph, PG_A, of $A_{N\times(n-1)}$ has $N/2$ edges. There are $2^{N/2}$ distinct possible 2-labelings of this graph because each pair of adjacent vertices can be labeled in two different ways (0-1 or 1-0). Each 2-labeling corresponds to a distinct column of length N with $N/2$ 0's and $N/2$ 1's. Thus the total number of distinct columns that agree with $A_{N\times(n-1)}$ is $2^{N/2}$. □

DEFINITION 2.11 (forward-routing, reverse-routing). *Assume that a setting of SBs of an interconnection network* $IN_{N\times k}$ *realizes the permutation* $h: i \Rightarrow h(i)$ *for* $0 \leq i \leq N-1$. *When* $A(i)$ *(i.e., row i of A) is located at input i of* $IN_{N\times k}$ *for every*

i, forward-routing *matrix A through $IN_{N\times k}$ with the above setting of SBs generates a new matrix, denoted A^F, at the outputs of $IN_{N\times k}$ by permuting the rows of A in accordance with the permutation h such that $A^F(h(i)) = A(i)$. Likewise, when $A(i)$ is located at output i of $IN_{N\times k}$ for every i,* reverse-routing *matrix A through $IN_{N\times k}$ with the above setting of SBs generates a new matrix, denoted A^R, at the inputs of $IN_{N\times k}$ by permuting the rows of A in accordance with the inverse of the permutation h, denoted h^{-1}, such that $A^R(h^{-1}(i)) = A(i)$.*

In this paper, the following *bit-controlled routing scheme* is used for routing inputs of a network to their destinations. The content of row i of a balanced matrix $A_{N\times k}$ is used as the *routing tag* for the input i. Similar to the labeling scheme of network stages shown in Figure 2.1, the bits of any routing tag are also labeled from left to right, starting with 1. The ith bit of the routing tag is used as the *control bit* in the following way at the ith stage for setting an SB to which the routing tag is an input: if the control bit equals 0, then the routing tag is sent to the upper output of the SB; otherwise, it is sent to the lower output. Because an SB is allowed to be set straight and cross only in the paper, the control bits of an SB must constitute the set $\{0, 1\}$ to avoid having any conflict.

DEFINITION 2.12 (realize, pass). *A network $IN_{N\times k}$ realizes a permutation represented by $A_{N\times n}$ if there is a network switch setting such that input i is sent to output $A_{N\times n}(i)$ for all $i = 0, 1, \ldots, N-1$. A network $IN_{N\times k}$, $k \geq 1$, passes a balanced matrix $B_{N\times k}$ if no conflict occurs in the SBs of the $IN_{N\times k}$ when $B_{N\times k}(i)$ is used as the routing tag in the way explained above for the ith input of the $IN_{N\times k}$.*

3. Frames and preliminary results. This section introduces the notion of a frame and establishes necessary fundamental properties of frames and how they relate to balanced matrices and INs of interest. Somewhat different versions of some of these definitions and a motivational example appeared in [22, 23]. Some preliminary results that will be used throughout the paper are also presented in this section.

Recall that γ and γ_0 denote a general permutation and the identity permutation, respectively. Also, for $1 \leq k \leq n$, let γ_k denote the permutation obtained by applying the *shuffle* operation to γ_{k-1}, that is, $\gamma_k = shuffle(\gamma_{k-1})$.

A frame looks like a grid with horizontal links of different lengths together with a labeling of the rows and columns. The frame is used to capture constraints that some rows and columns of balanced matrices need to satisfy in order to be realized by INs.

DEFINITION 3.1 (frame, standard frame, block of a frame). *A frame $F_{N\times k;\gamma}$ consists of k columns labeled f_j for $1 \leq j \leq k$ and $k \geq 1$ from left to right and N rows labeled according to a permutation γ such that the label of the ith row from the top equals $\gamma(i)$ for all i, $0 \leq i \leq N-1$. For $1 \leq j \leq n-1$, column f_j consists of 2^{n-j} blocks of 2^j rows (entries) each. For $j \geq n$, column f_j consists of a single block of N rows. If γ is the identity permutation (i.e., γ_0), then the frame is called the standard frame and may also be denoted by $F_{N\times k}$, in addition to the notation $F_{N\times k;\gamma_0}$. In the graphical representation of a frame, any polygon with four sides and four right angles is called a block of a frame. (See Figure* 3.1 *for some frames.)*

The notation f_{ij} denotes the ith entry of column f_j. The notation $F_{N\times k;\gamma}(i)$ is used to denote the ith row of $F_{N\times k;\gamma}$. If the number of rows in a frame is not specified, it is assumed to be equal to N. Therefore, if the number of rows is not specified, the notation $F_{N\times k;\gamma}$ and $F_{1:k;\gamma}$ refer to the same frame.

DEFINITION 3.2 ($F^r_{N\times k;\gamma}$, universal frame $F^{n-1}_{N\times k;\gamma}$). *Frame $F^r_{N\times k;\gamma}$, $r \in \{0, 1, \ldots, k-1\}$ and $k \in \{1, 2, \ldots, n\}$, is the same as $F_{N\times k;\gamma}$ except that for $j = 1, 2, \ldots, r+1$, each column f_j of $F^r_{N\times k;\gamma}$ consists of 2^{n-r-1} blocks of 2^{r+1} rows each (instead of*

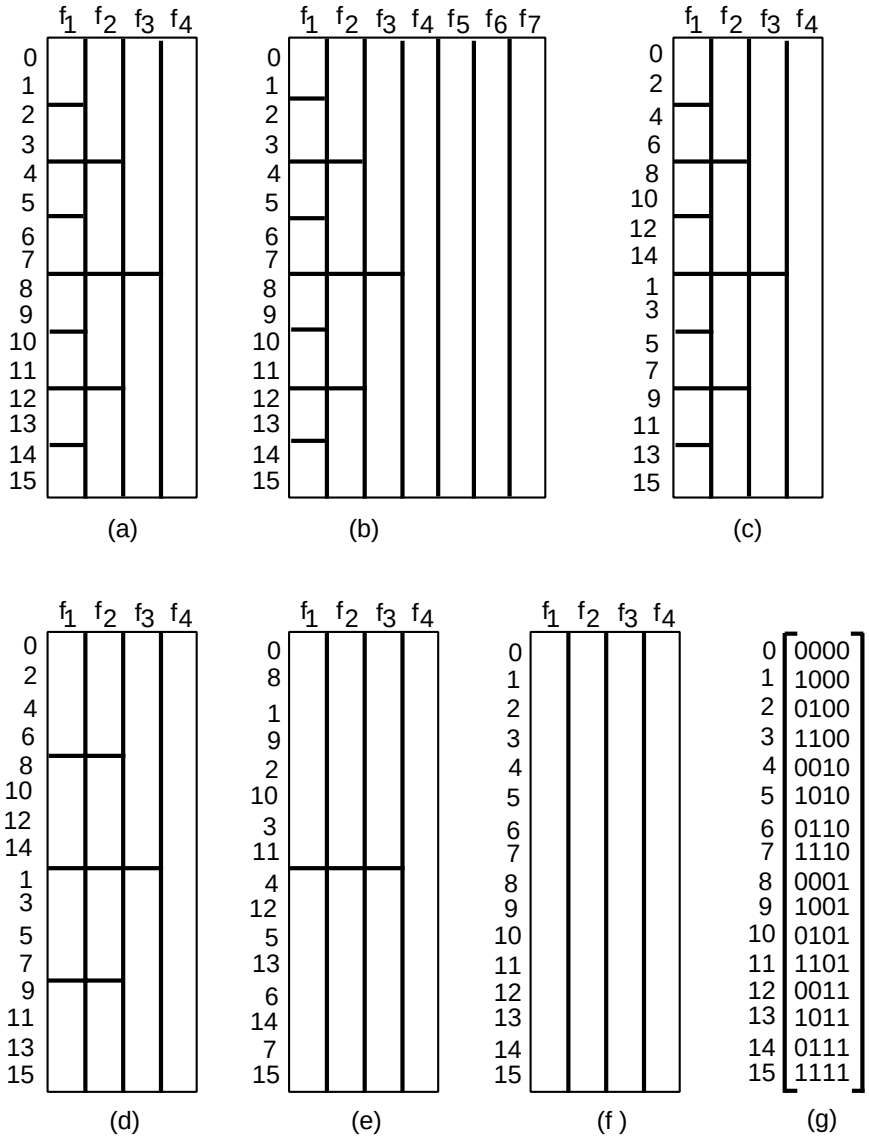

FIG. 3.1. *Let* $N = 16$. (a) $F_{16\times 4} = F^0_{1:4}$. (b) $F_{16\times 7} = F^0_{1:7}$. (c) $F_{16\times 4;\gamma_1} = F^0_{1:4;\gamma_1}$. (d) $F^1_{16\times 4;\gamma_1} = F^1_{1:4;\gamma_1}$. (e) $F^2_{16\times 4;\gamma_3} = F^2_{1:4;\gamma_3}$. (f) *The universal frame* $F^3_{16\times 4;\gamma_0} = F^3_{1:4}$. (g) *The reverse permutation matrix* $R_{16\times 4} = R_{1:4}$.

2^{n-j} *blocks of* 2^j *rows each). For* $r = n-1$, *the frame* $F^{n-1}_{N\times k;\gamma}$ *is called the universal frame.*

Note that every column of the universal frame is a single block of N rows. (See Figure 3.1 for some $F^r_{N\times k;\gamma}$ and the universal frame.) Also, note that $F_{N\times k;\gamma}$ and $F^0_{N\times k;\gamma}$ refer to the same frame.

DEFINITION 3.3 (fit). *Let* $k \geq 1$ *and* $1 \leq p \leq k$. *Consider a matrix* $A_{N\times k}$ *and a frame* F *with* N *rows and* k *columns. First, row* i *of* $A_{N\times k}$ *is placed into the row*

i of F. Then the matrix $A_{N\times k}$ is said to fit the frame F if and only if, for all p's, each and every one of those p-column blocks whose entries are located in columns f_1, $f_2, \ldots, f_p$ of F contains a balanced matrix.

Note that any balanced matrix of order $N \times k$ fits a universal frame with N rows and k columns because a universal frame requires a matrix to be balanced only.

Example 3.1. Note that the reverse permutation matrix $R_{16\times 4}$ shown in Figure 3.1(g) fits $F_{16\times 4}$ shown in Figure 3.1(a). However, $R_{16\times 4}$ does not fit $F_{16\times 4;\gamma_1}$ shown in Figure 3.1(c) because many blocks of $F_{16\times 4;\gamma_1}$ do not contain balanced matrices when row i of $F_{16\times 4;\gamma_1}$ is filled in by row i of $R_{16\times 4}$. For instance, in $F_{16\times 4;\gamma_1}$, the topmost block of f_1 does not contain a balanced matrix.

In the remainder of this section, some preliminary results are presented. The following lemma computes the number of matrices that fit $F_{N\times k}$.

LEMMA 3.4. *The number of those matrices of order $N \times k$ each of which fits $F_{N\times k}$ equals $2^{Nk/2}$ for $k \geq 1$.*

Proof. The first column f_1 of $F_{N\times k}$ consists of $N/2$ blocks each having only two rows. Because each block can constitute the set $\{0, 1\}$ in two different ways independently of the other blocks, there exist $2^{N/2}$ column vectors that fit the first column of $F_{N\times k}$. Each of these column vectors, say, x, generates $2^{N/2}$ column vectors, say, y's, in the sense that each of $[x\ y]$ fits the first two columns of $F_{N\times k}$. To select a vector y for column x, $N/2$ pairs of rows are first determined for x such that two rows of x form a pair if their contents are the same and their second entries on column y will belong to the same block of f_2 of $F_{N\times k}$. The rows of each pair are swapped/unswapped independently of the other pairs of rows. Thus each x generates $2^{N/2}$ y's such that any $[x\ y]$ fits the first two columns of $F_{N\times k}$. Similarly, to select a vector z for a given balanced matrix $[x\ y]$, $N/2$ pairs of rows are first determined for the matrix $[x\ y]$ such that two rows of $[x\ y]$ form a pair if their contents are the same and their third entries on column z will belong to the same block of f_3. The rows of each pair are swapped/unswapped independently of the other pairs of rows. Thus each $[x\ y]$ generates $2^{N/2}$ z's such that any $[x\ y\ z]$ fits the first three columns of $F_{N\times k}$. This generation of column vectors is continued until all matrices that fit $F_{N\times k}$ are generated. Thus the lemma holds. ∎

The following theorem establishes a relation between frames and permutations that pass RB networks. The basic idea behind the proof of the theorem appears in [22], and the complete proof is provided in the appendix.

THEOREM 3.5. *A matrix $D_{1:k} = [d_1\ d_2\ \ldots\ d_k]$ fits $F_{1:k}$ if and only if $D_{1:k}$ passes $RB_{1:k}$, $1 \leq k \leq n$. Moreover, $RB_{1:k}$ sends its ith input to its jth output, where j is equal to the sum of $(\lfloor i/2^k \rfloor \times 2^k)$ and the value of $D_{1:k}(i)$.*

Note that the sum described in Theorem 3.5 is a regular sum in the sense that no modular arithmetic is needed. Theorem 3.5 implies that, for $k = n$, a matrix $D_{1:k}$ fits $F_{1:k}$ if and only if $D_{1:k}$ is *realized* by $RB_{1:k}$. It is shown in [4] how balanced matrices can be used to determine the number of SE stages (or the number of passes through a single SE stage) necessary to realize a given permutation. Lemma 3.6 below restates their result using the notation of this paper.

