
In both cases the complexity of the algorithms is linear in $1/\epsilon$ and polylogarithmic in the size of the domain.

1.2. Techniques.

Convexity in one dimension. We start with the following basic observation: A function $f : [n] \to \mathbb{R}$ is convex if and only if for every $1 \leq i \leq n-1$, $(f(i+1) - f(i)) - (f(i) - f(i-1)) \geq 0$. Given this characterization, consider the *difference* function f', which is defined as $f'(i) = f(i) - f(i-1)$. The function f' can be viewed as the discrete analogue of the first derivative of f. By the above observation we have that f is convex if an only if f' is monotone nondecreasing. Hence, a tempting approach for testing whether f is convex would be to test whether f' is monotone nondecreasing, where this can be done in time $O(\log n/\epsilon)$ [EKK+00, BRW99, DGL+99].

Unfortunately, this approach does not work. There are functions f that are very far from convex, but their difference function f' is very close to monotone.[1] Therefore, instead of considering only consecutive points $i, i+1$, we consider pairs of points $i, j \in [n]$ that are not necessarily consecutive. More precisely, we select intervals $\{i, \ldots, j\}$ of varying lengths and check that for each interval selected, certain constraints are satisfied. If f is convex, then these constraints are satisfied for every interval. On the other hand, we show that if f is ϵ-far from convex, then the probability that we observe a violation of some constraint is sufficiently large.

Monge matrices. As stated above, it is convenient to represent 2-dimensional submodular functions as 2-dimensional Monge matrices. Thus a function $f : \{0, \ldots, n_1\} \times \{0, \ldots, n_2\} \to \mathbb{R}$ can be represented as the matrix $V = \{v_{i,j}\}_{i,j=0}^{i=n_1,j=n_2}$, where $v_{i,j} = f(i,j)$. Observe that for every pair of indices $(i,j'), (i',j)$ such that $i < i'$ and $j < j'$ we have that $(i,j') \vee (i',j) = (i',j')$ and $(i,j') \wedge (i',j) = (i,j)$. It follows from Definition 2 that V is a Monge matrix (f is a 2-dimensional submodular function) if and only if

$$\forall i, j, i', j' \quad \text{s.t.} \quad i < i',\ j < j' \ : \qquad v_{i,j} + v_{i',j'} \leq v_{i,j'} + v_{i',j}$$

and V is an inverse Monge matrix (f is a 2-dimensional supermodular function) if and only if

$$\forall i, j, i', j' \quad \text{s.t.} \quad i < i',\ j < j' \ : \qquad v_{i,j} + v_{i',j'} \geq v_{i,j'} + v_{i',j}\ .$$

That is, in both cases we have a constraint for every quadruple $v_{i,j}$, $v_{i',j'}$, $v_{i,j'}$, $v_{i',j}$ such that $i < i'$ and $j < j'$.[2] Our algorithm selects such quadruples according to a particular (nonuniform) distribution and verifies that the constraint is satisfied for every quadruple selected. Clearly, the algorithm always accepts Monge matrices. The main thrust of the analysis is in showing that if the matrix V is far from being Monge, then the probability of obtaining a "bad" quadruple is sufficiently large.

A central building block in proving the above is the following combinatorial problem, which may be of independent interest. Let C be a given matrix, possibly containing negative values, and let R be a subset of positions in C. We are interested in refilling the entries of C that reside in R with *nonnegative* values such that the following constraint is satisfied: for every position (i,j) that does not belong to R, the sum of the modified values in C that are below[3] (i,j) is the same as in the original

[1] In particular, consider the function f such that for every $i \leq n/2$, $f(i) = i$, and for $i > n/2$, $f(i) = i - 1$. In other words, $f'(i) = 1$ for every i except $i = n/2$, where $f'(i) = 0$. Then f' is very close to monotone, but it is not hard to verify that f is far from convex.

[2] It is easy to verify that for all other i, j, i', j' (with the exception of the symmetric case where $i' < i$ and $j' < j$), the constraint holds trivially (with equality).

[3] We denote the lower left position of the matrix C by $(0,0)$.

matrix C. That is, the sum of the modified values in entries (k, ℓ) such that $k \leq i$ and $j \leq \ell$ remains as it was.

We provide sufficient conditions on C and R under which the above is possible and describe the corresponding procedure that refills the entries of C that reside in R. Our starting point is a simple special case in which R corresponds to a submatrix of C. In such a case it suffices that for each row and each column in R, the sum of the corresponding entries in the original matrix C is nonnegative. Under these conditions a simple greedy algorithm can modify C as required. Our procedure for general subsets R is more involved but uses the submatrix case as a subroutine.

1.3. Further research. We suggest the following open problems. First, it remains open to determine the complexity of testing discrete convexity (concavity) when the dimension d of the input domain is greater than 1 and for testing submodular (supermodular) functions when the dimension d is greater than 2. Note that though submodular functions can be viewed as a certain interpretation of convexity in dimensions $d \geq 2$, they do not necessarily satisfy Definition 1.

It seems that our algorithm for testing Monge matrices and its analysis can be extended to work for testing the special case of distribution matrices of dimension $d > 2$, where the complexity of the resulting algorithm is $O((\prod_{q=1}^{d} \log n_q)/\epsilon)$. However, as opposed to the $d = 2$ case, where Monge matrices are only slightly more general than distribution matrices, for $d > 2$ Monge matrices are more expressive. Hence it is not immediately clear how to adapt our algorithm to testing Monge matrices in higher dimensions.

It would also be interesting to find an efficient testing algorithm for the subclass of submodular set functions, which are defined over binary domains.

Finally, in many optimization problems it is enough that the underlying cost matrix is a permutation of a Monge matrix. In such cases it may be useful to test whether a given matrix is a permutation of some Monge matrix or far from any permuted Monge matrix.

Organization. The testing algorithm for convexity is described in section 2. The remainder of the paper is dedicated to testing Monge matrices. In section 3 we describe several building blocks that will be used by our testing algorithm for Monge matrices. In section 4 we describe a testing algorithm for Monge matrices whose complexity is $O(n/\epsilon)$, where we assume for simplicity that the matrix is $n \times n$. Building on this algorithm and its analysis, in section 5 we present a significantly faster algorithm whose complexity is $O\left((\log^2 n)/\epsilon\right)$. We conclude this section with a short discussion concerning distribution matrices.

2. Testing convexity in one dimension. As noted in the introduction, in the case that the domain is $X = [n] = \{0, \ldots, n\}$, we get the following characterization for convexity, whose proof is included for completeness.

CLAIM 1. *A function $f : [n] \to \mathbb{R}$ is* convex *if and only if for all $1 \leq i \leq n-1$, $f(i) - f(i-1) \leq f(i+1) - f(i)$.*

Proof. If f is convex, then in particular for $x = i - 1$, $y = i + 1$, and $\alpha = 1/2$ we have $\alpha x + (1-\alpha)y = \frac{i-1}{2} + \frac{i+1}{2} = i$. By Definition 1, $f(i) \leq \frac{1}{2}f(i-1) + \frac{1}{2}f(i+1)$, or, equivalently, $f(i) - f(i-1) \leq f(i+1) - f(i)$.

In the other direction, suppose that $f(i) - f(i-1) \leq f(i+1) - f(i)$ for every $1 \leq i \leq n-1$. Consider any $x, y \in [n]$ and $0 < \alpha < 1$ such that $z = \alpha \cdot x + (1-\alpha) \cdot y$ is an integer. Assume without loss of generality that $x < y$. Now we have that

$$f(y)-f(y-1) \geq f(y-1)-f(y-2) \geq \cdots \geq f(z+1)-f(z) \geq f(z)-f(z-1) \geq \cdots \geq f(x+1)-f(x).$$

Then, since the differences are monotone nonincreasing, the average of the first $\alpha(y-x)$ differences is greater than or equal to the average of the next $(1-\alpha)(y-x)$ differences. Since $z = y - \alpha(y-x) = x + (1-\alpha)(y-x)$, we have that

$$\frac{(f(y)-f(y-1))+(f(y-1)-f(y-2))+\cdots+(f(z+1)-f(z))}{\alpha(y-x)} \tag{1}$$

$$\geq \frac{(f(z)-f(z-1))+(f(z-1)-f(z-2))+\cdots+(f(x+1)-f(x))}{(1-\alpha)(y-x)}. \tag{2}$$

This is equivalent to $(1-\alpha)(f(y)-f(z)) \geq \alpha(f(z)-f(x))$; that is, $f(z) \leq \alpha f(x) + (1-\alpha)f(y)$ as required. □

Denote by $I_{i,j}$ the interval $\{i, i+1, \ldots, j\}$ of points. Let $mid = \lfloor (i+j)/2 \rfloor$ be the midpoint of $I_{i,j}$.

DEFINITION 3. *For every $0 \leq i < j \leq n$ such that $j - i > 7$, we say that the interval $I_{i,j}$ is* good with respect to f *if the following holds:*

$$f(i+1)-f(i) \leq \frac{f(mid-1)-f(i+1)}{(mid-1)-(i+1)} \leq f(mid)-f(mid-1) \leq f(mid+1)-f(mid)$$
$$\leq f(mid+2)-f(mid+1) \leq \frac{f(j-1)-f(mid+2)}{(j-1)-(mid+2)} \leq f(j)-f(j-1).$$

Otherwise, we say that the interval is bad with respect to f. *If $j - i \leq 7$, then $I_{i,j}$ is good with respect to f if and only if the function f is convex over $I_{i,j}$.*

In order to test if f is convex we test recursively if subintervals of $I_{0,n}$ are good.

ALGORITHM 1 (Test-Convex).

1. *Repeat $2/\epsilon$ times:* Test-Interval($I_{0,n}$).
2. *If all of the tests in step 1 accepted, then accept; otherwise, reject.*

PROCEDURE 1 (Test-Interval($I_{i,j}$)).

1. *Check that $I_{i,j}$ is good with respect to f. If not, reject.*
2. *If $j - i > 7$, then: Uniformly at random call either* Test-Interval($I_{i,mid}$) *or* Test-Interval($I_{mid+1,j}$), *where $mid = \lfloor (i+j)/2 \rfloor$.*
3. *If the test in step 2 accepted, then accept; otherwise, reject.*

THEOREM 1. *If f is convex, then Algorithm 1 always accepts, and if f is ϵ-far from convex, then the algorithm rejects with a probability of at least $2/3$.*

Proof. For the sake of brevity, unless stated otherwise, when we say that an interval is good, then we mean with respect to f. If f is convex, then all intervals $I_{i,j}$ are good, and hence Algorithm 1 accepts with probability 1. In order to prove that if f is ϵ-far from convex, then the algorithm rejects with probability of at least $2/3$, we prove the contrapositive statement. Assume that the algorithm accepts with a probability greater than $1/3$. We will show that f is ϵ-close to a convex function.

To this end we define a tree whose vertices correspond to all possible intervals $I_{i,j}$ that may be tested recursively in calls to Test-Interval($I_{i,j}$). Specifically, the root of the tree corresponds to $I_{0,n}$. The children of the internal vertex corresponding to $I_{i,j}$ are the vertices corresponding to $I_{i,mid}$ and $I_{mid+1,j}$, where $mid = \lfloor (i+j)/2 \rfloor$. The leaves of the tree correspond to the smallest intervals tested, that is, intervals $I_{i,j}$ for which $j - i \leq 7$.

We say that an internal vertex in the tree is good if the corresponding interval is good. We say that a leaf is good if its corresponding interval and all its ancestors are good. Otherwise, the vertex (leaf) is bad. We say that a path from the root to a leaf is good if all vertices along it are good. Otherwise, the path is bad. For each level ℓ in the tree, $\ell = 0, \ldots, \log n$, let $\mathcal{B}_\ell$ be the subset of vertices in the ℓth level of the

tree that are bad but whose ancestors are all good. Let $\mathcal{B} = \bigcup_\ell \mathcal{B}_\ell$, and let ϵ_ℓ be the fraction of vertices in level ℓ of the tree that belong to $\mathcal{B}_\ell$.

Subclaim 1. If Algorithm 1 accepts f with a probability greater than $1/3$, then $\sum_\ell \epsilon_\ell \leq \epsilon$.

Proof. Assume by contradiction that $\sum_\ell \epsilon_\ell > \epsilon$. Observe that by the definition of $\mathcal{B}$, all leaves which are descendents of a vertex in $\mathcal{B}$ are bad, and every bad leaf either belongs to $\mathcal{B}$ or has a single ancestor in $\mathcal{B}$. Therefore, if $\sum_\ell \epsilon_\ell > \epsilon$, then the fraction of bad leaves is greater than ϵ. But in such a case, the probability that the algorithm does not follow a bad path to a bad leaf (passing through a vertex in $\mathcal{B}$) in any one of its $2/\epsilon$ iterations is at most $(1-\epsilon)^{2/\epsilon} < e^{-2} < 1/3$. This contradicts our assumption that the algorithm accepts with a probability greater than $1/3$.

Hence we assume from now on that $\sum_\ell \epsilon_\ell \leq \epsilon$. Note also that in this case $I_{0,n} \notin \mathcal{B}$. We show how to modify f in at most $\epsilon \cdot n$ places so that the resulting function, denoted g, is convex. In particular, we shall modify the value of f on every bad interval $I_{i,j}$ whose corresponding vertex in the tree belongs to $\mathcal{B}$. The value of g is defined to be the same as the value of f on all points outside of these intervals. Since $\sum_\ell \epsilon_\ell \leq \epsilon$, the total fraction of points modified is at most ϵ as required. Observe that by the definition of the tree and $\mathcal{B}$, for every two intervals whose corresponding vertices belong to $\mathcal{B}$, the intersection of the intervals is empty. Hence we can modify each one of these intervals independently.

Let $I_{i,j}$ be a bad interval corresponding to a vertex in $\mathcal{B}$. We modify f on points in $I_{i,j}$ as follows:

- $f(i), f(i+1)$, $f(j-1)$, and $f(j)$ remain unchanged. That is, set $g(i) = f(i)$, $g(i+1) = f(i+1)$, $g(j-1) = f(j-1)$, and $g(j) = f(j)$.
- For every t, $i+1 < t < j-1$, set $g(t) = f(i+1) + \frac{f(j-1)-f(i+1)}{(j-1)-(i+1)} \cdot (t-(i+1))$.

Subclaim 2. Let $I_{i,j}$ be a bad interval corresponding to a vertex in $\mathcal{B}$. Then for every $i < t < j$, $g(t) - g(t-1) \leq g(t+1) - g(t)$.

Proof. By definition of $\mathcal{B}$, the parent of $I_{i,j}$ is good (the parent exists by our assumption that $I_{0,n} \notin \mathcal{B}$). Hence

$$f(i+1) - f(i) \leq \frac{f(j-1) - f(i+1)}{(j-1)-(i+1)} \leq f(j) - f(j-1). \tag{3}$$

By definition of $g(\cdot)$, $g(i+1) - g(i) = f(i+1) - f(i)$, $g(j) - g(j-1) = f(j) - f(j-1)$, and for every $i+1 < t \leq j-1$, $g(t) - g(t-1) = \frac{f(j-1)-f(i+1)}{(j-1)-(i+1)}$. Therefore, for every $i+1 < t < j-1$, $g(t) - g(t-1) = g(t+1) - g(t)$, and for both $t = i+1$ and $t = j-1$, we have $g(t) - g(t-1) \leq g(t+1) - g(t)$ as required.

Subclaim 3. The function g is convex.

Proof. We shall first show that all intervals $I_{i,j}$ corresponding to vertices in the tree are good with respect to g, and from this we derive the convexity of g.

We start with the first part. Consider any such interval $I_{i,j}$ whose corresponding vertex in the tree is v. Let $\mathit{Anchor} = \{i, i+1, \mathit{mid}-1, \mathit{mid}, \mathit{mid}+1, \mathit{mid}+2, j-1, j\}$ be the set of points which participate in the definition of a good interval $I_{i,j}$. We will show that the value of g on points $p \in \mathit{Anchor}$ is such that the interval $I_{i,j}$ is good with respect to g. There are two cases:

1. The interval $I_{i,j}$ is good with respect to f, and v does not have any ancestors in $\mathcal{B}$. If v also has no descendents in $\mathcal{B}$, then it clearly remains good with respect to g, since no modification is performed on any point in the interval, and so $g(t) = f(t)$ for every $i \leq t \leq j$. Otherwise, v has a descendent in $\mathcal{B}$. In this case, let $p \in \mathit{Anchor}$, let v' be a descendent of v, and let $I_{i',j'}$ denote

the interval corresponding to v'. If $i' \le p \le j'$, then by definition of the tree, either $p = i'$ or $p = i' + 1$ or $p = j' - 1$ or $p = j'$. Therefore, even if $v' \in \mathcal{B}$ and the interval $I_{i',j'}$ is modified, then by the definition of g we have that $g(p) = f(p)$ for every $p \in Anchor$. Thus $I_{i,j}$ remains good with respect to g.

2. Either $v \in \mathcal{B}$ or v has an ancestor in $\mathcal{B}$. In the former case, let $v' = v$, and in the latter case let v' be the ancestor that v has in $\mathcal{B}$. Let $I_{i',j'}$ be the corresponding interval of v'. By definition, $I_{i,j} \subseteq I_{i',j'}$. By Subclaim 2, $g(t) - g(t-1) \le g(t+1) - g(t)$ for every $i' < t < j'$, and in particular for every $i < t < j$. It follows that $I_{i,j}$ is good with respect to g.

Hence all intervals corresponding to vertices in the tree are good with respect to g. We now prove that for every $0 < t < n$ it holds that $g(t) - g(t-1) \le g(t+1) - g(t)$, and thus g is convex. Let $I_{i,j}$ be the smallest interval in the tree such that $i < t < j$. If $j - i \le 7$, then we are done, since the goodness of $I_{i,j}$ in this case means that g is convex over the whole interval. Otherwise, either $t = mid$ or $t = mid + 1$, where $mid = \lfloor (i+j)/2 \rfloor$. To verify this, note that if this were not the case, then either $i < t < mid$ or $mid + 1 < t < j$. Hence t is contained in a smaller interval in the tree, contradicting the minimality of $I_{i,j}$. But since $I_{i,j}$ is good with respect to g, $g(mid) - g(mid-1) \le g(mid+1) - g(mid)$, and $g(mid+1) - g(mid) \le g(mid+2) - g(mid+1)$. Thus we are done with the proof of Subclaim 3, and Theorem 1 follows. □

3. Building blocks for our algorithms for testing inverse monge. From this point on we focus on inverse Monge matrices. Analogous claims hold for Monge matrices. We also assume for simplicity that the dimensions of the matrices are $n_1 = n_2 = n$. In what follows we provide a characterization of inverse Monge matrices that is exploited by our algorithms. Given any real valued matrix $V = \{v_{i,j}\}_{i,j=0}^{i,j=n}$ we define an $(n+1) \times (n+1)$ matrix $C'_V = \{c_{i,j}\}_{i,j=0}^{i,j=n}$ as follows:

- $c_{0,0} = v_{0,0}$.
- For $i > 0$: $c_{i,0} = v_{i,0} - v_{i-1,0}$.
- For $j > 0$: $c_{0,j} = v_{0,j} - v_{0,j-1}$.
- And for every $i, j > 0$,

$$\begin{aligned} c_{i,j} &= (v_{i,j} - v_{i-1,j}) - (v_{i,j-1} - v_{i-1,j-1}) \\ &= (v_{i,j} - v_{i,j-1}) - (v_{i-1,j} - v_{i-1,j-1}). \end{aligned} \tag{4}$$

Let $C_V = \{c_{i,j}\}_{i,j=1}^{i,j=n}$ be the submatrix of C'_V that includes all but the first (0th) row and column of C'_V. The following two claims are well known and easy to verify. We include their proofs for completeness.

CLAIM 2. *For every* $0 \le i, j \le n$, $v_{i,j} = \sum_{k=0}^{i} \sum_{\ell=0}^{j} c_{k,\ell}$.

Proof. The claim is proved by induction on i and j.

The base case $i, j = 0$ holds by definition of $c_{0,0}$.

Consider any $i > 0$ and assume that the claim holds for every $k < i$, $j = 0$. We prove it for i and for $j = 0$. By definition of $c_{i,0}$ we have $v_{i,0} = v_{i-1,0} + c_{i,0}$. By the induction hypothesis, $v_{i-1,0} = \sum_{k=0}^{i-1} c_{k,0}$, and the induction step follows. The claim is similarly proved for every $j > 0$ and $i = 0$.

Finally, consider any $i, j > 0$ and assume that the claim holds for every $k < i$ and $\ell \le j$, and for every $k \le i$ and $\ell < j$. We prove it for i, j. By definition of $c_{i,j}$,

$v_{i,j} = v_{i-1,j} + (v_{i,j-1} - v_{i-1,j-1}) + c_{i,j}$. By the induction hypothesis,

$$v_{i-1,j} + (v_{i,j-1} - v_{i-1,j-1}) = \sum_{k=0}^{i-1}\sum_{\ell=0}^{j} c_{k,\ell} + \sum_{\ell=0}^{j-1} c_{i,\ell},$$

and the induction step follows. ∎

CLAIM 3. *A matrix V is an inverse Monge matrix if and only if C_V is a nonnegative matrix.*

Proof. If V is an inverse Monge matrix, then, in particular, for every $i, j \geq 1$ we have that $v_{i,j} + v_{i-1,j-1} \geq v_{i,j-1} + v_{i-1,j}$, which is equivalent to the condition $c_{i,j} \geq 0$.

In the other direction, consider any two points (i, j) and (i', j') such that $0 \leq i < i' \leq n$, $0 \leq j < j' \leq n$. Using Claim 2 we obtain

$$\begin{aligned} & v_{i',j'} - v_{i',j} - v_{i,j'} + v_{i,j} \\ &= \sum_{k=0}^{i'}\sum_{\ell=0}^{j'} c_{k,\ell} - \sum_{k=0}^{i'}\sum_{\ell=0}^{j} c_{k,\ell} - \sum_{k=0}^{i}\sum_{\ell=0}^{j'} c_{k,\ell} + \sum_{k=0}^{i}\sum_{\ell=0}^{j} c_{k,\ell} \\ &= \sum_{k=i+1}^{i'}\sum_{\ell=j+1}^{j'} c_{k,\ell}. \end{aligned} \tag{5}$$

But C_V is nonnegative, and therefore $v_{i',j'} - v_{i',j} - v_{i,j'} + v_{i,j} \geq 0$ as required. ∎

It follows from Claim 3 that if we find some entry of C_V that is negative, then we have evidence that V is not an inverse Monge matrix. However, it is not necessarily true that if V is far from being an inverse Monge matrix, then C_V contains many negative entries. For example, suppose that C_V is 1 in all entries except the entry $c_{n/2,n/2}$ which is $-n^2$. Then it can be verified that V is very far from being an inverse Monge matrix (this can be proved by showing that there are $\Theta(n^2)$ disjoint quadruples $v_{i,j}, v_{i',j'}, v_{i,j'}, v_{i',j}$ in V such that from any such quadruple at least one value should be changed in order to transform V into an inverse Monge matrix). However, as our analysis will show, in such a case there are many submatrices in C_V whose sum of elements is negative. Thus our testing algorithms will sample certain submatrices of C_V and check that the sum of elements in each submatrix sampled is nonnegative. We first observe that it is possible to check this efficiently.

CLAIM 4. *Given access to V it is possible to check in time $O(1)$ if the sum of elements in a given submatrix A of C_V is nonnegative. In particular, if the lower-left entry of A is (i, j) and its upper-right entry is (i', j'), then the sum of elements of A is $v_{i',j'} - v_{i',j-1} - v_{i-1,j'} + v_{i-1,j-1}$.*

Proof. Assume that $A = (c_{k,\ell})_{k=i,\ell=j}^{k=i',\ell=j'}$ is a submatrix of C_V. Recall that for any q, p, we have $v_{q,p} = \sum_{k=0}^{q}\sum_{\ell=0}^{p} c_{k,\ell}$. Thus the sum of elements of A is

$$\begin{aligned} \sum_{k=i}^{i'}\sum_{\ell=j}^{j'} c_{k,\ell} &= \sum_{k=0}^{i'}\sum_{\ell=j}^{j'} c_{k,\ell} - \sum_{k=0}^{i-1}\sum_{\ell=j}^{j'} c_{k,\ell} \\ &= \left(\sum_{k=0}^{i'}\sum_{\ell=0}^{j'} c_{k,\ell} - \sum_{k=0}^{i'}\sum_{\ell=0}^{j-1} c_{k,\ell}\right) - \left(\sum_{k=0}^{i-1}\sum_{\ell=0}^{j'} c_{k,\ell} - \sum_{k=0}^{i-1}\sum_{\ell=0}^{j-1} c_{k,\ell}\right) \\ &= (v_{i',j'} - v_{i',j-1}) - (v_{i-1,j'} - v_{i-1,j-1}) \,. \end{aligned}$$

Therefore computing the sum of elements of any submatrix A of C_V can be done by checking only four entries in the matrix V. ∎

3.1. Filling submatrices. An important building block for the analysis of our algorithms is a procedure for "filling in" a submatrix. That is, given constraints on the sum of elements in each row and column of a given submatrix, we are interested in assigning values to the entries of the submatrix so that these constraints are met.

Specifically, let $a_1, \ldots, a_s$ and $b_1, \ldots, b_t$ be nonnegative real numbers such that $\sum_{i=1}^{s} a_i \geq \sum_{j=1}^{t} b_j$. Then it is possible to construct an $s \times t$ nonnegative real matrix T such that the sum of elements in column j is exactly b_j and the sum of elements in row i is at most a_i. In the special case that $\sum_{i=1}^{s} a_i = \sum_{j=1}^{t} b_j$, the sum of elements in row i will equal a_i. In particular, this can be done by applying the following procedure, which is the same as the one applied to obtain an initial feasible solution for the linear-programming formulation of the transportation problem.

PROCEDURE 2 (fill matrix $T = (t_{i,j})_{i,j=1}^{i=s,j=t}$).
Initialize $\bar{a}_i = a_i$ *for* $i = 1, \ldots, s$ *and* $\bar{b}_j = b_j$ *for* $j = 1, \ldots, t$.
(In each of the following iterations, $\bar{a}_i$ *is an upper bound on what remains to be filled in row* i*, and* $\bar{b}_j$ *is what remains to be filled in column* j*.)*
For $j = 1,\ldots,t$*:*
  For $i = 1,\ldots,s$*:*
    Assign to entry (i, j) *the value* $x = \min\{\bar{a}_i, \bar{b}_j\}$.
    Update $\bar{a}_i = \bar{a}_i - x$, $\bar{b}_j = \bar{b}_j - x$.

CLAIM 5. *Procedure 2 fills the matrix* T *with nonnegative values* $t_{i,j}$ *such that at the end of the procedure,* $\sum_{i=1}^{s} t_{i,j} = b_j$ *for every* $j = 1, \ldots, t$*, and* $\sum_{j=1}^{t} t_{i,j} \leq a_i$ *for every* $i = 1, \ldots, s$*. If initially* $\sum_{j=1}^{t} b_j = \sum_{i=1}^{s} a_i$*, then* $\sum_{j=1}^{t} t_{i,j} = a_i$ *for every* $i = 1, \ldots, s$.

Proof. Notice that initially $\bar{a}_i = a_i \geq 0$ and $\bar{b}_j = b_j \geq 0$. Thus when we update $\bar{a}_i = \bar{a}_i - x = \bar{a}_i - \min\{\bar{a}_i, \bar{b}_j\} \geq 0$ and similarly $\bar{b}_j = \bar{b}_j - x = \bar{b}_j - \min\{\bar{a}_i, \bar{b}_j\} \geq 0$. Therefore the $\bar{a}_i$'s and $\bar{b}_j$'s are always nonnegative. Hence all values x filled in T are nonnegative, since $x = \min\{\bar{a}_i, \bar{b}_j\} \geq 0$. Furthermore, after each such update the new sum over the $\bar{a}_i$'s equals the old sum over the $\bar{a}_i$'s minus x, and a similar statement holds for the sum over the $\bar{b}_j$'s. Thus at all stages of the procedure, $\sum_{i=1}^{s} \bar{a}_i \geq \sum_{j=1}^{t} \bar{b}_j$, and if initially $\sum_{i=1}^{s} a_i = \sum_{j=1}^{t} b_j$, then $\sum_{i=1}^{s} \bar{a}_i = \sum_{j=1}^{t} \bar{b}_j$.

We now show that the sum of elements in each column is as required. Observe that the procedure fills the columns one by one. Therefore when we start to fill column j we have $\bar{b}_j = b_j$. Since $\sum_{i=1}^{s} \bar{a}_i \geq \sum_{j=1}^{t} \bar{b}_j$ at this stage, and all $\bar{a}_i$'s are nonnegative, necessarily, $\sum_{i=1}^{s} \bar{a}_i \geq \bar{b}_j = b_j$. Let $1 \leq k \leq s$ be the minimum integer such that $\sum_{i=1}^{k} \bar{a}_i \geq b_j$. Then by definition of the procedure, for every $i < k$, the entry (i, j) is filled with the value $\bar{a}_i$, and the entry $(k + 1, j)$ is filled with the value $b_j - \sum_{i=1}^{k} \bar{a}_i$. The total is hence b_j as required.

As for the rows, at all stages $\bar{a}_i$ equals a_i minus the sum of all elements filled so far in row i. Therefore since $\bar{a}_i \geq 0$, then the sum of elements in row i is at most a_i. Furthermore, if initially $\sum_{i=1}^{s} a_i = \sum_{j=1}^{t} b_j$, then the sum of elements in row i will be exactly a_i. To show this note that at the end of the procedure, $\sum_{j=1}^{t} \bar{b}_j = 0$, since each $\bar{b}_j$ equals b_j minus the sum of all elements in column j, and we have shown that the sum of elements in column j is b_j. But $\sum_{i=1}^{s} \bar{a}_i = \sum_{j=1}^{t} \bar{b}_j$, and therefore also $\sum_{i=1}^{s} \bar{a}_i = 0$ at the end. Since $\bar{a}_i \geq 0$, this means that $\bar{a}_i = 0$. Hence the sum of elements in row i must be a_i. ∎

4. A testing algorithm for inverse monge matrices. We first present a simple algorithm for testing if a matrix V is an inverse Monge matrix whose running

time is $O(n/\epsilon)$. In the next section we show a significantly faster algorithm that is partly based on the ideas presented here. We may assume without loss of generality that n is a power of 2. This is true since our algorithms probe the coefficients matrix C_V, and we may simply "pad" it by 0's to obtain rows and columns that have lengths which are powers of 2 and run the algorithm with $\epsilon \leftarrow \epsilon/4$. We shall need the following two definitions for both algorithms.

DEFINITION 4 (subrows, subcolumns, and submatrices). *A* subrow *in an $n \times n$ matrix is a consecutive sequence of entries that belong to the same row. The subrow $((i,j),(i,j+1),\ldots,(i,j+t-1))$ is denoted by $[\,]_{i,j}^{1,t}$. A* subcolumn *is defined analogously and is denoted by $[\,]_{i,j}^{s,1} = ((i,j),(i+1,j),\ldots,(i+s-1,j))$. More generally, an $s \times t$ submatrix whose bottom-left entry is (i,j) is denoted $[\,]_{i,j}^{s,t}$.*

DEFINITION 5 (legal submatrices). *A subrow in an $n \times n$ matrix is a* legal *subrow if it can result from bisecting the row of length n that contains it in a recursive manner. That is, a complete (length n) row is legal, and if $[\,]_{i,j}^{1,t}$ is legal, then so are $[\,]_{i,j}^{1,t/2}$ and $[\,]_{i,j+t/2}^{1,t/2}$. A legal subcolumn is defined analogously. A submatrix is* legal *if both its rows and its columns are legal.*

Note that the legality of a subrow $[\,]_{i,j}^{1,t}$ is not dependent on the actual row i it belongs to, but rather it depends on its starting position j and ending position $j+t-1$ within its row. An analogous statement holds for legal subcolumns. See also Figure 1 for an illustration of the concept of legal submatrices.

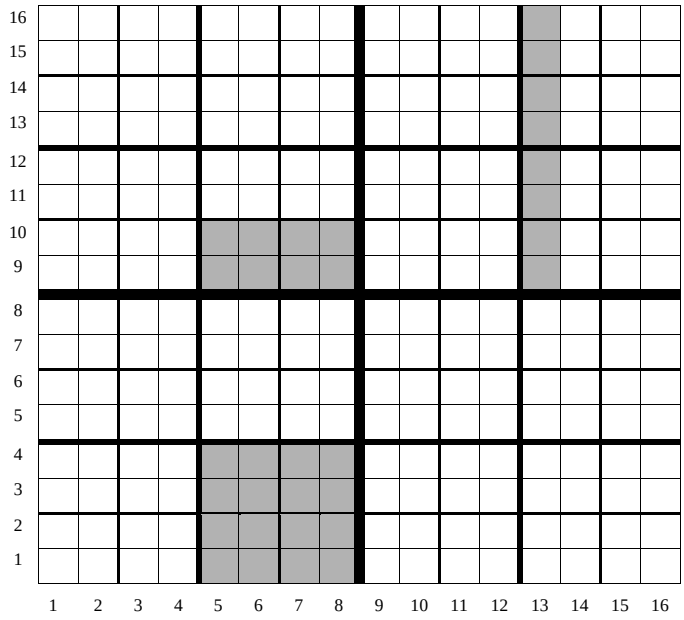

FIG. 1. *An illustration of three legal submatrices. One of the legal submatrices is a square (4×4) submatrix, and the other two are rectangular (but legal) submatrices. The 8×1 submatrix on the top-right is a legal subcolumn.*

Although a submatrix is just a collection of positions (entries) in an $n \times n$ matrix, we talk throughout the paper about sums of elements in certain submatrices A of C_V. In this we mean the sum of elements of C_V determined by the set of positions in A.

DEFINITION 6 (good and bad submatrices). *We say that a submatrix A of C_V is*

good *if the sum of elements in each row of A is nonnegative and the sum of elements in each column of A is nonnegative. Otherwise, A is* bad.

DEFINITION 7 (good and bad points). *We say that point (i, j) is* good *if all legal* square *submatrices A of C_V which contain (i, j) are good. Otherwise, the point is* bad.

ALGORITHM 2 (Test-Monge I).

1. *Choose $8/\epsilon$ points in the matrix C_V and check that they are good.*
2. *If all points are good, then accept; otherwise, reject.*

By Claim 4, it is possible to check in constant time that the sum of elements in a subrow (subcolumn) of C_V is nonnegative. Therefore, it is possible to test that an $s \times s$ square submatrix A of C_V is good in time $\Theta(s)$. Notice that every point in an $n \times n$ matrix is contained in $\log n$ legal square submatrices. Hence the time required to check whether a point is good is $O(n)+O(n/2)+\cdots+O(n/2^i)+\cdots+O(1) = O(n)$, and the complexity of the algorithm is $O(n/\epsilon)$.

THEOREM 2. *If V is an inverse Monge matrix, then Algorithm* 2 *always accepts, and if V is ϵ-far from being an inverse Monge matrix, then Algorithm* 2 *rejects with probability at least* $2/3$.

Proof. The first part of the theorem follows directly from Claim 3. In order to prove the second part of the theorem, we show that if V is ϵ-far from being inverse Monge, then C_V contains more than $(\epsilon/4)n^2$ bad points. The second part of the theorem directly follows because the probability in such a case that no bad point is selected by the algorithm is at most $(1-\epsilon/4)^{(8/\epsilon)} < e^{-2} < 1/3$.

Assume contrary to the claim that C_V contains at most $(\epsilon/4)n^2$ bad points. We shall show that by modifying at most ϵn^2 entries in V we obtain an inverse Monge matrix (in contradiction to our assumption concerning V). Let us look at the set of bad points in C_V, and for each such bad point look at the largest bad legal square submatrix in C_V that contains this bad point. By our assumption on the number of bad points, it must be the case that the area of all these maximal bad submatrices is at most $(\epsilon/4)n^2$, because all the points in a bad submatrix are bad.

For each maximal bad legal square submatrix B of C_V we will look at the legal square submatrix A that contains B. By definition of legal square submatrices, the matrix A is uniquely defined. By the maximality of B, the submatrix A must be good. Indeed, since B is maximal, if it is of size $s \times s$, where $s < n$, then the legal square submatrix of size $2s \times 2s$ that contains it must be good. But if $s = n$, then $B = C_V$, implying that all n^2 points in C_V are bad, contradicting our assumption on the number of bad points.

Next observe that every two different maximal bad legal square submatrices B and B' are disjoint. This is true since every two different legal square submatrices are either disjoint or one is contained in the other. Combining this with the fact that for each maximal bad legal square submatrix we take the good square legal submatrix that is four times its size, the area of the union of all these good submatrices is at most $4 \cdot (\epsilon/4)n^2 = \epsilon n^2$.

Turning to the collection of resulting good submatrices, note that every two of these submatrices are either disjoint, or are exactly the same, or one is contained in the other. If a good submatrix is strictly contained in another one, then we ignore it and deal only with the larger good submatrix containing it. Thus we have a set of disjoint good submatrices that contain all negative entries in the matrix. For each of these good submatrices A, we modify A so that it contains only nonnegative elements, and the sum of elements in each row and column of A remains as it was. This can

be done by applying Procedure 2 to A as described in section 3.1 (using the actual (nonnegative) sums of rows and columns of A as the input to the procedure).

Note that after modifying all these good submatrices of C_V, the new matrix C_V is nonnegative, and thus the corresponding new matrix V must be an inverse Monge matrix. It remains to show that at most ϵn^2 values were changed in V following the changes to C_V. Notice that we made sure that the sum of elements in each row and column of each modified submatrix A remains as it was. Therefore the values of all points $v_{k,\ell}$ in V that are outside A are not affected by the change to A, since by Claim 2 we have that $v_{k,\ell} = \sum_{i=0}^{k} \sum_{j=0}^{\ell} c_{i,j}$. □

5. A faster algorithm for inverse monge matrices. Algorithm 2 described above has running time linear in n, which is already sublinear in the size of the matrix, n^2. In this section we show how to significantly improve the dependence on n. We present a variant of the algorithm whose running time is $O(\epsilon^{-1} \log^2 n)$. The new algorithm will be based on a similar principle as that of Algorithm 2. That is, it will uniformly select points and verify that certain submatrices that contain them are good. However, there will be two main differences which we now describe briefly.

Algorithm 2 suffers from a relatively slow running time, since for each submatrix that the algorithm checks, it verifies that the sum of elements in *every* row and column is nonnegative. Therefore, we first relax the concept of a good submatrix and demand only that the sum of *all* its elements be nonnegative (instead of the sum of every row and column). This change, however, requires us to check for each point selected by the algorithm, not only that the legal *square* submatrices which contain it are good, but rather to verify that *all* legal submatrices that contain the point are good. Actually, we check something slightly stronger: The algorithm will verify for each legal submatrix T that it examines that the four legal equal-size submatrices that reside within T and are half of T's length in each dimension are good as well. In order to formalize the above, we first redefine the concepts of good (bad) submatrices and good (bad) points, and introduce the notion of tainted submatrices and tainted points.

DEFINITION 8 (good and bad submatrices and points). *A (legal) submatrix T of C_V is* good *if the sum of all its elements is nonnegative. Otherwise, T is* bad.

A point is good *if every legal submatrix of C_V that contains it is good. Otherwise, the point is* bad.

DEFINITION 9 (tainted submatrices and points). *A good legal submatrix T of C_V is* tainted *if any one of the four legal submatrices that it contains and that are half its height and half its width is bad. A point is* tainted *if some legal submatrix that contains it is tainted.*

Note that every bad point is tainted, but good points may be tainted as well.

For the sake of the presentation, we shall assume that every row and every column in C_V (that is, every subrow and subcolumn of length n) have nonnegative sums. In subsection 5.2 we explain how to remove this assumption. Note that this assumption implies that every $s \times n$ submatrix is good, and similarly every $n \times s$ submatrix is good (but of course it has no implications on smaller submatrices).

ALGORITHM 3 (Test-Monge II).

1. *Uniformly select $2/\epsilon$ points in the matrix C_V and check for each of them whether it is tainted.*
2. *If no point selected is tainted, then accept; otherwise, reject.*

Note that by Definition 5, each point in an $n \times n$ matrix is contained in $O(\log^2 n)$ legal submatrices. Thus by Claim 4, checking whether a point is tainted takes time

$O(\log^2 n)$. Therefore the running time of the algorithm is $O((\log^2 n)/\epsilon)$.

THEOREM 3. *If V is an inverse Monge matrix, then Algorithm* 3 *always accepts, and if V is ϵ-far from being an inverse Monge matrix, then Algorithm* 3 *rejects with probability at least* 2/3.

5.1. Outline of the proof of Theorem 3. If V is an inverse Monge matrix, then by Claim 3 all elements in C_V are nonnegative. This directly implies that all (legal) submatrices are good, and so all points are good and are not tainted. Hence in this case the algorithm always accepts. Suppose that V is ϵ-far from being inverse Monge. We claim that in such a case C_V must contain more than ϵn^2 tainted points, causing the algorithm to reject with probability at least

$$1 - (1-\epsilon)^{(2/\epsilon)} > 1 - e^{-2} > 2/3.$$

Assume contrary to the claim that C_V contains at most ϵn^2 tainted points. Our goal from this point on is to show that in such a case V is ϵ-close to being an inverse Monge matrix.

The proof of this part will follow along similar lines to those used in the proof of Theorem 2. That is, we consider all maximal bad legal submatrices of C_V, and for each such bad submatrix we consider the legal good submatrix that is four times its area and contains it. Once again, this submatrix is unique. By Definition 9, this submatrix is tainted. We then take the union of all these good but tainted submatrices. By our assumption on the number of tainted points, the area of this union is at most ϵn^2 since all points in the union are tainted.

Finally, we show how to modify the values in this union so that the resulting matrix is an inverse Monge matrix. This time, however, since the maximal bad submatrices may intersect (which was not the case in the slower algorithm), the good tainted submatrices that contain them may intersect in nontrivial ways (that is, not only by coinciding or by strict containment). As a result, the union of the good submatrices has a possibly complex structure (and in particular it is no longer a simple union of disjoint submatrices), and the process of properly modifying this union is much more involved. We now describe precisely the necessary definitions and proceed with a detailed proof.

DEFINITION 10 (maximal bad legal submatrix). *A bad legal submatrix T of C_V is a* maximal bad legal submatrix *of C_V if it is not contained in any larger bad legal submatrix of C_V.*

Now consider all maximal bad legal submatrices of C_V. Note that every negative entry in C_V is contained in the union of these bad submatrices. For each such submatrix B let us take the (unique) legal submatrix T that contains it and has twice the number of rows and twice the number of columns of B (by our assumption that all full rows and columns have a nonnegative sum it is indeed possible to double the rows and columns of B). Then by the maximality of B, the resulting submatrix is good. We now take the union of all these good (but tainted) legal submatrices. Recall that the area of the union of all tainted (legal) submatrices of C_V is at most ϵn^2. Denote the union of all these good tainted submatrices by R. See, for example, Figure 2.

In subsections 5.3 and 5.4 we show that it is possible to change the (at most ϵn^2) entries of C_V within R to nonnegative values so that the following property holds.

PROPERTY 1 (sum property for R). *For every point (i,j) outside of R, the sum of the elements in the modified entries (i',j') within R such that $i' \le i$ and $j' \le j$ is the same as in the original matrix C_V.*

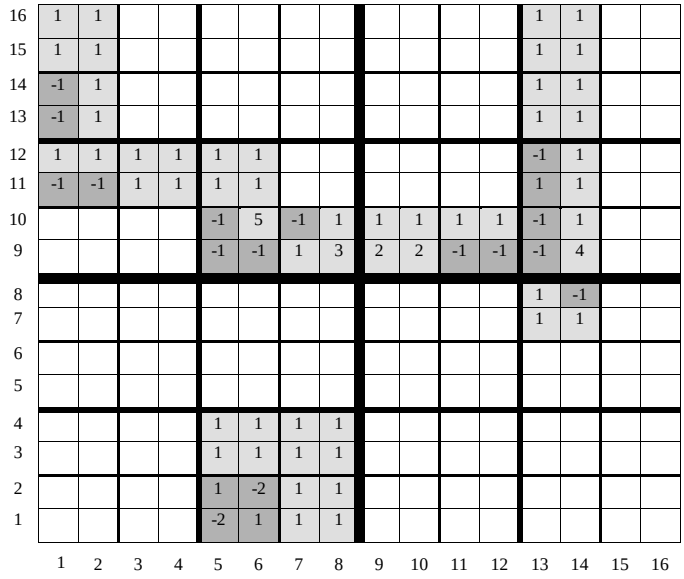

FIG. 2. *An example of the structure of a subset R, where R is the union of all gray cells in the matrix (both dark and light gray). All values in cells outside of R are nonnegative and are not displayed for the sake of simplicity. The bad legal submatrices determining R are the dark gray submatrices. Each is contained inside a good but tainted legal submatrix that has twice the number of rows and twice the number of columns (good tainted submatrices are marked both by light and dark gray). For example, there is a bad submatrix in column* 1*, rows* 13 *and* 14*, and the good legal submatrix containing it is the submatrix over columns* 1 *and* 2 *and rows* 13 *through* 16*. Observe that maximal bad legal submatrices may intersect. For example, the bad submatrix containing the two cells in row* 9 *and columns* 5 *and* 6 *intersects with the bad submatrix containing the two cells in column* 5 *and rows* 9 *and* 10*. Their corresponding good submatrices also intersect.*

Let $\tilde{C}_V$ be the matrix obtained from C_V by modifying R so that Property 1 holds, and let $\tilde{V}$ be the matrix which corresponds to $\tilde{C}_V$. Then it follows from Claim 2 that $\tilde{V}$ is at most ϵ-far from the original matrix V, and this completes the proof of Theorem 3. Before we continue with showing how to obtain Property 1, we explain shortly how to remove the assumption that all (full) rows and columns in C_V have a nonnegative sum.

5.2. Dealing with rows/columns having a negative sum. Suppose first that $\epsilon \leq 4/n$. Then we may directly check in time $O(1/\epsilon)$ that in fact all rows and columns of the matrix C_V have nonnegative sums (using Claim 4) and reject if some row or column has a negative sum. Hence in this case our assumption is valid. Thus assume that $\epsilon > 4/n$.

First we slightly modify Algorithm 3 so that it uniformly selects $4/\epsilon$ points in C_V (instead of $2/\epsilon$). In such a case, if C_V contains more than $(\epsilon/2)n^2$ tainted points, then the algorithm rejects with probability at least $2/3$. We thus assume that C_V contains at most $(\epsilon/2)n^2$ tainted points and strive to show that in such a case V is ϵ-close to being an inverse Monge matrix. Since we do not assume that every row and column in C_V has a nonnegative sum, we first modify C_V so that it has this property.

Consider each row i in C_V whose sum of elements in negative. Suppose that we modify the last entry in the row, $c_{i,n}$, so that the new sum of all elements is 0. Similarly, we modify the last entry $c_{n,j}$ in each column j that has a negative sum. Let $\bar{C}_V$ be the resulting matrix, and let $\bar{V}$ be the matrix corresponding to $\bar{C}_V$. Then

all rows and columns in $\bar{C}_V$ have a nonnegative sum, and by Claim 2 $\bar{V}$ and V differ on at most $2n-1 < (\epsilon/2)n^2$ entries (at most all elements in the last column and last row).

Now we may define the region R as we did in the previous subsection. Note that in this case the area of the region R is at most $(\epsilon/2)n^2$. We can therefore continue in proving that it is possible to modify only the elements within R so that they are all nonnegative and Property 1 holds. This will imply that the total number of entries that should be modified (first to obtain nonnegative rows and columns, and then to refill R) is at most ϵn^2, as desired.

5.3. Refilling R to obtain Property 1. Let R be as defined in section 5.1. Recall that R consists of a union of good legal submatrices. (The fact that they are tainted is no longer relevant.) In the following discussion, when we talk about elements in submatrices of R we mean the elements in C_V determined by the corresponding set of positions in R.

We are interested in refilling the entries in R with *nonnegative* values so that Property 1 will hold. Note that if R is just a submatrix (block) of C_V, then we can use Procedure 2 to refill R as desired. However, in general the structure of R is more complex. We show that there is a way to partition R into disjoint blocks and refill each block using Procedure 2. In subsection 5.3.1 we define precisely what blocks are and present several other notions that are needed for the refilling procedure. The refilling procedure for R is described in subsection 5.3.2, and its correctness is proved in subsection 5.4.

5.3.1. Preliminaries for the refilling procedure. As stated above, the refilling procedure will partition R into disjoint blocks (submatrices) and fill each block separately with nonnegative values so that Property 1 is maintained. We start with defining the following term that will be needed to define blocks.

DEFINITION 11 (maximal (legal) subrow/column). *Given a subset R of entries in an $n \times n$ matrix, a subrow T is a* maximal (legal) subrow with respect to R *if T is contained in R and there is no larger (legal) subrow T' such that $T \subset T' \subseteq R$. A* maximal (legal) subcolumn with respect to R *is defined analogously.*

For the sake of succinctness, whenever it is clear what R is, we shall just say maximal (legal) subrow and drop the suffix "with respect to R." Note that a maximal subrow is simply a maximal consecutive sequence of entries in R that belong to the same row, while a maximal legal subrow is a more constrained notion. In particular, a maximal subrow may be a concatenation of several maximal legal subrows. We can now define blocks as follows.

DEFINITION 12 (maximal block). *A maximal block $B = [\,]_{i,j}^{s,t}$ in R is a submatrix contained in R which has the following property: It consists of a maximal consecutive sequence of maximal legal subcolumns of the same height. The maximality of each subcolumn is as in Definition* 11. *That is, for every $j \le r \le j+t-1$, the column $[\,]_{i,r}^{s,1}$ is a maximal legal subcolumn (with respect to R).*

The height *of a maximal block B is the height of the columns in B (equivalently, the number of rows in B).*

The maximality of the sequence of subcolumns in a block $B = [\,]_{i,j}^{s,t}$ means that we can extend the sequence of columns neither to the left nor to the right. That is, neither $[\,]_{i,j-1}^{s,1}$ nor $[\,]_{i,j+t}^{s,1}$ is a maximal legal subcolumn in R. (Specifically, each either is not fully contained in R or R contains a larger legal subcolumn that contains it.)

We shall sometimes refer to maximal blocks simply as blocks. Observe that by this definition, R is indeed partitioned in a unique way into maximal disjoint blocks.

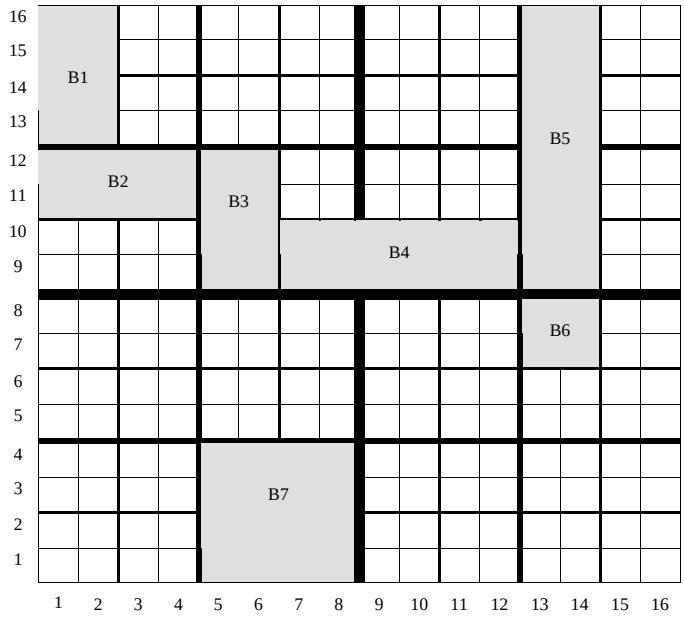

FIG. 3. *An example of the partition of R shown in Figure* 2 *into maximal blocks (numbered B_1–B_7). Note that the ratio between the heights of any two blocks is always a power of* 2. *Furthermore, the blocks are aligned in the following way. Suppose a block B has height s, and a block B' has height $s' \leq s$ and some of their subrows belong to the same row of the matrix (e.g., B_3 and B_4, or B_4 and B_5). Then the shorter block B' must be aligned with either the first or second half of B, or with one of the quarters of B, or with one of its eighths, etc.*

See Figure 3 for an illustration to how the subset R from Figure 2 is partitioned into maximal blocks.

Three additional notions that will be needed for the refilling procedure are defined below. The first two are illustrated in Figure 4.

DEFINITION 13 (covers). *We say that a submatrix A* covers *a given block B with respect to R if $B \subseteq A \subseteq R$ and the number of rows in A equals the height of B.*

We say that A is a maximal row-cover *with respect to R if A consists of maximal subrows with respect to R.*

DEFINITION 14 (borders). *We say that a submatrix $T = [\ ]_{i,j}^{s,t}$* borders *another submatrix $T' = [\ ]_{i',j'}^{s',t'}$ if $i' \leq i + s - 1$ and $i \leq i' + s' - 1$, and either $j' = j + t$ (so that T is to the left of T') or $j' + t' = j$ (so that T is to the right of T').*

DEFINITION 15 (sums). *For a given submatrix T, we denote the sum of the elements in T by $sum(T)$.*

5.3.2. The procedure for refilling *R*. We now describe the procedure that refills the entries of R with nonnegative values so as to obtain Property 1. Recall that R is a disjoint union of maximal blocks. Hence if we remove a maximal block from R, then the maximal blocks of the remaining structure are simply the remaining maximal blocks of R. For simplicity of this introductory discussion, after removing a block from R, we refer to the remaining structure as R. The procedure described below will remove the blocks of R one by one, in order of increasing (nondecreasing) height, and refill each block separately using Procedure 2.

Recall that when (re)filling an $s \times t$ submatrix, Procedure 2 is provided with non-

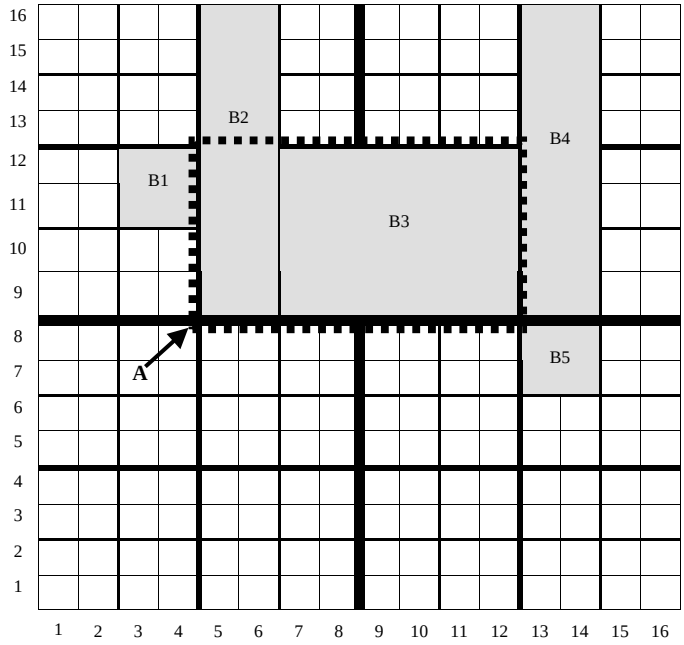

FIG. 4. *An illustration of the notions of covers and borders. Here the submatrix A (extending from row* 9 *to* 12 *and from column* 5 *to* 12*) covers the block* B_3 *(but is not a maximal row-cover with respect to R). The submatrix A borders block* B_1 *(from the left of A) and block* B_4 *(from the right of A).*

negative values $a_1, \ldots, a_s$ and $b_1, \ldots, b_t$ such that $\sum_{i=1}^{s} a_i \geq \sum_{j=1}^{t} b_j$. It then fills the submatrix with nonnegative values so that the sum of elements in column j is exactly b_j and the sum of elements in row i is at most a_i. Whenever we apply Procedure 2 to a block B, the column sums $b_1, \ldots, b_t$ are simply set to be the sums of the elements in the corresponding subcolumns of B in C_V. By definition of (maximal) blocks, these subcolumns are maximal legal subcolumns, and as we show in subsection 5.4.1, this ensures that their sums are nonnegative.

The setting of the upper bounds $a_1, \ldots, a_s$ for the row sums is a little more involved. At any point in the algorithm, each maximal subrow L is associated with a *designated* sum, denoted $\overline{sum}(L)$. This is the sum we intend it to have when the refilling procedure terminates. Initially, for every maximal subrow L in R, we set $\overline{sum}(L) = sum(L)$. That is, $\overline{sum}(L)$ is equal to the original sum of subrow L in C_V. In subsection 5.4.1 we show that these sums are all nonnegative. When refilling a block B, we first find the row-cover A of B that is a maximal row-cover with respect to (the current) R. Since the blocks are filled by order of height and blocks are removed after they are filled, such a maximal row-cover must exist when B is covered and is unique. We then use the designated sums of the (maximal) rows of A as the upper bounds $a_1, \ldots, a_s$ for the sums of rows of B. As we prove subsequently, it always holds that $\sum_{i=1}^{s} a_i \geq \sum_{j=1}^{t} b_j$ as required by Procedure 2. After removing a block B from R, we obtain new, shorter, maximal subrows in the remaining structure $R \setminus B$, and we must associate with these shorter subrows new designated sums. Procedure 2 is used here as well to determine how to set these designated row sums, in a manner explained in detail in step 3 below. For an illustration, see Figure 5.

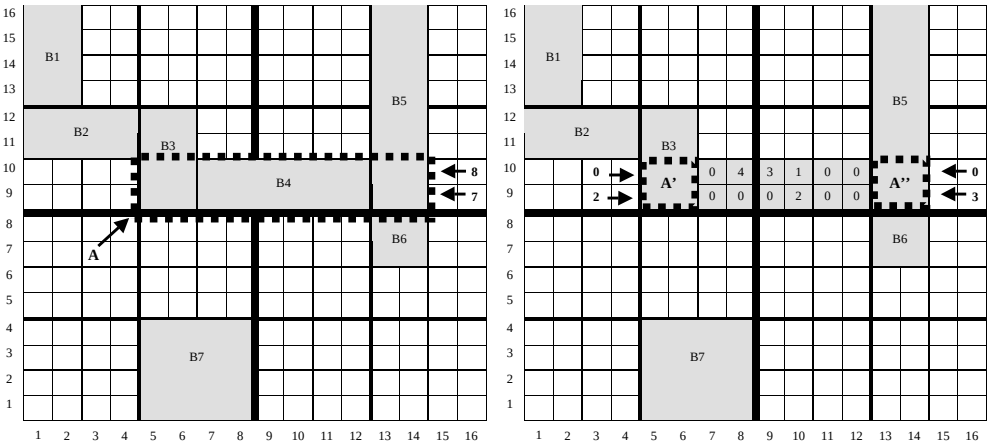

FIG. 5. *An illustration of one iteration of step* 3 *in Procedure* 3*, where we apply the procedure to the matrix illustrated in Figures* 2 *and* 3*. The first block filled may be either* B_2*,* B_4*, or* B_6 *(all three have height* 2*, which is the minimum among all blocks). Here we have selected to refill* B_4 *first. On the left we see the maximal row-cover* A *that covers* B_4*, where the designated sums of the two rows of* A *are* 8 *and* 7 *(in accordance with the values appearing in Figure* 2*). On the right we see the values that the Procedure* 2 *has entered in the cells of* B_4*. We also see the two submatrices,* A' *and* A''*, that remain of* A *after* B_4 *is removed from* R *and the designated sums of the new maximal rows in* A' *and* A''*.*

PROCEDURE 3 (refill R).

1. *We assign each maximal subrow* L *in* R *a designated sum of elements for that row, which is denoted by* $\overline{sum}(L)$*. Initially, we set* $\overline{sum}(L)$ *to be* $sum(L)$*.*
2. *Let* m *be the number of maximal blocks in* R*, and let* $R_1 = R$*.*
3. *For* $p = 1, \ldots, m$ *we do the following:*
   (a) *Let* B_p *be a maximal block in* R_p *whose height is minimum among all maximal blocks of* R_p*, and assume that* B_p *is an* $s \times t$ *submatrix. Let* A_p *be a maximal row-cover of* B_p *with respect to* R_p*. For* $1 \le \ell \le s$*, let* L_ℓ *denote the subrow of* A_p *that covers the* ℓ*th subrow of* B_p*.*
   (b) *Refill* B_p *by applying Procedure* 2 *(see section* 3.1*), where the sum filled in the* k*th subcolumn of* B_p*,* $1 \le k \le t$*, should be the original sum of this subcolumn in* C_V*, and the sum filled in the* ℓ*th subrow of* B_p*,* $1 \le \ell \le s$*, is at most* $\overline{sum}(L_\ell)$*.*
   For each $1 \le \ell \le s$*, let* x_ℓ *denote the sum of elements filled by Procedure* 2 *in the* ℓ*th subrow of* B_p*.*
   (c) *Let* $R_{p+1} = R_p \setminus B_p$*. We next assign designated sums to the rows of* R_{p+1} *that have been either shortened or broken into two parts by the removal of* B_p *from* R_p*. This is done as follows:*
   The set $A_p \setminus B_p$ *is the union of two nonconsecutive submatrices,* A' *and* A''*, so that* A' *borders* B_p *from the left of* B_p *and* A'' *borders* B_p *from the right of* B_p *(where it is possible that one or both of these submatrices does not exist). Let* L'_ℓ *and* L''_ℓ *be the subrows in* A' *and* A''*, respectively, that are contained in subrow* L_ℓ *of* A_p*. We assign to* L'_ℓ *and* L''_ℓ *nonnegative designated sums,* $\overline{sum}(L'_\ell)$ *and* $\overline{sum}(L''_\ell)$*, that satisfy the following:*

$$\overline{sum}(L'_\ell) + \overline{sum}(L''_\ell) = \overline{sum}(L_\ell) - x_\ell$$

and, furthermore,

$$\sum_{row\ L \in A'} \overline{sum}(L) = sum(A'), \qquad \sum_{row\ L \in A''} \overline{sum}(L) = sum(A'').$$

This is done by applying Procedure 2 *to a* $2 \times s$ *matrix whose sums of columns are* $sum(A')$ *and* $sum(A'')$ *and sums of rows are* $\overline{sum}(L_\ell) - x_\ell$, *where* $1 \le \ell \le s$.
(Note that one or both of A' *and* A'' *may not exist. This can happen if* B_p *bordered* $A_p \setminus B_p$ *on one side and its boundary coincided with* R_p *or if* $A_p = B_p$. *In this case, if, for example,* A' *does not exist, then we view it as a submatrix of height* 0, *where* $sum(A') = 0$.*)*

5.4. Proving that Procedure 3 is correct. In order to prove that Procedure 3 is correct we have to prove two claims. First, we have to show that the procedure does not "get stuck," namely, that all iterations of the procedure can be completed. Second, we have to prove that at the end of the procedure, the refilled structure R has Property 1. Before we prove these two claims we first prove some properties relating to the sum of elements in maximal blocks and other submatrices of R. These properties will be used to show that the procedure does not get stuck.

5.4.1. Sums of blocks and other submatrices. We first prove the following simple lemma regarding the sum of elements in maximal legal subrows and subcolumns of R.

LEMMA 6. *The sum of elements in every maximal legal subrow and every maximal legal subcolumn in* R *is nonnegative.*

Proof. We prove the lemma for maximal legal subrows. The claim for maximal legal subcolumns is analogous. Assume, contrary to the claim, that R contains some maximal legal subrow $L = [\ ]_{i,j}^{1,t}$ whose sum of elements is negative. Let T be the maximal bad legal submatrix in C_V that contains L. By the maximality of L, necessarily $T = [\ ]_{i',j}^{s,t}$ for some $i' \le i$ and $s \ge 1$. That is, the rows of T (one of which is L) are of length t. By the construction of R, R must contain a good legal submatrix T' that contains T and is twice as large in each dimension. But this contradicts the maximality of L. □

It directly follows from Lemma 6 that every maximal row in R has a nonnegative sum and that every maximal block has a nonnegative sum. We would like to characterize other submatrices of R whose sum is necessarily nonnegative.

LEMMA 7. *Consider any two maximal blocks* $B = [\ ]_{i,j}^{s,t}$ *and* $B' = [\ ]_{i',j'}^{s',t'}$, *where* $i \le i' \le i+s-1$, $i'+s' \le i+s$. *That is,* B *has height* s *and* B' *has height* $s' \le s$, *and* B' *starts at row* $i' \ge i$ *and ends at row* $i'+s'-1 \le i+s-1$. *Consider the submatrix* T *of height* s *"between them." That is,* $T = [\ ]_{i,j+t}^{s,j'-(j+t)}$ *or* $T = [\ ]_{i,j'+t'}^{s,j-(j'+t')}$. *Suppose that* $T \subset R$. *Then* $sum(T) \ge 0$.

See Figure 6 for a illustration of the lemma and its proof.

Proof. Assume without loss of generality that B' is to the right of B (that is, $j' \ge j+t$ and $T = [\ ]_{i,j+t}^{s,j'-(j+t)}$). If T is empty, then the claim follows trivially since $sum(T) = 0$. Hence we may assume from now on that T is not empty, and we separate the proof into two cases.

Case 1. T *is a legal submatrix.* Assume, contrary to the claim, that $sum(T) < 0$. That is, T is a bad legal submatrix. Let T' be the maximal bad legal submatrix containing T (where T' may equal T). By construction of R, R should contain a good legal submatrix T'' that contains T' and has twice the number of rows and twice the

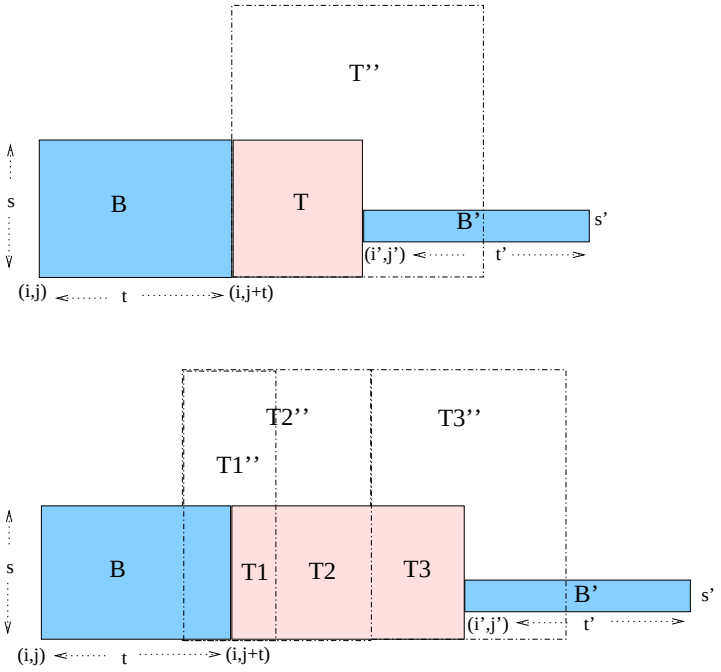

FIG. 6. *An illustration for Lemma* 7. *The figure on the top illustrates the case in the proof of Lemma* 7, *where* T *is a legal submatrix (for simplicity, we assume* $T' = T$*). The figure on the bottom illustrates the second case in the proof when* T *is a union of legal submatrices (all having the height of* B*).*

number of columns. But this would contradict the maximality of the subcolumns of B or of B'. To see why this is true, assume without loss of generality that for any legal subcolumn $[\,]^{s,1}_{i,r}$, the legal column that is twice its height is $[\,]^{2s,1}_{i,r}$ (the case in which it is $[\,]^{2s,1}_{i-s,r}$, is treated analogously). Then T'' must contain either the subcolumn $[\,]^{2s,1}_{i,j'}$ or the subcolumn $[\,]^{2s,1}_{i,j+t-1}$ (depending on the identity of the legal subrows that are twice the length of the rows of T). In the first case we would get a contradiction to the fact that B' is a maximal block, and in the second case we would get a contradiction to the fact that B is a maximal block.

Case 2. T *is not a legal submatrix.* Observe that its columns are necessarily legal subcolumns (given that the columns of B are legal). Hence, only its rows are not legal subrows. Therefore, T can be partitioned into submatrices $T_1, \ldots, T_k$ such that each is of height s and is a maximal legal submatrix *with respect to* T. We claim that for every T_ℓ, $sum(T_\ell) \geq 0$. Consider any fixed T_ℓ. By its maximality with respect to T, we know that the legal subrows that contain the rows of T_ℓ and are twice their length are not strictly contained in T, but rather they extend either to the right or to the left of T. Hence these rows (or some of them in case the height of B' is strictly smaller than the height of T_ℓ) must intersect either B or B'. Assume, contrary to what we claim, that $sum(T_\ell) < 0$. Let T'_ℓ be the maximal bad legal submatrix with respect to R that contains T_ℓ, and let T''_ℓ be the good legal submatrix that contains T'_ℓ and has twice its height and twice its width. Then T''_ℓ intersects either B or B', and in this intersection, the (legal) subcolumns of T''_ℓ strictly contain the subcolumns of B or B' (as in the case considered in the previous paragraph). But this contradicts the

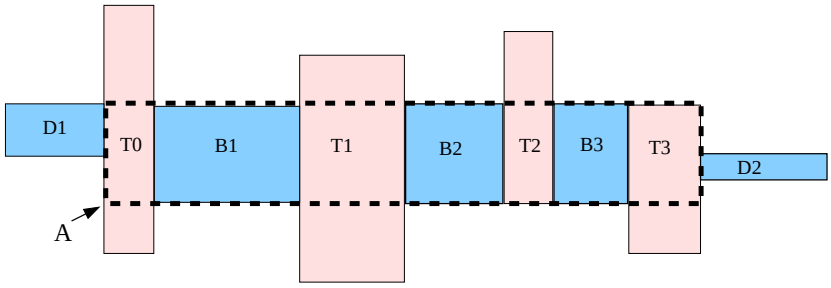

FIG. 7. *An illustration for Corollary* 8. *Here A covers the blocks B_1, B_2, and B_3 and borders the blocks D_1 and D_2. The submatrices T_0–T_4 are parts of larger blocks (that extend above and/or below A).*

maximality of B or B'. □

By Lemma 7, we get the following corollary whose proof is illustrated in Figure 7.

COROLLARY 8. *Let A be a submatrix of R that covers a given block B. If on each of its sides A either borders a block with height smaller than the height of B or its border coincides with the border of R, then* $sum(A) \geq sum(B)$.

Proof. Let $B_1, \ldots, B_k$ be the set of maximal blocks that are covered by A (where $B = B_i$ for some $1 \leq i \leq k$). Note that by definition of maximal blocks and covers, they are all of the same height, which is the height of A. Let D_1 and D_2 be two shorter blocks that border A on the left side and the right side of A, respectively. (If there is no such block on one of the sides, then we think of the corresponding D_i as having height 0.) Let $T_0, \ldots, T_k$ be the submatrices between these blocks (that have the same height as the blocks). That is, T_0 is between D_1 and B_1, T_k is between B_k and D_2, and for $1 \leq i \leq k-1$, T_i is between B_i and B_{i+1}. Then, by Lemma 7 and the fact that every block has a nonnegative sum we get that

$$sum(A) = \sum_{i=1}^{k} sum(B_i) + \sum_{i=0}^{k} sum(T_i) \geq sum(B). \qquad (6)$$ □

5.4.2. Proving that Procedure 3 does not get stuck. Recall that for each $1 \leq p \leq m$, R_p is what remains of R at the start of the pth iteration of Procedure 3. In particular, $R_1 = R$. In this section we show that the procedure does not "get stuck." That is, for each iteration p, Procedure 2 can be applied to the block B_p selected in this iteration, and it is possible to update the designated sums of the rows that have been shortened by the removal of B_p. Note that since the blocks are selected according to increasing (nondecreasing) height, then in each iteration there indeed exists a unique cover A_p of B_p that is a maximal row-cover with respect to R_p.

For every $1 \leq p \leq m$, let s_p be the minimum height of the maximal blocks of R_p, and let $s_0 = 1$. Observe that whenever s_p increases, it does so by a factor of 2^k for some k. This is true because the columns of maximal blocks are legal subcolumns.

LEMMA 9. *For every $1 \leq p \leq m$, Procedure 2 can be applied to the block B_p selected in R_p, and the updating process of the designated sum of rows can be applied. Moreover, if A is a submatrix of R_p with height of at least s_{p-1} whose columns are legal subcolumns and whose rows are maximal rows with respect to R_p, then* $\sum_{row\ L \in A} \overline{sum}(L) = sum(A)$.

Proof. Let B_p be the block selected in iteration p, where B_p is an $s \times t$ submatrix, and let A_p be the maximal row-cover of B_p with respect to R_p. As noted in

subsection 3.1, all that is required for Procedure 2 to work is the following:

(1) For every column K in B_p, $sum(K) \geq 0$.
(2) For every row L in A_p, $\overline{sum}(L) \geq 0$.
(3) $\sum_{\text{row } L \in A_p} \overline{sum}(L) \geq \sum_{\text{column } K \in B_p} sum(K)$.

In order for the updating process to succeed in step 3 of Procedure 3, we must have the following:

(4) For each $1 \leq \ell \leq s$, let x_ℓ be the sum of elements filled in the ℓth subrow of B_p, and let L_ℓ be the subrow of A_p that covers this subrow of B_p. Then $\overline{sum}(L_\ell) - x_\ell \geq 0$.
(5) If $A_p \setminus B_p$ consists of the two submatrices A' and A'' (between which resided B), then $sum(A') \geq 0$, $sum(A'') \geq 0$, and

$$\sum_{\text{row } L_\ell \in A_p} (\overline{sum}(L_\ell) - x_\ell) = sum(A') + sum(A'').$$

By Lemma 6, item (1) holds at the start of every iteration. In order to prove the other items for every p, we first extend and generalize item (2):

(2') Let A be any submatrix in R_p having height at least s_{p-1} whose columns are legal subcolumns and whose rows are maximal rows with respect to R_p. Then for every row L of A we have $\overline{sum}(L) \geq 0$, and $\sum_{\text{row } L \in A} \overline{sum}(L) = sum(A)$.

Observe that if item (2') holds at the start of iteration p, then in particular it holds for A_p. Hence by Corollary 8

$$\sum_{\text{row } L \in A_p} \overline{sum}(L) = sum(A_p) \geq sum(B_p) \tag{7}$$

and so item (3) holds as well.

Furthermore, if items (1)–(3) hold at the start of iteration p, then Procedure 2 can be applied successfully. Thus item (4) necessarily holds by definition of Procedure 2. The first part of item (5), concerning the nonnegativity of A' and A'', follows from Lemma 7 very similarly to the way Corollary 8 follows from this lemma. The second part of item (5) follows from item (2') holding for A_p and the fact that $\sum_{\ell=1}^{s} x_\ell = sum(B_p)$ (since Procedure 2 completed successfully). Hence,

$$\sum_{\text{row } L_\ell \in A_p} (\overline{sum}(L_\ell) - x_\ell) = sum(A_p) - sum(B_p) = sum(A') + sum(A'') \tag{8}$$

as required.

Hence, it remains to prove that item (2') holds at the start of every iteration p. We do so by induction on p. Consider the base case, $p = 1$, so that $R_p = R_1 = R$. By the initialization of Procedure 3, for every maximal subrow L of R, $\overline{sum}(L) = sum(L)$. By Lemma 6 (applied to the maximal legal subrows that partition L), we know that $\overline{sum}(L) \geq 0$. Furthermore, for every submatrix A of R having height of at least $s_{p-1} = s_0 = 1$ and whose rows are maximal subrows of R,

$$\sum_{\text{row } L \in A} \overline{sum}(L) = \sum_{\text{row } L \in A} sum(L) = sum(A) \tag{9}$$

as required.

Assuming that the induction claim holds for $p - 1$, we prove it for p. Consider any submatrix A having height at least s_{p-1} whose columns are legal subcolumns and

whose rows are maximal subrows with respect to R_p. If A also consisted of maximal subrows with respect to R_{p-1}, then we are done by the induction hypothesis.

Otherwise, the block B_{p-1} of height s_{p-1} that was removed from R_{p-1} bordered A on one of its sides. Let $A^1, \ldots, A^q$ be the disjoint submatrices of height s_{p-1} such that $A = \cup_{h=1}^{q} A^h$. That is, $A^1, \ldots, A^q$ are located one on top of the other (for an illustration, see Figure 8). In this case, all but at most one of these submatrices, say A^q, consisted of maximal subrows with respect to R_{p-1}, and B_{p-1} bordered A^q.

For each of the submatrices $A^1, \ldots, A^{q-1}$ we can apply the induction hypothesis (item (2')). We get the following for each such A^h: (a) for every row L in A^h, $\overline{sum}(L) \geq 0$; and (b) $\sum_{\text{row } L \in A^h} \overline{sum}(L) = sum(A^h)$.

As for A^q, assume without loss of generality that B_{p-1} bordered A^q from the right of A^q. Let A' be the submatrix that bordered B_{p-1} from the right of B_{p-1} (A' may be empty). This means that A_{p-1} is of the form $A_{p-1} = A^q \cup B_{p-1} \cup A'$ (see Figure 8). But then, by definition of the updating rule and since it succeeded by the induction hypothesis (items (4) and (5)), we have that for every row L in A^q, $\overline{sum}(L) \geq 0$ and $\sum_{\text{row } L \in A^q} \overline{sum}(L) = sum(A^q)$.

It follows that for every row L in A we have $\overline{sum}(L) \geq 0$ and

$$\sum_{\text{row } L \in A} \overline{sum}(L) = \sum_{h=1}^{q} \sum_{\text{row} L \in A^h} \overline{sum}(L) = \sum_{h=1}^{q} sum(A^h) = sum(A) \,. \tag{10}$$

The induction step is proven. □

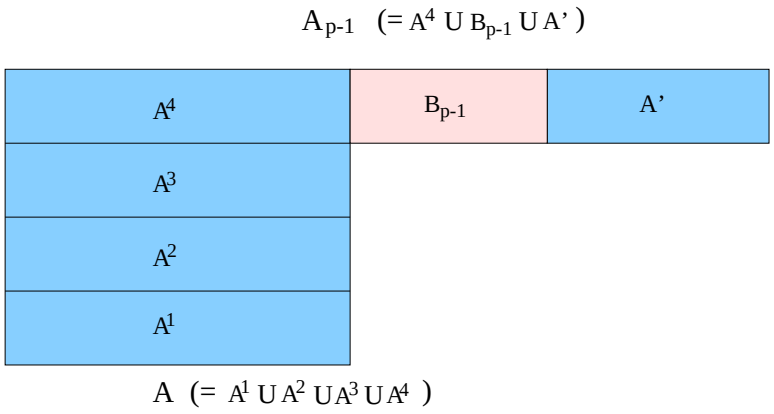

FIG. 8. *An illustration for the induction step in the proof of Lemma* 9 *(where* $q = 4$*).*

5.4.3. Proving that Property 1 holds at the end of Procedure 3. Finally, we have to show that when Procedure 3 terminates and R is refilled with nonnegative values, then Property 1 holds. This will complete the proof of Theorem 3.

Let $\tilde{C}_V = \{\tilde{c}_{i,j}\}$ be the matrix resulting from the application of Procedure 3 to the matrix $C_V = \{c_{i,j}\}$. For any submatrix T of C_V (and in particular of R), we let $\widetilde{sum}(T)$ denote the sum of elements of T in $\tilde{C}_V$. By definition of the procedure, $\widetilde{sum}(K) = sum(K)$ for every maximal legal subcolumn K of R. Hence this holds also for every maximal subcolumn of R. We next prove a related claim concerning rows.

LEMMA 10. *For every subrow* L *in* R *such that* L *is assigned* $\overline{sum}(L)$ *as a designated sum at some iteration of Procedure* 3*, we have that* $\widetilde{sum}(L) = \overline{sum}(L)$.

Observe that by combining Lemma 10 with Lemma 6 we get that for every maximal subrow L of R, $\widetilde{sum}(L) = \overline{sum}(L) = sum(L)$.

Proof. Let $\mathcal{L}$ be the set of subrows L of R such that L is assigned $\overline{sum}(L)$ as a designated sum at some iteration of Procedure 3. Observe that the set $\mathcal{L}$ consists exactly of those rows that are maximal subrows for some R_p. We prove the lemma by induction on the length of $L \in \mathcal{L}$. For the base of the induction, consider any subrow $L \in \mathcal{L}$ that is shortest among all subrows in $\mathcal{L}$. Since L is shortest, it must be completely filled in a single iteration as part of a block B (or otherwise there would be a shorter $L' \subset L$ with a designated sum $\overline{sum}(L')$). But by definition of the procedure, we get that $\widetilde{sum}(L) = \overline{sum}(L)$ as required.

Assume that the claim holds for every L of length less than ℓ; we prove it for L having length ℓ. Consider the first iteration after which L became a maximal subrow (and thus received the designated sum $\overline{sum}(L)$) in which part of L is filled. If all of L is filled, then the induction claim follows as in the base case. Otherwise, let x be the sum of elements that was filled in the part $P \subset L$. Let L' and L'' be what remains of L to the left and right of P, respectively. Then the procedure sets $\overline{sum}(L') + \overline{sum}(L'') = \overline{sum}(L) - x$. But L' and L'' are strictly shorter than L, and therefore by the induction hypothesis $\widetilde{sum}(L') = \overline{sum}(L')$ and $\widetilde{sum}(L'') = \overline{sum}(L'')$. Thus $\widetilde{sum}(L) = \widetilde{sum}(L') + \widetilde{sum}(L'') + x = \overline{sum}(L') + \overline{sum}(L'') + x = \overline{sum}(L)$ as required. ∎

Definition 16 (boundary). *We say that a point (i,j) is on the* boundary *of R if $(i,j) \in R$, but either $(i+1,j) \notin R$, or $(i,j+1) \notin R$, or $(i+1,j+1) \notin R$. We denote the set of boundary points by $\mathcal{B}$.*

Definition 17. *For a point (i,j), $1 \le i,j \le n$, let $R^{\le}(i,j)$ denote the subset of points $(i',j') \in R$, $i' \le i, j' \le j$, and let $sum^R(i,j) = \sum_{(i',j') \in R^{\le}(i,j)} c_{i',j'}$ and $\widetilde{sum}^R(i,j) = \sum_{(i',j') \in R^{\le}(i,j)} \tilde{c}_{i',j'}$.*

Property 1 and therefore Theorem 3 will follow directly from the next two lemmas.

Lemma 11. *For every point $(i,j) \in \mathcal{B}$, $\widetilde{sum}^R(i,j) = sum^R(i,j)$.*

Proof. Consider any point $(i,j) \in \mathcal{B}$, and let $U = R^{\le}(i,j)$. Let $\mathcal{C}(U) = \{B_1, \ldots, B_q\}$ be the minimal set of (maximal) blocks whose union contains U. For each $B_h \in \mathcal{C}(U)$ we know that $\widetilde{sum}(B_h) = sum(B_h)$. In particular, this is true for every $B_h \subset U$. Let $\mathcal{C}_1(U) = \{B_h \in \mathcal{C}(U) : B_h \subset U\}$. Hence we have that

$$\sum_{B_h \in \mathcal{C}_1(U)} \widetilde{sum}(B_h \cap U) = \sum_{B_h \in \mathcal{C}_1(U)} \widetilde{sum}(B_h) = \sum_{B_h \in \mathcal{C}_1(U)} sum(B_h)\,. \tag{11}$$

If every $B_h \in \mathcal{C}(U)$ is fully contained in U, then $\mathcal{C}_1(U) = \mathcal{C}(U)$ and we are done.

Otherwise, consider the remaining B_h's in $\mathcal{C}(U) \setminus \mathcal{C}_1(U)$ (i.e., blocks that are not fully contained in U but rather intersect it). Each of them contains either a column that is a subcolumn of column $j+1$ or a row that is a subrow of row $i+1$ (recall that $U = R^{\le}(i,j)$). Let the former subset be denoted $\mathcal{C}_2(U)$ and the latter $\mathcal{C}_3(U)$. Thus $\mathcal{C}_2(U)$ contains blocks that "intersect U from the right," and $\mathcal{C}_3(U)$ contain blocks that "intersect U from the top." See, for example, Figure 9.

It is important to note that $\mathcal{C}_2(U) \cap \mathcal{C}_3(U) = \emptyset$: If there existed a block $B_h \in \mathcal{C}_2(U) \cap \mathcal{C}_2(U)$, it would necessarily contain both (i,j) and the three neighboring points, $(i+1,j)$, $(i,j+1)$, and $(i+1,j+1)$. But this contradicts the fact that (i,j) is a boundary point.

For each $B_h \in \mathcal{C}_2(U)$, $B_h \cap U$ is a subset of maximal legal subcolumns with respect to R (since each $B_h \in \mathcal{C}_2(U)$ cannot extend beyond row i). Let $\mathcal{K}_2(U)$ denote the set

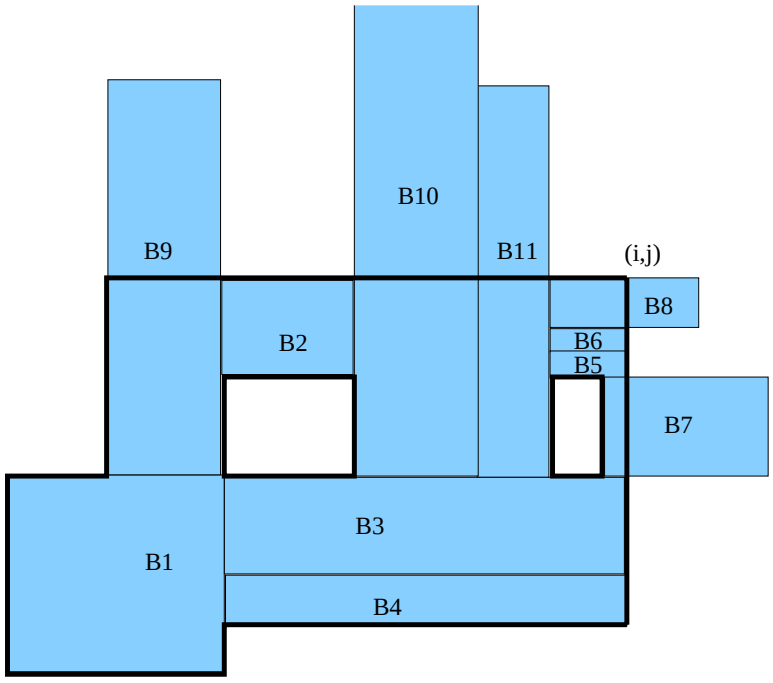

FIG. 9. *An illustration for the proof of Lemma* 11. *The solid line denotes the outline of* $U = R^{\leq}(i,j)$, *where point* (i,j) *is in the top-right corner. Blocks* B_1–B_6 *are fully contained in* U *and therefore belong to* $\mathcal{C}_1(U)$. *Blocks* B_7 *and* B_8 *belong to* $\mathcal{C}_2(U)$ *and blocks* B_9–B_{11} *belong to* $\mathcal{C}_3(U)$. *Block* B_{10} *is twice the height of* B_9 *and* B_{11} *and thus "extends out of the figure."*

of all maximal legal subcolumns that belong to $\bigcup_{B_h \in \mathcal{C}_2(U)}(B_h \cap U)$. Since for every maximal legal subcolumn K it holds that $\widetilde{sum}(K) = sum(K)$, we have that

$$\sum_{B_h \in \mathcal{C}_2(U)} \widetilde{sum}(B_h \cap U) = \sum_{K \in \mathcal{K}_2(U)} \widetilde{sum}(K) = \sum_{K \in \mathcal{K}_2(U)} sum(K). \tag{12}$$

Next consider the blocks $B_h \in \mathcal{C}_3(U)$. Let $\mathcal{L}_3(U)$ be the set of subrows in U that are maximal subrows with respect to $\bigcup_{B_h \in \mathcal{C}_3(U)}(B_h \cap U)$. Thus, $\bigcup_{B_h \in \mathcal{C}_3(U)}(B_h \cap U) = \bigcup_{L \in \mathcal{L}_3} L$. We next observe that for every $B_h \in \mathcal{C}_3(U)$, all blocks that border B_h and belong either to $\mathcal{C}_1(U)$ or to $\mathcal{C}_2(U)$ must be strictly shorter than B_h. This follows from the definition of legal subcolumns. Hence, the blocks in $\mathcal{C}_1(U)$ and $\mathcal{C}_2(U)$ are all removed before the blocks in $\mathcal{C}_3(U)$.

For each subrow in $\mathcal{L}_3(U)$ there exists the first iteration p in which it becomes a maximal subrow with respect to R_p (following the removal of some block in $\mathcal{C}_1(U) \cup \mathcal{C}_2(U)$ from R_{p-1}). We partition the rows in $\mathcal{L}_3(U)$ accordingly. Let $\mathcal{L}_3^p(U)$ denote all subrows in $\mathcal{L}_3(U)$ that are maximal subrows with respect to R_p but were not maximal subrows with respect to R_{p-1}. Observe that, in particular, $\mathcal{L}_3^1(U)$ is the set of subrows in $\mathcal{L}_3(U)$ that were already maximal subrows with respect to R. By this definition the subrows in $\mathcal{L}_3^p(U)$ constitute a submatrix of height s_{p-1}. By the second part of Lemma 9, $\sum_{L \in \mathcal{L}_3^p(U)} \widetilde{sum}(L) = \sum_{L \in \mathcal{L}_3^p(U)} sum(L)$, and by applying Lemma 10 we

get that $\sum_{L\in\mathcal{L}_3(U)} \widetilde{sum}(L) = \sum_{L\in\mathcal{L}_3(U)} sum(L)$. Therefore,

$$\sum_{B_h\in\mathcal{C}_3(U)} \widetilde{sum}(B_h\cap U) = \sum_{L\in\mathcal{L}_3(U)} \widetilde{sum}(L) = \sum_{L\in\mathcal{L}_3(U)} sum(L). \tag{13}$$

By combining (11)–(13) we get

$$\begin{aligned}\widetilde{sum}(U) &= \sum_{B_h\in\mathcal{C}(U)} \widetilde{sum}(B_h\cap U)\\ &= \sum_{q=1}^{3}\sum_{B_h\in\mathcal{C}_q(U)} \widetilde{sum}(B_h\cap U)\\ &= \sum_{B_h\in\mathcal{C}_1(U)} sum(B_h) + \sum_{K\in\mathcal{K}_2(U)} sum(K) + \sum_{L\in\mathcal{L}_3(U)} sum(L)\\ &= sum(U) \qquad \square\end{aligned}$$

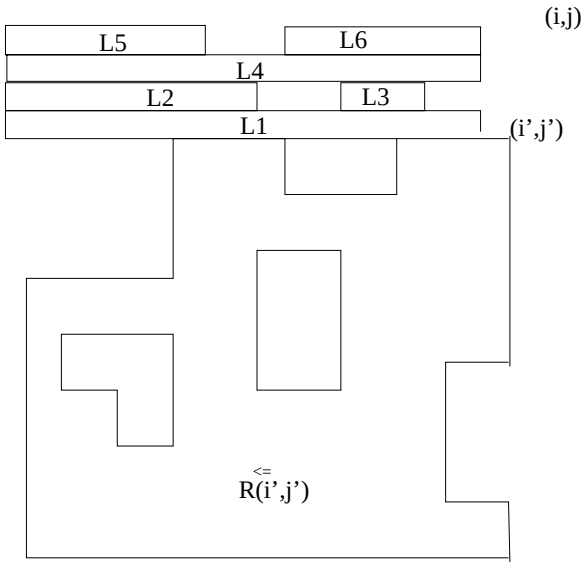

FIG. 10. *An illustration for the proof of Lemma* 12. *The point* (i', j') *is as defined in the proof, and the rows* $L_1, \ldots, L_6$ *are all maximal subrows of* R *that belong to rows* $i'+1, \ldots, i$ *and end by column* j *(that is, the set* $\mathcal{L}(i, i', j)$*).*

LEMMA 12. *Let* (i, j) *be any point such that* $(i, j) \notin R$. *Then* $\widetilde{sum}^R(i, j) = sum^R(i, j)$.

Proof. Let $(i', j') \in R$, $i' < i$, $j' \le j$, be the point for which j' is maximized, and if there are several such points, let it be the one amongst them for which i' is maximized. Thus, (i', j') is maximal in the sense that for every (i'', j''), $i'' < i$, $j'' \le j$ such that $(i'', j'') > (i', j')$ it holds that $(i'', j'') \notin R$. Furthermore, among all such maximal points it is the right-most one (i.e., it belongs to the column with the highest index). By definition, (i', j') belongs to $\mathcal{B}$, since $(i'+1, j')$ necessarily does not belong to R. Let $\mathcal{L}(i, i', j)$ be the subset of all maximal subrows of R that belong to rows $i'+1, \ldots, i$ and end by column j. Then $\widetilde{sum}^R(i, j) = \widetilde{sum}^R(i', j') + \sum_{L\in\mathcal{L}(i,i',j)} \widetilde{sum}(L)$. By

applying Lemma 11 and Lemma 10, we get that $\widetilde{sum}^R(i,j) = sum^R(i,j)$. For an illustration, see Figure 10. □

5.5. Distribution matrices. As noted in the introduction, a subfamily of inverse Monge matrices that is of particular interest is the class of *distribution matrices*. A matrix $V = \{v_{i,j}\}$ is said to be a distribution matrix if there exists a nonnegative *density matrix* $D = \{d_{i,j}\}$ such that every entry $v_{i,j}$ in V is of the form $v_{i,j} = \sum_{k \le i} \sum_{\ell \le j} d_{k,\ell}$. In particular, if V is a distribution matrix, then the corresponding density matrix D is simply the matrix C'_V (as defined in section 3). Hence, in order to test that V is a distribution matrix, we simply run our algorithm for inverse Monge matrix on C'_V instead of C_V.

Acknowledgments. We would like to thank Noam Nisan for suggesting to examine combinatorial auctions in the context of property testing. We would also like to thank the anonymous referees for their comments which helped us improve the presentation of this paper.

LOWER BOUNDS FOR MATRIX PRODUCT*

AMIR SHPILKA†

Abstract. We prove lower bounds on the number of product gates in bilinear and quadratic circuits that compute the product of two $n \times n$ matrices over finite fields. In particular we obtain the following results:

1. We show that the number of product gates in any *bilinear* (or *quadratic*) circuit that computes the product of two $n \times n$ matrices over GF(2) is at least $3n^2 - o(n^2)$.
2. We show that the number of product gates in any *bilinear* circuit that computes the product of two $n \times n$ matrices over GF(q) is at least $(2.5 + \frac{1.5}{q^3-1})n^2 - o(n^2)$.

These results improve the former results of [N. H. Bshouty, *SIAM J. Comput.*, 18 (1989), pp. 759–765; M. Bläser, *Proceedings of the 40th Annual IEEE Symposium on Foundations of Computer Science*, IEEE Computer Society, Los Alamitos, CA, 1999, pp. 45–50], who proved lower bounds of $2.5n^2 - o(n^2)$.

Key words. matrix product, lower bounds, linear codes

1. Introduction.

The problem of computing the product of two matrices is one of the most studied computational problems. We are given two $n \times n$ matrices $x = (x_{i,j})$, $y = (y_{i,j})$, and we wish to compute their product; i.e., there are n^2 outputs, where the (i,j)th output is

$$(x \cdot y)_{i,j} = \sum_{k=1}^{n} x_{i,k} \cdot y_{k,j}.$$

In 1969, Strassen surprised the world by showing an upper bound of $O(n^{\log_2 7})$ [Str69]. This bound was later improved, and the best upper bound today is $O(n^{2.376})$ [CW90] (see also [Gat88] for a survey). The best known lower bound, $2.5n^2 - o(n^2)$, on the number of products needed to compute the function is due to [Bsh89, Bla99]. Thus the following problem is still open: Can matrix products be computed by a circuit of size $O(n^2)$?

The standard computational model for computing polynomials is the model of arithmetic circuits, i.e., circuits over the base $\{+, \cdot\}$ over some field F. This is indeed the most general model, but for matrix products two other models are usually considered, *quadratic circuits* and *bilinear circuits*. In the quadratic model we require that product gates be applied on only two linear functions. In the bilinear model we also require that product gates be applied on only two linear functions, but in addition we require that the first linear function be linear in the variables of x and that the second linear function be linear in the variables of y. These models are more restricted than the general model of arithmetic circuits. However, it is interesting to note that over infinite fields we can always assume w.l.o.g. that any circuit for a matrix product is a quadratic circuit [Str73]. In addition we note that the best circuits that

†Division of Engineering and Applied Sciences, Harvard University, and Laboratory for Computer Science, M.I.T., Cambridge, MA 02138 (amirs@deas.harvard.edu).

we have today for matrix products are bilinear circuits (except for very small values of n, where the best circuits are quadratic circuits; see [Win68, Wak70, BCS97]).

In this paper we prove that any *quadratic* circuit that computes matrix products over the field GF(2) has at least $3n^2-o(n^2)$ product gates, and that any *bilinear* circuit for matrix products over the field GF(q) must have at least $(2.5+\frac{1.5}{q^3-1})n^2-o(n^2)$ product gates.

From now on we will use the notation MP_n to denote the problem of computing the product of two $n\times n$ matrices.

1.1. Known lower bounds. In contrast to the major advances in proving upper bounds, the attempts to prove lower bounds on the size of bilinear circuits that compute MP_n were less successful. Denote by $\mathrm{q}_*^{\mathrm{F}}(\mathrm{MP}_n)$ and $\mathrm{bl}_*^{\mathrm{F}}(\mathrm{MP}_n)$ the smallest number of product gates in a quadratic circuit for MP_n, and in a bilinear circuit for MP_n, respectively, over a field F. We also denote by $\mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n)$ the total number of gates in a smallest bilinear circuit for MP_n. In 1978, Brockett and Dobkin proved that $\mathrm{bl}_*^{\mathrm{F}}(\mathrm{MP}_n)\geq 2n^2-1$ over any field F (see [BD78]). This lower bound was later generalized by Lafon and Winograd to a lower bound on $\mathrm{q}_*^{\mathrm{F}}(\mathrm{MP}_n)$ over any field [LW78]. In 1989, Bshouty showed that $\mathrm{q}_*^{\mathrm{GF}(2)}(\mathrm{MP}_n)\geq 2.5n^2-O(n\log n)$ [Bsh89]. Recently, in a series of works, Bläser managed to prove a lower bound of $2.5n^2-3n$ on $\mathrm{q}_*^{\mathrm{F}}(\mathrm{MP}_n)$ over any field [Bla99, Bla00, Bla01].

In [RS01] it is shown that any bounded depth circuit for MP_n, over any field, has a superlinear (in n^2) size. Notice, however, that the best known circuits for MP_n have depth $\Omega(\log n)$.

1.2. Bilinear rank. An important notion that is highly related to the problem of computing matrix product in bilinear circuits is the notion of bilinear rank.

A bilinear form in two sets of variables x,y is a polynomial in the variables of x and in the variables of y, which is linear in the variables of x and linear in the variables of y. Clearly each output of MP_n is a bilinear form in $x=\{x_{i,j}\}$, $y=\{y_{i,j}\}$. The bilinear rank of a set of bilinear forms $\{b_1(x,y),\ldots,b_m(x,y)\}$ is the smallest number of rank-1 bilinear forms that span $b_1,\ldots,b_m$, where a rank-1 bilinear form is a product of a linear form in the x variables and a linear form in the y variables. We denote by $\mathrm{R}_{\mathrm{F}}(b_1,\ldots,b_m)$ the bilinear rank of $\{b_1,\ldots,b_m\}$ over the field F. For further background see [BCS97, Gat88].

We denote by $\mathrm{R}_{\mathrm{F}}(\mathrm{MP}_n)$ the bilinear rank over F of the n^2 outputs of the matrix product; i.e., it is the bilinear rank of the set $\{\sum_{k=1}^{n}x_{i,k}\cdot y_{k,j}\}_{i,j}$ over F.

The following inequalities are obvious (over any field):

- $\mathrm{q}_*^{\mathrm{F}}(\mathrm{MP}_n)\leq \mathrm{bl}_*^{\mathrm{F}}(\mathrm{MP}_n)\leq 2\mathrm{q}_*^{\mathrm{F}}(\mathrm{MP}_n)$.
- $\mathrm{R}_{\mathrm{F}}(\mathrm{MP}_n)=\mathrm{bl}_*^{\mathrm{F}}(\mathrm{MP}_n)$.

The following statement is less obvious, but also not so hard to see. When n grows to infinity, $\mathrm{bl}_*^{\mathrm{F}}(\mathrm{MP}_n)$ and $\mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n)$ are (roughly) of the same order of magnitude. This statement is formulated and proved in the appendix.

1.3. Results and methods. We prove that any *quadratic* circuit that computes MP_n over the field GF(2) has at least $3n^2-o(n^2)$ product gates (i.e., $\mathrm{q}_*^{\mathrm{GF}(2)}(\mathrm{MP}_n)\geq 3n^2-o(n^2)$). We also prove that over the field GF(q) every *bilinear* circuit for MP_n must have at least $(2.5+\frac{1.5}{q^3-1})n^2-o(n^2)$ product gates (i.e., $\mathrm{bl}_*^{\mathrm{GF}(q)}(\mathrm{MP}_n)\geq (2.5+\frac{1.5}{q^3-1})n^2-o(n^2)$). Both of these results actually hold for the bilinear rank as well.

The proof of the lower bound over GF(2) is based on techniques from the theory of linear codes. However, we cannot use known results from coding theory in a

straightforward way, since we are not dealing with codes in which every two words are distant, but rather with codes on matrices in which the distance between two code words, of two matrices, is proportional to the rank of the difference of the matrices. The reduction from circuits to codes and the proof of the bound are given in section 4.

The proof of the second bound is based on a lemma proved by Bläser in [Bla99]. We prove that in the case of finite fields we can use the lemma with better parameters than those used by Bläser. This result is proved in section 5.

1.4. Organization of the paper. In section 2 we present the models of bilinear circuits and quadratic circuits. In section 3 we present some algebraic and combinatorial tools that we need for the proofs of our lower bounds.

In section 4 we introduce the notion of linear codes of matrices and prove our lower bound on bilinear and quadratic circuits that compute MP_n over $\mathrm{GF}(2)$. In section 5 we prove our lower bound on bilinear circuits that compute MP_n over $\mathrm{GF}(q)$.

Finally we discuss the limits of our techniques in section 6.

2. Arithmetic models. In this section we present the models of quadratic circuits and bilinear circuits. These are the models for which we prove our lower bounds. We first give the definition of a general arithmetic circuit. An arithmetic circuit over a field F is a directed acyclic graph as follows. Nodes of in-degree 0 are called inputs and are labeled with input variables. Nodes of out-degree 0 are called outputs. Each edge is labeled with a constant from the field, and each node other than an input is labeled with one of the operations $\{ + ; \cdot \}$; in the first case the node is a plus gate and in the second case a product gate. The computation is done in the following way. An input just computes the value of the variable that labels it. Then, if $v_1, \ldots, v_k$ are the vertices that fan into v, we multiply the result of each v_i with the value of the edge that connects it to v. If v is a plus gate, we sum all the results; otherwise v is a product gate, and we multiply all the results. Obviously the value computed by each node in the circuit is a polynomial over F in the input variables.

We are interested in the problem of computing the product of two $n \times n$ matrices, MP_n. The input consists of two $n \times n$ matrices x, y. The output is the matrix $x \cdot y$, i.e., there are n^2 outputs, and the (i,j)th output is

$$(x \cdot y)_{i,j} = \sum_{k=1}^{n} x_{i,k} \cdot y_{k,j}.$$

Each output $(x \cdot y)_{i,j}$ is hence a bilinear form in x and y.

Since each output of MP_n is a bilinear form, it is natural to consider bilinear arithmetic circuits for it. A bilinear arithmetic circuit is an arithmetic circuit with the additional restriction that product gates are applied on only two linear functions, one function linear in the variables of x and the other function linear in the variables of y. Thus, bilinear circuits have the following structure. First, there are many plus gates computing linear forms in x and linear forms in y. Then there is one level of product gates that compute bilinear forms, and finally there are many plus gates that eventually compute the outputs. We will be interested in bounding from below the number of products in any bilinear circuit for MP_n. This model is more restricted than the general model of arithmetic circuits, but we note that all the known upper bounds (over any field) for MP_n are achieved using bilinear circuits.

Another model that we will consider is the model of quadratic circuits. A quadratic circuit is an arithmetic circuit with the additional restriction that product gates are applied on only two linear functions. Notice that the only difference between quadratic

circuits and bilinear circuits is that in the quadratic model the product gates compute *quadratic forms* in x, y, whereas in the bilinear model the product gates compute *bilinear forms* in x, y. This model is more general than the model of bilinear circuits, but it is still more restricted than the general model. However, it is interesting to note that over infinite fields we can assume w.l.o.g. that any arithmetic circuit for MP_n is a quadratic circuit [Str73].

3. Algebraic and combinatorial tools. In this section we present some algebraic and combinatorial tools that we will use.

The following lemma is a weak variant of the famous Schwartz–Zippel lemma, which shows that every nonzero polynomial (nonzero as a formal expression) over a large enough field has a nonzero assignment in the field (see [Sch80, Zip79]).

LEMMA 3.1. *Let P be a polynomial of total degree d in $x_1, \ldots, x_n$ over some field* F *such that $d < |\mathrm{F}|$ and such that at least one of the coefficients of P is not zero. Then we can find an assignment, $\rho \in \mathrm{F}^n$, to the x_i's such that $P(\rho_1, \ldots, \rho_n) \neq 0$.*

We say that two polynomials p, q in n variables are equivalent over a field F if $p(x_1, \ldots, x_n) = q(x_1, \ldots, x_n)$ for any $x_1, \ldots, x_n \in \mathrm{F}$. We define $p \equiv q$ if p and q are equivalent over F. (We omit F from the notation, as the field that we are dealing with will be clear from the context.)

LEMMA 3.2. *Let P be a polynomial of total degree d in the variables $x_1, \ldots, x_n$ over a field* F*. If $P \not\equiv 0$, then we can find an assignment, $\rho \in \mathrm{F}^n$, to the x_i's such that at most d of the ρ_i's get a nonzero value and such that $P(\rho_1, \ldots, \rho_n) \neq 0$.*

Proof. P is equal (as a function) to a polynomial $\bar{P}$ in which the degree of each variable is at most $|\mathrm{F}|-1$. We call $\bar{P}$ the reduction of P; notice that the total degree of $\bar{P}$ is at most the total degree of P. Consider some monomial M in $\bar{P}$ whose coefficient is not zero. We assign all the variables that do not appear in M to zero. The resulting polynomial (after the assignment) is a polynomial in the variables of M, which is not the zero polynomial, as it is a reduced polynomial which has a monomial with a nonzero coefficient (M, of course). Therefore according to Lemma 3.1 there is some assignment to the variables of M that gives this polynomial a nonzero value. Therefore we have found an assignment which gives nonzero values only to the variables of M (and there are at most d such variables) under which $P \neq 0$. □

The following useful lemma, which is a straightforward implication of the previous lemma, is the key lemma in most of our proofs. It deals with linear forms in n^2 variables. From now on we shall think about such linear forms as linear forms in the entries of $n \times n$ matrices.

LEMMA 3.3. *Let $\mu_1, \ldots, \mu_{n^2}$ be n^2 linearly independent linear forms in n^2 variables over some field* F*. Let P be a polynomial of total degree d in kn^2 variables over* F*; i.e., we can view P as a polynomial $P(x_1, \ldots, x_k)$ in the entries of k matrices, $x_1, \ldots, x_k$, each of size $n \times n$. Assume that $P \not\equiv 0$. Then we can find k matrices $a_1, \ldots, a_k \in \mathrm{M}_n(\mathrm{F})$ such that $P(a_1, \ldots, a_k) \neq 0$ and such that there exist $n^2 - d$ linear forms among $\mu_1, \ldots, \mu_{n^2}$ that vanish on all the a_i's.*

Proof. The idea of the proof is the following. Let $b_1, \ldots, b_{n^2}$ be the dual basis of $\mu_1, \ldots, \mu_{n^2}$, i.e., a basis of $\mathrm{M}_n(\mathrm{F})$ satisfying $\forall i, j$, $\mu_i(b_j) = \delta_{i,j}$. We wish to find k matrices $a_1, \ldots, a_k$ such that $P(a_1, \ldots, a_k) \neq 0$ and such that there exist $b_{i_1}, \ldots, b_{i_d}$ that span all of them. If we manage to find such matrices, then since the b_i's are the dual basis to the μ_i's, we will get that $n^2 - d$ of the μ_i's, vanish on $a_1, \ldots, a_k$. The way to find such matrices, which are contained in the span of a small subset of the b_i's, is based on Lemma 3.2.

Thus let $b_1, \ldots, b_{n^2}$ be the dual basis to $\mu_1, \ldots, \mu_{n^2}$; i.e., $\forall i, j$, $\mu_i(b_j) = \delta_{i,j}$. We

now change the variables of P. Let $\alpha_{i,j}$, $j = 1, \ldots, k$, $i = 1, \ldots, n^2$, be a set of kn^2 variables. Define $x_j = \sum_{i=1}^{n^2} \alpha_{i,j} b_i$. Thus we can write

$$P(x_1, \ldots, x_k) = P\left(\sum_{i=1}^{n^2} \alpha_{i,1} b_i, \ldots, \sum_{i=1}^{n^2} \alpha_{i,k} b_i\right) = Q(\alpha_{1,1}, \ldots, \alpha_{n^2,k}) .$$

Thus we have that $Q \not\equiv 0$ is a polynomial in the $\alpha_{i,j}$'s of total degree at most d. Hence, according to Lemma 3.2 there exists an assignment ρ to the $\alpha_{i,j}$'s such that at most d of them get a nonzero value and such that Q is nonzero. Define $a_j = \sum_{i=1}^{n^2} \rho_{i,j} b_i$. Clearly $P(a_1, \ldots, a_k) \neq 0$. Since at most d of the $\rho_{i,j}$'s have nonzero values, we see that there are at most d b_i's such that all the a_j's are linear combinations of them. Since the b_i's are the dual basis to $\mu_1, \ldots, \mu_{n^2}$, we get that there are at least $n^2 - d$ of the μ_i's that vanish on all the a_j's. Therefore $a_1, \ldots, a_k$ satisfy the requirements of the lemma. □

The next lemma will enable us to translate properties of matrices over large fields of characteristic p to properties of matrices (of higher dimension) over $\mathrm{GF}(q)$.

LEMMA 3.4. *There exists an injective ring homomorphism* $\phi : \mathrm{GF}(q^n) \hookrightarrow \mathrm{M}_n(\mathrm{GF}(q))$. *That is, there exists a mapping* $\phi : \mathrm{GF}(q^n) \mapsto \mathrm{M}_n(\mathrm{GF}(q))$ *such that*

- ϕ *is one-to-one.*
- $\phi(1) = I$, *where* I *is the* $n \times n$ *identity matrix.*
- ϕ *is linear, i.e.,* $\forall x, y \in \mathrm{GF}(q^n)$ *we have that* $\phi(x + y) = \phi(x) + \phi(y)$.
- ϕ *is multiplicative, i.e.,* $\forall x, y \in \mathrm{GF}(q^n)$ *we have that* $\phi(xy) = \phi(x) \cdot \phi(y)$.

This homomorphism also induces a homomorphism $\mathrm{M}_k(\mathrm{GF}(q^n)) \hookrightarrow \mathrm{M}_{nk}(\mathrm{GF}(q))$.

This lemma is a standard tool in algebra, but for completeness we give the proof.

Proof. $\mathrm{GF}(q^n)$ is an n dimensional vector space over $\mathrm{GF}(q)$. Each element $x \in \mathrm{GF}(q^n)$ can be viewed as a linear transformation $x : \mathrm{GF}(q^n) \mapsto \mathrm{GF}(q^n)$ in the following way:

$$\forall y \in \mathrm{GF}(q^n), \quad x(y) = x \cdot y.$$

Clearly this is a linear transformation of $\mathrm{GF}(q^n)$ into itself, as a vector space over $\mathrm{GF}(q)$. Therefore, by picking a basis to $\mathrm{GF}(q^n)$ we can represent the linear transformation corresponding to each $x \in \mathrm{GF}(q^n)$ by a matrix $a_x \in \mathrm{M}_n(\mathrm{GF}(q))$. Thus, we have defined a mapping $\phi : \mathrm{GF}(q^n) \mapsto \mathrm{M}_n(\mathrm{GF}(q))$ such that $\phi(x) = a_x$, and it is easy to verify that this mapping is an embedding of $\mathrm{GF}(q^n)$ into $\mathrm{M}_n(\mathrm{GF}(q))$. The way to generalize it to an embedding of $\mathrm{M}_k(\mathrm{GF}(q^n))$ into $\mathrm{M}_{nk}(\mathrm{GF}(q))$ is the following. Let $a = (a_{i,j}) \in \mathrm{M}_k(\mathrm{GF}(q^n))$ be some matrix. Every entry of $a_{i,j}$ of a is some element of $\mathrm{GF}(q^n)$. We can now replace $a_{i,j}$ with the matrix $\phi(a_{i,j})$. Thus the resulting matrix will be a $kn \times kn$ matrix whose entries are in $\mathrm{GF}(q)$. Again it is easy to verify that this is indeed an embedding of $\mathrm{M}_k(\mathrm{GF}(q^n))$ into $\mathrm{M}_{nk}(\mathrm{GF}(q))$. □

In addition to the algebraic lemmas we also need the following combinatorial tools.

DEFINITION 3.5. *Let* F *be a field, and let* v, u *be two vectors in* F^m. *We denote by* $\mathbf{weight}(v)$ *the number of nonzero coordinates of* v. *Let* $\mathbf{d_H}(v, u) = \mathbf{weight}(v - u)$; *i.e.,* $\mathbf{d_H}(v, u)$ *is the number of coordinates on which* u *and* v *differ.* $\mathbf{d_H}(v, u)$ *is also known as the Hamming distance of* u *and* v. *We also denote by* $\mathbf{agree}(u, v)$ *the number of coordinates on which* u *and* v *are equal; i.e.,* $\mathbf{agree}(u, v) = m - \mathbf{d_H}(v, u)$.

The next lemma shows that if a vector space contains a set of vectors such that every pair/triplet of them disagrees on many coordinates (i.e., their Hamming distance

is large), then it is of large dimension. There are numerous similar lemmas in coding theory, and in particular the first part of our lemma is the famous Plotkin bound (see [Lin92]).

LEMMA 3.6.

1. *In every set of k vectors in $\mathrm{GF}(q)^t$ such that $q < k$ there are two vectors that agree on at least $(\frac{t}{q} - \frac{t}{k})$ coordinates.*
2. *In every set of k vectors in $\mathrm{GF}(q)^t$ such that $2q < k$ there are three vectors that agree on at least $(\frac{t}{q^2} - \frac{3t}{qk})$ coordinates.*

Proof. We begin by proving the first claim. Let $v_1, \ldots, v_k$ be k vectors in $\mathrm{GF}(q)^t$. We are going to estimate $\sum_{i<j} \mathbf{agree}(v_i, v_j)$ in two different ways. On the one hand, this sum is at most $\binom{k}{2}$ times the maximum of $\mathbf{agree}(v_i, v_j)$. On the other hand, consider a certain coordinate. For every $\alpha \in \mathrm{GF}(q)$ denote by n_α the number of vectors among the v_i's that are equal to α on this coordinate. Clearly $\sum_{\alpha=0}^{q-1} n_\alpha = k$. The contribution of this coordinate to $\sum_{i<j} \mathbf{agree}(v_i, v_j)$ is exactly $\sum_{\alpha=0}^{q-1} \binom{n_\alpha}{2}$. By convexity

$$\sum_{\alpha=0}^{q-1} \binom{n_\alpha}{2} \geq p \cdot \frac{1}{2} \cdot \frac{k}{q} \left(\frac{k}{q} - 1 \right) = \frac{k(k-q)}{2q} .$$

We get that

$$\binom{k}{2} \cdot \max_{i<j}(\mathbf{agree}(v_i, v_j)) \geq \sum_{i<j} \mathbf{agree}(v_i, v_j) \geq t \cdot \frac{k(k-q)}{2q} .$$

Therefore

$$\max_{i<j}(\mathbf{agree}(v_i, v_j)) \geq \frac{t}{q} \cdot \frac{k-q}{k-1} \geq \frac{t}{q} \cdot \frac{k-q}{k} = \frac{t}{q} - \frac{t}{k} .$$

The proof of the second claim is similar. We give two different estimates for our $\sum_{i<j<l} \mathbf{agree}(v_i, v_j, v_l)$ (the number of coordinates on which v_i, v_j, and v_l are the same). In the same manner as before we get that

$$\max_{i<j<l}(\mathbf{agree}(v_i, v_j, v_l)) \geq \frac{t}{q^2} \cdot \frac{k-q}{k-1} \cdot \frac{k-2q}{k-2} \geq \frac{t}{q^2} - \frac{3t}{qk} . \qquad \square$$

COROLLARY 3.7. *If $\mathrm{GF}(2)$ contains k vectors $v_1, \ldots, v_k$ such that $2 < k$ and $\mathbf{d_H}(v_i, v_j) \geq N \ \forall i \neq j$, then $t \geq 2N - 4\frac{N}{k+2}$.*

Proof. According to Lemma 3.6 there are two vectors, w.l.o.g. v_1 and v_2, such that $\mathbf{agree}(v_1, v_2) \geq \frac{t}{2} - \frac{t}{k}$. Since $\mathbf{d_H}(v_1, v_2) = t - \mathbf{agree}(v_1, v_2)$, we get that

$$t - \left(\frac{t}{2} - \frac{t}{k} \right) \geq \mathbf{d_H}(v_1, v_2) \geq N,$$

and the result follows. $\square$

4. Lower bound over GF(2). In this section we prove our main theorems.

THEOREM 4.1. $\mathrm{bl}_*^{\mathrm{GF}(2)}(\mathrm{MP}_n) \geq 3n^2 - O(n^{\frac{5}{3}})$ *(in other words, $\mathrm{R}_{\mathrm{GF}(2)}(\mathrm{MP}_n) \geq 3n^2 - O(n^{\frac{5}{3}})$).*

The second theorem that we shall prove is a lower bound for quadratic circuits.

THEOREM 4.2. $q_*^{GF(2)}(MP_n) \geq 3n^2 - O(n^{\frac{5}{3}})$; *i.e., the number of product gates in any quadratic circuit that computes the product of two* $n \times n$ *matrices over* GF(2) *is at least* $3n^2 - O(n^{\frac{5}{3}})$.

Clearly Theorem 4.2 implies Theorem 4.1, but we first prove Theorem 4.1, as its proof is more intuitive and simple. We begin by introducing the notion of linear codes of matrices.

4.1. Linear codes of matrices.

DEFINITION 4.3. *A linear code of matrices is a mapping*

$$\Gamma : M_n(GF(2)) \mapsto GF(2)^m$$

(for some m*) with the following properties:*

- Γ *is linear.*
- *For any matrix* a, $\mathbf{weight}(\Gamma(a)) \geq n \cdot \mathrm{rank}(a)$.

From the linearity of Γ and the requirement on $\mathbf{weight}(\Gamma(a))$ we get the following corollary.

COROLLARY 4.4. Γ *is a one-to-one mapping, and for any two matrices* a *and* b, $\mathbf{d_H}(\Gamma(\mathrm{a}), \Gamma(\mathrm{b})) \geq n \cdot \mathrm{rank}(\mathrm{a} - \mathrm{b})$.

The following theorem shows that the dimension of the range of any linear code of matrices is large (i.e., m must be large).

THEOREM 4.5. *Let* $\Gamma : M_n(GF(2)) \mapsto GF(2)^m$ *be a linear code of matrices; then* $m \geq 3n^2 - O(n^{\frac{5}{3}})$.

Proof. Define

$$\Gamma(a) = (\mu_1(a), \ldots, \mu_m(a)).$$

The proof is based on the following lemma that shows that we can find $k = n^{\frac{1}{3}}$ matrices $a_1, \ldots, a_k \in M_n(GF(2))$, with the following properties:

- $\forall i \neq j$, $a_i - a_j$ is an invertible matrix.
- There are $n^2 - \binom{k}{2}n$ linear forms among the μ_i's that vanish on all the a_i's.

We state the lemma for every $k < 2^n$, but we apply it only to $k = n^{\frac{1}{3}}$.

LEMMA 4.6. *For every* n, k *such that* $k < 2^n$, *and for any* $\mu_1, \ldots, \mu_{n^2}$ *linearly independent linear forms in* n^2 *variables, over* GF(2), *there are* k *matrices* $a_1, \ldots, a_k \in M_n(GF(2))$ *such that for every* $i \neq j$, $a_i - a_j$ *is an invertible matrix, and such that* $n^2 - \binom{k}{2}n$ *of the* μ_i*'s vanish on them.*

Proof. Consider the following polynomial P in k matrices:

$$P(a_1, \ldots, a_k) = \text{determinant} \left(\prod_{i<j} (a_i - a_j) \right).$$

Clearly a set of k matrices $a_1, \ldots, a_k$ satisfy $P(a_1, \ldots, a_k) \neq 0$ iff all the matrices $a_i - a_j$ are invertible. In addition, it is easy to see that $\deg(P) = \binom{k}{2}n$. Therefore if we show that $P \not\equiv 0$ over GF(2), then according to Lemma 3.3 we will get what we wanted to prove.

In order to show that $P \not\equiv 0$ we just have to prove the existence of k matrices such that the difference of every two of them is invertible. Lemma 3.4 assures us that we can embed the field $GF(2^n)$ into $M_n(GF(2))$. Denote this embedding by $\Phi : GF(2^n) \hookrightarrow M_n(GF(2))$. We take k distinct elements in $GF(2^n)$, $x_1, \ldots, x_k$. Their images, $\Phi(x_1), \ldots, \Phi(x_k)$, are matrices in $M_n(GF(2))$ such that the difference of every

two of them, $\Phi(x_i) - \Phi(x_j) = \Phi(x_i - x_j)$, is an invertible matrix. This is because the x_i's are distinct (i.e., $x_i - x_j \neq 0$), and every nonzero element in $\mathrm{GF}(2^n)$ is invertible. Thus, $\Phi(x_1), \ldots, \Phi(x_k)$ are exactly the k matrices that we were looking for. This concludes the proof of the lemma. □

We proceed with the proof of Theorem 4.5. Let $k = n^{\frac{1}{3}}$. Since Γ is a one-to-one mapping, there are n^2 independent linear forms among $\mu_1, \ldots, \mu_m$. Therefore we can use Lemma 4.6 and get that there are k matrices $a_1, \ldots, a_k$ such that for every $i \neq j$, $a_i - a_j$ is invertible, and such that, w.l.o.g., $\mu_{m-r+1}, \ldots, \mu_m$ vanish on $a_1, \ldots, a_k$ for some $r \geq n^2 - \binom{k}{2} n \geq n^2 - n^{\frac{5}{3}}$.

Since the last r linear forms vanish on all the a_i's, we are going to restrict our attention to only the first $m - r$ linear forms. Thus from now on we consider only $\Gamma(a_i)$ restricted to its first $m - r$ coordinates.

Since each of the differences $a_i - a_j$ $(\forall i \neq j)$ is an invertible matrix, we get that $\mathbf{d_H}(\Gamma(a_i), \Gamma(a_j)) \geq n^2$. Thus, $\Gamma(a_1), \ldots, \Gamma(a_k)$ are k vectors contained in $\mathrm{GF}(2)^{m-r}$ (we consider only their first $m - r$ coordinates!) such that the Hamming distance of every pair of them is at least n^2. Therefore according to Corollary 3.7 we get that

$$m - r \geq 2n^2 - 4\frac{n^2}{k+2} .$$

Since $r \geq n^2 - n^{\frac{5}{3}}$ and $k = n^{\frac{1}{3}}$, we get that

$$m \geq 3n^2 - O(n^{\frac{5}{3}}),$$

which is what we wanted to prove. This concludes the proof of the theorem. □

4.2. Proof of Theorem 4.1. Assume that $\mathrm{bl}_*^{\mathrm{GF}(2)}(\mathrm{MP}_n) = m$. Let C be a smallest bilinear circuit for MP_n. Let

$$\mu_1(x) \cdot \eta_1(y), \ \ldots, \ \mu_m(x) \cdot \eta_m(y)$$

be the m bilinear forms computed in the product gates of C. We will show that these bilinear forms define in a very natural way a code on $\mathrm{M}_n(\mathrm{GF}(2))$. The code thus defined will have the property that the dimension of the space, into which the code maps $\mathrm{M}_n(\mathrm{GF}(2))$, is exactly m. Thus, according to Theorem 4.5 we will get that $m \geq 3n^2 - O(n^{\frac{5}{3}})$, which is what we wanted to prove.

We begin by defining a mapping from $\mathrm{M}_n(\mathrm{GF}(2))$ to $\mathrm{GF}(2)^m$. Let $\Gamma : \mathrm{M}_n(\mathrm{GF}(2)) \mapsto \mathrm{GF}(2)^m$ be the following mapping:

$$\Gamma(x) = (\mu_1(x), \ldots, \mu_m(x)).$$

Notice that we ignore the η_i's in the definition of Γ.

LEMMA 4.7. *Γ is a linear code of matrices.*

Proof. Clearly Γ is a linear transformation from $\mathrm{M}_n(\mathrm{GF}(2))$ to $\mathrm{GF}(2)^m$. Thus we only have to prove that, for every matrix $x \in \mathrm{M}_n(\mathrm{GF}(2))$, $\mathbf{weight}(\Gamma(x)) \geq n \cdot \mathrm{rank}(x)$. Let x be a matrix of rank r. Assume w.l.o.g. that $\mu_1(x) = \cdots = \mu_k(x) = 1$ and that $\mu_{k+1}(x) = \cdots = \mu_m(x) = 0$, i.e., $\mathbf{weight}(\Gamma(x)) = k$. We shall show that $k \geq nr$. For every $y \in \mathrm{M}_n(\mathrm{GF}(2))$, the n^2 entries of $x \cdot y$ are determined by the values of $\mu_1(x) \cdot \eta_1(y), \ldots, \mu_m(x) \cdot \eta_m(y)$. Since $\mu_{k+1}(x) = \cdots = \mu_m(x) = 0$, we get that $\eta_1(y), \ldots, \eta_k(y)$ determine $x \cdot y$. Therefore there are at most 2^k different matrices of the form $x \cdot y$. Since $\mathrm{rank}(x) = r$, we get that there are exactly 2^{nr} different matrices of the form $x \cdot y$. Therefore $k \geq nr$. This concludes the proof of the lemma. □

Therefore Γ is a linear code of matrices, and so according to Theorem 4.5 we get that $m \geq 3n^2 - O(n^{\frac{5}{3}})$, which is what we wanted to prove. This concludes the proof of Theorem 4.1. □

4.3. Proof of Theorem 4.2. As in the proof of Theorem 4.1, we will show that every quadratic circuit for MP_n defines a code on $\mathrm{M}_n(\mathrm{GF}(2))$. The code thus defined will have the property that m (i.e., the dimension of the space into which the code maps $\mathrm{M}_n(\mathrm{GF}(2))$) is exactly the number of product gates in the circuit. Thus, according to Theorem 4.5 we will get that $m \geq 3n^2 - O(n^{\frac{5}{3}})$, which is what we wanted to prove.

Let C be a quadratic circuit for MP_n. Assume that the product gates of C compute the quadratic forms $\mu_1(x,y) \cdot \eta_1(x,y), \ldots, \mu_m(x,y) \cdot \eta_m(x,y)$. Thus, each of the outputs $(x \cdot y)_{i,j}$ can be written as a sum of these quadratic forms:

$$(x \cdot y)_{i,j} = \sum_{k=1}^{m} \alpha_{i,j}^{(k)} \cdot \mu_k(x,y) \cdot \eta_k(x,y),$$

where $\alpha_{i,j}^{(k)} \in \mathrm{GF}(2)$.

We would like to have a proof similar to the proof of Theorem 4.1. In that proof we defined a code of matrices using the linear transformation $\mu_1, \ldots, \mu_m$. Unfortunately that method will fail here, as μ_i is a linear function in both the variables of x and the variables of y and not just in the variables of x as in the proof of Theorem 4.1. In order to overcome this obstacle we introduce a new set of variables $z = \{z_{i,j}\}_{i,j=1,\ldots,n}$. We think about z as an $n \times n$ matrix. Define the following m linear forms in z:

$$\gamma_k(z) = \sum_{i,j} \alpha_{i,j}^{(k)} z_{i,j}, \quad k = 1, \ldots, m.$$

We get that

$$\begin{aligned}
&\sum_{k=1}^{m} \mu_k(x,y) \cdot \eta_k(x,y) \cdot \gamma_k(z) \\
&= \sum_{k=1}^{m} \left(\sum_{i,j} z_{i,j} \cdot \alpha_{i,j}^{(k)} \right) \cdot \mu_k(x,y) \cdot \eta_k(x,y) \\
&= \sum_{i,j} z_{i,j} \sum_{k=1}^{m} \alpha_{i,j}^{(k)} \cdot \mu_k(x,y) \cdot \eta_k(x,y) \qquad (4.1) \\
&= \sum_{i,j} z_{i,j} \cdot (x \cdot y)_{i,j} = \mathbf{trace}(x \cdot y \cdot z^t),
\end{aligned}$$

where $(z^t)_{i,j} = z_{j,i}$. The computation just performed shows that the γ_k's that we introduced are quite natural. We also notice that z plays the same role in $\mathbf{trace}(x \cdot y \cdot z^t)$ as do x and y. These observations motivate us to try to repeat the proof of Theorem 4.1 using the γ_k's instead of the μ_i's.

Define a linear mapping $\Gamma : \mathrm{M}_n(\mathrm{GF}(2)) \mapsto \mathrm{GF}(2)^m$ by

$$\Gamma(z) = (\gamma_1(z), \ldots, \gamma_m(z)).$$

LEMMA 4.8. *Γ is a linear code of matrices.*

Proof. Clearly Γ is a linear mapping. So we have to prove only the claim about the weights. Let z_0 be a matrix of rank r, and assume w.l.o.g. that $\gamma_1(z_0) = \cdots = \gamma_k(z_0) = 1$ and $\gamma_{k+1}(z_0) = \cdots = \gamma_m(z_0) = 0$. We wish to prove that $k \geq nr$. From (4.1) we get that

$$\mathbf{trace}(x \cdot y \cdot {z_0}^t) = \sum_{h=1}^{k} \mu_h(x,y) \cdot \eta_h(x,y).$$

We now consider the discrete derivatives of this equation. Let $e_{i,j}$ be the matrix of all zeros but one in the (i,j)th place. Define

$$\frac{\partial}{\partial x_{i,j}} \mathbf{trace}(x \cdot y \cdot {z_0}^t) \stackrel{\text{def}}{=} \mathbf{trace}((x + e_{i,j}) \cdot y \cdot {z_0}^t) - \mathbf{trace}(x \cdot y \cdot {z_0}^t).$$

On the one hand,

$$\mathbf{trace}((x + e_{i,j}) \cdot y \cdot {z_0}^t) - \mathbf{trace}(x \cdot y \cdot {z_0}^t) = \mathbf{trace}(e_{i,j} \cdot y \cdot {z_0}^t) = (z_0 \cdot y^t)_{i,j}.$$

On the other hand, we have that

$$\mathbf{trace}((x + e_{i,j}) \cdot y \cdot {z_0}^t) - \mathbf{trace}(x \cdot y \cdot {z_0}^t)$$

$$= \sum_{h=1}^{k} (\mu_h(x + e_{i,j}, y) \cdot \eta_h(x + e_{i,j}, y) - \mu_h(x,y) \cdot \eta_h(x,y))$$

$$= \sum_{h=1}^{k} (\mu_h(e_{i,j}, 0) \cdot \eta_h(x,y) + \mu_h(x,y) \cdot \eta_h(e_{i,j}, 0)) \tag{4.2}$$

$$+ \sum_{h=1}^{k} \mu_h(e_{i,j}, 0) \cdot \eta_h(e_{i,j}, 0),$$

where the last equality follows from the linearity of the μ_h's and the η_h's. Since $(z_0 \cdot y^t)_{i,j}$ is a linear form in y, we actually get that

$$(z_0 \cdot y^t)_{i,j} = \frac{\partial}{\partial x_{i,j}} \mathbf{trace}(x \cdot y \cdot {z_0}^t)$$

$$= \sum_{h=1}^{k} (\mu_h(e_{i,j}, 0) \cdot \eta_h(x,y) + \mu_h(x,y) \cdot \eta_h(e_{i,j}, 0))$$

$$\in \mathbf{span}(\mu_h(x,y),\ \eta_h(x,y))$$

in the vector space of all linear forms in x, y. (Since $(z_0 \cdot y^t)_{i,j}$ is a linear form, the third summand of (4.2) sums to 0.) In the same manner we define

$$\frac{\partial}{\partial y_{i,j}}\mathbf{trace}(x \cdot y \cdot {z_0}^t) \stackrel{\text{def}}{=} \mathbf{trace}(x \cdot (y + e_{i,j}) \cdot {z_0}^t) - \mathbf{trace}(x \cdot y \cdot {z_0}^t).$$

We get that

$$(x^t \cdot z_0)_{i,j} = \frac{\partial}{\partial y_{i,j}}\mathbf{trace}(x \cdot y \cdot {z_0}^t)$$

$$= \sum_{h=1}^{k}(\mu_h(0, e_{i,j}) \cdot \eta_h(x, y) + \mu_h(x, y) \cdot \eta_h(0, e_{i,j}))$$

$$\in \mathbf{span}(\mu_h(x, y),\ \eta_h(x, y)).$$

Denote by PD the set of all the discrete partial derivatives

$$\left\{\frac{\partial}{\partial x_{i,j}}\mathbf{trace}(x \cdot y \cdot {z_0}^t), \frac{\partial}{\partial y_{i,j}}\mathbf{trace}(x \cdot y \cdot {z_0}^t)\right\}_{i,j}.$$

We just proved that PD is contained in the linear span of

$$\{\mu_h(x, y),\ \eta_h(x, y)\}_{h=1}^{k}.$$

Therefore

$$\dim(\mathbf{span}(\mathrm{PD})) \le \dim(\mathbf{span}\{\mu_h(x, y),\ \eta_h(x, y)\}_{h=1}^{k}) \le 2k. \tag{4.3}$$

We also showed that

$$\left\{\frac{\partial}{\partial x_{i,j}}\mathbf{trace}(x \cdot y \cdot {z_0}^t), \frac{\partial}{\partial y_{i,j}}\mathbf{trace}(x \cdot y \cdot {z_0}^t)\right\}_{i,j}$$

$$= \left\{(x^t \cdot z_0)_{i,j},\ (z_0 \cdot y^t)_{i,j}\right\}_{i,j}.$$

Therefore, using our assumption that $\mathrm{rank}(z_0) = r$, we get that

$$\dim(\mathbf{span}(\mathrm{PD})) = \dim(\mathbf{span}\left\{(x^t \cdot z_0)_{i,j},\ (z_0 \cdot y^t)_{i,j}\right\}_{i,j}) = 2nr. \tag{4.4}$$

Combining (4.3) and (4.4), we get that $2k \ge 2nr$. □

Theorem 4.2 now follows from applying Theorem 4.5 to the linear code of matrices Γ. □

5. Other finite fields. In this section we prove the following theorem.

THEOREM 5.1. *The number of product gates in any bilinear circuit that computes the product of two $n \times n$ matrices over* $\mathrm{GF}(q)$ *is at least* $(2.5 + \frac{1.5}{q^3-1})n^2 - O(n^{\frac{7}{4}})$ *(i.e.,* $\mathrm{bl}_*^{\mathrm{GF}(q)}(\mathrm{MP}_n) \ge (2.5 + \frac{1.5}{q^3-1})n^2 - O(n^{\frac{7}{4}})$ *over* $\mathrm{GF}(q)$*).*

Let C be a bilinear circuit for MP_n over $\mathrm{GF}(q)$. Assume that $\mu_1(x) \cdot \eta_1(y), \ldots, \mu_m(x) \cdot \eta_m(y)$ are the bilinear forms computed in the product gates of C. The following lemma of Bläser is the main tool in the proof of the theorem.

LEMMA 5.2 (see [Bla99]). *Let $[a,b] = ab - ba$. If there are two matrices a, b such that $[a,b]$ is an invertible matrix and such that there are t linear forms among $\mu_1, \ldots, \mu_m$ such that each of them vanishes on I, a, b, then $m \geq t + 1.5n^2$.*

We are going to prove that we can find a, b such that $(1 - \frac{1}{q^3})n^2 + \frac{m}{q^3} - O(n^{\frac{7}{4}})$ linear forms among $\mu_1, \ldots, \mu_m$ vanish on I, a, b and such that $[a,b]$ is invertible.

We are going to prove the theorem only for n even. (This certainly implies the lower bound for odd n as well.) Thus from now on we assume that *n is an even number*.

Proof of Theorem 5.1. We begin by proving that (w.l.o.g.) many of the μ_i's vanish on I. The following lemma shows that we can always find an invertible matrix such that many of the μ_i's vanish on it. As before, we assume that $\mu_1, \ldots, \mu_{n^2}$ are independent linear forms.

LEMMA 5.3. *There exists an invertible matrix c such that at least $(1 - \frac{1}{q})n^2 + \frac{m}{q} - O(n^{\frac{5}{3}})$ of the μ_i's vanish on it, where $n^2 - O(n^{\frac{5}{3}})$ of the μ_i's that vanish on it are among $\mu_1, \ldots, \mu_{n^2}$.*

In the proof of the lemma we assume for simplicity that $n^2 < m < 10n^2$, as it will not change the results.

Proof. An analogue of Lemma 4.6 over $\mathrm{GF}(q)$ guarantees that we can find $k = n^{\frac{1}{3}}$ matrices $a_1, \ldots, a_k \in \mathrm{M}_n(\mathrm{GF}(q))$ such that for $i \neq j$, $a_i - a_j$ is invertible and such that $n^2 - \binom{k}{2}n$ linear forms among $\mu_1, \ldots, \mu_{n^2}$ vanish on all of the a_i's. Define $r = n^2 - \binom{k}{2}n$, and assume w.l.o.g. that $\mu_1, \ldots, \mu_r$ vanish on all the a_i's.

Let us consider the following k vectors in $\mathrm{GF}(q)^{m-r}$:

$$\Gamma(a_i) \stackrel{\mathrm{def}}{=} (\mu_{r+1}(a_i), \ldots, \mu_m(a_i)), \quad i = 1, \ldots, k\ .$$

As in the proof of Theorem 4.1, we get that since $a_i - a_j$ is an invertible matrix $\forall i \neq j$, then $\mathbf{d_H}(\Gamma(a_i), \Gamma(a_j)) \geq n^2$. According to Lemma 3.6, two of these vectors agree on at least $\frac{m-r}{q} - \frac{m-r}{k}$ coordinates. Assume that $\Gamma(a_1)$ and $\Gamma(a_2)$ are these vectors. Define $c = a_1 - a_2$. We have that c is an invertible matrix such that the first $r = n^2 - \binom{k}{2}n$ linear forms (which are independent) vanish on it and such that all the linear forms that $\Gamma(a_1)$ and $\Gamma(a_2)$ agree on vanish on it as well. Therefore there are at least

$$r + \frac{m-r}{q} - \frac{m-r}{k}$$

linear forms that vanish on c. Since $r = n^2 - \binom{k}{2}n$ and $k = n^{\frac{1}{3}}$, we get that at least

$$\left(1 - \frac{1}{q}\right)n^2 + \frac{m}{q} - O(n^{\frac{5}{3}})$$

linear forms vanish on c, and $n^2 - O(n^{\frac{5}{3}})$ of them are among $\mu_1, \ldots, \mu_{n^2}$. This completes the proof of the lemma. ∎

Lemma 5.3 does not specify c, but using the *sandwiching method* (see below), we can assume that $c = I$: We know that $x \cdot y$ is computed using the bilinear forms

$$\mu_1(x) \cdot \eta_1(y), \ldots, \mu_m(x) \cdot \eta_m(y).$$

We now do the following trick: $x \cdot y = (x \cdot c) \cdot (c^{-1} \cdot y)$; therefore $x \cdot y$ can be computed using the bilinear forms

$$\tilde{\mu_1}(x) \cdot \tilde{\eta_1}(y), \ldots, \tilde{\mu_m}(x) \cdot \tilde{\eta_m}(y),$$

where

$$\tilde{\mu_i}(x) \stackrel{\text{def}}{=} \mu_i(x \cdot c) \quad \text{and} \quad \tilde{\eta_i}(y) \stackrel{\text{def}}{=} \eta_i(c^{-1} \cdot y).$$

Thus, if $\mu_i(c) = 0$, then we get that $\tilde{\mu_i}(I) = \mu_i(I \cdot c) = 0$. This trick is called sandwiching; for further background, see [Bla99, Gro78].

Thus, by combining the sandwiching method and Lemma 5.3, we get that we can assume w.l.o.g. that $(1 - \frac{1}{q})n^2 + \frac{m}{q} - O(n^{\frac{5}{3}})$ of the μ_i's, where $n^2 - O(n^{\frac{5}{3}})$ of them are among $\mu_1, \ldots, \mu_{n^2}$, vanish on I. The next lemma now assures us that we can find two matrices a, b that satisfy the requirements of Lemma 5.2.

LEMMA 5.4. *There are two matrices a, b such that $[a, b]$ is an invertible matrix and such that at least $(1 - \frac{1}{q^3})n^2 + \frac{m}{q^3} - O(n^{\frac{7}{4}})$ of the μ_i's vanish on I, a, b.*

Proof. The proof of this lemma is similar to the proof of Lemma 5.3. Let $k = n^{\frac{1}{4}}$. The following lemma shows that we can find k matrices such that many of the μ_i's vanish on all of them and such that among their differences there are matrices satisfying the requirements of Lemma 5.2.

LEMMA 5.5. *For every n, k such that $q^{\frac{n}{2}} > 4\binom{k}{3}$, and for any $\mu_1, \ldots, \mu_{n^2}$ linearly independent linear forms, in n^2 variables, over $\mathrm{GF}(q)$, there are k matrices $a_1, \ldots, a_k$ such that $\forall i < j < l$, $[a_i - a_l, a_j - a_l]$ is invertible and such that $n^2 - 2\binom{k}{3}n$ of the μ_i's vanish on all the a_i's.*

Proof. Again we use Lemma 3.3. Let P be the following polynomial:

$$P(a_1, \ldots, a_k) = \text{determinant}\left(\prod_{i<j<l} [a_i - a_l, a_j - a_l]\right).$$

Clearly $\deg(P) = 2\binom{k}{3}n$ (as a polynomial in the entries of the a_i's). Therefore if we prove that $P \not\equiv 0$, i.e., that there exist k matrices on which P is not zero, then according to Lemma 3.3 we are done. This is guaranteed by the following lemma.

LEMMA 5.6. *If $q^{\frac{n}{2}} > 4\binom{k}{3}$, then there exist k matrices in $\mathrm{M}_n(\mathrm{GF}(q))$, $a_1, \ldots, a_k$, such that $\forall i < j < l$, $[a_i - a_l, a_j - a_l]$ is invertible.*

This lemma is the reason that we assume that n is even. We do not know how to prove it for odd values of n.

Proof. Consider the following polynomial in $\mathbf{4k}$ variables (i.e., a polynomial in k matrices over $\mathrm{M}_{\mathbf{2}}(\mathrm{GF}(\mathbf{q}^{\frac{\mathbf{n}}{\mathbf{2}}}))$!):

$$Q(x_1, \ldots, x_k) = \text{determinant}\left(\prod_{i<j<l} [x_i - x_l, x_j - x_l]\right).$$

Q is a polynomial of degree $d = 4\binom{k}{3}$ over $\mathrm{GF}(q)$ in the entries of the a_i's. Clearly Q is not the zero polynomial (as it is a product of nonzero polynomials). Consider the field $F = \mathrm{GF}(q^{\frac{n}{2}})$. Since $d < |\mathrm{F}|$, we get by Lemma 3.1 that there are k matrices $\rho_1, \ldots, \rho_k \in \mathrm{M}_2(F)$ such that $Q(\rho_1, \ldots, \rho_k) \neq 0$. That is, $\forall i < j < l$, $[\rho_i - \rho_l, \rho_j - \rho_l]$ is an invertible matrix. According to Lemma 3.4 we can embed $\mathrm{M}_2(F)$ in $\mathrm{M}_n(\mathrm{GF}(q))$. Therefore there are k matrices in $\mathrm{M}_n(\mathrm{GF}(q))$ satisfying $\forall i < j < l$, $[a_i - a_l, a_j - a_l]$ is an invertible matrix, which is what we wanted to prove. □

This concludes the proof of Lemma 5.5. □

We proceed with the proof of Lemma 5.4. We now restrict our attention to the linear forms among $\mu_{n^2+1}, \ldots, \mu_m$ that vanish on I. We shall prove that three of the matrices guaranteed by Lemma 5.5 agree on many of these linear forms (more

formally on $\frac{m-n^2}{q^3} - O(n^{\frac{7}{4}})$ of them). Thus, if a_1, a_2, a_3 are these three matrices, then we get that $(1-\frac{1}{q^3})n^2 + \frac{m}{q^3} - O(n^{\frac{7}{4}})$ linear forms vanish on I, $(a_1 - a_3)$, $(a_2 - a_3)$, and that $[(a_1 - a_3), (a_2 - a_3)]$ is an invertible matrix, which is what we wanted to prove.

Assume w.l.o.g. that the linear forms $\mu_{n^2+1}, \ldots, \mu_{n^2+r}$ vanish on I (beside those among $\mu_1, \ldots, \mu_{n^2}$ that vanish on it), where $r \geq \frac{m-n^2}{q} - O(n^{\frac{5}{3}})$. Let $a_1, \ldots, a_k$ be the matrices guaranteed by Lemma 5.5. Consider the following vectors: $\forall 1 \leq i \leq k$,

$$v_i = (\mu_{n^2+1}(a_i), \ldots, \mu_{n^2+r}(a_i)) \in \mathrm{GF}(q)^r \ .$$

According to Lemma 3.6 three of these vectors, namely v_1, v_2, v_3, agree on at least $\frac{r}{q^2} - \frac{3r}{qk}$ coordinates. Therefore there are $\frac{r}{q^2} - \frac{3r}{qk}$ linear forms among $\mu_{n^2+1}, \ldots, \mu_{n^2+r}$ that vanish on $a_1 - a_3$ and $a_2 - a_3$. In addition there are $n^2 - 2\binom{k}{3}n$ linear forms among $\mu_1, \ldots, \mu_{n^2}$ that vanish on a_1, a_2, a_3; hence there are $n^2 - 2\binom{k}{3}n$ linear forms among $\mu_1, \ldots, \mu_{n^2}$ that vanish on $a_1 - a_3$ and on $a_2 - a_3$. Let $a = a_1 - a_3$, $b = a_2 - a_3$.

We get that there are $\frac{r}{q^2} - \frac{3r}{qk}$ linear forms among $\mu_{n^2+1}, \ldots, \mu_{n^2+r}$ that vanish on I, a, b. Since $n^2 - O(n^{\frac{5}{3}})$ of the first n^2 μ_i's vanish on I, we get that at least $n^2 - 2\binom{k}{3}n - O(n^{\frac{5}{3}})$ of the first n^2 μ_i's vanish on I, a, b. Putting it all together, we get that at least

$$n^2 - 2\binom{k}{3}n - O(n^{\frac{5}{3}}) + \frac{r}{q^2} - \frac{3r}{qk}$$

linear forms among $\mu_1, \ldots, \mu_m$ vanish on I, a, b. Since $r \geq \frac{m-n^2}{q} - O(n^{\frac{5}{3}})$ and $k = n^{\frac{1}{4}}$, we get that at least

$$\left(1 - \frac{1}{q^3}\right) n^2 + \frac{m}{q^3} - O(n^{\frac{7}{4}})$$

of the μ_i's vanish on I, a, b as well. This concludes the proof of Lemma 5.4. □

Putting everything together, we get by Lemmas 5.2 and 5.4 that

$$m \geq 1.5n^2 + \left(1 - \frac{1}{q^3}\right) n^2 + \frac{m}{q^3} - O(n^{\frac{7}{4}}).$$

Therefore

$$m \geq \left(2.5 + \frac{1.5}{q^3 - 1}\right) n^2 - O(n^{\frac{7}{4}}).$$

This concludes the proof of Theorem 5.1. □

6. Limits of our technique. The proof of our lower bound over GF(2) was based on a coding theoretic argument. We claimed that every code with a certain rate and minimal distance must have high length (Theorem 4.5). This lower bound implied the lower bound for bilinear circuits over GF(2). We also notice that any improvement of the lower bound in the theorem will improve, in the same way, our lower bound for bilinear circuits. The best techniques today are due to McEliece et al. [MRRW77], which yield a lower bound of $\approx m \geq 3.57n^2$ on the minimal m for which there is a linear code from $\mathrm{GF}(2)^{n^2}$ to $\mathrm{GF}(2)^m$, of minimal distance n^2. Since any such linear code also gives a code of matrices, we cannot hope to prove anything better than $m \geq 3.57n^2$ (unless we improve on [MRRW77], which is a major open

problem). On the other hand, we know that there are such linear codes with, say, $m < 5n^2$ (e.g., random linear codes). So even if we do improve on [MRRW77], we cannot prove any lower bound better than $5n^2$. Thus, new techniques are needed in order to prove better lower bounds.

Appendix. On the relation between $\mathbf{bl}_*^{\mathbf{F}}(\mathbf{MP}_n)$ and $\mathbf{bl}_{\mathbf{tot}}^{\mathbf{F}}(\mathbf{MP}_n)$.

THEOREM A.1. *If for some n_0 there exists a bilinear circuit that computes the product of two $n_0 \times n_0$ matrices over* F*, with ${n_0}^{2+w}$ multiplications and t additions, then for a large enough n we have that* $\mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n) = O(n^{2+w})$.

A similar claim was first proved by Strassen [Str69]. We give the proof for completeness (see also [BCS97, Proposition 15.1]).

Proof. The idea of the proof is to use Strassen's recursion method. Assume that we have a bilinear circuit that computes the product of two $n_0 \times n_0$ matrices and has m multiplication gates and t plus gates. Then, given two $n \times n$ matrices ($n \gg n_0$) X and Y, we partition each of them into ${n_0}^2$ submatrices of size $\frac{n}{n_0} \times \frac{n}{n_0}$ each. We now think about X, Y as matrices of size $n_0 \times n_0$, whose elements come from the ring of matrices. For clearance we denote by $\tilde{X}$ and $\tilde{Y}$ the matrices X and Y when we think about them as $n_0 \times n_0$ matrices whose elements are also matrices. In order to compute $X \cdot Y$ we apply the bilinear circuit for computing the product of two $n_0 \times n_0$ matrices on the input $\tilde{X}, \tilde{Y}$. When we have to compute a product of the form $\tilde{X}_{i,j} \cdot \tilde{Y}_{k,l}$, we recursively compute the product of the relevant $\frac{n}{n_o} \times \frac{n}{n_0}$ matrices. Whenever we have to compute a plus gate (which now adds two $\frac{n}{n_0} \times \frac{n}{n_0}$ matrices), we compute all the relevant $(\frac{n}{n_0})^2$ sums. We thus have the following recursion formula:

$$\mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n) \le m \cdot \mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_{\frac{n}{n_0}}) + t \cdot \left(\frac{n}{n_0}\right)^2 .$$

Hence

$$\mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n) \le m^{\frac{\log n}{\log n_0}} + t \cdot \frac{n^2}{{n_0}^2} \cdot \frac{\left(\frac{m}{{n_0}^2}\right)^{\frac{\log n}{\log n_0}} - 1}{\frac{m}{{n_0}^2} - 1} .$$

Thus, if $m = (n_0)^{2+w}$ and t is arbitrary, then we get

$$\mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n) \le n^{2+w} + t \cdot \frac{n^2}{{n_o}^2} \cdot \frac{n^w - 1}{{n_0}^w - 1} = O(n^{2+w}) . \qquad \square$$

As a corollary we get that the exponents of the total complexity and of the multiplicative complexity of matrix multiplication are the same. Formally let

$$\omega^{\mathrm{tot}}(F) = \inf\{\tau \in \mathbb{R} \mid \mathrm{bl}_{\mathrm{tot}}^{\mathrm{F}}(\mathrm{MP}_n) = O(n^\tau)\}$$

and

$$\omega^*(F) = \inf\{\tau \in \mathbb{R} \mid \mathrm{bl}_*^{\mathrm{F}}(\mathrm{MP}_n) = O(n^\tau)\}.$$

Then the above theorem implies that $\omega^{\mathrm{tot}}(F) = \omega^*(F)$.

Acknowledgments. I would like to thank Michael Ben-Or and Avi Wigderson for helpful conversations, and Ran Raz for commenting on an earlier draft of the paper. I would also like to thank the anonymous referees for their comments and for bringing [Win68, Wak70] to my attention.

SEARCHING FOR SORTED SEQUENCES OF KINGS IN TOURNAMENTS*

JIAN SHEN†, LI SHENG‡, AND JIE WU§

Abstract. A *tournament* T_n is an orientation of a complete graph on n vertices. A *king* in a tournament is a vertex from which every other vertex is reachable by a path of length at most 2. A *sorted sequence of kings* in a tournament T_n is an ordered list of its vertices $u_1, u_2, \ldots, u_n$ such that u_i dominates u_{i+1} ($u_i \to u_{i+1}$) and u_i is a king in the subtournament induced by $\{u_j : i \le j \le n\}$ for each $i = 1, 2, \ldots, n-1$. In particular, if T_n is transitive, searching for a sorted sequence of kings in T_n is equivalent to sorting a set of n numbers. In this paper, we try to find a sorted sequence of kings in a general tournament by asking the following type of binary question: "What is the orientation of the edge between two specified vertices u, v?" The *cost* for finding a sorted sequence of kings is the minimum number of binary questions asked in order to guarantee the finding of a sorted sequence of kings. Using an adversary argument proposed in this paper, we show that the cost for finding a sorted sequence of kings in T_n is $\Theta(n^{3/2})$ in the worst case, thus settling the order of magnitude of this question. We also show that the cost for finding a king in T_n is $\Omega(n^{4/3})$ and $O(n^{3/2})$ in the worst case. Finally, we show a connection between a sorted sequence of kings and a median order in a tournament.

1. Introduction.

A *digraph* $G = (V, E)$ contains a vertex set V and an edge set E, where each edge contains a tail u and a head v (and thus the orientation $u \to v$). For a vertex u in G, the *outdegree* $d^+(G, u)$ of u is the number of edges with tail u, and the *indegree* $d^-(G, u)$ of u is the number of edges with head u. We will use $d^+(u)$ and $d^-(u)$ to denote $d^+(G, u)$ and $d^-(G, u)$, respectively, if G is specified from the context. A *tournament* T_n is an orientation of a complete graph on n vertices; that is, between any two distinct vertices u, v, there is exactly one edge: either $u \to v$ or $v \to u$ (but not both). This concept is used to model a tournament of n players where every two players compete in a game and player u beats player v if and only if the vertex u dominates the vertex v ($u \to v$) in T_n. (Suppose no game has a draw.) A vertex u is called a *king* in T_n if every other vertex is reachable from u by a path of length at most 2; that is, for each $v \neq u$, either $u \to v$ or $u \to w \to v$ for some vertex w dependent of v. It is known [11] that a vertex with the maximum outdegree is always a king in T_n. A *sorted sequence of kings* in T_n is an ordered list of its vertices $u_1, u_2, \ldots, u_n$ such that $u_i \to u_{i+1}$ and u_i is a king in the subtournament induced by $\{u_j : i \le j \le n\}$ for each $i = 1, 2, \ldots, n-1$. In particular, if T_n is *transitive* (that is, $u \to v$ and $v \to w$ imply $u \to w$), searching for a sorted sequence of kings in T_n is

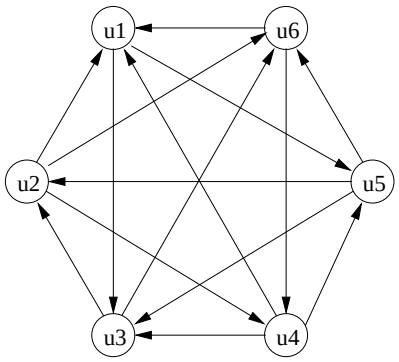

FIG. 1. *A sample tournament.*

equivalent to sorting a set of n numbers.

The existence of a sorted sequence of kings in any tournament was shown by Lou, Wu, and Sheng in [7], where an insertion sort algorithm with the worst case complexity of $O(n^3)$ was presented. A modified insertion sort algorithm with the worst case complexity of $O(n^2)$ was given by Wu and Sheng in [12]. It is easy to prove that a tournament has a unique sorted sequence of kings if and only if it is transitive. Thus in a general tournament the sorted sequence of kings is not unique. For example, Figure 1 shows the graph representation of a tournament. One sorted sequence of kings of the tournament is $u_2 \to u_4 \to u_1 \to u_5 \to u_3 \to u_6$, and another one is $u_2 \to u_6 \to u_4 \to u_1 \to u_5 \to u_3$.

In this paper, we try to find a sorted sequence of kings in T_n by asking the following type of binary question: "What is the orientation of the edge between two specified vertices u, v?" The *cost* for finding a sorted sequence of kings is the minimum number of questions asked in order to guarantee the finding of a sorted sequence of kings. In particular, if we are told that T_n is transitive, the worst case cost for finding a sorted sequence of kings in T_n is $\Theta(n \log n)$, which is the number of comparisons needed to sort n numbers in the worst case. We set to determine the worst case cost for finding a sorted sequence of kings in T_n (which may not be transitive).

For a vertex u in a digraph, let $\Gamma^+(u) = \{v : u \to v\}$ be the *first out-neighborhood* of u, $\Gamma^{++}(u) = \{w : u \to v \to w \text{ for some } v\} \setminus \Gamma^+(u)$ be the *second out-neighborhood* of u, and $\Gamma^-(u) = \{v : v \to u\}$ be the *first in-neighborhood* of u. The following lemma follows easily from the fact that each vertex in $\Gamma^+(u)$ is reachable from each vertex in $\Gamma^-(u)$ by a path of length at most 2.

LEMMA 1. *For a vertex u in T_n, let $u_1, \ldots, u_t$ be a sorted sequence of kings in the subtournament of T_n induced by $\Gamma^-(u)$, and let $u_{t+2}, \ldots, u_n$ be a sorted sequence of kings in the subtournament of T_n induced by $\Gamma^+(u)$. Then $u_1, \ldots, u_t, u, u_{t+2}, \ldots, u_n$ form a sorted sequence of kings in T_n. In particular, u_1 is a king in T_n.*

One can apply the above lemma recursively to obtain a *divide-and-conquer algorithm* for the search of a sorted sequence of kings in T_n as follows:

1. Choose a pivot vertex u arbitrarily.
2. Use $n-1$ questions to find the edge orientation between u and every other vertex, and thus obtain $\Gamma^-(u)$ and $\Gamma^+(u)$.
3. Apply the procedure recursively to $\Gamma^-(u)$ and $\Gamma^+(u)$.
4. Chain the outcomes of $\Gamma^-(u)$ and $\Gamma^+(u)$ with u in the way provided by Lemma 1.

This divide-and-conquer algorithm performs similarly to *quick sort*. It is known that quick sort has an average case performance of $\Theta(n \log n)$ and the worst case performance of $\Theta(n^2)$. The average cost for finding a sorted sequence of kings by using the above divide-and-conquer algorithm is satisfactory ($\Theta(n \log n)$) since it is equivalent to applying quick sort to n numbers [2]. On the other hand, the worst case cost by using this algorithm is $n(n-1)/2$ if at each stage of divide-and-conquer either $\Gamma^+(u)$ or $\Gamma^-(u)$ is the empty set. Similarly, one can also have a divide-and-conquer algorithm to search for a king in T_n with a satisfactory average cost of $\Theta(n \log n)$ and the worst case cost of $n(n-1)/2$. The motivation of this paper is to provide alternative algorithms for the search of a king and a sorted sequence of kings, respectively, in the case that avoiding the above mentioned worst case is crucial. We achieve this goal with some sacrifice in the average performance.

Let $f(n)$ and $g(n)$ be the cost in the worst case for finding a king and a sorted sequence of kings, respectively, in T_n. Using an adversary argument proposed in this paper, we prove that

$$\frac{\sqrt{3}}{3}(n-1)^{3/2} - \frac{3}{2}n \le g(n) \le \frac{8\sqrt{2}}{3}n^{3/2} + 25n^{5/4}.$$

Therefore, the worst case asymptotic cost for finding a sorted sequence of kings in T_n is $\Theta(n^{3/2})$. We also prove that

$$\frac{3\sqrt[3]{2}}{4}(n-1)^{4/3} - \frac{3}{2}(n-1) \le f(n) \le \frac{4\sqrt{2}}{3}n^{3/2}.$$

That is, the worst case asymptotic cost for finding a king in T_n is $\Omega(n^{4/3})$ and $O(n^{3/2})$. Our proofs for both upper bounds provide algorithms for finding a king and a sorted sequence of kings, respectively, in T_n both with a complexity of $O(n^{3/2})$. To prove the lower bounds for $f(n)$ and $g(n)$, we design a pro-small-outdegree-strategy for an *adversary argument* [5]. We prove that if the adversary uses this strategy, no algorithms can succeed with cost smaller than the above mentioned lower bounds in the worst case.

The paper is organized as follows. Section 2 introduces the idea of improving the worst cast performance with the sacrifice of the average performance, presents a pro-small-outdegree-strategy for the use of an adversary argument, and uses both ideas to prove an upper bound and a lower bound, respectively, for the worst case cost for finding a king in T_n. Section 3 is devoted to the proof that the worst case asymptotic cost for finding a sorted sequence of kings in T_n is $\Theta(n^{3/2})$. Section 4 shows a connection between a sorted sequence of kings and a median order in a tournament. Section 5 concludes the paper and raises two open problems.

2. Worst case cost for finding a king. If one uses the divide-and-conquer algorithm introduced in the previous section to search for a king in T_n, the worst case happens when $\Gamma^+(u) = \emptyset$ at each stage of divide-and-conquer. So in order to avoid the worst case, one should carefully choose a pivot vertex u with $\Gamma^+(u)$ large enough at each stage of divide-and-conquer. If we merge this idea into the divide-and-conquer algorithm, we call it the *revised-divide-and-conquer algorithm*. For this purpose, we need the following lemma for the choice of a pivot vertex.

LEMMA 2 (Landau [6]). *Suppose $d_1^+ \le d_2^+ \le \cdots \le d_n^+$ is the outdegree sequence of T_n. Then, for each i,*

$$\frac{i-1}{2} \le d_i^+ \le \frac{n+i-2}{2}.$$

A simple idea to use a revised-divide-and-conquer algorithm to prove $f(n) = O(n^{3/2})$ is as follows. First, we can use n questions to obtain the orientation of all edges in a subtournament of roughly $\sqrt{2n}$ vertices. (Note that this part is the sacrifice of the average performance.) We choose a vertex with the maximum outdegree in this subtournament as the pivot vertex to apply Lemma 1. Then, at each stage of divide-and-conquer, at least $\sqrt{2n}/2$ vertices are eliminated with a total cost of $\binom{\sqrt{2n}}{2} + n - \sqrt{2n} < 2n$. Once the size of remaining vertices is sufficiently small, say $\sqrt{2n}/2$, use the direct method to find a king. Thus eliminating $n-1$ vertices with a king remaining costs at most $2n \cdot n/\left(\sqrt{2n}/2\right) = 2\sqrt{2}n^{3/2}$. We use a recursive relation to prove an improved coefficient for $n^{3/2}$ in the next theorem.

THEOREM 1. *One can find a king in T_n with cost at most $(4\sqrt{2})n^{3/2}/3$; that is,*

$$f(n) \le \frac{4\sqrt{2}}{3} n^{3/2}.$$

Proof. Let S be a subset of vertices in T_n with $|S| = \lceil \sqrt{2n} \rceil$. Let T_S be the subtournament of T_n induced by S. Then we can obtain the orientation of all edges in T_S with cost $\binom{\lceil \sqrt{2n} \rceil}{2}$. Let u be a vertex with the maximum outdegree within the subtournament T_S. By Lemma 2, the outdegree of u within T_S is

$$d^+(T_S, u) \ge \frac{|S| - 1}{2} = \frac{\lceil \sqrt{2n} \rceil - 1}{2}.$$

Next we can obtain the orientation of the edge between u and each $v \in V(T_n) \setminus S$ with cost $n - \lceil \sqrt{2n} \rceil$. Then

$$|\Gamma^-(u)| = n - 1 - |\Gamma^+(u)| \le n - 1 - d^+(T_S, u) \le n - \frac{\sqrt{2n}}{2}.$$

To find a king in T_n, by Lemma 1, it suffices to find a king in the subtournament of T_n induced by $\Gamma^-(u)$ with cost at most $f(|\Gamma^-(u)|)$. Thus

$$f(n) \le f(|\Gamma^-(u)|) + \binom{\lceil \sqrt{2n} \rceil}{2} + n - \lceil \sqrt{2n} \rceil \le f\left(n - \frac{\sqrt{2n}}{2}\right) + 2n - \frac{\sqrt{2n}}{2}.$$

Now we use induction to prove $f(n) \le 4\sqrt{2}n^{3/2}/3$ for all $n \ge 1$. It holds for $n = 1$ trivially. Suppose it holds for all cases less than n. Then

$$\begin{aligned} f(n) &\le f\left(n - \tfrac{\sqrt{2n}}{2}\right) + 2n - \tfrac{\sqrt{2n}}{2} \\ &\le \tfrac{4\sqrt{2}}{3}\left(n - \tfrac{\sqrt{2n}}{2}\right)^{3/2} + 2n - \tfrac{\sqrt{2n}}{2} \\ &\le \tfrac{4\sqrt{2}}{3}\left(n - \tfrac{\sqrt{2n}}{2}\right)\left(\sqrt{n} - \tfrac{\sqrt{2}}{4}\right) + 2n - \tfrac{\sqrt{2n}}{2} \\ &< \tfrac{4\sqrt{2}}{3} n^{3/2}. \qquad \square \end{aligned}$$

Remark 1. In the actual implementation of the revised-divide-and-conquer algorithm given in Theorem 1, an extra number of $\Theta(|S|)$ comparisons in determining the vertex with the maximum outdegree in T_s will be introduced at each recursive call in selecting a pivot vertex. However, since the total number of extra comparisons needed is $O(n)$, the algorithm will have a complexity of at most $4\sqrt{2}n^{3/2}/3 + O(n)$.

Remark 2. We note that if only $\sqrt{2n}/2$ vertices are eliminated in the first stage of divide-and-conquer, a complete subtournament of $\sqrt{2n}/2$ vertices remains. Then we can take advantage of having known all edges within this remaining subtournament to obtain a second complete subtournament of $\sqrt{2n}$ vertices with a cost of only $\binom{\sqrt{2n}}{2} - \binom{\sqrt{2n}/2}{2} \approx 3n/4$ for the second stage of divide-and-conquer. This shows that either more than $\sqrt{2n}/2$ vertices can be eliminated in the first stage of divide-and-conquer or the second stage of divide-and-conquer can be performed with cost less than $2n$. If this is taken into consideration recursively, a much longer and tedious estimate shows that $f(n) \le 2\sqrt{6}n^{3/2}/3 + o(n^{3/2})$.

In order to prove a lower bound for the worst case cost for finding a king in T_n, we use an adversary argument. Our idea is to design a strategy for the adversary to answer each question. The adversary chooses his/her answers to try to force the algorithm to work hard. Suppose $e_1, e_2, \ldots, e_l$, where $l = f(n)$ is a sequence of edges that we ask the adversary about regarding their orientation. Let $\vec{e}_1, \vec{e}_2, \ldots, \vec{e}_l$ be the answers of the adversary. We define a sequence of digraphs $G_0, G_1, \ldots, G_l$ as follows:

1. Let G_0 be the empty digraph with the same vertex set as T_n.
2. Let $G_i = G_{i-1} + \vec{e}_i$ for each $i = 1, 2, \ldots, l$; that is, G_i is obtained by adding the edge $\vec{e}_i$ to G_{i-1}.

Suppose v_i and w_i are the two vertices incident to e_i. We design the following strategy for the adversary to determine his/her answer to the question about the orientation of e_i:

1. Let $v_i \to w_i$ if $d^+(G_{i-1}, v_i) < d^+(G_{i-1}, w_i)$.
2. Let $w_i \to v_i$ if $d^+(G_{i-1}, v_i) > d^+(G_{i-1}, w_i)$.
3. Orientate e_i arbitrarily if $d^+(G_{i-1}, v_i) = d^+(G_{i-1}, w_i)$.

We call the above strategy the pro-small-outdegree-strategy and call G_l the digraph constructed by using the pro-small-outdegree-strategy. From now on we use $d(v)$ to denote $d^+(G_l, v)$ if there is no confusion from the context.

LEMMA 3. *Suppose v is a vertex in G_l constructed by using the pro-small-outdegree-strategy. Then, for any $S \subseteq \Gamma^+(v)$,*

$$\sum_{w \in S} d(w) \ge \binom{|S|}{2}.$$

Proof. We may order the vertices of $\Gamma^+(v) = \{w_i : 1 \le i \le d(v)\}$ according to the ordering of the questions whose answers are of the type "$v \to w$." Then $d(w_i) \ge i - 1$ by the pro-small-outdegree-strategy. Thus

$$\sum_{w \in S} d(w) \ge \sum_{1 \le i \le |S|} (i-1) = \binom{|S|}{2}. \qquad \square$$

LEMMA 4. *Suppose v is a vertex in G_l constructed by using the pro-small-outdegree-strategy. Then, for any $S \subseteq \Gamma^{++}(v)$,*

$$\sum_{w \in S} d(w) \ge d(v) \cdot \binom{|S|/d(v)}{2}.$$

Proof. Let $\Gamma^+(v) = \{w_i : 1 \le i \le d(v)\}$. Since $S \subseteq \Gamma^{++}(v)$, we can partition S into pairwise disjoint sets as follows:

1. $S = \cup_{i=1}^{d(v)} S_i$. (It is possible that some S_i may be empty.)
2. $S_i \subseteq \Gamma^+(w_i)$ for each i, $1 \le i \le d(v)$.