LEMMA 3.6 (see [4]). *Let $M_{N\times m}$ and $C_{N\times k}$ be balanced matrices such that $M_{N\times m} = [I_{N\times n}\ C_{N\times k}]$, $k \geq 1$, and $n + k = m$. The k-stage SE network (i.e., $SE_{1:k}$) realizes the permutation represented only by $M_{(m+1-n):m}$.*

To illustrate Lemma 3.6, consider the identity permutation matrix $I_{8\times 3} = [i_1\ i_2\ i_3]$ and some balanced matrices $M_{8\times 4} = [I_{8\times 3}\ i_1]$, $M_{8\times 5} = [I_{8\times 3}\ i_1\ i_2]$, and $M_{8\times 6} = [I_{8\times 3}\ I_{8\times 3}]$. Because $M_{8\times 4}$, $M_{8\times 5}$, and $M_{8\times 6}$ are balanced, the permutations repre-

sented in binary by $[i_2\ i_3\ i_1]$, $[i_3\ i_1\ i_2]$, and $[i_1\ i_2\ i_3]$ are realized by the single-stage SE, two-stage SE, and three-stage SE with $N = 8$ inputs/outputs, respectively.

Lemma 3.6 can be used to establish the *lower bound* of $2n - 1$ stages for SE networks as follows. Since $M_{1:m}$ defined in Lemma 3.6 is a balanced matrix, every n consecutive columns of it form a balanced matrix. Even if only one column vector of a balanced matrix is already known, no other column of the balanced matrix can be an arbitrary column vector because each one of them has to form a balanced submatrix with the fixed column. Therefore, in order for $M_{(m+1-n):m}$ to represent any balanced matrix of order $N \times n$, it is required that the rightmost column i_n of $I_{1:n}$ does not form a balanced submatrix with any column of $M_{(m+1-n):m}$. This implies that there must be at least $n-1$ column vectors between i_n and the leftmost column $m+1-n$ of $M_{(m+1-n):m}$, which implies that $m+1-n$ must be equal to at least the sum of n and the number of columns of $I_{1:n}$, that is, $m+1-n \geq 2n$. Hence $m \geq 3n-1$. Since the k-stage SE network realizes the permutation represented by $M_{(m+1-n):m}$, where $k = m - n$, k must be at least $2n - 1$. Therefore, an SE network must have at least $2n - 1$ stages to be rearrangeable.

The following theorem shows that $F_{1:(n+m-1)}$ can be used to characterize the permutations realized by $RB_{1:(n-1)}SE_{1:m}$ for $m \geq 1$. The proof of this theorem is provided in the appendix.

THEOREM 3.7. *A balanced matrix $D_{1:(n+m-1)}$, $m \geq 1$, fits the frame $F_{1:(n+m-1)}$ if and only if $D_{1:(n+m-1)}$ passes the network $RB_{1:(n-1)}SE_{1:m}$. Moreover, $RB_{1:(n-1)}SE_{1:m}$ realizes the permutation represented by the last n columns of $D_{1:(n+m-1)}$, denoted by $D_{m:(n+m-1)}$.*

Now we introduce Figure 3.2 and explain below the basic idea behind Theorem 3.7. Let $(x_1^i x_2^i \dots x_n^i \dots x_{n+m-1}^i)$ denote the row i of a balanced matrix $D_{1:(n+m-1)}$ fitting $F_{1:(n+m-1)}$, where $0 \leq i \leq N-1$. As stated above, Theorem 3.5 implies that, for $k = n$, a matrix $D_{1:k}$ fits $F_{1:k}$ if and only if $D_{1:k}$ is *realized* by $RB_{1:k}$. Thus any permutation whose binary representation fits $F_{1:n}$ is realized by $RB_{1:n}$, and vice versa. This implies that when $(x_1^i x_2^i \dots x_n^i)$ is used as the routing tag of input i of $RB_{1:n}$, this routing tag (along with input i) reaches the output with label $(x_1^i x_2^i \dots x_n^i)$ of $RB_{1:n}$. (Note that the bit x_j^i, $1 \leq j \leq n$, is used as the control bit for setting SB at stage j of $RB_{1:n}$.) This also means that the matrix formed by all the N routing tags $(x_1^i x_2^i \dots x_n^i)$ at the outputs of $RB_{1:n}$ is the identity permutation matrix. Recall that the last stage of $RB_{1:n}$ is an SE stage, and hence $RB_{1:n}$ is identical to $RB_{1:(n-1)}SE_1$. Therefore, it follows that the permutation whose binary representation is the same as the submatrix $D_{1:n}$ of $D_{1:(n+m-1)}$ is realized by $RB_{1:(n-1)}SE_1$, and all the N routing tags $(x_1^i x_2^i \dots x_n^i)$ form the identity permutation matrix at the outputs of $RB_{1:(n-1)}SE_1$.

When an SE stage is appended to the right of $RB_{1:(n-1)}SE_1$ in order to form $RB_{1:(n-1)}SE_{1:2}$, the routing tag $(x_1^i x_2^i \dots x_n^i)$ is first shuffled through the shuffle pattern to the output with label $(x_2^i x_3^i \dots x_n^i x_1^i)$ of the shuffle pattern and is then switched by the exchange stage to the output with label $(x_2^i x_3^i \dots x_n^i x_{n+1}^i)$ of $RB_{1:(n-1)}SE_{1:2}$, where x_{n+1}^i is used as the control bit for setting the SB of the exchange stage. Because Theorem 3.7 guarantees that no conflict occurs in the SBs, the matrix formed by all the N routing tags $(x_2^i x_3^i \dots x_n^i x_{n+1}^i)$ at the outputs of $RB_{1:(n-1)}SE_{1:2}$ is now the identity permutation matrix. This implies that the permutation whose binary representation is the same as the submatrix $D_{2:(n+1)}$ is realized by $RB_{1:(n-1)}SE_{1:2}$. In general, when an SE stage is appended to the right of $RB_{1:(n-1)}SE_{1:(m-1)}$ in order to form $RB_{1:(n-1)}SE_{1:m}$, the routing tag $(x_{m-1}^i x_m^i \dots x_{n+m-2}^i)$ is first shuffled

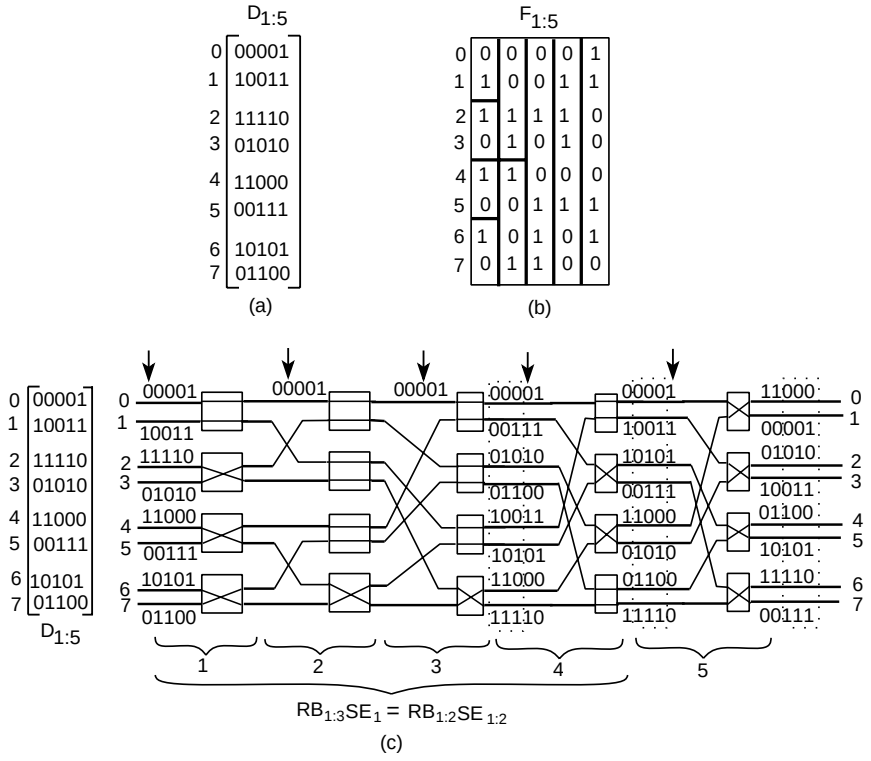

FIG. 3.2. *In this figure,* $N = 8$, $n = 3$, *and* $m = 3$. (a) *A balanced matrix* $D_{1:5}$ *fitting* $F_{1:5}$. (b) $F_{1:5}$ *along with the matrix* $D_{1:5}$. (c) *The network* $RB_{1:2}SE_{1:3}$ *realizes the permutation corresponding to the balanced submatrix* $D_{3:5}$ *(i.e., the last* n *columns of* $D_{1:5}$*), where the row* i *of* $D_{1:5}$ *is used as the routing tag of the input* i. *Arrows point to the control bits used to set the SBs. The matrices formed by the routing tags at the stages* 4, 5 *and the outputs of* $RB_{1:2}SE_{1:3}$ *are shown, and each identity permutation matrix is encircled by a dotted line box. The row labels of matrices that are formed in every stage of the network are in ascending order from* 0 *to* 7.

through the shuffle pattern to the output with label $(x_m^i x_{m+1}^i \dots x_{n+m-2}^i x_{m-1}^i)$ of the shuffle pattern and is then switched by the exchange stage to the output with label $(x_m^i x_{m+1}^i \dots x_{n+m-2}^i x_{n+m-1}^i)$ of $RB_{1:(n-1)}SE_{1:m}$. Because the matrix formed by all the N routing tags $(x_m^i x_{m+1}^i \dots x_{n+m-2}^i x_{n+m-1}^i)$ at the outputs of $RB_{1:(n-1)}SE_{1:m}$ is the identity permutation matrix, the permutation whose binary representation is the same as the submatrix $D_{m:(n+m-1)}$ is realized by $RB_{1:(n-1)}SE_{1:m}$. In other words, the permutation whose binary representation is the same as the last n columns of $D_{1:(n+m-1)}$ is realized by $RB_{1:(n-1)}SE_{1:m}$.

For $N = 8$ and $m = 3$, Figure 3.2 shows how the rows of a $D_{1:(n+m-1)}$ are used as the routing tags of the inputs of $RB_{1:(n-1)}SE_{1:m}$.

This figure also illustrates how the permutation corresponding to the last n columns of $D_{1:(n+m-1)}$ is realized by $RB_{1:(n-1)}SE_{1:m}$. The matrices formed by the routing tags at the third, fourth, and fifth stages of $RB_{1:2}SE_{1:3}$ are shown such that each identity permutation matrix formed by the routing tags is encircled by a dotted line box. The dotted line box at the outputs of $RB_{1:2}SE_{1:3}$ contains the last three columns of the matrix formed by the routing tags. This implies that the permutation

whose binary representation is $D_{3:5}$ is realized by $RB_{1:2}SE_{1:3}$.

4. Rearrangeability of network $RB_{0:(n-1)}SE_{1:n}$. The main result of this section, stated in Theorem 4.7, is that $RB_{1:(n-1)}SE_{1:n}$ is rearrangeable. This result is obtained as follows. Let T denote the set of all those balanced matrices of order $N \times (2n-1)$, each of which fits $F_{1:(2n-1)}$. Also, let M denote the set of all those balanced matrices of order $N \times n$, each of which is the same as the last n columns of at least one member of T. Theorem 3.7 states that $RB_{1:(n-1)}SE_{1:n}$ realizes every permutation whose binary representation is the same as the last n columns of a matrix fitting $F_{1:(2n-1)}$, and vice versa. Therefore, to prove that $RB_{1:(n-1)}SE_{1:n}$ is rearrangeable, it is sufficient to show that the set M contains all $N!$ balanced matrices of order $N \times n$. To show this, we introduce three algorithms, namely, COLUMN, GENERATE-π, and GENERATE-ALL. Algorithm GENERATE-ALL generates all matrices of T in $n-1$ steps. In each step, a column vector r of $N/2$ 0's followed by $N/2$ 1's is added to the left of every balanced matrix that is generated in the previous step. (In step 1, the column vector is added to the left of every one of $N!$ balanced matrices.) Since prepending the column vector makes some resulting matrices unbalanced, those unbalanced matrices are removed, and each of the remaining balanced matrices is reverse-routed through an ISE stage of $N/2$ switches in $2^{N/2}$ ways to generate new matrices. This reverse-routing is done in the same way as described in algorithms COLUMN and GENERATE-π. Algorithm COLUMN helps prove that every balanced matrix of order $N \times n$ is contained in the last n columns of at least one matrix generated by the reverse-routing. Algorithm GENERATE-π shows that the first $n-1$ columns of every generated matrix fit $F_{1:(n-1)}$.

Now we introduce algorithm COLUMN. Given a balanced matrix $B_{N\times(n-1)}$, $n \geq 1$ and $N = 2^n$, and $F_{N\times 1}$ (i.e., the first column of $F_{N\times n}$), algorithm COLUMN shown in Figure 4.1 determines a column vector V such that V fits $F_{N\times 1}$ and the matrix $[V\ B_{N\times(n-1)}]$ is balanced. Because $F_{N\times 1}$ consists of 2^{n-1} blocks of two rows each, the $2i$th and $(2i+1)$th entries of V constitute the set $\{0,1\}$ and hence do not cause any conflict when they become the control bits of a switch for $0 \leq i \leq 2^{n-1}-1$. Therefore, it is shown in Lemma 4.1 that, for $1 \leq k \leq n-1$, a stage of $N/2$ switches can partition any given balanced matrix $B_{N\times k}$ into two balanced matrices of order $2^{n-1} \times k$, one of which consists of only those rows of $B_{N\times k}$ sent to the upper outputs of switches, and the other matrix contains only the rows sent to the lower outputs. Corollary 4.2 shows that the reverse order of this partitioning process from the outputs side of the stage to the inputs side allows any $B_{N\times k}$ to be generated. After the proofs of Lemma 4.1 and Corollary 4.2, an example is introduced to help clarify these proofs and algorithm COLUMN.

The correctness proof of algorithm COLUMN is as follows. By the definition of perfect matching, each vertex of a perfect matching graph is incident with one edge only. Therefore, each vertex of the union of two perfect matching graphs is incident with two edges that belong to different perfect matching graphs. (The union of two perfect matching graphs may be regarded as a multigraph.) This means that each perfect matching graph has an equal number of edges in every cycle of the union graph. Therefore, each cycle contains an even number of edges, and hence 2-labeling every cycle is always possible. Because the two integers assigned to the vertices of an edge in 2-labeling constitute the set $\{0,1\}$, the vector V, whose ith entry equals the 2-label of the vertex i, agrees with $B_{1:(n-1)}$ and fits $F_{N\times 1}$.

LEMMA 4.1. *Consider a frame $F^{n-2}_{N\times k;\gamma}$ which is a pile of two universal frames, namely, upper and lower universal frames denoted UF and LF, respectively, each*

Algorithm COLUMN

Input: A balanced matrix $B_{N\times(n-1)}$ and $F_{N\times 1} = f_1$.

Output: A vector V that fits $F_{N\times 1}$ and a balanced matrix $[V\ B_{N\times(n-1)}]$.

begin

Step 1. Determine the perfect matching graph of $B_{1:(n-1)}$ by joining an edge between any two vertices that correspond to two identical rows of $B_{1:(n-1)}$.

Step 2. Determine the perfect matching graph of $F_{N\times 1}$ by joining an edge between any two vertices with labels $2m$ and $2m+1$ for $m = 0, 1, \ldots, 2^{n-1}-1$.

Step 3. 2-label the union of the perfect matching graphs of $B_{1:(n-1)}$ and $F_{N\times 1}$.

Step 4. Let the integer assigned to the vertex i in 2-labeling be the ith entry of the vector V (i.e., $V(i)$) for $0 \le i \le N-1$.

end

FIG. 4.1. *Algorithm COLUMN.*

having $N/2$ rows and k columns, where $N = 2^n$ and $1 \le k \le n-1$. Let ISE_j denote an inverse shuffle-exchange (ISE) stage with N inputs/outputs and $N/2$ switches of size 2×2 each, where $j \ge 1$. Then, for any given balanced matrix $B_{N\times k}$ fitting the universal frame *$F^{n-1}_{N\times k}$, there exists a switch setting of ISE_j such that, when $B_{N\times k}$ is forward-routed through ISE_j, a matrix fitting $F^{n-2}_{N\times k;\gamma}$ is obtained at the outputs side of ISE_j.*

Proof. We shall first prove the lemma for $k = n-1$. Recall that any balanced matrix $B_{N\times(n-1)}$ fits the universal frame $F^{n-1}_{N\times(n-1);\gamma}$. For a given balanced matrix $B_{N\times(n-1)}$, algorithm COLUMN finds a vector V of N entries such that V fits $F_{N\times 1}$ and the matrix $[V\ B_{N\times(n-1)}]$ is balanced. Let the ith entry, $0 \le i \le N-1$, of V be the control bit of the ith input of ISE_j. Thus, because V fits $F_{N\times 1}$, two control bits of each switch constitute the set $\{0,1\}$. Assume that B^u and B^l denote the matrices consisting of those rows of $B_{N\times(n-1)}$ sent to the upper and lower outputs, respectively, of switches. So, if $V(i) = 0$ (respectively, $V(i) = 1$), then row i of $B_{N\times(n-1)}$ will be forward-routed to the upper (respectively, lower) output of a switch. Because $[V\ B_{N\times(n-1)}]$ is also balanced, B^u (respectively, B^l) form a balanced matrix of order $2^{n-1}\times(n-1)$ that fits UF (respectively, LF). Therefore, the matrix obtained at the outputs of ISE_j fits $F^{n-2}_{N\times(n-1);\gamma}$.

Now, we shall prove the lemma for $1 \le k \le n-2$. It is shown above that the lemma holds for $k = n-1$. In the above proof, any $B_{N\times(n-1)}$ is forward-routed through ISE_j. Now, for any matrix $B_{N\times(n-1)}$ that was forward-routed through ISE_j, remove its rightmost $n-k-1$ columns, so that $B_{N\times(n-1)}$ is converted to a matrix $B_{N\times k}$. Similarly, remove the rightmost $n-k-1$ columns of B^u, B^l, and $F^{n-2}_{N\times(n-1);\gamma}$. Notice that the switch settings of ISE_j are not changed at all while these columns are being removed. Therefore, when any balanced matrix $B_{N\times k}$ that fits a *universal frame* $F^{n-1}_{N\times k}$ is forward-routed through ISE_j, the matrix that was obtained at the outputs side of ISE_j fits $F^{n-2}_{N\times k;\gamma}$. □

COROLLARY 4.2. *Consider the stage ISE_j and $F^{n-2}_{N\times k;\gamma}$, described in Lemma* 4.1, *where $N = 2^n$ and $1 \le k \le n-1$. Let T denote the set of all those matrices that fit $F^{n-2}_{N\times k;\gamma}$. When each and every member of T is reverse-routed through ISE_j in all possible $2^{N/2}$ ways, all balanced matrices of order $N \times k$ that fit a universal frame $F^{n-1}_{N\times k;\gamma}$ are obtained at the inputs side of ISE_j. (In reverse-routing of a member, the* contents *of rows are swapped/unswapped in every switch independently of the other switches; this is also true for forward-routing.)*

Proof. The proof is by construction. Let $B_{N\times k}$ be an arbitrary matrix that fits a universal frame $F^{n-1}_{N\times k;\gamma}$. $B_{N\times k}$ can be constructed by reverse-routing an element of T through a setting of switches of ISE_j. This construction is described below using Lemma 4.1.

Lemma 4.1 has shown that there exists a switch setting of ISE_j such that, when $B_{N\times k}$ is forward-routed through ISE_j, a matrix, say, $C_{N\times k}$, fitting $F^{n-2}_{N\times k;\gamma}$ is obtained at the outputs side of ISE_j. This implies that, when $C_{N\times k}$ is reverse-routed through the same switch setting of ISE_j, $B_{N\times k}$ is obtained at the inputs side of ISE_j. Because $C_{N\times k}$ fits $F^{n-2}_{N\times k;\gamma}$, $C_{N\times k}$ must be a member of T because T denotes the set of all those matrices that fit $F^{n-2}_{N\times k;\gamma}$. Therefore, when $C_{N\times k}$ is reverse-routed through ISE_j in all possible $2^{N/2}$ ways, one of the matrices obtained at the inputs side of ISE_j is identical to $B_{N\times k}$. □

Example 4.1. Let $N = 16$. Consider $B_{1:3}$ shown in Figure 4.2(c). Recall that any balanced matrix of order 16×3 fits the universal frame $F^3_{1:3}$ shown in Figure 4.2(a), where row i of $B_{1:3}$ is placed into row i of the universal frame. Because the *control* (or routing) bits of each switch of ISE_j must constitute the set $\{0, 1\}$, the input labels of each switch are the labels of the adjacent vertices of a distinct edge in the perfect matching graph of the switches of ISE_j, denoted PG_{ISE} and shown in Figure 4.2(e). The perfect matching graph of $B_{1:3}$ is shown in Figure 4.2(d). The union of PG_B and PG_{ISE}, denoted $PG_{B\bigcup ISE}$, and its 2-labeling are shown in Figure 4.2(f). The ith entry of vector V obtained from the 2-labeling is the control bit of the ith input of ISE_j. Vector V and the switch settings of ISE_j with respect to vector V are shown in Figures 4.2(g) and 4.2(h), respectively. When row i of the matrix $B_{1:3}$ is forward-routed through ISE_j according to the setting of the switch with input i, the resulting matrix fits the frame $F^2_{1:3;\gamma}$ shown in Figure 4.2(h). Note that the upper (respectively, lower) input and the upper (respectively, lower) output of a switch have the same label. It follows from Corollary 4.2 that, when the resulting matrix fitting $F^2_{1:3;\gamma}$ is reverse-routed through ISE_j with the same switch settings, the original matrix $B_{1:3}$ is obtained at the inputs side of ISE_j.

Recall that $R_{N\times n}$ (or $R_{1:n}$) denotes the reverse permutation matrix. So $R_{1:(n-1)}$ denotes a matrix consisting of the first $n-1$ columns of $R_{1:n}$. Lemma 4.3 shows that $R_{1:(n-1)}$ fits $F_{1:(n-1)}$. Figure 4.3 illustrates $R_{1:(n-1)}$ and $F_{1:(n-1)}$ for $N = 16$.

LEMMA 4.3. *$R_{1:(n-1)}$ fits $F_{1:(n-1)}$.*

Proof. Let $1 \le j \le n-1$. Let us partition $R_{1:j}$ into 2^{n-j} submatrices of 2^j rows and j columns each, denoted $R^h_{1:j}$ for $h = 0, 1, \ldots, 2^{n-j}-1$, such that the row labels of $R^h_{1:j}$ consist of all the numbers ranging from $h\times 2^j$ to $(h+1)2^j - 1$ inclusive. Because each $R^h_{1:j}$ is a balanced matrix of order $2^j \times j$, $R_{1:(n-1)}$ fits $F^0_{1:(n-1)}$. □

4.1. Algorithm GENERATE-π. Let π denote the set of all those balanced matrices of order $N\times(n-1)$, each of which fits $F_{1:(n-1)}$. Also, let r_k denote the kth column of the reverse permutation matrix $R_{1:(n-1)} = [r_1\, r_2 \ldots r_{n-1}]$, where $0 \le k \le n-1$. We now introduce an algorithm called GENERATE-π, shown in Figure 4.4, to gener-

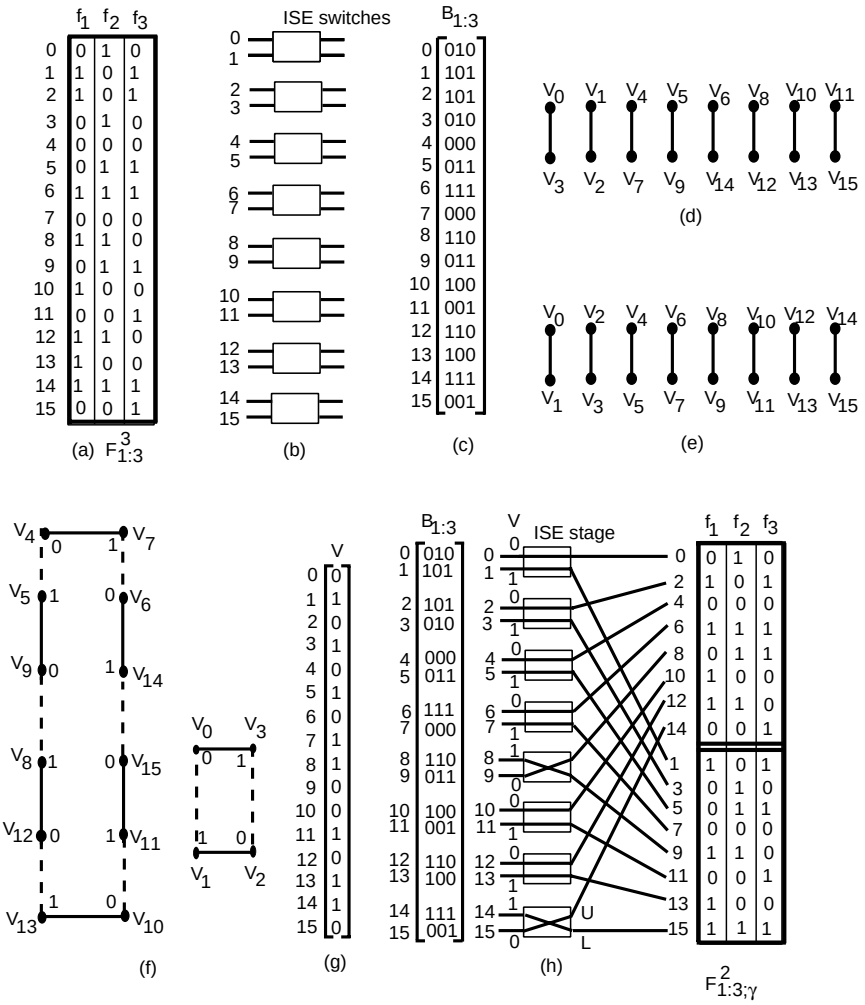

FIG. 4.2. (a) *A universal frame* $F^3_{1:3}$ *whose rows are filled in by a balanced matrix* $B_{1:3}$ *for* $N = 16$. (b) *The* $N/2$ *switches of an inverse shuffle-exchange stage* ISE_j. (c) $B_{1:3}$, *a balanced matrix.* (d) PG_B, *the perfect matching graph of* $B_{1:3}$. (e) PG_{ISE}, *the perfect matching graph of switches of* ISE_j. (f) $PG_{B \bigcup ISE}$, *where solid and dashed lines represent the edges of* PG_B *and* PG_{ISE}, *respectively; a possible* 2*-labeling of* $PG_{B \bigcup ISE}$ *is shown.* (g) *Vector* V. (h) *Switch settings of* ISE *with respect to* V. *The matrix that is obtained at the outputs side by forward-routing* $B_{1:3}$ *fits* $F^2_{1:3;\gamma}$.

ate all matrices of π in $n-1$ steps. The kth iteration of the *for* loop of GENERATE-π is referred to as the kth step. In each step, $N/2$ pairs of rows are formed. All those matrices fitting $F_{1:(n-1)}$ are generated in $n-1$ steps by swapping/unswapping the contents of each pair's rows independently of the other pairs' rows. Initially, r_{n-1} is placed into f_{n-1} of $F_{1:(n-1)}$. At the end of step k, column r_{n-k-1} of $R_{1:(n-1)}$ is inserted into column f_{n-k-1} of $F_{1:(n-1)}$, which amounts to saying that r_{n-k-1} is placed to the left of every matrix that has been generated so far. In step 1, all the generated matrices have single columns; that is, they are indeed just column vectors. In step 2, all matrices have two columns, and in step $n-1$ every matrix has $n-1$ columns.