(Note that such a partition of S may not be unique since a vertex in S could be dominated by more than one vertex in $\Gamma^+(v)$.) By Lemma 3,

$$\sum_{w\in S} d(w) = \sum_{i=1}^{d(v)} \sum_{w\in S_i} d(w) \ge \sum_{i=1}^{d(v)} \binom{|S_i|}{2} \ge d(v) \cdot \binom{\sum |S_i|/d(v)}{2} = d(v) \cdot \binom{|S|/d(v)}{2},$$

where the last inequality holds since the function $\binom{x}{2}$ is concave upward. □

THEOREM 2. *No algorithm can find a king in T_n with cost less than $3\sqrt[3]{2}(n-1)^{4/3}/4 - 3(n-1)/2$ in the worst case.*

Proof. Suppose G_l ($l = f(n)$) is the digraph constructed by using the pro-small-outdegree-strategy. Let v be a king in G_l. Then $V(G_l) = \{v\} \cup \Gamma^+(v) \cup \Gamma^{++}(v)$, and so $|\Gamma^{++}(v)| = n - d(v) - 1$. By Lemmas 3 and 4,

$$\begin{aligned} f(n) &= l = |E(G_l)| = d(v) + \sum_{w\in\Gamma^+(v)} d(w) + \sum_{w\in\Gamma^{++}(v)} d(w) \\ &\ge d(v) + \binom{d(v)}{2} + d(v) \cdot \binom{(n-d(v)-1)/d(v)}{2} \\ &> \tfrac{1}{2}\left(\tfrac{(n-1)^2}{d(v)} + (d(v))^2 - 3n + 3\right) \\ &\ge \tfrac{3}{4}\sqrt[3]{2}(n-1)^{4/3} - \tfrac{3}{2}(n-1), \end{aligned}$$

where the last inequality follows from minimizing the function $(n-1)^2/x + x^2$. □

By combining Theorems 1 and 2, we conclude that the worst case asymptotic cost for finding a king in T_n is $\Omega(n^{4/3})$ and $O(n^{3/2})$.

3. Worst case cost for finding a sorted sequence of kings. If one uses the divide-and-conquer algorithm introduced in section 1 to search for a sorted sequence of kings in T_n, the worst case happens when either $\Gamma^+(u) = \emptyset$ or $\Gamma^-(u) = \emptyset$ at each stage of divide-and-conquer. Therefore, in order to avoid the worst case, one should carefully choose a pivot vertex u with both $\Gamma^+(u)$ and $\Gamma^-(u)$ large enough at each stage of divide-and-conquer. Similar to the proof of Theorem 1, we can first use n questions to obtain the orientation of all edges in a subtournament of roughly $\sqrt{2n}$ vertices. (Again note that this part is the sacrifice of the average performance.) We choose a vertex with the median outdegree in this subtournament as the pivot vertex u to apply Lemma 1. Then, by Lemma 2, each of $\Gamma^+(u)$ and $\Gamma^-(u)$ contains at least $\sqrt{2n}/4$ vertices.

THEOREM 3. *One can find a sorted sequence of kings in T_n with cost at most $(8\sqrt{2})n^{3/2}/3 + O(n^{5/4})$; that is,*

$$g(n) \le \frac{8\sqrt{2}}{3} n^{3/2} + cn^{5/4}$$

for some constant c; for example, one may choose $c = 25$.

Proof. Let S be a subset of vertices in T_n with $|S| = \lceil \sqrt{2n} \rceil + 2$. Let T_S be the subtournament of T_n induced by S. Then we can obtain the orientation of all edges in T_S with cost $\binom{\lceil\sqrt{2n}\rceil+2}{2}$. Let $d_1^+(T_S) \le d_2^+(T_S) \le \cdots \le d_{|S|}^+(T_S)$ be the outdegree sequence of vertices within T_S. Let u be a vertex in T_S such that $d^+(T_S, u) = d_t^+(T_S)$,

where $t = \left\lceil \left\lceil \sqrt{2n} \right\rceil /2 \right\rceil + 1$. (That is, u is a vertex with the median outdegree in T_S.) By Lemma 2, we have

$$d^+(T_S, u) \geq \frac{t-1}{2} \geq \frac{\sqrt{2n}}{4}$$

and

$$d^-(T_S, u) = |S| - 1 - d^+(T_S, u) \geq |S| - 1 - \frac{|S| + t - 2}{2} \geq \frac{\sqrt{2n}}{4}.$$

Next we can obtain the orientation of the edge between u and each $v \in V(T_n) \setminus S$ with cost $n - 2 - \left\lceil \sqrt{2n} \right\rceil$. Then

$$\frac{\sqrt{2n}}{4} \leq d^+(T_S, u) \leq |\Gamma^+(u)| \leq n - 1 - d^-(T_S, u) \leq n - \frac{\sqrt{2n}}{4}$$

and, similarly,

$$\frac{\sqrt{2n}}{4} \leq |\Gamma^-(u)| \leq n - \frac{\sqrt{2n}}{4}.$$

To find a sorted sequence of kings in T_n, by Lemma 1, it suffices to find sorted sequences of kings in both subtournaments of T_n induced by $\Gamma^+(u)$ and by $\Gamma^-(u)$, respectively, with total cost at most $g(|\Gamma^+(u)|) + g(|\Gamma^-(u)|)$. Thus

$$\begin{aligned} g(n) &\leq g(|\Gamma^+(u)|) + g(|\Gamma^-(u)|) + \binom{\left\lceil \sqrt{2n} \right\rceil + 2}{2} + n - 2 - \left\lceil \sqrt{2n} \right\rceil \\ &\leq g(|\Gamma^+(u)|) + g(|\Gamma^-(u)|) + 2n + \tfrac{3\sqrt{2n}}{2}. \end{aligned}$$

Now we use induction to prove $g(n) \leq h(n)$, where $h(n) = 8\sqrt{2}n^{3/2}/3 + 25n^{5/4}$, for all $n \geq 1$. It holds for $n = 1$ trivially. Suppose it holds for all cases less than n. Then

$$g(|\Gamma^+(u)|) + g(|\Gamma^-(u)|) \leq h(|\Gamma^+(u)|) + h(|\Gamma^-(u)|) \leq h\left(\frac{\sqrt{2n}}{4}\right) + h\left(n - \frac{\sqrt{2n}}{4}\right),$$

where the last inequality holds since the function $h(x) = 8\sqrt{2}x^{3/2}/3 + 25x^{5/4}$ is concave upward. Thus

$$\begin{aligned} g(n) &\leq h\left(\tfrac{\sqrt{2n}}{4}\right) + h\left(n - \tfrac{\sqrt{2n}}{4}\right) + 2n + \tfrac{3\sqrt{2n}}{2} \\ &\leq \tfrac{8\sqrt{2}}{3}\left(\tfrac{\sqrt{2n}}{4}\right)^{3/2} + 25\left(\tfrac{\sqrt{2n}}{4}\right)^{5/4} + \tfrac{8\sqrt{2}}{3}\left(n - \tfrac{\sqrt{2n}}{4}\right)\left(\sqrt{n} - \tfrac{\sqrt{2}}{8}\right) \\ &\quad + 25\left(n - \tfrac{\sqrt{2n}}{4}\right)\left(\sqrt[4]{n} - \tfrac{\sqrt{2}}{16\sqrt[4]{n}}\right) + 2n + \tfrac{3\sqrt{2n}}{2} \\ &< \tfrac{8\sqrt{2}}{3}n^{3/2} + 25n^{5/4}. \qquad \square \end{aligned}$$

Remark 3. In the actual implementation of the revised-divide-and-conquer algorithm given in Theorem 3, an extra number of $\Theta(|S|)$ comparisons will be introduced at each recursive call to select a median. The median can be determined using a linear selection algorithm [2]. It is still unknown exactly how many comparisons are needed to determine the median. Dor and Zwick [3] showed that the upper bound is

slightly less than $2.95|S|$ and the lower bound is slightly more than $2|S|$. Again, since the total number of extra comparisons needed is $O(n)$, the revised-divide-and-conquer algorithm will have a complexity of at most $8\sqrt{2}n^{3/2}/3 + 25n^{5/4} + O(n)$.

THEOREM 4. *No algorithm can find a sorted sequence of kings in T_n with cost less than $\sqrt{3}(n-1)^{3/2}/3 - 3n/2$ in the worst case.*

Proof. Suppose G_l ($l = g(n)$) is the digraph constructed by using the pro-small-outdegree-strategy. Suppose $u_1, u_2, \ldots, u_n$ form a sorted sequence of kings in G_l. Since $g(n) = l = |E(G_l)|$, it suffices to prove $|E(G_l)| \geq \sqrt{3}(n-1)^{3/2}/3 - 3n/2$. The proof is split into two cases.

Case 1. Suppose $d(u_i) \geq \sqrt{3(n-i)}/2$ for all i, $1 \leq i \leq n$. Then

$$|E(G_l)| = \sum_{i=1}^{n} d(u_i) \geq \frac{1}{2}\sum_{i=1}^{n}\sqrt{3(n-i)} \geq \frac{1}{2}\int_0^{n-1}\sqrt{3x}\,dx = \frac{\sqrt{3}}{3}(n-1)^{3/2}.$$

Case 2. Suppose $d(u_i) < \sqrt{3(n-i)}/2$ for some i, $1 \leq i \leq n$. Let t be the smallest i satisfying $d(u_i) < \sqrt{3(n-i)}/2$. Let $S_1 = \Gamma^+(u_t) \cap \{u_i : i \geq t+1\}$ and $S_2 = \Gamma^{++}(u_t) \cap \{u_i : i \geq t+1\}$. By the definition of a sorted sequence of kings, we know that S_1 and S_2 form a disjoint partition of $\{u_i : i \geq t+1\}$ and, hence, $|S_2| = n - t - |S_1|$. Since $|S_1| \leq d(u_t) < \sqrt{3(n-t)}/2$, by Lemma 4,

$$\begin{aligned}
\sum_{i=t+1}^{n} d(u_i) &\geq \sum_{u_i \in S_2} d(u_i) \\
&\geq d(u_t) \cdot \binom{(n-t-|S_1|)/d(u_t)}{2} \\
&\geq \tfrac{1}{2}\left(\tfrac{(n-t)^2}{d(u_t)} - \tfrac{2n|S_1|}{d(u_t)} - n\right) \\
&\geq \tfrac{1}{2}\left(\tfrac{2(n-t)^2}{\sqrt{3(n-t)}} - 3n\right) \\
&= \tfrac{\sqrt{3}}{3}(n-t)^{3/2} - \tfrac{3}{2}n.
\end{aligned}$$

Thus

$$\begin{aligned}
|E(G_l)| &\geq \sum_{i=1}^{t-1} d(u_i) + \sum_{i=t+1}^{n} d(u_i) \\
&\geq \tfrac{1}{2}\sum_{i=1}^{t-1}\sqrt{3(n-i)} + \tfrac{\sqrt{3}}{3}(n-t)^{3/2} - \tfrac{3}{2}n \\
&\geq \tfrac{\sqrt{3}}{2}\int_{n-t}^{n-1}\sqrt{x}\,dx + \tfrac{\sqrt{3}}{3}(n-t)^{3/2} - \tfrac{3}{2}n \\
&= \tfrac{\sqrt{3}}{3}(n-1)^{3/2} - \tfrac{3}{2}n. \qquad \square
\end{aligned}$$

By combining Theorems 3 and 4, we conclude that the worst case asymptotic cost for finding a sorted sequence of kings in T_n is $\Theta(n^{3/2})$.

4. Connection with median order. A sorted sequence of kings may also be viewed as a weak approximation for ranking players in a tournament. In general, the *tournament ranking problem* [8] is a difficult one without applausive solution. Suppose $u_1, u_2, \ldots, u_n$ is a ranking of players such that u_i is ranked in the ith place. For any

pair of players u_i, u_j with $i < j$, a *happiness* is an outcome that u_i beats u_j, while an *upset* is an outcome that u_j beats u_i. A ranking strategy introduced in [10] is to minimize the number of total upsets. A *median order* of a tournament is defined as a ranking of players with the minimum number of total upsets. Similarly, a median order of a digraph can be defined as an ordered list of vertices which induces an acyclic digraph with the maximum number of edges. It is known that determining a median order of a digraph is NP-complete and that the complexity for determining a median order for a tournament is still unknown [1]. Now suppose $u_1, u_2, \ldots, u_n$ form a median order for T_n. Havet and Thomassé [4] showed that u_1 is a king for T_n. By the definition of a median order, it is easy to see that $u_i, u_{i+1}, \ldots, u_n$ form a median order for the subtournament induced by $\{u_j : i \leq j \leq n\}$ for each $i \leq n$. These facts reveal the following connection between a median order and a sorted sequence of kings in a tournament.

THEOREM 5. *Any median order in a tournament is a sorted sequence of kings.*

Theorem 5 suggests that one does not have to check all $n!$ possible orderings of vertices in order to find a median order of T_n. Instead, one may narrow the search within all sorted sequences of kings.

5. Conclusion. In this paper, we have shown that the worst case asymptotic cost for finding a sorted sequence of kings in T_n is $\Theta(n^{3/2})$. We have also shown that the worst case asymptotic cost for finding a king in T_n is $\Omega(n^{4/3})$ and $O(n^{3/2})$. The lower bounds are derived by using an adversary argument called pro-small-outdegree-strategy proposed in this paper. In addition, we have provided a revised-divide-and-conquer algorithm that finds a sorted sequence of kings (including a king) with a cost of $\Theta(n^{3/2})$ in the worst case. It is still an open problem on exactly how many binary questions are needed in the worst case to determine a sorted sequence of kings in a tournament. Also it would be interesting to know the worst case asymptotic cost for finding a king in a tournament.

AN OPTIMAL ALGORITHM FOR CHECKING REGULARITY*

Y. KOHAYAKAWA†, V. RÖDL‡, AND L. THOMA§

Abstract. We present a deterministic algorithm $\mathcal{A}$ that, in $O(m^2)$ time, verifies whether a given m by m bipartite graph G is *regular*, in the sense of Szemerédi [*Regular partitions of graphs*, in Problèmes Combinatoires et Théorie des Graphes (Orsay, 1976), Colloques Internationaux CNRS 260, CNRS, Paris, 1978, pp. 399–401]. In the case in which G is *not* regular enough, our algorithm outputs a *witness* to this irregularity. Algorithm $\mathcal{A}$ may be used as a subroutine in an algorithm that finds an ε-regular partition of a given n-vertex graph Γ in time $O(n^2)$. This time complexity is optimal, up to a constant factor, and improves upon the bound $O(M(n))$, proved by Alon et al. [*The algorithmic aspects of the regularity lemma*, J. Algorithms, 16 (1994), pp. 80–109], where $M(n) = O(n^{2.376})$ is the time required to square a 0–1 matrix over the integers.

Our approach is elementary, except that it makes use of linear-sized expanders to accomplish a suitable form of deterministic sampling.

1. Introduction and the main result.

Szemerédi's regularity lemma [31] is a fundamental result in graph theory (see [25] for an excellent survey). Roughly speaking, this lemma states that any graph admits a partition of its vertex set so that most pairs induce "pseudorandom" or *regular* bipartite graphs. The original proof of the regularity lemma was nonconstructive, but Alon et al. [1, 2] succeeded in developing a fast deterministic algorithm for finding such a partition. Many of the existential results based on the regularity lemma could then be turned into algorithmic results. The algorithm in [1, 2] finds a regular partition of an n-vertex graph in $O(M(n))$ deterministic time, where $M(n) = O(n^{2.376})$ (see [11]) is the time required to square a 0–1 matrix over the integers. More recently, Frieze and Kannan [18] (see also [19]) showed that *sampling* can be used to develop a $O(n)$ time *randomized* algorithm that, given an n-vertex graph G, outputs a partition for G that is regular with high probability.

In both algorithms above (and in all algorithms for variants of the regularity lemma), the main algorithmic problem is to decide whether a given m by m bipartite graph G is regular; if G is *not* regular, we are required to find a "witness" for this irregularity. In this paper, we present a *deterministic* algorithm that solves this problem in $O(m^2)$ time. Given our algorithm, one can derive in a standard way

an algorithm for Szemerédi's regularity lemma that finds a regular partition of an n-vertex graph in time $O(n^2)$. A key feature of our approach lies in the use of linear-sized expanders for carrying out a certain procedure that may be thought of as *deterministic sampling*.

1.1. The main result. Let $G = (A, B; E)$ be a bipartite graph. If $\emptyset \neq U \subset A$, $\emptyset \neq V \subset B$, the *density* of (U, V) in G is $d(U, V) = e(U, V)/|U||V|$, where we write $e(U, V) = e_G(U, V)$ for the number of edges with one endpoint in U and the other endpoint in V. For $\varepsilon > 0$, we say that G is *ε-regular* if, for all $U \subset A, |U| \geq \varepsilon|A|$, and $V \subset B, |V| \geq \varepsilon|B|$, we have

$$|d(U, V) - d(A, B)| \leq \varepsilon \,. \tag{1.1}$$

In case G is not ε-regular and a certain pair (U, V) certifies this fact, then we say that (U, V) is a *witness* to the *ε-irregularity* of G.

Let $\Gamma = (V, E)$ be a graph. A partition $(V_i)_{i=0}^k$ of the vertex set V, $V = \bigcup_{i=0}^k V_i$, is said to be an *equitable partition* (with the exceptional class V_0) if $|V_1| = \cdots = |V_k|$. If $V = \bigcup_{i=0}^k V_i$ is an equitable partition of V such that the size of the exceptional class $|V_0| \leq \varepsilon n$ and at least $(1 - \varepsilon)\binom{k}{2}$ pairs (V_i, V_j), where $1 \leq i < j \leq k$, are ε-regular, we say that the partition $(V_i)_{i=0}^k$ is an *ε-regular partition*. We say that a pair (U, W) is *ε-regular* if the bipartite graph induced by (U, W) is ε-regular.

Szemerédi's remarkable result may be stated as follows.

THEOREM 1.1. *For any $\varepsilon > 0$ and any $k_0 \geq 1$, there is $K_0(\varepsilon, k_0)$ such that any graph Γ admits an ε-regular partition into k parts for some k satisfying $k_0 \leq k \leq K_0(\varepsilon, k_0)$.*

Alon et al. [1, 2] proved the following algorithmic version of Theorem 1.1.

THEOREM 1.2. *There is a deterministic algorithm $\mathcal{A}_0$ that, given $\varepsilon > 0$, $k_0 \geq 1$, and Γ, produces an ε-regular partition for Γ into k parts for some k satisfying $k_0 \leq k \leq K_0'$, where $K_0' = K_0'(\varepsilon, k_0)$ depends only on ε and k_0. Moreover, algorithm $\mathcal{A}_0$ runs in time $O(M(n)) = O(n^{2.376})$ if Γ has n vertices.*

Consider now the following closely related decision problem.

PROBLEM 1.3. Given a graph G, a pair (U, W) of nonempty, pairwise disjoint sets of vertices of G, and a positive ε, decide whether (U, W) is ε-regular with respect to G.

As it turns out, *the problem above is coNP-complete* [1, 2]. However, as observed already in [1, 2], to prove Theorem 1.2 it suffices to solve an *approximate* version of the decision problem above. For instance, the following result [15] suffices.

THEOREM 1.4. *There exists an algorithm $\mathcal{A}_1$ for which the following holds. When $\mathcal{A}_1$ receives as input an $\varepsilon > 0$ and a bipartite graph $G = (A, B; E)$ with $|A| = |B| = m \geq (2/\varepsilon)^5$, it either correctly asserts that G is ε-regular or else it returns a witness for the ε'-irregularity of G, where $\varepsilon' = \varepsilon'_{\mathcal{A}_1}(\varepsilon) = \varepsilon^5/16$. The running time of $\mathcal{A}_1$ is $O(M(m)) = O(m^{2.376})$.*

(See Frieze and Kannan [20] for a somewhat different approach to verifying regularity, based on singular values of matrices.) Our main result is an improvement of Theorem 1.4 above and may be stated as follows.

THEOREM 1.5 (the main result). *There exists an algorithm $\mathcal{A}$ for which the following holds. When $\mathcal{A}$ receives as input an $\varepsilon > 0$ and a bipartite graph $G = (A, B; E)$ with $|A| = |B| = m \geq m_0(\varepsilon)$, it either correctly asserts that G is ε-regular or else it returns a witness for the ε'-irregularity of G, where $\varepsilon' = \varepsilon'_{\mathcal{A}}(\varepsilon) = \varepsilon^{20}/10^{24}$. The running time of $\mathcal{A}$ is $O(m^2)$.*

We describe our algorithm $\mathcal{A}$ in section 3.1. Deriving an algorithm for the regularity lemma from Theorem 1.5 is standard (cf. section 3.2).

COROLLARY 1.6. *There is a deterministic algorithm $\mathcal{A}_0'$ that, given $\varepsilon > 0$, $k_0 \geq 1$, and a graph Γ, produces an ε-regular partition for Γ into k parts for some k satisfying $k_0 \leq k \leq K_0''$, where $K_0'' = K_0''(\varepsilon, k_0)$ depends only on ε and k_0. Moreover, algorithm $\mathcal{A}_0'$ runs in time $O(n^2)$ if Γ has n vertices.*

Clearly, algorithm $\mathcal{A}_0'$ above has optimal time complexity, up to the constant implicit in the big-O notation. In [1, 2], several algorithmic consequences are derived from Theorem 1.2. In the examples presented there, the time complexity of the algorithms is $O(M(n))$. *Using $\mathcal{A}_0'$ from Corollary 1.6, one obtains algorithms with optimal time complexity $O(n^2)$.* We also observe that a similar improvement may be obtained from Theorem 1.5 for the subgraph counting algorithm given by Duke, Lefmann, and Rödl [15].

Let us also mention that an important variant of the regularity lemma, suitable for finding *induced subgraphs*, was recently discovered by Alon et al. [3, 4] in the context of *property testing* (see, e.g., [21] and [22, 23]). In the applications of their regularity lemma in [3, 4] the authors do not need algorithms for finding their regular partitions; however, they observe that an algorithmic version of their lemma readily follows from results such as Theorem 1.4. Again, an $O(n^2)$ time algorithm follows immediately from Theorem 1.5.

Finally, we mention that one may prove a "nonbipartite version" of Theorem 1.5. This variant of our result implies that one may check in time $O(n^2)$ whether a given n-vertex graph Γ is *quasi-random* in the sense of Chung, Graham, and Wilson [10]. Moreover, if Γ is not quasi-random, then our algorithm will produce a suitable witness proving this, i.e., an induced subgraph with $\Omega(n)$ vertices whose density deviates substantially from the density of Γ (see section 1.3.5 for more details).

1.2. Local conditions for regularity. One may prove Theorem 1.4 by considering a certain "local condition" on $G = (A, B; E)$ that is essentially equivalent to the regularity of G. For simplicity, let us suppose that G is degree-regular. The condition is simply that the following inequality should hold:

$$\sum_{x,\, y \in A} \left| d_G(x,y) - p(G)^2 m \right| \leq \delta p(G)^2 m^3, \tag{1.2}$$

where $d_G(x,y) = |N_G(x) \cap N_G(y)|$ is the so-called *codegree* of x and y, and $p(G) = |E|/|A||B| = |E|/m^2$, with $m = |A| = |B|$, is the density of G. Clearly, inequality (1.2) may be checked in $O(m^3)$ time, and, in fact, using fast matrix multiplication, one may verify (1.2) in $O(M(m)) = O(m^{2.376})$ time. The precise meaning of the equivalence of the ε-regularity of G and the validity of (1.2) is as follows: for all $\varepsilon > 0$ there is $\delta > 0$ such that if (1.2) holds, then G is ε-regular. Moreover, for all $\delta > 0$, there is $\varepsilon' > 0$ such that if (1.2) fails, then G is not ε'-regular, and, in fact, a witness to this ε'-irregularity may be constructed explicitly in the same deterministic time. Some of the ideas described in this paragraph have appeared in the literature under many guises. (For a detailed discussion on the combinatorial aspects, see [24]; for applications of these ideas in theoretical computer science, see [28] and the references therein.) Basically, we are obtaining a somewhat surprising amount of information from "pairwise independence." We do not go into the details here.

The key idea in the proof of Theorem 1.5 is that we may restrict the sum in (1.2) to a *small*, *randomly selected* collection of pairs $\{x, y\}$ (and, naturally, scale down the right-hand side). This would not be so satisfactory, as we would have a randomized

procedure: *we in fact show that we may achieve the same effect by "deterministic sampling," using the edge set of a linear-sized expander J* (see the definition of property $\mathcal{P}(J,\delta)$ in section 3.1.2).

1.3. Algorithmic applications. As mentioned above, algorithms $\mathcal{A}$ and $\mathcal{A}'_0$ immediately imply improvements on deterministic algorithms that are based on Szemerédi's regularity lemma. Here we present a few typical examples of such algorithms. For more algorithmic applications of the regularity lemma see [2] and [15].

1.3.1. MAXCUT in dense graphs. There has been considerable interest in the following computational problem recently.

PROBLEM 1.7 (MAXCUT). Given a graph G, find a partition (U,W) of the vertex set of G so that the number of edges $e(U,W)$ between U and W is maximum.

It follows from the algorithmic version of the regularity lemma that one may design a polynomial time approximation scheme (PTAS) for MAXCUT if the input graphs G are restricted to dense graphs. Let us be more precise.

Let α be a fixed positive real. In this section, we consider only graphs G with edge density $e(G)\binom{|V(G)|}{2}^{-1} \geq \alpha$. Theorem 1.2 implies the following result: for any ε and $\alpha > 0$, there exist a constant $C(\varepsilon,\alpha)$ and a *deterministic* algorithm $\mathcal{A}_{\rm MC}$ so that, given an n-vertex graph G with edge density $\geq \alpha$, algorithm $\mathcal{A}_{\rm MC}$ returns a solution (U',W') for MAXCUT such that

$$e(U',W') \geq (1-\varepsilon)e(U^*,W^*), \tag{1.3}$$

where (U^*,W^*) is an optimal solution for G. Furthermore, the running time of $\mathcal{A}_{\rm MC}$ is $\leq C(\varepsilon,\alpha)M(n)$.

Algorithm $\mathcal{A}_{\rm MC}$ uses algorithm $\mathcal{A}_0$ in Theorem 1.2 as a subroutine; we may use, instead, algorithm $\mathcal{A}'_0$ in Corollary 1.6: let $\mathcal{A}'_{\rm MC}$ be the corresponding algorithm.

THEOREM 1.8. *On input G as above, the deterministic algorithm $\mathcal{A}'_{\rm MC}$ produces a partition (U,W) satisfying* (1.3) *in time $\leq C'(\varepsilon,\alpha)n^2$, where $C'(\varepsilon,\alpha)$ is a constant that depends only on ε and α.*

We remark that a *randomized* algorithm with time complexity $O(n^2)$ was already given by de la Vega [14]. For related results concerning randomized algorithms, the reader is referred to Frieze and Kannan [18, 19].

1.3.2. The quasi-Ramsey number and maximum acyclic subgraphs. Let $f : E(K_n) \to \{-1,1\}$ be a function and set $f(S) = \sum_{e\in\binom{S}{2}} f(e)$, where $S \subseteq [n]$. Here, as usual, K_n stands for the complete graph on n vertices and $\binom{S}{2}$ denotes the set of all pairs on the set S.

The *quasi-Ramsey number* $g(n)$ is defined as

$$g(n) = \min_f \max_{S\subseteq[n]} |f(S)| .$$

Erdős and Spencer [17] showed that

$$c_1 n^{3/2} \leq g(n) \leq c_2 n^{3/2}$$

for some absolute constants c_1 and $c_2 > 0$.

Let T_n be a tournament and P_n a transitive tournament both on n vertices. Set $|T_n \cap P_n|$ to be the number of common oriented arcs of T_n and P_n. The tournament ranking function $h(n)$ is defined by

$$h(n) = \min_{T_n} \max_{P_n} |T_n \cap P_n|;$$

i.e., $h(n)$ is the maximum number of edges one can choose in any tournament of order n without creating an oriented cycle. Spencer [29, 30] showed that

$$c_1 n^{3/2} \le h(n) - \frac{1}{2}\binom{n}{2} \le c_2 n^{3/2}$$

for some absolute constants c_1 and $c_2 > 0$.

A polynomial time approximation scheme (PTAS) for a maximization problem is a family of algorithms $\{\mathcal{S}_\varrho \colon 0 < \varrho < 1\}$ as follows. For any given $0 < \varrho < 1$, algorithm $\mathcal{S}_\varrho$ runs in polynomial time and finds a solution whose value is at least $(1-\varrho)\,\mathrm{OPT}$, where OPT in the optimal value. Using a constructive version of the regularity lemma, Czygrinow, Poljak, and Rödl [13, Theorem 3] designed a PTAS for the "dense" quasi-Ramsey problem and for tournament ranking.

For $f : E(K_n) \to \{-1, 1\}$ set $\mathrm{OPT}(f) = \max_{S \subseteq [n]} |f(S)|$. Our algorithm for the regularity lemma implies an improvement on the time complexity of the PTAS designed in [13].

THEOREM 1.9. *Let $c > 0$ be fixed. For every $0 < \varrho < 1$, there is a $O(n^2)$ time algorithm that constructs a set S such that*

$$|f(S)| \ge (1-\varrho)\,\mathrm{OPT}(f)$$

for any instance $f \colon E(K_n) \to \{-1, 1\}$ with $\mathrm{OPT}(f) \ge cn^2$.

Now, let $\mathrm{OPT}(T_n) = \max_{P_n} |T_n \cap P_n|$, where T_n is a tournament. Algorithm $\mathcal{A}_0'$ in Corollary 1.6 improves the time complexity of the PTAS designed in [13] to $O(n^2)$.

THEOREM 1.10. *Let $0 < \varrho < 1$. Then there is a $O(n^2)$ time algorithm that, given a tournament T_n, constructs an ordering σ of the vertices of T_n so that at least $(1-\varrho)\,\mathrm{OPT}(T_n)$ arcs agree with σ.*

1.3.3. Robustly high-chromatic graphs. Goldreich, Goldwasser, and Ron [22, 23] have recently initiated a systematic study of *property testing* for combinatorial structures. Roughly speaking, in property testing one has a property P of interest, and one is given an object X and a real number $\varepsilon > 0$. The task is then to decide whether X has P or if it is ε-far from any object Y having P (we suppose our objects are in some metric space). Furthermore, we wish to perform this test extremely quickly; typically, the tests examine a small random portion of X and distinguish between the two cases above with high probability of success. Thus, in an appropriate computational model, the tests have sublinear complexity (see [22, 23] for details).

A graph property P that has been proved to be testable [22, 23] is the property of having chromatic number at least k for any fixed k. This result was in fact implicit in [16], where the regularity lemma is used to prove that "robustly high-chromatic graphs" admit witnesses of bounded size. Indeed, the existential result in Theorem 1.11 below was proved in [16]. The algorithmic result in Theorem 1.11, but with time complexity $O(M(n))$, was proved in [1, 2].

THEOREM 1.11. *Let $k \ge 3$ be an integer, and let $\varepsilon > 0$ be a real constant. Then there exist integers $n_0 = n_0(k, \varepsilon)$ and $f = f(k, \varepsilon)$ and a constant $\nu = \nu(k, \varepsilon) > 0$ such that if $G = (V, E)$ is a graph with $n \ge n_0$ vertices, then either*

(i) *there exists a graph H on $h \le f$ vertices with chromatic number $\chi(H) \ge k$ that occurs in G at least νn^h times as a subgraph or else*

(ii) *there exists a set $E' \subseteq E$ with $|E'| \le \varepsilon n^2$ such that the subgraph $G' = (V, E \setminus E')$ satisfies $\chi(G') < k$.*

Furthermore, there is a deterministic algorithm that receives as input a graph $G = (V, E)$ *as above and, in time* $O(n^2)$*, outputs either a graph* H *as in* (i) *or else it outputs a set of edges* E' *as in* (ii)*, together with a proper coloring* $\Delta\colon V \to \{1, \ldots, k-1\}$ *of the subgraph* G'*.*

The approach in [22, 23] does not use the regularity lemma and implies the existential part of Theorem 1.11. Moreover, that approach also gives a randomized, polynomial time algorithm for the constructive part of Theorem 1.11.

Finally, we mention that Czumaj and Sohler [12] have recently proved that the property of having chromatic number at least k is also testable for hypergraphs.

1.3.4. Counting subgraphs. In this section, we describe an algorithm for approximately counting small subgraphs in large graphs. This algorithm will also be an application of algorithm $\mathcal{A}_0'$ from Corollary 1.6.

We need to introduce some notation. We shall follow [15]. Let $G = (V, E)$ be a graph on n vertices whose vertex set $V = \{v_1, \ldots, v_n\}$ is ordered by $v_1 < \cdots < v_n$. Let the set $W = \{w_1, \ldots, w_k\}$ be ordered by $w_1 < \cdots < w_k$. We say that a graph H with vertex set W is *order isomorphic* to an induced subgraph H' of G if there exists an isomorphism $\phi : H \to H'$ with the property that for each i and j, if $w_i < w_j$, then $\phi(w_i) < \phi(w_j)$. Let $H_1, \ldots, H_t$, where $t = 2^{\binom{k}{2}}$, be the list of all graphs on the set W, and let $\sigma_k(G) = (h_1, \ldots, h_t)$ be the t-dimensional vector in which each h_i is the number of induced subgraphs of G to which H_i is order isomorphic.

The following proposition asserts the existence of a certain type of approximation algorithm for the vector $\sigma_k(G)$. For more details, see [15].

THEOREM 1.12. *Let* $k \geq 3$ *be a fixed integer, and suppose* $\delta > 0$ *is a fixed real. There is an algorithm that, on input* G*, a labeled, ordered graph on* n *vertices, produces an approximation* $\overline{\sigma}_k(G) = (\overline{h}_1, \ldots, \overline{h}_t)$ *to the vector* $\sigma_k(G) = (h_1, \ldots, h_t)$ *with the property that*

$$|h_i - \overline{h}_i| \leq \delta \binom{n}{k}$$

for all $1 \leq i \leq t$*. This algorithm runs in time* $O(n^2)$*.*

In [15], the authors consider the problem of approximating $\sigma_k(G)$ for $k = k(n)$ slowly increasing functions of n. Our results may be used to improve on the time complexity of the algorithms given in [15] for such $k = k(n)$, but we shall not go into the details.

1.3.5. Checking quasi-randomness. Thomason [32] and Chung, Graham, and Wilson [10] initiated a systematic study of *quasi-random* properties of graphs: these are properties that are shared by almost all graphs and are in fact *deterministically* asymptotically equivalent; i.e., if a large graph has one of these properties, then it in fact has all of them.

The investigation of quasi-randomness in combinatorics turned out to be a very rich line of research, as shown in the series of papers by Chung and Graham on the subject (for recent developments, see [9] and the references therein). Besides graphs, other combinatorial structures such as tournaments, set-systems, and subsets of $\mathbb{Z}/n\mathbb{Z}$ have been studied from this perspective (see [6, 7, 8]). Finally, we mention that applications of some of the underlying ideas in this area have occurred in the literature in different contexts; the interested reader is referred to [5, Chapter 9] and [24].

In this section, we shall consider the computational problem of determining whether or not a given graph is quasi-random. We are also interested in an additional requirement: in the case in which the input graph is *not* quasi-random, a "witness" to certify this fact should be efficiently produced.

We shall use the following definition.

DEFINITION 1.13. *Let reals $0 < \varepsilon \le 1$ and $0 < \delta \le 1$ be given. We shall say that a graph G is* $(1/2, \varepsilon, \delta)$-quasi-random *if, for all U, $W \subset V(G)$ with $U \cap W = \emptyset$ and $|U|$, $|W| \ge \delta n$, we have*

$$\left| e_G(U,W) - \frac{1}{2}|U||W| \right| \le \frac{1}{2}\varepsilon |U||W|.$$

In [24] the authors consider a new quasi-random property to develop an algorithm for testing quasi-randomness. Let G be a graph on n vertices, and let J be a (ϱ, L)-uniform graph on the same vertex set (for the definition, see section 2). To state the results we need to introduce some notation. For a vertex i of G we set $N(i)$ to be its neighborhood. Further, we write $N(i) \triangle N(j)$ for the symmetric difference of the sets $N(i)$ and $N(j)$.

To decide about the quasi-randomness of G we introduce the following couple of properties. Let $0 < \varepsilon, \delta \le 1$ be real numbers. We say that G satisfies property $\mathcal{T}_{\triangle}(J, \varepsilon)$ if we have

$$\sum_{\{i,j\} \in E(J)} \left| |N(i) \triangle N(j)| - \frac{1}{2}n \right| \le \frac{1}{2}\varepsilon n e(J) \, .$$

Note that this property is closely related to our property $\mathcal{P}$ introduced below. Similarly, we say that G satisfies property $\mathcal{T}'_{\triangle}(J, \gamma, \varepsilon)$ if the inequality

$$\left| |N(i) \triangle N(j)| - \frac{1}{2}n \right| \le \frac{1}{2}\varepsilon n$$

fails for at most $\gamma e(J)$ edges $\{i,j\} \in E(J)$.

The following two characterization theorems are proved in [24, Theorems 56 and 57].

THEOREM 1.14. *For any $0 < \varepsilon, \delta \le 1$ and any L, there exist $\varepsilon_0 = \varepsilon_0(\varepsilon, \delta, L) > 0$ and $r_0 = r_0(\varepsilon, \delta, L) \ge 1$ for which the following holds. Let G and J be two graphs on the same vertex set of n vertices. Assume further that J is a (ϱ, L)-uniform graph with the average degree $r = \varrho n \ge r_0$. Then, if G satisfies the property $\mathcal{T}_{\triangle}(J, \varepsilon')$ for some $0 < \varepsilon' \le \varepsilon_0$, then G is $(1/2, \varepsilon, \delta)$-quasi-random.*

THEOREM 1.15. *For any $0 < \gamma, \varepsilon \le 1$ and any L, there exist $\varepsilon_1 = \varepsilon_1(\gamma, \varepsilon, L) > 0$, $\delta_1 = \delta_1(\gamma, \varepsilon, L) > 0$, $r_1 = r_1(\gamma, \varepsilon, L) \ge 1$, and $N_1 = N_1(\gamma, \varepsilon, L) \ge 1$ for which the following holds. Let G and J be two graphs on the same vertex set of $n \ge N_1$ vertices. Assume further that J is a (ϱ, L)-uniform graph with the average degree $r = \varrho n \ge r_1$. Then, if G is $(1/2, \varepsilon', \delta')$-quasi-random for some $0 < \varepsilon' \le \varepsilon_1$ and $0 < \delta' \le \delta_1$, then property $\mathcal{T}'_{\triangle}(J, \gamma, \varepsilon)$ holds for G.*

It is straightforward to see that the properties $\mathcal{T}$ and $\mathcal{T}'$ can be checked in $O(n^2)$ deterministic time. Moreover, if a graph $\mathcal{G}$ does not satisfy property $\mathcal{T}'_{\triangle}(J, \gamma, \varepsilon)$, then one can, using the ideas from our present paper, construct a witness for the non–quasi-randomness of G in $O(n^2)$ time.

2. Preliminaries. In this section, we discuss some basic properties and the algorithmic construction of certain very well known random looking graphs.

2.1. (ϱ, L)-uniformity. Let $0 < \varrho \le 1$ and $L > 0$ be fixed. We say that a graph J on m vertices is (ϱ, L)-*uniform* if, for any U, $W \subset V(J)$ with $U \cap W = \emptyset$, we have

$$\big|e_J(U,W) - \varrho|U||W|\big| \le L\sqrt{r|U||W|}, \tag{2.1}$$

where $r = \varrho m$. The following lemma is immediate.

LEMMA 2.1. *Let $R = (V, E)$ be a (ϱ, L)-uniform, m-vertex graph and let $\emptyset \ne A \subset V$ be given. Put $J = R[A]$. Then J is an (ϱ, L')-uniform graph with $L' = L\sqrt{m/|A|}$.*

Notation 2.2. We use the following nonstandard notation: we write $O_1(x)$ for any term y such that $|y| \le x$.

We shall need estimates on the number of edges induced on subsets of (ϱ, L)-uniform graphs. Below, if Γ is a graph, we write $e(\Gamma)$ for the number of edges in Γ.

LEMMA 2.3. *Let $J = (V, E)$ be a (ϱ, L)-uniform graph, and let $S \subseteq V$ be a nonempty subset of vertices of J. Then*

$$\begin{aligned} e(J[S]) &= \varrho\binom{|S|}{2} + O_1\big(Lr^{1/2}(|S|+1)\big) \\ &= \varrho\frac{|S|^2}{2} + O_1\big(2Lr^{1/2}|S|\big), \end{aligned} \tag{2.2}$$

where $r = \varrho|V|$.

Proof. Put $s = |S|$. Note that, for any $1 \le t < s$, we have $2e(S)\binom{s-2}{t-1} = \sum_T e(T, S \setminus T)$, where the sum is extended over all $T \subset S$ with $|T| = t$. Thus

$$e(S) = \frac{1}{2}\binom{s}{t}\binom{s-2}{t-1}^{-1}\Big\{\varrho|T||S \setminus T| + O_1\big(L\{rt(s-t)\}^{1/2}\big)\Big\}$$

for any $1 \le t < s$. We use this relation with $t = \lfloor s/2 \rfloor$. Note that

$$\binom{s}{\lfloor s/2 \rfloor}\binom{s-2}{\lfloor s/2 \rfloor - 1}^{-1} = \frac{s(s-1)}{\lfloor s/2 \rfloor \lceil s/2 \rceil} \le 4,$$

and so

$$e(S) = \varrho\binom{s}{2} + O_1\big(2L\{r\lfloor s/2 \rfloor \lceil s/2 \rceil\}^{1/2}\big) = \varrho\binom{s}{2} + O_1\big(Lr^{1/2}(s+1)\big),$$

and the result follows. □

In what follows, the following simple consequences of Lemma 2.3 will be useful.

LEMMA 2.4. *Let $\eta > 0$ and $L > 0$ be given. Then there is an $\overline{r} = \overline{r}(\eta, L)$ such that any m-vertex (ϱ, L)-uniform graph J with $\varrho m \ge \overline{r}$ has the two properties below.*

(a) *If $S \subset V(J)$ is such that $|S| = \nu m \ge \eta m$, then*

$$e(J[S]) = (1 + O_1(\eta))\nu^2 e(J)\,. \tag{2.3}$$

(b) *If $S \subset V(J)$ is such that $|S| < \eta m$, then*

$$e(J[S]) < 2\eta^2 e(J)\,. \tag{2.4}$$

2.2. Auxiliary results on expander graphs. The celebrated Ramanujan graphs of Lubotzky, Phillips, and Sarnak [26, 27] are explicitly constructible examples of linear-sized $(\varrho, 2)$-uniform graphs. We shall make crucial use of their construction.

The Ramanujan graphs $X^{p,q}$ constructed in [26, 27] depend on certain primes p and q, which have to satisfy certain simple arithmetical conditions. The graphs $X^{p,q}$ that we shall be interested in are $(p+1)$-regular and have $q(q^2-1)/2$ vertices. However, we shall need to construct linear-sized $(\varrho, O(1))$-uniform graphs with m vertices and average degree around r, where m and r are arbitrary integers (which we may assume to be large). The main result of this section, Lemma 2.5, asserts that this can be done efficiently. As the reader will see, we shall simply check that, given m and r, we may find suitable primes p and q so that an induced subgraph of $X^{p,q}$ will do.

LEMMA 2.5. *There exists an algorithm $\mathcal{E}$ satisfying the following properties. There is an absolute constant r_1 such that for all $r_0 \geq r_1$ there are constants $m_0 = m_0(r_0)$ and $C_0 = C_0(r_0)$ for which the following holds. Algorithm $\mathcal{E}$ receives as input integers $r_0 \geq r_1$ and $m \geq m_0 = m_0(r_0)$, and returns an adjacency list representation of a particular $(\varrho, 3)$-uniform graph J on m vertices with $r = \varrho m$ satisfying $r_0 \leq r \leq 2r_0$. Furthermore, algorithm $\mathcal{E}$ runs in time $\leq C_0 m (\log m)^2$.*

In the remainder of this section, we prove Lemma 2.5 for completeness.

2.2.1. Ramanujan graphs. Before we start with the proof of Lemma 2.5, we recall the construction of Lubotzky, Phillips, and Sarnak [26, 27].

As usual, in what follows, if a is an integer and p is a prime with a not divisible by p, the Legendre symbol $(\frac{a}{p})$ is defined as 1 if a is a quadratic residue modulo p and as -1 if a is a quadratic nonresidue modulo p. To describe the construction in [26, 27], let p and q be two unequal primes satisfying

$$p,\, q \equiv 1 \pmod 4 \tag{2.5}$$

and

$$\left(\frac{p}{q}\right) = 1. \tag{2.6}$$

We now let S and T be the following sets. Below, i is an arbitrary fixed integer such that $i^2 \equiv -1 \pmod q$. We let

$$\begin{aligned} S = \big\{(\alpha_0, \alpha_1, \alpha_2, \alpha_3) \in \mathbb{Z}^4 \colon\ & \alpha_0^2 + \alpha_1^2 + \alpha_2^2 + \alpha_3^2 = p \\ & \text{with } \alpha_0 > 0,\ \text{odd, and } \alpha_1, \alpha_2, \alpha_3 \text{ even}\big\}, \end{aligned}$$

$$T = \left\{ \begin{pmatrix} \alpha_0 + i\alpha_1 & \alpha_2 + i\alpha_3 \\ -\alpha_2 + i\alpha_3 & \alpha_0 - i\alpha_1 \end{pmatrix} : (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \in S \right\}. \tag{2.7}$$

We now consider $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$ (the projective special linear group), which consists of the 2×2 matrices over $\mathbb{Z}/q\mathbb{Z}$ whose determinants are nonzero quadratic residues mod p, quotiented out by the equivalence relation that makes two such matrices equivalent if one is a nonzero scalar multiple of the other.

It will be convenient to observe that each element of $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$ (i.e., each equivalence class) may be represented by a matrix whose second row is either $(0, 1)$ or $(1, x)$, where x is some arbitrary element of $\mathbb{Z}/q\mathbb{Z}$. The existence of this simple "canonical representation" for the elements of $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$ will be helpful below.

Observe that if we consider the entries of the matrices in T modulo q, we get 2×2 matrices over $\mathbb{Z}/q\mathbb{Z}$, with determinant $p \pmod q$, which is a nonzero quadratic residue

modulo q (cf. (2.6)). By a well-known result of Jacobi and some simple arguments, one may check that there are $p+1$ elements in T and that they are all distinct in $\mathrm{PSL}(2,\mathbb{Z}/q\mathbb{Z})$.

The graph $X^{p,q}$ constructed in [26, 27] is the Cayley graph of $\mathrm{PSL}(2,\mathbb{Z}/q\mathbb{Z})$ relative to the set T. The vertices of $X^{p,q}$ are the elements of $\mathrm{PSL}(2,\mathbb{Z}/q\mathbb{Z})$, and the edge set of $X^{p,q}$ is so that $\{x,y\}$ is an edge of $X^{p,q}$ if and only if there is a $t\in T$ such that $x=ty$ (one may check that this is a symmetric relation). A key result concerning the graphs $X^{p,q}$ is the following.

THEOREM 2.6. *The graph $X^{p,q}$ is a nonbipartite $(p+1)$-regular graph on $n=q(q^2-1)/2$ vertices. Moreover, if the eigenvalues of $X^{p,q}$ are $|\lambda_1|\geq\cdots\geq|\lambda_n|$, then $\lambda_1=p+1$ and*

$$|\lambda_j|\leq 2\sqrt{p}\quad \textit{for all}\quad j>1. \tag{2.8}$$

Because of (2.8), the graphs $X^{p,q}$ are called *Ramanujan graphs*. We now state the following well-known pseudorandom property of the graphs $X^{p,q}$, which follows from (2.8) (see, e.g., Corollary 9.2.5 in [5]).

COROLLARY 2.7. *The graph $X^{p,q}$ is $(\varrho,2)$-uniform, where $\varrho=(p+1)/n$.*

Having covered the basics of the Lubotzky, Phillips, and Sarnak construction, we turn to the proof of Lemma 2.5.

2.2.2. Proof of Lemma 2.5. We start with a simple lemma asserting the existence of appropriate primes p and q.

LEMMA 2.8. *There exists an absolute constant r_1 such that, for any $r_0\geq r_1$, there exists an integer $m_0=m_0(r_0)$ for which the following holds. There is an algorithm $\mathcal{P}$ that, on input (r_0,m), where $r_0\geq r_1$ and $m\geq m_0=m_0(r_0)$, produces a pair of primes p and q which satisfy*

$$p\neq q,\quad p,\,q\equiv 1\ (\mathrm{mod}\ 4),\quad \text{and}\quad \left(\frac{p}{q}\right)=1, \tag{2.9}$$

$$1.4r_0\leq p+1\leq 2r_0, \tag{2.10}$$

and

$$\sqrt[3]{2.1m}\leq q\leq 1.1\sqrt[3]{2.1m}. \tag{2.11}$$

Algorithm $\mathcal{P}$ runs in time $\leq C_1 m^{1/2}(\log m)^2$, where $C_1=C_1(r_0)$ depends only on r_0.

Proof. Let us start recalling Dirichlet's theorem on primes in arithmetic progressions. In particular, the quantitative version of Dirichlet's theorem implies that for integers a and b with $(a,b)=1$, there is an integer $t_{a,b}$ such that for all $t\geq t_{a,b}$ there is a prime $p\equiv a\ (\mathrm{mod}\ b)$ in the interval $[t,11t/10]=\{x\colon t\leq x\leq 11t/10\}$.

We let $r_1=t_{1,8}+1$ and proceed to show that this choice of r_1 will do. Thus, let an arbitrary integer $r_0\geq r_1$ be given, and let us define $m_0=m_0(r_0)$ as required in our lemma. To that end, first observe that, by the choice of r_1, there is a prime $p\equiv 1\ (\mathrm{mod}\ 8)$ satisfying (2.10). We fix such a prime p. Observe that we have $p\equiv 1\ (\mathrm{mod}\ 4)$. Moreover, since $p\equiv 1\ (\mathrm{mod}\ 8)$, we have that

$$2 \text{ is a quadratic residue modulo } p. \tag{2.12}$$

Since $(4,p)=1$, by the Chinese remainder theorem, there is a unique integer s with $1\leq s\leq 4p$ satisfying

$$s\equiv 2\pmod{p}\qquad\text{and}\qquad s\equiv 1\pmod{4}. \tag{2.13}$$

We are finally ready to define $m_0 = m_0(r_0)$. We let

$$m_0 = m_0(r_0) = \max\left\{\frac{10}{21}t_{s,4p}^3,\ \frac{8}{2.1}r_0^3\right\}. \tag{2.14}$$

Our aim now is to show that the choice for $m_0 = m_0(r_0)$ in (2.14) will do. Thus, let $m \geq m_0(r_0)$ be given. We shall now describe a procedure $\mathcal{P}$ to find the primes p and q as required. Our description will be quite informal.

The prime p with $p \equiv 1 \pmod 8$ satisfying (2.10) may be found easily. We now need to determine a suitable value for q. We choose q among the integers in the arithmetic progression $\{4pk + s\colon k = 0, 1, 2, \dots\}$, where s is the integer satisfying $1 \leq s \leq 4p$ and (2.13). By Dirichlet's theorem and our choice of $m_0 \geq (10/21)t_{s,4p}^3$, there is a prime $q \equiv s \pmod{4p}$ satisfying (2.11). We claim that our choice of s implies all properties promised for q. Indeed, $q \equiv s \equiv 1 \pmod 4$. Furthermore, the quadratic reciprocity law implies $(\frac{p}{q}) = (\frac{q}{p})$, since both $p, q \equiv 1 \pmod 4$. Using that $q \equiv s \equiv 2 \pmod p$ and recalling (2.12), we have

$$\left(\frac{p}{q}\right) = \left(\frac{q}{p}\right) = \left(\frac{s}{p}\right) = \left(\frac{2}{p}\right) = 1.$$

Finally, note that $m_0 \geq 8r_0^3/2.1$ guarantees $q > p$ and, consequently, condition (2.9) is satisfied. Therefore, the primes p and q, as required, do exist.

Let us now consider the time complexity of our procedure $\mathcal{P}$ above. We first observe that the search for $p < 2r_0$ takes a quantity of steps that depends only on r_0. To find q, we have enough time to check all integers in the interval $[\sqrt[3]{2.1m}, 1.1\sqrt[3]{2.1m}]$. Since this interval is of length $O(m^{1/3})$, this will take $O(m^{1/3} \cdot m^{1/6}(\log m)^2) = O(m^{1/2}(\log m)^2)$ steps. The $(\log m)^2$ term accounts for the time complexity of arithmetic operations with integers having $O(\log m)$ digits. □

We now describe algorithm $\mathcal{E}$, the existence of which is asserted in Lemma 2.5. Consider the integer r_1 and the function $m_0(r_0)$ whose existences are guaranteed by Lemma 2.8. On input (r_0, m), where $r_0 \geq r_1$ and $m \geq m_0(r_0)$, algorithm $\mathcal{E}$ performs the following steps.

1. Run algorithm $\mathcal{P}$ on input (r_0, m) to obtain primes p and q as in the statement of Lemma 2.8.
2. List all elements of $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$, i.e., the vertex set of $X^{p,q}$, by enumerating all the canonical representatives of the elements in $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$.
3. Find all solutions to $\alpha_0^2 + \alpha_1^2 + \alpha_2^2 + \alpha_3^2 = p$ that belong to S and construct T (see (2.7)).
4. For each vertex x of $X^{p,q}$, construct its adjacency list.
5. Set J to be any induced subgraph of $X^{p,q}$ on m vertices.

The following claim will finish the proof of Lemma 2.5.

Claim 2.9. *Algorithm $\mathcal{E}$ produces a graph J that is $(\varrho, 3)$-uniform in time $\leq Cm(\log m)^2$, where $r = \varrho m$ satisfies $r_0 \leq r \leq 2r_0$, and C is a constant that depends only on r_0.*

Proof. We start with the correctness of $\mathcal{E}$. We already know that $\mathcal{P}$ produces suitable primes p and q. Hence, we need only to argue that the graph J obtained in step 5 has the required properties.

By Theorem 2.6 and Corollary 2.7, the graph $X^{p,q}$ constructed in steps 2–4 has $n = q(q^2-1)/2$ vertices, is $(p+1)$-regular, and is $(\varrho, 2)$-uniform with $\varrho = (p+1)/n$. Furthermore, note that (2.11) implies $1 \leq n/m \leq 1.05(1.1)^3$. Lemma 2.1 implies

J is a (ϱ, L)-uniform graph with $\varrho = (p+1)/n$ and $L = 2\sqrt{n/m} \le 2.1\sqrt{231/200} = 2.256\cdots < 3$. Thus J is indeed a $(\varrho, 3)$-uniform graph.

Since $1 \le n/m \le 1.05(1.1)^3$, we deduce that $r = \varrho m = (p+1)m/n$ is such that

$$r \le 2r_0$$

and

$$r \ge 1.4r_0 \cdot \frac{20}{21}\left(\frac{10}{11}\right)^3 \ge r_0 \ .$$

Finally, we argue about the time complexity of each of the steps in algorithm $\mathcal{E}$. By Lemma 2.8, we already know that step 1 takes time $\le C_1(r_0)m(\log m)^2$, where $C_1(r_0)$ is a constant that depends only on r_0.

Recalling the form of the canonical representatives of the elements in $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$, we see that step 2 may be performed in time $O(m(\log m)^2)$. The time complexity of step 3 depends only on r_0.

In step 4, we take one by one the vertices of $X^{p,q}$, i.e., the elements of $\mathrm{PSL}(2, \mathbb{Z}/q\mathbb{Z})$, and generate their adjacency lists. Since $|T| = p+1 \le 2r_0$, to generate the adjacency list of a particular vertex takes only $O((\log q)^2)$ steps.

Finally, taking m vertices of $X^{p,q}$ arbitrarily and adjusting their adjacency lists to create an adjacency list representation for the corresponding induced subgraph takes $O(m \log m)$ time. Therefore, the time complexity of algorithm $\mathcal{E}$ is $\le C_0(r_0)m(\log m)^2$, as promised. □

3. Algorithms. Before we describe the algorithm, let us introduce some notation. Let $\Gamma = (V, E)$ be a graph and $v \in V$ a vertex. We write $\Gamma(v)$ for the neighborhood of v, i.e., for the set of all vertices adjacent to v in Γ, and $d(v)$ for the degree of v, i.e., $d(v) = |\Gamma(v)|$. To shorten our notation we will use that same letter to denote a graph and the set of its edges. For example, Γ will also stand for $E(\Gamma)$, and hence $e(\Gamma) = |\Gamma|$.

3.1. Regularity of bipartite graphs. In this section we describe algorithm $\mathcal{A}$ which takes as an input a bipartite graph $G = (A, B; E), |A| = |B| = m$, and $0 < \varepsilon < 1$. The algorithm in time $O(m^2)$ either confirms that G is ε-regular or finds sets $A' \subseteq A, B' \subseteq B, |A'| \ge \varepsilon' m, |B'| \ge \varepsilon' m$, such that

$$|d(A', B') - d(A, B)| \ge \varepsilon' \ .$$

Our algorithm $\mathcal{A}$ consists of the preprocessing stage $\mathcal{A}_P$ and the main procedure $\mathcal{A}_M$.

3.1.1. The preprocessing stage. In order to describe the preprocessing stage we need to define

$$\varepsilon' = \left(\frac{\varepsilon}{10}\right)^{20} \frac{1}{10^4} \ . \tag{3.1}$$

To describe $\mathcal{A}_P$ we need the constants ε and ε' only. Note that other constants are used for describing the other part $\mathcal{A}_M$; these other constants will be defined later in section 3.1.2 and will be related to ε and ε' above.

Algorithm $\mathcal{A}_P$ is based on the following standard observation and Lemma 3.1. We observe that if the bipartite graph G on vertex set $A \cup B, |A| = |B| = m$, is such that $p(G) := d(A, B) = |G|/m^2 \le \varepsilon^3$, then G is ε-regular (we omit the proof of this standard observation).

Lemma 3.1 quantifies a further observation that we may remove some vertices of our graph G so that we either obtain a subgraph $H \subseteq G$ that is essentially degree-regular (all degrees are about the same) or else in the process of removing these vertices we locate a witness to the ε'-irregularity of G. This is formalized as follows.

LEMMA 3.1. *Suppose G is a bipartite graph with vertex set $A \cup B$, $|A| = |B| = m$, and suppose that $p(G) > \varepsilon^3$ holds. There is a procedure that runs in time $O(m^2)$ that either* (i) *produces a witness to the ε'-irregularity of G or* (ii) *produces a bipartite subgraph $H \subseteq G$, say $H = (U, V; F)$, such that*

(a)

$$(1 - 2\varepsilon')m < |U|, |V| \leq m \,, \tag{3.2}$$

(b)

$$\big|p(H) - p(G)\big| \leq 5\varepsilon', \tag{3.3}$$

where $p(H) = |H|/|U||V|$, and

(c) *for all $u \in U$ and $v \in V$ we have*

$$\begin{aligned} d(u) &= (p(H) + O_1(10\varepsilon')) \cdot |V| \,, \\ d(v) &= (p(H) + O_1(10\varepsilon')) \cdot |U| \,. \end{aligned} \tag{3.4}$$

Proof. We first omit the vertices v in V for which the condition

$$d(v) = (p(G) + O_1(\varepsilon'))m \tag{3.5}$$

fails. If the number of such vertices is $\geq 2\varepsilon' m$, we may easily produce a witness to the ε'-irregularity of G as in (i) in the statement of our lemma. Suppose therefore that the number of such vertices is $< 2\varepsilon' m$. Let $V \subseteq B$ be the resulting subset of B. Hence $|V| > (1 - 2\varepsilon')m$. We now omit the vertices $u \in A$ for which the condition

$$d(u) = (p(G) + O_1(\varepsilon')) \cdot |V| \tag{3.6}$$

fails. Again, if the number of such vertices is $\geq 2\varepsilon' m$, we may easily produce a witness to the ε'-irregularity of G. If the number of such vertices is $< 2\varepsilon' m$, the resulting graph H is as in (ii) in the statement of our lemma.

The time complexity assertion will be verified in the proof of Lemma 3.4 (cf. algorithm $\mathcal{A}_P$ below). □

For convenience, we let $\Psi(m, \varepsilon')$ be the family of subgraphs H of G that satisfy (a)–(c) in (ii) of Lemma 3.1 above.

Now we are ready to describe *algorithm $\mathcal{A}_P$*:

1. Given G and ε, decide if $p(G) < \varepsilon^3$.
2. If $p(G) \leq \varepsilon^3$, then G is ε-regular and $\mathcal{A}_P$ halts.
3. If $p(G) > \varepsilon^3$, apply Lemma 3.1 to construct a subgraph H of G which satisfies (a)–(c). (Algorithm $\mathcal{A}_M$ will be applied to H.)

3.1.2. The main procedure. In view of step 3 in algorithm $\mathcal{A}_P$ (cf. Lemma 3.1) we will now assume that $H \in \Psi(m, \varepsilon')$.

(a) *Definition of constants.* Before describing algorithm $\mathcal{A}_M$ we will define constants needed for it. Recall that algorithm $\mathcal{A}$, and thus $\mathcal{A}_M$, is given $0 < \varepsilon < 1$. In section 3.1.1 we already defined $\varepsilon' = (\varepsilon/10)^{20}/10^4$.

We first let

$$\delta = \frac{1}{4}\Big(\frac{\varepsilon}{2}\Big)^5, \qquad L = 5, \quad \text{and} \quad r_A = \frac{10^6}{\varepsilon^8}\,. \tag{3.7}$$

We now let

$$\mu = \Big(\frac{\varepsilon}{10}\Big)^{10}\frac{1}{100} \tag{3.8}$$

and put

$$\eta = \frac{\mu}{3}\,. \tag{3.9}$$

We also let $r_B = \overline{r}(\eta, L)$ be as given in Lemma 2.4 and let

$$r_0 = \max\{r_A, r_B\}. \tag{3.10}$$

Finally, we set

$$\varepsilon_1 = \frac{1}{4}\left(\frac{\varepsilon}{2}\right)^{16}\,. \tag{3.11}$$

This will be used only later in a proof. However, it might be helpful to see the relation of ε_1 to the other constants introduced here.

The reader may find it useful to keep in mind the following hierarchy of the constants for ε small:

$$\varepsilon' < \varepsilon^{20} \ll \varepsilon_1 < \varepsilon^{16} \ll \eta = \frac{\mu}{3} < \varepsilon^{10} \ll \delta \ll \varepsilon^3 \ll \varepsilon,\, p\,. \tag{3.12}$$

(Here inequalities "$<$" are used to compare two quantities which differ by an absolute constant.) Note that for the description of $\mathcal{A}_M$ we need only to know r_0 and δ defined above. The other constants are needed in the proofs below.

(b) *Property* $\mathcal{P}(J,\delta)$. We introduce some notation. Let H be a bipartite graph with vertex set $U \cup V$. Let J be a (ϱ, L)-uniform graph with vertex set U. We say that H *has property* $\mathcal{P}(J,\delta)$ if

$$\sum_{\{u,u'\}\in J} \big|d_H(u,u') - p(H)^2\cdot|V|\big| \le \delta p(H)^2|V|\cdot|J| \tag{3.13}$$

holds. Recall that due to our notation $\{u,u'\} \in J$ means that $\{u,u'\}$ is an edge of J. Moreover, let us write J_v ($v \in V$) for the graph $J[H(v)]$ induced by the neighborhood $H(v)$ of v in H. We define a 0–1 matrix $M = (m(e,v))_{e,v}$ indexed by $J \times V$ as follows:

$$m(e,v) = \begin{cases} 1 & \text{if } e \in J_v,\\ 0 & \text{otherwise.}\end{cases} \tag{3.14}$$

Therefore, clearly, $m(e,v) = 1$ if and only if both endpoints of e are adjacent to v.

(c) *Description of* $\mathcal{A}_M$. We assume $\mathcal{A}_M$ is given a bipartite graph $H \in \Psi(m,\varepsilon')$ having vertex set $U \cup V$. *Algorithm* $\mathcal{A}_M$ now proceeds as follows:

1. Apply procedure $\mathcal{E}$ to construct a (ϱ, L)-uniform graph J with vertex set U and average degree $r = \varrho\cdot|U|$ satisfying

   $$r_0 = r_0(\eta) \le r \le 2r_0 \tag{3.15}$$

   (cf. Lemma 2.5).

2. Verify whether H has $\mathcal{P}(J,\delta)$. If it does, then G is ε-regular (see Lemma 3.2 below) and $\mathcal{A}_M$ halts.
3. If $\mathcal{P}(J,\delta)$ fails for H, construct matrix $M=(m(e,v))_{e,v}$ defined above. Find and fix a vertex $v_0\in V$ such that

$$\sum_{v\in V}\sum_{e\in J_{v_0}} m(e,v)\ge\left(1+\frac{\delta^2}{2}\right)p(H)^4|V|\cdot|J|. \tag{3.16}$$

(The existence of such a vertex v_0 is proved later; cf. Lemma 3.5.)
4. Set $U'=H(v_0)$ and

$$V'=\left\{v'\in V:\ \sum\{m(e,v'):\,e\in J_{v_0}\}\ge\left(1+\frac{\delta^2}{4}\right)p(H)^4\cdot|J|\right\}. \tag{3.17}$$

5. $\mathcal{A}_M$ outputs (U',V') and claims that this is a witness to the ε'-irregularity of G.

3.1.3. Correctness and analysis of algorithm $\mathcal{A}$. The correctness of $\mathcal{A}$ follows from Lemmas 3.2 and 3.3. The first lemma says that if algorithm $\mathcal{A}_M$, and hence $\mathcal{A}$, claims that G is ε-regular in step 2, then this is indeed the case.

LEMMA 3.2. *If H enjoys property $\mathcal{P}(J,\delta)$, then G is ε-regular.*

LEMMA 3.3. *If property $\mathcal{P}(J,\delta)$ fails for H, then G is not ε'-regular, and the pair (U',V') produced by algorithm $\mathcal{A}_M$ is indeed a witness for the ε'-irregularity of G.*

We shall prove the two lemmas above in section 4. The next two lemmas immediately imply that $\mathcal{A}$ has time complexity $O(m^2)$.

LEMMA 3.4. *Algorithm $\mathcal{A}_P$ described in section* 3.1.1 *has time complexity $O(m^2)$.*

Proof. The steps of $\mathcal{A}_P$ have the following time complexity. The only computations are in steps 1 and 3.

Step 1. Since $p(G)=|G|/m^2$, it takes at most $O(m^2)$ steps to compute $p(G)$ and decide whether $p(G)<\varepsilon^3$.

Step 3. Based on the proof of Lemma 3.1, a vertex of G is put into H if and only if it satisfies (3.4). Hence, we proceed through all $2m$ vertices of G, each time checking (3.4), which takes $O(m)$ steps. Thus, this step takes $O(m^2)$ steps, too.

The overall time complexity of $\mathcal{A}_P$ is $O(m^2)$. □

LEMMA 3.5. *Algorithm $\mathcal{A}_M$ described in section* 3.1.2 *runs in time $O(m^2)$.*

Proof. The steps of $\mathcal{A}_M$ have the following time complexity.

Step 1. To perform procedure $\mathcal{E}$ we need $O(m(\log m)^2)$ steps; cf. Lemma 2.5.

Step 2. To verify $\mathcal{P}(J,\delta)$ we need to add $|J|=O(m)$ summands. Computing each of these summands takes $O(m)$ steps. Consequently, one can decide $\mathcal{P}(J,\delta)$ in $O(m^2)$ time.

Step 3. Deciding if $m(e,v)=1$ or 0 can be performed in constant time. Thus, constructing M takes $O(|J||V|)=O(m^2)$ time. To check (3.16), we first write it in the equivalent form

$$\sum_{e\in J_{v_0}}\sum_{v\in V} m(e,v)\ge\left(1+\frac{\delta^2}{2}\right)p(H)^4|V|\cdot|J|\,. \tag{3.18}$$

Using matrix M we compute the column sums $\sum_{v\in V}m(e,v)$ for each $e\in J$. This takes $O(m^2)$ steps.

Now to check (3.18) for a fixed vertex $v_0 \in V$, we first find J_{v_0}, which takes $|J_{v_0}| = O(m)$ steps. Then we add together the column sums $\sum_{v\in V} m(e,v)$ for all $e \in J_{v_0}$ and decide about the truth of (3.18). This takes another $O(m)$ steps. In the worst case we need to check all $v_0 \in V$. Since $|V| = m$, to find v_0 that satisfies (3.18) will take at most $O(m^2)$ steps.

Step 4. Since for each $v' \in V$ the condition $\sum_{e\in J_{v_0}} m(e,v') \geq (1+\delta^2/4)p(H)^4|J|$ can be verified in $O(m)$ time, the set V' can be constructed in $O(m^2)$ time.

Step 5. This step takes a constant time.

Therefore, the time complexity of $\mathcal{A}_M$ is $O(m^2)$. Finally, let us point out that the fact that J has $O(m)$ edges was crucial. □

3.2. The regularity lemma. For the sake of completeness, we include an algorithm necessary for proving Corollary 1.6. Given Theorem 1.5 we can derive the necessary algorithm in a standard way.

Let $V_0, V_1, \ldots, V_k$ be an equitable partition P of the set of vertices of a graph. We define the *index* of P (cf. [31]) by

$$\operatorname{ind}(P) = \frac{1}{k^2} \sum_{1\leq r<s\leq k} d(V_r, V_s)^2 .$$

To present a proof of Corollary 1.6 we will use the following lemma, which was proved in [31]. Note that no comment is made in [31] on the running time. However, the proof of the lemma implies an algorithm of time complexity $O(n)$.

LEMMA 3.6. *Fix k and γ, and let $G = (V,E)$ be a graph on n vertices. Let P be an equitable partition of V into classes $V_0, V_1, \ldots, V_k$. Assume $|V_1| > 4^{2k}$ and $4^k > 600\gamma^{-5}$. Given proofs that more than γk^2 pairs (V_r, V_s) are not γ-regular (where by proofs we mean subsets $X = X(r,s) \subseteq V_r$, $Y = Y(r,s) \subseteq V_s$ that violate the condition of γ-regularity of (V_r, V_s)), then one can find in $O(n)$ time an equitable partition P' (which is a refinement of P) into $1 + k4^k$ classes, with the exceptional class of cardinality at most $|V_0| + n/4^k$, and such that*

$$\operatorname{ind}(P') \geq \operatorname{ind}(P) + \frac{\gamma^5}{20} .$$

Proof of Corollary 1.6. Theorem 1.5 and Lemma 3.6 already imply Corollary 1.6. Let $\varepsilon > 0$ and k_0 be a positive integer. Let $\varepsilon' = \varepsilon^{20}/10^{24}$. We set $N = N(\varepsilon, k_0)$ and $T = T(\varepsilon, k_0)$ as follows: Let a be the least positive integer such that

$$4^a > 600 \left(\frac{\varepsilon'}{4}\right)^{-5}, \quad a \geq k_0 . \tag{3.19}$$

Let k_i be a sequence of integers defined inductively as

$$k_0 = a, \quad k_{i+1} = k_i 4^{k_i} .$$

Set $T = k_{\lceil 10(\varepsilon'/4)^{-5}\rceil}$ and $N = \max\{T4^{2T}, 2T/{\varepsilon'}^2\}$. Finally, we set $K_0'' = N \geq T$.

Let $\Gamma = (V,E)$ be a graph on n vertices, $n \geq N$. The following algorithm constructs an ε-regular partition of Γ into $k+1$ classes with $k_0 \leq k \leq T \leq K_0''$.

Algorithm $\mathcal{A}_0'$ proceeds as follows:

1. Arbitrarily divide the vertices of Γ into an equitable partition P_1 with classes $V_0, V_1, \ldots, V_a$, where $|V_1| = \lfloor n/a \rfloor$ and $|V_0| < a$. Set $k_1 = a$.

2. For every pair (V_r, V_s) of P_i, verify if it is ε-regular or find $V_r' \subseteq V_r$, $V_s' \subseteq V_s$, $|V_r'| \geq (\varepsilon'/4)|V_r|$, $|V_s'| \geq (\varepsilon'/4)|V_s|$, such that $|d(V_r', V_s') - d(V_r, V_s)| \geq \varepsilon'$.
3. If there are at most $\varepsilon\binom{k_i}{2}$ pairs that are not verified as ε-regular, then stop. The partition P_i is an ε-regular partition.
4. Apply Lemma 3.6, where $P = P_i$, $k = k_i$, and $\gamma = \varepsilon'/4$, and obtain a partition P' with $1 + k_i 4^{k_i}$ classes.
5. Let $k_{i+1} = k_i 4^{k_i}$, $P_{i+1} = P'$, and $i = i + 1$, and go to step 2.

CLAIM 3.7. *Algorithm $\mathcal{A}_0'$ as described is correct and runs in $O(n^2)$ time.*

Proof. To prove correctness of algorithm $\mathcal{A}_0'$ is quite standard. Since the index of partitions P_i constructed by $\mathcal{A}_0'$ strictly increases and at the same time is bounded by 1 from above, algorithm $\mathcal{A}_0'$ uses Lemma 3.6, and thus Theorem 1.5, only finitely many times. Each such use takes $O(n^2)$ time. □

4. Proofs of the main lemmas. We use the notation introduced in section 3.1. Before the proofs let us point out a straightforward estimate on the size of neighborhoods used throughout the proofs.

Remark 4.1. Let $H \in \Psi(m, \varepsilon')$ be the graph in the statement of Lemma 3.1, and let $u \in U$ and $v \in V$ be vertices of H. As an immediate consequence of (3.4) and the definition of ε' and μ, we get

$$\begin{aligned} |H(u)| &= (p(H) + O_1(10\varepsilon'))|V| = (1 + O_1(\mu))p(H)|V| \,, \\ |H(v)| &= (p(H) + O_1(10\varepsilon'))|U| = (1 + O_1(\mu))p(H)|U| \,. \end{aligned} \tag{4.1}$$

4.1. Proof of Lemma 3.2. Let $H \in \Psi(m, \varepsilon')$ be the input graph of algorithm $\mathcal{A}_M$. Let $U \cup V$ be the vertex set of H. Set $m_U = |U|$, $m_V = |V|$, and $p := p(H) = |H|/m_U m_V$.

We say that the graph H has *property* $\mathcal{Q}(J, \delta)$ if the inequality

$$\sum_{\{u,u'\} \in J} \left| d_H(u, u') + p^2 m_V - (d_H(u) + d_H(u'))p \right| \leq \delta p^2 m_V \cdot |J| \tag{4.2}$$

holds true.

CLAIM 4.2. *Let $\delta > 0$ be fixed. If a graph $H \in \Psi(m, \varepsilon')$ has property $\mathcal{P}(J, \delta)$, then it has property $\mathcal{Q}(J, 2\delta)$.*

Proof. Since H enjoys $\mathcal{P}(J, \delta)$ and $H \in \Psi(m, \varepsilon')$, we have

$$\begin{aligned} &\sum_{\{u,u'\} \in J} \left| d_H(u, u') + p^2 m_V - (d_H(u) + d_H(u'))p \right| \\ &\qquad \leq \sum_{\{u,u'\} \in J} \left| d_H(u, u') - p^2 m_V \right| \\ &\qquad\qquad + 2p \sum_{u \in U} \left| p m_V - d_H(u) \right| d_J(u) \\ &\qquad \leq \delta p^2 m_V |J| + 20 p \varepsilon' m_V \sum_{u \in U} d_J(u) \\ &\qquad \leq 2\delta p^2 m_V |J| \,, \end{aligned}$$

since $\varepsilon' \leq \delta\varepsilon^3/40 \leq \delta p/40$ (see (3.1), (3.7)). □

In view of Claim 4.2, we are going to prove the following claim.

CLAIM 4.3. *Every $H \in \Psi(m, \varepsilon')$ that has property $\mathcal{Q}(J, 2\delta)$ is $(\varepsilon/2)$-regular.*

The proof is presented below. First, let us observe that the $\varepsilon/2$-regularity of H implies the ε-regularity of G. Indeed, let $X \subseteq A$, $|X| \geq \varepsilon|A|$, and $Y \subseteq B$, $|Y| \geq \varepsilon|B|$. Set $X' = X \cap U$ and $Y' = Y \cap V$. By Lemma 3.1,

$$|X'| \geq \varepsilon|A| - 2\varepsilon'|A| \geq (\varepsilon - 2\varepsilon')|U| \geq \frac{\varepsilon}{2}|U|$$

and, similarly,

$$|Y'| \geq \frac{\varepsilon}{2}|V| \,.$$

A standard argument based on the fact that X' and Y' are almost equal to X and Y (recall Lemma 3.1) shows that $|d(X,Y) - d(X',Y')| \leq \varepsilon/4$. Thus, using the $\varepsilon/2$-regularity of H and Lemma 3.1, we get

$$\begin{aligned}|d(X,Y) - d(A,B)| &\leq |d(X,Y) - d(X',Y')| + |d(X',Y') - d(U,V)| \\ &\quad + |d(U,V) - d(A,B)| \leq \frac{\varepsilon}{4} + \frac{\varepsilon}{2} + 5\varepsilon' < \varepsilon \,.\end{aligned}$$

Hence, G is ε-regular. □

Proof of Claim 4.3. Let $\mathbb{A} = (a_{u,v})_{u,v}$ be a matrix indexed by $U \times V$ with entries

$$a_{u,v} = \begin{cases} -(1-p) & \text{if } \{u,v\} \in H, \\ p & \text{otherwise.} \end{cases}$$

Moreover, for $u \in U$, let $\xi_u = (a_{u,1}, \ldots, a_{u,m_V})$ be the uth row of $\mathbb{A}$. The following claim follows easily from the definition of property $\mathcal{Q}$ (see (4.2)).

Claim 4.4. *For every $H \in \Psi(m,\varepsilon')$ that has property $\mathcal{Q}(J,2\delta)$, the row-vectors of $\mathbb{A}$ satisfy the following inequality:*

$$\sum_{\{u,u'\} \in J} |\langle \xi_u, \xi_{u'} \rangle| \leq 2\delta p^2 m_V |J| \,. \tag{4.3}$$

Proof. Since

$$\begin{aligned}\langle \xi_u, \xi_{u'} \rangle &= d_H(u,u')(1-p)^2 - (d_H(u) + d_H(u') - 2d_H(u,u'))p(1-p) \\ &\quad + (m_V - (d_H(u) + d_H(u') - d_H(u,u'))p^2 \\ &= d_H(u,u')[(1-p)^2 + 2p(1-p) + p^2] + m_V p^2 - (d_H(u) + d_H(u'))p \\ &= d_H(u,u') + m_V p^2 - (d_H(u) + d_H(u'))p\end{aligned}$$

for any pair of vertices $u, u' \in U$, we have that $\sum_{\{u,u'\} \in J} |\langle \xi_u, \xi_{u'} \rangle|$ equals the sum on the left-hand side of (4.2). Thus the claim follows. □

Let $U' \subseteq U$ and $V' \subseteq V$. To shorten our notation $\sum_{u,u' \in J}^{U'}$ will denote summation over $\{u,u'\} \in J$ such that $u, u' \in U'$. Furthermore, for $u \in U'$ let ψ_u be the restriction of the vector ξ_u to V', i.e., $\psi_u = (a_{u,v})_{v \in V'}$. We clearly have $\sum_{u,u' \in J}^{U'} |\langle \xi_u, \xi_{u'} \rangle| \leq \sum_{\{u,u'\} \in J} |\langle \xi_u, \xi_{u'} \rangle|$. We now compare $\sum_{u,u' \in J}^{U'} \langle \xi_u, \xi_{u'} \rangle$ with $\sum_{u,u' \in J}^{U'} \langle \psi_u, \psi_{u'} \rangle$. We have

$$\sum\nolimits_{u,u' \in J}^{U'} \langle \xi_u, \xi_{u'} \rangle = \sum\nolimits_{u,u' \in J}^{U'} \langle \psi_u, \psi_{u'} \rangle + \sum_{v \notin V'} \sum\nolimits_{u,u' \in J}^{U'} a_{u,v} a_{u',v}. \tag{4.4}$$

For $v \in V$ we set $S_v^{U'} = \sum_{u,u' \in J}^{U'} a_{u,v} a_{u',v}$ and proceed to estimate this quantity. Let $S := H(v) \cap U' \subseteq U'$ be the set of neighbors of the vertex v in U' and $T := (U' \setminus S) \subseteq U'$ be the set of nonneighbors of the vertex v in U'.

Set $\alpha = |S|/|U'|$ and $\beta = |T|/|U'|$. Note $\alpha + \beta = 1$. Thus we can write

$$S_v^{U'} = e_J(S)(1-p)^2 + e_J(T)p^2 - e_J(S,T)p(1-p). \tag{4.5}$$

The (ϱ, L)-uniformity of J implies the following claim. Recall that for two numbers a, b we write $a = O_1(b)$ if and only if $|a| \le b$.

CLAIM 4.5. *For all $v \in V'$ and $U' \subseteq U$, we have*

$$S_v^{U'} = \frac{\varrho}{2}|U'|^2 \cdot \big[\alpha(1-p) - \beta p\big]^2 + O_1\big(3L\sqrt{r} \cdot |U'|\big)\,. \tag{4.6}$$

Proof. Set $m' = |U'|$. Since J is a (ϱ, L)-uniform graph, Lemma 2.3 implies

$$\begin{aligned}
e_J(S) &= \frac{\varrho}{2}|S|^2 + O_1\big(2L\sqrt{r} \cdot |S|\big) \\
&= \frac{\varrho}{2}(\alpha m')^2 + O_1\big(2L\sqrt{r} \cdot \alpha m'\big)\,, \\
e_J(T) &= \frac{\varrho}{2}|T|^2 + O_1\big(2L\sqrt{r} \cdot |T|\big) \\
&= \frac{\varrho}{2}(\beta m')^2 + O_1\big(2L\sqrt{r} \cdot \beta m'\big)\,, \\
e_J(S,T) &= \varrho|S| \cdot |T| + O_1\big(L\sqrt{r|S| \cdot |T|}\big) \\
&= \varrho\alpha\beta(m')^2 + O_1\big(L\sqrt{r\alpha\beta} \cdot m'\big)\,.
\end{aligned}$$

Using (4.5) we get

$$\begin{aligned}
S_v^{U'} &= \Big[\frac{\varrho}{2}(\alpha m')^2 + O_1\big(2L\sqrt{r} \cdot \alpha m'\big)\Big](1-p)^2 \\
&\qquad + \Big[\frac{\varrho}{2}(\beta m')^2 + O_1\big(2L\sqrt{r} \cdot \beta m'\big)\Big]p^2 \\
&\qquad - \big[\varrho\alpha\beta(m')^2 + O_1\big(L\sqrt{r\alpha\beta} \cdot m'\big)\big]p(1-p) \qquad (4.7) \\
&= \frac{\varrho}{2}(m')^2\big[\alpha(1-p) - \beta p\big]^2 + \Delta,
\end{aligned}$$

where

$$\Delta = O_1\big(2L\sqrt{r} \cdot \alpha m'(1-p)^2 + 2L\sqrt{r} \cdot \beta m' p^2 + L\sqrt{r\alpha\beta} \cdot m' p(1-p)\big)\,. \tag{4.8}$$

To bound Δ we are going to use the inequalities $\alpha(1-p)^2 + \beta p^2 \le \alpha + \beta$ and $\sqrt{\alpha\beta} \le (\alpha + \beta)$. Thus,

$$\begin{aligned}
|\Delta| &\le 2L\sqrt{r} \cdot \alpha m'(1-p)^2 + 2L\sqrt{r} \cdot \beta m' p^2 + L\sqrt{r\alpha\beta} \cdot m' p(1-p) \\
&\le L\sqrt{r} m'\big(2\alpha + 2\beta + \sqrt{\alpha\beta}\big) \\
&\le L\sqrt{r} m' \cdot 3(\alpha + \beta) \qquad (4.9) \\
&= 3L\sqrt{r} m'\,.
\end{aligned}$$

Expressions (4.7) and (4.9) already imply the claim. We note only that we got a bound on Δ linear in $m' = |U'|$ since L and r are constants. ∎

Next we proceed with an upper and lower bound on $\sum_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle$. To derive an upper bound for this quantity we use (4.4) to relate $\sum_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle$ and $S_v^{U'}$ as follows:

$$\sum\nolimits_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle=\sum\nolimits_{u,u'\in J}^{U'}\langle\xi_u,\xi_{u'}\rangle-\sum_{v\notin V'}S_v^{U'}.$$

Note that (4.6) implies $S_v^{U'}\ge -3L\sqrt{r}|U'|$. This lower bound and Claim 4.4 imply

$$\sum\nolimits_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle\le 2\delta p^2 m_V|J|+3L\sqrt{r}|U'|(m_V-|V'|)\,. \tag{4.10}$$

To estimate $\sum_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle$ from below, we first write

$$\sum\nolimits_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle=\sum_{v\in V'}\sum\nolimits_{u,u'\in J}^{U'}a_{u,v}a_{u',v}=\sum_{v\in V'}S_v^{U'}\,. \tag{4.11}$$

Using (4.6) we get a lower bound on the expression in our last equation:

$$\begin{aligned}\sum\nolimits_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle&=\sum_{v\in V'}S_v^{U'}\\ &\ge\sum_{v\in V'}\Big(\frac{\varrho}{2}|U'|^2\big[\alpha(1-p)-\beta p\big]^2-3L\sqrt{r}\cdot|U'|\Big)\\ &\ge\frac{\varrho}{2}\cdot\frac{|U'|^2}{|V'|}\left[\sum_{v\in V'}(\alpha(1-p)-\beta p)\right]^2-3L\sqrt{r}|U'|\cdot|V'|\,.\end{aligned} \tag{4.12}$$

We used the Cauchy–Schwarz inequality to get the last line of our bound. Comparing the lower and upper bounds on $\sum_{u,u'\in J}^{U'}\langle\psi_u,\psi_{u'}\rangle$ (cf. (4.12) and (4.10)), we infer

$$\Big[\sum_{v\in V'}(\alpha(1-p)-\beta p)\Big]^2\le\frac{2|V'|}{\varrho|U'|^2}\cdot\big(2\delta p^2m_V|J|+3L\sqrt{r}|U'|m_V\big)\,. \tag{4.13}$$

Now we are ready to show that H is $\frac{\varepsilon}{2}$-regular. Fix $U'\subseteq U$, $|U'|\ge\frac{\varepsilon}{2}|U|=\frac{\varepsilon}{2}m_U$, and $V'\subseteq V$, $|V'|\ge\frac{\varepsilon}{2}|V|=\frac{\varepsilon}{2}m_V$. Recall that $d(U,V)=p=p(H)$ in our notation. First we relate the difference of densities to the left-hand side of (4.13) as follows:

$$\begin{aligned}|d(U',V')-d(U,V)|^2&=\left|\frac{e(U',V')}{|U'||V'|}-p\right|^2\\ &=\frac{1}{|U'|^2|V'|^2}\Big[e(U',V')-p|U'|\cdot|V'|\Big]^2\\ &=\frac{1}{|U'|^2|V'|^2}\Big[\sum_{v\in V'}(|H(v)\cap U'|-p|U'|)\Big]^2\\ &=\frac{1}{|U'|^2|V'|^2}\Big[\sum_{v\in V'}\alpha|U'|-p|U'|\Big]^2\\ &=\frac{1}{|V'|^2}\Big[\sum_{v\in V'}(\alpha(1-p)-\beta p)\Big]^2\,.\end{aligned} \tag{4.14}$$

Finally, we bound the expression for the difference of densities in (4.14) using (4.13). We get

$$\begin{aligned}\big|d(U',V')-d(U,V)\big|^2 &\le \frac{2}{\varrho|U'|^2|V'|}\left(2\delta p^2 m_V|J| \ + 3L\sqrt{r}\cdot|U'|m_V\right)\\ &\le \frac{2}{\varrho|U'|^2|V'|}\times 2\delta p^2 m_V\times\frac{rm_U}{2}+\frac{6L\sqrt{r}\cdot|U'|m_V}{\varrho|U'|^2|V'|}\\ &\le \frac{2\delta p^2 {m_U}^2 m_V}{|U'|^2|V'|}+\frac{6Lm_Vm_U\sqrt{r}}{r|U'|\cdot|V'|}\\ &\le \frac{16\delta}{\varepsilon^3}+\frac{24L}{\sqrt{r}\cdot\varepsilon^2}\\ &\le \frac{1}{2}\cdot\left(\frac{\varepsilon}{2}\right)^2+\frac{1}{2}\cdot\left(\frac{\varepsilon}{2}\right)^2\\ &= \left(\frac{\varepsilon}{2}\right)^2.\end{aligned}$$

The last inequality follows because of our choice of δ and $r\ge r_0\ge r_A$. □

4.2. Proof of Lemma 3.3. For this proof, the reader may find it convenient to recall the hierarchy of the constants given in (3.12). Recall that we have

$$p=p(H)=p(G)+O_1(5\varepsilon')\ge\frac{1}{2}\varepsilon^3. \tag{4.15}$$

Note that (4.15) is guaranteed to hold for the graph H that we obtain after preprocessing H as described in section 3.1.1 since $p(G)\ge\varepsilon^3$ in this case. As in section 3.1.2 we assume $U\cup V$ is the vertex set of H and set $m_U=|U|$ and $m_V=|V|$.

Suppose that property $\mathcal{P}(J,\delta)$ fails for H. Thus

$$\sum_{\{u,u'\}\in J}|d_H(u,u')-p^2m_V|>\delta p^2m_V|J|\,. \tag{4.16}$$

Let us first observe that

$$\begin{aligned}&\sum_{\{u,u'\}\in J}\big(d_H(u,u')-p^2m_V\big)^2\\ &\quad=\sum_{\{u,u'\}\in J}\big(d_H(u,u')^2-2d_H(u,u')p^2m_V+p^4{m_V}^2\big) \qquad (4.17)\\ &\quad=\sum_{\{u,u'\}\in J}d_H(u,u')^2-2p^2m_V\sum_{\{u,u'\}\in J}d_H(u,u')+p^4{m_V}^2|J|\,.\end{aligned}$$

However,

$$\begin{aligned}\sum_{\{u,u'\}\in J}d_H(u,u')&=\sum_{\{u,u'\}\in J}|H(u)\cap H(u')|\\ &=\sum_{v\in V}|J_v|=\sum_{v\in V}(1+O_1(\eta))(1+O_1(\mu))^2p^2|J|\,.\end{aligned}$$

In the last inequality we used that due to preprocessing (cf. (4.1)), $|H(v)|=(1+O_1(\mu))pm_U$, and hence (a) in Lemma 2.4 gives (note that $(1+O_1(\mu))p\ge\eta$)

$$|J_v|=(1+O_1(\eta))(1+O_1(\mu))^2p^2|J|=(1+O_1(3\mu))p^2|J|\,.$$

Therefore

$$\sum_{\{u,u'\}\in J} d_H(u,u') = (1+O_1(3\mu))p^2 m_V |J| \,. \tag{4.18}$$

From (4.17) and (4.18) we obtain that

$$\begin{aligned}\sum_{\{u,u'\}\in J} \big(d_H(u,u') - p^2 m_V\big)^2 &\\ = \sum_{\{u,u'\}\in J} d_H(u,u')^2 - (1+O_1(6\mu))p^4 {m_V}^2 |J| &\\ \le \sum_{\{u,u'\}\in J} d_H(u,u')^2 - \left(1-\frac{\delta^2}{2}\right) p^4 {m_V}^2 |J| \,. &\end{aligned} \tag{4.19}$$

The last inequality holds true due to our choices of δ and μ; cf. (3.7), (3.8). On the other hand, in view of (4.16), we have by the Cauchy–Schwarz inequality that

$$\begin{aligned}\sum_{\{u,u'\}\in J} \big(d_H(u,u') - p^2 m_V\big)^2 &\ge \frac{1}{|J|}\Big(\sum_{\{u,u'\}\in J} |d_H(u,u') - p^2 m_V|\Big)^2 \\ &> \frac{1}{|J|}\big(\delta |J| p^2 m_V\big)^2 = \delta^2 p^4 {m_V}^2 |J| \,.\end{aligned} \tag{4.20}$$

Comparing (4.19) and (4.20), we deduce that

$$\sum_{\{u,u'\}\in J} d_H(u,u')^2 \ge \left(1+\frac{\delta^2}{2}\right) p^4 {m_V}^2 |J| \,. \tag{4.21}$$

We shall now evaluate the sum on the left-hand side of (4.21) in terms of the matrix $M = (m(e,v))_{e,v}$ defined in section 3.1.

Clearly, if $e = \{u,u'\} \in J$, then

$$d_H(u,u') = |H(u) \cap H(u')| = \sum_{v\in V} m(e,v),$$

and hence

$$d_H(u,u')^2 = \sum_{v\in V}\sum_{v'\in V} m(e,v) m(e,v') \,.$$

Therefore

$$\begin{aligned}\sum_{\{u,u'\}\in J} d_H(u,u')^2 &= \sum_{v\in V}\sum_{e\in J} m(e,v) \sum_{v'\in V} m(e,v') \\ &= \sum_{v\in V}\sum_{e\in J_v}\sum_{v'\in V} m(e,v') = \sum_{v\in V}\sum_{v'\in V}\sum_{e\in J_v} m(e,v') \,.\end{aligned} \tag{4.22}$$

Comparing (4.21) and (4.22) we infer that

$$\sum_{v\in V}\sum_{v'\in V}\sum_{e\in J_v} m(e,v') \ge \left(1+\frac{\delta^2}{2}\right) p^4 {m_V}^2 |J|,$$

and hence there is a vertex $v_0 \in V$ for which we have

$$\sum_{v' \in V} \sum_{e \in J_{v_0}} m(e, v') \geq \left(1 + \frac{\delta^2}{2}\right) p^4 m_V |J| \,. \tag{4.23}$$

Following the algorithm, we fix such a vertex v_0. We now *set*

$$V' := \left\{ v' \in V \,:\, \sum_{e \in J_{v_0}} m(e, v') \geq \left(1 + \frac{\delta^2}{4}\right) p^4 |J| \right\} . \tag{4.24}$$

As in the algorithm, we put $U' = H(v_0)$. One may prove that both U' and V' are large sets. The proof is postponed for the next section.

CLAIM 4.6. *$|U'| \geq \varepsilon_1 m_U$ and $|V'| \geq \varepsilon_1 m_V$.*

Recall that we defined $\varepsilon_1 = \frac{1}{4}\left(\frac{\varepsilon}{2}\right)^{16}$ in (3.11) to satisfy $\varepsilon' \ll \varepsilon_1 \ll \delta^2$. Before we proceed, using the definition of matrix M we observe that for all $v' \in V$ we have

$$\sum_{e \in J_{v_0}} m(e, v') = e(J[H(v_0) \cap H(v')]) \,. \tag{4.25}$$

Combining (4.25) and the fact that the edges of J are extremely well distributed we shall now provide a lower bound on $d_H(v_0, v')$, where v_0 is the vertex fixed above and v' is an arbitrary vertex of V'.

CLAIM 4.7. *For all $v' \in V'$, we have*

$$d_H(v_0, v') \geq \left(1 + \frac{\delta^2}{12}\right) p^2 m_U \,. \tag{4.26}$$

The proof of Claim 4.7 is given in next section. Since $U' = H(v_0)$, it follows immediately from Claim 4.7 that

$$e_H(U', V') \geq \left(1 + \frac{\delta^2}{12}\right) p^2 m_U |V'|, \tag{4.27}$$

which implies that

$$\begin{aligned} d_H(U', V') = \frac{e_H(U', V')}{|U'||V'|} &\geq \frac{(1 + \delta^2/12) p^2 m_U |V'|}{(1+\mu) p m_U |V'|} \\ &\geq \left(1 + \frac{\delta^2}{14}\right) p > p + \varepsilon_1 \,. \end{aligned} \tag{4.28}$$

Since we have already proved that $|U'| \geq \varepsilon_1 m_U$ and $|V'| \geq \varepsilon_1 m_V$ (see Claim 4.6), inequality (4.28) tells us that (U', V') is a witness to the ε_1-irregularity of H.

We shall now prove that (U', V') is in fact a witness to the ε'-irregularity of G. We have

$$|U'| \geq \varepsilon_1 m_U \geq \varepsilon_1 (1 - 2\varepsilon') m \geq \varepsilon' m \tag{4.29}$$

and, similarly,

$$|V'| \geq \varepsilon_1 m_V \geq \varepsilon_1 (1 - 2\varepsilon') m \geq \varepsilon' m \,. \tag{4.30}$$

Because of (3.3) and (4.28), we have

$$d(U', V') > p + \varepsilon_1 \geq p(G) - 5\varepsilon' + \varepsilon_1 \geq p(G) + \varepsilon'. \tag{4.31}$$

In view of (4.29), (4.30) inequality (4.31) implies that (U', V') is indeed a witness to the ε'-irregularity of G, as required.

4.2.1. Proofs of Claims 4.6 and 4.7. Here we give proofs of Claims 4.6 and 4.7.

Proof of Claim 4.6. Since $U' = H(v_0)$, estimates (4.1) and our definition of ε_1 imply $|U'| = (1 + O_1(\mu))pm_U \geq \varepsilon_1 m_U$.

Now we will give a lower bound on $|V'|$. By the definition of V', we have

$$\begin{aligned}\sum_{v'\in V}\sum_{e\in J_{v_0}} m(e,v') &= \sum_{v'\notin V'}\sum_{e\in J_{v_0}} m(e,v') + \sum_{v'\in V'}\sum_{e\in J_{v_0}} m(e,v') \\ &< \left(1+\frac{\delta^2}{4}\right)p^4|J|(m_V - |V'|) + |V'|e(J_{v'})\ . \end{aligned} \tag{4.32}$$

Since $|H(v')| = (1 + O_1(\mu))pm_V$ (cf. (4.1)), (a) in Lemma 2.4 implies (note $(1 + O_1(\mu))p \geq \eta$)

$$e(J_{v'}) = e(J[H(v')]) = (1 + O_1(\eta))(1 + O_1(\mu))^2p^2|J| = (1 + O_1(3\mu))p^2|J|\ .$$

Thus continuing with (4.32) we can write

$$\sum_{v'\in V}\sum_{e\in J_{v_0}} m(e,v') < \left(1+\frac{\delta^2}{4}\right)p^4|J|m_V + (1 + O_1(3\mu))|V'|p^2|J|\ . \tag{4.33}$$

Comparing (4.23) and (4.33), we obtain

$$2|V'| \geq (1 + O_1(3\mu))|V'| \geq \frac{1}{4}\delta^2p^2m_V,$$

and this, using the definition of δ and ε_1, gives

$$|V'| \geq \frac{1}{8}\delta^2p^2m_V \geq \frac{1}{128}\left(\frac{\varepsilon}{2}\right)^{10}\varepsilon^6m_V \geq \varepsilon_1 m_V\ ,$$

as required. □

Proof of Claim 4.7. Suppose to the contrary that (4.26) fails, i.e., $d_H(v_0, v') < (1 + \delta^2/12)p^2m_U$. We distinguish two cases: If $d_H(v_0, v') \geq \eta m_U$, then using (a) in Lemma 2.4 for $H(v_0) \cap H(v')$ implies

$$e(J[H(v_0) \cap H(v')]) < (1 + O_1(\eta))\left(1+\frac{\delta^2}{12}\right)^2 p^4|J|\ .$$

If, on the other hand, $d(v_0, v') < \eta m_U$ we have (cf. (b) in Lemma 2.4)

$$e(J[H(v_0) \cap H(v')]) < 2\eta^2|J|\ .$$

In either case, we have

$$e(J[H(v_0) \cap H(v')]) < \left(1+\frac{\delta^2}{4}\right)p^4|J|\ . \tag{4.34}$$

However, in view of the definition of V' (see (4.24), (4.25)), inequality (4.34) cannot hold. This contradiction shows that (4.26) must indeed hold. □

DIMENSION IN COMPLEXITY CLASSES*

JACK H. LUTZ†

Abstract. A theory of resource-bounded dimension is developed using *gales*, which are natural generalizations of martingales. When the resource bound Δ (a parameter of the theory) is unrestricted, the resulting dimension is precisely the classical Hausdorff dimension (sometimes called "fractal dimension"). Other choices of the parameter Δ yield internal dimension theories in E, E_2, ESPACE, and other complexity classes, and in the class of all decidable problems. In general, if $\mathcal{C}$ is such a class, then *every* set X of languages has a dimension in $\mathcal{C}$, which is a real number $\dim(X \mid \mathcal{C}) \in [0,1]$. Along with the elements of this theory, two preliminary applications are presented:

1. For every real number $0 \leq \alpha \leq \frac{1}{2}$, the set FREQ($\leq \alpha$), consisting of all languages that asymptotically contain at most α of all strings, has dimension $\mathcal{H}(\alpha)$—the binary entropy of α—in E and in E_2.
2. For every real number $0 \leq \alpha \leq 1$, the set SIZE($\alpha \frac{2^n}{n}$), consisting of all languages decidable by Boolean circuits of at most $\alpha \frac{2^n}{n}$ gates, has dimension α in ESPACE.

Key words. circuit-size complexity, complexity classes, computational complexity, gales, Hausdorff dimension, martingales, resource-bounded dimension

1. Introduction.

Since the development of resource-bounded measure in 1991 [9], the investigation of the internal, measure-theoretic structure of complexity classes has produced a rapidly growing body of new insights and results. As indicated by the survey papers [1, 3, 10, 12], this line of inquiry has shed light on a wide variety of topics in computational complexity. The ongoing fruitfulness of this research is not surprising because resource-bounded measure is a complexity-theoretic generalization of classical Lebesgue measure, which was one of the most powerful quantitative tools of twentieth-century mathematics.

In spite of this power, there are certain inherent limitations to the amount of quantitative information that resource-bounded measure can provide in computational complexity. One of these limitations arises from the resource-bounded Kolmogorov zero-one law, which was proven by Lutz [11] and has recently been strengthened by Dai [4]. For any class $\mathcal{C}$ in which resource-bounded measure is defined, and for any set X of languages that is—like most sets of interest in computational complexity—closed under finite variations, the zero-one law says that the measure of X in $\mathcal{C}$ must be 0 or 1 or undefined. A second limitation arises from the simple fact that even a measure 0 subset of a complexity class may have internal structure that we would like to elucidate quantitatively. Of course both these limitations were already present in classical Lebesgue measure theory.

In 1919, Hausdorff [7] augmented classical Lebesgue measure theory with a theory of dimension. This theory assigns to *every* subset X of a given metric space a real number $\dim_H(X)$, which is now called the *Hausdorff dimension* of X. In this paper, we are interested in the case where the metric space is the Cantor space $\mathbf{C}$, consisting

†Department of Computer Science, Iowa State University, Ames, IA (lutz@cs.iastate.edu).

of all decision problems (i.e., all languages $A \subseteq \{0,1\}^*$). In this case the Hausdorff dimension of a set $X \subseteq \mathbf{C}$ (which is defined precisely in section 3) is a real number $\dim_H(X) \in [0,1]$. The Hausdorff dimension is monotone, with $\dim_H(\emptyset) = 0$ and $\dim_H(\mathbf{C}) = 1$. Moreover, if $\dim_H(X) < \dim_H(\mathbf{C})$, then X is a measure 0 subset of $\mathbf{C}$. Hausdorff dimension thus overcomes both of the limitations mentioned in the preceding paragraph.

In this paper we develop *resource-bounded dimension*, which is a complexity-theoretic generalization of classical Hausdorff dimension. We carry out this generalization in two steps. We first prove a new characterization of classical Hausdorff dimension in terms of *gales*, which are natural generalizations of the martingales that are the basis of resource-bounded measure. (Our characterization can be regarded as an analogue of Ville's martingale characterization of the Lebesgue measure 0 sets [19].) We then generalize classical dimension by introducing a resource bound Δ (a parameter of the theory) and requiring the gales to be Δ-computable. We show that this induces a well-behaved notion of dimension in the corresponding class $R(\Delta)$, which is defined exactly as in resource-bounded measure. We write $\dim(X \mid R(\Delta))$ for the dimension of the set X in the class $R(\Delta)$. If Δ is unrestricted, then $R(\Delta) = \mathbf{C}$ and $\dim(X \mid R(\Delta)) = \dim(X \mid \mathbf{C})$ is precisely $\dim_H(X)$. However, other choices of Δ allow $R(\Delta)$ to be interesting complexity classes, in which case $\dim(X \mid R(\Delta))$ is a quantitative measure of the dimension of $X \cap R(\Delta)$ *as a subset of* $R(\Delta)$.

After presenting the elements of resource-bounded dimension, we present two preliminary applications of the theory. First, for each real number $\alpha \in [0,1]$, let $\mathrm{FREQ}(\leq \alpha)$ be the set of all languages that asymptotically contain at most α of all strings. (This set is defined precisely in section 5.) We prove that, for every real number $\alpha \in [0, \frac{1}{2}]$,

$$\dim(\mathrm{FREQ}(\leq \alpha) \mid \mathrm{E}) = \mathcal{H}(\alpha)$$

and

$$\dim(\mathrm{FREQ}(\leq \alpha) \mid \mathrm{E}_2) = \mathcal{H}(\alpha) \ ,$$

where $\mathrm{E} = \mathrm{DTIME}(2^{\mathrm{linear}})$, $\mathrm{E}_2 = \mathrm{DTIME}(2^{\mathrm{poly}})$, and $\mathcal{H}$ is the binary entropy function of Shannon information theory.

Our second application concerns Boolean circuit-size complexity in the complexity class $\mathrm{ESPACE} = \mathrm{DSPACE}(2^{\mathrm{linear}})$. For each real number $\alpha \in [0,1]$, let $\mathrm{SIZE}(\alpha \frac{2^n}{n})$ be the set of all languages that can be decided by Boolean circuits consisting of at most $\alpha \frac{2^n}{n}$ gates. We prove that for all $\alpha \in [0,1]$,

$$\dim\left(\mathrm{SIZE}\left(\alpha \frac{2^n}{n}\right) \middle| \mathrm{ESPACE}\right) = \alpha \ .$$

These applications are interesting because they show that resource-bounded dimension interacts informatively with information theory and Boolean circuit-size complexity. However, they are clearly only the beginning. Classical Hausdorff dimension is a sophisticated mathematical theory that has emerged as one of the most important tools for the investigation of fractal sets. (See, for example, [6] for a good introduction and overview.) Many sets of interest in computational complexity seem to have "fractal-like" structures. Resource-bounded dimension will be a useful tool for the study of such sets.

2. Preliminaries. A *decision problem* (a.k.a. *language*) is a set $A \subseteq \{0,1\}^*$. We identify each language with its characteristic sequence $[\![s_0 \in A]\!][\![s_1 \in A]\!][\![s_2 \in A]\!]\cdots$, where $s_0, s_1, s_2, \ldots$ is the standard enumeration of $\{0,1\}^*$ and $[\![\phi]\!] = \texttt{if } \phi \texttt{ then } 1 \texttt{ else } 0$. We write $A[i..j]$ for the string consisting of the ith through jth bits of (the characteristic sequence of) A. The Cantor space $\mathbf{C}$ is the set of all decision problems.

If $w \in \{0,1\}^*$ and $x \in \{0,1\}^* \cup \mathbf{C}$, then $w \sqsubseteq x$ means that w is a prefix of x, and $w \underset{\neq}{\sqsubset} x$ means that w is a proper prefix of x. The *cylinder* generated by a string $w \in \{0,1\}^*$ is $\mathbf{C}_w = \{A \in \mathbf{C} \mid w \sqsubseteq A\}$.

A *prefix set* is a language A such that no element of A is a prefix of any other element of A.

If A is a language and $n \in \mathbb{N}$, then we write $A_{=n} = A \cap \{0,1\}^n$ and $A_{\leq n} = A \cap \{0,1\}^{\leq n}$.

All logarithms in this paper are base 2.

For each $i \in \mathbb{N}$ we define a class G_i of functions from $\mathbb{N}$ into $\mathbb{N}$ as follows:

$$G_0 = \{f \mid (\exists k)(\forall^\infty n) f(n) \leq kn\},$$
$$G_{i+1} = 2^{G_i(\log n)} = \{f \mid (\exists g \in G_i)(\forall^\infty n) f(n) \leq 2^{g(\log n)}\}.$$

We also define the functions $\hat{g}_i \in G_i$ by $\hat{g}_0(n) = 2n$, $\hat{g}_{i+1}(n) = 2^{\hat{g}_i(\log n)}$. We regard the functions in these classes as growth rates. In particular, G_0 contains the linearly bounded growth rates and G_1 contains the polynomially bounded growth rates. It is easy to show that each G_i is closed under composition, that each $f \in G_i$ is $o(\hat{g}_{i+1})$, and that each $\hat{g}_i$ is $o(2^n)$. Thus G_i contains superpolynomial growth rates for all $i > 1$, but all growth rates in the G_i-hierarchy are subexponential.

Within the class DEC of all decidable languages, we are interested in the exponential complexity classes $\mathrm{E}_i = \mathrm{DTIME}(2^{G_{i-1}})$ and $\mathrm{E}_i\mathrm{SPACE} = \mathrm{DSPACE}(2^{G_{i-1}})$ for $i \geq 1$. The much-studied classes $\mathrm{E} = \mathrm{E}_1 = \mathrm{DTIME}(2^{\mathrm{linear}})$, $\mathrm{E}_2 = \mathrm{DTIME}(2^{\mathrm{polynomial}})$, and $\mathrm{ESPACE} = \mathrm{E}_1\mathrm{SPACE} = \mathrm{DSPACE}(2^{\mathrm{linear}})$ are of particular interest.

We use the following classes of functions:

$$\mathrm{all} = \{f \mid f : \{0,1\}^* \to \{0,1\}^*\},$$
$$\mathrm{comp} = \{f \in \mathrm{all} \mid f \text{ is computable}\},$$
$$\mathrm{p}_i = \{f \in \mathrm{all} \mid f \text{ is computable in } G_i \text{ time}\} \ (i \geq 1),$$
$$\mathrm{p}_i\mathrm{space} = \{f \in \mathrm{all} \mid f \text{ is computable in } G_i \text{ space}\} \ (i \geq 1).$$

(The length of the output *is* included as part of the space used in computing f.) We write p for p_1 and pspace for $\mathrm{p}_1$space. Throughout this paper, Δ and Δ' denote one of the classes all, comp, p_i $(i \geq 1)$, or $\mathrm{p}_i$space $(i \geq 1)$.

A *constructor* is a function $\delta : \{0,1\}^* \to \{0,1\}^*$ that satisfies $x \underset{\neq}{\sqsubset} \delta(x)$ for all x. The *result* of a constructor δ (i.e., the language *constructed* by δ) is the unique language $R(\delta)$ such that $\delta^n(\lambda) \sqsubseteq R(\delta)$ for all $n \in \mathbb{N}$. Intuitively, δ constructs $R(\delta)$ by starting with λ and then iteratively generating successively longer prefixes of $R(\delta)$. We write $R(\Delta)$ for the set of languages $R(\delta)$ such that δ is a constructor in Δ. The following facts are the reason for our interest in the above-defined classes of functions:

$R(\mathrm{all}) = \mathbf{C}$.
$R(\mathrm{comp}) = \mathrm{DEC}$.
For $i \geq 1$, $R(\mathrm{p}_i) = \mathrm{E}_i$.
For $i \geq 1$, $R(\mathrm{p}_i\mathrm{space}) = \mathrm{E}_i\mathrm{SPACE}$.

If D is a discrete domain, then a function $f : D \longrightarrow [0,\infty)$ is Δ-*computable* if there is a function $\hat{f} : \mathbb{N} \times D \longrightarrow \mathbb{Q} \cap [0,\infty)$ such that $|\hat{f}(r,x) - f(x)| \leq 2^{-r}$ for all

$r \in \mathbb{N}$ and $x \in D$ and $\hat{f} \in \Delta$ (with r coded in unary and the output coded in binary). We say that f is *exactly* Δ*-computable* if $f : D \longrightarrow \mathbb{Q} \cap [0, \infty)$ and $f \in \Delta$.

3. Gales and Hausdorff dimension. In this section we introduce gales and supergales, which are generalizations of martingales and supermartingales, and use these to give a new characterization of classical Hausdorff dimension.

DEFINITION 3.1. *Let* $s \in [0, \infty)$.

1. *An* s-supergale *is a function* $d : \{0,1\}^* \longrightarrow [0, \infty)$ *that satisfies the condition*

$$d(w) \geq 2^{-s}[d(w0) + d(w1)] \tag{3.1}$$

   for all $w \in \{0,1\}^*$.
2. *An* s-gale *is an* s*-supergale that satisfies* (3.1) *with equality for all* $w \in \{0,1\}^*$.
3. *A* supermartingale *is a* 1*-supergale.*
4. *A* martingale *is a* 1*-gale.*

LEMMA 3.2. *Let* $s \in [0, \infty)$. *If* d *is an* s*-supergale and* $B \subseteq \{0,1\}^*$ *is a prefix set, then for all* $w \in \{0,1\}^*$,

$$\sum_{u \in B} 2^{-s|u|} d(wu) \leq d(w).$$

Proof. We first use induction on n to prove that for all $n \in \mathbb{N}$, the lemma holds for all prefix sets $B \subseteq \{0,1\}^{\leq n}$. For $n = 0$, this is trivial. Assume that it holds for n, and let $A \subseteq \{0,1\}^{\leq n+1}$ be a prefix set. Let

$$A' = \{u \in \{0,1\}^n \mid u0 \in A \text{ or } u1 \in A\},$$

and let

$$B = A_{\leq n} \cup A'.$$

Note that B is a prefix set and $A_{\leq n} \cap A' = \emptyset$ (because A is a prefix set). Also, for all $w \in \{0,1\}^*$,

$$\begin{aligned}
\sum_{u \in A_{=n+1}} 2^{-s|u|} d(wu) &= 2^{-s(n+1)} \sum_{u \in A_{=n+1}} d(wu) \\
&\leq 2^{-s(n+1)} \sum_{u \in A'} [d(wu0) + d(wu1)] \\
&\leq 2^{-s(n+1)} \sum_{u \in A'} 2^s d(wu) \\
&= \sum_{u \in A'} 2^{-s|u|} d(wu).
\end{aligned}$$

Since $B \subseteq \{0,1\}^{\leq n}$, it follows by the induction hypothesis that for all $w \in \{0,1\}^*$,

$$\begin{aligned}
\sum_{u \in A} 2^{-s|u|} d(wu) &= \sum_{u \in A_{\leq n}} 2^{-s|u|} d(wu) + \sum_{u \in A_{=n+1}} 2^{-s|u|} d(wu) \\
&\leq \sum_{u \in A_{\leq n}} 2^{-s|u|} d(wu) + \sum_{u \in A'} 2^{-s|u|} d(wu) \\
&= \sum_{u \in B} 2^{-s|u|} d(wu) \\
&\leq d(w).
\end{aligned}$$

This completes the proof that for all $n \in \mathbb{N}$, the lemma holds for all prefix sets $B \subseteq \{0,1\}^{\leq n}$.

To complete the proof of the lemma, let B be an arbitrary prefix set. Then for all $w \in \{0,1\}^*$,

$$\sum_{u \in B} 2^{-s|u|} d(wu) = \sup_{n \in \mathbb{N}} \sum_{u \in B_{\leq n}} 2^{-s|u|} d(wu) \leq d(w). \qquad \square$$

COROLLARY 3.3. *Let $s \in [0,\infty)$, $0 < \alpha \in \mathbb{R}$, and $w \in \{0,1\}^*$. If d is an s-supergale such that $d(w) > 0$ and $B \subseteq \{0,1\}^*$ is a prefix set such that $d(wu) \geq \alpha 2^{(s-1)|u|} d(w)$ for all $u \in B$, then*

$$\sum_{u \in B} 2^{-|u|} \leq \frac{1}{\alpha}.$$

Proof. Assume the hypothesis. Then by Lemma 3.2,

$$d(w) \geq \sum_{u \in B} 2^{-s|u|} d(wu) \geq \alpha d(w) \sum_{u \in B} 2^{-|u|},$$

whence the corollary follows. $\square$

COROLLARY 3.4. *Let d be an s-supergale, where $s \in [0,1]$. Then for all $w \in \{0,1\}^*$, $l \in \mathbb{N}$, and $0 < \alpha \in \mathbb{R}$, there are fewer than $\frac{2^l}{\alpha}$ strings $u \in \{0,1\}^l$ for which*

$$\max_{v \sqsubseteq u} 2^{(1-s)|v|} d(wv) > \alpha d(w).$$

In particular, there is at least one string $u \in \{0,1\}^l$ such that $d(wv) \leq 2^{(s-1)|v|} d(w)$ for all $v \sqsubseteq u$.

Proof. Let d, s, w, l, and α be as given, and let

$$A = \left\{ u \in \{0,1\}^l \mid \max_{v \sqsubseteq u} 2^{(1-s)|v|} d(wv) > \alpha d(w) \right\}.$$

If $A = \emptyset$, the corollary is trivially affirmed, so assume that $A \neq \emptyset$. (Note that this implies $d(w) > 0$.) Let B be the set of all $v \in \{0,1\}^{\leq l}$ such that $2^{(1-s)|v|} d(wv) > \alpha d(w)$ but $2^{(1-s)|v'|} d(wv') \leq \alpha d(w)$ for all $v' \underset{\neq}{\sqsubset} v$. Then B is a prefix set, and

$$A = \{u \in \{0,1\}^l \mid (\exists v \sqsubseteq u) v \in B\},$$

so

$$|A| = \sum_{v \in B} 2^{l-|v|} = 2^l \sum_{v \in B} 2^{-|v|}.$$

Let

$$\alpha' = \min_{v \in B} 2^{(1-s)|v|} \frac{d(wv)}{d(w)},$$

and note that $\alpha < \alpha' < \infty$. Then B is a prefix set such that $d(wv) \geq \alpha' 2^{(s-1)|v|} d(w)$ for all $v \in B$, so Corollary 3.3 tells us that

$$|A| = 2^l \sum_{v \in B} 2^{-|v|} \leq \frac{2^l}{\alpha'} < \frac{2^l}{\alpha}.$$

This proves the main assertion of the corollary. The last sentence of the corollary follows immediately by taking $\alpha = 1$. □

COROLLARY 3.5. *If d is an s-supergale, where $s \in [0, \infty)$, then for all $w, u \in \{0,1\}^*$,*

$$d(wu) \leq 2^{s|u|} d(w).$$

Proof. Let d, s, w, and u be as given, and let $l = |u|$. Let $\beta > 2^{s|u|}$ be arbitrary. It suffices to show that $d(wu) \leq \beta d(w)$.

Let $\alpha = \beta 2^{(1-s)l}$. Then, for all $v \in \{0,1\}^l$,

$$d(wv) > \beta d(w) \Leftrightarrow d(wv) > \alpha 2^{(s-1)l} d(w),$$

so Corollary 3.4 tells us that there are fewer than $\frac{2^l}{\alpha}$ strings $v \in \{0,1\}^l$ for which $d(wv) > \beta d(w)$. Since $\frac{2^l}{\alpha} = \frac{2^{s|u|}}{\beta} < 1$, it follows that $d(wu) \leq \beta d(w)$. □

Observation 3.6. Let $s \in [0, \infty)$. For each $k \in \mathbb{N}$, let d_k be an s-gale, and let $a_k \in [0, \infty)$.

1. For each $n \in \mathbb{Z}^+$, $\sum_{k=0}^{n-1} a_k d_k$ is an s-gale.
2. If $\sum_{k=0}^{\infty} a_k d_k(\lambda) < \infty$, then $\sum_{k=0}^{\infty} a_k d_k$ is an s-gale.

DEFINITION 3.7. *Let d be an s-supergale, where $s \in [0, \infty)$.*

1. *We say that d* succeeds *on a language $A \in \mathbf{C}$ if*

$$\limsup_{n \to \infty} d(A[0 \ldots n-1]) = \infty.$$

2. *The* success set *of d is*

$$S^\infty[d] = \{A \in \mathbf{C} \mid d \text{ succeeds on } A\}.$$

We now review the classical definition of Hausdorff dimension. Since we are primarily interested in the computational complexities of decision problems, we focus on Hausdorff dimension in the Cantor space $\mathbf{C}$.

For each $k \in \mathbb{N}$, we let $\mathcal{A}_k$ be the collection of all prefix sets A such that $A_{<k} = \emptyset$. For each $X \subseteq \mathbf{C}$, we then let

$$\mathcal{A}_k(X) = \left\{ A \in \mathcal{A}_k \;\middle|\; X \subseteq \bigcup_{w \in A} \mathbf{C}_w \right\}.$$

If $A \in \mathcal{A}_k(X)$, then we say that the prefix set A *covers* the set X. For $X \in \mathbf{C}$, $s \in [0, \infty)$, and $k \in \mathbb{N}$, we then define

$$H_k^s(X) = \inf_{A \in \mathcal{A}_k(X)} \sum_{w \in A} 2^{-s|w|}.$$

Digression. Readers familiar with Hausdorff dimension may prefer to regard it as arising from a measure or, more commonly, a metric on the underlying space. If we regard Hausdorff dimension as arising from a measure on $\mathbf{C}$, then the term $2^{-s|w|}$ in the above sum is interpreted as $\mu(\mathbf{C}_w)^s$, where $\mu(\mathbf{C}_w) = 2^{-|w|}$ is the Lebesgue measure of the cylinder $\mathbf{C}_w$. If we instead regard Hausdorff dimension as arising from a metric on $\mathbf{C}$, then the metric is

$$d(A, B) = 2^{-\min\{n \in \mathbb{N} \mid A[n] \neq B[n]\}}$$

(where $\min \emptyset = \infty$ so $d(A, A) = 0$), and the term $2^{-s|w|}$ is interpreted as $\mathrm{diam}(\mathbf{C}_w)^s$, where

$$\mathrm{diam}(X) = \sup_{A,B \in X} d(A, B)$$

is the *diameter* of a set $X \subseteq \mathbf{C}$. Such interpretations may provide context, but our technical development does not use them.

DEFINITION 3.8. *For $s \in [0, \infty)$ and $X \subseteq \mathbf{C}$, the* s-dimensional Hausdorff cylinder outer measure *of X is*

$$H^s(X) = \lim_{k \to \infty} H^s_k(X).$$

Since $H^s_k(X)$ is nondecreasing in k, this limit $H^s(X)$ exists, though it may be infinite. In fact, it is well known that for every set $X \subseteq \mathbf{C}$, there is a real number $s^* \in [0, 1]$ with the following two properties:

(i) For all $0 \leq s < s^*$, $H^s(X) = \infty$.

(ii) For all $s > s^*$, $H^s(X) = 0$.

As the following definition states, this number s^* is the Hausdorff dimension of X.

DEFINITION 3.9. *The* Hausdorff dimension *of a set $X \subseteq \mathbf{C}$ is*

$$\dim_H(X) = \inf\{s \in [0, \infty) \mid H^s(X) = 0\}.$$

Notation. For $X \subseteq \mathbf{C}$, let $\mathcal{G}(X)$ be the set of all $s \in [0, \infty)$ such that there is an s-gale d for which $X \subseteq S^\infty[d]$.

The following theorem gives a new characterization of classical Hausdorff dimension.

THEOREM 3.10 (gale characterization of Hausdorff dimension). *For all $X \subseteq \mathbf{C}$, $\dim_H(X) = \inf \mathcal{G}(X)$.*

Proof. It suffices to show that for all $s \in [0, \infty)$,

$$H^s(X) = 0 \Leftrightarrow s \in \mathcal{G}(X).$$

First, assume that $H^s(X) = 0$. Then $H^s_0(X) = 0$, which implies that for each $r \in \mathbb{N}$, there is a prefix set $A_r \in \mathcal{A}_0(X)$ such that $\sum_{w \in A_r} 2^{-s|w|} \leq 2^{-r}$. For each $r \in \mathbb{N}$, then, fix such a prefix set A_r, and define a function $d_r : \{0,1\}^* \longrightarrow [0, \infty)$ as follows. Let $w \in \{0,1\}^*$. If there exists $v \sqsubseteq w$ such that $v \in A_r$, then $d_r(w) = 2^{(s-1)(|w|-|v|)}$. Otherwise,

$$d_r(w) = \sum_{\substack{u \\ wu \in A_r}} 2^{-s|u|}.$$

It is routine to verify that the following conditions hold for all $r \in \mathbb{N}$:

(i) d_r is an s-gale.

(ii) $d_r(\lambda) \leq 2^{-r}$.

(iii) For all $w \in A_r$, $d_r(w) = 1$.

Let $d = \sum_{r=0}^\infty 2^r d_{2r}$. By Observation 3.6, d is an s-gale. To see that $X \subseteq S^\infty[d]$, let $B \in X$, and let $r \in \mathbb{N}$ be arbitrary. Since the prefix set A_{2r} covers X, there exists $w \in A_{2r}$ such that $w \sqsubseteq B$. Then by (iii) above, $d(w) \geq 2^r d_{2r}(w) = 2^r$. Since $r \in \mathbb{N}$ is arbitrary, this shows that $B \in S^\infty$, confirming that $X \subseteq S^\infty[d]$.

We have now shown that d is an s-gale such that $X \subseteq S^\infty[d]$, whence $s \in \mathcal{G}(X)$.

Conversely, assume that $s \in \mathcal{G}(X)$. To see that $H^s(X) = 0$, let $k, r, \in \mathbb{N}$. It suffices to show that $H^s(X) \leq 2^{-r}$. If $X = \emptyset$, this is trivial, so assume that $X \neq \emptyset$.

Since $s \in \mathcal{G}(X)$, there is an s-gale d such that $X \subseteq S^\infty[d]$. Note that $d(\lambda) > 0$ because $X \neq 0$. Let

$$a = 1 + \max\{d(w) \mid w \in \{0,1\}^{\leq k}\},$$

and let

$$A = \left\{ w \in \{0,1\}^* \middle| d(w) \geq 2^r a \text{ and } (\forall v) \left[v \underset{\neq}{\sqsubset} w \Rightarrow d(v) < 2^r a \right] \right\}.$$

It is clear that A is a prefix set with $A_{<k} = \emptyset$, so $A \in \mathcal{A}_k$. It is also clear that

$$X \subseteq S^\infty[d] \subseteq \bigcup_{w \in A} \mathbf{C}_w,$$

whence $A \in \mathcal{A}_k(X)$. By Lemma 3.2 and the definition of A, we have

$$d(\lambda) \geq \sum_{w \in A} 2^{-s|w|} d(w) \geq 2^r d(\lambda) \sum_{w \in A} 2^{-s|w|}.$$

Since $A \in \mathcal{A}_k(X)$ and $d(\lambda) > 0$, it follows that

$$H^s_k(X) \leq \sum_{w \in A} 2^{-s|w|} \leq 2^{-r}. \qquad \square$$

It is clear from the proof of Theorem 3.10 that the s-dimensional Hausdorff cylinder outer measure $H^s(X)$ can also be characterized in terms of s-gales, but we refrain from elaborating here.

4. Dimension in complexity classes. Motivated by the gale characterization of classical Hausdorff dimension, we now use resource-bounded gales to develop dimension in complexity classes. As with resource-bounded measure [9], our development contains a parameter Δ—the resource bound—which may be any one of the classes all, comp, p, pspace, p_2, $\mathrm{p}_2$space, etc., defined in section 2.

Notation. For $X \subseteq \mathbf{C}$, let $\mathcal{G}_\Delta(X)$ be the set of all $s \in [0, \infty)$ such that there is a Δ-computable s-gale d for which $X \subseteq S^\infty[d]$.

DEFINITION 4.1. *Let* $X \subseteq \mathbf{C}$.

1. *The* Δ-dimension *of* X *is* $\dim_\Delta(X) = \inf \mathcal{G}_\Delta(X)$.
2. *The* dimension of X in $R(\Delta)$ *is* $\dim(X \mid R(\Delta)) = \dim_\Delta(X \cap R(\Delta))$.

Note that $\dim_\Delta(X)$ and $\dim(X \mid R(\Delta))$ are defined for *every* set $X \subseteq \mathbf{C}$. We call $\dim_{\mathrm{comp}}(X)$ and $\dim_{\mathrm{p}}(X)$ the *computable dimension* of X and the *feasible dimension* of X, respectively.

The following observations are elementary but useful.

Observation 4.2.

1. For all $X \subseteq Y \subseteq \mathbf{C}$,

$$\dim_\Delta(X) \leq \dim_\Delta(Y)$$

and

$$\dim(X \mid R(\Delta)) \leq \dim(Y \mid R(\Delta)).$$

2. If Δ and Δ' are resource bounds such that $\Delta \subseteq \Delta'$, then for all $X \subseteq \mathbf{C}$,
$$\dim_{\Delta'}(X) \leq \dim_{\Delta}(X).$$
3. For all $X \subseteq \mathbf{C}$, $0 \leq \dim(X \mid R(\Delta)) \leq \dim_{\Delta}(X) \leq 1$.
4. For all $X \subseteq \mathbf{C}$, $\dim(X \mid \mathbf{C}) = \dim_{\mathrm{all}}(X) = \dim_H(X)$.
5. For all $X \subseteq \mathbf{C}$,
$$\dim_{\Delta}(X) < 1 \Rightarrow \mu_{\Delta}(X) = 0$$
and
$$\dim(X \mid R(\Delta)) < 1 \Rightarrow \mu(X \mid R(\Delta)) = 0.$$

Proof. Observations 1, 2, 4, and 5 follow immediately from the definitions. For observation 3, it suffices to show that $\dim_{\Delta}(\mathbf{C}) \leq 1$. For this, fix $s > 1$ such that 2^s is rational. Then the function
$$d : \{0,1\}^* \to [0, \infty)$$
$$d(w) = 2^{(s-1)|w|}$$
is a Δ-computable s-gale such that $S^{\infty}[d] = \mathbf{C}$, so $s \in \mathcal{G}_{\Delta}(\mathbf{C})$, and thus $\dim_{\Delta}(\mathbf{C}) \leq s$. Since this holds for all $s > 1$ with 2^s rational, it follows that $\dim_{\Delta}(\mathbf{C}) \leq 1$. □

The fifth observation above shows that resource-bounded dimension offers a quantitative classification of sets that have resource-bounded measure 0. However, it should be emphasized that this classification is in terms of dimension, which is very different from measure. For example, Lemma 4.9 and its corollaries exhibit properties of dimension that contrast sharply with those of measure.

To proceed further, we need a little bit of technical machinery concerning the computability of gales and supergales.

Observation 4.3. If d is a Δ-computable s-gale, then the real number 2^s is Δ-computable.

LEMMA 4.4. *If d is a Δ-computable s-supergale and 2^s is Δ-computable, then there is a Δ-computable s-gale $\tilde{d}$ such that $S^{\infty}[d] \subseteq S^{\infty}[\tilde{d}]$. Moreover, if d is exactly Δ-computable and 2^s is rational, then $\tilde{d}$ is exactly Δ-computable.*

Proof. Assume the hypothesis. Define
$$\tilde{d} : \{0,1\}^* \longrightarrow [0, \infty)$$
$$\tilde{d}(\lambda) = d(\lambda),$$
$$\tilde{d}(w0) = \frac{1}{2}[2^s \tilde{d}(w) + d(w0) - d(w1)],$$
$$\tilde{d}(w1) = \frac{1}{2}[2^s \tilde{d}(w) - d(w0) + d(w1)].$$

Then $\tilde{d}$ is clearly a Δ-computable s-gale, and an easy induction shows that $\tilde{d}(w) \geq d(w)$ for all $w \in \{0,1\}^*$, whence $S^{\infty}[d] \subseteq S^{\infty}[\tilde{d}]$. Moreover, if d is exactly Δ-computable and 2^s is rational, then it is clear that $\tilde{d}$ is exactly Δ-computable. □

Observation 4.5. If d is an s-supergale and $s' \geq s$, then d is an s'-supergale.

COROLLARY 4.6. *Let $X \subseteq \mathbf{C}$ and $s' \geq s \geq 0$. If $s \in \mathcal{G}_\Delta(X)$ and $2^{s'}$ is Δ-computable, then $s' \in \mathcal{G}_\Delta(X)$.*

Proof. This follows immediately from Lemma 4.4 and Observation 4.5. □

Note that Corollary 4.6 implies that $\mathcal{G}_\Delta(X)$ is a dense subset of the interval $[\dim_\Delta(X), \infty)$.

The following consequence of Lemma 4.4 says that supergales can be used to establish upper bounds on dimension.

COROLLARY 4.7. *Let $X \subseteq \mathbf{C}$ and $s \in [0, \infty)$. If there is a Δ-computable s-supergale d such that $X \subseteq S^\infty[d]$, then $\dim_\Delta(X) \leq s$.*

Proof. Assume the hypothesis, and let $s' \geq s$ be arbitrary such that 2^s is Δ-computable. By Observation 4.5, d is a Δ-computable s'-supergale with $X \subseteq S^\infty[d]$. It follows by Lemma 4.4 that $s' \in \mathcal{G}_\Delta(X)$, whence $\dim_\Delta(X) \leq s'$. Since this holds for all $s' \geq s$ with $2^{s'}$ Δ-computable, it follows that $\dim_\Delta(X) \leq s$. □

LEMMA 4.8 (exact computation lemma). *If d is a Δ-computable s-supergale and 2^s is rational, then there is an exactly Δ-computable s-gale $\tilde{d}$ such that $S^\infty[d] \subseteq S^\infty[\tilde{d}]$.*

Proof. Assume the hypothesis. If $s = 0$, then $S^\infty[d] = \emptyset$ and the conclusion holds trivially, so assume that $s > 0$. By Lemma 4.4, it suffices to show that there is an exactly computable s-supergale $\tilde{d}$ such that $S^\infty[d] \subseteq S^\infty[\tilde{d}]$.

Since d is Δ-computable, there is an exactly Δ-computable function $\hat{d} : \{0,1\}^* \times \mathbb{N} \longrightarrow \mathbb{Q} \cap [0, \infty)$ such that for all $w \in \{0,1\}^*$ and $r \in \mathbb{N}$, $|\hat{d}(w, r) - d(w)| \leq 2^{-r}$. Let

$$a = 1 + \left\lceil \log \frac{1}{1 - 2^{-s}} \right\rceil,$$

so that $2^{1-a} \leq 1 - 2^{-s}$, and define

$$\tilde{d} : \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0, \infty)$$

$$\tilde{d}(w) = \hat{d}(w, |w| + a) + 2^{-|w|}.$$

It is clear that $\tilde{d}$ is exactly Δ-computable. Also, for all $w \in \{0,1\}^*$,

$$\begin{aligned}
&\tilde{d}(w) - 2^{-s}[\tilde{d}(w0) + \tilde{d}(w1)] \\
&\geq d(w) - 2^{-(|w|+a)} + 2^{-|w|} - 2^{-s}\left[d(w0) + d(w1) + 2\left[2^{-(|w|+a+1)} + 2^{-(|w|+1)}\right]\right] \\
&= d(w) - 2^{-s}[d(w0) + d(w1)] + 2^{-|w|}[1 - 2^{-s} - (1 + 2^{-s})2^{-a}] \\
&\geq 2^{-|w|}[1 - 2^{-s} - 2^{1-a}] \\
&\geq 0\ ,
\end{aligned}$$

so $\tilde{d}$ is an s-supergale. Finally, for all $w \in \{0,1\}^*$,

$$\tilde{d}(w) - d(w) \geq 2^{-|w|} - 2^{-(|w|+a)} > 0,$$

so $S^\infty[d] \subseteq S^\infty[\tilde{d}]$. □

LEMMA 4.9. *For all $X, Y \subseteq \mathbf{C}$,*

$$\dim_\Delta(X \cup Y) = \max\{\dim_\Delta(X), \dim_\Delta(Y)\}$$

and

$$\dim(X \cup Y \mid R(\Delta)) = \max\{\dim(X \mid R(\Delta)), \dim(Y \mid R(\Delta))\}.$$

Proof. The second identity follows from the first, so by Observation 4.2 it suffices to show that

$$\dim_\Delta(X \cup Y) \leq \max\{\dim_\Delta(X), \dim_\Delta(Y)\}.$$

For this, choose an arbitrary $s > \max\{\dim_\Delta(X), \dim_\Delta(Y)\}$ such that 2^s is Δ-computable. By Corollary 4.6, $s \in \mathcal{G}_\Delta(X) \cap \mathcal{G}_\Delta(Y)$, so there exist Δ-computable s-gales d_X and d_Y such that $X \subseteq S^\infty[d_X]$ and $Y \subseteq S^\infty[d_Y]$. Let $d = d_X + d_Y$. Then d is clearly Δ-computable , and d is an s-gale by Observation 3.6. It is clear that $X \cup Y \subseteq S^\infty[d]$, whence $s \in \mathcal{G}_\Delta(X \cup Y)$. It follows that $\dim_\Delta(X \cup Y) < s$. Since s is arbitrary here, we have shown that $\dim_\Delta(X \cup Y) \leq \max\{\dim_\Delta(X), \dim_\Delta(Y)\}$. □

Lemma 4.9 has the following immediate consequence.

COROLLARY 4.10. *For all $X \in \mathbf{C}$ and $n \in \mathbb{N}$,*

$$\dim_\Delta(X) = \max_{w \in \{0,1\}^n} \dim_\Delta(X \cap \mathbf{C}_w)$$

and

$$\dim(X \mid R(\Delta)) = \max_{w \in \{0,1\}^n} \dim(X \cap \mathbf{C}_w \mid R(\Delta)).$$

A set $X \subseteq \mathbf{C}$ is *closed under finite variations* if for every $A \in X$ and every finite set $D \subseteq \{0,1\}^*$, we have $A \triangle D \in X$, where $A \triangle D = (A - D) \cup (D - A)$ is the symmetric difference of A and D. A set X with this property is called a *tail set*.

COROLLARY 4.11. *If $X \subseteq \mathbf{C}$ is a tail set, then for all $w \in \{0,1\}^*$,*

$$\dim_\Delta(X \cap \mathbf{C}_w) = \dim_\Delta(X)$$

and

$$\dim(X \cap \mathbf{C}_w \mid R(\Delta)) = \dim(X \mid R(\Delta)).$$

Lemma 4.9 can be extended to countable unions, provided that these unions are sufficiently constructive.

DEFINITION 4.12. *Let $X, X_0, X_1, X_2, \ldots \subseteq \mathbf{C}$.*

1. *X is a Δ-union of the Δ-dimensioned sets $X_0, X_1, X_2, \ldots$ if $X = \bigcup_{k=0}^\infty X_k$ and for each $s > \sup_{k \in \mathbb{N}} \dim_\Delta(X_k)$ with 2^s rational, there is a function $d : \mathbb{N} \times \{0,1\}^* \to [0, \infty)$ with the following properties:*
   (i) *d is Δ-computable.*
   (ii) *For each $k \in \mathbb{N}$, if we write $d_k(w) = d(k, w)$, then the function d_k is an s-gale.*
   (iii) *For each $k \in \mathbb{N}$, $X_k \subseteq S^\infty[d_k]$.*
2. *X is a Δ-union of the sets $X_0, X_1, X_2, \ldots$ dimensioned in $R(\Delta)$ if $X = \bigcup_{k=0}^\infty X_k$ and $X \cap R(\Delta)$ is a Δ-union of the Δ-dimensional sets $X_0 \cap R(\Delta)$, $X_1 \cap R(\Delta)$, $X_2 \cap R(\Delta), \ldots$.*

LEMMA 4.13. *Let $X, X_0, X_1, X_2, \ldots \subseteq \mathbf{C}$.*

1. *If X is a Δ-union of the Δ-dimensioned sets $X_0, X_1, X_2, \ldots$, then*

$$\dim_\Delta(X) = \sup_{k \in \mathbb{N}} \dim_\Delta(X_k).$$

2. *If X is a Δ-union of the sets $X_0, X_1, X_2, \ldots$ dimensioned in $R(\Delta)$, then*

$$\dim(X \mid R(\Delta)) = \sup_{k \in \mathbb{N}} \dim(X_k \mid R(\Delta)).$$

Proof. It suffices to prove 1, since 2 follows immediately from 1. Assume the hypothesis of 1, and let $s > \sup_{k\in\mathbb{N}} \dim_\Delta(X_K)$ be arbitrary with 2^s rational and $s < 2$. By Observation 4.2, it suffices to show that $\dim_\Delta(X) \leq s$.

Since X is a union of the Δ-dimensioned sets $X_0, X_1, X_2, \ldots$, there is a Δ-computable function $d : \mathbb{N} \times \{0,1\}^* \longrightarrow [0,\infty)$ such that each d_k is an s-gale with $X_k \subseteq S^\infty[d_k]$. Without loss of generality (modifying d if necessary), we can assume that each $d_k(\lambda) \leq 1$.

Let $\tilde{d} = \sum_{k=0}^\infty 2^{-k} d_k$. By Observation 3.6, $\tilde{d}$ is an s-gale. Since d is Δ-computable, there is a function $\hat{d} : \mathbb{N} \times \mathbb{N} \times \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0,\infty)$ such that $\hat{d} \in \Delta$ and for all $r, k \in \mathbb{N}$ and $w \in \{0,1\}^*$, $|\hat{d}(r,k,w) - d(k,w)| \leq 2^{-r}$. Define

$$\hat{\tilde{d}} : \mathbb{N} \times \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0,\infty)$$

by

$$\hat{\tilde{d}}(r,w) = \sum_{k=0}^{r+2|w|+1} 2^{-k} \hat{d}(r+2,k,w).$$

Then $\hat{\tilde{d}} \in \Delta$ and for all $r \in \mathbb{N}$ and $w \in \{0,1\}^*$,

$$|\hat{\tilde{d}}(r,w) - \tilde{d}(w)| \leq |\tilde{d}(w) - a| + |a - \hat{\tilde{d}}(w)|,$$

where $a = \sum_{k=0}^{r+2|w|+1} 2^{-k} d_k(w)$. By Corollary 3.5,

$$\begin{aligned} |\tilde{d}(w) - a| &= \sum_{k=r+2|w|+2}^{\infty} 2^{-k} d_k(w) \\ &\leq \sum_{k=r+2|w|+2}^{\infty} 2^{-k} 2^{s|w|} d_k(\lambda) \\ &\leq \sum_{k=r+2|w|+2}^{\infty} 2^{2|w|-k} \\ &= 2^{-(r+1)}. \end{aligned}$$

Also,

$$\begin{aligned} |a - \hat{\tilde{d}}(w)| &\leq \sum_{k=0}^{r+2|w|+1} 2^{-k} |\tilde{d}(r+2,k,w) - d(k,w)| \\ &\leq \sum_{k=0}^{\infty} 2^{-(k+r+2)} \\ &= 2^{-(r+1)}. \end{aligned}$$

It follows that for all $r \in \mathbb{N}$ and $w \in \{0,1\}^*$,

$$|\hat{\tilde{d}}(r,w) - \tilde{d}| \leq 2^{-r},$$

whence $\hat{\tilde{d}}$ testifies that $\tilde{d}$ is Δ-computable. It is clear that $X = \bigcup_{k=0}^\infty X_k \subseteq \bigcup_{k=0}^\infty S^\infty[d_k] \subseteq S^\infty[\tilde{d}]$, so it follows that $\dim_\Delta(X) \leq s$. ∎

We now note that finite sets of languages have resource-bounded dimension 0, provided that the languages themselves do not exceed the resource bound.

LEMMA 4.14. *If $X \subseteq R(\Delta)$ is finite, then* $\dim(X \mid R(\Delta)) = \dim_\Delta(X) = 0$.

Proof. By Lemma 4.9, it suffices to prove this for singleton sets $X \subseteq R(\Delta)$, so assume that $X = \{A\}$, where $A \in R(\Delta)$. Let $s > 0$ be arbitrarily small with 2^s rational. It suffices to show that $\dim_\Delta(X) \leq s$. Define

$$d : \{0,1\}^* \longrightarrow [0,\infty)$$

$$d(w) = \begin{cases} 2^{s|w|} & \text{if } w \sqsubseteq A, \\ 0 & \text{if } w \not\sqsubseteq A. \end{cases}$$

Then $d \in \Delta$ (because $A \in R(\Delta)$ and 2^s is rational) and it is clear that d is an s-gale that succeeds on A. Thus $\dim_\Delta(X) \leq s$. □

Lemma 4.14 can be extended to subsets of $R(\Delta)$ that are "countable within the resource bound Δ" in the following sense. A set $X \subseteq \mathbf{C}$ is Δ-*countable* if there is a function $\delta : \mathbb{N} \times \{0,1\}^* \to \{0,1\}^*$ with the following properties:

(i) $\delta \in \Delta$.

(ii) For each $k \in \mathbb{N}$, if we write $\delta_k(w) = \delta(k,w)$, then the function δ_k is a constructor.

(iii) $X = \{R(\delta_k) \mid k \in \mathbb{N}\}$.

It is clear that if X is Δ-countable, then $X \subseteq R(\Delta)$. It was shown in [9] that every Δ-countable set has Δ-measure 0. We now show that more is true.

LEMMA 4.15. *If $X \subseteq \mathbf{C}$ is Δ-countable, then* $\dim(X \mid R(\Delta)) = \dim_\Delta(X) = 0$.

Proof. Let the function $\delta : \mathbb{N} \times \{0,1\}^* \longrightarrow \{0,1\}^*$ testify that X is Δ-countable. By Lemmas 4.13 and 4.14, it suffices to show that X is a Δ-union of the Δ-dimension 0 singleton sets $\{R(\delta_0)\}, \{R(\delta_1)\}, \{R(\delta_2)\}, \ldots$. For this, let $s > 0$ with 2^s rational, and define

$$d : \mathbb{N} \times \{0,1\}^* \longrightarrow [0,\infty)$$

$$d(k,w) = \begin{cases} 2^{s|w|} & \text{if } w \sqsubseteq R(\delta_k), \\ 0 & \text{if } w \not\sqsubseteq R(\delta_k). \end{cases}$$

Then d clearly has the required properties. □

If $\Delta =$ all, then Lemma 4.15 is the well-known fact that every countable set has Hausdorff dimension 0. For smaller resource bounds Δ, Lemma 4.15 has consequences of the following sort.

COROLLARY 4.16. *For every $k \in \mathbb{N}$,*

$$\dim(\mathrm{DTIME}(2^{kn}) \mid \mathrm{E}) = 0$$

and

$$\dim(\mathrm{DTIME}(2^{n^k}) \mid \mathrm{E}_2) = 0.$$

Analogous results hold in ESPACE, REC, etc. As noted above, every countable class of languages has Hausdorff dimension 0. In contrast, we now show that, even for countable resource bounds Δ, the Δ-dimension of $R(\Delta)$ is 1. This result, which is analogous to the measure conservation theorem of [9], endows the classes $R(\Delta)$ with

internal dimensional structure. (In fact, by Observation 4.2, this result follows from the measure conservation theorem, but we prove it directly here.)

THEOREM 4.17. $\dim(R(\Delta) \mid R(\Delta)) = \dim_\Delta(R(\Delta)) = 1$.

Proof. By definition, $\dim(R(\Delta) \mid R(\Delta)) = \dim_\Delta(R(\Delta))$, and by Observation 4.2, $\dim_\Delta(R(\Delta)) \leq 1$, so it suffices to show that $\dim_\Delta(R(\Delta)) \geq 1$. For this, fix an arbitrary $s \in [0,1)$ such that 2^s is rational. By Corollary 4.6, it suffices to show that $s \notin \mathcal{G}_\Delta(R(\Delta))$. For this, let $d \in \Delta$ be an exact s-gale. By the exact computation lemma, it suffices to show that $R(\Delta) \not\subseteq S^\infty[d]$. We do this by defining a constructor $\delta \in \Delta$ such that $R(\delta) \notin S^\infty[d]$.

For each $w \in \{0,1\}^*$, let

$$\delta(w) = w[\![d(w0) > d(w1)]\!].$$

Then δ is a constructor, and it is clear that $\delta \in \Delta$ (because $d \in \Delta$). The definition of δ ensures that for all $w \in \{0,1\}^*$,

$$d(\delta(w)) = \min\{d(w0), d(w1)\}.$$

It follows by Corollary 3.4 that for all $w \in \{0,1\}^*$, $d(\delta(w)) \leq 2^{s-1} d(w)$. By induction, this implies that for all $n \in \mathbb{N}$, $d(\delta^n(\lambda)) \leq 2^{(s-1)n} d(\lambda)$. Since $s \in [0,1)$, we then have

$$\lim_{n\to\infty} d(R(\delta)[0 \ldots n-1]) = \lim_{n\to\infty} d(\delta^n(\lambda)) = 0,$$

whence $R(\delta) \notin S^\infty[d]$. □

We now give an example in which we calculate the resource-bounded dimension of a simple set of languages.

PROPOSITION 4.18. *Given $l \in \mathbb{Z}^+$ and $\emptyset \neq S \subseteq \{0,1\}^l$, let*

$$X = \{A \in \mathbf{C} \mid (\forall k) A[kl..(k+1)l-1] \in S\}.$$

Then

$$\dim(X \mid \mathrm{E}) = \dim_{\mathrm{p}}(X) = \frac{\log|S|}{l}.$$

Proof. Since $\dim(X \mid \mathrm{E}) \leq \dim_{\mathrm{p}}(X)$, it suffices to show that $\dim_{\mathrm{p}}(X) \leq \frac{\log|S|}{l}$ and $\dim(X \mid \mathrm{E}) \geq \frac{\log|S|}{l}$.

To see that $\dim_{\mathrm{p}}(X) \leq \frac{\log|S|}{l}$, let $s > \frac{\log|S|}{l}$ be such that 2^s is rational. Define a function $d : \{0,1\}^* \longrightarrow [0,\infty)$ inductively as follows. Let $d(\lambda) = 1$. If $d(w)$ has been defined, where $|w|$ is a multiple of l, and if $0 < |u| \leq l$, then let $d(wu) = 2^{s|u|}\rho(u)d(w)$, where

$$\rho(u) = \frac{|\{v \in S \mid u \sqsubseteq v\}|}{|S|}.$$

It is clear that d is exactly p-computable, and it is routine to verify that d is an s-gale. The definition of d implies that if $|w|$ is a multiple of l and $u \in S$, then

$$d(wu) = 2^{sl}\frac{1}{|S|}d(w) = 2^{\varepsilon}d(w),$$

where $\varepsilon = sl - \log|S| > 0$ by our choice of s. It follows inductively that if $A \in X$, then for all $k \in \mathbb{N}$,

$$d(A[0 \ldots kl-1]) = 2^{\varepsilon k},$$

whence $A \in S^\infty[d]$. Thus $X \subseteq S^\infty[d]$. We have now established that $\dim_{\mathrm{p}}(X) \leq s$. Since this holds for a dense set of $s > \frac{\log|S|}{l}$, it follows that $\dim_{\mathrm{p}}(X) \leq \frac{\log|S|}{l}$.

To see that $\dim(X \mid \mathrm{E}) \geq \frac{\log|S|}{l}$, let $0 \leq s < \frac{\log|S|}{l}$ be such that 2^s is rational, and let d be an exactly p-computable s-gale. By the exact computation lemma, it suffices to show that $X \cap \mathrm{E} \not\subseteq S^\infty[d]$. Define a constructor δ as follows. If $|w|$ is a multiple of l, then $\delta(w) = wu$, where u is the lexicographically first element of S such that for all $v \in S$, $d(wu) \leq d(wv)$. If $|w|$ is not a multiple of l, then $\delta(w) = w0$. Since δ is exactly p-computable, it is clear that $\delta \in \mathrm{p}$. It is then easy to see that $R(\delta) \in X \cap R(p) = X \cap \mathrm{E}$. We finish the proof by showing that $R(\delta) \notin S^\infty[d]$.

For any string w, Corollary 3.4 (with $\alpha = \frac{2^l}{|S|}$) tells us that there are fewer than $|S|$ strings $u \in \{0,1\}^l$ for which $d(wu) > \frac{2^{sl}}{|S|}d(w)$. This implies that for all w such that $|w|$ is a multiple of l, $d(\delta(w)) \leq \frac{2^{sl}}{|S|}d(w)$. Thus for all $k \in \mathbb{N}$,

$$d(R(\delta)[0 \ldots kl-1]) \leq \left(\frac{2^{sl}}{|S|}\right)^k d(\lambda) = 2^{-\varepsilon k} d(\lambda),$$

where $\varepsilon = \log|S| - sl > 0$. It follows by Corollary 3.5 that for all $n \in \mathbb{N}$,

$$d(R(\delta)[0 \ldots n-1]) \leq 2^{sl - \varepsilon\lfloor \frac{n}{l} \rfloor} d(\lambda),$$

whence $R(\delta) \notin S^\infty[d]$. □

We conclude this section by mentioning some relevant earlier work relating martingales and supermartingales to computable dimension. Schnorr [14, 15] defined a martingale d to have *exponential order* on a sequence (equivalently, language) S if

$$\limsup_{n\to\infty} \frac{\log d(S[0..n-1])}{n} > 0 \tag{4.1}$$

and proved that no computable martingale can have exponential order on a Church-stochastic sequence. Terwijn [18] has noted that (4.1) is equivalent to the existence of an $s < 1$ for which the s-gale $d^{(s)}(w) = 2^{(s-1)|w|}d(w)$ succeeds on S. Thus Schnorr's result says that $\dim_{\mathrm{comp}}(\{S\}) = 1$ for every Church-stochastic sequence S.

Ryabko [13] and Staiger [17] defined the *exponent of increase* $\lambda_d(S)$ of a martingale d on a sequence S to be the left-hand side of (4.1). (We are using Staiger's notation here.) Both papers paid particular attention to the quantity

$$\lambda(S) = \sup\{\lambda_d(S) \mid d \text{ is a computable martingale}\}. \tag{4.2}$$

By Terwijn's above-mentioned observation, $1 - \lambda(S)$ is precisely $\dim_{\mathrm{comp}}(\{S\})$. The reader is referred to these papers for interesting results relating $\lambda(S)$—and hence computable dimension—to Kolmogorov complexity and Hausdorff dimension.

5. Dimension and frequency in exponential time. In this section we show that for each $0 \leq s \leq 1$ there is a natural set X that has dimension s in each of the exponential time complexity classes E and E_2. This set X consists of those languages that asymptotically contain at most α of all strings, where $0 \leq \alpha \leq \frac{1}{2}$ and $\mathcal{H}(\alpha) = s$. We now define this set more completely.

For each nonempty string $w \in \{0,1\}^+$, let

$$\mathrm{freq}(w) = \frac{\#(1,w)}{|w|},$$

where $\#(1, w)$ is the number of 1's in w. For each $A \in \mathbf{C}$ and $n \in \mathbb{Z}^+$, let

$$\text{freq}_A(n) = \text{freq}(A[0..n-1]).$$

That is, $\text{freq}_A(n)$ is the fraction of the first n strings in $\{0,1\}^*$ that are elements of A. For $\alpha \in [0,1]$, define the sets

$$\text{FREQ}(\alpha) = \{A \in \mathbf{C} \mid \lim_{n\to\infty} \text{freq}_A(n) = \alpha\},$$

$$\text{FREQ}(\leq \alpha) = \{A \in \mathbf{C} \mid \liminf_{n\to\infty} \text{freq}_A(n) \leq \alpha\}.$$

The set $\text{FREQ}(\leq \alpha)$ is the set X promised in the preceding paragraph.

Our results use the binary entropy function

$$\mathcal{H} : [0,1] \longrightarrow [0,1]$$

$$\mathcal{H}(\alpha) = \alpha \log \frac{1}{\alpha} + (1-\alpha) \log \frac{1}{1-\alpha}.$$

(The values $\mathcal{H}(0)$ and $\mathcal{H}(1)$ are both 0, so that $\mathcal{H}$ is continuous on [0, 1].) Our proofs use the "weighted entropy" function

$$h : (0,1) \times (0,1) \longrightarrow \mathbb{R}$$

$$h(x,y) = x \log \frac{1}{y} + (1-x) \log \frac{1}{1-y}.$$

For fixed x, $h(x,y)$ takes its minimum value $\mathcal{H}(x)$ at $y = x$ and strictly increases as y moves away from x.

We first show that $\mathcal{H}(\alpha)$ is an upper bound on the p-dimension of $\text{FREQ}(\leq \alpha)$.

LEMMA 5.1. *For all* $\alpha \in [0, \frac{1}{2}]$, $\dim_{\text{p}}(\text{FREQ}(\leq \alpha)) \leq \mathcal{H}(\alpha)$.

Proof. Let $0 \leq \alpha \leq \frac{1}{2}$. Let $s > \mathcal{H}(\alpha)$ be such that 2^s is rational, and let $\varepsilon = \frac{s - \mathcal{H}(\alpha)}{2}$. Fix $\delta > 0$ such that for all $x, y \in [\alpha-\delta, \alpha+\delta] \cap (0,1)$, $|h(x,y) - \mathcal{H}(\alpha)| < \varepsilon$, and let $y \in [\alpha - \delta, \alpha + \delta] \cap (0, \frac{1}{2}]$ be a rational number. Define

$$d : \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0, \infty)$$

$$d(\lambda) = 1,$$

$$d(w0) = (1-y)2^s d(w),$$

$$d(w1) = y2^s d(w).$$

It is clear that d is an exactly p-computable s-gale.

To see that $\mathrm{FREQ}(\leq \alpha) \subseteq S^\infty[d]$, let $A \in \mathrm{FREQ}(\leq \alpha)$. Then there exists an infinite set $J \subseteq \mathbb{N}$ such that for all $n \in J$, $\mathrm{freq}_A(n) \leq \alpha + \delta$. It follows that for all $n \in J$, if we write $w_n = A[0 \ldots n-1]$, then

$$\begin{aligned} d(w_n) &= y^{\#(1,w_n)}(1-y)^{\#(0,w_n)}2^{sn} \\ &= \left[y^{\mathrm{freq}_A(n)}(1-y)^{1-\mathrm{freq}_A(n)}2^s\right]^n \\ &\geq \left[y^{\alpha+\delta}(1-y)^{1-(\alpha+\delta)}2^s\right]^n \\ &= \left[2^{s-h(\alpha+\delta,y)}\right]^n \\ &\geq \left[2^{s-\mathcal{H}(\alpha)-\varepsilon}\right]^n \\ &= 2^{\varepsilon n} \ . \end{aligned}$$

Thus $A \in S^\infty[d]$.

We have now shown that $\dim_{\mathrm{p}}(\mathrm{FREQ}(\leq \alpha)) \leq s$. Since this holds for all $s > \mathcal{H}(\alpha)$ such that 2^s is rational, it follows that $\dim_{\mathrm{p}}(\mathrm{FREQ}(\leq \alpha)) \leq \mathcal{H}(\alpha)$. □

We next show that $\mathcal{H}(\alpha)$ is a lower bound on the dimension of $\mathrm{FREQ}(\alpha)$ in $R(\Delta)$. In general, this does not hold for arbitrary $\alpha \in [0,1]$, since if $R(\Delta)$ is countable, there can be only countably many α for which $\mathrm{FREQ}(\alpha) \cap R(\Delta) \neq \emptyset$. However, it does hold for all Δ-computable real numbers $\alpha \in [0,1]$.

LEMMA 5.2. *For all Δ-computable $\alpha \in [0,1]$, $\dim(\mathrm{FREQ}(\alpha) \mid R(\Delta)) \geq \mathcal{H}(\alpha)$.*

Proof. The inequality holds trivially for $\alpha \in \{0,1\}$, so assume that $\alpha \in (0,1)$ is Δ-computable. Fix $s \in (0, \mathcal{H}(\alpha))$ such 2^s is rational, and let d be an exactly Δ-computable s-gale. By the exact computation lemma, it suffices to show that $\mathrm{FREQ}(\alpha) \cap R(\Delta) \not\subseteq S^\infty[d]$.

Although the details are a bit involved, the idea of the proof is simple. We want to define a constructor $\delta \in \Delta$ such that $R(\delta) \in \mathrm{FREQ}(\alpha) - S^\infty[d]$. Given a string w of length n, δ computes a rational approximation $\frac{k(n)}{m(n)}$ of α and extends w by a string u of length $m(n)$ containing exactly $k(n)$ 1's and having the property that d makes no progress along u. Such a string u exists because $s < \mathcal{H}(\frac{k(n)}{m(n)})$, and it can be found within the resource bound Δ because $m(n)$ is logarithmic in n. On the other hand, $m(n) \to \infty$ as $n \to \infty$, so $R(\delta) \in \mathrm{FREQ}(\alpha)$, and d makes no progress along $R(\delta)$, so $R(\delta) \notin S^\infty[d]$. We now develop this idea.

Since α is Δ-computable, there is a function $\hat{\alpha} : \mathbb{N} \to \mathbb{Q} \cap (0,1)$ such that $\hat{\alpha} \in \Delta$ and for all $r \in \mathbb{N}$, $|\hat{\alpha}(r) - \alpha| \leq 2^{-r}$. Fix $\epsilon > 0$ such that

$$\epsilon \leq \alpha, \quad \epsilon \leq 1 - \alpha, \tag{5.1}$$

and for all $x \in [0,1]$,

$$|x - \alpha| < \epsilon \Rightarrow |\mathcal{H}(x) - \mathcal{H}(\alpha)| < \frac{\mathcal{H}(\alpha) - s}{2}. \tag{5.2}$$

Choose a positive integer c satisfying the conditions

$$c > 2^{1+\frac{2}{\epsilon}}, \tag{5.3}$$

$$c > 1 + \log \frac{1}{\epsilon}, \tag{5.4}$$

$$\frac{\log c}{\log \log c} > \frac{4}{\mathcal{H}(\alpha) - s}. \tag{5.5}$$

For each $n \in \mathbb{N}$, let

$$m(n) = \lfloor \log(n+c) \rfloor,$$
$$k(n) = \lfloor \hat{\alpha}(m(n)+c)m(n) \rfloor.$$

We first show that $\frac{k(n)}{m(n)}$ is a useful approximation of α. By (5.3),

$$m(n) \geq \lfloor \log c \rfloor \geq \frac{2}{\epsilon} \tag{5.6}$$

for all $n \in \mathbb{N}$. In particular, $m(n)$ is always positive. By (5.4) and (5.1),

$$\begin{aligned} \hat{\alpha}(m(n)+c) &\geq \alpha - 2^{-c} \geq \alpha - 2^{-1+\log \epsilon} \\ &= \alpha - \frac{\epsilon}{2} \geq \frac{\alpha}{2} \end{aligned} \tag{5.7}$$

for all $n \in \mathbb{N}$. It follows from (5.6), (5.7), and (5.1) that

$$k(n) \geq \left\lfloor \frac{2}{\epsilon} \frac{\alpha}{2} \right\rfloor > 0 \tag{5.8}$$

for all $n \in \mathbb{N}$. Also by (5.4) and (5.1),

$$\begin{aligned} \hat{\alpha}(m(n)+c) &\leq \alpha + 2^{-c} < \alpha + 2^{-1+\log \epsilon} \\ &\leq \alpha + 2^{-1+\log(1-\alpha)} = \frac{1+\alpha}{2} < 1, \end{aligned}$$

so

$$k(n) = \lfloor \hat{\alpha}(m(n)+c)m(n) \rfloor < m(n) \tag{5.9}$$

for all $n \in \mathbb{N}$. By (5.8) and (5.9), we now have

$$0 < \frac{k(n)}{m(n)} < 1 \tag{5.10}$$

for all $n \in \mathbb{N}$. In fact,

$$\frac{k(n)}{m(n)} = \frac{\lfloor \hat{\alpha}(m(n)+c)m(n) \rfloor}{m(n)},$$

so

$$\hat{\alpha}(m(n)+c) - \frac{1}{m(n)} < \frac{k(n)}{m(n)} \leq \hat{\alpha}(m(n)+c),$$

and thus

$$\left| \frac{k(n)}{m(n)} - \alpha \right| \leq \frac{1}{m(n)} + 2^{-(m(n)+c)} \tag{5.11}$$

for all $n \in \mathbb{N}$. It follows by (5.4) and (5.6) that

$$\left| \frac{k(n)}{m(n)} - \alpha \right| \leq \epsilon,$$

whence by (5.2),

$$\left|\mathcal{H}\left(\frac{k(n)}{m(n)}\right) - \mathcal{H}(\alpha)\right| < \frac{\mathcal{H}(\alpha) - s}{2} \tag{5.12}$$

for all $n \in \mathbb{N}$. This is the first sense in which $\frac{k(n)}{m(n)}$ is a useful approximation of α.

For each $n \in \mathbb{N}$, define the set

$$B_n = \left\{ u \in \{0,1\}^{m(n)} \,\middle|\, \#(1,u) = k(n) \right\}.$$

Using (5.10) and the well-known approximation $e\left(\frac{N}{e}\right)^N < N! < eN\left(\frac{N}{e}\right)^N$, valid for all $N \geq 1$, it is easy to see that

$$\begin{aligned} |B_n| = \binom{m(n)}{k(n)} &> \frac{1}{ek(n)(m(n)-k(n))} 2^{m(n)\mathcal{H}\left(\frac{k(n)}{m(n)}\right)} \\ &\geq \frac{4}{em(n)^2} 2^{m(n)\mathcal{H}\left(\frac{k(n)}{m(n)}\right)} \\ &> 2^{m(n)\mathcal{H}\left(\frac{k(n)}{m(n)}\right) - 2\log m(n)} \end{aligned}$$

for all $n \in \mathbb{N}$. It follows by (5.12) that

$$\begin{aligned} |B_n| &> 2^{m(n)\left[\mathcal{H}(\alpha) - \frac{\mathcal{H}(\alpha)-s}{2}\right] - 2\log m(n)} \\ &= 2^{m(n)\frac{\mathcal{H}(\alpha)+s}{2} - 2\log m(n)} \end{aligned}$$

for all $n \in \mathbb{N}$. Now (5.5) and the monotonicity of $\frac{\log x}{\log\log x}$ tell us that

$$m(n)\frac{\mathcal{H}(\alpha) - s}{2} \geq 2\log m(n),$$

so it follows that

$$|B_n| > 2^{m(n)\left[\frac{\mathcal{H}(\alpha)+s}{2} - \frac{\mathcal{H}(\alpha-s)}{2}\right]} = 2^{sm(n)} \tag{5.13}$$

for all $n \in \mathbb{N}$.

Corollary 3.4 tells us that for each $w \in \{0,1\}^*$ there are fewer than $2^{sm(n)}$ strings $u \in \{0,1\}^{m(n)}$ for which $\max_{v \sqsubseteq u} d(wv) > d(w)$. It follows by (5.13) that the function

$$\delta : \{0,1\}^* \to \{0,1\}^*$$

$$\begin{aligned} \delta(w) = wu, \quad &\text{where } u \text{ is the lexicographically} \\ &\text{first element of } B_{|w|} \text{ such that} \\ &d(wv) \leq d(w) \text{ for all } v \sqsubseteq u, \end{aligned}$$

is a well-defined constructor. Also, since $d \in \Delta$ and $|\{0,1\}^{m(|w|)}| \leq |w| + c$, it is clear that $\delta \in \Delta$. To conclude the proof, then, it suffices to show that $R(\delta) \in \mathrm{FREQ}(\alpha) - S^\infty[d]$.

To see that $R(\delta) \in \mathrm{FREQ}(\alpha)$, define a sequence $n_0, n_1, \ldots$ by the recursion

$$n_0 = 0, \quad n_{i+1} = n_i + m(n_i),$$

and note that $R(\delta)$ is of the form

$$R(\delta) = u_0 u_1 u_2 \cdots,$$

where $|u_i| = m(n_i)$ and $\text{freq}(u_i) = \frac{k(n_i)}{m(n_i)}$ for all $i \in \mathbb{N}$. Also, by (5.11) we have

$$\left| \frac{k(n)}{m(n)} - \alpha \right| \leq \frac{2}{m(n)}$$

for all $n \in \mathbb{N}$. Since $m(n) \to \infty$ as $n \to \infty$, it follows that

$$\lim_{i \to \infty} \text{freq}(u_i) = \lim_{i \to \infty} \frac{k(n_i)}{m(n_i)} = \alpha.$$

(This is the second sense in which $\frac{k(n)}{m(n)}$ is a useful approximation of α.) Since $|u_i|$ is nondecreasing, this implies that $R(\delta) \in \text{FREQ}(\alpha)$.

The definition of δ implies that $d(w) \leq d(\lambda)$ for all $w \sqsubseteq R(\delta)$, so $R(\delta) \notin S^\infty[d]$. □

From these two lemmas we get the main result of this section.

THEOREM 5.3.

1. *For all Δ-computable $\alpha \in [0,1]$,* $\dim(\text{FREQ}(\alpha) \mid R(\Delta)) = \mathcal{H}(\alpha)$.
2. *For all $\alpha \in [0, \frac{1}{2}]$,* $\dim(\text{FREQ}(\leq \alpha) | R(\Delta)) = \mathcal{H}(\alpha)$.

Proof.

1. This follows immediately from Lemmas 5.1 and 5.2 and Observation 4.2.
2. Let $\alpha \in [0, \frac{1}{2}]$. By Lemma 5.1 and Observation 4.2,

$$\begin{aligned} &\dim(\text{FREQ}(\leq \alpha) \mid R(\Delta)) \\ &= \dim_\Delta(\text{FREQ}(\leq \alpha) \cap R(\Delta)) \\ &\leq \dim_\Delta(\text{FREQ}(\leq \alpha)) \\ &\leq \dim_{\text{p}}(\text{FREQ}(\leq \alpha)) \\ &\leq \mathcal{H}(\alpha). \end{aligned}$$

For the reverse inequality, let α' be an arbitrary rational such that $\alpha' \leq \alpha$. Then by Lemma 5.2 and Observation 4.2,

$$\begin{aligned} &\dim(\text{FREQ}(\leq \alpha) \mid R(\Delta)) \\ &\geq \dim(\text{FREQ}(\alpha') \cap R(\Delta)) \\ &\geq \mathcal{H}(\alpha'). \end{aligned}$$

Since this holds for all rational $\alpha' \leq \alpha$ and $\mathcal{H}$ is continuous, it follows that

$$\dim(\text{FREQ}(\leq \alpha) \mid R(\Delta)) \geq \mathcal{H}(\alpha). \quad \square$$

The case $\Delta =$ all of Theorem 5.3 says simply that the classical Hausdorff dimensions of $\text{FREQ}(\alpha)$ and $\text{FREQ}(\leq \alpha)$ are both $\mathcal{H}(\alpha)$. This was proven in 1949 by Eggleston [5, 2]. The proof here yields a new proof, using gales, of this classical result. However, it is complexity-theoretic results of the following kind that are of interest in this paper.