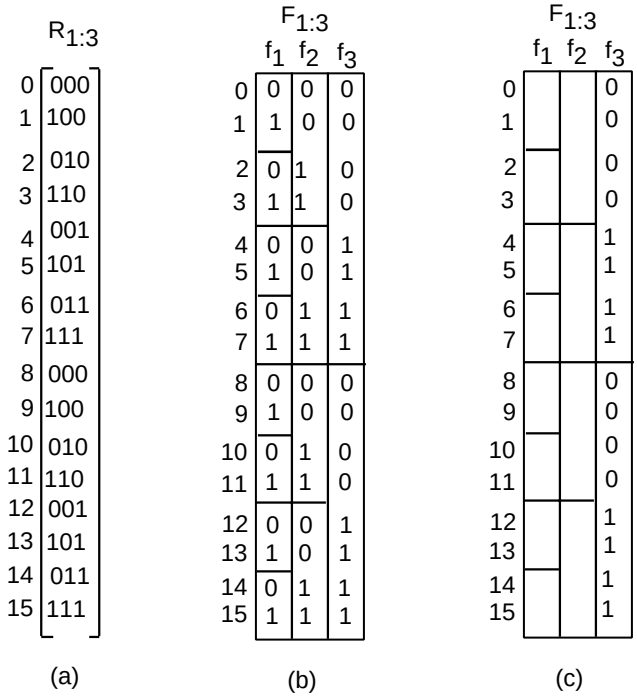

FIG. 4.3. $N = 16$. (a) $R_{1:3}$, *the first three columns of the reverse permutation matrix.* (b) $F_{1:3}$ *containing* $R_{1:3}$. (c) $F_{1:3}$ *containing the third column of* $R_{1:3}$.

As an alternative way of generating all matrices fitting $F_{1:(n-1)}$, we could have initially placed all columns of $R_{1:(n-1)}$ into $F_{1:(n-1)}$ and then generated all $2^{N(n-1)/2}$ matrices fitting $F_{1:(n-1)}$. However, the above method is adopted in algorithm GENERATE-π since algorithm GENERATE-ALL (to be introduced later in this section) uses the same method in generating the first $n-1$ columns of matrices. An example is provided first to illustrate the algorithm for $N = 16$, and then Lemma 4.4 is presented to show its correctness.

Example 4.2. This example describes how algorithm GENERATE-π works for $N = 16$. Initially, both π_0 and $F_{1:3}$ contain only r_3 of $R_{1:3}$. Figure 4.3(c) illustrates that column f_3 of $F_{1:3}$ contains r_3. The sets $\pi_1, \pi_2, \ldots, \pi_{n-1}$ are initially empty sets. In the *first step*, each of the following eight sets contains the row labels of a pair of r_3: $\{0,4\}$, $\{1,5\}$, $\{2,6\}$, $\{3,7\}$, $\{8,12\}$, $\{9,13\}$, $\{10,14\}$, and $\{11,15\}$. By swapping and unswapping the rows' *contents* of each pair independently of the contents of the other pairs of rows, r_3 generates 2^8 matrices of single columns. These generated matrices are inserted into π_1. In line 12 of GENERATE-π, column r_2 is placed to the left of each and every matrix of π_1.

In the *second step*, each of the following eight sets contains the row labels of a pair of any matrix of π_1: $\{0,2\}$, $\{1,3\}$, $\{4,6\}$, $\{5,7\}$, $\{8,10\}$, $\{9,11\}$, $\{12,14\}$, and $\{13,15\}$. By swapping and unswapping the rows' contents of each pair independently

Algorithm GENERATE-π

Input: $R_{1:(n-1)}$ and $F_{1:(n-1)}$.

Output: All balanced matrices fitting $F_{1:(n-1)}$.

begin

1. Let π_0 denote a set containing only column r_{n-1} of $R_{1:(n-1)}$.
2. Insert column r_{n-1} of $R_{1:(n-1)}$ into column f_{n-1} of $F_{1:(n-1)}$.
3. **for** $k \leftarrow 1$ **to** $n-1$ **do**
4. Let π_k be an empty set.
5. **while** π_{k-1} is not empty **do**
6. Remove a member of π_{k-1} and denote it by $C^{k-1}_{(n-k):(n-1)}$ having N rows and k columns.
7. Determine those 2^{n-1} pairs of rows in $C^{k-1}_{(n-k):(n-1)}$ such that the row labels $i = (i_1 i_2 \dots i_n)$ and $j = (j_1 j_2 \dots j_n)$ of each pair are identical in their binary representation except that bits i_{k+1} and j_{k+1} are different.
8. Generate all those $2^{N/2}$ balanced matrices by swapping/unswapping the *contents* of each pair's rows of $C^{k-1}_{(n-k):(n-1)}$ independently of the other pairs of rows. (Note that the row labels are never swapped). Denote each generated matrix by $C^{k}_{(n-k):(n-1)}$.
9. Insert all the generated matrices into π_k.
10. **endwhile**
11. **if** $k < n-1$ **then**
12. Append (or place) column r_{n-k-1} of $R_{1:(n-1)}$ to the left of each member of π_k, so that r_{n-k-1} now becomes its first column.
13. Insert column r_{n-k-1} of $R_{1:(n-1)}$ into column f_{n-k-1} of $F_{1:(n-1)}$.
14. **endif**
15. **endfor**
16. Let π be identical to π_{n-1}.

Comment: π_{n-1} consists of all matrices fitting $F_{1:(n-1)}$.

end

FIG. 4.4. *Algorithm GENERATE-π.*

of the contents of the other pairs of rows, any matrix of π_1 generates new 2^8 matrices. In line 12 of GENERATE-π, column r_1 is placed to the left of each and every matrix of π_2. In the *third step*, each of the following eight sets contains the row labels of a pair of any matrix of π_2: $\{0,1\}$, $\{2,3\}$, $\{4,5\}$, $\{6,7\}$, $\{8,9\}$, $\{10,11\}$, $\{12,13\}$, and $\{14,15\}$. Each matrix of π_2 generates new 2^8 matrices fitting $F_{1:3}$. All these new generated matrices become the members of π_3.

LEMMA 4.4. *A matrix of order $N \times (n-1)$ fits $F_{1:(n-1)}$ if and only if the matrix is in the set π_{n-1} generated in algorithm GENERATE-π.*

Proof. Let $x_{1:(n-1)} = (x_1 x_2 \dots x_{n-1})$ and $y_{1:(n-1)} = (y_1 y_2 \dots y_{n-1})$ denote the

contents of rows $i = (i_1 i_2 \dots i_n)$ and $j = (j_1 j_2 \dots j_n)$, respectively, of $R_{1:(n-1)}$, where i and j are row labels. Because the row labels of $F_{1:(n-1)}$ and any matrix of π_k, $1 \le k \le n-1$, are in ascending order from 0 to $N-1$, the binary representation of the row labels form the identity permutation matrix $I_{1:n}$. By Definition 2.1, $I_{1:n}$ is the matrix whose $(k+1)$th column is the $(n-k)$th column of $R_{1:(n-1)}$. Therefore, if the row labels i and j are identical in their binary representation except that their $(k+1)$th bits (i.e., bits i_{k+1} and j_{k+1}) are different, then row contents $x_{1:(n-1)}$ and $y_{1:(n-1)}$ are identical except that their $(n-k)$th bits (i.e., bits x_{n-k} and y_{n-k}) are different.

Because the lemma considers the members of π_{n-1}, we can assume that all columns of $R_{1:(n-1)}$ are inserted into $F_{1:(n-1)}$. (Note that when columns of $R_{1:(n-1)}$ are inserted one by one into $F_{1:(n-1)}$, $R_{1:(n-1)}$ is inserted into $F_{1:(n-1)}$ eventually.) Recall from Lemma 4.3 that $R_{1:(n-1)}$ fits $F_{1:(n-1)}$. When the contents $x_{1:(n-1)}$ and $y_{1:(n-1)}$ of a pair of $C^{k-1}_{(n-k):(n-1)}$ are swapped (without swapping the row labels), bits x_{n-m} and y_{n-m} change their positions *within the same block* of column $n-m$ of $F_{1:(n-1)}$, for each and every m, $1 \le m \le k$. Therefore, when the contents $x_{1:(n-1)}$ and $y_{1:(n-1)}$ of a pair of $C^{k-1}_{(n-k):(n-1)}$ are swapped independently of the other pairs of rows, the difference between bits x_{n-m} and y_{n-m} does not prevent the generated matrix from fitting $F_{1:(n-1)}$. Thus, any $C^{n-1}_{1:(n-1)}$ of π_{n-1} fits $F_{1:(n-1)}$.

We will now show that any matrix that fits $F_{1:(n-1)}$ is contained in the set π_{n-1}. Let $A^{n-1}_{1:(n-1)}$ be an arbitrary matrix that fits $F_{1:(n-1)}$. To show that $A^{n-1}_{1:(n-1)}$ is contained in π_{n-1}, $A^{n-1}_{1:(n-1)}$ can be converted to $R_{1:(n-1)}$ by backtracking operations of algorithm GENERATE-π from step $n-1$ to step 1 as follows. In the first step, $A^{n-1}_{1:(n-1)}$ can be converted to a matrix $[r_1\ A^{n-2}_{2:(n-1)}]$ by swapping/unswapping the rows' contents as in line 8 of GENERATE-π for $k = n-1$. In the second step, $[r_1\ A^{n-2}_{2:(n-1)}]$ can be converted to a matrix $[r_1 r_2\ A^{n-3}_{3:(n-1)}]$ by swapping/unswapping the rows' contents as in line 8 of GENERATE-π for $k = n-2$. In the $(n-1)$th step, $[r_1 r_2 \dots r_{n-2}\ A^{1}_{(n-1):(n-1)}]$ can be converted to a matrix $[r_1 r_2 \dots r_{n-1}] = R_{1:(n-1)}$ by swapping/unswapping the rows' contents as in line 8 of GENERATE-π for $k = 1$. Thus $A^{n-1}_{1:(n-1)}$ can be generated by algorithm GENERATE-π by starting with r_{n-1} and then producing $A^{1}_{(n-1):(n-1)}$, $A^{2}_{(n-2):(n-1)}$, $\dots$, $A^{n-1}_{1:(n-1)}$ in order. Also, it is shown in the previous paragraph that any matrix of π_{n-1} fits $F_{1:(n-1)}$. Note that π_{n-1} consists of $2^{N(n-1)/2}$ matrices because each matrix of π_{k-1} in step k of GENERATE-π generates new $2^{N/2}$ matrices that become the members of π_k. Because it is shown in Lemma 3.4 that the maximum number of matrices fitting $F_{1:(n-1)}$ is $2^{N(n-1)/2}$, π_{n-1} consists precisely of those $2^{N(n-1)/2}$ matrices that fit $F_{1:(n-1)}$. □

Swapping and unswapping the contents of a pair's rows of a matrix are equivalent to routing the contents in two different ways through a switch of size (2×2) that can be set cross or straight independently of other switches, where swapping and unswapping correspond to setting the switch to cross and straight, respectively. Algorithm GENERATE-π can be easily implemented by an $(n-1)$-stage ISE network (denoted $ISE_{1:(n-1)}$) in which the label of output i is equal to the inverse shuffle-permutation $\gamma_{n-1}(i)$, and the inputs are labeled by γ_0 as usual in ascending order from 0 to $N-1$. An ISE with such input and output labels is shown in Figure 4.5 for $N = 16$. The $n-1$ stages of the ISE network are denoted by ISE_1, $ISE_2, \dots, ISE_{n-1}$ from the leftmost stage to the rightmost stage, respectively. Note that the label of input i of ISE_k is equal to $\gamma_{k-1}(i)$, which is defined in the beginning of section 3. Algorithm

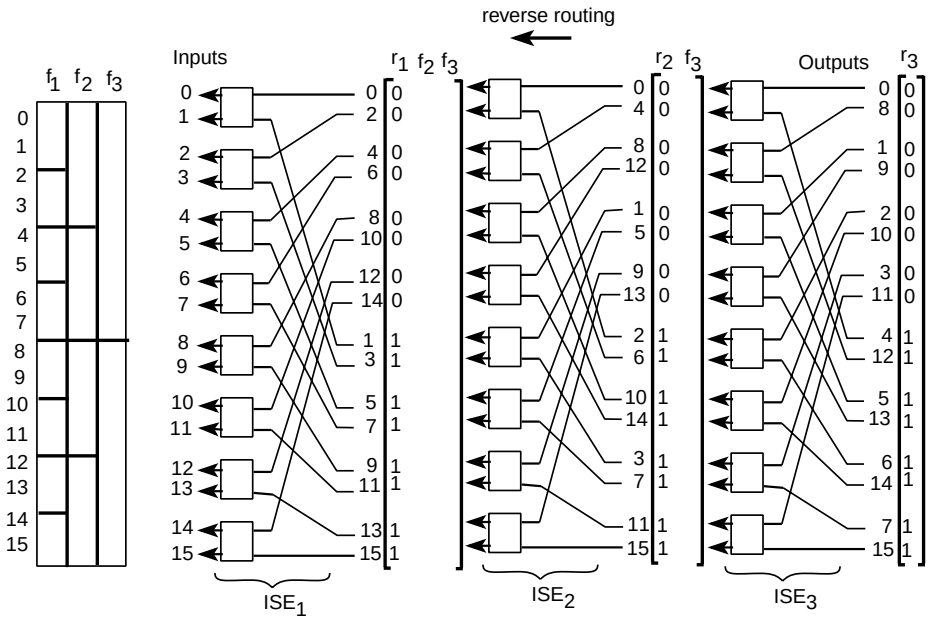

FIG. 4.5. *The inverse-shuffle exchange network* $ISE_{1:(n-1)}$ *for* $N = 16$. *The stages are labeled from left to right. As explained in section* 2, *input* i *of* ISE_j *is labeled by* $\gamma_{j-1}(i)$ *for all* i, $0 \le i \le N-1$. *Algorithm GENERATE-*π *is implemented as follows:* (1) *reverse-route column* r_3 *through* ISE_3 *in all switch settings;* (2) *insert* r_2 *to the left of any column vector that is obtained at the inputs of* ISE_3, *and reverse-route each of the resulting two-column matrices through* ISE_2 *in all switch settings;* (3) *insert* r_1 *to the left of any two-column matrix that was obtained at the inputs of* ISE_2, *and reverse-route each of the resulting three-column matrices through* ISE_1 *in all switch settings. Finally, all matrices that fit* $F^0_{1:3}$ *are obtained at the inputs side of* ISE_1.

GENERATE-π is implemented by $ISE_{1:(n-1)}$ as follows. In the first step, the entries of column r_{n-1} are *reverse-routed* through the stage ISE_{n-1} from its outputs to inputs in all possible $2^{N/2}$ settings of switches. In the second step, column r_{n-2} is first placed to the left of each generated column vector, and then the resulting matrix is reverse-routed through ISE_{n-2} in all possible $2^{N/2}$ different ways. In general, in the kth step, column r_{n-k} is first placed to the left of each generated matrix that is available at the outputs side of ISE_{n-k}, and then the resulting matrix is reverse-routed through ISE_{n-k} in all possible ways. Notice that those two entries of r_{n-k} that are reverse-routed through the same switch of ISE_{n-k} constitute the set $\{0, 1\}$, thereby forming a pair of rows mentioned in GENERATE-π. The pairs of row labels that are formed in step k of GENERATE-π are the same as the pairs of row labels formed by the switches of ISE_{n-k}. Thus the set of all those matrices that are generated by reverse-routing r_{n-1}, r_{n-2}, ..., r_1 through $ISE_{1:(n-1)}$ in the way described above is identical to the set π_{n-1}.

4.2. Algorithm GENERATE-ALL and rearrangeability of $RB_{1:(n-1)}SE_{1:n}$. Let S denote the set of all $N!$ distinct balanced matrices of order $N \times n$. Also, let T denote the set of all those balanced matrices of order $N \times (2n-1)$, each of which fits $F^0_{1:(2n-1)}$ (or denoted $F_{1:(2n-1)}$). We now aim to show that each member of S appears as the last n columns of at least one member of T. Specifically, we show

that for any balanced matrix, say, $B_{1:n}$, of S, there exists at least one $C^{n-1}_{1:(n-1)}$ fitting $F_{1:(n-1)}$ such that the matrix $[C^{n-1}_{1:(n-1)}\ B_{1:n}]$ is balanced. We propose another algorithm, called GENERATE-ALL, to generate all matrices fitting the frame $F_{1:(2n-1)}$ in $n-1$ steps. Each step has two objectives. The first objective is to keep guaranteeing that the submatrices formed by the last n columns of all matrices generated in each step constitute the set S, starting with the set S initially. The second objective is to gradually generate all those matrices fitting $F_{1:(n-1)}$ in the same way that algorithm GENERATE-π generates them and to guarantee that $[C^{n-1}_{1:(n-1)}\ B_{1:n}]$ is balanced.

Algorithm GENERATE-ALL is presented next, where the kth iteration of the *for* loop is referred to as *step* k. To show the steps of GENERATE-ALL for $N = 16$, an example is provided just after the algorithm.

Algorithm GENERATE-ALL.

Input: A set of all $N!$ distinct balanced matrices of order $N \times n$. An $(n-1)$-stage inverse-shuffle exchange $ISE_{1:(n-1)}$ network such that the label of input i of ISE_k is equal to $\gamma_{k-1}(i)$ and the label of output i of ISE_k is $\gamma_k(i)$.

Output: All those balanced matrices of order $N \times (2n-1)$ that fit $F_{1:(2n-1)}$ such that each balanced matrix of order $N \times n$ appears in the last n columns of at least one of them. The sets α_{n-1} and β_{n-1} are generated. α_{n-1} contains all balanced matrices that fit $F_{1:(2n-1)}$. β_{n-1} contains every distinct submatrix that is formed by the last n columns of each member of α_{n-1}.

begin

1. Let α_0 denote the set of all $N!$ distinct balanced matrices of order $N \times n$ such that rows are labeled by the inverse-shuffle permutation γ_{n-1}. A member of α_0 is denoted by $A^0_{n:(2n-1)}$ whose columns are labeled by $n,\ n+1, \ldots, 2n-1$ from left to right. Let β_0 be identical to α_0.
2. Let α_k and β_k be empty sets for each and every k, $1 \le k \le n-1$.
3. **for** $k \leftarrow 1$ **to** $n-1$ **do**
4. Let $A^{k-1}_{(n-k+1):(2n-1)}$ denote a member of α_{k-1}. Insert column r_{n-k} to the left of each $A^{k-1}_{(n-k+1):(2n-1)}$ such that the ith entry of r_{n-k} is placed to the left of the ith row of $A^{k-1}_{(n-k+1):(2n-1)}$. If the resulting matrix $[r_{n-k}\ A^{k-1}_{(n-k+1):(2n-1)}]$ is balanced, then keep it in α_{k-1}; otherwise, remove it from α_{k-1}.
5. **while** α_{k-1} is not empty **do**
6. Pick up a member $[r_{n-k}\ A^{k-1}_{(n-k+1):(2n-1)}]$ of α_{k-1} and remove it from α_{k-1}.
7. Generate $2^{N/2}$ matrices by reverse-routing the *contents* of all rows of $[r_{n-k}\ A^{k-1}_{(n-k+1):(2n-1)}]$ through in all $2^{N/2}$ switch settings of stage ISE_{n-k}. Note that in reverse-routing, the matrix row with label $\gamma_{n-k}(i)$ is reverse-routed through output i of stage ISE_{n-k}.
8. Insert each generated matrix, denoted $A^k_{(n-k):(2n-1)}$, into α_k. Also, insert the submatrix $A^k_{n:(2n-1)}$ of each $A^k_{(n-k):(2n-1)}$ into β_k if the submatrix is not already a member of β_k.
9. **endwhile**
10. **endfor**

end

Before introducing formal proofs related to the identification and combinatorial properties of the matrices generated by algorithm GENERATE-ALL, an example is presented next to show how algorithm GENERATE-ALL generates matrices.

Example 4.3. Let $N = 16$ and $n = 4$. All those matrices fitting $F^0_{1:7}$ are generated in three steps. To illustrate how GENERATE-ALL works, Figures 4.6, 4.7, and 4.8,

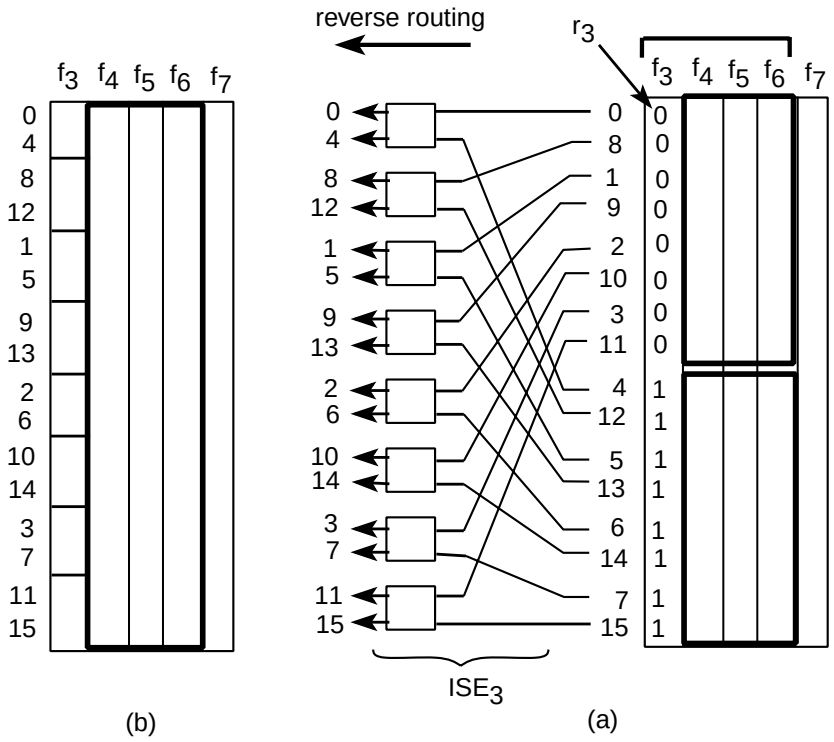

FIG. 4.6. *The implementation of the first step of GENERATE-ALL for* $N = 16$.

corresponding to steps 1, 2, and 3, respectively, will be discussed in this example. In step k, stage ISE_{n-k} is used.

Initially, α_0 contains all 16! balanced matrices of order 16×4. In step 1, column r_3 is placed to the left of every member of α_0 such that the ith entry of r_3 is placed to the left of the ith row of each member of α_0, as shown in Figure 4.6(a). If the resulting matrix is balanced, then it remains in α_0; otherwise, it is removed from α_0. In particular, every matrix that fits $F^2_{4:7}$ remains balanced when r_3 is inserted to the left; thus all these matrices remain in α_0. ($F^2_{4:7}$ consists of a pile of two universal frames each having $N/2$ rows and $n-1$ columns, followed by a single block of N rows, as shown in Figure 4.6 for $N = 16$.) Then each member of the latest α_0 is reverse-routed through ISE_3 in all $2^{16/2}$ different ways, and the matrices that are obtained at the inputs side of ISE_3 constitute the set α_1. Each member of α_1 fits the frame shown in Figure 4.6(b). All submatrices of order $N \times n$ that are formed by the last n columns of every member of α_1 are inserted into β_1. It will be shown later that β_1 contains all $N!$ balanced matrices of order $N \times n$. Note that each of the following eight sets contains the input/output labels of a switch of ISE_3: $\{0,4\}$, $\{8,12\}$, $\{1,5\}$, $\{9,13\}$, $\{2,6\}$, $\{10,14\}$, $\{3,7\}$, and $\{11,15\}$. These eight sets are also the same as the sets of eight row pairs of column r_3 that are formed in algorithm GENERATE-π.