COROLLARY 5.4.

1. *For all p-computable reals* $\alpha \in [0,1]$,

$$\dim(\mathrm{FREQ}(\alpha) \mid \mathrm{E}) = \dim(\mathrm{FREQ}(\alpha) \mid \mathrm{E}_2) = \mathcal{H}(\alpha).$$

2. *For all* $\alpha \in [0, \frac{1}{2}]$,

$$\dim(\mathrm{FREQ}(\leq \alpha) \mid \mathrm{E}) = \dim(\mathrm{FREQ}(\leq \alpha) \mid \mathrm{E}_2) = \mathcal{H}(\alpha).$$

Since $\mathcal{H}(0) = 0$, $\mathcal{H}(\frac{1}{2}) = 1$, and $\mathcal{H}$ is continuous, part 2 of the corollary implies that for every $s \in [0,1]$ there exists $\alpha \in [0, \frac{1}{2}]$ such that

$$\dim(\mathrm{FREQ}(\leq \alpha) \mid \mathrm{E}) = \dim(\mathrm{FREQ}(\leq \alpha) \mid \mathrm{E}_2) = s.$$

6. Dimension and circuit size in exponential space. We now examine the dimensions of Boolean circuit-size complexity classes in the complexity class ESPACE.

Our Boolean circuit model and terminology are standard. Details may be found in [9], but our result is not sensitive to minor details of the model. The *circuit-size complexity* of a language $A \subseteq \{0,1\}^*$ is the function $CS_A : \mathbb{N} \longrightarrow \mathbb{N}$, where $CS_A(n)$ is the number of gates in the smallest n-input Boolean circuit that decides $A \cap \{0,1\}^n$. For each function $f : \mathbb{N} \longrightarrow \mathbb{N}$, we define the circuit-size complexity class

$$\mathrm{SIZE}(f) = \{A \in \mathbf{C} \mid (\forall^\infty n) CS_A(n) \leq f(n)\}.$$

Shannon [16] showed (essentially) that $\mathrm{SIZE}(\alpha \frac{2^n}{n})$ has measure 0 in $\mathbf{C}$ for all $\alpha < 1$, and Lutz [9] showed that $\mathrm{SIZE}(\alpha \frac{2^n}{n})$ also has measure 0 in ESPACE for all $\alpha < 1$. We now use resource-bounded dimension to give a quantitative refinement of these results.

Assume that all n-input Boolean circuits are enumerated in a canonical order in which all circuits of size (number of gates) t precede all those of size $t+1$ for all $t \in \mathbb{Z}^+$. Call a circuit in this enumeration *novel* if there is no previous circuit in the enumeration that decides the same subset of $\{0,1\}^n$. For each $n \in \mathbb{N}$ and $t \in \mathbb{Z}^+$, let $N(n,t)$ be the number of novel n-input Boolean circuits with at most t gates. The following specific bound on $N(n,t)$ was proven in [9], but as noted there, the idea is essentially due to Shannon [16].

LEMMA 6.1. *For all* $n \in \mathbb{N}$ *and* $t > n$, $N(n,t) \leq (48et)^t$.

LEMMA 6.2. *For every real* $\alpha \in [0,1]$, $\dim_{\mathrm{pspace}}(\mathrm{SIZE}(\alpha \frac{2^n}{n})) \leq \alpha$.

Proof. Let $\alpha \in (0,1]$, and let $s > \alpha$ be such that 2^s is rational. Define $d : \{0,1\}^* \longrightarrow [0,\infty)$ inductively as follows:

(i) Let $d(\lambda) = 1$.

(ii) Assume that $d(w)$ has been defined, where $|w| = 2^n - 1$ for some $n \in \mathbb{N}$. For each u with $0 < |u| \leq 2^n$, define $d(wu) = 2^{s|u|}\rho(u)d(w)$, where

$$\rho(u) = \frac{N(n,t,u)}{N(n,t)}$$

and $N(n,t,u)$ is the number of novel n-input Boolean circuits with at most t gates that decide the sets $B \subseteq \{0,1\}^n$ whose first $|u|$ decisions are the bits of u. It is easy to check that d is an exactly pspace-computable s-gale. The definition of d implies that if $|w| = 2^n - 1$ and u is the characteristic string

of a set $B \subseteq \{0,1\}^n$ that can be decided by a circuit with at most $\alpha\frac{2^n}{n}$ gates, then for sufficiently large n,

$$\begin{aligned} d(wu) &= 2^{s2^n}\frac{1}{N(n,\alpha\frac{2^n}{n})}d(w) \\ &= 2^{s2^n-\alpha\frac{2^n}{n}[\log 48e+\log\alpha+n-\log n]}d(w) \\ &= 2^{(s-\alpha)2^n+\alpha\frac{2^n}{n}[\log n-\log 48e-\log\alpha]}d(w) \\ &\geq 2^{(s-\alpha)2^n}d(w). \end{aligned}$$

Since $s-\alpha>0$, this implies that $\mathrm{SIZE}(\alpha\frac{2^n}{n}) \subseteq S^\infty[d]$. □

LEMMA 6.3. *If $0<\beta<\alpha\leq 1$, then for all sufficiently large n there are at least $2^{\beta 2^n}$ different sets $B\subseteq\{0,1\}^n$ that are decided by Boolean circuits of fewer than $\alpha\frac{2^n}{n}$ gates.*

Proof. Let $m=n+\log\beta$. Then there are $2^{2^m}=2^{\beta 2^n}$ different sets $C\subseteq\{0,1\}^m$. If we let $\varepsilon=\frac{\alpha-\beta}{2\alpha}$, so that $\beta=\alpha(1-2\varepsilon)$, then for all sufficiently large n, Lupanov [8] has shown that each of these sets is decided by a circuit of at most $\frac{2^m}{m}(1+\varepsilon)$ gates. Now for sufficiently large n,

$$\begin{aligned} \frac{2^m}{m} &= \frac{\beta 2^n}{n+\log\beta} \\ &= \alpha\frac{2^n}{n}(1-2\varepsilon)\left(\frac{n}{n+\log\beta}\right) \\ &< \alpha\frac{2^n}{n}(1-\varepsilon), \end{aligned}$$

so

$$\frac{2^m}{m}(1+\varepsilon) < \alpha\frac{2^n}{n}(1-\varepsilon^2) < \alpha\frac{2^n}{n}.$$

Thus, for each $C\subseteq\{0,1\}^m$, if we let $B_C=\{w0^{n-m}\mid w\in C\}$, then B_C is decided by a Boolean circuit of fewer than $\alpha\frac{2^n}{n}$ gates. □

Recall that in section 2 we defined constructors and showed that $R(\mathrm{pspace}) = \mathrm{ESPACE}$.

LEMMA 6.4. *For every real $\alpha\in[0,1]$, $\dim_H(\mathrm{SIZE}(\alpha\frac{2^n}{n}))\geq\alpha$ and*

$$\dim\left(\mathrm{SIZE}\left(\alpha\frac{2^n}{n}\right)\,\middle|\,\mathrm{ESPACE}\right)\geq\alpha.$$

Proof. This is clear if $\alpha=0$, so assume that $\alpha\in(0,1]$. Let $0<s<\alpha$ with 2^s rational, and let d be an arbitrary s-gale. Define a constructor $\delta:\{0,1\}^*\to\{0,1\}^*$ as follows. If $|w|$ is not of the form 2^n-1, then $\delta(w)=w0$. If $|w|$ is of the form 2^n-1 (i.e., w is the characteristic string of a subset of $\{0,1\}^{<n}$), then $\delta(w)=wu$, where u is the first string in $\{0,1\}^{2^n}$ that minimizes $\max_{v\sqsubseteq u}d(wv)$, subject to the constraint that u is the characteristic string of a set $B\subseteq\{0,1\}^n$ that is decided by a Boolean circuit with fewer than $\alpha\frac{2^n}{n}$ gates. It is clear that $R(\delta)\in\mathrm{SIZE}(\alpha\frac{2^n}{n})$.

Fix β such that $s<\beta<\alpha$. By Lemma 6.3, for all sufficiently large n there are at least $2^{\beta 2^n}$ different sets $B\subseteq\{0,1\}^n$ that are decided by Boolean circuits of fewer than $\alpha\frac{2^n}{n}$ gates. By Corollary 3.4, for all w such that $|w|=2^n-1$, there are fewer than

$2^{\beta 2^n}$ strings $u \in \{0,1\}^{2^n}$ such that $\max_{v \sqsubseteq u} d(wv) > 2^{|v|(s-\beta)} d(w)$. Taken together, these last two sentences imply that for all sufficiently large n and w with $|w| = 2^n - 1$,

$$\max_{wv \sqsubseteq \delta(w)} d(wv) \leq 2^{|v|(s-\beta)} d(w) \leq d(w).$$

It follows from this that $R(\delta) \notin S^\infty[d]$.

We now have that $R(\delta) \in \mathrm{SIZE}(\alpha \frac{2^n}{n}) - S^\infty[d]$, whence $\mathrm{SIZE}(\alpha \frac{2^n}{n}) \not\subseteq S^\infty[d]$. Since d is arbitrary here, this shows that $\dim_H(\mathrm{SIZE}(\alpha \frac{2^n}{n})) \geq \alpha$.

Now let d be as above, and assume further that d is exactly pspace-computable. Then the constructor δ defined above is in pspace, so $R(\delta) \in R(\mathrm{pspace}) = \mathrm{ESPACE}$, and thus we have $\mathrm{SIZE}(\alpha \frac{2^n}{n}) \cap \mathrm{ESPACE} \not\subseteq S^\infty[d]$. It follows by Lemma 4.8 that $\dim(\mathrm{SIZE}(\alpha \frac{2^n}{n}) | \mathrm{ESPACE}) \geq \alpha$. □

THEOREM 6.5. *For every real $\alpha \in [0,1]$,*

$$\dim\left(\mathrm{SIZE}\left(\alpha \frac{2^n}{n}\right) \middle| \mathrm{ESPACE}\right) = \dim_H\left(\mathrm{SIZE}\left(\alpha \frac{2^n}{n}\right)\right) = \alpha.$$

Proof. This follows immediately from Lemma 6.2, Lemma 6.4, and Observation 4.2. □

We note that for any $\alpha < 1$, Lutz [9] has shown that the class $\mathrm{SIZE}(\frac{2^n}{n}(1 + \frac{\alpha \log n}{n}))$ has measure 0 in ESPACE and in $\mathbf{C}$. By the above results, this class is thus a natural example of a set that, in both ESPACE and $\mathbf{C}$, has dimension 1 but measure 0.

Acknowledgments. I am very grateful to Elvira Mayordomo, John Hitchcock, and Dan Mauldin for useful discussions.

THE NATURAL WORK-STEALING ALGORITHM IS STABLE*

PETRA BERENBRINK†, TOM FRIEDETZKY†, AND LESLIE ANN GOLDBERG‡

Abstract. In this paper we analyze a very simple dynamic work-stealing algorithm. In the work-generation model, there are n (work) *generators*. A *generator-allocation function* is simply a function from the n generators to the n processors. We consider a fixed, but arbitrary, distribution $\mathcal{D}$ over generator-allocation functions. During each time step of our process, a generator-allocation function h is chosen from $\mathcal{D}$, and the generators are allocated to the processors according to h. Each generator may then generate a unit-time task, which it inserts into the queue of its host processor. It generates such a task independently with probability λ. After the new tasks are generated, each processor removes one task from its queue and services it. For many choices of $\mathcal{D}$, the work-generation model allows the load to become arbitrarily imbalanced, even when $\lambda < 1$. For example, $\mathcal{D}$ could be the point distribution containing a single function h which allocates all of the generators to just one processor. For this choice of $\mathcal{D}$, the chosen processor receives around λn units of work at each step and services one. The natural work-stealing algorithm that we analyze is widely used in practical applications and works as follows. During each time step, each *empty* processor (with no work to do) sends a request to a randomly selected other processor. Any *nonempty* processor having received at least one such request in turn decides (again randomly) in favor of one of the requests. The number of tasks which are transferred from the nonempty processor to the empty one is determined by the so-called *work-stealing function* f. In particular, if a processor that accepts a request has ℓ tasks stored in its queue, then $f(\ell)$ tasks are transferred to the currently empty one. A popular work-stealing function is $f(\ell) = \lfloor \ell/2 \rfloor$, which transfers (roughly) half of the tasks. We analyze the *long-term behavior* of the system as a function of λ and f. We show that the system is *stable* for any constant generation rate $\lambda < 1$ and for a wide class of functions f. Most intuitively sensible functions are included in this class (for example, every monotonically nondecreasing function f which satisfies $0 \le f(\ell) \le \ell/2$ and $f(\ell) = \omega(1)$ as a function of ℓ is included). Furthermore, we give *upper bounds* on the average system load (as a function of f and n). Our proof techniques combine Lyapunov function arguments with domination arguments, which are needed to cope with dependency.

Key words. work-stealing, dynamic, stability

1. Introduction.

Load balancing is the process of distributing load among a set of processors. There are two main approaches to distributed load balancing, namely, *sender-initiated* strategies, in which processors may decide to give away tasks, and *receiver-initiated* strategies (which are often referred to as *work-stealing*), in which processors may request extra work. In both cases, the decision to transfer tasks is typically *threshold based*. That is, it is based on having too many or too few tasks in one's own queue.

In recent years, there has been a lot of work devoted to rigorously analyzing load balancing, most of which concentrates on sender-initiated approaches or related

allocation processes such as *balls-into-bins games*. However, it appears that many practitioners prefer the receiver-initiated approach (work-stealing) because this approach appears to work better for their applications. The efficiency of work-stealing probably helps to explain the success of Leiserson et al.'s language `Cilk` [10], a language for multithreaded parallel programming which uses work-stealing in its kernel. There are numerous examples of practical applications of work-stealing. In [17], Feldmann, Mysliwietz, and Monien investigate the behavior of parallel MIN/MAX-tree evaluation in the context of parallel game (chess) programs employing work-stealing strategies. In [14], Decker introduces VDS (virtual data space), a load-balancing system for irregular applications that makes use of work-stealing and other strategies. In [23], Mahapatra and Dutt use work-stealing for parallel branch and bound algorithms.

Despite the practical usefulness of work-stealing, there are not many known theoretical results about its performance. Most existing theoretical work on load balancing assumes a rather well-behaved system. For instance, most work on sender-initiated load balancing uses a work-generation model in which each processor generates at most a constant number of new tasks per step. In balls-into-bins games, each ball (task) chooses its bin (processor) uniformly at random (u.a.r.), which also yields a relatively balanced system.

In this paper we analyze a simple and fully distributed work-stealing algorithm. Our work-generation model allows for an arbitrary placement of n so-called *generators* among the set of n processors. Each generator generates a new task with a certain probability λ at each time step. In the extreme case, there can be one processor being host to n generators. In this case the one processor has an expected increase of $\lambda n - 1$ tasks per step, whereas all other processors do not generate tasks at all.

Our load-balancing algorithm follows a very simple and natural work-stealing approach. At each time step, each *empty* processor sends a request to one randomly chosen other processor. Each *nonempty* processor having received at least one such request selects one of them randomly. Now each empty processor P whose request is accepted by a processor Q "steals" $f(\ell)$ tasks from Q, where ℓ denotes Q's load.

Our results are concerned mostly with the *stability* of the system. A system is said to be *unstable* if the system load (the sum of the load of all processors) grows unboundedly with time. We present both negative and positive results, depending on the work-stealing function f. First we show that if the work-stealing function is $\omega(1)$ as a function of the load (i.e., $f(\ell) = \omega(1)$ as a function of ℓ), then the system is stable (provided f is monotonically nondecreasing and satisfies $0 \le f(\ell) \le \ell/2$). This result still holds if we put an upper bound on the amount of work that can be "stolen" by a single request. That is, for an upper bound h_z which is independent of ℓ (but depends on n) and will be defined in Lemma 2, the work-stealing function defined by $f'(\ell) = \min(f(\ell), f(h_z))$ is also stable. The value h_z depends upon the function f, but it need not be very large. For the function $f(\ell) = \lfloor \ell/2 \rfloor$, the value h_z is bounded from above by a polynomial in n. See section 3 for details. Our stability results are complemented by a straightforward lower bound: The system is unstable if $f(\ell)$ is too small, for example, if $f(\ell) < \lambda n - 1$. Finally, we provide upper bounds on the system load in a stationary system (again, depending on f).

1.1. New results. Before we state our results, we introduce our model and the work-stealing algorithm.

The model. We start with a collection of n synchronized *processors*, connected by some network topology. During each time step, every processor may send a request

(requesting extra work) to at most one other processor, and any processor receiving more than one such request accepts at most one of them.

In our model, we have n *generators.* A *generator-allocation function* is a function from the n generators to the n processors. We consider a fixed, but arbitrary, distribution $\mathcal{D}$ over generator-allocation functions. During each time step of our process, a generator-allocation function h is chosen from $\mathcal{D}$, and the generators are allocated to the processors according to h. Each generator may then generate a unit-time task which it inserts into the queue of its host processor. It generates such a task independently with probability $\lambda \in [0, 1]$. After the new tasks are generated, each processor removes one task from its queue and services it. We assume constant service time for all tasks.

In the absence of a load-balancing mechanism, many choices of $\mathcal{D}$ allow the load to become arbitrarily imbalanced, even when $\lambda < 1$.

The algorithm. The work-stealing algorithm is very simple and natural. During each time step, each *empty* processor (with no work to do) sends a request to one other processor, which is chosen independently and u.a.r. Each *nonempty* processor that received at least one request selects one of these independently and u.a.r. Then each empty processor whose request was accepted "steals" tasks from the other processor.

The number of tasks which are transferred from the nonempty processor to the empty one is determined by the so-called *work-stealing function* f. In particular, if a processor that accepts a request has ℓ tasks stored in its queue, then $f(\ell)$ tasks are transferred to the currently empty one. A popular work-stealing function is $f(\ell) = \lfloor \ell/2 \rfloor$, which transfers (roughly) half of the tasks.

The results. Recall that a system is said to be stable if the system load (the sum of the load of all processors) does not grow unboundedly with time. Obviously, stability for large arrival rates is one of the most desirable features of load-balancing algorithms.

In Theorem 10 we show that, given a suitable work-stealing function, our algorithm yields a stable system for *any* constant arrival rate $\lambda < 1$ and any distribution of the generators. Most intuitively sensible work-stealing functions are suitable (for example, every monotonically nondecreasing function $f(\ell)$ which is $\omega(1)$ as a function of ℓ and satisfies $0 \le f(\ell) \le \ell/2$ is suitable). The rough requirement (for f to be suitable) is that for some finite value Φ_f (which may depend upon n) and some $z = O(\log n)$ and $T = \Theta(\log n)$, we may apply f to Φ_f z times and the resulting value is still at least $2T$. (That is, $f^z(\Phi_f) \ge 2T$.) Our stability result still holds if we put an appropriate upper bound on the amount of work that can be stolen by a single request. Details are given in section 3.

In Theorem 12 we provide upper bounds on the expected system load as well as corresponding tail bounds. The upper bounds are described in terms of Φ_f and n. For many natural work-stealing functions f, Φ_f is at most a polynomial in n, so the system-load bounds are polynomial in n. For example, Φ_f is at most a polynomial in n for the natural work-stealing function $f(\ell) = \lfloor \ell/2 \rfloor$.

Finally, in Theorem 22, we classify some work-stealing functions that do not result in a stable system. For example, the system is unstable if $f(\ell) < \lambda n - 1$.

The proofs. Since the proofs are technical, we briefly introduce the underlying idea. We model our system by a discrete-time, countable Markov chain in which states are tuples giving the number of tasks currently allocated to each processor. The standard method for determining whether such a Markov chain is ergodic (i.e., whether it

has a stationary distribution) is to find an appropriate Lyapunov function [11, 16, 25] (a potential function with an appropriate drift). Foster's theorem (see Theorem 2.2.3 of [16]) shows that the chain is ergodic if and only if there is a positive Lyapunov function which is expected to decrease by a positive amount from every state except some finite subset of the state space. For many computer science applications, it is apparently prohibitively difficult to find such a one-step Lyapunov function, even when one is known to exist. Thus, multiple-step analysis is used [21, 18, 3]. We use the multiple-step extension of Foster's theorem due to Fayolle, Malyshev, and Menshikov (see Lemma 7). The technical difficulty of our proof arises because of the lack of independence as the system evolves over multiple steps. To derive our results, we study the behavior of a different and simpler Markov chain. The new Markov chain does not dominate the original chain forever, but we show that it does dominate the original chain for a sufficiently long period of time, and this enables us to prove that the original chain is ergodic. The proof of ergodicity, together with a martingale bound of [8], gives us our bound on the stationary behavior of the chain.

1.2. Known results. Most known theoretical results on load balancing are for unconditional algorithms (which perform load balancing every few steps, regardless of the system state) or for sender-initiated approaches. First, there has been a lot of work on *static* problems, in which the number of jobs to be serviced is fixed and may even be known in advance. For these results, see [4, 34, 13, 2, 5].

In our paper, we work on *dynamic* load balancing, in which tasks are generated over time. We will now describe previous work on this problem. In [1], Adler, Berenbrink, and Schröder consider a process in which m jobs arrive in each round to n servers and each server is allowed to remove one job per round. They introduce a simple algorithm in which each job chooses between 2 random servers. They show that, provided $m \leq n/6e$, no job is likely to wait more than $O(\log \log n)$ rounds. In [12] the authors analyze several dynamic balls-into-bins games with deletion.

In [26], Mitzenmacher presents a new differential-equations approach for analyzing both static and dynamic load-balancing strategies. He demonstrates the approach by providing an analysis of the supermarket model: jobs (customers) arrive as a Poisson stream of rate λn, $\lambda < 1$, at a collection of n servers. Each customer chooses d servers independently and u.a.r. and waits for service at the one with the shortest queue. The service time of the customers is exponentially distributed with mean 1. Mitzenmacher achieves results on the expected time that a customer spends in the system. Furthermore, he shows that for any time interval of fixed length, the maximum system load is likely to be at most $\log \log n / \log d + O(1)$. In [35] Vvedenskaya, Dobrushin, and Karpelevich independently present similar results. For related results, see [27, 30, 28].

In [33], Rudolph, Slivkin-Allalouf, and Upfal present a simple distributed load-balancing strategy. They consider a work-generation model in which, at every time step, the load change of any processor due to local generation and service is bounded by some constant. The balancing strategy works as follows. Each processor stores its tasks in a local queue. Whenever a processor accesses its local queue, the processor performs a balancing operation with a probability inversely proportional to the size of its queue. The balancing operation examines the queue size of a randomly chosen processor and then equalizes their load. They show that the expected load of any processor at any point of time is within a constant factor of the average load.

In [22], Lüling and Monien use a similar work-generation model. A processor initiates a load-balancing action if its load has changed by a constant factor since

its last balancing action. They show that the expected load difference between any two processors is bounded by a constant factor. They also bound the corresponding variance.

In [6, 7] the authors introduce and investigate the performance of certain randomized load-balancing algorithms under stochastic and adversarial work-generation models. They consider two different work-generation models. In the first model, in each step, each processor generates a task with some probability $p < 1$, and then each nonempty processor services a task with probability $p(1+\epsilon)$ for $\epsilon > 0$. In the second model, each processor is allowed to change its load in each step, provided that the load is only increased or decreased by at most a fixed constant amount. With high probability, the algorithms balance the system load up to additive terms of $O(\log\log n)$ and $O((\log\log n)^2)$, respectively. In particular, in the first model, the maximum load of any processor can be upper bounded by one of these terms (depending on the algorithm), whereas in the second model, the maximum load of any processor can be upper bounded by the average load plus $O(\log\log n)$. The algorithms and analysis of [6, 7] are fundamentally different from the one considered here. In particular, their algorithms are sender-initiated, i.e., overloaded processors seek to distribute their load. Moreover, their algorithms are considerably more complicated than ours.

There is relatively little existing theoretical work on receiver-initiated approaches. The interesting thing is that this approach seems to be highly efficient in practice (much more than, say, "give-away-if-overloaded"), but there are no (or hardly any) rigorous theoretical results.

In [29], Mitzenmacher applies his differential-equations approach in order to analyze several randomized work-stealing algorithms in a dynamic setting. In contrast to our work, he assumes that every processor has a Poisson generating process with rate $\lambda < 1$. Hence, in contrast to our generation model, the load is generated in a more-or-less balanced fashion and the system is stable even without any work-stealing. Each task has an exponentially distributed service time with mean 1. He models a number of work-stealing algorithms with differential equations and compares the equations with each other in order to predict which strategies will be most successful. For each set of equations, he shows that the queue-lengths decrease more quickly than for a set of equations which models the process with no work-stealing.

In [9], Blumofe and Leiserson analyze a scheduling strategy for *strict multithreaded computations*. A multithreaded computation consists of a set of threads, each of which is a sequential ordering of unit-time tasks. During a computation, a thread can spawn other threads, which are stored in a local queue. They present a work-stealing algorithm in which every idle processor tries to steal a thread from a randomly chosen other processor. The analysis shows that the expected time to execute such a multithreaded computation on P processors is $O(T_1/P + T_\infty)$, where T_1 denotes the minimum sequential execution time of the multithreaded computation, and T_∞ denotes the minimum execution time with an infinite number of processors. Furthermore, they estimate the probability that the execution time is increased by an additional factor. In [15], Fatourou and Spirakis develop an algorithm for k-strict multithreaded computations. In this case, all data dependencies of a thread are directed to ancestors in at most k higher levels.

2. The work-stealing process. Suppose that we have n processors and n generators, which create work for the processors. Each processor keeps a queue of jobs which need to be done. The evolution of the system can be described by a Markov chain X. The state X_t after step t is a tuple $(X_t(1), \ldots, X_t(n))$ in which $X_t(i)$ rep-

resents the length of the ith processor's queue after step t. Initially, all of the queues are empty, so the start state is $(0, \ldots, 0)$.

Let $N = \{1, \ldots, n\}$. Let $\mathcal{P} = \{h \mid N \to N\}$ be the set of all generator-allocation functions. When generators are allocated according a particular function $h \in \mathcal{P}$, $h(i)$ is designated as the host of the ith generator. The Markov chain X has three parameters. $\mathcal{D}$ is an arbitrary distribution over $\mathcal{P}$. A new generator-allocation function is selected from $\mathcal{D}$ during each step of the chain. The parameter λ governs the rate at which jobs are generated—each generator creates a job during each step independently with probability λ and adds the job to the queue of its current host. Finally, the function f is the work-stealing function. In section 3, we will state the properties that f must satisfy for our analysis. Figure 1 describes the transition from state X_t to state X_{t+1}.

1. Choose the generator-allocation function h_t from $\mathcal{D}$.
2. Each generator generates a new job independently with probability λ. It adds the job to the queue of its current host. In particular, the ith processor updates the size of its queue from $X_t(i)$ to $X'_t(i)$, where $X'_t(i)$ is defined to be $X_t(i)$ plus the sum of $|h_t^{-1}(i)|$ independent Bernoulli random variables with mean λ.
3. Each processor with an empty queue chooses a request destination u.a.r. from N. Formally, $r_t(i)$ is defined to be 0 if $X'_t(i) > 0$. Otherwise, $r_t(i)$ is chosen u.a.r. from N.
4. Each processor which receives a request chooses a recipient and allocates some of its load to give away to the recipient. Formally, we start by setting $j_t^+(i) = j_t^-(i) = 0$ for all $i \in N$. Then every $k \in N$ for which $r_t^{-1}(k)$ is nonempty chooses ℓ u.a.r. from $r_t^{-1}(k)$ and sets $j_t^+(\ell) = j_t^-(k) = f(X'_t(k))$.
5. The work is shared and then each queue processes one job. Formally, for all i, $X_{t+1}(i)$ is set to $\max(0, X'_t(i) + j_t^+(i) - j_t^-(i) - 1)$.

FIG. 1. *The Markov chain X. The transition from X_t to X_{t+1}.*

3. Work-stealing functions. In this section, we state the properties that the work-stealing function, f, must satisfy for our analysis.

DEFINITION 1. *We assume that for a positive constant δ, the arrival rate λ is at most $1 - \delta$. Let c be a constant which is sufficiently large with respect to δ^{-1} (see the proof of Lemma 14) and let $\alpha = 4e(c+1)$. Let $z = \lceil \alpha \lg n \rceil$. Let $\nu = n^{-2} + n^{-\alpha}$ and let $T = \lceil \frac{2c}{1-\lambda/(1-\nu)} \lg n \rceil$. Note that T is positive as long as $\nu < \delta$, and we will consider values of n for which this is true. Let g be the function given by $g(\ell) = f(\ell - T)$. We will use the function g in our analysis of the work-stealing process. Suppose that a processor has ℓ units of work in its queue. If no units of work are generated or stolen during T steps, it will then have $\ell - T$ units. Finally, it may give away $f(\ell - T) = g(\ell)$ units to another processor which requests work. Let Φ_f be the smallest integer such that, for all $j \in \{0, \ldots, z\}$, $g^j(\Phi_f/n) \geq 2T$, where $g^j(y)$ denotes the j-fold application of function g to argument y. That is, $g^0(y) = 1$, $g^1(y) = g(y)$, $g^2(y) = g(g(y))$, and so on. If no such integer Φ_f exists, say $\Phi_f = \infty$. Informally, Φ_f is a quantity that is so large that if we start with Φ_f units of work and focus on the (at least Φ_f/n) units of work in some particular queue and allow this work to be stolen up to z times, the quantity of work remaining at every processor involved is at least $2T$. This idea will be made more precise later.*

We require the work-stealing function f to satisfy the following properties.

Property 1. $0 \le f(\ell) \le \ell/2$.

Property 2. $f(\ell)$ is monotonically nondecreasing in ℓ.

Property 3. Φ_f is finite.

Properties 1 and 2 are natural and easy to understand. We conclude this section by showing that many natural work-stealing functions which satisfy Properties 1 and 2 also satisfy Property 3. We start with a general lemma and then conclude with particular examples.

LEMMA 2. *Suppose that the work-stealing function f satisfies Properties* 1 *and* 2. *Let $h_0 = 2T$. Suppose that there are positive integers $h_1, \ldots, h_z$ satisfying $f(h_i - T) \ge h_{i-1}$. Then $\Phi_f \le nh_z$.*

Proof. We wish to show that for all $j \in \{0, \ldots, z\}$, $g^j(h_z) \ge 2T$. Since f satisfies Property 1, the condition $f(h_i - T) \ge h_{i-1}$ implies that $h_{i-1} \le h_i$. Therefore, for any $j \in \{0, \ldots, z\}$, $h_{z-j} \ge h_0 \ge 2T$. Thus, it suffices to prove $g^j(h_z) \ge h_{z-j}$, which we will do by induction on j with base case $j = 0$. For the inductive step, note that

$$g^{j+1}(h_z) = f(g^j(h_z) - T) \ge f(h_{z-j} - T) \ge h_{z-(j+1)},$$

where the first inequality uses the monotonicity of f (Property 2) and the inductive hypothesis. □

COROLLARY 3. *Suppose that the work-stealing function f satisfies Properties* 1 *and* 2. *Suppose that $f(\ell) = \omega(1)$ as a function of ℓ. Then f satisfies Property* 3.

Proof. Since $f(\ell) = \omega(1)$, the function gets arbitrarily big and the values $h_1, \ldots, h_z$ in Lemma 2 exist. □

Corollary 3 demonstrates that having $f(\ell) = \omega(1)$ is *sufficient* in the sense that this, together with Properties 1 and 2, implies Property 3. Having $f(\ell) = \omega(1)$ is not *necessary* though, as the following observation shows.

OBSERVATION 4. *Suppose that the work-stealing function f satisfies Properties* 1 *and* 2. *Let $h_0 = 2T$. Suppose (as in Lemma* 2*) that there are positive integers $h_1, \ldots, h_z$ satisfying $f(h_i - T) \ge h_{i-1}$. Let f' be the work-stealing function given by $f'(\ell) = \min(f(\ell), f(h_z))$. Then f' satisfies Properties* 1–3 *and has $\Phi_{f'} \le nh_z$.*

We end the section by giving an upper bound for Φ_f when f is a member of a popular class of work-stealing functions.

LEMMA 5. *Let $f(\ell) = \lfloor \ell/r \rfloor$ for some $r \ge 2$. This function satisfies Properties* 1–3 *and satisfies*

$$\Phi_f \le n(2T + 2r)(2r)^z.$$

Proof. We use Lemma 2. Let $h_i = (2T + 2r)(2r)^i$ for $i \in \{1, \ldots, z\}$. Then for $i \in \{1, \ldots, z\}$,

$$\begin{aligned} f(h_i - T) &= f((2T + 2r)(2r)^i - T) \\ &\ge \frac{(2T + 2r)(2r)^i}{r} - \frac{T}{r} - 1 \\ &= \frac{(2T + 2r)(2r)^i}{2r} + \frac{(2T + 2r)(2r)^i}{2r} - \frac{2T}{2r} - \frac{2r}{2r} \\ &\ge (2T + 2r)(2r)^{i-1} \\ &\ge h_{i-1}. \end{aligned}$$

□

Remark 6. The value Φ_f corresponding to the function f in Lemma 5 is bounded from above by a polynomial in n. To see this, note that the multiplier in the definition of T is

$$\frac{1}{1-\frac{\lambda}{1-\nu}} \le \frac{1}{1-\frac{1-\delta}{1-\nu}} = \frac{1-\nu}{\delta-\nu} \le \frac{1}{\delta-\nu} \le \frac{2}{\delta},$$

where the last inequality assumes $\nu \le \delta/2$, which is true if n is sufficiently large with respect to the constant δ^{-1}.

4. Upper bounds. In this section we prove that the system is stable for every work-stealing function satisfying Properties 1–3 in section 3. Our analysis does not depend upon the particular distribution $\mathcal{D}$ which governs the allocation of generators—the analysis works for an arbitrary distribution.

As already outlined in section 1, the basic idea is the following. The Markov chain X models our system. Since this chain is difficult to analyze directly, we introduce a second chain Z and investigate properties of Z instead. Then, using a coupling, we relate the results to chain X itself.

To put it *very* informally and nonrigorously, the core idea is to show that during an interval of length $T = O(\log n)$ not too many requests are sent. Since in our model not sending a request means servicing a task, we can show that in this case the system load decreases. Obviously, the crux is bounding the number of requests during the interval. Informally, this is done by assuming (for contradiction) that there are many requests during the interval, say at least R. Since the system load is initially high, there is at least one processor, processor P, which initially has a high load. This implies that after around $R' < R$ requests, we can view most of the requests that have been accepted in a tree with P at the root, and the leaves being processors that either directly or indirectly received a portion of P's initial load. By showing that (i) there are many leaves, and (ii) the tree does not grow very deep, we can conclude that after R' requests, there are many processors having a large load (at least T), and none of them will send a request during the next T steps. Hence, we can contradict the assumption that R requests get sent during the interval. Of course, this kind of proof-by-contradiction is invalid if we want to avoid conditioning the random variables during the T steps, so we have to do things more carefully.

4.1. Background. We start with some brief definitions regarding Markov chains. For more details, see [19]. The Markov chains that we consider are *time-homogeneous* (transition probabilities do not change over time) and *irreducible* (every state is reachable from every other) and *aperiodic* (the gcd of the lengths of valid paths from state i to itself is 1). An irreducible aperiodic Markov chain (Υ_t) is said to be *recurrent* if, with probability 1, it returns to its start state. That is, it is recurrent if

$$\Pr(\Upsilon_t = \Upsilon_0 \text{ for some } t \ge 1) = 1.$$

Otherwise, it is said to be *transient*. It is said to be *positive recurrent* or *ergodic* if the expected time that it takes to return to the start state is finite. In particular, let

$$T_{\text{ret}} = \min\{t \ge 1 \mid \Upsilon_t = \Upsilon_0\}.$$

The chain is said to be positive recurrent if $E[T_{\text{ret}}] < \infty$. A positive recurrent chain has a unique stationary distribution π. When we analyze the Markov chain X we will use the following generalization of Foster's theorem, due to Fayolle, Malyshev, and Menshikov (Theorem 2.2.4 of [16]).

LEMMA 7 (Foster; Fayolle, Malyshev, Menshikov [16]). *A time-homogeneous irreducible aperiodic Markov chain ζ with a countable state space Ω is positive recurrent if and only if there exists a positive function $\Phi(x)$, $x \in \Omega$, a number $\xi > 0$, a positive integer-valued function $\beta(x)$, $x \in \Omega$, and a finite set $C' \subseteq \Omega$ such that the following inequalities hold:*

$$E[\Phi(\zeta_{t+\beta(\zeta_t)}) - \Phi(\zeta_t) \mid \zeta_t = x] \le -\xi\beta(x), \qquad x \notin C', \tag{1}$$

$$E[\Phi(\zeta_{t+\beta(\zeta_t)}) \mid \zeta_t = x)] < \infty, \qquad x \in C'. \tag{2}$$

We also use the following Chernov–Hoeffding inequalities. The first of these is a special case of Theorem 4.2 of [31] and the second is taken from Theorem 5.7 of [24].

LEMMA 8 (Chernov). *Let $Z_1, \ldots, Z_s$ be independent Bernoulli trials with $\Pr(Z_i = 1) = p$. Let $\widehat{Z} = \sum_{i=1}^{s} Z_i$. Then for any ρ in $(0, 1]$, $\Pr(\widehat{Z} < (1-\rho)sp) \le \exp(-sp\rho^2/2))$.*

LEMMA 9 (Hoeffding). *Let $Z_1, \ldots, Z_s$ be independent random variables with $a_i \le Z_i \le b_i$ for suitable constants a_i, b_i and all $1 \le i \le s$. Also let $\widehat{Z} = \sum_{i=1}^{s} Z_i$. Then for any $t > 0$,*

$$\Pr\bigl(|\widehat{Z} - E(\widehat{Z})| \ge t\bigr) \le \exp\Bigl(-2t^2 \Big/ \sum_{i=1}^{s} (b_i - a_i)^2\Bigr).$$

4.2. Results. Our Markov chain X is time-homogeneous, irreducible, and aperiodic. Its state space is countable. Therefore, it satisfies the initial conditions of Lemma 7. We will prove the following theorem.

THEOREM 10. *Let δ be a positive constant and λ an arrival rate which is at most $1 - \delta$. Let f be a work-stealing function satisfying Properties 1–3 in section 3. Then for every n which is sufficiently large with respect to δ^{-1}, the Markov chain X is positive recurrent.*

Theorem 10 guarantees that the Markov chain X has a stationary distribution π. The next theorem is concerned with the value of the total system load in the stationary distribution. Recall from Definition 1 that $\nu = n^{-2} + n^{-\alpha}$. Our next theorem uses the following additional definitions.

DEFINITION 11. *Let ϵ be $(1 - \lambda/(1 - \nu))/4$. Let $\Phi(X_t)$ be the system load after step t. That is, $\Phi(X_t) = \sum_{i=1}^{n} X_t(i)$.*

THEOREM 12. *Let δ be a positive constant and λ an arrival rate which is at most $1 - \delta$. Let f be a work-stealing function satisfying Properties 1–3 in section 3. Then for every n which is sufficiently large with respect to δ^{-1},*

$$E_\pi[\Phi(X_t)] \le \Phi_f + 2nT/\epsilon + nT,$$

and for any nonnegative integer m,

$$\Pr_\pi[\Phi(X_t) > \Phi_f + 2nTm + nT] \;\le\; \exp(-\ln(1+\epsilon)(m+1)).$$

4.3. A simpler Markov chain. Let C be the set of states x with $\Phi(x) < \Phi_f$. In this section we define a simpler Markov chain Z that will be used in order to analyze the Markov chain X with a start state $x \notin C$.

The state space of Z is more complicated than the state space of X, but in some sense the information contained in a state of Z is less precise than the information contained in a state of X. In particular, a state Z_t consists of a tuple

$$(L_t(1), \ldots, L_t(n), Y_t(1), \ldots, Y_t(n)).$$

The variable $L_t(i)$ gives a crude indication of the load at processor i after step t. In any initial state that we will consider, *exactly one* processor (which we will call J_x) will have $L_0(J_x)$ large. All other processors will have $L_0(i) = 0$. Informally, these variables will have the following role for a processor i. Let t be the first time step during which processor i steals some of the work that originally sat at processor J_x. For $t' \leq t$, the variable $Y_{t'}(i)$ denotes the load of processor i and $L_{t'}(i) = 0$. For $t' > t$, the variable $L_{t'}(i)$ is positive and $Y_{t'}(i) = 0$. The exact value of $L_{t'}(i)$ gives an indication of how many times the work that processor i acquired at step t has been split (and, therefore, of how long it will last).

We will be observing the evolution of the Markov chain X starting at a state $X_0 = x$ with $\Phi(x) \geq \Phi_f$. This condition guarantees that for some $i \in N$, $X_0(i) \geq \Phi_f/n$. Let J_x be the smallest such i. In the following, we will be paying special attention to a load which originates at processor J_x. Thus, in the Markov chain Z, the state Z_0 which corresponds to X_0 is defined as follows. $L_0(J_x) = 2^z$ and $Y_0(J_x) = 0$. For all $i \neq J_x$, $L_0(i) = 0$ and $Y_0(i) = X_0(i)$. For convenience, we will say that a processor i is "heavily loaded" in state Z_t if and only if $L_t(i) > 0$. Thus, J_x is the only processor which is deemed to be "heavily loaded" in Z_0. Note that the state Z_0 is strictly a function of x. We will refer to this state as $Z(x)$. The transition from Z_t to Z_{t+1} is described in Figure 2. It may look surprising at first that the "heavy load" parameter $L_t(k)$ is halved every time a heavily loaded processor transfers load. This halving allows us to study the dissemination of load from J_x without considering the many dependent events.

Let R'_t be the set of requests made during the transition from Z_t to Z_{t+1}. (This transition is referred to as "step $t+1$.") That is, $R'_t = |\{i \mid r'_t(i) > 0\}|$. Let τ' be the smallest integer such that $R'_0 + \cdots + R'_{\tau'-1} \geq cn \lg n$. Let Ψ be the smallest integer such that, for some i, $L_\Psi(i) = 1$. Intuitively, $L_\Psi(i) = 1$ means that i has received load (directly or indirectly) from J_x (so it is "heavily loaded"), but this load has been

1. Choose the generator-allocation function h_t from $\mathcal{D}$.
2. If $L_t(i) > 0$, then $Y'_t(i)$ is defined to be 0 (just like $Y_t(i)$). Otherwise, $Y'_t(i)$ is defined to be $Y_t(i)$ plus the sum of $|h_t^{-1}(i)|$ Bernoulli random variables with mean λ.
3. $r'_t(i)$ is defined to be 0 *except* when $L_t(i) = 0$ and $Y'_t(i) = 0$. In this case, $r'_t(i)$ is chosen u.a.r. from N.
4. Start by setting
$$j_t^+(i) = j_t^-(i) = l_t^-(i) = l_t^+(i) = 0$$
for each $i \in N$. Then every $k \in N$ for which ${r'_t}^{-1}(k)$ is nonempty chooses ℓ u.a.r. from ${r'_t}^{-1}(k)$ and sets $l_t^+(\ell) = l_t^-(k) = L_t(k)/2$ and $j_t^+(\ell) = j_t^-(k) = f(Y'_t(k))$.
5. For all $i \in N$, $L_{t+1}(i)$ is set to $L_t(i) + l_t^+(i) - l_t^-(i)$. If $L_{t+1}(i) > 0$, then $Y_{t+1}(i) = 0$. Otherwise, $Y_{t+1}(i)$ is set to
$$\max(0, Y'_t(i) + j_t^+(i) - j_t^-(i) - 1).$$

FIG. 2. *The transition from Z_t to Z_{t+1}.*

split many times (it has been split z times, in fact). The following lemma shows that, with high probability, there are no such i and Ψ if at most $cn \log n$ requests are sent.

LEMMA 13. *Suppose $x \notin C$. Run Markov chain Z starting at $Z_0 = Z(x)$. Then*

$$\Pr(\Psi \leq \tau') \leq n^{-\alpha}.$$

Proof. Since at most n requests are sent in a single step, the total number of requests sent during steps $1, \ldots, \tau'$ is at most $(c+1)n \lg n$.

Recall the construction of $Z(x)$ from the beginning of section 4.3. In particular, there is one "heavily loaded" processor, J_x, with $L_0(J_x) = 2^z$. Every other processor i has $L_0(i) = 0$.

Imagine that the value $L_0(J_x) = 2^z$ corresponds to a collection of 2^z tokens which initially sit at processor J_x. The value $L_t(k)$ gives the number of tokens which sit at processor k following step t. This is always a power of 2. If $L_t(k) > 1$, then the instruction $l_t^+(\ell) = l_t^-(k) = L_t(k)/2$ in step 3 of the transition from Z_t to Z_{t+1} splits the collection of tokens sitting at processor k and transfers half of these tokens to processor ℓ. The event $\Psi \leq \tau'$ occurs if and only if some token has its group split z times during steps $1, \ldots, \tau'$.

What is the probability that a given token has its group split z times? This is at most

$$\binom{(c+1)n \lg n}{z} n^{-z} \leq \left(\frac{e(c+1) \lg n}{z} \right)^z.$$

The probability that there exists a token which has its group split z times is thus at most

$$\left(\frac{2e(c+1) \lg n}{z} \right)^z \leq \left(\frac{2e(c+1)}{\alpha} \right)^{\alpha \lg n} = n^{-\alpha}. \qquad \square$$

The next lemma shows that, with high probability, the number of requests sent during the observed T time steps is less than $cn \log n$. This means that we have very little idle time during this period, which in turn implies the decrease of the system load (as we will see later).

LEMMA 14. *Suppose $x \notin C$. Run Markov chain Z starting at $Z(x)$.*

$$\Pr(\tau' \leq T) \leq n^{-2}.$$

Proof. Recall that R'_t is the number of requests during the transition from Z_t to Z_{t+1}. In particular, $R'_t = |\{i \mid L_t(i) = 0 \wedge Y'_t(i) = 0\}|$. R'_t is a random variable which depends only upon the state Z_t and upon the host-distribution function h_t. In particular, every processor i with $L_t(i) = 0$ and $Y_t(i) = 0$ contributes 1 to R'_t independently with probability $(1-\lambda)^{|h_t^{-1}(i)|}$ and contributes 0 to R'_t otherwise.

To make the conditioning clear, we will let $R'(s,h)$ be the random variable whose distribution is the same as that of R'_t, conditioned on $Z_t = s$ and $h_t = h$.

By Lemma 9,

$$\Pr\left(|R'(s,h) - E(R'(s,h))| \geq \frac{cn \lg n}{8T} \right) \leq \exp\left(-2 \left(\frac{cn \lg n}{8T} \right)^2 / n \right).$$

Let σ denote $\exp(-2(\frac{cn \lg n}{8T})^2/n)$. Note that σ is exponentially small in n. (This follows from the definition of T.)

Say that (s, h) is "dangerous" if

$$E(R'(s,h)) \geq (cn \lg n)/(4T).$$

Note that if (Z_t, h_t) is not dangerous, then, with probability at least $1-\sigma$, the number of requests during the transition from Z_t to Z_{t+1} is at most

$$(cn \lg n)/(4T) + (cn \lg n)/(8T) \leq (cn \lg n)/(2T).$$

Now suppose that (s, h) is dangerous and let k be any processor. Then

$$\begin{aligned}\Pr({r'_t}^{-1}(k) = \emptyset \mid Z_t = s \wedge h_t = h) &\leq \sigma + \left(1 - \frac{1}{n}\right)^{\frac{cn \lg n}{8T}} \\ &\leq \sigma + \left(1 - \frac{1}{n}\right)^{\frac{\delta n}{18}} \\ &\leq 1 - \gamma\end{aligned}$$

for a small positive constant γ which depends upon δ (but not upon c or n). Let M_t denote the number of heavily loaded processors during step t, i.e.,

$$M_t = |\{i \mid L_t(i) > 0\}|.$$

Let ξ_t denote the number of heavily loaded processors during step t that don't get requested, i.e.,

$$\xi_t = |\{k \mid L_t(k) > 0 \wedge {r'_t}^{-1}(k) = \emptyset\}|.$$

If (s, h) is dangerous, then

$$E[\xi_t \mid Z_t = s \wedge h_t = h] \leq (1-\gamma)M_t.$$

Thus by Markov's inequality,

$$\Pr\big(\xi_t \geq (1-\gamma/2)M_t \mid Z_t = s \wedge h_t = h\big) \leq 1 - \frac{\gamma}{2-\gamma}.$$

If $\xi_t < (1-\gamma/2)M_t$, then at least $(\gamma/2)M_t$ of the M_t heavily loaded processors give away work, so $M_{t+1} \geq (1+\gamma/2)M_t$. We say that the step following on from a dangerous state is "useful" if this occurs. We have just seen that for every dangerous state (s, h), the probability that the next step is useful is at least $\frac{\gamma}{2-\gamma}$.

Thus, if we have D dangerous states during some time interval, the number of useful steps following them dominates (from above) the sum of D independent Bernoulli random variables with probability $p = \frac{\gamma}{2-\gamma}$. Applying Lemma 8 with $D = (2/p)\log_{1+\gamma/2}(n)$ and $\rho = 1/2$, we find that the probability that this sum is less than $\log_{1+\gamma/2}(n)$ is at most $\exp(-\log_{1+\gamma/2}(n)/4)$. This means that if we have D dangerous states, then the probability that there are at least $\log_{1+\gamma/2}(n)$ useful steps following them is at least $1 - \exp(-\log_{1+\gamma/2}(n)/4)$.

Now, if there are actually at least $\log_{1+\gamma/2}(n)$ useful steps during steps 1–t, $M_{t+1} = n$, so there can be no further dangerous states. We conclude that with probability at least $1 - \exp(-\log_{1+\gamma/2}(n)/4)$ there are at most D dangerous steps *ever*.

If we make c sufficiently large with respect to γ, then $D < c \lg n/2$.

Now we have that, except for probability $\exp(-\log_{1+\gamma/2}(n)/4)$, the dangerous steps contribute fewer than $cn \lg n/2$ requests (ever). Furthermore, except for probability at most σT, the nondangerous steps contribute at most $cn \lg n/2$ requests during the first T steps. Thus, the probability that $\tau' \leq T$ is at most

$$\exp(-\log_{1+\gamma/2}(n)/4) + \sigma T \leq n^{-2}. \qquad \square$$

Lemmas 13 and 14 imply the following.

COROLLARY 15. *Suppose $x \notin C$. Run Markov chain Z starting at $Z(x)$.*

$$\Pr(T < \tau' < \Psi) \geq 1 - n^{-\alpha} - n^{-2}.$$

LEMMA 16. *Suppose $x \notin C$. Run Markov chain Z starting at $Z(x)$. For any $t \leq \Psi$ and any $i \in N$, either $L_t(i) = 0$ or, for some $j \in \{0, \ldots, z\}$, $L_t(i) = 2^j$.*

Proof. The lemma is proved by induction on t with the base case $t = 0$. Consider the assignment

$$L_{t+1}(i) = (L_t(i) - l_t^-(i)) + l_t^+(i)$$

in the transition from Z_t to Z_{t+1} in Figure 1. If the second term in the expression, $l_t^+(i)$, is greater than zero, then it is equal to $L_t(k)/2$ for some k with $r'_t(i) = k$, so $L_t(i) = 0$. The first term in the expression, $L_t(i) - l_t^-(i)$, is either $L_t(i)$ or $L_t(i)/2$. Thus, either $L_{t+1}(i)$ is $L_t(i)$ or it is $L_t(k)/2$ for some k. Using the terminology from the proof of Lemma 13, $L_{t+1}(i) = 2^{z-m}$ means that the tokens that sit at processor i after step $t+1$ have had their group split m times. Since $t \leq \Psi$, $m \leq z$. $\square$

4.4. Proof of Theorem 10. Our first task is to relate the Markov chain X to the simpler Markov chain Z. Recall the definitions of τ', R'_t, and Ψ from section 4.3. Let R_t be the set of requests made during the transition from X_t to X_{t+1}. That is, $R_t = |\{i \mid r_t(i) > 0\}|$. Let τ be the smallest integer such that $R_0 + \cdots + R_{\tau-1} \geq cn \lg n$.

LEMMA 17. *If $x \notin C$, then*

$$\Pr(\tau \leq T \mid X_0 = x) \leq \nu.$$

Proof. A (Markovian) coupling[1] of the Markov chains X and Z is a stochastic process (X_t, Z_t) such that (X_t), considered marginally, is a faithful copy of X, and (Z_t), considered marginally, is a faithful copy of Z. We will describe a coupling starting from state $(x, Z(x))$. That is, in our coupling, $X_0 = x$ and $Z_0 = Z(x)$. The coupling will have the property that for all $t \leq \min(T, \tau', \Psi)$ and all i,

$$r'_t(i) = r_t(i). \tag{3}$$

From (3), we can conclude that whenever the Z chain satisfies $T < \tau' < \Psi$, the coupled X chain satisfies $T < \tau$. Thus,

$$\Pr(T < \tau \mid X_0 = x) \geq \Pr(T < \tau' < \Psi \mid Z_0 = Z(x)),$$

so the lemma follows from Corollary 15.

To give the details of the coupling, we will use the notation in Figures 1 and 2. Recall from Definition 1 that g is the function given by $g(y) = f(y - T)$, where f is

[1] The word "coupling" is normally used in reference to combining two copies of the same Markov chain, so we are using the word in a slightly nonstandard way.

the work-stealing function which is guaranteed to satisfy $g^j(\Phi_f/n) \geq 2T$ for a finite Φ_f and for all $j \in \{0, \ldots, z\}$.

Our coupling will satisfy the following invariants for any $i \in N$ and any $t \leq \min(T, \tau', \Psi)$:

(1) $r'_t(i) = r_t(i)$,
(2) $L_t(i) = 0$ implies $X_t(i) = Y_t(i)$, and
(3) $L_t(i) = 2^j$ implies $X_t(i) \geq g^{z-j}(\Phi_f/n) - t$.

As we observed above, our objective is to describe a coupling that satisfies invariant (1). The other invariants will help us to show that our constructed coupling is indeed a coupling in the sense that the marginal distributions are correct. The purpose of the third invariant is to ensure that, in the chain X, a node will not become empty soon if the corresponding node in chain Z is heavily loaded.

The coupling is as follows. We start with $X_0 = x$ and $Z_0 = Z(x)$. Recall the construction of $Z(x)$ from section 4.3. In particular, $L_0(J_x) = 2^z$ and $Y_0(J_x) = 0$. For every other i, $L_0(i) = 0$ and $Y_0(i) = x(i)$. Invariants (2) and (3) are satisfied for $t = 0$ since $X_0(J_x) \geq \Phi_f/n$.

Now the transition from (X_t, Z_t) to (X_{t+1}, Z_{t+1}) is given as follows. In part 1 of the transition, the same generator-allocation function h_t is chosen for both chains. The $X'_t(i)$ variables are defined in part 2 of the transition from X_t to X_{t+1}. In part 2 of the coupled transition from Z_t to Z_{t+1}, we set $Y'_t(i) = 0$ if $L_t(i) > 0$. Otherwise, we set $Y'_t(i) = X'_t(i)$. Note that, since invariant (2) held after step t, the $Y'_t(i)$ variables are set according to the correct marginal distribution. The $r_t(i)$ variables are defined in part 3 of the transition from X_t to X_{t+1}. In part 3 of the coupled transition from Z_t to Z_{t+1}, we set $r'_t(i) = r_t(i)$. To show that the marginal distribution is correct, we observe that if $L_t(i) = 0$, then we defined $Y'_t(i)$ to be $X'_t(i)$. Thus, the $r'_t(i)$ variables are assigned correctly. On the other hand, if $L_t(i) > 0$, then, by Lemma 16, $L_t(i) = 2^j$ for some $j \in \{0, \ldots, z\}$ so by invariant (3), $X_t(i) \geq g^{z-j}(\Phi_f/n) - t \geq 2T - t > 0$. Thus, $X'_t(i) > 0$, and $r'_t(i)$ is defined correctly. In part 4 of the transition from X_t to X_{t+1}, we do the following. For every $k \in N$ for which $r_t^{-1}(k)$ is nonempty, we choose ℓ u.a.r. from $r_t^{-1}(k)$. Since ${r'_t}^{-1}(k) = {r_t}^{-1}(k)$, we can make the same choice for k in part 4 of the transition from Z_t to Z_{t+1}.

We need to prove that the coupling maintains invariants (1), (2), and (3). Invariant (1) (the one that we actually want) is by construction. Invariant (2) is not too difficult. Lemma 16 shows that all of the variables $L_t(i)$ are nonnegative. Furthermore, the analysis in the proof of Lemma 16 reveals that $L_{t+1}(i) = 0$ implies $L_t(i) = 0$. (To see this, recall that $L_{t+1}(i) = (L_t(i) - l_t^-(i)) + l_t^+(i)$. The second of these terms is nonnegative, and the first is either $L_t(i)$ or $L_t(i)/2$.) Thus, whenever we have $L_{t+1}(i) = 0$ we have $Y_t(i) = X_t(i)$, and in the coupling we get $Y'_t(i) = X'_t(i)$. In part 5 of the transition from X_t to X_{t+1} we set $X_{t+1}(i) = \max(0, X'_t(i) + j_t^+(i) - j_t^-(i) - 1)$, and in part 5 of the transition from Z_t to Z_{t+1}, we set $Y_{t+1}(i) = \max(0, Y'_t(i) + j_t^+(i) - j_t^-(i) - 1)$. Thus we need only argue that the $j_t^+(i)$ and $j_t^-(i)$ variables get the same values in both copies. The $j_t^-(i)$ variable is the same since $Y'_t(i) = X'_t(i)$. The $j_t^+(i)$ variables are positive only if processor i made a request, namely, $r_t(i) = r'_t(i) = k$, for some k. Since $L_{t+1}(i) = 0$, we know $L_t(k) = 0$. Hence, $Y'_t(k) = X'_t(k)$, and the $j_t^+(i)$ values are indeed the same.

Finally, we need to prove that the coupling maintains invariant (3). Suppose that $L_{t+1}(i) = 2^j$. We wish to show that $X_{t+1}(i) \geq g^{z-j}(\Phi_f/n) - (t+1)$. First, suppose

$L_t(i) = 0$. In this case, $L_{t+1}(i) = L_t(k)/2$, where $r_t(i) = k$. Then

$$\begin{aligned} X_{t+1}(i) &\geq f(X_t(k)) - 1 \\ &\geq f(g^{z-j-1}(\Phi_f/n) - t) - 1 \\ &\geq f(g^{z-j-1}(\Phi_f/n) - T) - 1 \\ &= g^{z-j}(\Phi_f/n) - 1 \\ &\geq g^{z-j}(\Phi_f/n) - (t+1), \end{aligned}$$

where the first inequality follows from the transition in Figure 1 and the second inequality follows from the facts that invariant (3) held after step t and that f is monotonically nondecreasing (Property 2 in section 3). The third inequality also follows from the fact that f is monotonically nondecreasing.

Second, suppose $L_t(i) = 2^j$. In this case $r_t^{-1}(i)$ is empty, so

$$X_{t+1}(i) \geq X_t(i) - 1 \geq g^{z-j}(\Phi_f/n) - t - 1.$$

Finally, suppose $L_t(i) = 2^{j+1}$. (To see that these are the only cases, namely, that $L_t(i) \in \{0, 2^j, 2^{j+1}\}$, see the proof of Lemma 16.) In this case r_t^{-1} is nonempty, so

$$X_{t+1}(i) \geq X_t(i) - f(X_t(i)) - 1.$$

Since f satisfies $f(\ell) \leq \ell/2$ (Property 1 in section 3), we have

$$X_{t+1}(i) \geq f(X_t(i)) - 1,$$

which is the same as the first case. □

The next lemma shows that the load has an appropriate drift when $\tau > T$.

LEMMA 18. *If $x \notin C$, then*

$$E[\Phi(X_T) \mid (X_0 = x) \wedge (\tau > T)] \leq \Phi(x) - 2\epsilon nT.$$

Proof. Let A_t be the number of new jobs that arrive in the system during the transition from X_t to X_{t+1}. Namely,

$$A_t = \sum_{i \in N} (X'_t(i) - X_t(i)).$$

Let $Y = A_0 + \cdots + A_{T-1}$. Splitting $E[Y \mid X_0 = x]$ into two conditional expectations, conditioned on whether or not $\tau > T$, we find

$$\begin{aligned} &E[Y \mid (X_0 = x) \wedge (\tau > T)] \\ &= \frac{E[Y \mid X_0 = x] - \Pr(\tau \leq T \mid X_0 = x) E[Y \mid (X_0 = x) \wedge (\tau \leq T)]}{\Pr(\tau > T \mid X_0 = x)}. \end{aligned}$$

By Lemma 17, the denominator is at least $1 - \nu$. The numerator is at most $E[Y \mid X_0 = x]$, which is λnT, since during each of the T steps each of the n generators generates a new job independently with probability λ. Thus,

$$E[Y \mid (X_0 = x) \wedge (\tau > T)] \leq \frac{\lambda nT}{1 - \nu}.$$

If $\tau > T$, then the number of jobs serviced during steps 1–T is at least $nT - cn \lg n$. (If a processor does not make a request, then it certainly services a job.) Thus, the quantity

$$E[\Phi(X_T) \mid (X_0 = x) \wedge (\tau > T)]$$

is at most the initial load, $\Phi(x)$, plus the expected number of arrivals, which we have seen above is at most $\frac{\lambda nT}{1-\nu}$, minus the expected number of services, which is at least $nT - cn \lg n$. Putting all of this together, we get

$$\begin{aligned} E[\Phi(X_T) \mid (X_0 = x) \wedge (\tau > T)] &\leq \Phi(x) - \left(1 - \frac{\lambda}{1-\nu}\right) nT + cn \lg n \\ &\leq \Phi(x) - \frac{1 - \frac{\lambda}{1-\nu}}{2} nT \\ &= \Phi(x) - 2\epsilon nT, \end{aligned}$$

where the second inequality uses the definition of T in Definition 1 and the equality uses the definition of ϵ in Definition 11. ∎

LEMMA 19. *Suppose that n is sufficiently large with respect to δ^{-1}. If $x \notin C$, then*

$$E[\Phi(X_T) \mid X_0 = x] \leq \Phi(x) - \epsilon nT.$$

Proof.

$$\begin{aligned} E[\Phi(X_T) \mid X_0 = x] = &\Pr(\tau > T \mid X_0 = x) E[\Phi(X_T) \mid (X_0 = x) \wedge \tau > T] \\ &+ \Pr(\tau \leq T \mid X_0 = x) E[\Phi(X_T) \mid (X_0 = x) \wedge \tau \leq T]. \end{aligned}$$

By Lemma 18, this is at most

$$\Pr(\tau > T \mid X_0 = x)(\Phi(x) - 2\epsilon nT) + \Pr(\tau \leq T \mid X_0 = x) E[\Phi(X_T) \mid (X_0 = x) \wedge \tau \leq T].$$

Since at most n messages arrive per step, this is at most

$$\Pr(\tau > T \mid X_0 = x)(\Phi(x) - 2\epsilon nT) + \Pr(\tau \leq T \mid X_0 = x)(\Phi(x) + nT).$$

This can be rearranged as

$$\begin{aligned} &\Phi(x) - (1 - \Pr(\tau \leq T \mid X_0 = x))(2\epsilon nT) + \Pr(\tau \leq T \mid X_0 = x)(nT) \\ = \ &\Phi(x) - 2\epsilon nT + \Pr(\tau \leq T \mid X_0 = x)(2\epsilon nT + nT). \end{aligned}$$

By Lemma 17, this is at most

$$\Phi(x) - 2\epsilon nT + \nu(2\epsilon nT + nT) = \Phi(x) - \epsilon nT - (\epsilon nT - \nu 2\epsilon nT - \nu nT).$$

The lemma follows from the fact that

$$\nu \leq \frac{\epsilon}{2\epsilon + 1}, \tag{4}$$

which is true, provided that n is sufficiently large with respect to δ^{-1}. To establish (4), refer to Definitions 1 and 11. If n is sufficiently large, then $\nu \leq \delta/2$, so

$$4\epsilon = 1 - \frac{\lambda}{1-\nu} \geq 1 - \frac{1-\delta}{1-\nu} = \frac{\delta - \nu}{1-\nu} \geq \frac{\delta}{2}.$$

Also,

$$\nu \leq \frac{\delta/8}{2(\delta/8) + 1} \leq \frac{\epsilon}{2\epsilon + 1}. \qquad ∎$$

Combining Lemmas 19 and 7, we get a proof of Theorem 10.

4.5. Proof of Theorem 12. The proof of Theorem 12 uses the following theorem, which is Theorem 1 of [8].

LEMMA 20 (Bertsimas, Gamarnik, and Tsitsiklis [8]). *Consider a time-homogeneous Markov chain ζ with a countable state space Ω and stationary distribution π'. If there is a positive function $\Phi(x)$, $x \in \Omega$, a number $\xi > 0$, and a number $\beta \geq 0$ such that*

$$E[\Phi(\zeta_{t+1}) - \Phi(\zeta_t) \mid \zeta_t = x] \leq -\xi, \qquad \Phi(x) > \beta, \tag{5}$$

and

$$|\Phi(\zeta_{t+1}) - \Phi(\zeta_t)| \leq \nu_{\max}, \tag{6}$$

and, for any x,

$$\Pr[\Phi(\zeta_{t+1}) > \Phi(\zeta_t) \mid \zeta_t = x] \leq p_{\max} \tag{7}$$

and

$$E_{\pi'}[\Phi(\zeta_t)] < \infty, \tag{8}$$

then for any nonnegative integer m,

$$\Pr_{\pi'}[\Phi(\zeta_t) > \beta + 2\nu_{\max} m] \leq \left(\frac{p_{\max}\nu_{\max}}{p_{\max}\nu_{\max} + \xi}\right)^{m+1}$$

and

$$E_{\pi'}[\Phi(\zeta_t)] \leq \beta + \frac{2p_{\max}(\nu_{\max})^2}{\xi}.$$

Let $W_i = \Phi(X_{iT})$ for $i \in \{0, 1, 2, \dots\}$. Lemma 19 shows that the process $W_0, W_1, \dots$ behaves like a supermartingale above Φ_f. That is, it satisfies (5) with $\xi = \epsilon nT$ and $\beta = \Phi_f$. In itself, this does not imply that $E[W_t]$ is bounded (see Pemantle and Rosenthal's paper [32] for counterexamples). However, we also have

$$|W_{t+1} - W_t| \leq nT \tag{9}$$

for any t. That is, (6) is satisfied with $\nu_{\max} = nT$. This implies (for example, by Theorem 1 of [32] or by Theorem 2.3 of [20]) that $E_\pi[W_t]$ is finite (so (8) is satisfied). Lemma 20 can now be applied with $p_{\max} = 1$ to get

$$E_\pi[W_t] \leq \Phi_f + 2nT/\epsilon, \tag{10}$$

and for any nonnegative integer m,

$$\Pr_\pi[W_t > \Phi_f + 2nTm] \leq \left(\frac{nT}{nT + \epsilon nT}\right)^{(m+1)}. \tag{11}$$

The theorem now follows from the observation that for $0 \leq j < T$,

$$\Phi(X_{iT+j}) \leq \Phi(X_{iT}) + nj.$$

5. Lower bounds. In this section we give the straightforward lower bound, which shows that the system is not stable for unsuitable work-stealing functions. Of course we have to put some restrictions on $\mathcal{D}$ in order to obtain instability. For example, if $\mathcal{D}$ is the point distribution containing a single function h which allocates one generator to each processor, then the system will be stable even without any work-stealing.

The proof of our lower bound uses the following lemma, which is Theorem 2.2.7 of [16].

LEMMA 21 (Fayolle, Malyshev, and Menshikov [16]). *An irreducible aperiodic time-homogeneous Markov chain ζ with countable state space Ω is transient if there is a positive function Φ with domain Ω and there are positive constants C, d, and ξ such that*

1. *there is a state x with $\Phi(x) > C$, and a state x with $\Phi(x) \le C$,*
2. *$E[\Phi(\zeta_1) - \Phi(\zeta_0) \mid \zeta_0 = x] \ge \xi$ for all x with $\Phi(x) > C$, and*
3. *if $|\Phi(x) - \Phi(y)| > d$, then the probability of moving from x to y in a single move is 0.*

If we use $k = 1$ in the statement of the following theorem, we find that the system is unstable if $f(\ell) < \lambda n - 1$.

THEOREM 22. *Let δ be a positive constant and λ an arrival rate which is at most $1 - \delta$. Suppose that $\mathcal{D}$ contains a single generator-allocation function h which distributes the n generators equally among some set of k processors. Suppose that for all ℓ, $f(\ell) \le j(n)$. Then the Markov chain X is transient if*

$$k \cdot (j(n) + 1) < \lambda n.$$

Proof. This theorem can be proven easily using Lemma 21. Recall that the start state X_0 is $(0, \ldots, 0)$ (all queues are initially empty). First, we bound the amount of work that can be done during any given step. When a processor steals work, it only gets enough work for at most $j(n)$ rounds. Since each processor gives work to only one other processor per round, and there are at most k processors with generators, at most $j(n)k$ processors without generators have work to do during any given step. Thus, at most $(j(n) + 1)k$ tasks can be done during any step. The expected load increase of the system during a step is λn. Using Lemma 21 with Φ as the system load, it is easy to see that the system is transient if $k(j(n) + 1) < \lambda n$. □

6. Conclusions. We have analyzed a very simple work-stealing algorithm, which is successfully being used in practical applications. In this paper we have analyzed its performance for a wide range of parameters. We have shown that it is stable for any constant generation rate $\lambda < 1$ and a wide class of work-stealing functions f. On the other hand, we have shown that for every $\lambda > 0$ there is a class of unsuitable work-stealing functions, for which it is not stable. Finally, we have derived upper bounds on the system load when the system is stable.

It would be interesting to know whether there is a nice characterization of the class of functions that lead to stability. It would also be interesting to know how far our upper bounds on system load are from the truth. We suspect that the system load is actually much smaller than our upper bounds indicate, but it would be useful to have rigorous experimental results.

Acknowledgments. We thank Hesham Al-Ammal for useful discussions. We also thank the referees, both of whom provided many helpful comments.

THE ALGEBRAIC APPROACH TO THE DISCRETE COSINE AND SINE TRANSFORMS AND THEIR FAST ALGORITHMS*

MARKUS PÜSCHEL† AND JOSÉ M. F. MOURA†

Abstract. It is known that the discrete Fourier transform (DFT) used in digital signal processing can be characterized in the framework of the representation theory of algebras, namely, as the decomposition matrix for the regular module $\mathbb{C}[Z_n] = \mathbb{C}[x]/(x^n - 1)$. This characterization provides deep insight into the DFT and can be used to derive and understand the structure of its fast algorithms. In this paper we present an algebraic characterization of the important class of discrete cosine and sine transforms as decomposition matrices of certain regular modules associated with four series of Chebyshev polynomials. Then we derive most of their known algorithms by pure algebraic means. We identify the mathematical principle behind each algorithm and give insight into its structure. Our results show that the connection between algebra and digital signal processing is stronger than previously understood.

1. Introduction.

Many algorithms in digital signal processing are based on the use of linear discrete signal transforms. Mathematically, such a transform is a matrix-vector multiplication $a \mapsto M \cdot a$, where $a \in \mathbb{F}^n$ is the sampled signal, and $M \in \mathbb{F}^{n \times n}$ is the transform over some base field $\mathbb{F}$. We will consider only $\mathbb{F} = \mathbb{C}$. Crucial for the applicability of a signal transform M is the existence of fast algorithms that allow its computation within $O(n \log n)$ operations (or better), compared with $O(n^2)$ arising from a direct matrix-vector multiplication. The problem of finding these algorithms for different transforms has been a major research topic leading to a vast number of publications in signal processing and mathematics.

In this paper we present an algebraic approach to the class of the 16 trigonometric transforms in the framework of algebra representation theory. Then we use algebraic methods to derive most of their known fast algorithms. Our results give insight into the structure and the existence of these algorithms and extend the relationship between signal processing and algebra that is currently restricted mainly to the discrete Fourier transform (DFT).

1.1. Transforms and algorithms.

Probably the most famous example of a signal transform is the DFT, which is used in harmonic analysis to decompose a signal into its frequency components. Important algorithms for the DFT include the "fast Fourier transform" (FFT) found by Cooley and Tukey [11] (originally due to Gauß; see [23]), Rader's algorithm for prime size [39], Winograd's algorithms [54], and several others. An overview on DFT algorithms can be found, for example, in [49].

Another important class of transforms consists of the eight different types of dis-

†Department of Electrical and Computer Engineering, Carnegie Mellon University, Forbes Ave. 5000, Pittsburgh, PA 15213 (pueschel@ece.cmu.edu, moura@ece.cmu.edu).

crete cosine and sine transforms (DCTs and DSTs, respectively), also called discrete trigonometric transforms (DTTs). Their applications include image and video compression [40]. Important algorithms for the trigonometric transforms were developed by Chen, Smith, and Fralick [7], Wang [52], Yip and Rao [56, 57], Vetterli and Nussbaumer [50], Lee [28], Feig [20], Chan and Ho [6], Steidl and Tasche [46], and Feig and Winograd [21].

Each of these algorithms has been derived through insightful manipulation of the transform matrix entries. The algorithms are highly structured, a property that can be used to write them as sparse factorizations of the transform matrix in a very concise way using mathematical operators. As examples, the Cooley–Tukey FFT can be written as

$$\mathrm{DFT}_{mn} = (\mathrm{DFT}_m \otimes \mathrm{I}_m) \cdot D \cdot (\mathrm{I}_m \otimes \mathrm{DFT}_n) \cdot P, \tag{1.1}$$

and an example of an algorithm for the DCT-2 is

$$\text{DCT-2}_{2n} = Q \cdot (\text{DCT-2}_n \oplus \text{DCT-4}_n) \cdot B. \tag{1.2}$$

The notation will be explained in section 2; the matrices D, P, Q, B are all sparse. Both algorithms are of a recursive nature.

1.2. The algebraic characterization of the DFT. It is well known that a DFT (of size n) can be introduced in strict algebraic terms as the decomposition matrix for the group algebra $\mathbb{C}[Z_n]$ of a cyclic group Z_n with n elements,

$$\mathrm{DFT}_n : \ \mathbb{C}[Z_n] \to \mathbb{C} \oplus \cdots \oplus \mathbb{C}, \tag{1.3}$$

or, equivalently, as the decomposition matrix for the algebra $\mathbb{C}[x]/(x^n - 1)$,

$$\mathrm{DFT}_n : \ \mathbb{C}[x]/(x^n - 1) \to \mathbb{C}[x]/(x - \omega_n^0) \oplus \cdots \oplus \mathbb{C}[x]/(x - \omega_n^{n-1}), \tag{1.4}$$

with respect to appropriate bases in each case. These decompositions are instantiations of the Wedderburn theorem for the semisimple algebra $\mathbb{C}[Z_n] \cong \mathbb{C}[x]/(x^n - 1)$. Equations (1.3) and (1.4) show that the DFT is indeed an algebraic object and thus provides a deep understanding of its use in signal processing. Furthermore, (1.3) and (1.4) can be used to easily derive and explain the structure of fast DFT algorithms by algebraic constructions rather than by manipulation of the DFT entries. As an example, (1.1) arises from a stepwise decomposition of $\mathbb{C}[Z_n]$, as has been shown by Auslander, Feig, and Winograd [2] and Beth [3].

Given the algebraic characterization of the DFT, we naturally obtain the following question: Is it possible to generalize (1.3) or (1.4) to capture a larger class of signal transforms in an algebraic framework? And, in the affirmative case: How do we use the algebraic characterization to derive and explain their fast algorithms?

1.3. Beyond the DFT. Depending on the interpretation of the DFT in (1.3) and (1.4), there have been two threads of generalization.

First, (1.3) has been generalized to arbitrary finite groups $G \neq Z_n$, leading to the area of "Fourier analysis on groups" that provides a rich class of transforms and the theory to derive their fast algorithms. Examples of important results in this field include the work of Beth [4], Clausen [9], Diaconis and Rockmore [13], and Rockmore [43]; a nice overview on this area can be found in [10] and in the survey articles [29] and [44]. However, with few exceptions, the Fourier transforms on groups do

not correspond to the transforms actually used in signal processing. This problem initiated a further generalization by Minkwitz [32, 31] to include $\mathbb{C}[G]$-modules that afford an arbitrary permutation representation. A matrix that decomposes such a module was said to have "symmetry." Minkwitz discovered that the DCT (type 3) possesses such a symmetry and derived, by pure algebraic means, a fast algorithm. That approach was further generalized by Egner and Püschel to include monomial representations: A decomposition theory [37, 36] and tools to analyze a matrix for symmetry and automatically derive a factorization [19, 15, 17] were developed. In [16] these tools were successfully applied to several signal transforms. Among the DTTs, the DCT and DST of type 3 and 4 exhibited symmetry and could be decomposed by these techniques.

Second, the generalization of (1.4) to arbitrary polynomials $p(x) \neq x^n - 1$ and arbitrary bases of $\mathbb{C}[x]/p(x)$ leads to the class of "polynomial transforms." If p is arbitrary and $(1, x, \ldots, x^{n-1})$ is chosen as a basis, one obtains a Vandermonde matrix, which is known to have a sparse factorization (see e.g., [5]). Driscoll, Healy, and Rockmore [14] developed a fast algorithm for the case of arbitrary (separable) polynomials p and bases consisting of orthogonal polynomial sequences. Independently, Potts, Steidl, and Tasche provided a numerically stable version of this algorithm [35]. In their paper the DCT of type 1 is recognized as a polynomial transform. Steidl and Tasche [46] also recognized the DCT of type 3 as a polynomial transform and used this property to derive a fast algorithm. In a different context, the DCTs and DSTs of types 1–4 have been related to polynomial transforms, in some cases after appropriate normalization [26].

Taken together, we encounter the following situation with respect to the DTTs:

1. There are 16 types of DTTs and a large number of publications on their fast algorithms.
2. In signal processing the DTTs are characterized as eigenmatrices of certain linear time-invariant processes with given boundary conditions [33, 47].
3. Four DTTs have been shown to exhibit group symmetries, and, in each case, an algorithm has been derived by algebraic means.
4. Two DTTs have been shown to be polynomial transforms. (Note that this property is not equivalent to point 3.) In one case this has been used to derive a fast algorithm. Further, six DTTs have been recognized as polynomial transforms after suitable normalization.

This sets the framework for the results presented in this paper.

1.4. The algebraic characterization of the DTTs. In this paper we present the algebraic characterization of the DTTs. This shows that, like the DFT, the DTTs are algebraic objects. Then we use the algebraic framework to derive, and explain, most of the fast DTT algorithms known in the literature. The results extend our previous preliminary work [38].

In particular we present the following:

1. A complete algebraic characterization of all 16 DTTs as scaled polynomial transforms (a generalization of polynomial transforms to be defined) arising from polynomial algebras $A = \mathbb{C}[x]/p(x)$ and A-modules of the form $f \cdot A$, where f is a scaling function. The construction of these modules follows the defining signal processing properties of the DTTs as eigenmatrices of certain linear time-invariant processes with given boundary conditions. Thus, our construction relates the domain of signal processing to the domain of algebra representation theory. As polynomials, four series of Chebyshev polynomials will naturally come into play.

2. A comprehensive overview of existing fast algorithms and their derivation by pure algebraic means, i.e., by manipulating modules and algebras rather than matrix entries. The algorithms are divided into classes depending on the mathematical principle that accounts for their existence. Examples, based on a direct manipulation of the A-module M and polynomial $p(x)$ associated with a DTT, include: (a) translation of a DTT into another DTT by a sparse base change in M; (b) recursive decomposition based on a factorization of p; and (c) recursive decomposition based on a decomposition of p. We continue our investigation by deriving a striking property of the DTTs. The characterization of the DTTs as scaled polynomial transforms, i.e., in a framework of polynomial algebras and their representations, leads naturally to group symmetry properties, i.e., properties in the framework of groups and their representations. We will identify two ways in which group symmetries come into play (a) by extending the A-module M to a suitable $\mathbb{C}[G]$-module, where G is a finite group, and (b) through certain subgroups of the automorphism group of A. These symmetry properties lead to algorithms that are structurally different from the ones obtained by direct derivation (see above). All techniques used for the derivation of fast DTT algorithms are potentially more generally applicable.

Taken together, our results provide a comprehensive framework that puts previous results on the DTTs into a common context, thus tying together their signal processing properties, their algebraic properties, and the structure of their fast algorithms.

1.5. Organization. The paper is divided into two parts. Part I (sections 2–6) provides the mathematical framework and establishes the algebraic interpretation of the DTTs. Part II (sections 7–10) uses different algebraic methods to derive and explain most of the known fast algorithms for the DTTs.

Part I. In section 2 we briefly describe the notation and mathematical concepts we use. Polynomial transforms and scaled polynomial transforms are introduced in section 3, together with their module-theoretic interpretations. In section 4 we present a generalization of Chebyshev polynomials, with particular attention to four special series and their properties. The 16 types of DTTs are introduced in section 5, together with their defining signal processing properties. In section 6 we construct for each DTT, using its signal processing properties, an associated module, which reveals that the DTTs are scaled polynomial transforms.

Part II. In section 7 we present general methods for obtaining fast algorithms for polynomial transforms and discuss results known from the literature. In section 8 we use the algebraic properties of the DTTs to derive and understand several known fast algorithms for the DTTs. Other classes of algorithms for the DTTs are explained in section 9 and are based on group representation symmetries. In section 10 we will briefly discuss algorithms that are not covered by the previous methods.

2. Notation and terminology. We will use the following notation and mathematical background.

Matrices. An $(n \times n)$-matrix with entry $a_{k,\ell}$ at row k and column ℓ is written as $[a_{k,\ell}]$. In most cases we provide the index range of k, ℓ as subscript. We denote by $A \oplus B = \left[\begin{smallmatrix} A & \\ & B \end{smallmatrix}\right]$ the direct sum of A and B. If $A = [a_{k,\ell}]$, then $A \otimes B = [a_{k,\ell} \cdot B]$ denotes the tensor or Kronecker product of A and B. The conjugation is written as $A^B = B^{-1} \cdot A \cdot B$. A monomial matrix has exactly one nonzero entry in every row and column. If σ is a permutation (usually written in cycle notation), we will denote a corresponding $(n \times n)$-matrix as $[\sigma, n]$, which has ones at positions $(i, \sigma(i))$. The special case $\sigma : i \mapsto ki \bmod n - 1$, $i = 0, \ldots, n-2$, and $n-1 \mapsto n-1$, for $k \mid n$, is

called "stride permutation," and we write $[\sigma, n] = \mathrm{L}^n_k$. A diagonal matrix is written as $\mathrm{diag}(L)$, where L is the list of diagonal elements. A monomial matrix is denoted by $[\sigma, L] = [\sigma, |L|] \cdot \mathrm{diag}(L)$.

Polynomials. Polynomials are denoted by lowercase letters, $p(x)$, $q(x)$, etc. We will often drop the argument for convenience. A polynomial is called separable if its zeros are pairwise distinct; i.e., if $\deg(p) = n$, then

$$p(x) = \prod_{k=0}^{n-1} (x - \alpha_k), \quad \alpha_i \neq \alpha_j, \quad \text{for } i \neq j.$$

Algorithms. If B is an $(n \times n)$-matrix, we mean by "a fast algorithm for B" a fast algorithm for computing the matrix vector product $x \mapsto B \cdot x$. Algorithms are given by factorizations, $B = B_1 \cdots B_k$, where all B_i are sparse. If we refer to the arithmetic cost of an algorithm or the arithmetic complexity of matrices B, we mean the number of additions and multiplications different from $1, -1$ (cf. [5]).

Algebras and modules. We assume that the reader is familiar with the basic theory of algebras and modules. Examples of introductory books on this topic are [12, 25]. All algebras in this paper are $\mathbb{C}$-algebras. In particular, we will consider the polynomial algebra $\mathbb{C}[x]$ and factor algebras $\mathbb{C}[x]/p(x)$, where p is a separable polynomial, and group algebras $\mathbb{C}[G]$, where G is a finite group. Each of the algebras $A = \mathbb{C}[x]/p(x)$ or $A = \mathbb{C}[G]$ is of finite dimension and semisimple; i.e., every finite-dimensional (left or right) A-module can be decomposed into a direct sum of irreducible submodules,

$$M \cong M_1 \oplus \cdots \oplus M_k,$$

which is called the *Wedderburn decomposition* of M. If bases in M and M_i, $i = 1, \ldots, k$, are chosen, then this isomorphism can be expressed by a matrix, which we will refer to as a *Wedderburn matrix*. The module M is usually a left module unless otherwise stated. If M has dimension n as $\mathbb{C}$ vector space, and a basis is chosen, then M affords a matrix representation of A, i.e., a homomorphism

$$\phi : \ A \to \mathbb{C}^{n \times n}.$$

The Wedderburn decomposition of M is equivalent to a decomposition of ϕ into a direct sum of irreducible representations. In the special case where $M \cong A$ (as A-modules), M is called the *regular* A-module, and a corresponding representation is also called regular.

The *annihilator* of M in A is defined as

$$\mathrm{ann}_A(M) = \{a \in A \mid a \cdot m = 0, \text{for all } m \in M\};$$

it is a two-sided ideal in A. If M is an A-module, then M is also an $A/\mathrm{ann}_A(M)$-module.

3. Polynomial algebras, modules, and transforms. In this section we introduce polynomial transforms and their algebraic interpretation as decomposition matrices of polynomial algebras. Then we extend the definition to the more general class of "scaled" polynomial transforms. This extension will enable us to capture all trigonometric transforms in an algebraic framework.

3.1. Polynomial transforms. Let

$$p(x) = \prod_{k=0}^{n-1} (x - \alpha_k)$$

be a separable polynomial. Then the algebra $A = \mathbb{C}[x]/p(x)$ is semisimple, and the Wedderburn decomposition of (the regular module) $M = A$ is given by the Chinese remainder theorem (CRT) as

$$\mathbb{C}[x]/p(x) \cong \bigoplus_{k=0}^{n-1} \mathbb{C}[x]/(x - \alpha_k). \tag{3.1}$$

We want to represent the isomorphism in (3.1) by a matrix.

DEFINITION 3.1 (polynomial transform). *Let $b = (p_0, \ldots, p_{n-1})$ be a basis of polynomials in $\mathbb{C}[x]/p(x)$, p separable, and $\alpha = (\alpha_0, \ldots, \alpha_{n-1})$ the vector of zeros of p, and assume that the one-dimensional algebras $\mathbb{C}[x]/(x - \alpha_k)$ have the base vector $1 = x^0$, respectively. With these choices, the isomorphism* (3.1) *is given by the $(n \times n)$-matrix*

$$\mathcal{P}_{b,\alpha} = [p_\ell(\alpha_k)]_{k,\ell=0,\ldots,n-1}, \tag{3.2}$$

where k is the row index. The Wedderburn matrix $\mathcal{P}_{b,\alpha}$ is called the polynomial transform *w.r.t. the polynomials b and the sample points α. (Note that the order of base polynomials and sample points matters.)*

The polynomial transform $\mathcal{P}_{b,\alpha}$ can also be characterized via the representation ϕ afforded by the module $A = M$ with basis b. This is the subject of the following lemma.

LEMMA 3.2. *We use previous notation. Let $p(x) = \prod_{k=0}^{n-1}(x - \alpha_k)$ be separable, $A = \mathbb{C}[x]/p(x)$, and $M = A$ be the (regular) left module with basis $b = (p_0, p_1, \ldots, p_{n-1})$ and polynomial transform $\mathcal{P}_{b,a}$. Let ϕ be the corresponding representation of A. Then*

(i) *$\mathcal{P}_{b,\alpha}^{-1}$ decomposes ϕ into a direct sum of irreducible representations. More precisely,*

$$\mathcal{P}_{b,\alpha} \cdot \phi(q(x)) \cdot \mathcal{P}_{b,\alpha}^{-1} = \operatorname{diag}(q(\alpha_0), \ldots, q(\alpha_{n-1})) \quad \text{for } q(x) \in A.$$

All such decomposition matrices are given by $\mathcal{P}_{b,\alpha}^{-1} \cdot D$, where D is diagonal and invertible.

(ii) *$\mathcal{P}_{b,\alpha}^{T}$ decomposes ϕ^T into a direct sum of irreducible representations. More precisely,*

$$(\mathcal{P}_{b,\alpha}^{T})^{-1} \cdot \phi^T(q(x)) \cdot \mathcal{P}_{b,\alpha}^{T} = \operatorname{diag}(q(\alpha_0), \ldots, q(\alpha_{n-1})) \quad \text{for } q(x) \in A.$$

All such decomposition matrices are given by $\mathcal{P}_{b,\alpha}^{T} \cdot D$, where D is diagonal and invertible.

Proof. The matrix $\mathcal{P}_{b,\alpha}$ expresses the basis b of $M = A$ in the basis of the decomposed module $M' = \bigoplus_{k=0}^{n-1} \mathbb{C}[x]/(x - \alpha_k)$. Thus, the representation ρ afforded by M' is given by $\rho = \phi^{\mathcal{P}_{b,\alpha}^{-1}}$. Since all the $\mathbb{C}[x]/(x - \alpha_k)$ are submodules (of dimension 1) of M, ρ is diagonal. The projection of $q(x) \in A$ onto $\mathbb{C}[x]/(x - \alpha_k)$ is just the evaluation $q(\alpha_k)$. Since for $q(x) = x$ all eigenvalues of $\phi(x)$ are distinct, all decomposition

matrices are given by $\mathcal{P}_{b,\alpha}^{-1} \cdot D$, D diagonal (and invertible). This shows (i). Part (ii) follows from (i) by transposition. □

Remark. The representation ϕ^T arises from the *right* regular module A.

Example 3.3 (Vandermonde matrix). Let $A = M = \mathbb{C}[x]/p(x)$, with separable p as above. We consider the special case $b = (x^0, x^1, \ldots, x^{n-1})$. Then the polynomial transform

$$\mathcal{P}_{b,\alpha} = \left[\alpha_k^\ell\right]_{k,\ell=0,\ldots,n-1}$$

is precisely the transpose of a Vandermonde matrix [5].

Next, we construct the regular representation ϕ of A with respect to the basis b. Since A is cyclic (generated by the polynomial x), it is sufficient to determine the image of $x \in A$ under ϕ. Let $p(x) = \sum_{i=0}^{n} \eta_i \cdot x^i$. Then

$$\begin{aligned} x \cdot x^i &= x^{i+1}, \quad i = 0, \ldots, n-2, \text{ and} \\ x \cdot x^{n-1} &= x^n \equiv \sum_{i=0}^{n-1} -\eta_i \cdot x^i \bmod p(x). \end{aligned}$$

Thus we obtain

$$\phi(x) = \begin{bmatrix} 0 & & & & -\eta_0 \\ 1 & 0 & & & -\eta_1 \\ & \ddots & \ddots & & \vdots \\ & & 1 & 0 & -\eta_{n-2} \\ & & & 1 & -\eta_{n-1} \end{bmatrix},$$

which is the transpose of the companion matrix of p. Using Lemma 3.2,

$$\phi(x)^{\mathcal{P}_{b,\alpha}^{-1}} = (\phi(x)^T)^{\mathcal{P}_{b,\alpha}^T} = \operatorname{diag}(\alpha_0, \ldots, \alpha_{n-1}).$$

Example 3.4 (discrete Fourier transform). We expand upon Example 3.3 by requiring also that $p(x) = x^n - 1$, which implies that $\alpha_k = e^{2\pi i k/n}$, $k = 0, \ldots, n-1$. In this case the transposed Vandermonde matrix coincides with the DFT of size n,

$$\mathrm{DFT}_n = \left[e^{2\pi i k\ell/n}\right]_{k,\ell=0,\ldots,n-1}.$$

This identifies the DFT as a polynomial transform. The corresponding representation ϕ maps x to the cyclic shift,

$$\phi(x) = \begin{bmatrix} 0 & & & 1 \\ 1 & 0 & & 0 \\ & \ddots & \ddots & \vdots \\ & & 1 & 0 \end{bmatrix},$$

and, by Lemma 3.2 and since DFT_n is symmetric,

$$(\phi(x)^T)^{\mathrm{DFT}(n)} = \operatorname{diag}_{k=0}^{n-1}(e^{2\pi i k/n}).$$

3.2. Scaled polynomial transforms. In section 3.1 we introduced polynomial transforms as Wedderburn matrices of regular A-modules M, where $A = M = \mathbb{C}[x]$. To capture all DTTs in an algebraic framework, we must generalize slightly the notion of polynomial transforms. In short, we will consider *scaled* polynomial transforms. These arise when the polynomials p_ℓ in (3.2) are replaced by $f \cdot p_\ell$, where f is a complex-valued function. Every scaled polynomial transform is associated with a regular module $M \cong A$, where M can be $\neq A$. We start with the following definition.

DEFINITION 3.5 (scaled polynomial transforms). *Let $\mathbb{C}[x]/p(x)$, b, and α be as in Definition* 3.1. *Further, let f be a complex-valued function satisfying $f(\alpha_k) \neq 0$, $k = 0, \ldots, n-1$. We define the* scaled *polynomial transform w.r.t. the scaling function f, basis b, and sample points α as*

$$\mathcal{P}_{f \cdot b, \alpha} = [(f \cdot p_\ell)(\alpha_k)]_{k,\ell=0,\ldots,n-1}. \tag{3.3}$$

We can associate a regular module to a scaled polynomial transform $\mathcal{P}_{f \cdot b, \alpha}$ in the following way. The vector space $f \cdot \mathbb{C}[x] = \{f \cdot q \mid q \in \mathbb{C}[x]\}$ naturally becomes a $\mathbb{C}[x]$-module by defining

$$r \cdot (f \cdot q) = f \cdot rq \quad \text{for } r \in \mathbb{C}[x].$$

Let p be a separable polynomial with zeros $\alpha = (\alpha_0, \ldots, \alpha_{n-1})$, and $A = \mathbb{C}[x]/p$. Then $\mathbb{C}[x] \cdot (f \cdot p)$ is a $\mathbb{C}[x]$-submodule of $f \cdot \mathbb{C}[x]$, and we can construct the factor module $M = f \cdot \mathbb{C}[x]/(\mathbb{C}[x] \cdot (f \cdot p)) = f \cdot \mathbb{C}[x]/(f \cdot p)$. We will briefly write $M = f \cdot A$. Its $\mathrm{ann}_{\mathbb{C}[x]}(M) = \mathbb{C}[x] \cdot p$, and thus M is an A-module, and if $b = (p_0, \ldots, p_{n-1})$ is a basis of A, then $f \cdot b = (f \cdot p_0, \ldots, f \cdot p_{n-1})$ is a basis of M.

We summarize the properties of the module $M = f \cdot A$ and the scaled polynomial transform $\mathcal{P}_{f \cdot b, \alpha}$ in the following lemma.

LEMMA 3.6. *Let $A = \mathbb{C}[x]/p(x)$, $b = (p_0, \ldots, p_{n-1})$ be a basis of A, and p be a separable polynomial with zeros $\alpha = (\alpha_0, \ldots, \alpha_{n-1})$. Assume that f is defined as above, and that $f(\alpha_k) \neq 0$, $k = 0, \ldots, n-1$. Further, let $M = f \cdot A$ with basis $f \cdot b$ as defined above. Then the following hold:*

(i) *M is a regular A-module.*

(ii) *The (regular) representation ϕ of A afforded by M and $f \cdot b$ is equal to the (regular) representation of A afforded by A and b.*

(iii) $\mathcal{P}_{f \cdot b, \alpha} = \mathrm{diag}(f(\alpha_0), \ldots, f(\alpha_{n-1})) \cdot \mathcal{P}_{b, \alpha}$.

(iv) *The representation ϕ is diagonalized by $\mathcal{P}^{-1}_{f \cdot b, \alpha}$, and the representation ϕ^T is diagonalized by $\mathcal{P}^T_{f \cdot b, \alpha}$.*

Proof. (i) follows, since $f \not\equiv 0$, $p_i \mapsto f \cdot p_i$, $i = 0, \ldots, n-1$, defines an isomorphism $A \to f \cdot A$. (ii) is obvious. (iii) follows straight from the definitions in (3.2) and (3.3). (iv) follows from (iii) and Lemma 3.2. ∎

Remark. The scaled polynomial transform $\mathcal{P}_{f \cdot b, \alpha}$ is not the Wedderburn matrix of the module $f \cdot A$ with basis $f \cdot b$. The mapping $f \cdot p_k \mapsto p_k$, $k = 0, \ldots, n-1$, defines an A module isomorphism between $f \cdot A$ and A. The corresponding matrix (w.r.t. the bases $f \cdot b$ and b) is the identity. Hence $f \cdot A$ and A have the same Wedderburn matrix $\mathcal{P}_{b, \alpha}$.

4. Chebyshev polynomials. In this section we introduce a general class of Chebyshev polynomials and their properties that we will use throughout this paper. We start with the classical cases.

TABLE 4.1
T_n and U_n for $-2 \le n \le 3$.

n	-2	-1	0	1	2	3
T_n	$2x^2-1$	x	1	x	$2x^2-1$	$4x^3-3x$
U_n	-1	0	1	$2x$	$4x^2-1$	$8x^3-4x$

4.1. The classical cases. The classical Chebyshev polynomials (of the first kind) T_n are given by the three-term recurrence

$$T_0(x) = 1, \quad T_1(x) = x, \quad T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x), \ n \ge 2. \tag{4.1}$$

T_n is a polynomial of degree n and can be written in a closed form as

$$T_n(x) = \cos n\theta, \quad \cos\theta = x \quad \text{for } x \in (-1,1). \tag{4.2}$$

The recurrence formula in (4.1) is symmetric and can also be run in the other direction to obtain Chebyshev polynomials with negative n. Doing this, we obtain the symmetry property $T_{-n} = T_n$, as can also be seen from (4.2). The sequence $\{T_n \mid n \ge 0\}$ is orthogonal on the interval $(-1,1)$ w.r.t. the weight function $w(x) = (1-x^2)^{-1/2}$, i.e.,

$$\int_{-1}^{1} T_n(x)T_m(x)w(x)dx = 0 \quad \text{for } n \ne m.$$

From the closed form (4.2) for T_n, we also readily read off its zeros as

$$\cos\frac{(k+1/2)\pi}{n}, \quad k = 0, \dots, n-1.$$

Using recurrence (4.1) with changed initial conditions yields the Chebyshev polynomials U_n of the second kind:

$$U_0(x) = 1, \quad U_1(x) = 2x, \quad U_n(x) = 2xU_{n-1}(x) - U_{n-2}(x), \ n \ge 2.$$

The closed form of U_n is given by

$$U_n(x) = \frac{\sin(n+1)\theta}{\sin\theta}, \quad \cos\theta = x \quad \text{for } x \in (-1,1),$$

and we get $U_{-1} = 0$ and the symmetry $U_{-n-2} = -U_n$. For $-2 \le n \le 3$ the polynomials T_n, U_n are shown in Table 4.1.

A thorough introduction to Chebyshev polynomials and orthogonal polynomials in general can be found in the books of Chihara [8], Szegö [48], and Rivlin [42].

4.2. Generalized Chebyshev polynomials. Now we consider the set $\mathcal{C}$ of all polynomial sequences $\{P_n \mid n \in \mathbb{Z}\}$ that satisfy the three-term recurrence

$$P_n(x) = 2xP_{n-1}(x) - P_{n-2}(x). \tag{4.3}$$

We will refer to each such sequence as Chebyshev polynomials.

LEMMA 4.1. *Let $\{P_n \mid n \in \mathbb{Z}\}$ be a sequence of Chebyshev polynomials (we drop the argument x for simplicity). Then the following hold:*

(i) $P_n = P_1 \cdot U_{n-1} - P_0 \cdot U_{n-2}$.
(ii) $T_k \cdot P_n = (P_{n+k} + P_{n-k})/2$.

TABLE 4.2
Four series of Chebyshev polynomials. The range for the zeros is $k = 0, \dots, n-1$.

	$n = 0, 1$	Closed form	Symmetry	Zeros	Weight $w(x)$
T_n	$1, x$	$\cos(n\theta)$	$T_{-n} = T_n$	$\cos \frac{(k+\frac{1}{2})\pi}{n}$	$\frac{1}{(1-x^2)^{1/2}}$
U_n	$1, 2x$	$\frac{\sin(n+1)\theta}{\sin\theta}$	$U_{-n} = -U_{n-2}$	$\cos \frac{(k+1)\pi}{n+1}$	$(1-x^2)^{1/2}$
V_n	$1, 2x-1$	$\frac{\cos(n+\frac{1}{2})\theta}{\cos\frac{1}{2}\theta}$	$V_{-n} = V_{n-1}$	$\cos \frac{(k+\frac{1}{2})\pi}{n+\frac{1}{2}}$	$\frac{(1+x)^{1/2}}{(1-x)^{1/2}}$
W_n	$1, 2x+1$	$\frac{\sin(n+\frac{1}{2})\theta}{\sin\frac{1}{2}\theta}$	$W_{-n} = -W_{n-1}$	$\cos \frac{(k+1)\pi}{n+\frac{1}{2}}$	$\frac{(1-x)^{1/2}}{(1+x)^{1/2}}$

Proof. Clearly, a sequence P_n is uniquely determined by its initial conditions P_0 and P_1. If P_0, P_1 give rise to the sequence P_n, and if Q is any polynomial, then $Q \cdot P_0, Q \cdot P_1$ give rise to the sequence $Q \cdot P_n$. If, further, P_0', P_1' give rise to the sequence P_n', then $P_0 + P_0', P_1 + P_1'$ give rise to $P_n + P_n'$.

(i) First we consider the initial polynomials $0, 1$ and $1, 0$ and obtain (cf. Table 4.1)

$$\begin{aligned} P_0 = 1,\ P_1 = 0: &\quad P_n = -U_{n-2}, \\ P_0 = 0,\ P_1 = 1: &\quad P_n = U_{n-1}. \end{aligned}$$

With the previous remark, this shows (i).

(ii) Induction on k. For $k = 0$ it is trivial; for $k = 1$ this is the defining recurrence (4.3) for P_n. Further, we have

$$\begin{aligned} T_{k+1} \cdot P_n &= (2xT_k - T_{k-1}) \cdot P_n \\ &= 2x \cdot (P_{n+k} + P_{n-k})/2 - (P_{n+k-1} + P_{n-k+1})/2 \\ &= (P_{n+k+1} + P_{n-k-1})/2, \end{aligned}$$

where we used the induction hypothesis in the second step, and (4.3) in the last step. □

Remarks. (1) Both assertions in Lemma 4.1 remain valid when the polynomials P_n and hence P_0, P_1 are allowed to be arbitrary complex-valued functions. (2) Lemma 4.1 shows that $\mathcal{C}$ is a free $\mathbb{C}[x]$-module of rank 2.

We are particularly interested in four polynomial sequences, T_n, U_n, V_n, W_n, in $\mathcal{C}$ arising from different initial conditions. The sequences T_n and U_n are the Chebyshev polynomials of the first and second kind, as introduced above. All four sequences can be written in a closed form, have simple symmetry properties, and are orthogonal on $(-1, 1)$ w.r.t. some weight function $w(x)$. The zeros in all cases can be obtained from the closed form. These properties are summarized in Table 4.2. The results on V_n and W_n can be found in [8, pp. 37, 39].

Later we will need the following arithmetic properties of the Chebyshev polynomials.

LEMMA 4.2. *The following hold for all $m, n \in \mathbb{Z}$:*

(i) $T_{mn} = T_n(T_m) = T_m(T_n)$.
(ii) $U_{mn-1} = U_{m-1}(T_n)U_{n-1}$.
(iii) $U_{2m} = V_m \cdot W_m$.

TABLE 4.3
Identities among the four series of Chebyshev polynomials; P_n has to be replaced by T_n, U_n, V_n, W_n to obtain rows $1, 2, 3, 4$, respectively.

	$P_n - P_{n-2}$	P_n	$P_n - P_{n-1}$	$P_n + P_{n-1}$
T_n	$2(x^2-1)U_{n-2}$	T_n	$(x-1)W_{n-1}$	$(x+1)V_{n-1}$
U_n	$2T_n$	U_n	V_n	W_n
V_n	$2(x-1)W_{n-1}$	V_n	$2(x-1)U_{n-1}$	$2T_n$
W_n	$2(x+1)V_{n-1}$	W_n	$2T_n$	$2(x+1)U_{n-1}$

(iv) $W_n(x) = (-1)^n V_n(-x)$.
(v) $T_n(1) = 1$.

Proof. The proof follows from the closed form of the polynomials (Table 4.2) and trigonometric identities. □

We conclude this section by stating an interesting property of the four types of Chebyshev polynomials introduced. Let P_n be any of T_n, U_n, V_n, W_n. Then, using well-known trigonometric identities, $P_n - P_{n-2}, P_n - P_{n-1}, P_n + P_{n+1}$ can again be expressed using these polynomials. In particular, this allows us to determine their zeros using Table 4.2. The complete set of identities is given in Table 4.3. The second column is trivial and is introduced to make the table comply with later investigations. As an example, row 2, column 1 shows that $U_n - U_{n-2} = 2T_n$.

Remarks. (1) In a few places in the literature, e.g., in [30], the four series of Chebyshev polynomials occur together. (2) If we use the closed forms of T_n, U_n to extend their definitions to rational $n \in \mathbb{Q}$, we can write $V_n = T_{n+1/2}/T_{1/2}$ and $W_n = U_{n-1/2}/U_{-1/2}$. (3) For a complete overview on the factorization of T_n and U_n over $\mathbb{Q}$, see [41].

5. The 16 types of DTTs. The first discrete cosine transform was introduced by Ahmed, Natarajan, and Rao [1]. The complete set of all eight types of DCTs and DSTs, respectively, was first presented by Wang and Hunt [53]. We will sometimes refer to them together as DTTs. Each of the transforms is given by an $(n \times n)$-matrix M, $n \geq 0$, which multiplies to a signal vector a from the left, $a \mapsto M \cdot a$. As examples, we will use the symbol DCT-2 to refer to a DCT of type 2, and DST-7_n to refer to a DST of type 7 and size n. If an arbitrary trigonometric transform is addressed, we will write DTT or DTT$_n$. In this notation, the first DCT introduced was of type 2.

TABLE 5.1
Eight types of DCTs and DSTs, given for size n. The entry at row k and column ℓ is given for $k, \ell = 0, \ldots, n-1$.

	DCTs	DSTs
type 1	$\cos k\ell \frac{\pi}{n-1}$	$\sin(k+1)(\ell+1)\frac{\pi}{n+1}$
type 2	$\cos k(\ell+\frac{1}{2})\frac{\pi}{n}$	$\sin(k+1)(\ell+\frac{1}{2})\frac{\pi}{n}$
type 3	$\cos(k+\frac{1}{2})\ell\frac{\pi}{n}$	$\sin(k+\frac{1}{2})(\ell+1)\frac{\pi}{n}$
type 4	$\cos(k+\frac{1}{2})(\ell+\frac{1}{2})\frac{\pi}{n}$	$\sin(k+\frac{1}{2})(\ell+\frac{1}{2})\frac{\pi}{n}$
type 5	$\cos k\ell \frac{\pi}{n-\frac{1}{2}}$	$\sin(k+1)(\ell+1)\frac{\pi}{n+\frac{1}{2}}$
type 6	$\cos k(\ell+\frac{1}{2})\frac{\pi}{n-\frac{1}{2}}$	$\sin(k+1)(\ell+\frac{1}{2})\frac{\pi}{n+\frac{1}{2}}$
type 7	$\cos(k+\frac{1}{2})\ell\frac{\pi}{n-\frac{1}{2}}$	$\sin(k+\frac{1}{2})(\ell+1)\frac{\pi}{n+\frac{1}{2}}$
type 8	$\cos(k+\frac{1}{2})(\ell+\frac{1}{2})\frac{\pi}{n+\frac{1}{2}}$	$\sin(k+\frac{1}{2})(\ell+\frac{1}{2})\frac{\pi}{n-\frac{1}{2}}$

Table 5.1 gives the definitions of all 16 types of DCTs and DSTs by stating the

respective entry at position (k, ℓ), where k is the row index, for $k, \ell = 0, \ldots, n-1$. As can be seen, all entries are pure cosines or sines of the form $\cos r\pi$ or $\sin r\pi$, where r is some rational number. Thus, all entries are elements in a suitable cyclotomic field over $\mathbb{Q}$. The definitions given in Table 5.1 are the *unscaled* versions of the DCTs and DSTs, which will be considered in this paper. The *scaled* versions of the DCTs and DSTs are orthonormal and arise from the unscaled versions by multiplying in some cases the first and/or last row and/or column by $1/\sqrt{2}$, which makes the matrix orthogonal. In addition, the entire matrix is multiplied by a factor to achieve orthonormality. As an example, the orthonormal version of the DCT-2 has entries

$$\sqrt{\frac{2}{n}} \cdot c_k \cdot \cos k \left(\ell + \frac{1}{2}\right) \frac{\pi}{n}, \quad k, \ell = 0, \ldots, n-1,$$

where $c_k = \sqrt{1/2}$ for $k = 0$ and $c_k = 1$ elsewhere. For the convenience of the reader, the scaled, orthonormal versions of the DCTs and DSTs are given in Table A.1 in the appendix. Note that the set of all DTTs is closed under matrix transposition. From Table 5.1 it is easily seen that the DCT and the DST of types 1, 4, 5, and 8 are symmetric, and that types 2 and 3 and types 6 and 7 are converted into each other, respectively, by transposition.

All 16 DCTs and DSTs arise as eigenmatrices of certain tridiagonal matrices [47, 45] of size $(n \times n)$, which can be chosen of the form

$$B(\beta_1, \beta_2, \beta_3, \beta_4) = \frac{1}{2} \cdot \begin{bmatrix} \beta_1 & \beta_2 & & & & & \\ 1 & 0 & 1 & & & & \\ & 1 & 0 & 1 & & & \\ & & \cdot & \cdot & \cdot & & \\ & & & 1 & 0 & 1 & \\ & & & & \beta_3 & \beta_4 & \end{bmatrix}. \tag{5.1}$$

The internal structure of $B(\beta_1, \beta_2, \beta_3, \beta_4)$ corresponds to the equation

$$a_k = \frac{1}{2}(a_{k-1} + a_{k+1}), \quad 1 \le k \le n-2. \tag{5.2}$$

The entries β_1, β_2 are determined by a choice of *left boundary conditions (b.c.)* that determine how a_{-1} is chosen in (5.2) for $k = 0$. The four left b.c. considered are $a_{-1} = a_1$, $a_{-1} = 0$, $a_{-1} = a_0$, $a_{-1} = -a_0$. For example, the choice $a_{-1} = a_1$ leads to $\beta_1 = 0, \beta_2 = 2$. Similarly, the entries β_3, β_4 are determined by right b.c. arising from the choice of a_n in (5.2) for $k = n-1$. The right b.c. are the mirrored versions of the left b.c.: $a_n = a_{n-2}$, $a_n = 0$, $a_n = a_{n-1}$, $a_n = -a_{n-1}$. The complete set of values $\beta_1, \beta_2, \beta_3, \beta_4$ for all 16 possible combinations of b.c. is given in Table 5.2. If b.c., and thus values $\beta_1, \beta_2, \beta_3, \beta_4$, are chosen, and if $a = (a_0, \ldots, a_{n-1})^T$, then (5.2), $k = 0, \ldots, n-1$, can be written as

$$a = B(\beta_1, \beta_2, \beta_3, \beta_4) \cdot a.$$

Remarks. (1) The matrices $B(\cdot)$ in (5.1) correspond to linear time-invariant processes with b.c. [33, 47]. (2) The b.c. $a_{-1} = 0$ and $a_{-1} = -a_0$ are the discrete versions of Dirichlet b.c.; $a_{-1} = a_1$ and $a_{-1} = a_0$ are the discrete versions of Neumann b.c. Analogously for the right b.c. [33, 47].

The 16 DTTs correspond to these different choices of b.c. as shown in Table 5.3 (see [47]). The relationship is as follows. If numbers $\beta_1, \beta_2, \beta_3, \beta_4$ (and hence left and

right b.c.) are chosen from row k and row ℓ, respectively, of Table 5.2 ($k, \ell = 1, \ldots, 4$), then the corresponding matrix $B(\beta_1, \beta_2, \beta_3, \beta_4)$ is diagonalized by *the transpose* of the DTT of size n given in row k and column ℓ of Table 5.3.

Example 5.1. As an example, we choose left b.c. $a_{-1} = a_0$ and right b.c. $a_n = a_{n-1}$ and obtain $\beta_1 = \beta_2 = \beta_3 = \beta_4 = 1$. The $(n \times n)$-matrix

$$B(1,1,1,1) = \frac{1}{2} \cdot \begin{bmatrix} 1 & 1 & & & & \\ 1 & 0 & 1 & & & \\ & \cdot & \cdot & \cdot & & \\ & & 1 & 0 & 1 & \\ & & & 1 & 1 \end{bmatrix} \tag{5.3}$$

is diagonalized by DCT-2_n^T = DCT-3_n; i.e., $B(1,1,1,1)^{\text{DCT-3}_n}$ is diagonal.

Remarks. (1) The DTTs of types 5–8 are also called "odd" DTTs of types 1–4, respectively. (2) Reference [47] considers the matrices $2\,\mathrm{I} - 2B(\cdot)$ rather than the matrices $B(\cdot)$, which leads to equivalent diagonalization properties. Also the definition of the DTTs is transposed to our definition. We chose the original [53] and commonly used definition.

6. The algebraic characterization of the DTTs. In this section we will show that all 16 DTTs are scaled polynomial transforms (see section 5) by constructing the corresponding modules and bases. To connect, for a given DTT, its diagonalization property, i.e., the associated matrix $B(\beta_1, \beta_2, \beta_3, \beta_4)$ (cf. section 5), with the algebra/module framework, we will construct a module with basis b that affords a representation ϕ such that

$$\phi^T(x) = B(\beta_1, \beta_2, \beta_3, \beta_4).$$

In other words, the operation of x (via multiplication) on b is reflected by the matrix $B(\beta_1, \beta_2, \beta_3, \beta_4)$. Lemma 3.6(iv) will establish the correspondence between the DTT and the module constructed this way.

The construction of the module and its base is a three-step procedure. Assume a DTT and an associated matrix $B(\cdot)$ are given.

1. *Internal structure* (section 6.1). Determine a sequence of polynomials that yields the internal structure of $B(\cdot)$, i.e., the $\ldots, \frac{1}{2}, 0, \frac{1}{2}, \ldots$ in each column. This will bring into play generalized Chebyshev polynomials in a natural way.

2. *Left boundary conditions* (section 6.2). Fix the left b.c. This corresponds to fixing the initial conditions for the Chebyshev polynomials, i.e., the choice of a particular sequence of Chebyshev polynomials.

3. *Right boundary conditions* (section 6.3). Fix the right b.c. This corresponds to choosing the appropriate polynomial p for the module (and the algebra) $\mathbb{C}[x]/p$.

6.1. Internal structure. First we will consider n-dimensional modules that carry the structure given in (5.2). Rewriting (4.3) in a slightly different form as

$$x \cdot P_k = \frac{1}{2}(P_{k-1} + P_{k+1}) \tag{6.1}$$

shows that this is afforded by any regular module $A = \mathbb{C}[x]/p$, $\deg(p) = n$, if we choose the basis $b = (P_0, \ldots, P_{n-1})$, where the P_k are generalized Chebyshev polynomials. In other words, the image of x under the representation ϕ afforded by A with basis b will have an internal structure similar to the matrices given in (5.1).

6.2. Left boundary conditions. The four left b.c. associated with the DTTs are (see Table 5.3)

$$a_{-1} = a_1, \quad a_{-1} = 0, \quad a_{-1} = a_0, \quad a_{-1} = -a_0. \tag{6.2}$$

They apply in the boundary case $k = 0$ in (5.2). An equivalent behavior is obtained in (6.1) if we choose the four special sequences of Chebyshev polynomials T_k, U_k, V_k, W_k introduced in Table 4.2. The symmetry properties of these polynomials (cf. Table 4.2) correspond to the left b.c. in (6.2),

$$T_{-1} = T_1, \quad U_{-1} = 0, \quad V_{-1} = V_0, \quad W_{-1} = -W_0,$$

respectively. As an example, *every* regular module $\mathbb{C}[x]/p$ with basis $(T_0, \ldots, T_{n-1})$ carries the left b.c. $a_{-1} = a_1$.

6.3. Right boundary conditions. The four right b.c. associated with the DTTs mirror the left b.c. (see Table 5.3):

$$a_n = a_{n-2}, \quad a_n = 0, \quad a_n = a_{n-1}, \quad a_n = -a_{n-1}. \tag{6.3}$$

The right b.c. are determined by the choice of p in $\mathbb{C}[x]/p$. As an example, to introduce the right b.c. $a_n = a_{n-2}$, we choose $p = P_n - P_{n-2}$, where $P \in \{T, U, V, W\}$. Thus the choices of p corresponding to (6.3) are

$$P_n - P_{n-2}, \quad P_n, \quad P_n - P_{n-1}, \quad P_n + P_{n-1}, \tag{6.4}$$

respectively. To determine the zeros of p in these cases, and hence the decomposition of A and its associated decomposing polynomial transform, we need to consult Table 4.3, which covers all cases in (6.4) for $P \in \{T, U, V, W, \}$.

6.4. Summary. Before we state the interpretation of the DTTs as scaled polynomial transforms, it is perhaps instructive to consider an example.

Example 6.1 (DST-3). We choose the left b.c. $a_{-1} = 0$, which leads to the choice of the basis $b = (U_0, \ldots, U_{n-1})$. As right b.c. we choose $a_n = a_{n-2}$, which leads to

$p = U_n - U_{n-2} = 2T_n$ using Table 4.3. The decomposition of the regular module $A = \mathbb{C}[x]/T_n$ (the 2 can be dropped) is determined by the zeros of T_n, which are $\alpha = (\cos \frac{1}{2}\pi/n, \ldots, \cos(n - \frac{1}{2})\pi/n)$ (cf. Table 4.2), i.e.,

$$A = \mathbb{C}[x]/(U_n - U_{n-2}) = \mathbb{C}[x]/T_n = \bigoplus_{k=0}^{n-1} \mathbb{C}[x]/\left(x - \cos\left(k + \tfrac{1}{2}\right)\pi/n\right).$$

The decomposing polynomial transform is given by

$$\begin{aligned}\mathcal{P}_{b,\alpha} &= [U_\ell(\cos(k+1/2)\pi/n)]_{k,\ell=0,\ldots,n-1} \\ &= \left[\frac{\sin(\ell+1)(k+1/2)\pi/n}{\sin(k+1/2)\pi/n}\right]_{k,\ell=0,\ldots,n-1} \\ &= \operatorname{diag}_{k=0}^{n-1}\left(\frac{1}{\sin(k+1/2)\pi/n}\right) \cdot \text{DST-3}_n,\end{aligned}$$

which shows that DST-3_n is the scaled polynomial transform

$$\text{DST-3}_n = \mathcal{P}_{f\cdot b,\alpha}, \quad f = \sin\theta,$$

associated with the module $f \cdot A$ with basis $f \cdot b$.

Next we construct the representation ϕ afforded by A with basis b. By construction, we have $x \cdot U_0 = \frac{1}{2}U_1$, $x \cdot U_\ell = \frac{1}{2}(U_{\ell-1} + U_{\ell+1})$ for $\ell = 1, \ldots, n-2$, and $x \cdot U_{n-1} = U_{n-2}$ (in A). We get

$$\phi(x) = \frac{1}{2} \cdot \begin{bmatrix} 0 & 1 & & & & \\ 1 & 0 & 1 & & & \\ & \cdot & \cdot & \cdot & & \\ & & 1 & 0 & 2 & \\ & & & 1 & 0 & \end{bmatrix}.$$

Lemma 3.6 shows that $\phi(x)^T$ is diagonalized by DST-3_n^T = DST-2_n, namely,

$$\phi^T(x)^{\text{DST-2}_n} = \operatorname{diag}\left(\cos\tfrac{1}{2}\pi/n, \ldots, \cos\left(n - \tfrac{1}{2}\right)\pi/n\right).$$

Using the notation from section 5, $\phi(x)^T = B(0, 1, 2, 0)$, which corresponds to the DST-3 (see Tables 5.2 and 5.3), as desired.

Remarks. (1) It is intriguing that the left and right b.c. seem to be handled differently (initial conditions versus factor polynomial). In section 8.1 we will see that this construction can be reversed. (2) Note that the boundary conditions corresponding to the *left* module constructed affect the first and last *column* of the *left* representation $\phi(x)$. Lemma 3.2 shows that the *right* representation ϕ^T is decomposed by the transpose of the corresponding DTT, which complies with the fact that the b.c. affect the first and last *rows* in the matrices $B(\cdot)$ (cf. section 5). (3) The polynomial defining the right b.c. in Example 6.1 can be written in two ways, $U_n - U_{n-2} = 2T_n$ (cf. Table 4.3). The left form determines the b.c.; the right form provides the decomposition of $\mathbb{C}[x]/T_n$, which corresponds to the zeros of T_n.

The complete correspondence between DTTs and modules is given in Theorem 6.2 below. To provide a convenient overview, and because we will repeatedly use it in the following, we have combined Tables 4.3 and 5.3 and the respective scaling functions into Table 6.1.

TABLE 6.1

Overview of the DTTs and associated modules. The left b.c. and right b.c. are in the first column (value of a_{-1}) and row, respectively. A given DTT_n is associated with the module $f \cdot \mathbb{C}[x]/Q_n$, where Q_n is given below the DTT and the scaling function f in the second column. The basis of $\mathbb{C}[x]/Q_n$ is given in the third column.

			$a_n - a_{n-2}$	a_n	$a_n - a_{n-1}$	$a_n + a_{n-1}$
a_1	1	T_ℓ	DCT-1 $2(x^2-1)U_{n-2}$	DCT-3 T_n	DCT-5 $(x-1)W_{n-1}$	DCT-7 $(x+1)V_{n-1}$

THEOREM 6.2. *Define the four scaling functions $f_1 = 1$, $f_2 = \sin\theta$, $f_3 = \cos\frac{1}{2}\theta$, and $f_4 = \sin\frac{1}{2}\theta$, with $\cos\theta = x$. Choose a combination of left and right boundary conditions with index i, j from Table 6.1, $i, j = 1, \ldots, 4$, and let DTT_n be the corresponding discrete trigonometric transform. Denote the polynomial below the DTT in Table 6.1 by Q_n and its zeros by $\alpha = (\alpha_0, \ldots, \alpha_{n-1})$. Choose a basis of $A = \mathbb{C}[x]/Q_n$ as $b = (P_0, \ldots, P_{n-1})$, where $P = T, U, V, W$ for $i = 1, 2, 3, 4$, respectively. Then*

(i) *DTT_n is the scaled polynomial transform*

$$\mathrm{DTT}_n = \mathcal{P}_{f_i \cdot b, \alpha}$$

associated with the module $f_i \cdot A$ and basis $f_i \cdot b$.

(ii) *If ϕ is the representation afforded by A with b, then $\phi(x)^T$ is the matrix $B(\cdot)$ in (5.1) given by the left and right b.c. chosen.*

(iii) *The matrix $\phi(x)^T$ is diagonalized by DTT_n^T, namely,*

$$(\mathrm{DTT}_n^T)^{-1} \cdot \phi(x)^T \cdot \mathrm{DTT}_n^T = \mathrm{diag}(\alpha_0, \ldots, \alpha_{n-1}),$$

which implies that DTT_n^T is a decomposition matrix for the (right) regular representation ϕ^T of A.

Proof. The proof follows by computations completely analogous to Example 6.1 for all 16 cases. ∎

Remarks. (1) Theorem 6.2 shows that a DTT is a polynomial transform (i.e., not scaled) iff it appears in the first row of Table 6.1. For the DCT-1 and the DCT-3 this has been recognized in [35] and [46], respectively. (2) The sparse matrices $B(\cdot)$ occur as images of $T_1 = x$ under the (right) representation ϕ^T of the respective module. Using Lemma 4.1(ii), one can compute the images $\phi^T(T_k)$, $k = 0, \ldots, n-1$, which all turn out to be sparse. This makes $(T_0, \ldots, T_{n-1})$ a natural choice of basis in the algebra (not the module) A in all 16 cases. The image $\phi^T(a)$ (or $\phi(a)$) of a generic element $a = \sum a_k T_k \in A$ has a structure that is usually referred to as Toeplitz + Hankel.

With the algebraic characterization of the DTTs given in Theorem 6.2, we are now in the position to derive and explain many of their fast algorithms known from the literature. This is the subject of the remaining sections.

7. Fast algorithms for polynomial transforms. Fast algorithms for the matrix-vector multiplication with polynomial transforms, $z \mapsto \mathcal{P}_{b,\alpha} \cdot z$ or, equivalently, sparse factorizations of $\mathcal{P}_{b,\alpha}$, have been the subject of several papers. In [46]

the DCT-3 and the real and imaginary parts of the DFT are recognized as polynomial transforms, which is used for their factorization. In [14] and in [35] an $O(n \log^2 n)$ algorithm is derived for the case in which b is an arbitrary sequence of orthogonal polynomials and α a list of arbitrary (distinct) evaluation points. Using this result in combination with Theorem 6.2 shows that the complexity of computing a DTT_n is $O(n \log^2 n)$. The fast DTT algorithms known from the literature, however, and the following discussion show that the complexity is indeed $O(n \log n)$.

In this section we will present two general techniques that can be used to factor a polynomial transform $\mathcal{P}_{b,\alpha}$ associated with the regular module $\mathbb{C}[x]/p$. They apply in the cases

1. $p(x) = q(x) \cdot r(x)$ (p factors),
2. $p(x) = q(r(x))$ (p decomposes).

An important question is to know when the resulting matrix factors are sparse, yielding a fast algorithm. We note that it is also possible to factor $\mathcal{P}_{b,\alpha}$ if

3. $p(x) = q(x) \otimes r(x)$ (p is a tensor product),

but we omit this case since it does not apply to the DTTs. Because of Lemma 3.6, the problems of finding fast algorithms for $\mathcal{P}_{b,\alpha}$ and $\mathcal{P}_{f \cdot b,\alpha}$ are equivalent.

Throughout this section, p is a separable polynomial with zero vector α.

7.1. Direct sum. One straightforward way of obtaining a fast polynomial transform is by splitting the polynomial p recursively, using the fact that, if $p = q \cdot r$,

$$\mathbb{C}[x]/p \cong \mathbb{C}[x]/q \oplus \mathbb{C}[x]/r. \tag{7.1}$$

This reduces the problem of computing one polynomial transform to the computation of two smaller polynomial transforms.

LEMMA 7.1. *Let $p = q \cdot r$, and assume that p, q, r have the zero vectors α, β, γ, respectively. Further, let b, c, d be bases of $\mathbb{C}[x]/p$, $\mathbb{C}[x]/q$, $\mathbb{C}[x]/r$, respectively. Then*

$$\mathcal{P}_{b,\alpha} = P \cdot (\mathcal{P}_{c,\beta} \oplus \mathcal{P}_{d,\gamma}) \cdot B,$$

where B is the base change matrix $b \to (c, d)$ (concatenation) corresponding to (7.1) *and P is a permutation matrix mapping $(\beta, \gamma) \mapsto \alpha$.*

Proof. The proof follows from the definitions of B and P. ∎

Clearly, the decomposition in Lemma 7.1 is useful for a fast algorithm only if B is sparse or has a fast algorithm itself. As an example, the fast algorithm for the Vandermonde matrix relies on the fact that in this case B has a Toeplitz structure, which permits its computation with $O(n \log n)$ arithmetic operations [14, 34].

7.2. Decomposition. A more interesting factorization of a polynomial transform can be derived if p *decomposes* into two polynomials, $p(x) = q(r(x))$. We will need the following lemma.

LEMMA 7.2. *Let p be separable and of degree n with zeros $\alpha_0, \ldots, \alpha_{n-1}$. Assume $p(x) = q(r(x))$ with q of degree k and r of degree ℓ. Then for each zero β of q there are precisely ℓ zeros α_m of p such that $r(\alpha_m) = \beta$.*

Proof. Let α_m be a zero of p. Then $0 = p(\alpha_m) = q(r(\alpha_m))$. Thus r maps the $n = k\ell$ zeros of p to the k zeros of q. If β is one of the k zeros of q, then the equation $r(\alpha_m) = \beta$ has maximal $\deg(r) = \ell$ solutions α_m; thus it has precisely ℓ solutions. ∎

As in Lemma 7.2, let the degrees of p, q, r be n, k, ℓ, respectively, $n = k\ell$. We

choose bases $c = (q_0, \dots, q_{k-1})$ of $\mathbb{C}[x]/q$ and $d = (r_0, \dots, r_{\ell-1})$ of $\mathbb{C}[x]/r$. Then

$$\begin{aligned} b' = (&r_0 \cdot q_0(r), \dots, r_0 \cdot q_{k-1}(r),\\ &r_1 \cdot q_0(r), \dots, r_1 \cdot q_{k-1}(r),\\ &\dots\dots\dots\dots\dots\dots\dots\dots\\ &r_{\ell-1} \cdot q_0(r), \dots, r_{\ell-1} \cdot q_{k-1}(r)) \end{aligned}$$

is a basis of $\mathbb{C}[x]/p$. Using the shorter notation $p_{j,i,m} = (r_j \cdot q_i(r))(\alpha_m)$, the corresponding polynomial transform is given by

$$\mathcal{P}_{b',\alpha} = \begin{bmatrix} p_{0,0,0} & \cdots & p_{0,k-1,0} & \cdots & p_{\ell-1,0,0} & \cdots & p_{\ell-1,k-1,0} \\ p_{0,0,1} & \cdots & p_{0,k-1,1} & \cdots & p_{\ell-1,0,1} & \cdots & p_{\ell-1,k-1,1} \\ \dots & & \dots & & \dots & & \dots \\ p_{0,0,n-1} & \cdots & p_{0,k-1,n-1} & \cdots & p_{\ell-1,0,n-1} & \cdots & p_{\ell-1,k-1,n-1} \end{bmatrix}.$$

Because of Lemma 7.2, for each i, the n numbers $q_i(r(\alpha_m))$, $m = 0, \dots, n-1$, will divide into k groups of ℓ equals. We permute α into α' with a permutation P such that $r(\alpha_{i+jk}) = \beta_i$, $i = 0, \dots, k-1$, $j = 0, \dots, \ell-1$, i.e.,

$$\mathcal{P}_{b',\alpha'} = P \cdot \mathcal{P}_{b',\alpha}.$$

Now $\mathcal{P}_{b',\alpha'}$ reveals the following block structure:

$$\begin{aligned} \mathcal{P}_{b',\alpha'} &= [D_{h,j} \cdot \mathcal{P}_{c,\beta}]_{h,j=0,\dots,\ell-1}, \quad \text{with} \\ D_{h,j} &= \operatorname{diag}(r_j(\alpha'_{hk}), r_j(\alpha'_{hk+1}), \dots, r_j(\alpha'_{hk+k-1})). \end{aligned}$$

Thus we can write $\mathcal{P}_{b',\alpha'}$ as

$$\mathcal{P}_{b',\alpha'} = [D_{h,j}]_{h,j=0,\dots,\ell-1} \cdot (\mathrm{I}_\ell \otimes \mathcal{P}_{c,\beta}).$$

Since $D_{h,j}$ is diagonal, $h, j = 0, \dots, \ell-1$, the matrix $[D_{h,j}]$ consists of k $(\ell \times \ell)$ blocks at stride k. Thus,

$$[D_{h,j}]^{\mathrm{L}^n_\ell}$$

is a direct sum of $(\ell \times \ell)$-matrices, which turn out to again be polynomial transforms. Using $(\mathrm{L}^n_\ell)^{-1} = \mathrm{L}^n_k$, we get the following theorem.

THEOREM 7.3. *We use the previous notation. Then*

$$\mathcal{P}_{b,\alpha} = P \cdot \left(\bigoplus_{i=0}^{k-1} \mathcal{P}_{d,\overline{\alpha}_i} \right)^{\mathrm{L}^n_k} \cdot (\mathrm{I}_\ell \otimes \mathcal{P}_{c,\beta}) \cdot B,$$

where B is the matrix giving the base change $b \to b'$, P is a permutation matrix, and

$$\overline{\alpha}_i = (\alpha'_{0 \cdot k+i}, \alpha'_{1 \cdot k+i}, \dots, \alpha'_{(\ell-1) \cdot k+i}).$$

As in Lemma 7.1, the value of this factorization for deriving a fast algorithm for $\mathcal{P}_{b,\alpha}$ depends on the base change matrix B.

Theorem 7.3 can be interpreted as a generalization of the Cooley–Tukey FFT as we will see in the next example.

Example 7.4 (FFT, size 4). We consider the case $p(x) = x^4 - 1 = (x^2)^2 - 1$, i.e., $q(x) = x^2 - 1$, and $r(x) = x^2$. As bases we choose $b = (1, x, x^2, x^3)$ and $c = d = (1, x)$.

The zeros of p are $\alpha = (1, i, -1, -i)$, and the zeros of q are $\beta = (1, -1)$. This is the situation of Example 3.4, $\mathcal{P}_{b,\alpha} = \mathrm{DFT}_4$, $\mathcal{P}_{c,\beta} = \mathrm{DFT}_2$. Since $r(1) = r(-1)$ and $r(i) = r(-i)$, it is $\alpha' = \alpha$. Further, $b' = (1, x^2, x, x^3)$, and thus $B = [(2, 3), 4] = \mathrm{L}^4_2$. It remains to compute $\mathcal{P}_{d,\overline{\alpha}_0}, \mathcal{P}_{d,\overline{\alpha}_1}$:

$$\mathcal{P}_{d,\overline{\alpha}_0} = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} = \mathrm{DFT}_2, \qquad \mathcal{P}_{d,\overline{\alpha}_1} = \begin{bmatrix} 1 & i \\ 1 & -i \end{bmatrix} = \mathrm{DFT}_2 \cdot \mathrm{diag}(1, i).$$

As a result we get the FFT of size 4,

$$\mathrm{DFT}_4 = (\mathrm{DFT}_2 \otimes \mathrm{I}_2) \cdot \mathrm{diag}(1, 1, 1, i) \cdot (\mathrm{I}_1 \otimes \mathrm{DFT}_2) \cdot \mathrm{L}^4_2 .$$

Remark. It is worth giving an algebraic interpretation of Theorem 7.3 using the notation above. Since $p(x) = q(r(x))$, $A' = \mathbb{C}[r(x)]/p(x) = \mathbb{C}[y]/q(y)$ $(y = r(x))$ is a subalgebra of $A = C[x]/p(x)$. We have

$$A \cong r_0 \cdot A' \oplus \cdots \oplus r_{\ell-1} \cdot A'$$

as vector spaces; i.e., $d = (r_0, \ldots, r_{\ell-1})$ is a transversal of A' in A. In a similar way as was done for $\mathbb{C}[G]$-modules (G a group) [12, p. 73], we can construct the induced module

$$A \otimes_{A'} A' = (r_0 \otimes A') \oplus \cdots \oplus (r_{\ell-1} \otimes A'),$$

which has the basis b'. The modules A and $A \otimes'_A A'$ are isomorphic with the base change given by the matrix B. Thus, Theorem 7.3 (for polynomial algebras) is the equivalent of Theorem 3.33 (for group algebras of solvable groups) in [37]. They coincide for the case $\mathbb{C}[Z_n] \cong \mathbb{C}[x]/(x^n - 1)$ (Z_n = cyclic group of order n), where they yield the Cooley–Tukey FFT (cf. Example 7.4).

8. Fast DTTs via decomposition of polynomial transforms. In this section we derive and explain several different recursive algorithms for the DTTs directly from their algebraic interpretation. In contrast to the derivations given in the literature, we do not manipulate matrix entries; rather, we obtain the algorithm directly from the underlying modules. This makes the derivation simpler and more transparent, and provides a mathematically satisfying insight into the structure of the algorithm.

The algorithms presented in this section can be loosely grouped into the following categories:

1. *Translation* (section 8.1). A DTT is translated into another DTT using sparse matrices. Two different methods are identified.
2. *Direct sum* (section 8.2). A DTT is decomposed into the direct sum of smaller DTTs using sparse matrices. These algorithms are due to Lemma 7.1.
3. *Reduction* (section 8.3). A DTT is decomposed into smaller DTTs of the same type using sparse matrices. These algorithms are due to Theorem 7.3.

It is important to note that we can always derive, from any given fast algorithm, new fast algorithms by straightforward operations like symbolic transposition or inversion, since these are compatible with $\otimes$ and $\oplus$. As an example, a factorization like

$$\text{DCT-2}_n = P \cdot (\text{DCT-2}_{n/2} \oplus \text{DCT-4}_{n/2}) \cdot B$$

can be transposed to yield

$$\text{DCT-3}_n = B^T \cdot (\text{DCT-3}_{n/2} \oplus \text{DCT-4}_{n/2}) \cdot P^T,$$

since $\text{DCT-2}^T = \text{DCT-3}$, and DCT-4 is symmetric. Moreover, it is always possible to locally manipulate these formula expressions. As an example, let Q and R be permutations. Then

$$Q \cdot (\mathrm{I}_n \otimes \mathrm{DFT}_2) \cdot R = (QP^{-1}) \cdot (\mathrm{I}_n \otimes \mathrm{DFT}_2) \cdot (PR)$$

for any permutation P permuting (2×2)-blocks ($n!$ such P). We will consider algorithms that can be transformed into each other using manipulations of this kind as "algebraically equivalent." The comparisons between the algorithms we derive here and the algorithms from the literature have to be understood "modulo" this equivalence, though, in many cases, the comparison will be exact.

8.1. Translation between DTTs. In this section we will discuss and derive sparse relationships between the different types of DTTs. We say that DTT_n and DTT'_n are in sparse relationship if DTT_n can be derived from DTT'_n using $O(n)$ operations. An example of a sparse relationship is the equation

$$\mathrm{DTT}_n = B_n \cdot \mathrm{DTT}'_n \cdot C_n,$$

where B_n, C_n are sparse matrices ($O(n)$ entries). These relationships are important for fast algorithms. If a fast algorithm for DTT_n is given, and DTT_n and DTT'_n are in sparse relationship, then we obtain a fast algorithm for DTT'_n, and vice versa.

Examining Table 6.1, we observe that transform pairs at transposed positions (i, j) and (j, i), $i, j = 1, \ldots, 4$, have the same associated algebra (i.e., the same polynomial Q_n). As an example, DCT-5 and DCT-6 both arise from $\mathbb{C}[x]/(x-1)W_{n-1}$ with different bases. This leads to the concept of duality introduced in the next definition.

Definition 8.1 (duality). *We call a pair* DTT_n, DTT'_n *dual to each other if the left b.c. of* DTT_n *correspond to the right b.c. of* DTT'_n *and vice versa. Equivalently,* DTT_n *and* DTT'_n *appear in transposed positions* (i, j) *and* (j, i) *in Table* 6.1. *If* $i = j$, *we call* $\mathrm{DTT}_n = \mathrm{DTT}'_n$ *self-dual.*

We show how this duality can be used to derive a sparse relationship between the transforms.

In section 6 we derived a module for a given pair of b.c. by fixing (1) a base sequence of Chebyshev polynomials P_n depending on the left b.c. and (2), depending on the right b.c., a polynomial p in $\mathbb{C}[x]/p$. Since the recursion formula (4.3) for Chebyshev polynomials is symmetric, this can be done in a reverse way. We illustrate this with the pair DCT-3 and DST-3. The DST-3 has the left b.c. $a_{-1} = 0$ that fixes the base sequence U_ℓ, and it has the right b.c. $a_n = a_{n-2}$ that is fixed by $p = U_n - U_{n-2} = 0$. Alternatively, we can realize the same b.c. by the sequence T_ℓ, $\ell = -n+1, \ldots, 0$. Now the right b.c. are given by $a_{-1} = a_1$, i.e., $T_1 = T_{-1}$, which corresponds to $U_n - U_{n-2} = 0$. The left b.c. are fixed by $p = T_{-n} = T_n = 0$. The correspondence between the forward U_ℓ and the backward T_ℓ is as follows:

$$\begin{array}{l|ccc|l} 0 = U_{-1} & U_0, & \ldots, & U_{n-1} & U_n = U_{n-2}, \\ 0 = T_{-n} & T_{-(n-1)}, & \ldots, & T_0 & T_{-1} = T_1, \end{array}$$

where the vertical lines indicate the boundaries. In other words, using $T_{-\ell} = T_\ell$, the two bases $(U_0, \ldots, U_{n-1})$ and $(T_{n-1}, \ldots, T_0)$ afford identical representations of $A =$

$\mathbb{C}[x]/T_n$. Thus, the corresponding polynomial transforms must be scaled versions of each other. And indeed, if α_k denotes the zeros of T_n, we get, using basic trigonometric identities,

$$\begin{aligned} T_{n-1-\ell}(\alpha_k) &= \cos(n-1-\ell)\left(k+\tfrac{1}{2}\right)\pi/n \\ &= (-1)^k \cdot \sin\left(\ell+1\right)\left(k+\tfrac{1}{2}\right)\pi/n, \end{aligned}$$

and thus, using the definition of DST-3 and DCT-3 (Table 5.1),

$$\operatorname{diag}_{k=0}^{n-1}((-1)^k) \cdot \text{DST-3}_n = \text{DCT-3}_n \cdot \mathrm{J}_n, \tag{8.1}$$

where J_n denotes the opposite identity, i.e., the permutation matrix exchanging $i \leftrightarrow n-i$, $i = 0, \ldots, n-1$. Similar computations for all pairs of dual transforms yield the following result.

THEOREM 8.2 (translation by duality). *Let* DTT_n *and* DTT'_n *be a pair of dual transforms. Then*

$$\operatorname{diag}_{k=0}^{n-1}((-1)^k) \cdot \text{DTT}_n = \text{DTT}'_n \cdot \mathrm{J}_n\,.$$

In particular, dual DTTs have the same arithmetic complexity.

A second class of sparse relationships can be obtained in certain cases by appropriate base changes and will be explained in the following. Going back to Table 6.1, we see that the 16 DTTs are partitioned into four groups of four transforms each depending on the polynomial Q_n, which is essentially equal to one of the Chebyshev polynomials T_n, U_n, V_n, W_n. For example, on the main diagonal in Table 6.1 are all DTTs in the "U-group," which are exactly the self-dual transforms. Each of the other groups consists of two pairs of dual DTTs, respectively. For every two DTTs within the same group the corresponding algebra $\mathbb{C}[x]/Q_n$ is basically equal. The difference is in the basis chosen in the module. Thus, it is possible to derive a sparse relationship by performing an appropriate base change. We will illustrate this in the following two examples.

Example 8.3 (DCT-3 and DST-3). We consider again the pair DCT-3_n and DST-3_n. Using Table 6.1, we see that both transforms correspond to the same algebra, but with different bases,

$$\begin{aligned} \text{DCT-3}_n &\leftrightarrow \mathbb{C}[x]/T_n,\ b = (T_0, \ldots, T_{n-1}), \\ \text{DST-3}_n &\leftrightarrow \mathbb{C}[x]/T_n,\ b' = (U_0, \ldots, U_{n-1}), \end{aligned}$$

and that $\text{DCT-3}_n = [T_\ell(\alpha_k)]$ and $\text{DST-3}_n = D \cdot [U_\ell(\alpha_k)]$, where α_k are the zeros of T_n and $D = \operatorname{diag}_{k=0}^{n-1}(\sin(k+\frac{1}{2})\pi/n)$ arises from the scaling function. To compute the base change matrix B for $b \to b'$, we use that $T_\ell = \frac{1}{2}(U_\ell - U_{\ell-2})$ (by the 2nd row, 1st column in Table 4.3) and get

$$B = \frac{1}{2} \cdot \begin{bmatrix} 2 & 0 & -1 & & & \\ & 1 & 0 & -1 & & \\ & & \cdot & \cdot & \cdot & \\ & & & 1 & 0 & -1 \\ & & & & 1 & 0 \\ & & & & & 1 \end{bmatrix}.$$

Thus, $[T_\ell(\alpha_k)] = [U_\ell(\alpha_k)] \cdot B$, and hence

$$D \cdot \text{DCT-3}_n = \text{DST-3}_n \cdot B.$$

Note that this relationship is different from the one arising from the duality of DCT-3_n and DST-3_n (Theorem 8.2).

Example 8.4 (DCT-1 and DST-2). We will translate a DCT-1_{n+1} into a DST-2_n. Using Table 6.1 again, we get as associated algebras and bases

$$\begin{aligned} \text{DCT-1}_{n+1} &\leftrightarrow \mathbb{C}[x]/(x^2-1)U_{n-1}, \quad b &= (T_0,\dots,T_n),\\ \text{DST-2}_n &\leftrightarrow \mathbb{C}[x]/(x+1)U_{n-1}, \quad b' &= (W_0,\dots,W_{n-1}). \end{aligned}$$

Note that we have to choose size $n+1$ and n, respectively, to obtain comparable algebras. We have DCT-$1_{n+1} = [T_\ell(\alpha_k)]$ and DST-$2_n = D \cdot [W_\ell(\alpha_k)]$, where $\alpha_k = \cos k\pi/n$, $k = 0,\dots,n$, are the zeros of $(x^2-1)U_{n-1}$ (2nd row in Table 4.2). For the DST-2_n, $\alpha_0 = 1$ is skipped. The scaling matrix is $D = \operatorname{diag}_{k=0}^{n-1}(\sin(k+1)\pi/2n)$ (Table 6.2). We compute the base change matrix B for

$$\mathbb{C}[x]/(x^2-1)U_{n-1} \cong \mathbb{C}[x]/(x-1) \oplus \mathbb{C}[x]/(x+1)U_{n-1}.$$

The bases are $b, (1), b'$, respectively. Using $T_\ell = \frac{1}{2}(W_\ell - W_{\ell-1})$ (4th row, 3rd column in Table 4.3) and $T_n = \frac{1}{2}(W_n - W_{n-1}) \equiv -W_{n-1} \bmod (x+1)U_{n-1}$ (because, again from Table 4.3, $(x+1)U_{n-1} = \frac{1}{2}(W_n + W_{n-1})$), we get

$$B = \frac{1}{2} \cdot \begin{bmatrix} 2 & 2 & 2 & \cdot & \cdot & 2 \\ 2 & -1 & & & & \\ & 1 & -1 & & & \\ & & \cdot & \cdot & & \\ & & & \cdot & -1 & \\ & & & & 1 & -2 \end{bmatrix}.$$

The 1's in the first row are due to $T_\ell(1) = 1$ (Lemma 4.2). We get $[T_\ell(\alpha_k)] = (\mathrm{I}_1 \oplus [W_\ell(\alpha_k)]) \cdot B$ and hence

$$(\mathrm{I}_1 \oplus D) \cdot \text{DCT-1}_{n+1} = (\mathrm{I}_1 \oplus \text{DST-2}_n) \cdot B.$$

We obtain the following theorem.

THEOREM 8.5 (translation by base change). *All DTTs of types* 1–4 *are in sparse relationship. All DTTs of types* 5–8 *are in sparse relationship.*

Proof. Similar computations as in Examples 8.3 and 8.4 show that all DTTs of types 1 and 2 (the "U-group") are in sparse relationship, and that all DTTs of types 3 and 4 (the "T-group") are in sparse relationship. By transposition, we obtain sparse relationship for DTTs of types 2 and 4 and thus for all DTTs of types 1–4, which is the first assertion. The other statement is proved analogously. ∎

Of particular importance is the translation between a DCT-4 and DCT-2, which, together with Theorem 8.6, yields a fast algorithm for the DCT-2 (see [28]).

Remarks. (1) Aside from Definition 8.1 there is another, more obvious, form of duality among the DTTs: DTT and DTT′ are dual if $\text{DTT}^T = \text{DTT}'$. Currently, we have no algebraic explanation for this duality. (2) Note that "sparse relationship" does not define an equivalence relation. Every two matrices (of the same size) can be converted into each other using a (long enough) sequence of sparse matrices.

8.2. Direct sum: Fast algorithms via polynomial factorization. In this section we will derive recursive algorithms for all DTTs in the U-group, i.e., the DCT and DST of types 1 and 2. The algorithms are based on the rational factorization of the polynomials U_n given in Lemma 4.2(ii)–(iii).

As an example we will consider a DCT-2_n, where $n = 2m$. Consulting Table 6.1, we get as corresponding algebra $\mathbb{C}[x]/(x-1)U_{n-1}$ with basis $b = (V_0, \ldots, V_{n-1})$. Lemma 4.2(ii) gives the factorization $U_{2m-1} = 2 \cdot U_{m-1} \cdot T_m$, which leads to the isomorphism

$$\mathbb{C}[x]/(x-1)U_{2m-1} \cong \mathbb{C}[x]/(x-1)U_{m-1} \oplus \mathbb{C}[x]/T_m. \tag{8.2}$$

For the summands we choose bases b, b', b', respectively, $b' = (V_0, \ldots, V_{m-1})$. The zeros of $(x-1)U_{n-1}$ are $\cos k\pi/n$, $k = 0, \ldots, n-1$. Thus, the first summand in (8.2) collects the zeros with even k, and the second summand the zeros with odd k (cf. Table 4.2). Now the decomposition of DCT-2_n follows Lemma 7.1. To compute the base change matrix B in (8.2) we need

$$\begin{aligned} &V_{m+k} \equiv V_{m-k-1} \bmod (x-1)U_{m-1} \text{ and} \\ &V_{m+k} \equiv -V_{m-k-1} \bmod T_m, \end{aligned}$$

which can be shown by induction using $(x-1)U_{m-1} = V_m - V_{m-1}$, $T_m = V_m + V_{m+1}$, and (4.3). We get

$$B = \begin{bmatrix} 1 & & & & & 1 \\ & . & & & . & \\ & & 1 & 1 & & \\ 1 & & & & & -1 \\ & . & & & . & \\ & & 1 & -1 & & \end{bmatrix} = \begin{bmatrix} \mathrm{I}_m & \mathrm{J}_m \\ \mathrm{I}_m & -\mathrm{J}_m \end{bmatrix} = (\mathrm{DFT}_2 \otimes \mathrm{I}_m)(\mathrm{I}_m \oplus \mathrm{J}_m).$$

The summands in (8.2) are decomposed recursively using a DCT-2_m and DCT-4_m, respectively. The resulting one-dimensional summands are permuted in canonical order using the stride permutation L^n_m (see section 2). Since DCT-2 and DCT-4 have the same scaling function, we get

$$\text{DCT-2}_{2m} = \mathrm{L}^{2m}_m \cdot (\text{DCT-2}_m \oplus \text{DCT-4}_m) \cdot B.$$

Besides DCT-2, similar derivations can be performed on the three remaining transforms in the U-group, DCT-1, DST-1, and DST-2, using $U_{2m-1} = 2U_{m-1}T_m$ and using $U_{2m} = V_m W_m$. The complete set of identities can be stated using two types of block matrices and two types of permutation matrices. The block matrices give the base change

$$B_{2m} = \begin{bmatrix} \mathrm{I}_m & \mathrm{J}_m \\ \mathrm{I}_m & -\mathrm{J}_m \end{bmatrix}, \quad B_{2m+1} = \begin{bmatrix} \mathrm{I}_m & 0 & \mathrm{J}_m \\ 0 & 1 & 0 \\ \mathrm{I}_m & 0 & -\mathrm{J}_m \end{bmatrix},$$

and the permutation matrices give the reordering of the irreducible modules

$$\begin{aligned} &P_{2m} = \mathrm{L}^{2m}_m, \\ &P_{2m+1} : \ i \to (m+1)i \bmod 2m+1, \quad i = 0, \ldots, 2m. \end{aligned}$$

THEOREM 8.6. *The following recursive algorithms for DTTs are based on the rational factorization $U_{2m-1} = 2 \cdot U_{m-1} \cdot T_m$. We also indicate where they first appeared in the literature (to our best knowledge).*

(i) DCT-$1_{2m+1} = P_{2m+1} \cdot (\text{DCT-1}_{m+1} \oplus \text{DCT-3}_m) \cdot B_{2m+1}$ [27].

(ii) $\text{DST-1}_{2m-1} = P_{2m-1} \cdot (\text{DST-3}_m \oplus \text{DST-1}_{m-1}) \cdot B_{2m-1}$ [55].
(iii) $\text{DCT-2}_{2m} = P_{2m} \cdot (\text{DCT-2}_m \oplus \text{DCT-4}_m) \cdot B_{2m}$ [7].
(iv) $\text{DST-2}_{2m} = P_{2m} \cdot (\text{DST-4}_m \oplus \text{DST-2}_m) \cdot B_{2m}$ [52].

Theorem 8.6 is complemented by the decompositions in the following theorem. We did not find these in the literature.

THEOREM 8.7. *The following recursive algorithms for DTTs are based on the rational factorization* $U_{2m} = V_m W_m$.

(i) $\text{DCT-1}_{2m} = P_{2m} \cdot (\text{DCT-5}_m \oplus \text{DCT-7}_m) \cdot B_{2m}$.
(ii) $\text{DST-1}_{2m} = P_{2m} \cdot (\text{DST-7}_m \oplus \text{DST-5}_m) \cdot B_{2m}$.
(iii) $\text{DCT-2}_{2m+1} = P_{2m+1} \cdot (\text{DCT-6}_{m+1} \oplus \text{DCT-8}_m) \cdot B_{2m+1}$.
(iv) $\text{DST-2}_{2m+1} = P_{2m+1} \cdot (\text{DST-8}_{m+1} \oplus \text{DST-6}_m) \cdot B_{2m+1}$.

Remarks. (1) Transposition of the decompositions in Theorems 8.6 and 8.7 yields algorithms for the DTTs of type 3. (2) Theorem 8.6 reveals why the DCT-1 and the DST-1 are usually considered at sizes $2^k + 1$ and $2^k - 1$, respectively. The available algorithms are more efficient since there are no simple sparse factorizations of the DTTs of types 5–8. (3) Combining Theorems 8.5 and 8.6 gives a complete set of algorithms for the DTTs of types 1–4, of 2-power size. (For type 1 the size differs by 1; see remark (2).) (4) It is possible to derive algorithms for the more general case $n = k\ell$, using the factorization in Lemma 4.2(ii).

8.3. Reduction: Fast algorithms via polynomial decomposition. In this section we derive algorithms based on the decomposition of the polynomial T_n in Lemma 4.2(i). This decomposition property allows the decomposition of all *DTTs* in the T-group, i.e, DCT and DST of types 3 and 4, using Theorem 7.3.

As an example we will consider a DCT-3_n, where $n = 2m$. Using Table 6.1, we get the corresponding algebra $\mathbb{C}[x]/T_n$ with basis $b = (T_0, \ldots, T_{n-1})$. We use the decomposition $T_{2m} = T_m(T_2)$ (Lemma 4.2). Following Theorem 7.3 and its proof, we choose bases $c = (T_0, \ldots, T_{m-1})$ and $d = (T_0, T_1)$ of $\mathbb{C}[x]/T_m$ and $\mathbb{C}[x]/T_2$, respectively. We get the new basis

$$b' = (T_0, T_2, \ldots, T_{2m-2}, T_1, (T_1 + T_3)/2, \ldots, (T_{2m-3} + T_{2m-1})/2).$$

Thus, the base change $b' \to b$ is given by

$$B = \begin{bmatrix} 1 & & & 0 & & & \\ 0 & 0 & & 1 & \frac{1}{2} & & \\ 0 & 1 & & 0 & 0 & & \\ 0 & 0 & & 0 & \frac{1}{2} & \frac{1}{2} & \\ & \vdots & & & & \vdots & \\ & & & & & & \frac{1}{2} \\ & & 1 & & & & 0 \\ & & 0 & & & & \frac{1}{2} \end{bmatrix},$$

and the base change $b \to b'$ by B^{-1}. The zeros of T_n are $\alpha_k = \cos(k + \frac{1}{2})\pi/n$, $\alpha_k = -\alpha_{n-1-k}$, and $T_2(\alpha_k) = T_2(\alpha_{n-1-k})$. Thus, the permutation P in Theorem 7.3 is $P = (\text{I}_m \oplus \text{J}_m)$. Further,

$$\mathcal{P}_{d,\overline{\alpha}_i} = \begin{bmatrix} T_0(\alpha_i) & T_1(\alpha_i) \\ T_0(\alpha_{n-1-i}) & T_1(\alpha_{n-1-i}) \end{bmatrix} = \begin{bmatrix} 1 & \alpha_i \\ 1 & -\alpha_i \end{bmatrix} = \text{DFT}_2 \cdot \text{diag}(1, \alpha_i)$$

for $i = 0, \ldots, m$. This can be used to derive $(\bigoplus_{i=0}^{m-1} \mathcal{P}_{d,\overline{\alpha}_i})^{\text{L}_m^{2m}} = (\text{DFT}_2 \otimes \text{I}_m) \cdot$

$(\mathrm{I}_m \oplus \mathrm{diag}_{i=0}^{m-1}(\alpha_i))$, and we get

$$\text{DCT-3}_{2m} = P \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_m) \cdot (\mathrm{I}_m \oplus \mathrm{diag}_{i=0}^{m-1}(\alpha_i)) \cdot (\mathrm{I}_2 \otimes \text{DCT-3}_m) \cdot B^{-1}.$$

Further simplification can be achieved by writing $B = C \cdot (\mathrm{I}_m \oplus \frac{1}{2}\,\mathrm{I}_m)$ and observing that $\mathrm{I}_m \oplus 2\,\mathrm{I}_m$ commutes with $\mathrm{I}_2 \otimes \text{DCT-3}_m$. For simplicity we set $D = \mathrm{diag}_{i=0}^{m-1}(\alpha_i)$ and get

$$\text{DCT-3}_{2m} = P \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_m) \cdot (\mathrm{I}_m \oplus 2D) \cdot (\mathrm{I}_2 \otimes \text{DCT-3}_m) \cdot C^{-1}. \tag{8.3}$$

Equation (8.3) is also a good example for studying the effect of transposition and inversion on deriving new algorithms from known ones. Transposition of (8.3) is straightforward and yields

$$\text{DCT-2}_{2m} = C^{-T} \cdot (\mathrm{I}_2 \otimes \text{DCT-2}_m) \cdot (\mathrm{I}_m \oplus 2D) \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_m) \cdot P. \tag{8.4}$$

For the inversion of (8.3) we need $\text{DCT-3}_n^{-1} = \frac{2}{n} \cdot \mathrm{diag}(\frac{1}{2}, 1, \ldots, 1) \cdot \text{DCT-2}_n$. After simplifications we get

$$\text{DCT-2}_{2m} = C_1 \cdot (\mathrm{I}_2 \otimes \text{DCT-2}_m) \cdot (\mathrm{I}_m \oplus (2D)^{-1}) \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_m) \cdot P, \tag{8.5}$$

where C_1 arises from C by setting the entry 2 at position $(2, m+1)$ to 1. C_1 incurs only additions. Transposing (8.5) (or, equivalently, inverting (8.4)) yields again an algorithm for DCT-3,

$$\text{DCT-3}_{2m} = P \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_m) \cdot (\mathrm{I}_m \oplus (2D)^{-1}) \cdot (\mathrm{I}_2 \otimes \text{DCT-3}_m) \cdot C_1^T. \tag{8.6}$$

Equations (8.5) and (8.6) are very similar to (8.4) and (8.3), respectively, with the difference that inverting the entries in the diagonal (middle factor) saves one multiplication by 2 in the base change matrix (C_1 vs. C). More crucial, the additions in C_1 and C_1^T can be performed in parallel (i.e., the critical path has length 1), which does not hold for C^{-1} and C^{-T}.

Each of the equations (8.3)–(8.6) occurs in the literature. The references are (8.3) and (8.4) in [24], (8.5) in [57] (transposed definition of DTTs), and (8.6) in [28] and [56] (transposed definition of DTTs).

Note that (8.4) can also be obtained by first applying Theorem 8.6(iii) and then translating the resulting DCT-4 using Theorem 8.5.

Similar computations for the other DTTs in the T-group yield the following result.

THEOREM 8.8. *Let $n = 2m$. All DTTs in the T-group have a fast recursive algorithm of the form*

$$\mathrm{DTT}_{2m} = P \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_m) \cdot (\mathrm{I}_m \oplus D) \cdot (\mathrm{I}_2 \otimes \mathrm{DTT}_m) \cdot B,$$

where P is a permutation matrix, D is diagonal, and B is sparse. This factorization is based on $T_{2m} = T_m(T_2)$, and the concrete form of P and B can be obtained using Theorem 7.3.

For the DST-3 the factorization can also be found in [56]. For DCT-4 and DST-4, the factorizations do not appear in the literature. They are less efficient with respect to arithmetic cost.

Remark. It is possible to derive a recursive algorithm based on $T_{k\ell} = T_n(T_m)$ using Theorem 7.3. The problem for larger m is the further decomposition of the occurring matrices $\mathcal{P}_{d,\overline{\alpha}_i}$ in Theorem 7.3.

9. Fast DTTs via group symmetries. In this section we will derive fast DTT algorithms that are based on "group symmetries" in the sense defined below. In the cases where they occur, these symmetries are a direct consequence of the DTT properties in Theorem 6.2. We will identify two ways in which group symmetries might come into play.

1. *Extension* (section 9.2). By extension to a group algebra of the algebra $A = \mathbb{C}[x]/p$ associated to a DTT.

2. *Automorphisms* (section 9.3). By subgroups of the automorphism group of A.

These symmetries lead to algorithms that are substantially different from the ones derived in section 8.

For the convenience of the reader, we briefly overview group symmetry–based matrix factorization. In the following we take a "representation" approach, instead of the equivalent "module-with-basis" point of view.

9.1. Group symmetry–based matrix factorization. Matrix factorization based on group symmetries has its origin in [31, 32] and was generalized in [15, 36, 37, 19] to the form presented here. In [18] the technique was successfully applied to several discrete signal transforms, which initiated the research presented in this paper. Due to space limitations we can give only a brief overview and refer to those references for further details.

In the following, G is a finite solvable group. All representations of G (or, equivalently, of $\mathbb{C}[G]$) in the following arise from *right* G-modules. The entire approach is based on the following definition of symmetry.

DEFINITION 9.1. *Let B be an arbitrary complex matrix. A pair (ϕ_1, ϕ_2) of representations of G is called a* symmetry *of B if*

$$\phi_1(g) \cdot B = B \cdot \phi_2(g) \quad \textit{for } g \in G.$$

G is then called a symmetry group *of B.*

If B has a symmetry, we can factor B according to Figure 9.1. We choose matrices A_1, A_2 that decompose ϕ_1, ϕ_2, respectively, into a direct sum of irreducible representations ρ_1 and ρ_2. Then we compute the matrix

$$D = A_1^{-1} \cdot B \cdot A_2$$

so that the diagram commutes. We obtain the factorization

$$B = A_1 \cdot D \cdot A_2^{-1}.$$

The matrix D is sparse since it is the conjugating matrix for two reduced representations ρ_1, ρ_2 (a consequence of Schur's lemma [12]). This means that the factorization of B is useful as a fast algorithm for B if the A_i's are sparse or can themselves be written as products of sparse matrices. This is possible in at least the following two cases: (1) ϕ_i is a permuted direct sum of irreducible representations, i.e., $\phi_i = \rho_i^P$, where P is a permutation matrix. In this case we say that ϕ_i is of type "irred." It is $A_i = P^{-1}$. (2) ϕ_i is monomial. (A representation is monomial if all its images are monomial matrices, i.e., have exactly one nonzero entry in each row and column.) In this case we say that ϕ_i is of type "mon." The decomposition matrix A_i can be determined as a product of sparse matrices using the algorithm in [37]. Briefly sketched, this algorithm translates the monomial representation into

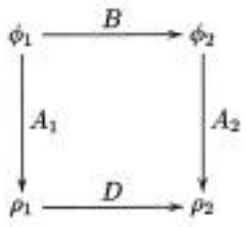

FIG. 9.1. *Factorization of the matrix M with symmetry (ϕ_1, ϕ_2).*

TABLE 9.1
Types of symmetry that can be used for factorizing B (irrs = irreducible representations).

mon-mon symmetry	ϕ_1 and ϕ_2 monomial
mon-irred symmetry	ϕ_1 monomial, ϕ_2 permuted direct sum of irrs
irred-mon symmetry	ϕ_2 monomial, ϕ_1 permuted direct sum of irrs

an induction that is decomposed stepwise along a composition series using certain recursion formulas similar to Theorem 7.3. We say that ϕ_i is of type "mon."

Depending on the types of the ϕ_i, we obtain the three types of symmetry shown in Table 9.1. We have omitted the type "irred-irred" since it requires that B already be sparse.

Algorithms for finding symmetry [19] and the algorithm [37] for the stepwise decomposition of monomial representations have been implemented as part of the GAP [22] share package AREP [17, 16] for constructive group representation theory. Thus, AREP can find these factorizations automatically and can be used as a discovery tool for sparse matrix factorizations, i.e., fast algorithms.

In the remainder of this section, we will show that mon-irred symmetries as well as mon-mon symmetries occur among the DTTs and how these symmetries can be derived. We will also discuss the structure of the resulting algorithms.

9.2. Algorithms by extension to group algebras. In this section we will show which DTTs possess a mon-irred symmetry that can be used for deriving fast algorithms. In [18] exactly four DTTs exhibited a mon-irred symmetry with dihedral symmetry groups in all cases. The transforms were the DCT and DST of types 3 and 4. We will now explain and derive these symmetries. Note that we will deal with right representations (arising from right modules) to comply with the symmetry definition 9.1. A right representation is the transpose of a left representation.

We start with the general case of a scaled polynomial transform. As usual, let b be a basis of $A = \mathbb{C}[x]/p$, and let α be the zero vector of p. Further, let f be a scaling function. If ϕ is the *right* representation afforded by the regular module A (or, equivalently, $f \cdot A$), then, by Lemma 3.6,

$$\phi \cdot \mathcal{P}^T_{f \cdot b, \alpha} = \mathcal{P}^T_{f \cdot b, \alpha} \cdot \rho,$$

where ρ is a direct sum of one-dimensional irreducible representations of A. If ϕ can be extended to a representation $\overline{\phi}$ of a group algebra $\mathbb{C}[G]$ of a finite group G, then ρ extends to a permuted direct sum of irreducible representations of $\mathbb{C}[G]$. (On extension, the one-dimensional irreducibles in ρ—not necessarily adjacent ones—may

fuse to irreducibles of $\mathbb{C}[G]$ of larger dimension.) In other words, $\mathcal{P}^T_{f\cdot b,\alpha}$ decomposes $\overline{\phi}$, up to a permutation. We obtain the following result.

LEMMA 9.2. *We use previous notation. If the right regular representation ϕ of $A = \mathbb{C}[x]/p$ can be extended to a representation $\overline{\phi}$ of a group algebra $\mathbb{C}[G]$, where G is finite, then*

$$\overline{\phi} \cdot \mathcal{P}^T_{f\cdot b,\alpha} = \mathcal{P}^T_{f\cdot b,\alpha} \cdot \overline{\rho},$$

where $\overline{\rho}$ is a permuted direct sum of irreducible representations of $\mathbb{C}[G]$. If, in particular, $\overline{\phi}$ is monomial, then $\mathcal{P}^T_{f\cdot b,\alpha}$ has a mon-irred symmetry, and $\mathcal{P}_{f\cdot b,\alpha}$ has an irred-mon symmetry, both with symmetry group G.

Now we will apply Lemma 9.2 to determine which DTTs possess a mon-irred symmetry. Consider a fixed DTT with associated regular representation ϕ. The representation ϕ can be extended to a monomial representation iff all images $\phi(q)$, $q \in A$, can be written as a linear combination of monomial matrices. Since A is cyclic, it is sufficient to consider the images of the generator $\phi(x)$, which is given by the corresponding matrix $B(\cdot)$ in (5.1).