In step 2, the frames and matrices of α_1 that are obtained at the end of step 1 are now located at the outputs side of ISE_2, as shown in Figure 4.7(a). Column r_2 is

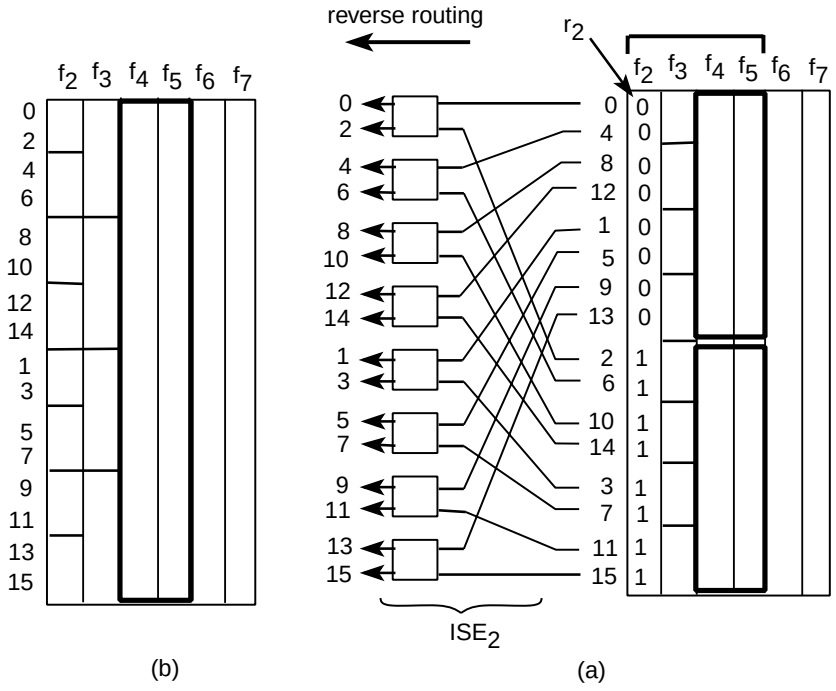

FIG. 4.7. *The implementation of the second step of GENERATE-ALL for* $N = 16$.

placed to the left of every member of α_1. If the resulting matrix is balanced, then it remains in α_1; otherwise, it is removed from α_1. Then each member of the latest α_1 is reverse-routed through ISE_2 in all $2^{16/2}$ different ways, and the matrices that are obtained at the inputs side of ISE_2 constitute the set α_2. Each member of α_2 fits the frame shown in Figure 4.7(b). All submatrices that are formed by the last n columns of every member of α_2 are inserted into β_2. It will be shown later that β_2 contains all $N!$ balanced matrices of order $N \times n$. Note that each of the following eight sets contains the input/output labels of a switch of ISE_2: $\{0, 2\}$, $\{4, 6\}$, $\{8, 10\}$, $\{12, 14\}$, $\{1, 3\}$, $\{5, 7\}$, $\{9, 11\}$, and $\{13, 15\}$. These eight sets are the same as the sets of eight pairs of column r_2 that are formed in algorithm GENERATE-π.

In step 3, column r_1 is placed to the left of each member of α_2, as shown in Figure 4.8(a). If the resulting matrix is balanced, then it remains in α_2; otherwise, it is removed from α_2. Then each member of the latest α_2 is reverse-routed through ISE_1 in all $2^{16/2}$ different ways, and the matrices that are obtained at the inputs side of ISE_1 constitute the set α_3. Each member of α_3 fits the frame $F^0_{1:7}$ shown in Figure 4.8(b). All submatrices that are formed by the last n columns of every member of α_3 are inserted into β_3. It will be shown later that β_3 contains all $N!$ balanced matrices of order $N \times n$. Note that each of the following eight sets contains the input/output labels of a switch of ISE_1: $\{0, 1\}$, $\{2, 3\}$, $\{4, 5\}$, $\{6, 7\}$, $\{8, 9\}$, $\{10, 11\}$, $\{12, 13\}$, and $\{14, 15\}$. These eight sets are the same as the sets of eight pairs of column r_1 that are formed in algorithm GENERATE-π.

Lemma 4.5 shows that $A^{n-1}_{1:(2n-1)}$ fits $F_{1:(2n-1)}$; that is, $A^{n-1}_{1:(2n-1)}$ is balanced, and

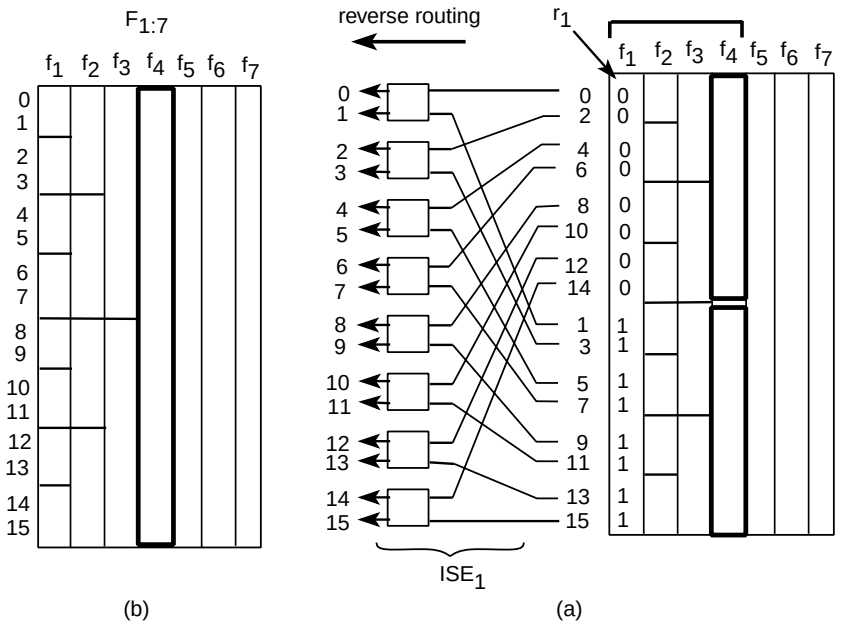

FIG. 4.8. *The implementation of the third step of GENERATE-ALL for* $N = 16$.

$A^{n-1}_{1:(n-1)}$ fits $F_{1:(n-1)}$. Theorem 4.6 proves that β_k contains any balanced matrix of order $N \times n$.

LEMMA 4.5. *Any member* $A^{n-1}_{1:(2n-1)}$ *of the set* α_{n-1} *fits* $F_{1:(2n-1)}$.

Proof. Let $M_{1:(2n-1)}$ be a matrix of order $N \times (2n-1)$ whose first $n-1$ columns (i.e., $M_{1:(n-1)}$) fit $F_{1:(n-1)}$. By the definition of fit (Definition 3.3), in order for a matrix to fit a frame, each p-column block of the frame is required to contain a balanced matrix when row i of the matrix is placed into row i of the frame. Note that each column of the subframe $F_{n:(2n-1)}$ of $F_{1:(2n-1)}$ is a single block of N entries. Therefore, when $F_{n:(2n-1)}$ is appended to the right of $F_{1:(n-1)}$ to form $F_{1:(2n-1)}$, the columns of $F_{n:(2n-1)}$ require the above matrix $M_{1:(2n-1)}$ to be balanced only. (Recall from Definition 2.6 that a matrix having more than n columns is balanced if each and every n consecutive column forms a balanced matrix.) This implies that, in order for a matrix $A^{n-1}_{1:(2n-1)}$ to fit $F_{1:(2n-1)}$, the following two conditions are necessary and sufficient: (1) $A^{n-1}_{1:(n-1)}$ fits $F_{1:(n-1)}$, and (2) $A^{n-1}_{1:(2n-1)}$ is balanced.

We shall first show that the first condition holds. Note that input labels of a switch of ISE_{n-k} are the same as the row labels of a pair of $C^{k-1}_{(n-k):(n-1)}$ generated in step k of GENERATE-π. Also, reverse-routing the contents of a pair's rows through a switch in two different ways independently of other switches is equivalent to swapping/unswapping the contents of the pair's rows independently of other pairs. In addition, the first $n-1$ columns of any $A^{n-1}_{1:(2n-1)}$ are generated in $n-1$ steps by first inserting column r_{n-k} of the reverse permutation matrix into f_{n-k} in step k and then reverse-routing the rows of the existing matrix through ISE_{n-k}. This implies that any submatrix $A^{n-1}_{1:(n-1)}$ is generated in GENERATE-ALL in the same way as

any $C^{n-1}_{1:(n-1)}$ is generated in GENERATE-π. Hence it follows from Lemma 4.4 that $A^{n-1}_{1:(n-1)}$ fits $F^0_{1:(n-1)}$. Thus the first condition holds.

When the rows of a balanced matrix are swapped/unswapped arbitrarily, the resulting matrix is still balanced. After inserting column r_{n-k} to the left of each member of α_{k-1} in the beginning of step k, those resulting matrices that happen to be unbalanced are removed from α_{k-1}. Thus only balanced matrices are reverse-routed through ISE_{n-k} in step k. Reverse-routing a matrix just swaps/unswaps the contents of rows, which does not make a balanced matrix unbalanced. Therefore, all the matrices of α_k that are obtained at the inputs side of ISE_{n-k} in step k are balanced. Hence any $A^{n-1}_{1:(2n-1)}$ is balanced, and the second condition holds as well. Therefore, $A^{n-1}_{1:(2n-1)}$ fits $F_{1:(2n-1)}$. □

In the beginning of every step of algorithm GENERATE-ALL, β_{k-1} contains every balanced matrix of order $N \times n$. However, then r_{n-k} is inserted to the left of each member of α_{k-1}, and the resulting *unbalanced* matrices are removed from α_{k-1}. Because the operation of inserting column r_{n-k} to the left of each member of α_{k-1} starts with step 1, Theorem 4.6 treats step 1 as a "special" case. The proof of step 1 is "easier" because it follows directly from Corollary 4.2. However, the other steps make use of the results of both Corollary 4.2 and algorithm GENERATE-π.

THEOREM 4.6. *The set β_k contains all $N!$ balanced matrices of order $N \times n$ for each k, $1 \le k \le n-1$.*

Proof. β_k is the set of all those balanced matrices of order $N \times n$, each of which appears in the last n columns of at least one member of α_k. Thus a member of β_k is denoted by the submatrix $A^k_{n:(2n-1)}$.

Proof of Step 1. Let $k = 1$. Initially, α_0 denotes a set containing any balanced matrix of order $N \times n$. Specifically, α_0 contains any balanced matrix fitting the universal frame $F^{n-1}_{n:(2n-1);\gamma_{n-1}}$. When r_{n-1} is inserted to the left of each member $A^0_{n:(2n-1)}$ of α_0, we examine whether any submatrix $[r_{n-1}\ A^0_{n:(2n-2)}]$ is a balanced matrix. Those matrices $A^0_{n:(2n-1)}$ for which $[r_{n-1}\ A^0_{n:(2n-2)}]$ is not balanced are removed from α_0. Now let us identify those matrices that are not removed from α_0. Note that the upper 2^{n-1} entries of r_{n-1} are 0's, and the lower 2^{n-1} entries are 1's. The 2^{n-1} 0's of r_{n-1} require that any $(n-1)$-bit row must appear only *once* in the upper 2^{n-1} rows of the submatrix $A^0_{n:(2n-2)}$ so that $[r_{n-1}\ A^0_{n:(2n-2)}]$ becomes a balanced matrix. Likewise, the 2^{n-1} 1's of r_{n-1} require that any $(n-1)$-bit row must appear only *once* in the lower 2^{n-1} rows of the submatrix $A^0_{n:(2n-2)}$ so that $[r_{n-1}\ A^0_{n:(2n-2)}]$ becomes a balanced matrix. Because this is the only constraint imposed by r_{n-1}, any balanced matrix of order $2^{n-1} \times (n-1)$ can occur in the upper 2^{n-1} rows of the submatrix $A^0_{n:(2n-2)}$ as well as in the lower 2^{n-1} rows of the submatrix $A^0_{n:(2n-2)}$. This amounts to saying that the latest α_0 contains any matrix fitting $F^{n-2}_{n:(2n-2);\gamma_{n-1}}$ which consists of a pile of two universal frames, denoted $UF_{n:(2n-2)}$ and $LF_{n:(2n-2)}$, each having 2^{n-1} rows and $n-1$ columns. When each matrix of the latest α_0 is reverse-routed through ISE_{n-1} in all $2^{N/2}$ different ways, all matrices that are obtained at the inputs side of ISE_{n-1} constitute the set α_1. In the reverse-routing of all matrices, note that a distinct row label of $UF_{n:(2n-2)}$ and a distinct row label of $LF_{n:(2n-2)}$ are paired and connected to the outputs of the same switch. Therefore, it follows from Corollary 4.2 that $F^{n-2}_{n:(2n-2);\gamma_{n-1}}$ is converted to the universal frame $F^{n-1}_{n:(2n-2);\gamma_{n-2}}$, and, therefore, any submatrix fitting $F^{n-1}_{n:(2n-1);\gamma_{n-2}}$ is obtained at the inputs side of ISE_{n-1}. Therefore, β_1 contains every balanced matrix

of order $N \times n$. Thus the theorem holds for $k = 1$.

Proof of Steps 2 *to* $n-1$. Let $2 \le k \le n-1$. It is shown above that the theorem holds for β_1. Because steps 2 to $n-1$ are implemented successively, we assume that the theorem holds for β_{k-1} and show that it holds for β_k as well. When r_{n-k} is inserted to the left of each member $A^{k-1}_{(n-k+1):(2n-1)}$ of α_{k-1} in the beginning of step k (line 4 of algorithm GENERATE-ALL), the submatrix $[r_{n-k}\ A^{k-1}_{(n-k+1):(n-1)}]$ automatically becomes balanced because $A^{k-1}_{(n-k+1):(n-1)}$ has been constructed by reverse-routing columns $r_{n-1},\ r_{n-2}, \ldots, r_{n-k+1}$ through $ISE_{n-1},\ ISE_{n-2},\ \ldots,\ ISE_{n-k+1}$ in the way explained earlier for the implementation of algorithm GENERATE-π. ($A^{k-1}_{(n-k+1):(n-1)}$ fits $F^0_{1:(k-1);\gamma_{n-k}}$, and eventually $A^{n-1}_{1:(n-1)}$ fits $F^0_{1:(n-1)}$ as shown in the proof of Lemma 4.5.) Thus, when r_{n-k} is inserted to the left of each $A^{k-1}_{(n-k+1):(2n-1)}$, $[r_{n-k}\ A^{k-1}_{(n-k+1):(n-1)}]$ is always balanced, and, therefore, the set of submatrices $A^{k-1}_{(n-k+1):(n-1)}$ remains the same when column r_{n-k} is inserted. Thus r_{n-k} can lead only the set of submatrices $A^{k-1}_{n:(2n-k-1)}$ to be changed.

In order for the matrix $[r_{n-k}\ A^{k-1}_{(n-k+1):(2n-k-1)}]$ to be balanced, the following must be satisfied: (1) any $(n-1)$-bit row must appear *once* in the upper 2^{n-1} rows of any submatrix $A^{k-1}_{(n-k+1):(2n-k-1)}$ because the upper 2^{n-1} entries of r_{n-k} are all 0's, and (2) any $(n-1)$-bit row must appear *once* in the lower 2^{n-1} rows of any submatrix $A^{k-1}_{(n-k+1):(2n-k-1)}$ because the lower 2^{n-1} entries of r_{n-k} are all 1's. Thus r_{n-k} requires both the upper 2^{n-1} rows and the lower 2^{n-1} rows of any submatrix $A^{k-1}_{n:(2n-k-1)}$ to have a balanced matrix of order $2^{n-1} \times (n-k)$. However, (1) prior to insertion of r_{n-k}, the set of submatrices $A^{k-1}_{n:(2n-k-1)}$ contained every balanced matrix of order $N \times (n-k)$ because the set β_{k-1} contains any balanced matrix of order $N \times n$, and (2) it is shown above that r_{n-k} affects only the set of submatrices $A^{k-1}_{n:(2n-k-1)}$. Therefore, after inserting column r_{n-k}, any balanced matrix of order $2^{n-1} \times (n-k)$ can occur in the upper 2^{n-1} rows of the submatrix $A^{k-1}_{n:(2n-k-1)}$ as well as in the lower 2^{n-1} rows of the submatrix $A^{k-1}_{n:(2n-k-1)}$. This amounts to saying that the set of all submatrices $A^{k-1}_{n:(2n-k-1)}$ contains any matrix fitting a frame $F^{n-2}_{n:(2n-k-1);\gamma_{n-k}}$, which consists of a pile of two universal frames, denoted $UF_{n:(2n-k-1)}$ and $LF_{n:(2n-k-1)}$, each having $N/2$ rows and $n-k$ columns. When each matrix of the latest α_{k-1} is reverse-routed through ISE_{n-k} in all $2^{N/2}$ different ways, all matrices that are obtained at the inputs side of ISE_{n-1} constitute the set α_k. In the reverse-routing of all matrices, note that a distinct row label of $UF_{n:(2n-k-1)}$ and a distinct row label of $LF_{n:(2n-k-1)}$ are paired and connected to the outputs of the same switch. Therefore, it follows from Corollary 4.2 that $F^{n-2}_{n:(2n-k-1);\gamma_{n-k}}$ is converted to the universal frame $F^{n-1}_{n:(2n-k-1);\gamma_{n-k-1}}$ and, therefore, any submatrix fitting the universal frame $F^{n-1}_{n:(2n-1);\gamma_{n-2}}$ is obtained at the inputs side of ISE_{n-k}. Therefore, β_k contains every balanced matrix of order $N \times n$. Thus the theorem holds for any k. □

The purpose of obtaining all the results so far in this section is to help prove that $RB_{1:(n-1)}SE_{1:n}$ is a rearrangeable network.

THEOREM 4.7. *$RB_{1:(n-1)}SE_{1:n}$ is a rearrangeable network.*

Proof. Lemma 4.5 has shown that any $A^{n-1}_{1:(2n-1)}$ of α_{n-1} fits $F_{1:(2n-1)}$. Therefore, it follows from Theorem 3.7 that any $A^{n-1}_{1:(2n-1)}$ passes the network $RB_{1:(n-1)}SE_{1:n}$, and the network $RB_{1:(n-1)}SE_{1:n}$ realizes the permutation represented by the subma-

trix $A^{n-1}_{n:(2n-1)}$. Because $A^{n-1}_{n:(2n-1)}$ is a member of β_{n-1} and Theorem 4.6 has shown that β_{n-1} contains every balanced matrix of order $N \times n$, the network realizes any permutation. Thus $RB_{1:(n-1)}SE_{1:n}$ is rearrangeable. □

5. Rearrangeability of SE networks. In this section, the rearrangeability of $SE_{1:(2n-1)}$ is proven in Theorem 5.2. As a corollary to this result, it is shown in Corollary 5.3 that two passes through an Omega network are sufficient to realize any permutation. Before proceeding to the proofs of these theorems, a preliminary result concerning the functional equivalence of $RB_{1:n}$ and $SE_{1:n}$ is introduced.

Two INs are *functionally equivalent* if they realize the same set of permutations, whereas two INs are *topologically equivalent* if the graphs corresponding to their topologies are isomorphic. (Two graphs are isomorphic if there exists a bijection from the vertices of one of these graphs into the vertices of the other one such that the relationship of adjacency is preserved [5].) Given a set of topologically equivalent networks, one can rename the inputs and/or outputs of one of these networks to simulate any other network in the set. In [13, 17], it is shown that $RB_{1:n}$ and $SE_{1:n}$ are topologically equivalent. Lemma 5.1 shows that they can also be made functionally equivalent by relabeling their inputs. Its proof is provided in the appendix.

LEMMA 5.1. *$RB_{1:n}$ and $SE_{1:n}$ are functionally equivalent if the ith input of one of them is relabeled by the value of $R_{N\times n}(i)$, where $0 \le i \le N-1$.* □

THEOREM 5.2. *The $(2n-1)$-stage SE network, $SE_{1:(2n-1)}$, is rearrangeable.*

Proof. Let IP_a be an interconnection pattern such that its inputs are labeled from 0 to $N-1$ in ascending order, and the label of its ith output is equal to the value of $R_{N\times n}(i)$, where $0 \le i \le N-1$. So IP_a implements a permutation, say, r, that sends (or maps) the input i to the output whose value equals $R_{N\times n}(i)$. By Lemma 5.1, $IP_aRB_{1:n}$ is functionally equivalent to $SE_{1:n}$. Therefore, $SE_{1:(2n-1)}$ is functionally equivalent to $IP_aRB_{1:n}SE_{1:(n-1)}$. Also, because $RB_{1:n}SE_{1:(n-1)}$ is identical to $RB_{1:(n-1)}SE_{1:n}$, $SE_{1:(2n-1)}$ is functionally equivalent to $IP_aRB_{1:(n-1)}SE_{1:n}$. Let S and T be the set of permutations realized by $SE_{1:(2n-1)}$ and $RB_{1:(n-1)}SE_{1:n}$ networks, respectively. It follows that $S = r \times T$. Because $RB_{1:(n-1)}SE_{1:n}$ is rearrangeable by Theorem 4.7, T contains $N!$ distinct permutations. When each of the $N!$ distinct permutations is multiplied by the same permutation r, the set of $N!$ permutations is mapped onto itself. Therefore, $SE_{1:(2n-1)}$ is rearrangeable. □

COROLLARY 5.3. *For $k \ge 0$, $SE_{1:(2n+k)}$ is rearrangeable.*

Proof. Assume that all the switches of the subnetwork $SE_{2n:(2n+k)}$ are always set straight. This leads $SE_{2n:(2n+k)}$ to be functionally equivalent to an interconnection pattern, and hence it always realizes the same permutation, say, b. Thus the set of permutations realized by $SE_{1:(2n+k)}$ is obtained by multiplying each and every permutation realized by $SE_{1:(2n-1)}$ by b. By Theorem 5.2, the cardinality of the set of the permutations realized by $SE_{1:(2n-1)}$ is $N!$. Because multiplying each and every member of the set of $N!$ permutations by the same permutation b results in $N!$ distinct permutations, $SE_{1:(2n+k)}$ is rearrangeable. □

Corollary 5.3 implies that two passes through an Omega network are sufficient to realize any permutation due to the fact that the network obtained by cascading two Omega networks in serial is the same as $SE_{1:2n}$. This implies that a network consisting of two cascaded butterflies is, in general, rearrangeable.

6. Conclusions. This paper has proven that the $(2n-1)$-stage SE network with 2^n inputs and 2^n outputs is a rearrangeable network; that is, it can realize each and every one of $2^n!$ permutations in a single pass through the network. The paper has also

shown that two passes through the Omega network are sufficient to implement any permutation. In obtaining these results, permutations realized by some multistage INs are identified using the notion of balanced matrices and frames. We have shown that frames are a very useful tool in identifying and characterizing permutations realized by multistage INs.

Appendix.

Proof of Theorem 3.5. Recall that a matrix has $N = 2^n$ rows, unless otherwise stated. ($\Rightarrow$) It is shown that (1) if $D_{1:k}$ fits $F_{1:k}$, then $D_{1:k}$ passes $RB_{1:k}$, and (2) $RB_{1:k}$ sends its ith input to its jth output, where j is equal to the sum of $(\lfloor i/2^k \rfloor \times 2^k)$ and the value of $D_{1:k}(i)$. The proof is by induction on k.

Basis step. Let $k = 1$. By definition, f_1 contains 2^{n-1} blocks, each of size 2. By induction hypothesis, $D_{1:k}$ fits $F_{1:k}$, which implies that the leftmost column d_1 fits f_1. Therefore, the $2r$th and $(2r + 1)$th entries of d_1 constitute the set $\{0, 1\}$, where $0 \le r \le 2^{n-1} - 1$. Hence, when the $2r$th and $(2r + 1)$th entries of d_1 are used as the control bits to set the rth SB of $RB_{1:1}$, no conflict occurs, and $RB_{1:1}$ sends its ith input to its jth output, where j is equal to the sum of $(\lfloor i/2 \rfloor \times 2)$ and the value of the ith entry of d_1, where $0 \le i \le N - 1$.

Induction step. Let $2 \le k \le n$. Assuming that the theorem holds for $k - 1$ in the ($\Rightarrow$) direction, it is shown next that the theorem also holds for k in the ($\Rightarrow$) direction.

Note that $RB_{1:m}$ $(k - 1 \le m \le k)$ consists of a pile of 2^{n-m} copies of $RB_{2^m \times m}$. Let RB^a and RB^b denote the top two $RB_{2^{k-1} \times (k-1)}$'s of $RB_{1:(k-1)}$. Also, let $RB_{2^k \times k}$ denote the topmost $RB_{2^k \times k}$ of $RB_{1:k}$. By induction hypothesis, $D_{1:(k-1)}$ passes $RB_{1:(k-1)}$. This implies that, for $0 \le p \le 2^{k-1} - 1$, the first $(k - 1)$ entries of the row that is sent to the pth output of RB^a are the same as the first $(k - 1)$ entries of the row that is sent to the pth output of RB^b. Also, if $D_{1:k}$ fits $F_{1:k}$, the kth entries of those two rows sent to the pth outputs of RB^a and RB^b constitute the set $0, 1$. Moreover, those two rows enter the pth SB of the last SE stage of $RB_{2^k \times k}$, and their kth entries are the control bits of the SB. Hence no conflict occurs in the switches of the last stage of $RB_{2^k \times k}$, and $RB_{2^k \times k}$ sends its hth input to the output whose value is equal to the contents of $D_{1:k}(h)$, where $0 \le h \le 2^k - 1$. Because this holds for every $RB_{2^k \times k}$ of $RB_{1:k}$, the theorem also holds for k in the ($\Rightarrow$) direction.

($\Leftarrow$) It is shown that, if $D_{1:k}$ passes $RB_{1:k}$, then $D_{1:k}$ fits $F_{1:k}$. The proof is by induction on k.

Basis step. Let $k = 1$. The fact that d_1 passes RB_1 implies that no conflict occurs in the SBs of RB_1 when the ith entry of d_1 is used as the control bit for the ith input of RB_1 in setting its rth SB. Because the control bits of the rth SB of RB_1 constitute the set $\{0, 1\}$ and fit the rth block of f_1, d_1 fits f_1.

Induction step. Let $2 \le k \le n$. Assuming that the theorem holds for $k - 1$ in the ($\Leftarrow$) direction, it is shown next that the theorem also holds for k in the ($\Leftarrow$) direction.