THEOREM 9.3. *The four transforms* DCT_n *and* DST_n *of types* 3 *and* 4, $n \geq 0$, *are the only DTTs that have a mon-irred symmetry (ϕ, ρ). Denote by $D_{2k} = \langle \sigma, \tau \mid \sigma^2 = \tau^2 = (\sigma\tau)^k = 1 \rangle$ the dihedral group with $2k$ elements. Further, let, for even n,*

$$\pi_1 = (1,2)(3,4), \ldots, (n-1,n) \quad \textit{and} \quad \pi_2 = (2,3)(4,5), \ldots, (n-2,n-1),$$

and, for odd n,

$$\pi_1 = (1,2)(3,4), \ldots, (n-2,n-1) \quad \textit{and} \quad \pi_2 = (2,3)(4,5), \ldots, (n-1,n)$$

(viewed as a permutation on $\{1, \ldots, n\}$). The symmetry group for DCT-3_n *and* DST-3_n *is D_{2n}, for* DCT-4_n *and* DST-4_n *is D_{4n}. The respective monomial representation ϕ is given for even n by*

$$\begin{array}{ll}
\text{DCT-3}_n: & \sigma \mapsto [\pi_1, n],\ \tau \mapsto [\pi_2, n], \\
\text{DST-3}_n: & \sigma \mapsto [\pi_1, n],\ \tau \mapsto [\pi_2, (-1, 1, \ldots, 1, -1)], \\
\text{DCT-4}_n: & \sigma \mapsto [\pi_1, n],\ \tau \mapsto [\pi_2, (1, \ldots, 1, -1)], \\
\text{DST-4}_n: & \sigma \mapsto [\pi_1, n],\ \tau \mapsto [\pi_2, (-1, 1 \ldots, 1,)],
\end{array}$$

and for odd n by

$$\begin{array}{ll}
\text{DCT-3}_n: & \sigma \mapsto [\pi_1, n],\ \tau \mapsto [\pi_2, n], \\
\text{DST-3}_n: & \sigma \mapsto [\pi_1, (1, \ldots, 1, -1)],\ \tau \mapsto [\pi_2, (-1, 1, \ldots, 1)], \\
\text{DCT-4}_n: & \sigma \mapsto [\pi_1, (1, \ldots, 1, -1)],\ \tau \mapsto [\pi_2, n], \\
\text{DST-4}_n: & \sigma \mapsto [\pi_1, n],\ \tau \mapsto [\pi_2, (-1, 1 \ldots, 1,)].
\end{array}$$

Proof. For all 16 DTTs and their associated representations ϕ, we have to consider the matrices $\phi(x) = B(\beta_1, \beta_2, \beta_3, \beta_4)$, with β_i as given in Table 5.2. Because of its structure, $B(\cdot)$ can be written as a linear combination of monomial matrices iff it can be written as the sum of two monomial matrices. Assume $\beta_1 = 0$. Writing $B(0, \ldots)$ as the sum of two monomial matrices M_1, M_2 requires that both M_1 and M_2 have an entry $\neq 0$ at position $(1,2)$. Since the entry $(3,2)$ of $B(0, \ldots)$ is also $\neq 0$, this decomposition is not possible. Analogously, a decomposition is not possible if $\beta_4 = 0$. In the remaining four cases the decomposition is possible and yields the desired results. We will give one case as an example. It is readily verified that

$$B(1,1,1,1) = [\pi_1, n] + [\pi_2, n].$$

The permutations π_1, π_2 are involutions and hence generate a dihedral group D_{2m}. The number m is the order of the product $\pi_1\pi_2$, here n. By Theorem 6.2 and Table 5.2, $B(1,1,1,1)$ is diagonalized by DCT-3_n, which proves the result. The other three cases can be treated analogously. □

Remark. Theorem 9.3 explains the symmetries found in [18].

We want to briefly sketch the decomposition procedure for a DCT-4. For full details we refer the reader to [18, 19, 37].

Example 9.4 (DCT-4). We consider a DCT-4 of size $n = 2^k$. By Theorem 9.3, the matrix $B = \text{DCT-4}_{2^k}$ has a mon-irred symmetry (ϕ, ρ) with dihedral symmetry group $D_{2^{k+2}}$. We follow Figure 9.1. The decomposition algorithm will decompose ϕ stepwise along the composition series

$$D_{2^{k+2}} \geq D_{2^{k+1}} \geq \cdots \geq D_{2^2},$$

using a recursion formula for the induction of representations. Note that the last representation of D_{2^2} is decomposed since it is of dimension 1. This gives rise to a factorized decomposition matrix A_1 of ϕ. The representation ρ is a permuted direct sum of irreducible representations and can thus be decomposed by a permutation matrix A_2. The correction matrix D is computed as $D = A_1^{-1} \cdot B \cdot A_2$ to yield

$$\text{DCT-4}_{2^k} = A_1 \cdot D \cdot A_2^{-1}.$$

As an example, we give a factorization of a DCT-4_8 as it is automatically found by AREP,

$$\begin{aligned}
\text{DCT-4}_8 \quad = \quad & [(1,2,8)(3,6,5), (1,-1,1,1,1,-1,1,1)] \\
& \cdot (\mathrm{I}_2 \otimes ((\mathrm{I}_2 \oplus \tfrac{1}{\sqrt{2}} \cdot \mathrm{DFT}_2) \cdot [(3,4),4] \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_2))) \\
& \cdot [(1,3)(2,4)(5,7)(6,8),8] \cdot (\mathrm{I}_4 \oplus \mathrm{R}_{\frac{15}{8}\pi} \oplus \mathrm{R}_{\frac{11}{8}\pi}) \\
& \cdot (\mathrm{DFT}_2 \otimes \mathrm{I}_4) \cdot [(3,5,7)(4,6,8),8] \\
& \cdot \tfrac{1}{2} \cdot (\mathrm{R}_{\frac{31}{32}\pi} \oplus \mathrm{R}_{\frac{19}{32}\pi} \oplus \mathrm{R}_{\frac{27}{32}\pi} \oplus \mathrm{R}_{\frac{23}{32}\pi}) \\
& \cdot [(1,8,5,6,3,2)(4,7),8].
\end{aligned} \tag{9.1}$$

The (factorized) matrix A_1 is given in lines 1–4, the matrix D in line 5, and the matrix A_2^{-1} in line 6 (the last line).

We observe that the factorization in (9.1) contains rotation matrices

$$R_a = \begin{bmatrix} \cos(a) & \sin(a) \\ -\sin(a) & \cos(a) \end{bmatrix},$$

which do not occur in the algorithms derived in section 8. The general (arbitrary $n = 2^k$) version of this algorithm can be found in [7] (corrected in [51, 52]). Combining this algorithm with Theorem 8.6(iii) yields a factorization of DCT-2, and thus, by transposition, of DCT-3, into rotation matrices [7]. The obtained algorithm coincides with the one derived from the mon-irred symmetry of the DCT-3.

Note that the algorithms arising from a mon-irred symmetry occur only in an iterative form in the literature; i.e., the transform matrix is completely factorized (as in (9.1)) and not into transforms of smaller size. The reason is in the decomposition procedure (cf. Figure 9.1), since not B, but A_1 is decomposed recursively.

Remark. It is striking that, e.g., the algorithm for a DCT-3_{2^k} arising from its mon-irred symmetry and the algorithm from Theorem 8.8 have precisely the same arithmetic cost [7, 28, 56].

9.3. Algorithms from automorphism groups. In section 9.2 we showed how, in certain cases, a mon-irred symmetry of a DTT can be derived from its interpretation as a (scaled) polynomial transform. In the following we will show that a—completely different—type of mon-mon symmetry also occurs among the DTTs. This type of symmetry, if present, arises from the automorphism group of the associated algebra. All modules in this section will be right modules.

We introduce the following notation. Let $A = \mathbb{C}[x]/p$. Automorphisms of A will be denoted by letters g, h. We multiply automorphisms from left to right; i.e., in gh, g is applied before h. This complies with applying automorphisms from the right; i.e., if $q \in A$, we write q^g for the image of q under g. If ϕ is a representation of A, and g an automorphism, then $\phi^g : \ q \mapsto \phi(q^g)$ defines another representation of A. As suggested by this notation, $(\phi^g)^h = \phi^{gh}$.

A possible source of a mon-mon symmetry of a polynomial transform $\mathcal{P}_{b,\alpha}$ is described in the following theorem.

THEOREM 9.5. *Let $A = \mathbb{C}[x]/p$ be a regular module with basis b. The polynomial p is separable and has zeros $\alpha = (\alpha_0, \ldots, \alpha_{n-1})$. Denote by ϕ the (right regular) representation afforded by A and b. Assume that A has a group G of automorphisms with the property that for each $g \in G$ there exists a monomial matrix M_g with*

$$\phi^g = \phi^{M_g{}^{-1}}. \tag{9.2}$$

Then $\mathcal{P}_{b,\alpha}^T$ has a mon-mon symmetry (χ, ψ) with symmetry group $\overline{G} \cong \langle M_g \mid g \in G \rangle$. Then $G \cong \overline{G}/N$, where $N \trianglelefteq \overline{G}$ denotes the normal subgroup defined by

$$\begin{aligned} g' \in N &\Leftrightarrow \phi(q) \cdot \chi(g') = \chi(g') \cdot \phi(q) \quad \textit{for all } q \in A \\ &\Leftrightarrow \chi(g') \in \phi(A). \end{aligned}$$

If D is any invertible diagonal matrix, then $(D \cdot \mathcal{P}_{b,\alpha})^T = \mathcal{P}_{b,\alpha}^T \cdot D$ has the same mon-mon symmetry as $\mathcal{P}_{b,\alpha}^T$.

Proof. First we note that the set $S = \{M_g \mid g \in G\}$ is not a group, since for every g there are (if any) many possible choices for M_g, e.g., all $a \cdot M_g$, where $a \in \mathbb{C}$. Conversely, every $M_g \in S$ uniquely defines an automorphism of A, since $\phi^g = \phi^h$, and ϕ faithful, implies $g = h$. Now we reverse the situation by defining a mapping $\gamma : \ S \to G$, $M_g \mapsto g$. Let $\overline{G} = \langle S \rangle$ (the group generated by S). Then γ can be extended to a homomorphism $\overline{\gamma} : \ \overline{G} \to G$, since, for $M, M' \in S$ and using (9.2),

$$\phi^{\overline{\gamma}(MM')} = \phi^{(MM')^{-1}} = (\phi^{M'^{-1}})^{M^{-1}} = (\phi^{\overline{\gamma}(M')})^{M^{-1}} = (\phi^{M^{-1}})^{\overline{\gamma}(M')} = \phi^{\overline{\gamma}(M)\overline{\gamma}(M')}.$$

By definition, $\overline{\gamma}$ is surjective, and the kernel of $\overline{\gamma}$ is given by $N = \{M \mid \phi = \phi^M\}$, and thus $G \cong \overline{G}/N$. Since $M \in N$ implies that M commutes with each $\phi(q)$, $q \in A$, $M \in \phi(A)$. Viewing $\overline{G}$ as a monomial representation χ of itself shows all assertions on $\overline{G}$.

It remains to show that $\mathcal{P}_{b,\alpha}^T$ has a mon-mon symmetry (χ, ψ). To this end we choose an arbitrary monomial matrix $M = \chi(M)$ in $\overline{G}$. The representation ϕ is decomposed by $\mathcal{P}_{b,\alpha}^T$ into a direct sum of irreducible representations ρ (cf. Lemma 3.2). Thus, $\phi^{\overline{\gamma}(M)}$ is also decomposed by $\mathcal{P}_{b,\alpha}^T$ into a direct sum of irreducible representations ρ'. Following Figure 9.2, there is a unique matrix M' such that

$$M \cdot \mathcal{P}_{b,\alpha}^T = \mathcal{P}_{b,\alpha}^T \cdot M'.$$

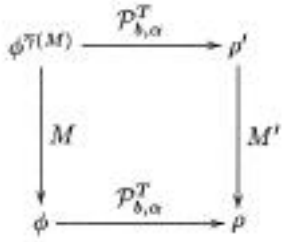

FIG. 9.2. *Constructing a mon-mon symmetry for* $\mathcal{P}^T_{b,\alpha}$.

Since M' conjugates ρ' onto ρ, it is monomial. Setting $\psi(M) = M'$ defines a monomial representation of $\overline{G}$ and shows that $\mathcal{P}^T_{b,\alpha}$ has the mon-mon symmetry (χ, ψ).

If D is any invertible diagonal matrix, then $\rho^D = \rho$ and ${\rho'}^D = \rho'$, since all irreducible summands of ρ, ρ' are of dimension 1. Thus, we can replace $\mathcal{P}^T_{b,\alpha}$ by $\mathcal{P}^T_{b,\alpha} \cdot D$ in Figure 9.2, obtaining the same mon-mon symmetry. This completes the proof. □

Remarks. (1) $\mathcal{P}^T_{b,\alpha}$ has the mon-mon symmetry (χ, ψ) iff $\mathcal{P}_{b,\alpha}$ has the mon-mon symmetry (ψ^T, χ^T). (2) The last assertion in Theorem 9.5 shows that we can apply it to scaled polynomial transforms and thus to the DTTs.

In the remainder of this section, we will use Theorem 9.5 to derive the mon-mon symmetries for the DTTs whose transposes are in the T-group, i.e., those with associated algebra $\mathbb{C}[x]/T_n$ (cf. Table 6.1) for the special case where $n = 2^m$ is a 2-power. A complete investigation of all DTTs and sizes would exceed the space available.

First we need a suitable group G of automorphisms of $A = \mathbb{C}[x]/T_n$.

LEMMA 9.6. *Let* $n = 2^m$ *and* $A = \mathbb{C}[x]/T_n$. *Each mapping*

$$g_k : T_1 \mapsto T_k \quad \text{and} \quad g_{-k} : T_1 \mapsto -T_k, \qquad 1 \le k \le n, \ k \text{ odd},$$

defines an automorphism of the algebra A. *The set* G_n *of all such* $g_{\pm k}$ *is a cyclic group of order* n.

Proof. Before we start the proof we investigate the sequence T_k, $k \ge 0$, in A. The following two equations allow the reduction of each T_k modulo T_n:

$$\begin{aligned} 0 \equiv T_n T_{n-k} = \tfrac{1}{2}(T_{2n-k} + T_k) \quad &\Rightarrow \quad T_k \equiv -T_{2n-k}, \\ 0 \equiv T_n T_{n+k} = \tfrac{1}{2}(T_{2n+k} + T_k) \quad &\Rightarrow \quad T_k \equiv -T_{2n+k}. \end{aligned} \tag{9.3}$$

The latter equation also shows that $T_k \equiv T_{k+4n}$, i.e., the sequence T_k, $k \ge 1$, has period $4n$ (in A). Using (9.3), we can compute the reduced T_k, $k = 0, \ldots, 4n-1$, as

$$T_0, \ldots, T_{n-1} \mid 0 \ -T_{n-1}, \ldots, -T_1 \mid -T_0, \ldots, -T_{n-1} \mid 0 \ T_{n-1}, \ldots, T_1 \mid, \tag{9.4}$$

where the vertical lines indicate the reflection points at multiples of n.

Now we start the proof of Lemma 9.6. Let $n = 2^m$. We will repeatedly use that T_n is an even function and that T_k, k odd, is an odd function. Also note that $g_{\pm k}$ maps $T_\ell = T_\ell(T_1) \mapsto T_\ell(\pm T_k)$.

(1) $g_{\pm k}$ is a homomorphism, since $T_n(\pm T_k) = T_n(T_k) = T_k(T_n) \equiv 0$ (Lemma 4.2, (i)); i.e., the defining equation $T_n = 0$ in A is preserved. (2) $g_{\pm k}$ is invertible; G_n is

a group. Let g_k be given, k odd. We choose an ℓ with $k\ell \equiv 1 \bmod 4n$. The mapping $T_1 \mapsto T_\ell$ inverts g_k, since $T_{k\ell} \equiv T_1$ (see beginning of this proof). Similarly, $T_1 \mapsto -T_\ell$ inverts g_{-k}. Using (9.3), we can reduce $T_\ell \equiv T_{\ell'}$ or $\equiv -T_{\ell'}$ for a suitable odd $\ell' < n$. This shows that G_n is closed under inversion. Also $g_{\pm k} g_{\pm \ell} : T_1 \mapsto \pm T_\ell(\pm T_k) = \mp T_{k\ell}$, which can be reduced analogously. Thus, G_n is a group. (3) G_n is cyclic. For $n = 2$, g_{-1} has order 2. For $n = 4$, g_3 has order 4 ($T_3(T_3) = T_9 \equiv -T_1$). For $n > 4$, we show that g_5 has order n. Observing (9.4), we get that g_5^e is the identity iff $5^e \equiv \pm 1 \bmod 4n$. Since 5^e is never $\equiv -1$ and 5 has order $n \bmod 4n$ ($n = 2^m$), we get the desired assumption. □

Now we will use the group G_n of automorphisms (Lemma 9.6) and Theorem 9.5 to derive mon-mon symmetries for all DTTs whose inverses are in the T-group.

THEOREM 9.7. *Let $n = 2^m \geq 4$ and G_n be as defined in Lemma 9.6. The transforms* DCT-2$_n$, DST-2$_n$, DCT-4$_n$, DST-4$_n$ *have a mon-mon symmetry (χ, ψ) with nonzero matrix entries ± 1 arising from the group of automorphisms G_n of $\mathbb{C}[x]/T_n$ (cf. Theorem 9.5). Denote by $Z_n = \langle \sigma \mid \sigma^n = 1 \rangle$ the cyclic group of order n. The symmetry group for* DCT-2$_n$, DST-2$_n$ *is Z_n; for* DCT-4$_n$, DST-4$_n$ *it is Z_{2n}. The respective monomial representation χ is given by*

$$
\begin{aligned}
&\text{DCT-2}_n: && \sigma \mapsto (T_i \mapsto T_{ki} \bmod T_n)^{-1},\\
&\text{DST-2}_n: && \sigma \mapsto (U_i \mapsto U_{k-1+ki} \bmod T_n)^{-1},\\
&\text{DCT-4}_n: && \sigma \mapsto (V_i \mapsto V_{(k-1)/2+ki} \bmod T_n)^{-1},\\
&\text{DST-4}_n: && \sigma \mapsto (W_i \mapsto W_{(k-1)/2+ki} \bmod T_n)^{-1},
\end{aligned}
\tag{9.5}
$$

where $i = 0, \ldots, n-1$, and $k = 3$ for $n = 4$, and $k = 5$ for $n \geq 8$.

Proof. Let $g_k \in G_n$, i.e., $T_1^{g_k} = T_k$. We consider the first case DCT-2$_n$ = DCT-3$_n^T$ with associated algebra $A = \mathbb{C}[x]/T_n$ and $b = (T_0, \ldots, T_{n-1})$, i.e., DCT-2$_n$ decomposes the right regular representation of A (Theorem 6.2). Following Theorem 9.5, we have to find a monomial base change matrix $M_{g_k} : b \to b'$ such that T_1 operates on b as $T_1^{g_k} = T_k$ on b'. This is afforded by $b' = (T_{k\cdot 0}, T_{k\cdot 1}, \ldots, T_{k\cdot n-1})$, since, using Lemma 4.1(ii),

T_1 on b			T_k on b'		
$T_1 \cdot T_0$	=	T_1	$T_1 \cdot T_{k\cdot 0}$	=	$T_{k\cdot 1}$
$T_1 \cdot T_i$	=	$(T_{i-1} + T_{i+1})/2$	$T_1 \cdot T_{ki}$	=	$(T_{k(i-1)} + T_{k(i+1)})/2$
$T_1 \cdot T_{n-1}$	=	$T_{n-1}/2$	$T_1 \cdot T_{k(n-1)}$	=	$T_{k(n-1)}/2$

where $i = 2, \ldots, n-2$ and in the last line we used $T_n \equiv 0$, and thus $T_{kn} = T_k(T_n) \equiv 0$, since T_k is an odd function. The base change $b \to b'$ is given by the matrix $M_k : T_i \mapsto T_{ki}$, $i = 0, \ldots, n-1$, and thus

$$\phi^{g_k} = \phi^{M_k}.$$

(Note that we consider right representations, where ϕ is conjugated into $\phi^{M^{-1}}$ by a base change with matrix M.) As in the proof of Lemma 9.6, we see that M_k is monomial, since every T_{ki} can be reduced to a suitable $\pm T_\ell \bmod T_n$, $0 \leq \ell \leq n-1$. Theorem 9.5 establishes a mon-mon symmetry for (χ, ψ). It remains to show that the symmetry group is cyclic of order n. To this end we need the sequence of T_ℓ, $\ell \geq 0$, reduced mod T_n, given in the first row of Table 9.2. We see that $M_k^e = \mathrm{I}_n$ iff $T_{k^e i} \equiv T_i \bmod T_n$ ($i = 0, \ldots, n-1$) iff $k^e \equiv \pm 1 \bmod 4n$. As in the proof of Lemma 9.6, this shows that the maximum order $e = n$ is obtained for $k = 3$ if $n = 4$, and $k = 5$ if $n \geq 8$.

TABLE 9.2

For $P \in \{T, U, V, W\}$ the sequence of polynomials $P_0, \dots, P_{4n-1}$ (i.e., one period) reduced mod T_n. The vertical lines indicate multiples of n.

DCT-3 :	$T_0 \; \dots \; T_{n-1}$	$0 \; -T_{n-1} \; \dots \; -T_1$	$-T_0 \; \dots \; -T_{n-1}$	$0 \; T_{n-1} \; \dots \; T_1$
DST-3 :	$U_0 \; \dots \; U_{n-1}$	$U_{n-2} \; \dots \; U_0 \; 0$	$-U_0 \; \dots \; -U_{n-1}$	$-U_{n-2} \; \dots \; -U_0 \; 0$
DCT-4 :	$V_0 \; \dots \; V_{n-1}$	$-V_{n-1} \; \dots \; -V_0$	$-V_0 \; \dots \; -V_{n-1}$	$V_{n-1} \; \dots \; V_0$
DST-4 :	$W_0 \; \dots \; W_{n-1}$	$W_{n-1} \; \dots \; W_0$	$-W_0 \; \dots \; -W_{n-1}$	$-W_{n-1} \; \dots \; -W_0$

The proof of the other three cases is analogous. The base b is replaced by $b = (P_0, \dots, P_{n-1})$, where $P = U, V, W$, respectively.

The respective base change $b \to b'$ given by the matrix M_k corresponding to the automorphism g_k is given in lines 2–4 of (9.5) (without the inversion). The operation of T_k on b' can again be established using Lemma 4.1(ii). To determine the order of M_k we need, in each case, the sequence of P_ℓ reduced mod T_n given in Table 9.2. (Each of these sequences has period $4n$.) Surprisingly, it turns out that for the DCT-4 and DST-4, the symmetry group is a factor of 2 larger than G_n. We consider the example DCT-4_n. Denote by $V_{a_{e,i}}$ the image of V_i under M_k^e, $i = 0, \dots, n-1$. We get the recurrence and its solution

$$a_{0,i} = i, \quad a_{e,i} = (k-1)/2 + k \cdot a_{e-1,i} \quad \Rightarrow \quad a_{e,i} = (k^e - 1)/2 + ik^e.$$

Using the third row of Table 9.2, we get

$$\begin{aligned} & V_{(k^e-1)/2+ik^e} \equiv V_i \bmod T_n \quad (i = 0, \dots, n-1) \\ \Leftrightarrow \; & (k^e - 1)/2 + ik^e \equiv i \text{ or } -i-1 \bmod 4n \quad (i = 0, \dots, n-1) \\ \Leftrightarrow \; & k^e(2i+1) \equiv \pm(2i+1) \bmod 8n \quad (i = 0, \dots, n-1) \\ \Leftrightarrow \; & k^e \equiv \pm 1 \bmod 8n, \end{aligned}$$

which shows that the maximum order $e = 2n$ is obtained for $k = 3$ if $n = 4$, and $k = 5$ if $n \geq 8$. ∎

We conclude this section with a small example.

Example 9.8 (DCT-4, size 4). *Using Theorem* 9.7, *the* DCT-4_4 *has a mon-mon symmetry (χ, ψ) with a cyclic symmetry group $Z_8 = \langle \sigma \rangle$. The image $\chi(\sigma)$ is determined by the inverse of $V_i \mapsto V_{1+3i}$* mod T_4, *$i = 0, \dots, 3$. Using Table* 9.2, *we get $V_4 \equiv -V_3$, $V_7 \equiv -V_0$, $V_{10} \equiv -V_2$, and thus*

$$\chi(\sigma) = \begin{bmatrix} 0 & 0 & -1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & -1 & 0 & 0 \end{bmatrix}, \quad \psi(\sigma) = \begin{bmatrix} 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 \end{bmatrix}.$$

The matrix $\psi(\sigma)$ was computed using AREP. Both matrices have order 8.

The mon-mon symmetry of the DCT-4_4 given in Example 9.8 has been used in [21] to derive a fast algorithm (the symmetry is stated in a different way) and, using Theorem 8.6(iii), a fast algorithm for the DCT-2_8. The derivation essentially follows Figure 9.1, but the two monomial representations ϕ_1, ϕ_2 are decomposed over $\mathbb{Q}$. This concentrates all nonrational operations in the correction matrix D.

Remark. Using AREP, we have verified (up to a certain size) that all 16 types of DTTs possess mon-mon symmetries for every size n.

10. Other fast algorithms. The algebraic methods presented in sections 8 and 9 explain most of the algorithms from the literature. There is one class of algorithms, however, that cannot be explained by the methods presented so far. We will briefly discuss these algorithms to make this paper a comprehensive overview on DTT algorithms.

In short, it is possible to compute DTTs by embedding the transform matrix into a larger transform that can be computed efficiently. As an example, we consider the first algorithm proposed for the DCT-$2_n = [\cos k(\ell + \frac{1}{2})\pi/n]$ (see [1]). If we define the DFT by

$$\mathrm{DFT}_n = [e^{2\pi ikl/n}]_{k,\ell=0,\dots,n-1},$$

we can readily derive

$$\mathrm{re}(\mathrm{diag}_{k=0}^{2n-1}(e^{\pi ik/2n}) \cdot \mathrm{DFT}_{2n}) = \left[\cos k\left(\ell + \frac{1}{2}\right)\pi/n\right]_{k,\ell=0,\dots,2n-1},$$

where $\mathrm{re}(M)$ denotes the real part of the matrix M. This shows that a DCT-2_n can be computed by padding an input vector x of length n with n zeros, followed by multiplying with a scaled DFT of size $2n$. The first n entries contain the result.

Similar constructions allow the computation of each DTT via a DFT of appropriate length. This shows that the arithmetic complexity of each DTT_n is $O(n \log n)$, independent of the size n. In particular, this includes the DTTs of types 5–8, for which no other algorithms exist in the literature.

Embeddings into other transforms are also possible. For example, Theorem 8.7 allows us to embed a DTT of type 5–8 into a DTT of type 1 or 2.

11. Summary. We have given a complete characterization of all 16 types of DTTs as scaled polynomial transforms corresponding to appropriate A-modules M with basis b, where $A = \mathbb{C}[x]/p(x)$, $M = f \cdot A$ with a scaling function f, and b is a sequence of Chebyshev polynomials (Theorem 6.2). Every DTT is uniquely determined by this algebraic property.

We then used the algebraic characterization to derive by algebraic means most of the fast DTT algorithms known in the literature, and identified the mathematical principles behind each algorithm. In particular we derived the following:

1. *Algorithms by direct manipulation/decomposition of M* (section 8): (a) Translation between DTTs by duality (Theorem 8.2), (b) translation between DTTs by base change (Theorem 8.5), (c) decomposition by polynomial factorization (Theorems 8.6 and 8.7), (d) decomposition by polynomial decomposition (Theorem 8.8).
2. *Algorithms by group symmetries* (section 9): (a) Decomposition by mon-irred symmetry (Theorem 9.3), (b) decomposition by mon-mon symmetry (Theorem 9.5).
3. *Algorithms by embedding* (section 10).

Our results show clearly that the connection between digital signal processing and the representation theory of algebras goes beyond the DFT. The question that remains is to what extent this connection can be extended to include other transforms and their fast algorithms and how this connection can be exploited for applications in signal processing. We want to conclude by posing this question: *To what extent is signal processing algebraic?*

Appendix. Orthonormal DCTs and DSTs. Table A.1 gives the orthonormal versions of the 16 DTTs.

TABLE A.1

Definition of the orthonormal versions of the DCTs and DSTs; $a_{k,l}$ is the entry at row k and column l of the respective unscaled DTT as given in Table 5.1. All matrices have size $(n \times n)$, with row index $k = 0, \ldots, n-1$ and column index $\ell = 0, \ldots, n-1$. The row/column scaling factors are given by $c_i = 1/\sqrt{2}$ for $i = 0$ and $= 1$ else; $d_i = 1/\sqrt{2}$ for $i = n-1$ and $= 1$ else.

	DCTs	DSTs
type 1	$\sqrt{\frac{2}{n-1}} \cdot c_k c_\ell d_k d_\ell \cdot a_{k,l}$	$\sqrt{\frac{2}{n+1}} \cdot a_{k,l}$
type 2	$\sqrt{\frac{2}{n}} \cdot c_k \cdot a_{k,l}$	$\sqrt{\frac{2}{n}} \cdot c_k \cdot a_{k,l}$
type 3	$\sqrt{\frac{2}{n}} \cdot c_\ell \cdot a_{k,l}$	$\sqrt{\frac{2}{n}} \cdot c_\ell \cdot a_{k,l}$
type 4	$\sqrt{\frac{2}{n}} \cdot a_{k,l}$	$\sqrt{\frac{2}{n}} \cdot a_{k,l}$
type 5	$\sqrt{\frac{2}{n-1/2}} \cdot c_k c_\ell \cdot a_{k,l}$	$\sqrt{\frac{2}{n+1/2}} \cdot a_{k,l}$
type 6	$\sqrt{\frac{2}{n-1/2}} \cdot c_k d_\ell \cdot a_{k,l}$	$\sqrt{\frac{2}{n+1/2}} \cdot a_{k,l}$
type 7	$\sqrt{\frac{2}{n-1/2}} \cdot d_k c_\ell \cdot a_{k,l}$	$\sqrt{\frac{2}{n+1/2}} \cdot a_{k,l}$
type 8	$\sqrt{\frac{2}{n+1/2}} \cdot a_{k,l}$	$\sqrt{\frac{2}{n-1/2}} \cdot d_k d_\ell \cdot a_{k,l}$

APPROXIMATION SCHEMES FOR MINIMUM LATENCY PROBLEMS*

SANJEEV ARORA† AND GEORGE KARAKOSTAS‡

Abstract. The *minimum latency problem*, also known as the traveling repairman problem, is a variant of the traveling salesman problem in which the starting node of the tour is given and the goal is to minimize the sum of the *arrival times* at the other nodes. We present a quasi-polynomial time approximation scheme (QPTAS) for this problem when the instance is a weighted tree, when the nodes lie in $\mathbb{R}^d$ for some fixed d, and for planar graphs. We also present a polynomial time constant factor approximation algorithm for the general metric case. The currently best polynomial time approximation algorithm for general metrics, due to Goemans and Kleinberg, computes a 3.59-approximation.

1. Introduction.

The *minimum latency problem*, also known as the *deliveryman* or *traveling repairman* problem (Afrati et al. [1], Minieka [16], Lucena [15], Bianco, Mingossi, and Ricciardelli [9]), is a variant of the traveling salesman problem (TSP) in which the starting node of the tour is given and the goal is to minimize the sum of the arrival times or *latencies* at the other nodes. (The *latency* of a node is the distance covered before reaching that node.) This natural combinatorial problem arises in many day-to-day situations, whenever a server (e.g., a repairman or a disk head) has to accommodate a set of requests (each represented by a point) so as to minimize their total (or average) waiting time. The tour that achieves this goal will henceforth be called the *minimum latency tour* (MLT).

More formally, the problem is defined as follows.

MINIMUM LATENCY TOUR

Input: A set of n points (one of them designated as the starting point p_1), and a symmetric distance matrix $[d_{ij}]$.

Output: A tour $p_1 \to p_2 \to \cdots \to p_n$ that visits *all* points and minimizes the total latency

$$\sum_{i=2}^{n} \sum_{j=1}^{i-1} d_{p_j, p_{j+1}}. \tag{1.1}$$

By rearrangement, the objective function (1.1) can be rewritten as a weighted sum:

$$\sum_{i=1}^{n-1}(n-i)d_{p_i,p_{i+1}}. \tag{1.2}$$

Here we study the restriction of the problem to distance matrices that define a metric; i.e., the distances satisfy the triangle inequalities. From the objective function formulation (1.2) it becomes apparent that the MLT problem is a weighted variation of the TSP (where the objective function to be minimized by the tour is $\sum_{i=1}^{n-1} d_{p_i,p_{i+1}}$). However, it has a reputation for being much harder than the TSP.

For example, the MLT does not possess the locality property of the TSP for local changes in the structure of a metric space. Even a very small local change of a tour can affect the arrival time of *all* the points visited by the tour afterwards, and it may change the value of (1.2) by too much. On the other hand, local changes affect the *length* of the tour only locally. This lack of locality is conceivably prohibitive for the design of "divide and conquer" algorithms. This is not the case, for example, for the Euclidean TSP, where recent "divide and conquer" algorithms by Arora [4] (and, independently, Mitchell [17]) solve the problem almost optimally.

It is easy to prove (Blum et al. [10]) that calculating the MLT is at least as hard as calculating the TSP: Given an instance of the TSP, create an instance for the MLT by adding m new points (for a large m) at infinity (i.e., far enough away from the points of the TSP instance). Then the MLT on the augmented set of points will have to follow the TSP tour on the original points before visiting the new ones. This reduction proves the NP-hardness of the MLT for all the metric spaces where TSP is NP-hard. But even for metrics where the TSP is solvable trivially, the computation of the MLT may be hard. Such is the case for tree metrics (the points are vertices of a tree with nonnegative edge lengths, and the distance between two points is the length of the unique tree path that connects them). MLT was recently proven to be NP-hard even for tree metrics [19].

Afrati et al. [1] give a simple dynamic programming algorithm that solves the problem when the points are on a line in polynomial time. Minieka [16] and Blum et al. [10] prove that in the case of *unweighted* trees (trees whose edges have unit length), any depth-first walk on the tree is an optimal MLT. Minieka [16] gives also an exponential time algorithm that solves the problem exactly for any weighted tree. For general metric spaces, Bianco, Mingossi, and Ricciardelli [9] and Lucena [15] give exponential time algorithms that find a MLT.

The general metric case of the latency problem is MAX-SNP-hard (this follows from the reduction that proves the MAX-SNP-hardness of TSP with distances either 1 or 2 by Papadimitriou and Yannakakis [18]), and therefore the results of Arora et al. [8] imply that unless P = NP, a polynomial time approximation scheme (PTAS) does not exist. Blum et al. [10] gave a 144-approximation algorithm for the metric case and an 8-approximation for weighted trees. Goemans and Kleinberg [12] then gave a 21.55-approximation in the metric case. The Goemans–Kleinberg algorithm requires as a subroutine a good approximation algorithm for the k-TSP problem ("given n nodes and a number k, find the shortest salesman tour containing k nodes"). Their algorithm achieves a 3.59-approximation ratio for the tree case and a $3.59 \times$ (*appr. ratio for k-MST*) approximation ratio for general metric spaces. Currently, the best approximation ratio for the general metric k-MST is $2+\varepsilon$ for any constant $\varepsilon > 0$ due to Arora and Karakostas [7] and $1+\varepsilon$ for any $\varepsilon > 0$ for constant-dimensional Euclidean spaces due to Arora [4] (for planar instances, see also Mitchell [17]). These

can be used to improve the approximation ratio achieved by the Goemans–Kleinberg algorithm in these cases, achieving a 7.18-approximation in the metric case and a 3.59-approximation in the Euclidean case. Subsequently to the first appearance of our work, Archer and Williamson [3] gave a faster approximation algorithm for the MLT (although their approximation factor is somewhat worse than the Goemans–Kleinberg one), and Fakcharoenphol, Harrelson, and Rao [11] present approximation algorithms for the generalization of the traveling repairman with k repairmen.

We present a new and very simple technique that leads to *approximation schemes* for minimum latency for all weighted trees and constant-dimensional Euclidean spaces. To compute a $(1+\varepsilon)$-approximation for the problem on n nodes, the algorithm requires $n^{O(\log^2 n/\varepsilon)}$ time on weighted trees and $n^{O(\log n/\varepsilon)}$ time in $\mathbb{R}^2$. We also present an 11.656-approximation in the metric case. Though this approximation ratio is worse than that of the algorithm by Goemans and Kleinberg [12], our algorithm seems to be simpler.

Previous papers have taken the approach of computing solutions to a sequence of k-TSP instances, for $k = 1, 2, \ldots, n$, and concatenating some of these tours to get the final tour. The main intuition in these algorithms may be described as follows: Visit the nodes closest to the start node as soon as possible. The main idea in our algorithm is easier to state. The algorithm finds the tour as a union of $O(\log n/\varepsilon)$ tours, containing $n_1, n_2, \ldots$ nodes. The important difference is that the choice of $n_1, n_2, \ldots$, does not depend on the instance; it depends only on n, ε. (Thus, as noted in section 3, our algorithm can be viewed as an approximation-preserving reduction to a version of vehicle routing.) In fact, in our algorithm for the general metric case, the first salesman tour contains more than $n/2$ nodes. This seems to go against the received intuition of "visit the nodes closest to the start node first." Conceivably, our technique could be combined with that intuition to get better algorithms, but we do not currently know how.

1.1. MLT and the randomized search ratio. Koutsoupias, Papadimitriou, and Yannakakis [14] consider a graph exploration problem in which an explorer is presented with a weighted graph on n nodes. One of the nodes contains a treasure, which the explorer will recognize only when he sees it. The goal is to design a walk on the graph such that the explorer arrives at the treasure as quickly as possible. The *search ratio* of the graph is the worst-case ratio of the arrival time and the distance of the treasure to the start node. The *randomized search ratio* is defined similarly, except the walk may be randomized, and so we need the *expected* arrival time at the treasure.

More formally, the two problems are defined as follows.

SEARCH RATIO

Input: A graph G with distances on edges, and a root vertex r.

Output:

$$\sigma(G, r) = \min_{\pi} \max_{v \in G} \frac{d_\pi(r, v)}{d(r, v)},$$

where $d(r, v)$ denotes the distance from r to v and $d_\pi(r, v)$ denotes the distance from r to v in the walk π.

RANDOMIZED SEARCH RATIO

Input: A graph G with distances on edges, and a root vertex r.

Output:

$$\rho(G,r) = \min_{\Delta} \max_{v \in G} \frac{E_{\Delta}[d_{\pi}(r,v)]}{d(r,v)},$$

where Δ ranges over *distributions of walks* and $E_{\Delta}[d_{\pi}(r,v)]$ denotes the *expected* distance from r to v in the walk π, when π is drawn randomly according to distribution Δ.

As shown in Koutsoupias, Papadimitriou, and Yannakakis [14], computing the search ratio and the randomized search ratio of a graph G with respect to a root node r is NP-complete and MAX-SNP-hard. They also show that the minimum latency problem is the polyhedral separation problem of the dual of the randomized search ratio problem. Indeed, the randomized search ratio can be expressed as the solution of the following $(n+1) \times n!$ linear program:

$$\begin{aligned}
&\min\ \rho \ \text{ s.t.}\\
&\sum_{\text{walk } \pi} x_{\pi} d_{\pi}(r,v) \le \rho \cdot d(r,v) \quad \forall v \in V,\\
&\sum_{\text{walk } \pi} x_{\pi} = 1,\\
&x_{\pi} \ge 0.
\end{aligned}$$

Its dual is

$$\begin{aligned}
&\min \sum_{v} d(r,v) y_v - z \ \text{ s.t.}\\
&\sum_{v} d_{\pi}(r,v) y_v - z \ge 0 \quad \forall \text{ walk } \pi,\\
&y_v \ge 0.
\end{aligned}$$

To solve the dual by using the ellipsoid algorithm using the general framework of Grötschel, Lovász, and Schrijver [13], we should be able to check whether a given point $(\vec{y}, z) \in \mathbb{R}^{n+1}$ lies in a feasible solution or not. In case it is *not* feasible, we need a violated inequality; i.e., we should be able to decide whether $\min_{\pi} \sum_{v} d_{\pi}(r,v) y_v \le z$. Koutsoupias, Papadimitriou, and Yannakakis [14] observe that this decision problem is *polynomially equivalent* to the MLT problem, under some very mild restrictions that do not affect approximability.

Using the general framework for convex optimization in Grötschel, Lovász, and Schrijver [13], É. Tardos has observed that if the minimum latency problem has a PTAS for a certain class of metrics, then the randomized search ratio problem has an approximation scheme for that same class of metrics (Koutsoupias, Papadimitriou, and Yannakakis [14]). Thus our algorithm implies the existence of a quasi-polynomial time approximation scheme (QPTAS) for the randomized search ratio for trees and Euclidean spaces. We do not know of a previous use of the framework in Grötschel, Lovász, and Schrijver [13] to design an approximation scheme.

2. The main idea: Local structure does not matter. It is well known that minimizing the total tour length may give a tour of very high latency. In this section we show that the strategy of minimizing tour lengths works, as long as it is done in a local fashion. Namely, to find a $(1+\varepsilon)$-approximate MLT, it suffices to find the tour as a union of $O(\log n/\varepsilon)$ segments, where the number of nodes in successive segments

decreases geometrically. Within each segment the order of visits to the nodes does not matter, as long as the total length is close to minimum. Of course, we have not specified thus far how to partition nodes into the segments in the correct way. In the Euclidean and tree-metric cases, we can do this with a simple dynamic programming. In the metric case, we recourse to a greedy strategy that introduces another source of suboptimality.

We note that the idea of finding a low latency tour as a union of salesman tours/paths is present in all earlier papers. However, those earlier strategies decided in an adaptive fashion which salesman tours to combine. In contrast, our algorithm can decide at the very start how many nodes must be present in each salesman path. We prove that we can break an MLT tour into segments so that local changes within a segment does not affect the total latency by much, and then replace each segment by an optimum salesman path, so that the new tour is still near optimal.

Let $\mathcal{T}$ be an optimal tour with total latency OPT. Let $\varepsilon > 0$ be any parameter. Break this tour into $k = O(\log n/\varepsilon)$ segments so that in segment i we visit n_i nodes, where

$$n_i = (1+\varepsilon)^{k-1-i} \text{ for } i = 1, \ldots, k-1,$$
$$n_k = 1/\varepsilon.$$

Depending on n and ε, some n_i may not be integers. This means that some nodes will be "broken" in two fractions, belonging to two segments. Since for our calculations up to section 4.6 the start node of a segment is the finish node of the previous segment, it does not matter what fraction of this node belongs to each segment. Let the length of the ith segment be T_i. If we let $n_{>i}$ denote the total number of nodes visited in segments numbered $i+1$ and later, then a simple calculation shows that (and this was the reason for our choice of n_i's)

$$n_{>i} = \sum_{j>i} n_j = \frac{n_i}{\varepsilon} \text{ for every } i = 1, \ldots, k-1. \tag{2.1}$$

Now imagine doing the following in each segment except the last one: replace that segment by the minimum-cost traveling salesman path on the same subset of nodes while maintaining the starting and ending points. We claim that the new latency is at most $(1+\varepsilon)OPT$. First, note that $\sum_{j=1}^{m-1} T_j$ is a lower bound on the latency of any node in the mth segment. Adding over all segments, we get the following lower bound on OPT:

$$OPT \geq \sum_{i=1}^{k-1} n_{>i} \cdot T_i. \tag{2.2}$$

Consider the effect of replacing the ith segment with the shortest salesman path on that subset of nodes. The length of the segment cannot increase, and thus neither can the latency of nodes in later segments. The latency of nodes within the segment can only rise by $n_i T_i$. Thus the new latency is at most the lower bound in (2.2) plus

$$\sum_{i=1}^{k-1} n_i \cdot T_i. \tag{2.3}$$

Now condition (2.1) implies that the new latency is at most $(1+\varepsilon)OPT$, as claimed, and the proof of the main idea is complete.

THEOREM 2.1. *Let OPT be the total latency of the MLT. There exists a tour that is a concatenation of* $O(\frac{\log n}{\varepsilon})$ *optimal salesman paths and whose total latency is at most* $(1+\varepsilon)OPT$.

The importance of this structure theorem for the design of approximation schemes is apparent for cases where the TSP is efficiently solvable (e.g., weighted trees). All one has to do is to decide which node goes into which segment and then calculate the optimal salesman path for each segment. Even if, instead of the optimum salesman path in each segment, we use a $(1+\gamma)$-approximate salesman path, then the latency of the tour of Theorem 2.1 is $(1+\gamma\cdot\varepsilon+\gamma+\varepsilon)OPT$. This is the case, for example, for Euclidean spaces of fixed dimension, where there are approximation schemes for the TSP (cf. Arora [4]). For these cases the difficulty lies in the placement of nodes into the appropriate segments. This has the flavor of a vehicle routing problem, and this will become more precise in the following section.

3. Reduction from minimum latency to weighted vehicle routing. The purpose of this section is to note that our technique described above implies a quasi-polynomial time approximation-preserving reduction from minimum latency to a version of weighted vehicle routing with *per-mile costs*. We do not know of a prior result along these lines.

WEIGHTED VEHICLE ROUTING WITH PER-MILE COSTS

Input: A set of n clients, who have to be visited by a fleet of m vehicles. Vehicle i has a designated depot s_i at which to start and another depot t_i at which to finish. It also has a *capacity* (which is the number of clients it can visit) c_i and a *per-mile cost* d_i.

Output: Assign clients to vehicles so as to respect the capacity constraints and minimize the total cost, which is the sum of distances covered by the vehicles, weighted by the per-mile cost

$$\sum_{i=1}^{m} d_i T_i,$$

where T_i is the distance traveled by vehicle i.

Suppose we are given an oracle for this version of vehicle routing. We can use this oracle to solve the MLT problem. Given a set of n nodes, the reduction proceeds as follows, where $k, n_i, n_{>i}$ have the same meaning as in section 2: "Let p_0 denote the starting node of the MLT. For every sequence of k nodes $p_1, p_2, \ldots, p_k$, use the vehicle routing oracle to construct a solution to the instance in which there are k vehicles, and the capacity of the ith vehicle is n_i, its per-mile cost is $n_{>i}$, and its start and end depots are p_i and p_{i+1} respectively. At the end, output the lowest cost solution found (over the choice of all sequences of k points)."

Clearly, if the vehicle routing oracle computes a ρ-approximation in polynomial time, our reduction will lead to a $\rho(1+\varepsilon)$-approximate solution for MLT in $n^{O(\log n/\varepsilon)}$ time. This follows from Theorem 2.1, since it suffices to go over all possible sequences $p_1, p_2, \ldots, p_k$, and this increases the running time by a factor of at most $O(n^k) = n^{O(\frac{\log n}{\varepsilon})}$.

4. Approximation algorithms for the MLT. The essence of Theorem 2.1 is that there is a near optimal latency tour of a potentially simpler structure, since it is the collection of just a few optimal salesman paths. We take advantage of this simpler structure in order to compute a near optimal tour for the cases of trees, Euclidean (and other norm) spaces, and planar graphs. The algorithms for these

cases are quasi-polynomial time *approximation schemes*. We also give a constant factor polynomial time approximation algorithm for the general metric case as an immediate result of Theorem 2.1. Although its approximation factor is somewhat worse than the approximation factor achieved by Goemans and Kleinberg [12], it seems simpler.

4.1. The tree case. The optimum salesman tour on a tree may in general need to visit a node an unbounded number of times. For example, in a star graph it must visit the center node $n-1$ times. However, the tour never needs to visit an edge more than twice, as is easily checked. Thus an optimum tour has very simple structure and can be found by depth-first search.

A MLT, on the other hand, could have a very complicated structure. Consider, for example, a complete binary tree in which all edges have zero weight except those attached to leaves. The MLT will first visit all the internal nodes in some arbitrary order, and then all the leaf nodes in sorted order by weight, thus crossing the root node potentially $n/2$ times.

However, our technique from section 2 allows us to view a near-optimum latency tour as a union of $O(\log n/\varepsilon)$ salesman paths. By observing that within each salesman path an edge is only visited twice, we can then ensure that each edge is visited only $O(\log n/\varepsilon)$ times overall. This idea underlies the proof of our *structure theorem* below and the approximation scheme for trees.

4.1.1. The structure theorem for trees. In this subsection we prove that there is a tour on a weighted tree whose latency is near optimal but crosses each node of the tree only a few times.

DEFINITION 1. *An $\alpha : \beta$-partition of a tree $\mathcal{T}$ with n nodes is the recursive partition of $\mathcal{T}$ into two subtrees with a common root so that for each subtree*

$$\alpha\ n \leq \textit{(size of subtree)} \leq \beta\ n.$$

The partition is recursive, and each separator can be thought as belonging to both subtrees it separates. At the bottom level of the recursion there are pairs of nodes connected by an edge.

It is easy to show that one can always find a $\frac{1}{3} : \frac{2}{3}$-partition of a tree.

LEMMA 4.1. *In any tree we can always find a node with the following property: Let $m \geq 2$ denote its degree and $f_1, \ldots, f_m$ denote the sizes of the subtrees attached to the node. There exists a subset $S \subseteq \{1, \ldots, m\}$ such that*

$$\left\lfloor \frac{n}{3} \right\rfloor \leq \sum_{i \in S} f_i \leq \left\lceil \frac{2n}{3} \right\rceil.$$

Proof. Start by picking a node of the tree. If there is a subtree with more than $\lceil \frac{2n}{3} \rceil$ nodes pick the root of this subtree and continue. If there is a subtree with number of nodes between $\lfloor \frac{n}{3} \rfloor$ and $\lceil \frac{2n}{3} \rceil$, then the current node satisfies the lemma requirements. If all subtrees have less than $\lfloor \frac{n}{3} \rfloor$ nodes (obviously, $m \geq 3$ in this case) it is easy to see that the lemma holds for the current node. ∎

We designate the node guaranteed to exist by Lemma 4.1 as a *separator node* and the $|S|$ components as the *left* of the tree and the other $m - |S|$ as the *right* of the tree. (The node itself is copied twice and appears in both sides.) Then we recur on the two sides. This gives a recursive partition of the tree. We say that a tour *crosses* the separator node if it goes from the left side to the right. Notice that a node may be visited many times before it is crossed.

It is obvious that since a minimum salesman tour is obtained by depth-first search, it needs to cross each separator node only twice. The combination of this fact with our main idea gives the following.

THEOREM 4.2 (structure theorem for weighted trees). *The following is true for every integer $n > 0$ and every $\varepsilon > 0$: For every weighted tree on n nodes with a node–separator-based partition as defined above, a tour exists with latency at most $(1+\varepsilon)OPT$ that crosses each separator node only $O(\log n/\varepsilon)$ times.*

Proof. Let $\mathcal{T}$ be the optimum tour. Divide it into $O(\log n/\varepsilon)$ segments as in section 2 and replace each segment by the optimum salesman path. Now use the fact that a minimum salesman path does not cross a separator node going from the left side to the right (or vice versa) of the partition at that node more than twice. ∎

4.1.2. The algorithm for trees. A simple dynamic programming approach that relies on the structure theorem, Theorem 4.2 can be used to compute a $(1+\varepsilon)$-approximate latency tour for general weighted trees.

ALGORITHM 1.

1. Identify a recursive $\frac{1}{3} : \frac{2}{3}$-partition of the tree.
2. Identify the node-separator at the top level of the partition.
3. "Guess" the number of times the tour crosses this node, and for each crossing, the length of the tour portion after the crossing and the number of nodes on that portion.
4. Keep track of the "guess" and recur on each side of the node-separator; i.e., compute a collection of paths that visits *all* the nodes on each side of the separator, is consistent with the "guess" in terms of lengths and number of nodes visited, and achieves minimum latency among all such paths.
5. Store the cost (latency) of the combined (at the separator) subtour in the "guess" entry of the dynamic programming table and return. ∎

By "guessing" in step 3 we refer to the exhaustive enumeration of all possible values for length and number of nodes for *each crossing* of the separator. Since the subtours on the two sides of the separator are the optimum subtours that are consistent with our "guess," their combination will be the optimum one that is consistent with this "guess." In the end of the enumeration, the algorithm will have created a collection of candidate solutions (one for each set of values for our "guesses"). Its output will be the tour with the minimum total latency. One of these tours calculated by the algorithm must be the near optimal tour guaranteed by the structure theorem, Theorem 4.2, since the algorithm is bound to encounter the specific set of "guesses" defined by it due to exhaustive enumeration. Hence the tour it produces is at least as good as this tour, and the algorithm is indeed an *approximation scheme*. The only thing remaining to prove is that it is a *quasi-polynomial* approximation scheme.

The running time of the algorithm is obviously dominated by the number of possible "guesses." The number of crossings through a node is at most $O(\log n/\varepsilon)$ (Theorem 4.2), and the number of nodes visited between two crossings cannot be greater than n. But notice that the length of the tour between two crossings can be exponential in the size of the input. This is the case when an edge has weight exponential in the size of the input. Then the number of guesses is also exponential, and the algorithm runs in exponential time, instead of quasi-polynomial. In order to get around this problem, we *round* the given instance by running the following **rounding procedure**:

1. Let L be the length of the longest path in the tree and $\delta > 0$ any constant smaller than ε. Merge (by contracting edges) all pairs of nodes with internode

distance at most $\delta L/n^2$.
2. Round each edge weight to its closest multiple of $\delta L/n^2$.
3. Divide each edge weights by $\delta L/n^2$.

After solving the problem on the rounded instance, we reinstate the merged edges to output the tour computed on the original instance.

LEMMA 4.3. *Let OPT be the optimal latency in the given instance, and L, δ are as in the above procedure. Then the MLT on the rounded instance and OPT differ by at most δ OPT. Moreover, the maximum internode distance in the rounded instance is at most $O(n^2/\delta) = O(n^2/\varepsilon)$.*

Proof. The second part of the lemma is obvious. Also, it is easy to see that the latency of each node in the original MLT has not changed by more than $O(\delta L/n)$, for a total change of $O(\delta L) = \delta OPT$. Notice that when we reinstate the merged edges, the latency increase cannot be more that δOPT. This means that we need to compute an $(1+\varepsilon-\delta)$-approximation tour on the rounded instance instead of a $(1+\varepsilon)$-approximation. But we certainly can do that since δ is an arbitrary constant. □

Thus if we run Algorithm 1 on the new rounded instance, the running time is quasi-polynomial.

THEOREM 4.4. *Algorithm 1 runs in time $n^{O(\log^2 n/\varepsilon)}$ and computes a tour whose latency is at most $(1+\varepsilon)$ OPT.*

Proof. If δ is the constant in the rounding procedure, then we apply Theorem 4.2 so that the approximation factor for the rounded instance is $1+\varepsilon-\delta$. Because of Lemma 4.3 the approximation factor for the tour we compute in the original instance will be $(1+\varepsilon)$.

For each separator considered by the algorithm, we guess the number of crossings and for each crossing the length and the number of vertices visited. So the total number of guesses for each crossing is $O(\frac{n^2}{\varepsilon} \cdot n) = O(\frac{n^3}{\varepsilon})$ (because of Lemma 4.3), for a total of $O(\frac{\log n}{\varepsilon} \cdot (\frac{n^3}{\varepsilon})^{O(\log n/\varepsilon)}) = n^{O(\log n/\varepsilon)}$ guesses for a node. If $T(n)$ is the running time of Algorithm 1 when run on a rounded instance of n nodes, then

$$T(n) = n^{O(\log n/\varepsilon)} \cdot 2T\left(\frac{2n}{3}\right),$$

for an overall running time of $n^{O(\log^2 n/\varepsilon)}$.

Notice that the look-up table stores *costs* instead of subtours, so at the end the algorithm has computed the *cost* of a near-optimal tour and not the tour itself. But it is easy to reconstruct this tour from the look-up table and the decision made at each step of the dynamic programming. □

4.2. The Euclidean plane. In section 2, we reduced the minimum latency problem to the problem of finding a covering of the n nodes using $O(\log n/\varepsilon)$ salesman paths. We use a simple modification of Arora's ideas [4] for the Euclidean TSP to show that this set of $O(\log n/\varepsilon)$ salesman paths together have a very simple structure. Thus they can be computed by dynamic programming in quasi-polynomial time in a way similar to the tree case. We will start by describing the algorithm for the Euclidean plane. The generalization to spaces of higher dimension will follow. Our exposition follows the exposition in Arora [4].

4.2.1. The partition. Arora [4] describes a very simple *geometric* partition which we use here to break the given instance into smaller instances. In what follows we assume that all coordinates of the given points are integral. Later we will show

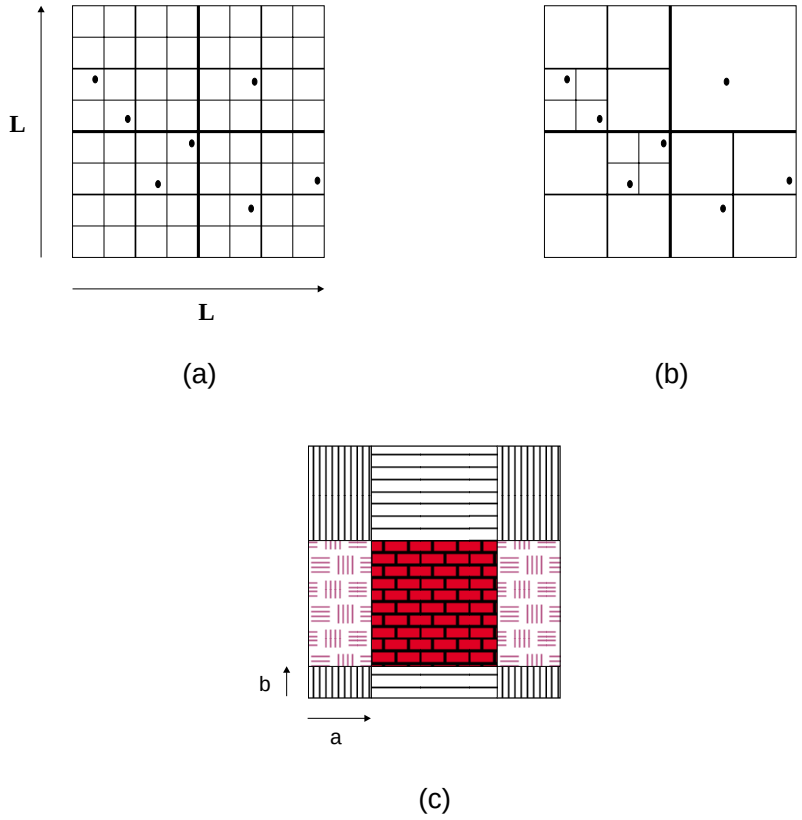

FIG. 4.1. *A dissection* (a)*, the corresponding quadtree* (b)*, and its shift by* (a, b) (c).

how to "perturb" the instance so that this assumption is fulfilled without increasing the cost of our solution by too much.

Suppose that the given instance is bounded by a square, and let L be the size of the smallest axis-aligned bounding square. Then the *dissection* of the bounding square is its recursive partition into smaller squares in the obvious way: break the bounding square into 4 equal squares; then break each smaller square into 4 equal squares and so on until the smallest squares have side size ≤ 1 (and thus cannot contain more than 1 point). This partition defines a tree: the root is the bounding square, and the nodes of the tree at each level are the squares created at the same level of the dissection. Each square has 4 children. Obviously, the tree has $O(L^2)$ nodes, and its depth is $O(\log L)$. If we stop partitioning a square as soon as it contains at most 1 node, then this truncated version of the dissection tree is called a *quadtree*. Examples of a dissection and a quadtree are shown in Figure 4.1.

The partition we are going to use is a randomized version of the quadtree. Imagine

that we pick randomly two integers a, b in $[0, L)$ and then *shift* the dissection defined above along the x- and y-axis by a and b, respectively. At the same time we "wrap-around" this shifted dissection as in Figure 4.1(c). Thus every horizontal line with initial y-coordinate y_1 will now have a new y-coordinate $(y_1 + b) \mod L$, and every vertical line with initial x-coordinate x_1 will now have a new x-coordinate $(x_1 + a) \mod L$. We call this dissection a *randomly shifted dissection*, and the corresponding quadtree (i.e., the quadtree resulting by cutting of the partitioning at squares that contain at most 1 point) is called a *randomly shifted quadtree*. The random (a, b)-shift is crucial for the algorithm, but since we still treat each "wrapped-around" square as a single region the reader can think of the quadtree as the unshifted one in much of what follows.

The geometric partition we just defined resembles in many ways the recursive partition in the tree case. But while a tour on a tree could cross partition boundaries only through a tree node, the boundaries of the quadtree partition are lines that can be crossed at any of an infinite number of points. In what follows we will prove that there is a near optimal tour that crosses not only the boundary of each square in the quadtree only a few times but also that these crossings happen at a small set of prespecified points called *portals*. Each square has 4 portals on its corners and m other equally spaced portals on each side, where m is a power of 2. A portal of a square is a portal in every descendent of the square in the quadtree.

DEFINITION 2. *Let m, k be positive integers. An* (m, k)-light tour *is one that crosses each quadtree boundary at most k times and always at one of its m portals.*

In what follows we prove the existence of an (m, k)-light tour (for appropriate values of m, k) that has near-optimal latency. Then we will describe a dynamic programming algorithm that can compute such a tour in quasi-polynomial time.

4.2.2. The structure theorem for the Euclidean plane. In section 4.2.1 we assumed that the given points have integral coordinates. We will also demand that all internode distances are integers between 8 and $O(n^2)$. Such an instance is called *well-rounded*. Obviously, the given instance need not be well-rounded, but by adding a *rounding step* similar to the one used in the tree case the algorithm can transform the given instance into a well-rounded one without increasing the MLT by too much. We prove the following structure theorem for the Euclidean plane.

THEOREM 4.5 (structure theorem for Euclidean plane). *There exist constants e, f such that the following is true for every integer $n > 0$ and every $\varepsilon > 0$: For every well-rounded Euclidean instance with n nodes, a randomly shifted dissection has with probability at least $1/2$ an associated tour that is $(e \log n/\varepsilon, f \log n/\varepsilon)$-light and whose latency is at most $(1 + \varepsilon)OPT$, where OPT denotes the latency of the MLT.*

Proof. The main ideas are the same as in Arora's proof [4] after we break up the MLT into $O(\log n/\varepsilon)$ salesman paths. The crucial observation is that Arora's proof relies on an expectation calculation that can be extended to the MLT case due to the linearity of expectation.

Let $\mathcal{T}$ be the optimum tour. By applying our main idea, we can break it up into $k = O(\log n/\delta)$ segments, where the ith segment has n_i nodes. We replace each segment by the optimum salesman path for that segment to get a new tour of total latency within a factor $(1+\delta)$ of the optimum. We use the following structure theorem by Arora [4] (Theorem 2 in [4]).

THEOREM 4.6 (Arora [4]). *Let $c > 0$ be any constant. Let the minimum nonzero*

internode distance in a TSP instance be 8*, and let* L *be the size of its bounding box.*[1] *Let shifts* $0 \le a, b \le L$ *be picked randomly. Then with probability at least* $1/2$*, there is a salesman path of cost at most* $(1 + 1/c)TSP$ *that is* (m, r)*-light with respect to the dissection with shift* (a, b)*, where* $m = O(c \log L)$*,* $r = O(c)$*, and* TSP *is the length of the optimal salesman path.*

We apply Theorem 4.6 simultaneously to our $k = O(\log n/\delta)$ salesman paths $T_1, T_2, \ldots, T_k$. The new tour crosses the boundary of each quadtree square at most $O(ck)$ times (since a salesman path never needs to cross a square boundary more than $r = O(c)$ times).

In order to prove Theorem 4.6, Arora [4] proves that the expected increase of a salesman path length after it is modified to become (m, r)-light is bounded as follows:

$$E_{a,b}[\text{increase of salesman path length}] \le \frac{g}{r} TSP, \tag{4.1}$$

where g is a constant.

For the effect of the modified tour on the latency, note that we are interested in a *weighted* sum of salesman path lengths, where the weight assigned to the ith salesman path is $n_i + n_{>i}$ (these are the vertices whose latency is affected by the change in length of T_i). Inequality (4.1) implies that the expected latency increase due to the length increase of path T_i is

$$\begin{aligned} E_{a,b}[\text{total latency increase due to } T_i] &\le \frac{g}{r}(n_i + n_{>i})TSP_i \\ &\overset{(2.1)}{\le} \frac{g(1+\delta)}{r} n_{>i} TSP_i, \end{aligned} \tag{4.2}$$

where TSP_i is the length of the optimum (i.e., shortest) T_i. By linearity of expectation, the total expected latency increase is

$$\begin{aligned} E_{a,b}[\text{total latency increase due to } T_1, \ldots, T_k] &\le \frac{g(1+\delta)}{r} \sum_{i=1}^{k} n_{>i} TSP_i \\ &\le \frac{g(1+\delta)}{r} OPT \end{aligned}$$

because of lower bound (2.2) in section 2.

By picking $\delta = O(\varepsilon)$ and $c = O(1/\varepsilon)$ the total latency increase is no more than $\varepsilon \cdot OPT$, and the new tour satisfies the theorem requirements. □

Thus in this section we proved that there is a tour with latency within a factor $1 + \varepsilon$ of the optimal that crosses each square boundary in the quadtree only $O(\frac{\log n}{\varepsilon})$ times and always through a portal. In the next section we show how to use dynamic programming in order to compute this tour.

4.2.3. The algorithm for the plane. In this section we describe our QPTAS for the Euclidean plane.

Until now we assumed that the given instance is *well-rounded*. Namely, it satisfies two conditions: (i) all nodes have integral coordinates, and (ii) all internode distances are between 1 and $O(n^2/\varepsilon)$. This assumption is easily met if the first step of the algorithm is a **rounding procedure** very similar to the rounding procedure used in the tree case:

[1] In our case $L = O(n^2)$ due to the instance rounding.

1. Let L be the length of the side of the bounding box. Place a grid of granularity $g = \Theta(\delta L/n^2)$, where δ is a constant $(0 < \delta < \varepsilon)$.
2. Move each point to its nearest gridpoint.
3. Divide all edge weights by g.

By an analysis similar to that in the proof of Lemma 4.3 we get the following.

LEMMA 4.7. *The procedure above transforms a given instance of optimal latency OPT into a well-rounded instance of optimal latency increased by at most δ OPT.*

The well-rounded instance has one more property that we will use in the analysis of the algorithm. Namely, the set of possible lengths for parts of the tour is *discrete* with at most $n^{O(1)}$ elements and can be generated quite easily in polynomial time. Hence when we refer to "guesses" for subtour lengths we will refer to values from this polynomially large set.

The algorithm takes a well-rounded instance as its input.

ALGORITHM 2.

1. Build a randomly shifted quadtree for the given instance. Since $L = O(n)$ the quadtree depth is $O(\log n)$ and the number of its nodes is $O(n \log n)$ since it has only n leaves.

   Do the following in a "bottom-up" fashion starting from the leaves of the quadtree:
2. Identify a node (i.e., square) at the current level of the quadtree.
3. "Guess" how many times the tour enters the square, and for each of these times the portals it crosses to enter and leave the square, what is the length of the tour portion after each crossing, and how many points are on that tour portion.
4. Search the dynamic programming look-up table for subtours consistent with the "guesses."
5. Combine the subtours found to create a new bigger subtour. If the new subtour is consistent with the fact that we are looking for a $(O(\log n/\varepsilon), O(\log n/\varepsilon))$-light tour, store this new subtour in the look-up table and go to step 2. □

Again, by "guessing" we refer to exhaustive enumeration of all possible values of the guessed quantities. This enumeration will produce possibly more than one candidate tour. We pick the tour with the minimum total latency as our solution, and this will be the output of Algorithm 2.

At a first glance the algorithm seems to miss a key ingredient for the calculation of a tour from its subtours: the order in which the portals are visited in each square. In fact this piece of information is implicit, since the guessed number of nodes visited after each portal crossing also tells us the order in which they occur in the tour (the first portal visited is the one with the longest subsequent tour length guessed, the second is the one with the second longest subsequent tour length, and so on). Now it is easy to see that at every step of the algorithm we have the information necessary to reconstruct a bigger subtour from the subtours already calculated. As in the tree case, the exhaustive enumeration guarantees that one of the tours constructed is the tour of the structure theorem, Theorem 4.5, so Algorithm 2 is indeed an approximation scheme.

It remains to prove that Algorithm 2 is a QPTAS.

THEOREM 4.8. *Algorithm 2 runs in time $n^{O(\frac{\log n}{\varepsilon})}$ and computes a tour whose latency is at most $(1+\varepsilon)$ OPT.*

Proof. If δ is the constant in the rounding procedure, then we apply Theorem 4.5

so that the approximation factor for the rounded instance is $1+\varepsilon-\delta$. Because of Lemma 4.7 the approximation factor for the tour we compute in the original instance will be $(1+\varepsilon)$.

The running time of the algorithm is dominated by the size of the dynamic programming look-up table. We prove the time bound by induction on the depth of the quadtree. The first level (leaves) contains squares with at most one point in them. The tour we are computing is $(c\log n/\varepsilon, f\log n/\varepsilon)$-light (with c, f being the constants in Theorem 4.5), so a leaf square is entered and left by the tour $O(\log n/\varepsilon)$ times through a pair of portals. This involves enumerating all choices for (a) a multiset of $O(\log n/\varepsilon)$ portals on the four sides of the square and (b) the order in which the portals in (a) are crossed by the (m,r)-light tour, where $m = O(\log n/\varepsilon)$ and $r = O(\log n/\varepsilon)$. It is easy to see that the number of choices in (a) is at most $m^{O(r)} = O(\log n/\varepsilon)^{O(\log n/\varepsilon)}$ and the number of choices in (b) is $r^{O(r)} = O(\log n/\varepsilon)^{O(\log n/\varepsilon)}$, for a total of $2^{O(\log n \log\log n/\varepsilon)}$ choices. In addition we need to "guess" the length of the tour portion after each crossing ($O(n^{O(1)}/\varepsilon)$ possibilities since all distances between points form a set of polynomially many values) and how many points are on that tour portion (n possibilities) for each one of the $O(\log n/\varepsilon)$ possible crossings of the tour through the square boundaries. Notice that since we guessed the number of nodes visited after each portal crossing, we know exactly the tour portion that contains the point in the current square. The total number of guesses is thus no more than

$$\begin{aligned}
&\#\text{ portal arrangements} \times (\text{length} \times \#\text{ points})^{\#\text{ crossings}} \\
&= O\left(2^{\frac{\log n \log\log n}{\varepsilon}}\right) \times \left(O\left(\frac{n^{O(1)}}{\varepsilon}\right) \times n\right)^{O(\frac{\log n}{\varepsilon})} \\
&= n^{O(\frac{\log n}{\varepsilon})}.
\end{aligned}$$

The analysis is the same for the inductive step. Assume that we have calculated all possible subtours for all squares in depth $> i$. Let S be a square at depth i and S_1, S_2, S_3, S_4 be its four children in the quadtree. We guess the same numbers as before for each S_j, $j = 1, \ldots, 4$ ($n^{O(\frac{\log n}{\varepsilon})}$ choices), and we look them up in the look-up table constructed thus far. If the choices we find there are consistent with our current guess, we store this guess in the look-up table and continue. Otherwise the algorithm will reject it and will go on to the next possible guess. So the total extra amount of work for each square in the quadtree is $n^{O(\frac{\log n}{\varepsilon})}$, and the total running time of the algorithm is $O(n\log n) \times n^{O(\frac{\log n}{\varepsilon})} = n^{O(\frac{\log n}{\varepsilon})}$ (recall that the quadtree contains only $O(n\log n)$ nodes). □

Derandomization: The algorithm described is a *randomized* one. But it can be easily derandomized: random shifts a and b take discrete values between 1 and L. By trying all possible $O(n^2)$ values for the pair (a,b) and running the algorithm for each one, we are bound to try one of the "good" values (i.e., one that will give the tour guaranteed by Theorem 4.5). This procedure will increase the running time by a factor $O(n^2)$.

4.3. Euclidean spaces of higher dimension. Since the results in Arora [4] generalize to Euclidean spaces of any *constant* dimension d in a straightforward manner, the plane algorithm for the MLT generalizes to higher dimensions as well. We will give just the changes needed in order for the proofs in the plane case to apply here.

The grid we place in the d-dimensional *cube* of side length L that surrounds the instance to transform it into a well-rounded one has granularity $\Theta(\varepsilon L/(n^2\sqrt{d}))$. Then all internode distances are bound by $O(\sqrt{d}n^2/\varepsilon)$.

Instead of randomly shifted quadtrees we use an obvious extension, the 2^d-ary trees. Instead of squares, we are dealing with d-dimensional cubes, so their boundaries are $(d-1)$-dimensional cubes. The m portals placed on these cubes form an orthogonal *lattice* with granularity $W/m^{\frac{1}{d-1}}$, where W is the side length of the cube we place the portals on. The structure theorem now states the following.

THEOREM 4.9 (structure theorem for Euclidean space of dimension d). *There exist constants e, f such that the following is true for every integer $n > 0$ and every $\varepsilon > 0$. For every well-rounded instance in Euclidean space of dimension d with n nodes, a randomly shifted dissection has with probability at least $1/2$ an associated tour that is $(e \cdot (O(\sqrt{d}\log n/\varepsilon))^d, f \cdot (O(\sqrt{d}/\varepsilon))^d \log n)$-light and whose latency is at most $(1+\varepsilon)OPT$, where OPT denotes the latency of the MLT.*

The dynamic programming algorithm will run in time $O((\frac{\log n}{\varepsilon})^{(\sqrt{d}/\varepsilon)^{O(d)}})n^{O(\frac{\log n}{\varepsilon})}$.

4.4. Extension to other norms. Like Arora's algorithm for the Euclidean TSP, our algorithm for the MLT generalizes to any *Minkowski* norm in $\mathbb{R}^d$. Any symmetric body C that is symmetric around the origin can be used to define a Minkowski norm: the length of $x \in \mathbb{R}^d$ is defined to be $\frac{\|x\|^2}{\|y\|^2}$, where y is the intersection of the surface of C with the line connecting x to the origin. This definition generalizes the l_p norm for $p \geq 1$ (in the case of l_p norm C is the l_p-unit ball centered at the origin).

Distances in any Minkowski norm are within a constant factor of the distances under the l_2 norm. Hence the algorithm described for the Euclidean case works for *any* Minkowski norm as well (with the necessary adjustments of the constants in the structure theorem, Theorem 4.9 and the running time calculations).

4.5. Planar graphs. Our techniques apply also to the MLT problem on *weighted planar graphs* (planar graphs with nonnegative edge lengths). The distance between two nodes is defined as the length of the shortest path in the graph that connects them.

Arora et al. [5] have extended the ideas from Arora [4] to devise a PTAS for the TSP on planar graphs. The first step in their algorithm is the extraction of a *spanner* of the input graph. Informally, a spanner is the subgraph of the input graph that approximates within a factor $1+\varepsilon$ the distances in the original graph but with a total edge length that is much smaller (just $O(1/\varepsilon)$ times the cost of the minimum spanning tree in the input graph). They use a construction by Althofer et al. [2] that runs in polynomial time.

Let G be the input graph and G' its spanner. In order to apply dynamic programming we need the notion of a separator (like the $\frac{1}{3} : \frac{2}{3}$-partition in the tree case or the quadtree in the Euclidean case) and a *hierarchical decomposition* of the instance. The separator in this case is a *Jordan curve* that cuts a "hole" in the graph, thus separating it into an *exterior* (i.e., the hole) and an *exterior*. By defining the *weight* of a planar graph in an appropriate way, Arora et al. [5] show that in polynomial time they can compute such a curve with two essential properties: (a) the interior and exterior weights are a constant fraction of the total weight, and (b) the interior is connected to the exterior only via a set of $k = O(\log n/\varepsilon^2)$ vertices. They show that there is a salesman path whose length is at most $(1+\varepsilon)OPT$ and crosses the boundary of each region at most $O(\log n/\varepsilon^2)$ times. Hence a QPTAS similar to the Euclidean one works for planar graphs, too. The role of the square boundaries is played by the

Jordan curves, and the role of portals is played by the k connecting vertices. Our "guesses" are exactly the same as in the Euclidean case.

THEOREM 4.10. *The algorithm for weighted planar graphs runs in time* $n^{O(\frac{\log n}{\varepsilon^2})}$ *and computes a tour whose latency is at most* $(1+\varepsilon)$ OPT.

Proof. The proof is analogous to the proof of Theorem 4.8. Notice that the approximation scheme for the planar TSP is *not* randomized; therefore the proof of Theorem 4.8 is applied without the expectations. □

4.6. General metrics. In this section we will use our main idea to derive an algorithm for the MLT for general metrics. The only requirement for the distances between points in the given instance is to satisfy the triangle inequalities. For this general case we give a simple *polynomial time* 11.656-approximation algorithm that uses an approximation algorithm for the k-minimum spanning tree (k-MST) as a subroutine. The k-MST problem is defined as the problem of finding the minimum cost tree that spans *exactly* k vertices of a given weighted graph.

Our algorithm has the same flavor as the approximation algorithms in Blum et al. [10] and Goemans and Kleinberg [12]. We note that Goemans and Kleinberg [12] give an improved 7.18-approximation algorithm, which is more complicated.

The general approach is motivated by the observation in section 2, and we use the numbers $n_1, n_2, \ldots, n_k$ defined there, where $k = O(\log n/\varepsilon)$. We will choose $\varepsilon = \sqrt{2}$. Our algorithm for general metrics is quite different to the algorithms for the tree or the Euclidean space, and in this case we have to take into account the fact that due to n and our choice for ε some nodes may be "broken" in two, with each fraction being in a different segment. Let R_i be the fraction of the first node of segment i that belongs to segment i (that means that the rest $1 - Ri$ belongs to segment $i-1$). Note that since segment $i-1$ may end in a whole node (i.e., $\sum_{l=1}^{i-1} n_l$ is an integer), R_i may also take the value 0. R_{k+1} is always 0.

The algorithm is as follows. Let P be the starting node. For $i = 1, \ldots, k$, find, using the algorithm for k-MST, a tour L_i that starts at P and visits $n_i + R_{i+1} - R_i$ nodes that are not visited by $L_1, \ldots, L_{i-1}$. This number of nodes is *integer* and is equal to the number of nodes in segment i, minus the fraction of the start node for segment i that belongs to i (this fraction was visited by L_{i-1}), plus the fraction R_{i+1} of the last node of i that *does not* belong to i but is visited nevertheless by L_i. Of the two possible directions of each tour, pick the one that minimizes the latency. Output the concatenation of these tours (using shortcuts to avoid multiple visits to already visited points). Assume for simplicity that we know the last segment in the tour, which contains $[1/\sqrt{2}] = 1$ vertex and 1 edge.

THEOREM 4.11. *The algorithm just described runs in polynomial time and achieves an approximation factor of* 11.656.

Proof. We analyze this algorithm as follows. Let $\mathcal{T}$ be the optimum tour. Denote by T_i the length of the ith segment of $\mathcal{T}$ (which contains n_i nodes). Then, as in (2.2), a lower bound on OPT, the latency of the optimum tour, is

$$OPT \geq \sum_{i=1}^{k} n_{>i} \cdot T_i, \tag{4.3}$$

where $n_{>i} = n_{i+1} + n_{i+2} + \cdots + n_k$ is the number of nodes appearing in the last $k-i$ segments.

Let d_i be the length of the tour L_i computed by our algorithm. We claim the following.

CLAIM 1.

$$d_i \le (2+\delta) \times 2(T_1 + \cdots + T_i) \text{ for } i = 1, 2, \ldots, k-1. \tag{4.4}$$

Proof of Claim 1. The reason for the "$(2+\delta)$" is that it is the approximation ratio of the k-MST algorithm. From now on we will treat this factor as equal to 2 (by making δ very small, e.g., $\delta = 10^{-6}$). The rest of the expression is explained as follows. Consider the closed tour starting from P, including the first i segments of $\mathcal{T}$, and returning to P. Its length is at most $2(T_1 + T_2 + \cdots + T_i)$, and it includes at least $(n_1 + n_2 + \cdots + n_i + R_{i+1})$ nodes (this is an integer number). At least $n_i + R_{i+1} - R_i$ of these nodes are not in $T_1, \ldots, T_{i-1}$ (since these first $i-1$ segments contain in total only $n_1 + n_2 + \cdots + n_{i-1} + R_i$ nodes). Thus $2(T_1 + T_2 + \cdots + T_i)$ is an upper bound on the length of shortest tour that starts and finishes at P and includes at least $n_i + R_{i+1} - R_i$ nodes not on $T_1, \ldots, T_{i-1}$. This finishes the justification for Claim 1. □

Now notice that the latency of the $n_i + R_{i+1} - R_i$ new nodes visited during tour L_i is upper bounded by $\frac{1}{2}(n_i + R_{i+1} - R_i)d_i + (n_i + R_{i+1} - R_i)\sum_{l=1}^{i-1} d_l$. The second term is an upper bound for the total latency incurred due to the $i-1$ segments of $\mathcal{T}$ preceding the ith segment. The first term is an upper bound for the latency due to the ith segment itself, since the latency in the forward direction plus the latency in the backward direction is equal to $(n_i + R_{i+1} - R_i)d_i$, and we traverse tour L_i in the direction that minimizes the latency of the $n_i + R_{i+1} - R_i$ new points visited. So the total latency of our solution—ignoring the last segment—is upper bounded by

$$\begin{aligned}
A &= \sum_{i=1}^{k-1} \left[(n_i + R_{i+1} - R_i) \left(\frac{1}{2} d_i + \sum_{l=1}^{i-1} d_l \right) \right] \\
&= \frac{1}{2} \sum_{i=1}^{k-1} (n_i + R_{i+1} - R_i) d_i + \sum_{i=1}^{k-1} \sum_{l=1}^{i-1} (n_i + R_{i+1} - R_i) d_l \\
&= \frac{1}{2} \sum_{i=1}^{k-1} (n_i + R_{i+1} - R_i) d_i + \sum_{i=1}^{k-1} d_i (n_{>i} - R_{i+1}) \\
&= \frac{1}{2} \sum_{i=1}^{k-1} n_i d_i + \sum_{i=1}^{k-1} n_{>i} d_i - \frac{1}{2} \sum_{i=1}^{k-1} (R_i + R_{i+1}) d_i \\
&\le \frac{1}{2} \sum_{i=1}^{k-1} n_i d_i + \sum_{i=1}^{k-1} n_{>i} d_i.
\end{aligned}$$

From section 2, $n_i = (1+\varepsilon) n_{i+1}$ and $n_{>i} = \frac{n_i}{\varepsilon}$, so

$$\begin{aligned}
A &\le \frac{1+\varepsilon}{2} \sum_{i=1}^{k-1} n_{i+1} d_i + \frac{1+\varepsilon}{\varepsilon} \sum_{i=1}^{k-1} n_{i+1} d_i \\
&= \frac{(1+\varepsilon)(2+\varepsilon)}{2\varepsilon} \sum_{i=1}^{k-1} n_{i+1} d_i.
\end{aligned}$$

Observing that $n_{>i} = \sum_{j=i+1}^{k} n_j$ and ignoring the last segment (which was com-

puted optimally) we also have

$$\begin{aligned}\sum_{l=1}^{k-1} n_{l+1} d_l &\overset{(4.4)}{\leq} 4 \sum_{l=1}^{k-1} n_{l+1} \sum_{i=1}^{l} T_i \\ &= 4 \sum_{l=1}^{k-1} n_{>l} T_l \\ &\leq 4 \times OPT,\end{aligned}$$

and thus

$$A \leq 2 \frac{(1+\varepsilon)(2+\varepsilon)}{\varepsilon}\, OPT.$$

The factor $\frac{(1+\varepsilon)(2+\varepsilon)}{\varepsilon}$ is minimized for $\varepsilon = \sqrt{2}$, and its value is $3+2\sqrt{2} = 5.828$. Thus $A \leq 11.565\ OPT$. □

5. Extending the MLT problem. Our main idea is general enough to apply to a broader category of objective functions. In this section we study the following *weighted* version of MLT.

WEIGHTED MINIMUM LATENCY TOUR (WMLT)

Input: A set of n points (one of them designated as the starting point p_1), a symmetric distance matrix $[d_{ij}]$, and an integral weight $w_i \geq 0$ for each node $i = 1, 2, \ldots, n$.

Output: A tour $p_1 \to p_2 \to \cdots \to p_n$ that visits *all* points and minimizes the total *weighted* latency

$$\sum_{i=2}^{n} \left[w_{p_i} \sum_{j=1}^{i-1} d_{p_j, p_{j+1}} \right]. \tag{5.1}$$

Obviously, this is an extension to the MLT problem: the contribution of each node to the objective function is the length of the tour from the start to the first visit at the node, *weighted by the weight of the node* w_i. When $w_i = 1$, for all i we get the MLT problem as defined in section 1. Notice that again we can express the objective function in a form similar to formula (1.2), namely,

$$\sum_{i=1}^{n-1} \left[\sum_{j=i+1}^{n} w_{p_j} \right] d_{p_i, p_{i+1}}. \tag{5.2}$$

We study instances where d defines a metric (i.e., distances satisfy the triangle inequalities). When a weight w_i is 0, point i can be moved to the end of a tour without increase to the value of the objective function, and it is enough to solve the problem for the subset of points with nonzero weights. Hence from now on the w_i's will be integers greater than 0.

Let $\mathcal{T} = p_1 \to p_2 \to \cdots \to p_n$ be an optimal tour with total weighted latency OPT. Let $W = \sum_{i=1}^{n} w_{p_i}$ be the total point weight and $\varepsilon > 0$ any parameter. We will assume that the following is true for this instance of WMLT.

ASSUMPTION 1. *$\mathcal{T}$ can be broken into k segments so that in segment i it visits n_i points with total weight W_i given by the following expressions:*

$$W_1 = \frac{\varepsilon\, W}{1+\varepsilon}, \qquad W_i = \frac{W_{i-1}}{1+\varepsilon}, \quad i = 2, 3, \ldots, k. \tag{5.3}$$

Obviously, $k = O(\frac{\log W}{\varepsilon})$. Let the length of the ith segment be T_i. If we let $W_{>i}$ denote the total weight of nodes visited in segments numbered $i+1$ and later, then a simple calculation shows that (and this was the reason for our choice of W_i's)

$$W_{>i} = \sum_{j>i} W_j = \frac{W_i}{\varepsilon} \text{ for every } i = 1, \ldots, k-1. \tag{5.4}$$

As in the case of the MLT, we are going to show that if one replaces each segment by the minimum-cost traveling salesman path on the same subset of nodes, while maintaining the starting and ending points, the new total weighted latency is at most $(1+\varepsilon)OPT$. The lower bound on the OPT is similar to the lower bound in the MLT case:

$$OPT \geq \sum_{j=1}^{m-1} W_{>j} \cdot T_j. \tag{5.5}$$

By replacing each segment T_i with the optimum salesman path T_i' we increase the weighted latency of points within the segment by at most $W_i T_i'$. Hence the total weighted latency of the new tour $\mathcal{T}'$ can be upper bounded as follows:

$$\begin{aligned} \text{cost}(\mathcal{T}') &\leq \sum_{i=1}^{k} W_i T_i' + \sum_{i=1}^{k} W_{>i} T_i' \\ &\leq \varepsilon \cdot \sum_{i=1}^{k} W_{>i} T_i + \sum_{i=1}^{k} W_{>i} T_i \\ &\overset{(5.5)}{\leq} (1+\varepsilon)\ OPT. \end{aligned}$$

Thus we have shown that under Assumption 1, the analogue of Theorem 2.1 can be proven.

THEOREM 5.1. *Let OPT be the total latency of the WMLT under Assumption 1. There exists a tour that is a concatenation of $O(\frac{\log W}{\varepsilon})$ optimal salesman paths and whose total weighted latency is at most $(1+\varepsilon)OPT$.*

Even if, instead of the optimum salesman path in each segment, we use a $(1+\gamma)$-approximate salesman path, then the latency of the tour of Theorem 5.1 is $(1+\gamma\cdot\varepsilon+\gamma+\varepsilon)OPT$.

The approximation-preserving reduction from the MLT to the weighted vehicle routing with per-mile costs in section 3 works also for the WMLT. If the vehicle routing oracle computes a ρ-approximation in polynomial time, our reduction will lead to a $\rho(1+\varepsilon)$-approximate solution for WMLT in $n^{O(\log W/\varepsilon)}$ time. This follows from Theorem 5.1, since it suffices to go over all possible sequences $p_1, p_2, \ldots, p_k$ for $k = O(\log W/\varepsilon)$, and this increases the running time by a factor of at most $O(n^k) = n^{O(\frac{\log W}{\varepsilon})}$.

5.1. Approximation algorithms for the WMLT. First we point out the differences between our rounding procedures for the MLT and the rounding for the WMLT. In this case it suffices to assume w.l.o.g. that the minimum nonzero internode distance is 1 and maximum internode distance is $O(n \cdot W/\varepsilon)$, where $W = \sum_{i=1}^{n} w_i$ and $\varepsilon > 0$ is any parameter. The reason is that if L denotes the diameter of the space, then L is a lower bound on the weighted minimum latency. Again we merge all pairs of nodes with internode distance at most $\frac{\varepsilon L}{n \cdot W}$. This affects the latency of the optimum tour by at most $\varepsilon L \leq \varepsilon OPT$. Furthermore, the ratio of the maximum internode distance and the minimum nonzero internode distance is $O(nW/\varepsilon)$. Since ε is constant, we will often think of the maximum internode distance as $O(nW)$. Note that in the weighted case the internode distance (and therefore the running time of our algorithms) depend directly on W. If W is, for example, exponential in the size of the input, our algorithms will run in exponential time. We give the running times of algorithms described for the MLT when they are applied in the case of WMLT. Their correctness is ensured by Assumption 1 and the extension of our main idea.

THEOREM 5.2. *Algorithm* 1 *runs in time* $(nW)^{O(\log n \log W/\varepsilon)}$ *and computes a tour whose weighted latency is at most* $(1+\varepsilon)\ OPT$.

The proof is identical to Theorem 4.4 and uses Theorem 5.1.

THEOREM 5.3. *The algorithm for the MLT in Euclidean spaces of constant dimension d runs in time* $O((\frac{\log W}{\varepsilon})^{(\sqrt{d}/\varepsilon)^{O(d)}})(nW)^{O(\frac{\log W}{\varepsilon})}$ *and computes a tour whose weighted latency is at most* $(1+\varepsilon)\ OPT$.

For the proof, see section 4.3 and adapt structure theorem, Theorem 4.9 to work with Theorem 5.1. This result extends also to any Minkowski norm (cf. section 4.4).

THEOREM 5.4. *The algorithm for weighted planar graphs runs in time* $(nW)^{\frac{\log W}{\varepsilon}}$ *and computes a tour whose weighted latency is at most* $(1+\varepsilon)\ OPT$.

The proof is identical to Theorem 4.10 in section 4.5.

REACHABILITY AND DISTANCE QUERIES VIA 2-HOP LABELS*

EDITH COHEN†, ERAN HALPERIN‡, HAIM KAPLAN‡, AND URI ZWICK‡

Abstract. Reachability and distance queries in graphs are fundamental to numerous applications, ranging from geographic navigation systems to Internet routing. Some of these applications involve huge graphs and yet require fast query answering. We propose a new data structure for representing all distances in a graph. The data structure is *distributed* in the sense that it may be viewed as assigning *labels* to the vertices, such that a query involving vertices u and v may be answered using only the labels of u and v.

Our labels are based on 2-*hop covers* of the shortest paths, or of all paths, in a graph. For shortest paths, such a cover is a collection S of shortest paths such that, for every two vertices u and v, there is a shortest path from u to v that is a concatenation of *two* paths from S. We describe an efficient algorithm for finding an *almost optimal* 2-hop cover of a given collection of paths. Our approach is general and can be applied to directed or undirected graphs, exact or approximate shortest paths, or to reachability queries.

We study the proposed data structure using a combination of theoretical and experimental means. We implemented our algorithm and checked the size of the resulting data structure on several real-life networks from different application areas. Our experiments show that the total size of the labels is typically not much larger than the network itself, and is usually considerably smaller than an explicit representation of the transitive closure of the network.

Key words. shortest-path queries, reachability queries, distance labels, 2-hop labels

1. Introduction.

We consider the problem of efficiently answering distance or reachability queries in directed or undirected graphs. We focus on scenarios in which the graph/network is given to us explicitly and we are able to do some preprocessing of it. The generated data structure should be fairly compact and should accelerate query answering by as much as possible. Often, the computational resources available for processing queries are weaker than those available during the preprocessing stage. This is the case, for example, in geographic navigation systems, where the preprocessing may be done on a large computer, while queries are answered using a much weaker processor installed in a car.

There are two naive solutions to the problem. The first is to precompute answers to all possible queries, e.g., by solving the all-pairs shortest-paths (APSP) problem or by computing the transitive closure of the network. Each query could then be answered in constant time. This, however, is not a viable option, especially for sparse networks, as the data structure produced for an n-vertex graph would be of size $\Omega(n^2)$. The second solution approach is to do no preprocessing at all and answer each query, e.g., using a single-source shortest-path (SSSP) computation. The space requirements here are minimal, but answering a query on an m-edge graph may take $\Omega(m)$ time.

We present here a new processing scheme, and a corresponding query-answering algorithm, for answering reachability and distance queries. Our preprocessing scheme

generates a data structure of reasonable size, i.e., not much larger than the original network, and typically much smaller than, say, an explicit representation of the transitive closure of the network. Given the precomputed data structure, our query-answering algorithm can answer distance and reachability queries quickly, much faster than is possible without preprocessing.

The data structure generated by our preprocessing algorithm is distributed. We assign to each vertex of the network a *distance* or *reachability* label such that we can later calculate the distance (or reachability relation) between two vertices using only the labels of these two vertices. Distance labels were considered by, among others, Peleg [10], Gavoille et al. [4], and Thorup and Zwick [12]. All these papers, however, consider only *undirected graphs*, and only worst-case results. We are interested mainly in directed graphs, and in the performance of the proposed labeling scheme on networks that occur in practice.

Our labels are based on the concept of 2-*hop covers*. Let $G = (V, E)$ be a (directed or undirected) graph. For every $u, v \in V$, let P_{uv} be a collection of paths from u to v in G. (For example, P_{uv} may be the set of all shortest paths from u to v.) We define a *hop* to be a pair (h, u), where h is a path in G and $u \in V$, the *handle* of the hop, is one of the endpoints of h. We say that a collection of hops H is a 2-hop cover of the collection $P = \cup_{uv} P_{uv}$ if, for every $u, v \in V$, if $P_{uv} \neq \emptyset$, then there is a path $p \in P_{uv}$ and two hops $(h_1, u) \in H$ and $(h_2, v) \in H$ such that p is the concatenation $h_1 h_2$. We show how to obtain a 2-*hop labeling* from such a cover by mapping each hop to an item in the label of its handle node.

The nature of each such item and the interpretation of the labels depend on the specific variant of the problem that we want to solve. Consider, for example, undirected distance queries. Each set of paths P_{uv} contains all shortest paths between u and v. The item in the label $L(u)$ of u that corresponds to a hop $(h = (u = v_0, \ldots, v_k), u)$ is $(w(h), v_k)$, where $w(h)$ is the weight of the path h. The distance between two nodes u and v can then be obtained from their labels by taking the minimum, over all nodes that appear in *both* $L(u)$ and $L(v)$, of the sum of the two weights.

The total size of the labels is thus $|H|$. (We count here the *number* of hops in the cover, not their combined length.) Each distance/reachability query can then be answered in time that is linear in the size of the corresponding labels—therefore, on *average*, in $O(|H|/n)$ time.

We show that finding a 2-hop cover (and thus, a 2-hop labeling) of minimum size is an NP-hard problem. We present, however, an efficient and practical algorithm, which we implemented, for obtaining almost-optimal 2-hop covers. The size of the 2-hop cover returned by this algorithm is larger than the minimum possible 2-hop cover by at most a logarithmic factor. In practice, we expect the performance ratio of this algorithm to be much better.

Our algorithm produces an almost optimal 2-hop labeling of *any* input graph. Some graphs may have shorter labelings that are not 2-hop labelings. But, for many interesting families of graphs such as planar graphs, the optimal 2-hop labelings are almost as short as the optimal labeling. Thus, without being specifically designed for any such graph family, our algorithm produces almost optimal labelings. It is also expected, as verified by our experiments, to work well on graphs that are, say, "mostly" planar, or "mostly" tree-like, as many practical problem are.

We *conjecture* that any n-vertex, m-edge directed graph has a 2-hop cover, and thus a 2-hop labeling, of total size $\tilde{O}(nm^{1/2})$. We show there exist graphs for which

any distance or reachability labeling is of size $\Omega(nm^{1/2})$.

A useful property of our approach is that by properly selecting the underlying set of paths, labels can be produced for different variants of the shortest paths problem: reachability or distances, directed or undirected, exact or approximate distances, and for the complete or partial set of vertex-pairs. Even though exact directed distance labeling for all pairs of vertices is the most general variant in the sense that all other variants can be reduced to it, the distinction is important, as a less-constrained variant often enjoys a more compact labeling. One such example is the family of directed planar graphs: Reachability or $(1+\epsilon)$-approximate shortest paths have worst-case 2-hop labels of size $O(n \log^2 n)$ (using some slight modification of a construction by Thorup [11]), whereas for exact-distances there is a known $\Omega(n^{4/3})$ lower bound for any labeling scheme [4]. It is also not too hard to construct specific graphs which admit more compact labeling for less-constrained variants. Thus, 2-hop labels should always be produced for the least-constrained appropriate variant.

We have made an experimental study of our proposed labeling scheme. We used several real-world networks and obtained promising results, showing that the size of the labels produced is typically significantly smaller than what would have been required for explicit representation.

2. Reachability and distance queries. Let $G = (V, E)$ be a weighted graph (which may be directed or undirected) with $n = |V|$ and $m = |E|$. If $(u, v) \in E$ is an edge, we let $w(u, v)$ be the weight (or cost, or length) attached to that edge. In networks used in applications, the weights attached to the edges are nonnegative. Our approach, however, works also when there are edges of negative weight. We let $\delta(u, v)$ be the *distance* from u to v in the graph, i.e., the smallest weight of a path from u to v, if one exists, in the graph, or ∞ otherwise. (We assume that there are no negative weight cycles in the graph, and so all distances are well defined.)

We would like to preprocess the graph G and obtain a compact representation of it such that, given a pair of vertices $u, v \in E$, we could quickly answer the following queries:

reach(u, v)**:** Is there a path from u to v in the graph?

dist(u, v)**:** What is the distance from u to v in the graph? Sometimes, we would be satisfied with $(1+\epsilon)$-approximate distances.

first-edge(u, v)**:** Which edge emanating from u is a first edge on a (shortest) path from u to v?

path(u, v)**:** Find a (shortest) path from u to v in the graph.

Reachability queries are of course special cases of (directed) distance queries, as there is a path from u to v if and only if the distance from u to v is finite. If we are interested only in reachability properties, we may assume that the weight of all the edges of the graph is 0. Path queries could be answered using repeated first-edge queries. In some cases, it would be possible to accelerate the processing of repeated first-edge queries so that if a shortest path from u to v contains, say, ℓ edges, then the processing time of the ℓ first-edge queries producing it would require substantially less time than ℓ times the time required by a typical first-edge query.

3. 2-hop labels. A possible scheme for achieving the objective set forth above is the following: During the preprocessing stage, we attach to each vertex u of the graph a relatively short label $L(u)$ such that, for any two vertices u and v, the two labels $L(u)$ and $L(v)$ would contain enough information to answer the required queries. More formally we use the following.

DEFINITION 3.1 (distance labelings). *A* distance labeling *of a weighted, directed or undirected, graph $G = (V, E)$ is a pair (L, F), where $L : V \to \{0,1\}^*$ and $F : \{0,1\}^* \times \{0,1\}^* \to (\mathbb{R} \cup \{\infty\}) \times (E \cup \{\phi\})$, such that for every $u, v \in V$, if $F(L(u), L(v)) = (d, e)$, then $d = \delta(u, v)$, the distance from u to v in the graph. If $d = \infty$, then $e = \phi$. Otherwise, e is the first edge on a (shortest) path from u to v in the graph. The* total bit-size *of the labeling is $\sum_{v \in V} |L(v)|$, where $|L(v)|$ is the length of $L(v)$. The* maximum label size *is naturally $\max_{v \in V} |L(v)|$. We say that a labeling scheme has* linear complexity *if $F(L(v), L(u))$ can be computed in $O(|L(u)| + |L(v)|)$ time.*

Reachability labelings are defined similarly, and $(1+\epsilon)$-approximate distance labelings are defined by requiring $\delta(u, v) \le d \le (1+\epsilon)\delta(u, v)$. We focus on reachability/distance labels of the following form.

DEFINITION 3.2 (2-hop distance labeling). *Let $G = (V, E)$ be a weighted directed graph. A* 2-hop distance labeling *of G assigns to each vertex $v \in V$ a label $L(v) = (L_{in}(v), L_{out}(v))$ such that $L_{in}(v)$ is a collection of pairs $(x, \delta(x, v))$, where $x \in V$, and similarly, $L_{out}(v)$ is a collection of pairs $(x, \delta(v, x))$, where $x \in V$. With a slight abuse of notation, we also consider $L_{in}(v)$ and $L_{out}(v)$ to be subsets of V, and for any two vertices $u, v \in V$ we require that*

$$\delta(u, v) \;=\; \min_{x \in L_{out}(u) \cap L_{in}(v)} \delta(u, x) + \delta(x, v).$$

The size of the labeling is defined to be $\sum_{v \in V} |L_{in}(v)| + |L_{out}(v)|$.

For approximate distances we relax the requirement to $\min_{x \in L_{out}(u) \cap L_{in}(v)} \delta(u, x) + \delta(x, v) \le (1+\epsilon)\delta(u, v)$.

For undirected graphs we can simplify the definition: For every vertex v, there is only one collection $L(v)$ of pairs $(x, \delta(x, v))$, such that for every $u, v \in V$ we have $\delta(u, v) = \min_{x \in L(u) \cap L(v)} \delta(u, x) + \delta(x, v)$. The size of the labeling is then $\sum_{v \in V} |L(v)|$.

A slightly more general class of distance labelings is the following.

DEFINITION 3.3 (Steiner 2-hop distance labeling). *A* Steiner 2-hop distance labeling *is a labeling in which $L_{in}(v)$ and $L_{out}(v)$ consist of pairs of the form $(x, d(x, v))$ and $(x, d(v, x))$, respectively, where $x \in X$, $d(x, v), d(v, x) \in \mathbb{R}$, and X is some arbitrary finite set. We require that*

$$\delta(u, v) \;=\; \min_{x \in L_{out}(u) \cap L_{in}(v)} d(u, x) + d(x, v).$$

(A similar definition can be stated for undirected graphs and for approximate distances.)

Note that any 2-hop distance labeling is a Steiner 2-hop labeling, with $X = V$ and $d(x, v) = \delta(x, v)$.

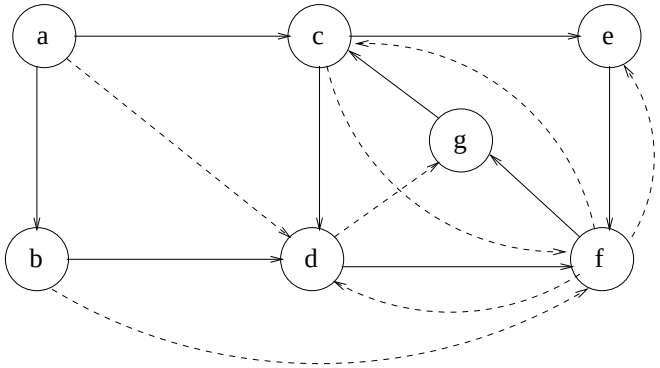
We also use the following definition of 2-hop reachability labels.

DEFINITION 3.4 (2-hop reachability labeling). *Let $G = (V, E)$ be a directed graph. A 2-hop reachability labeling of G assigns to each vertex $v \in V$ a label $L(v) = (L_{in}(v), L_{out}(v))$, such that $L_{in}(v), L_{out}(v) \subseteq V$ and there is a path from every $x \in L_{in}(v)$ to v and from v to every $x \in L_{out}(v)$. Furthermore, for any two vertices $u, v \in V$, we should have*

$$u \rightsquigarrow v \quad \textit{iff} \quad L_{out}(u) \cap L_{in}(v) \neq \phi.$$

The size of the labeling is defined to be $\sum_{v \in V} |L_{in}(v)| + |L_{out}(v)|$.

A *2-hop Steiner reachability labeling* is defined similarly, but we allow $L_{in}(v)$ and $L_{out}(v)$ to contain vertices from an arbitrary finite set X.



v	$L_{in}(v)$	$L_{out}(v)$
a		b, c, d
b		f, d
c	f	d, f
d	f, c	g, f
e	c, f	f
f	d, c	g, c, e
g	d, f	c

FIG. 1. *Solid edges are the edges of the graph. Dashed lines are hops that are not edges of the graph.*

Remarks. (1) In Definition 3.1, we measure the label size in bits. On the other hand, in Definitions 3.2 and 3.4 we measure the size of 2-hop labels by the total number of hops they contain. (2) Our 2-hop labelings, as defined, do not support **first-edge** queries. However, it is easy to add first-edge information to the hops so that they will support such queries.

Given the labels $L(u) = (L_{in}(u), L_{out}(u))$ and $L(v) = (L_{in}(v), L_{out}(v))$, we can easily compute $\delta(u, v)$, the distance from u to v in $O(|L_{out}(u)| + |L_{in}(v)|)$ time. (We keep $L_{out}(u)$ and $L_{in}(v)$ in sorted order and merge them to find their intersection.) We can in fact do it also in $O(\min\{|L_{out}(u)|, |L_{in}(v)|\})$ time, if we keep hash tables for the sets $L_{out}(u)$ and $L_{in}(v)$. As an example for 2-hop reachability labeling, consider the graph in Figure 1 and the 2-hop labeling shown in the table next to it. We assume there that each vertex v is contained, by default, in $L_{in}(v)$ and $L_{out}(v)$.

4. 2-hop covers. Closely related to 2-hop labelings is the notion of a 2-hop cover of a collection of paths in a graph.

DEFINITION 4.1 (2-hop cover). *Let $G = (V, E)$ be a graph. For every $u, v \in V$, let P_{uv} be a collection of paths from u to v (for undirected graphs we have $P_{uv} \equiv P_{vu}$). Let $P = \{P_{uv}\}$. We define a* hop *to be a pair (h, u), where h is a path in G and $u \in V$ is one of the endpoints of h. We refer to u as the* handle *of the hop. A collection of hops H is said to be a 2-hop cover of P if for every $u, v \in V$ such that $P_{uv} \neq \phi$ there is a path $p \in P_{uv}$, and two hops $(h_1, u) \in H$ and $(h_2, v) \in H$, such that $p = h_1 h_2$, i.e., p is the concatenation of h_1 and h_2. The size of the cover is $|H|$, the number of hops in H.*

Intuitively, a path p can be covered by two hops if p is a concatenation of the two hop paths *and* the handles of the hops are the endpoints of p. We obtain 2-hop labels from 2-hop covers by mapping a hop with handle v to an item in the label of the node v. Thus, the size of this labeling is equal to the size of the 2-hop cover. Specifically, we can obtain reachability labels from a 2-hop cover H of the set of *all paths* in G by setting $L_{in}(v) = \{x \mid ((x \rightsquigarrow v), v) \in H\}$ and $L_{out}(v) = \{x \mid ((v \rightsquigarrow x), v) \in H\}$. The converse also holds: From reachability labels of G we can obtain a 2-hop cover of the same size by adding to H a hop consisting of an arbitrary path $v \rightsquigarrow x$ and endpoint v if $x \in L_{out}(v)$ and a hop consisting of an arbitrary path $x \rightsquigarrow v$ and endpoint v if $x \in L_{in}(v)$. Similarly we can obtain 2-hop distance labels from a 2-hop cover of the set of *all shortest paths* in G, and vice versa. We could also obtain approximate

distance labels from a 2-hop cover of the set of all approximate shortest paths and vice versa. Thus we obtain that the size of an optimal 2-hop cover for the set of all paths, the set of all shortest paths, and the set of all approximate shortest paths is equal to the minimum size of a 2-hop reachability labeling, 2-hop distance labeling, and 2-hop approximate distance labelings, respectively.

The common property of the set of all paths, the set of all shortest paths, and the set of all approximate shortest paths, which makes their 2-hop covers correspond to 2-hop labelings, is the following.

DEFINITION 4.2 (hop invariance). *A set of paths $P = \{P_{uv}\}$ in a graph $G = (V, E)$ is said to be* hop invariant *if there exists a collection Q of paths such that*

- *for any two vertices v_i and v_j, there is at most one path $q_{ij} \in Q$ such that $v_i \rightsquigarrow^{q_{ij}} v_j$;*
- *whenever $v_i \rightsquigarrow^{p_1} v_j \rightsquigarrow^{p_2} v_k$ is a path of P, then q_{ij} and q_{jk} exist and $q_{ij}q_{jk} \in P$.*

LEMMA 4.1. *A set P consisting of all shortest paths between a particular set of vertex-pairs (in directed or undirected graphs) is 2-hop invariant. In particular, the set of all shortest paths is hop invariant. A similar statement holds for $(1+\epsilon)$-approximate shortest paths and for the set of all directed paths.*

Proof. In all these cases, it is sufficient to place in Q an arbitrary *shortest* path connecting each pair of nodes. □

THEOREM 4.1. *Finding a minimum 2-hop cover of a collection P of shortest paths in a directed graph is an NP-hard problem.*

Proof. We reduce 3-SAT to the decision version of the minimum 2-hop cover problem of shortest paths in directed graphs. Let S be an instance of 3-SAT with variables $x_1, x_2, x_3, \ldots, x_n$ and clauses $C_1, C_2, \ldots, C_m$. We build an instance for the 2-hop cover problem as follows. The graph G consists of a pivot vertex p together with a collection of variable gadgets and clause gadgets. The variable gadget corresponding to a variable x consists of

1. six vertices a_1^x, a_2^x, b^x, $b^{\overline{x}}$, e_1^x, and e_2^x,
2. eight arcs (a_1^x, b^x), $(a_1^x, b^{\overline{x}})$, (a_2^x, b^x), $(a_2^x, b^{\overline{x}})$, (b^x, e_1^x), $(b^{\overline{x}}, e_1^x)$, (b^x, e_2^x), and $(b^{\overline{x}}, e_2^x)$.

We connect the pivot p to the variable gadget by adding the arcs (p, b^x) and $(p, b^{\overline{x}})$.

Let C be a clause $C = (X, Y, Z)$, where X, Y, and Z are literals of the variables x, y, and z, respectively. For each such clause C we add a vertex c and the arcs (b^X, c), (b^Y, c), and (b^Z, c) (i.e., if $X = x$, we add the arc (b^x, c), and if $X = \overline{x}$, we add the arc $(b^{\overline{x}}, c)$, and similarly for y and z).

For every variable x we define $P_{a_i^x e_j^x}$, $i, j \in \{1, 2\}$, to be the set of directed paths from a_i^x to e_j^x. We also define $P_{pe_j^x}$ to consist of the directed paths from p to e_j^x, $j \in \{1, 2\}$. We call the sets $P_{a_i^x e_j^x}$ and $P_{pe_j^x}$ the *variable paths* that correspond to variable x. For a clause $C = (X, Y, Z)$ we define $P_{b^X c}$, $P_{b^Y c}$, and $P_{b^Z c}$ to be the set containing the directed path of a single edge from b^X to c, from b^Y to c, and from b^Z to c, respectively. We also define P_{pc} to consist of the three directed paths from p to c. We define every P_{uv} not mentioned above to be empty.

We claim that the 3-SAT instance S is satisfiable if and only if the 2-hop cover instance has a solution of size at most $5n + 3m$.

The proof of this claim is as follows. Assume S is satisfiable, and let f be a satisfying assignment. We define a 2-hop cover H as follows. For every variable x if $f(x) = 1$, we add the hops $((a_1^x, b^x), a_1^x)$, $((a_2^x, b^x), a_2^x)$, $((p, b^x), p)$, $((b^x, e_1^x), e_1^x)$, and $((b^x, e_2^x), e_2^x)$ to H. Otherwise we add the hops $((a_1^x, b^{\overline{x}}), a_1^x)$, $((a_2^x, b^{\overline{x}}), a_2^x)$, $((p, b^{\overline{x}}), p)$,

$((b^{\overline{x}}, e_1^x), e_1^x)$, and $((b^{\overline{x}}, e_2^x), e_2^x)$ to H. For each clause $C = (X, Y, Z)$ we add the hops $((b^X, c), c)$, $((b^Y, c), c)$, and $((b^Z, c), c)$ to H. It is straightforward to check that if f is satisfying, then H is indeed a cover. The size of H is $5n + 3m$.

For the other direction, let H be a 2-hop cover of size $5n + 3m$. To cover the sets $P_{b^x c}$ and $P_{b^{\overline{x}} c}$ for all variables x and clauses C, the cover H must include $3m$ distinct hops of the form (b^X, c) for every clause C and literal $X \in C$. To cover the variable paths corresponding to x we need at least five hops, consisting of arcs incident with vertices from the variable gadget corresponding to x, and p.

Since H is a 2-hop cover of size $5n + 3m$, we cover the variable paths of each variable with exactly five hops. It is easy to check that the only way to cover the variable paths with five hops is either to include the hops $((a_1^x, b^x), a_1^x)$, $((a_2^x, b^x), a_2^x)$, $((p, b^x), p)$, $((b^x, e_1^x), e_1^x)$, and $((b^x, e_2^x), e_2^x)$ in H or to include the hops $((a_1^x, b^{\overline{x}}), a_1^x)$, $((a_2^x, b^{\overline{x}}), a_2^x)$, $((p, b^{\overline{x}}), p)$, $((b^{\overline{x}}, e_1^x), e_1^x)$, and $((b^{\overline{x}}, e_2^x), e_2^x)$ in H. We define a satisfying assignment to S by setting $f(x) = 1$ if and only if the former set of hops is in H. Since H also covers the sets P_{pc} for all clauses C, it follows that S must be a satisfying truth assignment. □

We can, however, efficiently find an almost optimal 2-hop cover if the collection of paths P is hop invariant.

THEOREM 4.2. *Let $G = (V, E)$ be a graph with $|V| = n$, and let P be a hop invariant set of paths in G. Then there is an efficient algorithm for finding a 2-hop cover of P whose size is larger than the smallest such cover by at most an $O(\log n)$ factor.*

Before proving the theorem, we introduce some notation. As before, let P_{uv}, for $u, v \in V$, be the paths of P that start at u and end at v. Let $B_{uv} \subseteq V$ be the set of vertices that appear on paths from P_{uv}. (Note that $u, v \in B_{uv}$ if $P_{uv} \neq \phi$.) A moment of reflection shows that the size of the minimum 2-hop cover of P depends only on the sets B_{uv}, for $u, v \in V$. We also need to define the *densest subgraph* problem and state some results that are known for it.

DEFINITION 4.3 (densest subgraph). *The* densest subgraph problem *is defined as follows: Given an undirected graph $G = (V, E)$, find a subset $S \subseteq V$ for which the average degree in the subgraph induced by S is maximized, i.e., a set that maximizes the ratio $|E(S)|/|S|$, where $E(S)$ is the set of edges connecting two vertices of S.*

The densest subgraph problem can be solved exactly in polynomial time using flow techniques. One such algorithm is given by Lawler [8, Chapter 4]. The best time bound currently available for the problem is $O(mn \log(n^2/m))$, due to Gallo, Grigoriadis, and Tarjan [3]. It is obtained by reducing the densest subgraph problem to a parametric min-cut problem and then solving it using a parametric max-flow algorithm whose running time is the same as the running time of the nonparametric max-flow algorithm of Goldberg and Tarjan [5].

Of more practical interest is a much simpler linear time 2-approximation algorithm for the densest subgraph problem, which is a slight modification of an algorithm mentioned by Kortsarz and Peleg [7]. This algorithm iteratively removes a vertex of minimum degree from the graph. This generates a sequence of n subgraphs of the original graph. The algorithm returns the densest of these subgraphs. It is not difficult to check that this algorithm can be implemented to run in linear time, and that it is a 2-approximation algorithm for the densest subgraph problem; i.e., the average degree in the subgraph returned is at least half of the average degree in the densest possible subgraph.

We can now present a proof of Theorem 4.2.

Proof of Theorem 4.2. We cast the problem of finding a minimum 2-hop cover of P as a minimum set cover problem. We then apply the greedy algorithm and find a cover that is larger than the optimal cover by at most a logarithmic factor (Chvátal [1], Johnson [6], Lovász [9]). One difficulty that arises is that the resulting set cover instance is huge. We show, however, that it is possible to apply the greedy algorithm to this set cover instance *without* generating it explicitly.

We first recall the flow of the greedy algorithm of the set cover problem. The instance of the set cover problem is a ground set T, and a set $\mathcal{S}$ of subsets of T. For each $S \in \mathcal{S}$, there is an associated weight $w(S)$. The goal is to find a subset $\mathcal{U} \subseteq \mathcal{S}$ such that $\cup_{S \in \mathcal{U}} S = T$ and $\sum_{S \in \mathcal{U}} w(S_i)$ is minimized. The greedy algorithm for the problem is the following. We maintain the set of uncovered elements T', which is initialized to $T' = T$. In each iteration of the algorithm, we add to $\mathcal{U}$ a set S, which maximizes the ratio $\frac{|S \cap T'|}{w(S)}$. We iterate until $T' = \phi$.

The set cover instance corresponding to the 2-hop cover instance is constructed as follows. The ground set of elements to be covered is $T = \{(u, v) \mid P_{uv} \neq \phi\}$. For each vertex $w \in V$ and two subsets $C_{in}, C_{out} \subseteq V$, we have a set

$$S(C_{in}, w, C_{out}) \;=\; \{\, (u, v) \in T \mid u \in C_{in}\,,\; v \in C_{out}\,,\; w \in B_{uv}\,\}.$$

The weight attached to this set is $|C_{in}| + |C_{out}|$. The vertex w is called the *center* of the set $S(C_{in}, w, C_{out})$. The goal is to find a collection of such sets of minimum total weight that cover T. (Note that the collection of sets is *exponential* in size.)

The proof that this set cover instance is equivalent to the 2-hop cover problem is as follows: If H is a 2-hop directed cover of minimum size, we let $C_{in}(w) = \{u|((u, w), u) \in H\}$ and $C_{out}(w) = \{u|((w, u), u) \in H\}$. We can then cover the set T using the sets $S(C_{in}(w), w, C_{out}(w))$ for $w \in V$.

Conversely, we first claim that we may assume w.l.o.g. that the minimum cover contains at most one set with a given center. If a cover contains two sets with the same center, i.e., $S(C'_{in}, w, C'_{out})$ and $S(C''_{in}, w, C''_{out})$, then these two sets can be replaced, without increasing the size of the cover, by the set $S(C'_{in} \cup C''_{in}, w, C'_{out} \cup C''_{out})$.

Thus, let $S(C_{in}(w), w, C_{out}(w))$ be the set corresponding to $w \in V$. We can now define a corresponding 2-hop cover in the following way: $((u, w), u) \in H$ if and only if $u \in C_{in}(w)$, and $((w, u), u) \in H$ if and only if $u \in C_{out}(w)$.

To see that this is indeed a 2-hop cover, consider a pair (u, v) such that $P_{uv} \neq \emptyset$. From the construction of the set cover instance, there exists $w \in B_{uv}$ such that $u \in C_{in}(w)$ and $v \in C_{out}(w)$, and thus the hops $((u, w), u)$ and $((w, v), v)$ are in H.

We next have to show that we can efficiently apply the greedy algorithm to this exponential size set cover instance. Let T' be the part of T that is still uncovered. Initially $T' \leftarrow T$. In each step of the greedy algorithm we are supposed to find a set S with the best ratio $\frac{|S \cap T'|}{w(S)}$. In the directed case we are looking for a set $S(C_{in}, w, C_{out})$ for which the ratio

$$\frac{|S(C_{in}, w, C_{out}) \cap T'|}{|C_{in}| + |C_{out}|}$$

is maximized.

To do that we find, for every $w \in V$, the set $S(w)$ which maximizes the above ratio over all the sets $S(C_{in}, w, C_{out})$, in which w is their center. We construct an auxiliary undirected bipartite graph $G_w = (V_w, E_w)$, which we call *the center graph of* w, in the following way. The vertex set V_w contains two vertices v_{in} and v_{out} for each vertex v

of the original graph G. We have the undirected edge $(u_{out}, v_{in}) \in E_w$ if and only if $(u, v) \in T'$ and $w \in B_{uv}$. Many of the vertices in G_w may be isolated and can therefore be removed from the graph. It is straightforward to prove that the problem of finding the sets C_{in} and C_{out} that maximize the ratio $|S(C_{in}, w, C_{out}) \cap T'|/(|C_{in}| + |C_{out}|)$ is exactly the problem of finding the *densest subgraph* of G_w.

We solve this problem, computing $S(w)$ for each center $w \in V$, and finally choose the vertex w for which $S(w)$ has the best ratio. We then add the corresponding set $S(w)$ to the cover, update T', and repeat until T' is empty. It is shown by Johnson [6], Lovász [9], and Chvátal [1] that the greedy heuristic achieves a performance ratio of H_t for the set cover problem, where t is the number of elements to be covered and H_t is the Harmonic number. For our problem, the number of elements is equal to the number of vertex-pairs such that there is at least one path in P between them. Thus, we obtain an approximation ratio of

$$H_{|\{ij|P_{ij}\neq\emptyset\}|} \leq H_{n^2} < 2\log n + O(1).$$

This construction is slightly different for undirected paths. The set T to be covered is a set of (unordered) vertex-pairs $\{u, v\}$ such that $B_{uv} \neq \emptyset$. For each vertex $w \in V$ and a subset $C \subseteq V$, we have a set $S(C, w) = \{\{u, v\} \mid u \in C,\ v \in C,\ w \in B_{uv}\}$. The proof that this set cover problem is equivalent to our original 2-hop cover problem is essentially as for the directed case: Let $S(C(w), w)$ be the set corresponding to w; then $((u, w), w) \in H$ if and only if $u \in C(w)$. To solve the set cover instance, we are interested in $S(C, w)$, which maximizes $\frac{|S(C,w)\cap T'|}{|C|}$. We again first solve this maximization problem separately for each w. Here the auxiliary graph $G_w = (V, E_w)$ contains a single copy of each vertex of V and generally is not bipartite. We have the edge $(u, v) \in E_w$ if and only if $(u, v) \in T'$ and $w \in B_{uv}$. Similarly, the problem of finding the set $S(w) = (C, w)$ that maximizes the ratio $|S(C, w) \cap T'|/|C|$ is then exactly the problem of finding the *densest subgraph* of G_w. □

Our approximation algorithm has ingredients similar to those of an approximation algorithm given by Kortsarz and Peleg [7] for the 2-spanner problem.

4.1. A simple example.

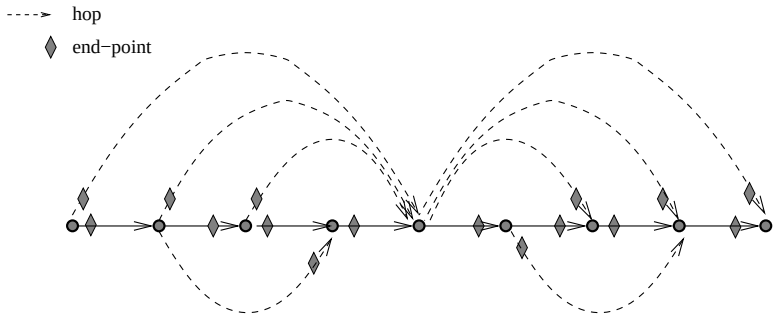


FIG. 2. *A 2-hop cover of a path. Hops are dashed lines or original edges. The diamonds indicate which endpoint is the handle of the hop.*

To better visualize the working of our algorithm, we demonstrate its operation for the special case where the input is a graph that consists of single directed path (see Figure 2). We name the nodes on the path by consecutive integers $(1, 2, 3, \ldots, n)$. Consider the center graph G_j of vertex j. For every i, k such that $i < j$ and $k > j$

there is an edge from i_{out} to k_{in} in G_j that corresponds to the path from i to k going through j. The subgraph induced by the $x = j-1$ hops of the form $l \rightsquigarrow j$ $(l < j)$ and the $y = n-j$ hops of the form $j \rightsquigarrow l$ $(l > j)$ has density $\frac{xy}{x+y}$. Since $x+y = n-1$, the density is maximized when $x = y = (n-1)/2$. Thus, the first densest subgraph that our algorithm will pick would be the whole center graph that corresponds to the node $j = \lceil n/2 \rceil$. Following this choice, all shortest paths traversing the center are covered, and we are left with two independent subproblems: the paths induced by the first half of the original path (up to and excluding the middle node) and the paths induced by the second half of the original path. By the same argument, the algorithm will continue and pick the center graph of the middle node in each of the subproblems. It is easy to see that the total number of hops selected by the algorithm is $O(n \log n)$.

Note that if we consider the corresponding 2-hop labels, then the maximum label of a node (number of hops in which the node constitutes the marked endpoint) is $O(\log n)$. Observe that even though the algorithm tends to select large center graphs, the corresponding labels are stored only at the "outer" nodes. Thus, it tends to perform well also according to the maximum label metric.

The algorithm works similarly on trees, iteratively selecting as a center the "center of gravity" of the subtree and thus generating labeling of size $O(n \log n)$ with a maximum label of size $O(\log n)$.

4.2. Specific graph families. We have seen that our algorithm generates 2-hop labeling of size $O(n \log n)$ for all trees (for any variant of the problem). This matches a lower bound of $\Omega(n \log^2 n)$ on the *bit-size* of any tree labeling, due to Gavoille et al. [4].

Some other graph families are known to have compact 2-hop labeling: Graphs with separator-decomposition of size $O(n^\mu)$ have 2-hop labels of size $O(n^{1+\mu} \log n)$ (e.g., see [2]). It is possible that the optimal 2-hop labeling for small-separator graphs is $o(n^{1+\mu} \log n)$. (This would be the case if our Conjecture 5.1 is true.)

For planar graphs, Thorup [11] shows that $O(n \log n)$ size reachability and approximate distance labels are possible. It follows from his construction that there are corresponding 2-hop labels of size $O(n \log^2 n)$. We are not aware of a matching lower bound for 2-hop reachability labelings; thus, it is possible that there are optimal 2-hop reachability labelings of size $O(n \log n)$ for planar graphs. Thorup's result is particularly intriguing since there is an $\Omega(n^{4/3})$ lower bound on exact distance labels for planar graphs.

Another particular family of interest consists of graphs with bounded degree d where for each pair of vertices there is at least one path between them of length at most $D = \log_d n + o(\log_d n)$ edges. For example, a random d-regular graph will have this property with high probability. For such graphs we can obtain 2-hop labelings of size $O(n^{1.5+\epsilon})$ by picking the hops $((v,u),v)$ and $((v,u),u)$ for every two nodes v, u such that there is a path of at most $\lceil D/2 \rceil$ edges from v to u. Observe that the total number of hops is $O(nd^{D/2}) = O(n^{3/2+\epsilon})$.

5. Lower bounds on reachability and distance labelings. In this section we prove lower bounds on the size of reachability labels and 2-hop reachability labels in directed graphs. The bounds we prove also hold for distance labelings in directed and undirected graphs, and it is straightforward to extend the proofs for these cases. We begin with the following simple lemma that gives a lower bound on the size in bits of any reachability labeling (not necessarily a 2-hop reachability labeling).

LEMMA 5.1. *Any reachability labeling scheme must assign some n-vertex m-edge graph reachability labels of total size $\Omega(m \log(n^2/m))$ bits.*

Proof. Consider the set of all directed m-edge graphs on the set of vertices $V = \{1, 2, \ldots, n\}$ in which all edges are directed from $V_1 = \{1, 2, \ldots, n/2\}$ to $V_2 = \{n/2 + 1, n/2 + 2, \ldots, n\}$. (Assume that n is even.) There are $\binom{(n/2)^2}{m}$ such graphs, and each of them has a distinct transitive closure. Hence, no two of these graphs may be assigned reachability labels that are identical for every vertex. It follows that most of these graphs must be assigned reachability labels of total size $\Omega(\log \binom{(n/2)^2}{m}) = \Omega(m \log(n^2/m))$. ∎

Note that each graph from the family of graphs considered in the proof of Lemma 5.1 may be assigned 2-hop reachability labels of total size $O(m \log n)$ bits. We simply let $L_{out}(v) = \{u \in V_2 \mid (v, u) \in E\}$ for every $v \in V_1$, $L_{in}(v) = \{v\}$ for every $v \in V_2$, and all other sets be empty. Thus, 2-hop reachability labels are almost optimal for this family of graphs. The corollary below summarizes this discussion and shows that 2-hop labels are almost optimal in the following sense.

COROLLARY 5.1. *Let $g(n, L)$ be the collection of n-node graphs with 2-hop labels (distance or reachability) of size L ($L \log n$ bits). Then any general labeling scheme assigns labels of maximum size $\Omega(L \log(n^2/m))$ bits on $g(n, L)$.*

Proof. Consider the family of graphs considered in the proof of Lemma 5.1, with n nodes and $L = m$ edges. These graphs have 2-hop labels of size L. The corollary follows from the proof of the lemma. ∎

We next use Lemma 5.1 to obtain a stronger lower bound on the total size of reachability labels.

THEOREM 5.1. *Any reachability labeling scheme must assign to some graphs with n vertices and m edges reachability labels of total size $\Omega(nm^{1/2})$ bits.*

Proof. Consider graphs of the following form. Start with a bipartite graph on vertex sets V_1 and V_2, where $|V_1| = |V_2| = m^{1/2}$, with $m/2$ directed edges going from V_1 to V_2. Next, make each vertex of V_1 the center of a star with $n/m^{1/2}$ leaves. All these leaves are disjoint, and the edges from these leaves are directed towards the vertices of V_1. Similarly, make each vertex of V_2 the center of a star with $n/m^{1/2}$ leaves. Edges this time are directed away from the vertices of V_2. The total number of vertices in this graph is $2m^{1/2} \cdot n/m^{1/2} + 2m^{1/2} = 2(n + m^{1/2}) = \Theta(n)$, and the number of edges is $2m^{1/2} \cdot n/m^{1/2} + m/2 = m/2 + 2n = \Theta(m)$. (Note that $n \le m \le n^2$ and therefore $m^{1/2} \le n$.)

Let U_i, for $1 \le i \le n/m^{1/2}$, be the set composed of the ith leaf of every star. For every i, the reachability relation restricted to U_i is isomorphic to the reachability relation on the set $V_1 \cup V_2$. It follows from Lemma 5.1 that, for at least one such graph, we need reachability labels of total size at least $\Omega(m)$ bits. Thus, the total size of the labels attached to all the vertices must be at least $\Omega(n/m^{1/2} \cdot m) = \Omega(nm^{1/2})$ bits. ∎

Our next lemma will allow us to obtain a slightly better lower bound than the one in Theorem 5.1 on the size of 2-*hop reachability labelings*. The lemma establishes a lower bound on the size of the optimal 2-hop cover for a set of paths. To specify this lemma we need the following definitions. Given a set P of paths and $v, w \in V$, we define $\overline{h}_v(w)$ to be the number of vertices reachable from v via a path in P going through w. We also define $\underline{h}_v(w)$ to be the number of vertices from which you can reach v through a path in P going through w. Formally, $\overline{h}_v(w) = |\{u \mid w \in B_{vu}\}|$ and $\underline{h}_v(w) = |\{u \mid w \in B_{uv}\}|$. The quantity $\overline{h}_v(w)$ (and similarly $\underline{h}_v(w)$) can be thought of as a bound on the effectiveness of selecting the hop $((w, v), v)$ to our 2-hop

cover; $\overline{h}_v(w)$ bounds the maximum number of pairs such that this particular hop can participate in their cover. Similarly, we can bound the maximum effectiveness of the covering of a particular pair by considering the maximum, over all 2-hop combinations that can cover it, of the maximum number of pairs that the less effective of these two hops can participate in covering. Formally, for each pair of nodes (a, b) we define the *efficiency of covering* P_{ab} as follows:

$$\text{eff}(a,b) = \max_{p \in P_{ab}} \max_{v \in p} \min\{\overline{h}_a(v), \underline{h}_b(v)\}.$$

LEMMA 5.2. *For any 2-hop cover,*

$$|H| \geq \sum_{(a,b)|P_{ab} \neq \emptyset} 1/\text{eff}(a,b).$$

Proof. Any pair (a, b) is eventually covered by two hops. One of these hops participates in at most $\text{eff}(a, b)$ paths. Thus, if the cost of each hop is partitioned among the pairs it covers, (a, b)'s share is at least $1/\text{eff}(a, b)$. Thus, the total number of hops is at least $\sum_{ab} 1/\text{eff}(a, b)$. □

We can obtain a slightly stronger lower bound for 2-hop reachability labels than the bound in Theorem 5.1 for general labelings. In Theorem 5.1 the lower bound of $\Omega(nm^{1/2})$ is on the size of the labels in bits, whereas in the following theorem the lower bound is on the total number of hops in the 2-hop labels.

THEOREM 5.2. *There exist n-vertex m-edge graphs for which any 2-hop reachability labeling scheme must have a total size of* $\Omega(nm^{1/2})$.

Proof. The graphs we consider are a subset of those used in the proof of Theorem 5.1. We start with a *complete* bipartite graph with $|V_1| = |V_2| = m^{1/2}$. As before, we make each vertex of V_1 and V_2 the center of a star with $n/m^{1/2}$ leaves. The proof follows using Lemma 5.2. □

Last, we show that some graphs with large 2-hop reachability labels have much shorter Steiner labels.

COROLLARY 5.2. *There exists a family of graphs with Steiner reachability labels of size* $O(n)$*, where the best proper 2-hop reachability labels are of size* $\Omega(nm^{1/2})$.

Proof. The graphs in the proof of Theorem 5.2 can be viewed as 4-layer graphs, with v reachable from u if and only if the layer of u is lower than the layer of v. We use the set $X = \{x_{1,2}, x_{1,3}, x_{1,4}, x_{2,3}, x_{2,4}, x_{3,4}\}$; the identifier $x_{i,j}$ is placed in $L_{out}(v)$ for all v in layer i, and in $L_{in}(v)$ for all v in layer j. □

A similar, slightly more involved construction can be used to generate $O(n)$-size Steiner labels for the undirected uniform-weighted version of this construction as follows.

COROLLARY 5.3. *There exists a family of undirected graphs with Steiner distance labels of size* $O(n)$ *where the best proper 2-hop distance labels are of size* $\Omega(nm^{1/2})$.

We conjecture that the bound given in Theorem 5.2 is best possible.

CONJECTURE 5.1. *Let* $G = (V, E)$ *be a directed graph with* $|V| = n$ *and* $|E| = m$*, and let* P *be the set of all shortest paths in* G*. Then there is a 2-hop cover of* P *of size* $O(nm^{1/2})$.

6. The pairs-cover problem. The algorithm in the proof of Theorem 4.2 applies to the following more general problem.

PROBLEM 6.1 (pairs-cover). **Input:** $P_1, \ldots, P_k$*, where each* P_i *is a set of pairs or triples of integers.*

Output: *A set H of pairs of integers of minimum size such that, for every $i = 1, \ldots, k$, one of the following holds:*

- *there exists a triple $(c, a, b) \in P_i$ such that $(c, a) \in H$ and $(c, b) \in H$, or*
- *there exists a pair $(c, a) \in P_i$ such that $(c, a) \in H$.*

The problem of computing a 2-hop cover for a hop invariant set of paths P can be mapped to the following pairs-cover instance: Let $V = \{v_0, \ldots, v_{n-1}\}$ be the set of nodes of G. Each nonempty $P_{v_i v_j}$ is mapped to a different P_ℓ in the pairs-cover instance.

For each v_c that is an interior node on some path in $P_{v_i v_j}$ we append the following pairs/triples to the corresponding P_ℓ (mapping is slightly different for undirected or directed graphs):

- For directed paths, we include the triple $(c, n + i, j)$ and the pairs (i, j) and $(j, n + i)$ in P_ℓ;
- For undirected paths, we include the triple (c, i, j) and the pairs (i, j) and (j, i) in P_ℓ.

We interpret the output H of the pairs-cover instance as follows: If $(c, i) \in H$ $(i < n)$, then the hop $((v_c, v_i), v_i)$ is placed in the cover. (Recall that since P is hop invariant, hops can be specified by their endpoints.) For undirected instances hops contain undirected paths. For directed instances hops contain directed paths. We can also have a pair $(c, i) \in H$ with $(i \geq n)$, in which case we rewrite it as $(c, n + a) \in H$ (where $i = n + a$). In this case we place the hop $((v_a, v_c), v_a)$ in the cover.

We now discuss another natural set of problems which this framework covers. We first consider a variant of the 2-hop cover problem where hops do not have handles. Thus, every hop is simply a path, and P_{uv} is covered if there are $P \in P_{uv}$ and two paths $h_1, h_2 \in H$ such that $P = h_1 h_2$. Observe that any solution with handles can be converted to a solution without handles by omitting the handles. Conversely, a solution without handles can be converted to a solution with handles by introducing two hops, with both endpoints as handles for every original hop. Thus, the optimal solution to the variant with handles is at most twice that of the variant without handles. Our greedy algorithm can hence be applied to the version without handles, albeit with a loss of another factor of 2 in the approximation ratio. Curiously, it seems that there is no natural modification of the greedy algorithm that obtains the same approximation ratio for the variant without handles.

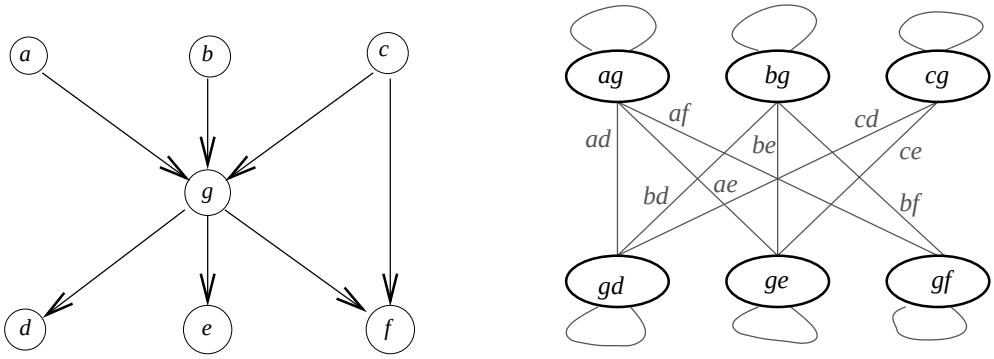
The variant with handles better fits the labeling application, as there is 1-1 correspondence between 2-hop covers with handles and 2-hop labelings, but variants without handles can have applications.

One such conceivable application is the following problem.

PROBLEM 6.2 (minimum 2-hop representation). *Let P be an arbitrary collection of strings. A minimum 2-hop representation of P is a set of substrings H such that every string $s \in P$ is a concatenation $s = h_1 h_2$ of two strings $h_1, h_2 \in H$.*

7. Implementation. Our implementation computes the cover in two phases. The first phase is different for different applications (i.e., reachability, approximate or exact, directed or undirected distances) and produces an instance of the pairs-cover problem. The second phase is an approximation algorithm for the pairs-cover problem.

The second phase then constructs a data structure of *center-graphs*: With each number that appears as the first coordinate in some triple we associate a *center*. For each center c we construct an (undirected) *center-graph*. There is a node i in the center-graph of c if and only if there is a pair (c, i) or a triple of the form $(c, \bullet, i)$ or



Directed Shortest Paths

Center-graph of node "g"

P_{ad}	=	$\{(a, d\text{-in}),\ (d, a\text{-out}),\ (g, a\text{-out}, d\text{-in})\}$
P_{ag}	=	$\{(a, g\text{-in}),\ (g, a\text{-out})\}$
P_{cf}	=	$\{(c, f\text{-in}),\ (f, c\text{-out})\}$
P_{gd}	=	$\{(g, d\text{-in}),\ (d, g\text{-out})\}$

Some entries of the pairs-cover instance

FIG. 3. *This is an example for the construction of a pairs-cover instance and center-graphs for an instance of the directed shortest-paths problem on a graph. The graph has seven nodes labeled* $\{a, b, c, d, e, f, g\}$. *The finite distances in these graphs consist of seven ordered pairs with distance* 1 *and eight ordered pairs of distance* 2. *The corresponding pairs-cover instance has a set of pairs/triples for each of these fifteen ordered pairs of nodes with a finite distance. The table shows some of the entries; other entries are symmetric. Specifically, the entries for* P_{xy} *for all shortest paths of length* 2 *(*$ad, ae, af, bd, be, bf, cd, ce$*) are symmetric to* P_{ad}; P_{bg} *and* P_{cg} *are symmetric to* P_{ag}; *and* P_{ge} *and* P_{gf} *are symmetric to* P_{gd}. *The right-hand figure shows the center-graph for the center* g. *There are six nodes in this center-graph, which correspond to shortest-paths for the ordered pairs* $\{ag, bg, cg, gd, ge, gf\}$. *These hops are denoted by a-out, b-out, c-out, d-in, e-in, and* f*-in in the pairs-cover instance. The edges of the center-graph are ordered pairs for which the two hops constitute a shortest path; equivalently,* xy *labels an edge if the triple* $(g, x\text{-out}, y\text{-in})$ *(or* $(g, y\text{-in}, x\text{-out})$*, which is the same) appears in the pairs-cover instance. Self-loops correspond to paths that consist of a single hop. The densest subgraph of this particular center-graph is obtained by selecting all nodes; this subgraph thus covers fourteen of the shortest paths using six hops. Note that* P_{cf} *(the path from* c *to* f*) is not covered by this center-graph, since there is no shortest-path that traverses the node* g. *This path can be covered via a single hop (a single node with self-loop) in the center-graph of* c *or the center-graph of* f. *For this instance, the minimum* 2*-hop cover consists of seven hops.*

$(c, i, \bullet)$ in the input. For each triple (c, i, j) there is an edge (i, j) in the center-graph of c. For each pair (c, i) there is a self-loop on the node i in the center-graph c.[1] Figure 3 provides an example of the construction of a center-graph.

The algorithm proceeds in iterations, where the basic operation in each such iteration is *subgraph selection*: We choose a center-graph and *select* a subset of the remaining nodes and the corresponding incident remaining edges. The selected nodes are removed. The selected subgraph is in fact an (approximate) densest subgraph in this center-graph. Our implementation of approximate densest subgraph (ADS) is linear in the size (number of edges and nodes) of the center-graph: Nodes are

[1]We remark that center-graphs are bipartite when the original network is directed, but this is generally not true with undirected networks.

maintained sorted by remaining degree (initially using bucket-sort), and each edge is looked at once.

Each input set P_ℓ is "responsible" for many edges that lie in different center-graphs. (Each such edge corresponds to a triple or pair in P_ℓ.) In our data structure all these edges are *linked* (via a doubly linked list). Once one of these edges is *selected*, the set P_ℓ is considered *covered*, and all these linked edges are removed from their respective center-graphs. Thus, subgraph selection in one center-graph may result in removed edges at other center-graphs.

The main loop guides the selection of the center-graph from which a subgraph selection is made. Centers are maintained in a heap. The key of a center c is the ratio of edges to nodes in the most recently computed ADS of the center-graph G_c. The heap is initialized through an ADS computation in each center-graph. The main loop repeats the following until all paths are covered (all center-graphs' edges are removed):

- A center c of maximum key is removed from the heap.
- If edges got removed from the center-graph G_c since the last ADS computation was performed, then the ADS is recomputed, and c is placed in the heap with a new key.
- Otherwise, if the center-graph was untouched, the ADS is selected. If unselected edges remain in G_c, then a new ADS is computed, and c is inserted into the heap with a new key.

For this implementation to work correctly, it is important that a center of (approximately) minimum key is selected at each step. To see this, notice that the key of a center-graph (ratio of edges to nodes in the densest subgraph) can only decrease if edges are removed from the graph.

We implemented a variant of the greedy set cover algorithm slightly different from the one outlined in the proof of Theorem 4.2: After the algorithm selects several subsets which correspond to the same center—$S(C_1, w), S(C_2, w), \ldots, S(C_k, w)$—the ratio attached to a remaining subset $S(C, w)$ is updated to

$$|S(C, w) \cap T'| / \left| C \setminus \bigcup_{i=1}^{k} C_i \right|$$

(instead of $|S(C, w) \cap T'|/|C|$), where T' is the set of uncovered edges in the center-graph G_w. This is achieved by removing from the center-graph nodes that are already selected. (Note that edges are removed only if both endpoints are selected.)

Observe that the numerator of this ratio can decrease as subsets are selected in other centers. The denominator can also decrease but only as a result of a subset's being selected from the same center. Even though the ratio associated with a particular subset may increase, it is easy to see that it can never exceed that of the most recently selected densest subgraph from the same center (if it did, then this subset combined with the recent densest subgraph would yield a denser subgraph, hence a contradiction). Thus, the maximum ratio of the densest subgraph of a center is non-increasing. As a new densest subgraph is computed when a center is placed back in the heap, a center with maximum ratio is still found by our heap implementation.

On our data sets, this variant performed better than the variant where the denominator of the ratio of a subset remains $|C|$. We show that the worst-case approximation ratio is the same as for the other variant, as follows.

LEMMA 7.1. *This variant achieves a worst-case approximation ratio of* $O(\log n)$.

Proof. For every set $S = (C_S, w)$, let L_S be the elements of C_S that were already chosen in previous rounds of the algorithm. Let $S_1, \ldots, S_k$ be the sets used by our algorithm, in that order. Consider an element v that was covered for the first time by a set S. We let $w_v = \frac{|C_S \setminus L_S|}{|S \cap T'|}$. Notice that

$$\sum_{i=1}^{k} w(S_i) = \sum_{i=1}^{k} |C_{S_i}| \geq \sum_{i=1}^{k} |C_{S_i} \setminus L_{S_i}| = \sum_{v \in T} w_v.$$

Therefore, it is sufficient to show that when v is the jth element covered, then $w_v \leq \frac{OPT}{|T|-j}$, where OPT is the value of the optimal solution. Before v was covered, $|T'| \geq |T| - j$. Let $O_1, \ldots, O_{k'}$ be the sets of an optimal cover, in which each two sets have different centers. Clearly, $\sum_{i=1}^{k'} |C_{O_i}| = OPT$. Furthermore, $\sum_{i=1}^{k'} |O_i \cap T'| \geq |T'| \geq |T| - j$. Therefore, there is at least one set O_i such that

$$\frac{|O_i \cap T'|}{|C_{O_i} \setminus L_{O_i}|} \geq \frac{|O_i \cap T'|}{|C_{O_i}|} \geq \frac{|T| - j}{OPT}.$$

By definition of the greedy algorithm, the set S which covers v will also satisfy that $\frac{|S \cap T'|}{|C_S \setminus L_S|} \geq \frac{|T|-j}{OPT}$, and thus $w_v \leq \frac{OPT}{|T|-j}$, and the claim follows. ∎

8. Experiments. We used different synthetic and real networks to evaluate our labeling algorithm. Our selection of data sets was guided by two important applications of our labeling scheme, namely, routing and geographic navigation systems. For geographic navigation, distance queries can tell a user the time or distance to reach a desired destination. First-edge queries can be used to generate turn-by-turn driving directions.

Routing tables for packets traveling in a communication network constitute another application of distance labels. The model is that each packet carries its destination label, and the current router obtains the next-hop and, if desired, the "distance," by considering the label at the current router and the destination label. This is somewhat similar to the way Internet routing is performed now: Each packet carries its destination IP-address. The router looks up the IP-address (longest prefix match) in its local routing table in order to obtain the next-hop. Routing tables, however, are growing in size. IP networks typically have small diameter. For inter-AS graphs,[2] the core of the graph has high expansion, whereas intra-AS networks could be almost planar.

ISP-net is the network of a large-backbone ISP (internet service provider). The nodes and (directed) edges of the network correspond to routers and links. This particular ISP uses OSPF (open shortest path first) routing, and the edge-weights are the OSPF weights of the links.

BGP is the set of (directed) paths advertised by BGP (border gateway protocol) routers.[3] The nodes of the network are all ASs in the Internet reachable from the core. The paths are all advertised paths.[4] We considered only paths of three or more

[2] AS stands for an autonomous system, which is an independent subnetwork of the global network.

[3] This data set was given to us by Andre Broido from CAIDA (University of California, San Diego).

[4] In this case the paths are not necessarily shortest paths and also do not necessarily possess the hop invariance property. (Due to business and other considerations, actual BGP routes do not necessary correspond to shortest paths.) We applied only the second phase of the implementation, looking for a 2-hop representation of *every* path in P.

TABLE 1
Parameters and performance for different networks.

hops, as shorter paths can be reconstructed by maintaining edge information at each node.

Roads is the road map of Alpine County, CA (USA), obtained from the TIGER census data [13]. This graph is undirected, with weights corresponding to actual distances.

Grid-k is a synthetic network. The underlying network is a $k \times k$ grid. Edges are directed in a Manhattan fashion, with even and odd row-edges directed in opposite directions and, similarly, even and odd column-edges directed in opposite directions. The edge weights were selected uniformly at random from $[1, 100]$.

Table 1 lists for each network the number of nodes, number of edges, number of pairs of nodes such that there is a path from one to the other, and the total size of labels (number of hops). The compression ratio is the ratio of the number of pairs to the total size of the labels. The compression ratio varies with different graph sizes and structures and was between 3 and 19.6. Generally, we expect better ratios for larger graphs. In particular, our analysis shows that for the planar k-grid graphs the total size of the labels is $O(k^3)$, whereas explicit representation is $\Theta(k^4)$; thus the ratio is at least $\Omega(k)$.

So far we have considered the total size of the labels. Another parameter of interest is the maximum label size of a particular node. This parameter is particularly important for distributed applications. It is also relevant since the actual computation of the distance from the labels is linear in the size of the labels. For directed graphs we also consider the maximum size of the in-list or out-list of a node. The average and maximum label sizes for the different networks are listed in Table 2. Although geared to minimizing the total label size, our algorithm seems to perform well also with respect to the maximum-label metric.

Another interesting question regards the dependence of the label size on the number of covered paths. Our algorithm can be set to stop after any given fraction of the paths is covered (and, actually, it provides the same performance guarantees even in this case). The dependence seemed Zipf-like and similar across networks (e.g., 20%–25% of the hops suffices to cover half the paths).

9. Concluding remarks. We have introduced simple and natural distance and reachability labeling schemes for directed and undirected graphs. Our labelings are derived from 2-hop covers of sets of paths in graphs. We give an efficient algorithm for constructing a 2-hop cover whose size is larger than the smallest 2-hop cover by a factor of at most $O(\log n)$. We *conjecture* that there exists a 2-hop cover of size $\tilde{O}(nm^{1/2})$ of the set of shortest paths in any weighted directed graph with n vertices and m edges. Proving, or disproving, this conjecture is perhaps the most interesting problem left open. We have also demonstrated the effectiveness of our schemes by an experimental analysis using synthetic and real networks from applications such as geographic navigation and Internet routing.

ON THE COMPLEXITY OF MATRIX PRODUCT*

RAN RAZ†

Abstract. Our main result is a lower bound of $\Omega(m^2 \log m)$ for the size of any arithmetic circuit for the product of two matrices, over the real or complex numbers, as long as the circuit does not use products with field elements of absolute value larger than 1 (where $m \times m$ is the size of each matrix). That is, our lower bound is superlinear in the number of inputs and is applied for circuits that use addition gates, product gates, and products with field elements of absolute value up to 1.

We also prove size-depth tradeoffs for such circuits: We show that if a circuit, as above, is of depth d, then its size is $\Omega(m^{2+1/O(d)})$.

Key words. lower bounds, circuit complexity, algebraic complexity, arithmetic circuits, bounded coefficients model, singular values

AMS subject classification. 68Q17

DOI. 10.1137/S0097539702402147

1. Introduction. Matrix product is among the most extensively studied computational problems. Surprising upper bounds of $O(m^{2+\alpha})$ (where $\alpha < 1$ and $m \times m$ is the size of each matrix) were obtained by Strassen in [Str] and improved in many other works. The best current upper bound (obtained by Coppersmith and Winograd) achieves $\alpha \approx 0.376$ [CW] (see [Gat] for a survey). The best lower bounds, however, are linear lower bounds of between $2.5 \cdot m^2$ and $3 \cdot m^2$ (depending on the field) for the number of products needed [Bsh, Bla, Shp].

In particular, the following seminal problem is still open: Can matrix product be computed by circuits of size $O(m^2)$, that is, circuits of size linear in the number of inputs? Superlinear lower bounds for matrix product are known only for bounded depth circuits [RS]. Note, however, that Strassen's method, as well as many other methods for matrix product, use circuits of larger depth.

The standard computational model for matrix product is by arithmetic circuits over some field F. The inputs for the circuit are the entries of the two matrices, and the allowed gates are product and addition over F. Products with field elements are also allowed. In this work, we take F to be the field of real numbers (all of our results hold for the complex numbers as well), and we restrict our arithmetic circuit in the following way: The circuit cannot use products with field elements of absolute value larger than 1. We call such a circuit *a bounded coefficients arithmetic circuit*.

We prove that any such circuit for matrix product is of size $\Omega(m^2 \log m)$.

More generally, if we require that the circuit does not use products with field elements of absolute value larger than $c = c(m)$ (for any function $c(m) \geq 1$), we obtain that any such circuit for matrix product is of size $\Omega(m^2 \log_{2c} m)$. This follows from the case $c = c(m) = 1$ by a simple reduction (just by replacing each product with a field element of absolute value smaller than or equal to c by up to $\log_2 c$ additions and one product with a field element of absolute value smaller than or equal to 1). Hence, in the rest of the paper, we concentrate on the case $c = 1$.

Besides our main result, we also prove size-depth tradeoffs for bounded coefficients arithmetic circuits for matrix product. We show that any such circuit of depth d is of size $\Omega(m^{2+1/O(d)})$. Note that for general arithmetic circuits only much weaker size-depth tradeoffs are known [RS].

Since a preliminary version of our paper has appeared, Burgisser and Lotz used our methods (together with some new methods) to obtain a similar lower bound of $\Omega(n \log n)$ for any bounded coefficients arithmetic circuit for the product of two polynomials of degree n (as well as for the division of two polynomials with reminder) [BL].

1.1. Previous work. Bounded coefficients arithmetic circuits were suggested and motivated as a natural model for arithmetic computations by Morgenstern [Mor] and by Chazelle [Cha]. Morgenstern and Chazelle observed that many algorithms for arithmetic problems (e.g., the fast Fourier transform algorithm) do not use field elements at all (or use only small field elements). Morgenstern and Chazelle were mainly interested in the case of linear functions and proved lower bounds of $\Omega(n \log n)$ for several such functions (e.g., for the Fourier transform). Note that for general arithmetic circuits no superlinear lower bound is known for any linear function (or any constant degree polynomial).

Several works proved size-depth tradeoffs of $\Omega(n^{1+1/O(d)})$ for bounded coefficients arithmetic circuits [NW, Lok, Pud]. As in [Mor, Cha], the focus of these works was linear functions. As far as we know, no previous result was obtained for the complexity of matrix product (or similar functions) in the bounded coefficients model.

1.2. Organization of the paper. The paper is organized as follows. In section 2, we give some basic definitions. In section 3, we give lower bounds for linear functions. These lower bounds are then used in section 4 to prove our lower bound for matrix product. The proof of the main lemma is deferred to section 5. In section 6, we prove our size-depth tradeoff for matrix product.

2. Preliminaries. As mentioned above, we consider arithmetic circuits over the field of real numbers. All of our results hold for the complex numbers as well.

An arithmetic circuit is a directed acyclic graph as follows: Nodes of in-degree 0 are called inputs and are labelled with input variables. Nodes of out-degree 0 are called outputs. Each edge is labelled with a field element (we think of this element as multiplying the outcome of the edge). Each node other than an input is labelled with either $+$ or $\times$ (in the first case the node is a plus gate and in the second case a product gate).

The computation is done in the following way. An input just computes the value of the variable that labels it. For every noninput node v, if $v_1, \ldots, v_k$ are the nodes that fan into v, then we multiply the result of each v_i with the field element that labels the edge that connects it to v. If v is a plus gate we sum all the results; otherwise, v is a product gate, and we multiply all the results. Obviously, each node in the circuit computes a polynomial in the input variables.

The *size* of a circuit C is defined to be the number of edges in it and is denoted by $\mathrm{Size}(C)$. The *depth* of a circuit C is defined to be the length of the longest directed path between an input and an output in C and is denoted by $\mathrm{Depth}(C)$.

We say that an arithmetic circuit (over the real numbers) is a *bounded coefficients arithmetic circuit* if all field elements labelling the edges of the circuit are of absolute value smaller than or equal to 1.

We say that an arithmetic circuit is *linear* if all gates in it are plus gates (i.e., the circuit contains no product gates). Obviously, the outputs of a linear circuit

are linear functions in the input variables. Let $L_1, \ldots, L_k$ be k linear functions (in the variables $z_1, \ldots, z_n$). It is well known (and easy to prove) that (over any field with characteristic 0) any arithmetic circuit for $L_1, \ldots, L_k$ can be translated into a linear circuit for $L_1, \ldots, L_k$, with only a constant-factor increase in the size and depth of the circuit. In the same way, any bounded coefficients arithmetic circuit for $L_1, \ldots, L_k$ can be translated into a bounded coefficients linear circuit for $L_1, \ldots, L_k$, with only a constant-factor increase in the size and depth of the circuit. We can hence assume w.l.o.g. that linear forms $L_1, \ldots, L_k$ are computed by linear circuits. Given an $n \times n$ matrix H, we say that a linear circuit computes H if it computes the linear functions that correspond to the rows of H; that is, the circuit computes the functions $\sum_{j=1}^{n} H_{i,j} \cdot z_j$, where $z_1, \ldots, z_n$ are the input variables for the circuit.

In this paper, we prove lower bounds on the size of circuits for the product of two $m \times m$ matrices. The input for such a circuit is of size $2m^2$, and it consists of two $m \times m$ matrices X, Y. The output is the matrix $X \cdot Y$. That is, there are m^2 outputs, and the (i,j)th output is $\sum_{k=1}^{m} X_{i,k} \cdot Y_{k,j}$. Each output is a bilinear form in X and Y.

Since the product of two matrices is a bilinear form, it is natural to consider bilinear arithmetic circuits for it. We say that an arithmetic circuit is *bilinear* if each product gate in it computes the product of two linear functions, one in the variables $\{X_{i,j}\}$ and the other in the variables $\{Y_{i,j}\}$. Thus, a bilinear circuit has the following structure. First, there are many plus gates, computing linear forms in X and linear forms in Y. Then there is one level of product gates that compute bilinear forms. Finally, there are many plus gates that eventually compute the outputs.

Obviously, the outputs of a bilinear circuit are bilinear functions in the input variables of X and Y. Let $f_1, \ldots, f_k$ be k bilinear functions (in the variables of X and Y). It is well known (and easy to prove) that (over any field with characteristic 0) any arithmetic circuit for $f_1, \ldots, f_k$ can be translated into a bilinear circuit for $f_1, \ldots, f_k$, with only a constant-factor increase in the size and depth of the circuit. In the same way, any bounded coefficients arithmetic circuit for $f_1, \ldots, f_k$ can be translated into a bounded coefficients bilinear circuit for $f_1, \ldots, f_k$, with only a constant-factor increase in the size and depth of the circuit. We can hence assume w.l.o.g. that bilinear forms $f_1, \ldots, f_k$ are computed by bilinear circuits.

3. Lower bounds for linear functions. In this section, we prove lower bounds for the size of bounded coefficients linear circuits. In all that follows, we assume w.l.o.g.[1] that all gates in the circuit are of fan-in 2.

Lower bounds for the size of bounded coefficients linear circuits were first proved by Morgenstern [Mor]. Morgenstern observed that for any matrix H, the size of any bounded coefficients linear circuit for H is bounded from below by $\log_2 |\mathrm{Det}[H]|$. For our purpose, we will need the following simple generalization of this result (Lemma 3.1).

Let $L_1, \ldots, L_k$ be k linear functions in the variables $z_1, \ldots, z_n$. We think of each L_i as a vector in the vector space R^n. For every $1 \leq r \leq n$, denote by $\mathrm{Vol}_r[L_1, \ldots, L_k]$ the maximal volume spanned by r vectors from $\{L_1, \ldots, L_k\}$ and $n-r$ arbitrary unit vectors (i.e., vectors with L^2-norm equal to 1). That is,

$$\mathbf{Vol_r}[\mathbf{L_1}, \ldots, \mathbf{L_k}] = \mathrm{MAX}_{i_1,\ldots,i_r,e_{r+1},\ldots,e_n} |\mathrm{Det}[L_{i_1}, \ldots, L_{i_r}, e_{r+1}, \ldots, e_n]|,$$

where $e_{r+1}, \ldots, e_n$ are arbitrary unit vectors in R^n. Equivalently,

$$\mathbf{Vol_r}[\mathbf{L_1}, \ldots, \mathbf{L_k}] = \mathrm{MAX}_{i_1,\ldots,i_r} (\mathrm{Det}[AA^T])^{1/2},$$

[1] Recall that the size of a circuit is defined as the number of edges in it and not the number of nodes.

where A is the $n \times r$ matrix $[L_{i_1}, \ldots, L_{i_r}]$, and A^T is the transpose of A.

In the same way, for a matrix H of size $n \times n$, we define for every $1 \leq r \leq n$,

$\mathbf{Vol_r[H]} = \mathrm{Vol}_r[L_1, \ldots, L_n]$,
where $L_1, \ldots, L_n$ are the linear forms corresponding to the rows of H.

LEMMA 3.1. *Let C be a bounded coefficients linear circuit for $L_1, \ldots, L_k$. Then, for every $1 \leq r \leq n$,*

$$\mathrm{Size}(C) \geq \log_2(\mathrm{Vol}_r[L_1, \ldots, L_k]).$$

Proof. Let $s = \mathrm{Size}(C)$. Note that since C is a directed acyclic graph, it induces a partial order on its nodes (a node v is larger than a node u if there exists a directed path from u to v). Let $f_1, \ldots, f_s$ be the linear functions corresponding to all nodes in C and such that the order of $f_1, \ldots, f_s$ agrees with the partial order induced by the circuit C and $f_1 = z_1, \ldots, f_n = z_n$ (where $z_1, \ldots, z_n$ are the input variables for the circuit).

Since the order of $f_1, \ldots, f_s$ agrees with the order of the circuit, for every $i > n$ there exist $i_1, i_2 < i$ and c_1, c_2 of absolute value ≤ 1 such that $f_i = c_1 \cdot f_{i_1} + c_2 \cdot f_{i_2}$. Hence, by the linear property of the determinant, it is easy to verify that

$$\mathrm{Vol}_r[f_1, \ldots, f_i] \leq 2 \cdot \mathrm{Vol}_r[f_1, \ldots, f_{i-1}],$$

and, since $\mathrm{Vol}_r[f_1, \ldots, f_n] = 1$, we have

$$\mathrm{Vol}_r[f_1, \ldots, f_s] \leq 2^{s-n} < 2^s.$$

Since $\{f_1, \ldots, f_s\}$ include the functions $L_1, \ldots, L_k$, we have

$$\mathrm{Vol}_r[L_1, \ldots, L_k] \leq \mathrm{Vol}_r[f_1, \ldots, f_s] < 2^s. \qquad \square$$

For a linear function L in n variables and for a vector space $V \subset \mathrm{R}^n$, denote by $\mathbf{Dist}[\mathbf{L}, \mathbf{V}]$ the L^2-distance between L and V (as before, we think of L as a vector in R^n). For r linear functions, $L_1, \ldots, L_r$, denote by $\mathbf{Span}[\mathbf{L_1}, \ldots, \mathbf{L_r}]$ the vector space in R^n spanned by $L_1, \ldots, L_r$. Let $L_1, \ldots, L_k$ be k linear functions in n variables. For every $1 \leq r \leq n$, denote

$\mathbf{Rig_r}[\mathbf{L_1}, \ldots, \mathbf{L_k}] = \mathrm{MIN}_V \mathrm{MAX}_i(\mathrm{Dist}[L_i, V])$,
where $V \subset \mathrm{R}^n$ is a vector space of dimension r.

In the same way, for a matrix H of size $n \times n$, we define for every $1 \leq r \leq n$,

$\mathbf{Rig_r}[\mathbf{H}] = \mathrm{Rig}_r[L_1, \ldots, L_n]$,
where $L_1, \ldots, L_n$ are the linear forms corresponding to the rows of H.

A notion similar (but not identical) to $\mathrm{Rig}_r[H]$ was defined in [Lok] and was used there to prove size-depth tradeoffs for bounded coefficients arithmetic circuits. Here, we connect $\mathrm{Rig}_r[L_1, \ldots, L_k]$ to $\mathrm{Vol}_r[L_1, \ldots, L_k]$, and hence to the size of the smallest bounded coefficients arithmetic circuit for $L_1, \ldots, L_k$.

LEMMA 3.2. *For every k linear functions $L_1, \ldots, L_k$, and every $1 \leq r \leq n$,*

$$\log_2(\mathrm{Vol}_r[L_1, \ldots, L_k]) \geq r \cdot \log_2(\mathrm{Rig}_r[L_1, \ldots, L_k]).$$

Proof. Assume w.l.o.g. that $r < k$ (otherwise, $\mathrm{Rig}_r[L_1, \ldots, L_k] = 0$). Assume w.l.o.g. that the order of $L_1, \ldots, L_k$ is as follows: L_1 is a function $L \in \{L_1, \ldots, L_k\}$

such that $\mathrm{Vol}_1[L]$ is maximal. L_2 is a function $L \in \{L_2, \ldots, L_k\}$ such that $\mathrm{Vol}_2[L_1, L]$ is maximal, and so on (i.e., for every $1 \leq i \leq k$, we have that L_i is a function $L \in \{L_i, \ldots, L_k\}$ such that $\mathrm{Vol}_i[L_1, \ldots, L_{i-1}, L]$ is maximal).

Denote $\upsilon_1 = \mathrm{Vol}_1[L_1]$, and for every $1 < i \leq k$ denote $\upsilon_i = \mathrm{Vol}_i[L_1, \ldots, L_i]/\mathrm{Vol}_{i-1}[L_1, \ldots, L_{i-1}]$. Then, by our assumption on the order of $L_1, \ldots, L_k$, it is easy to verify that

$$\upsilon_1 \geq \upsilon_2 \geq \cdots \geq \upsilon_k.$$

Therefore,

$$\mathrm{Vol}_r[L_1, \ldots, L_r] = \prod_{i=1}^{r} \upsilon_i \geq (\upsilon_{r+1})^r.$$

On the other hand (again by our assumption on the order of $L_1, \ldots, L_k$),

$$\upsilon_{r+1} = \mathrm{MAX}_i(\mathrm{Dist}[L_i, V]),$$

where $V = \mathrm{Span}[L_1, \ldots, L_r]$, and hence

$$\mathrm{Rig}_r[L_1, \ldots, L_k] \leq \upsilon_{r+1}.$$

Thus,

$$\mathrm{Vol}_r[L_1, \ldots, L_k] \geq \mathrm{Vol}_r[L_1, \ldots, L_r] \geq (\upsilon_{r+1})^r \geq (\mathrm{Rig}_r[L_1, \ldots, L_k])^r. \qquad \square$$

Given a matrix H of size $m \times m$, we can use Lemmas 3.1 and 3.2 to prove lower bounds for bounded coefficients arithmetic circuits for H. For our purpose, we will also need to prove lower bounds for bounded coefficients arithmetic circuits for the tensor product $I \otimes H$ (where I is the identity matrix of size $m \times m$). Recall that $I \otimes H$ is a matrix of size $m^2 \times m^2$ that consists of $m \times m$ blocks of size $m \times m$ each such that the m blocks on the diagonal contain copies of the matrix H and all other blocks contain the zero matrix (of size $m \times m$). We will use the following proposition.

PROPOSITION 3.3. *Let H be an arbitrary matrix of size $m \times m$, and let I be the identity matrix of size $m \times m$. Then, for every $1 \leq r \leq m$,*

$$\log_2(\mathrm{Vol}_{r \cdot m}[I \otimes H]) \geq m \cdot \log_2(\mathrm{Vol}_r[H]).$$

Proof. By the properties of the determinant, for every matrix A (of size $m \times m$),

$$\mathrm{Det}[I \otimes A] = (\mathrm{Det}[A])^m.$$

Hence, by the definition of Vol,

$$\mathrm{Vol}_{r \cdot m}[I \otimes H] \geq (\mathrm{Vol}_r[H])^m. \qquad \square$$

COROLLARY 3.4. *Let H be an arbitrary matrix of size $m \times m$, and let I be the identity matrix of size $m \times m$. Let C be a bounded coefficients linear circuit for $I \otimes H$. Then, for every $1 \leq r \leq m$,*

$$\mathrm{Size}(C) \geq r \cdot m \cdot \log_2(\mathrm{Rig}_r[H]).$$

Proof. By Lemma 3.1, Proposition 3.3, and Lemma 3.2,

$$\mathrm{Size}(C) \geq \log_2(\mathrm{Vol}_{r \cdot m}[I \otimes H]) \geq m \cdot \log_2(\mathrm{Vol}_r[H]) \geq m \cdot r \cdot \log_2(\mathrm{Rig}_r[H]). \qquad \square$$

4. Lower bounds for matrix product. In this section, we prove a lower bound for the size of bounded coefficients arithmetic circuits for matrix product. Our bound is based on the lower bounds given in the previous section and on Lemma 4.1. The proof of Lemma 4.1 is given in the next section. In the following lemma, we assume for simplicity that $m/10$ is integer.

LEMMA 4.1 (main lemma). *Let $L_1, \ldots, L_k$ be k linear functions (over* R*) in the m^2 variables $y_{1,1}, \ldots, y_{m,m}$ (we think of $y_{1,1}, \ldots, y_{m,m}$ as the entries of a matrix of size $m \times m$). Denote $r = m/10$, and assume (for simplicity) that m is large enough (i.e., $m > m_0$ for some global constant m_0). Then there exists a matrix Y of size $m \times m$ (over* R*), such that*

1. *for every $1 \leq i \leq k$,*

$$|L_i(Y_{1,1}, \ldots, Y_{m,m})| \leq \mathrm{Rig}_{r \cdot m}[L_1, \ldots, L_k] \cdot (2 \ln k + 10)^{1/2};$$

2.

$$\mathrm{Rig}_r[Y] \geq \sqrt{m/9}.$$

We will now state and prove our main result.