As explained above, the rows that are sent to the pth outputs of RB^a and RB^b enter the pth SB of the last SE stage of $RB_{2^k \times k}$, and their kth entries are used as the control bits for the SB. So, if $D_{1:k}$ passes $RB_{1:k}$, then the kth entries of those two rows of $D_{1:k}$ that enter an SB of $RB_{1:k}$ must constitute the set $\{0, 1\}$ to avoid having a conflict in the SB. Therefore, $D_{1:k}$ fits $F_{1:k}$. □

Proof of Theorem 3.7. Because the last stage of $RB_{1:n}$ is an SE stage, the network $RB_{1:n}SE_{1:(m-1)}$ is the same as the network $RB_{1:(n-1)}SE_{1:m}$. Therefore, the theorem can be equivalently restated by substituting $RB_{1:n}SE_{1:(m-1)}$ for $RB_{1:(n-1)}SE_{1:m}$ as follows: a balanced matrix $D_{1:(n+m-1)}$, $m \ge 1$, fits the frame $F_{1:(n+m-1)}$ if and only

if $D_{1:(n+m-1)}$ passes the network $RB_{1:n}SE_{1:(m-1)}$, where $SE_{1:(m-1)}$ is assumed to be nil if $m = 1$. Moreover, $RB_{1:n}SE_{1:(m-1)}$ realizes the permutation represented by the last n columns of $D_{1:(n+m-1)}$, denoted by $D_{m:(n+m-1)}$. This is proven next.

($\Rightarrow$) It is shown that if $D_{1:(n+m-1)}$ fits $F_{1:(n+m-1)}$, then $D_{1:(n+m-1)}$ passes $RB_{1:n}SE_{1:(m-1)}$, and the permutation represented in binary by $D_{m:(n+m-1)}$ is realized by $RB_{1:n}SE_{1:(m-1)}$.

Because $D_{1:(n+m-1)}$ fits $F_{1:(n+m-1)}$ by hypothesis, $D_{1:n}$ fits $F_{1:n}$. Assume $RB_{1:n}$ maps the matrix $D_{1:(n+m-1)}$ located at the inputs side into the matrix $D^*_{1:(n+m-1)}$ located at the outputs side when $D_{1:(n+m-1)}(i)$, $0 \le i \le N-1$, is used as the routing tag for the ith input of $RB_{1:n}$. Theorem 3.5 has shown that any balanced matrix $D_{1:n}$ fitting the frame $F_{1:n}$ passes the network $RB_{1:n}$. So $RB_{1:n}$ maps any $D_{1:n}$ fitting the frame $F_{1:n}$ to $I_{1:n}$. This implies that, when $D_{1:(n+m-1)}(i)$ is used as the routing tag for the ith input of $RB_{1:n}SE_{1:(m-1)}$, the submatrix $D^*_{1:n}$ of $D^*_{1:(n+m-1)}$ is the same as the identity permutation matrix $I_{1:n}$. Therefore, $D^*_{1:(n+m-1)}$ is equal to the balanced matrix $[I_{1:n}\ D^*_{(n+1):(n+m-1)}]$. By Lemma 3.6, $SE_{1:(m-1)}$ realizes the permutation represented by $D^*_{m:(n+m-1)}$, and no conflict occurs in the SBs of $SE_{1:(m-1)}$ when $D^*_{(n+1):(n+m-1)}(i)$ is used as the routing tag for the ith input of $SE_{1:(m-1)}$. Therefore, $D_{1:(n+m-1)}$ passes $RB_{1:n}SE_{1:(m-1)}$. Also, if the entries of $D_{1:(n+m-1)}(i)$ are denoted in binary by $(x^i_1 x^i_2 \dots x^i_n \dots x^i_{n+m-1})$, then $RB_{1:n}SE_{1:(m-1)}$ sends $D_{1:(n+m-1)}(i)$ to the output whose value equals $(x^i_m x^i_{m+1} \dots x^i_{n+m-1})$. This means that the permutation represented by $D_{m:(n+m-1)}$ is realized by $RB_{1:n}SE_{1:(m-1)}$.

($\Leftarrow$) It is shown that, if $D_{1:(n+m-1)}$ passes $RB_{1:n}SE_{1:(m-1)}$, then $D_{1:(n+m-1)}$ fits $F_{1:(n+m-1)}$, and $RB_{1:n}SE_{1:(m-1)}$ realizes the permutation represented by $D_{m:(n+m-1)}$.

In order for a matrix of order $N \times (n+m-1)$ to fit $F_{1:(n+m-1)}$, the two necessary and sufficient conditions are (1) the matrix is balanced, and (2) the first $n-1$ columns of the matrix fit $F_{1:(n-1)}$. As for $D_{1:(n+m-1)}$, it is a given *balanced* matrix. Because $D_{1:(n+m-1)}$ passes $RB_{1:n}SE_{1:(m-1)}$ by hypothesis, the submatrix $D_{1:n}$ of $D_{1:(n+m-1)}$ passes $RB_{1:n}$. So, by Theorem 3.5, the submatrix $D_{1:n}$ fits $F_{1:n}$, which implies that $D_{1:(n-1)}$ fits $F_{1:(n-1)}$. So $D_{1:(n+m-1)}$ satisfies the above two conditions, and hence it fits $F_{1:(n+m-1)}$.

The first part ($\Rightarrow$) of the proof has shown that the permutation represented by $D_{m:(n+m-1)}$ is realized by $RB_{1:n}SE_{1:(m-1)}$ if $D_{1:(n+m-1)}$ fits $F_{1:(n+m-1)}$. Because it is shown above that $D_{1:(n+m-1)}$ fits $F_{1:(n+m-1)}$, $RB_{1:n}SE_{1:(m-1)}$ realizes the permutation represented by $D_{m:(n+m-1)}$. □

Proof of Lemma 5.1. We begin by showing first that, if $[R_{1:n}\ D_{1:n}]$ is balanced, then $D_{1:n}$ fits $F_{1:n}$. Let $1 \le j \le n$. Partition the balanced matrix $[R_{(j+1):n}\ D_{1:j}]$ into 2^{n-j} submatrices $S^h_{2^j \times n} = [R^h_{(j+1):n}\ D^h_{1:j}]$, $0 \le h \le 2^{n-j}-1$, such that each of $S^h_{2^j \times n}$, $R^h_{(j+1):n}$, and $D^h_{1:j}$ contains 2^j rows whose labels belong to the rows of the same block under column f_j of $F_{1:n}$, where the row labels of $S^h_{2^j \times n}$, $R^h_{(j+1):n}$, and $D^h_{1:j}$ consist of the numbers $h \times 2^j$ to $[(h+1) \times 2^j] - 1$ inclusive. (As an example, for $n = 3$ and $j = 1$, the row labels of submatrices $R^0_{2:3}$, $R^1_{2:3}$, $R^2_{2:3}$, and $R^3_{2:3}$, form the sets $\{0,1\}$, $\{2,3\}$, $\{4,5\}$, and $\{6,7\}$, respectively. (As an example, for $n = 3$ and $j = 2$, the row labels of submatrices $R^0_{3:3}$ and $R^1_{3:3}$ form the sets $\{0,1,2,3\}$ and $\{4,5,6,7\}$, respectively.) It follows from the definition of the reverse permutation matrix $R_{1:n}$ (Definition 2.1) that the row contents of $R^h_{(j+1):n}$ are identical. Moreover, since $[R_{1:n}\ D_{1:n}]$ is balanced by hypothesis, $[R_{(j+1):n}\ D_{1:j}]$ must also be balanced because of the definition of a balanced matrix. Therefore, $D^h_{1:j}$ must be a balanced matrix of order $2^j \times j$ (because $R^h_{(j+1):n}$ are identical as mentioned above). Since this is true for all values of j and

h, it follows from the definitions of $F_{1:n}$ and "fit" that $D_{1:n}$ fits $F_{1:n}$.

By Theorem 3.5, a matrix $D_{1:n}$ fits $F_{1:n}$ if and only if the matrix $D_{1:n}$ is realized by $RB_{1:n}$. Also, it is shown above that, if $[R_{1:n}\ D_{1:n}]$ is balanced, then $D_{1:n}$ fits $F_{1:n}$. Therefore, if $[R_{1:n}\ D_{1:n}]$ is balanced, then $D_{1:n}$ is realized by $RB_{1:n}$. On the other hand, it follows from Lemma 3.6 that if $[I_{1:n}\ D_{1:n}]$ is balanced, then $D_{1:n}$ is realized by $SE_{1:n}$.

Relabeling the ith input of $RB_{1:n}$ (respectively, $SE_{1:n}$) by the value of $R_{1:n}(i)$ is equivalent to moving the row of $R_{1:n}$ (respectively, $I_{1:n}$) with a label equal to $R_{1:n}(i)$ to the location of the ith row. Also, note that if $R_{1:n}(i) = j$, then $R_{1:n}(j) = i$ for $0 \le i, j \le N-1$. Therefore, the rearrangement of the rows of $R_{1:n}$ and $I_{1:n}$ due to relabeling results in the matrices $I_{1:n}$ and $R_{1:n}$, respectively. This implies that, after the relabeling, the matrix $[I_{1:n}\ D_{1:n}]$ (respectively, $[R_{1:n}\ D_{1:n}]$) must be balanced in order for a given matrix $D_{1:n}$ to be realized by $RB_{1:n}$ (respectively, $SE_{1:n}$). Thus relabeling the inputs of $RB_{1:n}$ and $SE_{1:n}$ in the way described above enables them to exactly simulate each other. It follows that the lemma holds. □

Acknowledgments. I am very grateful to Jose A. B. Fortes for his very valuable comments and the very generous use of his time in painstakingly checking on the correctness of the proofs in the preliminary versions of this paper. Without the support and guidance of Jose A. B. Fortes while he was my Ph.D. thesis advisor at Purdue University, I would not have been able to come up with some proofs presented in this paper. I also thank Frank K. Hwang of Chiaotung University for his constructive comments that helped improve the technical presentation of the paper. Finally, I am grateful to the anonymous referees for their very constructive comments that greatly improved the paper.

IDENTITY-BASED ENCRYPTION FROM THE WEIL PAIRING*

DAN BONEH† AND MATTHEW FRANKLIN‡

Abstract. We propose a fully functional identity-based encryption (IBE) scheme. The scheme has chosen ciphertext security in the random oracle model assuming a variant of the computational Diffie–Hellman problem. Our system is based on bilinear maps between groups. The Weil pairing on elliptic curves is an example of such a map. We give precise definitions for secure IBE schemes and give several applications for such systems.

Key words. identity-based encryption, bilinear maps, Weil pairing, Tate pairing, elliptic curve cryptography, escrow ElGamal

1. Introduction.

In 1984, Shamir [41] asked for a public key encryption scheme in which the public key can be an arbitrary string. In such a scheme, there are four algorithms: (1) Setup generates global system parameters and a master-key; (2) Extract uses the master-key to generate the private key corresponding to an arbitrary public key string $\mathsf{ID} \in \{0,1\}^*$; (3) Encrypt encrypts messages using the public key ID; and (4) Decrypt decrypts messages using the corresponding private key.

Shamir's original motivation for suggesting identity-based encryption (IBE) was to simplify certificate management in e-mail systems. When Alice sends mail to Bob at `bob@company.com`, she simply encrypts her message using the public key string "`bob@company.com`." There is no need for Alice to obtain Bob's public key certificate. When Bob receives the encrypted mail, he contacts a third party, which we call the private key generator (PKG). Bob authenticates himself to the PKG in the same way he would authenticate himself to a certificate authority (CA) and obtains his private key from the PKG. Bob can then read his e-mail. Note that, unlike in the existing secure e-mail infrastructure, Alice can send encrypted mail to Bob even if Bob has not yet set up his public key certificate. Also note that key escrow is inherent in identity-based e-mail systems: the PKG knows Bob's private key. We discuss key revocation, as well as several new applications for IBE schemes, in the next section.

Since the problem was posed in 1984, there have been several proposals for IBE schemes [11, 45, 44, 31, 25] (see also [33, p. 561]). However, none of these are fully satisfactory. Some solutions require that users not collude. Other solutions require the PKG to spend a long time for each private key generation request. Some solutions require tamper resistant hardware. It is fair to say that, until the results in [5], constructing a usable IBE system was an open problem. Interestingly, the related notions of identity-based signature and authentication schemes, also introduced by Shamir [41], do have satisfactory solutions [15, 14].

In this paper, we propose a fully functional IBE scheme. The performance of our system is comparable to the performance of ElGamal encryption in $\mathbb{F}_p^*$. The security of our system is based on a natural analogue of the computational Diffie–Hellman assumption. Based on this assumption, we show that the new system has chosen ciphertext security in the random oracle model. Using standard techniques from threshold cryptography [20, 22], the PKG in our scheme can be distributed so that the master-key is never available in a single location. Unlike common threshold systems, we show that robustness for our distributed PKG is free.

Our IBE system can be built from any bilinear map $e : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ between two groups $\mathbb{G}_1, \mathbb{G}_2$ as long as a variant of the computational Diffie–Hellman problem (CDH) in $\mathbb{G}_1$ is hard. We use the Weil pairing on elliptic curves as an example of such a map. Until recently, the Weil pairing has mostly been used for attacking elliptic curve systems [32, 17]. Joux [26] recently showed that the Weil pairing can be used for "good" by using it for a protocol for three party one round Diffie–Hellman key exchange. Sakai, Ohgishi, and Kasahara [40] used the pairing for key exchange, and Verheul [46] used it to construct an ElGamal encryption scheme where each public key has two corresponding private keys. In addition to our IBE scheme, we show how to construct an ElGamal encryption scheme with "built-in" key escrow, i.e., where one global escrow key can decrypt ciphertexts encrypted under any public key.