THEOREM 4.2. *Let C be a bounded coefficients arithmetic circuit (over the real or complex numbers) for the product of two matrices of size $m \times m$. Then*

$$\mathrm{Size}(C) = \Omega(m^2 \log m).$$

Proof. First note that w.l.o.g. we can assume that the circuit is over the real numbers. This is true because any circuit over the complex numbers can be translated into a circuit over the real numbers (and vice versa) with a constant-factor increase in its size. As before, we assume w.l.o.g. that all gates in the circuit are of fan-in 2. Recall also that we can assume w.l.o.g. that the circuit is bilinear. We assume w.l.o.g. that m is large enough (and, in particular, $m > m_0$, where m_0 is the global constant from Lemma 4.1), and we assume for simplicity that $m/10$ is integer. Define

$$r = m/10.$$

Assume, for a contradiction to the statement of the theorem, that

$$\mathrm{Size}(C) < 0.001 \cdot m^2 \log_2 m.$$

Denote by $v_1, \ldots, v_k$ the product gates of the circuit C. Since the circuit is bilinear, each product gate v_i computes the product of two linear functions, one in the variables $\{x_{i,j}\}$ (of the first matrix) and the other in the variables $\{y_{i,j}\}$ (of the second matrix). Denote the first linear function by R_i and the second linear function by L_i. Thus, v_i computes the product of $R_i(x_{1,1}, \ldots, x_{m,m})$ and $L_i(y_{1,1}, \ldots, y_{m,m})$.

Consider the linear functions $L_1, \ldots, L_k$. These functions are computed by a linear circuit of size smaller than $0.001 \cdot m^2 \log_2 m$ (in the input variables $y_{1,1}, \ldots, y_{m,m}$). Hence, by Lemmas 3.1 and 3.2,

$$r \cdot m \cdot \log_2(\mathrm{Rig}_{r \cdot m}[L_1, \ldots, L_k]) < 0.001 \cdot m^2 \log_2 m.$$

That is,

$$\mathrm{Rig}_{r \cdot m}[L_1, \ldots, L_k] < m^{1/100}.$$

Hence, by Lemma 4.1, there exists a matrix Y of size $m \times m$ (over R) such that

1. for every $1 \leq i \leq k$,

$$|L_i(Y_{1,1}, \ldots, Y_{m,m})| \leq m^{1/100} \cdot (2 \ln k + 10)^{1/2} < m^{1/99}$$

(for large enough m);

2.

$$\mathrm{Rig}_r[Y] \geq \sqrt{m/9}.$$

We fix the input variables $y_{1,1}, \ldots, y_{m,m}$ to be the entries $Y_{1,1}, \ldots, Y_{m,m}$. Denote the obtained circuit by C'. Since we fixed $y_{1,1}, \ldots, y_{m,m}$, each product gate v_i in C turned into a product with the field element $L_i(Y)$. The circuit C' is hence a linear arithmetic circuit, and it is not hard to see that it computes the matrix $I \otimes Y$ in the input variables $x_{1,1}, \ldots, x_{m,m}$.

The circuit C' is not a bounded coefficients arithmetic circuit, because the absolute value of each field element $L_i(Y)$ is not bounded by 1. We would like to convert C' into a bounded coefficients arithmetic circuit C''. This could be done by replacing the product with each field element $L_i(Y)$ by up to $\log_2 |L_i(Y)|$ additions plus one product with a field element of absolute value ≤ 1. Note, however, that k may be almost as large as the size of C', and hence this method may increase the size of C' by more than a constant factor. Instead, we will convert C' into C'' by the following two steps: First, replace the product with each field element $L_i(Y)$ by a product with the field element $L_i(Y)/m^{1/99}$ (which is of absolute value ≤ 1) and multiply each output of the circuit by the field element $m^{1/99}$. (Since the original circuit C was bilinear, it is not hard to see that this step does not change the outputs of the circuit, and the circuit still computes $I \otimes Y$.) Then replace each product (of an output) with the field element $m^{1/99}$ by up to $\log_2(m^{1/99})$ additions plus one product with a field element of absolute value ≤ 1. Since the number of outputs is m^2, this increases the size of the circuit by at most $(1/99) \cdot m^2 \log_2 m$.

Thus, the obtained circuit C'' is a bounded coefficients arithmetic circuit that computes the matrix $I \otimes Y$ and such that

$$\mathrm{Size}(C'') < (1/90) \cdot m^2 \log_2 m.$$

However, by Corollary 3.4,

$$\mathrm{Size}(C'') \geq r \cdot m \cdot \log_2(\mathrm{Rig}_r[Y]) \geq (1/20) \cdot m^2 \log_2(m/9),$$

which is a contradiction (for large enough m). □

5. Proof of the main lemma. In this section, we give a proof of Lemma 4.1.

We think of each linear function L in the variables $y_{1,1}, \ldots, y_{m,m}$ also as a vector in $\mathrm{R}^{m \times m}$, and we think of each vector in $\mathrm{R}^{m \times m}$ also as a linear function in the variables $y_{1,1}, \ldots, y_{m,m}$. Assignments to the variables $y_{1,1}, \ldots, y_{m,m}$ are matrices Z of size $m \times m$. We think of each such matrix also as a vector in $\mathrm{R}^{m \times m}$, and we think of each vector in $\mathrm{R}^{m \times m}$ also as a matrix of size $m \times m$. Given a linear function L in the variables $y_{1,1}, \ldots, y_{m,m}$ and an assignment Z to $y_{1,1}, \ldots, y_{m,m}$, the value $L(Z)$ is the value of the function L on the assignment Z. The norm that we use in $\mathrm{R}^{m \times m}$ is the L^2-norm. This norm is used to measure distances between vectors and lengths of vectors in $\mathrm{R}^{m \times m}$. Hence, it is also used to measure distances between matrices and norms of matrices, and distances between linear functions and norms of linear functions. We denote the L^2-norm of a linear function L by $\|L\|$, and we denote the

L^2-norm of a matrix Z by $\|Z\|$ (this is known as the Frobenius norm of the matrix Z).

Denote

$$R = \mathrm{Rig}_{r\cdot m}[L_1, \ldots, L_k].$$

By the definition of Rig, there exists a vector space $V \subset \mathrm{R}^{m\times m}$ of dimension $r \cdot m$ such that for every $1 \le i \le k$,

$$\mathrm{Dist}[L_i, V] \le R.$$

Denote by $V^\perp \subset \mathrm{R}^{m\times m}$ the vector space orthogonal to V. Note that $V^\perp$ is a vector space of dimension $(m-r)\cdot m$. For every $1 \le i \le k$, we can write L_i as

$$L_i = L_i'' + L_i',$$

where $L_i'' \in V$ and $L_i' \in V^\perp$. Since $\|L_i'\| = \mathrm{Dist}[L_i, V]$, we have for every $1 \le i \le k$,

$$\|L_i'\| \le R.$$

Recall that we can think of V and $V^\perp$ also as subspaces of matrices Z of size $m \times m$. Obviously, $V^\perp$ is the vector space of all matrices $Z \in \mathrm{R}^{m\times m}$ such that every $L \in V$ satisfies $L(Z) = 0$. In the same way, V is the vector space of all matrices $Z \in \mathrm{R}^{m\times m}$ such that every $L \in V^\perp$ satisfies $L(Z) = 0$.

Our construction for the matrix Y will be probabilistic. We will define a random matrix Y that will satisfy the requirements of the lemma with high probability. The definition of Y will be in two stages. First, define the matrix W in the following way. Each entry $W_{i,j}$ is defined to be an independently chosen Gaussian random variable with expectation 0 and variance 1 (i.e., $W_{i,j}$ is chosen independently according to the distribution $N(0,1)$). Thus, the entries of the matrix W form a multinormal distribution. We can write the matrix W as

$$W = W'' + W',$$

where $W'' \in V$ and $W' \in V^\perp$. We define

$$Y = W'$$

(i.e., Y is the projection of W on $V^\perp$). We will show that with high probability Y satisfies the requirements of the lemma.

Claim 5.1. *With high probability (say, with probability of at least* 0.98*), for every* $1 \le i \le k$,

$$|L_i(Y)| \le R \cdot (2\ln k + 10)^{1/2}.$$

Proof. Note that $L_i''(Y) = L_i''(W') = 0$ and that $L_i'(W'') = 0$. Hence, for every $1 \le i \le k$,

$$L_i(Y) = L_i'(Y) = L_i'(W).$$

Each $L_i'(W)$ is a weighted sum of independently chosen Gaussian random variables with expectation 0 and variance 1, and hence $L_i'(W)$ is a Gaussian random variable with expectation 0 and variance $\|L_i'\|^2$.

Since $\|L_i'\| \leq R$, the probability of the event $|L_i'(W)| > R \cdot (2 \ln k + 10)^{1/2}$ can be bounded by $2/(e^5 \cdot k)$ (see, for example, [ASE, Appendix A]). Hence, by the union bound, with probability of at least 0.98, for every $1 \leq i \leq k$,

$$|L_i(Y)| = |L_i'(W)| \leq R \cdot (2 \ln k + 10)^{1/2}. \qquad \square$$

Thus, with high probability, the matrix Y satisfies the first requirement of the lemma. To prove the second requirement, we will need the following claim.

CLAIM 5.2. *Assume that m is large enough (i.e., $m > m_0$ for some global constant m_0). With high probability (say, with probability of at least 0.97), for any matrix D of size $m \times m$ and rank r,*

$$\|Y - D\| \geq m/3.$$

Proof. For the proof of the claim, we will use the spectral method developed by Lokam in [Lok]. Lokam proves a similar lemma for the Hadamard matrix (and for a generalized Hadamard matrix). We will use a similar method, plus some additional facts and observations, to prove our claim for the matrix Y.

Let A be a matrix of size $m \times m$ (of real or complex numbers). The ith *singular value*, $\sigma_i(A)$, is defined by

$$\sigma_i(A) = \sqrt{\lambda_i(AA^*)},$$

where A^* is the conjugate transpose of A, and $\lambda_i(AA^*)$ is the ith largest eigenvalue of AA^* (for $1 \leq i \leq m$).

It is well known that for every matrix A (of size $m \times m$), there exist unitary matrices U, V (of size $m \times m$) such that U^*AV is a diagonal matrix with values $\sigma_1(A), \ldots, \sigma_m(A)$ on the diagonal (see, e.g., [GV, sec. 2.3]).

For the proof of the claim we will need the following six facts. The facts are true for any constant $\epsilon > 0$. The global constant m_0 (from the statement of the claim) depends on the actual ϵ chosen (i.e., we assume that $m > m_0(\epsilon)$).

1. With high probability (say, with probability of at least 0.99),

$$\|W\| \geq (1 - \epsilon) \cdot m.$$

Proof. Note that $\|W\|^2$ is the sum of the squares of m^2 standard Gaussian random variables. Hence, $\|W\|^2$ is a random variable with expectation m^2 and variance $2m^2$, and (by the central limit theorem) with very high probability its value is very close to its expectation. In particular, for large enough m, the probability for $\|W\| < (1 - \epsilon) \cdot m$ is smaller than 0.01 (this follows, e.g., by Chernoff bounds; see, e.g., [ASE, Appendix A]).

2. With high probability (say, with probability of at least 0.99),

$$\|W''\| \leq (1 + \epsilon) \cdot \sqrt{r \cdot m}.$$

Proof. Recall that the entries of W form a multinormal distribution. Since a multinormal distribution does not change under unitary transformations and since W'' is the projection of W on V, we can present $\|W''\|^2$ as the sum of the squares of $r \cdot m$ standard Gaussian random variables. Hence, $\|W''\|^2$ is a random variable with expectation rm and variance $2rm$, and (by the central limit theorem) with very high probability its value is very close to its expectation. In particular, for large enough m, the probability for $\|W''\| > (1 + \epsilon) \cdot \sqrt{r \cdot m}$ is smaller than 0.01 (this follows, e.g., by Chernoff bounds; see, e.g., [ASE, Appendix A]).

3. With high probability (say, with probability of at least 0.99),
$$\sigma_1(W) < (2+\epsilon)\cdot\sqrt{m}.$$
Proof. The proof was given in [Gem] (see also [Sil]).
4. For any matrix D of size $m \times m$ and rank r,
$$\sigma_{r+1}(D), \ldots, \sigma_m(D) = 0.$$
Proof. As mentioned above, there exist unitary matrices U, V (of size $m \times m$) such that U^*DV is a diagonal matrix with values $\sigma_1(D), \ldots, \sigma_m(D)$ on the diagonal. Since unitary transformations do not change the rank of a matrix, we conclude that $\sigma_{r+1}(D), \ldots, \sigma_m(D) = 0$.
5. For any matrix A of size $m \times m$,
$$\|A\|^2 = \sigma_1^2(A) + \cdots + \sigma_m^2(A).$$
Proof. As mentioned above, there exist unitary matrices U, V (of size $m \times m$) such that U^*AV is a diagonal matrix with values $\sigma_1(A), \ldots, \sigma_m(A)$ on the diagonal. Since unitary transformations do not change the norm of a matrix, we conclude that $\|A\|^2 = \sigma_1^2(A) + \cdots + \sigma_m^2(A)$.
6. For any two matrices A, B of size $m \times m$,
$$\sum_{i=1}^{m} [\sigma_i(A) - \sigma_i(B)]^2 \le \|A - B\|^2.$$
Proof. This inequality is know as the Hoffman–Wielandt inequality [HW]. For a proof of this version of the inequality, see [GV, sec. 8.3].

We are now ready to complete the proof of the claim. Assume that the above six facts are all true for $\epsilon = 0.01$ (for large enough m, this happens with probability of at least 0.97). Let D be any matrix of size $m \times m$ and rank r. By facts 6 and 4,
$$\|W - D\|^2 \ge \sum_{i=1}^{m} [\sigma_i(W) - \sigma_i(D)]^2 \ge \sum_{i=r+1}^{m} [\sigma_i(W)]^2.$$
By fact 5, fact 3, and fact 1 (and since $\epsilon = 0.01$ and $r = m/10$),
$$\sum_{i=r+1}^{m} [\sigma_i(W)]^2 = \|W\|^2 - \sum_{i=1}^{r} [\sigma_i(W)]^2 \ge \|W\|^2 - 4.0401 \cdot r \cdot m \ge 0.98 \cdot m^2 - 0.40401 \cdot m^2.$$
Hence,
$$\|W - D\|^2 \ge (0.75 \cdot m)^2,$$
and, by the triangle inequality and fact 2,
$$\|Y - D\| \ge \|W - D\| - \|W - Y\| \ge 0.75 \cdot m - 0.32 \cdot m > m/3. \qquad \square$$

Let us now finish the proof of Lemma 4.1. Note that if $\mathrm{Rig}_r[Y] < \sqrt{m/9}$, then (by the definition of Rig) there exists a matrix D of rank r such that all rows of $Y - D$ are of L^2-norm $< \sqrt{m/9}$, and hence $\|Y - D\|^2 < m \cdot m/9$ (in contradiction to Claim 5.2).

Thus, by Claim 5.1 we know that with high probability Y satisfies the first requirement of the lemma, and by Claim 5.2 we know that with high probability Y satisfies the second requirement of the lemma. Altogether, with probability of at least 0.95, the matrix Y satisfies both requirements. $\square$

6. Size-depth tradeoffs. The following lemma is implicit in [Lok].

LEMMA 6.1. *Let C be a bounded coefficients linear circuit of size s and depth d for the linear functions $L_1, \ldots, L_k$ (in n variables). Then, for every $1 \leq r \leq n$,*

$$\mathrm{Rig}_r[L_1, \ldots, L_k] \leq \left(\frac{s}{r}\right)^{2d}.$$

Proof. Let $v_1, \ldots, v_l$ be all nodes in C of in-degree larger than s/r. Obviously, $l \leq r$. Denote by $f_1, \ldots, f_l$ the l linear functions outputted at the nodes $v_1, \ldots, v_l$. Denote by C' the circuit C after removing from it the l nodes $v_1, \ldots, v_l$ and all edges connected to them. Then each L_i can be written as $L_i = L''_i + L'_i$, where L''_i is a linear combination of the functions $f_1, \ldots, f_l$, and L'_i is the ith output of the circuit C'.

Since the maximal in-degree in C' is at most s/r and since C' is of depth d, the L^1-norm of each L'_i is bounded by $(s/r)^d$, and hence its L^2-norm is bounded by $(s/r)^{2d}$. Hence, if we denote $V = \mathrm{Span}[f_1, \ldots, f_l]$, then for every $1 \leq i \leq k$ we have $\mathrm{Dist}[L_i, V] \leq (s/r)^{2d}$. Thus, $\mathrm{Rig}_r[L_1, \ldots, L_k] \leq \mathrm{Rig}_l[L_1, \ldots, L_k] \leq (s/r)^{2d}$. ∎

For our size-depth tradeoff for matrix product, we will also need the following version of Lemma 4.1. Note that for the proof of Theorem 4.2 we could have used Lemma 6.2 rather than Lemma 4.1. We preferred to use Lemma 4.1 because it makes the proof of Theorem 4.2 more intuitive.

LEMMA 6.2. *Let $L_1, \ldots, L_k$ be k linear functions (over R) in the m^2 variables $y_{1,1}, \ldots, y_{m,m}$ (we think of $y_{1,1}, \ldots, y_{m,m}$ as the entries of a matrix of size $m \times m$). Denote $r = m/10$, and assume (for simplicity) that m is large enough (i.e., $m > m_0$ for some global constant m_0). Then there exists a matrix Y of size $m \times m$ (over R) such that*

1. *for every $1 \leq i \leq k$,*

$$|L_i(Y_{1,1}, \ldots, Y_{m,m})| \leq \mathrm{Rig}_{r \cdot m}[L_1, \ldots, L_k] \cdot (2 \ln k + 10)^{1/2};$$

2.

$$\mathrm{Rig}_{r \cdot m}[I \otimes Y] \geq \sqrt{m/9}.$$

Proof. The proof is similar to the proof of Lemma 4.1.

We define R, W, W'', and Y as in the proof of Lemma 4.1. Thus, by Claim 5.1, with high probability the matrix Y satisfies the first requirement of the lemma. To prove the second requirement, we will need the following version of Claim 5.2.

CLAIM 6.1. *Assume that m is large enough (i.e., $m > m_0$ for some global constant m_0). With high probability (say, with probability of at least 0.97), for any matrix D of size $m^2 \times m^2$ and rank $r \cdot m$,*

$$\|(I \otimes Y) - D\| \geq m^{1.5}/3.$$

Proof. The proof is similar to the proof of Claim 5.2. The first three facts (out of the six given in the proof of Claim 5.2) are replaced by the following three facts. As before, the facts are true for any constant $\epsilon > 0$. The global constant m_0 (from the statement of the claim) depends on the actual ϵ chosen (i.e., we assume that $m > m_0(\epsilon)$).

1. With high probability (say, with probability of at least 0.99),

$$\|I \otimes W\| \geq (1 - \epsilon) \cdot m^{1.5}.$$

Proof. The proof is obvious, since $\|I \otimes W\| = m^{0.5} \cdot \|W\|$.

2. With high probability (say, with probability of at least 0.99),

$$\|I \otimes W''\| \leq (1+\epsilon) \cdot r^{0.5} \cdot m.$$

Proof. The proof is obvious, since $\|I \otimes W''\| = m^{0.5} \cdot \|W''\|$.

3. With high probability (say, with probability of at least 0.99),

$$\sigma_1(I \otimes W) < (2+\epsilon) \cdot m^{0.5}.$$

Proof. The proof is obvious, since $\sigma_1(I \otimes W) = \sigma_1(W)$.

The proof of the claim is now completed as before. Assume that the above six facts are all true for $\epsilon = 0.01$ (for large enough m, this happens with probability of at least 0.97). Let D be any matrix of size $m^2 \times m^2$ and rank $r \cdot m$. By facts 6 and 4,

$$\|(I \otimes W) - D\|^2 \geq \sum_{i=1}^{m^2} [\sigma_i(I \otimes W) - \sigma_i(D)]^2 \geq \sum_{i=r\cdot m+1}^{m^2} [\sigma_i(I \otimes W)]^2.$$

By fact 5, fact 3, and fact 1 (and since $\epsilon = 0.01$ and $r = m/10$),

$$\sum_{i=r\cdot m+1}^{m^2} [\sigma_i(I \otimes W)]^2 = \|I \otimes W\|^2 - \sum_{i=1}^{r\cdot m} [\sigma_i(I \otimes W)]^2 \geq 0.98 \cdot m^3 - 0.40401 \cdot m^3.$$

Hence,

$$\|(I \otimes W) - D\|^2 \geq (0.75 \cdot m^{1.5})^2,$$

and, by the triangle inequality and fact 2,

$$\|(I \otimes Y) - D\| \geq \|(I \otimes W) - D\| - \|(I \otimes W) - (I \otimes Y)\| > m^{1.5}/3. \qquad \square$$

Let us now finish the proof of Lemma 6.2. Note that if $\mathrm{Rig}_{r\cdot m}[I \otimes Y] < \sqrt{m/9}$, then (by the definition of Rig) there exists a matrix D of rank $r \cdot m$ such that all rows of $(I \otimes Y) - D$ are of L^2-norm $< \sqrt{m/9}$, and hence $\|(I \otimes Y) - D\|^2 < m^2 \cdot m/9$ (in contradiction to Claim 6.1).

Thus, by Claim 5.1 we know that with high probability Y satisfies the first requirement of the lemma, and by Claim 6.1 we know that with high probability Y satisfies the second requirement of the lemma. Altogether, with probability of at least 0.95, the matrix Y satisfies both requirements. $\square$

We will now state and prove our size-depth tradeoff for matrix product. We did not attempt here to optimize the constant ϵ.

THEOREM 6.3. *Let C be a bounded coefficients arithmetic circuit of depth d (over the real or complex numbers) for the product of two matrices of size $m \times m$. Then, for some global constant $\epsilon > 0$ (say, $\epsilon = 1/20$),*

$$\mathrm{Size}(C) = \Omega(m^{2+\epsilon/d}).$$

Proof. The proof follows along the lines of the proof of Theorem 4.2. As before, w.l.o.g. we assume that the circuit is over the reals and that the circuit is bilinear. We assume w.l.o.g. that m is large enough (and, in particular, $m > m_0$, where m_0 is the global constant from Lemma 6.2), and we assume for simplicity that $m/10$ is integer. Define

$$r = m/10.$$

Assume, for a contradiction to the statement of the lemma, that

$$\text{Size}(C) < 0.001 \cdot m^{2+\epsilon/d}.$$

As before, denote by $v_1, \ldots, v_k$ the product gates of the circuit C. Since the circuit is bilinear, each product gate v_i computes the product of two linear functions, one in the variables $\{x_{i,j}\}$ (of the first matrix) and the other in the variables $\{y_{i,j}\}$ (of the second matrix). Denote the first linear function by R_i and the second linear function by L_i. Thus, v_i computes the product of $R_i(x_{1,1}, \ldots, x_{m,m})$ and $L_i(y_{1,1}, \ldots, y_{m,m})$.

Consider the linear functions $L_1, \ldots, L_k$. These functions are computed by a linear circuit of depth at most d and size at most $0.001 \cdot m^{2+\epsilon/d}$ (in the input variables $y_{1,1}, \ldots, y_{m,m}$). Hence, by Lemma 6.1,

$$\text{Rig}_{r \cdot m}[L_1, \ldots, L_k] < (0.01)^{2d} \cdot m^{2\epsilon}.$$

Hence, by Lemma 6.2, there exists a matrix Y of size $m \times m$ (over R), such that

1. for every $1 \leq i \leq k$,

$$|L_i(Y_{1,1}, \ldots, Y_{m,m})| \leq (0.01)^{2d} \cdot m^{2\epsilon} \cdot (2 \ln k + 10)^{1/2} < (0.01)^{2d} \cdot m^{2\epsilon} \cdot \ln m$$

(for large enough m);

2.

$$\text{Rig}_{r \cdot m}[I \otimes Y] \geq \sqrt{m/9}.$$

Denote

$$c = (0.01)^{2d} \cdot m^{2\epsilon} \cdot \ln m.$$

We fix the input variables $y_{1,1}, \ldots, y_{m,m}$ to be the entries $Y_{1,1}, \ldots, Y_{m,m}$. Denote the obtained circuit by C'. Since we fixed $y_{1,1}, \ldots, y_{m,m}$, each product gate v_i in C turned into a product with the field element $L_i(Y)$. The circuit C' is hence a linear arithmetic circuit for the matrix $I \otimes Y$ in the input variables $x_{1,1}, \ldots, x_{m,m}$.

As before, the circuit C' is not a bounded coefficients arithmetic circuit. We will convert C' into a bounded coefficients arithmetic circuit C'' by the following two steps: First, replace the product with each field element $L_i(Y)$ by a product with the field element $L_i(Y)/c$ (which is of absolute value ≤ 1) and multiply each output of the circuit by the field element c. Then replace each product (of an output) with the field element c by $2d$ consecutive additions of fan-in $c^{1/2d}$ each (plus one product with a field element of absolute value ≤ 1). Since the number of outputs is m^2, this increases the size of the circuit by at most $m^2 \cdot 2d \cdot c^{1/2d}$, and hence the size of C'' is at most $0.01 \cdot m^{2+\epsilon/d} \cdot \ln m$ (for large enough m).

Thus, the obtained circuit C'' is a bounded coefficients arithmetic circuit of depth $3d$ that computes the matrix $I \otimes Y$ and such that

$$\text{Size}(C'') < 0.01 \cdot m^{2+\epsilon/d} \cdot \ln m.$$

However, since C'' is of depth $3d$, by Lemma 6.1,

$$\text{Size}(C'') \geq r \cdot m \cdot (\text{Rig}_{r \cdot m}[I \otimes Y])^{1/6d} \geq 0.01 \cdot m^{2+1/12d},$$

which is a contradiction (for large enough m and, say, $\epsilon = 1/20$). □

MINIMIZING TOTAL COMPLETION TIME ON PARALLEL MACHINES WITH DEADLINE CONSTRAINTS*

JOSEPH Y.-T. LEUNG† AND MICHAEL PINEDO‡

Abstract. Consider n independent jobs and m identical machines in parallel. Job j has a processing time p_j and a deadline $\bar{d}_j$. It must complete its processing before or at its deadline. All jobs are available for processing at time $t = 0$ and preemptions are allowed. A set of jobs is said to be *feasible* if there exists a schedule that meets all the deadlines; such a schedule is called a feasible schedule. Given a feasible set of jobs, our goal is to find a schedule that minimizes the total completion time $\sum C_j$. In the classical $\alpha \mid \beta \mid \gamma$ scheduling notation this problem is referred to as $P \mid prmt, \bar{d}_j \mid \sum C_j$. Lawler (*Recent Results in the Theory of Machine Scheduling*, in Mathematical Programming: The State of the Art, A. Bachem, M. Grötschel, and B. Korte, eds., Springer, Berlin, 1982, pp. 202–234) raised the question of whether or not the problem is NP-hard. In this paper we present a polynomial-time algorithm for every $m \geq 2$, and we show that the more general problem with m unrelated machines, i.e., $R \mid prmt, \bar{d}_j \mid \sum C_j$, is strongly NP-hard.

Key words. parallel and identical machines, unrelated machines, total completion time, deadline constraints, preemptive scheduling, maximum lateness, polynomial-time algorithm

1. Introduction.

Consider m identical machines in parallel and n jobs. Job j has a processing time p_j and a deadline $\bar{d}_j$. Job j must complete its processing before or at its deadline $\bar{d}_j$. All jobs are available for processing at $t = 0$ and preemptions are allowed. A set of jobs is said to be *feasible* if there exists a schedule that meets all its deadlines; such a schedule is called a feasible schedule. Given a feasible set of jobs, our objective is to find a schedule that minimizes the total completion time $\sum C_j$. In the 3-field notation $\alpha \mid \beta \mid \gamma$ introduced by Graham et al. (1979), this problem is referred to as $P \mid prmt, \bar{d}_j \mid \sum C_j$.

The special case with m machines and n jobs without deadlines, i.e., $d_j = \infty$ for all j, can be solved via the well-known shortest processing time first (SPT) rule. This rule will always generate a schedule with minimum $\sum C_j$ (see Pinedo (2002)). The SPT rule selects, whenever a machine has been freed, among the remaining jobs the job with the smallest processing time. Since McNaughton (1959) showed that preemptions cannot reduce $\sum C_j$, the SPT rule solves $P \mid prmt \mid \sum C_j$ as well as $P \mid\mid \sum C_j$.

For the special case with a single machine and n jobs with deadlines, Smith (1956) provided an $O(n \log n)$ algorithm that works as follows. Schedule the jobs backwards, starting at time $t = \sum p_j$. From among all the jobs that can finish their processing at time t (i.e., jobs with $\bar{d}_j \geq t$) select the one with the longest processing time. This leaves a set of $n - 1$ jobs to which the same rule can be applied. Preemptions cannot reduce $\sum C_j$ when there is a single machine and all jobs are released at the same time. So Smith's rule solves $1 \mid prmt, \bar{d}_j \mid \sum C_j$ as well as $1 \mid \bar{d}_j \mid \sum C_j$.

If each job j has, instead of a deadline, a release date r_j (before which it cannot start its processing), then minimizing $\sum C_j$ is NP-hard in the nonpreemptive case but solvable in polynomial time in the preemptive case. Lenstra (1977) showed that $1 \mid r_j \mid \sum C_j$ is NP-hard, and Baker (1974) presented an $O(n \log n)$ algorithm for $1 \mid prmt, r_j \mid \sum C_j$. Baker's rule schedules, at each point in time, the job with the smallest remaining processing time from among all the available jobs.

Lawler (1982) posed the single machine problem with release dates and deadlines, i.e., $1 \mid prmt, r_j, \bar{d}_j \mid \sum C_j$, and raised the question of whether it can be solved in polynomial time. This question has been answered in the negative by Du and Leung (1993), who showed that the problem is NP-hard. Thus, as far as polynomial-time algorithms are concerned, we cannot both have release dates and deadlines in the problem. Hence, we are forced to consider problems either with release dates or deadlines but not both.

Du and Leung (1993) also generalized Baker's rule and Smith's rule to solve a much broader class of problem instances, namely, those that contain no ordered triple of jobs (i, j, k) with

$$r_i, r_k < r_j < \bar{d}_i < \bar{d}_j, \bar{d}_k$$

and $p_j < p_i, p_k$; such a triple is called an obstruction. The generalized Baker's algorithm, the generalized Smith's algorithm, and an algorithm that recognizes problem instances with no obstruction can all be implemented in $O(n^2)$ time. Note that problem instances that contain no obstruction include those for which (1) intervals $[r_j, \bar{d}_j]$, $j = 1, 2, \ldots, n$, are nested; (2) release dates and deadlines are oppositely ordered; (3) processing times and deadlines are similarly ordered; (4) processing times and release dates are similarly ordered; (5) processing times are identical.

Lawler (1982) also raised the question of whether $P \mid prmt, r_j \mid \sum C_j$ and $P \mid prmt, \bar{d}_j \mid \sum C_j$ can be solved in polynomial time. Du, Leung, and Young (1990) showed that the first one of these two problems is NP-hard, even for two identical and parallel machines. In this paper we show that the second of these two problems, i.e., $P \mid prmt, \bar{d}_j \mid \sum C_j$, can be solved in polynomial time for every $m \geq 2$. (As noted before, the single machine case had already been settled by Smith (1956).)

Polynomial-time algorithms that check whether a set of jobs is feasible do exist, even when the jobs have release dates and deadlines. Horn (1974) showed that the problem of determining feasibility can be reduced to a network flow problem. Faster algorithms exist if the jobs have identical release dates or identical deadlines (see Sahni (1979)), or the special case when the intervals $[r_j, \bar{d}_j]$, $j = 1, 2, \ldots, n$, are nested (see Hong and Leung (1989)).

Gonzalez (1978) and McCormick and Pinedo (1995) described a polynomial-time algorithm for a feasible set of jobs that all have a common deadline. As we will see later, the scheduling problem becomes more complex when the jobs have different deadlines.

In the next section we present a polynomial-time algorithm for $P \mid prmt, \bar{d}_j \mid \sum C_j$. In the following section we show that the more general problem with unrelated machines, i.e., $R \mid prmt, \bar{d}_j \mid \sum C_j$, is strongly NP-hard. In the last section we present extensions and our conclusions.

2. The algorithm. In this section we assume that we are given a feasible set of jobs. All schedules are assumed to be feasible unless stated otherwise. Let

$$D_1 < D_2 < \cdots < D_z$$

denote the distinct deadlines of the n jobs, and let $D_0 = 0$. Every schedule S induces a deadline $d_j(S)$ for each job j, where $d_j(S)$ is defined as the smallest D_k with $C_j \leq D_k$ in S. If the context is clear, we drop the S and simply denote the induced deadline by d_j. Note that the induced deadline d_j of job j may be smaller than its original deadline $\bar{d}_j$. However, every feasible schedule has the property that $d_j \leq \bar{d}_j$ for each job j.

We motivate our algorithm by asking two key questions. Suppose a "birdie" were to tell us the induced deadline of each job in an optimal schedule. Having only this information, can we construct an optimal schedule? Second, how do we get the information that the "birdie" has? It is clear that the answers to these two questions immediately yield an optimal algorithm for our problem.

We proceed with answering the first question. The next lemma shows that if a short job has an induced deadline that is no later than that of a long job, then the short job is completed no later (and possibly earlier) than the long job. Lemma 1 can be shown via a standard interchange argument that is omitted here.

LEMMA 1. *Suppose we have two jobs j and k such that $p_j \leq p_k$. If there is a schedule S such that $d_j(S) \leq d_k(S)$, then there is another schedule S' with total completion time $\sum C_j$ not larger than that of S, and job j completes no later (and possibly earlier) than job k in S'.*

Lemma 1 yields a completion sequence in an optimal schedule. That is, jobs with induced deadlines equal to D_1 finish first in ascending order of their processing times, followed by jobs with induced deadlines equal to D_2 in ascending order of their processing times, and so on. Since the jobs complete in this order, they should also be scheduled in the same order. Thus, we consider a list scheduling algorithm with the list L of jobs ordered according to the given completion sequence. Whenever a machine becomes free for assignment, the next job in L will be scheduled in such a way that it completes as early as possible, with the provision that the remaining jobs in L can meet their induced deadlines. We refer to this procedure as the Scheduling Algorithm *SA*. The input into *SA* is the ordering L in which the algorithm will try to complete the n jobs. The output of *SA* is a complete schedule with the starting times, preemptions and completion times of all n jobs. However, the sequence in which the jobs complete their processing in the schedule generated by *SA* may not be identical to the target ordering L. (As we shall see later, the completion sequence will be identical to L if L is an optimal ordering.) The *SA* algorithm consists of eight steps.

Step 1 (initialization). Reindex the jobs so that job 1 is supposed to finish first, job 2 second, and so on. So $L = (1, 2, \ldots, n)$. Let $j = 1$.

Step 2 (computation of machine availabilities). Suppose we have scheduled the first $j-1$ jobs and we consider job j. Let f_i, $i = 1, \ldots, m$, denote the time machine M_i becomes available (is freed) after the first $j-1$ jobs have been completed. Reindex the machines so that

$$f_1 \leq f_2 \leq \cdots \leq f_m.$$

Clearly, if job j were to complete as early as possible, it should be scheduled on machine M_1 beginning at time f_1. However, this may lead to an infeasible schedule. Thus, we need to determine the minimum amount of time that we need to delay job j's starting time in order to have a feasible schedule. The following steps contain a procedure for determining the exact starting time and completion time of job j.

Step 3 (selection of the $m-1$ jobs with least slack). For each job k that follows

job j in L, let LST_k denote its latest possible starting time. Clearly,

$$LST_k = d_k - p_k,$$

i.e., its induced deadline minus its processing time. Job k can meet its induced deadline if and only if it starts at or before LST_k. Let jobs $k_1, k_2, \ldots, k_{m-1}$ be the $m-1$ jobs with the earliest LST_k among all the jobs that follow job j in L, i.e., the $m-1$ jobs with the least slack. (If there are ties, then select the job with the earliest induced deadline.) Reindex these jobs so that they are in ascending order of their latest-starting-times (LSTs); i.e.,

$$LST_{k_1} \leq LST_{k_2} \leq \cdots \leq LST_{k_{m-1}}.$$

Step 4 (computation of deficits and idle times). Assign job k_i to machine M_{i+1}, $i = 1, \ldots, m-1$. If $f_{i+1} \leq LST_{k_i}$ for each $1 \leq i \leq m-1$, then this is feasible. In general, however, it may happen that $f_{i+1} > LST_{k_i}$ for some index i and $f_{i+1} \leq LST_{k_i}$ for some other index i. If $f_{i+1} < LST_{k_i}$, then machine M_{i+1} is said to have an *idle time* and

$$\sigma_{i+1} = LST_{k_i} - f_{i+1}$$

denotes the length of this idle time. If $f_{i+1} > LST_{k_i}$, then machine M_{i+1} is said to have a *deficit* and

$$\delta_{i+1} = f_{i+1} - LST_{k_i}$$

denotes the size of this deficit. To meet the induced deadline of job k_i, we need to schedule an amount δ_{i+1} of job k_i by the time f_{i+1} on machines with an index lower than $i+1$. (Note that machines with index higher than $i+1$ have no idle times prior to f_{i+1} since the machines are indexed in ascending order of their finishing times.) For each deficit machine M_{i+1}, we associate with job k_i a deficit $\hat{\delta}_i$ and a deadline $\hat{d}_i$, where $\hat{\delta}_i = \delta_{i+1}$ and $\hat{d}_i = f_{i+1}$. This signifies that an amount of $\hat{\delta}_i$ of job k_i needs to be processed by the time $\hat{d}_i$ on some other machines.

Step 5 (redistribution of deficits). We now describe a procedure to redistribute the deficits of some jobs to machines with idle times. Let jobs $k_{i_1}, k_{i_2}, \ldots, k_{i_x}$ be all the jobs with deficits and machines $M_{j_1}, M_{j_2}, \ldots, M_{j_y}$ be all the machines with idle times. We assume that $i_1 < i_2 < \cdots < i_x$ and $j_1 < j_2 \cdots < j_y$. Going from job k_{i_x} to job k_{i_1}, we repeat the following steps. Consider job k_{i_a}. Look for the largest indexed machine M_{j_b} that is still lower in index than the machine to which job k_{i_a} is assigned originally; i.e., $j_b < i_a + 1$. We schedule as much as possible of job k_{i_a} on machine M_{j_b}. If $\sigma_{j_b} \geq \hat{\delta}_{i_a}$, then all of the deficits of job k_{i_a} can be scheduled on machine M_{j_b}. In this case we decrement σ_{j_b} by $\hat{\delta}_{i_a}$, delete job k_{i_a} from the list, and repeat the steps with the next job. On the other hand, if $\sigma_{j_b} < \hat{\delta}_{i_a}$, then only a portion of the deficit of job k_{i_a} can be scheduled on machine M_{j_b}, and the rest will have to be redistributed to other machine(s). In this case we decrement both $\hat{\delta}_{i_a}$ and $\hat{d}_{i_a}$ by σ_{j_b}, delete machine M_{j_b} from the list, and repeat the step with job k_{i_a} on the next lower indexed machine (i.e., machine $M_{j_{b-1}}$).

When the above procedure halts, either the list of jobs is exhausted or the list of machines is exhausted. If the list of jobs is exhausted, then we have successfully redistributed the deficits of all the jobs to other machines.

Step 6 (scheduling of job j and remaining deficits on machine 1). If the list of jobs is exhausted, then schedule job j on machine M_1, beginning at time f_1. Otherwise, if

the list of machines is exhausted and there are still some jobs with deficits, schedule the deficits of the remaining jobs on machine M_1, along with job j. Let jobs $k_{i_1}, k_{i_2}, \ldots, k_{i_z}$ be the remaining jobs on the list, with their corresponding deficits and deadlines. Job j has a processing time p_j and an induced deadline d_j. We schedule these $z+1$ "pieces" by the *earliest deadline rule;* i.e., the pieces are scheduled in ascending order of their deadlines. (If the list L corresponds to an optimal completion sequence, there would be no deadline violations in scheduling these $z+1$ pieces. However, if L does not correspond to an optimal completion sequence, then there may be some deadline violations.) If the *earliest deadline* schedule does not generate any deadline violations, then we will attempt to improve the completion time of job j. This is done by moving job j ahead of the pieces that were scheduled before it by the *earliest deadline rule,* provided that it does not generate any deadline violations.

Step 7 (update schedule and other data for next iteration). When job j is settled in the earliest possible position in the above procedure, the pieces that are scheduled before job j will be fixed in their positions, along with job j. We reduce the processing times of the corresponding jobs by the amounts fixed on machine M_1. The pieces that are scheduled after job j on machine M_1 will not be scheduled yet; neither will the jobs scheduled on machines $M_2, M_3, \ldots, M_m$. In other words, the only pieces that are scheduled in this step consist of job j in its entirety as well as all the pieces scheduled before job j; nothing else is scheduled in this step. Since the processing times of some jobs have been reduced, the remaining jobs need be reordered so that jobs with smaller remaining processing times precede jobs with larger remaining processing times in the event that they have identical induced deadlines.

Step 8 (stopping criterion). If $j < n-1$, increase j by 1 and go back to Step 2. If $j = n-1$, schedule the remaining part of the last job in such a way that it is completed as early as possible and STOP (the schedule is complete).

This completes the description of the algorithm. The following example illustrates the algorithm.

Example 1. Consider three machines and 9 jobs.

Jobs	1	2	3	4	5	6	7	8	9
p_j	4	5	7	8	10	12	13	14	15
d_j	∞	∞	∞	10	12	12	25	27	30
LST_j	∞	∞	∞	2	2	0	12	13	15

Apply algorithm *SA* so as to complete the jobs in the order $1, 4, 5, 6, 7, 8, 9, 2, 3$.

The first iteration of *SA* starts with $f_1 = f_2 = f_3 = 0$. Furthermore,

$$LST_{k_1} = LST_6 = 0,$$

$$LST_{k_2} = LST_4 = 2.$$

So job 1 can be scheduled in the interval $[0, 4]$ on machine 1.

The second iteration of *SA* considers job 4. Now $f_1 = f_2 = 0$ and $f_3 = 4$. The two jobs with the earliest LST are jobs 5 and 6, and

$$LST_6 = 0,$$

$$LST_5 = 2.$$

So job 5 is put on machine 3 but can be processed only during the interval $[4, 12]$ since $f_3 = 4$. So there is a deficit of 2. Job 6 is assigned to machine 2 and occupies the interval $[0, 12]$. So $\delta = 2$, and the processing of job 4 on machine 1 has to be postponed 2 time units. So the result of this iteration is that job 5 is processed on machine 1 during interval $[0, 2]$ and job 4 during interval $[2, 10]$. Before going to the next iteration of *SA* the processing time of job 5 has to be adjusted from 10 time units to 8 time units.

The third iteration of *SA* considers job 5. Now $f_1 = 0$, $f_2 = 4$, and $f_3 = 10$. The two jobs with the earliest LST are jobs 6 and 7:

$$LST_6 = 0,$$

$$LST_7 = 12.$$

Job 7 can go on machine 3, and there is an idle time. Job 6 can go on machine 2, and there is a deficit of 4. Job 6 therefore has to be processed on machine 1 during the interval $[0, 4]$ and $\delta = 4$. So job 5 can be processed on machine 1 during the interval $[4, 12]$, and this assignment is feasible. So the result of this iteration is that job 6 is processed during the interval $[0, 4]$ and job 5 during the interval $[4, 12]$. Before moving to the fourth iteration the processing time of job 6 has to be adjusted from 12 to 8.

Continuing in this fashion *SA* can schedule all jobs so that they are completed in the order $1, 4, 5, 6, 7, 8, 9, 2, 3$.

The next theorem is instrumental in proving that *SA* yields an optimal schedule.

THEOREM 1. *Given the order of completions in an optimal schedule, there exists an optimal schedule (i.e., a schedule with minimum* $\sum C_j$*) in which each job is completed as early as possible, provided that all the jobs that follow can meet their induced deadlines.*

Proof. Let $L = (1, 2, \ldots, n)$ denote the completion sequence in an optimal schedule. Let S denote the schedule in which each job is completed as early as possible (provided that all the jobs following it can meet their induced deadlines), and let S' be another schedule that does not complete each job as early as possible. Let j be the smallest index such that job j completes earlier in S than in S'. Let job j complete at time t in S'. Since job j does not finish as early as possible, there must be a noncritical job k (i.e., job k completes before its original deadline), $k > j$, such that job k is processed in the interval $[\bar{t} - \delta, \bar{t})$, $\bar{t} < t$, while job j is not processed in the same interval. Let job k complete at time t' in S'.

Consider the following triple interchange (see Figure 1). Move the piece of job j in the interval $[t - \delta, t)$ to the interval $[\bar{t} - \delta, \bar{t})$ where job k was. Move the piece of job k in the interval $[\bar{t} - \delta, \bar{t})$ to the interval $[t', t' + \delta)$, possibly moving out one job l processed in that interval. Finally, move job l to the interval $[t - \delta, t)$ where job j was. It is clear that the interchange is always feasible if $t' + \delta \leq \bar{d}_k$. After the interchange, job j's completion time goes down by δ, whereas job k's completion time goes up by δ, and job l's completion time cannot go up (and may go down). Thus, the total completion time of the new schedule is less than or equal to that of the old schedule. We can repeat the same argument until job j is completed as early as possible. ∎

THEOREM 2. *Given the completion sequence in an optimal schedule, the algorithm* SA *always constructs an optimal schedule.*

Proof. The scheduling algorithm above schedules each job to complete as early as possible. By Theorem 1, it produces the minimum $\sum C_j$. It remains to be shown that *SA* produces a feasible schedule, given that the completion sequence is feasible.

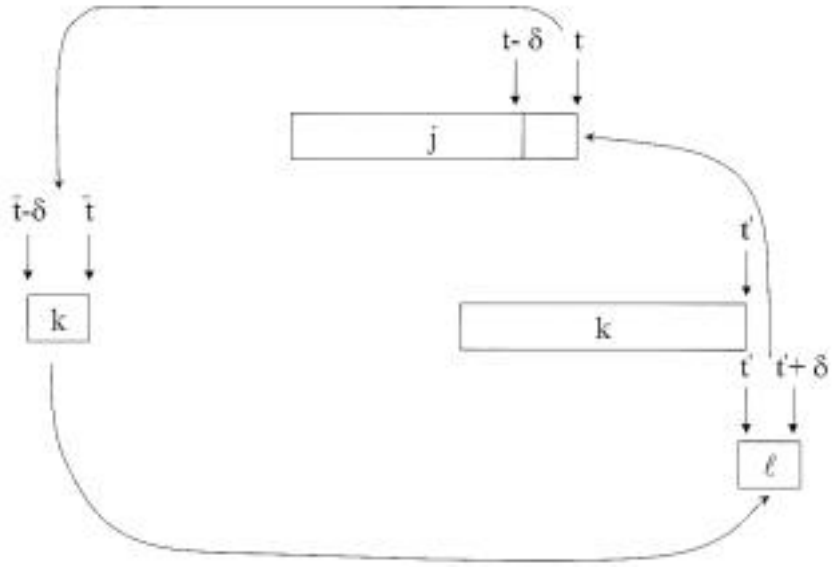

FIG. 1. *Triple interchange.*

SA schedules job j in sequence, $j = 1, 2, \ldots, n$. The proof is by induction on j. The base case $j = 1$ is obvious. Assume that it is true for $j < i$; we will show that it is true for $j = i$.

Recall that SA tries to schedule job i on machine M_1, beginning at time f_1. To check if the remaining jobs can complete by their induced deadlines, the algorithm considers the $m - 1$ jobs with the earliest LSTs, $k_1, k_2, \ldots, k_{m-1}$, where

$$LST_{k_1} \leq LST_{k_2} \leq \cdots \leq LST_{k_{m-1}}.$$

Job k_j is assigned to machine M_{j+1}, $1 \leq j \leq m - 1$, up against its induced deadline. If there is any overlap of job k_j with a job that is already scheduled on machine M_{j+1}, it redistributes the overlapped portion to a machine with a lower index. After the redistribution process, let machine M_l be the lowest indexed machine that has idle time; i.e., machines $M_2, M_3, \ldots, M_{l-1}$ have no idle time; see Figure 2. (If none of these machines have idle time, we define l to be $m + 1$.) Refer to jobs $k_1, k_2, \ldots, k_{l-2}$ as the critical jobs (i.e., the jobs scheduled on machines $M_2, M_3, \ldots, M_{l-1}$) and to jobs $k_{l-1}, k_l, \ldots, k_{m-1}$ as the noncritical jobs. By the induction hypothesis, the $m-1$ jobs as well as job i can be scheduled in a feasible manner.

We want to show that the remaining jobs (other than the $m - 1$ jobs) can also be feasibly scheduled after job i is scheduled. We consider two cases, depending on whether or not $l = m + 1$. If $l = m + 1$, then all $m - 1$ jobs are critical. Since job i must complete before any of the remaining jobs, the remaining jobs can be feasibly scheduled by the induction hypothesis. Thus, we may assume that $l < m + 1$. In this case, job i will start at or before f_l, since the δ amount from the critical jobs (scheduled on machine M_1) cannot extend beyond f_l (or else the critical jobs are not feasibly scheduled). On the other hand, the LST of any of the remaining jobs must

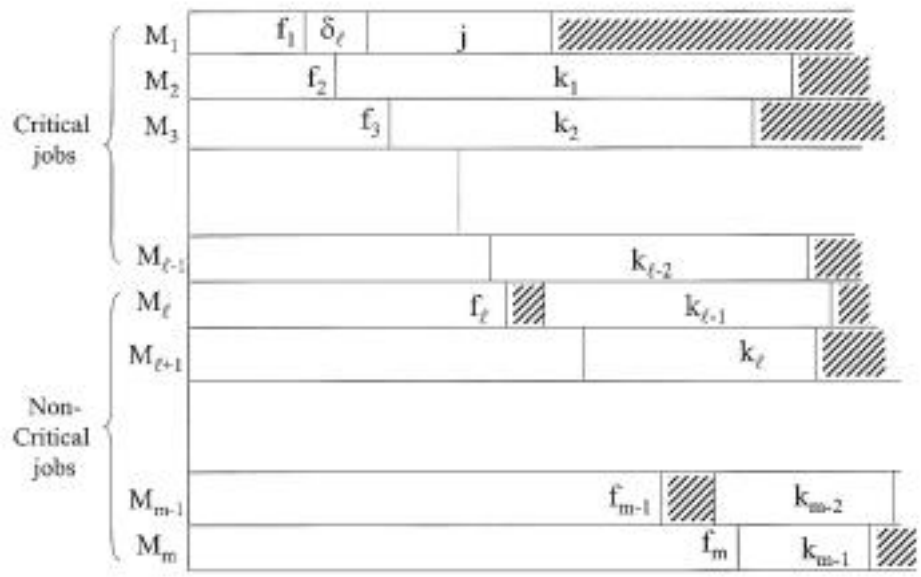

FIG. 2. *Illustrating feasibility.*

be greater than f_l. Thus, all of the remaining jobs as well as the noncritical jobs can be feasibly scheduled if there are enough machine capacities. But this last point is guaranteed since the completion sequence is obtained from an optimal schedule (which is a feasible schedule). □

We now focus on the second question, "How do we get the information the 'birdie' has?" The basic idea is to use the SPT rule, ignoring the deadline constraints. Afterall, if the SPT schedule does not have any deadline violations, then the schedule is already optimal. In general, however, the SPT schedule may have some deadline violations. We need some mechanism to avoid deadline violations while maintaining as much of an SPT-type structure as possible. In what follows we describe the algorithm that generates the optimal ordering, and we refer to this algorithm as the Ordering Algorithm *OA*. (This ordering algorithm uses the *SA* algorithm as a subroutine.) *OA* consists of an initialization step and a main step. The input of this algorithm is the list of jobs L which orders the jobs in increasing order of their processing times and, when there are ties, in increasing order of their original deadlines. The output of the algorithm is a list $\bar{L}$ that specifies the order in which the jobs are completed in an optimal schedule.

Step 1 (initialization). Reindex the jobs in ascending order of their processing times and in ascending order of their original deadlines for identical processing times. Let $L = (1, 2, \ldots, n)$ be the list of jobs in ascending order of their indexes. For each job j, initialize its induced deadline as its original deadline $\bar{d}_j$. (This is a slight abuse of notation since induced deadlines are defined with respect to a schedule. As we shall see later, the induced deadlines are updated to correspond to the induced deadlines in an optimal schedule.) Set $k = 1$ and $\bar{L} = L$.

Step 2 (main). In what follows we reorder the jobs in $\bar{L}$ to form an ordering of the completion sequence of an optimal schedule. We consider each job in turn, starting

with the first job in $\bar{L}$. Suppose we have fixed the position of the first $k-1$ jobs and we are considering the kth job. Let $\bar{L} = (i_1, i_2, \ldots, i_n)$, and let $R(i_{k+1}, i_{k+2}, \ldots, i_n)$ denote the list obtained by reordering the last $n-k$ jobs in $\bar{L}$ in ascending order of their induced deadlines and in ascending order of their processing times for identical induced deadlines. We now construct a schedule S by applying SA to the list

$$\hat{L} = (i_1, i_2, \ldots, i_k) \,||\, R(i_{k+1}, i_{k+2}, \ldots, i_n).$$

The outcome of the application of SA may fall into one of three cases.

Case (i). S is a feasible schedule, and job i_k is completed no later than any one of the jobs in $(i_{k+1}, i_{k+2}, \ldots, i_n)$. In this case job i_k is fixed in position k, and its induced deadline is updated and made equal to its deadline induced by S. $\bar{L}$ will be the same as before (i.e., $\bar{L} = (i_1, i_2, \ldots, i_n)$), and the above process will be repeated with k increased by 1.

Case (ii). S is feasible, but job i_k is completed later than some of the jobs in $(i_{k+1}, i_{k+2}, \ldots, i_n)$. In this case we move all the jobs that are completed earlier than job i_k ahead of job i_k. Again, these jobs (that were moved ahead) will be rearranged in ascending order of their processing times and in ascending order of their induced deadlines for identical processing times. Let L' be the list of these jobs, and let

$$L'' = (i_{k+1}, i_{k+2}, \ldots, i_n) - L'.$$

We set $\bar{L}$ to be

$$\bar{L} = (i_1, i_2, \ldots, i_{k-1}) \,||\, L' \,||\, (i_k) \,||\, L''.$$

The above process will be repeated with the new $\bar{L}$ but the same k. (In other words, k is not increased by 1.)

Case (iii). S is infeasible, and job i_j is the first job that encounters infeasibility when it is scheduled by SA. Recall that SA detects infeasibility when it tries to schedule job i_j on machine 1 along with "pieces" of some other jobs. Let i_x be the job with the earliest induced deadline among all these jobs. In this case we move all the jobs in $(i_{k+1}, i_{k+2}, \ldots, i_n)$ with induced deadlines less than or equal to that of job i_x ahead of job i_k. These jobs (that were moved ahead) will be rearranged in ascending order of their processing times and in ascending order of their induced deadlines for identical processing times. Let L' be the list of these jobs, and let

$$L'' = (i_{k+1}, i_{k+2}, \ldots, i_n) - L'.$$

Set

$$\bar{L} = (i_1, i_2, \ldots, i_{k-1}) \,||\, L' \,||\, (i_k) \,||\, L''.$$

The above process will be repeated with the new $\bar{L}$ but the same k (in other words, k is not increased by 1).

Step 3 (stopping criterion). If $k = n$, then STOP; otherwise go back to Step 2.

When the ordering algorithm stops, $\bar{L}$ specifies the completion sequence of an optimal schedule. The following example illustrates the algorithm.

Example 2. Consider the same three machines and 9 jobs of Example 1.

Jobs	1	2	3	4	5	6	7	8	9
p_j	4	5	7	8	10	12	13	14	15
d_j	∞	∞	∞	10	12	12	25	27	30
LST_j	∞	∞	∞	2	2	0	12	13	15

First iteration of OA ($k = 1$). The input is

$$\bar{L} = 1, 2, 3, 4, 5, 6, 7, 8, 9.$$

The ordering algorithm calls the algorithm *SA* to apply it to the list

$$\hat{L} = 1, 4, 5, 6, 7, 8, 9, 2, 3.$$

This input into *SA* is exactly the instance considered in Example 1, and in Example 1 it is shown how a schedule can be generated according to $\hat{L}$. This completes the first iteration of the ordering algorithm (Case (i)), and job 1 is put in the first position. The induced deadline of job 1 is $d_1(\hat{L}) = 10$, and k is increased by 1.

Second iteration of OA ($k = 2$). The input is the same $\bar{L}$ as in the first iteration since this has not been changed in the first iteration. An attempt has to be made to schedule job 2 (the second shortest job) by applying the *SA* algorithm on

$$\hat{L} = 1, 2, 4, 5, 6, 7, 8, 9, 3.$$

The fitting of job 1 (with $f_1 = f_2 = f_3 = 0$) is similar to the fitting of job 1 in the application of *SA* in the first iteration of the ordering algorithm. *SA* proceeds with the fitting of job 2, given that $f_1 = f_2 = 0$ and $f_3 = 4$. The two jobs with the smallest LST are jobs 4 and 6:

$$LST_6 = 0,$$

$$LST_4 = 2.$$

Machine 3 has a deficit of 2 with job 4, and machine 2 has a deficit of 0 with job 6. So $\delta = 2$. So job 4 has to be processed during the interval $[0, 2]$ on machine 1, and job 2 has to be processed during the interval $[2, 7]$ on machine 1. Before continuing with the third iteration of the *SA* algorithm the processing time of job 4 is modified from 8 to 6.

The third iteration of *SA* tries to fit in job 4 with $f_1 = 0$, $f_2 = 4$, and $f_3 = 7$. The two jobs with the smallest LST are jobs 5 and 6:

$$LST_6 = 0,$$

$$LST_5 = 2.$$

Machine 3 has a deficit of 5 when fitting in job 5, and the deadline of the deficit "piece" of job 5 is 7. Machine 2 has a deficit of 4 when fitting in job 6, and the deadline of the deficit "piece" of job 6 is 4. These two deficits have to be scheduled on machine 1 together with job 4 (which has a processing time of 6 and a deadline of 10). This is infeasible. So the application of *SA* results in Case (iii) of the ordering algorithm and the first job that encounters infeasibility is job 4. Among the three jobs that we tried to schedule on machine 1 (namely jobs 4, 5, and 6), job 4 has the earliest deadline. So this implies that only job 4 is moved before job 2, and the new list is

$$\bar{L} = 1, 4, 2, 3, 5, 6, 7, 8, 9.$$

So we go back to Step 2 of *OA* with $k = 2$.

The remaining iterations of this example have been relegated to the appendix.

The following theorem shows that the algorithm *OA* does generate an optimal completion ordering.

THEOREM 3. *The algorithm* OA *yields an optimal completion ordering* $\bar{L}$.

Proof. Let $L' = (1', 2', \ldots, n')$ be an optimal ordering and S' be an optimal schedule with completion sequence $1', 2', \ldots, n'$. By Theorem 2, we may assume that S' is constructed by *SA* using the list L'. Let $\bar{L} = (1, 2, \ldots, n)$ be the ordering obtained by the above algorithm. Let k be the smallest index such that $k' \neq k$; i.e., $i' = i$ for each $1 \leq i < k$ but $k' \neq k$. We differentiate among three cases, depending upon the processing times of jobs k' and k.

Case I. $p_{k'} < p_k$. Since $p_{k'} < p_k$, job k' appears before job k in the initial ordering of $\bar{L}$, but it appears after job k in the final ordering of $\bar{L}$. This means that job k' was considered in the job ordering process before job k but was overtaken by job k. In the *OA* algorithm, a job will be overtaken by other jobs only if (i) it fails to produce a feasible schedule or (ii) it fails to complete before all of the remaining jobs. In the first case, S' (with job completion sequence identical to L') is not a feasible schedule. In the second case, it can be shown that S' is not optimal.

Case II. $p_{k'} = p_k$. If the original deadline of job k' is greater than or equal to that of job k, i.e., $\bar{d}_{k'} \geq \bar{d}_k$, then we can swap k' with k in L', and the new ordering will produce a feasible schedule with total completion time equal to that of S'. Thus, we may assume that $\bar{d}_{k'} < \bar{d}_k$. In this case job k' appears before job k in the initial ordering of $\bar{L}$, but it appears after job k in the final ordering. Again, this means that job k' was overtaken by job k in the job ordering process. But this is impossible since if it is feasible to complete job k before job k', it must also be feasible to complete job k' before job k. (Recall that $p_{k'} = p_k$ and $\bar{d}_{k'} < \bar{d}_k$.)

Case III. $p_{k'} > p_k$. If $\bar{d}_{k'} \geq \bar{d}_k$, then we can swap k' with k in L', and the new ordering will produce a feasible schedule with total completion time less than that of S'. Thus, we may assume that $\bar{d}_{k'} < \bar{d}_k$. If job k completes by $\bar{d}_{k'}$ in S', then we can swap k' with k in L', and the new ordering will produce a feasible schedule with total completion time less than that of S'. Thus, we may assume that job k completes later than $\bar{d}_{k'}$ (but at or before $\bar{d}_k$) in S'. Let $\bar{d}_{k'} = D_x$ and the induced deadline of job k in S' be D_y. By our assumption, $D_x < D_y$.

Observe that our scheduling algorithm schedules the noncritical jobs nonpreemptively, while the critical jobs (the jobs that were pushed against the deadline and involved in the computation of LST) may be preempted. Consider the jobs that follow job k' in L' up until job k. We assert that there is a noncritical job j with its original deadline $\bar{d}_j > D_{y-1}$ and job j starts before D_{y-1} in S'. This is because $\bar{L}$ (with job k in the kth position) indicates that it is possible to complete job k along with all the jobs whose original deadlines are less than or equal to D_{y-1} by D_{y-1}. Since job k does not complete by D_{y-1} in S', there must be another job in its place. We consider two cases, depending upon the processing times of jobs j and k.

If $p_j < p_k$, then job j was considered in the job ordering process before job k, but it was overtaken by job k. But this is impossible since S' indicates that it is feasible to complete job j before job k.

If $p_j \geq p_k$, then we can swap j with k in L', and the new ordering will produce a feasible schedule with total completion time less than or equal to that of S'. We can repeat the above argument until job k completes by $\bar{d}_{k'}$, at which time we can swap job k' with job k. □

Theorems 2 and 3 yield our main result.

THEOREM 4. *$P \mid prmt, \bar{d}_j \mid \sum C_j$ can be solved in polynomial time for each $m \geq 2$.*

The running time of our algorithm is $O(mn^3 \log mn)$. Step 1 (initialization) of algorithm OA takes $O(n \log n)$ time. Step 2 (main) of OA takes at most $O(n^2)$ iterations, since in the worst case the algorithm may completely reverse the initial ordering. Each iteration involves rearranging the last $n-k$ jobs in ascending order of their induced deadlines, calling SA with the list $\hat{L}$, and modifying $\bar{L}$ if the outcome of the application of SA falls into Cases (ii) or (iii). In what follows we show that each of these steps can be implemented in $O(mn \log mn)$ time.

The most efficient way to rearrange the last $n-k$ jobs in ascending order of their induced deadlines is to maintain a balanced tree of the remaining jobs (i.e., the last $n-k$ jobs) in ascending order of their induced deadlines (and in case of ties in ascending order of their processing times). This tree can initially be built in $O(n \log n)$ time. When we need the required ordered list, we simply walk over the tree in linear time. As k increases, we need to delete some jobs from the balanced tree. But this can all be done in the required time bound $O(mn \log mn)$.

The algorithm SA can be implemented in $O(mn \log mn)$ time. There are n jobs to schedule, and each job can be scheduled in $O(m \log m + m \log n)$ time. The machines can be sorted in ascending order of their finishing times in $O(m \log m)$ time. The $m-1$ jobs with the earliest LSTs can be determined in $O(m \log n)$ time if we maintain a balanced tree of jobs in ascending order of their LST. The redistribution of deficits of some jobs to other machines takes $O(m)$ time, and the scheduling of the deficits on machine 1 takes the same amount of time.

Modifying $\bar{L}$ can also be implemented to run in the required time bound. Identifying the jobs in L' can be done in linear time. Sorting them in ascending order of their processing times (and in case of ties in ascending order of their induced deadlines) takes $O(n \log n)$ time. Deleting the jobs in L' from the list $(i_{k+1}, i_{k+2}, \ldots, i_n)$ takes linear time if $\bar{L}$ is maintained as a doubly linked list. Thus, the new $\bar{L}$ can be obtained in $O(n \log n)$ time.

3. Complexity results. In this section we show that generalizing $P \mid prmt, \bar{d}_j \mid \sum C_j$ to a parallel machine environment with machines that are unrelated results in a problem that is strongly NP-hard. (Recall that in a parallel machine environment that is unrelated the processing time of job j on machine i is p_{ij}; i.e., the processing time of job j depends on the machine on which it is processed.)

Our proof that shows the NP-hardness of $R \mid prmt, \bar{d}_j \mid \sum C_j$ also shows the NP-hardness of the nonpreemptive $R \mid \bar{d}_j \mid \sum C_j$ problem. It shows that, even when all the jobs have a single common deadline, the problem is NP-hard. In what follows we first present the proof for the nonpreemptive environment and then explain why it also applies to the preemptive environment.

We shall reduce the strongly NP-complete 3-DIMENSIONAL MATCHING (3DM) problem to the decision version of $R \mid \bar{d}_j \mid \sum C_j$. The 3DM problem can be stated as follows (see Garey and Johnson (1979)): Given three disjoint sets $A = \{a_1, a_2, \ldots, a_q\}$, $B = \{b_1, b_2, \ldots, b_q\}$, and $C = \{c_1, c_2, \ldots, c_q\}$ and a set $M = \{m_1, m_2, \ldots, m_l\}$ with each m_k, $1 \leq k \leq l$, being a triple with the first component drawn from A, the second from B, and the third from C, is there a subset M' of M such that every element in A, B, and C occurs in exactly one of the triples in M'?

Given an instance of the 3DM problem, we construct an instance of the decision version of $R \mid \bar{d}_j \mid \sum C_j$ as follows. Let there be l machines, where machine i

corresponds to the triple m_i. For each a_j in A, construct a job A_j with processing times $p_{ij} = 1$ if a_j is in m_i; otherwise, $p_{ij} = 2$. Similarly, for each b_j (resp., c_j) in B (resp., C), construct a job B_j (resp., C_j) with processing times $p_{ij} = 1$ if b_j (resp., c_j) is in m_i; otherwise, $p_{ij} = 2$. In addition, create $l - q$ dummy jobs $D_1, D_2, \ldots, D_{l-q}$. The processing times of each of the dummy jobs are 6, independent of the machine on which they are processed. The deadlines of all the jobs (A, B, C, and D jobs) are 6. Finally, let $\omega = 6l$ be the threshold of $\sum C_j$.

We first show that there is a feasible, nonpreemptive schedule for this set of jobs, regardless of whether the instance of 3DM has a matching. Schedule the A, B, and C jobs on q machines, three jobs per machine. The completion time of every job is no larger than 6. Schedule the dummy jobs on the remaining machines, one job per machine. The completion time of each dummy job is 6. Thus, every job meets its deadline.

The next lemma shows that the given instance of 3DM has a solution if and only if the constructed instance of $R \mid \bar{d}_j \mid \sum C_j$ has a solution.

LEMMA 2. *There is a matching if and only if there is a schedule with* $\sum C_j \leq \omega$.

Proof. Suppose there is a matching. Let $m_{i1}, m_{i2}, \ldots, m_{iq}$ be the triples that constitute the matching. We schedule the jobs as follows. Let m_{ik}, $1 \leq k \leq q$, contain a_x, b_y, and c_z. Assign jobs A_x, B_y, and C_z to machine ik. The completion times of these three jobs are 1, 2, and 3, respectively. Assign the dummy jobs D_j to an unassigned machine, one job per machine. The completion time of each dummy job is 6. This schedule has a total completion time

$$\sum C_j = 6(l - q) + q + 2q + 3q = \omega.$$

Conversely, suppose there is a feasible schedule S with $\sum C_j \leq \omega$. We will show that there is a matching. Since the dummy jobs have deadlines 6 and their processing times are 6 on any machine, they must be assigned one job per machine. The total completion time of all the dummy jobs is $6(l - q)$. A machine with a dummy job assigned can no longer be used for assignment, since all jobs have deadlines less than or equal to 6. Let machines $i1, i2, \ldots, iq$ be the machines still available. The A, B, and C jobs must be assigned to these machines. Since S has $\sum C_j \leq \omega$, the total completion time of all of the A, B, and C jobs is less than or equal to $6q$. But this can be attained only if all of these jobs have processing time 1 unit on the machine to which it is assigned, which means that there is a matching.

The same reduction works also for $R \mid prmt, \bar{d}_j \mid \sum C_j$ since preemption cannot reduce the $\sum C_j$ in the constructed instance. □

The following theorem follows immediately from the previous lemma.

THEOREM 5. *$R \mid prmt, \bar{d}_j \mid \sum C_j$ and $R \mid \bar{d}_j \mid \sum C_j$ are both strongly NP-hard.*

4. Extensions and conclusions. In this paper we presented a polynomial-time algorithm for $P \mid prmt, \bar{d}_j \mid \sum C_j$, and we showed that the more general $R \mid prmt, \bar{d}_j \mid \sum C_j$ problem is strongly NP-hard. Note that our algorithm also solves the single machine case (which had been solved by Smith (1956)); i.e., $1 \mid \bar{d}_j \mid \sum C_j$. Recently, we learned that Sitters (2001) had independently shown that the $R \mid prmt \mid \sum C_j$ problem is strongly NP-hard. While Sitters's result implies the strong NP-hardness of $R \mid prmt, \bar{d}_j \mid \sum C_j$, its proof is significantly more complex than ours.

The polynomial-time algorithm presented in this paper can be used to solve other scheduling problems as well. Suppose that, instead of a deadline, each job j has a due date d_j, and the objective is to minimize the maximum lateness, where the lateness

of a job is defined to be the difference between its completion time and its due date. (In the 3-field notation, this problem is denoted by $P \mid prmt \mid L_{\max}$.) This problem can be solved as follows. Parametrize on the maximum lateness. Assume $L_{\max} = z$, and create for all jobs the deadlines $d_j + z$. We then check if there is a feasible schedule with this set of deadlines. The optimal value for the maximum lateness can be obtained by conducting a binary search of z in a range between a lower and an upper bound. Once the minimal value of z has been obtained, say z^*, we can use the algorithm described in this paper to find a schedule that minimizes $\sum C_j$. In this way we can solve the problem of minimizing $\sum C_j$ subject to the constraint that $L_{\max}$ is minimum. Of course, the algorithm will also work for any $L_{\max}$ greater than or equal to z^*.

Appendix. This appendix contains the remaining iterations of Example 2.

Third iteration of OA ($k = 2$). The algorithm *SA* has to be applied now on

$$\hat{L} = 1, 4, 5, 6, 7, 8, 9, 2, 3.$$

Jobs 1 and 4 are inserted in the same way as they are inserted in Example 1. After having put jobs 1 and 4 in, the partial schedule has job 1 processed during the interval $[0, 4]$, job 5 during the interval $[0, 2]$, and job 4 during the interval $[2, 10]$. So $f_1 = 0$, $f_2 = 4$, and $f_3 = 10$. In the third iteration of this application of the scheduling algorithm job 5 is considered. The two jobs with the smallest LST are jobs 6 and 7 with

$$LST_6 = 0,$$

$$LST_7 = 12.$$

Job 7 can be assigned to machine 3 with an idle time of two time units. Job 6 can be assigned to machine 2 with a deficit of four time units. So $\delta = 4$, and it is possible to put job 5 (with processing time $10 - 2 = 8$ and deadline 12) on machine 1 when $\delta = 4$. So after this iteration of the scheduling algorithm job 6 is processed during the interval $[0, 4]$ (and has a remaining processing time of 8), and job 5 is processed during the interval $[4, 12]$. The machines are available at $f_1 = 4$, $f_2 = 10$, and $f_3 = 12$.

In the next iteration the scheduling algorithm tries to put in job 6 (with a processing time of 8). The two jobs with the smallest LST are jobs 7 and 8:

$$LST_7 = 12,$$

$$LST_8 = 13.$$

Putting in job 8 on machine 3 has an idle time of 1, and putting in job 7 on machine 2 has an idle time of 2. So $\delta = 0$. Putting in job 6 on machine 1 is feasible. So job 6 is processed during the interval $[4, 12]$. The machines are available at $f_1 = 10$, $f_2 = 12$, and $f_3 = 12$.

In the next iteration the scheduling algorithm tries to put in job 7 (with a processing time of 13). The two jobs with the smallest LST are jobs 8 and 9:

$$LST_8 = 13,$$

$$LST_9 = 15.$$

Both jobs 8 and 9 can be scheduled on machines 2 and 3 with idle times. Job 7 can be scheduled on machine 1. The scheduling algorithm can complete the schedule in a feasible manner.

The result of the application of the scheduling algorithm is that job 4 is completed at 10, and job 4 is completed before any one of the jobs following it (i.e., Case (i) of algorithm *OA*). The counter k is increased by 1, and the list $\bar{L}$ remains the same; i.e.,

$$\bar{L} = 1, 4, 2, 3, 5, 6, 7, 8, 9.$$

Fourth iteration of OA ($k = 3$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 2, 5, 6, 7, 8, 9, 3.$$

Job 1 can be scheduled as usual. Job 4 has to be considered with $f_1 = f_2 = 0$ and $f_3 = 4$. Jobs 5 and 6 have the smallest LST:

$$LST_6 = 0,$$

$$LST_5 = 2.$$

Two time units of job 5 have to be processed on machine 1 during interval $[0, 2]$. Job 4 can be processed on machine 1 during interval $[2, 10]$. The remaining processing time of job 5 is 8 and $f_1 = 0$, $f_2 = 4$, and $f_3 = 10$. Job 2 is considered next. Jobs 5 and 6 again have the smallest LST:

$$LST_6 = 0,$$

$$LST_5 = 4.$$

Putting jobs 5 and 6 on machines 2 and 3 result in a total deficit of $6 + 4 = 10$. However, these deficits can be scheduled feasibly on machine 1. Job 6 can be processed on machine 1 during the interval $[0, 4]$ and job 5 during the interval $[4, 10]$, implying that job 2 can start at 10 and is completed at 15. The result of this application of the scheduling algorithm is that the schedule is feasible but that job i_k is completed after some of the jobs in set $(i_{k+1}, \ldots, i_n)$, namely jobs 5 and 6. So jobs 5 and 6 have to be moved before job 2 (Case (ii) of *OA*). So

$$\bar{L} = 1, 4, 5, 6, 2, 3, 7, 8, 9.$$

Fifth iteration of OA ($k = 3$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 5, 6, 7, 8, 9, 2, 3.$$

But this is the same list as in the first iteration of the ordering algorithm. So the schedule is feasible, and job 5 is completed no later than any of the jobs following it (Case (i) of *OA*). So job 5 is fixed in the third position, its induced deadline remains the same, $\bar{L}$ remains the same, and k is increased by 1.

Sixth iteration of OA ($k = 4$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 5, 6, 7, 8, 9, 2, 3.$$

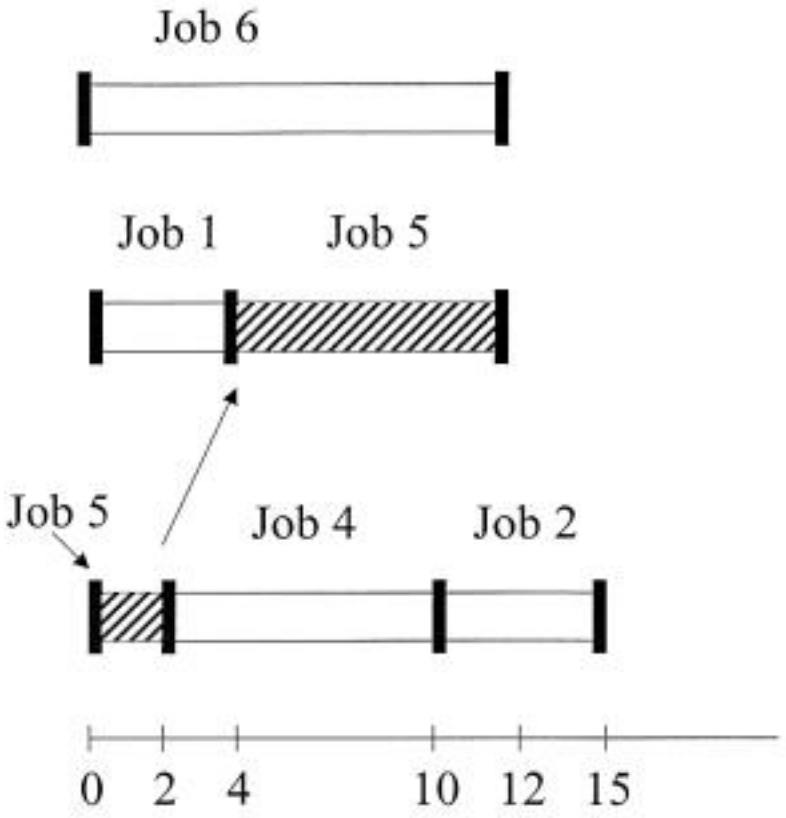

FIG. 3. *Partial schedule.*

This $\hat{L}$ is the same as in the previous iteration, and job 6 is again completed no later than any of the jobs following it and is fixed in the fourth position. Its induced deadline remains the same. $\bar{L}$ remains the same and k is increased by 1.

Seventh iteration of OA ($k = 5$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 5, 6, 2, 7, 8, 9, 3.$$

The scheduling algorithm generates a feasible schedule with job 2 completed before any one of the jobs following it (see Figure 3). The new induced deadline of job 2 is $d_2(\hat{L}) = 25$. $\bar{L}$ remains the same and k is increased by 1.

Eighth iteration of OA ($k = 6$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 5, 6, 2, 3, 7, 8, 9.$$

The ready times of the three machines, when trying to schedule job 3, are $f_1 = 12$, $f_2 = 12$, and $f_3 = 15$. When trying to put in job 3 the jobs with the smallest LST

are jobs 7 and 8:

$$LST_7 = 12,$$

$$LST_8 = 13.$$

Putting jobs 7 and 8 on machines 2 and 3 result in a deficit of 2 because of job 8. So job 8 has to be scheduled on machine 1 during the interval $[12, 14]$, and job 3 can then be processed during the interval $[14, 21]$. So before going to the next step of the scheduling algorithm the processing time of job 8 is updated and becomes 12, and its LST is updated and becomes 15. The next step of the scheduling algorithm tries to put in job 7, while $f_1 = 12$, $f_2 = 15$, and $f_3 = 21$. The two jobs with the smallest LST are jobs 8 and 9:

$$LST_8 = 15,$$

$$LST_9 = 15.$$

It turns out that job 7 cannot be feasibly scheduled. So the eighth iteration of the ordering algorithm ends up in Case (iii). Between the two jobs that we tried to schedule on machine 1 (namely jobs 7 and 9), job 7 has the earliest induced deadline. So job 7 has to be put before job $i_6 = 3$, i.e.,

$$\bar{L} = 1, 4, 5, 6, 2, 7, 3, 8, 9.$$

The k remains the same.

Ninth iteration of OA ($k = 6$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 5, 6, 2, 7, 8, 9, 3.$$

Applying the scheduling algorithm on this order results in a feasible schedule; i.e., it leads to Case (i) in algorithm *OA*. This implies that $\bar{L}$ remains the same. The induced deadline of job 7 has to be updated, but the update does not result in a different deadline. The counter k is increased by 1.

Tenth iteration of OA ($k = 7$). The scheduling algorithm has to be applied to the list

$$\hat{L} = 1, 4, 5, 6, 2, 7, 3, 8, 9.$$

The scheduling algorithm has to try to put in job 3. The times the machines become available after completing the processing of the first six jobs are $f_1 = 12$, $f_2 = 15$, and $f_3 = 25$. There are two jobs listed after job 3 and

$$LST_8 = 13,$$

$$LST_9 = 15.$$

Both machines have a deficit. Machine 2 has a deficit of 2, and machine 3 has a deficit of 10. However, both these deficits can be scheduled feasibly on machine 1, and job 3

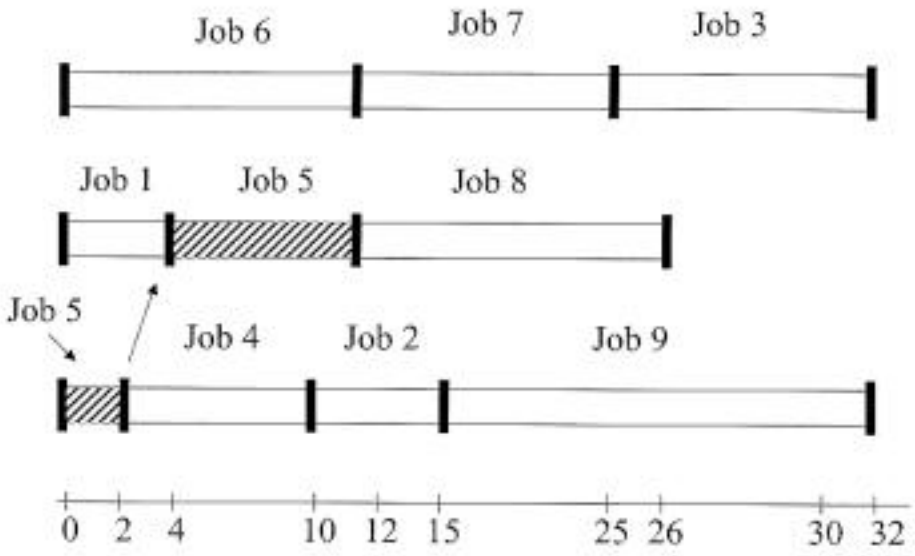

FIG. 4. *Optimal schedule.*

can be scheduled (feasibly) thereafter. This iteration of *OA* ends up in Case (ii). We have to change $\bar{L}$, and it now becomes

$$\bar{L} = 1, 4, 5, 6, 2, 7, 8, 9, 3.$$

The counter k remains the same.

The algorithm needs another two iterations: one for $k = 7$ and one for $k = 8$. In the eleventh iteration ($k = 7$) job 8 is feasibly scheduled, and in the twelfth iteration ($k = 8$) job 9 is feasibly scheduled. The optimal schedule is then obtained by putting in job 3 on the machine that is first available (see Figure 4).

KOLMOGOROV COMPLEXITY AND DETERMINISTIC CONTEXT-FREE LANGUAGES*

OLIVER GLIER†

Abstract. We deal with a criterion for deterministic context-free languages that was originally formulated by Li and Vitányi [*SIAM J. Comput.*, 24 (1995), pp. 398–410]. Their result—called the KC-DCF lemma—relates Kolmogorov complexity to pushdown automata and works on a superset of examples compared to traditional iteration and pumping lemmas. Sadly, their KC-DCF lemma has a flaw. In this paper, we give a counterexample to the original KC-DCF lemma and also provide a corrected version.

Key words. formal language theory, Kolmogorov complexity, deterministic context-free languages

AMS subject classifications. 68Q30, 68Q45

DOI. 10.1137/S0097539702417754

First we settle some notation and give a quick introduction to Kolmogorov complexity as far as it is needed for our result (for more details and applications of Kolmogorov complexity, see [LiVi97]). Let Σ be an alphabet with at least two distinct symbols 0 and 1. For a word $x = x_1 \cdots x_n \in \Sigma^*$ we define

$$x^{\$} := 1^{|\mathtt{bin}(n)|}0\mathtt{bin}(n)x$$

as the *self-delimiting code* for x, where $\mathtt{bin}(n)$ is the binary representation of the number n. In what follows, let U be a universal machine which expects some input of the form $p^{\$}q$, $p, q \in \Sigma^*$ and then simulates the program p on input q. Now we define the following for $x, q \in \Sigma^*$:

$$C(x|q) := \min\{|p| : U(p^{\$}q) = x, p \in \Sigma^*\}$$

is the *conditional Kolmogorov complexity* of x with the additional information q, and

$$C(x) := \min\{|p| : U(p^{\$}) = x, p \in \Sigma^*\}$$

is the *Kolmogorov complexity* of x (without additional information).

The following immediate consequences are stated without proof.

PROPOSITION 1.

(i) $C(x|q) \leq C(x) \leq |x| + O(1)$.

(ii) *For any totally recursive function* $f : \Sigma^* \to \Sigma^*$, *we have*

$$C(f(x)|q) \leq C(x|q) + O(1).$$

(iii) $C(x) \leq C(q) + C(x|q) + O(\min(\log|x|, \log|q|))$. □

For any natural number $n = 0, 1, 2, \ldots$, we denote by $\underline{n}$ the nth word of Σ^* in lexicographic order. Further, we set $\lg(n) := |\underline{n}|$. Informally, the following proposition states that any sufficiently large number m can be enclosed by the length of a number r and by r's much smaller Kolmogorov complexity.

PROPOSITION 2. *For sufficiently large m, there always exists an $r \in \mathbb{N}$ with $\lg(r) > m$ and $C(\underline{r}) < \lg(\lg(m))$.*

Proof. We choose $t = \lg(\lg(m))$ and $r = f(f(f(t)))$, where $f : \mathbb{N} \to \mathbb{N}$ maps a number n to the (unique) number n' such that $\underline{n'}$ is the word 1^{n+1}. By applying Proposition 1(ii), we get

$$C(\underline{r}) \leq C(\underline{t}) + O(1) \leq \lg(t) + O(1) < t = \lg(\lg(m))$$

for sufficiently large m. On the other hand, if m is large enough, we have $f(\lg(m)) > m$ and $\lg(f(m)) > m$. It follows that $\lg(r) > m$. □

We say that a word $x \in \Sigma^*$ is *compressible* iff $C(x) < |x|$; otherwise, it is *incompressible*. Similarly, a number $n \in \mathbb{N}$ is compressible if the nth word in lexicographic enumeration $\underline{n}$ is compressible. For $n \in \mathbb{N}$ there are only $2^n - 1$ many words of length shorter than n. Therefore we have the following result.

THEOREM 3 (incompressibility theorem). *For each $n \in \mathbb{N}$ there exists at least one incompressible word of length n. Hence, there exist infinitely many incompressible words.*

1. The KC-DCF lemma. For a language $L \subseteq \Sigma^*$ and a word $x \in \Sigma^*$, we denote by $x^{-1}L := \{v \in \Sigma : vx \in L\}$ the set of words v that extend x to a word in L. A context-free language $L \subseteq \Sigma^*$ is *deterministic* context-free if there exists a deterministic pushdown automaton (dpda) that recognizes L. Sometimes an iteration or pumping lemma can be applied in order to prove that a given context-free language is not deterministic context-free. However, those lemmas are difficult to handle. In [LiVi95] the authors use the incompressibility argument in order to give a more intuitive, necessary criterion for deterministic context-free languages. Since the formulation of their KC-DCF lemma is considerably complicated, they also derive a weaker corollary which is easier to apply. Sadly, the formulation and the proof of the KC-DCF lemma contain some mistakes that also affect the corollary and hence invalidate them both. Before we give an alternative formulation for both the lemma and its corollary, we will discuss the original formulation of the corollary. By giving a counterexample, we disprove the original corollary and—consequently—the original KC-DCF lemma.

Let $x, y \in \Sigma^*$ and c be any constant, and let ω be a recursive sequence over Σ^*. The idea is to repeat y in the input of a dpda that recognizes L, while limiting the amount of information that the dpda keeps on its stack. Eventually, too much information is lost in order to properly unwind the stack. Li and Vitányi's corollary of the KC-DCF lemma states the following: There exists a constant c' such that, for $u, v, w \in \Sigma^*$, where u is a suffix of the left-infinite word $\cdots yyx$ and v is a prefix of ω, the following three conditions imply $C(w) \leq c'$:

(1) $C(v|p_{uv'}) \leq c$ for all prefixes v' of v and programs $p_{uv'}$ that list $(uv')^{-1}L$ in lexicographic order;
(2) $C(w|p_{uv}) \leq c$ for all programs p_{uv} that list $(uv)^{-1}L$ in lexicographic order;
(3) $C(v) \geq 2 \cdot \lg(\lg(|u|))$.

Remark. In [LiVi95], condition (1) is restricted to only the prefix $v' = \varepsilon$ as the empty word, omitting all other prefixes of v. However, then the corollary is not a direct consequence of the original KC-DCF lemma anymore, since it will not suffice in order to reconstruct all required configurations of the dpda in the corresponding condition of the lemma. However, this is not the essential mistake in [LiVi95] (which we point out later in our proof of the KC-DCF lemma). Condition (1) above yields a statement which is logically implied by the KC-DCF lemma and its corollary. The

following counterexample disproves this statement and therefore the original KC-DCF lemma and its corollary.

We show now that there exist deterministic context-free languages L and $u, v, w \in \Sigma^*$ satisfying (1), (2), (3), but $C(w) \geq c'$ for any constant c'.

EXAMPLE 1. *Set $u = 0^{2n}$, $v = 1^n$, $w = 0^n$, and $L = \{0^n 1^m 0^k : n = m + k\}$. Now, for all prefixes v' of v, v is the first half of the lexicographically first word in $(uv')^{-1}L$ which is all 1, while w is the lexicographically first word in $(uv)^{-1}L$ which is all 0. Thus (1) and (2) are satisfied. Now let $c' > 0$ be any constant, and choose an incompressible n with $C(w) > c'$. If n is sufficiently large, we get $C(v) > \log |u|$ and therefore (3). However, L is obviously deterministic context-free.*

From now on we assume that $L \subseteq \Sigma^*$ is an arbitrary nontrivial deterministic context-free language, and that A is a dpda that recognizes L. Without loss of generality (see [Ha78]), we assume that A always reads its entire input. Also, whenever we don't explicitly mention the initial configuration, we assume that the dpda A starts on the input with its initial state and with an empty stack.

The following proposition is already implicitly used in [LiVi95].

PROPOSITION 4. *Given any $x, y \in \Sigma^*$, there exists a constant $c_0 \in \mathbb{N}$ such that the following proposition holds. Let r be some arbitrary positive integer, and let $u \in \Sigma^*$ be any suffix of the (left-infinite) word $\cdots yyx$ such that, after processing u, the dpda's stack size is $c_0 + k$ for some $k \geq 0$. Then there exists another suffix u' of $\cdots yyx$ with length $|u'| = r + s$ for some $s \leq c_0$ such that, after the inputs u and u' are processed, the state of A is the same for each, and the segment of the k topmost stack symbols is also the same in each case.*

The proof is rather technical but straightforward and is therefore omitted here. Also, the proof is already sketched in [LiVi95].

We will now proceed directly with a corrected version of the KC-DCF lemma. For $v, v_1, v_2 \in \Sigma^*$, we call v_1, v_2 a *splitting* of v iff $v_1 v_2 = v$.

PROPOSITION 5 (KC-DCF lemma, corrected). *Let $x, y \in \Sigma^*$ and c be a constant. Then there exists a constant c' with the following property: Let $u, v, w \in \Sigma^*$, where u is a suffix of the left-infinite word $\cdots yyx$. Then the following three conditions imply $C(w) \leq c'$:*

(i) *$C(v''|k^{\$}q) \leq c$ for all splittings $v'v'' = v$. Here, k, q is any pair of stack and state such that, starting with k, q on input v'', the behavior of A is essentially the same as when starting from the configuration after processing uv' and then continuing with v''.*

(ii) *$C(w|k^{\$}q) \leq c$, where k and q are stack and state after processing uv.*

(iii) *$C(v) \geq 2 \cdot \lg(\lg(|u|))$.*

In (i), "essentially the same behavior" of the dpda A on input v'' means that, by observing only the dpda's state, its current position in v'', and its operations on the topmost stack symbol—while ignoring the rest of the stack(!)—the observed sequences are the same each time, whether the dpda started with k, q as stack and state or with the stack and state reached after processing uv'.

Proof of the KC-DCF lemma. Let c_0 be the constant from Proposition 4. We distinguish two cases for the pairs (u, v). In the proof in [LiVi95], infinitely many pairs of (u, v) have been missed due to an improper formulation of the defining conditions for the two different cases. This is also the reason why our conditions in the KC-DCF lemma are different.

Case 1. Assume that for all but finitely many pairs (u, v) which satisfy (i) and (iii) the size of the stack shrinks below c_0 during processing of the v-part of input uv.

Then there exists a constant m such that, for each pair (u, v), the stack has size less than m in at least one step i during processing of v. Let v' be the the part of v which has already been read in step i, and let $K(i)$ be the configuration (i.e., the complete stack, state, and input position) in step i. Since the stack size is bounded, $K(i)$ can be described with a finite number of symbols.

Now let v'' be the unique word with $v'v'' = v$. Having $K(i)$, v'' can be reconstructed with only finitely many additional symbols by using condition (i). The same holds true for the complete stack and the state after processing uv: In order to reconstruct them, we just start with the configuration $K(i)$ but take the previously reconstructed v'' as input. It follows that any word w which satisfies (ii) can be constructed with only c additional symbols. Because $K(i)$'s stack size is bounded by c_0, it follows that $C(w) \leq c'$ for some other constant $c' = c_0 + O(1)$.

Case 2. Now we show that Case 1 always holds. We assume that for infinitely many pairs (u, v) which satisfy (i) and (iii) the stack size will always be larger than c_0 during processing of the v part of the input.

Because of (i), for each u there exist only finitely many appropriate v. From the assumption that there are infinitely many such pairs (u, v) it follows then that we can choose u to be arbitrarily long and still find a v such that the stack size remains larger than c_0 while processing v on input uv. Using Proposition 2, we choose $|u|$ large enough such that there exists a number $r \in \mathbb{N}$ with $\lg(r) > |u|$ and

$$C(\underline{r}) < \lg(\lg(|u|)).$$

Using Proposition 4, we can find $s \leq c_0$ such that, after processing the suffix u' of $\cdots yyx$ with length $|u'| = r + s$, the dpda A will be in the same state as it has after processing u. In addition, the segment of the stack above position c_0 after processing u will also be the topmost segment after processing u'. Because the stack doesn't shrink below c_0, the observable behavior during processing v on input uv is the same as on input $u'v$. Hence, (i) implies that v can be reconstructed with finitely many additional symbols when only u' is known. Because s is bounded, we have $C(u') \leq C(\underline{r}) + O(1)$. For sufficiently large u we get

$$C(u') < \lg(\lg(|u|)).$$

Putting it all together, we get

$$\begin{aligned} C(v) &\leq C(u') + O(1) \\ &\leq \lg(\lg(|u|)) + O(1). \end{aligned}$$

This contradicts condition (iii). □

Since the KC-DCF lemma itself is difficult to apply, we also give the corresponding corrected formulation of its corollary (see [LiVi95]). We say that a program p *decides* L_1 *for* L_2 iff on input $u \in L_2$ the program p terminates and decides $u \in L_1$ correctly.

COROLLARY 6. *Let $L \subseteq \Sigma^*$ be a deterministic context-free language, $x, y \in \Sigma^*$, and let c be a constant. Then there exists a constant c' with the following property: If $u, v, w \in \Sigma^*$, where u is the suffix of $\cdots yyx$, then the following three conditions imply $C(w) \leq c'$:*

(i) *$C(v''|p_{uv'}) \leq c$ for all splittings $v'v'' = v$ and for all programs $p_{uv'}$ that decide $(uv')^{-1}L$ for* prefix$\{v''\}$;
(ii) *$C(w|p_{uv}) \leq c$ for all programs p_{uv} that list $(uv)^{-1}L$ in lexicographic order;*
(iii) *$C(v) \geq 2 \cdot \lg(\lg(|u|))$.*

Proof. Let A be a dpda that recognizes L. If $L = \emptyset$ or $L = \Sigma^*$, nothing has to be shown. Otherwise the KC-DCF lemma (Proposition 5) holds, and we can show that under the given premises, (i) and (ii) from the corollary imply (i) and (ii) from the KC-DCF lemma.

Assume that, under the given premises, u, v satisfy (i) from the corollary. Let $v'v'' = v$, and let k, q be the required additional information from Proposition 5(i). Now, if by using only finitely many additional symbols we can construct a program $p_{uv'}$ that decides $(uv')^{-1}L$ for prefix$\{v''\}$, then the bound in condition (i) from the corollary induces the bound in Proposition 5(i). This construction of $p_{uv'}$ can be obtained by observing the dpda A on input v'' when starting with state q and stack k.

With a similar argument, (ii) from above implies Proposition 5(ii). □

Though the original KC-DCF lemma and its corollary have been weakened in order to make them correct, they still can be applied for several nondeterministic context-free languages without much additional effort. We next give two examples taken from [LiVi95].

EXAMPLE 2. *The set of palindromes* $L = \{x \in \Sigma^* : x = x^{-1}\}$ *is not deterministic context-free.*

Proof. Set $y = 0$, $x = 1$, $u = 0^n1$, and $v = 0^n$. For an incompressible n we have

$$C(v) + O(1) = C(\underline{n}) \geq \lg(n) = \lg(|u| - 1),$$

implying Corollary 6(iii) for sufficiently large n. Let $v'v'' = v$; then v'' is the lexicographically first word in $(uv')^{-1}L$. Since all v are all 0, (i) is also satisfied. The lexicographically first word in $(uv)^{-1}L$ starting with 1 is 10^n; hence $w = 10^n$ satisfies (ii). On the other hand,

$$C(w) + O(1) = C(\underline{n}) \geq \lg(n),$$

and hence L cannot be deterministic context-free. □

EXAMPLE 3. $L = \{xy \in \{0,1\}^* : |x| = |y|$, *y contains at least one* $1\}$ *is not deterministic context-free.*

Proof. Set $y = 0$, $x = 1$, $u = 0^n1$, with $|u|$ even, and $v = 0^{n+1}$. For incompressible n we have

$$C(v) + O(1) = C(\underline{n}) \geq \lg(n) = \lg(|u| - 1),$$

thus implying Corollary 6(iii) for sufficiently large n. Let $v'v'' = v$. We need only one bit to code the information, whether $|v'|$ is even or odd. If $|v'|$ is even (odd), then v'' is the shortest word of even (odd) length that is all 0 and does not belong to $(uv')^{-1}L$. This shows that (i) is also satisfied. The lexicographically first word which does not belong to $(uv)^{-1}L$ and which starts with 1 is 10^{2n+3}. Thus with $w = 10^{2n+3}$, condition (ii) is satisfied, too. On the other hand, we have

$$C(w) + O(1) = C(\underline{n}) \geq \lg(n),$$

and hence L cannot be deterministic context-free. □

Acknowledgments. I'm indebted to the anonymous referee and to my colleagues Ulrike Brandt and Hermann K.-G. Walter for their valuable suggestions and corrections. Also I want to thank Ming Li for his kind email in response to my questions in 1999. Finally it should be mentioned that the idea behind the corrected KC-DCF lemma is essentially the same as that from the original paper by Ming Li and Paul Vitányi.

FINDING A PATH OF SUPERLOGARITHMIC LENGTH*

ANDREAS BJÖRKLUND† AND THORE HUSFELDT†

Abstract. We consider the problem of finding a long, simple path in an undirected graph. We present a polynomial-time algorithm that finds a path of length $\Omega\big((\log L/\log\log L)^2\big)$, where L denotes the length of the longest simple path in the graph. This establishes the performance ratio $O\big(n(\log\log n/\log n)^2\big)$ for the longest path problem, where n denotes the number of vertices in the graph.

Key words. approximation algorithms, graph algorithms, longest path

AMS subject classifications. 68R10, 68W25

1. Introduction.

Given an unweighted, undirected graph $G = (V, E)$ with $n = |V|$, the *longest path* problem is to find the longest sequence of distinct vertices $v_1 \cdots v_k$ such that $v_i v_{i+1} \in E$.

This is a classical optimization problem; the Hamiltonian path problem is a special case of it and appears in Karp's original list of NP-complete problems [8]. While today the approximability of most of these problems is well understood, the longest path problem has remained elusive, and notoriously so [5]: In spite of a considerable body of research the gap between upper and lower bounds is very wide.

Previous work. The first approximation algorithms for longest path are due to Monien [9] and Bodlaender [3], both finding a path of length $\Omega(\log L/\log\log L)$ in a graph with longest path length L.

A natural and harder variant of the problem is to find a path of length $\log n$ if it exists. Papadimitriou and Yannakakis [10] conjectured that this could be done in polynomial time, which was confirmed by Alon, Yuster, and Zwick [1], introducing the important method of *color-coding*. If the longest path has length $O(\log n)$, then their algorithm finds it (or, rather, it finds *a* longest path); else it finds a path of length $\Omega(\log n)$. Especially, the algorithm finds an $\Omega(\log L)$-path and thus has the performance ratio $O\big(n/\log n\big)$, which is the best ratio for the longest path problem known prior to the present paper.

Motivated by the weakness of these bounds for general graphs the problem has received additional study for restricted classes of graphs. In Hamiltonian graphs the algorithm of Vishwanathan [11] finds a path of length $O\big((\log n/\log\log n)^2\big)$. In *sparse* Hamiltonian graphs, Feder, Motwani, and Subi [5] find even longer paths. Moreover, they prove the following remarkable result: If a graph with vertices of degree at most 3 has a cycle of length r, then one can find in polynomial time a cycle of length at least r^c, where $c = \frac{1}{2}\log_3 2$.

The hardness results for this problem are mainly due to Karger, Motwani, and Ramkumar [7]: The longest path problem does not belong to APX unless P = NP, and it cannot be approximated within $2^{\log^{1-\epsilon} n}$ unless NP $\subseteq$ DTIME$\big(2^{O(\log^{1/\epsilon} n)}\big)$ for

any $\epsilon > 0$. More recently, it was shown that for *directed* graphs, the problem admits stronger lower bounds [2].

This paper. We present a polynomial-time algorithm that finds a path of length $\Omega\big((\log L/\log\log L)^2\big)$ in a graph with longest path length L. Since $L < n = |V|$, this corresponds to a performance ratio of order

$$O\left(\frac{n(\log\log n)^2}{\log^2 n}\right). \tag{1.1}$$

The main idea of our algorithm is a new graph decomposition which forms the basis of a recursive procedure. We find a cycle C of length $\log n/\log\log n$, using the algorithm from [3], remove C, and continue recursively in the resulting connected components. This decomposes the graph into a number of disjoint cycles of sufficient length which can be assembled into a long path.

The performance ratio (1.1) was obtained earlier by Vishwanathan [11] but only for Hamiltonian graphs.

For bounded degree graphs, we can improve the ratio to $O\big(n\log\log n/\log^2 n\big)$. For 3-connected graphs, we establish the performance ratio (1.1) for the *longest cycle* problem, a variant of the problem that also requires $v_1v_k \in E$.

2. Paths and cycles. In what follows, we consider a connected graph $G = (V, E)$ with $n = |V|$ vertices and $e = |E|$ edges. We write $G[W]$ for the graph induced by the vertex set W.

The *length* of a path and a cycle is its number of edges. The length of a cycle C is denoted $l(C)$. A k-cycle is a cycle of length k, and a k^+-cycle is a cycle of length k or larger. A k-path and k^+-path are defined similarly. For vertices x and y, an xy-path is a (simple) path from x to y. If P is a path containing u and v, we write $P[u, v]$ for the subpath from u to v. We let $L_G(v)$ denote the length of the longest path from a vertex v in the graph G. The *path length* of G is $\max_{v\in V} L_G(v)$.

We need the following result: Theorem 5.3(i) of [3].

THEOREM 1 (Bodlaender). *Given a graph, two of its vertices s, t, and an integer k, one can find a k^+-path from s to t (if it exists) in time $O\big((2k)!2^{2k}n + e\big)$.*

COROLLARY 1. *Given a graph, one of its vertices s, and an integer k, one can find a k^+-cycle through s (if it exists) in time $O\big(((2k)!2^{2k}n + e)n\big)$.*

Proof. For all neighbors t of s, apply the theorem on the graph with the edge st removed. □

We also need the following easy lemma.

LEMMA 1. *If a connected graph contains a path of length r, then every vertex is an endpoint of a path of length at least $\frac{1}{2}r$.*

Proof. Given vertices $u, v \in V$, let $d(u, v)$ denote the length of the shortest path between u and v.

Let $P = p_0 \cdots p_r$ be a path, and let v be a vertex. Find i minimizing $d(p_i, v)$. By minimality there is a path Q from v to p_i that contains no other vertices from P. Now either $QP[p_i, p_r]$ or $QP[p_i, p_0]$ has length at least $\frac{1}{2}r$. □

2.1. Decomposition into cycles. The next lemma is central to our construction and describes the graph decomposition that underlies our recursive algorithm. It formalizes the following observation: Assume that a vertex v originates a long path P and v lies on a cycle C. Then the removal of C decomposes G into connected components, one of which must contain a large part of P.

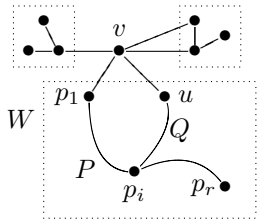

FIG. 1. *Statement* 1 *of Lemma* 2. *The path* $P = vp_1 \cdots p_r$ *continues in the component* W. *We assume that* v *does not lie on a large cycle. This means that an arbitrary path* Q *from* v*'s neighbor* u *must intersect* P *"early"; i.e.,* $QP[p_i, p_r]$ *is long.*

Pretending for a moment that our algorithm knew which component this is, we could continue the decomposition in it, recursively removing cycles until P is exhausted. In the end, we would have produced a long string of connected cycles. Especially, this string contains a path (using at least half the vertices of each cycle) that will be longer than the length of each individual cycle. The gist of this is that if we can find long *cycles* in graphs (like with Bodlaender's algorithm), then with our decomposition we can find even longer *paths*.

The lemma needs to distinguish between two cases, depending on whether or not v lies on a large cycle.

LEMMA 2. *Assume that a connected graph* G *contains a simple path* P *of length* $L_G(v) > 1$ *originating in vertex* v. *Then there exists a connected component* $G[W]$ *of* $G[V - v]$ *such that the following holds:*

1. *If* $G[W + v]$ *contains no* k^+*-cycle through* v, *then every neighbor* $u \in W$ *of* v *is the endpoint of a path of length*

$$L_{G[W]}(u) \geq L_G(v) - k.$$

2. *If* C *is a cycle in* $G[W + v]$ *through* v *of length* $l(C) < L_{G[W+v]}(v)$, *then there exists a connected component* H *of* $G[W - C]$ *that contains a neighbor* u *of* $C - v$ *in* $G[W + v]$. *Moreover, every such neighbor* u *is the endpoint of a path in* H *of length*

$$L_H(u) \geq \frac{L_G(v)}{2l(C)} - 1.$$

Proof. Let $r = L_G(v)$ and $P = p_0 \cdots p_r$, where $p_0 = v$. Note that $P[p_1, p_r]$ lies entirely in one of the components $G[W]$ of $G[V - v]$.

First consider statement 1; see Figure 1. Let $u \in W$ be a neighbor of v. Since $G[W]$ is connected, there exists a path Q from u to some vertex of P. Consider such a path. The first vertex p_i of P encountered on Q must have $i < k$, since otherwise the three paths vu, $Q[u, p_i]$, and $P[p_0, p_i]$ form a k^+-cycle. Thus the path $Q[u, p_i]P[p_i, p_r]$ has length at least $r - k + 1 > r - k$.

We proceed to statement 2; see Figure 2. Consider any cycle C in $G[W + v]$ through v. We will show that depending on how often P intersects C, there exists a long subpath in one of the components of $G[W - C]$. The length of this subpath is inversely proportional to the number of intersections, which could be no more than the length of C.

Case 1. First assume that $P \cap C = v$ so that one component H of $G[W - C]$ contains all of P except v. Let N be the set of neighbors of $C - v$ in H. First note

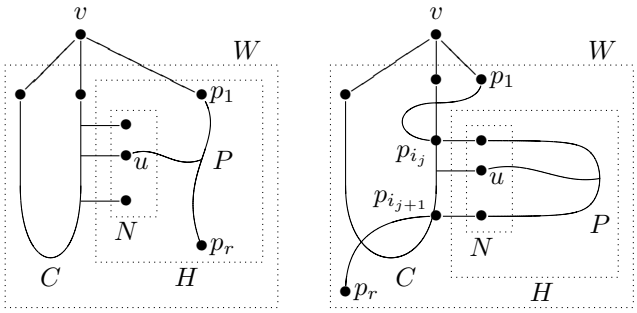

FIG. 2. *Statement* 2 *of Lemma* 2. *Here we assume that* v *does lie on a large cycle* C. *In Case* 1 *(left) the path* $P = vp_1 \cdots p_r$ *does not intersect* C *after it leaves* v. *Thus* $P[p_1, p_r]$ *lies entirely in a component* H *of* $W - C$. *Any neighbor* $u \in N$ *of* C *in this component must be the head of a long path using at least half of* $P[p_1, p_r]$. *In Case* 2 *(right) the path* P *intersects* C *in several places. Consider the largest section of* P *that lies entirely in a component* H *of* $W - C$, *here shown as a "loop" starting after* p_{i_j} *and ending before* $p_{i_{j+1}}$. *Any neighbor* $u \in N$ *of* C *in this component must be the head of a long path using at least half of the "loop."*

that N is nonempty, since $G[W]$ is connected. Furthermore, the path length of H is at least $r - 1$, so Lemma 1 gives $L_H(u) \geq (r-1)/2$ for every $u \in N$.

Case 2. Assume instead that $|P \cap C| = s > 1$. Enumerate the vertices on P from 0 to r and let $i_1, \ldots, i_s$ denote the indices of vertices in $P \cap C$, in particular $i_1 = 0$. Let $i_{s+1} = r$. An averaging argument shows that there exists j such that $i_{j+1} - i_j \geq r/s$. Consequently, there exists a connected component H of $G[W - C]$ containing a simple path of length $r/s - 2$. At least one of the i_jth or i_{j+1}th vertices of P must belong to $C - v$, so the set of neighbors N of $C - v$ in H must be nonempty. As before, Lemma 1 ensures $L_H(u) \geq r/2s - 1$ for every $u \in N$, which establishes the bound after noting that $s \leq l(C)$. □

3. Result and algorithm. The construction in this section and its analysis establishes the following theorem, accounting for the worst-case performance ratio of (1.1) as claimed in the introduction.

THEOREM 2. *If a graph contains a simple path of length* L, *then we can find a simple path of length*

$$\Omega\left(\left(\frac{\log L}{\log\log L}\right)^2\right)$$

in polynomial time.

We first give a brief overview of the algorithm; the next two sections will provide the details.

Assume for simplicity that the input graph is connected; if not, then we can iterate the algorithm over each connected component of the input graph and return the longest path found.

Pick any vertex v. Lemma 1 ensures that v is the head of a path of length at least $r > L/2$. In the next sections we will pretend that we know the value

$$k = \left\lceil \frac{2\log r}{\log\log r} \right\rceil;$$

but this is not a restriction since we can (in polynomial time) run the algorithm for every value of $k = 6, \ldots, \lceil 2\log n/\log\log n \rceil$ and return the longest path found.

Given v and k we will construct a tree $T_k(G, v)$ as detailed in section 3.1; this tree will describe a recursive decomposition of the input graph G into paths and cycles. Finally, we find a long (weighted) path in $T_k(G, v)$. This path will describe a path in G which will have the desired length as shown in section 3.2.

In summary, assuming a connected input graph, the algorithm proceeds as follows:

1. Pick any vertex $v \in G$.
2. For every $k = 6, \ldots, \lceil 2 \log n / \log \log n \rceil$ perform the following two steps and return the longest path found:
3. Construct the tree $T_k(G, v)$ as detailed in section 3.1.
4. Find a longest weighted path in $T_k(G, v)$ and return the path in G described by it, as detailed in section 3.2.

Steps 3 and 4 take polynomial time (see below), so the entire algorithm takes polynomial time.

3.1. Construction of the cycle decomposition tree. Given a vertex v in G, our algorithm constructs a node-weighted tree $T_k = T_k(G, v)$, rooted at v, called the *cycle decomposition tree*. Every node of T_k is either a *singleton* or a *cycle* node: A singleton node corresponds to a single vertex $u \in G$ and is denoted $\langle u \rangle$, while a cycle node corresponds to a cycle C with a specified vertex $u \in C$ and is denoted $\langle C, u \rangle$. Every singleton node has unit weight, and every cycle node $\langle C, u \rangle$ has weight $\frac{1}{2} l(C)$.

The tree $T_k(G, v)$ is constructed as follows. Initially, T_k contains a singleton node $\langle v \rangle$, and a call is made to the following procedure with arguments G and v:

1. [Iterate over components:] For every maximal connected component $G[W]$ of $G[V - v]$, execute step 2.
2. [Find cycle:] Search for a k^+-cycle through v in $G[W + v]$ using Theorem 1. If such a cycle C is found, then execute step 3; otherwise, execute step 5.
3. [Insert cycle node:] Insert the cycle node $\langle C, v \rangle$ and the tree edge $\langle v \rangle \langle C, v \rangle$. For every connected component H of $G[W - C]$ execute step 4.
4. [Recurse:] Choose an arbitrary neighbor $u \in H$ of $C - v$, and insert the singleton node $\langle u \rangle$ and the tree edge $\langle u \rangle \langle C, v \rangle$. Then, recursively execute step 1 to compute $T_k(H, u)$.
5. [Insert singleton node and recurse:] Pick an arbitrary neighbor $u \in G[W + v]$ of v, insert the node $\langle u \rangle$ and the tree edge $\langle v \rangle \langle u \rangle$, and recursively execute step 1 to compute $T_k\big(G[W], u\big)$.

Note that each recursive step constructs a tree that is connected to other trees by a single edge, so T_k is indeed a tree. Also note that the ancestor of every cycle node must be a singleton node. The root of T_k is $\langle v \rangle$.

To see that the running time of this procedure is polynomial, first note that step 2 is polynomial because of the corollary to Theorem 1. The number of recursive steps is linear, since every step inserts a node into T_k, which is clearly of linear size after the procedure.

3.2. Paths in the cycle decomposition tree. Our algorithm proceeds by finding a path of greatest weight in T_k. This can be done in linear time by depth first search. The path found in T_k represents a path in G if we interpret paths through cycle nodes as follows. Consider a path in T_k through a cycle node $\langle C, u \rangle$. Both neighbors are singleton nodes, so we consider the subpath $\langle u \rangle \langle C, u \rangle \langle v \rangle$. By construction, v is connected to some vertex $w \in C$ with $w \neq u$. One of the two paths from u to w in C must have length at least half the length of C; call it P. We will interpret the path $\langle u \rangle \langle C, u \rangle \langle v \rangle$ in T_k as a path uPv in G. If a path ends in a cycle node $\langle C, u \rangle$, we may associate it with a path of length $l(C) - 1$ by moving along C from u in any of its two

directions. Thus a path of weight m in T_k from the root to a leaf identifies a path of length at least m in G.

We need to show that T_k for some small k has a path of sufficient length.[1]

LEMMA 3. *If G contains a path of length $r \geq 2^8$ starting in v, then $T_k = T_k(G, v)$ for*

$$k = \left\lceil \frac{2 \log r}{\log \log r} \right\rceil$$

contains a weighted path of length at least $\frac{1}{8}k^2 - \frac{1}{4}k - 1$.

Proof. We follow the construction of T_k in section 3.1.

We need some additional notation. For a node $x = \langle w \rangle$ or $x = \langle C, w \rangle$ in T_k we let $L(x)$ denote the length of the longest path from w in the component $G[X]$ corresponding to the subtree rooted at x. More precisely, for every successor y of x (including $y = x$), the set X contains the corresponding vertices w' (if $y = \langle w' \rangle$ is a singleton node) or C' (if $y = \langle w', C' \rangle$ is a cycle node).

Furthermore, let $\mathbf{S}(n)$ denote the singleton node children of a node n, and let $\mathbf{C}(n)$ denote its cycle node children. Consider any singleton node $\langle v \rangle$.

Lemma 2 asserts that

$$L(v) \leq \max \left\{ \max_{w \in \mathbf{S}\langle v \rangle} L(w) + k, \max_{\substack{\langle C, v \rangle \in \mathbf{C}\langle v \rangle \\ w \in \mathbf{S}\langle C, v \rangle}} \big(2L(w) + 2\big) l(C) \right\}. \tag{3.1}$$

Define $n(v) = w$ if $\langle w \rangle$ maximizes the right-hand side of the inequality (3.1), and consider a path $Q = \langle x_0 \rangle \cdots \langle x_t \rangle$ from $\langle v \rangle = \langle x_0 \rangle$ described by these heavy nodes. To be precise, we have either $n(x_i) = x_{i+1}$ or $n(x_i) = x_{i+2}$; in the latter case, the predecessor of $\langle x_{i+2} \rangle$ is a cycle node.

We will argue that the gaps in the sequence

$$L(x_0) \geq L(x_1) \geq \cdots \geq L(x_t)$$

cannot be too large due to the inequality above. This, combined with the fact that $L(x_t)$ must be small (otherwise, we are done), implies that Q contains a lot of cycle nodes or even more singleton nodes.

Let s denote the number of cycle nodes on Q. Since every cycle node has weight at least $\frac{1}{2}k$ the total weight of Q is at least $\frac{1}{2}sk + (t - s) = s(\frac{1}{2}k - 1) + t$.

Consider a singleton node that is followed by a cycle node. There are s such nodes; we will call them *cycle parents*. Assume $\langle x_j \rangle$ is the first cycle parent node. Thus, according to the first part of Lemma 2, its predecessors $\langle x_0 \rangle, \ldots, \langle x_j \rangle$ satisfy the relation $L(x_{i+1}) \geq L(x_i) - k$, so

$$L(x_j) \geq r - jk \geq r - \tfrac{1}{8}k^3 \geq \tfrac{7}{8}r,$$

since $j \leq t \leq \frac{1}{8}k^2$ (otherwise, we are finished) and $r \geq k^3$.

From the second part of Lemma 2 we have

$$L(x_{j+2}) \geq \frac{7r}{16 l(C)} - 1 \geq \frac{r}{k^2},$$

[1] All logarithms are to the base 2, and the constants involved have been chosen aiming for simplicity of the proof rather than optimality.

where we have used $l(C) \le \frac{1}{4}k^2$ (otherwise, we are finished) and $r \ge \frac{4}{3}k^2$.

This analysis may be repeated for the subsequent cycle parents as long as their remaining length after each cycle node passage is at least k^3. Note that Q must pass through as many as $s' \ge \lceil \frac{1}{4}k - 1 \rceil$ cycle nodes before

$$\frac{r}{k^{2s'}} < k^3,$$

at which point the remaining path may be shorter than k^3. Thus we either have visited $s \ge s'$ cycle nodes, amounting to a weighted path Q of length at least

$$s(\tfrac{1}{2}k + 1) \ge \tfrac{1}{8}k^2 - \tfrac{1}{4}k - 1$$

(remembering that any two consecutive cycle nodes must have a singleton node in between), or there are at most $s < s'$ cycle nodes on Q. In that case there is a tail of singleton nodes starting with some $L(x) \ge k^3$. Since $L(x_j) \le L(x_{j+1}) + k$ for the nodes on the tail, the length of the tail (and thus the weight of Q) is at least k^2. □

It remains to check that the path found by our algorithm satisfies the stated approximation bound: For the right k, the preceding lemma guarantees a weighted path in $T_k(G, v)$, and hence a path in G, of length

$$\frac{k^2}{8} - \frac{k}{4} - 1 = \Omega\left(\left(\frac{\log r}{\log\log r}\right)^2\right) = \Omega\left(\left(\frac{\log L}{\log\log L}\right)^2\right)$$

because $r \ge \frac{1}{2}L$ by Lemma 1. This finishes the proof of Theorem 2.

4. Extensions.

4.1. Bounded degree graphs. As in [11], the class of graphs with their maximum degree bounded by a constant admits a relative $\log\log n$-improvement over the performance ratio shown in this paper. All paths of length $\log n$ can be enumerated in polynomial time for these graphs. Consequently, we can replace the algorithm from Theorem 1 by an algorithm that efficiently finds cycles of logarithmic length or larger through any given vertex if they exist.

PROPOSITION 1. *If a constant degree graph contains a simple path of length L, then we can find a simple path of length*

$$\Omega\left(\frac{\log^2 L}{\log\log L}\right)$$

in polynomial time.

This gives the performance ratio $O\big(n \log\log n / \log^2 n\big)$ for the longest path problem in constant degree graphs.

4.2. 3-connected graphs. Bondy and Locke [4] have shown that every 3-connected graph with path length L must contain a cycle of length at least $2L/5$. Moreover, their construction is easily seen to be algorithmic and efficient. This implies the following result on the longest cycle problem.

PROPOSITION 2. *If a 3-connected graph contains a simple cycle of length L, then we can find a simple cycle of length*

$$\Omega\left(\left(\frac{\log L}{\log\log L}\right)^2\right)$$

in polynomial time.

This gives the performance ratio $O\big(n(\log\log n/\log n)^2\big)$ for the longest cycle problem in 3-connected graphs. Note that for 3-connected cubic graphs, [5] shows a considerably better bound.

Acknowledgments. We thank Andrzej Lingas for bringing [11] to our attention and Gerth Stølting Brodal for commenting on a previous version of this paper.

Note added in proof. Recently, Gabow and Nie [6] have improved the bound in Corollary 1 to $O(e) + 2^{O(k)} n \log n$. As a consequence, the bounds in Theorem 2 and Proposition 2 are improved to $\Omega(\log^2 L/\log\log L)$, and the performance ratio for longest path becomes $O\big(|V|\log\log|V|/\log^2|V|\big)$.

BETTER ALGORITHMS FOR UNFAIR METRICAL TASK SYSTEMS AND APPLICATIONS*

AMOS FIAT† AND MANOR MENDEL†

Abstract. Unfair metrical task systems are a generalization of online metrical task systems. In this paper we introduce new techniques to combine algorithms for unfair metrical task systems and apply these techniques to obtain improved randomized online algorithms for metrical task systems on arbitrary metric spaces.

Key words. online algorithms, randomized algorithms

AMS subject classifications. 68W20, 68W25, 68W40

1. Introduction. Metrical task systems (MTSs), introduced by Borodin, Linial, and Saks [11], can be described as follows: A server in some internal state receives *tasks* that have a service cost associated with each of the internal states. The server may switch states, paying a cost given by a metric space defined on the state space, and then pays the service cost associated with the new state.

MTSs have been the subject of a great deal of study. A large part of the research into online algorithms can be viewed as a study of some particular MTS. In modelling some of these problems as MTSs, the set of permissible tasks is constrained to fit the particulars of the problem. In this paper we consider the original definition of MTSs, where the set of tasks can be arbitrary.

A deterministic algorithm for any n-state MTS with a competitive ratio of $2n-1$ is given in [11], along with a matching lower bound for any metric space.

The *randomized* competitive ratio of the MTS problem is not as well understood. For the uniform metric space, where all distances are equal, the randomized competitive ratio is known to within a constant factor and is $\Theta(\log n)$ [11, 16]. In fact, it has been conjectured that the randomized competitive ratio for MTS is $\Theta(\log n)$ in any n-point metric space. Previously, the best upper bound on the competitive ratio for arbitrary n-point metric space was $O(\log^5 n \log\log n)$ due to Bartal et al. [3] and Bartal [2]. The best lower bound for arbitrary n-point metric space is $\Omega(\log n/\log\log n)$ due to Bartal, Bollobás, and Mendel [4] and Bartal et al. [5], improving the previous lower bounds of Karloff, Rabani, and Ravid [18] and Blum et al. [10].

As observed in [18, 10, 1], the randomized competitive ratio of the MTS is conceptually easier to analyze on "decomposable spaces": spaces that have a partition to subspaces with a small diameter compared to that of the entire space. Bartal [1] introduced a class of decomposable spaces called *hierarchically well-separated trees* (HSTs). Informally, a k-HST is a metric space having a partition into subspaces such that (i) the distances between the subspaces are all equal; (ii) the diameter of each

†School of Computer Science, Tel-Aviv University, Tel-Aviv, Israel (fiat@tau.ac.il, mendelma@yahoo.com).

subspace is at most $1/k$ times the diameter of the whole space; and (iii) each subspace is recursively a k-HST.

Following [1, 3], we obtain an improved algorithm for HSTs. In order to reduce the MTS problem on arbitrary metric space to an MTS problem on a HST we use probabilistic embedding of metric spaces into HSTs [1]. It is shown in [2] that any n-point metric space has probabilistic embedding in k-HSTs with *distortion* $O(k \log n \log\log n)$. Thus, an MTS problem on an arbitrary n-point metric space can be reduced to an MTS problem on a k-HST with overhead of $O(k \log n \log\log n)$ [1].

Our algorithm for HSTs follows the general framework given in [10] and explicitly formulated in [20, 3], where the recursive structure of the HST is modelled by defining an unfair metrical task system (UMTS) problem [20, 3] on a uniform metric space. In a UMTS problem, associated with every point v_i of the metric space is a cost ratio r_i. We charge the online algorithm a cost of $r_i c_i$ for dealing with the task $(c_1, \ldots, c_i, \ldots, c_n)$ in state v_i, which multiplies the online costs for processing tasks in that point. Offline costs remain as before. The cost ratio r_i roughly corresponds to the competitive ratio of the online algorithm in a subspace of the HST. For UMTSs on uniform metric spaces, tight upper bounds are known only for two point spaces [10, 20, 3] and for n-point spaces with equal cost ratios [3]. A tight lower bound is known for any number of points and any cost ratios [4].

In this paper we introduce a general notation and technique for combining algorithms for UMTSs on hierarchically decomposable metric spaces. This technique is an improvement on the previous methods [10, 20, 3]. Using this technique, we obtain randomized algorithms for UMTSs on the uniform metric space that are better than the algorithm of [3]. Using the algorithm for UMTSs on uniform metric space and the new method for combining algorithms, we obtain $O(\log n \log\log n)$-competitive algorithms for MTS on HST spaces, which implies an $O((\log n \log\log n)^2)$-competitive randomized algorithm for MTSs on any metric space.

We also study the *weighted caching problem*. Weighted caching is the paging problem where there are different costs to fetch different pages. Deterministically, a competitive ratio of k is achievable [12, 23], with a matching lower bound following from the k-server bound [19]. No randomized algorithm is known to have a competitive ratio better than the deterministic competitive ratio for general metric spaces. However, in some special cases progress has been made. Irani [15] has shown an $O(\log k)$-competitive algorithm when page fetch costs are one of two possible values. Blum, Furst, and Tomkins [9] have given an $O(\log^2 k)$-competitive algorithm for arbitrary page costs when the total number of pages is $k+1$; they also present a lower bound of $\Omega(\log k)$ for any page costs. As the weighted caching problem on $k+1$ pages with cache size k is a special case of MTS on star-like metric spaces, we are able to obtain an $O(\log k)$-competitive algorithm for this case, improving [9]. This is tight up to a constant factor.

Outline of the paper. In section 2 the MTS problem is formally defined, along with several technical conditions that later allow us to combine algorithms for subspaces together. In section 3 we deal with the main technical contribution of our paper. We introduce a novel technique to combine algorithms for subspace into an algorithm for the entire space. Section 4 is devoted to introducing algorithms for UMTSs on uniform spaces. In section 5 we give the applications mentioned above by combining the algorithms of section 4.

2. Preliminaries. UMTSs [20, 3] are a generalization of MTSs [11]. A UMTS $U = (M; (r_u)_{u \in M}; s)$ consists of a metric space M with a distance metric d_M, a

sequence of *cost ratios* $r_u \in \mathbb{R}^+$ for $u \in M$, and a *distance ratio* $s \in \mathbb{R}^+$.

Given a UMTS U, the associated online problem is defined as follows. An online algorithm A occupies some state $u \in M$. When a task arrives the algorithm may change state to v. A task is a tuple $(c_x)_{x \in M}$ of nonnegative real numbers, and the cost for algorithm A associated with servicing the task is $s \cdot \mathrm{d}_M(u,v) + r_v c_v$. The cost for A associated with servicing a sequence of tasks σ is the sum of costs for servicing the individual tasks of the sequence consecutively. We denote this sum by $\mathrm{cost}_A(\sigma)$. An online algorithm makes its decisions based only upon tasks seen so far.

An offline player is defined that services the same sequence of tasks over U. The cost of an offline player, if it were to do exactly as above, would be $\mathrm{d}_M(u,v) + c_v$. Thus, the concept of *unfairness*, the costs for doing the same thing, are different.

Given a sequence of tasks σ we define the *work function* [13] at v, $w_{\sigma,U}(v)$, to be the minimal cost, for any offline player, to start at the initial state in U, deal with all tasks in σ, and end up in state v. We omit the use of the subscript U if it is clear from the context. Note that for all $u, v \in M$, $w_\sigma(u) - w_\sigma(v) \leq \mathrm{d}_M(u,v)$. If $w_\sigma(u) = w_\sigma(v) + \mathrm{d}_M(u,v)$, u is said to be *supported* by v. We say that $u \in M$ is *supported* if there exists some $v \in M$ such that u is supported by v.

We define $\mathrm{cost}_{\mathrm{OPT}}(\sigma)$ to be $\min_v w_\sigma(v)$. This is simply the minimal cost, for any offline player, to start at the initial state and process σ. As the differences between the work function values on different states is bounded by a constant (the diameter of the metric space) independent of the task sequence, it is possible to use a convex combination of the work function values instead of the minimal one. We say that $\alpha = (\alpha(u))_{u \in M}$ is a *weight vector* when $\{\alpha(u) | u \in M\}$ are nonnegative real numbers satisfying $\sum_{u \in M} \alpha(u) = 1$. We define the α-optimal-cost of a sequence of tasks σ to be $\mathrm{cost}_{\alpha\text{-OPT}}(\sigma) = \langle \alpha, w_\sigma \rangle = \sum_{u \in M} \alpha(u) w_\sigma(u)$. As observed above, $\mathrm{cost}_{\alpha\text{-OPT}}(\sigma) \leq \mathrm{cost}_{\mathrm{OPT}}(\sigma) + \mathrm{diam}(M)$, where $\mathrm{diam}(M) = \max_{u,v \in M} \mathrm{d}_M(u,v)$ is the diameter of M.

A randomized online algorithm A for a UMTS is a probability distribution over deterministic online algorithms. The expected cost of a randomized algorithm A on a sequence σ is denoted by $E[\mathrm{cost}_A(\sigma)]$.

DEFINITION 2.1 (see [22, 17, 7]). *A randomized online algorithm A is called r-competitive against an oblivious adversary if there exists some c such that for all task sequences σ, $E[\mathrm{cost}_A(\sigma)] \leq r\ \mathrm{cost}_{\mathrm{OPT}}(\sigma) + c$.*

Observation 1. We can limit the discussion on the competitive ratio of UMTSs to distance ratios equal to one since a UMTS $U = (M; (r_u)_{u \in M}; s)$ has a competitive ratio of r if and only if $U' = (M; (s^{-1} r_u)_{u \in M}; 1)$ has a competitive ratio of rs^{-1}. Moreover, an rs^{-1} competitive algorithm for U' is an r-competitive algorithm for U, since in both U' and U the offline costs are the same, but the online costs in U are multiplied by a factor of s compared to the costs in U'. When $s = 1$, we drop it from the notation.

Given a randomized online algorithm A for a UMTS U with state space M and a sequence of tasks σ, we define $p_{\sigma,A}$ to be the vector of probabilities $(p_{\sigma,A}(u))_{u \in M}$, where $p_{\sigma,A}(u)$ is the probability that A is in state u after serving the request sequence σ. We drop the subscript A if the algorithm is clear from the context.

Let $x \circ y$ denote the concatenation of sequences x and y. Let U be a UMTS over the metric space M with distance ratio s. Given two successive probability distributions on the states of U, p_σ and $p_{\sigma \circ e}$, where e is the next task, we define the set of transfer matrices from p_σ to $p_{\sigma \circ e}$, denoted $T(p_\sigma, p_{\sigma \circ e})$, as the set of all matrices

$T = (t_{uv})_{u,v \in M}$ with nonnegative real entries, where

$$\sum_{v \in M} t_{uv} = p_\sigma(u),\ u \in M; \qquad \sum_{u \in M} t_{uv} = p_{\sigma \circ e}(v),\ v \in M.$$

We define the *unweighted moving cost* from p_σ to $p_{\sigma \circ e}$:

$$\mathrm{mcost}_M(p_\sigma, p_{\sigma \circ e}) = \min_{\substack{(t_{uv}) \in \\ T(p_\sigma, p_{\sigma \circ e})}} \sum_{u,v} t_{uv}\, \mathrm{d}_M(u,v),$$

the *moving cost* is defined as $\mathrm{mcost}_U(p_\sigma, p_{\sigma \circ e}) = s \cdot \mathrm{mcost}_M(p_\sigma, p_{\sigma \circ e})$, and the *local cost* on a task $e = (c_u)_{u \in M}$ is defined as $\sum_{u \in M} p_{\sigma \circ e}(u) c_u r_u$. Due to linearity of expectation, $E[\mathrm{cost}_A(\sigma \circ e)] - E[\mathrm{cost}_A(\sigma)]$ is equal to the sum of the moving cost from p_σ to $p_{\sigma \circ e}$ and the local cost on e. Hence we can view A as a deterministic algorithm that maintains the probability mass on the states whose cost on task e given after sequence σ is

$$\mathrm{cost}_A(\sigma \circ e) - \mathrm{cost}_A(\sigma) = \mathrm{mcost}_U(p_\sigma, p_{\sigma \circ e}) + \sum_{u \in M} p_{\sigma \circ e}(u) c_u r_u. \tag{2.1}$$

In what follows we will use the terminology of changing probabilities, with the understanding that we are referring to a deterministic algorithm charged according to (2.1).

We next develop some technical conditions that make it easier to combine algorithms for UMTSs. *Elementary tasks* are tasks with only one nonzero entry; we use the notation (v, δ), $\delta \geq 0$, for an elementary task of cost δ at state v. Tasks $(v, 0)$ can simply be ignored by the algorithm.

DEFINITION 2.2 (see [3]). *A* reasonable *algorithm is an online algorithm that never assigns a positive probability to a supported state.*

DEFINITION 2.3 (see [3]). *A* reasonable task sequence *for algorithm A is a sequence of tasks that obeys the following:*

1. *All tasks are elementary.*
2. *For all σ, the next task (v, δ) must obey that for all δ', if $\delta > \delta' \geq 0$, then $p_{\sigma \circ (v, \delta')}(v) > 0$.*

It follows that a reasonable task sequence for A never includes tasks (v, δ), $\delta > 0$, if the current probability of A on v is zero.

The following lemma is from [3]. For the sake of completeness, we include a sketch of a proof here.

LEMMA 2.4. *Given a randomized online algorithm A_0 that obtains a competitive ratio of r when the task sequences are limited to being reasonable task sequences for A_0, then, for all $\varepsilon > 0$, there also exists a randomized algorithm A_3 that obtains a competitive ratio of $r + \varepsilon$ on all possible sequences.*

Proof (sketch). The proof proceeds in three stages. In the first stage, we convert an algorithm A_0 for reasonable task sequences to a *lazy* algorithm A_1 (an algorithm that does not move the server when receiving a task with zero cost) for reasonable task sequences. In the second stage, we convert an algorithm A_1 to an algorithm A_2 for elementary task sequences, and then, in the third stage, we convert A_2 to an algorithm A_3 for general task sequences.

The first stage is well known.

The second stage. Given an elementary task sequence, every elementary task $e = (v, x)$ is converted to a task (v, y) such that $y = \sup\{z | z < x$ and the probability

induced by A_1 on v is greater than 0}. The resulting task sequence is reasonable and is fed to A_1. A_2 imitates the movements of A_1.

The third stage. Let σ be an arbitrary task sequence. First, we convert σ into an elementary task sequence $\hat{\sigma}$; each task $\tau = (\delta_1, \ldots, \delta_n)$ in σ is converted to a sequence of tasks $\hat{\sigma}_\tau$ as follows: Let $\varepsilon' > 0$ be a small constant to be determined later, and assume for simplicity that $\delta_i \geq \delta_{i+1}$. Then $\hat{\sigma}_\tau = \varsigma_1 \circ \varsigma_2 \circ \cdots \circ \varsigma_N$, where $N = \lfloor \delta_1/\varepsilon' \rfloor$ and $\varsigma_j = (v_1, \varepsilon') \circ (v_2, \varepsilon') \circ \cdots \circ (v_{k_j}, \varepsilon')$, where $k_j = \max\{i | \delta_i \geq j \cdot \varepsilon'\}$. Note that the optimal offline cost on $\hat{\sigma}$ is at most the optimal offline cost on σ, since any servicing for σ when applied to $\hat{\sigma}$ would have a cost no bigger than the original cost. Consider an r-competitive online algorithm A_2 for elementary tasks operating on $\hat{\sigma}$, and construct an online algorithm A_3 for σ. A_3 maintains the invariant that the state of A_3 after processing some task τ is the same state as A_2 after processing the sequence $\hat{\sigma}_\tau$. Consider the behavior of A_2 on $\hat{\sigma}_\tau$. It begins in some state v_{i_0}, passes through some set S of states, and ends up in some state v_{i_2}. Consider the original task $\tau = (\delta_1, \ldots, \delta_n)$. Let v_{i_1} be the state in S with the lowest cost in τ. Algorithm A_3 begins in state v_{i_0}, immediately moves to v_{i_1}, serves τ in v_{i_1}, and then moves to v_{i_2}.

Informally, on each task A_2 pays either a local cost of ε' or a moving cost of at least ε', and therefore these costs are larger than the local cost of A_3. A_3 also has a moving cost of at most the moving cost of A_2. By a careful combination of these two we conclude that the cost of A_3 on σ is at most $(1 + \varepsilon)$ times the cost of A_2 on $\hat{\sigma}$. □

Hereafter, we assume only reasonable task sequences. This is without loss of generality due to Lemma 2.4.

Observation 2. When a reasonable algorithm A is applied to a reasonable task sequence $\sigma = \tau_1 \tau_2 \cdots \tau_m$, any elementary task $\tau = (v, \delta)$ causes the work function at v, $w(v)$, to increase by δ. This follows because v would not have been supported following any alternative request (v, δ'), $\delta' < \delta$. See [3, Lemma 1] for a rigorous treatment. This also implies that for any state v, $w_\sigma(v) = \sum_{j=1}^{m} \tau_j(v)$.

DEFINITION 2.5. *An online algorithm A is said to be* sensible *and r-competitive on the UMTS $U = (M; (r_u)_{u \in M}; s)$ if it obeys the following:*

1. *A is reasonable.*
2. *A is a* stable algorithm [13], *i.e., the probabilities that A assigns to the different states are purely a function of the work function.*
3. *Associated with A are a weight vector α_A and a potential function Φ_A such that*
   - *$\Phi_A : \mathbb{R}^b \mapsto \mathbb{R}^+$ is purely a function of the work function, bounded, nonnegative, and continuous.*
   - *For all task sequences σ and all tasks e,*

$$\text{cost}_A(\sigma \circ e) - \text{cost}_A(\sigma) + \Phi_A(w_{\sigma \circ e}) - \Phi_A(w_\sigma) \leq r \cdot \langle \alpha_A, w_{\sigma \circ e} - w_\sigma \rangle. \tag{2.2}$$

Observation 3. An online algorithm that is sensible and r-competitive (against reasonable task sequences) according to Definition 2.5 is also r-competitive according to Definition 2.1. This is so since summing up the two sides in inequality (2.2) over the individual tasks in the task sequence, we get a telescopic sum such that $\text{cost}_A(\sigma) + \Phi_A(w_\sigma) - \Phi_A(w_\varepsilon) \leq r \cdot \langle \alpha_A, w_\sigma - w_\varepsilon \rangle$, where w_ε is the initial work function. We conclude that $\text{cost}_A(\sigma) \leq r \cdot \text{cost}_{\text{OPT}}(\sigma) + r\Delta(M) + \sup_w \Phi(w)$.

When combining sensible algorithms we would like the resulting algorithm to also be sensible. The problematic invariant to maintain is reasonableness. In order

to maintain reasonableness there is a need for a stronger concept, which we call *constrained algorithms*.

DEFINITION 2.6. *A sensible r-competitive algorithm A for the UMTS $U = (M; (r_u)_{u\in M}; s)$ with associated potential function Φ is called (β, η)-constrained, $0 \le \beta \le 1$, $0 \le \eta$, if the following hold:*

1. *For all $u, v \in M$, if $w(u) - w(v) \ge \beta\, \mathrm{d}_M(u, v)$, then the probability that A assigns to u is zero ($p_{w,A}(u) = 0$).*
2. *$\|\Phi\|_\infty \le \eta\ \mathrm{diam}(M) r$, where $\|\Phi\|_\infty = \sup_w \Phi(w)$.*

Observation 4.

1. For a (β, η)-constrained algorithm competing against a reasonable task sequence, *for all* $u, v \in M$, $|w(u) - w(v)| \le \beta\ \mathrm{d}_M(u, v)$. The argument here is similar to the one given in Observation 2.
2. A sensible r-competitive algorithm for a metric space of diameter Δ is by definition $(1, |\Phi_A|/(r\Delta))$-constrained.
3. A (β, η)-constrained algorithm is trivially (β', η')-constrained for all $\beta \le \beta' \le 1$ and $\eta \le \eta'$.

3. A combining theorem for UMTSs. Consider a metric space M having a partition to subspaces $M_1, \ldots, M_b$, with "large" distances between subspaces compared to the diameters of the subspaces. A MTS on M induces MTSs on M_i, $i \in \{1, \ldots, b\}$. Assume that for every i, we have an $\hat{r}_i$-competitive algorithm A_i for the induced MTS on M_i. Our goal is to combine the A_i algorithms so as to obtain an algorithm for the original MTS defined on M. To do so we make use of a "combining algorithm" $\hat{A}$. $\hat{A}$ has the role of determining which of the M_i subspaces contains the server. Since the "local cost" of $\hat{A}$ on subspace M_i is $\hat{r}_i$ times the optimal cost on subspace M_i, it is natural that $\hat{A}$ should be an algorithm for the UMTS $\hat{U} = (\hat{M}; (\hat{r}_1, \ldots, \hat{r}_b))$, where $\hat{M} = \{z_1, \ldots, z_b\}$ is a space with points corresponding to the subspaces and distances that are roughly the distances between the corresponding subspaces. Tasks for M are translated to tasks for the M_i induced MTSs simply by restriction. It remains to define how one translates tasks for M to tasks for $\hat{U}$.

Previous papers [10, 20, 3] use the cost of the optimal algorithm for the task in the subspace M_i as the cost for z_i in the task for $\hat{U}$. This way the local cost for $\hat{A}$ is $\hat{r}_i$ times the cost for the optimum; however, *this is true only in the amortized sense*. In order to bound the fluctuation around the amortized cost, those papers have to assume that the diameters of the subspace are very small compared to the distances between M_i subspaces. We take a different approach: the cost for a point $z_i \in \hat{U}$ is (an upper bound for) *the cost of A_i on the corresponding task, divided by $\hat{r}_i$*. In this way the amortization problem disappears, and we are able to combine subspaces with a relatively large diameter. A formal description of the construction is given below.

THEOREM 3.1. *Let U be a UMTS $U = (M; (r_u)_{u\in M}; s)$, where M is a metric space on n points. Consider a partition of the points of M, $P = (M_1, M_2, \ldots, M_b)$. $U_j = (M_j; (r_u)_{u\in M_j}; s)$ is the UMTS induced by U on the subspace M_j. Let $\hat{M}$ be a metric space defined over the set of points $\{z_1, z_2, \ldots, z_b\}$ with a distance metric $\mathrm{d}_{\hat{M}}(z_i, z_j) \ge \max\{\mathrm{d}_M(u, v) : u \in M_i, v \in M_j\}$. Assume that*

- *for all j, there is a (β_j, η_j)-constrained $\hat{r}_j$-competitive algorithm A_j for the UMTS U_j;*
- *there is a $(\hat{\beta}, \hat{\eta})$-constrained r-competitive algorithm $\hat{A}$ for the UMTS $\hat{U} = (\hat{M}; (\hat{r}_1, \ldots, \hat{r}_b); s)$.*

Define

(3.1)
$$\beta = \max\left\{ \max_i \beta_i,\ \max_{i\neq j} \frac{\hat{\beta}\,\mathrm{d}_{\hat{M}}(z_i,z_j) + \beta_j\ \mathrm{diam}(M_j) + \beta_i\ \mathrm{diam}(M_i) + \eta_i\,\mathrm{diam}(M_i)}{\min_{p\in M_i, q\in M_j} \mathrm{d}_M(p,q)} \right\}$$

and

$$\eta = \hat{\eta}\frac{\mathrm{diam}(\hat{M})}{\mathrm{diam}(M)} + \max_i\ \eta_i \frac{\mathrm{diam}(M_i)}{\mathrm{diam}(M)}. \tag{3.2}$$

If $\beta \leq 1$, then there exists a (β,η)-constrained and r-competitive algorithm, A, for the UMTS U.

In our applications of Theorem 3.1, the metric space M has a "nice" partition $P = (M_1,\ldots,M_b)$, parameterized with $k \geq 1$: $d_M(u,v) = \mathrm{diam}(M)$ for all $i \neq j$ $u \in M_i$, $v \in M_j$; and $\mathrm{diam}(M_i) \leq \mathrm{diam}(M)/k$. In this case the statement of Theorem 3.1 can be simplified as follows.

COROLLARY 3.2. *Under the assumptions of Theorem* 3.1*, and assuming the partition is "nice" (with parameter k), in the above sense, define*

$$\beta = \max\left\{ \max_i \beta_i, \hat{\beta} + \frac{\max_{i\neq j}(\beta_i+\beta_j+\eta_i)}{k} \right\} \tag{3.3}$$

and

$$\eta = \hat{\eta} + \frac{\max_i \eta_i}{k}. \tag{3.4}$$

If $\beta \leq 1$, then there exists a (β,η)-constrained and r-competitive algorithm, A, for the UMTS U.

In section 3.1 we define the combined algorithm A declared in Theorem 3.1. Section 3.2 contains the proof of Theorem 3.1. We end the discussion on the combining technique with section 3.3, in which we show how to obtain constrained algorithms needed in the assumptions of Theorem 3.1.

3.1. The construction of the combined algorithm. Denote by Φ_j and α_j the associated potential function and weight vector of algorithm A_j, respectively. Similarly, denote by $\hat{\Phi}$ and $\hat{\alpha}$ the associated potential function and weight vector of algorithm $\hat{A}$, respectively.

Given a sequence of elementary tasks $\sigma = (v_1,\delta_1)\circ(v_2,\delta_2)\circ\cdots\circ(v_{|\sigma|},\delta_{|\sigma|})$, $v_i \in M$, we define the sequences

$$\sigma|_{M_\ell} = (u_1^\ell,\delta_1^\ell)\circ(u_2^\ell,\delta_2^\ell)\circ\cdots\circ(u_{|\sigma|}^\ell,\delta_{|\sigma|}^\ell),\ \text{where}$$

- $u_j^\ell = v_j$ and $\delta_j^\ell = \delta_j$ if $v_j \in M_\ell$,
- u_j^ℓ is an arbitrary point in M_ℓ and $\delta_j^\ell = 0$ if $v_j \notin M_\ell$.

Informally, $\sigma|_{M_\ell}$ is the restriction of σ to subspace M_ℓ.

For $u \in M$, define $s(u) = i$ if and only if $u \in M_i$. We define the sequence

$$\chi(\sigma) = (z_{s(v_1)},\hat{\delta}_1)\circ(z_{s(v_2)},\hat{\delta}_2)\circ\cdots\circ(z_{s(v_{|\sigma|})},\hat{\delta}_{|\sigma|})$$

inductively. Let $e = (v,\delta)$, $s(v) = \ell$, then $\chi(\sigma\circ e) = \chi(\sigma)\circ(z_\ell,\hat{\delta})$, where

(3.5)
$$\hat{\delta} = \big(\langle \alpha_\ell, w_{(\sigma\circ e)|_{M_\ell},U_\ell}\rangle - \Phi_\ell(w_{(\sigma\circ e)|_{M_\ell},U_\ell})/\hat{r}_\ell\big) - \big(\langle \alpha_\ell, w_{\sigma|_{M_\ell},U_\ell}\rangle - \Phi_\ell(w_{\sigma|_{M_\ell},U_\ell})/\hat{r}_\ell\big).$$

Note that $\hat{\delta}$ is an upper bound on the cost of A_ℓ for the task (v, δ), divided by $\hat{r}_\ell$. This fact follows from (2.2) since A_ℓ is sensible, and $\sigma|_{M_\ell}$ is a reasonable task sequence for A_ℓ (see Lemma 3.3). It also implies that $\hat{\delta} \geq 0$, which is a necessary requirement for $(z_\ell, \hat{\delta})$ to be a well-defined task.

ALGORITHM A. The algorithm works as follows:

1. It simulates algorithm A_ℓ on the task sequence $\sigma|_{M_\ell}$ for $1 \leq \ell \leq b$.
2. It also simulates algorithm $\hat{A}$ on the task sequence $\chi(\sigma)$.
3. The probability assigned to a point $v \in M_\ell$ is the product of the probability assigned by A_ℓ to v and the probability assigned by $\hat{A}$ to z_ℓ (i.e., $p_{\sigma,A}(v) = p_{\sigma|_{M_\ell},A_\ell}(v) \cdot p_{\chi(\sigma),\hat{A}}(z_\ell)$).

We remark that the simulations above can be performed in an online fashion.

3.2. Proof of Theorem 3.1. To simplify notation we use the following shorthand notation. Given a task sequence σ and a task e, with respect to σ, we define

$$\begin{aligned} w &= w_{\sigma,U}; & w^e &= w_{\sigma\circ e,U}; \\ w_k &= w_{\sigma|_{M_k},U_k},\ 1 \leq k \leq b; & w_k^e &= w_{(\sigma\circ e)|_{M_k},U_k},\ 1 \leq k \leq b; \\ \hat{w} &= w_{\chi(\sigma),\hat{U}}; & \hat{w}^e &= w_{\chi(\sigma\circ e),\hat{U}}. \end{aligned}$$

Define p, p_k, and $\hat{p}$ to be the probability distributions on the states of U, U_k, and $\hat{U}$ as induced by algorithms A, A_k, and $\hat{A}$ on the sequences σ, $\sigma|_{M_k}$, and $\chi(\sigma)$, $1 \leq k \leq b$, respectively. Likewise, we define p^e, p_k^e, and $\hat{p}^e$, where the sequences are $\sigma \circ e$, $\sigma \circ e|_{M_k}$, and $\chi(\sigma \circ e)$.

LEMMA 3.3. *If the task sequence σ given to algorithm A on U is reasonable, then the simulated task sequences $\sigma|_{M_i}$ for algorithms A_i on U_i and the simulated task sequence $\chi(\sigma)$ for algorithm $\hat{A}$ on $\hat{U}$ are also reasonable.*

Proof. We first prove that $\sigma'|_{M_\ell}$ is reasonable for A_ℓ by induction on $|\sigma'|$. Say $\sigma' = \sigma \circ e$, $e = (v, \delta)$, and $v \in M_\ell$. Since σ' is reasonable for A, if the task e would have been replaced with the task $e' = (v, \delta')$, for $\delta' \in [0, \delta)$, then by the reasonableness of σ', $p^{e'}(v) > 0$. Since $p^{e'}(v) = p_\ell^{e'}(v)\hat{p}^{e'}(z_\ell)$ it follows that $p_\ell^{e'}(v) > 0$. This implies $\sigma'|_{M_\ell}$ is reasonable for A_ℓ.

We next prove that $\chi(\sigma')$ is a reasonable task sequence for $\hat{A}$, by induction on $|\sigma'|$. Let $\sigma' = \sigma \circ e$, $e = (v, \delta)$, $v \in M_\ell$. Denote by $\hat{e} = (z_\ell, \hat{\delta})$ the last task in $\chi(\sigma)$. Consider a hypothetical task (v, x) in U for $0 \leq x \leq \delta$. Denote by $(z_\ell, f(x))$ the corresponding task for $\hat{U}$, where $f(x)$ is determined according to (3.5). f is continuous (since Φ_ℓ is continuous), $f(0) = 0$, and $f(\delta) = \hat{\delta}$. Therefore for any $0 \leq \hat{\delta}' < \hat{\delta}$ there exists $0 \leq \delta' < \delta$ such that $f(\delta') = \hat{\delta}'$, and since $0 < p^{(v,\delta')} = p_\ell^{(v,\delta')}(v) \cdot \hat{p}^{(v,\delta')}(z_\ell)$ we conclude that $0 < \hat{p}^{(v,\delta')}(z_\ell)$ (the probability induced by $\hat{A}$ on z_ℓ after the task $(z_\ell, \hat{\delta}')$). This implies that $\chi(\sigma)$ is a reasonable task sequence for $\hat{A}$. ∎

LEMMA 3.4. *For all σ and for all ℓ, $\hat{w}(z_\ell) = \langle \alpha_\ell, w_\ell \rangle - \Phi_\ell(w_\ell)/\hat{r}_\ell$.*

Proof. It follows from Lemma 3.3 that the task sequence $\chi(\sigma)$ for $\hat{A}$ is reasonable. As $\hat{A}$ is sensible it follows from Observation 2 that $\hat{w}(z_\ell)$ is exactly the sum of costs in $\chi(\sigma)$ for z_ℓ. By the definition of $\chi(\sigma)$ (see (3.5)) it follows that this sum is $\langle \alpha_\ell, w_\ell \rangle - \Phi_\ell(w_\ell)/\hat{r}_\ell$. ∎

LEMMA 3.5. *Assume that $w(u) = w_\ell(u)$ for all $1 \leq \ell \leq b$, $u \in M_\ell$. Then any state $u \in U$ for which there exists a state v such that $w(u) - w(v) \geq \beta\, \mathrm{d}_M(u, v)$ has $p(u) = 0$.*

Proof. Consider states u and v as above, i.e., $w(u) - w(v) \geq \beta\, \mathrm{d}_M(u, v)$. We now consider two cases:

1. $u, v \in M_i$. We want to show that $w_i(u) - w_i(v) \geq \beta_i \, \mathrm{d}_{M_i}(u, v)$, as A_i is (β_i, η_i)-constrained; this implies that $p_i(u) = 0$, which implies that $p(u) = 0$. From the conditions above we get
$$w_i(u) - w_i(v) = w(u) - w(v) \geq \beta \, \mathrm{d}_M(u, v) \geq \beta_i \, \mathrm{d}_{M_i}(u, v).$$
2. $u \in M_i$, $v \in M_j$, $i \neq j$. Our goal now will be to show that $\hat{w}(z_i) - \hat{w}(z_j) \geq \hat{\beta} \, \mathrm{d}_{\hat{M}}(z_i, z_j)$, as this implies that $\hat{p}(z_i) = 0$, which implies that $p(u) = 0$.
A lower bound on $\hat{w}(z_i)$ is
$$\hat{w}(z_i) = \langle \alpha_i, w_i \rangle - \|\Phi_i\|_\infty / r_i \tag{3.6}$$
$$\geq w_i(u) - \beta_i \operatorname{diam}(M_i) - \|\Phi_i\|_\infty / r_i \tag{3.7}$$
$$= w(u) - \beta_i \operatorname{diam}(M_i) - \eta_i \operatorname{diam}(M_i). \tag{3.8}$$
To justify (3.6) one uses the definitions and Lemma 3.4. Inequality (3.7) follows because a convex combination of values is at least one of these values minus the maximal difference. The maximal difference between work function values is bounded by β_i times the distance; see Observation 4. Equation (3.8) follows from our assumption that the work functions are equal and from the definition of η_i.
Similarly, to obtain an upper bound on $\hat{w}(z_j)$, we derive
$$\hat{w}(z_j) = \langle \alpha_j, w_j \rangle - \|\Phi_j\|_\infty / r_j \leq w(v) + \beta_j \operatorname{diam}(M_j). \tag{3.9}$$
It follows from (3.8) and (3.9) that
$$\hat{w}(z_i) - \hat{w}(z_j) \geq (w(u) - w(v)) - \beta_i \operatorname{diam}(M_i) - \beta_j \operatorname{diam}(M_j) - \eta_i \operatorname{diam} M_i$$
$$\geq \beta d_M(u, v) - \beta_i \operatorname{diam}(M_i) - \beta_j \operatorname{diam}(M_j) - \eta_i \operatorname{diam} M_i \geq \hat{\beta} \, \mathrm{d}_{\hat{M}}(z_i, z_j).$$
The last inequality follows from (3.1). □

LEMMA 3.6. *For any reasonable task sequence σ, subspace M_ℓ, and $v \in M_\ell$ it holds that $w_\ell(v) = w(v)$.*

Proof. Assume the contrary. Let σ' be the shortest reasonable task sequence for which there exists $v \in M_\ell$ satisfying $w_{\sigma'|_{M_\ell}}(v) \neq w_{\sigma'}(v)$. It is easy to observe that $\sigma' = \sigma \circ e$, where $e = (v, \delta)$. As the sequence $(\sigma \circ e)|_{M_\ell}$ is a reasonable task sequence (Lemma 3.3) and A_ℓ is reasonable, it follows that $w_\ell^e(v) = w_\ell(v) + \delta$. Since $w_\ell(v) = w(v)$ and $w^e(v) \leq w(v) + \delta$ we deduce that $w_\ell^e(v) > w^e(v)$.

Let $e_x = (v, x)$; define $\delta' = \sup\{x : w^{e_x}(v) = w_\ell^{e_x}(v)\}$. Obviously, $0 \leq \delta' \leq \delta$. Define $e' = (v, \delta')$. By continuity of the work function, $w^{e'}(v) = w_\ell^{e'}(v)$, and thus $\delta' < \delta$. The conditions above imply that an elementary task in v after $w^{e'}$ will not change the work function, which means that v is supported in $w^{e'}$. Hence, the assumptions of Lemma 3.5 are satisfied (here we use the assumption that $\beta \leq 1$). By Lemma 3.5, $p^{e'}(v) = 0$, and since the sequence σ is reasonable for A, it follows that $\delta \leq \delta'$, a contradiction. □

PROPOSITION 3.7. *For all σ and all tasks $e = (v, \delta)$,*
$$\operatorname{cost}_A(\sigma \circ e) - \operatorname{cost}_A(\sigma) \leq \operatorname{cost}_{\hat{A}}(\chi(\sigma \circ e)) - \operatorname{cost}_{\hat{A}}(\chi(\sigma)).$$

Proof. Let us denote the subspace containing v by M_ℓ. We split the cost of A into two main components: the moving cost $\operatorname{mcost}_U(p, p^e)$ and the local cost $r_v p^e(v)\delta = r_v \hat{p}^e(z_\ell) p_\ell(v_i)\delta$ (see (2.1)).

We give an upper bound on the moving cost of A by considering a possibly suboptimal algorithm that works as follows:

1. Move probabilities between the different M_j subspaces; i.e., change the probability $p(u) = \hat{p}(z_j)p_j(u)$ for $u \in M_j$ to an intermediate stage $\hat{p}^e(z_j)p_j(v)$. The moving cost for A to produce this intermediate probability is bounded by $\mathrm{mcost}_{\hat{U}}(\hat{p}, \hat{p}^e)$, as the distances in $\hat{M}$ are an upper bound on the real distances for A ($\mathrm{d}_{\hat{M}}(z_i, z_j) \geq \mathrm{d}_M(u, v)$ for $u \in M_i$, $v \in M_j$). We call this cost the interspace cost for A.
2. Move probabilities within the M_j subspaces; i.e., move from the intermediate probability $\hat{p}^e(z_j)p_j(u)$, $u \in M_j$, to the probability $p^e(u) = \hat{p}^e(z_j)p^e_j(u)$. As all algorithms A_j, $j \neq \ell$, get a task of zero cost, $p^e_j = p_j$, $j \neq \ell$. The moving cost for A to produce $p^e(u)$, $u \in M_\ell$, from the intermediate stage, is no more than $\hat{p}^e(z_\ell) \cdot \mathrm{mcost}_{U_\ell}(p_\ell, p^e_\ell)$. We call this cost the intraspace cost for A.

Taking the local cost for A and the intraspace cost for A,

$$
\begin{aligned}
&r_u \hat{p}^e(z_\ell)p_\ell(u)\delta + \hat{p}^e(z_\ell) \cdot \mathrm{mcost}_{U_\ell}(p_\ell, p^e_\ell) \\
&\qquad = \hat{p}^e(z_\ell)\left(\mathrm{cost}_{A_\ell}(\sigma \circ e) - \mathrm{cost}_{A_\ell}(\sigma)\right) && (3.10) \\
&\qquad \leq \hat{p}^e(z_\ell)\hat{r}_\ell\big((\langle \alpha_\ell, w^e_\ell\rangle - \Phi_\ell(w^e_\ell)/\hat{r}_\ell) - (\langle \alpha_\ell, w_\ell\rangle - \Phi_\ell(w_\ell)/\hat{r}_\ell)\big). && (3.11)
\end{aligned}
$$

To obtain (3.10) we use the definition of online cost (see (2.1)). To obtain (3.11) we use the fact that A_ℓ is $\hat{r}_\ell$-competitive and sensible (see (2.2)).

Let $\hat{e}$ be the last task in $\chi(\sigma \circ e)$. Formula (3.11) is simply the local cost for algorithm $\hat{A}$ on task $\hat{e}$. Thus, we have bounded the cost for algorithm A on task e to be no more than the cost for algorithm $\hat{A}$ on task $\hat{e}$. □

Proof of Theorem 3.1. We associate a weight vector α and a bounded potential function Φ with algorithm A, where

$$
\alpha(v) = \hat{\alpha}(z_\ell)\alpha_\ell(v) \quad \text{for } v \in M_\ell\,; \qquad \Phi(w) = \hat{\Phi}(\hat{w}) + r\sum_i \hat{\alpha}(z_i)\Phi_i(w_i)/\hat{r}_i.
$$

We remark that from Lemma 3.4 and Lemma 3.6 it follows that $\hat{w}$ and w_i are determined by w, so $\Phi(w)$ is well defined.

We derive the following upper bound on the cost of A:

$$
\begin{aligned}
&\mathrm{cost}_A(\sigma \circ e) - \mathrm{cost}_A(\sigma) \\
&\qquad \leq \mathrm{cost}_{\hat{A}}(\chi(\sigma \circ e)) - \mathrm{cost}_{\hat{A}}(\chi(\sigma)) && (3.12) \\
&\qquad \leq r\Big(\sum_i \hat{\alpha}(z_i)\hat{w}^e(z_i) - \sum_i \hat{\alpha}(z_i)\hat{w}(z_i)\Big) - \Big(\hat{\Phi}(\hat{w}^e) - \hat{\Phi}(\hat{w})\Big) && (3.13) \\
&\qquad = r\left(\sum_i \sum_{v \in M_i} \hat{\alpha}(z_i)\alpha_i(v)w^e_i(v) - \sum_i \sum_{v \in M_i} \hat{\alpha}(z_i)\alpha_i(v)w_i(v)\right) \\
&\qquad\quad - \left(\left(\hat{\Phi}(\hat{w}^e) + r\sum_i \hat{\alpha}(z_i)\Phi_i(w^e_i)/\hat{r}_i\right) - \left(\hat{\Phi}(\hat{w}) + r\sum_i \hat{\alpha}(z_i)\Phi_i(w_i)/\hat{r}_i\right)\right) && (3.14) \\
&\qquad = r(\langle \alpha, w^e\rangle - \langle \alpha, w\rangle) - (\Phi(w^e) - \Phi(w)). && (3.15)
\end{aligned}
$$

Inequality (3.12) follows from Proposition 3.7. Inequality (3.13) is implied as $\hat{A}$ is a sensible r-competitive algorithm. We obtain (3.14) by substituting $\hat{w}^e(z_i)$ and $\hat{w}(z_i)$ according to Lemma 3.4 and rearranging the summands. Equation (3.15) follows from the definition of α and Φ above, and using Lemma 3.6.

We now prove that A is (β, η)-constrained. It follows from Lemma 3.5 and Lemma 3.6 that the condition on β is satisfied (see Definition 2.6). It remains to

show the condition on η:

$$\|\Phi\|_\infty \le \|\hat{\Phi}\|_\infty + r\sum_i \hat{\alpha}(z_i)\|\Phi_i\|_\infty/\hat{r}_i \tag{3.16}$$

$$\le \hat{\eta} r \cdot \operatorname{diam}(\hat{M}) + r\sum_i \hat{\alpha}(z_i)\eta_i\hat{r}_i \cdot \operatorname{diam}(M_i)/\hat{r}_i \tag{3.17}$$

$$\le r \cdot \operatorname{diam}(M)\big(\hat{\eta}\tfrac{\operatorname{diam}(\hat{M})}{\operatorname{diam}(M)} + \max_i\{\eta_i \tfrac{\operatorname{diam}(M_i)}{\operatorname{diam}(M)}\}\big)$$

$$= r \cdot \operatorname{diam}(M)\eta.$$

Inequality (3.16) follows by the definition of Φ; (3.17) follows because $\hat{A}$ is $(\hat{\beta},\hat{\eta})$-constrained and A_i is (β_i,η_i)-constrained, $1 \le i \le b$.

We have therefore shown that A is a (β,η)-constrained and r-competitive algorithm. ∎

3.3. Constrained algorithms. Theorem 3.1 assumes the existence of constrained algorithms. In this section we show how to obtain such algorithms. The proof is motivated by similar ideas from [20, 3].

DEFINITION 3.8. *Fix a metric space M on b states and cost ratios $r_1,\dots,r_b$. Assume that for all $s>0$ there is a (β,η)-constrained $f(s)$-competitive algorithm A_s for the UMTS $U_s = (M; r_1,\dots,r_b; s)$ against reasonable task sequences. For $\rho > 0$ we define the ρ-variant of A_s (if it exists) to be a $(\beta\rho,\eta\rho)$-constrained $f(s/\rho)$-competitive algorithm for U_s.*

LEMMA 3.9. *Let $0 < \beta \le 1$ and $0 < \beta/\rho \le 1$. Assume there exists a $(\beta/\rho,\eta/\rho)$-constrained and r-competitive online algorithm A' for the UMTS $U' = (\rho M; r_1,\dots,r_b; s/\rho)$. Then there exists a (β,η)-constrained and r-competitive algorithm A for the UMTS $U = (M; r_1,\dots,r_b; s)$.*

Proof. Algorithm A on the UMTS U simulates algorithm A' on the UMTS U' by translating every task (v,δ) to task (v',δ). The probability that A associates with state v is the same as the probability that algorithm A' associates with state v'. If the task sequence for A' is reasonable, then the simulated task sequence for A' is also reasonable simply because the probabilities for v and v' are identical.

The costs of A or A' on task (v,δ) or (v',δ) can be partitioned into moving costs and local costs. As the probability distributions are identical, the local costs for A and A' are the same. The unweighted moving costs for A are $1/\rho$ the unweighted moving costs for A' because all distances are multiplied by $1/\rho$. However, the moving costs for A' are the unweighted moving costs multiplied by a factor of s/ρ, whereas the moving costs for A are the unweighted moving costs multiplied by a factor of s. Thus, the moving costs are also equal.

To show that A is (β,η)-constrained (and hence reasonable) we first need to show that if the work functions in U and U' are equal, then this implies that if u and v are two states such that $w(u) \ge w(v) + \beta\,\mathrm{d}_M(u,v)$, then $p(u) = 0$. This is true because A' is $(\beta/\rho,\eta/\rho)$-constrained, and thus $w(u') \ge w(v') + (\beta/\rho)\cdot \mathrm{d}_{\rho M}(u',v')$ implies a probability of zero on u' for A', which implies a probability of zero on u for A. Next, one needs to show that the work functions are the same; this can be done using an argument similar to the proof of Lemma 3.6.

As the work functions and costs are the same for the online algorithms A and A' it follows that we can use the same potential function. To show that $|\Phi| \le \eta\cdot\operatorname{diam}(M)$ we note that $|\Phi| \le (\eta/\rho)\operatorname{diam}(\rho M)$. ∎

Observation 5. Assume there exists a (β,η)-constrained and r-competitive algorithm A for a UMTS $U=(M;r_1,\ldots,r_b;s)$. Then, for all $\rho>0$, a natural modification of A, A', is a (β,η)-constrained, r-competitive algorithm for the UMTS $U'=(\rho M;r_1,\ldots,r_b;s)$.

LEMMA 3.10. *Under the assumptions of Definition* 3.8*, for all* $\rho>0$ *such that* $\beta\rho\le 1$*, and for all* $s>0$*, the* ρ*-variant of* A_s *exists.*

Proof. For all $\rho>0$ such that $\beta\rho\le 1$, we have the following:

1. By the assumption, there exists a (β,η)-constrained, $f(s/\rho)$-competitive algorithm for the UMTS $(M;r_1,\ldots,r_b;s/\rho)$.
2. It follows from Lemma 3.9 that there exists an online algorithm that is $(\rho\beta,\rho\eta)$-constrained, $f(s/\rho)$-competitive for the UMTS $(\rho^{-1}M;r_1,\ldots,r_b;s)$.
3. It now follows from Observation 5 that there exists a $(\rho\beta,\rho\eta)$-constrained, $f(s/\rho)$-competitive online algorithm for the UMTS $(M;r_1,\ldots,r_b;s)$. This means that the ρ variant of A_s exists. ∎

4. The uniform metric space. Let $\mathcal{U}_b^d$ denote the metric space on b points, where all pairwise distances are d (a uniform metric space). In this section we develop algorithms for UMTSs whose underlying metric is uniform. We begin with two special cases that were previously studied in the literature.

The first algorithm works for the UMTS $U=(\mathcal{U}_b^d;(r_1,\ldots,r_b);s)$, $b\ge 2$, and $r_1=r_2=\cdots=r_b$. However, it can be defined for arbitrary cost ratios. The algorithm, called ODDEXPONENT, was defined and analyzed in [3]. Applying our terminology to the results of [3], we obtain the following lemma.

LEMMA 4.1. ODDEXPONENT *is* $(1,1)$*-constrained and* $(\max_i r_i+6s\ln b)$*-competitive.*

Proof. Algorithm ODDEXPONENT, when servicing a reasonable task sequence, allocates for configuration v the probability $p(v)=\frac{1}{b}+\frac{1}{b}\sum_u\left(\frac{w(u)-w(v)}{d}\right)^t$, where t is chosen to be an odd integer in the range $[\ln b,\ln b+2)$.

In our terminology, Bartal et al. [3] prove that ODDEXPONENT is sensible, that it is $(\max_i r_i+6s\ln b)$-competitive, and that the associated potential function $|\Phi_1|\le(\max_i r_i/(t+1)+s)d\le(1/\lceil\ln b\rceil)(\max_i r_i+6s\ln b)d$. This implies that ODDEXPONENT is $(1,1/\lceil\ln b\rceil)$-constrained. ∎

The second algorithm works for the two point UMTS $U=(\mathcal{U}_2^d;r_1,r_2;s)$. The algorithm, called TWOSTABLE, was defined and analyzed in [20] and [3], based on an implicit description of the algorithm that appeared previously in [10]. Applying our terminology to the results of [20, 3], we obtain the following lemma.

LEMMA 4.2. TWOSTABLE *is* $(1,4)$*-constrained and* r*-competitive, where*

$$r=r_1+\frac{r_1-r_2}{e^{(r_1-r_2)/s}-1}=r_2+\frac{r_2-r_1}{e^{(r_2-r_1)/s}-1}.$$

Proof. TWOSTABLE works as follows: Let $y=w(v_1)-w(v_2)$, and $z=(r_1-r_2)/s$. The probability on point v_1 is $p(v_1)=\left(e^z-e^{z(\frac{1}{2}+\frac{y}{2d})}\right)/\left(e^z-1\right)$. TWOSTABLE is shown to be sensible and r-competitive in [3, 20], and the potential function associated with TWOSTABLE, Φ_2, obeys $|\Phi_2|\le(2r_2+s)d$.

It remains to show that $|\Phi_2|\le 4rd$. We use the fact that, in general, if $|z|\le 1/2$, then $1/2\le z/(e^z-1)$, and we do a simple case analysis. If $\max\{r_1,r_2\}>\frac{1}{2}s$, then $|\Phi_2|\le(2r_2+s)d\le(2r+2r)d\le 4rd$. Otherwise, $|z|\le 1/2$, so $r=r_2+\frac{z}{e^z-1}s\ge r_2+\frac{s}{2}$. Hence $|\Phi_2|\le 2rd$. ∎

To gain an insight about the competitive ratio of TwoStable, we have the following proposition.

Proposition 4.3. *Let* $f(s,r_1,r_2) = r_1+(r_1-r_2)/\big(e^{(r_1-r_2)/s}-1\big)$. *Let* $x_1,x_2 \in \mathbb{R}^+$ *such that* $r_1 \le 2s(\ln x_1+1)$ *and* $r_2 \le 2s(\ln x_2+1)$. *Then* $f(s,r_1,r_2) \le 2s(\ln(x_1+x_2)+1)$.

Proof. First we show that f is a monotonic nondecreasing function of both r_1 and r_2. Since the formula is symmetric in r_1 and r_2 it is enough to check monotonicity in r_1. Let $x=(r_1-r_2)/s$; it suffices to show that $g(x)=sx+r_2+sx/(e^x-1)$ is monotonic in x. The derivative satisfies

$$g'(x) = s\cdot\frac{e^x(e^x-(1+x))}{(e^x-1)^2} \ge 0, \text{ since } e^x \ge 1+x.$$

Therefore we may assume that $r_1 = 2s(\ln x_1+1)$ and $r_2 = 2s(\ln x_2+1)$. Without loss of generality we can assume that $x_1 \ge x_2$, and let $y \ge 2$ be such that $x_1 = (x_1+x_2)(1-1/y)$. By substitution we get $r_1-r_2 = 2s\ln(y-1)$ and

$$\begin{aligned} f(s,r_1,r_2) = r_1+\frac{r_1-r_2}{e^{(r_1-r_2)/s}-1} &= 2s\Big(\ln(x_1+x_2)+1+\ln(y-1)-\ln y+\frac{\ln(y-1)}{(y-1)^2-1}\Big) \\ &\le 2s\Big(\ln(x_1+x_2)+1-\frac{1}{y}+\frac{\ln(y-1)}{(y-1)^2-1}\Big). \end{aligned}$$

We now prove that for $y \ge 2$, $-\frac{1}{y}+\frac{\ln(y-1)}{(y-1)^2-1} \le 0$. When y approaches 2, the limit of the expression is zero. For $y>2$, we multiply the left side by $(y-1)^2-1$ and get $g(y) = -(y-2)+\ln(y-1)$. Since $g(2)=0$ and $g'(y) = -1+1/(y-1) < 0$ for $y>2$, we are done. ∎

We next describe a new algorithm, called Combined, defined on a UMTS $U = (\mathcal{U}_b^d; r_1,\dots,r_b; s)$. This algorithm is inspired by *Strategy* 3 [3]. Like *Strategy* 3, Combined combines OddExponent and TwoStable on subspaces of $\mathcal{U}_b^d$; however, it does so in a more sophisticated way that is impossible using the combining technique of [3]. Figure 4.1 presents the scheme of the combining process.

Algorithm Combined. As discussed in Observation 1, we may assume that $s=1$. Let x_i be the minimal real number such that $r_i \le 100\ln x_i \ln\ln x_i$ and $x_i \ge e^{e^6+1}$, and let x denote $\sum_i x_i$. For a set $S \subset M_b^d$ let $U(S)$ denote the UMTS induced by U on S.

Let $\mathcal{U}_b^d = \{v_1,\dots,v_b\}$, where v_i has cost ratio r_i. We partition the points of $\mathcal{U}_b^d$ as follows: let $Q_\ell = \{v_i : e^{\ell-1} \le x_i < e^\ell\}$. Let $P = \{Q_\ell : |Q_\ell| \ge \ln x\} \cup \{\{v\} : v \in Q_\ell \text{ and } |Q_\ell| < \ln x\}$, P being a partition of $\mathcal{U}_b^d$. For $S \in P$ let $x(S) = \sum_{v_i \in S} x_i$. Without loss of generality we assume $P = \{S_1, S_2, \dots, S_{b'}\}$, where $b' = |P|$ and $x(S_j) \ge x(S_{j+1})$, $1 \le j \le b'-1$.

We associate with every set S_i an algorithm $A(S_i)$ on the UMTS $U(S_i)$. If $|S_i| \ge \ln x$ we choose $A(S_i)$ to be the (1/10)-variant of OddExponent. If $|S_i| < \ln x$, then $|S_i| = 1$, and we choose $A(S_i)$ to be the trivial algorithm on one point; this algorithm has a competitive ratio equal to the cost ratio, and it is $(0,0)$-constrained. Let $r(S_i)$ denote the competitive ratio of $A(S_i)$ on $U(S_i)$.

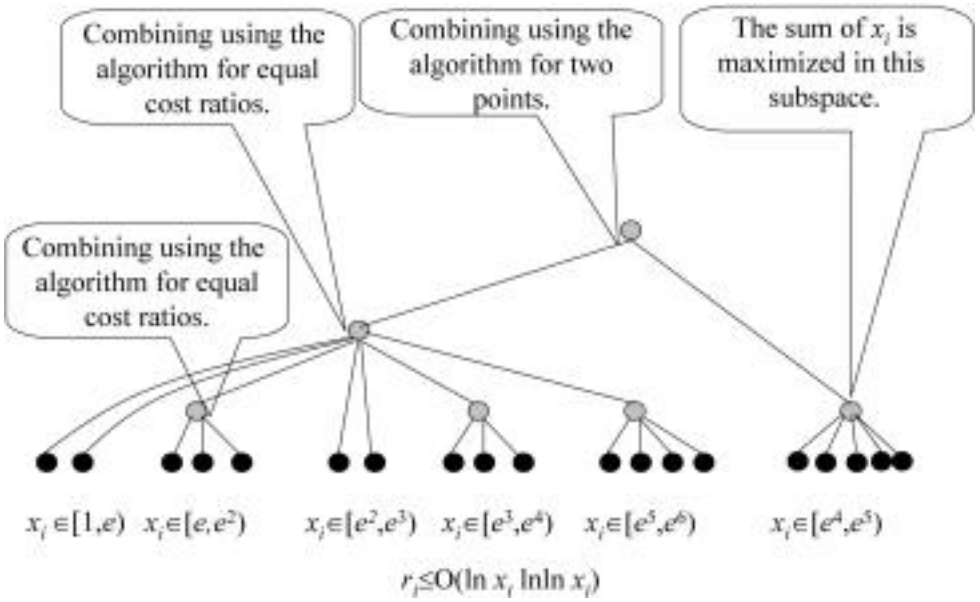

FIG. 4.1. *Schematic description of* COMBINED.

If $b' = 1$ we choose COMBINED to be $A(S_1)$, and we are done. If $b' \geq 2$, let $\tilde{M} = \cup_{i=2}^{b'} S_i$. We want to construct an algorithm, $A(\tilde{M})$, for $U(\tilde{M})$. If $b' = 2$, we choose $A(\tilde{M})$ to be $A(S_2)$. Otherwise, we apply Theorem 3.1 on $\tilde{M}$ with the partition $\{S_2, \ldots, S_{b'}\}$. We define $\hat{M}$ from Theorem 3.1 to be $\mathcal{U}_{b'-1}^d$. Likewise, $\hat{A}$ from Theorem 3.1 is the application of the (1/5)-variant of ODDEXPONENT on $\hat{U} = (\mathcal{U}_{b'-1}^d; r(S_2), \ldots, r(S_{b'}))$. Let $r(\tilde{M})$ denote the competitive ratio of $\hat{A}$.

Next, we choose the partition $\{S_1, \tilde{M}\}$ of $\mathcal{U}_b^d$. We combine the two algorithms $A(S_1)$ and $A(\tilde{M})$ using the (1/10)-variant of TWOSTABLE (this is the $\hat{A}$ required in Theorem 3.1) on the UMTS $(\mathcal{U}_2^d; r(S_1), r(\tilde{M}))$ (the UMTS $\hat{U}$ of Theorem 3.1). We denote the competitive ratio of $\hat{A}$ by r. The resulting combined algorithm, $A(M)$, is our final algorithm, COMBINED.

LEMMA 4.4. *Given that* $x = \sum_i x_i$, $r_i \leq 100s \ln x_i \ln\ln x_i$, *and* $x_i \geq e^{e^6+1}$, *algorithm* COMBINED *for the UMTS* $U = (\mathcal{U}_b^d; r_1, \ldots, r_b; s)$ *is* $(1, 1/2)$*-constrained and* r*-competitive, where* $r \leq 100s \ln x \ln\ln x$.

Proof. As before, without loss of generality, we assume $s = 1$. First we calculate the constraints of the algorithm.

From Lemma 4.1 and Lemma 3.10, $A(S_i)$ is $(1/10, 1/10)$-constrained for every $1 \leq i \leq b'$. We would like to show that $A(\tilde{M})$ is $(1/2, 3/10)$-constrained. If $b' = 2$, then it is obviously $(1/10, 1/10)$-constrained. Otherwise, $(b' > 2)$, the combining algorithm for $\tilde{M}$, is the (1/5)-variant of ODDEXPONENT, which is $(1/5, 1/5)$-constrained. Hence, from (3.3), $\beta \leq 1/5+1/10+1/10+1/10 = 1/2$, and from (3.4), $\eta \leq 1/5+1/10 = 3/10$. From Corollary 3.2, $A(\tilde{M})$ is $r(\tilde{M})$-competitive.

The (β, η)-constraints of algorithm COMBINED are calculated as follows: The (1/10)-variant of TWOSTABLE is $(1/10, 2/10)$-constrained; therefore $\beta = 1/10+1/10+1/2+3/10 = 1$ and $\eta = 2/10+3/10 = 1/2$. From Corollary 3.2, $A(M)$ is r-competitive.

To summarize, COMBINED is an $(1, 1/2)$-constrained and r-competitive algorithm for the UMTS U.

It remains to prove the bound on r. First we show that for all $1 \le j \le b'$, $r(S_j) \le 100s \ln x(S_j) \ln\ln x(S_j)$. If $|S_j| = 1$, we are done. Otherwise, $|S_j| \ge \ln x$, and $S_j = Q_\ell$ for some ℓ.

$$
\begin{aligned}
r(S_j) &\le 100 \ln e^\ell \ln\ln e^\ell + 6 \cdot 10 \ln |S_j| && (4.1)\\
&\le 100\big(\ln e^{\ell-1} \ln\ln e^{\ell-1} + \ln \ell + \tfrac{1}{\ell-1} \ln e^{\ell-1}\big) + 60 \ln |S_j| \\
&\le 100\big(\ln e^{\ell-1} \ln\ln e^{\ell-1} + \ln\ln x + \tfrac{60}{100} \ln |S_j| + 1\big) && (4.2)\\
&\le 100\big(\ln e^{\ell-1} \ln\ln e^{\ell-1} + 2 \ln |S_j|\big) && (4.3)\\
&\le 100 \ln(|S_j| e^{\ell-1}) \ln\ln(|S_j| e^{\ell-1}) \\
&\le 100 \ln x(S_j) \ln\ln x(S_j). && (4.4)
\end{aligned}
$$

Inequality (4.1) is derived as follows. Since $S_j = Q_\ell$, it follows that $r_i \le 100s \ln e^\ell \ln\ln e^\ell$ for all $v_i \in S_j$. By the bound on the competitive ratio of the (1/10) variant of OddExponent (See Lemma 4.1 and Lemma 3.10) we obtain (4.1). Inequality (4.2) follows since $\ell \le \ln x$. Inequality (4.3) follows because $\ln |S_j| \ge \ln\ln x$, and $\ln\ln x \ge 6$. The last inequality follows because $e^{\ell-1}$ is a lower bound on x_i for $v_i \in S_j$, and thus $|S_j| e^{\ell-1} \le x(S_j)$.

Observe that $b' \le \ln^2 x$, as there are at most $\ln x$ sets Q_i, and each such set contributes at most $\ln x$ sets S_i to P. We next derive a bound on $r(\tilde{M})$.

$$
\begin{aligned}
r(\tilde{M}) &\le \max_{2 \le i \le b'} r(S_i) + 6 \cdot 5 \cdot \ln(b' - 1) && (4.5)\\
&\le 100 \cdot \ln x(S_2) \ln\ln x + 30 \cdot (2 \ln\ln x) && (4.6)\\
&= 100(\ln x(S_2) + 0.6) \ln\ln x.
\end{aligned}
$$

Inequality (4.5) follows since the algorithm used is a (1/5)-variant of OddExponent. Inequality (4.6) follows by using the previously derived bound on $r(S_i)$ and noting that $x(S_2)$ is maximal amongst $x(S_2), \ldots, x(S_{b'})$ and that $x(S_i) \le x$.

From Lemma 3.10 we know that the competitive ratio of the (1/10)-variant of TwoStable is $f(10, r(S_1), r(\tilde{M}))$, where f is the function as given in Proposition 4.3. We give an upper bound on $f(10, r(S_1), r(\tilde{M}))$ using Proposition 4.3. To do this we need to find values y_1 and y_2 such that

$$
\begin{aligned}
r(S_1) &\le 100 \ln x(S_1) \ln\ln x = 2 \cdot 10(\ln y_1 + 1), \\
r(\tilde{M}) &\le 100(\ln x(\tilde{M}) + 0.6) \ln\ln x = 2 \cdot 10(\ln y_2 + 1).
\end{aligned}
$$

Indeed, the following values satisfy the conditions above: $y_1 = x(S_1)^{5 \ln\ln x}/e$ and $y_2 = (e^{0.6} x(\tilde{M}))^{5 \ln\ln x}/e$. Using Proposition 4.3 we get a bound on r as follows:

$$
\begin{aligned}
r &\le 2 \cdot 10(\ln(y_1 + y_2) + 1) && (4.7)\\
&\le 20 \ln\big(x(S_1)^{5 \ln\ln x} + (e^{0.6} x(\tilde{M}))^{5 \ln\ln x}\big) \\
&\le 20 \ln\big(x(S_1)^{5 \ln\ln x} + (2^{5 \ln\ln x} - 1) x(\tilde{M})^{5 \ln\ln x}\big) && (4.8)\\
&\le 20 \ln\big((x(S_1) + x(\tilde{M}))^{5 \ln\ln x}\big) && (4.9)\\
&\le 100 \ln x \ln\ln x.
\end{aligned}
$$

Inequality (4.7) follows from Proposition 4.3. Inequality (4.8) follows because $\ln\ln x \ge 6$. Inequality (4.9) follows since, in general, for $a \ge b > 0$ and $z \ge 1$, $a^z + (2^z - 1) b^z \le (a + b)^z$. This is because for $a = b$ it is an equality, and the

derivative with respect to a of the right-hand side is clearly larger than the derivative with respect to a of the left-hand side. ∎

Next, we present a better algorithm when all the cost ratios but one are equal.

LEMMA 4.5. *Given a UMTS $U = (\mathcal{U}_b^d; r_1, r_2, \ldots, r_b)$ with $r_2 = r_3 = \cdots = r_b$, there exists a $(1, 3/5)$-constrained and r-competitive online algorithm,* WCOMBINED, *where*

$$r = 30\Big(\ln\big(e^{\frac{r_1}{30}-\frac{1}{3}} + (b-1)e^{\frac{r_2}{30}-\frac{1}{3}}\big) + \tfrac{1}{3}\Big).$$

Proof. The proof is a simplified version of the proof of Lemma 4.4, and we just sketch it here. We define x_1, x_2 such that

$$r_1 = 30(\ln x_1 + \tfrac{1}{3}) = 2 \cdot 5 \cdot (\ln x_1^3 + 1), \quad r_2 = 30(\ln x_2 + \tfrac{1}{3}) = 2 \cdot 5 \cdot (\ln x_2^3 + 1).$$

Let $\tilde{M} = \{v_2, \ldots, v_b\}$. We use a (1/5)-variant of ODDEXPONENT on the UMTS $U(\tilde{M})$. The competitive ratio of this algorithm is at most

$$r(\tilde{M}) \le r_2 + 30\ln(b-1) \le 30\big(\ln((b-1)x_2) + \tfrac{1}{3}\big) = 10\big(\ln((b-1)x_2)^3 + 1\big),$$

and it is $(1/5, 1/5)$-constrained. We combine it with the trivial algorithm for $U(\{v_1\})$ using a (1/5)-variant of algorithm TWOSTABLE. The resulting algorithm is $(1, 3/5)$-constrained, and by Proposition 4.3 we have

$$r \le 10(\ln(x_1^3+((b-1)x_2)^3+1) \le 10(\ln(x_1+(b-1)x_2)^3+1) = 30(\ln(x_1+(b-1)x_2)+\tfrac{1}{3}).$$

Substituting for x_i gives the required bound. ∎

5. Applications.

5.1. An $O((\log n \log\log n)^2)$-competitive algorithm for MTSs. Bartal [1] defines a class of decomposable spaces called HSTs.[1]

DEFINITION 5.1. *For $k \ge 1$, a k-HST is a metric space defined on the leaves of a rooted tree T. Associated with each vertex $u \in T$ is a real-valued label $\Delta(u) \ge 0$, and $\Delta(u) = 0$ if and only if u is a leaf of T. The labels obey the rule that for every vertex v, a child of u, $\Delta(v) \le \Delta(u)/k$. The distance between two leaves $x, y \in T$ is defined as $\Delta(\mathrm{lca}(x, y))$, where $\mathrm{lca}(x, y)$ is the least common ancestor of x and y in T. Clearly, this is a metric.*

Bartal [1, 2] shows how to approximate any metric space using an efficiently constructible probability distribution over a set of k-HSTs . His result allows us to reduce a MTS problem on an arbitrary metric space to MTS problems on HSTs. Formally, he proves the following theorem.

THEOREM 5.2 (see [2]). *Suppose there is an r-competitive algorithm for any n-point k-HST metric space. Then there exists an $O(rk \log n \log\log n)$-competitive randomized algorithm for* any *n-point metric space.*

Thus, it is sufficient to construct an online algorithm for a MTS, where the underlying metric space is a k-HST. Following [3] we use the UMTS model to obtain an online algorithm for a MTS over a k-HST metric space.

[1] The definition given here for k-HST differs slightly from the original definition given in [1]. We choose the definition given here for simplicity of the presentation. For $k > 1$ the metric spaces given by these two definitions approximate each other to within a factor of $k/(k-1)$.

ALGORITHM RHST. We define the algorithm RHST(T) on the metric space $M(T)$, where T is a k-HST with $k \geq 5$. Algorithm RHST(T) is defined inductively on the size of the underlying HST, T.

When $|M(T)| = 1$, RHST(T) serves all task sequences optimally. It is $(0,0)$-constrained. Otherwise, let the children of the root of T be $v_1, \ldots, v_b$, and let T_i be the subtree rooted at v_i. Denote $d = \Delta(T)$, and so $\mathrm{diam}(T_i) \leq d/k$. Every algorithm RHST($T_i$) is an algorithm for the UMTS $U_i = (M(T_i); 1, \ldots, 1; 1)$.

We construct a metric space $\hat{M} = \mathcal{U}_b^d$ and define cost ratios $r_1, \ldots, r_b$, where $r_i = r(T_i)$ is the competitive ratio of RHST(T_i). We now use Theorem 3.1 to combine algorithms RHST(T_i). The role of $\hat{A}$ is played by the $(1/2)$-variant of COMBINED on the UMTS $\hat{U} = (\hat{M}; r_1, \ldots, r_b; 1)$. The combined algorithm is a RHST(T) on the UMTS $(M(T); 1, \ldots, 1; 1)$.

We remark that the application of Theorem 3.1 requires that the algorithms will be constrained. We show that this is true in the following lemma.

LEMMA 5.3. *The algorithm* RHST(T) *is* $O(\ln n \ln\ln n)$, *where* $n = |M(T)|$.

Proof. Let $n' = e^{e^6+1} n$. We prove by induction on the depth of the tree that RHST(T) is $(1,1)$-constrained and $200 \ln n' \ln\ln n'$-competitive.

When $|M(T)| = 1$, it is obvious. Otherwise, let $n_i = |M(T_i)|$, $n_i' = e^{e^6+1} n_i$, and $n' = \sum_i n_i'$. We assume inductively that each of the RHST(T_i) algorithms is $(1,1)$-constrained and $200 \ln n_i' \ln\ln n_i'$-competitive on $M(T_i)$. The combined algorithm, RHST(T), is (β, η)-constrained. From (3.3), and given that $k \geq 5$, we get that

$$\beta \leq \max\{1, \tfrac{1}{2} + \tfrac{1}{k} + \tfrac{1}{k} + \tfrac{1}{2k}\} \leq \max\{1, 1\} = 1.$$

From (3.4) we obtain that $\eta \leq \frac{1}{2} + \frac{1}{k} \leq 1$ for $k \geq 5$. This proves that the algorithm is well defined and $(1,1)$-constrained.

We next bound the competitive ratio using Lemma 4.4. Lemma 3.10 implies that the competitive ratio obtained by the $(1/2)$-variant of COMBINED on $(\hat{M}; r_1, \ldots, r_b)$ is the same as the competitive ratio attained by COMBINED on $(\hat{M}; r_1, \ldots, r_b; 2)$. The values $(x_i)_i$ computed by COMBINED are at most $(n_i')_i$, respectively. Hence it follows from Lemma 4.4 that the competitive ratio of RHST(T) is at most $100 \cdot 2 \ln x \ln\ln x \leq 200 \ln n' \ln\ln n'$, since $x = \sum_i x_i$. ∎

Since every HST T can be 5-approximated by a 5-HST T' (see [2]), the bound we have just proved holds for any HST.

Combining Theorem 5.2 with Lemma 5.3, we get the following theorem.

THEOREM 5.4. *For any MTS over an n-point metric space, the randomized competitive ratio is* $O((\log n \log\log n)^2)$.

5.2. K-weighted caching on $K+1$ points. Weighted caching is a generalized paging problem, where there is a different cost to fetch different pages. This problem is equivalent to the K-server problem on a *star metric space* [23, 9]. A star metric space is derived from a depth-one tree with distances on the edges, the points of the metric space are the leaves of the tree, and the distance between a pair of points is the length of the (2 edge) path between them. This is so, since we can assign any edge (r, u) in the tree a weight of half the fetch cost of u. Together, an entrance of a server into a leaf from the star's middle-point (page in) and leaving the leaf to the star's middle-point (page out) have the same cost of fetching the page.

The K-server problem on a metric space of $K+1$ points is a special case of the MTS problem on the same metric space, and hence any upper bound for the MTS translates to an upper bound for the corresponding K-server problem.

Given a star metric space M, we 12-approximate it with a 6-HST T. T has the special structure that for every internal vertex, all children, except perhaps one, are leaves. It is not hard to see that one can find such a tree T such that for any $u, v \in M$, $\mathrm{d}_M(u,v) \le \mathrm{d}_T(u,v) \le 12 \cdot \mathrm{d}_M(u,v)$. Essentially, the vertices furthest away from the root (up to a factor of 6) in the star are children of the root of T, and the last child of the root is a recursive construction for the rest of the points.

We now follow the construction of RHST given in the previous section, on a 6-HST T, except that we make use of (1/2)-variant of WCOMBINED rather than (1/2)-variant of COMBINED. The special structure of T implies that all the children of an inner vertex, except perhaps one, are leaves and therefore have a trivial 1-competitive algorithm on their "subspaces." Hence we can apply WCOMBINED. Using Lemma 4.5 with induction on the depth of the tree, it is easy to bound from above the competitive ratio on a 6-HST with $K+1$ leaves by $60(\ln(K+1)+1/3)$.

Combining the above with the lower bound of [9] we obtain the following theorem.

THEOREM 5.5. *The competitive ratio for the K-weighted caching problem on $K+1$ points is $\Theta(\log K)$.*

5.3. A MTS on equally spaced points on the line. The metric space of n equally spaced points on the line is considered important because of its simplicity and the practical significance of the k-server on the line (for which this problem is a special case). The best lower bound currently known on the competitive ratio is $\Omega(\log n/\log\log n)$ [10]. Previously, the best upper bound known was $O(\log^3 n/\log\log n)$ due to [3].

We are able to slightly improve the upper bound on the competitive ratio from section 5.1 to $O(\log^2 n)$. Bartal [1] proves that n equally spaced points on the line can be $O(\log n)$ probabilistically embedded into a set of *binary* 4-HSTs. We present an $O(\log n)$-competitive randomized algorithm for binary 4-HST, similar to RHST except that we make use of (1/4)-variant of TWOSTABLE instead of (1/2)-variant of COMBINED. Similar arguments show that this algorithm is $(1,1)$-constrained, and using Proposition 4.3 we conclude that the algorithm is $8\ln n$-competitive. Combining the probabilistic embedding into binary 4-HST with the algorithm for binary 4-HST we obtain the following theorem.

THEOREM 5.6. *The competitive ratio of the MTS problem on metric space of n equally spaced points on the line is $O(\log^2 n)$.*

6. Concluding remarks. This paper presents algorithms for the MTS problem and related problems with significantly improved competitive ratios. An obvious avenue of research is to further improve the upper bound on the competitive ratio for the MTS problem. A slight improvement to the competitive ratio of the algorithm for arbitrary n-point metric spaces is reported in [6]. The resulting competitive ratio there is $O(\log^2 n \log\log n \log\log\log n)$, and the improvement is achieved by refining the reduction from arbitrary metric spaces to HST spaces (i.e., that improvement is orthogonal to the improvement presented in this paper). However, in order to break the $O(\log^2 n)$ bound, it seems that one needs to deviate from the black box usage of Theorem 5.2. Maybe the easiest special case to start with is the metric space of equally spaced points on the line.

Another interesting line of research would be an attempt to apply the techniques of this and previous papers to the randomized k-server problem, or even for a special

case such as the randomized weighted caching on k pages problem; see also [8, 21].

Acknowledgments. We would like to thank Yair Bartal, Avrim Blum, and Steve Seiden for helpful discussions.

Note added in proof. Theorem 5.2 has been improved in [14]. Therefore the bound in Theorem 5.4 is also improved to $O(\log^2 n \log\log n)$.

MATRIX ROUNDING UNDER THE L_p-DISCREPANCY MEASURE AND ITS APPLICATION TO DIGITAL HALFTONING*

TETSUO ASANO†, NAOKI KATOH‡, KOJI OBOKATA†, AND TAKESHI TOKUYAMA§

Abstract. We study the problem of rounding a real-valued matrix into an integer-valued matrix to minimize an L_p-discrepancy measure between them. To define the L_p-discrepancy measure, we introduce a family $\mathcal{F}$ of regions (rigid submatrices) of the matrix and consider a hypergraph defined by the family. The difficulty of the problem depends on the choice of the region family $\mathcal{F}$. We first investigate the rounding problem by using integer programming problems with convex piecewise-linear objective functions and give some nontrivial upper bounds for the L_p discrepancy. We propose "laminar family" for constructing a practical and well-solvable class of $\mathcal{F}$. Indeed, we show that the problem is solvable in polynomial time if $\mathcal{F}$ is the union of two laminar families. Finally, we show that the matrix rounding using L_1 discrepancy for the union of two laminar families is suitable for developing a high-quality digital-halftoning software.

1. Introduction.

Rounding is an important operation in numerical computation and plays key roles in digitization of analog data. Rounding of a real number a is basically a simple problem: We round it to either $\lfloor a \rfloor$ or $\lceil a \rceil$, and we usually choose the one nearer to a. However, we often encounter a datum consisting of more than one real number instead of a singleton. If it has n numbers, we have 2^n choices for rounding since each number is rounded into either its floor or ceiling. If the original data set has some feature, we need to choose a rounding so that the rounded result inherits as much of the feature as possible. The feature is described by using some combinatorial structure; we indeed consider a hypergraph $\mathcal{H}$ on the set. A typical input set is a multidimensional array of real numbers, and we consider a hypergraph whose hyperedges are its subarrays with contiguous indices. In this paper, we focus on two-dimensional arrays; in other words, we consider rounding problems on matrices.

1.1. Rounding problem and discrepancy measure.

Given an $M \times N$ matrix $A = (a_{ij})_{1 \le i \le M, 1 \le j \le N}$ of real numbers, its rounding is a matrix $B = (b_{ij})_{1 \le i \le M, 1 \le j \le N}$ of integral values such that b_{ij} is either $\lfloor a_{ij} \rfloor$ or $\lceil a_{ij} \rceil$ for each (i, j). There are 2^{MN} possible roundings of a given A, and we would like to find an optimal rounding with respect to a given criterion. This is called the *matrix rounding problem*. Without loss of generality, we can assume that each entry of A is in the closed interval $[0, 1]$ and each entry is rounded to either 0 or 1.

In order to give a criterion to determine the quality of roundings, we define a distance in the space of all $[0,1]$-valued $M \times N$ matrices. Let $n = MN$. Let $\mathcal{F}$ be a family of *regions* (i.e., subsets) of the $M \times N$ integer grid G_{MN}. Let $\mathcal{A} = \mathcal{A}(G_{MN})$ be the space of all $[0,1]$-valued matrices with the index set G_{MN}, and let $\mathcal{B} = \mathcal{B}(G_{MN})$ be its subset consisting of all $\{0,1\}$-valued matrices. Let R be a region in $\mathcal{F}$.[1] For an element $A \in \mathcal{A}$, let $A(R)$ be the sum of entries of A located in the region R, that is,

$$A(R) = \sum_{(i,j)\in R} a_{ij}.$$

We define a distance $Dist_p^{\mathcal{F}}(A, A')$ between two elements A and A' in $\mathcal{A}$ for a positive integer p by

$$Dist_p^{\mathcal{F}}(A, A') = \left[\sum_{R\in\mathcal{F}} |A(R) - A'(R)|^p\right]^{1/p}.$$

The distance is called the L_p distance with respect to $\mathcal{F}$. The L_∞ distance with respect to $\mathcal{F}$ is defined by

$$Dist_\infty^{\mathcal{F}}(A, A') = \lim_{p\to\infty} Dist_p^{\mathcal{F}}(A, A') = \max_{R\in\mathcal{F}} |A(R) - A'(R)|.$$

Using the notations above, we can formally define the matrix rounding problem.

L_p-optimal matrix rounding problem. $\mathcal{P}(G_{MN}, \mathcal{F}, p)$: Given a $[0,1]$-matrix $A \in \mathcal{A}$, a family $\mathcal{F}$ of subsets of G_{MN}, and a positive integer p, find a $\{0,1\}$-matrix $B \in \mathcal{B}$ that minimizes

$$Dist_p^{\mathcal{F}}(A, B) = \left[\sum_{R\in\mathcal{F}} |A(R) - B(R)|^p\right]^{1/p}.$$

Also, we are interested in the following combinatorial problem.

L_p-discrepancy bound. Given a $[0,1]$-matrix $A \in \mathcal{A}$, a family $\mathcal{F}$ of subsets of G_{MN}, and a positive integer p, investigate upper and lower bounds of

$$\mathcal{D}(G_{MN}, \mathcal{F}, p) = \sup_{A\in\mathcal{A}} \min_{B\in\mathcal{B}} Dist_p^{\mathcal{F}}(A, B).$$

The pair $(G_{MN}, \mathcal{F})$ defines a hypergraph on G_{MN}, and $\mathcal{D}(G_{MN}, \mathcal{F}, \infty)$ is called the *inhomogeneous discrepancy* of the hypergraph [6]. Abusing the notation, we call $\mathcal{D}(G_{MN}, \mathcal{F}, p)$ the (inhomogeneous) L_p discrepancy of the hypergraph and also often call $Dist_p^{\mathcal{F}}(A, B)$ the L_p-discrepancy measure of (the quality of) the output B with respect to $\mathcal{F}$.

1.2. Motivation and our application. The most popular example of the family $\mathcal{F}$ is the set of all rectangular subregions in G_{MN} (i.e., the set of all rigid submatrices), and the corresponding L_∞-discrepancy measure is utilized in many application areas such as Monte Carlo simulation and computational geometry. Unfortunately, if we consider the family of all rectangular subregions, the discrepancy bound (for the

[1] Strictly speaking, R can be any subset of G_{MN}. Although we implicitly assume that R forms some connected portion on the grid G_{MN}, the connectivity assumption is not used throughout the paper.

L_∞ measure) is known to be $\Omega(\log n)$ and $O(\log^3 n)$. See Beck and Sós's survey [6] for the theory. It seems hard to find an optimal solution to minimize the discrepancy. In fact, it is NP-hard [2].

Therefore, we seek a family of regions for which low discrepancy rounding is useful in an important application and also can be computed in polynomial time. For the application, L_∞ rounding is not always suitable, and L_p discrepancy (with $p = 1$ or 2) is preferable. For the purpose, we present a geometric structure of a family of regions reflecting the combinatorial discrepancy bound and computational difficulty of the matrix rounding problem.

In particular, we focus on the digital-halftoning application of the matrix rounding problem, where we should consider smaller families of rectangular subregions as $\mathcal{F}$. More precisely, the input matrix represents a digital (gray) image, where a_{ij} represents the brightness level of the (i, j)-pixel in the $M \times N$ pixel grid. Typically, M and N are between 256 and 4096, and a_{ij} is an integral multiple of $1/256$: This means that we use 256 brightness levels. If we want to send an image using fax or print it out by a dot (or ink-jet) printer, brightness levels available are limited. Instead, we replace A by an integral matrix B so that each pixel uses only two brightness levels. Here, it is important that B looks similar to A; in other words, B should be a good approximation of A.

For each pixel (i, j), if the average brightness level of B in each of its neighborhoods (regions containing (i, j) in a suitable family of regions) is similar to that of A, we can expect that B is a good approximation of A. For this purpose, the set of all rectangles is not suitable (i.e., it is too large), and we may use a more compact family. Moreover, since human vision detects global features, the L_1 or L_2 measure should be better than the L_∞ measure to obtain a clear output image. This intuition is supported by our experimental results; for example, edges of objects are often blurred in the output based on the L_∞-discrepancy measure, while they are sharply displayed if we use the L_1-discrepancy measure.

1.3. Known results on L_∞ measure. For the L_∞ measure, the following beautiful combinatorial result is classically known.

THEOREM 1.1 (Baranyai [5]). *Given a real-valued matrix $A = (a_{ij})$ and a family $\mathcal{F}$ of regions consisting of all rows, all columns, and the whole matrix, there exists an integer-valued matrix $B = (b_{ij})$ such that $|A(R) - B(R)| < 1$ holds for every $R \in \mathcal{F}$.*

Translating the theorem in our terminologies, the L_∞ discrepancy of the matrix rounding problem for the family of regions consisting of all rows, all columns, and the whole matrix is bounded by 1. Also, the combinatorial structure and algorithmic aspects of roundings of (one-dimensional) sequences with respect to the L_∞-discrepancy measure are investigated in recent studies [2, 19].

The *incidence matrix* $\mathcal{C}(G_{MN}, \mathcal{F}) = (\mathcal{C}_{ij})$ of the hypergraph $(G_{MN}, \mathcal{F})$ is defined by $\mathcal{C}_{ij} = 1$ if the jth element of G_{MN} belongs to the ith region R_i in $\mathcal{F}$ and 0 otherwise.[2] A hypergraph is called *unimodular* if its incidence matrix is totally unimodular, where a matrix $\mathcal{C}$ is *totally unimodular* if the determinant of each square submatrix of $\mathcal{C}$ is equal to 0, 1, or -1.

Both the Baranyai problem and the sequence rounding problems correspond to rounding problems with respect to unimodular hypergraphs. The L_∞-discrepancy problem can be formulated as an integer programming problem, and the unimodularity implies that its relaxation has an integral solution. A classical theorem of

[2] We implicitly assume a one-dimensional ordering of elements in G_{MN}.

Ghouila-Houri [10] implies that unimodularity is a necessary and sufficient condition for the existence of a rounding with a L_∞ discrepancy less than 1. Moreover, the following sharpened result is given by Doerr [7].

THEOREM 1.2. *If $(G_{MN}, \mathcal{F})$ is a unimodular hypergraph, there exists a rounding $B = (b_{ij})$ of $A = (a_{ij})$ satisfying*

$$|A(R) - B(R)| < \min\left\{1 - \frac{1}{n+1}, 1 - \frac{1}{m}\right\}$$

for every $R \in \mathcal{F}$, where $n = MN$, $m = |\mathcal{F}|$.

This bound is sharp. Moreover, L_∞-optimal rounding can be computed in polynomial time if $\mathcal{F}$ is unimodular.

1.4. Our results. We would like to consider the L_p-discrepancy measure instead of the L_∞-discrepancy measure. If the hypergraph is unimodular, an $|\mathcal{F}|^{1/p}$ upper bound for the L_p discrepancy can be derived from Theorem 1.2 trivially. We first improve the upper bound to $\frac{1}{2}|\mathcal{F}|^{1/p}$ for $p \leq 3$ and show that the bound is tight. We also consider the family $\mathcal{F}$, consisting of all 2×2 rigid submatrices, for which the matrix rounding problem is known to be NP-hard [2] (accordingly, the family is not unimodular).

Next, we consider the optimization problem. If the hypergraph is unimodular, the rounding minimizing the L_p discrepancy can be computed in polynomial time by translating it to a separable convex programming problem and applying known general algorithms [11, 12]. However, we want to define a class of region families for which we can compute the optimal solution more efficiently, as well as a class that is useful in applications (in particular, the digital-halftoning application). We consider the union of two laminar families (defined in section 3) and show that the matrix rounding problem can be formulated into a minimum cost flow problem, and hence solved in polynomial time. Finally, we implemented the algorithm using LEDA [14]. Some output pictures of the algorithm applying to the digital-halftoning problem are included.

2. Mathematical programming formulations.

2.1. Formulation as a piecewise-linear separable convex programming problem. We give a formulation of the L_p-discrepancy problem into an integer convex programming problem where the objective function is a separable convex function, i.e., a sum of univariate convex functions.

Introducing a new variable $y_i = B(R_i) = \sum_{(j,k)\in R_i} b_{jk}$ for each $R_i \in \mathcal{F}$, the problem $\mathcal{P}(G_{MN}, \mathcal{F}, p)$ is described in the following form:

$$\begin{aligned} \text{(P1)} : \text{minimize} \quad & \left[\sum_{R_i \in \mathcal{F}} |y_i - A(R_i)|^p\right]^{1/p} \\ \text{subject to} \quad & y_i = \sum_{(j,k)\in R_i} b_{jk}, \ i = 1, \ldots, m = |\mathcal{F}|, \\ \text{and} \quad & B \in \mathcal{B}(G_{MN}). \end{aligned}$$

When $p < \infty$, the objective function can be replaced with $\sum_{R_i \in \mathcal{F}} |y_i - c_i|^p$, where $c_i = A(R_i) = \sum_{(j,k)\in R_i} a_{jk}$ is a constant depending only on input values. Now $|y_i - c_i|^p$ is a convex function independent of other y_j's. The constraints $y_i = \sum_{(j,k)\in R_i} b_{jk}$,

$i = 1, \ldots, m$, are represented by $(-I, \mathcal{C}(G_{MN}, \mathcal{F}))Y = 0$ using the incidence matrix $\mathcal{C}(G_{MN}, \mathcal{F})$ defined in section 1.3, where $Y = (y_1, \ldots, y_m, b_{11}, \ldots, b_{MN})^T$ and I is an identity matrix.

Although the objective function is now a separable convex function, its nonlinearity makes it difficult to analyze the properties of the solution. Thus, we apply the idea of Hochbaum and Shanthikumar [11] to replace $|y_i - c_i|^p$ with a piecewise-linear convex continuous function $f_i(y_i)$ which is equal to $|y_i - c_i|^p$ for each integral value of y_i in $[0, |R_i|]$. This is because we need only integral solutions, and, if each b_{p_j} is integral, y_i must be a nonnegative integer less than or equal to $|R_i|$. Typically for $p = 1$, $f_i(y_i)$ is illustrated in Figure 1.

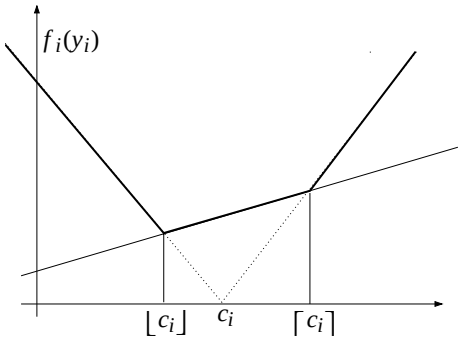

FIG. 1. *Conversion of the convex objective function $|y_i - c_i|$ into a piecewise-linear convex function $f_i(y_i)$ with integral breakpoints (shown in bold lines).*

Thus, we obtain the following problem (P2):

$$\begin{aligned} \text{(P2)} : \text{minimize} \quad & \sum_{R_i \in \mathcal{F}} f_i(y_i) \\ \text{subject to} \quad & y_i = \sum_{(j,k) \in R_i} b_{jk}, \ i = 1, \ldots, m = |\mathcal{F}|, \\ \text{and} \quad & B \in \mathcal{B}(G_{MN}). \end{aligned}$$

Thus, we can formulate the problem into an integer programming problem where the objective function is a separable piecewise-linear convex function.

2.2. Relaxation and totally unimodularity. Let (P3) be the continuous relaxation obtained from (P2) by replacing the integral condition of b_{ij} with the condition $0 \le b_{ij} \le 1$. Note that this is different from the continuous relaxation of (P1), since the objective function of (P2) is larger than that of (P1) at nonintegral values.

If the matrix is totally unimodular, (P3) has an integral solution by the theorem below. This is a key to derive discrepancy bounds and also algorithms.

THEOREM 2.1 (Hochbaum and Shanthikumar [11]). *A nonlinear separable convex optimization problem* $\min\{\sum_{i=1}^{n} f_i(x_i) \mid Ax \ge b\}$ *on linear constraints with a totally unimodular matrix A can be solved in polynomial time.*

This theorem is translated into our terminologies as follows.

COROLLARY 2.2. *The matrix rounding problem $\mathcal{P}(G_{MN}, \mathcal{F}, p)$ for $p < \infty$ is solved in polynomial time in $n = MN$ if its associated incidence matrix $\mathcal{C}(G_{MN}, \mathcal{F})$ is totally unimodular.*

3. Geometric families of regions defining unimodular hypergraphs. In this section we consider interesting classes of families whose associated incidence matrices are totally unimodular. We call such a family a *unimodular family*, since the associated hypergraph is unimodular. A family $\mathcal{F} = \{R_1, R_2, \ldots, R_m\}$ is a *partition family* (or a partition) of G_{MN} if $\bigcup_{i=1}^{m} R_i = G_{MN}$ and $R_i \cap R_j = \emptyset$ for any $R_i \neq R_j$ in $\mathcal{F}$. A *k-partition family* is a family of regions on a matrix which is the union of k different partitions of G_{MN}.

A family $\mathcal{F}$ of regions on a grid G_{MN} is a *laminar family* if one of the following holds for any pair R_i and R_j in $\mathcal{F}$: (1) $R_i \cap R_j = \emptyset$, (2) $R_i \subset R_j$, or (3) $R_j \subset R_i$. The family is also called a laminar decomposition of the grid G_{MN}. In general, a *k-laminar family* is a family of regions on a matrix which is the union of k different laminar families.

PROPOSITION 3.1. *A 2-laminar family is unimodular.*

Direct applications of Proposition 3.1 lead to various unimodular families of regions. The family of regions defined in Baranyai's theorem is a 2-laminar family. Also, take any 2-partition family consisting of 2×2 regions on a matrix. For example, take all 2×2 regions with their upper left corners located in even points (where the sums of their row and column indices are even). The set of all those regions defines 2-partition families $\mathcal{F}_{even}$ and $\mathcal{F}_{odd}$, where $\mathcal{F}_{even}$ (resp., $\mathcal{F}_{odd}$) consists of all 2×2 squares with their upper left corners lying at even (resp., odd) rows (see Figure 2). This kind of family plays an important role in section 5.2 and also in our experiment.

A 3-partition family is not unimodular in general. However, there are some families which are not 2-laminar but unimodular: For example, the set of all rectangular rigid submatrices of size 2 (i.e., domino tiles) is a 4-partition family, but it is unimodular.

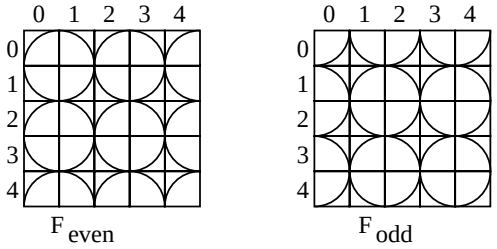

FIG. 2. *2-partition family of* 2×2 *regions.*

4. Algorithms for computing the optimal rounding. The arguments so far guarantee the polynomial-time solvability of our problem. However, we needed a more practical algorithm for our experiments that runs fast for large-scale problem instances. In this section we will show how to solve the matrix rounding problem for a 2-laminar family based on the minimum-cost flow algorithm. To improve the readability, we mainly discuss the case for the L_1-discrepancy measure.

Our main result is the following.

THEOREM 4.1. *Given a* $[0,1]$*-matrix* A *and a 2-laminar family* $\mathcal{F}$*, an optimal binary matrix* B *that minimizes the distance* $Dist_1^{\mathcal{F}}(A,B)$ *is computed in* $O(n^2 \log^2 n)$ *time, where* n *is the number of matrix elements.*

Proof. We can transform the problem into that of finding a minimum-cost circulation flow in the network defined as follows.

Let $\mathcal{F}$ be a 2-laminar family given as the union of two laminar families $\mathcal{F}_1 = \{R_0, R_1, \ldots, R_m\}$ and $\mathcal{F}_2 = \{R'_0, R'_1, \ldots, R'_{m'}\}$ over the grid G_{MN}, where R_0 and R'_0 are the entire region G_{MN}. The network to be constructed consists of three parts. The first part is an in-tree T_1 derived from $\mathcal{F}_1$ whose root is R_0; the second one is an out-tree T_2 from $\mathcal{F}_2$ whose root is R'_0; and the third part connects T_1 and T_2. The lattice structure implied by $\mathcal{F}_1$ naturally defines an in-tree T_1 such that the vertex set is the set of regions in $\mathcal{F}_1$, and there is a directed edge (R_i, R_j) if and only if $R_i \subseteq R_j$ and there is no other region R_k such that $R_j \subseteq R_k \subseteq R_i$. Then each region R_i, $i \geq 1$, has a unique outgoing edge, which is denoted by $e(R_i)$. We can similarly define T_2 for the laminar family $\mathcal{F}_2$, in which the edge direction is reversed in T_2; that is, each node R'_i, $i \geq 1$, has a unique incoming edge, which is denoted by $e(R'_i)$.

In addition, leaves of T_1 and T_2 are connected by edges corresponding to elements of G_{MN}. Because of the definition of $\mathcal{F}_1$ and $\mathcal{F}_2$, each element (k, l) of G_{MN} belongs to exactly one region in $\mathcal{F}_1$ which is a leaf in T_1 and to exactly one region in $\mathcal{F}_2$ which is a leaf in T_2. If (k, l) belongs to R_i and R'_j, then we have a directed edge $e(i, j)$ from R'_j to R_i. Finally, we draw an edge from R_0 to R'_0.

Now we define the capacity and cost coefficient of each edge. (The lower bound on the flow of each edge is defined to be 0.) The capacity of an edge $e(i, j)$ is determined simply as 1 because the value associated with an element of G_{MN} is to be rounded to 0 or 1.

Determining the cost coefficients of edges $e(R_i)$ and $e(R'_j)$ are not straightforward, although the cost coefficients of $e(i, j)$s and $e(R_0, R'_0)$ are defined to be 0s. This is because each term of the objective function depends on the difference between $B(R_i)$ and $A(R_i)$ or between $B(R'_j) - A(R'_j)$; that is, $|B(R_i) - A(R_i)|$ or $|B(R'_j) - A(R'_j)|$.

Recall the argument in section 2: To prove the polynomial-time solvability we have introduced a new variable $y_k = B(R_k) = \sum_{(i,j)\in R_k} b_{ij}$. $|B(R_k) - A(R_k)|$ is converted into $|y_k - c_k|$, where $c_k = A(R_k) = \sum_{(i,j)\in R_k} a_{ij}$ is a constant determined by input values. $|y_k - c_k|$ is further replaced by the piecewise-linear convex function $f_k(y_k)$ which coincides with $|y_k - c_k|$ at each integral value of y_k.

To reflect the new form of the objective function (see Figure 1), we replace each edge $e(R_k)$ by three parallel edges with different capacities and costs: $e_1(R_k)$ has capacity $\lfloor c_k \rfloor$ and cost $c^1 = -1$. $e_2(R_k)$ has capacity $\lceil c_k \rceil - \lfloor c_k \rfloor$ and cost $c^2 = \lfloor c_k \rfloor + \lceil c_k \rceil - 2c_k$. For the third edge $e_3(R_k)$, its capacity is ∞ and its cost is $c^3 = 1$. Since $c^1 \leq c^2 \leq c^3$, to minimize the overall cost for these three edges the flow at $e_2(R_k)$ is zero unless the first edge $e_1(R_k)$ is full; that is, the flow at $e_1(R_k)$ is $\lfloor c_k \rfloor$. Similarly, flow at $e_3(R_k)$ is positive only if the two edges $e_1(R_k)$ and $e_2(R_k)$ are both full.

The cost associated with an edge is determined by multiplying the above coefficient to the flow in the edge. When the total amount of flow in the three edges is given by y_k, the total cost is given by $f_k(y_k) - c_k$ in any case (see, e.g., Ahuja, Magnanti, and Orlin [1]). Since c_k is a constant, the constant term does not affect the optimality.

Once a network is constructed, we can find an optimal rounding in time $O(|E| \log U(|E| + |V| \log |V|))$ for a network with node set V and edge set E and the largest integral capacity U, using the scaling algorithm by Edmonds and Karp [8]. In our case, $|V|$, $|E|$, and U are all $O(n)$, and thus we have $O(n^2 \log^2 n)$, where n is the number of matrix elements. □

THEOREM 4.2. *Given a* $[0, 1]$*-matrix* A *and a 2-laminar family* $\mathcal{F}$*, an optimal binary matrix* B *that minimizes the distance* $Dist_p^{\mathcal{F}}(A, B)$ *(*$p \geq 2$*) can be computed*

in $O(n^2 \log^3 n)$ time.

Proof. In this case, f_i is a piecewise-linear convex function with $O(n)$ break points. We apply the convex-cost flow algorithm [18]. We omit details. □

5. Upper bounds for the L_p discrepancy.

5.1. L_p discrepancy for a unimodular hypergraph. In this subsection, we prove the following theorem for the L_p discrepancy of a unimodular family.

THEOREM 5.1. *If $\mathcal{F}$ is unimodular and $p \leq 3$, for any $A \in \mathcal{A}$ we have*

$$\min_{B \in \mathcal{B}} Dist_p^{\mathcal{F}}(A, B) \leq \frac{1}{2}|\mathcal{F}|^{1/p}.$$

Proof. There exists $\hat{B} \in \mathcal{B}$ such that $|\hat{B}(R_i) - A(R_i)| \leq 1$ holds for any R_i. The existence of such $\hat{B}$ is known by Theorem 1.2. However, for completeness, we shall give the proof. Consider the problem (P2) and its continuous relaxation (P3). It is then obvious that

$$\begin{aligned} &b_{ij} = a_{ij} \text{ for every } i \text{ and } j \text{ and} \\ &y_k = A(R_k) \quad \text{for every} \quad R_k \in \mathcal{F} \end{aligned} \tag{5.1}$$

is a feasible solution to (P3). Now we add lower and upper bound constraints for each variable y_k:

$$\lfloor A(R_k) \rfloor \leq y_k \leq \lceil A(R_k) \rceil.$$

Notice that the addition of these constraints to (P3) maintains total unimodularity of the constraints. Let (P4) denote the problem (P3) with these constraints. Since $f_k(y_k)$ is a linear function in the interval $[\lfloor A(R_k) \rfloor, \lceil A(R_k) \rceil]$, (P4) is a linear program.

Since (P3) has a feasible solution satisfying all constraints of (P4), (P4) also has a feasible solution. Since (P4) is a linear program over totally unimodular constraints, its optimal solution is an integral solution, and the corresponding objective value gives an upper bound on the optimal objective value of (P2). Thus, the objective value for (P4) of the above defined feasible solution gives an upper bound on the optimal objective value of (P2).

Let us now estimate the upper bound on $f_k(y_k)$ at $y_k = A(R_k)$. Let $a = A(R_k) - \lfloor A(R_k) \rfloor$. We then have $f_k(\lfloor A(R_k) \rfloor) = a^p$ and $f_k(\lceil A(R_k) \rceil) = (1-a)^p$. Therefore,

$$f_k(A(R_k)) = a^p(1-a) + (1-a)^p a \tag{5.2}$$

holds. We can see $f_k(A(R_k)) \leq (1/2)^p$ holds if $p \leq 3$. Thus, the optimal objective value of (P4) is at most $(1/2)^p|\mathcal{F}|$. Since the optimal objective value of (P4) is an upper bound on that for (P2), $(1/2)^p|\mathcal{F}|$ gives an upper bound on the optimal objective value for (P2). □

It is easy to give an instance to show that the bound is tight: Consider Baranyai's problem on a matrix having $\frac{1}{2}$ entries in its diagonal position (other entries are zeros).

For the case $p > 3$, we have the following.

THEOREM 5.2. *If $\mathcal{F}$ is unimodular and $p > 3$, for any $A \in \mathcal{A}$ we have*

$$\begin{aligned} &\min_{B \in \mathcal{B}} Dist_p^{\mathcal{F}}(A, B) \\ &\leq (p^p/(p+1)^{p+1} + 2^p(p-1)/(p+1)^{p+1})^{1/p}|\mathcal{F}|^{1/p}. \end{aligned}$$

Proof. This follows from the fact that $a^p(1-a)+(1-a)^p a < p^p/(p+1)^{p+1} + 2^p(p-1)/(p+1)^{p+1}$ for $0 \le a \le 1$. □

The term $(p^p/(p+1)^{p+1} + 2^p(p-1)/(p+1)^{p+1})^{1/p}$ is 0.550 and 0.587 if $p=4$ and $p=5$, respectively, and it is always less than $p/(p+1)$.

5.2. Discrepancy bounds for the family of 2×2 regions. The method in the previous subsection does not work for a nonunimodular case. A simple but interesting family defining a nonunimodular hypergraph is the family of all 2×2 regions of A. The known upper bound is merely $\frac{5}{3}|\mathcal{F}|^{1/p}$ from the corresponding L_∞ result [3]. We obtain the following result.

THEOREM 5.3. *For any $A \in \mathcal{A}(G_{MN})$ and a family $\mathcal{F}$ of 2×2 regions of the matrix, we have*

$$\min_{B \in \mathcal{B}} Dist_1^{\mathcal{F}}(A,B) \le \frac{3}{4}|\mathcal{F}|.$$

Proof. Let us consider the matrix rounding problem $P = \mathcal{P}(G_{MN}, \mathcal{F}, 1)$ for the family $\mathcal{F}$ of all 2×2 regions. We define another problem $\hat{P}$ defined over another family $\hat{\mathcal{F}}$ of regions consisting of two tiles:

$$\mathcal{T}_1 = \{(i,j),(i+1,j)\} \text{ for } (i,j) \in G_{MN},$$
$$\mathcal{T}_2 = \{(i,j),(i+1,j),(i,j+1),(i+1,j+1)\} \text{ for } (i,j) \in G_{MN} \text{ and } i+j = \text{even}.$$

Let B^* and $\hat{B}$ denote the optimal binary matrix for P and $\hat{P}$, respectively.

We now show

$$\sum_{R \in \mathcal{F}} |A(R) - B^*(R)| \le 3|\mathcal{F}|/4.$$

Let (R_1, R_2) be a partition of a 2×2 region R into two disjoint 2×1 regions. Then for any A and B we have

$$\begin{aligned} &|A(R) - B(R)| \\ &\le |A(R_1) - B(R_1)| + |A(R_2) - B(R_2)|. \end{aligned} \tag{5.3}$$

Recall that $\mathcal{F}$ consists of all 2×2 regions and $\hat{\mathcal{F}}$ consists of constrained 2×2 regions and all 2×1 regions. Then $\mathcal{F} \backslash \hat{\mathcal{F}}$ consists of 2×2 regions that are not included in $\hat{\mathcal{F}}$, $\mathcal{F} \cap \hat{\mathcal{F}}$ consists of 2×2 regions that are included in $\hat{\mathcal{F}}$, and $\hat{\mathcal{F}} \backslash \mathcal{F}$ consists of all 2×1 regions. Now we have

$$\begin{aligned} &\sum_{R \in \mathcal{F}} |A(R) - B^*(R)| \\ &= \sum_{R \in \mathcal{F} \backslash \hat{\mathcal{F}}} |A(R) - B^*(R)| + \sum_{R \in \mathcal{F} \cap \hat{\mathcal{F}}} |A(R) - B^*(R)| \\ &\le \sum_{R \in \mathcal{F} \backslash \hat{\mathcal{F}}} |A(R) - \hat{B}(R)| + \sum_{R \in \mathcal{F} \cap \hat{\mathcal{F}}} |A(R) - \hat{B}(R)| \\ &\le \sum_{R \in \mathcal{F} \cap \hat{\mathcal{F}}} |A(R) - \hat{B}(R)| + \sum_{R \in \hat{\mathcal{F}} \backslash \mathcal{F}} |A(R) - \hat{B}(R)| \\ &\quad \text{(from (5.3))} \\ &= \sum_{R \in \hat{\mathcal{F}}} |A(R) - \hat{B}(R)|. \end{aligned} \tag{5.4}$$

Since $\hat{\mathcal{F}}$ is a 2-laminar family, its associated incidence matrix is totally unimodular. As in the proof of Theorem 5.1, we consider the linear program $\hat{Q}'$ which is a continuous relaxation of $\hat{P}$ with the additional constraints

$$\lfloor A(R_k) \rfloor \leq y_k \leq \lceil A(R_k) \rceil$$

for all $R_k \in \hat{\mathcal{F}}$. From the total unimodularity of the incidence matrix, there exists an optimal solution to $\hat{Q}'$ such that it is integral. Let $\hat{B}'$ denote such solution. For a feasible solution to $\hat{Q}'$ defined by

$$\begin{aligned} &b_{ij} = a_{ij} \text{ for every } i \text{ and } j \\ &\quad \text{and } y_k = A(R_k) \text{ for every } R_k \in \hat{\mathcal{F}}, \end{aligned} \tag{5.5}$$

its objective value gives an upper bound on the optimal objective value of $\hat{Q}'$ which in turn gives an upper bound on the optimal objective value of $\hat{P}$. Therefore, we have

$$\begin{aligned} \sum_{R_k \in \hat{\mathcal{F}}} |A(R_k) - \hat{B}(R_k)| &\leq \sum_{R_k \in \hat{\mathcal{F}}} |A(R_k) - \hat{B}'(R_k)| \\ &\leq \sum_{R_k \in \hat{\mathcal{F}}} f_k(A(R_k)). \end{aligned} \tag{5.6}$$

From Theorem 5.1, the rightmost term of (5.6) is bounded by $|\hat{\mathcal{F}}|/2$, which is almost equal to $3|\mathcal{F}|/4$ for a sufficiently large n. This completes the proof of the theorem. □

6. Application to digital halftoning. The quality of color printers has been drastically improved in recent years, mainly based on the development of the fine control mechanism. On the other hand, there seems to be no great invention on the software side of the printing technology. What is required is a technique to convert a continuous-tone image into a binary image consisting of black and white dots so that the binary image looks very similar to the input image. From a theoretical standpoint, the problem is how to approximate an input $[0,1]$-array by a binary array. Since this is one of the central techniques in computer vision and computer graphics, a great number of algorithms have been proposed (see, e.g., [13, 9, 4, 15, 17]). However, there have been very few studies toward the goal of achieving an optimal binary image under some reasonable criterion; maybe it is because the problem itself is very practically oriented. A desired output image is the one which looks similar to the input image to the human visual system. The most popular distortion criterion that is used in practice is perhaps frequency weighted mean square error (FWMSE) [16], which is defined by

$$W(G,X) = \sum_{(i,j) \in G_{MN}} \left[\sum_{k=-K}^{K} \sum_{l=-K}^{K} v_{|k||l|} a_{i+k,j+l} - \sum_{k=-K}^{K} \sum_{l=-K}^{K} v_{|k||l|} b_{i+k,j+l} \right]^2.$$

Here, $V = (v_{|k||l|})$, $-K \leq k, l \leq K$, is an impulse response that approximates the characteristics of the human visual system and K is some small constant, say 3. Our discrepancy measure which has been discussed in this paper is a hopeful replacement. Indeed, the L_2-discrepancy measure can be regarded as a simplified version of the FWMSE criterion.

We have implemented the algorithm using LEDA [14] functions for finding minimum-cost flow and applied it to several test images to compare its results with the error diffusion algorithm which is most commonly used in practice. The data we used for our experiments are *standard high precision picture data* created by the Institute of Image Electronics Engineers of Japan, which include four standard pictures called "Bride," "Harbor," "Wool," and "Bottles." They are color pictures of eight bits each in RGB. Their original picture size is 4096×3072. In our experiments we scaled them down to 1024×768 in order to shorten the running time of the program. Figure 3 shows experimental results for "Wool" to compare our algorithm with error diffusion. Our algorithm has been implemented using a 2-laminar family defined by the two tiles (b) and (c) depicted in Figure 4. We have used the L_1 measure. By our experience through experiments, it seems hard to have such a nice-looking output by the L_∞ measure.

FIG. 3. *Experimental results. Output images by the error diffusion algorithm (above) and the algorithm in this paper (below).*

7. Concluding remarks. We have considered the matrix rounding problem based on L_p-discrepancy measure. Although we have shown that the measure is useful in application to the digital-halftoning application, the current algorithm is too

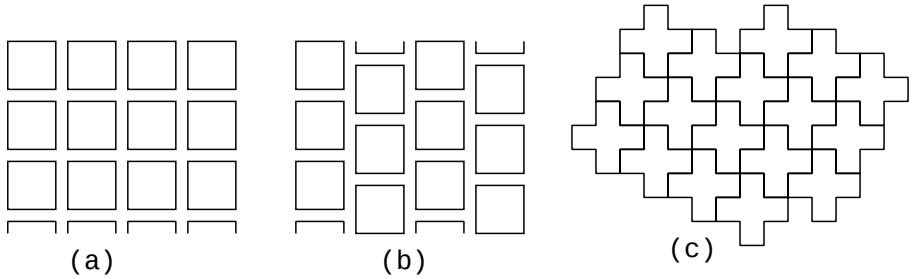

FIG. 4. *Three different partitions of the image plane* (a) *by* 2×2 *squares,* (b) *vertically shifted* 2×2 *squares, and* (3) *cross patterns consisting of five pixels.*

slow if we want to require speed together with the high-quality requirement. The problem comes from the quadratic time complexity. It is desired to design a faster algorithm (even an approximation algorithm). Moreover, it is an interesting question to investigate what kind of region families give the best criterion for the halftoning application. Once we know such a region family, it is valuable to design an algorithm (heuristic algorithm if the problem for solving the optimal solution is intractable) for the criterion.

Acknowledgments. The authors would like to thank Tomomi Matsui, Koji Nakano, and Hiroshi Nagamochi for their valuable comments and helpful discussions.

FINDING POINTS ON CURVES OVER FINITE FIELDS*

JOACHIM VON ZUR GATHEN†, IGOR SHPARLINSKI‡, AND ALISTAIR SINCLAIR§

Abstract. We solve two computational problems concerning plane algebraic curves over finite fields: generating a uniformly random point, and finding all points deterministically in amortized polynomial time (over a prime field, for nonexceptional curves).

Key words. finite fields, algebraic curves, algebraic geometry, computer algebra, probabilistic algorithms, random sampling

DOI. 10.1137/S0097539799351018

1. Introduction.

Let q be a prime power, let $\mathbb{F}_q$ be a finite field with q elements, let $f \in \mathbb{F}_q[x, y]$ of total degree n, and let $\mathcal{C} = \{(a, b) \in \mathbb{F}_q^2 : f(a, b) = 0\} = \{f = 0\}$ be the plane curve defined by f. We consider two problems of finding points on this curve: probabilistically finding a uniformly distributed random point, and deterministically computing all its points.

Curves over finite fields play a role in several applications: factoring integers with elliptic curves, testing primality with elliptic curves (or more general algebraic varieties), algebro-geometric Goppa codes, and fast multiplication over finite fields. For these applications, special methods for finding points (if needed) are used. This paper presents the first general and systematic approach to the problem, to the authors' knowledge.

Throughout this paper, we will assume that f is squarefree and denote by σ the number of absolutely irreducible components of $\mathcal{C}$ which are defined over $\mathbb{F}_q$. The famous theorem of Weil says that the number of points $\#\mathcal{C}$ on $\mathcal{C}$ satisfies

$$| \#\mathcal{C} - \sigma q | \leq n^2 q^{1/2}. \tag{1.1}$$

The case of an *exceptional curve*, corresponding to $\sigma = 0$, needs special treatment and is dealt with in section 5. So for now we assume that $\sigma \geq 1$.

In section 2, we provide a polynomial-time solution for the probabilistic variant of our question: generating a uniform random point on $\mathcal{C}$. The algorithm is elementary and is based on the idea of rejection sampling. We also use this algorithm to obtain arbitrarily good probabilistic estimates of $\#\mathcal{C}$.

With deterministic methods, the "brute force" approach to computing all points on $\mathcal{C}$ via finding, for each $a \in \mathbb{F}_q$, all $b \in \mathbb{F}_q$ with $f(a, b) = 0$ takes $O^{\sim}(n^2 q^{3/2})$ operations in $\mathbb{F}_q$, using the fastest known deterministic algorithms to factor the univariate

polynomial $f(a,y)$ for all $a \in \mathbb{F}_q$ (Shoup (1990), section 1.1 of Shparlinski (1999), von zur Gathen and Shoup (1992)). We present in section 3 a deterministic method that uses $O^{\sim}(n^5 q)$ operations, i.e., polynomial time per point. The central tool for our estimates is a bound of Perel'muter (1969) on a certain exponential sum. In order to use this, we have to study in section 4 some geometric and arithmetic properties of the fiber square $\mathcal{C} \times_\pi \mathcal{C}$. Our approach works only in the case of a prime field $\mathbb{F}_q$, with $q = p$ prime, and does not work for exceptional curves.

Shoup (1990) has exhibited a deterministic univariate factoring algorithm which for almost all polynomials runs in polynomial time. Our deterministic result has two interpretations: the first is that the members of a "small" parametrized family $f(a,y)$ of univariate polynomials for all $a \in \mathbb{F}_p$ can be factored deterministically in (amortized) polynomial time. The second is that all points on a plane algebraic curve over $\mathbb{F}_p$ can be found deterministically in (amortized) polynomial time.

Finally, section 5 presents a discussion of the case of exceptional curves which has been excluded in the other sections.

A different set of results on our problem (and higher-dimensional varieties) was obtained by Adleman and Huang (2001), Huang and Wong (1999), Huang and Ierardi (1998), and Huang and Wong (1998).

2. Generating uniform random points. In order to generate random points on a plane curve, it is natural to take random points on a coordinate axis and compute points "above" them. So let $\pi\colon \mathcal{C} \to \mathbb{F}_q$ be the projection onto the first coordinate. For $0 \le i \le n$, let

$$R_i = \{a \in \mathbb{F}_q \colon \#\pi^{-1}(\{a\}) = i\}$$

be the set of points with exactly i preimages, and let $r_i = \#R_i$. We assume that $\mathcal{C}$ contains no vertical lines so that no $x-a$ with $a \in \mathbb{F}_q$ divides f. Then $\mathbb{F}_q = \bigcup_{0\le i\le n} R_i$ is a partition, and

$$q = \sum_{0\le j\le n} r_j, \quad \#\mathcal{C} = \sum_{1\le j\le n} j r_j.$$

Algorithm 2.1 (random point).
Input: $f \in \mathbb{F}_q[x,y]$ of degree n.
Output: Either a uniform random point (a,b) on $\mathcal{C} = \{f = 0\} \subseteq \mathbb{F}_q^2$, or "failure".

1. Choose $a \in \mathbb{F}_q$ uniformly at random.
2. Compute $f_a = \gcd(y^q - y, f(a,y)) \in \mathbb{F}_q[y]$.
3. Choose a random root $b \in \mathbb{F}_q$ of f_a. [Then $(a,b) \in \mathcal{C}$.]
4. Set $i = \deg f_a$. [Then $a \in R_i$.]
5. Choose YES with probability i/n, and NO with probability $1 - i/n$. If YES was chosen, return (a,b), and otherwise return "failure".

Theorem 2.2. *Suppose that $\mathcal{C}$ is a nonexceptional curve without vertical lines. Then the algorithm returns a uniform random point on $\mathcal{C}$ with probability*

$$\frac{\#\mathcal{C}}{nq} \ge \frac{1}{n}\left(1 - n^2 q^{-1/2}\right),$$

and "failure" with probability $1 - \#\mathcal{C}/nq$. For every $P \in \mathcal{C}$, P is returned with probability $1/nq$. The algorithm can be performed with an expected number of $O(n \log n \log(nq) \cdot \operatorname{loglog} n)$ operations in $\mathbb{F}_q$.

Proof. Let $P = (a, b) \in \mathcal{C}$ with $a \in R_i$. Then

$$\text{prob}\{P \text{ is returned}\} = \frac{1}{q} \cdot \frac{1}{i} \cdot \frac{i}{n} = \frac{1}{nq}.$$

We denote by $\mathsf{M}(n)$ a *multiplication time* so that the product of two polynomials in $\mathbb{F}_q[x]$ of degree at most n can be computed with $O(\mathsf{M}(n))$ operations in $\mathbb{F}_q$. Then we can take $\mathsf{M}(n) = n \log n \log\log n$, and a gcd can be computed with $O(\mathsf{M}(n) \log n)$ operations. Using repeated squaring to calculate $y^q \bmod f(a, y)$ with $O(\mathsf{M}(n) \log q)$ operations, the cost of step 2 is $O(\mathsf{M}(n) \log(nq))$. The polynomial f_a is a product of $i = \deg f_a$ many linear factors in $\mathbb{F}_q[x]$. If we find a root using the randomized algorithms of Cantor and Zassenhaus (1981), it will be uniformly randomly distributed among these i roots. The algorithm splits the polynomial recursively into two factors, one of which is $\gcd(y^{(q-1)/2} - 1, f_a(y + b))$ for a random $b \in \mathbb{F}_q$, and continues with the smaller factor. (For even q, a different formula is used.) We expect $O(\log i)$ splits to suffice, and each costs $O(\mathsf{M}(i) \log(qi))$ operations in $\mathbb{F}_q$. □

We think of q as being much larger than n, say, $q \geq c^2 n^4$ for some constant c. Then the success probability of Algorithm 2.1 is at least $\frac{1}{n}(1 - c^{-1})$. Of course, we can increase the success probability by repeated runs of the algorithm.

We can adapt Algorithm 2.1 to obtain an arbitrarily good approximation for $\#\mathcal{C}$, the number of points on $\mathcal{C}$. An (ϵ, δ)-*approximation* ρ to $\#\mathcal{C}$ satisfies

$$\text{prob}\ \{|\ \rho - \#\mathcal{C}\ | \leq \epsilon \#\mathcal{C}\} \geq 1 - \delta.$$

To achieve this, we simply run Algorithm 2.1 k times, count the number t of times that YES was chosen in step 5, and return the value $\rho = tnq/k$. Since YES is output with probability $\#\mathcal{C}/nq$, the expected value of ρ is exactly $\#C$, so it is an unbiased estimator. The unbiased estimator theorem of Karp, Luby, and Madras (1989) tells us how large k, the number of samples, should be to guarantee an (ϵ, δ)-approximation. This value is

$$k = \lceil 4\beta \log_e(2/\delta) \epsilon^{-2} \rceil, \tag{2.1}$$

where β is an upper bound on $nq/\#\mathcal{C}$. However, $nq/\#\mathcal{C} \leq n(1 - n^2 q^{-1/2})^{-1}$, so β is not very large. In fact, assuming as before that $q \gg n^4$, the number of samples required is only about $4n \log_e(2/\delta)\epsilon^{-2}$.

It is even easier in principle to estimate the individual r_i's. We choose k random values $a \in \mathbb{F}_q$, determine for each the j with $a \in R_j$, count the number t of times that $j = i$ occurred, and return the value $\rho_i = tq/k$. This is obviously an unbiased estimator of r_i, and the number of samples required for an (ϵ, δ)-approximation is as in (2.1), where now $\beta = \beta_i$ is an upper bound on q/r_i. With a parameter α, this implies that, by taking

$$k = \lceil 4\alpha n \log_e(2/\delta) \epsilon^{-2} \rceil,$$

we get an (ϵ, δ)-approximation for any r_i satisfying $r_i \geq q/\alpha$. Since

$$n \sum_{1 \leq i \leq n} r_i \geq \sum_{1 \leq i \leq n} i r_i = \#\mathcal{C},$$

the r_i's are on average at least $\#\mathcal{C}/n^2 \geq q(n^{-2} - q^{-1/2})$. Thus "on average" k will only be about $4n^2 \log_e(2/\delta)\epsilon^{-2}$, assuming as before that $q \gg n^4$. Such a value will

enable us to estimate the "large" r_i's though not, of course, the small ones. In fact, when q is large compared to n^{6n}, then the r_i separate into two classes: Lemma 2.3 of von zur Gathen and Shparlinski (1998) implies that either $r_i \geq \frac{q}{i!(n-i)!} - 2n^{2n}q^{1/2}$ is reasonably large or $r_i \leq 2n^{2n}q^{1/2}$ is very small. Of course, the "reasonably large" may still be very small, and about q/r_i samples are required. Thus if we use $\beta_i = n!$, then in the first case we obtain an (ϵ, δ)-approximation scheme for r_i, and in the second we expect to find no $a \in R_i$.

Since

$$\frac{\#\mathcal{C}}{n} \leq \sum_{1 \leq i \leq n} r_i \leq \sum_{1 \leq i \leq n} i r_i = \#\mathcal{C},$$

the r_i's are on average at least $\#\mathcal{C}/n^2$. To find approximations only to the "large" r_i's, we might use $\beta_i = \lambda n^2$, with some small number λ.

3. Deterministic construction of all points. In this section, we present a deterministic algorithm for finding all points on $\mathcal{C} = \{f = 0\}$ over a prime field $\mathbb{F}_p$. It employs a deterministic polynomial-time algorithm for finding all roots of the univariate polynomials $f(a, y)$, with $a \in \mathbb{F}_p$. This algorithm does not factor $f(a, y)$ completely for all a, but we show that there are only about $\sqrt{p}$ exceptional a, and for these we use an always successful deterministic algorithm with time about $\sqrt{p}$; thus the total time is proportional to p, which is about the size of $\mathcal{C}$. Everything is polynomial in the degree n.

As a first step, we factor f into irreducible factors in $\mathbb{F}_p[x, y]$. The bivariate factoring algorithms (Lenstra (1985), von zur Gathen (1984), von zur Gathen and Kaltofen (1985)) can actually be made into deterministic reductions from bivariate to univariate factorization over finite fields. Thus f can be factored with $n^{O(1)}p^{1/2}$ operations in $\mathbb{F}_p$. From now on, we assume that f is irreducible.

The projection $\pi : \mathcal{C} = \{f = 0\} \to \mathbb{F}_p$ onto the first coordinate is called *separable* if and only if $h_y = \partial h/\partial y \neq 0$ for each irreducible factor $h \in \mathbb{F}_p[x, y]$ of f. A simple example of an inseparable projection is given by $f = x - y^p \in \mathbb{F}_p[x, y]$. The curve $\mathcal{C} = \{x = y^p\}$ is smooth, and all tangents to $\mathcal{C}$ are vertical.

Let $\varphi: \mathbb{F}_p \to \mathbb{F}_p$ denote the absolute Frobenius map, with $\varphi(a) = a^p$. For our algorithms, it is convenient to have π separable, and the next lemma describes a simple procedure for achieving this by factoring out φ. (It actually works over any finite field of characteristic p.)

LEMMA 3.1. *Let $f \in \mathbb{F}_p[x, y]$ be irreducible. We can compute in polynomial time $g \in \mathbb{F}_p[x, y]$ and an integer $k \leq \log_p(\deg_y f)$ such that*

$$\mathrm{id} \times \varphi^k: \mathbb{F}_p^2 \longrightarrow \mathbb{F}_p^2$$

gives a bijection between $\{f = 0\}$ and $\{g = 0\}$, $\deg_x g = \deg_x f, \deg_y g \leq \deg_y f$, and $\pi: \{g = 0\} \to \mathbb{F}_p$ is separable.

Proof. We write $f = \sum_{i,j} f_{ij} x^i y^j$, with each $f_{ij} \in \mathbb{F}_p$. Then

$$f_y = 0 \Longleftrightarrow \forall i, j \ (f_{ij} \neq 0 \Rightarrow p \mid j).$$

If $f_y = 0$ and

$$h = \sum_{\substack{i,j \\ p \mid j}} f_{ij} x^i y^{j/p} \in \mathbb{F}_p[x, y],$$

then $f(a,b) = h(a,b^p)$ for all $(a,b) \in \mathbb{F}_p^2$, and thus $\mathrm{id} \times \varphi: \mathbb{F}_p^2 \to \mathbb{F}_p^2$ gives a bijection between $\{f=0\}$ and $\{h=0\}$. Furthermore, h is irreducible. We repeat this process until we obtain a polynomial $g \in \mathbb{F}_p[x,y]$ and $k \in \mathbb{N}$ with $g_y \neq 0$ and $\mathrm{id} \times \varphi^k$ a bijection between $\{f=0\}$ and $\{g=0\}$. □

ALGORITHM 3.2 (finding all points).
Input: $f \in \mathbb{F}_p[x,y]$ of degree n, where p is a prime.
Output: A list of all points $(a,b) \in \mathbb{F}_p^2$ with $f(a,b) = 0$.

1. Set $h = 288n^4\lceil \log_2 p \rceil^2$.
2. For all $a \in \mathbb{F}_p$
3. Compute $f_a = f(a,y) \in \mathbb{F}_p[y]$.
4. Compute $f_a^* = \gcd(y^p - y, f_a) \in \mathbb{F}_p[y]$.
5. For $0 \le t < h$ compute the two factors

$$g_{a,t} = \gcd\big((y-t)^{(p-1)/2} - 1, f_a^*\big),\ g_{a,t}^* = \gcd(y-t, f_a^*) \in \mathbb{F}_p[y]$$

of f_a^*.
6. Compute the common refinement of the partial factorizations from step 5.
7. If step 6 returns only linear factors $y-b$, then add all these (a,b) to the list. Otherwise, completely factor f_a^* with the deterministic algorithm of von zur Gathen and Shoup (1992), and add all resulting (a,b) to the list.

THEOREM 3.3. *Let p be a prime, $f \in \mathbb{F}_p[x,y]$ squarefree and nonexceptional, and $\pi: \mathcal{C} = \{f=0\} \to \mathbb{F}_p$ separable. Then the algorithm correctly computes all points on $\mathcal{C}$. It uses*

$$O(n^5 p \log n \operatorname{loglog} n \log(np) \log^2 p)$$

or $O^{\sim}(n^5 p)$ operations in $\mathbb{F}_p$.

Proof. For all $a, b \in \mathbb{F}_p$, we have

$$f(a,b) = 0 \iff f_a^*(b) = 0 \iff y - b \mid f_a^*.$$

Since step 7 returns all linear factors of f_a^*, the final list correctly contains all points of $\mathcal{C} = \{f=0\}$.

It remains to analyze the running time. The crucial point is to understand when step 6 succeeds in completely factoring f_a^*. Denote by $S \subseteq \mathbb{F}_p$ the set of all a for which this is not the case, and $s = \#S$. Furthermore, $\mathcal{C}_a = \pi_2(\mathcal{C} \cap (\{a\} \times \mathbb{F}_p))$ consists of all $b \in \mathbb{F}_p$ with $(a,b) \in \mathcal{C}$. Thus

$$S = \{a \in \mathbb{F}_p : \exists b, c \in \mathcal{C}_a\ b \neq c; b, c \ge h,\ \text{and } \forall t < h\ (y-b \mid g_{a,t} \iff y-c \mid g_{a,t})\}.$$

The refinement cost in step 6, if done along a binary tree, is $O(\mathsf{M}(n)\log n)$ for each t, or $O(h\,\mathsf{M}(n)\log n)$ in total. For $a \in S$, an application of the algorithm from von zur Gathen and Shoup (1992) costs $O(\mathsf{M}(n)\, p^{1/2} \log(np))$ operations in $\mathbb{F}_p$. The gcds in steps 4 and 5 are computed by repeated squaring for the required power of y and $y-t$, reducing after each multiplication modulo f_a and f_a^*, respectively.

For each a in step 2, we find the following number of operations in $\mathbb{F}_p$:

- step 3: $O(n^2)$,
- step 4: $O(\mathsf{M}(n)\log(np))$,
- step 5: $O(h\,\mathsf{M}(n)\log(np))$,
- step 6: $O(h\,\mathsf{M}(n)\log n)$,

∘ step 7: 0 if $a \in \mathbb{F}_p \setminus S$, and $O(\mathsf{M}(n)\, p^{1/2} \log(np))$ if $a \in S$.

The total cost is

$$O\big(p \cdot (n^2 + n^4 \mathsf{M}(n) \log(np) \log^2 p) + s\, \mathsf{M}(n) p^{1/2} \log(np)\big) \tag{3.1}$$

operations, and we now show that s is $O(n^2(n^2 + \log p)p^{1/2})$. This will imply the claim about the running time. We let

$$Q = \{u \in \mathbb{F}_p^\times : \exists v \in \mathbb{F}_p^\times \ u = v^2\} = \{u \in \mathbb{F}_p^\times : u^{(p-1)/2} = 1\}$$

be the set of nonzero squares in $\mathbb{F}_p$ and χ the quadratic character on $\mathbb{F}_p$, with

$$\chi(b) = \begin{cases} 1 & \text{if } b \in Q, \\ -1 & \text{if } b \notin Q,\ b \neq 0, \\ 0 & \text{if } b = 0. \end{cases}$$

For the time being, we work with an arbitrary integer parameter h; only at the end will we substitute the value from step 1. Set $H = \{0, \dots, h-1\} \subseteq \mathbb{F}_p$, where we identify $\mathbb{F}_p$ with $\{0, \dots, p-1\}$. Two distinct elements $b, c \in \mathbb{F}_p$ are *h-separated* if and only if $\chi(b-t) \neq \chi(c-t)$ for some $t \in H$. A set $B \subseteq \mathbb{F}_p$ is *h-separated* if any two distinct elements of B are. With this notation, we have, for $a \in \mathbb{F}_p$,

$$a \in S \Longrightarrow \mathcal{C}_a \text{ is not } h\text{-separated}.$$

The reverse implication is true if the non-h-separated $b, c \in \mathcal{C}_a$ are both at least h. If $a \in S$, then, for at least one pair of distinct elements $b, c \in \mathcal{C}_a$,

$$h = \sum_{0 \le t < h} \chi\big((t-b)(t-c)\big).$$

Now we let $k \in \mathbb{N}$ and

$$\begin{aligned} w &= \sum_{a \in \mathbb{F}_p} \sum_{\substack{b,c \in \mathcal{C}_a \\ b \neq c}} \Big| \sum_{0 \le t < h} \chi\big((t-b)(t-c)\big)\Big|^{2k} \\ &= \sum_{0 \le t_1, \dots, t_{2k} < h} \ \sum_{a \in \mathbb{F}_p} \sum_{\substack{b,c \in \mathcal{C}_a \\ b \neq c}} \chi\big((t_1-b)(t_1-c)\cdots(t_{2k}-b)(t_{2k}-c)\big). \end{aligned}$$

Then, by the above, $sh^{2k} \le w$. We consider the set

$$\mathcal{D}_0 = \{(a,b,c) \in \mathbb{F}_p^3 : f(a,b) = f(a,c) = 0, b \neq c\} \subseteq \mathbb{F}_p^3.$$

The fiber product $\mathcal{D} = \mathcal{C} \times_\pi \mathcal{C}$ is the closure of $\mathcal{D}_0$ in $\mathbb{F}_p^3$; it has degree at most $n(n-1) < n^2$ and is discussed in detail in section 4. Then

$$w = \sum_{t \in H^{2k}} \sum_{P \in \mathcal{D}} \chi\big(\psi_t(P)\big),$$

where the inner sum is over all $\mathbb{F}_p$-rational points $P = (a,b,c) \in \mathcal{D}$ with $b \neq c$, ψ_t is the polynomial

$$\psi_t = (y - t_1)\cdots(y - t_{2k})(z - t_1)\cdots(z - t_{2k}) \in \mathbb{F}_p[y,z]$$

in indeterminates y and z, and $\psi_t((a,b,c))$ is obtained by substituting b and c for y and z, respectively. Theorem 4.4 says that there are at most $(12kn^2h^{1/2})^{2k}$ values of $t \in H^{2k}$ for which $\rho(\psi_t)$ is a square in the global ring $\mathcal{O}_\mathcal{A}$ of some irreducible component $\mathcal{A} \subseteq \mathbb{F}^3$ of $\mathcal{D}$, where $\rho\colon \mathbb{F}[x,y,z] \longrightarrow \mathcal{O}_\mathcal{A}$ is the restriction map.

For other vectors $t \in \mathbb{F}^{2k}$, we may apply the bound on character sums along a curve from Perel'muter (1969) that gives

$$\sum_{P \in \mathcal{D}} \chi\big(\psi_t(P)\big) \le d \cdot \big(n^2(n^2+2k)p^{1/2}\big) \tag{3.2}$$

for some constant d. Perel'muter's bound holds for each irreducible component of $\mathcal{D}$; we also use the fact that no such component is vertical (Lemma 3.1 of von zur Gathen, Karpinski, and Shparlinski (1996)). Since their degrees sum to $\deg \mathcal{D} < n^2$, (3.2) follows. Therefore,

$$w \le (12kn^2h^{1/2})^{2k}p + d \cdot n^2(n^2+2k)h^{2k}p^{1/2},$$

$$s \le (12kn^2h^{-1/2})^{2k}p + d \cdot n^2(n^2+2k)p^{1/2}.$$

Now, using $k = \lceil \log_2 p \rceil$ and h as in step 1 of Algorithm 3.2, we find

$$(12kn^2h^{-1/2})^{2k} \le 2^{-k} \le 2^{-\log_2 p} = p^{-1}.$$

Hence

$$s = O\big(n^2(n^2+\log p)p^{1/2}\big).$$

Together with (3.1), this proves the estimate of the total cost. □

4. Squares on the fiber product. The goal of this section is to bound the number of products Ψ_t which are squares on some irreducible component of $\mathcal{D}$; this was used in the previous proof.

Let $\mathbb{F}$ be an algebraically closed field, let $f \in \mathbb{F}[x,y]$ be squarefree of degree $n \ge 1$, let $\mathcal{C} = \{f = 0\} \subseteq \mathbb{F}^2$ be the associated plane curve, and let $\pi\colon \mathcal{C} \longrightarrow \mathbb{F}$ be the first projection. We assume that π is separable. Then $\mathcal{D} = \mathcal{C} \times_\pi \mathcal{C} \subseteq \mathbb{F}^3$, the fiber square over π, can be defined as the closure in $\mathbb{F}^3$ of

$$\mathcal{D}_0 = \{(a,b,c) \in \mathbb{F}^3 \colon f(a,b) = f(a,c) = 0, b \ne c\}.$$

Furthermore, let $g = (f(x,y) - f(x,z))/(y-z) \in \mathbb{F}[x,y,z]$.

A smooth point $P = (a,b) \in \mathcal{C}$ is *critical* for π if and only if the tangent line $T_{P,\mathcal{C}}$ in $\mathbb{F}^2$ is vertical, as illustrated in Figure 4.1. If f is irreducible, this is equivalent to $f_y(a,b) = 0$, where $f_y = \partial f/\partial y \in \mathbb{F}[x,y]$; in general, we have to replace f by its (unique) irreducible factor on whose component P lies. Since π is separable, $\mathcal{C}$ has only finitely many critical points.

THEOREM 4.1. *Let $f \in \mathbb{F}[x,y]$ be squarefree, and let π be separable.*

(i) $\mathcal{D} = \{f(x,y) = g(x,y,z) = 0\}$.

(ii) $\mathcal{D} = \mathcal{D}_0 \cup \{(a,b,b)\colon (a,b) \in \mathcal{C}$ *is singular or critical*$\}$.

(iii) $(a,b,c) \in \mathcal{D}$ *with $b \ne c$ is singular on $\mathcal{D}$ if and only if either (a,b) or (a,c) is singular on $\mathcal{C}$, or both (a,b) and (a,c) are critical on $\mathcal{C}$. All points of $\mathcal{D} \setminus \mathcal{D}_0$ are singular on $\mathcal{D}$.*

(iv) $\deg \mathcal{D} \le n(n-1) < n^2$.

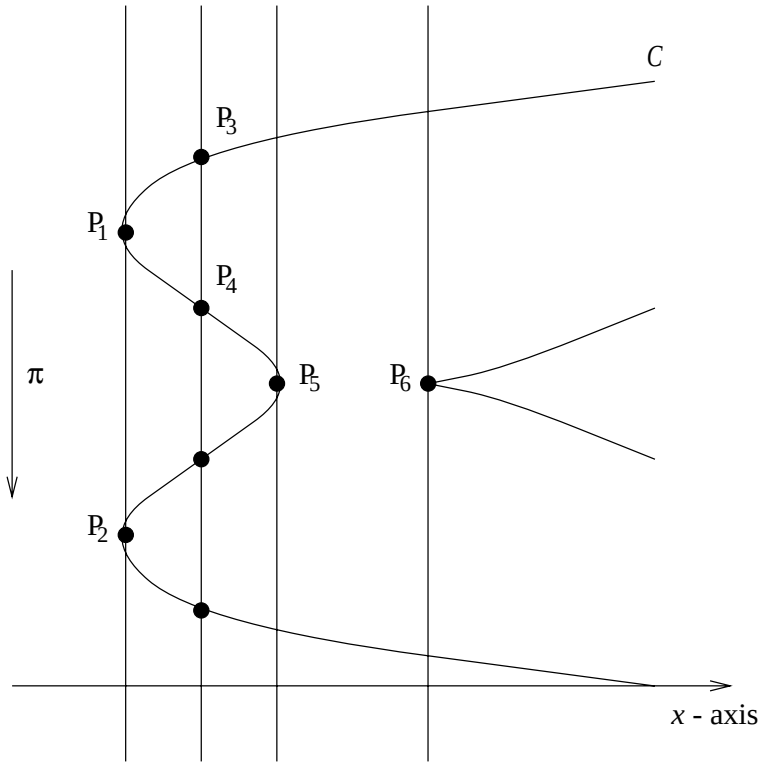

FIG. 4.1. *P_1, P_2, P_5 are critical for π, and P_6 is singular on $\mathcal{C}$. If $P_i = (a_i, b_i)$, then $(a_i, b_i, b_i) \in \mathcal{D} \cap \Delta$ for $i = 1, 2, 5, 6$. These four points are singular on $\mathcal{D}$. Furthermore, $(a_1, b_1, b_2) \in \mathcal{S} \subseteq \mathcal{D}$, and $(a_3, b_3, b_4) \in \mathcal{D} \setminus \mathcal{S}$.*

Proof. Let

$$\Delta = \{(a, b, b) \in \mathbb{F}^3 : a, b \in \mathbb{F}\}, \quad \mathcal{D}_1 = \{f(x, y) = g(x, y, z) = 0\}$$

so that Δ is the diagonal. Clearly $\mathcal{D} \setminus \Delta = \mathcal{D}_0$, and $\mathcal{D}_0 \subseteq \mathcal{D}_1$. By definition, $\mathcal{D}$ is the closure of $\mathcal{D}_0$, and thus $\mathcal{D} \subseteq \mathcal{D}_1$. We prove in the following that (ii) is valid with $\mathcal{D}_1$ instead of $\mathcal{D}$. Thus $\mathcal{D}_1 \cap \Delta$ is finite, and $\mathcal{D} = \mathcal{D}_1$ follows; this implies (i), (ii), and (iv).

So let u, v be indeterminates over $\mathbb{F}[x, y]$. Then the Taylor expansion of f around (u, v) of order 1 is

$$f(x, y) = f(u, v) + f_x(u, v)(x - u) + f_y(u, v)(y - v) + h$$

in $\mathbb{F}[x, y, u, v]$, with some $h \in (x - u, y - v)^2$. Therefore,

$$\begin{aligned} &g(x, y, z) \\ &= \frac{1}{y - z} \cdot (f_y(u, v)(y - v) - f_y(u, v)(z - w) + h(x, y, u, v) - h(x, z, u, v)) \\ &= f_y(u, v) + H, \end{aligned}$$

with some $H \in (x - u, y - v, z - v)$. Thus, for $(a, b) \in \mathcal{C}$,

$$(a, b, b) \in \mathcal{D}_1 \iff f_y(a, b) = 0 \iff (a, b) \text{ is singular or critical on } \mathcal{C}.$$

For (iii), let $(a,b,c) \in \mathcal{D}$ with $b \neq c$. The Jacobian of $\mathcal{D}$ at (a,b,c) is

$$J(a,b,c) = \begin{pmatrix} f_x(a,b) & \dfrac{f_x(a,b) - f_x(a,c)}{b-c} \\ f_y(a,b) & \dfrac{f_y(a,b)}{b-c} \\ 0 & \dfrac{-f_y(a,c)}{b-c} \end{pmatrix}.$$

After multiplying the second column by $c-b$ and then adding the first column to the second, we obtain the matrix

$$A = \begin{pmatrix} f_x(a,b) & f_x(a,c) \\ f_y(a,b) & 0 \\ 0 & f_y(a,c) \end{pmatrix}.$$

Thus

$$\begin{aligned} &(a,b,c) \text{ is singular on } \mathcal{D} \iff \text{rank } (J(a,b,c)) \leq 1 \\ &\iff \text{rank } (A) \leq 1 \\ &\iff (a,b) \text{ or } (a,c) \text{ is singular on } \mathcal{C}, \text{ or both are critical on } \mathcal{C}. \qquad \square \end{aligned}$$

The condition that π be separable is necessary since otherwise all points on $\mathcal{C}$ are critical. Recall the example $\mathcal{C} = \{x = y^p\}$, where $p = \operatorname{char} \mathbb{F}$, from section 3. Then $f_y = 0$, $\mathcal{C}$ is smooth, and all tangent lines to $\mathcal{C}$ are vertical. Furthermore, $\mathcal{D}_0 = \emptyset$, $g = (y^p - z^p)/(y-z) = (y-z)^{p-1}$, and $\mathcal{C} \times_\pi \mathcal{C}$ equals $\{(a,b,b) \in \mathbb{F}^3 : a = b^p\}$, counted $p-1$ times. On the other hand, when $\mathcal{C} = \{y = g(x)\}$ is the graph of a polynomial $g \in \mathbb{F}_q[x]$, then π is separable, and $\mathcal{D} = \emptyset$.

We define

$$\mathcal{S} = \{(a,b,c) \in \mathcal{D} : (a,b) \text{ or } (a,c) \text{ is singular or critical on } \mathcal{C}\}.$$

We now let $\mathcal{A}$ be an irreducible component of $\mathcal{D}$, and we want to estimate the number of t such that

$$\psi_t = \prod_{1 \leq i \leq 2k} (t_i - y)(t_i - z)$$

is a square in $\mathcal{O}_\mathcal{A}$. We let $\rho : \mathbb{F}[x,y,z] \longrightarrow \mathcal{O}_\mathcal{A}$ be the restriction map.

Let $t \in \mathbb{F}^{2k}$, and $T = \{1, \ldots, 2k\}$. The overall goal of this section is to show in Theorem 4.4 that only a few $\rho(\psi_t)$ are squares when t is chosen from a finite subset H of $\mathbb{F}^{2k}$. For a simple example of a square, we take the parabola $f = x - y^2$ so that $\mathcal{C} = \{x = y^2\}$, and $\mathcal{D} = \{x - y^2 = y + z = 0\}$ is irreducible. If $k = 1$ and $t_2 = -t_1$, then

$$\rho(\psi_t) = \rho((t_1 - y)(t_1 - z)(t_2 - y)(t_2 - z)) = \rho((t_1 - y)^2 (t_1 + y)^2) \tag{4.1}$$

is a square on $\mathcal{D}$.

The condition that $\rho(\psi_t)$ not be a square for (3.2) to hold is not an artifact of Perel'muter's proof, but without it (3.2) may actually fail to be true.

In what follows, we define several combinatorial objects on the index set T. We first collect pairs of equal values of t_i in a systematic way. Namely, we take the

lexicographically first maximal matching on the directed graph with vertex set T, and where (i,j) are connected if and only if $i<j$ and $t_i=t_j$. Then $T_1\subseteq T$ is defined as the set of these first coordinates i, and $\tau_1\colon T_1\to T$ is defined by $\tau_1(i)=j$ if (i,j) occurs in that matching. As an example, if $t_3=t_5=t_8=t_{11}=t_{13}$ and no other t_i equals these, then $T_1=\{3,5\}$, $\tau_1(3)=8$, and $\tau_1(5)=11$.

Next, we set

$$T_2=\{i\in T\setminus(T_1\cup\tau_1(T_1))\colon \mathcal{A}\cap\{y=t_i\}\subseteq\mathcal{S} \text{ or } \mathcal{A}\cap\{z=t_i\}\subseteq\mathcal{S}\}.$$

Then the t_i for

$$i\in T_3=T\setminus(T_1\cup\tau_1(T_1)\cup T_2)$$

are pairwise distinct, and $(T_1,\tau_1(T_1),T_2,T_3)$ is a partition of T. Next, we let

$$S_0=T_3\times\{0\},\quad S_1=T_3\times\{1\}$$

be two disjoint copies of T_3, and we now define a bipartite undirected graph $G=(S_0\cup S_1,E)$ as follows. For $i,j\in T_3$, $(i,0)$ and $(j,1)$ are connected in G if and only if there is some $(a,b,c)\in\mathcal{A}\setminus\mathcal{S}$ such that $b=t_i$ and $c=t_j$.

In the example (4.1) of a parabola, we have $T_1=T_2=\emptyset$, and

$G\ =$ 
.

LEMMA 4.2. *If $t\in\mathbb{F}^{2k}$ is such that $\rho(\psi_t)\in\mathcal{O}_{\mathcal{A}}$ is a square, then each vertex in G has degree at least one.*

Proof. By symmetry, it is sufficient to show the claim for a vertex $(i,0)\in S_0$.

Since $i\notin T_2$, we can choose some $P=(a,t_i,c)\in\mathcal{A}\setminus\mathcal{S}$; then $c\neq t_i$. Let

$$U_0=\{j\in T\colon t_j=t_i\},\quad U_1=\{j\in T\colon t_j=c\},$$

$\rho\colon\mathbb{F}[x,y,z]\to\mathcal{O}_{\mathcal{A}}$ be the restriction to $\mathcal{A}$, $\mathcal{R}=\mathcal{O}_{P,\mathcal{A}}$ be the local ring at P, which is a unique factorization domain (see, e.g., Shafarevich (1974), Theorem II.3.2), and $\lambda=(\mathcal{O}_{\mathcal{A}}\to\mathcal{O}_{P,\mathcal{A}})\circ\rho$ be the composition of ρ with the localization at P. Then $i\in U_0$ and $U_0,U_1\subseteq T\setminus T_2$.

For every $j\in T\setminus(U_0\cup\tau_1(U_0)\cup\{i\})$, we have $t_j\neq t_i$, and thus $\lambda(y-t_j)$ is a unit in $\mathcal{R}$. Similarly, each $\lambda(z-t_j)$ with $t_j\neq c$ is a unit in $\mathcal{R}$. Since $(a,t_i)\in\mathcal{C}$ is not critical for π, we have $f_y(a,t_i)\neq 0$, and therefore $\lambda(y-t_i)\in\mathcal{R}$ is a local parameter in $\mathcal{R}$. Similarly, each $\lambda(z-t_j)$ with $t_j=c$ is a local parameter in $\mathcal{R}$.

By the above, there is a unit $u\in\mathcal{R}$ such that

$$\begin{aligned}\lambda(\psi_t)&=\prod_{j\in T}\lambda(y-t_j)\cdot\prod_{j\in T}\lambda(z-t_j)\\&=u\cdot\prod_{j\in U_0\cup\tau_1(U_0)\cup\{i\}}\lambda(y-t_j)\cdot\prod_{j\in U_1}\lambda(z-t_j)\end{aligned}$$

is a square in $\mathcal{R}$. Thus the total number of local parameters in the product is even. We have $\#U_0=\#\tau_1(U_0)$ and $i\notin U_0\cup\tau_1(U_0)$. It follows that, in the left-hand product, the number of local parameters is odd, and therefore the same is true for the

right-hand product. Thus there exists some $j \in T_3$ with $t_j = c$; then $\{(i,0),(j,1)\} \in E$. ∎

We now take a maximal "disjoint" matching (V_0, V_1) in G of the following type. The sets $V_0, V_1 \subseteq T_3$ are disjoint, G induces a perfect matching on $(V_0 \times \{0\}) \cup (V_1 \times \{1\})$, and this matching is maximal. Furthermore, let $\mu : V_0 \longrightarrow V_1$ be the corresponding bijection, with $\mu(i) = j$ if and only if $\{(i,0),(j,1)\}$ occurs in the matching.

For every $i \in V_2 = T_3 \setminus (V_0 \cup V_1)$, $(i,0)$ is connected to some $(j,1) \in T_3 \times \{1\}$, and by the maximality of the matching, we have $j \in V_0 \cup V_1$. We take $\mu\colon V_2 \longrightarrow V_0 \cup V_1$ such that $\mu(i) = j$ for some such j and note that (V_0, V_1, V_2) is a partition of T_3.

Finally, we indicate how to describe t_i for $i \in V_0$ succinctly if $\{(i,0),(j,1)\} \in E$ and t_j is known. For this, we take an arbitrary total order $\prec$ on $\mathbb{F}$. For each $t \in \mathbb{F}$, $\mathcal{C} \cap \{y = t\}$ has at most n points, say, $(a_1,t),\dots,(a_l,t)$ with $l \le n$ and $a_1 \prec \cdots \prec a_l$. If $j = \mu(i)$ and $t = t_j$, then $(a_r, t_i, t_j) \in \mathcal{D} \setminus \mathcal{S}$ for one of those points, with $1 \le r \le l$. We choose the smallest such r; then $\mathcal{C} \cap \{x = a_r\}$ consists again of at most n points. We let v be the position of (a_r, t_i) in this list, ordered according to $\prec$, and set $\tau_3(i) = (r,v)$. Then t_i is determined by $j = \mu(i)$, t_j, and $\tau_3(i)$.

Similarly, we define $\tau_3\colon V_2 \longrightarrow \{1,\dots,n\}^2$ so that, for $i \in V_2$, t_i is determined by $j = \mu(i)$, t_j, and $\tau_3(i)$.

We have thus associated the following data to any $t \in \mathbb{F}^{2k}$ with $\rho(\psi_t)$ a square:

$$T_1, \tau_1, T_2, V_0, \mu, \tau_3, \text{ and } t_i \text{ for } i \in T_1 \cup T_2 \cup V_1. \tag{4.2}$$

LEMMA 4.3. *If $\rho(\psi_t)$ is a square in $\mathcal{O}_{\mathcal{A}}$, then t is determined by the data in* (4.2).

Proof. $(T_1, \tau_1(T_1), T_2, V_0, V_1, V_2)$ is a partition of T, and $t_i = t_{\tau_2(i)}$ for each $i \in T_1$. Thus it remains to show that each t_i with $i \in V_0 \cup V_2$ is determined by (4.2). However, that is precisely what the construction of μ and τ_3 achieves. ∎

We are now ready for the main result of this section, an upper bound on the number of ψ_t which are squares. The bound is rather coarse but sufficient for our purposes.

THEOREM 4.4. *Let $\mathbb{F}$ be an algebraically closed field, let $f \in \mathbb{F}[x,y]$ be squarefree, let $\mathcal{C} = \{f = 0\}$ with $\pi\colon \mathcal{C} \to \mathbb{F}$ be separable, let $H \subseteq \mathbb{F}$ be a finite set with h elements, and let $k \in \mathbb{N}$ be positive. The number of $t \in H^{2k}$ such that $\rho(\psi_t)$ is a square in $\mathcal{O}_{\mathcal{A}}$ for some irreducible component $\mathcal{A}$ of $\mathcal{C} \times_\pi \mathcal{C}$ is at most $(12kn^2h^{1/2})^{2k}$.*

Proof. We first fix a component $\mathcal{A}$ of $\mathcal{D}$ and show the corresponding bound. By Lemma 4.3, it is sufficient to give an upper bound on the number of choices for the data in (4.2).

The six sets $T_1, \tau_1(T_1), T_2, V_0, V_1, V_2$ form a partition of T, and there are at most 6^{2k} choices for this partition.

Suppose that these sets are chosen, with cardinalities $c_1, c_2, c_3, c_4, c_5, c_6$, respectively. Then $c_1 = c_2$, $c_3 < n^2$, and $c_4 = c_5$. The number of choices for τ_1 is at most $(2k)^{c_1}$, for μ at most $(2k)^{c_4+c_6}$, for τ_3 at most $(n^2)^{c_4+c_6}$, and for all t_i's required in (Theorem 4.1) at most $h^{c_1+c_5} \cdot (n^2)^{c_3}$. Since $c_1 + c_5 \le 2k/2 = k$, the total comes to

$$m = 6^{2k} \cdot (2k)^{c_1+c_4+c_6} \cdot (n^2)^{c_3+c_4+c_6} \cdot h^{c_1+c_5}. \tag{4.3}$$

Since $\deg \mathcal{D} \le n(n-1)$ by Theorem 4.1 (i), $\mathcal{D}$ has at most $n(n-1) < n^2$ irreducible components. So the total number of t considered is at most $n^2 m$, and

$$n^2 m \le 6^{2k} \cdot (2k)^{2k} \cdot (n^2 h^{1/2})^{2k}.$$

Here we use that either $c_1 + c_2 + c_5 > 0$ and then $n^2 \cdot (n^2)^{c_3+c_4+c_6} \le (n^2)^{2k}$, or $c_2 + c_3 + c_4 + c_6 > 0$ and then $n^2 (h)^{c_1+c_5} \le h^k$. ∎

5. Exceptional polynomials. In this section, we deal with the somewhat troublesome case excluded so far: exceptional polynomials, for which $\sigma = 0$. No analogue of the deterministic result of Theorem 3.3 is known for them, while the probabilistic results of section 2 carry over easily.

We first note that it is not surprising that they are difficult to deal with since any subset of $\mathbb{F}_q^2$ is an exceptional curve. If $c \in \mathbb{F}_q$ is a nonsquare and $f = x^2 + cy^2$, then f is exceptional and

$$\{f = 0\} = \{(0,0)\}, \tag{5.1}$$

and by translation and finite unions the claim follows. If char $\mathbb{F}_q \geq 3$, then (5.1) also holds for $f = x^{q-1} + y^{q-1}$. If $b \in \mathbb{F}_{q^2} \backslash \mathbb{F}_q$ with $b^2 \in \mathbb{F}_q$, then $b^{q-1} = (b^2)^{(q-1)/2} = -1$. Thus f is the product of all $x - by$ with these b, and thus f is exceptional, too.

Now, given an arbitrary $f \in \mathbb{F}_q[x,y]$ of degree n, there are well-known probabilistic algorithms with time polynomial in $n \log q$ that factor f into its irreducible factors over $\mathbb{F}_q$ (von zur Gathen and Kaltofen (1985)) and test each such factor for absolute irreducibility (Kaltofen (1985)). For simplicity, assume now that f is irreducible over $\mathbb{F}_q$ and not absolutely irreducible. Then Kaltofen's algorithm can be used to find a field extension K of $\mathbb{F}_q$ with $[K:\mathbb{F}_q] \leq n$ and a proper factorization of f over K. If g and h are two distinct factors, then the first coordinate of any common root is a root of

$$\operatorname{res}_y(g,h) \in K[x].$$

Thus it is easy to calculate all common roots of g and h, to check which ones are in $\mathbb{F}_q^2$, and to determine whether they are indeed roots of f. All roots of f are found in this way; there are at most $n^2/4$ of them (von zur Gathen, Karpinski, and Shparlinski (1996)).

THEOREM 5.1. *Let $f \in \mathbb{F}_q[x,y]$ have degree n. There is a probabilistic algorithm using $(n \log q)^{O(1)}$ operations in $\mathbb{F}_q$ that determines whether f is exceptional and, if it is, finds all points of $\{f = 0\}$.*

ON FRICTIONAL MECHANICAL SYSTEMS AND THEIR COMPUTATIONAL POWER*

JOHN H. REIF† AND ZHENG SUN‡

Abstract. In this paper we define a class of mechanical systems consisting of rigid objects (defined by linear or quadratic surface patches) connected by frictional contact linkages between surfaces. (This class of mechanisms is similar to the analytical engine developed by Babbage in the 1800s, except that we assume frictional surfaces instead of toothed gears.) We prove that a universal Turing Machine (TM) can be simulated by a (universal) frictional mechanical system in this class consisting of a constant number of parts. Our universal frictional mechanical system has the property that it can reach a distinguished final configuration through a sequence of legal movements if and only if the universal TM accepts the input string encoded by its initial configuration. There are two implications from this result. First, the robotic mover's problem is undecidable when there are frictional linkages. Second, a mechanical computer can be constructed that has the computational power of any conventional electronic computer and yet has only a constant number of mechanical parts.

Previous constructions for mechanical computing devices (such as Babbage's analytical engine) either provided no general construction for finite state control or the control was provided by electronic devices (as was common in electromechanical computers such as Mark I subsequent to Turing's result). Our result seems to be the first to provide a general proof of the simulation of a universal TM via a purely mechanical mechanism.

In addition, we discuss the universal frictional mechanical system in the context of an error model that allows an error up to ϵ in each mechanical operation. We first show that, for a universal TM M, a frictional mechanical system in this ϵ-error model can be constructed such that, given any space bound S, the system can simulate the computation of M on any input string ω if M decides ω in space bound S, provided that $\epsilon < 2^{-cS}$ for some constant c. We also show that, for any universal TM M and space bound S, there exists a frictional mechanical system in the ϵ-error model with $\epsilon = \Omega(1)$; it has $O(S)$ parts and can simulate M on any input ω that M decides in space bound S.

Key words. robotics, motion planning, complexity, mechanical computing device

1. Introduction.

1.1. Motivation.

There are two contexts where our result may be of interest: robotic mover's problems and mechanical computing machines.

1.1.1. Robotic mover's problems.

The objective of *robotic mover's problems* (or *motion planning problems*) is to plan the motion of a robot between distinguished configurations under specified physical constraints (e.g., avoiding obstacles) and possibly also dynamic constraints. There are two categories of problems studied in this area: decision problems and optimization problems. The goal of a decision problem is to decide, given the physical and dynamic constraints, whether or not there

is a sequence of legal movements that will allow the robot to reach the goal configuration; the goal of an optimization problem is to find an optimal path (trajectory) that leads to the goal configuration, according to a predefined cost function on paths (trajectories).

The first hardness result for a robotic mover's problem was presented by Reif [9]. He showed that the generalized mover's problem of moving n linked polyhedra through a set of three-dimensional (3D) obstacles is PSPACE-hard. His proof used a reduction of the computation of any reversible Turing machine (TM) on an input string to an instance of the mover's problem. Hopcroft, Joseph, and Whitesides [7] improved on this result by proving that the mover's problem for two-dimensional (2D) linkages is PSPACE-hard. Later, the generalized mover's problem was proved to be in PSPACE by Canny [2]. Using a *path coding* technique, Canny and Reif [3] also proved that computing the shortest path for a point robot moving amidst polyhedral obstacles is NP-hard. Asano, Kirkpatrick, and Yap [1] introduced the problem of computing the d_1-optimal motion for a 2D rod (defined by a directed line segment) amidst polygonal obstacles and showed that this problem is NP-hard.

There are also many hardness results on various extensions of the basic robotic mover's problem, such as moving obstacles, multirobots, etc. For example, in [8] Hopcroft, Schwartz, and Sharir proved that motion planning for multiple independent rectangular boxes sliding inside a rectangular box is PSPACE-hard. A similar problem of moving multiple discs inside a polygon in a 2D space, however, could be proved only to be strongly NP-hard [14]. Reif and Sharir [10] introduced the 3D mover's problem in the presence of moving obstacles and showed that this problem is PSPACE-hard even in a case where the object to be moved is a disc with bounded velocity. By extending the path coding technique of [3], Reif and Wang [12] proved that the 2D curvature-constrained shortest-path problem is NP-hard. Later, Reif and Sun [11] showed that the time-optimum path planning problem for a point robot in a 3D space composed of polyhedral regions with flows is PSPACE-hard.

Most robotic mover's problems assume that the obstacles are the only objects in the robot's workspace besides the robot itself. One exception is the *movable object problem*, which is to ask whether a robot can move certain objects amidst obstacles in a space to reach a target configuration. That is, there are two types of objects in the space: obstacles that cannot be moved and penetrated (or even touched) by the robot, and objects whose placements can be changed by the robot. The goal of the robot is either to rearrange the movable objects in the space to a desired configuration or reach a target configuration of itself, or both. The first result on the movable object problem was given by Wilfong [15], who studied this problem for the case of a polygonal robot moving in translation amidst polygonal movable objects in a bounded polygonal space. He proved that if the final configurations of the objects are not specified as part of the goal of the motion planning problem, this problem is NP-hard; otherwise, it is PSPACE-hard. He also gave one algorithm for each of the two cases where only one movable object is present.

In Wilfong's model, a robot can grasp an object only from a finite number of positions. This problem is considered to be more difficult when this number is infinite. Chen and Hwang [4] gave a heuristic algorithm to solve one model of this problem where the total weight of objects moved by a robot is to be minimized. Dacre-Wright, Laumond, and Alami [5] extended Wilfong's work by providing an $O(n^3 \log n)$ algorithm for the infinite grasping position case where the final configurations of the objects are specified as part of the goal.

1.1.2. Mechanical computing machines. In 1822, Charles Babbage designed and constructed the difference engine. This machine was specially designed for the evaluation of polynomials. Later, in 1833, Babbage proposed (but did not fully construct) a new device, the analytical engine, which was conceived to solve general arithmetic problems. It resembled the modern digital computer in the following ways.

Input device. Just like any modern computer, the analytical engine was designed to have an input mechanism, such as punch cards.

Memory. The analytical engine was supposed to store the data encoded by mechanical positions; e.g., distinct digits were stored via rotational positions of distinct mechanical dials.

Arithmetic unit. The machine was able to manipulate the data and, in particular, to execute the arithmetic operations. This was done by a part called the "mill" using various gearing mechanisms.

Control unit. The machine was also envisioned by Babbage to have a mechanism that could control the sequence of operations to carry out the computations.

About half a century after Babbage's death, Dr. Vannevar Bush resumed the work of building a mechanical computing device. In 1925 he, along with some associates, made a mechanical calculator powered by an electric motor. His machine was an analog one, in the sense that arithmetic operations were carried out by mechanical means and in terms of physical measurements.

In 1939, Howard Aiken, in collaboration with four IBM engineers, built a general purpose computing machine, the so called automatic sequence controlled calculator, Mark I. Just like Babbage's analytical engine, Mark I performed computation by manipulating mechanical devices. The key difference between Mark I and the previous mechanical computers such as the analytical engine and Bush's machine is that, while the analytical engine and Bush's computer were purely mechanical, the operations of mechanical parts of Mark I were controlled electrically.

As electronic devices were not available in the 1800s, Babbage had to exploit a purely mechanical system to build a computer. Subsequent electromechanical computers could exploit electronics for control, and of course so do the modern computers. Today, Babbage's concept of a purely mechanical computer would at first seem to be out of date, as computers built by much faster electronic technology prevail in every corner of the world. However, the emergence of nanotechnology provides new motivation on studies of mechanical computers.

1.2. Our results.

1.2.1. Frictional mechanical system and frictional mover's problem. All the robotic mover's problems mentioned above assume that there is no friction between objects, and most of the models allow only collision-free movements so that different objects cannot even make contact with each other. The only work that addressed motion planning in the presence of friction is by Sellen [13]. He proved that the dynamic motion planning problem with forbidden movements (in particular, sliding) is undecidable by showing that the actions of a TM can be realized by logical and arithmetic operations, which can be implemented by mechanical means. However, in his model, the motions of the objects corresponding to the computations of the TM cannot be generated deterministically. Therefore, this model cannot be used for constructing a mechanical computer.

We define a *frictional mechanical system* to be a collection of rigid objects in 3D space whose surfaces are composed of linear or quadratic surface patches specified by rational coefficients. All objects are nonpenetrable; i.e., the only allowed intersection

is via surface contact. Each surface patch of each object is also specified as either *frictional* or *sliding* (nonfrictional). If two objects with frictional surfaces make contact with each other, it is assumed that there is no sliding[1] between them. If at least one of the two contacting surfaces is designated to be a sliding surface, there will be no friction between them so that they can slide freely. Furthermore, some objects in the space are specified to move monotonically. In particular, there may be some discs in the system that can rotate only in one direction (clockwise or counterclockwise). We say that the objects can be moved *legally* if all the above constraints are satisfied.

We define the *resource bound*, denoted by R, to be the number of distinct objects in the frictional mechanical system. As each object can be specified by a constant number of surface patches, each of which can be specified by a constant number of rational coefficients, the total number of binary bits used to encode an object is bounded by a constant. Hence, the total number of bits in the binary representation of the frictional mechanical system is $O(R)$.

The *frictional mover's problem* is to determine whether these objects in the frictional mechanical system can be moved legally from a specified initial configuration to a specified final configuration. This problem can be regarded as a generalization of the movable object problem. Compared to the previous works, our model is in 3D space, and the surfaces of the objects in the space can be nonlinear. Further, in addition to moving an object by grasping or pushing (directly or indirectly), a robot in our model can move objects by using the friction between it and surrounding objects. More specifically, a *power disc* in the frictional mechanical system can be deemed as a rather "dumb" robot; it is restricted to rotate in a specified direction without translation. And the problem is to ask whether this robot can rearrange the objects in the system to a target configuration by its rotation.

We prove that the frictional mover's problem is undecidable by reducing the acceptance problem for a Turing machine[2] (TM), A_{TM},[3] to the frictional mover's problem. Given a universal TM[4] M, we construct a frictional mechanical system to simulate this machine. This frictional mechanical system will have the property that the objects in this system can be moved from an initial configuration, which encodes an input string ω of M, to a configuration corresponding to the accepting state of M if and only if M accepts ω. Therefore, as the acceptance problem for a TM is undecidable, so is the frictional mover's problem. This implies that there is no realistic machine that can solve this problem.

An interesting property of this frictional mechanical system is that if M accepts ω, there will be a unique simple path (i.e., one that does not repeat the same configuration) from the initial configuration to the final configuration.

The proof will actually construct, for any given TM M, a frictional mechanical system that simulates M. Every movable object in the system is engaged or linked directly or indirectly with the power disc so that, when the power disc rotates, it will make those objects move accordingly. For any input string ω of M, this frictional

[1]Sliding is a move in a direction tangent to the surfaces at the contact point.

[2]A Turing machine is an abstract machine with a finite state control and a tape that can store an infinite string of symbols. There is a read-write head on the tape that allows the machine to read or write the symbol at the current position of the head. The machine can write to the current position and move the head left or right according to the current state and the current symbol in a specified way.

[3]The acceptance problem A_{TM} for a TM is to determine, given the description of a TM M and its input ω, whether M accepts ω.

[4]A universal TM M will take the description of any TM M' and any input string ω of M' as an input and simulate the behavior of M' presented with input ω.

mechanical system can be set to an initial configuration encoding ω so that, after the power disc has rotated a sufficient number of cycles, this system will result in a configuration encoding the accepting state (rejecting state) of M if and only if M accepts (rejects) ω.

Even though Babbage claimed that the analytical machine could be used to solve any arithmetic problem, it is doubtful whether this machine is as powerful as a universal computing machine. The difficulty is that Babbage did not have a general concept of an abstract computing machine, such as a TM, which was later introduced by Alan Turing in 1936. To show that a mechanical system has the computational power of an electronic computer, it is sufficient and necessary to show that this mechanical system can simulate a universal TM, as proposed by Turing. Although Babbage designed his analytical machine to have a control unit used to guide the arithmetic operations, it was not explicitly shown by Babbage how it could simulate a general finite state control, which is the core of a universal TM. The electromechanical computer, Mark I, was designed to be capable of fulfilling any computing tasks and thus should be as powerful as the modern computers. However, it used an electronic device as the central controller. To our knowledge, our mechanical system, as it will be described in later sections, is the first mechanical system that can perform general-purpose computation without using any electronic devices.

Another limitation of Babbage's analytical engine is its representation of numbers. The analytical engine was a digital computer. Each digit of a number was represented by a mechanical device, such as a dial. The accuracy of Babbage's machine, in terms of the number of decimal places, was determined by the number of dials used to represent a number. Therefore, no matter how precisely the machine was built, it would not improve its accuracy. The only way to improve the accuracy of the machine's computation (or increase the number of data bits) is to increase the number of dials used to represent a number. This will change the structure of the analytical engine and make it bigger and more complicated. Our frictional mechanical system, however, is an analog computer, in the sense that a number (in fact, the entire data of the computation) is represented by the rotational position of a single disc. The accuracy of our system depends on the accuracy of the measurement and the precision of the mechanical devices. Therefore, it can be arbitrarily accurate as we reduce the error in transitional (or rotational) measurement as well as the error in building mechanical devices.

For our proof of the undecidability of the frictional mover's problem, we adopt a simple deterministic model for frictional contacts between objects. Note that there exists a number of considerably more complex models (for example, see [6]) for frictional contacts between objects where the objects in contact with surfaces may make nondeterministic motions. However, our simple deterministic model for frictional contacts will suffice for us to adequately model frictional contacts in the simple cases we employ in our constructions and thus to prove our undecidability result for movement planning with frictional contacts. Moreover, many of these more complex models for frictional contacts reduce to our simple deterministic model for frictional contacts in the simple cases we employ in our constructions.

1.2.2. Frictional mechanical system with error. We prove that a frictional mechanical system can be constructed to simulate a universal TM. Therefore, this system can be used for arbitrary finite computation, just like any conventional computer. However, the underlying assumption is that this frictional mechanical system can be constructed exactly as it is specified. We are also interested in the computa-

tional power of such a frictional mechanical system in the case where inaccuracy is allowed in the construction of the mechanical devices in the system.

There are many factors that might induce errors in the computations of a frictional mechanical system, including the precision of manufacturing the parts. For example, the circumference of a disc may not exactly be manufactured to be a circle. The radius of a disc may not be manufactured to be exactly as it is specified. When two discs are very close but still not in contact with each other theoretically, they may already have surface contact so that the rotation of one disc will move the other one, even though they are not supposed to do so.

Since there are a constant number of mechanical devices in our mechanical system, we can let ϵ be the upper bound for the errors that occur in a single operation. This is our ϵ-error model. We prove that, given a space bound S, our frictional mechanic system in this ϵ-model can simulate the universal TM M on any input string ω that can be decided by M in space bound S, provided that $\epsilon = O(2^{-cS})$ for some constant c.

We also prove that, given a universal TM M with space bound S, there exists an $\epsilon = \Omega(1)$ such that a frictional mechanical system in ϵ-error model can simulate the computation of M presented with any input ω if M decides ω in space bound S. This result provides decreased required precision of parts at the expense of increased number of parts, which increases with S.

1.3. Notation. In the following sections, the universal TM with end-marks is denoted by quintuple $M = (Q, \Sigma, \delta, q_0, \{q_{\sigma-2}, q_{\sigma-1}\})$ as follows:

1. $Q = \{q_0, q_1, \ldots, q_{\sigma-1}\}$ is the set of states.
2. $\Sigma = \{0, 1, \ldots, m-1\}$ is the tape alphabet. Here 0 denotes the *blank* symbol. 1 and 2 are the left and right end-marks, respectively.
3. $\delta : Q \times \Sigma \to Q \times \Sigma \times \{L, R\}$ is the transition function.
4. q_0 is the start state.
5. $\{q_{\sigma-2}, q_{\sigma-1}\}$ is the set of halting states. In particular, $q_{\sigma-2}$ is the rejecting state and $q_{\sigma-1}$ is the accepting state.

In our following discussion, m and σ are considered as constants.

At any time during the computation, we use the *current working space* of the TM to denote the portion of the tape that the read-write head has visited so far. The current working space is always bounded by a left end-mark and a right end-mark. We denote the tape status by a string $\omega_1\omega_2\cdots\omega_{k_1-1}\check{\omega_{k_1}}\omega_{k_1+1}\cdots\omega_{k_2}$. Here ω_1 and ω_{k_2} are the left and right end-mark, respectively, and $\check{\omega_{k_1}}$ denotes that the read-write head is at the k_1th cell of the tape. The read-write head will never replace the left end-mark by another symbol nor will it go beyond the left end-mark. Whenever the read-write head replaces the right end-mark by another symbol, it will pad a right end-mark to the right of the symbol.

It is easy to see that, for any TM (without end-marks) M', there is an equivalent TM with end-marks as described above. Therefore, all universal TMs mentioned in the following discussion are assumed to have end-marks.

Since discs, in particular the rotational positions of discs, play a very important role in our frictional mechanical system, we want to specify several terminologies which we will be using frequently in the following discussion.

Each disc used in our system has a specified orientation called the *initial orientation*. Therefore, the rotational position of a disc D can be specified by the angle the disc has rotated from its initial orientation. For our convenience, we will use "the angle of D" to denote this angle. Also, we will say that the angle recorded (or

represented) by the rotational position of disc D is θ. Further, if we say "to increase (decrease) the angle or rotational position of a disc D by an angle of θ," we mean to rotate D counterclockwise (clockwise, respectively) by an angle of θ.

A *partial disc* is a portion of a disc bounded by two radii and the remaining portion of the circumference. As we will show later, partial discs are very useful in our system too.

1.4. Organization of this paper. Section 2 presents several basic mechanical devices widely used in our frictional mechanical system. After that, we provide the full description of the frictional mechanical system that simulates a universal TM. In the last section, the model of the frictional mechanical system with errors is discussed.

2. Basic gadgets. We prove the reduction from A_{TM} to the frictional mover's problem by constructing a frictional mechanical system for a universal TM M. This system is composed of discs, partial discs, cylinders, and other geometric objects. There is a special disc, the power disc, which is specified to rotate only clockwise. The rotation of this disc will force other objects in the system to move, due to frictional linkages between them. This frictional mechanical system can "simulate" M in the sense that, for any input string ω of M, this system can be set to a corresponding initial configuration so that a distinguished final configuration can be reached if and only if M accepts ω. Therefore, if one can decide this instance of the frictional mover's problem, he can also decide the corresponding instance of A_{TM}. As it is well known that A_{TM} is undecidable, so must be the frictional mover's problem.

Friction is very important in this system, as it not only provides a method of moving other objects in the system but also preserves the state of the system and thus the state of the TM the system simulates. It also guarantees the system properly transfers from one state to another.

Before giving the construction of the frictional mechanical system, we first introduce in this section several "gadgets" that perform the basic functionalities and thus are used widely in our system.

There are seven kinds of basic gadgets:

Converting device. A converting device is used to convert between rotational displacement and transitional displacement.

Sequencer. A sequencer is composed of a group of discs and partial discs that share the same axis and rotate with the same angular speed at any time. These discs (and partial discs) are engaged with some surrounding discs in the frictional mechanical system so that, when rotating, they will make the surrounding discs rotate with them and in turn move other objects in the system. The sequencer is a key component in the frictional mechanical system, as it provides a mechanism for moving all the objects in the system in a specified way.

Transitional movement sequence controller. A transitional event sequencer controller allows the sequencer to periodically move an object in the system by a constant distance and then move it back.

Rotational movement sequence controller. A rotational event sequencer controller allows the sequencer to periodically rotate a disc by a constant angle.

Resettable rotational disc. A resettable rotational disc has two states: the free rotation state, when it can be rotated by engaging with another disc, and the reset state when it will return to a specified initial orientation no matter how much it is rotated in the free rotation period. Virtually all devices need to use resettable rotational discs.

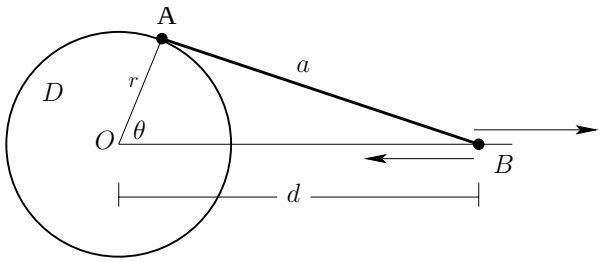

FIG. 1. *Converting device.*

Nonlinear mapping controller. A nonlinear mapping device is used to implement a nonlinear mapping between rotations. This is a very crucial component in the construction of the simulation of a finite state control.

Selection controller. A selection controller helps the sequencer to initiate one among several event sequences, depending on the rotational (or transitional) position of an object in the system. This is yet another key component in the construction of the simulation of a finite state control.

In the following subsections, we will give a detailed description for each of the basic gadgets.

2.1. Converting device. The most basic device is one that can convert a rotational displacement to a transitional displacement or vice versa. This can be done by the device described in Figure 1.

As can be seen from the figure, one end A of an arm of length a is attached to a fixed position on the rim of the disc D. The other end B of this arm is restricted to move along a line l passing the center of the disc. The rotation of the disc D, θ, and the distance d between the center of the disc and B satisfy $d = r\cos\theta + \sqrt{a^2 - r^2\sin^2\theta}$. Here r is the radius of D.

Therefore, if θ varies between $\pi/4$ and $3\pi/4$, then d will vary between $\sqrt{a^2 - r^2/2} - r/\sqrt{2}$ and $\sqrt{a^2 - r^2/2} + r/\sqrt{2}$. Further, d is a monotone function of θ. Therefore, the rotational displacement of disc D can be converted to the transitional displacement of B and vice versa.

2.2. Sequencer. All the objects in the system are moved, directly or indirectly, by a mechanism called a sequencer, which is composed of a group of discs and partial discs. These discs and partial discs share the same axis and rotate with the same angular speed at any time. Each disc or partial disc is engaged with one or more surrounding discs. Therefore, when the sequencer is rotating, it will make these surrounding discs rotate. Also, the rotation of these surrounding discs will then move other objects in the system.

In Figure 2, there are three discs and two partial discs in the sequencer. Each of the discs of the sequencer will make its surrounding disc rotate with it, possibly at a different angular speed. Each of the partial discs, however, will move the surrounding disc for a certain period and then lose contact with it.

Each cycle of the sequencer finishes one step of computation of the universal TM it simulates. As the rotation of the sequencer determines the starting and finishing of any movement sequence of any other object linked with it, we may use an interval $[\theta_1, \theta_2]$ to denote the time period during which the sequencer rotates from angle θ_1 to angle θ_2 in each cycle rather than using the actual time.

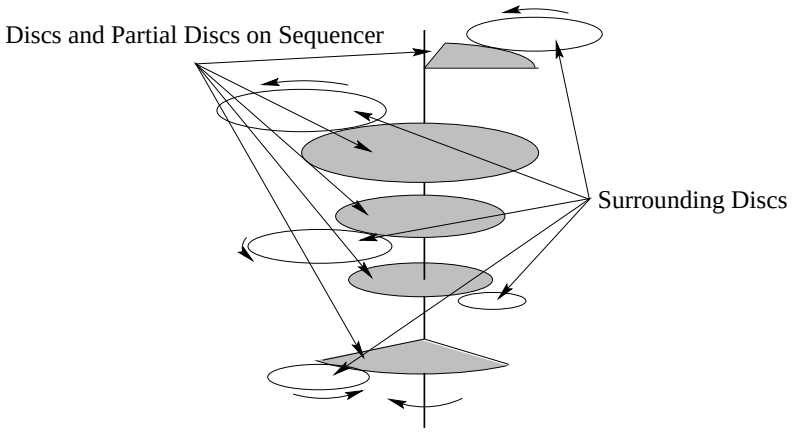

FIG. 2. *Sequencer.*

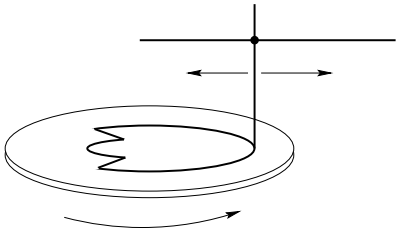

FIG. 3. *Transitional movement sequence controller.*

2.3. Transitional movement sequence controller. It will be useful if the sequencer can move an object to a specified position during time period $[\theta_1, \theta_2]$ of each rotational cycle and move it away from that position otherwise. This can be done by the controller shown in Figure 3.

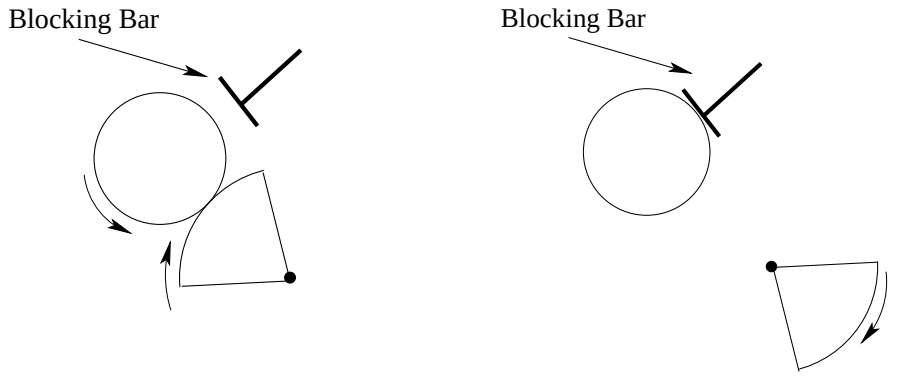
There is a circular gap on the surface of the disc which is on the sequencer. The curve of this gap is defined by $r = r(\theta)$ in a polar coordinate with origin at the center of the disc. A vertical bar is restricted in the circular gap. Also, it is restricted to move on a line passing the center of the disc. $r(\theta)$ has the property that

$$\begin{aligned} r(\theta) &= r_0 \quad \text{for } \theta \in [\theta_1, \theta_2], \\ r(\theta) &> r_0 \quad \text{for } \theta \notin [\theta_1, \theta_2]. \end{aligned}$$

Here r_0 is a constant. Therefore, when the controller is rotating in one direction, the bar will move back and forth along the line. More specifically, in time interval $[\theta_1, \theta_2]$, the vertical bar is at the position of $(r_0, 0)$ (in a polar coordinate). At any other time, it is at some position $(r', 0)$, where $r' > r_0$.

For our convenience, in the following discussion, we may say "the sequencer moves an object to a certain position during a certain time period in each rotational cycle," implicitly assuming that we have constructed a transitional movement sequence controller, as described here, that fulfills this task.

Transitional movement sequence controllers will be used frequently in our frictional system. All the rotational discs, except those on the sequencer, need to be clamped down whenever they are not rotated, directly or indirectly, by the sequencer so that their orientations will be maintained. This can be done by moving a *blocking*



(a) Rotating period (b) Clamping period

FIG. 4. *Rotational movement sequence controller.*

bar (a bar with a frictional surface) to a position where it has surface contact with the disc in the clamping period of each cycle.

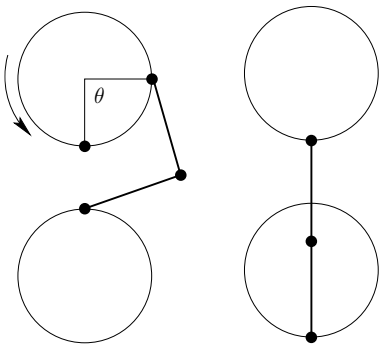
2.4. Rotational movement sequence controller. A rotational movement sequence controller is a partial disc in the sequencer used to rotate another disc, called a *target disc*, in a specified time interval during each cycle (see Figure 4). With a transitional movement sequence controller, a blocking bar can be moved to clamp the target disc when the partial disc loses contact with the target disc. When the partial disc rotates to such an orientation that its rim contacts the rim of the target disc, this bar is moved away from the target disc so that this disc can be rotated by the partial disc.

Therefore, the disc will stay stationary during the clamping period and rotate with the partial disc otherwise. The length of the rotating period is determined by the angle of the partial disc. And the total angle the target disc rotates during the rotating period is determined by the length of the arc of the partial disc as well as the radius of the target disc. Therefore, by setting these parameters appropriately, we can let the target disc rotate by a certain angle, say, π in each cycle.

Again, for our convenience, in the following discussion, we will say "the sequencer rotates a disc by a specified angle during a certain time period," implicitly assuming that we have constructed a rotational movement sequence controller, as described in this subsection, to do it.

2.5. Resettable rotational disc. With a rotational movement sequence controller, the sequencer can rotate a disc by a constant angle during each cycle. Frequently, it is necessary to rotate a target disc by a certain angle θ recorded by a *source disc* and then reset it by rotating it by θ in the reverse direction, no matter what θ is. This kind of disc is called a *resettable rotational disc*. As shown in Figure 5, two discs are linked by a two-segment arm. Each of these two discs has a radius of 1. The distance between the centers of the two discs is d, and the total length of the two-segment arm is d too.

The upper disc is the target disc. The lower disc connects to a rotational movement sequence controller so that at the time when we want to reset the target disc,



(a) Free rotating period (b) Resetting period

FIG. 5. *Resettable rotational disc.*

the lower disc will rotate by an angle of π. Because the length of the two-segment is exactly the same as the distance between the centers of two discs, the upper disc will be forced to rotate to such an orientation that the point where the arm is attached is at the lowest position. When it is time to release the target disc and allow it to be rotated freely by another disc it engages with, the lower disc rotates by another π so that it restores its initial orientation.

Therefore, each resettable rotational disc can be regarded as a register. It can hold a value that is represented by its current angle θ.

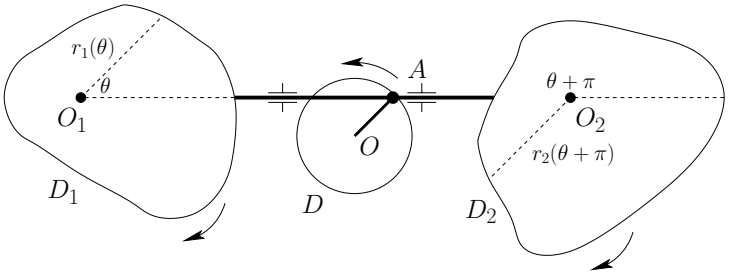
Using resettable rotational discs, we can construct a mechanical device that will increase the angle of a disc by the angle recorded by another disc. Suppose we have two resettable rotational discs. Disc D_1 is set at θ_1, and D_2 is set at θ_2. We want to increase the angle of D_2 by θ_1 while having the angle of D_1 remain unchanged. A third disc D_3 is needed here, and it is set at its initial orientation. The radii of D_1, D_2, and D_3 are the same.

First, both D_2 and D_3 are engaged with D_1, and then D_1 is reset to its initial orientation. D_2 (and D_3) will be rotated counterclockwise by an angle of θ_1. This will set D_2 to angle $\theta_1 + \theta_2$ and D_3 to angle θ_1. Then D_2 is disengaged from D_1. The next step is to reset D_3 to its initial orientation. As D_3 is still engaged with D_1, D_1 will be rotated counterclockwise by an angle of θ_1. Therefore, the orientations of D_1 and D_3 will be set just the same as they were before, while the angle of D_2 is increased by θ_1, which is the angle recorded by D_1.

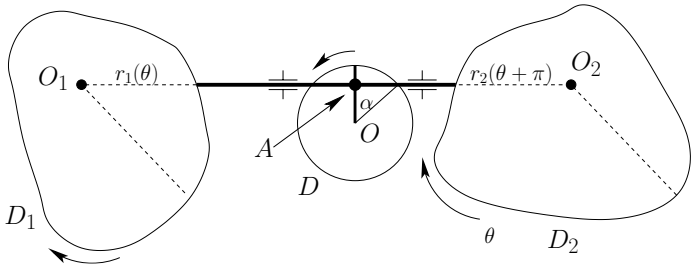
Observe that we can amplify or reduce θ_1 by a constant factor C before adding it to D_2. This can be done by setting $r_1 = r_3 = Cr_2$, where r_1, r_2, and r_3 are the radii of the three discs, respectively.

Here we will digress to address the necessity of using discs with frictional linkages. If gears instead of discs were used, it might be possible that teeth of the gears could not match after they resume contact with each other, since the two gears might rotate by a different angle after they are disengaged.

2.6. A nonlinear mapping device. Engaging a source disc and a target disc will allow us to perform linear mapping from the angle of rotation of the source disc to the angle of rotation of the target disc. By "linear mapping" we mean that if the



(a) Initial position



(b) After rotating by a degree of θ

FIG. 6. *Nonlinear mapping device.*

source disc rotates by an angle of θ, the target disc will rotate by an angle of $C \cdot \theta$, where C is the radius ratio between the two discs. However, sometimes it is necessary to perform nonlinear (or even nonmonotone) mapping on the rotations of discs. In particular, a device with the following property is needed.

PROPERTY 1. *A nonlinear mapping device has two discs, an input disc and an output disc, each of which can rotate by any angle* $\theta \in [0, \pi/2]$ *from its initial orientation. Given* $\theta_1, \theta_2, \ldots, \theta_n$, $\alpha_1, \alpha_2, \ldots, \alpha_n$, $0 \le \theta_1 < \theta_2 < \cdots < \theta_n \le \pi/2$, $0 \le \alpha_i \le \pi/2$, *if the rotation of the input disc is* θ_i, *the rotation of the output disc should be* α_i. *Further, if* $\alpha_1 < \alpha_2 < \cdots < \alpha_n$, *the mapping should be monotone. That is, for any* θ, $\theta_i < \theta < \theta_{i+1}$, *if the rotation of the input disc is* θ, *the rotation of the output disc,* α, *should be in the range of* (α_i, α_{i+1}).

Nonlinear mapping can be implemented by the device described in Figure 6. It consists of four parts, a central (regular) disc D centered at point O, a horizontal bar, and two irregular discs D_1 and D_2 centered at O_1 and O_2, respectively. In each operation D_1 and D_2 will rotate clockwise by an angle of θ_i for some $i, 1 \le i \le n$. The motion of D_1 and D_2 will cause D, through the horizontal bar connecting them, to rotate by an angle of α_i from its initial orientation.

The horizontal bar, which lies on line $\overline{O_1O_2}$ between D_1 and D_2, is restricted to move horizontally only. Each end of the horizontal bar touches, but is not attached to, the rim (circumference) of one of the two irregular discs. The bar is connected to D through a joint A between the bar and a spoke (a radiating bar from the center of a disc to its circumference) of D. The joint has the property that it can move along

the spoke but will remain stationary with respect to the bar. Therefore, when D_1 and D_2 rotate, they will in turn push the bar back and forth horizontally, which in turn will move the spoke and thus make D rotate accordingly.

During each operation, D_1 and D_2 need to "complement" each other in the sense that they keep constant contact with the horizontal bar. Nor can the two irregular discs "squeeze" the bar, as we assume that all objects are rigid and cannot be compressed. Therefore, we want to design the shapes of D_1 and D_2 in such a way that, when D_1 and D_2 rotate clockwise with the same angular speed, the distance between D_1 and D_2 on line $\overline{O_1O_2}$ is a constant. This implies that $r_1(\theta)+r_2(\theta+\pi)$ is a constant for any $\theta \in [0, \pi/2]$, where, for each $j = 1, 2$, $r_j(\theta)$ is the distance between O_j and the intersection point of the rim of D_j and the ray with angle θ that starts from O_j.

Initially, D is set at the orientation such that the angle between the spoke of D and the x-axis is $\pi/4$, as shown in Figure 6(a). We choose the vertical distance between O and the horizontal bar to be $R/\sqrt{2}$, where R is the radius of D. Therefore, the range of the angle between the spoke and the x-axis is $[\pi/4, 3\pi/4]$. Let h_1 be the horizontal distance between O and O_1, and let d_1 be the length of the part of the horizontal bar between its left end and the joint A with the spoke. To achieve the desired property, it is sufficient that the following equality holds:

$$\frac{r_1(\theta_i) + d_1 - h_1}{R/\sqrt{2}} = \tan(\pi/4 - \alpha_i) \text{ for } i = 1, 2, \ldots, n. \tag{1}$$

This can be done by choosing $r_1(\theta_i)$ to be $h_1 - d_1 + R\tan(\pi/4 - \alpha_i)/\sqrt{2}$ for all $i, 1 \le i \le n$. Also, the initial orientation of D implies that $\alpha = 0$ if $\theta = 0$. Therefore, we have $r_1(0) = h_1 - d_1 + R/\sqrt{2}$. For our convenience, we let $\theta_0 = 0$ and $\alpha_0 = 0$.

To ensure that the mapping is monotone in interval $[\theta_i, \theta_{i+1}]$, for any $\theta \in (\theta_i, \theta_{i+1})$, we specify

$$r_1(\theta) = \frac{(\theta - \theta_i) \cdot r_1(\theta_{i+1}) + (\theta_{i+1} - \theta) \cdot r_1(\theta_i)}{\theta_{i+1} - \theta_i}. \tag{2}$$

Note that $r_1(\theta)$ is a linear function of θ inside interval (θ_i, θ_{i+1}). If $\alpha_1 < \alpha_2 < \cdots < \alpha_n$, the nonlinear mapping will be monotone in interval $[0, \theta_n]$.

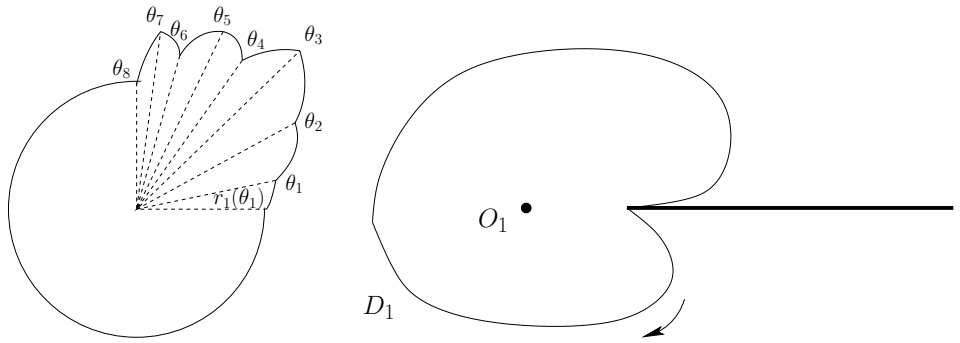
In the above we have shown how to decide $r_1(\theta)$ for any $\theta \in [0, \theta_n]$. For any $\theta \in (\theta_n, 2\pi)$, we let

$$r_1(\theta) = \frac{(\theta - \theta_n) \cdot r_1(0) + (2\pi - \theta) \cdot r_1(\theta_n)}{2\pi - \theta_n}.$$

This completes the specification of D_1. For D_2, we need only to let $r_2(\theta) = |\overline{O_1O_2}| - d - r_1(\theta - \pi)$ so that $r_1(\theta) + r_2(\theta + \pi)$ is a constant for any $\theta \in [0, 2\pi)$. Here d is the length of the horizontal bar.

As shown in Figure 7(a), the boundary of each irregular disc D_j described above is piecewise smooth, with derivative $r_j'(\theta)$ defined everywhere except for $\theta = \theta_0, \theta_1, \ldots, \theta_n$. At these values, function $r_j(\theta)$ has a "left derivative" $r_j'(\theta^-)$ and a "right derivative" $r_j'(\theta^+)$, which in most cases are different. The difference between $r_j'(\theta^-)$ and $r_j'(\theta^+)$ would not hinder the proper functioning of the device.

The only concern is that there should not be a "dimple" on the boundary, where $r_j'(\theta^+) = +\infty$ for some $\theta \in [0, 2\pi)$. In this case, the irregular disc would not be able to push the horizontal bar away from it, and, even worse, the bar would actually prohibit the irregular disc from further rotating, as shown in Figure 7(b). This would lead to a



(a) The boundary is piecewise smooth

(b) A dimple that causes crash

FIG. 7. *Irregular discs.*

complete stop of the computation of the frictional mechanical system. However, since inside each interval $[\theta_i, \theta_{i+1}]$ the curve $r_j(\theta)$ is a linear function of θ (see (2)), $r'_j(\theta^+)$ cannot be $+\infty$ as long as each $r_j(\theta_i)$ is chosen to be a finite number. Therefore, we have ruled out this potential difficulty.

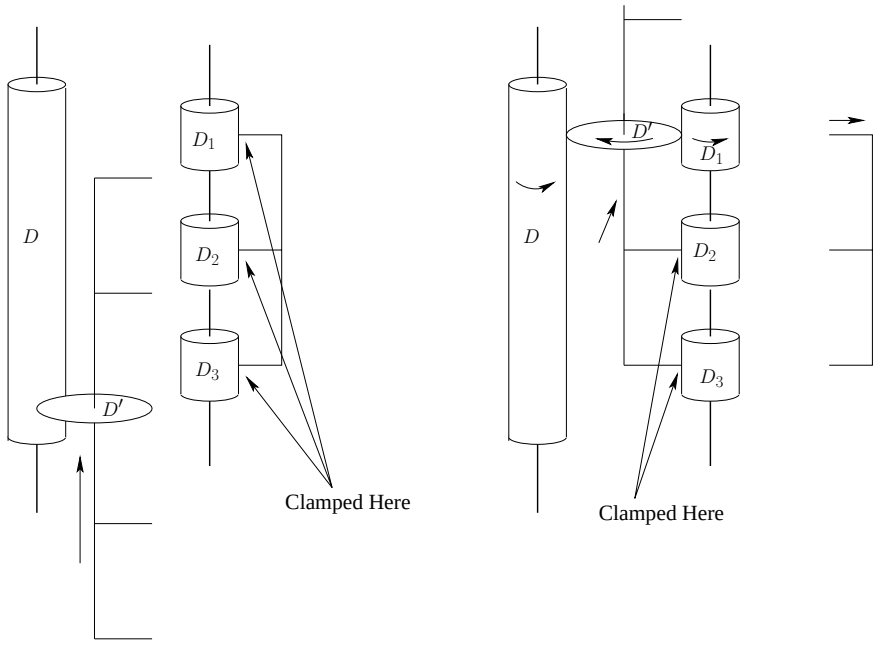
Observe that even though the above mapping device can implement only a mapping from $[0, \pi/2]$ to $[0, \pi/2]$, with a linear mapping device that can amplify or reduce angle, for any nonlinear mapping, we can construct a device to simulate it.

2.7. Selection controller. Another useful device is the so-called *selection controller*, which will rotate one of several cylinders, depending on the transitional displacement of a bar from its initial position or, equivalently, the rotational displacement of a disc from its initial orientation. Therefore, different positions of the bar will incur different movements of the objects in the space.

Suppose there are n cylinders, called *choice cylinders*, from which one is chosen to be rotated, depending on the transitional displacement of a sliding bar. Let l denote the transitional displacement of the sliding bar. We assume that $0 < l < 1$. Further, if $2i/(2n-1) < l < (2i+1)/(2n-1)$ for some i, $0 \le i \le n-1$, the selection controller will select the ith choice cylinder to rotate. This can be implemented by the device in Figure 8.

To the left there is a long cylinder S engaged with a rotational movement sequence controller so that S is rotated by an angle of 2π during a certain period of each cycle and remains static at any other time. To the right there is a pile of n identical cylinders, $D_0, D_1, \ldots, D_{n-1}$. These cylinders share the same axis, but each can rotate independently. The height of each cylinder is $1/(2n-1)$, and the distance between two contiguous cylinders is also $1/(2n-1)$. The radii of $D_0, D_1, \ldots, D_{n-1}$, and D are all r. The distance between D's axis and D_is's axis is $2r + 2R$.

The sliding bar is attached to what we call a *selective engager* shown in the middle of Figure 8. The selective engager consists of a disc D' with radius R and $2n-2$ blocking bars, each of which has length R. $n-1$ of these blocking bars are above D', and the others are below D'. The vertical distance between any two contiguous bars is $2/(2n-1)$, and so are the distance between D' and the bar immediately above D' as well as the distance between D' and the bar immediately below D'.



(a) Disengaging period (b) Engaging period

FIG. 8. *Selection controller.*

In each cycle, initially the selective engager is placed in such a position that D' is at the same height as the lower face of D_1. Also, the selective engager does not contact either D or any D_is. After the sliding bar moves vertically by a distance of l, $2i/(2n-1) < l < (2i+1)/(2n-1)$ for some i, the selective engager will move upwards by a distance of l accordingly so that it will be at the same height as D_i.

Then the selective engager is moved horizontally to the position right between D and D_is. Since the distance between D's axis and D_is's axis is $2r + 2R$, D' will contact both D and D_i. Also, any of $D_0, D_1, \ldots, D_{n-1}$ other than D_i will contact one of those blocking bars so that they are forbidden from rotating.

After removing the blocking bars originally clamping the n cylinders, only n_i can rotate freely. Therefore, when D is rotated by an angle of 2π, it will rotate D', which in turn rotates D_i. Since D and D_i have the same radius, D_i will be rotated by exactly 2π.

The functionality of this device is just like the *switch–case* structure in a C program. In our remaining section, we will say "If the transitional (rotational) displacement of a bar (disc, respectively) is in the range of (a, b), the sequencer will do ...," implicitly assuming that we have constructed a particular selection controller as described here to do this task.

3. Simulation of a universal TM. Given the basic gadgets described above, we are ready to construct a frictional mechanical system that simulates a universal TM. Our frictional mechanical system consists of two components: a *control component* simulating the finite state control and a *tape component* simulating the read-write

tape. All the objects in the system are linked or engaged with a sequencer, which controls the behavior of those objects. The sequencer is engaged with the power disc that is constantly rotating clockwise. Therefore, the sequencer will be rotating counterclockwise constantly, and it will drive all the objects in the system in a specified way as it rotates.

In the control component, there is a disc D_{state} whose rotational position represents the current state of the universal TM. Similarly, in the tape component, there are three discs $D_{current}$, D_{left}, and D_{right} whose rotational positions together represent the status of the read-write tape. (The status of the tape includes the contents of the tape as well as the current position of the read-write head.)

The control component will take the current symbol and the current state of the universal TM, both of which are represented by rotational positions of certain discs, as input and compute the next state, the next move of the head, and the symbol replacing the current symbol, all of which are also represented by rotational positions. The tape component will then modify the rotational positions of $D_{current}$, D_{left}, and D_{right}, depending on the next move and the replacing symbol provided by the control component.

The first subsection presents the methods used to encode the current state of the universal TM and the current status of the read-write tape by rotational positions. The next two subsections describe the construction of the control component and the tape component, respectively. The last subsection shows how these two components work together to simulate a universal TM and, subsequently, how the two main theorems of this paper are proved.

3.1. Encoding the configuration of the universal TM. The configuration of a TM includes the current state, the current tape contents, and the current head location. To be able to simulate a TM, our frictional mechanical system should be able to record the configuration of the TM by rotational positions of discs in the system.

The status of the read-write tape of the universal TM can be encoded by the rotational positions of three discs $D_{current}$, D_{left}, and D_{right}. If $\omega_1\omega_2\cdots\omega_{k_1-1}\check{\omega_{k_1}}$ $\omega_{k_1+1}\cdots\omega_{k_2}$ is the current tape status, the rotation of $D_{current}$, $\beta_{current}$, the rotation of D_{left}, β_{left}, and the rotation of D_{right}, β_{right} are set as follows:

$$\beta_{current}(\omega_1\omega_2\cdots\check{\omega_{k_1}}\cdots\omega_{k_2}) = \frac{2\omega_{k_1}\pi}{2m+1}, \tag{3}$$

$$\beta_{left}(\omega_1\omega_2\cdots\check{\omega_{k_1}}\cdots\omega_{k_2}) = 2\pi\left(\sum_{i=1}^{k_1-1}\frac{\omega_{k_1-i}}{(2m+1)^i}\right), \tag{4}$$

$$\beta_{right}(\omega_1\omega_2\cdots\check{\omega_{k_1}}\cdots\omega_{k_2}) = 2\pi\left(\sum_{i=1}^{k_2-k_1}\frac{\omega_{i+k_1}}{(2m+1)^i}\right). \tag{5}$$

In particular, $\beta_{left} = 0$ if $k_1 = 1$, and $\beta_{right} = 0$ if $k_1 = k_2$.

Therefore, $\beta_{current}$ encodes the current symbol, and D_{left} (D_{right}, respectively) encodes the substring to the left (right, respectively) of the current symbol.

It is easy to see that this encoding function has the following properties: (i) $(2i-1)\pi/(2m+1) < \beta_{current} < (2i+1)\pi/(2m+1)$ if $\omega_{k_1} = i$; (ii) $(2i-1)\pi/(2m+1) < \beta_{left} < (2i+1)\pi/(2m+1)$ if $\omega_{k_1-1} = i$; and (iii) $(2i-1)\pi/(2m+1) < \beta_{right} < (2i+1)\pi/(2m+1)$ if $\omega_{k_1+1} = i$.

Therefore, linking a selection controller with each of $D_{current}$, D_{left}, and D_{right} will allow the frictional mechanical system to decide the current symbol of the tape and the two symbols next to it, which will be used by the control component and the tape component.

During the simulation of the universal TM, if the current state of the universal TM is q_i, D_{state} will be set at a rotational position of $\lambda_i = i\pi/(2\sigma)$. Observe that every rotational position of D_{state} that represents a state is between 0 and $\pi/2$. Again, linking a selection controller with D_{state} will allow the frictional mechanical system to decide the current state of the tape.

3.2. Finite state control component. We let $\delta_1 : Q\times\Sigma \to Q$, $\delta_2 : Q\times\Sigma \to \Sigma$, and $\delta_3 : Q \times \Sigma \to \{L, R\}$ denote the three components of the transition function δ, respectively. More specifically, if the current state is q_j and the current symbol is i, the next state is $\delta_1(q_j, i)$, the symbol to replace the current symbol is $\delta_2(q_j, i)$, and the next move of the head is $\delta_3(q_j, i)$.

The control component consists of $3m$ nonlinear mapping devices. The first m of these nonlinear mapping devices, $M_{1,0}$, $M_{1,1}$, ..., $M_{1,m-1}$, are used to implement δ_1, the next state function. For each i, $0 \le i \le m-1$, $M_{1,i}$ is designed in such a way that if the input disc of $M_{1,i}$ is rotated by an angle of $\lambda_j = j\pi/(2\sigma)$ from its initial orientation, the output disc will be rotated by an angle of $\lambda_{j'} = j'\pi/(2\sigma)$. Here $\delta_1(q_j, i) = q_{j'}$. In other words, if the input disc is rotated by an angle corresponding to the current state of the universal TM, the output disc will be rotated by an angle corresponding to the next state of the TM.

Suppose the current state is q_j and the current symbol is i. As the current symbol can be determined by applying a selection controller to $D_{current}$, the sequencer will be able to choose $M_{1,i}$ from $M_{1,0}, M_{1,1}, \ldots, M_{1,m-1}$ and rotate the input disc of $M_{1,i}$ by an angle of λ_j, which is recorded by D_{state}. Then D_{state} will be set at the angle recorded by the output disc of $M_{1,i}$ and the nonlinear mapping device $M_{1,i}$ will be reset to its initial position.

In the remaining $2m$ nonlinear mapping devices, $M_{2,0}$, $M_{2,1}$, ..., $M_{2,m-1}$ are used to implement δ_2; and $M_{3,0}$, $M_{3,1}$, ..., $M_{3,m-1}$ are used to implement δ_3. For each $i, 0 \le i \le m-1$, $M_{2,i}$ has the property that if the input disc of $M_{2,i}$ is rotated by an angle of $\lambda_j = j\pi/(2\sigma)$ from its initial orientation, the output disc will be rotated by an angle of $2\delta_2(q_j, i)\pi/(2m+1)$ from its initial orientation. Similarly, for each i, $0 \le i \le m-1$, $M_{3,i}$ has the property that if the input disc of $M_{3,i}$ is rotated by an angle of λ_j, the output disc will be rotated by an angle of $\pi/4$ if $\delta_3(q_j, i) = L$ or $\pi/2$ if $\delta_3(q_j, i) = R$.

Therefore, the next move and the replacing symbol will be represented by rotational positions of certain discs. These rotational positions will be used by the tape component to update the rotational positions of $D_{current}$, D_{left}, and D_{right} according to the transition function δ.

3.3. Read-write tape component. As mentioned above, the control component will generate two rotational positions, one representing the next move and the other representing the replacing symbol. Let $\omega_1\omega_2\cdots\omega_{k_1}^{\check{}}\cdots\omega_{k_2}$ be the current tape status and ω'_{k_1} be the replacing symbol.

For our convenience, we use $\beta_{current,t}$ to denote the angle of $D_{current}$ at the beginning of the tth rotational cycle (of the sequencer). $\beta_{left,t}$, $\beta_{right,t}$, and $\beta_{state,t}$ are defined likewise. First, suppose the next move of the head is to go rightward. There are three cases:

1. $k_1 = k_2$; i.e., the head is at the right end-mark:
The status of the tape will be changed to $\omega_1\omega_2\cdots\omega'_{k_1}\omega_{\check{k_2+1}}$. Here $\omega_{k_2+1} = 2$ (indicating the right end-mark) as the head will pad a right end-mark to the right. Therefore, we have the following recursive equations:

$$\beta_{current,t+1} = 2\frac{2\pi}{2m+1}, \tag{6}$$

$$\beta_{right,t+1} = 0, \tag{7}$$

$$\beta_{left,t+1} = \frac{\beta_{left,t}}{2m+1} + \frac{2\pi\omega'_{k_1}}{2m+1}. \tag{8}$$

2. $k_1 = 1$; i.e., the head is at the left end-mark:
As the universal TM will never overwrite the left end-mark, ω_1 will still be 1 (indicating the left end-mark), and the status of the tape will be changed to $\omega_1\check{\omega_2}\omega_3\cdots\omega_t$. Therefore, we have

$$\beta_{current,t+1} = \frac{2\pi\omega_2}{2m+1}, \tag{9}$$

$$\beta_{right,t+1} = \left(\beta_{right,t} - \frac{2\pi\omega_2}{2m+1}\right)\cdot(2m+1), \tag{10}$$

$$\beta_{left,t+1} = \frac{2\pi}{2m+1}. \tag{11}$$

3. $1 < k_1 < k_2$:
The status of the tape will be changed to $\omega_1\omega_2\cdots\omega'_{k_1}\omega_{\check{k_1+1}}\omega_{k_1+2}\cdots\omega_{k_2}$. Thus, correspondingly, the recursive equations are

$$\beta_{current,t+1} = \frac{2\pi\omega_{k_1+1}}{2m+1}, \tag{12}$$

$$\beta_{right,t+1} = \left(\beta_{right,t} - \frac{2\pi\omega_{k_1+1}}{2m+1}\right)\cdot(2m+1), \tag{13}$$

$$\beta_{left,t+1} = \frac{\beta_{left,t}}{2m+1} + \frac{2\pi\omega'_{k_1}}{2m+1}. \tag{14}$$

Similarly, if the next move is to go leftward, there are two cases (the read-write head cannot go leftward if it is at the left end-mark):

1. If $k_1 = k_2$, i.e., the head is at the right end-mark:

$$\beta_{current,t+1} = \frac{2\pi\omega_{k_1-1}}{2m+1}, \tag{15}$$

$$\beta_{right,t+1} = \begin{cases} \frac{2\cdot 2\pi}{2m+1} & \text{if } \omega'_{k_1} = 2, \\ \frac{2\pi\omega'_{k_1}}{2m+1} + \frac{2\cdot 2\pi}{(2m+1)^2} & \text{if } \omega'_{k_1} \neq 2, \end{cases} \tag{16}$$

$$\beta_{left,t+1} = \left(\beta_{left,t} - \frac{2\pi\omega_{k_1-1}}{2m+1}\right)(2m+1). \tag{17}$$

2. If $1 < k_1 < k_2$:

$$\beta_{current,t+1} = \frac{2\pi\omega_{k_1-1}}{2m+1}, \tag{18}$$

$$\beta_{right,t+1} = \frac{\beta_{right,t}}{2m+1} + \frac{2\pi\omega'_{k_1}}{2m+1}, \tag{19}$$

$$\beta_{left,t+1} = \left(\beta_{left,t} - \frac{2\pi\omega_{k_1-1}}{2m+1}\right)(2m+1). \tag{20}$$

With selection controllers, the system can change the rotational positions of $D_{current}$, D_{left}, and D_{right} from $\beta_{current,t}$, $\beta_{left,t}$, and $\beta_{right,t}$ to $\beta_{current,t+1}$, $\beta_{left,t+1}$, and $\beta_{right,t+1}$, respectively, according to the recursive equations described above.

3.4. Putting it together. With mechanical components that can simulate the transition function and the tape of a universal TM, the frictional mechanical system that simulates the universal TM is almost immediate. The movements of the objects in this system are controlled by the rotations of the sequencer. In each cycle of rotation of the sequencer, the frictional mechanical system will finish the simulation of one step of the universal TM.

At the beginning of each cycle, the symbol at the current head location is decided, depending on the rotational position of $D_{current}$. According to the current symbol as well as the current state recorded by D_{state}, the control component will make a sequence of moves and then decide (i) the next state, (ii) the symbol replacing the current symbol, and (iii) the next move of the tape head. The tape component will then make a sequence of moves to change the rotational positions of $D_{current}$, D_{left}, and D_{right} according to the symbol replacing the current symbol and the next move. This finishes the simulation of one step of the computation of the universal TM.

Initially, D_{state} is set at the orientation encoding the start state of the TM. The orientations of $D_{current}$, D_{left}, and D_{right} also correspond to the initial status of the read-write tape. The simulation for the computation of the universal TM terminates when the rotational position of D_{state} is found to be corresponding to the accepting or rejecting state of the universal TM (we call these rotational positions *terminating orientations*) at the beginning of a rotational cycle of the sequencer.[5]

Hence, we have proved the following theorem.

THEOREM 3.1. *For any universal TM M, a frictional mechanical system can be constructed which has the property that, for any input string ω of M, the objects to the system can be set in a corresponding initial configuration so that a specified final configuration can be reached if and only if M accepts ω.*

As M is a universal TM, our frictional mechanical system can be used for general-purpose computing. Thus it has the computational power of any conventional electronic computer.

4. A frictional mechanical system with error. As mentioned in the introduction of this paper, our mechanical frictional system can simulate a universal TM without any error only if the system can be constructed and work exactly as it is specified. In the presence of errors, it is not possible to record the current configuration of the universal TM by the rotational positions of D_{state}, $D_{current}$, D_{left}, and D_{right} exactly as it is. Therefore, the computational power of the frictional mechanical system is restricted, as the errors in the rotational positions of these discs may be accumulated significant enough to induce an incorrect result in the simulation of the universal TM.

[5]Observe that D_{state} might be at a terminating orientation momentarily as it rotates around. However, if at the beginning of a rotational cycle D_{state} stays at a terminating orientation, this means that the universal TM has reached an accepting or rejecting state.

We use ϵ to denote the upper bound for the error in an angle which occurs in a single mechanical operation. ϵ is determined by the degree of accuracy in constructing mechanical devices as well as measuring rotational (and transitional) displacements.

4.1. A constant size frictional mechanical system in ϵ-error model. We first discuss a frictional mechanical system in this ϵ-error model; this system has exactly the same structure as the system in the exact model, and therefore it has only a constant number of parts.

Let $\beta'_{state,t}$ denote the correct angle of D_{state} at the beginning of the tth rotational cycle if the frictional mechanical system has no error. Further, let $\Delta_{state,t} =\mid \beta'_{state,t} - \beta_{state,t} \mid$; i.e., $\Delta_{state,t}$ is the error in $\beta_{state,t}$. $\beta'_{current,t}$, $\Delta_{current,t}$, $\beta'_{left,t}$, $\Delta_{left,t}$, $\beta'_{right,t}$, and $\Delta_{right,t}$ are defined accordingly.

In each rotational cycle, it takes a sequence of angle operations to generate each of $\beta_{state,t+1}$, $\beta_{current,t+1}$, $\beta_{left,t+1}$, and $\beta_{right,t+1}$ in the frictional mechanical system. Each operation involves adding an angle to (or deducting an angle from) the rotational position of a disc, multiplying an angle by a constant factor, or a nonlinear mapping. It is easy to see that there exist two constants c_1 and c_2 such that if the error in a rotational position is Δ, after any single operation, the error is bounded by $c_1\Delta + c_2\epsilon$. Further, as in each cycle the number of operations performed to get $\beta_{current,t+1}$, $\beta_{right,t+1}$, $\beta_{left,t+1}$, and $\beta_{state,t+1}$ is bounded by a constant, we can assume that there are two constants C_1 and C_2 such that $\Delta_{state,t+1} < C_1\Delta_{state,t} + C_2\epsilon$, $\Delta_{current,t+1} < C_1\Delta_{current,t} + C_2\epsilon$, $\Delta_{right,t+1} < C_1\Delta_{right,t} + C_2\epsilon$, and $\Delta_{left,t+1} < C_1\Delta_{left,t} + C_2\epsilon$.

For simplicity, we assume $C_1, C_2 > 2$.

There are only m valid values for $\beta'_{current,t+1}$ (i.e., $0, 2\pi/(2m+1), \ldots, 2(m-1)\pi/(2m+1)$), and the difference between any two valid values is at least $2\pi/(2m+1)$. Therefore, as long as $\Delta_{current,t+1} < \pi/(2(2m+1))$, a selection controller can be used to determine $\beta'_{current,t+1}$ from $\beta_{current,t+1}$. This means that $\beta_{current,t+1}$ can be corrected at the beginning of each cycle, given that $\epsilon < d_1/m$ for some constant $d_1 > 0$.

The same analysis applies to $\beta_{state,t+1}$: if $\epsilon < d_2/\sigma$ for some constant $d_2 > 0$, $\beta_{state,t+1}$ can be corrected at the beginning of each cycle. Therefore, only the errors in $\beta_{left,t}$ and $\beta_{right,t}$ may be accumulated to the next cycle. As at each step $\beta_{left,t}$ and $\beta_{right,t}$ are used only to distinguish ω_{k_1-1} and ω_{k_1+1}, errors in $\beta_{left,t}$ and $\beta_{right,t}$ will not cause any incorrectness if they are less than $\pi/(2(2m+1))$.

Observe that if the read-write head reaches the left end-mark, the error in $\beta_{left,t}$ will be discarded. This is because when the head moves rightward from the end-mark, none of $\beta_{current,t+1}$, $\beta_{right,t+1}$, and $\beta_{left,t+1}$ will depend on $\beta_{left,t}$, as shown in (9), (10), and (11). Similarly, if the read-write head reaches the right end-mark, the error in $\beta_{right,t}$ will be discarded too. Therefore, if the head of the universal TM visits the left and right end-marks periodically during the computation, the errors in β_{left} and β_{right} will be corrected periodically.

We define another TM M'. M' will simulate the computation of M. The difference between M' and M is that each time after M' finishes simulating M by a constant number K of steps of computation (this constant will be specified later), the head of M' will make a sweep of the tape. By "sweep" we mean that it will first move leftward until it reaches the left end-mark; then it will move rightward until it reaches the right end-mark; afterwards, it will move leftward again and return to the location where it was before the sweep. After it finishes the sweep, M' will start simulating the next K steps of the computation of M. It is easy to see that M' has the property that, at any time, if the current working space is s, the head of M' will reach the left

and right end-marks within at most $2S + 2K$ steps.

Clearly, M' is equivalent to M in the sense that it decides exactly the same language as M does. Therefore, to simulate M, it suffices to construct a frictional mechanical system that can simulate M'. For any input string ω of M', if M' decides ω in space S, the errors in β_{left} and β_{right} will be accumulated through at most $2S + 2K$ steps before they are discarded.

Thus, if the errors in β_{left} and β_{right} accumulated in $2S + 2K$ steps can be bounded by $\pi/(2(2m + 1))$ (otherwise incorrect values of ω_{k_1-1} and ω_{k_1+1} might be used), it will not induce any incorrect result in simulating the universal TM M' (and thus in simulating M) on input string ω.

Suppose at the tth step the read-write head moves rightward from the left end-mark. As the accumulated error of β_{left} is discarded at this moment, $\Delta_{left,t}$ is bounded by a constant, say, $C_3\epsilon$. As $\Delta_{left,t+1} < C_1\Delta_{left,t} + C_2\epsilon$, we have

$$\begin{aligned}\Delta_{left,t+2S+2K} &< C_1^{2S+2K}\Delta left, t + C_2\frac{C_1^{2S+2K} - 1}{C_1 - 1}\epsilon \\ &< C_1^{2S+2K}C_3\epsilon + C_2C_1^{2S+2K}\epsilon.\end{aligned}$$

To bound Δ_{left} by $\pi/(2(2m + 1))$, it suffices to let

$$\epsilon < \frac{1}{2(2m + 1)(C_3C_1^{2S+2K} + C_2C_1^{2S+2K})} < d \cdot 2^{-c(S+K)}$$

for some constants c and d.

If we let K be 1, M' will sweep the tape after each step of simulating M. Therefore, for any input string ω, it will take at most $(2S + 1)T$ steps for M' to decide ω if M decides ω in time T and space S. Since $S \leq T$, the total time used by M' is bounded by $(2T + 1)T$. Hence, we have the following theorem.

THEOREM 4.1. *For any universal TM M, a frictional mechanical system with error can be constructed to simulate M. It has the property that, for any space bound S, if the single-operation error of the system, ϵ, is bounded by* $\min\{d \cdot 2^{-cS}, d_1/m, d_2/\sigma\}$ *for some constants c, d, d_1, and d_2, then, given any input string ω that M decides in space bound S, the frictional mechanical system will reach a distinguished final configuration from an initial configuration encoding ω if and only if M accepts ω. Further, the frictional mechanical system will take at most $(2T + 1)T$ cycles to finish the computation if M decides ω in T steps.*

If we let $K = S$, M' will simulate M by S steps between two consecutive sweeps. Thus, it will take at most three times as much time as M takes to finish the computation. The disadvantage is that now M' (and hence our frictional mechanical system) depends on S. For different values of S, a different frictional mechanical system needs to be constructed to simulate M.

With some additional reasonable assumption, we can show that a periodic sweeping is not necessary. Given that $\epsilon = O(2^{-cS})$, if M can decide an input string ω in space S, our frictional mechanical system will finish simulating M with the correct result. Due to the length of the proof, we will include it in the appendix.

4.2. A frictional mechanical system in ϵ-error model with $\epsilon = \Omega(1)$. The analysis of the above system implies that $1/\epsilon$ will have to increase exponentially as S increases to maintain the correctness of the frictional mechanical system. If in a frictional mechanical system $O(S)$ discs instead of three discs are used to encode the contents of the tape, each representing one cell, this frictional mechanical system in

ϵ-error model can simulate the universal TM M with space bound S, where $\epsilon = \Omega(1)$. This is because now each disc has only a constant number of valid rotational positions, and selection controllers can be used to distinguish the correct value represented by the disc. This is better than the previous result in the sense that $1/\epsilon$ does not increase as S increases. However, the frictional mechanical system is now dependent on S, as it needs S discs to encode the tape. In other words, this model of frictional mechanical systems is a digital computer, just like the analytical engine. If we want to increase the computational power of the frictional mechanical system by using larger space bound S, we will have to add more discs used to represent the tape.

More specifically, for the kth cell of the tape, four discs are used to represent the current state of the cell: $D_{k,symbol}$ represents the symbol in the current cell; $D_{k,head}$ indicates whether the read-write head is located at this cell; $D'_{k,head}$ indicates whether the read-write head was located at this cell at the end of last step; and $D_{k,next}$ indicates the next move of the head. Also, for each cell, there is a set of nonlinear mapping devices which implement the transition function. We call all the parts used to represent the kth cell the kth cell component and denote it by C_k. In addition, there is a single disc D_{state} which records the current state of the universal TM.

At the beginning of each rotational cycle of the power disc, both $D_{k,head}$ and $D'_{k,head}$ are set at $\pi/4$ if the head is located at the kth cell or 0 if not. $D_{k,symbol}$ is set at $2i\pi/(2m+1)$ if the symbol in the kth cell is i. And D_{state} is set at $j\pi/(2\sigma)$, indicating that the current state of the TM is q_j. Then, if the rotational position of $D'_{k,head}$ is $\pi/4$, the rotational position of $D_{k,symbol}$ will be changed to $2i'\pi/(2m+1)$, where $i' = \delta_2(q_j, i)$. If the rotational position of $D'_{k,head}$ is 0, $D_{k,symbol}$ will be clamped so that its rotational position will not be changed. Also, the rotational position of $D_{k,next}$ is set at 0 if the next move is to go leftward and $\pi/4$ if the next move is to go rightward.

The only thing remaining is to change each $D_{k,head}$ accordingly. More specifically, for each k, if the rotational position of $D_{k,head}$ is $\pi/4$, (i.e., the head is at the kth cell), $D_{k-1,head}$ (or $D_{k+1,head}$) will be changed to $\pi/4$ if $D_{k,next}$ is set at 0 (or $\pi/4$, respectively) while $D_{k,head}$ will be reset to 0; if the rotational position of $D_{k,head}$ is 0, $D_{k,head}$, $D_{k-1,head}$, and $D_{k+1,head}$ will be clamped.

The problem is that there will be some conflicts in the movements of different components. For example, suppose the current head is located at the k_1th cell. Then, the k_1th component will try to change $D_{k_1-1,head}$ in case the next move is to go leftward. However, the (k_1-1)th component itself will try to clamp $D_{k_1-1,head}$ as the rotational position of $D'_{k_1-1,head}$ is 0. To resolve this problem, we divide the S head components into three groups so that C_k belongs to the (k mod 3)th group. First, the components in group 0 will be activated to change all the $D_{k,head}$s according to the rules described above. Then the components in group 1 will be activated. And last are the components in group 2. By this, no two components that have conflict movement will be activated at the same time.

After all components have been activated, for each k, $D_{k,head}$ will represent whether the read-write head is located at the kth cell at the beginning of the next step. Then the rotational position of $D_{k,head}$ is copied to $D'_{k,head}$ so that each component is ready for the simulation of the next computation of the universal TM.

It is easy to see that for a frictional mechanical system constructed as above, ϵ can be set to a constant regardless of the space bound S, as each disc has only a constant number of valid orientations and operations; only constant number of operations are needed to finish one step of simulation.

5. Reduction from A_{TM} to the frictional mover's problem. We prove the undecidability of the frictional mover's problem by a reduction from the A_{TM} problem. It suffices to show that every input of the A_{TM} problem, which is the description of a TM M along with an input string ω of M, can be transformed to an input of the frictional mover's problem, which is a frictional mechanical system with initial and goal configurations such that (i) the transformation can be performed by a specified procedure that terminates in a finite period of time and (ii) M accepts ω if and only if the frictional mechanical system can reach the goal configuration from its initial configuration.

Therefore, it is necessary that all the objects in the resulting frictional mechanical system and their positions can be described by rational coefficients. For example, for each disc, its radius as well as the location of its center need to be specified by rational numbers. Similarly, the length, orientation, and location of a bar need to be specified by rational numbers.

Recall that a universal frictional mechanical system involves only operations that add to a value (represented by the rotational position of a certain disc) a rational number or multiply the value by a rational number. Therefore, we can easily specify all the discs (including partial discs), bars, and cylinders in the system by rational coefficients without changing the functionalities of the various devices constructed by these parts.

The only exception is the irregular discs used in the nonlinear mapping devices. Each irregular disc has to be specified by some irrational coefficients, as indicated by (1). Here we prove the following lemma.

LEMMA 5.1. *The possibly irrational coefficients specifying the irregular discs used in the nonlinear mapping devices can be replaced by rational numbers without inducing any error in simulating the universal TM.*

Proof. Let D_1 be an irregular disc. It can be specified by the following two sets of parameters: $\{\theta_1, \theta_2, \ldots, \theta_n\}$, $\{r_1(\theta_0), r_1(\theta_1), \ldots, r_1(\theta_n)\}$. (Recall that $\theta_0 = 0$.) The boundary of D_1 inside the interval of $[\theta_i, \theta_{i+1}]$ is described by a linear function $r_1(\theta) = ((\theta - \theta_i) \cdot r_1(\theta_{i+1}) + (\theta_{i+1} - \theta) \cdot r_1(\theta_i))/(\theta_{i+1} - \theta_i)$, whose coefficients are entirely determined by $\theta_i, \theta_{i+1}, r_1(\theta_i)$, and $r_1(\theta_{i+1})$. Recall that in a universal frictional mechanical system, nonlinear mapping devices are used to implement the transition function δ, which takes only rational numbers as input. Therefore, $\theta_1, \theta_2, \ldots, \theta_n$ are all rational numbers. However, the exact value of each $r_1(\theta_i)$, denoted by $r_{1,i}$, could be an irrational number, as the computation involves irrational number $\sqrt{2}$ as well as the function tan. We replace each $r_{1,i}$ by a rational number $r'_{1,i}$ such that $|r'_{1,i} - r_{1,i}| < \epsilon'$ for some small $\epsilon' > 0$.

The nonlinear mapping device constructed with these "rationalized" parameters may cause two types of errors: *mechanical errors* and *logical errors*. A mechanical error occurs when two mechanical parts lose contact with, or crush into, each other while they are supposed to maintain continuous contact. A logic error occurs when the error of the resulting angle α causes a false interpretation by the universal frictional mechanical system.

We first show that mechanical errors can be avoided. We let D_2 be the coupling irregular disc of D_1 in the same nonlinear mapping device. We need to show that D_2 can also be described by rational numbers while keeping $r_1(\theta) + r_2(\theta + \pi)$ a constant for all $\theta \in [0, 2\pi]$. For each $\theta_i, i = 0, i, 2, \ldots, n$, the radius of D_2 at angle $\theta_i + \pi$ is computed by $r_2(\theta_i + \pi) = |\overline{O_1O_2}| - d - r_1(\theta_i)$. Since now $r_1(\theta_i)$ is chosen to be a rational number $r'_{1,i}$, and $|\overline{O_1O_2}|$ and d are all rational numbers, $r_2(\theta_i + \pi)$ is a rational

number. Therefore, the boundary of D_2 can be decomposed into $n+1$ subboundaries, corresponding to angular intervals $[\pi, \pi+\theta_1]$, $[\pi+\theta_1, \pi+\theta_2]$, ..., $[\pi+\theta_{n-1}, \pi+\theta_n]$, $[\theta_n - \pi, \pi]$, respectively. In each interval, the boundary can be specified by a linear function $r_2(\theta)$ of θ, just like the case for D_1. Therefore, D_2 can be described by rational numbers. For any $\theta \in (\theta_i, \theta_{i+1})$,

$$\begin{aligned} r_1(\theta) + r_2(\theta+\pi) &= \tfrac{(\theta-\theta_i)\cdot r_1(\theta_{i+1})+(\theta_{i+1}-\theta)\cdot r_1(\theta_i)}{\theta_{i+1}-\theta_i} + \tfrac{(\theta-\theta_i)\cdot r_2(\theta_{i+1}+\pi)+(\theta_{i+1}-\theta)\cdot r_2(\theta_i+\pi)}{\theta_{i+1}-\theta_i} \\ &= \tfrac{(\theta-\theta_i)(r_1(\theta_{i+1})+r_2(\theta_{i+1}+\pi))+(\theta_{i+1}-\theta)(r_1(\theta_i)+r_2(\theta_i+\pi))}{\theta_{i+1}-\theta_i} \\ &= |\overline{O_1O_2}| - d. \end{aligned}$$

This implies that irregular disc D_2 as described above still completely "complements" D_1 as defined in subsection 2.6. Therefore, during each operation D_1 and D_2 maintain continuous contact with the horizontal bar but do not compress it, thus causing no mechanical error.

Next we show that any mechanical error can be corrected. With the "rationalized" nonlinear mapping device, when the input angle is θ_i, the output angle is not exactly α_i but a value α_i' very close to α_i. Since nonlinear mapping devices are used to implement the transition function, each α_i is a rational number, as it encodes either a symbol or a state. Further, there exists a constant ϵ'' such that $|\alpha_i - \alpha_j| > \epsilon''$ if $\alpha_i \neq \alpha_j$. Here $= c \cdot \min\{\frac{1}{\sigma}, \frac{1}{m}\}$, where $c = \Omega(1)$. Therefore, there exists another constant $c' = \Omega(1)$ such that $|\alpha_i - \alpha_i'| < \frac{\epsilon''}{3}$ for all i if $\epsilon' < c' \cdot \min\{\frac{1}{\sigma}, \frac{1}{m}\} \cdot R$. Hence, a selection controller is able to find out the correct value of α_i from α_i', as α_i' is closer to α_i than to any other valid value.

This finishes the proof. □

With this lemma, we have the following theorem.

THEOREM 5.2. *The frictional mover's problem is undecidable.*

6. Conclusion. In this paper we introduced frictional mechanical systems and proved that a universal frictional mechanical system can simulate the computation of a universal TM. We also gave some results for the case where there are limited errors for the mechanical parts in the system. Our work implies that the frictional mover's problem is undecidable. It is, however, unclear to us what the implication of our work is to building nanocomputers at the macromolecule level when the nanotechnology further matures.

Appendix A. Error bound for β_{right} and β_{left} under additional assumption.

We have proved that by forcing the read-write head to visit the left and right end-marks periodically, the errors in β_{left} and β_{right} can be discarded after a certain number of steps so that they will not affect the result of simulating the universal TM. Here, we will show that, with the following assumption, there is no need for periodic sweeps of the tape.

Assumption 1. For any operation that will multiply an angle by a constant factor C, if before the operation the error in the angle is Δ, after the operation the error will become $C\Delta + k\epsilon$ for some constant k.

Under this assumption, an error in an angle θ will be reduced if the operation is to reduce θ by a constant factor (i.e., $C < 1$).

Now we will examine how the error in β_{right} is accumulated in each step using this assumption. We decompose $\Delta_{right,t}$ into two components: $\Delta^1_{right,t+1}$ and $\Delta^2_{right,t+1}$. The first component is due to $\Delta_{right,t}$, and the other component is the

error which occurs during the angle operations in this cycle. As in one cycle the number of operations to generate β_{right} is bounded by a constant number, we can assume $\Delta^2_{right,t+1} \leq C'_1\epsilon$ for some constant C'_1. $\Delta^1_{right,t+1}$, however, is determined by $\Delta_{right,t}$ as well as the angle operation on $\beta_{right,t}$ to generate $\beta_{right,t+1}$.

If the next move is rightward, according to (10) and (13), $\beta_{right,t}$ is multiplied by a factor of $(2m+1)$ and then added to another angle to get $\beta_{right,t+1}$. Therefore, the error in $\beta_{right,t}$ is amplified by a factor of $(2m+1)$, i.e., $\Delta^1_{right,t+1} = \Delta_{right,t} \cdot (2m+1)$. Similarly, if the next move is leftward, we have $\Delta^1_{right,t+1} = \Delta_{right,t}/(2m+1)$, as in (16) and (19) $\beta_{right,t+1}$ has a component $\beta_{right,t}/(2m+1)$.

Therefore, in each cycle, the error in β_{right} which is accumulated in previous cycles either is amplified by a factor of $(2m+1)$ or reduced to $1/(2m+1)$, depending on the move of the head. Hence we have the following recursive function:

$$\Delta_{right,t+1} \leq f(t)\Delta_{right,t} + \Delta^2_{right,t+1}. \tag{21}$$

Here $f(t)$ is defined as follows:

$$f(t) = \begin{cases} 2m+1 & \text{if the move of the head in the } t\text{th step is rightward,} \\ \frac{1}{2m+1} & \text{if the move of the head in the } t\text{th step is leftward.} \end{cases}$$

$\Delta_{right,1}$ is the error in β_{right} at the beginning of the computation. This error is due to the inaccuracy in setting the starting orientation of D_{right}. We can assume that $\Delta_{right,1} \leq C'_2\epsilon$.

According to the recursive equation, we can compute $\Delta_{right,t'+1}$ for any t':

$$\begin{aligned} & \Delta_{right,t'} \\ \leq\ & f(t'-1)\Delta_{right,t'-1} + \Delta^2_{right,t'} \\ \leq\ & f(t'-1)(f(t'-2)\Delta_{right,t'-2} + \Delta^2_{right,t'-1}) + \Delta^2_{right,t'} \\ & \vdots \\ & \vdots \\ \leq\ & \Delta_{right,1}\left(\prod_{i=1}^{t'-1} f(i)\right) + \sum_{j=2}^{t'} \Delta^2_{right,j}\left(\prod_{i=j}^{t'-1} f(i)\right). \end{aligned}$$

For any input string ω of M, we let S denote the working space M needs to use to decide ω. It is easy to see that, for any t' and j, $\prod_{i=j}^{t'-1} f(i) \leq (2m+1)^S$ as the right moves could outnumber the left moves at most by S. Therefore, $\Delta_{rught,t'}$ is bounded by

$$\Delta_{right,1}(2m+1)^S + \sum_{j=2}^{t'} \Delta^2_{right,j}(2m+1)^S \leq C'_2\epsilon(2m+1)^S + 2^{cS}C'_1\epsilon(2m+1)^S,$$

as $t' < 2^{cS}$ for some constant c.

To bound Δ_{right} by $1/(2(2m+1))$ (so that at each cycle correct value of ω_{k_1+1} could be retrieved from β_{right}), we need only

$$\epsilon \leq \frac{1}{2(2m+1)} \cdot \frac{1}{(\epsilon(2m+1)^S)(C'_2 + 2^{cS}C'_1)} < d' \cdot 2^{-c''S}$$

for some constants c'' and d'.

We have thus proved the following theorem.

THEOREM A.1. *For any universal TM M, a frictional mechanical system with error can be constructed to simulate M. It has the property that, for any space bound S, if the single-operation error of the system, ϵ, is bounded by* $\min(d' \cdot 2^{-c''S}, d_1/m, d_2/\sigma)$ *for some constants c'', d', d_1, and d_2, then, given any input string ω that M decides in space bound S, the frictional mechanical system will reach a distinguished final configuration from an initial configuration encoding ω if and only if M accepts ω. Further, the frictional mechanical system will take T cycles to finish the computation if M decides ω in T steps.*

COMPUTING ELEMENTARY SYMMETRIC POLYNOMIALS WITH A SUBPOLYNOMIAL NUMBER OF MULTIPLICATIONS*

VINCE GROLMUSZ†

Abstract. Elementary symmetric polynomials S_n^k are the building blocks of symmetric polynomials. In this work we prove that for constant k's, S_n^k modulo composite numbers $m = p_1p_2$ can be computed using only $n^{o(1)}$ multiplications if the coefficients of monomials $x_{i_1}x_{i_2}\cdots x_{i_k}$ are allowed to be 1 either mod p_1 or mod p_2 but not necessarily both. To the best of our knowledge, no previous result yielded even a sublinear (i.e., n^ε, $0 < \varepsilon < 1$) number of multiplications for similar tasks. Moreover, our algorithm fits in the model of the most restrictive depth-3 arithmetic circuits (homogeneous, multilinear, or the graph model). In contrast, by a lower bound of Nisan and Wigderson [*Comput. Complexity*, 6 (1997), pp. 217–234], any homogeneous depth-3 circuit needs size $\Omega((n/2k)^{k/2})$ for computing S_n^k modulo primes. Moreover, the number of multiplications in our algorithm remains sublinear while $k = O(\log\log n)$. Our results generalize for other nonprime-power composite moduli as well. The proof uses perfect hashing functions and the famous BBR polynomial of Barrington, Beigel, and Rudich.

Key words. symmetric polynomials, arithmetic circuits, algebraic algorithms, composite modulus

1. Introduction.

Surprising ideas sometimes lead to considerable improvements in algorithms even for the simplest computational tasks. Let us mention here the integer-multiplication algorithm of Karatsuba and Ofman [19] and the matrix-multiplication algorithm of Strassen [27].

A new field with surprising algorithms is quantum computing. The most famous and celebrated results are Shor's algorithm for integer factorization [25] and Grover's database-search algorithm [17].

Since realizable quantum computers can handle only very few bits today, there are no practical applications of these fascinating quantum algorithms.

Computations involving composite, nonprime-power moduli (say, 6), on the other hand, can actually be performed on any desktop PC; unfortunately, we have little evidence of the power or applicability of computations modulo composite numbers (see, e.g., the circuit given by Kahn and Meshulam [18], or the low-degree polynomial of Barrington, Beigel, and Rudich [3]).

One of the problems here is the interpretation of the output of the computation. Several functions are known to be hard if computed modulo a prime. If we compute the same function f with 0-1 values modulo 6, then it will also be computed modulo—say, 3—since $f(x) \equiv 1 \pmod 6 \implies f(x) \equiv 1 \pmod 3$ and $f(x) \equiv 0 \pmod 6 \implies f(x) \equiv 0 \pmod 3$; consequently, computing f this way cannot be easier mod 6 than mod 3. This difficulty is circumvented in a certain sense by the definition of the weak representation of Boolean functions by mod 6 polynomials, defined in [28] and [3].

We will consider here another interpretation of the output, called a-strong representation (Definition 2). This definition will be more suitable for computations in which the output is a polynomial and not just a number.

Our goal is to compute this representation of the elementary symmetric polynomials

$$S_n^k = \sum_{\substack{I\subset\{1,2,\ldots,n\}\\ |I|=k}} \prod_{i\in I} x_i \tag{0}$$

modulo nonprime-power composite numbers with a much smaller number of multiplications than is possible over rationals or prime moduli.

Informally, the a-strong representation modulo 6 of the polynomial S_n^k is a polynomial of the form

$$\sum_{\substack{I\subset\{1,2,\ldots,n\}\\ |I|=k}} a_I \prod_{i\in I} x_i, \tag{1}$$

where either $a_I \equiv 1 \pmod 3$ or $a_I \equiv 1 \pmod 2$, but not necessarily both.

1.1. Our main result. Our main contribution here is an algorithm, using only $n^{o(1)}$ multiplications, computing—for constant k's—an a-strong representation of S_n^k of the form (1) modulo nonprime-power, composite integers (Theorems 4 and 7 and Corollaries 5 and 8).

1.1.1. Why do we count only the multiplications? In algebraic algorithms it is quite usual to count only the multiplications in a computation (for example, in the algorithm of Karatsuba and Ofman [19], or in the matrix-multiplication algorithms of Strassen [27] or Coppersmith and Winograd [5]). The reason for this is that the multiplication is *considered* to be a harder operation than the addition in most practical applications, and moreover, the multiplication is *proven* to be harder in most theoretical models of computation.

For example, computing the PARITY is reduced to computing the multiplication of two n-bit sequences, and, consequently, two n-bit sequences cannot be multiplied on a polynomial-size, constant-depth Boolean circuit [7], while it is well known that two n-bit sequences can be added in such a circuit.

1.2. Previous lower bounds. Most existing lower bounds were proven in the arithmetic circuit model of depth 3; circuits in this model are often called $\Sigma\Pi\Sigma$ circuits [22], [26].

$\Sigma\Pi\Sigma$ circuits perform computations of the following form:

$$\sum_{i=1}^{r} \prod_{j=1}^{s_i} (a_{ij1}x_1 + a_{ij2}x_2 + \cdots + a_{ijn}x_n + b_{ij}).$$

If all the $b_{ij} = 0$ and all the s_i's are the same number, then the circuit is called a homogeneous circuit; otherwise it is inhomogeneous. The size of the circuit is the number of gates in it: $1 + r + \sum_{i=1}^{r} s_i$.

A special class of homogeneous $\Sigma\Pi\Sigma$ circuits is called in [22] *the graph model*: here all $s_i = 2$ and all $a_{ij\ell}$ coefficients are equal to 1, and, moreover, the clauses of a product cannot contain the same variable twice. Consequently, such a product corresponds to a complete bipartite graph on the variables as vertices.

Note. Our algorithms fit into this very restrictive graph model of depth-3 circuits.

Graham and Pollak [8] asked how many edge-disjoint bipartite graphs can cover the edges of an n-vertex complete graph. They proved that $n-1$ bipartite graphs are sufficient and necessary. Later, Tverberg gave a very nice proof for this statement [30]. Having relaxed the disjointness property, Babai and Frankl [2] asked what is the minimum number of bipartite graphs, which covers every edge of an n-vertex complete graph by an odd multiplicity. Babai and Frankl proved that $(n-1)/2$ bipartite graphs are necessary. The optimum upper bound for the odd-cover was proved by Radhakrishnan, Sen, and Vishwanathan [22]. Radhakrishnan, Sen, and Vishwanathan also gave matching upper bounds for covers, when the off-diagonal elements of matrix M are covered by multiplicity 1 modulo a prime.

Nisan and Wigderson [21] showed that any homogeneous $\Sigma\Pi\Sigma$ circuit needs size $\Omega((n/2k)^{k/2})$ for computing S_n^k. This result shows that the homogeneous circuits are much weaker in computing elementary symmetric polynomials than the inhomogeneous ones. Nisan and Wigderson also examined bilinear and multilinear circuits in [21]. Note that the circuits in our constructions for $S_n^2(x,y)$ and for $S_n^k(x^1,x^2,\ldots,x^k)$ are also multilinear circuits.

We should note that exponential lower bounds were proved recently for simple functions for $\Sigma\Pi\Sigma$ circuits by Grigoriev and Razborov [10] and by Grigoriev and Karpinski [9].

Most recently, Raz and Shpilka got nice lower bound results for arithmetic circuits [24], and Raz [23] proved a $\Omega(n^2\log n)$ lower bound for matrix-multiplication in the model where the constants in the arithmetic circuits are bounded, solving a long-standing open problem.

1.3. Previous upper bounds. By a result of Ben-Or [26], every elementary symmetric polynomial S_n^k can be computed over fields by size-$O(n^2)$ inhomogeneous $\Sigma\Pi\Sigma$ circuits, using one-variable polynomial interpolation. Note that our construction with homogeneous circuits modulo nonprime-power composites beats Ben-Or's bound for k's less than $c\log\log n$ (for some positive c's).

In a somewhat related model, Muller and Preparata [20] showed that n-variable symmetric Boolean functions can be computed by depth-$O(\log n)$, size-$O(n)$ Boolean circuit.

To the best of the author's knowledge, there are no previous results concerning the computation of some form of the elementary symmetric polynomials even with a sublinear (i.e., n^{ε}, $0<\varepsilon<1$) number of multiplications, in any depth. Our results give a sub*polynomial* (that is, $n^{o(1)}$) number of multiplications even in the most restrictive depth-3 circuit model.

2. Alternative strong representation of polynomials. S_n^k can be naturally computed by $\binom{n}{k}$ product-gates by a homogeneous $\Sigma\Pi\Sigma$ circuit over any ring by the circuit of (0). One can save a little bit from the cost of this obvious construction (e.g., for $k=2n-1$ multiplications instead of $\binom{n}{2}$ is enough), but, as we already mentioned, by the result of Nisan and Wigderson [21], size $\Omega((n/2k)^{k/2})$ is needed to compute S_n^k on homogeneous $\Sigma\Pi\Sigma$ circuits.

It is quite plausible to think that if we change the nonzero coefficients of the monomials of S_n^k to some other nonzero coefficients, then the computational complexity of this modified polynomial will not be changed much: simply because even in the modified polynomial we would still need to generate the monomials with the nonzero coefficients somehow.

This intuition is verified by the next lemma (proven in the last section) in the case of finite fields.

LEMMA 1. *Suppose that a homogeneous* $\Sigma\Pi\Sigma$ *circuit computes polynomial*

$$g(x) = \sum_{\substack{I\subset\{1,2,\ldots,n\}\\ |I|=k}} a_I \prod_{i\in I} x_i$$

over the q *element field* F_q *with* u *gates, where* $a_I \neq 0$ *in* F_q. *Then* S_n^k *can be computed by a homogeneous* $\Sigma\Pi\Sigma$ *circuit of size* $O(u^{q-1})$.

From this lemma and from the $\Omega((n/2k)^{k/2})$-lower bound of Nisan and Wigderson [21] it is obvious that computing g over finite fields needs

$$\Omega((n/2k)^{\frac{k}{2(q-1)}})$$

multiplication gates.

Consequently, we cannot save much by computing g instead of S_n^k: if computing S_n^k needs polynomially many gates in n, then computing g still needs polynomially many gates in n (for any constant k).

Our main result is, however, that we *can save* much by computing certain strong representations of the elementary symmetric polynomials, say, over the modulo 15 integers, Z_{15}. More exactly, such representations can be computed by $\Sigma\Pi\Sigma$ circuits containing subpolynomially many multiplication gates. (We call a function $h(n)$ subpolynomial if for all $\varepsilon > 0$, $h(n) = O(n^{\varepsilon})$.)

Several authors (e.g., [28], [3]) defined the weak and strong representations of Boolean functions for integer moduli. Here we need the definition of a sort of strong representation of polynomials modulo composite numbers. We call this representation *alternative-strong* representation, abbreviated *a-strong representation*.

DEFINITION 2. *Let* m *be a composite number* $m = p_1^{e_1}p_2^{e_2}\cdots p_\ell^{e_\ell}$. *Let* Z_m *denote the ring of modulo* m *integers. Let* f *be a polynomial of* n *variables over* Z_m:

$$f(x_1, x_2, \ldots, x_n) = \sum_{I\in\{0,1,2,\ldots,d\}^n} a_I x_I,$$

where $a_I \in Z_m$, $x_I = \prod_{i=1}^n x_i^{\nu_i}$, *where* $I = \{\nu_1, \nu_2, \ldots, \nu_n\} \in \{0, 1, 2, \ldots, d\}^n$. *Then we say that*

$$g(x_1, x_2, \ldots, x_n) = \sum_{I\in\{0,1,2,\ldots,d\}^n} b_I x_I$$

is an a-strong representation *of* f *modulo* m *if*

$$\forall I \in \{0, 1, 2, \ldots, d\}^n \quad \exists j \in \{1, 2, \ldots, \ell\}, \quad a_I \equiv b_I \pmod{p_j^{e_j}},$$

and if for some i, $a_I \not\equiv b_I \pmod{p_i^{e_i}}$, *then* $b_I \equiv 0 \pmod{p_i^{e_i}}$.

Example. Let $m = 6$, and let $f(x_1, x_2, x_3) = x_1x_2 + x_2x_3 + x_1x_3$; then $g(x_1, x_2, x_3) = 3x_1x_2 + 4x_2x_3 + x_1x_3$ is an a-strong representation of f modulo 6.

Remarks on the definition of the a-strong representations.

- The requirements of Definition 2 for the coefficients are more restrictive than the requirements for the coefficients of f in Lemma 1, since the latter requires that the coefficients should not be zero, while the former prescribes that they should satisfy some congruencies.

- Definition 2 is a natural generalization of reducing a polynomial modulo an integer m. Usually, it can be done by reducing the coefficients modulo m, and when we compute the value of the polynomial for a given substitution, then the additions and multiplications should be done modulo m. If m has only one prime-divisor, then our definition and the usual one coincide. On the other hand, for example, $m = p_1^{\alpha_1} p_2^{\alpha_2}$ (p_1, p_2 are primes), and if we consider a polynomial P where all the coefficients are one (e.g., one of the elementary symmetric polynomials), then any computation which outputs P modulo m can also be viewed modulo p_1 or p_2, and also outputs P modulo p_1 or p_2. Consequently, by the usual definition of modulo m polynomials, one cannot compute any such P faster modulo a composite m than modulo a prime.
- The earlier (strong-, weak-)representations of functions [28], [3] contained constraints for the *value* of certain polynomials. Now we are requiring that the *form* of the representation satisfy modular constraints. The requirement on the form of the representation, in general, will not imply that the value corresponds in some transparent way to the represented polynomial. Let us consider the elementary symmetric polynomial $S_n^k(x)$, and suppose that polynomial $f(x)$ a-strongly represents $S_n^k(x)$ modulo 15. Then, for any $x' \in \{0,1\}^n$ which contains exactly k 1's, $f(x')$ will be 1 either mod 3 or mod 5; but, in general, $f(x)$ will not necessarily be even symmetric, and it can be 0 modulo 15 at points other than $S_n^k(x)$. On the other hand, every coefficient of the polynomial $S_n^k(x) - f(x)$ should be zero either mod 3 or mod 5.
- The a-strong representation is not unique; for example, polynomial $f(x)$ is always an a-strong representation of itself.
- In a sequel to the present work (available as a preprint [16]), we defined a complement of the a-strong representation of polynomials and showed how to compute such a representation of the dot-product of two length-n vectors with $n^{o(1)}$ multiplications, or the representation of the product of two $n \times n$ matrices with $n^{2+o(1)}$ multiplications.

Our goal in this work is to show that the elementary symmetric polynomials have a-strong representations modulo composites which can be computed by much smaller homogeneous $\Sigma\Pi\Sigma$ arithmetic circuits than the original polynomial.

Unfortunately, we cannot hope for such results for all multivariate polynomials, as is shown by the next theorem.

THEOREM 3. *Let*

$$f(x_1, x_2, \ldots, x_n, y_1, y_2, \ldots, y_n) = \sum_{i=1}^{n} x_i y_i$$

be the inner product function. Suppose that a $\Sigma\Pi\Sigma$ circuit computes an a-strong representation of f modulo 6. Then the circuit must have at least $\Omega(n)$ multiplication gates.

Proof. Let g be the a-strong representation of f. Then in g, at least half of the monomials $x_i y_i$ have coefficients equal to 1 modulo either 2 or 3. Without restricting the generality, let us assume that monomials $x_1 y_1, x_2 y_2, \ldots, x_{\lceil n/2 \rceil} y_{\lceil n/2 \rceil}$ have coefficients 1 modulo 3. When we compute g modulo 6 we will learn also the inner product of two vectors modulo 3, each consisting of the first $\lceil n/2 \rceil$ variables. It is well known that the communication complexity of computing the inner product mod 3 is $\Omega(n)$ (see, e.g., [11]).

Since arithmetic $\Sigma\Pi\Sigma$ circuits modulo 6 with u multiplication gates of in-degree 2

can be evaluated by a 2-party communication protocol using only $O(u)$ bits, we get $u = \Omega(n)$. □

3. Our constructions. First we construct a-strong representations with a small number of multiplications for the polynomial

$$S_n^2(x,y) = \sum_{\substack{i,j\in\{1,2,\ldots,n\}\\ i\neq j}} x_i y_j,$$

and for $x = y$ we will get that $2S_n^2(x) = S_n^2(x,x)$. This will imply our result for any composite, odd, nonprime-power moduli m.

THEOREM 4.

(i) *Let $m = p_1p_2$, where $p_1 \neq p_2$ are primes. Then there exists an a-strong representation of $S_n^2(x,y)$ modulo m,*

$$\sum_{\substack{i,j\in\{1,2,\ldots,n\}\\ i\neq j}} a_{ij}x_i y_j, \tag{2}$$

which can be computed on a homogeneous $\Sigma\Pi\Sigma$ circuit of size

$$\exp\left(O\left(\sqrt{\log n \log\log n}\right)\right).$$

Moreover, this representation satisfies that for all $i \neq j$, $a_{ij} = a_{ji}$.

(ii) *Let the prime decomposition of $m = p_1^{e_1}p_2^{e_2}\cdots p_r^{e_r}$. Then there exists an a-strong representation of $S_n^2(x,y)$ modulo m of the form (2) which can be computed on a homogeneous $\Sigma\Pi\Sigma$ circuit of size*

$$\exp\left(O\left(\sqrt[r]{\log n(\log\log n)^{r-1}}\right)\right).$$

Moreover, this representation satisfies that for all $i \neq j$, $a_{ij} = a_{ji}$.

COROLLARY 5.

(i) *Let $m = p_1p_2$, where $p_1 \neq p_2$ are odd primes. Then there exists an a-strong representation of the second elementary symmetric polynomial $S_n^2(x)$ modulo m which can be computed on a homogeneous $\Sigma\Pi\Sigma$ circuit of size*

$$\exp\left(O\left(\sqrt{\log n \log\log n}\right)\right).$$

(ii) *Let the prime decomposition of the odd m be $m = p_1^{e_1}p_2^{e_2}\cdots p_r^{e_r}$. Then there exists an a-strong representation of the second elementary symmetric polynomial $S_n^2(x)$ modulo m which can be computed on a homogeneous $\Sigma\Pi\Sigma$ circuit of size*

$$\exp\left(O\left(\sqrt[r]{\log n(\log\log n)^{r-1}}\right)\right).$$

Since the $\Sigma\Pi\Sigma$ circuit in our construction correspond to the graph model [22], we have the following graph-theoretical corollary, showing a cover with much fewer bipartite graphs than in the linear lower bound of Graham and Pollak.

COROLLARY 6. *For any $m = p_1^{e_1}p_2^{e_2}\cdots p_r^{e_r}$, there exists an explicitly constructible bipartite cover of the edges of the complete n-vertex graph such that for all edges e*

there exists an i, $1 \le i \le r$, that the number of the bipartite graphs covering e is congruent to 1 modulo $p_i^{e_i}$. Moreover, the total number of the bipartite graphs in the cover is

$$\exp\left(O\left(\sqrt[r]{\log n(\log\log n)^{r-1}}\right)\right).$$

3.1. Our results for larger k's. The following theorem gives our result for general k. Our goal is to compute an a-strong representation of polynomials $S_n^k(x)$ for $n \ge k \ge 2$. Let us first define

$$S_n^k(x^{(1)}, x^{(2)}, \dots, x^{(k)}) = \sum_{i_1, i_2, \dots, i_k} x_{i_1}^{(1)} x_{i_2}^{(2)} \cdots x_{i_k}^{(k)},$$

where the summation is done for all $k!$ orders of all k-element subsets $I = \{i_1, i_2, \dots, i_k\}$ of $\{1, 2, \dots, n\}$, and $x^{(j)} = (x_1^{(j)}, x_2^{(j)}, \dots, x_n^{(j)})$ for $j = 1, 2, \dots, k$.

THEOREM 7. *Let $m = p_1^{e_1} p_2^{e_2} \cdots p_r^{e_r}$. Then there exists an a-strong representation of $S_n^k(x^{(1)}, x^{(2)}, \dots, x^{(k)})$ modulo m,*

$$\sum_{i_1, i_2, \dots, i_k} a_{i_1, i_2, \dots, i_k} x_{i_1}^{(1)} x_{i_2}^{(2)} \cdots x_{i_k}^{(k)},$$

which can be computed on a homogeneous multilinear $\Sigma\Pi\Sigma$ circuit of size

$$\exp\left(\exp(O(k))\sqrt[r]{\log n}\log\log n\right).$$

Moreover, coefficients $a_{i_1, i_2, \dots, i_k}$ depend only on set $a\{i_1, i_2, \dots, i_k\}$ and not on the particular order of indices $i_1, i_2, \dots, i_k$.

Note that this circuit-size is subpolynomial in n for any constant k and for large enough n. Moreover, the subpolynomiality holds while $k < c \log\log n$ for a small enough $c > 0$.

For moduli m, relative prime to $k!$, this implies the following.

COROLLARY 8. *If m is a relative prime to $k!$, then there exists an a-strong representation of $S_n^k(x)$ modulo m which can be computed on a homogeneous $\Sigma\Pi\Sigma$ circuit of size*

$$\exp\left(\exp(O(k))\sqrt[r]{\log n}\log\log n\right).$$

3.2. The construction for computing S_n^2.

Proof of Theorem 4. We prove the more general case (ii) of the theorem.

Note that $S_n^2(x, y)$ contains the sum of the monomials $x_i y_j$ for all $i \ne j$. Let us arrange these monomials as follows: Let the x_i's and y_j's be assigned to the rows and columns of an $n \times n$ matrix M, respectively, and let the position in row i and column j contain monomial $x_i y_j$:

$$M = \begin{array}{c} \\ x_1 \\ x_2 \\ \vdots \\ x_n \end{array} \begin{array}{c} \begin{array}{cccc} y_1 & y_2 & \cdots & y_n \end{array} \\ \begin{pmatrix} x_1y_1 & x_1y_2 & \cdots & x_1y_n \\ x_2y_1 & x_2y_2 & \cdots & x_2y_n \\ \vdots & \vdots & \ddots & \vdots \\ x_ny_1 & x_ny_2 & \cdots & x_ny_n \end{pmatrix} \end{array}. \tag{3}$$

Then any product of the form

$$(x_{i_1} + x_{i_2} + \cdots + x_{i_v})(y_{j_1} + y_{j_2} + \cdots + y_{j_w}) \tag{4}$$

naturally corresponds to a $v \times w$ submatrix of matrix M. We call these submatrices rectangles. Clearly, any a-strong representation modulo m of polynomial $S_n^2(x, y)$ can be obtained from a cover of matrix M by rectangles of the form (4), satisfying the following properties.

Property (a). The number of rectangles covering any elements of the diagonal is a multiple of $m = p_1^{e_1} p_2^{e_2} \cdots p_r^{e_r}$.

Property (b). Any nondiagonal element $x_i y_j$ of M is covered by d_{ij} rectangles, where

- there exists a $k \in \{1, 2, \ldots, r\}$: $d_{ij} \equiv 1 \pmod{p_k}$ and it is either 0 or 1 mod p_2;
- for all $k \in \{1, 2, \ldots, r\}$, $d_{ij} \equiv 0 \pmod{p_k}$ or $d_{ij} \equiv 1 \pmod{p_k}$.

Clearly, a (bilinear) $\Sigma\Pi\Sigma$ circuit computes an a-strong representation of polynomial $S_n^2(x, y)$ if and only if the corresponding rectangle cover satisfies Properties (a) and (b). The construction of such a low-cardinality rectangle cover is implicit in papers [12] and [13]. We present here a short direct proof which is easily generalizable for proving the results in the next section for higher dimensional matrices.

Rectangles, covering M, will be denoted

$$R(I, J) = \left(\sum_{i \in I} x_i\right)\left(\sum_{j \in J} y_j\right).$$

We now define an initial cover of the nondiagonal elements of M by rectangles.

Let $N = \lceil \log n \rceil$, and for $1 \le i, j \le n$, let $i = (i_1, i_2, \ldots, i_g)$ and $j = (j_1, j_2, \ldots, j_g)$ denote their N-ary forms (i.e., $0 \le i_t, j_t \le N - 1$ for $t = 1, 2, \ldots, g$, where $g = \lceil \log_N(n + 1) \rceil$).

Then let us define, for $t = 1, 2, \ldots, g$ and $\ell = 0, 1, \ldots, N - 1$,

$$I_t^\ell = \{i : i_t = \ell\}, \quad J_t^\ell = \{j : j_t \neq \ell\}.$$

Now consider the cover given by the following rectangles:

$$R(I_t^\ell, J_t^\ell) : t = 1, 2, \ldots, g, \ \ell = 0, 1, \ldots, N - 1.$$

Now, in this cover, any element $x_i y_j$ of M will be covered $H_N(i, j)$ times, where $H_N(i, j)$ stands for the Hamming distance of the N-ary forms of i and j, that is, at most g times. Note that the diagonal elements are not covered at all, so Property (a) is satisfied, while Property (b) is typically not. Moreover, $x_i y_j$ is covered by the same number of rectangles as $x_j y_i$, that is, $H_N(i, j)$ times.

The total number of covering rectangles is $h = gN = O((N \log n)/\log N)$.

Now, our goal is to turn this cover into another one, which already satisfies not only Property (a) but also Property (b). For this transformation we need to apply a multivariate polynomial f to our rectangle cover in a way very similar to how we applied polynomials to set-systems in [14] and to codes in [15].

DEFINITION 9. *Let $R_1, R_2, \ldots, R_h$ be a rectangle cover of a matrix $M = \{x_i y_j\}$, and let f be an h-variable multilinear polynomial written in the form*

$$f(z_1, z_2, \ldots, z_h) = \sum_{K \subset \{1, 2, \ldots, h\}} a_K z_K,$$

where $0 \le a_K \le m-1$ are integers, and $z_K = \prod_{k\in K} z_k$. Then the f-transformation of the rectangle cover $R_1R_2,\dots,R_h$ contains $\sum_{K\subset\{1,2,\dots,h\}} a_K$ rectangles, each corresponding to a monomial of f. $z_K = \prod_{k\in K} z_k$ correspond to the (possibly empty) rectangle of $\bigcap_{k\in K} R_k$.

Note that another way of interpreting this definition is as follows: the variables z_k correspond to the rectangles of the cover, and if we imagine the rectangles filled with 1's, then the product of the variables, i.e., the monomials, corresponds to the Hadamard product (see, e.g., [14]) of the corresponding all-1 rectangles, resulting in an all-1 rectangle, which, in turn, is equal to their intersection.

Note also that polynomial f is, in fact, considered over the ring Z_m, along with a fixed (small) representation of its coefficients from the set of nonnegative integers.

LEMMA 10. *Let $u^{ij} \in \{0,1\}^h$ characterize the rectangle cover of the entry x_iy_j of matrix M as follows:*

$$R_s \text{ covers } x_iy_j \iff u^{ij}_s = 1.$$

Then entry x_iy_j is covered by exactly $f(u^{ij})$ rectangles from the f-transformation of the rectangle cover $R_1, R_2, \dots, R_h$.

Proof. In $f(z)$, exactly those monomials z_K contribute 1 to the value of $f(u^{ij})$ whose variables are all 1 in vector u^{ij}. This happens exactly when $u^{ij}_k = 1$ for all $k \in K$; that is, x_iy_j is covered by the intersection of rectangles $\bigcap_{k\in K} R_k$. □

The proof of the following lemma is obvious.

LEMMA 11. *The intersection of finitely many rectangles is a (possibly empty) rectangle. Any rectangle, covering a part of matrix M of* (3)*, corresponds to a single (bilinear) multiplication.*

It remains to prove that there exists an f, with a small number of monomials, and with properties which lead to a cover, satisfying Properties (a) and (b). We will use the famous BBR polynomial of Barrington, Beigel, and Rudich [3].

THEOREM 12 (Barrington, Beigel, and Rudich [3]). *Let $m = p_1^{e_1}p_2^{e_2}\cdots p_r^{e_r}$. For any integers d, ℓ, $1 \le d \le \ell$, there exists an $f_{d,\ell}$ explicitly constructible, symmetric, ℓ-variable, degree-$O(d^{1/r})$ multilinear polynomial with coefficients from Z_m, such that*

(i) *for any $z \in \{0,1\}^\ell$, which contains at most d 1's,*

$$f_{d,\ell}(z) \equiv 0 \pmod m \iff z = 0;$$

(ii) *if $f_{d,\ell}(z) \not\equiv 0 \pmod m$, then there exists $i \in \{1,2,\dots,r\}$: $f_{d,\ell}(z) \equiv 1 \pmod{p_i^{e_i}}$, and if $f_{d,\ell}(z) \not\equiv 1 \pmod{p_j^{e_j}}$, then $f_{d,\ell}(z) \equiv 0 \pmod{p_j^{e_j}}$.*

Proof. (i) The proof of part (i) is given in [3] (see also [13]).

(ii) We consider $m = p_1^{e_1}p_2^{e_2}\cdots p_r^{e_r}$ to be a constant. Let us define $q_i = m/p_i^{e_i}$, and let $q_i^{-1}q_i \equiv 1 \pmod{p_i^{e_i}}$ for $i = 1,2,\dots,r$.

Let w denote the (symmetric) polynomial satisfying the requirements of (i).

Suppose first that $e_k = 1$ for $k = 1,2,\dots,r$. Then

$$f_{d,\ell} = \sum_{i=1}^{r} q_i q_i^{-1} w^{p_i-1}$$

is also symmetric and clearly satisfies the requirements of (ii). Indeed, if $w(z) \not\equiv 0 \pmod{p_i}$, then $f_{d,\ell}(z) \equiv 1 \pmod{p_i}$, and if $w(z) \equiv 0 \pmod{p_i}$, then $f_{d,\ell}(z) \equiv 0 \pmod{p_i}$. Moreover, the degrees of $f_{d,\ell}$ and w differ only in a constant multiplier.

In general, let us first consider the polynomial w which satisfies (i) for modulus $m' = p_1 p_2 \cdots p_r$. From the results of Toda [29], Yao [31], and Beigel and Tarui [4], for every k there exist polynomials P_k of degree $O(k)$ satisfying

$$\begin{aligned} P_k(x) &\equiv 0 \pmod{x^k}, \\ P_k(x+1) &\equiv 1 \pmod{x^k}. \end{aligned}$$

Now, let us define

$$f_{d,\ell} = \sum_{i=1}^{r} q_i q_i^{-1} P_{e_i}(w^{p_i - 1}).$$

It is easy to verify that (ii) is satisfied for this polynomial, and the degree is still $O(d^{1/r})$. Moreover, $f_{d,\ell}$ is also symmetric. □

Now we can prove Theorem 4; let us consider the more general statement of (ii). Let $\ell = h = gN$, $d = g$. Then $f_{g,gN}$ has

$$\binom{h}{O(g^{1/r})} \tag{5}$$

monomials. Consequently, if we transform our cardinality-h rectangle cover by Definition 9 with polynomial $f_{g,gN}$, then the resulting cover satisfies Properties (a) and (b) and has cardinality (5). This implies an $\exp(O(\sqrt[r]{\log n (\log\log n)^{r-1}}))$ cover. By Lemma 11, a $\Sigma\Pi\Sigma$ circuit is immediate with $\exp(O(\sqrt[r]{\log n (\log\log n)^{r-1}}))$ multiplication gates. Since the original, cardinality-h rectangle cover covered $x_i y_j$ and $x_j y_i$ with the same number of rectangles, and since $f_{g,gN}$ is a symmetric polynomial, by Lemma 10 our transformed rectangle cover will also cover $x_i y_j$ and $x_j y_i$ with the same number of rectangles. □

4. The construction in general. In this section we prove Theorem 7.

We describe a construction similarly to that of the case $k = 2$.

Note that in this section, instead of the more correct notation for vectors x with upper index u: $x^{(u)}$, we will write simply x^u.

First, let $M' = \{m_{i_1,i_2,\ldots,i_k}\}$ be a k-dimensional analogue of M of (3), that is, an

$$\overbrace{n \times n \times n \times \cdots \times n}^{k}$$

matrix, where $m_{i_1,i_2,\ldots,i_k} = x^1_{i_1} x^2_{i_2} \cdots x^k_{i_k}$.

Now we should again construct a cover of M', this time with k-dimensional boxes, corresponding to k-linear products,

$$R(I_1, I_2, \ldots, I_k) = \prod_{i=1}^{k} \sum_{j \in I_i} x^i_j,$$

satisfying that only those entries will be covered which have no two equal (lower) indices, and the covering multiplicity of these entries should be nonzero modulo m. Additionally, we also require that the covering multiplicity of entry $m_{i_1,i_2,\ldots,i_k}$ depend only on the set $\{i_1, i_2, \ldots, i_k\}$ and not on the particular order of the indices $i_1, i_2, \ldots, i_k$.

First we need to define an initial box cover of those entries of the k-dimensional matrix M' which have no two identical indices.

For our proof it is very important that this initial cover has low multiplicity: every covered element of M' should be covered only by $O(\log n)$ k-dimensional boxes for constant k's. The construction of such initial cover in the $k = 2$ case was quite easy; now we must use a more intricate approach.

Let us consider a family of perfect hash functions (see, e.g., [6] or the work [1] for an explicit (i.e., derandomized) construction), and let us list their respective values in the column of a matrix. This way, for integers n, k, b, $2 \le k \le b = O(k)$, $k \le n$, we can obtain a matrix $H(n,k,b) = \{h_{ij}\}$ with $u = \exp(O(k)) \log n$ rows and n columns, with entries from the set $\{0, 1, \dots, b-1\}$, such that for any k-element subset J of the n columns, there exists a row i, $1 \le i \le u$:

$$h_{ij}, \quad j \in J$$

are pairwise different elements of the set $\{0, 1, \dots, b-1\}$.

This matrix $H(n,k,b)$ will be used for the definition of our initial cover as follows:

For any i, $1 \le i \le u$, and for any $\sigma : \{1, 2, \dots, k\} \to \{0, 1, \dots, b-1\}$ injective function we define the k-dimensional box

$$R(i,\sigma) = \{m_{j_1,j_2,\dots,j_k} : h_{ij_1} = \sigma(1), h_{ij_2} = \sigma(2), \dots, h_{ij_k} = \sigma(k)\}.$$

There are u possible i's and $k^{O(k)}$ possible σ's, so there are $k^{O(k)} \log n$ boxes in this cover. Box $R(i,\sigma)$ covers only $m_{j_1,j_2,\dots,j_k}$'s with pairwise different indices.

It is important to note that even for a fixed i, the covering multiplicities of the elements $m_{j_1,j_2,\dots,j_k}$ and $m_{\pi(j_1)\pi(j_2)\dots,\pi(j_k)}$ are the same for any permutations π of the numbers $\{j_1, j_2, \dots, j_k\}$.

Any $m_{j_1,j_2,\dots,j_k}$ with pairwise different indices is covered by exactly as many k-dimensional boxes from this cover as the number of rows with pairwise different elements of the submatrix, containing column j_1, column j_2, …, column j_k of matrix $H(n,k,b)$. This number is at least 1 (from the perfect-hashing property) and at most u (that is, the number of rows of $H(n,k,b)$).

Now, exactly as in the proof of the S_n^2 case, we would like to apply the polynomial $f_{d,\ell}$ of Theorem 12 with $d = u$, $\ell = k^{O(k)} \log n$ to this box cover.

However, first we need to give the higher-dimension analogues of Definition 9 and Lemma 10.

DEFINITION 13. *Let $R_1, R_2, \dots, R_h$ be a box cover of a matrix M', and let f be an h-variable multilinear polynomial written in the form*

$$f(z_1, z_2, \dots, z_h) = \sum_{K \subset \{1,2,\dots,h\}} a_K z_K,$$

where $0 \le a_K \le m-1$ are integers, and $z_K = \prod_{k \in K} z_k$. Then the f-transformation of the box cover $R_1 R_2, \dots, R_h$ contains $\sum_{K \subset \{1,2,\dots,h\}} a_K$ boxes, each corresponding to a monomial of f. $z_K = \prod_{k \in K} z_k$ corresponds to the (possibly empty) box of $\bigcap_{k \in K} R_k$.

LEMMA 14. *Let $u^{i_1,i_2,\dots,i_k} \in \{0,1\}^h$ characterize the box cover of the entry $m_{i_1,i_2,\dots,i_k}$ of matrix M' as follows:*

$$R_s \text{ covers } m_{i_1,i_2,\dots,i_k} \iff u_s^{i_1,i_2,\dots,i_k} = 1.$$

Then entry $m_{i_1,i_2,\dots,i_k} = x_{i_1}^1 x_{i_2}^2 \cdots x_{i_k}^k$ is covered by exactly $f(u^{i_1,i_2,\dots,i_k})$ boxes from the f-transformation of the box cover $R_1, R_2, \dots, R_h$.

Proof. In $f(z)$, exactly those monomials z_K contribute 1 to the value of $f(u^{i_1,i_2,\ldots,i_k})$ whose variables are all 1 in vector $u^{i_1,i_2,\ldots,i_k}$. This happens exactly when $u_s^{i_1,i_2,\ldots,i_k} = 1$ for all $s \in K$; that is, $m_{i_1,i_2,\ldots,i_k} = x_{i_1}^1 x_{i_2}^2 \cdots x_{i_k}^k$ is covered by the intersection of boxes $\bigcap_{k\in K} R_k$. □

Note that for any symmetric polynomial f and any box cover which has covering multiplicity on $m_{i_1,i_2,\ldots,i_k}$, depending only on set $\{i_1, i_2, \ldots, i_k\}$, the f-transformation of the cover will also have the same multiplicity on $m_{j_1,j_2,\ldots,j_k}$ and on $m_{\pi(j_1)\pi(j_2)\ldots,\pi(j_k)}$ for any permutations π of the numbers $\{j_1, j_2, \ldots, j_k\}$.

The proof of the following lemma is obvious.

LEMMA 15. *The intersection of finitely many boxes is a (possibly empty) box. Any box covering a part of matrix M' corresponds to a single (multilinear) product.*

The result of applying $f_{d,\ell}$ with $d = u$, $\ell = k^{O(k)} \log n$ to our initial box cover of cardinality ℓ is a box cover of cardinality

$$\exp(\exp(O(k))(\log n)^{1/r} \log\log n),$$

proving Theorem 7. □

4.1. Proof of Lemma 1. Let $R_1, R_2, \ldots, R_h$ be the covering boxes defined by the homogeneous ΣΠΣ circuit. Let us remark that every degree-k monomial $\prod_{i\in I} x_i$ with pairwise different indices is covered by $a_I \neq 0$ boxes in this cover. In F_q, for any nonzero element s, $s^{q-1} = 1$. Now, let us apply polynomial

$$f(z_1, z_2, \ldots, z_h) = (z_1 + z_2 + \cdots + z_h)^{q-1}$$

to the box cover $R_1, R_2, \ldots, R_h$ according to Definition 13. Then, by Lemma 14, the covering multiplicity of the degree-k monomials $\prod_{i\in I} x_i$ with pairwise different indices will be 1 in F_q, while all the others will remain 0. That is, the corresponding ΣΠΣ circuit computes S_n^k over F_q. □

OPTIMAL EXTERNAL MEMORY INTERVAL MANAGEMENT*

LARS ARGE† AND JEFFREY SCOTT VITTER‡

Abstract. In this paper we present the external interval tree, an optimal external memory data structure for answering stabbing queries on a set of dynamically maintained intervals. The external interval tree can be used in an optimal solution to the dynamic interval management problem, which is a central problem for object-oriented and temporal databases and for constraint logic programming. Part of the structure uses a weight-balancing technique for efficient worst-case manipulation of balanced trees, which is of independent interest. The external interval tree, as well as our new balancing technique, have recently been used to develop several efficient external data structures.

Key words. interval management, stabbing queries, I/O efficient, data structures

AMS subject classifications. 68P05, 68P10, 68P15

DOI. 10.1137/S009753970240481X

1. Introduction.

In recent years external memory data structures have been developed for a wide range of applications, including spatial, temporal, and object-oriented databases and geographic information systems. Often the amount of data manipulated in such applications is too large to fit in main memory, and the data must reside on disk. In such cases the input/output (I/O) communication between main memory and disk can become a bottleneck. In this paper we develop an I/O-optimal and space-optimal external interval tree data structure for answering stabbing queries among a changing set of intervals. The structure is the central part of an optimal solution to the dynamic interval management problem.

1.1. Memory model and previous results.

We will be working in the standard model for external memory with one (logical) disk [31, 4]. We assume that each external memory access (called an *I/O operation* or just *I/O*) transmits one page of B elements. We measure the efficiency of an algorithm in terms of the number of I/Os it performs and the number of disk blocks it uses.[1]

The *dynamic interval management problem* is the problem of maintaining a set of intervals such that, given a query interval I_q, all intervals intersecting I_q can be reported efficiently. As discussed in [29, 30, 38], the problem is crucial for indexing constraints in constraint databases and in temporal databases. The key component of dynamic interval management is the ability to answer *stabbing queries* [30]. Given a set of intervals, a stabbing query with a point q asks for all intervals containing q.

This work was done while this author was at Duke University.

[1]Often it is assumed that the main memory is capable of holding $\Omega(B^2)$ elements, that is, $\Omega(B)$ blocks. The structures developed in this paper work without this assumption.

By representing an interval $[x, y]$ as the point (x, y) in the plane, a stabbing query reduces to the special case of 2-sided 2-dimensional range searching called a *diagonal corner query*. In the diagonal corner query problem a set of points in the plane above the diagonal line $x = y$ should be stored such that, given a query point (q, q), all points (x, y) with $x \leq q$ and $y \geq q$ can be reported efficiently. The problem of 2-dimensional range searching has been the subject of much research. While B-trees and their variants [12, 21] have been an unqualified success in supporting 1-dimensional external range searching, they are inefficient at handling higher-dimensional problems. In internal memory many worst-case efficient structures have been proposed for 2-dimensional and higher-dimensional range search; see [3] for a survey. Unfortunately, most of these structures are not efficient when mapped to external memory. The practical need for I/O support has also led to the development of a large number of external data structures that do not have good theoretical worst-case update and query I/O bounds but do have good average-case behavior for common problems; see [24, 35] for surveys. The worst-case performance of these data structures is much worse than the optimal bounds achievable for dynamic external 1-dimensional range search using a B-tree.

Prior to the development of the structure presented in this paper, a number of attempts had been made to solve the external stabbing query problem. Kanellakis et al. [30] developed the metablock tree for answering diagonal corner queries in optimal $O(\log_B N + T/B)$ I/Os using optimal $O(N/B)$ blocks of external memory. Here T denotes the number of points reported. The structure supports insertions only in $O(\log_B N + (\log_B^2 N)/B)$ I/Os amortized. A simpler static structure with the same bounds was described by Ramaswamy [37]. In internal memory, the priority search tree of McCreight [32] can be used to answer more general queries than diagonal corner queries, namely 3-sided range queries, and a number of attempts have been made at externalizing this structure [16, 28, 39]. The structure by Icking, Klein, and Ottoman [28] uses optimal space but answers queries in $O(\log_2 N + T/B)$ I/Os. The structure by Blankenagel and Güting [16] also uses optimal space but answers queries in $O(\log_B N+T)$ I/Os (see also [14]). In both papers a number of nonoptimal dynamic versions of the structures are also developed. Ramaswamy and Subramanian [39] developed a technique called *path caching* for transforming an efficient internal memory data structure into an I/O-efficient structure. Using this technique on the priority search tree results in a structure that can be used to answer 2-sided queries, which are more general than diagonal corner queries but less general than 3-sided queries. This structure answers queries in the optimal $O(\log_B N+T/B)$ I/Os and supports updates in amortized $O(\log_B N)$ I/Os but uses nonoptimal $O((N/B)\log_2\log_2 B)$ space. Various other external data structures for answering 3-sided queries are also developed in [30] and [39]. Subramanian and Ramaswamy also designed the p-range tree for answering 3-sided queries [40]. The structure uses linear space, answers queries in $O(\log_B N + T/B + IL^*(B))$ I/Os, and supports updates in $O(\log_B N + (\log_B^2 N)/B)$ I/Os amortized. ($IL^*(\cdot)$ denotes the iterated $\log^*$ function, that is, the number of times $\log^*$ must be applied to get below 2). Finally, following the publication of the extended abstract version of this paper (and based on the results in this paper), Arge, Samoladas, and Vitter [8] developed an optimal external priority search tree, immediately implying an optimal stabbing query structure. Several structures have also been developed for the general 2- and higher-dimensional range searching problem, as well as for several other related problems. See [5, 6, 41] for surveys.

TABLE 1.1
Comparison of our data structure for stabbing queries with other data structures.

	Space (blocks)	Query I/O bound	Update I/O bound
Pri. search tree [28]	$O(\frac{N}{B})$	$O(\log_2 N + T/B)$	
XP-tree [16]	$O(\frac{N}{B})$	$O(\log_B N + T)$	
[37]	$O(\frac{N}{B})$	$O(\log_B N + T/B)$	
Metablock tree [30]	$O(\frac{N}{B})$	$O(\log_B N + T/B)$	$O(\log_B N + (\log_B N)^2/B)$ amortized (inserts only)
P-range tree [40]	$O(\frac{N}{B})$	$O(\log_B N + T/B + IL^*(B))$	$O(\log_B N + (\log_B N)^2/B)$ amortized
Path caching [39]	$O(\frac{N}{B}\log_2\log_2 B)$	$O(\log_B N + T/B)$	$O(\log_B N)$ amortized
Our result [11] ([8])	$O(\frac{N}{B})$	$O(\log_B N + T/B)$	$O(\log_B N)$

1.2. Overview of our results. The main contribution of this paper is an optimal external memory data structure for the stabbing query problem. As mentioned, our data structure gives an optimal solution to the interval management problem, and thus it settles an open problem highlighted in [30, 39, 40]. The structure uses $O(N/B)$ disk blocks to maintain a set of N intervals such that insertions and deletions can be performed in $O(\log_B N)$ I/Os and such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os. In Table 1.1 we compare our result with previous solutions. Unlike previous nonoptimal structures, the update I/O bounds for our data structure are worst-case, and our structure works without assuming that the internal memory is capable of holding $\Omega(B^2)$ elements. Our structure is significantly different from the recently developed external priority search tree [8] and is probably of greater practical interest since it uses relatively fewer random I/Os when answering a query. Most disk systems are optimized for sequential I/O, and, consequently, random I/Os often take a much longer time than sequential I/Os.

Our solution to the stabbing query problem is an external version of the interval tree [22, 23]. In section 2, we present the basic structure, where the endpoints of the intervals stored in the structure belong to a fixed set of N points. In section 3, we then remove this "fixed endpoint-set assumption." In internal memory, the assumption is normally removed using a BB[α]-tree [34] as the base search tree structure [33], and this leads to amortized update bounds. However, as BB[α]-trees are unsuitable for implementation in external memory, we develop a new *weight-balanced B-tree* for use in external memory. This structure resembles the *k-fold tree* of Willard [43]. Like in internal memory, the use of a weight-balanced B-tree as the base tree results in amortized update bounds. In section 4, we then show how to remove the amortization from the structure.

Our external interval tree has been used to develop I/O-efficient structures for dynamic point location [1, 9].[2] It has also been used in several visualization applications [18, 19, 20]. Our weight-balanced B-tree has also found several other applications. In internal memory it can, for example, be used to convert amortized bounds to worst-case bounds. (Fixing B to a constant in our result yields an internal-memory interval tree with worst-case update bounds.) It can also be used as a (simpler) alternative to the rather complicated structure developed in [42] in order to add range restriction capabilities to internal-memory dynamic data structures. (It seems possible to

[2] Even though the external priority search tree [8] solves a more general problem than the external interval tree, it cannot be used as an alternative to the external interval tree in the point location structures.

use the techniques in [42] to remove the amortization from the update bound of the internal interval tree, but our method is much simpler.) In external memory, it has been used in the recently developed optimal external priority search tree [8], as well as in numerous other structures (e.g., [25, 26, 13, 1, 9]).

Finally, in section 5, we discuss how to use the ideas utilized in our external interval tree to develop an external segment tree using $O((N/B)\log_B N)$ space. This improves upon previously known external segment tree structures, which use $O((N/B)\log_2 N)$ disk blocks [15, 39].

2. External memory interval tree with fixed endpoint set. In this section, we present our external interval tree structure, assuming that the endpoints of the intervals stored in the structure belong to a fixed set E of size N. We also assume that the internal memory is capable of holding $O(B)$ blocks. We remove these assumptions in sections 3 and 4.

2.1. Preliminaries. Our external interval tree makes extensive use of two kinds of auxiliary structures: the B-tree [12, 21] and the "corner structure" [30]. B-trees, or more generally (a, b)-trees [27], are search tree structures suitable for external memory.

LEMMA 2.1. *A set of N elements can be stored in a B-tree structure using $O(N/B)$ disk blocks such that updates and queries can be performed in $O(\log_B N)$ I/Os. The T smallest (largest) elements can be reported in $O(T/B+1)$ I/Os. Given N sorted elements a B-tree can be built in $O(N/B)$ I/Os.*

A "corner structure" [30] is a data structure that can be used to answer stabbing queries on $O(B^2)$ intervals.

LEMMA 2.2. *(Kanellakis et al. [30]) A set of $K \le B^2$ intervals can be stored in an external data structure using $O(K/B)$ disk blocks such that a stabbing query can be answered in $O(T/B+1)$ I/Os, where T is the number of reported intervals.*

As discussed in [30], the corner structure can easily be made dynamic: updates are inserted into an update block, and the structure is rebuilt using $O(B)$ I/Os once B updates have been performed. The rebuilding is performed simply by loading the structure into internal memory, rebuilding it, and writing it back to external memory.

LEMMA 2.3. *Assuming $M \ge B^2$, a set of $K \le B^2$ intervals can be stored in an external data structure using $O(K/B)$ disk blocks such that a stabbing query can be answered in $O(T/B+1)$ I/Os and such that an update can be performed in $O(1)$ I/Os amortized. The structure can be constructed in $O(K/B)$ I/Os.*

In section 4.2 (where it will become clearer why the structure is called a "corner structure"), we show how the update bound can be made worst-case. In the process we also remove the assumption on the size of the internal memory.

2.2. The structure. An internal memory interval tree consists of a binary base tree on the sorted set of endpoints E, with the intervals stored in secondary structures associated with internal nodes of the tree [22]. An interval X_v consisting of all endpoints below v is associated with each internal node v in a natural way. The interval X_r of the root r is thus divided in two by the intervals X_{v_l} and X_{v_r} associated with its two children, v_l and v_r, and an interval is stored in r if it contains the "boundary" between X_{v_l} and X_{v_r} (if it overlaps both X_{v_l} and X_{v_r}). Intervals on the left (right) side of the boundary are stored recursively in the subtree rooted in v_l (v_r). Intervals in r are stored in two structures: a search tree sorted according to left endpoints of the intervals and one sorted according to right endpoints. A stabbing query with q is answered by reporting the intervals in r containing q and recursively reporting the relevant intervals in the subtree containing q. If q is contained in X_{v_l},

the intervals in r containing q are found by traversing the intervals in r sorted according to left endpoints, from the intervals with smallest left endpoints toward the ones with largest left endpoints, until an interval not containing q is encountered. None of the intervals in the sorted order after this interval can contain q. Since $O(T_r)$ time is used to report T_r intervals in r, a query is answered in $O(\log_2 N + T)$ time in total.

In order to externalize the interval tree structure in an efficient way, we need to increase the fan-out of the base tree to decrease its height to $O(\log_B N)$. This creates several problems. The main idea behind our successful externalization of the structure, as compared with previous attempts [16, 39], is to use a fan-out of $\sqrt{B}$ instead of B (following ideas from [7, 10]).

Structure. The external interval tree on a set of intervals I with endpoints in a fixed set E of size N is defined as follows. (We assume without loss of generality that the endpoints of the intervals in I are distinct.) The *base tree* $\mathcal{T}$ is a perfectly balanced fan-out $\sqrt{B}$ tree over the sorted set of endpoints E. Each leaf represents B consecutive points from E. (If $|E|$ is not $(\sqrt{B})^i B$ for some $i \geq 0$ we adjust the degree of the root of $\mathcal{T}$ to be smaller than $\sqrt{B}$.) The tree has height $O(\log_{\sqrt{B}}(N/B)) + 1 = O(\log_B N)$. As in the internal case, with each internal node v we associate an interval X_v consisting of all endpoints below v. The interval X_v is divided into $\sqrt{B}$ subintervals by the intervals associated with the children $v_1, v_2, \ldots, v_{\sqrt{B}}$ of v. Refer to Figure 2.1. For illustrative purposes, we call the subintervals *slabs* and the left (right) endpoint of a slab a *slab boundary*. We define a *multislab* to be a contiguous range of slabs, such as, for example, $X_{v_2} X_{v_3} X_{v_4}$ in Figure 2.1. In a node v we store intervals from I that cross one or more of the slab boundaries associated with v but none of the slab boundaries associated with *parent*(v). In a leaf l we store intervals with both endpoints among the endpoints in l. The number of intervals stored in a leaf is less than $B/2$ and can therefore be stored in one block. We store the set of intervals $I_v \subset I$ associated with v in the following $\Theta(B)$ secondary structures associated with v.

- For each of $\sqrt{B} - 1$ slab boundaries b_i, $1 < i \leq \sqrt{B}$, we store the following:
  - A right *slab list* R_i containing intervals from I_v with right endpoint between b_i and b_{i+1}. R_i is sorted according to right endpoints.
  - A left *slab list* L_i containing intervals from I_v with left endpoint between b_i and b_{i-1}. L_i is sorted according to left endpoints.
  - $O(\sqrt{B})$ *multislab lists*—one for each boundary to the right of b_i. The list $M_{i,j}$ for boundary b_j $(j > i)$ contains intervals from I_v with left endpoint between b_{i-1} and b_i and right endpoint between b_j and b_{j+1}. $M_{i,j}$ is sorted according to right endpoints.
- If the number of intervals stored in a multislab list $M_{i,j}$ is less than $\Theta(B)$, we instead store them in an *underflow structure* U along with intervals associated with all the other multislab lists with fewer than $\Theta(B)$ intervals. More precisely, only if more than B intervals are associated with a multislab do we store the intervals in the multislab list. Similarly, if fewer than $B/2$ intervals are associated with a multislab, we store the intervals in the underflow structure. If the number of intervals is between $B/2$ and B, they can be stored in either the multislab list or in the underflow structure. Since $O((\sqrt{B})^2) = O(B)$ multislabs lists are associated with v, the underflow structure U always contains fewer than B^2 intervals.

We implement all secondary list structures associated with v using B-trees and the underflow structure using a corner structure (Lemmas 2.1 and 2.3). In each node v, in $O(1)$ *index blocks*, we also maintain information about the size and place of each

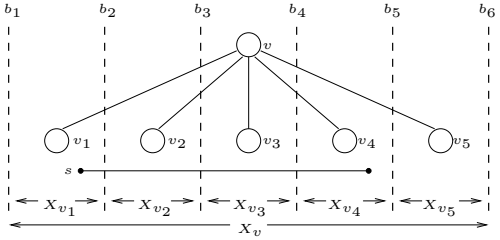

FIG. 2.1. *A node in the base tree. Interval s is stored in L_2, R_4, and either $M_{2,4}$ or U.*

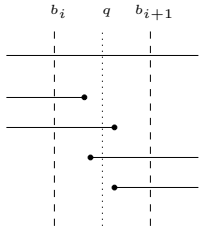

FIG. 2.2. *Intervals containing q are stored in R_{b_i}, $L_{b_{i+1}}$, the multislab lists spanning the slab, and U.*

of the $O(B)$ structures associated with v.

With the definitions above, an interval in I_v is stored in two or three structures: two slab lists L_i and R_j and possibly in either a multislab list $M_{i,j}$ or in the underflow structure U. For example, we store interval s in Figure 2.1 in the left slab list L_2 of b_2, in the right slab list R_4 of b_4, and in either the multislab list $M_{2,4}$ corresponding to b_2 and b_4 or the underflow structure U. Note the similarity between the slab lists and the two sorted lists of intervals in the nodes of an internal interval tree. As in the internal case, s is stored in a sorted list for each of its two endpoints. This represents the part of s to the left of the leftmost boundary contained in s and the part to the right of the rightmost boundary contained in s. Unlike in the internal case, in the external case we also need to represent the part of s between the two extreme boundaries. We do so using one of $O(B)$ multislab lists.

The external interval tree uses linear space: the base tree $\mathcal{T}$ itself uses $O(|E|/B)$ blocks, and each interval is stored in a constant number of linear space secondary structures (Lemmas 2.1 and 2.3). The number of other blocks used in a node is $O(\sqrt{B})$: $O(1)$ index blocks and one block for the underflow structure and for each of the $2\sqrt{B}$ slab lists. Since $\mathcal{T}$ has $O(|E|/(B\sqrt{B}))$ internal nodes, the structure uses a total of $O(|E|/B)$ blocks. Note that if we did not store the sparse multislab lists in the underflow structure, we could have $\Omega(B)$ sparsely utilized blocks in each node, which would result in a superlinear space bound.

Query. In order to answer a stabbing *query* q, we search down $\mathcal{T}$ for the leaf containing q, reporting all relevant intervals among the intervals I_v stored in each node v encountered. Assuming q lies between slab boundaries b_i and b_{i+1} in v, we report the relevant intervals in I_v as follows:

- We load the $O(1)$ index blocks.
- We report intervals in all multislab lists containing intervals crossing b_i and b_{i+1}, that is, multislab lists $M_{l,k}$ with $l \le i$ and $k > i$.
- We perform a stabbing query with q on the underflow structure U and report the result.
- We report intervals in R_i from the largest toward the smallest (according to right endpoint) until we encounter an interval not containing q.
- We report intervals in L_{i+1} from the smallest toward the largest until we encounter an interval not containing q.

It is easy to see that our algorithm reports all intervals in I_v containing q: all relevant intervals are stored either in a multislab list $M_{l,k}$ with $l \le i < k$, in U, in R_i, or in L_{i+1}. Refer to Figure 2.2. We correctly report all intervals in R_i containing q, since if an interval in the right-to-left order of this list does not contain q, then neither

does any other interval to the left of it. A similar argument holds for the left-to-right search in L_{i+1}.

The query algorithm uses an optimal $O(\log_B N + T/B)$ I/Os. In $\mathcal{T}$ we visit $O(\log_{\sqrt{B}} N) = O(\log_B N)$ nodes. In each node v we use only $O(1)$ I/Os that are not "paid for" by reportings (blocks read that contain $\Theta(B)$ output intervals): we use $O(1)$ I/Os to load the index blocks, $O(1)$ overhead to query U, and $O(1)$ overhead for R_i and L_{i+1}. Note how U is crucial for obtaining the $O(\log_B N + T/B)$ bound since it guarantees that all visited multislab lists contain $\Theta(B)$ intervals.

LEMMA 2.4. *Assuming $M \geq B^2$, there exists a data structure using $O(N/B)$ disk blocks to store intervals with unique endpoints in a set E of size N such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os.*

Updates. We insert a new interval s in the external interval tree as follows: we search down $\mathcal{T}$ to find the first node v where s contains one or more slab boundaries. Then we load the $O(1)$ index blocks of v and insert s into the two relevant slab lists L_i and R_j. If the multislab list $M_{i,j}$ exists, we also insert s there. Otherwise, the other intervals (if any) corresponding to $M_{i,j}$ are stored in the underflow structure U, and we insert s in this structure. If that brings the number of intervals corresponding to $M_{i,j}$ up to B, we delete them all from U and insert them in $M_{i,j}$. Finally, we update and store the index blocks. Similarly, in order to delete an interval s, we search down $\mathcal{T}$ until we find the node storing s. We then delete s from two slab lists L_i and R_j. We also delete s from U or $M_{i,j}$; if s is deleted from $M_{i,j}$ and the list now contains $B/2$ intervals, we delete all intervals in $M_{i,j}$ and insert them into U. Finally, we again update and store the index blocks.

To analyze the number of I/Os used to perform an update, first note that for both insertions and deletions we use $O(\log_B N)$ I/Os to search down $\mathcal{T}$, and then in *one* node we use $O(\log_B N)$ I/Os to update the secondary list structures. The manipulation of the underflow structure U uses $O(1)$ I/Os, except in the cases where $\Theta(B)$ intervals are moved between U and a multislab list $M_{i,j}$. In the latter case we use $O(B)$ I/Os, but then there must have been at least $B/2$ updates involving intervals in $M_{i,j}$ and requiring only $O(1)$ I/Os since the last time an $O(B)$ cost was incurred. Hence the amortized I/O cost is $O(1)$, and we obtain the following.

THEOREM 2.5. *Assuming $M \geq B^2$, there exists a data structure using $O(N/B)$ disk blocks to store intervals with unique endpoints in a set E of size N such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os in the worst case and such that updates can be performed in $O(\log_B N)$ I/Os amortized.*

3. General external interval tree. In order to remove the fixed endpoint assumption from our external interval tree, we need to use a dynamic search tree as the base tree. In internal memory a BB[α]-tree [34] is often used as the base tree for structures with secondary structures. In such a tree, a node v with weight w (i.e., with w elements below it) can be involved in a rebalancing operation only once for every $\Omega(w)$ updates that access (i.e., pass through) v [17, 33]. If the necessary reorganization of the secondary structures after a rebalance operation on v can be performed in $O(w)$ time, we then obtain an $O(1)$ amortized bound on performing a rebalancing operation. Unfortunately, a BB[α]-tree is not suitable for implementation in external memory; it is binary, and there seems to be no easy way of grouping nodes together in order to increase the fan-out while at the same time maintaining its other useful properties. On the other hand, a B-tree, which is the natural choice as dynamic base structure, does not have the property that a node v of weight w can be involved in a rebalance operation only for every $\Omega(w)$ updates accessing v.

In section 3.1, we describe a variant of B-trees, called *weight-balanced B-trees*, combining the useful properties of B-trees and BB[α]-trees. They are balanced using normal B-tree operations (split and fusion of nodes) while at the same time having the weight property of a BB[α]-tree. An important feature of a weight-balanced B-tree is that the ratio between the largest and smallest weight subtree rooted in children of a node v is a small constant factor. In a B-tree this ratio can be exponential in the height of the subtrees. In section 3.2, we use the weight-balanced B-tree to remove the fixed endpoint assumption from our external interval tree.

3.1. Weight-balanced B-tree. In a normal B-tree [12, 21] all leaves are on the same level, and each internal node has between a and $2a-1$ children for some constant a. In a weak B-tree, or (a,b)-tree [27], a wider range in the number of children is allowed. We define the weight-balanced B-tree by imposing constraints on the weight of subtrees rather than on the number of children. The other B-tree characteristics remain the same: the leaves are all on the same level (level 0), and rebalancing is performed by splitting and fusing internal nodes.

DEFINITION 3.1. *The weight $w(v_l)$ of a leaf v_l is defined as the number of elements stored in it. The weight of an internal node v is defined as $w(v) = \sum_{v=parent(c)} w(c)$.*

COROLLARY 3.2. *The weight $w(v)$ of an internal node v is equal to the number of elements in leaves below v.*

DEFINITION 3.3. *$\mathcal{T}$ is a weight-balanced* B-tree *with branching parameter a and leaf parameter k, $a > 4$ and $k > 0$, if the following conditions hold:*

- *All leaves of $\mathcal{T}$ are on the same level and have weight between k and $2k-1$.*
- *An internal node on level l has weight less than $2a^l k$.*
- *Except for the root, an internal node on level l has weight larger than $\frac{1}{2}a^l k$.*
- *The root has more than one child.*

LEMMA 3.4. *Except for the root, all nodes in a weight-balanced B-tree with parameters a and k have between $a/4$ and $4a$ children. The root has between 2 and $4a$ children.*

Proof. The leaves fulfill the internal node weight constraint, since $k > \frac{1}{2}a^0 k$ and $2k-1 < 2a^0 k$. Thus the minimal number of children an internal node on level l can have is $\frac{1}{2}a^l k / 2a^{l-1}k = a/4$, and the maximal number of children v can have is $2a^l k / \frac{1}{2}a^{l-1}k = 4a$. The root upper bound follows from the same argument, and the lower bound is by definition. ∎

COROLLARY 3.5. *The height of an N element weight-balanced B-tree with parameters a and k is $O(\log_a(N/k))$.*

To perform an *update* on a weight-balanced B-tree $\mathcal{T}$, we first search down $\mathcal{T}$ for the relevant leaf. After performing the actual update, we may need to rebalance $\mathcal{T}$ in order to fulfill the constraints in Definition 3.3. For simplicity we consider only insertions in this section. Deletions can easily be handled using global rebuilding [36] (as discussed further in the next section). After inserting an element in leaf u of $\mathcal{T}$, the nodes on the path from u to the root of $\mathcal{T}$ can be out of balance; that is, the node v_l on level l can have weight $2a^l k$. In order to rebalance the tree we split all such nodes starting with u and working towards the root. If u is a leaf containing $2k$ elements we split it into two leaves u and u', each containing k elements, and insert a reference to u' in $parent(u)$. In general, on level l we want to split a node v_l of weight $2a^l k$ into two nodes v_l' and v_l'' of weight $a^l k$ and insert a reference in $parent(v_l)$. (If $parent(v_l)$ does not exist, that is, if we are splitting the root, we create a new root with two children.) However, a perfect split is generally not possible if we want to perform the split so that v_l' gets the first (leftmost) i of v's children and v_l'' gets the rest of the

children. Nonetheless, since nodes on level $l-1$ have weight less than $2a^{l-1}k$, we can always find an i such that if we split at the ith child the weights of both v'_l and v''_l are between $a^lk - 2a^{l-1}k$ and $a^lk + 2a^{l-1}k$. Since $a > 4$, v'_l and v''_l fulfill the constraints of Definition 3.3; that is, their weights are strictly between $\frac{1}{2}a^lk$ and $2a^lk$.[3] Note that splitting node v does not change the weight of $parent(v)$. As a result, the structure is relatively simple to implement. In each node we need only to store its level and the weight of each of its children, information we can easily maintain during an update. The previous discussion and Corollary 3.5 combine to prove the following.

LEMMA 3.6. *The number of rebalancing operations (splits) after an insertion in a weight-balanced B-tree $\mathcal{T}$ with parameters a and k is bounded by $O(\log_a(|T|/k))$.*

The following lemma will be crucial in our application.

LEMMA 3.7. *After a split of a node v_l on level l into two nodes v'_l and v''_l, at least $a^lk/2$ inserts have to be performed below v'_l (or v''_l) before it splits again. After a new root r in a tree containing N elements is created, at least $3N$ insertions have to be performed before r splits again.*

Proof. After a split of v_l the weight of each of v'_l and v''_l is less than $a^lk + 2a^{l-1}k < 3/2a^lk$. Each such node will split again when its weight reaches $2a^lk$. It follows that the weight must increase by at least $a^lk/2$. When a root r is created on level l it has weight $2a^{l-1}k = N$. It will not split before it has weight $2a^lk > 2 \cdot 4a^{l-1}k = 4N$. □

One example of how the weight-balanced B-tree can be used as a simpler alternative to existing *internal memory* data structures is in adding range restriction capabilities to dynamic data structures [42]. The general technique for adding range restrictions developed in [42] utilizes a base BB[α]-tree with each interval node v augmented with a dynamic data structure on the set of elements below v. This structure needs to be rebuilt when a rebalancing operation is performed on v, and the use of a BB[α]-tree leads to amortized bounds. In [42] it is shown how worst-case bounds can be obtained by a relatively complicated redefinition of the BB[α]-tree. On the other hand, using our weight-balanced B-tree with branching parameter $a = 5$ and leaf parameter $k = 1$ as base tree we immediately obtain worst-case bounds: the large number of updates between splits of a node immediately implies good amortized bounds, and the bounds can easily be made worst-case by performing the secondary structure rebuilding lazily. The ideas and techniques used in this construction are very similar to the ones presented in the succeeding sections of this paper and are therefore omitted. The use of lazy rebuilding in the BB[α]-tree solution is complicated because rebalancing is performed using rotations, which means that we cannot simply continue to query and update the old secondary structure while lazily building new ones.

As mentioned, the weight-balanced B-tree has been used in the development of numerous efficient internal as well as external data structures (e.g., [26, 13, 8, 25, 9, 2, 41]). In order to obtain an external tree structure suitable for use in our interval tree, we choose $4a = \sqrt{B}$ and $2k = B$ and obtain the following.

THEOREM 3.8. *There exists an N element search tree data structure using $O(N/B)$ disk blocks such that a search or an insertion can be performed in $O(\log_B N)$ I/Os in the worst case.*

Each internal node v at level l in the structure, except for the root, has $\Theta(\sqrt{B})$ children, dividing the $w(v) = \Theta((\sqrt{B})^lB)$ elements below v into $\Theta(\sqrt{B})$ sets. The root

[3] If $a > 8$ we can even split the node at child $i-1$ or $i+1$ instead of at child i and still fulfill the constraints. We will use this property in the next section.

has $O(\sqrt{B})$ children. Rebalancing after an insertion is performed by splitting nodes. When a node v is split, at least $\Theta(w(v))$ elements must have been inserted below v since the last time v was split. In order for a new root to be created, $\Theta(N)$ elements have to be inserted into the data structure.

Proof. Each internal node can be represented using $O(1)$ blocks, and the space bound follows since each leaf contains $\Theta(B)$ elements. A split at v can be performed in $O(1)$ I/Os: we load the $O(1)$ blocks storing v into internal memory, split v, and write the $O(1)$ blocks defining the two new nodes back to disk. Finally, we update the information in the parent using $O(1)$ I/Os. Thus the insertion and search I/O bounds follow directly from Corollary 3.5 and Lemma 3.6.

The second part of the theorem follows directly from Definition 3.3, Corollary 3.2, and Lemmas 3.4 and 3.7. □

3.2. Using the weight-balanced B-tree to remove the fixed endpoint assumption. We now show how to remove the fixed endpoint assumption from our external interval tree using the weight-balanced B-tree as the base tree $\mathcal{T}$. To insert an interval, we first insert the two new endpoints in the base tree and perform the necessary rebalancing. Then we insert the interval as described in section 2. Since rebalancing is performed by splitting nodes, we need to consider how to split a node v in our interval tree. Figure 3.1 illustrates how the slabs associated with v are affected when v splits into nodes v' and v'': All the slabs on one side of a slab boundary b get associated with v'; the boundaries on the other side of b get associated with v''; and b becomes a new slab boundary in *parent*(v). As a result, all intervals in the secondary structures of v that contain b need to be inserted into the secondary structures of *parent*(v). The rest of the intervals need to be stored in the secondary structures of v' and v''. Furthermore, as a result of the addition of the new boundary b, some of the intervals in *parent*(v) containing b also need to be moved to new secondary structures. Refer to Figure 3.2.

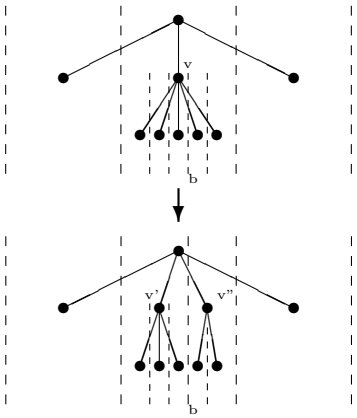

FIG. 3.1. *Splitting a node; v splits along b, which becomes a new boundary in parent(v).*

First consider the intervals in the secondary structures of v. Since each interval is stored in a left slab list and a right slab list, we can collect all intervals containing b (to be moved to *parent*(v)) by scanning through all of v's slab lists. We first construct a list L_r of the relevant intervals sorted according to right endpoint by scanning through the right slab lists. We scan through every right slab list (stored in the leaves of a B-tree) of v in order, starting with the rightmost slab boundary,

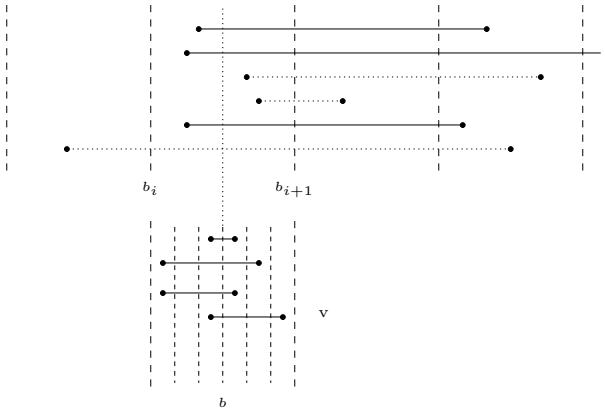

FIG. 3.2. *All solid intervals need to move. Intervals in v containing b move to parent(v), and some intervals move within parent(v).*

adding intervals containing b to L_r. This way L_r will automatically be sorted. We construct a list L_l sorted according to left endpoint by scanning through the left slab lists in a similar way. Since the secondary structures of v contain $O(w(v))$ intervals (they all have an endpoint below v), and since we can scan through each of the $O(\sqrt{B})$ slab lists in a linear number of I/Os (Lemma 2.1), we construct L_r and L_l in $O(\sqrt{B} + w(v)/B) = O(w(v)/B)$ I/Os. Next we construct the slab lists of v' and v'', simply by removing intervals containing b from each slab list of v. We remove the relevant intervals from a given slab list by scanning through the leaves of its B-tree, collecting the intervals for the new list in sorted order, and then constructing a new list (B-tree). This way we construct all the slab lists in $O(w(v)/B)$ I/Os. We construct the multislab lists for v' and v'' simply by removing all multislabs lists containing b. Since each removed list contains $\Omega(B)$ intervals, we can do so in $O(w(v)/B)$ I/Os. We construct the underflow structures for v' and v'' by first scanning through the underflow structure for v and collecting the intervals for the two structures, and then constructing them individually using $O(w(v)/B)$ I/Os (Lemma 2.3). We complete the construction of v' and v'' in $O(w(v)/B)$ I/Os by scanning though the lists of each of the nodes, collecting the information for the index blocks.

Next consider *parent*(v). We need to insert the intervals in L_l and L_r into the secondary structures of *parent*(v) and move some of the intervals already in these structures. The intervals we need to consider all have one of their endpoints in X_v. For simplicity we consider only intervals with *left* endpoint in X_v; intervals with right endpoint in X_v are handled similarly. All intervals with left endpoint in X_v that are stored in *parent*(v) cross boundary b_{i+1}. Thus we need to consider each of these intervals in one or two of $\sqrt{B} + 1$ lists, namely, in the left slab list L_{i+1} of b_{i+1} and possibly in one of $O(\sqrt{B})$ multislab lists $M_{i+1,j}$. When introducing the new slab boundary b, some of the intervals in L_{i+1} need to be moved to the new left slab list of b. In a scan through L_{i+1} we collect these intervals in sorted order in $O(|X_v|/B) = O(w(v)/B)$ I/Os. The intervals in L_l also need to be stored in the left slab list of b, so we merge L_l with the collected list of intervals and construct a B-tree on the resulting list. We can easily do so in $O(w(v)/B)$ I/Os (Lemma 2.1), and we can update L_{i+1} in the same bound. Similarly, some of the intervals in multislab lists $M_{i+1,j}$ need to be moved to new multislab lists corresponding to multislabs with

b as left boundary instead of b_{i+1}. We can easily move the relevant intervals (and thus construct the new multislab lists) in $O(w(v)/B)$ I/Os using a scan through the relevant multislab lists, similarly to the way we moved intervals from the left slab list of b_{i+1} to the left slab list of b. (Note that intervals in the underflow structure do not need to be moved.) If any of the new multislab lists contain fewer than $B/2$ intervals, we instead insert the intervals into the underflow structure U. We can easily do so in $O(B) = O(w(v)/\sqrt{B})$ I/Os by rebuilding U. Finally, to complete the split process we update the index blocks of $parent(v)$.

To summarize, we can split a node v in $O(w(v)/\sqrt{B})$ I/Os, and since $O(w(v))$ endpoints must have been inserted below v since it was constructed (Theorem 3.8), the amortized cost of a split is $O(1/\sqrt{B})$ I/Os. Since $O(\log_B N)$ nodes split during an insertion, we obtain the following.

LEMMA 3.9. *Assuming $M \geq B^2$, there exists a data structure using $O(N/B)$ disk blocks to store N intervals such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os in the worst case and such that an interval can be inserted in $O(\log_B N)$ I/Os amortized.*

As mentioned in section 3.1, deletions can be handled using global rebuilding [36]. To delete an interval s we first delete it from the secondary structures as described in section 2 *without* deleting the endpoints of s from the base tree $\mathcal{T}$. Instead we just mark the two endpoints in the leaves of the base tree as deleted. This does not increase the number of I/Os needed to perform a later update or query operation, but it does not decrease it either. After $N/2$ deletions have been performed we rebuild the structure in $O(N \log_B N)$ I/Os, leading to an $O(\log_B N)$ amortized delete I/O bound: first we scan through the leaves of the old base tree and construct a sorted list of the undeleted endpoints. This list is then used to construct the new base tree. All of this can be done in $O(N/B)$ I/Os. Finally, we insert the $O(N)$ intervals one by one without rebalancing the base tree, using $O(N) \cdot O(\log_B N)$ I/Os.

THEOREM 3.10. *Assuming $M \geq B^2$, there exists an external interval tree using $O(N/B)$ disk blocks to store N intervals such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os in the worst case and such that updates can be performed in $O(\log_B N)$ I/Os amortized.*

4. Removing amortization. In this section, we discuss how to make the update bound of Theorem 3.10 worst-case. Amortized bounds appeared in several places in our structure; in the fixed endpoint version of our structure, amortization was introduced as a result of the amortized $O(1)$ update bound of the underflow structure (Lemma 2.3), as well as when moving intervals between the underflow and multislab lists. In the dynamic base tree version, amortization was introduced in the amortized node split bound (insertions) as well as in the use of global rebuilding (deletions).

In sections 4.1 and 4.2, we show how to remove amortization from the node split and underflow (corner structure) update bounds, respectively. In section 4.2, we also show how to remove the $M \geq B^2$ assumption from the corner structure and thus from our external interval tree. The remaining amortization can be removed using standard lazy global rebuilding techniques [36]. We make the global rebuilding (deletion) bound worst-case as follows: instead of using $O(N \log_B N)$ I/Os to rebuild the entire structure when the number of endpoints fall below $N/2$, we distribute the rebuilding over the next $1/3 \cdot N/2$ updates using $O(\log_B N)$ I/Os on rebuilding at each update. We use and update the original structure while constructing the new structure. When the new structure is completed the $1/3 \cdot N/2$ updates that occurred after the rebuilding started still need to be performed in the new structure. We

perform these updates during the next $1/3 \cdot (1/3 \cdot N/2)$ operations. This process continues until both structures store the same set of intervals (with at least $(1 - (1/3 + 1/9 + \cdots))N/2 \geq 1/2 \cdot N/2$ endpoints). Then we dismiss the old structure and use the new one instead. Since the rebuilding is finished before the structure contains only $N/4$ endpoints, we are in the process of constructing at most one new structure at any given time. The amortization introduced when moving intervals between the underflow structure and multislab lists can be removed in a similar way: recall that we moved B intervals using $O(B)$ I/Os when the underflow structure contained B intervals belonging to the same multislab list $M_{i,j}$ and when the number of intervals in a multislab list fell below $B/2$. We remove this amortization by moving the intervals over $B/4$ updates. If the size of a multislab list $M_{i,j}$ falls to $B/2$, we move two intervals from $M_{i,j}$ to the underflow structure over each of the next $B/4$ insertions or deletions involving $M_{i,j}$. Insertions themselves are also performed on the underflow structure, and deletions are performed on the underflow structure or $M_{i,j}$. When all intervals are moved there are between $\frac{1}{4}B$ and $\frac{3}{4}B$ intervals belonging to $M_{i,j}$ stored in U. Similarly, if the number of intervals in the underflow structure belonging to $M_{i,j}$ reaches B, we move the B intervals during the next $B/4$ updates involving $M_{i,j}$. Even though this way $M_{i,j}$ can contain $o(B)$ intervals, the optimal space and query bounds are maintained since $M_{i,j}$ and U together contain $\Theta(B)$ intervals during the process. This proves our main result.

THEOREM 4.1. *There exists an external interval tree using $O(N/B)$ disk blocks to store N intervals such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os in the worst case and such that updates can be performed in $O(\log_B N)$ I/Os in the worst case.*

4.1. Splitting nodes lazily. Recall that when a node v splits along a boundary b the intervals in v containing b need to be moved to *parent*(v), and some of the intervals in *parent*(v) containing b need to move internally in *parent*(v) (Figure 3.2). In section 3, we showed how to move the intervals in $O(w(v)/\sqrt{B})$ I/Os, and since $O(w(v))$ updates have to be performed below v between splits (Theorem 3.8) we obtained an $O(1/\sqrt{B})$ amortized split bound. When performing an update in a leaf l it affects the weight of $O(\log_B N)$ nodes on the path from the root to l. These nodes are all *accessed* in the search for l performed before the actual insertion. In this section we show how to split a node v (move the relevant intervals) lazily using $O(1)$ I/Os during the next $O(w(v))$ updates accessing v while still being able to query the secondary structures of v efficiently. This way we are done splitting v before a new split is needed, and we obtain an $O(1)$ worst-case split bound.

Our lazy node splitting algorithm works as follows. When v needs to be split along a boundary b, in $O(1)$ I/Os we first insert b as a *partial* slab boundary into *parent*(v). The boundary remains partial until we have finished the split. In order to keep different split processes from interfering with each other, we want to avoid splitting nodes along partial boundaries. Since v, or rather the nodes it splits into, cannot split again as long as b is partial, at most every second boundary in *parent*(v) can be partial. As discussed in section 3.1 (footnote 3), this means that we can always split a node along a nonpartial boundary without violating the constraints on the base weight-balanced B-tree $\mathcal{T}$. Next we move the relevant intervals in two phases: in an *up phase*, we first construct the new secondary structures for v' and v'' as before, by removing the intervals in secondary structures of v containing b and collecting them in two sorted lists L_l and L_r. Below we show how to do so lazily using $O(1)$ I/Os over $O(w(v)/\sqrt{B})$ updates accessing v so that we can still

query and update the "old" secondary structures of v. During this phase we can therefore perform queries as before, simply by ignoring the partial slab boundary b in *parent*(v). Next, in the *rearrange phase*, in $O(1)$ I/Os, we split v into v' and v'' by switching to the new structures and splitting the index blocks. We also associate the lists L_l and L_r with the partial boundary b in *parent*(v). Then we move the relevant intervals in *parent*(v) containing b by constructing new updated versions of all secondary structures containing intervals with endpoints in X_v. Below we discuss how to do so lazily over $O(w(v)/\sqrt{B})$ updates accessing v (v' and v'') so that the "old" structures can still be queried and updated. In order to answer queries between b_i and b_{i+1} in *parent*(v) correctly during the rearrange phase, we first perform a query as before while ignoring the partial slab boundary b. To report the relevant intervals among the intervals we have removed from v and inserted into L_l and L_r, we then query the relevant one of the two slab lists. Since this adds only $O(1)$ I/Os to the query procedure in *parent*(v), the optimal query bound is maintained. At the end of the rearrange phase, we finish the split of v in $O(1)$ I/Os by switching to the new structures and marking b as a normal slab boundary.

All that remains is to describe how to perform the up and rearrange phases. Each of these phases can be performed lazily using $O(1)$ I/Os during each of $O(w(v)/\sqrt{B})$ updates accessing v. However, our algorithms will assume that only one up or rearrange phase is in progress on a node v at any given time, which means that when we want to perform a phase on v we might need to wait until we have finished another phase. In fact, other phases may also be waiting, and we may need to wait until v has been accessed enough times for us to finish all of them. Luckily, since an up and rearrange phase requires only $O(w(v)/\sqrt{B})$ accesses to finish, and since we need only to finish our phase in $O(w(v))$ accesses, we can afford to wait for quite a while. Before an up phase can be performed on v we at most have to finish $O(\sqrt{B})$ rearrange phases (one for each partial slab boundary), each requiring $O((w(v)/\sqrt{B})/\sqrt{B}) = O(w(v)/B)$ accesses, for a total of $O(w(v)/\sqrt{B})$ accesses. After finishing the up phase on v we might need to finish $O(\sqrt{B})$ other rearrange phases and one up phase on *parent*(v) before performing the rearrange phase. These phases require at most $O(\sqrt{B}) \cdot O(w(v)/\sqrt{B}) + O((w(v) \cdot \sqrt{B})/\sqrt{B}) = O(w(v))$ accesses. Thus in total we finish the split of v in the allowed $O(w(v))$ accesses. Note that the waiting can be implemented simply by associating a single block with v storing a queue with information about the $O(\sqrt{B})$ phases waiting at v. When we want to perform a phase on v we simply insert it in the queue, and each time v is accessed $O(1)$ I/Os are performed on the phase in the front of the queue. When v has been accessed enough times to finish one phase we start the next phase in the queue. Note also that while we are waiting to perform a phase on a node v, or even while we are performing the phase, new partial slab boundaries may be inserted in v, and new slab lists may be inserted for such boundaries (due to splits of children of v). However, this does not interfere with the up or rearrange phase, since we do not split along partial boundaries and since the intervals in the two new slab lists for a partial boundary contain only the partial boundary.

After having described how to guarantee that we are working on only one up or rearrange phase in a node v at any given time, we can now describe how to perform such a phase lazily over $O(w(v)/\sqrt{B})$ accesses. We do so basically using lazy global rebuilding: during normal updates we maintain a copy of each secondary structure—called a *shadow* structure. Maintaining such shadow structures along with the original structures does not change the asymptotic space, update, or query bounds of the

interval tree. When we start an up or rearrange phase on v, we first "freeze" the shadow structures of v; that is, instead of performing updates on them we just store updates as they arrive. Then we perform the necessary movement of intervals on the *shadow* structures as described in section 3. It is easy to realize how we can perform these movements over the next $O(w(v)/\sqrt{B})$ updates accessing v such that $O(1)$ I/Os are used at each access. The only slight complication is that we need to make sure that updates performed in v during the process (that is, updates that were stored at v and still need to be performed on the shadow structures) are performed after we have moved the relevant intervals. To do so within the $O(w(v)/\sqrt{B})$ bound, we actually perform $\Theta(\log_B N)$ instead of only $O(1)$ I/Os on the shadow structure movement process every time an update is performed in v. This does not change the overall $O(\log_B N)$ update I/O bound, since an update (insertion or deletion of an interval) takes place only in *one* node of $\mathcal{T}$ (or, equivalently, since we are already using $O(\log_B N)$ I/Os to perform the update on the original secondary structures of v). After finishing the interval movement, we then perform the stored updates lazily using $O(1)$ I/Os each time v is accessed. Since we performed $\Theta(\log_B N)$ I/Os on the shadow structures each time an update was stored at v, we are guaranteed that we will finish performing the updates within $O(w(v)/\sqrt{B})$ accesses to v. Finally, after moving intervals and performing updates, we (lazily) make a copy (shadow) of the new shadow structures in the same I/O bound. We handle updates performed during this copying in the same way we handled updates during global rebuilding of the external interval tree (to remove delete amortization). We finish the phase by discarding the old secondary structures and instead use the updated shadow structures (along with their shadow) as the secondary structures.

4.2. Removing amortization from the corner structure. In this section we sketch the "corner structure" of Kannelakis et al. [30] (Lemma 2.3) and discuss how its $O(1)$ amortized update bound can be made worst-case. At the same time we remove the assumption that $M \geq B^2$.

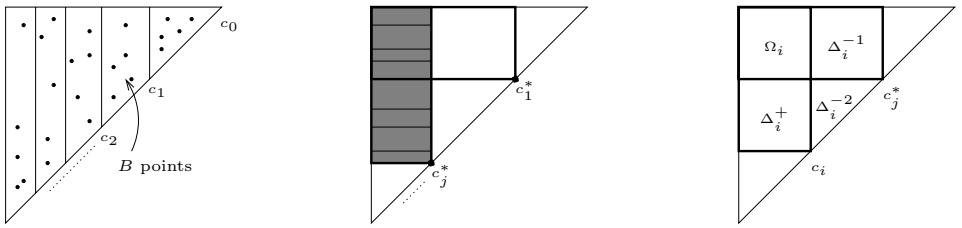

FIG. 4.1. *(a) Vertical regions. (b) The set C^* (the marked points). The dark lines represent the boundaries of queries whose corners are points in C^*. One (horizontally blocked) query is shaded. (c) The sets Ω_i, Δ_i^{-1}, Δ_i^{-2}, and Δ_i^+. c_j^* is the last point that was added to C^*, and c_i is being considered for inclusion in C^*.*

The corner structure is designed to store a set S of $K \leq B^2$ points in the plane above the $x = y$ line such that diagonal corner queries can be answered in $O(1+T/B)$ I/Os [30]. As discussed in the introduction, this problem is equivalent to the stabbing query problem. The structure is defined as follows: First S is divided into $\lceil K/B \rceil$ *vertical* regions containing B points each. Refer to Figure 4.1(a). The points in these regions are stored in $\lceil K/B \rceil$ blocks. Let C be the set of points at which the right boundaries of the $\lceil K/B \rceil$ regions intersect the $y = x$ line. An iterative procedure is

used to choose a subset C^* of these points, and one or more *horizontally* oriented blocks are used to explicitly store the answer to each query with a corner $c^* \in C^*$. Refer to Figure 4.1(b). First the highest point $c_1^* \in C$ is included in C^*. Then each point in C is considered in turn along the $x = y$ line. Let c_j^* be the point of C most recently added to C^*; initially, this is c_1^*. When considering $c_i \in C$, the sets $\Omega_i \subset S$, $\Delta_i^{-1} \subset S$, $\Delta_i^{-2} \subset S$, and $\Delta_i^+ \subset S$ are defined as shown in Figure 4.1(c). The set $S_j^* = \Omega_i \cup \Delta_i^{-1}$ is the answer to a query whose corner is c_j^*, and $S_i = \Omega_i \cup \Delta_i^+$ is the answer to a query whose corner is c_i. Let $\Delta_i^- = \Delta_i^{-1} \cup \Delta_i^{-2}$. The point c_i is then added to C^* if and only if

$$|\Delta_i^-| + |\Delta_i^+| > |S_i|.$$

In [30] it is shown that the total number of blocks used to store the sets S_i^* is $O(K/B)$. The corner structure consists of these blocks, as well as $O(1)$ blocks storing the sets C and C^*. In [30] it is also shown how a diagonal corner query can be answered in $O(1 + T/B)$ I/Os using this representation.

The corner structure can easily be constructed in $O(K/B)$ I/Os when $M \geq B^2$ (since in this case it fits in main memory). As discussed, the structure can therefore easily be made dynamic with an $O(1)$ amortized update bound using an update block and global rebuilding [30]. In the following we show how to construct the structure in $O(K/B)$ I/Os incrementally over $O(K/B)$ updates such that no more than $O(1)$ blocks are loaded into main memory at any time. This immediately removes the $M \geq B^2$ assumption. Using this result and lazy global rebuilding, the $O(1)$ amortized update bound can then be made worst-case: once $B/2$ updates have been collected in the update block, the structure is rebuilt during the next $B/2$ updates using $O(1)$ I/Os at each update.

We first discuss how to construct a corner structure on K points in $O(K/B)$ I/Os using $O(1)$ blocks of main memory. After that we discuss how the construction can be performed lazily. We assume that the K points are given in two lists sorted according to x- and y-coordinates, respectively. We can easily store two such lists along with the corner structure itself using $O(K/B)$ space. At the start of a rebuilding process, we first merge the $O(B)$ points in the update block into these two lists in $O(K/B)$ I/Os using $O(1)$ blocks of main memory. Then we construct the corner structure in three steps: first we compute the vertical blocking, that is, the set C. Then we compute C^*. Finally, we construct the horizontal blocking corresponding to each of the points in C^*.

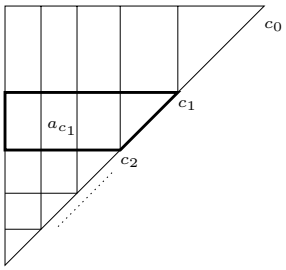

FIG. 4.2. *Definition of* a_{c_i}.

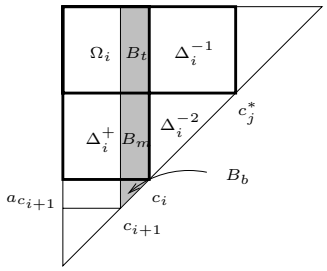
The vertical blocking is simply the list sorted according to x-coordinates. We can easily make a copy of this list and thus compute the set C in $O(K/B)$ I/Os



$$
\begin{aligned}
|\Delta_{i+1}^{-1}| &= |\Delta_i^{-1}| + |B_t| \\
|\Delta_{i+1}^{-2}| &= |\Delta_i^{-2}| + |B_m| + |B_b| \\
|\Omega_{i+1}| &= |\Omega_i| - |B_t| \\
|\Delta_{i+1}^{+}| &= |\Delta_i^{+}| - |B_m| + (a_{c_{i+1}} - |B_b|)
\end{aligned}
$$

FIG. 4.3. *Definition of B_t, B_m, and b_b and computation of C^*.*

using $O(1)$ blocks of memory. Let $c_i \in C$ be the ith point in the sorted sequence of points on the $x = y$ line. To aid the computation of C^* we first compute for each $c_i \in C$ a number a_{c_i}. We define a_{c_i} to be the number of points with y-coordinates between the y-coordinates of c_i and c_{i+1}. Refer to Figure 4.2. We compute all a_{c_i}s in $O(K/B)$ I/Os using $O(1)$ blocks of main memory in a single scan of the list of points sorted by y-coordinates. We then compute C^* as previously by proceeding along the $x = y$ line and including $c_i \in C$ in C^* if $|\Delta_i^-| + |\Delta_i^+| > |S_i|$. Since the number of points in C is $O(K/B)$, our goal is to decide if c_i should be included in $O(1)$ I/Os. We can do so if we can compute $|\Omega_{i+1}|$, $|\Delta_{i+1}^+|$, $|\Delta_{i+1}^{-1}|$, and $|\Delta_{i+1}^{-2}|$ in $O(1)$ I/Os, given $|\Omega_i|$, $|\Delta_i^+|$, $|\Delta_i^{-1}|$, $|\Delta_i^{-2}|$, c_j^*, c_i, c_{i+1}, and a_{i+1}. (These values/points can all be loaded into main memory in $O(1)$ I/Os.) Figure 4.3 illustrates how we can compute $|\Omega_{i+1}|$, $|\Delta_{i+1}^+|$, $|\Delta_{i+1}^{-1}|$, and $|\Delta_{i+1}^{-2}|$ once B_t, B_m, and B_b have been computed. We compute these three sets, containing a total of B points, in $O(1)$ I/Os, simply by loading the relevant vertical block. Thus overall we can compute C^* in $O(K/B)$ I/Os.

To compute and horizontally block the points in the answer S_j^* to a query at each of the points $c_j^* \in S^*$, we again proceed along the $x = y$ line considering each point $c_i^* \in C^*$ in turn. Assume we have already blocked S_j^* and that we know the position p of the last (lowest y-coordinate) point in S_j^* in the list of points sorted by y-coordinates. Initially, S_j^* is empty, and p is the first point in the list of points sorted by y-coordinates. To block S_{j+1}^*, we scan through the horizontal blocking of S_j^*, collecting the points with x-coordinate smaller than the x-coordinate of c_{j+1}^*. This way we obtain the points in S_{j+1}^* above the y-coordinate of s_j^* horizontally blocked (sorted by y-coordinates). Then we collect the remaining points in S_{j+1}^* horizontally blocked by scanning through the list of points sorted by y-coordinates, starting at p. Altogether we use $O(|S_j^*|/B + |S_{j+1}^*|/B)$ I/Os to compute the blocking of S_{j+1}^*. Thus we use $O(2\sum_{j \in 1..|S^*|} |S_j^*/B|)$ I/Os to compute the blocking corresponding to all the points in C^*. This is $O(K/B)$ since the structure uses linear space.

We have shown how to construct the corner structure in $O(K/B)$ I/Os using $O(1)$ blocks of main memory. We can easily modify the algorithm to work in an incremental way, that is, to run in $O(K/B)$ steps of $O(1)$ I/Os without using any main memory between two steps: throughout the algorithm we can represent the current state of the algorithm by a constant number of pointers and values. We can therefore perform one step by loading the current state into main memory using $O(1)$ I/Os, performing the step using $O(1)$ I/Os, and finally using $O(1)$ I/Os to write the new state back to disk. In total we have proved the following.

LEMMA 4.2. *A set of $K \leq B^2$ intervals can be stored in an external data structure using $O(K/B)$ disk blocks such that a stabbing query can be answered in $O(T/B+1)$ I/Os and such that updates can be performed in $O(1)$ I/Os. The structure can be constructed in $O(K/B)$ I/Os.*

5. External segment tree. In this section we sketch how the ideas used in the external interval tree can also be used to develop an external segment tree-like structure with a better space bound than previously known for such structures [15, 39]. Like an interval tree, a segment tree solves the stabbing query problem. Unlike the interval tree, however, it uses superlinear space. It is often used as base tree structure in multidimensional structures (refer, e.g., to [10, 3]).

Structure. In internal memory, as in the case of the interval tree, a segment tree consists of a binary base tree with intervals stored in secondary structures of internal nodes. Unlike for the interval tree, an interval can be stored in the secondary structures of up to two nodes on each level of the base tree. More precisely, an interval s is stored in all nodes v such that s contains the interval associated with at least one of v's children but not the interval X_v associated with v. As in the interval tree case, we externalize the structure by using a weight-balanced B-tree (Theorem 3.8) as the base tree. As previously, an internal node v defines $\Theta(\sqrt{B})$ slabs and $\Theta(B)$ multislabs, and $\Theta(B)$ secondary structures are associated with v. An interval s is stored only in the secondary structures of v if it spans one of v's *slabs* but not the whole interval X_v. Thus, unlike in the external interval tree, where s is stored only in the highest node for which it contains a slab *boundary*, s can be stored in $O(\log_B N)$ nodes—refer to Figure 5.1(a). As in the interval tree, s is stored in a multislab list corresponding to the largest multislab it spans, and as before intervals from multislab lists containing $o(B)$ intervals are stored in an underflow structure. Note how an external segment tree corresponds to an external interval tree, where parts of an interval not completely spanning a slab in a node v are stored recursively instead of in a slab list. Multislab lists are implemented as simple (unordered) lists, and with each interval s we store pointers to the copies of s in the nearest ancestor and descendent of v storing copies of s. These pointers are not directly maintained for intervals in underflow structures. Instead we keep a separate lists of intervals in the underflow structure of each node v, and pointers are maintained for these intervals. This allows us to rebuild an underflow structure containing K intervals in $O(K/B)$ I/Os and thus maintain the $O(1)$ update bound of the underflow structure (Lemma 4.2); maintaining pointers would have required $O(K)$ I/Os. Finally, we maintain an auxiliary B-tree containing all intervals in the structure, ordered according to right endpoint, such that given an interval s we can obtain a pointer to the copy of s stored in the topmost node storing s. This B-tree uses linear space, and since the secondary structures of a node also use linear space the external segment tree uses $O((N/B)\log_B N)$ disk blocks to store N intervals.

Query. We answer a stabbing *query* q on an external segment tree in $O(\log_B N + T/B)$ I/Os, simply by searching down the base tree for q and in each node querying the underflow structure and reporting all intervals in lists corresponding to multislabs containing q.

Updates. To *insert* an interval s into an external segment tree we first insert the endpoints of s in the base tree and rebalance the tree by splitting nodes. Below we show how a node v can be split in $O(w(v))$ I/O such that an endpoint is inserted in $O(\log_B N)$ I/Os amortized. Then we perform the actual insertion of s by traversing two paths in the base tree, inserting s in the relevant multislab lists. As the multislab lists are unsorted, we can insert s in a list in $O(1)$ I/O while at the same time

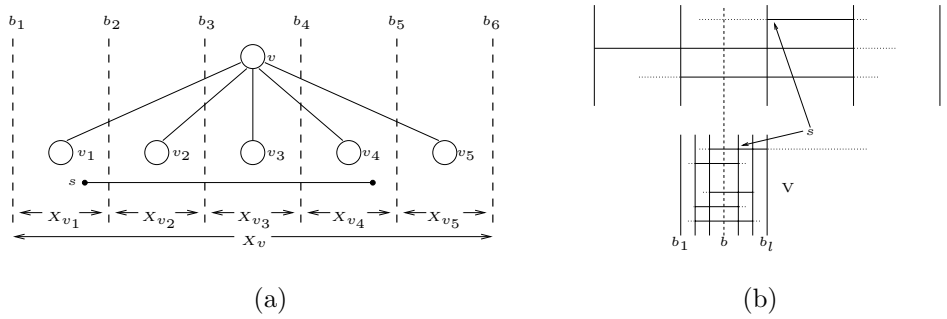


FIG. 5.1. (a) *Node v in the base tree. The interval s is stored in v as well as (recursively) in v_1 and v_4.* (b) *Splitting a segment tree node.*

storing the relevant pointers to other copies of s. We handle the cases involving the underflow structure in $O(1)$ I/Os precisely as in the external interval tree case. In total we can perform an insertion in $O(\log_B N)$ I/Os. We *delete* an interval s from an external segment tree in $O(\log_B N)$ I/Os simply by locating s in the auxiliary B-tree—obtaining a pointer to the topmost of the $O(\log_B N)$ occurrences of s—deleting s from the B-tree, and then using the pointers between copies of s to find and remove all occurrences of s in $O(\log_B N)$ I/Os; note that even though in a node where s is stored in the underflow structure we obtain a pointer to the separate list of intervals, we can still delete s from the underflow structure in $O(1)$ I/Os. As in the interval tree case, we remove the endpoints of s from the base tree in $O(\log_B N)$ I/Os using global rebuilding.

All that remains is to describe how to efficiently split a node v along a slab boundary b. When v splits into v' and v'', all intervals in multislabs containing b need to be moved. These intervals fall into two categories: intervals that contain the leftmost or rightmost slab boundaries b_1 and b_l of v and those that do not. Refer to Figure 5.1(b). Intervals not containing b_1 or b_l (but containing b) need to be stored in multislab lists of both v' and v''. Thus to move these intervals we simply need to make a copy of the relevant lists for both v' and v''. We also need to update the relevant pointers between intervals. We can easily do so in $O(w(v))$ I/Os. Intervals that contain b_1 or b_l (and b) need to be inserted in v' or v'', as well as moved within *parent*(v). Consider, for example, intervals containing b and b_l (e.g., interval s in Figure 5.1(b). Such intervals need to be inserted in multislab lists for v', as well as either inserted into *parent*(v) or moved within *parent*(v): if one of these intervals s is already stored in *parent*(v) we use the pointer stored with s in v to locate and delete s in *parent*(v), and then we insert s in the relevant new multislab list. Since each interval can be moved in $O(1)$ I/Os, and since all moved intervals have an endpoint in X_v, we use $O(w(v))$ I/Os in total to split a node v. Finally, as in the interval tree case, we can perform the split over $O(w(v))$ updates accessing v and thus obtain worst-case bounds.

THEOREM 5.1. *There exists an external segment tree using $O((N/B)\log_B N)$ disk blocks to store N intervals such that stabbing queries can be answered in $O(\log_B N + T/B)$ I/Os and such that updates can be performed in $O(\log_B N)$ I/Os.*

COVERING RECTILINEAR POLYGONS WITH AXIS-PARALLEL RECTANGLES*

V. S. ANIL KUMAR† AND H. RAMESH‡

Abstract. We give an $O(\sqrt{\log n})$ factor approximation algorithm for covering a rectilinear polygon with holes using axis-parallel rectangles. This is the first polynomial time approximation algorithm for this problem with an $o(\log n)$ approximation factor.

Key words. approximation algorithms, covering polygons

AMS subject classifications. 52C15, 68W25, 68W40

DOI. 10.1137/S0097539799358835

1. Introduction.

We consider the problem of covering rectilinear polygons with axis-parallel rectangles. Given a rectilinear polygon P with complexity n (complexity refers to the minimum of the number of vertical edges and the number of horizontal edges in the polygon), this problem requires determining the minimum number of axis-parallel rectangles whose union covers P. The polygon P may have holes in it.

Applications. Cheng, Iyengar, and Kashyap [5] showed that this problem has applications to image compression. They claim that representing an image using a rectangle covering of its white pixels gives compression superior to that achieved by quadtrees. It also has applications to printing integrated circuits [9].

Hardness. Much effort has gone into determining the computational complexity of this problem. In spite of this, the exact complexity of this problem has remained open for many years and continues to do so. Masek [19] showed that this problem is NP-complete. Later, Culberson and Reckhow [6] used a clever reduction from 3-SAT to show that this is the case even when P has no holes. The next natural question is whether the number of rectangles needed to cover P can be computed *approximately*. Berman and Dasgupta [2] showed that this problem is MaxSNP-Hard for polygons with holes, ruling out the possibility of a polynomial time approximation scheme.

Approximation results. Note that the rectangle covering problem is a special case of the general set covering problem. Therefore, it admits an approximation algorithm with a performance guarantee of $O(\log n)$, using the greedy scheme due to Johnson [10] and Lovasz [16]. This was the best approximation factor known for the rectangle covering problem until now. Further, it is known that the general set covering problem cannot be approximated any better, modulo constant terms, unless $NP = P$ [17, 18]. However, this proof of hardness assumes certain properties about the set system which do not hold for the rectangle covering problem. In this paper, we address the issue of whether the $\Omega(\log n)$ approximation factor barrier can be broken in polynomial time for the rectangle covering problem.

There seem to be only a few examples of nontrivial algorithms breaking this

barrier for specific instances of the set covering problem. Brönnimann and Goodrich [3] showed that the covering problem for any set system with Vapnik–Chervonenkis dimension d can be approximated within an $O(d \log(dc))$ factor, where c is the cost of the optimal covering. For the rectangle covering problem, while d is a constant, c can be shown to be $\Omega(\sqrt{n})$; therefore, the Brönnimann–Goodrich algorithm gives only an $O(\log n)$ approximation factor. Brönnimann and Goodrich [3] also showed that $O(c)$ sized set covers can be computed for two-dimensional disc covering and a problem related to three-dimensional polytope separation as these set systems admit ϵ-nets of small size. It is not clear whether the rectangle covering problem admits ϵ-nets of small size.

Special situations. There are special situations when the above barrier can indeed be broken. When P is hole-free, Franzblau [7] showed a factor 2 approximation guarantee. When P has holes, Franzblau also gave an $O(n \log n)$ time heuristic which gives an $O(\log n)$ approximation factor. When P is both vertically and horizontally convex (i.e., the intersection of any vertical or horizontal line and P is just a single line segment), Chaiken et al. [4] gave a polynomial time algorithm which computed the minimum number of rectangles required, exactly. This was improved upon by Franzblau and Kleitman [8], who achieved the same result under the weaker restriction that P is just vertically convex. Note that both restrictions preclude the presence of holes.

Other papers which have dealt with this problem are [9, 11, 12, 13, 5].

Our result. We give the first algorithm to break the $\Omega(\log n)$ barrier even when P has holes. Our algorithm gives an approximation guarantee of $O(\sqrt{\log n})$.

Our algorithm is in fact trivial, and our contribution lies entirely in showing a lower bound. For simplicity, assume that all holes in P are point holes.[1] Then our algorithm simply puts one rectangle for each *strip*, i.e., a stretch of points between two vertically aligned holes (e.g., strip s and its associated rectangle R in Figure 1; this is defined formally in section 2). This rectangle covers the strip entirely and is made as thick as possible. It is easy to see that the rectangles for all strips together cover P (the boundary of P must be treated as being lined by point holes for this). Also note that the rectangles for two distinct strips could be identical (e.g., strips B and D in Figure 2). We show that the total number of distinct rectangles $\#N$ obtained in the above process is $O(\sqrt{\log n} * |OPT|))$, where OPT is the minimum cover.

The lower bound. The main hurdle in breaking the $\Omega(\log n)$ barrier is to obtain a good lower bound for the optimum. One such lower bound is the cardinality of the largest *independent set* or *antirectangle*, i.e., a set of points in P, no two of which can be covered by the same rectangle. Chvatal (as reported in [4]) originally conjectured that the size of the minimum covering equals the size of the largest independent set. While this is indeed true for vertically and horizontally convex P, as shown by Chaiken et al. [4], it is not true for general P, with or without holes. Szemeredi found a counterexample with holes, and Chung found one without holes (both reported in [4]). Erdos (as reported in [4]) asked whether the ratio of the sizes of the minimum covering and the largest independent sets is bounded. It is easy to show that this ratio is $O(\log n)$. However, to the best of our knowledge, the best lower bound on this ratio known to date is just $21/17 - \epsilon$, due to [4].

Instead of using the above independent set bound, we use the *clique covering* lower bound. Consider the finite set of all points in P after suitable discretization.

[1] The case when the holes are arbitrary can effectively be reduced to the case of point holes, as we will show later in this paper.

Consider the graph G with these points as vertices and an edge between two points if and only if they are both covered by some rectangle. It is easy to see that $|OPT|$ is exactly the size of the smallest clique cover of this graph (i.e., a collection of cliques that covers all vertices). We shall lower bound the clique cover number by obtaining an upper bound on the sizes of cliques in OPT.

One problem we face in the process is that the cliques of G could be very different in size and therefore do not admit a uniform upper bound. However, we show that if none of the strips are *jumpers* (we will define this term in section 3.2), then we can choose $\Theta(\#N)$ points such that the maximum clique size in the subgraph induced by them is $O(\sqrt{\log n})$, and therefore $|OPT| = \Omega(\#N/\sqrt{\log n})$, as required. Our proof of this fact is based on a somewhat detailed exploration of the structure of cliques in G.

There is a correspondence between the points that are chosen in the above induced subgraph and the set of strips. We choose two points for each strip, one to its left and one to its right, after partitioning the strips into disjoint sets called *families* (defined later); this ensures that the induced subgraph has $\Theta(\#N)$ points. As mentioned earlier, if there are no jumpers, we show that the maximum clique size is $O(\sqrt{\log n})$ (this is not strictly true; we show that a further subset of this set of points has this property). Also, the number of jumpers turns out to be at most $(|OPT|\sqrt{\log n})$, so we can ignore such strips and argue about the points defined by the rest. The above description is very incomplete and will be developed formally in the remaining sections.

A significant point to note is that while we show a lower bound on the clique covering number of graph G in the absence of jumpers, we are unable to show a good lower bound on the size of the largest independent set. We can show that the number of families is a lower bound on the size of the largest independent set; however, the average family size can be as large as $\Omega(\log n)$, as we shall show later.

Roadmap. In section 2, we show how to discretize the polygon and then describe our algorithm for laying rectangles. For simplicity and clarity, we first explain the arguments in section 3 under some restrictive assumptions. The general case requires a refinement of these ideas and is handled in section 4. Section 5 describes an example where the average family size is large. Section 6 mentions the loose threads which remain in this problem and also describes some related problems.

2. Preliminaries. Consider the grid formed by drawing infinitely long lines through each vertical and horizontal edge of the polygon (i.e., both the polygon boundary and the hole boundaries) (see Figure 1). Note that this need not be a uniform grid; the spacing between adjacent grid lines is not necessarily the same. Let n denote the *vertical complexity* of P, i.e., the number of horizontal grid lines. Without loss of generality, we assume that the vertical complexity is at most as large as the horizontal complexity.

Viewing the entire plane as partitioned into grid cells, the term *hole* shall henceforth denote any grid cell which is in the exterior of the polygon (i.e., either outside the outer boundary or within one of the holes). Since any grid cell lies either completely in the interior of the polygon or completely in the exterior of the polygon (see Figure 1), the above term is well defined.

Note that any two holes are either perfectly aligned or completely misaligned with respect to the grid lines. Also note that two holes could lie side by side, touching each other (e.g., holes A, B in Figure 1). If we treat each grid cell as a point, we get the case of point holes. However, the rest of the description will be in terms of cells.

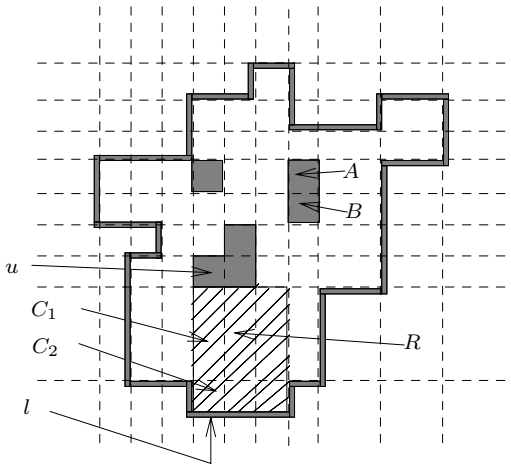

FIG. 1. *The grid: Dark cells and external cells are holes.* C_1, C_2 *form a strip* s *of length* 2. R *is the rectangle associated with* s*, and* u *and* l *are its upper and lower holes, respectively.*

2.1. Defining strips and laying rectangles. A sequence of consecutive vertically aligned nonhole cells bounded by holes on the top and the bottom constitutes a *strip* (see Figure 1). The *length* of a strip A is the number of cells in it and is denoted by $l(A)$. The *upper hole* for a strip is the hole which lies immediately above the topmost cell for that strip. The *lower hole* is similarly defined.

For each strip, we define its *associated rectangle* to be the unique rectangle that covers this strip and extends as far as possible to the left and to the right. In other words, the associated rectangle is obtained by sweeping the strip to the left and right until it is blocked by some holes on both sides (see Figure 1). The algorithm simply adds the associated rectangle of every strip to the overall cover. Lemma 2.1 shows that these rectangles indeed cover the given polygon. The rest of the paper proves that this naive way of covering is at most an $O(\sqrt{\log n})$ factor larger than the optimum.

The hole which blocks the associated rectangle of a strip S on the right is called the *right blocking hole* of S, with ties broken in favor of the topmost hole. *Left blocking holes* are defined similarly.

LEMMA 2.1. *Each point in the polygon is contained in the associated rectangle of some strip.*

Proof. Each nonhole grid cell, c, belongs to a unique strip. This is because if the cell c is swept vertically up and down, it would hit a hole in both directions. The rectangle associated with this strip contains c. □

Note that two strips could have identical associated rectangles (e.g., strips B, D in Figure 2). Consider equivalence classes of strips, where strips with the same associated rectangle are in one class. All but the rightmost of the strips in an equivalence class are called *unnecessary strips*. Clearly, an unnecessary strip can be ignored. It suffices to account for the rectangles associated with necessary strips.

2.2. Spanning, nestedness, and disjointness. A rectangle associated with strip A is said to *pass through* strip B if some but not all of the cells in strip B are contained in this rectangle (see Figure 2). In this situation, B is said to *l-span* A if it is to the left of A and *r-span* A if it is to the right of A. Note the strict condition in the above definition; i.e., the length of B must be strictly greater than that of A.

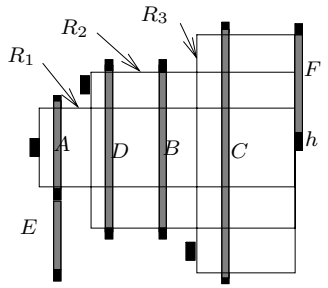

FIG. 2. *A family: Strips A, B, C are in one right family and have the common blocking hole h. D is unnecessary and has the same associated rectangle as B. B r-spans A. Strips E and F are disjoint.*

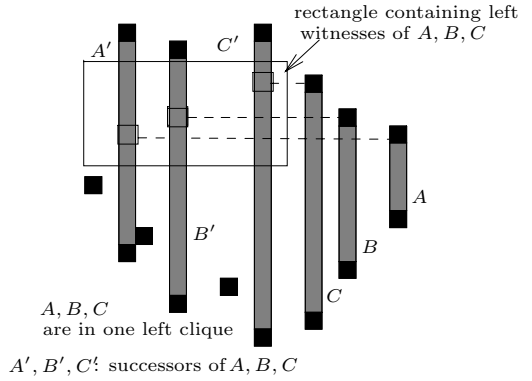

FIG. 3. *A left clique. B l-spans A, and C l-spans B.*

A collection of strips is called *right nested* if the strips increase in length from left to right and each strip r-spans all smaller strips. Left nesting is defined analogously. The strips A, B, and C in Figure 3 are left nested.

Two strips A, B are said to be *disjoint* if one of the following conditions holds: (i) the lower hole of A is horizontally aligned with or higher than the upper hole of B, or (ii) the upper hole of A is horizontally aligned with or below the lower hole of B (see Figure 2).

2.3. Successors, terminals, and witness cells. We bound the approximation factor of our algorithm by first identifying a subset of the nonhole cells and then showing lower bounds on the number of rectangles needed to cover these cells. The nonhole cells we identify are called *witness* cells. There are two kinds of witness cells, *left witness* cells and *right witness* cells. To define witness cells, we need the notion of successor strips.

We will formally define successor strips in section 3.1. Here, we introduce some properties of successors. The *right successor* strip for a strip A r-spans A, and the *left successor* for a strip A l-spans A. Not each necessary strip has a right successor; those strips which do not have right successors are called *right terminal* strips. *Left terminal* strips are defined analogously.

Given successors and terminals, witnesses are defined as follows. For each right terminal strip A, its right witness cell is the cell in A which is horizontally aligned with its right blocking hole (see Figure 4). For each right nonterminal strip A, its

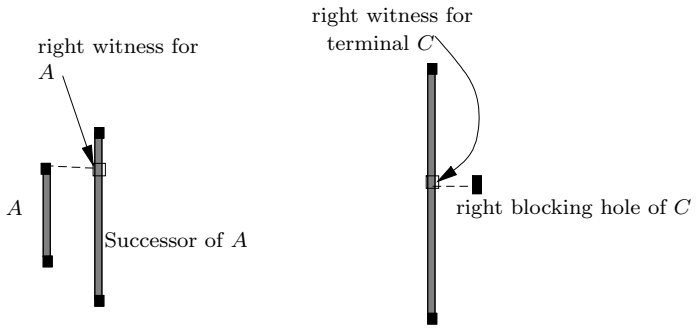

FIG. 4. *Right witnesses for nonterminal strip A and terminal strip C.*

right witness is the cell in its right successor strip which is horizontally aligned with A's upper hole (see Figure 4). The left witness is defined in a similar manner.

Note that right witnesses for right nonterminal strips A are not well defined if the upper hole of the right successor of A is aligned with the upper hole of A. An analogous fact holds for left witnesses of left nonterminal strips. This is clearly a problem because the above process may not define sufficiently many witness cells to obtain a good enough lower bound on the size of the optimum. We solve this problem by first identifying a constant fraction of the necessary strips with the following property: each such strip has a well-defined left witness. The remaining necessary strips are called *discarded* strips, and they play no role in the proof.

The precise definition of successor strips and the description of which strips are discarded appear in subsequent sections. We set up some more preliminaries in this section.

2.4. Cliques and the optimum cover. The optimum cover, denoted by OPT, must cover all the witness cells defined above. Consider a graph G whose vertices are the various witness cells defined above and whose edges denote that the two associated cells can be covered together by a single rectangle. Note that each cell is either completely inside or completely outside any maximal rectangle (one which has holes touching all four sides). Two witness cells are said to be *independent* if no single rectangle covers both of them; i.e., there is no edge between them in G. The following lemma holds.

LEMMA 2.2. *All witness cells contained in any rectangle form a clique in G. Conversely, any clique in G comprises witness cells which can be covered by just one rectangle.*

Proof. The first statement of the lemma follows from the definition of G.

We now show that any clique C in G can be covered by one rectangle. Let a, b, c, d be the leftmost, topmost, rightmost, and bottommost witness cells in C, respectively. Note that a, b, c, d need not be all distinct. We claim that the rectangle R having a, b, c, d on its left, top, right, and bottom edges, respectively, is hole-free (see Figure 5). The claim then follows since a, b, c, d are extreme points.

To show that R is hole-free consider all edges between witness cells a, b, c, d. If a, b, c, d are all distinct there will be six such edges, and fewer otherwise. There exist up to six rectangles, each of which covers both witness cells for one of the above edges (see Figure 5). Clearly, R is contained in the union of these rectangles. □

We partition the witness cells into $O(|OPT|)$ cliques, where $|OPT|$ denotes the number of rectangles used by OPT, in the following manner. For each witness cell,

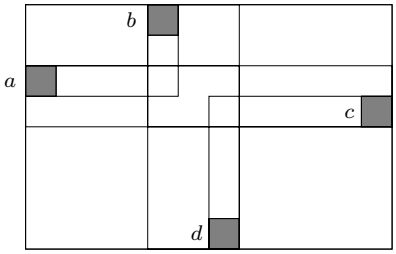

FIG. 5. *The rectangle R formed by a, b, c, d and the six possible rectangles formed by each pair of witness cells, which together cover R.*

assign it to some rectangle covering it in OPT, breaking ties arbitrarily. From Lemma 2.2 above, this corresponds to a partition of witness cells into cliques. We partition each clique further into two parts, one containing left witness cells and another containing right witness cells; these parts are called the *left clique* and the *right clique*, respectively.

Remark. We say that a strip is *in* a particular left clique (right clique, respectively) if its left witness cell (right witness cell, respectively) is in that clique, and, by abuse of notation, we will sometimes identify a strip with its witness cell.

To bound the approximation factor of our algorithm, we will show a lower bound on the number of cliques obtained above. This lower bound will exploit several interesting properties of these cliques. However, before we describe these properties, we need to specify how successors are determined and how strips to be discarded are identified. We start by describing the above for a simpler special case so as to bring out the intuition behind our proof.

We again remind the reader that unnecessary strips are being ignored, and any reference to a strip in the rest of the paper denotes a necessary strip.

3. The lower bound argument: A special case. We make the following assumptions in this section and illustrate the main ideas of the proof of the lower bound for this special case. We shall return to the general case in section 4.

Assumption 1. The length of each strip is a power of 2.

Assumption 2. The upper hole of a strip is not horizontally aligned with that of its left or right successor strip. The notion of a successor strip was introduced in section 2, and successors will be defined shortly.

Recall the preceding discussion on discarded strips in section 2. Assumption 2 precludes exactly those situations which forced us to introduce the notion of discarded strips. It follows that there is no need to discard any strips. Thus, all necessary strips will have associated left and right witnesses. Assumption 1 will make the definition of successor strips a little easier.

3.1. Defining families and successors. We organize strips into families as follows. Our proofs crucially exploit the interplay between cliques and families.

We define a *right family* to be a set of strips with the same right blocking hole (Figure 2). It is easy to see that strips in a right family are right nested (the strict increase in strip lengths from left to right is a consequence of the absence of unnecessary strips). The *right successor* of a strip A in a right family is defined as the next strip A' to the right in the family. The rightmost strip in the family does not have a successor and is a *right terminal strip*. Left families, successors, and terminal strips

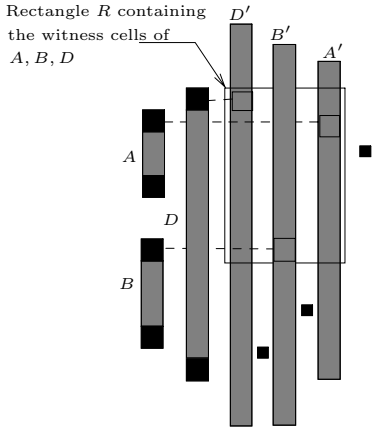

FIG. 6. *A, B, D are in a right clique. A', B', D' are their respective right successors. A is an exception.*

are defined analogously. It follows from Assumption 1 and the nestedness property that the number of strips in a family is at most $\log n$.

Remark. The notion of successor defined above will have to be changed when we deal with the general case in section 4 in the following manner. We will define two types of strips and use the above definition for strips of the first kind; strips of the second kind will require a different definition, and the successor of such a strip A will have length $< 2l(A)$. However, it will continue to be the case that the right successor of A r-spans A, and, similarly, the left successor of A l-spans A for all undiscarded strips A. Note that Assumption 1 precludes the existence of strips of the second kind above.

3.2. Properties of cliques. Our proof is based on some structural facts, which we state in the following lemmas. In section 3.3, we will use these lemmas to obtain the approximation factor. The proofs of these lemmas appear in section 3.4.

LEMMA 3.1. *All right (left, respectively) witness cells associated with right (left, respectively) terminal strips are independent. Therefore, the number of families and terminal strips is $O(|OPT|)$.*

All further references to strips in subsequent lemmas in this section will be to nonterminal strips.

LEMMA 3.2. *Strips in a right (left, respectively) clique belong to distinct right (left, respectively) families.*

LEMMA 3.3. *With the exception of at most one strip, all strips in a right (left, respectively) clique constitute a right (left, respectively) nested set of strips.*

Thus, each clique of OPT has at most two exceptions, one in each direction. The total number of exception strips is therefore $O(|OPT|)$. These exception strips can be removed from consideration. Figure 6 shows an example of an exception strip in a right clique. All further references to cliques in this section will assume that exception strips are not present.

LEMMA 3.4. *Strips in any right (left, respectively) clique are in distinct length categories; i.e., if a particular strip has length in the range $[2^i, 2^{i+1})$, then the next strip to the right (left, respectively) has length at least [2] 2^{i+1}.*

[2]Strips in a clique will actually at least double in length by Assumption 1. However, we prefer

In addition, for any $x > 0$, the number of strips in a right (left, respectively) clique or a right (left, respectively) family whose length is at least 2^x times the length of one of the two previous strips to the left (right, respectively) is $O(\frac{\log n}{x})$.

LEMMA 3.5. *Let A, B be strips in a particular right (left, respectively) clique, with $l(A) < l(B)$. Let A', B' be the right (left, respectively) successors of A, B, respectively. These four strips must be in the following order from left to right (right to left, respectively): A, B, B', A'. In addition, A' cannot r-span (l-span, respectively) B and must have its upper hole above that of B.*

DEFINITIONS. A strip A is called a *right jumper* if its right successor has length at least $2^{\Delta} l(A)$, where Δ is a parameter. This parameter will be set to $\Theta(\sqrt{\log n})$ at the end. Left jumpers are defined analogously. The *vertical separation* between two holes a, b is the vertical distance between their lower boundaries, measured in terms of the number of grid cells (see Figure 12).

LEMMA 3.6. *Let A, B be nonjumper strips in some right (left, respectively) clique, with $l(A) < l(B)$. The following two facts hold.*

1. *The vertical separation between the upper holes of A and B is at most $2^{\Delta} l(A)$.*
2. *If A is not amongst the smallest $\gamma\Delta$ nonjumper strips in this right clique (left clique, respectively), the vertical separation between the upper holes of A and B is at most $\frac{l(B)}{2^{(\gamma-1)\Delta}}$.*

LEMMA 3.7. *Let A and B be strips belonging to the same right (left, respectively) clique, with $l(A) < l(B)$. Then A lies completely above the right (left, respectively) blocking hole of B.*

LEMMA 3.8. *Let C and C' be the left and right cliques, respectively, containing the left and right witness cells, respectively, of strip A. Let B be a strip in C smaller than A. Let B' be a strip in C' smaller than A. Then B' cannot l-span B, and B cannot r-span B'.*

3.3. Accounting for strips. The number of terminal strips is $O(|OPT|)$ by Lemma 3.1. The number of jumper strips is $O(|OPT| * \frac{\log n}{\Delta})$ by Lemma 3.4. All references to strips in the rest of this section are to nonterminal, nonjumper, nonexception (see Lemma 3.3) strips. All references to cliques assume that terminal, jumper, and exception strips have been removed; references to clique sizes denote sizes subsequent to this removal.

We now consider the remaining strips and show that there exists a large subset W of the witnesses associated with these strips such that the graph induced by W has only small, i.e., size $\Theta(\Delta)$, cliques. A rough reason why such a subset W exists is as follows.

By the nestedness property of strips in a clique and by Assumption 1, large cliques will necessarily have long strips and will therefore require proportionately large vertical space. In addition, Lemma 3.6 states that if A, B are strips in a large clique, then the vertical separation between the upper holes of A and B is small. Given the properties of cliques stated above, we will show that the left cliques containing A, B and the right cliques containing A, B cannot all satisfy the dual requirements of large vertical space and small vertical separation, unless one of these cliques is small. This intuition is formalized below.

Remark. We mention here that the rest of this section uses only Lemmas 3.1, 3.2, 3.3, 3.4, 3.5, 3.6, 3.7, and 3.8. Assumptions 1 and 2 will not be used directly. When we drop these assumptions and proceed to the general case, we will apply the

---

to work with this weaker condition, as it generalizes even when Assumption 1 is dropped.

description below to a carefully chosen subset of strips for which the above lemmas will indeed hold.

DEFINITION. The *right follower* of a strip B is defined to be the unique next longer strip, if any, in the right clique containing B (uniqueness holds from Lemma 3.3 and since exceptions are ignored). In Figure 6, D is a follower of B. Strip A also has D as its follower, but A is dropped as it is an exception strip. *Left followers* are defined similarly.

LEMMA 3.9. *Let P, Q be strips in some right clique C, with Q being the right follower of P (Q need not exist). Then one of the following must hold.*

1. *P is among the smallest 3Δ strips in C, or P is the largest strip in C.*
2. *Q is among the smallest $5\Delta+1$ strips in C'', where C'' denotes the left clique containing Q.*
3. *$2^{\Delta} l(P) \leq l(Q)$.*
4. *Let C' denote the left clique containing P. Let P' be the strip in C' whose left follower is P. Either P' does not exist or $2^{\Delta} l(P') \leq l(P)$.*
5. *Let $Q_1, \ldots, Q_k$, in increasing order of length, be the strips in C'' which are smaller than Q. Then $2^{2\Delta} l(Q_{k-1}) \leq l(Q)$.*

Analogous statements hold for strips P, Q in a left clique C.

Proof. We suppose that none of the above five conditions holds to get a contradiction.

Since condition 1 is not satisfied, Q exists. Since condition 2 is not satisfied, $k \geq 5\Delta+1$. By Lemma 3.8, none of $Q_1, \ldots, Q_k$ r-span P (see Figure 7(a)). Similarly, P cannot l-span any of $Q_1, \ldots, Q_k$. By Lemma 3.3, Q r-spans P, and l-spans each of $Q_1, \ldots, Q_k$; therefore, the hatched regions must be hole-free. We consider two cases now, depending upon whether the upper hole of Q_k is above or below that of P.

First, suppose the upper hole of Q_k is aligned with or above that of P (see Figure 7(a)). The lower hole of Q_k must be above that of P; otherwise, Q_k r-spans P, which contradicts Lemma 3.8. Therefore, the left blocking hole of Q_k will be horizontally aligned with or above the upper hole of P. By Lemma 3.7, Q_{k-1} is completely above this blocking hole and therefore completely above P. Since the fifth condition is not satisfied, $2^{2\Delta} l(Q_{k-1}) > l(Q)$. Then the vertical separation between P and Q is at least $l(Q_{k-1}) > \frac{l(Q)}{2^{2\Delta}}$. Since the first condition is not satisfied, Lemma 3.6 implies that the vertical separation between P and Q is at most $\frac{l(Q)}{2^{2\Delta}}$, a contradiction. While applying Lemma 3.6, recall that jumpers have been excluded from cliques earlier.

Second, suppose the upper hole of Q_k is below that of P (see Figure 7(b)). The bottom hole of Q_k must be below that of P; otherwise, P will l-span Q_k, which contradicts Lemma 3.8. Since Q_k l-spans each of $Q_1, \ldots, Q_{k-1}$, these must also have their upper holes below that of P. Since P cannot l-span $Q_1, \ldots, Q_k$ (by Lemma 3.8), their lower holes must also be below that of P. Since condition 4 is violated, P' exists. By Lemma 3.3, P l-spans P', and therefore P' must be to the right of Q (see Figure 7(b)). Since P l-spans P', Q l-spans each of $Q_1, \ldots, Q_k$ (by Lemma 3.3), and lower holes of $Q_1, \ldots, Q_k$ are below that of P, it must be the case that each of $Q_1, \ldots, Q_k$ either l-spans P' or is completely below it (Q_k l-spans P', while Q_i lies below P' in Figure 7(b)). We claim that at most 2Δ of $Q_1, \ldots, Q_k$ can l-span P'. This is shown in the next paragraph. Then the vertical separation between the upper holes of $Q_{k-2\Delta}$ (which is completely below P') and Q is at least $l(P') > \frac{l(P)}{2^{\Delta}} > \frac{l(Q)}{2^{2\Delta}}$ (because conditions 3 and 4 are not satisfied). Since $k - 2\Delta > 3\Delta$, Lemma 3.6 applied to $Q_{k-2\Delta}$ and Q implies that the vertical separation between the upper holes of these two strips is at most $\frac{l(Q)}{2^{2\Delta}}$, a contradiction.

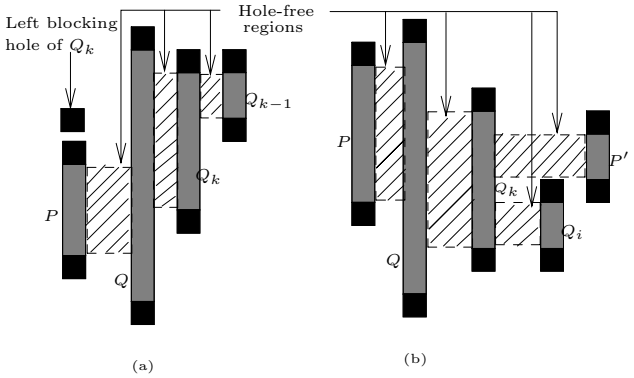

FIG. 7. *Two situations for the upper hole of* Q_k.

It remains to show that at most 2Δ of $Q_1, \ldots, Q_k$ can l-span P'. We show that $Q_{k-2\Delta}$ cannot l-span P'. Suppose this is not true. Then $Q_{k-2\Delta}, \ldots, Q_k$ all l-span P' and $l(Q_{k-2\Delta}) > l(P')$. By Lemma 3.4, $Q_{k-2\Delta}, \ldots, Q_k$ are in distinct length categories, and therefore $l(Q) \geq 2^{2\Delta} l(Q_{k-2\Delta}) > 2^{2\Delta} l(P') > 2^{\Delta} l(P)$. The last inequality follows from the violation of condition 4. Then condition 3 is satisfied, a contradiction. □

COROLLARY 3.10. *The number of nonterminal, nonjumper, nonexception strips is* $O(|OPT| * (\frac{\log n}{\Delta} + \Delta))$.

Proof. Each nonterminal, nonjumper, nonexception strip P must be in some right clique C and in some left clique C'.

We consider five classes of these strips, depending upon which of the conditions in Lemma 3.9 is satisfied. The number of strips P which satisfy the first condition is clearly $O(|OPT| * \Delta)$ because each clique in OPT has $O(\Delta)$ such strips. The number of strips P which satisfy the third condition is $O(|OPT| * (\frac{\log n}{\Delta}))$ by Lemma 3.4. Similarly, the number of strips P which satisfy the fourth condition is $O(|OPT| * \frac{\log n}{\Delta})$. Next, consider strips P which satisfy either condition 2 or 5. Such a strip P has a unique right follower Q. Note that any strip is the right follower of at most one strip. Thus it suffices to bound the number of strips Q which are right followers of strips P satisfying condition 2 or 5. Using the same argument as for condition 1, the number of strips Q satisfying condition 2 is $O(|OPT| * \Delta)$. Using an argument similar to that for condition 4, the number of strips Q satisfying condition 5 is $O(|OPT| * \frac{\log n}{\Delta})$. □

Thus, given Assumptions 1 and 2, by setting $\Delta = \Theta(\sqrt{\log n})$ we get that the number of rectangles laid out by our algorithm is within an $O(\sqrt{\log n})$ factor of the optimal.

3.4. Proofs. We give the proofs of Lemmas 3.1, 3.2, 3.3, 3.4, 3.5, 3.6, 3.7, and 3.8 in that order. For the general case, we will not repeat the proofs of these lemmas. To convince the reader that these proofs would continue to hold even in the absence of Assumptions 1 and 2, we describe the proofs so that they are dependent only on the following facts and on proofs of previous lemmas in the above order, instead of Assumptions 1 and 2 directly. These facts are consequences of Assumptions 1 and 2 and of the way in which families and successors were defined. Thus, as long as the general case obeys these facts, and if we derive the generalizations of these lemmas in the same order, these proofs will continue to hold. However, there is one exception, namely the first part of Lemma 3.4, where we shall use Assumption 1. This shall

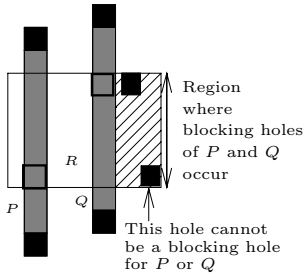

FIG. 8. *Witnesses of terminal strips are independent.*

require reproving when we get to the general case. This will be made precise in section 4.4.

We state Facts 1–6 here.

FACT 1. *Strips in a right (left, respectively) family are right (left, respectively) nested and have the same right (left, respectively) blocking hole. Further, strips in distinct right (left, respectively) families have distinct right (left, respectively) blocking holes.*

FACT 2. *Each family has one terminal strip. Further, strips in a family lie in distinct length categories (length categories are given by the length ranges* $[2^i, 2^{i+1})$, $1 \leq i \leq \log n - 1$*).*

Note that by Assumption 1*, strips in a family satisfy a stronger property; namely, they at least double in size. However, the weaker property stated above will be all that is available in the general case.*

FACT 3. *The right (left, respectively) successor of a strip A is the next strip to the right (left, respectively) in the right (left, respectively) family containing A.*

FACT 4. *The right (left, respectively) successor of a strip A r-spans (l-spans, respectively) A.*

FACT 5. *The right (left, respectively) witness of a nonterminal strip A, if it exists, is horizontally aligned with the upper hole of A and lies on the right (left, respectively) successor of A.*

Note that the condition "if it exists" always holds by Assumption 2*. However, this will not be true in the general case, after Assumptions* 1, 2 *are dropped.*

FACT 6. *The right (left, respectively) witness of a terminal strip lies on the terminal strip itself and is horizontally aligned with its right (left, respectively) blocking hole.*

We now give the proofs. At the end of each proof below, we make a careful note of which of the above facts are used.

Proof of Lemma 3.1. We give the proof for right terminals. The proof for left terminals is similar.

Suppose for a contradiction that there are two right terminal strips P, Q whose right witnesses are not independent. P and Q must be in distinct right families, and their right blocking holes are distinct, by Facts 1 and 2. Recall that the right witness cells of P and Q are in P and Q, respectively, and are horizontally aligned with their respective right blocking holes (see Fact 6).

Consider a rectangle containing the two witness cells; such a rectangle exists by Lemma 2.2 (see Figure 8). Clearly, both P and Q must have their upper holes above and lower holes below this rectangle. Without loss of generality, assume P is to the left of Q. Note that the right blocking holes for both P and Q must be in the hatched

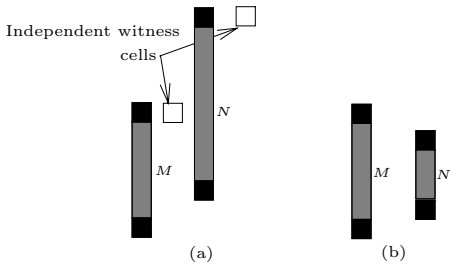

FIG. 9. *Two situations for M, N in Lemma 3.3 if N neither r-spans M nor is disjoint from M.*

region (i.e., the extension of the above rectangle to the right; the rectangle itself must be hole-free). Therefore, both blocking holes must be to the right of Q. Then it follows that whichever one of these holes occurs further to the right of the other cannot be the right blocking hole for either P or Q. In addition, if the two blocking holes are vertically aligned, the lower one cannot be the right blocking hole for either P or Q.[3] This gives a contradiction. □

Remark. Note that the above proof used only Facts 1, 2, and 6 among the six facts listed above.

Proof of Lemma 3.2. We show that if A and B are two strips in the same right family, their right witness cells are independent. Similar arguments hold for the right.

Without loss of generality, assume that $l(A) < l(B)$. By Fact 1, B is to the right of A and r-spans A. By Facts 3 and 5, A defines its right witness cell either on B (if B is the right successor of A) or to the left of B. Since B defines its right witness cell on the horizontal line containing the upper hole of B and to the right of the upper hole of B, it is easy to see that any rectangle containing the right witness cells of A and B has to contain the upper hole of B. This implies that these two witness cells are independent and cannot be in a clique. □

Remark. Note that the above proof used only Facts 1, 3, and 5 among the six facts listed above.

Proof of Lemma 3.3. We prove the lemma for a right clique C; similar arguments hold for left cliques. The following fact will be useful.

FACT. Suppose strips M and N are two strips in C, and M is either to the left of N or vertically aligned with it. Then either M and N are disjoint or N r-spans M. This must be true; otherwise, one of the two situations shown in Figure 9 holds, and then M's right witness cell will be independent from the right witness cell of N (recall Facts 4 and 5).

Suppose the strips in C are not right nested. By the above fact, if each strip in C r-spans the smallest strip in C, then there are no disjoint strips in C, and the strips in C must be right nested. So there must exist a strip in C which is disjoint from the smallest strip A in C; consider the smallest such strip B. Clearly, neither A nor B can r-span any strip in C. We will show that all other strips D in C must r-span the lower of A, B. It would then follow from the above fact that the strips in C with the upper of A, B removed are right nested. We consider the case when B is below A; the other case is similar.

Consider a strip D in C, other than the strips A, B, and suppose for a contradiction that D does not r-span B. Recall from the previous paragraph that neither

[3]Here, we use the fact that ties for the blocking hole were broken in favor of the upper hole.

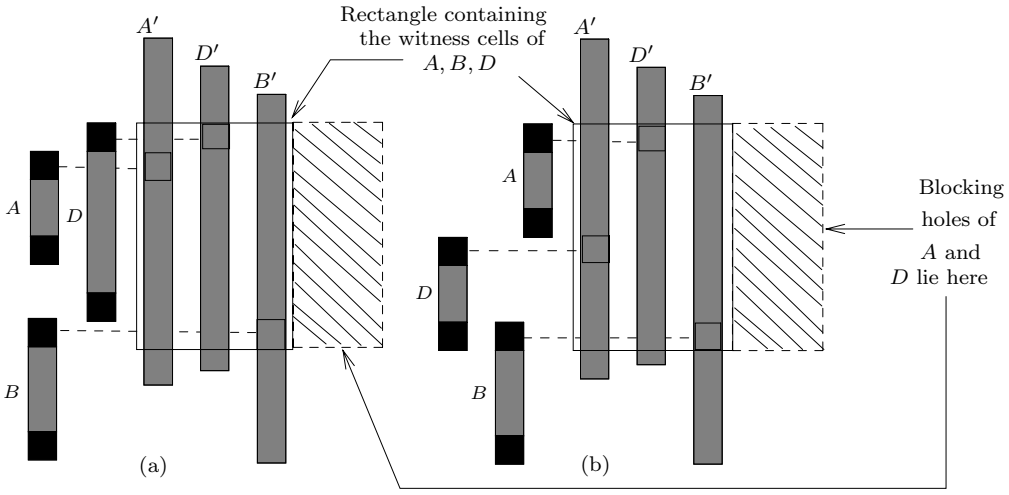

FIG. 10. (a) *D r-spans A but not B.* (b) *A, B, D are disjoint. The order in which the successors A', B', D' are present is not important.*

A nor B r-span any other strips in C. By the above fact, D must be disjoint from B. Further, D either is disjoint from A or is to the right of A and r-spans A (see Figure 10(a),(b)). We will show in the next paragraphs that the right blocking holes of the two upper strips among A, B, D must be identical. But, by Lemma 3.2, A, B, D must all be in distinct right families, and therefore, by Fact 1, they have distinct right blocking holes, a contradiction.

To show that the right blocking holes of the two upper strips among A, B, D must be identical, consider the rectangle R associated with clique C (by Lemma 2.2, such a rectangle exists). This rectangle has the following properties. The right witness cells for A, B, D are all in R, and A, B, D are themselves to the left of R. By Fact 5, the right witness cells of A, B, D are aligned with their respective upper holes and lie on their respective right successors, A', B', D'. By Fact 4, A', B', D' r-span A, B, D, respectively. Therefore, R must have its upper edge above the upper holes of A, B, D and its lower edge below all these holes. In addition, A', B', D' must all have their upper holes above R and bottom holes below R (see Figure 10); these successor strips must stab vertically through R. Note that the relative placement of A', B', D' is not important, though Figure 10 shows D' placed between A' and B'. Recall again that A, B are disjoint, D, B are disjoint, and D either r-spans A or is disjoint from A.

It follows from these properties that the right blocking holes of the upper two strips X, Y amongst strips A, B, D must be in the hatched region, i.e., the right extension of R. Next, since a strip and its right successor must have the same right blocking hole by Facts 1 and 3, the leftmost hole in the hatched region must be the right blocking hole for both X, Y, as required. □

Remark. Note that the above proof directly used only Facts 1, 3, 4, and 5 among the six facts listed above, and Lemma 3.2.

Proof of Lemma 3.4. Strips in a right (or left) clique strictly increase in length by Lemma 3.3. The first part of the lemma then follows from Assumption 1.

Next, we prove the second part of Lemma 3.4. Right families are right nested by Fact 1. By Lemma 3.3, right cliques are also right nested. Therefore, in both right

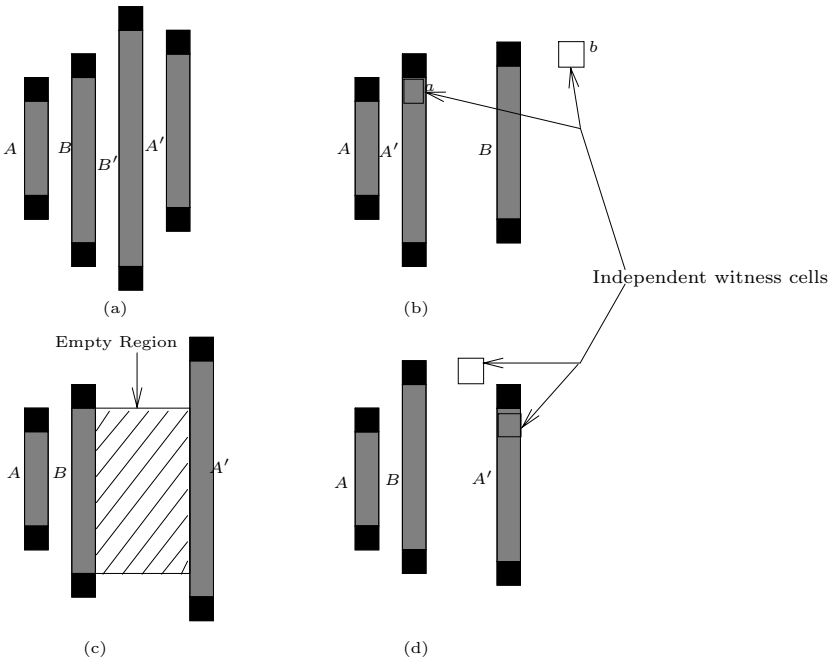

FIG. 11. (a) *B and B′ lie between A and A′.* (b) *A′ lies to the left of B.* (c) *A′ r-spans B.* (d) *Upper hole of A′ lies below that of B.*

families and right cliques, strip lengths increase strictly monotonically to the right. Since the smallest strip length is 2^0 and the largest is $2^{\log n}$, the lemma follows. A similar argument holds for left families and cliques. □

Remark. Note that the above proof directly used Assumption 1, only Fact 1 among the six facts listed above, and Lemma 3.3.

Proof of Lemma 3.5. We prove the lemma for a right clique C. The argument for left cliques is similar.

From Lemma 3.3, it follows that B r-spans A and hence must lie to the right of A. If B is to the right of A', then the right witness cells a and b of A and B, respectively, are independent (see Figure 11(b); also see Facts 4 and 5). Therefore, B is to the left of A' and to the right of A. To show that the right successor of B also lies between A and A', we show in the next paragraph that A' cannot r-span B. Since A' and B both r-span A, they cannot be disjoint either. Then it follows that the right blocking hole of B is vertically aligned with or to the left of A'. Therefore, the right successor of B is also to the left of A' (since, by Facts 1 and 3, a strip and its right successor have the same right blocking hole).

Suppose A' r-spans B. Then the right blocking hole of B would be the same as that of A (which is identical to that of A' by Facts 1 and 3) (see Figure 11(c); the hatched region must be hole-free); then A and B would be in the same right family by Fact 1. This contradicts Lemma 3.2.

It remains to show that the upper hole of A' is above that of B. By Fact 5, B's right witness cell lies on the horizontal line containing the upper hole of B. If the upper hole of A' is horizontally aligned with or below that of B, the witness cells a and b of A and B, respectively, would be independent (see Figure 11(d)). Hence, the upper hole of A' lies above that of B. □

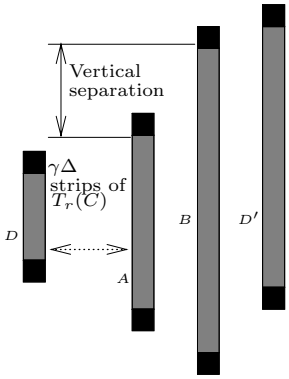

FIG. 12. *Vertical separation in a right clique.*

Remark. Note that the above proof directly used only Facts 1, 3, 4, and 5 among the six facts listed above, and Lemmas 3.2 and 3.3.

Proof of Lemma 3.6. We prove the lemma for a right clique C. An analogous argument holds for left cliques.

First, consider part 1. Let A' be the right successor of A. By Fact 4, A' r-spans A. By Lemma 3.3, B must r-span A. By Lemma 3.5, the upper hole of A' is above that of B. It follows that the vertical separation between the upper holes of B and A is at most $l(A')$ and $l(A') \leq l(A)2^{\Delta}$, because A is not a right jumper. Part 1 follows.

Next, consider part 2. Let D be the smallest nonjumper strip in C, and let D' be the right successor of D (see Figure 12). D' exists because D is not a terminal. We will show in the next paragraph that the vertical separation between the upper holes of B and A is at most $l(D')$. Since D is not a right jumper, $l(D') \leq l(D)2^{\Delta}$. Further, since there are at least $\gamma\Delta$ strips smaller than A in C, using the increase in length categories given by Lemma 3.4, we get $l(D') \leq l(D)2^{\Delta} \leq \frac{l(B)}{2^{(\gamma)\Delta}}2^{\Delta} = \frac{l(B)}{2^{(\gamma-1)\Delta}}$, as required.

It remains to show that the vertical separation between the upper holes of B and A is at most $l(D')$. By Lemma 3.3, A and B both r-span D. By Lemma 3.5, A and B are between D and D'. Since D' is the right successor of D, D' must r-span D (see Fact 4); therefore, the lower hole of D' is below the upper hole of A. Further, by Lemma 3.5, the upper hole of D' is above that of B. It follows that the vertical separation between the upper holes of B and A is at most $l(D')$. □

Remark. Note that the above proof directly used only Fact 4 among the six facts listed above, and Lemmas 3.3, 3.4, and 3.5.

Proof of Lemma 3.7. We prove the lemma for a right clique C; the argument for the left is analogous.

By Lemma 3.3, B r-spans A. Let A' be the right successor of A and B' that of B. By Fact 4, A' r-spans A. By Lemma 3.5, B and B' are between A and A', A' cannot r-span B, and the upper hole of A' is above that of B. It follows that the right blocking hole d of B must be to the left of A' (see Figure 13) and d can be only in the two hatched regions in the figure. But if it is in the upper of these two regions, by Fact 5, the right witness cells for A and B are independent. Therefore, it must be in the lower hatched region, which is completely below A. □

Remark. Note that the above proof directly uses only Facts 4 and 5 among the six facts listed above, and Lemmas 3.3 and 3.5.

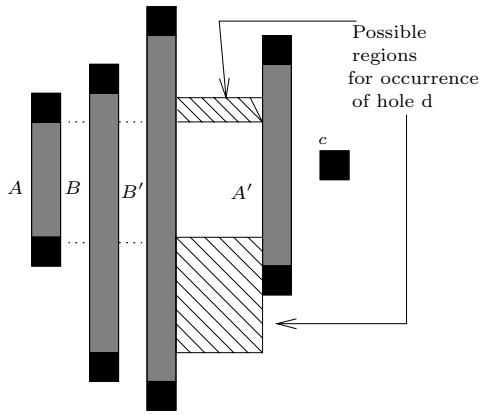

FIG. 13. *Possible locations of the blocking hole of B.*

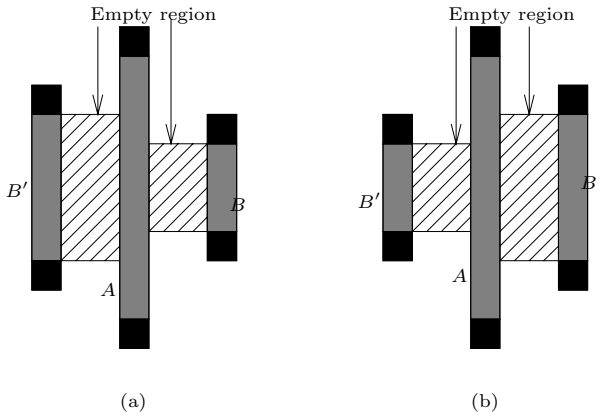

FIG. 14. *Possibilities precluded by Lemma* 3.8: (a) *B′ l-spans B.* (b) *B r-spans B′.*

Proof of Lemma 3.8. Suppose B' l-spans B (Figure 14(a)). The hatched region must be hole-free since A l-spans B and r-spans B' (see Lemma 3.3). This means that B has its left blocking hole to the left of B'. Next, B's left successor is either to the left of B' or to the right of A. This is true because any strip between B' and A which l-spans B must r-span B' as well and cannot have its left blocking hole to the left of B' (recall from Facts 1 and 3 that B and its left successor must have the same left blocking hole). Using Facts 4 and 5, it follows that the left witness cell of B is independent from that of A, a contradiction. Therefore B' cannot l-span B.

By an argument symmetric (see Figure 14(b)) to the one above, B cannot r-span B'. □

Remark. Note that the above proof directly used only Facts 1, 3, 4, and 5 among the six facts listed above, and Lemma 3.3.

4. The general case: Removing ill-behaved strips. We now need to handle the general case. Assumption 2 is not very hard to handle; it is possible to show that a good fraction of strips define witnesses on at least one of the two sides. Assumption 1 is the most severe: strips of arbitrary lengths could result in large families and cliques in which the progression of strip lengths described by Lemma 3.4 is absent. This

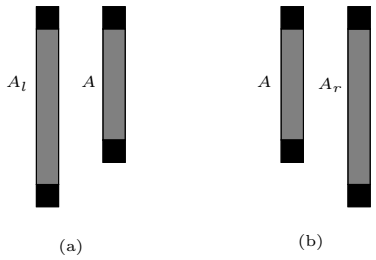

FIG. 15. *The two kinds of strips considered in Lemma* 4.1.

forces us to alter the notion of successor/family defined in this section and partition strips into classes based on the nature of left and right successors. A detailed analysis is then needed for each of these classes.

Recall that we have already identified and decided to ignore unnecessary strips. The aim now is to discard some more ill-behaved strips and then redefine successors and families for the strips which remain. These remaining strips will constitute a constant fraction of the number of the rectangles laid out by our algorithm, and each such strip will have the property that it defines either a left witness cell or a right witness cell or both. Unlike the previous special case, it will no longer be true that each strip is part of some family. Each strip will still have a successor, though.

4.1. Discarding strips. Consider two sets of strips. The first set comprises necessary strips A with the property that A_l exists, where A_l is the closest necessary strip to the left, if any, such that the upper holes of A_l and A are horizontally aligned (Figure 15(a)) and A_l l-spans A. The second set comprises necessary strips A with the property that A_r exists, where A_r is the closest necessary strip to the right, if any, such that the upper hole of A_r and A are horizontally aligned (Figure 15(b)) and A_r r-spans A. By Lemma 4.1 below, the strips in the smaller of the above two sets can be ignored. Without loss of generality, assume that the former set is smaller. Let $\mathcal{S}'$ denote the set comprising the remaining strips. For all strips A in $\mathcal{S}'$, A_l does not exist. This property, along with the subsequent definition of successors, will ensure that left witnesses are always defined for all strips in $\mathcal{S}'$.

LEMMA 4.1. *One of the above two sets must have size at most half the number of necessary strips.*

Proof. This follows because if A is in the first set then A_l is not in the second. □

Defining categories, doubling strips and nondoubling strips. We classify strips in $\mathcal{S}'$ into categories based on length. All strips with length in the range $[2^i, 2^{i+1})$ are in the ith category, $i \leq \log n - 1$.

Consider a strip A in $\mathcal{S}'$. Let B be the closest strip to the right of A in $\mathcal{S}'$, if any, which r-spans A and is in the same category as A. If B exists, then A is said be *right nondoubling*, and B is said to be the *right successor* of A. In this case, any strip in $\mathcal{S}'$ to the right of A and to the left of B which r-spans A must be in a higher category than A and therefore has its right blocking hole vertically aligned with or to the left of B. All other strips A are called *right doubling* strips. Analogous notions are defined to the left. As will be shown in Lemma 4.5 shortly, each strip is the right successor of at most one right nondoubling strip.

Note that we have not yet defined successors for right/left doubling strips. We will do so after we redefine families later in this section.

Remark. The strips considered in sections 3 and 3.1 are right and left doubling because of Assumption 1. As remarked in section 3.1, the notion of successor defined there is different from that defined above. The successor defined earlier corresponds to the successor of a right or left doubling strip.

LEMMA 4.2. *The number of strips in $\mathcal{S}'$ which are both right nondoubling and left nondoubling is at most $|\mathcal{S}'|/2$.*

Proof. Consider strip A, which is both right nondoubling and left nondoubling. Let B be its right successor. Note that no other right nondoubling strip has B as a right successor (this will be shown formally in Lemma 4.5). We show in the next paragraph that B cannot be a left nondoubling strip. It follows that for each A which is both right nondoubling and left nondoubling, there is a unique B which is left doubling. The lemma follows.

Suppose B is left nondoubling. Let D denote its left successor. Then D is between A and B and l-spans B. Since B r-spans A, D r-spans A as well. Since A, B, D are all in the same category, D would be the right successor of A, a contradiction. □

Let $\mathcal{S}$ denote the subset of $\mathcal{S}'$ comprising strips which are either left doubling or right doubling or both. The following lemma shows that $\mathcal{S}$ contains at least one-fourth of all the necessary strips. All further references to strips in the paper will be to the strips in $\mathcal{S}$. We will account for only these strips; the remaining strips are discarded.

LEMMA 4.3. *The number of strips in $\mathcal{S}$ is at least one-fourth the number of rectangles laid out to cover the polygon.*

Proof. Three kinds of strips have been ignored so far in defining the set $\mathcal{S}$:

1. unnecessary strips;
2. strips A with the property that A_l exists, where A_l is the closest necessary strip to the left such that the upper holes of A_l and A are horizontally aligned (Figure 15(a)) and A_l l-spans A;
3. strips A, which are both left and right nondoubling.

Unnecessary strips have the same associated rectangle as some necessary strip. By Lemma 4.1, the number of strips of the second type is at most half the total number of necessary strips. Finally, by Lemma 4.2, the number of strips of the last type is at most half of the remainder obtained by removing strips of the first two types. □

4.2. Defining families and witnesses. A crucial difference from before is that right families comprise only right doubling strips, and similarly for left families.

A *right family* is defined to be a set of right doubling strips in $\mathcal{S}$ with the same right blocking hole. The right successor of a right doubling strip is the next strip A' to the right in the family. The rightmost strip in a right family has no successor, and is called a right terminal strip, as before. Left families and successors are defined similarly. Notice that this is the same definition as in section 3.1, where all strips were left and right doubling.

We have now defined successors for all strips, whether doubling or not. As before, the right (left, respectively) witness cell of a nonterminal strip A (whether doubling or nondoubling) is the cell in its right (left, respectively) successor, horizontally aligned with the upper hole of A. This witness is not defined if the upper holes of A and its successor are horizontally aligned. The right (left, respectively) witness cell of a right (left, respectively) terminal strip A is defined as before; i.e., it is the cell in A which is horizontally aligned with its right (left, respectively) blocking hole.

The next lemma shows that each strip in $\mathcal{S}$ defines a left witness and is a straightforward consequence of the definition of $\mathcal{S}'$.

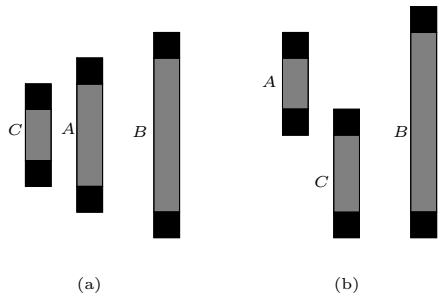

FIG. 16. *Two possible configurations of strips A, B, C, where B is the right nondoubling successor of both A and C.*

LEMMA 4.4. *For all nonterminal strips $A \in \mathcal{S}$, the upper hole of A is not horizontally aligned with the upper hole of its left successor. Therefore, each strip A defines a left witness cell and possibly a right witness cell.*

LEMMA 4.5. *Any strip is the right (left, respectively) successor of at most two strips, one right (left, respectively) nondoubling and one right (left, respectively) doubling.*

Proof. We prove the "right" case; the "left" case is analogous. First, suppose there are two right nondoubling strips A, C whose right successor is strip B. Then A, B, C belong to the same category, and hence $l(A) < l(B) < 2l(A)$ and $l(C) < l(B) < 2l(C)$. B must r-span both A and C. This can happen only either if A r-spans C (or vice versa) or A and C are both disjoint (see Figure 16). The former possibility cannot arise, since in that case the right successor of C would be A (or vice versa), and in the latter case, $l(B) \geq l(A) + l(C) \geq 2\min\{l(A), l(C)\}$, which implies that B cannot be in the same category as either A or C, a contradiction.

Next, consider right doubling strips. If the right successor of a right doubling strip A is strip B, then A and B must belong to the same right family and B is the first strip to the right of A in its family. So B cannot be the right successor of any other right doubling strip. ∎

4.3. Classifying strips. Based on the above, we can classify strips in $\mathcal{S}$ as follows. Recall that strips in $\mathcal{S}$ are left doubling or right doubling or both.

Class 1 This class contains all strips which are either terminal strips or jumper strips. This class has two subclasses.
- *Class* 1.1 This class contains all strips which are either right terminals strips or left terminal strips.
- *Class* 1.2 This class contains all strips which are either right jumper strips or left jumper strips.

Class 2 This class includes all strips not in Class 1 and which define witness cells in both directions. This class has three subclasses.
- *Class* 2.1 This class contains strips which are left doubling and right doubling.
- *Class* 2.2 This class contains strips which are left doubling and right nondoubling.
- *Class* 2.3 This class contains strips which are left nondoubling and right doubling.

Class 3 This class includes all strips not in Class 1 and which define only left witness cells. This class has two subclasses.
- *Class* 3.1 This class contains strips which are left doubling.
- *Class* 3.2 This class contains strips which are left nondoubling.

The aim now is to bound the number of strips in each class by $O(|OPT|(\Delta + \frac{\log n}{\Delta}))$.

4.4. Properties of cliques: The general case. This section deals with the properties of cliques in the general case. We will generalize all the lemmas stated in section 3.2. We partition the optimal clique cover, OPT, into disjoint cliques in the same way as described in section 2.4.

DEFINITIONS. Define $T_r(C, i)$ to be the set of strips of class i, i being one of 1.1, 1.2, 2.1, 2.2, 2.3, 3.1 or 3.2, whose right witness cells are in clique C of OPT. $T_l(C, i)$ for left witness cells is defined similarly. As mentioned earlier, we will sometimes abuse notation and identify a strip with its witness cell.

Before continuing, we reiterate that all right families comprise right doubling strips only, and, similarly, left families comprise left doubling strips only. Note that with our new definition of successors and families for strips in $\mathcal{S}$, left versions (right versions, respectively) of Facts 1–6 of section 3.4 continue to hold for left doubling (right doubling, respectively) strips. This will allow us to use the proofs in section 3.4 here as well for these strips. In addition, it is clear that Facts 4 and 5 continue to hold for all cliques (and not just cliques associated with doubling strips). Therefore, the lemmas in section 3.2 which use only these facts will generalize to both the doubling and the nondoubling cases directly.

The following lemma is exactly Lemma 3.1 stated for the new definition of terminal strips. The proof is exactly the same as Facts 1, 2, and 6 continue to hold for doubling strips.

LEMMA 4.6. *All right (left, respectively) witness cells associated with right (left, respectively) terminal strips are independent. Therefore, the number of terminal strips is* $O(|OPT|)$.

The following lemma is exactly Lemma 3.2, stated in terms of the classes defined above. Again, the proof is exactly the same, because Facts 1, 3, and 5 continue to hold for doubling strips.

LEMMA 4.7. *All strips in* $T_r(C, i)$ *(*$T_l(C, i)$*, respectively) belong to distinct right families (left families, respectively) for all cliques* C *in* OPT *and* i *being one of* $2.1, 2.3$ *(*$2.1, 2.2, 3.1$*, respectively).*

The following lemma, a generalization of Lemma 3.3, proves nested structure for cliques (modulo exceptions).

LEMMA 4.8. *For any clique* C *in* OPT *and any class* i*,* i *being one of* $2.1, 2.2, 2.3$ *(*$2.1, 2.2, 2.3, 3.1, 3.2$*, respectively), there exists at most one strip (called the* exception*) whose removal makes* $T_r(C, i)$ *(*$T_l(C, i)$*, respectively) right nested (left nested, respectively).*

Proof. The proof for $T_l(C, i)$, i being one of 2.1, 2.2, 3.1, and for $T_r(C, i)$, i being one of 2.1, 2.3, is described in Lemma 3.3 (the same proof holds because Facts 1, 3, 4, and 5 and Lemma 4.7 continue to hold for doubling strips).

We shall consider the remaining case for $T_r(C, i)$ here, involving nondoubling cliques (i.e., i being 2.2). A similar proof will hold for $T_l(C, i)$ with i being one of 2.3, 3.2. We cannot appeal to the proof of Lemma 3.3 directly because Fact 3 does not hold for nondoubling strips.

However, it is easy to see that the fact stated in the beginning of the proof of Lemma 3.3 still holds. We will give the rest of the proof, assuming this fact is true.

Suppose the strips in $T_r(C, i)$ are not right nested. By the above fact, if each strip in $T_r(C, i)$ r-spans the smallest strip in $T_r(C, i)$, then there are no disjoint strips, and the strips in $T_r(C, i)$ must be right nested. So there must exist a strip in $T_r(C, i)$ which is disjoint from the smallest strip A in $T_r(C, i)$; consider the smallest such strip B. Clearly, neither A nor B can r-span any strip in $T_r(C, i)$. We will show that all

other strips D in $T_r(C,i)$ must r-span the lower of A,B. It would then follow from the above fact that the strips in $T_r(C,i)$ with the upper of A,B removed are right nested. We consider the case when B is below A; the other case is identical.

Consider a strip D as above, and suppose it does not r-span B. By the fact above, it must be disjoint from B; in addition, it either r-spans A or is disjoint from A as well. Let X,Y denote the upper two strips among A,B,D. So either X and Y are disjoint (as in Figure 10(b)) or (without loss of generality) $l(X) < l(Y)$ and Y r-spans X (as in Figure 10(a)). Let X',Y' be the right successors of X,Y, respectively. Since the right witnesses of A,B,D form a clique, rectangle R containing these witnesses has its lower edge below the lower holes of X,Y and upper edge above the upper holes of X,Y. This, coupled with the fact that X' must stab vertically through R, implies that $l(X') > l(Y), l(X)$; further, if X,Y are indeed disjoint, then $l(X') > l(X)+l(Y) > 2l(X)$. But the latter cannot happen as X is right nondoubling, and therefore X' and X are in the same category, which implies that $l(X') < 2l(X)$. Thus, it must be the case that Y and X are not disjoint; i.e., Y r-spans X. Then $l(X) < l(Y) \leq l(X')$, and Y must be in the same category as X. Since Y r-spans X, is in the same category as X, and is to the left of X', X' cannot be the right successor of X, a contradiction. □

Remark. As we mentioned earlier in section 3.2, we can now ignore exception strips from all cliques of OPT.

Next, we generalize Lemma 3.4.

LEMMA 4.9. *Strips in $T_l(C,i)$, i being one of* $2.1, 2.2, 2.3, 3.1, 3.2$*, and in $T_r(C,i)$, i being one of* $2.1, 2.2, 2.3$*, are in distinct size categories.*

Further, consider a right family (left family, respectively) or a set $T_r(C,i)$ of strips, i being one of $2.1, 2.2, 2.3$ *(set $T_l(C,i)$ of strips, respectively, i being one of* $2.1, 2.2, 2.3, 3.1, 3.2$*) for some clique C in OPT. For any x, the number of strips whose length is more than 2^x times the length of one of the two previous strips to the left (right, respectively) is $O(\frac{\log n}{x})$.*

Proof. For the first part, we cannot use the proof of the first part of Lemma 3.4, because that proof was based on Assumption 1, and so we describe it below.

Suppose two strips A,B in $T_l(C,i)$, i being one of 2.1, 2.2, 2.3, 3.1, 3.2, are in the same size category. Without loss of generality, assume B is to the left of A. By Lemma 4.8, B l-spans A. By the definition of a left nondoubling strip, A must be left nondoubling, and its left successor must either lie to the right of B or be B itself. In either case, A's left witness cell will be independent from B's left witness cell, a contradiction.

A similar proof holds for two strips A,B in $T_r(C,i)$, i being one of 2.1, 2.2, 2.3.

The second part of the lemma follows by using the same argument as in Lemma 3.4, since this uses only Fact 1 for families, and the first part for cliques. □

The following lemma generalizes Lemma 3.5.

LEMMA 4.10. *Let $A,B \in T_r(C,i)$ ($T_l(C,i)$, respectively) for some clique C in OPT and some class i, i being one of* $2.1, 2.2, 2.3$ *(*$2.1, 2.2, 2.3, 3.1, 3.2$*, respectively), with $l(A) < l(B)$. Let A',B' be the right successors (left successors, respectively) of A,B, respectively. These four strips must be in the following order from left to right (right to left, respectively): A,B,B',A'. In addition, A' cannot r-span (l-span, respectively) B and must have its upper hole above that of B.*

Proof. The proof for $T_l(C,i)$, i being one of 2.1, 2.2, 3.1, and for $T_r(C,i)$, i being one of 2.1, 2.3, is described in Lemma 3.5 (the same proof holds because Facts 1, 3, 4, and 5 continue to hold for doubling strips).

We need to prove the lemma for the remaining cases only. We prove the lemma for $T_r(C, 2.2)$; the other cases have analogous proofs.

From Lemma 4.8, it follows that B r-spans A and hence must lie to the right of A. If B is to the right of A', then the right witness cells a and b of A and B, respectively, are independent (see Figure 11(b)). Therefore, B is to the left of A' and to the right of A. To show that the right successor of B also lies between A and A', we show in the next paragraph that A' cannot r-span B. Since A' and B both r-span A, they cannot be disjoint either. Then it follows that the right blocking hole of B is vertically aligned with or to the left of A'. Therefore, the right successor of B is also to the left of A'.

Suppose A' r-spans B. Since we are considering category 2.2, A' and A are in the same category. Since B r-spans A and A' r-spans B, A, B are also in the same category, and then B, and not A', will be the right successor of A.

It remains to show that the upper hole of A' is above that of B. Recall that B's right witness cell lies on the horizontal line containing the upper hole of B. If the upper hole of A' is horizontally aligned with or below that of B, the witness cells a and b of A and B, respectively, would be independent (see Figure 11(d)). Hence, the upper hole of A' lies above that of B. □

DEFINITIONS. As before, we define strip A to be a *right jumper* if its right successor has length at least $2^{\Delta} l(A)$. Since Δ will be set to at least 1, all right jumpers are actually right doubling strips. Left jumpers are defined analogously.

The following lemma generalizes Lemma 3.6.

LEMMA 4.11. *Consider strips $A, B \in T_r(C, i)$ ($T_l(C, i)$, respectively) for some clique C in OPT and i being one of* $2.1, 2.2, 2.3$ *(*$2.1, 2.2, 2.3, 3.1, 3.2$*, respectively). Suppose $l(A) < l(B)$. The following two facts hold.*

1. *The vertical separation between the upper holes of A and B is at most $2^{\Delta} l(A)$.*
2. *If A is not amongst the smallest $\gamma\Delta$ nonjumper strips in $T_r(C, i)$ ($T_l(C, i)$, respectively), the vertical separation between the upper holes of A and B is at most $\frac{l(B)}{2^{(\gamma-1)\Delta}}$.*

Proof. The proof is identical to that of Lemma 3.6 (the appropriate generalizations of the lemmas used there have to be invoked) because that proof uses only Fact 4 and Lemmas 4.8, 4.9, and 4.10, which hold for both doubling and nondoubling strips. □

We generalize Lemma 3.7 next.

LEMMA 4.12. *Let $A, B \in T_r(C, i)$ ($T_l(C, i)$, respectively) for some clique C in OPT and i being one of* $2.1, 2.2, 2.3$ *(one of* $2.1, 2.2, 2.3, 3.1, 3.2$*, respectively). Further, suppose $l(A) < l(B)$. Then A lies completely above the right (left, respectively) blocking hole of B.*

Proof. The proof is the same as that of Lemma 3.7 (again, the appropriate generalizations of the lemmas used there have to be invoked), as that proof uses only Facts 4 and 5 and Lemmas 4.8 and 4.10, which continue to hold for both doubling and nondoubling strips. □

Finally, we need the following lemma, which generalizes Lemma 3.8.

LEMMA 4.13. *Let C and C' be the cliques in OPT containing the right and left witness cells, respectively, of a strip A. Let B be a strip in $T_r(C, i)$ smaller than A. Let B' be strip in $T_l(C', i)$ smaller than A. If i is one of* 2.1 *or* 2.2*, then B' cannot l-span B. If i is one of* 2.1 *or* 2.3*, then B cannot r-span B'.*

Proof. The proof for $i = 2.1, 2.2$ is identical to that of Lemma 3.8 as Facts 1, 3, 4, and 5 used in that proof continue to hold in the left direction for $i = 2.1, 2.2$ (these

involve left doubling strips). Note that the whole of the proof for Lemma 3.8 is not being invoked; rather, only the first half is being invoked. To invoke the second half (namely, B cannot r-span B') as well, we will need the above facts to hold in the right direction. This is indeed true for Class 2.1, which is right doubling as well but not for Class 2.2. Invoking this second half for Class 2.1, we get the last part of the lemma for this class. The proof for $i = 2.3$ is analogous. □

4.5. Accounting for strips. The strips in each class are accounted for separately. The number of strips in Class 1.1 is $O(|OPT|)$ by Lemma 4.6. The number of strips in Class 1.2 is $O(|OPT|\frac{\log n}{\Delta})$ by Lemmas 4.6 and 4.9.

Class 2.1 contains strips that are doubling in both directions, like the strips in the special case considered in previous sections. The number of strips in Class 2.1 can be shown to be $O(|OPT|(\Delta + \frac{\log n}{\Delta}))$ by a proof identical to those of Lemma 3.9 and Corollary 3.10; however, invocations of lemmas in section 3.2 need to be modified to point to their respective counterparts in section 4.4 (see the remark in section 3.3).

The reason why the proof of Lemma 3.9 does not extend to other classes as well is that Lemma 3.9 uses Lemma 3.8 in both directions, i.e., to claim that B' cannot r-span B and B cannot l-span B'; this can be done only for Class 2.1. Therefore, the remaining classes need separate proofs, which are given below.

4.5.1. Classes 2.2 and 2.3.

LEMMA 4.14. *Consider a strip $P \in T_r(C, 2.2)$ and its right follower $Q \in T_r(C, 2.2)$ (Q need not be defined). Then one of the following must hold.*

1. *P is either the largest strip or among the smallest $\Delta + 2$ strips in $T_r(C, 2.2)$.*
2. *Q is among the smallest $4\Delta + 1$ strips in $T_l(C', 2.2)$, where C' denotes the clique in OPT containing the left witness cell of Q.*
3. *Let P' be the strip in $T_r(C, 2.2)$ which is to the left of P and shorter than P such that the number of strips longer than P' and shorter than P in $T_r(C, 2.2)$ is 3. Then either P' does not exist or $2^{3\Delta} l(P') \leq l(Q)$.*
4. *Let Q' denote the strip in $T_l(C', 2.2)$ whose left follower is Q. Then $2^{\Delta} l(Q') \leq l(Q)$.*

Proof. We suppose that none of the four conditions hold and derive a contradiction.

Since condition 1 does not hold, Q exists. The proof then proceeds using the following claims, which are proved in sebsequent paragraphs. We claim that any strip in $T_r(C, 2.2)$ with length less than $l(Q')/2$ must lie completely above Q'. Since condition 3 is violated, P' must exist. We then show that P' has length less than $l(Q')/2$ and therefore lies above Q'. Since Q r-spans P' by Lemma 4.8, the vertical separation between the upper holes of Q and Q' is at least $l(P')$. By the violation of condition 2 and Lemma 4.11 applied to Q' and Q, the vertical separation between the upper holes of Q and Q' is at most $\frac{l(Q)}{2^{3\Delta}}$. It follows that $l(P') \leq \frac{l(Q)}{2^{3\Delta}}$. This satisfies condition 3, a contradiction.

First, we show that any strip R in $T_r(C, 2.2)$ with length less than $l(Q')/2$ must lie completely above Q'. Clearly, R lies to the left of Q. Its right successor S is to the right of Q, by Lemma 4.10. Further, S has size less than $l(Q')$ (since $l(R) < l(Q')/2$ and Class 2.2 is right nondoubling). In addition, by Lemma 4.10, the upper hole of S is above that of Q. It follows that the lower hole of S must also be above that of Q'; otherwise, $l(S) \geq l(Q')$, a contradiction. Suppose that R is not completely above Q'. We will get a contradiction as follows. Since R is not completely above Q' and S r-spans R, S is not completely above Q' either. Then one of the two situations shown

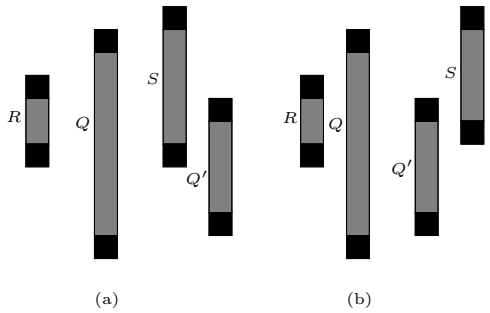

FIG. 17. (a) *S is to the left of Q', and Q does not l-span Q'.* (b) *S is to the right of Q', and S does not r-span R since it is not above Q'.*

in Figure 17 must hold, depending upon whether S is to the left or right of Q'. In the first case, Q cannot l-span Q', and in the second case S cannot r-span R, both contradictions. Therefore, R is completely above Q'.

Second, we show that P' has length less than $l(Q')/2$. To do this, we will show that $l(P) \leq 2l(Q')$. Then, since there are three strips between P and P' in $T_r(C, 2.2)$, $l(P') < l(P)/4 \leq l(Q')/2$. That $l(P) \leq 2l(Q')$ is shown as follows. We show in the next paragraph that P must have its upper hole aligned with or below that of Q and its lower hole aligned with or above that of Q'. Thus $l(P)$ is at most the vertical separation between the upper hole of Q and the lower hole of Q'. Since condition 2 is violated, Lemma 4.11 applied to Q' and Q implies that the vertical separation between their upper holes is at most $\frac{l(Q)}{2^{3\Delta}}$. Thus the vertical distance between the upper hole of Q and the lower hole of Q' is at most $l(Q') + \frac{l(Q)}{2^{3\Delta}} < l(Q')(1 + \frac{1}{2^{2\Delta}})$, by the violation of condition 4. Thus $l(P) \leq l(Q')(1 + \frac{1}{2^{2\Delta}}) \leq 2l(Q')$, as required.

It remains to show that P must have its upper hole aligned with or below that of Q and its lower hole aligned with or above that of Q'. By Lemma 4.8, Q r-spans P, and therefore the upper hole of P is aligned with or below that of Q. By the violation of condition 1 and by Lemma 4.8, which states that all strips in $T_r(C, 2.2)$ are in distinct categories, there exists a strip R in $T_r(C, 2.2)$ such that $l(R) < \frac{l(P)}{2^{\Delta+1}} < \frac{l(Q)}{2^{\Delta+1}}$. Then, by the violation of condition 4, $l(R) < l(Q')/2$. From the earlier part of this proof, it follows that R lies completely above Q'. Clearly, R is to the left of P. By Lemma 4.8, P r-spans R, and therefore the upper hole of P is above that of Q'. Further, by Lemma 4.13, P cannot l-span Q'. Therefore, the lower hole of P must be aligned with or above that of Q'. □

COROLLARY 4.15. *The number of strips in Class* 2.2 *is* $O(|OPT| * (\frac{\log n}{\Delta} + \Delta))$.

Proof. We consider four subclasses, depending upon which of the conditions in Lemma 4.14 is satisfied. The number of strips P which satisfy the first condition is clearly $O(|OPT| * \Delta)$ because each clique in OPT has $O(\Delta)$ such strips. The number of strips P which satisfy the third condition is $O(|OPT| * \frac{\log n}{\Delta})$, using arguments similar to those used for conditions 4 and 5 of Lemma 3.9 in the proof of Corollary 3.10. Next, consider strips P such that either condition 2 or 4 holds. Such a strip P has a unique right follower Q in $T_r(C, 2.2)$. Note that any strip in $T_r(C, 2.2)$ is the right follower of at most one strip. Thus it suffices to bound the number of strips Q which are right followers of strips P satisfying condition 2 or 4. Using arguments similar to those in Corollary 3.10, the number of such strips Q satisfying condition 2 can be shown to be $O(|OPT| * \Delta)$, and the number of such strips Q satisfying

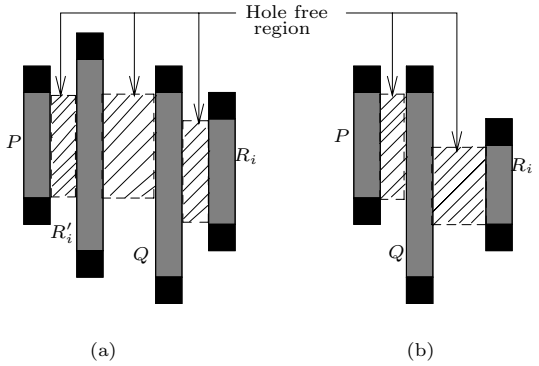

FIG. 18. *The two scenarios in Lemma* 4.17: (a) $j = 2.3, 3.2$. (b) $j = 2.1, 2.2, 3.1$.

condition 4 can be shown to be $O(|OPT| * \frac{\log n}{\Delta})$. □

A similar argument as above works for Class 2.3.

COROLLARY 4.16. *The number of strips in Class* 2.3 *is* $O(|OPT| * (\frac{\log n}{\Delta} + \Delta))$.

4.5.2. Classes 3.1 and 3.2.

LEMMA 4.17. *Consider a strip* P *in* $T_l(C, 3.1)$ *or* $T_l(C, 3.2)$. *Let* Q *be the right successor of* P. *Let* j *be the class containing strip* Q *and* C' *be the clique containing the left witness cell of* Q. *Then either* $j = 1.1$ *or* $j = 1.2$, *or* Q *is among the smallest* $2\Delta + 2$ *strips in* $T_l(C', j)$.

Proof. Since P belongs to Class 3.1 or Class 3.2 and not to Class 1.1, it has a well-defined right successor Q. Further, since P does not define a right witness cell, the upper holes of P and Q are horizontally aligned (see Figure 18). In addition, if P is right nondoubling, then $l(Q) < 2l(P)$, and if P is right doubling, then $l(Q) \leq l(P)2^{\Delta}$, as P is not a right jumper (i.e., it is not in Class 1.2). Note that if P is in Class 3.2, then it must be right doubling, as all strips in $\mathcal{S}$ are either left doubling or right doubling or both (recall the definition of $\mathcal{S}$ from section 4). We consider various cases depending upon the nature of Q.

Suppose $j \neq 1.1$ and $j \neq 1.2$. Then Q is not a left terminal strip. Let $T_l(C', j)$ have k strips smaller than Q. Let these be $R_1, \ldots, R_k$, in increasing order of length. We need to show that $k \leq 2\Delta + 1$.

By Lemmas 4.8 and 4.9, the R_is and Q together form a left nested set of strips and therefore belong to distinct categories. Note that since $j \neq 1.1$, Q and each of the R_is have left successors. Let R'_i denote the left successor of R_i. There are two cases now, depending upon whether j is one of 2.3, 3.2 or one of 2.1, 2.2, 3.1.

First, suppose j is one of 2.3, 3.2. Then Q and the R_is are all left nondoubling (see Figure 18(a)). Then R'_i is in the same category as R_i. Since all R_is and Q are left nested and in distinct size categories, $l(R'_1) < l(R'_2) < \cdots < l(R'_k) < l(Q)$, and $2^{k-1}l(R'_1) < l(Q)$. All R'_is must be between P and Q. For R'_i cannot be to the right of Q by Lemma 4.10. And, if R'_i is to the left of P, then the left witness cells of Q and R_i are independent because Q's left witness cell is on the horizontal line joining the upper holes of P and Q. From Lemma 4.10, the upper hole of each R'_i is above the upper holes of both Q and P. Each R'_i must r-span P because R'_i must l-span R_i and the hatched region is hole-free (because Q r-spans P). Thus $l(P) < l(R'_1)$. Therefore $l(Q) > 2^{k-1}l(R'_1) > 2^{k-1}l(P)$. So if $k \geq \Delta + 1$, $l(Q) > l(P)2^{\Delta}$, a contradiction (see the first paragraph of this proof; note that $\Delta \geq 1$). It follows that $k \leq \Delta$ in this case.

Second, suppose j is one of 2.1, 2.2, 3.1. Q and the R_is are all left doubling (see Figure 18(b)). Note that the hatched regions in the figure must be hole-free, as Q must r-span P and l-span R_i. Then the lower hole of each R_i must be below that of P; otherwise, the left witness cell for R_i will be on or to the left of P and independent from the left witness cell for Q, a contradiction. Therefore, the vertical distance between the upper hole of P (or of Q) and the lower hole of R_1 is at least $l(P)$. Since the R_is and Q belong to distinct categories, $2^{\Delta}l(P) \geq l(Q) > 2^{k-1}l(R_1)$ (the first inequality follows from the first paragraph of this proof). It follows that the vertical separation t between the upper holes of R_1 and Q is at least $l(P) - l(R_1) > (2^{k-1-\Delta} - 1)l(R_1)$. For $k \geq 2\Delta + 2$, $t > (2.2^{\Delta} - 1)l(R_1) > 2^{\Delta}l(R_1)$. This contradicts Lemma 4.11 (the first part, applied to R_1 and Q). Thus $k \leq 2\Delta + 1$ in this case, as required. □

COROLLARY 4.18. *The number of strips in Classes* 3.1 *and* 3.2 *is* $O(|OPT| * (\frac{\log n}{\Delta} + \Delta))$.

Proof. Each strip in these two classes has a right successor, which in turn has a left witness by Lemma 4.4. Further, by Lemma 4.5, any strip is the right successor of at most two strips. By Lemma 4.17, either (a) the right successor of a strip in these two classes is in Class 1.1 or 1.2, or (b) the right successor of a strip in these two classes is in some class $j \neq 1.1, 1.2$ and is amongst the smallest $2\Delta + 2$ strips in $T_l(C', j)$ for some clique C' in OPT. Strips in Classes 3.1 and 3.2 for which the right successor satisfies the latter property are clearly $O(|OPT| * \Delta)$ in number. And strips for which the right successor satisfies the former property are $O(|OPT|\frac{\log n}{\Delta})$ in number by Lemmas 4.6 and 4.9. □

4.5.3. Summing up.

THEOREM 4.19. *The number of rectangles needed to cover the given polygon is* $\Omega(\#N/\sqrt{\log n})$*, where* $\#N$ *is the number of necessary strips and therefore the number of rectangles used by our algorithm.*

Proof. From Corollaries 3.10, 4.15, 4.16, and 4.18, it follows that $|\mathcal{S}| = O(|OPT| * \max\{\frac{\log n}{\Delta}, \Delta\})$. By Lemma 4.3, $|\mathcal{S}|$ is at least a quarter of the number of rectangles used by our algorithm, which is equal to the number of necessary strips. The theorem follows by setting $\Delta = \sqrt{\log n}$. □

5. Counterexample. If the average family size was $O(1)$ for all polygons, then our claim that there always exist $\#F$ independent points will give a constant factor approximation algorithm. Unfortunately, this is not the case. Here we give an example of a polygon in which the average family size is $\theta(\frac{\log n}{\log \log n})$.

This example can also be slightly modified in a way such that all right witness points can be covered by $O(\frac{\#N \log \log n}{\log n})$ cliques and the average right clique size is $\Theta(\frac{\log n}{\log \log n})$, but the average family size (both left and right) remains $\Theta(\frac{\log n}{\log \log n})$. However, in this example, covering the left witness points requires $\Omega(\#N)$ cliques, and the maximum clique size is $O(1)$ for these points. This example was the key to our lower bound. We do not know whether there are examples where the average clique size is superconstant for both the left witness points and the right witness points. In this sense, our bound of $\sqrt{\log n}$ does not seem like an unnatural meeting point.

Let l be a parameter, which we will ultimately set to $\log n$. We give an example where the average left family size, average right family size, and average right clique size are all $\Theta(\log_l n)$.

Our polygon will have two kinds of holes, *nonblocking* and *blocking*. There will be $\Theta(n)$ blocking holes and $\Theta(n \log_l n)$ nonblocking holes; so most holes will be non-

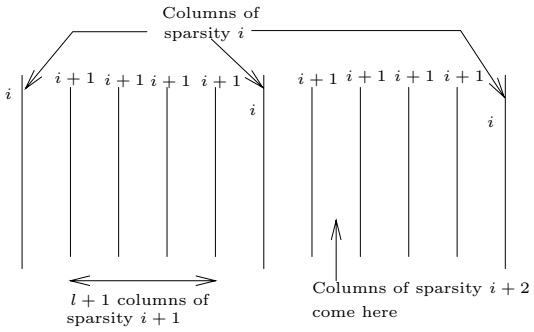

FIG. 19. *Arrangement of columns of sparsity i and $i+1$.*

blocking. First, we will describe the arrangement of nonblocking holes and then that of blocking holes. All subsequent references to strips will be to those formed by nonblocking holes.

Nonblocking holes are arranged in columns. Each column has a certain *sparsity*. A column with sparsity i will have $\frac{n}{l^i}+1$ holes in it, where $0 \le i \le \log_l n$; these holes will be put in rows $0, l^i, 2l^i, \ldots$. So the least sparse column will have $n+1$ holes in rows $0, 1, 2, 3, \ldots, n$, and the most sparse will have 2 holes in rows $0, n$. There will be $l^{i-1}(l+1)$ columns of sparsity i, $i \ge 1$. Therefore, the total number of nonblocking holes will be $\Theta(n \log_l n)$. The arrangement of these columns can be described by the following sequential procedure.

The leftmost and rightmost columns will have sparsity 0. Between these two columns, put $l+1$ columns of sparsity 1; these $l+1$ columns together constitute a *pack*. Then, between each pair of consecutive columns of sparsity 1, put a pack of $l+1$ columns of sparsity 2, and so on, as shown in Figure 19. Note here that a pack of sparsity $i+1$ columns is put only between pairs of consecutive columns of sparsity i which belong to the same pack; these sparsity i columns will not have any columns of sparsity less than i between them.

Blocking holes will always be placed as follows. First, we form right families comprising strips formed by nonblocking holes in columns which are not the last in their respective packs. Note that most (all but $\Theta(n)$) nonblocking holes lie in such columns. Consider a column C with sparsity i which is not the rightmost column in its pack. There are $\frac{n}{l^i}$ strips in such a column. These strips are organized into *groups* of l strips each, the strips in each group being vertically consecutive. Consider one such strip which is the jth strip in its group. We define a right successor s' for s, where s' is the unique strip in the column C' defined below which r-spans s; C' is the jth leftmost column amongst the pack of $l+1$ sparsity $i+1$ columns nested between C and the next sparsity i column to the right of C. The size of each right family defined by the above right successors is clearly large, i.e., $\Theta(\log_l n)$.

We will now arrange blocking holes so that all strips in each right family defined above will indeed have a common right blocking hole. For each right family defined above, put a blocking hole immediately to the right of the rightmost strip in such a way that it blocks all strips in this family. The number of blocking holes put is clearly $\Theta(n)$.

Thus, what we have achieved above is an arrangement of $\Theta(n \log_l n)$ holes where all but $O(n)$ strips lie in right families of size $\Theta(\log_l n)$. We remark here that all but $O(n)$ strips lie in left families of size $\Theta(\log_l n)$ as well in this arrangement. The picture

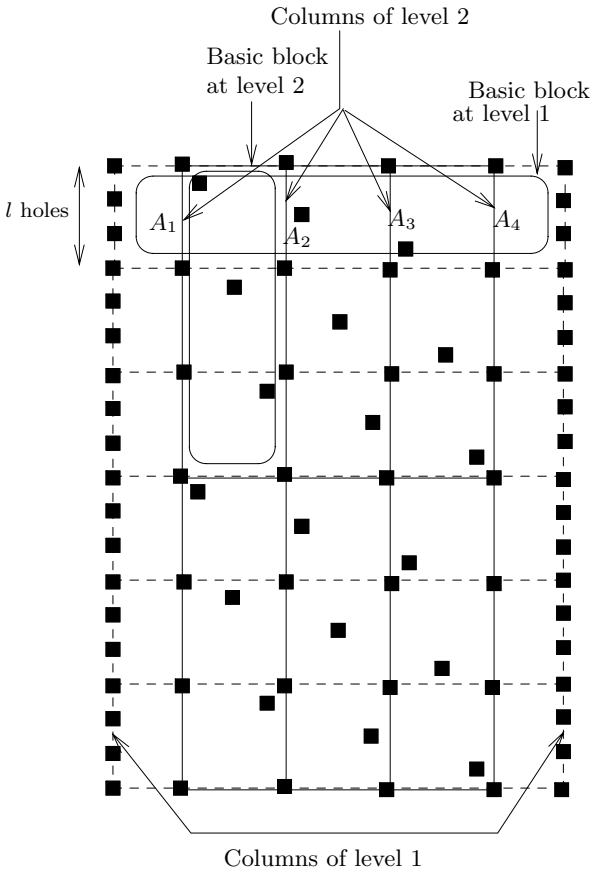

FIG. 20. *A basic block.*

of a "basic block" shown in Figure 20 will be helpful in seeing that this is true.

A basic block comprises the following holes.

1. holes bounding a group of strips on a column C of sparsity i, where C is not the rightmost column in its pack. Let h, h' be the topmost and bottommost such holes (see Figure 20);
2. all blocking holes whose vertical position is between h and h' and whose horizontal position is between C and the next column in the pack containing C;
3. all nonblocking holes which are located vertically between h and h' and are on columns of sparsity $i+1$ between C and the next column in the pack containing C.

5.1. Getting large right cliques. We need to make a modification to the above construction to get large right clique sizes while leaving left and right family sizes as before.

The modification is that columns containing nonblocking holes need to be shifted downwards by varying amounts while maintaining most (but not all) of the right and left families as such. This shifting is described by the following sequential procedure.

The shifting procedure is carried out in rounds. In the ith round, only columns of sparsity i or more will be shifted. Assume that the procedure has already been

executed for i rounds. At this point, for any column C of sparsity i, all columns of sparsity $i+1$ or more which appear between C and the next column in its pack will not have experienced any shift relative to C. For each strip s in a column C of sparsity i which is not the rightmost in its pack, let $map(s)$ denote that strip which has the same right blocking hole as s and lies on a column of sparsity $i+1$ between C and the next sparsity i column in C's pack. It can be verified from the shifting procedure below that $map(s)$ is always well defined and that a basic block (such as the one shown in Figure 21) has blocking holes for strips in C forming a group distributed diagonally (this basic block requires forming groups of l consecutive strips on column C, leaving the first $l-1$ strips out of this grouping; this is to account for the shifts made to C so far). So each basic block formed by groups on C looks like the one in Figure 21, except that holes in this basic block on sparsity $i+1$ columns between C and the next sparsity i column D in C's pack are all aligned with h, the top hole of this group. The $i+1$st round proceeds as follows.

For each column C of sparsity i which is not the rightmost column in its pack, consider any group of strips on C. Let h be the topmost hole in this group. Each strip s in this group is considered in turn. Let $\mathcal{P}$ denote the pack of sparsity $i+1$ strips nested between C and the next sparsity i strip to the right. The column C'' immediately preceding the column C' containing $map(s)$ in $\mathcal{P}$ is shifted down so that the hole which was horizontally aligned with h is now aligned with the upper hole of s (see Figure 21). In addition, all columns nested between C'' and C' will also be shifted down so that no relative shift is introduced between C'' and these columns in this round. For future reference, we denote the strip on C'' which now r-spans s by $cmap(s)$ and the strip on C' which now r-spans s by $newmap(s)$. Note that $cmap(s)$ is defined unless s is the first strip in its group. Figure 21 shows a basic block after this modification.

The above shifting procedure modifies right families, because right successors of strips could have changed. For each strip s in C, the right successor changes from $map(s)$ to $newmap(s)$. Families defined by this new definition of right successor are also large, essentially because a right successor can be defined for every strip other than those which are on the last columns in their packs. Thus, all but $O(n)$ of the strips will continue to be in right families of size $\Theta(\log_l n)$.

Also, the average right clique size is $\Theta(\log_l n)$. To see this, note that the right witness points of $s, cmap(s), cmap(cmap(s)), \ldots$ form a right clique and that $cmap(s)$ is defined for all those s which are not the first strips in their respective groups or in the last columns in their respective packs. Since there are only $O(n)$ strips s which are either the first strips in their respective groups or in the last columns in their respective packs, the total number of right cliques is $\Theta(n)$ and the average right clique size is $\Theta(\log_l n)$.

It now remains to show that left families continue to be large after the above modification. Consider a column C of sparsity i and the next column D to its right in its pack. As is clear from Figure 21, left successors can be defined in the pack $\mathcal{P}$ for each of the strips in D, except those strips which are either the first or last in their respective groups. Defining left successors recursively in this way ensures that the average left family size is also $\Theta(\log_l n)$.

5.2. Large left and right cliques? In the above example, it can be seen with some effort that all left cliques have size $O(1)$. We do not know whether this example can be modified so that the average left and right cliques sizes are both large.

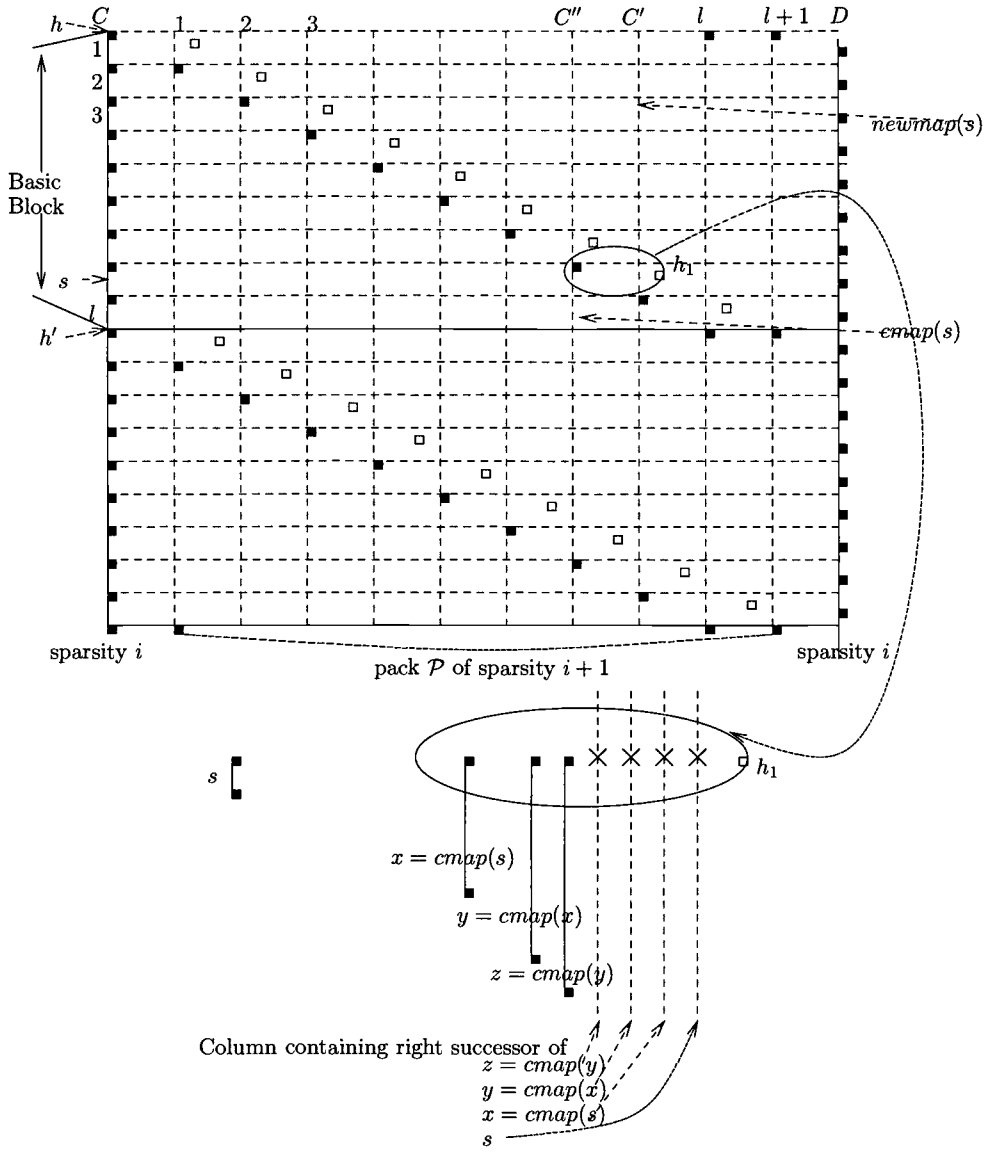

FIG. 21. *Two basic blocks obtained after the $i+1$st round of shifting. White holes are blocking holes. One large clique has been highlighted. The crosses are right witness points.*

6. Conclusions. A number of loose ends remain for this problem. The main question, of course, is whether the approximation factor can be brought down to $O(1)$. Another question is whether there exists a polygon whose clique cover and independent set numbers are small-o of the number of necessary strips.

Related problems. We briefly mention some related problems and the current state of knowledge on these problems.

Non–axis-parallel rectangles. One variant of the above rectangle covering problem is when the covering rectangles need not be axis-parallel.

Our techniques do not seem to extend to this case. However, they do extend

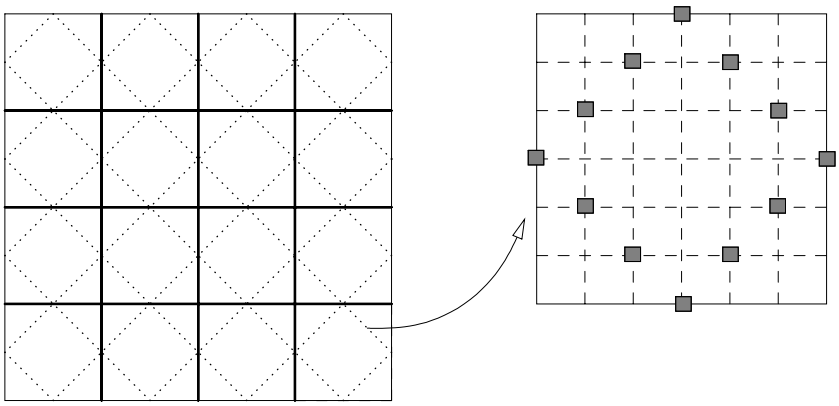

FIG. 22. *Covering with non–axis-parallel rectangles.*

even when all the covering rectangles must be inclined at the same angle or at one of a constant number of angles. But there are examples where rectangles inclined at an arbitrary number of angles are involved in the optimal cover. And, in this case, the issue seems to be different and related to the problem of covering a given set of points using a minimum number of straight lines. We do not know the exact nature of this relationship though. No $o(\log n)$ approximation factor is known for this problem either (see [1]). We describe an example below where the optimum cover has size $O(n)$ when non–axis-parallel rectangles are allowed, whereas it is $\Omega(n\sqrt{n})$ if only axis-parallel rectangles are allowed. This gives support for the intuition that the size of the minimum cover should be much smaller if non–axis-parallel rectangles are allowed.

Partition the $n \times n$ grid into a^2 tiles of size n^2/a^2 each (as in Figure 22(a)). One such tile is shown in Figure 22(b). Each tile has dimensions $n/a \times n/a$. The structure of the tiles results in a partition of the grid into triangles along the boundary and rhombuses inside. Each rhombus has n/a holes on each of its sides. First, consider the case when only axis-parallel rectangles are allowed. Each rhombus needs n/a axis-parallel rectangles for covering. Similarly, each triangle needs n/a rectangles to be covered. The total number of triangles is $4a$, and the total number of rhombuses is $\Theta(a^2)$. Therefore, the optimum has size $\Theta(a^2 n/a + 4an/a)$. Next, consider the case when arbitrarily oriented rectangles are allowed. Now each rhombus can be covered by just one rectangle. Therefore the cover size is $\Theta(an/a + 4an/a)$. For $a = \sqrt{n}$, the cover sizes are $\Theta(n\sqrt{n})$ and $\Theta(n)$, respectively.

Nonrectilinear polygons. When the polygon itself is not rectilinear but has only obtuse angles, suitably discretizing the problem so as to apply the greedy set covering algorithm [10] is itself nontrivial. Levcopoulos and Gudmundsson [14] showed that this can indeed be done. So this problem too has an $O(\log n)$ factor approximation algorithm, and no better bound is known.

Rectilinear polygons and fat rectangles. When the covering objects are squares or rectangles with bounded aspect ratio, then Levcopoulos and Gudmundsson [15] give a constant factor approximation algorithm.

Acknowledgment. We thank the referees for extensive comments that have helped to improve the presentation.

ON THE AUTOREDUCIBILITY OF RANDOM SEQUENCES*

TODD EBERT†, WOLFGANG MERKLE‡, AND HERIBERT VOLLMER§

Abstract. A binary sequence $A = A(0)A(1)\ldots$ is called infinitely often (i.o.) Turing-autoreducible if A is reducible to itself via an oracle Turing machine that never queries its oracle at the current input, outputs either $A(x)$ or a don't-know symbol on any given input x, and outputs $A(x)$ for infinitely many x. If in addition the oracle Turing machine terminates on all inputs and oracles, A is called i.o. truth-table-autoreducible.

We obtain the somewhat counterintuitive result that every Martin-Löf random sequence, in fact even every rec-random or p-random sequence, is i.o. truth-table-autoreducible. Furthermore, we investigate the question of how dense the set of guessed bits can be when i.o. autoreducing a random sequence. We show that rec-random sequences are never i.o. truth-table-autoreducible such that the set of guessed bits has positive constant density in the limit and that a similar assertion holds for Martin-Löf random sequences and i.o. Turing autoreducibility. On the other hand, we show that for any rational-valued computable function r that goes nonascendingly to zero, any rec-random sequence is i.o. truth-table-autoreducible such that on any prefix of length m at least a fraction of $r(m)$ of the m bits in the prefix are guessed.

We include a self-contained account of the hat problem, a puzzle that has received some attention outside of theoretical computer science. The hat problem asks for guessing bits of a finite sequence, thus illustrating the notion of i.o. autoreducibility in a finite setting. The solution to the hat problem is then used as a module in the proofs of the positive results on i.o. autoreducibility.

Key words. random sequences, autoreducibility, infinitely often autoreducibility, density of guessed bits, hat problem, Martin-Löf random sequences, rec-random sequences, p-random sequences, Turing autoreducibility, truth-table autoreducibility, error-correcting codes, hypercube topology

1. Introduction.

In probability theory one fundamental idea is the concept of independence. A collection of random variables $X_1, X_2, \ldots$ is independent if the information obtained from observing the outcome of the variables X_j where $j \neq i$ leaves the distribution of X_i unaffected, in that the a posteriori distribution of X_i equals its a priori distribution. Moreover, viewed from a computational standpoint this idea can be translated as saying that an algorithm whose goal on input i is to guess or estimate the outcome of X_i should not benefit from querying about the outcome of the X_j where $j \neq i$. For example, consider the chance experiment where the bits of an infinite binary sequence $R(0)R(1)R(2)\ldots$ are obtained by successive tosses of a fair coin. If we want to come up with a procedure that on input i computes the bit $R(i)$ while having access only to the remaining bits of R but not to $R(i)$, the a posteriori probability of guessing $R(i)$ given knowledge of $R(j)$ for all $j \neq i$ equals the a priori probability of guessing $R(i)$; thus the chance of success when guessing $R(i)$ cannot be better than $1/2$, and the probability that all bits of R are guessed correctly by the given rule is 0. In particular, it seems natural to regard the information obtained

from observing $R(j)$ with $j \neq i$ as unhelpful for guessing $R(i)$. However, somewhat counterintuitively, we demonstrate in this paper that there are algorithms that with probability 1 are, infinitely often and without error, capable of guessing the outcome of $R(i)$ by querying an oracle about the outcomes of $R(j)$, $i \neq j$.

For the moment, say an effective procedure with limited access to R as described above *autoreduces* R in case the procedure computes $R(i)$ for all i, and the procedure *infinitely often (i.o.) autoreduces* R in case the procedure computes $R(i)$ for infinitely many i, while for all other inputs the procedure eventually signals ignorance about the correct value. Then it appears that for any effective procedure it is impossible to autoreduce or even to i.o. autoreduce R because at first glance it would seem certain that in the limit, half of the membership guesses must be wrong. Indeed, by Corollary 6.5 below, for almost all sequences R (i.e., with probability 1) the sequence R cannot be autoreduced. However, and this comes as a slight surprise, almost all sequences R can be i.o. autoreduced according to Theorem 5.1.

But how can it be that almost all sequences can be i.o. autoreduced when the bits of these sequences, hence in particular all the bits guessed, are chosen independently of all the other bits? Recall that by the strong law of large numbers, with probability 1 the frequency $(R(0)+\cdots+R(n-1))/n$ of 1's in R converges to $1/2$. Furthermore, given a sequence of subsets of the natural numbers where the kth set has cardinality k, the Borel–Cantelli lemma tells us that with probability 1, at most finitely many of these sets have an empty intersection with R [38]. This shows that independent random events considered collectively may possess certain properties with probability 1. Thus we may assume that certain properties are present in almost all sequences, and for appropriate properties this can be exploited in order to compute certain bits of a sequence. In summary, the crux of the following investigation rests on determining degrees to which properties that are present in almost all sequences may be used to occasionally compute the outcome of a random variable by observing the outcomes of other random variables where the random variables are mutually independent.

Being almost convinced that random sequences might indeed be i.o. autoreducible, we might still wonder how we can overcome the obstacle that when guessing $R(i)$ for given places i, necessarily we err half the time. The key observation is that a procedure that i.o. autoreduces R can decide on its own whether to make a guess on a certain input i. Then, by assuming an appropriate property that is present in almost all sequences, for all such sequences an effective procedure may compute infinitely many bits, despite its querying limitations. Observe in this connection that for the autoreductions to be constructed in the sequel, for almost all sequences the places that are guessed form a set that is not computable. Furthermore, the set of guessed bits cannot have constant positive density in the set of all words.

In what follows, we use the known concept of autoreducibility by oracle Turing machines for capturing the idea of using a sequence A as oracle in order to compute A, yet not being able to query A about the bit to be computed. The concept of i.o. autoreducibility, where just infinitely many bits of A have to be computed, is modeled by means of oracle Turing machines that, in addition to 0 and 1, may also output a special don't-know symbol. Moreover, we will consider restricted concepts of autoreducibility and i.o. autoreducibility that correspond to various reducibilities considered in recursion theory and complexity theory. For example, we introduce i.o. tt-autoreducibility, which is defined similarly to the usual truth-table reducibility from recursion theory.

Furthermore, we do not just show that almost all sequences can be i.o. autoreduced by effective reductions of truth-table type, but, and this is more, the latter as-

sertion holds for all Martin-Löf random, rec-random, and even p-random sequences. The positive results on general i.o. autoreducibility are complemented by negative results on i.o. autoreducibility, where, for example, a positive constant fraction of all bits has to be guessed correctly. These negative results exhibit interesting interactions between the type of random sequence considered and the type of autoreduction employed, intuitively speaking.

The aim and scope of this paper can then be summarized as follows. We try to contribute to the investigation of the question of which types of random sequences are i.o. autoreducible, at which density, and with respect to which types of reducibilities.

We conclude this section with an outline of the paper and an overview on its technical contributions. In section 2 we state a puzzle, the *hat problem*, also known as *colored hat problem* or *prisoners' problem*. By means of the hat problem we illustrate how techniques from coding theory can be applied when trying to autoreduce random sequences. More precisely, we review perfect one-error-correcting codes and show that these codes can be used to derive optimal solutions for certain instances of the hat problem. In subsequent sections, the solutions are then used as basic modules when constructing autoreductions. The hat problem was introduced by Ebert [19] in order to illustrate the problem of autoreducing random sequences and has recently become well known outside of theoretical computer science [14, 35, 37]. In an attempt to provide a reference for the hat problem that is also accessible to readers that are not interested in applications to autoreducibility, we have tried to make section 2 self-contained.

In section 3 we review effective random sequences and related issues in effective measure theory, and in section 4 we give formal definitions for the concepts of autoreducibility that are subsequently used.

In section 5, we consider i.o. autoreducibility of random sequences. We prove that *every* rec-random sequence is i.o. truth-table-autoreducible and, what is more, in fact any p-random sequence is i.o. truth-table-autoreducible via an oracle Turing machine that runs in polynomial time. As mentioned above, this result seems somewhat surprising and even paradoxical in that the machine that witnesses the autoreducibility has the task of infinitely often guessing a bit of a random sequence and guessing correctly each time despite a high chance of error for each guess. We then show that these results require Turing machines where the number of queries made for a single input is unbounded. This is accomplished by proving that no rec-random sequence is i.o. bounded truth-table-autoreducible, i.e., i.o. autoreducible by an oracle Turing machine that is restricted to some fixed number of queries, and an analogous result is shown in a setting of polynomial time bounds.

In section 6, we introduce the notion of autoreducibility with density $r(m)$ as a gauge of how often an oracle machine can guess the bits of a random sequence or, in other words, how dense the set of guessed bits can be with respect to the entire set of bits. A sequence is i.o. autoreducible with density $r(m)$ if it is i.o. autoreducible such that for all m, at least a fraction of $r(m)$ of the first m bits of the sequence is guessed. In Theorem 6.3 it is shown that rec-random sequences are never i.o. truth-table-autoreducible with positive constant density (i.e., with density $r(m) = \varepsilon m$ for some $\varepsilon > 0$) and that a similar assertion holds with respect to Martin-Löf random sequences and i.o. Turing autoreducibility. On the other hand, Theorem 6.6 asserts that for any computable function r that goes nonascendingly to 0, any rec-random sequence is i.o. truth-table-autoreducible with density $r(m)$. So we obtain essentially matching bounds on the density of guessed bits for i.o. truth-table autoreductions of

rec-random sequences.

Related work. The current article is an extended joint version of conference articles by Ebert and Vollmer [21] and Ebert and Merkle [20]. The hat problem was originally introduced in the literature by Ebert [19] in order to illustrate the problem of autoreducing random sequences. The hat problem has led to work in coding theory [26] since there are instances of the problem for which the optimal solution (code) is not known. Moreover, the hat problem has become well known outside of theoretical computer science [14, 35, 37]. Independently and considerably earlier, towards the end of the 1980s, Aspnes et al. [9] considered voting problems that have a flavor similar to the hat problem. Moreover, Rudich [36] points out that the hat problem is essentially the same as a variant of the voting problems called "voting with abstention," and he reports unpublished earlier work on the latter. The concept of i.o. autoreducibility has been investigated by Beigel, Fortnow, and Stephan [10], who construct a sequence in exponential time that is not i.o. truth-table-autoreducible in polynomial time.

Notation. We use standard notation, which is elaborated further in the references [6, 11, 12, 29].

We consider words over the binary alphabet $\{0,1\}$, which are ordered by the usual length-lexicographical ordering; the $(i+1)$st word in this ordering is denoted by s_i; hence, for example, s_0 is the empty word λ. Occasionally, we identify words with natural numbers via the mapping $i \mapsto \mathrm{s}_i$.

If not explicitly stated differently, a sequence is an infinite binary sequence, and a class is a set of sequences. A subset A of the natural numbers $\mathbb{N}$ is identified with its characteristic sequence $A(0)A(1)\ldots$, where $A(x)$ is 1 if $x \in A$ and $A(x)$ is 0 otherwise; notation defined for such subsets is extended to the corresponding sequences; e.g., an oracle Turing machine may reduce one sequence to another. The term class refers to a set of sequences.

An *assignment* is a (total) function from some subset of the natural numbers to $\{0,1\}$. An assignment is *finite* if and only if its domain is finite. An assignment with domain $\{0,\ldots,n-1\}$ is identified in the natural way with a word of length n. For an assignment σ with domain $\{z_0 < \cdots < z_{n-1}\}$, the *word associated with* σ is the (unique) word w of length n that satisfies $w(i) = \sigma(z_i)$ for $i = 0,\ldots,n-1$.

The restriction of an assignment σ to a set I is denoted by $\sigma|I$. In particular, for any sequence X, the assignment $X|I$ has domain I and agrees there with X. For a sequence X and an assignment σ, we write $\langle X,\sigma\rangle$ for the sequence that agrees with σ for all arguments in the domain of σ and agrees with X otherwise.

The class of all sequences is referred to as *Cantor space* and is denoted by $\{0,1\}^\infty$. The class of all sequences that have a word x as a common prefix is called the *cylinder generated by* x and is denoted by $x\{0,1\}^\infty$. For a set W, let $W\{0,1\}^\infty$ be the union of all the cylinders $x\{0,1\}^\infty$ where the word x is in W.

We write Prob[.] for probability measures and $\mathbf{E}$[.] for expected values. Unless stated otherwise, all probabilities refer to the *uniform measure* (or *Lebesgue measure*) on Cantor space, which is the probability distribution obtained by choosing the individual bits of a sequence by independent tosses of a fair coin. Usually we write Prob[A satisfies ...] instead of Prob[$\{A \in \{0,1\}^\infty : A$ satisfies ...$\}$] in case it is understood from the context that the measure is with respect to A.

Logarithms are to base 2. The function $\langle .,. \rangle$ from $\mathbb{N}\times\mathbb{N}$ to $\mathbb{N}$ is the usual effective and effectively invertible pairing function [42].

2. The hat problem and error-correcting codes. This section features the hat problem, which asks for guessing a single bit of a randomly chosen finite sequence from the remaining bits, a problem that resembles the task of i.o. autoreducing random infinite sequences. Subsequently, in constructions that solve the latter task, the hat problem and its solution are used as a basic module. The hat problem is formulated as a puzzle, and as such has received some attention in the public [14, 35, 37].

The hat problem.

In the hat problem for a team of n players, a binary sequence of n bits is chosen by independent tosses of a fair coin. Player i is assigned the ith bit (or, equivalently, is assigned one of two possible hat colors according to this bit).

Afterwards, each player may cast a guess on its own bit (or may abstain from guessing) under the following conditions. The players know the bits of all other players but not their own bit. Once the game begins, the players are neither allowed to communicate nor do they know whether the other players have already guessed. However, the players can meet for a strategy session before the game begins.

The team wins if and only if there is at least one correct and no incorrect guess.

At first sight, since each player may observe only events that are independent of his own hat color, one might expect that the team should have no more than a 50% chance of winning. However, since they converse before the game, we demonstrate how collaboration can increase their chances.

EXAMPLE 2.1. *Consider the hat problem with $n = 3$ players, and suppose the team agrees on the following guessing strategy. Upon the start of the game, each player observes the hats of his two teammates. If both hats have the same color, then the player guesses his hat is colored differently. However, if the hats have different colors, then he passes.*

To compute the chances for a win under this strategy, we distinguish two cases. The first case occurs when all three hats have the same color, i.e., for two out of the 8 equiprobable assignments. In this case, each player will incorrectly guess. The second case is exactly two of the three hats are colored the same. Here exactly one player will venture a guess; this guess is correct, and the team wins. Hence the probability of winning using the above strategy is $1 - 2/8 = 3/4$.

Next we want to extend the solution to the hat problem with three players given in Example 2.1 to other team sizes. For a given team size n, identify assignments of colors with words of length n in the natural way; i.e., the players are numbered from 1 to n, and the jth bit of the word represents player j's hat color. The word that represents the actual assignment of colors is called the *true word*. With the true word understood, there are exactly two words of length n that agree with player j's view: the true word and the word that differs from the true word exactly at the jth position. Call these two words the *consistent words* of player j.

Specifying a strategy amounts to determining for any player and for any possible pair of consistent words for this player whether the player should cast a vote and, if yes, in favor of which of the two consistent words. This means that a strategy can be pictured as a directed graph G in the following way. The nodes of the graph are just the possible assignments, i.e., the words in $\{0,1\}^n$. The graph contains an edge from u to v if and only if these two nodes may occur as the consistent nodes of some player,

and in this situation the player votes in favor of v. Formally, we have $G = (V, E)$ where

$$V = \{0,1\}^n, \qquad E \subseteq \{(u,v) \mid u \text{ and } v \text{ differ exactly in one position }\},$$

and for any pair u and v of nodes in V, at most one of the edges (u,v) and (v,u) is in E.

Consider any strategy and its associated graph, and assume that the strategy is applied in a situation where the true word is u. The team wins if according to the given strategy some player casts a vote in favor of u but no player guesses in favor of a word different from u. In terms of the associated graph, this means that the team wins on the assignment u if and only if

(2.1) some edge is pointing to u and no edge is pointing away from u.

From this characterization of winning assignments we obtain an equivalent formulation of the hat problem as a network problem, which is stated in Remark 2.2. Afterwards, we construct solutions to this network problem and translate them back to the hat problem. The point in considering the network problem is that the way its solutions work is more easily understood than for the hat problem.

REMARK 2.2. *The hat problem can be reformulated as a problem on communication networks with a hypercube topology, where the nodes of the network correspond to the possible assignments of hat colors to the players.*

In order to obtain an equivalent version of the hat problem with n players, we consider a network of 2^n processors or nodes. The nodes are connected according to a hypercube topology [25]. *That is, each node is labelled by a unique word of length n, and between any two distinct nodes there is a link if and only if their labels differ in exactly one bit. The links are capable of transmitting information in either direction but only in one direction at a time. The task is to give a pattern of communication such that there is a maximum number of nodes u such that*

(2.2) *some node is sending to u and u is not sending to any node.*

A pattern of communication specifies for each link either the status idle or an orientation, i.e., one of the two possible directions of sending.

Any pattern of communication translates naturally into a strategy for the hat problem with n players and vice versa. Furthermore, under this translation the fraction of nodes that satisfy (2.2) *coincides with the success probability of the strategy. For a proof of the two latter assertions it suffices to observe that the representation of a strategy as directed graph is essentially identical to a pattern of communication and to compare the conditions* (2.1) *and* (2.2).

EXAMPLE 2.3. *The solution of the hat problem with $n = 3$ players from Example* 2.1 *translates as follows into a solution of the network problem. The network has a hypercube topology with 2^3 nodes, and the pattern of communication specifies that*

> *exactly the nodes* 000 *and* 111 *are sending, and each of them sends to all its neighbors in the hypercube.*

This way every processor u with a label different from 000 *and* 111 *is receiving but does not send and thus satisfies* (2.2).

In order to extend the solution to the network problem given in Example 2.3 to larger networks, we review some notation and facts from coding theory. The

(Hamming) distance $\mathrm{d}(u,v)$ between two words u and v of identical length is the number of positions at which u and v differ. Furthermore, the *unit ball* with *center* u is the set of all words that have the same length as u and differ from u at most at one position, i.e., the set

$$\{v : \mathrm{d}(u,v) \leq 1\}.$$

The *surface* of a unit ball is just the ball with its center removed.

In the network problem, the set of neighbors of a node w coincides with the surface of the unit ball centered at w. Accordingly, the solution to the network problem from Example 2.3 can be reformulated as follows.

> Exactly the nodes 000 and 111 are sending, and each of them sends to all nodes on the surface of the unit ball centered at this node.

The easy idea underlying this solution works also for networks where the parameter n is larger than 3. Just select a subset C of all words of length n, and let each node (labelled by a word) in C send to all nodes that are on the surface of the unit ball centered at this node but are not in C themselves. If, for example, we choose the set C such that the unit balls around the words in C are disjoint, then exactly the nodes on the surfaces of these unit balls satisfy (2.2); i.e., these are the nodes that receive but do not send. The fraction of such nodes becomes maximum among all corresponding choices of C in case the unit balls around the words in C partition the set of all words of the given length. Such partitions are studied in coding theory under the name of perfect one-error-correcting codes.

DEFINITION 2.4. *Any subset of* $\{0,1\}^n$ *is called a* code *with* (codeword) length n. *A code* C *with length* n *is called* perfect one-error-correcting *if the unit balls around the codewords in* C *form a partition of* $\{0,1\}^n$ *(i.e., if for any word* w *of length* n *there is exactly one word* $c \in C$ *such that* $\mathrm{d}(w,c) \leq 1$*).*

For any perfect one-error-correcting code of length n, the number of all words 2^n must be divisible by the unit ball volume $n+1$; hence $n+1$ must be a power of 2. It is well known that this necessary condition on the codeword length is also sufficient [22, 45].

FACT 2.5. *Let* n *be of the form* $2^k - 1$ *where* $k > 0$ *is a natural number. Then there is a perfect one-error-correcting code* C_n *of codeword length* n. *Furthermore, the codes* C_n *can be chosen such that their union* $\bigcup_{\{n:n=2^k-1\}} C_n$ *is decidable in polynomial time. For example, such codes are given by the well-known family of binary Hamming codes* [45].

Proof. We identify words and binary vectors in the obvious way; hence the words of any given length form a vector space under addition modulo 2 and over the field with two elements. Let M be the $k \times n$ binary matrix where for $i = 1, \ldots, n$, column i of M is the binary representation of the number i. The matrix M defines a linear mapping $w \mapsto Mw$ from words of length n to words of length k. Let C_n denote the kernel space of this mapping, i.e., the set of all words that are mapped to 0^k. Then C_n is a perfect one-error-correcting code of length n.

For a proof, first observe that trivially every word in the kernel has length n. Second, any word w of length n is contained in a unit ball centered at a word in C_n. In case Mw is zero, this is obvious. Otherwise, Mw appears as a column of M, say, as column j, hence flipping the jth bit of w results in a word in C_n. Third, the unit balls centered at the words in C_n are mutually disjoint. Fix any two distinct words u and v in C_n. Then M maps both u and v to 0^k, and, by linearity of matrix multiplication,

the same holds for $u-v$. On the other hand, $M(u-v)$ is just the sum over all column vectors j of M such that u and v differ at the jth position. Now the sum over one or over two distinct column vectors of M cannot be equal to 0^k; hence $\mathrm{d}(u,v) \geq 3$, and, in particular, the unit balls centered at u and v must be disjoint. (The third item is a special form of a well-known result in coding theory that the minimum distance of a code which is the kernel space of some matrix M is equal to d, where d is the least number for which there are d linearly dependent column vectors of M. In our case it is easy to check that M has three linearly dependent vectors, but not two. Thus C_n has a minimum distance of 3.)

Finally, the problem of deciding if a word belongs to $\bigcup_{\{n:n=2^k-1\}} C_n$ can be solved in polynomial time, as essentially it involves only multiplying the input with a matrix that has moderate size and is easy to compute. □

Remark 2.6 summarizes the application of error-correcting codes to the hat problem and the related network problem.

REMARK 2.6. *Let n be of the form 2^k-1 for some natural number $k>0$, and consider the hat problem and the network problem with parameter n. Fix a perfect one-error-correcting code of code word length n, and call the words in this code, as well as the nodes labelled by these words,* designated.

A solution to the network problem is given by the following pattern of communication. By Remark 2.2*, under this pattern of communication exactly the nodes that are* not *designated satisfy* (2.2).

> *Every designated node sends to all its neighbors in the hypercube; the other nodes do not send.*
> *(That is, every designated node w sends to all nodes on the surface of the unit ball centered at w.)*

A solution to the hat problem with n players is given by the strategy where each player behaves according to the following rule. By Remark 2.2*, under this strategy the team wins exactly for the assignments that are* not *designated.*

> *In case one of the consistent words is a designated word, venture a guess according to the assumption that the true word is the other consistent word; otherwise, pass.*
> *(That is, in case the consistent words are a designated word w and a word on the surface of the ball centered at w, guess in favor of the consistent word on the surface, i.e., the one different from w.)*

The fraction of designated words is $1/(n+1)$ because the balls centered at the designated words partition $\{0,1\}^n$, and each such ball consists of one designated and n other words. Hence if this strategy is applied in the hat problem with n players, the team wins with probability $1-1/(n+1)$.

EXAMPLE 2.7. *Consider the hat problem with $n=7$ players. For the strategy described in Remark* 2.6*, the codewords comprise a fraction of* $1/8$ *of the* 128 *words in $\{0,1\}^7$; hence there are* 16 *codewords and* 112 *error words, and the team wins with probability* $112/128 = 0.875$.

In the network problem with parameter n, a node can send at most to n other nodes; hence, among all nodes that send or receive, at least a fraction of $1/(n+1)$ nodes must send. The pattern of communication described in Remark 2.6 achieves this bound and thus is an optimum solution to the network problem; hence by the discussion in Remark 2.2 also the corresponding strategy for the hat problem is optimum.

Remark 2.8 contains an alternate, somewhat more formal proof for the optimality of this strategy, which features the idea that for any strategy the expected number of correct and incorrect guesses is the same.

REMARK 2.8. *Let n be of the form $n = 2^k - 1$. For the hat problem with n players, the probability of success of $1 - 1/(n+1)$ that is achieved by the strategy described in Remark* 2.6 *is optimum.*

For a proof, fix any strategy. Recall that the colors of the hats are assigned according to independent tosses of a fair coin; hence, whenever the strategy tells a player to guess, the probability of a correct guess is exactly $1/2$. *As a consequence, the expected number of correct and incorrect guesses per player is the same, and, by linearity of expectation, the same holds for the entire team; i.e., if we define the random variables g_c and g_i as equal to the number of correct and incorrect guesses, respectively, for the entire team, their expected values $\mathbf{E}[g_c]$ and $\mathbf{E}[g_i]$ coincide. Furthermore, if the strategy considered has probability of success of p, then we have*

$$p \leq \mathbf{E}[g_c] = \mathbf{E}[g_i] \leq (1-p)n. \tag{2.3}$$

In (2.3)*, the equation holds by the preceding discussion, the left-hand inequality follows because for each assignment that leads to a win there must be at least one correct guess, and the right-hand inequality holds because for any winning assignment there is no wrong guess, while for any other assignments there are at most n wrong guesses. So we have $p \leq (1-p)n$, and by rearranging we obtain $p \leq 1 - 1/(n+1)$.*

Lenstra and Seroussi [26] discuss applications of coding theory to the hat problem. They investigate good strategies for numbers of players that are not of the form $2^k - 1$ and for more general versions of the hat problem with more than two colors. For the hat problem with two colors, they show that strategies are equivalent to covering codes. Their observation is reviewed in Remark 2.9, where we give an equivalent formulation in terms of communication patterns for the network problem.

REMARK 2.9. *A code of length n is called a covering code (more precisely, a* 1*-covering code) if any word of length n differs at most at one position from some word in the code. For example, perfect one-error-correcting codes are covering codes; however, in general the unit balls centered at the words in a covering code are not mutually disjoint.*

Given a pattern of communication for the network problem with parameter n, let C be the set of all nodes that do not satisfy (2.2)*; i.e., C contains the nodes that are sending or are neither sending nor receiving, and the complement of C contains the nodes that receive but do not send. Then C is a covering code because the nodes not in C are receiving; hence each such node must be at distance at most* 1 *from a sending node, which then must be a node in C. Conversely, given any covering code of length n, there is a pattern of communication where every node in C sends to all its neighbors that are not in C themselves. With this pattern, exactly the nodes that are not in C satisfy* (2.2)*.*

3. Random sequences. This section gives a brief introduction to the theory of effective measure. We focus on effective random sequences and related concepts that are used in the following. For more comprehensive accounts of effective measure we refer the reader to the references [5, 6, 29].

Imagine a casino that offers roulette, and consider the sequence of outcomes red and black that occur in the course of the game. We would certainly not call this sequence random if there were a method to determine any next bit before the corresponding drawing has actually taken place. But also if we just knew a strategy

that guarantees winning an unbounded amount of money when starting with finite initial capital, this would indicate that the sequence is nonrandom. So we might be tempted to call a sequence nonrandom if there is such a strategy. The problem with this definition is that for any sequence there is a strategy that wins against this sequence, e.g., the one that works by always predicting correctly the next bit of the sequence. However, the latter is not a problem for real casinos because for them a sequence is "random enough" if it does not permit a winning strategy that a gambler can actually play. In general, this suggests defining randomness relative to a certain class of admissible betting strategies instead of striving for an absolute concept. In what follows, the admissible betting strategies are just the ones that are computable in a specific model of computation. A sequence is called random with respect to such a model of computation if none of the admissible betting strategies leads to an unbounded gain when playing against this sequence.

In order to formalize the ideas of the preceding paragraph, consider the following gamble. Imagine a player that successively places bets on the individual bits of an unknown sequence A. The betting proceeds in rounds $i = 1, 2, \ldots$. During round i, the player receives as input the length $i-1$ prefix of A and then, first, decides whether to bet on the ith bit being 0 or 1 and, second, determines the stake that shall be bet. The stake might be any fraction between 0 and 1 of the capital accumulated so far; i.e., in particular, the player is not allowed to incur debts. Formally, a player can be identified with a *betting strategy*

$$b\colon \{0,1\}^* \to [-1,1]$$

where on input w the absolute value of $b(w)$ is the fraction of the current capital that shall be at stake, and the bet is placed on the next bit being 0 or 1 depending on whether $b(w)$ is negative or nonnegative.

The player starts with positive, finite capital. At the end of each round, in case of a correct guess, the capital is increased by that round's stake and, otherwise, is decreased by the same amount. So given a betting strategy b, we can inductively compute the corresponding *payoff function* d_b by applying the equations

$$d_b(w0) = d_b(w) - b(w)\cdot d_b(w), \qquad d_b(w1) = d_b(w) + b(w)\cdot d_b(w).$$

Intuitively speaking, the payoff $d_b(w)$ is the capital the player accumulates until the end of round $|w|$ by betting on a sequence that has the word w as a prefix. The payoff function d_b satisfies the fairness condition

$$d_b(w) \;=\; \frac{d_b(w0) + d_b(w1)}{2}\;. \tag{3.1}$$

We call a function d from words to nonnegative reals a *martingale* if and only if $d(\lambda) > 0$ and d satisfies the fairness condition (3.1), with d_b replaced by d, for all words w. By the discussion above, for a betting strategy b the function d_b is always a martingale, and, conversely, it can be shown that every martingale has the form d_b for some betting strategy b. Hence betting strategies and martingales are essentially equivalent. Accordingly, we extend occasionally notation defined for betting strategies to martingales and vice versa.

DEFINITION 3.1. *A betting strategy b* succeeds *on a sequence A if the corresponding martingale d_b is unbounded on the prefixes of A, i.e., if*

$$\limsup_{n\in\mathbb{N}}\; d_b(A|\{0,\ldots,n\}) \;=\; \infty.$$

In what follows, we will consider computable betting strategies. Any computable betting strategy b is confined to rational values, and there is a Turing machine that on input w outputs some appropriate finite representation of $b(w)$.

Computable betting strategies are not only of interest in connection with the definition of random sequences but are also the basis of the theory of effective measure. A betting strategy is said to *succeed on* or to *cover* a class if and only if it succeeds on every sequence in the class. Ville demonstrated that a class has uniform measure 0 if and only if the class can be covered by some, not necessarily effective, betting strategy [6, 47]. This result justifies the following notation. A class has *measure* 0 with respect to a given class of betting strategies if and only if it is covered by some betting strategy in the class. By appropriately restricting the class of admissible betting strategies, one obtains restricted concepts of measure 0 classes, which are useful when investigating classes occurring in recursion theory or complexity theory. Most of these classes are countable and hence have uniform measure 0; i.e., from the point of view of uniform measure all these classes have the same size. However, given a specific class $\boldsymbol{C}$, we might try to restrict the class of admissible betting strategies such that the resulting concept of measure 0 class is interesting in the sense that we can still cover relevant subclasses of $\boldsymbol{C}$ but not the class $\boldsymbol{C}$ itself. In the context of recursion theory, this led to the consideration of computable betting strategies [5, 39, 40, 43, 48]. In connection with complexity classes one imposes additional resource bounds [6, 28, 29, 31]; e.g., in the case of the class $\mathbf{E}$ of sequences that can be computed in deterministic linear exponential time, i.e., in time $2^{\mathrm{O}(n)}$, Lutz proposed using betting strategies that are computable in polynomial time.

REMARK 3.2. *The resources needed to compute a betting strategy are measured with respect to the length of the input w; for example, a betting strategy b is computable in polynomial time if $b(w)$ can be computed in time $|w|^c$ for some constant c.*

A prefix w of a sequence A encodes $A(\mathrm{s}_0)$ through $A(\mathrm{s}_{|w|-1})$, and accordingly on input w, a betting strategy determines a bet on whether $x = \mathrm{s}_{|w|}$ is in the unknown sequence or not. Observe that the length of x is approximately $\log|w|$; thus, for example, a time bound $|w|^c$ translates to a time bound of the form $2^{\mathrm{O}(|x|)}$.

After this short digression to effective measure theory we return to the endeavor of defining concepts of random sequences via restricted classes of betting strategies.

DEFINITION 3.3. *A sequence is* rec-random *if no computable betting strategy succeeds on it. A sequence is* p-random *if no betting strategy that is computable in polynomial time succeeds on this sequence.*

Besides p-random and rec-random sequences, we will consider Martin-Löf random sequences [30]. Let $W_0, W_1, \ldots$ be the standard enumeration of the computably enumerable sets [42].

DEFINITION 3.4. *A class $\mathcal{N}$ is called a* Martin-Löf null class *if and only if there exists a computable function $g\colon \mathbb{N} \to \mathbb{N}$ such that for all i*

$$\mathcal{N} \subseteq W_{g(i)}\{0,1\}^\infty \quad \textit{and} \quad \mathrm{Prob}[W_{g(i)}\{0,1\}^\infty] < \frac{1}{2^i}\,.$$

For such a function g, the sequence $W_{g(0)}, W_{g(1)}, \ldots$ is called a Martin-Löf null cover *for $\mathcal{N}$. A sequence is* Martin-Löf random *if it is not contained in any Martin-Löf null class.*

Martin-Löf random sequences have been characterized in terms of martingales by Schnorr [40]. A sequence is *Martin-Löf random* if and only if it cannot be covered by a subcomputable martingale. A martingale d is *subcomputable* if and only if there

is a computable function $\widetilde{d}$ in two arguments such that for all words w, the sequence $\widetilde{d}(w,0), \widetilde{d}(w,1), \ldots$ is nondecreasing and converges to $d(w)$.

REMARK 3.5. *For any sequence X we have*

$$X \text{ Martin-Löf random} \Rightarrow X \text{ rec-random} \Rightarrow X \text{ p-random}, \tag{3.2}$$

and both implications are strict.

The first implication in (3.2) *is immediate by the characterization of Martin-Löf random sequences in terms of subcomputable martingales and the observation that for a computable betting strategy the corresponding martingale is computable, too. Likewise, the second implication follows from the definitions of rec-random and p-random sequences in terms of computable and polynomial-time computable betting strategies. Furthermore, the second implication is strict because one can construct a computable p-random sequence by diagonalizing against an appropriate weighted sum of all betting strategies that are computable in polynomial time. The strictness of the first implication was implicitly shown by Schnorr* [40]. *For a proof, it suffices to recall that the prefixes of a Martin-Löf random sequence cannot be compressed by more than a constant* [27, *Theorem* 3.6.1] *while a corresponding statement for rec-random sequences is false* [27, 33].

By definition, a class $\mathcal{N}$ has uniform measure 0 if the condition in Definition 3.4 is satisfied for some arbitrary sequence of sets $V_0, V_1, \ldots$ in place of $W_{g(0)}, W_{g(1)}, \ldots$. Thus the concept of a Martin-Löf null class is indeed an effective variant of the classical concept of a class that has uniform measure 0. In particular, any Martin-Löf null class has uniform measure 0. By σ-additivity and since there are only countably many computable functions, the union of all Martin-Löf null classes has uniform measure 0. Accordingly, the class of Martin-Löf random sequences, and hence by Remark 3.5 also the classes of rec-random and of p-random sequences, have uniform measure 1. We note in passing that it can be shown that the union of all Martin-Löf null classes is again a Martin-Löf null class [17, section 6.2].

We conclude this section by describing a standard technique for the construction of betting strategies.

REMARK 3.6. *Let I be a finite set, and let Θ be a subset of all partial characteristic functions with domain I. Then there is a betting strategy that, by betting on places in I, increases its capital by a factor of $2^{|I|}/|\Theta|$ for all sequences B where the restriction of B to I is in Θ.*

The betting strategy is best described in terms of the corresponding martingale. The martingale takes the capital available when betting on the least element of I and distributes it evenly among the elements of Θ, and then computes values upwards according to the fairness condition for martingales.

4. Autoreducibility. For the moment, call a sequence X *autoreducible* if there is an effective procedure that on input x computes $X(x)$ while having access to the values $X(y)$ for $y \neq x$. Intuitively speaking, for an autoreducible sequence the information on $X(x)$ is not only stored at x but can also be effectively recovered from the remainder of the sequence. For example, any computable sequence is autoreducible, and for an arbitrary sequence Y, the sequence $Y(0)Y(0)Y(1)Y(1)\ldots$ is autoreducible. In a recursion theoretic setting, the concept of autoreducibility was introduced by Trakhtenbrot [44]. Further investigations showed, among other results, that autoreducibility is tightly connected to the concepts of mitoticity and introreducibility [8, 18, 23, 24]. The concept of autoreducibility was transferred to complexity theory by Ambos-Spies [2], and subsequently resource-bounded versions of autoreducibility

have been studied by several authors [10, 15, 16, 46]. Self-reducibility is a special form of autoreducibility where only queries less than the current input may be asked [11, 41]; it can be shown that certain forms of self-reducibility characterize certain types of generic sets [3, 4, 13].

Now consider the question of whether a random sequence can be autoreducible. By definition, the bits of an autoreducible sequence depend on each other in an effective way. This suggests that by exploiting the dependencies, we might come up with an effective betting strategy that succeeds on this sequence. Indeed Martin-Löf random sequences are never autoreducible, and, similarly, rec-random sequences are not autoreducible by reductions that are confined to nonadaptive queries; see Corollary 6.5 below.

Pushing the issue further, we might ask whether for a random sequence R it is at least possible to recover some of the values $R(x)$ from the values $R(y)$ with $y \neq x$. Trivially, this is possible for finitely many places x, so let us consider the case of infinitely many x. For the moment, call a sequence X *i.o. autoreducible* if there is an effective procedure that for infinitely many inputs x computes $X(x)$ while having access to the values $X(y)$ for $y \neq x$, whereas for all other inputs the procedure eventually signals that it cannot compute the correct value. For example, any sequence that, if viewed as a set, has an infinite computable subset is i.o. autoreducible; hence, in particular, any sequence that corresponds to an infinite computably enumerable set is i.o. autoreducible. Observe that by a standard diagonalization argument of finite extension type, one can easily construct a sequence that is computable in the halting problem and is not i.o. autoreducible.

For an i.o. autoreducible sequence R there are infinitely many places x where the value of $R(x)$ depends in an effective way on the remainder of the sequence R. On first sight, the situation looks rather similar to the case of an autoreducible sequence, and indeed it is tempting to assume that random sequences cannot be i.o. autoreducible. So the following result is somewhat surprising. *Every* p-random sequence is i.o. autoreducible by a reduction procedure that runs in polynomial time. This and related results are demonstrated in section 5. In the remainder of this section, we give formal definitions for various concepts of autoreducibility.

Recall the concept of an *oracle Turing machine* [11], which is a Turing machine that during its computation has access to a sequence X, the oracle. In case an oracle Turing machine M eventually terminates on input x and with oracle X, let $M(X, x)$ denote the computed value and, otherwise, i.e., if M does not terminate, say that $M(X, x)$ is undefined. But rather than use standard oracle machines M whose defined outputs $M(X, x)$ belong to $\{0, 1\}$, we also allow the machines to output a special "don't-know-symbol" $\perp$, which has the intended meaning of signaling that the correct value is not known.

DEFINITION 4.1. *Let M be an oracle Turing machine (with output in $\{0, 1, \perp\}$), and let A, B, and E be sequences. Then M* reduces *A to B on E if and only if*

(i) $M(B, x) = A(x)$ *for all x, where $M(B, x) \neq \perp$, and*
(ii) $M(B, x) \neq \perp$ *for all $x \in E$.*

If an oracle Turing machine M reduces a sequence A to a sequence B on an infinite set, we say that M *infinitely often reduces* or, for short, *i.o. reduces* A to B. If M reduces A to B on the set of all words, we say that M *reduces* A to B. Obviously, the latter notion coincides with the usual concept of reduction by a $\{0, 1\}$-valued oracle Turing machine, where it is required that $M(B, x)$ agrees with $A(x)$ for all x.

DEFINITION 4.2. *Let M be an oracle Turing machine, let A be a sequence, and let E be a set. The set of query words occurring during the computation of M on input x and with oracle A is denoted by* $\mathrm{Q}(M, A, x)$.

The sequence A is autoreduced on set E by M *if M reduces the sequence A to itself on E and $x \notin \mathrm{Q}(M, A, x)$ for all x. The sequence A is* i.o. autoreduced *by M if A is autoreduced by M on an infinite set. The sequence A is* autoreduced *by M if A is autoreduced by M on the set of all words.*

Next we define concepts of autoreducibility that correspond to the standard effective reducibilities considered in recursion theory [42] and to the standard reducibilities computable in polynomial time considered in complexity theory [11]. More precisely, for

$$r \in \{\mathrm{T}, \mathrm{tt}, \mathrm{btt}, \mathrm{btt}(k), \text{p-T}, \text{p-tt}, \text{p-btt}, \text{p-btt}(k)\},$$

we define the concepts of r-autoreducibility on a set E, of i.o. r-autoreducibility, and of r-autoreducibility.

For a start, we consider Turing- or, for short, T-autoreducibility. A sequence is *T-autoreducible on E* if it can be autoreduced on E by some oracle Turing machine M. A sequence is *i.o. T-autoreducible* if it is T-autoreducible on an infinite set, and a sequence is *T-autoreducible* if it is T-autoreducible on the set of all words.

The definitions for the remaining cases are basically the same; however, the oracle Turing machine M that performs the autoreduction has to, in addition, satisfy certain requirements. In particular, in the following M must always be total; i.e., on all inputs and for all oracles, M must eventually finish its computation. In the case of *truth-table autoreducibility* (tt), M has to ask its queries nonadaptively; i.e., M computes a list of queries that are asked simultaneously, and, after receiving the answers, M is not allowed to access the oracle again. In the case of *bounded truth-table autoreducibility* (btt), the queries have to be asked nonadaptively, while the number of queries that might be asked on a single input is bounded by a constant. Even more restrictive, in the case of *btt(k)-autoreducibility* the number of nonadaptive queries is bounded by the fixed constant k. The concepts of *polynomial time-bounded autoreducibility* like p-T- or p-tt-autoreducibility are defined accordingly where it is required in addition that M runs in polynomial time.

We conclude this section with some technical remarks on the representation of oracle Turing machines. By definition, tt-autoreductions are performed by total oracle Turing machines that query the oracle nonadaptively. Such an oracle Turing machine can be conveniently represented by a pair of computable functions g and h where $g(x)$ gives the set of words queried on input x and $h(x)$ specifies how the answers to the queries in the set $g(x)$ are evaluated; i.e., $h(x)$ tabulates a $\{0, 1, \perp\}$-valued function over $|g(x)|$ variables. In this situation we refer to $h(x)$ as a truth-table. Likewise, oracle Turing machines that witness a p-btt-autoreduction can be represented by pairs of functions g and h that are computable in polynomial time (whereas in general this is not possible for p-tt-autoreductions because the size of the corresponding truth-tables may be exponential in the input length).

REMARK 4.3. *Alternative to the $\{0, 1, \perp\}$-valued oracle Turing machine model, one could use the standard model, in that rather than output "don't-know," the Turing machine would simply query the oracle about the value of x and output that value. This formulation was originally used by Ebert* [19]*; a similar model is used by Arslanov* [8]*, with different notation and in the special case of a weak truth-table reduction that infinitely often queries the oracle only at places strictly less than the current input.*

We emphasize that the results of this paper hold for both the $\{0,1,\perp\}$-valued and the standard model; the main motivation for adopting the former is that it complies better with the usual classification of reducibilities according to whether they query the oracle adaptively or nonadaptively; i.e., the definitions of the various concepts of i.o. autoreducibility of truth-table type preserve the idea of accessing the oracle only once.

5. Autoreductions of random sequences. Next we apply the solution of the hat problem as discussed in section 2 to the construction of i.o. autoreductions of rec-random sequences.

THEOREM 5.1. *Every rec-random sequence is i.o. tt-autoreducible.*

Proof. Fix any rec-random sequence R. Partition the natural numbers into consecutive intervals $I_1, I_2, \ldots$ where I_k has size $l_k = 2^k - 1$. Write R in the form

$$R = w_1 w_2 \ldots \qquad \text{where for all } k, \quad |w_k| = l_k \ ;$$

i.e., w_k is the word associated with the restriction of R to I_k. Furthermore, for every $k > 0$ fix a perfect one-error-correcting code C_k of codeword length l_k such that given x, we can decide in polynomial time whether x is in one of the codes C_k.

In a nutshell, the proof of Theorem 5.1 works as follows. The code words in C_k comprise such a small fraction of all words of length l_k that in case infinitely many words w_k were in C_k there would be a computable betting strategy that succeeds on R. But R is assumed to be rec-random; hence w_k is not in C_k for almost all k. Then in order to construct an oracle Turing machine that witnesses that R is i.o. tt-autoreducible, we handle the intervals I_k individually and when working on I_k, we simulate the solution of the hat problem with l_k players. This way we can compute $R(x)$ for a single place x in I_k whenever w_k is not in C_k. But the latter is the case for almost all k; thus we are able to autoreduce R as required. Details follow.

CLAIM 1. *For almost all k, w_k is not in C_k.*

Proof. Consider the following betting strategy. For every $k > 0$, a portion $a_k = 1/2^k$ of the initial capital 1 is exclusively used for bets on words in the interval I_k. On each interval I_k, the betting strategy follows the strategy described in Remark 3.6, where C_k plays the role of Θ; i.e., the capital a_k is bet on the event that (the word associated with) the restriction of the unknown sequence to I_k is in C_k. By construction, just a fraction of $a_k = 1/(l_k + 1)$ of all words of length l_k belongs to C_k; hence the capital a_k increases to 1 for all k such that the restriction of the unknown sequence to I_k is in C_k. As a consequence, the betting strategy succeeds on any sequence such that for infinitely many k, the restriction of the sequence to the interval I_k is an element of C_k. But no computable betting strategy can succeed on the rec-random sequence R; hence Claim 1 follows. □

Observe that the proof of Claim 1 depends on the choice of the l_k only insofar as it is required that the sum over the a_k, where $a_k = 1/(l_k + 1)$, converges.

Next we define an oracle Turing machine M that witnesses that R is i.o. tt-autoreducible. By Claim 1, fix k_0 such that w_k is not in C_k for all $k > k_0$. On inputs in the intervals I_1 through I_{k_0}, M simply outputs $\perp$. On any input x in an interval I_k with $k > k_0$, M queries the oracle nonadaptively on all words in I_k that are different from x. Thereby M determines two words, u' and u'', and knows that w_k is equal to one of the words

$$v_0 = u'0u'' \quad \text{and} \quad v_1 = u'1u'' \ ,$$

where the uncertainty is with respect to the value of $R(x)$. Then M outputs i in case $v_{1-i} \in C_k$ and $v_i \notin C_k$, and, otherwise, i.e., if neither v_0 nor v_1 is in C_k, M outputs $\perp$.

By construction, M is computable, queries its oracle nonadaptively, and never queries its oracle at the input. On intervals I_k with $k \leq k_0$, M always outputs $\perp$. On any interval I_k with $k > k_0$, M simulates the strategy for the hat problem with l_k players from Remark 2.6 where C_k is the set of designated words. For any such interval, w_k is not in C_k by choice of k_0; hence the discussion in section 2 shows that M computes the correct value $R(x)$ at the single input x in the interval at which w_k differs from the closest code word in C_k, while M outputs $\perp$ for all other inputs in the interval. In summary, M i.o. tt-autoreduces R. □

Subsequently, the statement of Theorem 5.1 will be strengthened in various ways. As an immediate improvement, we note that the proof of Theorem 5.1 can be adjusted in order to obtain the following stronger but also more technical version of the theorem. Given a computable function t, we call a sequence *$t(m)$-random* if no betting strategy that is computable in time $\mathrm{O}(t(m))$ succeeds on this sequence, where m denotes the length of the prefix of the unknown set that a betting strategy receives as input.

THEOREM 5.2. *Let $q\colon \mathbb{N} \to \mathbb{N}$ be an unbounded and nondecreasing computable function. Every m^2-random sequence is i.o. tt-autoreducible by an oracle Turing machine M that on inputs of length n runs in time $\mathrm{O}(n)$ and asks at most $q(n)$ queries.*

Proof. The proof of Theorem 5.2 is rather similar to the proof of Theorem 5.1. We just indicate the necessary adjustments. Recall that the i.o. tt-autoreductions, as well as the betting strategy in the proof of Theorem 5.1 are built up from modules that work essentially independently on the intervals I_j. The key trick in the proof of Theorem 5.2 is to shift the intervals such that the length of the words contained in them are considerably larger than the length of the corresponding interval. More precisely, the interval I_k contains the first l_k words of length n_k, where the sequence $n_0, n_1, \ldots$ is chosen such that we have for all k,

$$\text{(i) } 2^{n_k} < n_{k+1}\ , \qquad \text{(ii) } 2^{l_k} < n_k\ , \qquad \text{(iii) } l_k < q(n_k).$$

In addition, we assume that there is a Turing machine that on input 1^n uses at most n steps to decide whether n appears in the sequence $n_0, n_1, \ldots$ and if so to compute the index k with $n = n_k$. Such a sequence can be obtained by standard methods as described in the chapter on uniform diagonalization and gap languages in Balcázar, Díaz, and Gabarró [11]. For example, we can first define a sufficiently fast growing time-constructible function $r : \mathbb{N} \to \mathbb{N}$ and then let n_i be the value of the i-fold iteration of r applied to 0.

Similar to Claim 1 in the proof of Theorem 5.1, we can argue that for any m-random sequence R and for almost all k, the restriction w_k of R to the interval I_k is not in the code C_k. Otherwise, there would be a betting strategy similar to the one used in the proof of the mentioned claim that wins on R; i.e., on any interval I_k the strategy bets a fraction of $1/2^k$ of its initial capital on the event that w_k is in C_n. By choice of the n_k, this strategy can be chosen to run in time m^2. Recall in connection with this time bound that the individual bets are specified as a fraction of the current capital; hence placing the bets related to interval I_k requires computing the outcomes of the bets on the previous intervals.

The sequence R is then i.o. tt-autoreducible by a reduction that simulates the solution to the hat problem on every interval I_k where w_k is not in C_k. On an input of length n, this reduction runs in time n and asks at most $q(n)$ queries because of (ii) and (iii), respectively. □

For a proof of the following corollary it suffices to observe that p-random sequences are in particular m^2-random, while every m^2-random sequence in turn is i.o. tt-autoreducible in polynomial time according to Theorem 5.2.

COROLLARY 5.3. *Every p-random sequence is i.o. p-tt-autoreducible.*

The next theorem shows that neither Theorems 5.1 and 5.2 nor Corollary 5.3 extends to i.o. btt-autoreducibility; i.e., the proofs of these results require oracle Turing machines that ask an unbounded number of queries.

THEOREM 5.4.

(a) *No rec-random sequence is i.o. btt-autoreducible.*

(b) *No p-random sequence is i.o. p-btt-autoreducible.*

Proof. (a) Fix any sequence A that is i.o. btt-autoreducible. It suffices to show that A is not rec-random, i.e., that there is a computable betting strategy b that succeeds on A.

Among all oracle Turing machines $M = (g, h)$ that i.o. btt-autoreduce A, we will consider only the ones that are *normalized* in the sense that the set of queries $g(x)$ is empty whenever the truth-table $h(x)$ is constant (i.e., whenever $h(x)$ evaluates to the same value for all assignments on $g(x)$). Furthermore, among all normalized oracle Turing machines that i.o. btt-autoreduce A, let $M = (g, h)$ be one such that its norm

$$l = \sup_{x \in \{0,1\}^*} |g(x)|$$

is minimum. In case $l = 0$, M is independent of the oracle, and we can compute $A(x)$ for the infinitely many places x where the reduction does not yield $\perp$; hence A is not rec-random, and we are done. So assume $l > 0$.

For any word x, there is a word $r(x) > x$ such that $g(r(x))$ has size l and contains only words strictly larger than x. Assuming otherwise, by hard-wiring $A(z)$ into M for all $z \leq x$ and for all z that are contained in one of the sets $g(y)$ with $y \leq x$, we would obtain an oracle Turing machine that again btt-autoreduces A and has norm strictly smaller than M, thus contradicting the choice of M. Let x_1 be the least word x such that $g(x)$ has size l and for $s > 1$, let

$$x_{s+1} = r(\max J_s) \quad \text{where} \quad J_s = \{x_s\} \cup g(x_s)\ .$$

By choice of r, this inductive definition yields an infinite sequence $x_1, x_2, \ldots$ such that the function $s \mapsto x_s$ is computable, the sets J_s all have size $l + 1$, and any element of J_s is less than any element in J_{s+1}.

Consider an arbitrary index s. Then $h(x_s)$ is not constant because $g(x_s)$ has size $l > 0$ and M is normalized. Thus there is an assignment on $g(x_s)$ such that $h(x_s)$ evaluates to a value different from $\perp$. Let α be the least such assignment, and let i_s be the value obtained by applying the truth-table $h(x_s)$ to α. Extend α to an assignment α_s on the set J_s where $\alpha_s(x_s) = 1 - i_s$. Observe that J_s and α_s can be computed from s.

We construct now a computable betting strategy b that succeeds on A. The construction is based on the observation that for all s, the restriction of A to J_s differs from α_s. Otherwise, $M(A, x_s) = i_s$ would differ from $A(j_s) = 1 - i_s$ and M would not autoreduce A.

The betting strategy b can be viewed as working in stages $s = 1, 2, \ldots$. The bets of stage s are all on places in J_s and use the capital accumulated until the beginning of stage s for betting against the event that the restriction of the unknown sequence to J_s is equal to α_s. Formally, the bets at stage s are performed according to the

strategy described in Remark 3.6 where $\Theta = \Theta_s$ contains all assignments on J_s that differ from α_s. The size of J_s is $l+1$; hence there are 2^{l+1} assignments to J_s, and Θ_s contains a fraction of

$$\delta = \frac{2^{l+1}-1}{2^{l+1}}$$

of all assignments on J_s. As a consequence, if the unknown sequence is indeed A, then the capital increases by the constant factor $1/\delta > 1$ during each stage s; hence b succeeds on A.

(b) Fix any sequence A that is i.o. p-btt-autoreducible. Again it suffices to show that A is not p-random, i.e., that there is a betting strategy b that is computable in polynomial time and succeeds on A. The ideas underlying the construction of b are similar to the ones used in the proof of assertion (a). The remaining differences relate to the fact that b now has to be computable in polynomial time and hence cannot perform an essentially unbounded search for places where the reduction does not yield $\perp$.

Fix an oracle Turing machine $M = (g, h)$ that p-btt-autoreduces A. For the scope of this proof, given a word w, we write x_w for $s_{|w|}$; i.e., if w is viewed as prefix of a sequence X, then x_w is the first word y such that $X(y)$ is not encoded into w. Furthermore, we write m_w and n_w for the length of w and of x_w. For any word w, let M_w be defined by

$$M_w(X, x) = M(\langle X, w\rangle, x);$$

i.e., in order to obtain M_w, the word w is hard-wired into M by overwriting the length m_w prefix of the oracle by w. For all words w, let

$$J(w) = \{x_w\} \cup \{z : z \in g(x_w) \text{ and } x_w < z\}.$$

For the scope of this proof, call a word w *promising* if $M_w(X, x_w) \neq \perp$ for some sequence X. For any promising word w, among all such sequences X let $X(w)$ be the one such that the restriction of X to $J(w) \setminus \{x_w\}$ is minimum, and let γ_w be the corresponding restriction. Let $i(w) = M_w(X(w), x_w)$, and extend γ_w to an assignment α_w on $J(w)$ by letting $\alpha_w(x_w) = 1 - i(w)$. Similar to the proof of the first assertion we can argue that for any promising prefix w of A, the restriction of A to $J(w)$ differs from α_w because otherwise M did not i.o. btt-autoreduce A.

We construct now a betting strategy b that is computable in polynomial time and succeeds on A. Define a partition $I_0, I_1, \ldots$ of the set of all words by

$$I_s := \{x : d(s) \leq |x| < d(s+1)\} \quad \text{where } d(0) = 1,\ \ d(s+1) = 2^{d(s)}.$$

There are infinitely many promising prefixes of A because in particular any prefix w of A where $M(A, x_w) \neq \perp$ is promising. In what follows we assume that there are infinitely many promising prefixes w of A such that x_w is contained in one of the even intervals $I_0, I_2, \ldots$, and we omit the virtually identical considerations for the symmetrical case where there are infinitely many promising prefixes w where x_w is contained in an odd interval.

The betting strategy b works similarly to the one used in the proof of assertion (a), and we leave the details of its construction and verification to the reader. By definition of the intervals I_i, we can pick an index s_0 such that for all $s > s_0$ and for all w with x_w in I_{2s}, the set $J(w)$ is contained in the double interval $I_{2s} \cup I_{2s+1}$. During stage s,

the betting strategy b bets on words in this double interval as follows. If $s \leq s_0$ or if there is no promising prefix v of the current input w such that x_v is in I_{2s}, abstain from betting. Otherwise, let v_s be the shortest promising prefix of w such that x_v is in I_{2s}, and bet against the event that the restriction of the unknown sequence to $J(v_s)$ is equal to α_{v_s}. In case the unknown sequence is indeed A, there are infinitely many stages where the otherwise case applies, and, during each such stage, the capital increases at least by some constant positive factor. □

The proof of Theorem 5.4 actually shows that any i.o. p-btt-autoreducible sequence can be covered by an m^2-martingale. By standard techniques [6], one can construct an m^3-martingale that covers all sequences that are covered by an m^2-martingale; hence the class of i.o. p-btt-autoreducible sequences has measure 0 with respect to betting strategies that are computable in polynomial time.

REMARK 5.5. *Theorem* 5.4 *extends by essentially the same proof to truth-table reducibilities that may ask an arbitrary number of queries that are strictly less than the current input with respect to length-lexicographical ordering plus a constant number of strictly larger queries.*

6. A sharp bound on the density of guessed bits. From Theorem 5.1 we know that every random sequence is i.o. autoreducible. An interesting problem involves finding lower and upper bounds to the frequency at which computable autoreductions may yield bits of a random sequence.

DEFINITION 6.1. *For all $m > 0$, the* density $\rho(E, m)$ *of a set E up to m is defined by*

$$\rho(E, m) \;=\; \frac{|E \cap \{\mathrm{s}_0 \ldots \mathrm{s}_{m-1}\}|}{m}\,. \tag{6.1}$$

An oracle Turing machine M i.o. T-autoreduces a sequence X with density $r(m)$ *if M i.o. T-autoreduces X on a set E such that $\rho(E, m) \geq r(m)$ for all $m > 0$ (i.e., the density of the set of words x such that M guesses $X(x)$ is always at least $r(m)$).*

A sequence A is called i.o. T-autoreducible with density $r(m)$ *if there is some oracle Turing machine that i.o. T-autoreduces A with density $r(m)$. Concepts like* i.o. tt-autoreducible with density $r(m)$ *are defined in the same manner.*

Thus, autoreducibility with density $r(m)$ measures the density of the guessed bits of an autoreduced sequence A in the sense that the ratio of guessed bits to bits considered is at least $r(m)$. It should be noted that the concept of density is sort of inverse to the previous concept of *rate* [19], where an autoreduction has rate $r(m)$ if the mth place guessed is not larger than $\mathrm{s}_{r(m)}$.

We now study the question of what is the highest density a reducibility may achieve with random sequences of a certain type. A lower bound on the achievable density is easily obtained from the proof of Theorem 5.1, by noting that the autoreductions employed there obtain densities that depend on the length of the codewords in the employed error-correcting codes. In Example 6.2, we state corresponding bounds that are obtained by choosing the lengths of the codewords according to specific converging sums. Afterwards, in Theorem 6.6, we improve on this bound by elaborating the proof of Theorem 5.1.

EXAMPLE 6.2. *Fix any rec-random sequence R. Let $j_1, j_2, \ldots$ be any nondecreasing computable sequence such that*

$$\sum_{k=0}^{\infty} \frac{1}{l_k} \;<\; \infty \qquad \text{where } l_k = 2^{j_k} - 1 > 0.$$

Then also the sum over the $\frac{1}{l_k+1}$ *converges; hence as in the proof of Theorem* 5.1 *we can find perfect one-error-correcting codes* C_k *of codeword length* l_k *such that the sequence* R *can be written as* $w_1 w_2 \dots$ *where each word* w_k *has length* l_k *and almost all* w_k *are not in* C_k*. Moreover, by hard-wiring finitely many bits of* R *plus applying the solution of the hat problem to the words* w_k*, we obtain an autoreduction of* R *which guesses exactly one bit of each of the words* w_k*. In this situation, let* E *be the set of the bits that are guessed correctly, and let* $\rho(E, m)$ *be the density of* E *defined in* (6.1)*.*

We aim at deriving upper and lower bounds for $\rho(E, m)$*. If we let* $i(m)$ *be the maximum index* i *such that* $a_i = l_1 + \cdots + l_i \leq m$*, then by construction for all* m *we have*

$$\frac{i(m)}{m} \leq \rho(E, m) \leq \frac{i(m)+1}{m}\ ; \tag{6.2}$$

i.e., in order to bound $\rho(E, m)$ *it suffices to bound* $i(m)$*.*

If, as in the proof of Theorem 6.6*, we let* $l_k = 2^k - 1$*, then accordingly* a_i *is equal to* $2^{i+1} - i - 2$*, and* $i(m)$ *and* $\rho(E, m)$ *are approximately* $\log m$ *and* $\log m/m$*, respectively. In order to improve on this density, we might try to use values for* l_k *that grow slower. If we fix* $\delta > 1$*, the sum* $\sum 1/(k \log^\delta k)$ *converges; hence we might choose* l_k *as the least number of the form* $2^j - 1$ *that is greater than or equal to* $k \log^\delta k$*. Some easy calculations, which are left to the reader, show that for almost all* i*, we have* $i^2 \leq a_i \leq i^{2.001}$*; thus, by* $a_{i(m)} \leq m \leq a_{i(m)+1}$*,*

$$i(m)^2 \leq m \leq (i(m)+1)^{2.001} \leq i(m)^{2.002}\ ; \quad \textit{hence} \quad m^{\frac{1}{2.002}} \leq i(m) \leq m^{\frac{1}{2}}\ .$$

By (6.2)*, for almost all* m *the density* $\rho(E, m)$ *is between* $m^{\frac{1}{2.002}}/m$ *and* $m^{\frac{1}{2}}/m$*; i.e., the achieved density is approximately equal to* $1/\sqrt{m}$*.*

In what follows, we prove something much stronger than the result from Example 6.2, namely, that for any computable function r that goes nonascendingly to 0, any rec-random sequence is i.o. truth-table-autoreducible with density $r(m)$. This result is consummately complemented by our next theorem, which shows that rec-random sequences are never i.o. truth-table-autoreducible with positive constant density (i.e., with density $r(m) = \varepsilon m$ for some $\varepsilon > 0$) and that a similar assertion holds with respect to Martin-Löf random sequences and i.o. Turing autoreducibility.

THEOREM 6.3.

(a) *No rec-random sequence is i.o. tt-autoreducible with positive constant density.*

(b) *No Martin-Löf random sequence is i.o. T-autoreducible with positive constant density.*

Proof. Assertions (a) and (b) are proved by showing that if a sequence is i.o. autoreducible with constant density, then the sequence cannot be random. In both cases, the argument relies on Claims 1 and 2 below.

Fix an oracle Turing machine M and a rational $\varepsilon_0 > 0$. We want to show that if M i.o. autoreduces a sequence with density $\varepsilon_0 m$, then this sequence cannot be random; i.e., an appropriate betting strategy succeeds on this sequence. Recall that the cylinder generated by a word w is the class $w\{0,1\}^\infty$ of all sequences that extend w. We argue that for any w, the fraction of sequences in this cylinder that are i.o. autoreduced by M with density ε_0 is bounded by a constant $\delta < 1$, which does not depend on w. Let $\varepsilon = \varepsilon_0/2$, and for any $m > 0$ let

$$i(m) = \left\lceil \frac{m}{\varepsilon} \right\rceil\ , \qquad I(m) = \{\mathrm{s}_m, \dots, \mathrm{s}_{m+i(m)-1}\}; \tag{6.3}$$

that is, assuming $|w| = m$, the interval $I(m)$ contains the first $i(m)$ words that are not in the domain of w. For any sequence X and any finite set I, let

$$\begin{aligned} \text{correct}(X, I) &= |\{x \in I : M(X, x) = X(x)\}|, \\ \text{incorrect}(X, I) &= |\{x \in I : M(X, x) = 1 - X(x)\}|. \end{aligned}$$

That is, for all inputs x in I such that $M(X, x)$ is defined and differs from $\perp$, we count for how many of these inputs the guess $M(X, x)$ is correct and for how many it is incorrect. In the remainder of this proof and with M and ε understood from the context, we say a sequence X is consistent with a word w of length m if

(i) X is an extension of w,
(ii) for all x in $I(m)$, the value $M(X, x)$ is defined and is computed without querying the oracle at place x,
(iii) $\text{incorrect}(X, I(m)) = 0$,
(iv) $\text{correct}(X, I(m)) \geq \varepsilon |I(m)|$.

CLAIM 1. *If M i.o. T-autoreduces a sequence with density ε_0, then this sequence is consistent with any prefix of itself.*

Proof. Fix any sequence A that satisfies the assumption of the claim, and consider any prefix w of A. Then the conditions (i), (ii), and (iii) are satisfied by definition (recall that $M(A, x)$ is always defined in case M i.o. T-autoreduces A). If condition (iv) was false, then contrary to our assumption on A the oracle Turing machine M with oracle A would guess in the interval $I(m)$ and among the m smaller words in total strictly less than

$$m + \varepsilon |I(m)| \;\leq\; 2\,\varepsilon |I(m)| \;=\; \varepsilon_0 |I(m)| \tag{6.4}$$

bits, where the relations in (6.4) hold by (6.3) and by choice of ε. □

For any word w, let the sequence X_w be an extension of w that is obtained by the chance experiment where the bits of X_w that are not already determined by w are obtained by independent tosses of a fair coin. Let $\delta = 1/(1+\varepsilon)$, and observe that $\delta < 1$ due to $\varepsilon > 0$.

CLAIM 2. *For any word w, the probability that X_w is consistent with w is at most δ.*

Proof. Fix any word w of length m. The key observation in the proof of Claim 2 is the following. If we examine for all inputs x in $I(m)$ such that the value $M(X_w, x)$ is in $\{0, 1\}$ at all, whether this value is a correct guess in the sense that it agrees with $X_w(x)$, then the expected number of correct and incorrect guesses is the same; i.e.,

$$\mathbf{E}[\text{correct}(X_w, I(m))] \;=\; \mathbf{E}[\text{incorrect}(X_w, I(m))]\,. \tag{6.5}$$

For a proof, first consider a single input x in $I(m)$. The assignment to X_w at x and at the places different from x are stochastically independent; hence by (ii) the same holds for $X_w(x)$ and $M(X_w, x)$. Furthermore, since $X_w(x)$ is chosen uniformly from $\{0, 1\}$, it follows that the probability for a correct and for an incorrect answer at x are both exactly half of the probability that $M(X_w, x)$ is in $\{0, 1\}$. Hence also the expected number of correct and incorrect answers at x coincide, and (6.5) follows by linearity of expectation. Now we distinguish two cases.

Case I: $\mathbf{E}[\text{correct}(X_w, I(m))] \leq \delta\varepsilon |I(m)|$.

The random variable $\text{correct}(X_w, I(m))$ is nonnegative; hence the case assumption implies that the probability that $\text{correct}(X_w, I(m))$ is at least $\varepsilon |I(m)|$ is at most δ.

So also the probability that X_w is consistent with w is at most δ by condition (iv) in the definition of consistency.

Case II: $\mathbf{E}[\text{correct}(X_w, I(m))] > \delta\varepsilon|I(m)|$.

By (6.5), we also have $\mathbf{E}[\text{incorrect}(X_w, I(m))] > \delta\varepsilon|I(m)|$. The latter implies that the probability that $\text{incorrect}(X_w, I(m))$ is strictly larger than 0 is at least $\delta\varepsilon$ because by definition, the random variable $\text{incorrect}(X_w, I(m))$ is bounded by $|I(m)|$. Due to condition (iii), the probability that X_w is consistent is then at most

$$1 - \delta\varepsilon = 1 - \frac{\varepsilon}{1+\varepsilon} = \frac{1}{1+\varepsilon} = \delta\ . \tag{6.6}$$

The assertion of Claim 2 holds in both cases; hence the claim follows. □

Proof of (a). We can assume that M is in fact a tt-reduction, say, $M = (g, h)$. Fix any sequence A such that M i.o. tt-autoreduces A with density $r(m) = \varepsilon_0 m$. It suffices to show that A is not rec-random, and this is done by constructing a computable betting strategy that succeeds on A.

The set of all words is partitioned into consecutive intervals $J_0, J_1, \ldots$, where the cardinality of J_i is denoted by l_i (i.e., J_0 contains the first l_0 words, J_1 the next l_1 words, and so on). The J_i are defined via specifying the l_i inductively. For all i, let $m_i = l_0 + l_1 + \cdots + l_i$. Let $l_0 = 1$, and for all i choose l_{i+1} so large that the union of the intervals J_0 through J_{i+1} contains $I(m_i)$ as well as the query sets $g(x)$ for all x in $I(m_i)$. This way, for any word w of length m_i, the consistency with w of any sequence X that extends w depends only on the restriction of X to the interval J_{i+1}. Call an assignment on J_{i+1} consistent with such a word w if the assignment is the restriction of a sequence that is consistent with w. By Claims 1 and 2, for any given word w of length m_i the following assertions hold with respect to the assignments on J_{i+1}.

- If w is a prefix of A, then the assignment obtained by restricting A to J_{i+1} is consistent with w.
- The assignments that are consistent with w comprise a fraction of at most δ of all assignments.

Now consider the betting strategy that for each interval J_{i+1} uses the capital accumulated up to the first element of the interval in order to bet according to Remark 3.6 against all assignments on this interval that are not consistent with the already seen length m_i prefix of the unknown sequence. By the preceding discussion, in case the unknown sequence is indeed A, then on each interval b increases its capital at least by the constant factor $1/\delta > 1$; i.e., in this case b succeeds on A. Furthermore, the betting strategy b is computable since consistency of assignments can be decided effectively.

Proof of (b). For a given word w, let $\boldsymbol{E}_w$ be the class of all sequences that are consistent with w. For a word w of length $m \geq 1$, call a word u a consistent extension of w if for some sequence U,

- w is a prefix of u and u is a prefix of U, while U is consistent with w;
- the domain of u contains $I(m)$, and all queries that are made while computing $M(U, x)$ for any x in $I(m)$;
- for all x in $I(m)$, the computation of $M(U, x)$ terminates in at most $|u|$ steps.

Let $E(w)$ be the set of minimum consistent extensions of w (i.e., $E(w)$ contains any word if the word itself but none of its prefixes is a consistent extension of w). Then for any nonempty word w,

(i) $\boldsymbol{E}_w$ is the disjoint union of the cylinders generated by words in $E(w)$,

(ii) $\boldsymbol{E}_w$ comprises at most a fraction of δ of the cylinder generated by w,
(iii) $E(w)$ is computably enumerable in w.

Assertions (ii) and (iii) hold, respectively, due to Claim 2 and because for given w and u, it can be effectively checked whether u is a consistent extension of w. Concerning assertion (i), first observe that for any sequence in $\boldsymbol{E}_w$ all prefixes of sufficient length are consistent extensions of w. On the other hand, for any consistent extension u of w, the cylinder generated by u is a subclass of $\boldsymbol{E}_w$ because any sequence that extends u is consistent with w. Furthermore, by the minimality condition in the definition of $E(w)$, the words in $E(w)$ are mutually incomparable; hence the cylinders generated by these words are mutually disjoint.

Let $\boldsymbol{C}$ be the class of all sequences that are i.o. T-autoreduced by M with density ε_0. We conclude the proof of assertion (b) by constructing a Martin-Löf null cover for $\boldsymbol{C}$. Let $V_0 = \{0, 1\}$, and for all $i \geq 0$, let

$$V_{i+1} \quad = \quad \bigcup_{w \in V_i} E(w) \, .$$

Then the sets V_i are uniformly computably enumerable; i.e., $V_i = \mathrm{W}_{h(i)}$ for some computable function h. Using (i) and the fact that any sequence in this class is consistent with all of its prefixes, an induction argument shows that for all i the class $\boldsymbol{C}$ is contained in the union of the cylinders generated by the words in $\mathrm{W}_{h(i)}$. Furthermore, another induction argument, which uses (ii) in the induction step, shows that the union of the cylinders generated by $\mathrm{W}_{h(i)}$ has measure of at most δ^i. So if we fix a constant c such that δ^c is at most $1/2$, then $\mathrm{W}_{h(ci)}$ has measure at most $1/2^i$. In summary, $\mathrm{W}_{h(c0)}, \mathrm{W}_{h(c1)}, \ldots$ is a Martin-Löf null cover for $\boldsymbol{C}$. □

The concept of density can be relativized to an infinite subset Z of all words; i.e., we might say an oracle Turing machine M i.o. T-autoreduces a given sequence with *density $r(m)$ relative to Z* if the fraction of guessed bits among the first m words in Z is always at least $r(m)$. By a straightforward adaptation of the proof of Theorem 6.3, it is possible to demonstrate Corollary 6.4, from which Corollary 6.5 can be obtained as a special case.

Corollary 6.4.

(a) *No rec-random sequence is i.o. tt-autoreducible with positive constant density relative to an infinite computable set.*
(b) *No Martin-Löf random sequence is i.o. T-autoreducible with positive constant density relative to an infinite computable set.*

Corollary 6.5.

(a) *No rec-random sequence is i.o. tt-autoreducible on a computable set.*
(b) *No Martin-Löf random sequence is i.o. T-autoreducible on a computable set.*

Trakhtenbrot [44] observed that no Kolmogorov–Loveland stochastic sequence [27, 32] is T-autoreducible, and his argument easily extends to i.o. T-autoreducibility on a computable set; from the latter, assertion (b) in Corollary 6.5 is immediate, because the Martin-Löf random sequences form a proper subclass of the Kolmogorov–Loveland stochastic sequences.

The "negative" assertions in Theorem 6.3 and Corollaries 6.4 and 6.5 are complemented by the two following "positive" assertions due to Merkle and Mihailović [34]. There are rec-random sequences that are weak truth-table-autoreducible. There are Martin-Löf random sequences that are self-reducible with respect to the reducibility *being computably enumerable in*, where self-reducible means autoreducible while asking only queries that are less than the current input with respect to length-lexicographical ordering.

Apparently, the arguments used in this section do not carry over to show that p-random sequences cannot be p-T- or p-tt-autoreducible; in fact, the latter assertion relates to major open problems in complexity theory. These relations are implicit in the work of Buhrman et al. [16], from which, among others, the two following implications are immediate. First, if there are p-random sequences that are p-tt-autoreducible, then the complexity classes **MA** and **EXP** are the same. Second, if no p-random sequence is p-tt-autoreducible, then the complexity classes **BPP** and **EXP** differ. The first implication is immediate by the result of Buhrman et al. that **MA** $\neq$ **EXP** implies that the p-tt-autoreducible sequences have measure 0 with respect to polynomial-time computable betting strategies. For a proof of the second implication assume that **BPP** = **EXP**. By a result of Allender and Strauss [1], any p-random sequence is p-tt-complete for **BPP**. But **EXP** contains p-random sequences; hence by our assumption some p-random sequence is p-tt-complete for **EXP**. The assertion now follows by the result of Buhrman et al. that **BPP** = **EXP** implies that all p-tt-complete sequences for **EXP** are p-tt-autoreducible.

Recall the negative result on constant bounds in Theorem 6.3; i.e., a rec-random sequence cannot be i.o. tt-autoreduced with constant positive density. This result is essentially matched by Theorem 6.6, which states that for any computable, rational-valued function r that goes nonascendingly to 0, every rec-random sequence is i.o. tt-autoreducible with density $r(m)$.

THEOREM 6.6. *Let $g\colon \mathbb{N} \to \mathbb{N}$ be any computable function that is unbounded and nondecreasing. Then every rec-random sequence is i.o. tt-autoreducible with density $r(m) = 1/g(m)$.*

Proof. Fix any rec-random sequence R. It suffices to show that R is i.o. tt-autoreducible with density $r(m)$ by some oracle Turing machine M. For every $k > 0$, let

$$l_k = 2^k - 1 \, .$$

For further use, fix perfect one-error-correcting codes C_k of codeword length l_k such that given x, we can decide effectively whether x is in one of the codes C_k. The function g is computable and unbounded; thus we can define a computable sequence of numbers $t_0 < t_1 < \cdots$, where $g(t_k) \geq l_{k+1}$, and hence

$$r(t_k) \;\leq\; \frac{1}{l_{k+1}} \, .$$

For every $k > 0$, partition the set of all words into consecutive intervals $J_k^1, J_k^2, \ldots$ of length l_k; i.e., J_k^1 contains the first l_k words, J_k^2 contains the next l_k words, and so on. Let c_k be minimum such that the $(t_k{+}1)$th word s_{t_k} is in $J_k^{c_k}$, and let

$$H_k = J_k^2 \cup \cdots \cup J_k^{c_k} \, .$$

We construct M from oracle Turing machines $M_1, M_2, \ldots$, which we refer to as modules. Intuitively, module k is meant to ensure density $1/l_k$ in the interval between s_0 and s_{t_k}. Before defining the modules, we describe their properties and how they are combined to form M.

Module k never queries any place outside the set $J_k^1 \cup H_k$ and outputs $\perp$ on all inputs that are not in H_k. Furthermore, on oracle R, module k never makes a wrong guess and guesses exactly one bit in each of the intervals J_k^2 through $J_k^{c_k}$. In addition, we will ensure that the M_k are uniformly effective in the sense that there is an oracle

Turing machine M_0 such that the values $M_k(x, X)$ and $M_0(\langle x, k\rangle, X)$ are always either both undefined or both defined and identical.

Then M is obtained by running the modules in parallel as follows. For input x, if x is equal to s_0 or s_1, then M just outputs $R(x)$. Otherwise, M determines the finitely many k such that $x \in H_k$ and simulates the corresponding modules with input x and the current oracle. If any of these modules outputs a value different from $\perp$, then M outputs the value output by the least such module; otherwise, M outputs $\perp$. Assuming the properties of the modules stated so far, we can already prove that M works as required.

Claim 1. *The oracle Turing machine M i.o. tt-autoreduces the sequence R with density $r(m)$.*

Proof. From the module assumptions, it is immediate that M is computable and that M queries its oracle nonadaptively and never queries the oracle at the current input. Moreover, on oracle R, all guesses of the modules and hence all guesses of M are correct.

Let E be the set of all inputs x such that $M(R, x)$ differs from $\perp$. Fix k and assume that m is in J_k^1 through $J_k^{c_k}$. Then we have

$$\rho(E, m) \geq 1/l_k \ . \tag{6.7}$$

This follows because M guesses the first two bits, while module k and hence M guess at least one bit in every interval except the first one, where the intervals have length l_k. So if m is in interval J_k^j, up to m there are at most jl_k words and at least j guesses; hence the density up to m is at least $1/l_k$, and (6.7) holds.

In order to prove $\rho(E, m) \geq r(m)$, fix any m and choose k such that $t_{k-1} \leq m < t_k$. Then we have

$$\rho(E, m) \geq \frac{1}{l_k} \geq r(t_{k-1}) \geq r(m) \ , \tag{6.8}$$

where the inequalities follow because m is in J_k^1 through $J_k^{c_k}$, and hence (6.7) applies, by choice of t_{k-1}, and since r is nonascending. ∎

In order to construct modules that have the required properties, let w_k^j be the restriction of R to J_k^j; i.e.,

$$R = w_k^1 w_k^2 \ldots, \quad \text{where } |w_k^j| = l_k, \text{ and let} \quad w_k = w_k^1 \oplus \cdots \oplus w_k^{c_k} \ ,$$

where $\oplus$ is bit-wise exclusive-or. The idea underlying the construction of the modules is as follows. The code words in C_k comprise such a small fraction of all words of length l_k that in case infinitely many words w_k were in C_k, there would be a computable betting strategy that succeeds on R. But R is assumed to be rec-random; hence w_k is not in C_k for almost all k. So in order to guess bits of w_k and then also of w_k^1 through $w_k^{c_k}$, we can apply the solution to the hat problem described in Remark 2.6.

Claim 2. *For almost all k, w_k is not in C_k.*

Proof. Suppose we bet on the bits of an unknown sequence X. Similar to the definition of w_k, let v_k^j be the restriction of X to the interval J_k^j, and let v_k be equal to $v_k^1 \oplus \cdots \oplus v_k^{c_k}$. Recall that C_k contains a fraction of $a_k = 1/2^k$ of all words of length l_k, and observe that the mapping

$$o_k \colon u \mapsto v_k^1 \oplus \cdots \oplus v_k^{c_k - 1} \oplus u$$

is a bijection of $\{0,1\}^{l_k}$. Thus o_k maps just a fraction of a_k of all length l_k words to C_k. When betting on the places in $J_k^{c_k}$, we have already seen v_k^1 through $v_k^{c_k-1}$. Under the assumption that v_k is in C_k, we can exclude all but a fraction of $1/a_k$ of the possible assignments on $J_k^{c_k}$, and hence, by betting in favor of these assignments according to Remark 3.6, we can increase our capital by a factor of $1/a_k$ in case the assumption is true.

Now consider the following betting strategy. For every k, a portion of a_k of the initial capital 1 is exclusively used for bets on the the interval $J_k^{c_k}$. On each such interval, the bets are in favor of the a_k-fraction of assignments that o_k maps to C_k. Then the capital a_k increases to 1 for all k such that v_k is in C_k, and consequently the betting strategy succeeds on any sequence such that the latter occurs for infinitely many k. But no computable betting strategy can succeed on the rec-random sequence R; hence Claim 2 follows. We leave it to the reader to show that this strategy is indeed computable. Observe in this connection that each word is contained in at most finitely many intervals of the form $J_k^{c_k}$, and consequently at most finitely many of the strategies related to these intervals might act in parallel. □

It remains to construct the modules. By Claim 2, fix k_0 such that w_k is not in C_k for all $k > k_0$. First assume $k \leq k_0$. Consider the least elements of the intervals J_k^2 through $J_k^{c_k}$ and for all these x, hard-wire $R(x)$ into module k. On all these x, module k outputs $R(x)$, while the module outputs $\perp$ on all other inputs.

Next assume $k > k_0$. On inputs that are not in H_k, module k simply outputs $\perp$. Now consider an input x in H_k, and suppose that

$$x \text{ is element } i_0 \text{ of interval } J_k^{j_0}, \quad 0 \leq i_0 < l_k, \;\; 2 \leq j_0 \leq c_k \; .$$

For the given oracle X, define v_k and the v_k^j as in the proof of Claim 2; i.e., v_k^j is the restriction of X to J_k^j, and v_k is the bit-wise exclusive-or of the v_k^j. Then on input x, module k queries its oracle at the remaining words in $J_k^1 \cup H_k$; i.e., the module obtains all bits of the words

$$v_k^j = v_k^j(0)\, v_k^j(1) \, \ldots \, v_k^j(l_k - 1) \; , \quad j = 1, \ldots, c_k \; ,$$

except for the bit $X(x) = v_k^{j_0}(i_0)$. In order to guess this bit, the module tries to guess the bit $v_k(i_0)$. From the latter and from the already known bits $v_k^j(i_0)$ for $j \neq j_0$, the bit $v_k^{j_0}(i_0)$ can then be computed easily since $v_k(i_0)$ is the exclusive-or of the $v_k^j(i_0)$.

In order to guess $v_k(i_0)$, module k mimics the solution of the hat problem with l_k players that is given in Remark 2.6. More precisely, the module computes the remaining bits of v_k from the $v_k^j(i)$ and obtains two consistent words u_0 and u_1. In case for some r the word u_r is in C_k, the module guesses $u_{1-r}(i_0)$, while the module abstains from guessing otherwise. By assumption on k, on oracle R the word v_k is not in C_k; hence the discussion in Remark 2.6 shows that module k never guesses incorrectly and guesses exactly one bit in each of the intervals J_k^2 through $J_k^{c_k}$ (in fact, for some i, in each interval bit i is guessed). □

Acknowledgments. We especially thank Ken Rose (Santa Barbara) for his enlightening discussions on error-correcting codes. We also acknowledge helpful hints from Klaus Ambos-Spies (Heidelberg), Charles Akemann (Santa Barbara), Dieter van Melkebeek (Madison), Klaus W. Wagner (Würzburg), and anonymous referees.

THE QUANTUM COMMUNICATION COMPLEXITY OF SAMPLING*

ANDRIS AMBAINIS†, LEONARD J. SCHULMAN‡, AMNON TA-SHMA§, UMESH VAZIRANI¶, AND AVI WIGDERSON‖

Abstract. Sampling is an important primitive in probabilistic and quantum algorithms. In the spirit of communication complexity, given a function $f : X \times Y \to \{0,1\}$ and a probability distribution $\mathcal{D}$ over $X \times Y$, we define the sampling complexity of $(f, \mathcal{D})$ as the minimum number of bits that Alice and Bob must communicate for Alice to pick $x \in X$ and Bob to pick $y \in Y$ as well as a value z such that the resulting distribution of (x, y, z) is close to the distribution $(\mathcal{D}, f(\mathcal{D}))$.

In this paper we initiate the study of sampling complexity, in both the classical and quantum models. We give several variants of a definition. We completely characterize some of these variants and give upper and lower bounds on others. In particular, this allows us to establish an exponential gap between quantum and classical sampling complexity for the set-disjointness function.

Key words. communication complexity, quantum communication complexity, quantum information theory, set-disjointness, the log-rank conjecture in communication complexity

1. Introduction.

A central question in quantum information theory is the amount of information that can be encoded into n qubits. There are different ways to formulate this question and, surprisingly, they yield completely different answers. The most natural variant of this question is the maximal amount of mutual information that can exist between a classical random variable X and a classical probability distribution Y that is obtained from a short quantum encoding of X. More than two decades ago Holevo [10] proved that the mutual information can be at most the number of qubits communicated. That is, although $2^n - 1$ complex numbers are necessary to specify the state of n quantum bits, only n bits of information can be retrieved from a superposition on n quantum bits, and communicating qubits is not more useful than just communicating classical bits.

However, there is something in quantum bits that is more powerful than classical ones. The first demonstration of that was by Bennett and Wiesner [5] who showed that if the two parties share predefined entangled qubits (that are absolutely independent of the message), then Alice can communicate $2n$ classical bits to Bob using only n

communication qubits.

Another example was supplied by Ambainis et al. [3] and by Nayak [14], where Alice's task was to encode m classical bits into n qubits ($m > n$) such that Bob could choose to read any *one* of the m encoded bits of his choice (thereby possibly destroying the information about the remaining $m-1$ bits). On the positive side they showed a scheme beating Holevo's bound, but on the negative side they showed that n can be no smaller than $\Omega(m)$.

A rich hunting ground for relevant examples is the communication complexity model [21, 20]. Buhrman, Cleve, and Wigderson [6] considered the disjointness function, where Alice and Bob get two subsets x, y of $[1, \ldots, n]$, and $DISJ(x, y) = 1$ iff x and y are disjoint. It is well known that any classical probabilistic protocol must exchange a linear number of communication bits. On the other hand, they showed that the task can be carried out with only $O(\sqrt{n}\log(n))$ quantum bits. The result is based on Grover's quantum search algorithm [9]. This provided the first asymptotic separation in power between classical and quantum communication. Recently, Razborov [17] showed an $\Omega(\sqrt{n})$ lower bound on the quantum communication complexity of the problem, and Aaronson and Ambainis [1] showed that Razborov's bound is tight up to constant factors.

Buhrman, Cleve, and Wigderson [6] also gave another communication task based on the Deutsch–Jozsa problem [8], where the number of classical bits required to compute a function *with zero error* is exponentially larger than the corresponding number of quantum bits. However, there is a probabilistic protocol with a small error probability where the number of bits exchanged is as small as the number exchanged by the quantum protocol. Raz [19] showed such an exponential gap for a *partial* function even in the presence of errors. However, the result applies only for partial functions when the two players are given a promise that their inputs come from a small (in fact, tiny) set of possible inputs.

In this paper we give the first example of a communication task for a *total* function which can be carried out by transferring exponentially fewer quantum bits than classical bits even when error is allowed. We consider the problem $DISJ_k$ that is the disjointness problem on cardinality k subsets $x, y \subseteq [n]$. However, we do not consider the number of communication bits required to *compute* the function, but rather the number of communication bits required to *sample* the function. The task is the following: Alice has a cardinality k subset $S \subseteq \{1, \ldots, n\}$, and Bob must pick a uniformly random cardinality k subset $T \subseteq \{1, \ldots, n\}$ disjoint from S. We consider the case $k = \Theta(\sqrt{n})$, and give a quantum protocol in which Alice sends $O(\log n \cdot \log 1/\epsilon)$ quantum bits to Bob, enabling him to sample from a distribution which is ϵ close (in total variation distance) to the desired uniform distribution on subsets disjoint from S. We also show that any purely classical protocol for this task must involve the exchange of $\Omega(\sqrt{n})$ bits between Alice and Bob.

We observe that applying Holevo's bound to the quantum protocol yields the following corollary: Alice and Bob can sample (with a small error) two disjoint subsets of cardinality $\sqrt{n}$ such that the number of bits of information that Bob has about Alice's subset (or that Alice has about Bob's subset) is bounded by the number of qubits transmitted, which is $O(\log(n) \cdot \log(1/\epsilon))$. It is an open question whether this secrecy can be amplified so that Alice and Bob have arbitrarily small amounts of information about each other's subsets.

More generally, given a function $f : X \times Y \to \{0, 1\}$, we consider three communication complexity measures, which we now informally discuss (and formally define

in section 2):

- The usual communication complexity of f, where Alice gets input x, Bob gets input y, and we measure the number of communication bits/qubits needed to compute $f(x,y)$. We denote the classical probabilistic communication complexity by $R_\epsilon(f)$, where ϵ is the error probability, and this probability is over the random coins of Alice and Bob. The communication complexity when no error is allowed is denoted by $D(f)$. The quantum communication complexity is denoted by $Q_\epsilon(f)$.
- The communication complexity of generating the superposition of the function. Here, there is no input to the two parties, and we measure the number of qubits needed to generate the superposition $\sum_{x,y}(-1)^{f(x,y)}|x,y\rangle$, where Alice holds the X register and Bob the Y register. We call this the complexity of *generating* the function, and denote it by $\overset{\bullet}{Q}_\epsilon(f)$.
- The communication complexity of sampling values of f. Here, Alice and Bob are again given no input, and they want to sample $(x,y,z=f(x,y))$, where Alice holds x and Bob holds y. We call this the complexity of sampling the function, and denote it by $\overset{\circ}{R}_\epsilon(f)$ in the classical case and $\overset{\circ}{Q}_\epsilon(f)$ in the quantum case.

For formal definitions, see section 2. As expected, sampling is easier than generating, which in turn is easier than solving the problem on a given instance, $\overset{\circ}{Q}_\epsilon(f) \leq \overset{\bullet}{Q}_\epsilon(f) \leq Q_\epsilon(f)$. For the precise statements we prove, see Lemmas 5.1 and 5.2.

We show a tight characterization of $\overset{\bullet}{Q}_\epsilon(f)$, the complexity of generating a function. Given f, we define the matrix M_f, $M_f[x,y] = (-1)^{f(x,y)}$. We show that $\overset{\bullet}{Q}_\epsilon(f)$ relates to the best low-rank approximation of M_f, namely,

$$\overset{\bullet}{Q}_\epsilon(f) \approx \min_{A:||A-M_f||_2^2 \leq \epsilon} \log(\mathrm{rank}(A)).$$

We believe that this characterization is important by itself. From that we deduce that

$$\overset{\bullet}{Q}_\epsilon(DISJ_k) = O(\log n \cdot \log 1/\epsilon).$$

We also show, using a combinatorial lemma of Babai, Frankl, and Simon [4], that for some constant $\epsilon > 0$

$$\overset{\circ}{R}_\epsilon(DISJ_k) = \Omega(\sqrt{n}),$$

establishing an exponential gap between classical and quantum sampling. Also, as we can efficiently quantum sample (generate) the $DISJ_k$ function, we can also efficiently quantum sample (generate) the $DISJ$ function. Razborov's lower bound [17] then shows an exponential gap between quantum sampling (generating) and normal quantum communication complexity.

We conclude with a remark concerning the log-rank conjecture in communication complexity. The conjecture asks whether always $D(f) \leq Poly(\log(\mathrm{rank}(M_f)))$. Raz and Spieker [18] were the first to show a superlinear gap, and the biggest gap known today, due to Nisan and Wigderson [15], exhibits an f with $D(f) \geq \log(\mathrm{rank}(M_f))^{1.6\ldots}$ (see [16, section 2.5]). It is quite possible, for example, that $D(f) \leq \log(\mathrm{rank}(M_f))^2$. The above characterization shows that when $\epsilon = 0$, $\overset{\bullet}{Q}_0(f) = \Theta(\log(\mathrm{rank}(M_f)))$. In

fact, we show that this holds not only for quantum generating f, but also for quantum sampling f, and $\overset{\circ}{Q}_0(f) = \Theta(\log(\mathrm{rank}(M_f)))$. For the precise statement, see Theorem 8.1. This is the first example of a communication task for which the famous log-rank conjecture holds.

Furthermore, we show that zero error classical computing is almost as easy as sampling, or more precisely that $\sqrt{D(f)} \leq \overset{\circ}{R}_0(f) \leq D(f)$. We thus see that the log-rank conjecture is equivalent to the conjecture that $\overset{\circ}{R}_0(f) \leq Poly(\overset{\circ}{Q}_0(f))$, and can be cast as asking about the relative power of quantum and classical sampling in the no error case.

2. Sampling. The two-party communication complexity model, as introduced by Yao [21], consists of two players that have private inputs and wish to compute a known function that depends on both inputs. The players follow a predefined protocol and exchange communication bits until they are ready to make a decision.

In the quantum communication complexity model [20], Alice and Bob hold qubits. When the game starts, Alice holds x and Bob holds y, and so the initial superposition is simply $|x, y\rangle$. The players take turns. Suppose it is Alice's turn to play. Alice can make an arbitrary unitary transformation on her qubits and then send one or more qubits to Bob. Sending qubits does not change the overall superposition but rather changes the ownership of the qubits, allowing Bob to apply his next unitary transformation on the newly received qubits. Each player can also (partially) measure his/her qubits. By the end of the protocol, the two players have to decide on a value. If during the protocol the two players are in the system ϕ, then ϕ_{Alice} denotes the state of the subsystem of Alice's qubits, and ϕ_{Bob} is the state of the subsystem of Bob's qubits. ϕ_{Alice} and ϕ_{Bob} are usually mixed states.

The complexity of a classical (quantum) protocol is the number of bits (qubits) exchanged between the two players. We say a (quantum) protocol *computes* $f : X \times Y \mapsto \{0, 1\}$ with $\epsilon \geq 0$ error if for any input x, y the probability that the two players compute $f(x, y)$ is at least $1-\epsilon$. We denote by $R_\epsilon(f)$ ($Q_\epsilon(f)$) the complexity of the best (quantum) protocol that computes f with at most ϵ error. The deterministic complexity $D(f)$ is simply $R_0(f)$.

2.1. Sampling complexity. In the previous definitions the two players had to *compute* the right answer for a given input (x, y). A sampling protocol, however, starts with no input to the two players. Instead, by the end of the protocol, Alice holds some $x \in X$, Bob holds some $y \in Y$, and they also hold some "answer" $z \in \{0, 1\}$. We say that the protocol induces a distribution $\mathcal{P}$ on (x, y, z), where $\mathcal{P}(x, y, z)$ is the probability that x and y are sampled along with the answer z.

DEFINITION 2.1. *A classical distribution over X is a function $\mathcal{D} : X \mapsto [0, 1]$ such that (s.t.) $\sum_{x \in X} \mathcal{D}(x) = 1$. Given two distributions $\mathcal{D}_1, \mathcal{D}_2$ over X, the variational distance between them is $|\mathcal{D}_1 - \mathcal{D}_2|_1 \stackrel{\text{def}}{=} \sum_x |\mathcal{D}_1(x) - \mathcal{D}_2(x)|$.*

DEFINITION 2.2 (sampling). *Let $f : X \times Y \mapsto \{0, 1\}$, and let $\mathcal{D}$ be any distribution on $X \times Y$. We say that the protocol samples f according to $\mathcal{D}$ with ϵ error if the distribution the protocol induces on $\{(x, y, z)\}$ is ϵ close, in the total variation distance, to the distribution $(\mathcal{D}, f(\mathcal{D}))$ obtained by first picking (x, y) according to $\mathcal{D}$ and then evaluating $f(x, y)$. We denote by $\overset{\circ}{R}_\epsilon(f, \mathcal{D})$ ($\overset{\circ}{Q}_\epsilon(f, \mathcal{D})$) the number of communication bits (qubits) needed for a randomized (quantum) protocol P to sample f according to $\mathcal{D}$ with ϵ error. When $\mathcal{D}$ is the uniform distribution, we sometimes omit it.*

2.2. q–generating. In the quantum model it makes sense not only to sample the right classical distribution, but also to approximate the right quantum superposition. For example, we can ask how many communication qubits are needed for two players to generate (or approximate) the superposition $\psi = \sum_{x,y}(-1)^{\sum_i x_i y_i}|x,y\rangle$. We need to specify what is a good approximation of a superposition, and a natural choice is the so called "fidelity" measure: ϕ approximates ψ to within ϵ if $|\langle\phi|\psi\rangle| \geq 1-\epsilon$. We also allow the players to use ancillary bits.

DEFINITION 2.3 (q–generating). *We say that a quantum protocol q–generates a superposition $\psi = \sum_{x\in X, y\in Y} a_{x,y}|x,y\rangle$ to within ϵ error if it starts with no inputs to the two players and by the end of the protocol the two players compute a superposition ϕ, where ϕ_{Alice} has support in $X \otimes Ancila_X$, ϕ_{Bob} has support in $Y \otimes Ancila_Y$, and $|\langle\phi|\psi\rangle| \geq 1-\epsilon$.*

DEFINITION 2.4. *Let $f : X \times Y \mapsto \{0,1\}$ be any Boolean function and $\mu : X \times Y \mapsto C$ an l_2 distribution (i.e., $\sum_{x,y}|\mu_{x,y}|^2 = 1$). We say that a quantum protocol q–generates f according to the distribution μ with ϵ error if it q–generates the superposition $\sum_{x,y}\mu_{x,y}(-1)^{f(x,y)}|x,y\rangle$ to within ϵ error. We denote the number of communication qubits needed for this by $\overset{\bullet}{Q}_\epsilon(f,\mu)$.*

3. Preliminaries. Two superpositions that are close to each other in the fidelity norm (i.e., $|\langle\phi_1|\phi_2\rangle| \geq 1-\epsilon$) cannot be effectively distinguished. More precisely, for a superposition ϕ and a complete measurement $\mathcal{O}$ over it, let us denote by $\phi^{\mathcal{O}}$ the classical distribution (over all possible results) obtained by applying the measurement $\mathcal{O}$ over ϕ. By, e.g., Aharonov, Kitaev, and Nisan [2, Lemma 11], we have the following.

FACT 3.1 (see [2]). *For any two superpositions ϕ_1, ϕ_2 and any complete measurement $\mathcal{O}$,*

$$|\phi_1^{\mathcal{O}} - \phi_2^{\mathcal{O}}|_1 \leq 2\sqrt{1-|\langle\phi_1|\phi_2\rangle|^2}.$$

3.1. Some matrix algebra. Any normal matrix N can be diagonalized by an appropriate unitary basis change; that is, there is some unitary transformation U s.t. $UNU^\dagger$ is diagonal with the eigenvalues $\lambda_1, \ldots, \lambda_N$ on the diagonal. Singular values and the singular value decomposition theorem generalize this to arbitrary matrices. Given any (possibly nonsquare) matrix M, $MM^\dagger$ is a nonnegative matrix and hence has a complete set of nonnegative eigenvalues $\lambda_1 \geq \cdots \geq \lambda_N \geq 0$. The ith singular value, $\sigma_i(M)$, is $\sqrt{\lambda_i}$. The SVD theorem says the following.

THEOREM 3.1 (see [11, Lemma 7.3.1]). *For any matrix M there are unitary transformations U_1, U_2 s.t. $U_1 M U_2$ is diagonal with the singular values $\sigma_1(M), \ldots, \sigma_N(M)$ on the diagonal.*

Given a matrix $A = (a_{i,j})$, we define its norm $||A||_2 \stackrel{\text{def}}{=} (\sum_{i,j}|a_{i,j}^2|)^{1/2}$, i.e., $||A||_2^2 = Trace(AA^\dagger)$. The Hoffman–Wielandt theorem states the next result.

THEOREM 3.2 (see [11, Corollary 7.3.8]). *Let A and B be two matrices of the same dimensions. Then,*

$$\sum_{i=1}^{N}[\sigma_i(A) - \sigma_i(B)]^2 \leq ||B-A||_2^2.$$

Let B be an arbitrary norm one matrix, $||B||_2^2 = 1$. It follows that $\sum_i \sigma_i^2(B) = Tr(BB^\dagger) = 1$. Let $K_\epsilon(B)$ denote the number of singular values we need to take to collect $1-\epsilon$ weight; i.e., it is the first integer k such that $\sum_{i=1}^k \sigma_i^2(B) \geq 1-\epsilon$.

CLAIM 3.1. $K_\epsilon(B) = \min_{A:||A-B||_2^2 \leq \epsilon} \text{rank}(A)$.

Proof. Let us define $K'_\epsilon(B) = \min_{A:||A-B||_2^2 \le \epsilon} \operatorname{rank}(A)$.

On the one hand, say $K_\epsilon(B) = k$ and $B = U_1 D U_2$, where D is a diagonal matrix with the singular values on the diagonal. Let $\bar{D}$ be the matrix containing only the first k singular values, and $A = U_1 \bar{D} U_2$. Then A has low rank and approximates B to within ϵ. It follows that $K'_\epsilon(B) \le k = K_\epsilon(B)$.

On the other hand, say $K'_\epsilon(B) = k$ and A has rank k and $||A - B||_2^2 \le \epsilon$. It then follows by the Hoffman–Wielandt theorem that $\sum_{i=1}^N [\sigma_i(A) - \sigma_i(B)]^2 \le ||B - A||_2^2 \le \epsilon$. As A has rank k, for at least $N - k$ values i, $\sigma_i(A) = 0$. It then must follow that the squares of the $N - k$ smallest singular values of B must sum up to no more than ϵ, i.e., $K_\epsilon(B) \le K'_\epsilon(B)$. ∎

4. A tight bound on q–generating. We completely characterize the complexity of q–generating. With each superposition $\psi = \sum_{x \in X, y \in Y} a_{x,y} |x, y\rangle$ we associate a $|X| \times |Y|$ matrix $M_\psi = (a_{x,y})$. We characterize the complexity of q–generating ψ in terms of the spectrum of M_ψ. We prove the following result.

THEOREM 4.1. *For any pure state ψ and $0 \le \epsilon \le \frac{1}{2}$*

$$\lceil \log K_{2\epsilon} \rceil \le \overset{\bullet}{Q}_\epsilon(\psi) \le \lceil \log K_\epsilon \rceil,$$

where $K_\epsilon = \min_{A:||M_\psi - A||_2^2 \le \epsilon} \operatorname{rank}(A)$. Equivalently, K_ϵ is the first integer K s.t. $\sum_{i=1}^K \sigma_i^2(M_\psi) \ge 1 - \epsilon$.

4.1. The upper bound. Suppose that Alice and Bob are in a superposition $\phi = \sum_{x,y} M_{x,y} |x, y\rangle$ represented by the matrix $M = M_\phi$ (i.e., $M[x, y] = M_{x,y}$). Let us check how the matrix representation changes as Alice applies a local unitary transformation T on her qubits. The resulting superposition is

$$\begin{aligned}
(T \otimes I)\phi &= \sum_{x,y} M_{x,y} |Tx, y\rangle \\
&= \sum_{x,y} M_{x,y} \sum_z T_{z,x} |z, y\rangle \\
&= \sum_{z,y} \left(\sum_x T_{z,x} M_{x,y} \right) |z, y\rangle \\
&= \sum_{z,y} (TM)_{z,y} |z, y\rangle,
\end{aligned}$$

and so the resulting superposition is represented by TM. Similarly if *Bob* applies a local transformation T on M, the resulting superposition is represented by MT^t.

Suppose that the parties want to generate a superposition ψ represented by $M = M_\psi$. By the singular decomposition theorem (Theorem 3.1) there are unitary transformations U_1, U_2 s.t. $U_1^{-1} M U_2^{-1}$ is the diagonal matrix D with $\sigma_1(M), \ldots, \sigma_N(M)$ on the diagonal. Let $\Lambda = \{w_i | i = 1, \ldots, K\}$ be the set of the first $K = K_\epsilon$ ("heavy") eigenvectors. Let Π be the projection operator onto Λ, i.e., $\Pi[x, y]$ is 1 if $x = y$ and $1 \le x \le K$, and zero otherwise. The protocol is the following:

- Alice prepares the superposition $D\Pi$ (which is simply the superposition $c \cdot \sum_{i=1}^K \sigma_i(M) |i, i\rangle$, where $c = 1/\sqrt{\sum_{i=1}^K \sigma_i^2(M)}$, and notice that $1 \le c \le 1/\sqrt{1 - \epsilon}$) and sends the Y qubits to Bob.
- Alice applies the transformation U_1 on her qubits, and Bob applies the transformation U_2^t on his qubits.

Say that the resulting superposition is ϕ and its matrix is M_ϕ. We know that $M_\phi = cU_1 D\Pi U_2$. We have

$$\begin{aligned}||M_\phi - M_\psi||_2^2 &= ||cU_1 D\Pi U_2 - U_1 D U_2||_2^2 \\ &= ||U_1(cD\Pi - D)U_2||_2^2 \\ &= ||cD\Pi - D||_2^2 \\ &= \sum_{i>K} \sigma_i^2(M) + (c-1)^2 \sum_{i=1}^{K} \sigma_i^2(M) \\ &\leq \epsilon + \frac{(c-1)^2}{c^2} \leq \epsilon + \epsilon^2 \leq 2\epsilon.\end{aligned}$$

The third equality is due to the fact that for every matrix X and unitary matrix U, $||UX||_2^2 = \langle UX|UX\rangle = \langle X|X\rangle = ||X||_2^2$. To see the last inequality, remember that $c \leq \frac{1}{\sqrt{1-\epsilon}}$, and therefore $\frac{c-1}{c} \leq \frac{1/\sqrt{1-\epsilon}-1}{1/\sqrt{1-\epsilon}} = 1 - \sqrt{1-\epsilon} \leq \epsilon$.

To finish the proof of the upper bound of Theorem 4.1, we claim the following.

CLAIM 4.1. $|\langle\phi|\psi\rangle| \geq 1 - \epsilon$.

Proof. We treat the matrices M_ϕ, M_ψ as vectors of length $|X| \cdot |Y|$ and notice that $\langle M_\phi | M_\psi\rangle = \langle\phi|\psi\rangle$ by the way the matrices M_ϕ, M_ψ were defined.

Also, since $(U_1^{-1} \otimes U_2^{-1})\psi = \sum_i \sigma_i |i,i\rangle$ and $(U_1^{-1} \otimes U_2^{-1})\phi = c\sum_{i\in\Lambda} \sigma_i |i,i\rangle$, it follows that $\langle\phi|\psi\rangle$ is real. We then see that

$$\begin{aligned}||M_\phi - M_\psi||_2^2 &= \langle M_\phi - M_\psi | M_\phi - M_\psi\rangle \\ &= \langle M_\phi|M_\phi\rangle + \langle M_\psi|M_\psi\rangle - 2\langle M_\phi|M_\psi\rangle.\end{aligned}$$

However, $||M_\phi||_2 = ||M_\psi||_2 = 1$, and so

$$||M_\phi - M_\psi||_2^2 = 2(1 - \langle\phi|\psi\rangle).$$

Plugging $||M_\phi - M_\psi||_2^2 \leq 2\epsilon$ into this, we get $\langle\phi|\psi\rangle \geq 1 - \epsilon$ as desired. ∎

4.2. The lower bound. The lower bound idea is an extension of an idea from Kremer's thesis [12], where it is attributed to Yao. We first show that the outcome of any quantum protocol that uses only l communication qubits can be described as a linear combination of up to 2^l product superpositions (we give a precise statement soon). We use this to show that a quantum sampling protocol is actually a low rank approximation of M_ψ. We then use the Hoffman–Wielandt inequality to derive a lower bound on l.

CLAIM 4.2 (see [12]). *Suppose that P is a quantum protocol that uses l communication qubits, starts with no input, and computes the superposition ϕ. Further assume that the last qubit communicated is w_l. Then $\phi = \sum_{w\in\{0,1\}^l} |A(w), w_l, B(w)\rangle$, where A and B depend only on w.*

Proof. The proof is by induction on l. The case $l = 0$ is immediate. Suppose it is true for l; let us prove it for $l+1$. Assume after l steps that the two parties are in the superposition $\sum_{w\in\{0,1\}^l} |A(w), w_l, B(w)\rangle$ and w.l.o.g. it is now Alice's turn to play. Alice first does some unitary transformation on her qubits, which results in $\sum_{w\in\{0,1\}^l} |A'(w_1,\ldots,w_l), B(w_1,\ldots,w_l)\rangle$. Then she sends the qubit z to Bob. For every $w_1,\ldots,w_l$ we can represent $|A'(w_1,\ldots,w_l)\rangle$ as a superposition of the possible values of z, which completes the induction. ∎

Now suppose that P q–generates ψ (represented by M_ψ) with ϵ error and l communication qubits. Let us denote by $\phi = \sum_{x,y} a_{x,y}|x,y\rangle$ the final superposition that

the two parties compute (which is, again, represented by M_ϕ). By Claim 4.2 we know that we can represent ϕ as $\phi = \sum_{w\in\{0,1\}^l} |A(w), B(w)\rangle$. Because ϕ_{Alice} has support in X, and ϕ_{Bob} in Y, this is actually $\phi = \sum_{w\in\{0,1\}^l} \sum_{x,y} a_x(w)\cdot b_y(w)|x,y\rangle$, where $a_x(w)$ and $b_y(w)$ are complex numbers. Thus

$$M_\phi[x,y] = \sum_{w\in\{0,1\}^l} a_x(w)b_y(w).$$

Let us define an $|X|\times 2^l$ matrix A by $A[x,w] = a_x(w)$, and a $2^l\times|Y|$ matrix $B[w,y] = b_y(w)$. We see that $M_\phi = A\cdot B$, where the $\cdot$ operation is matrix multiplication. In particular,

$$\operatorname{rank}(M_\phi) \le \operatorname{rank}(A) \le 2^l.$$

Since ϕ ϵ-approximates ψ, we know that $||M_\phi - M_\psi||_2^2 = \langle M_\phi - M_\psi | M_\phi - M_\psi\rangle = 2(1-\langle\phi|\psi\rangle) \le 2\epsilon$. It follows that $K_{2\epsilon} = \min_{M:||M-M_\psi||_2^2\le 2\epsilon} \operatorname{rank}(M) \le \operatorname{rank}(M_\phi) \le 2^l$, as desired.

5. Relationships between sampling and computing. We say that a function $g: X\times Y \mapsto M$ is a "product" function if $g(x,y) = g_1(x)g_2(y)$ for some functions g_1 and g_2. For product distributions μ we show that sampling is not harder than q–generating, which in turn is not harder than worst-case solving the problem.

5.1. Sampling vs. q–generating.

LEMMA 5.1. *Suppose that $f: X\times Y\mapsto\{0,1\}$, and μ is an l_2* product *distribution. Let $\mathcal{D}: X\times Y\mapsto[0,1]$ be the classical distribution associated with μ, $\mathcal{D}(x,y) = |\mu_{x,y}|^2$. Then $\overset{\circ}{Q}_{4\sqrt{\epsilon}}(f,\mathcal{D}) \le \overset{\bullet}{Q}_\epsilon(f,\mu) + O(1)$.*

Proof. Suppose that the approximation protocol computes ϕ s.t. $|\langle\phi|\psi\rangle| \ge 1-\epsilon$, where ψ is the ideal superposition $\psi = \sum_{x,y}\mu_{x,y}(-1)^{f(x,y)}|x,y\rangle$. We give a sampling protocol:

1. Alice computes the superposition $|00\rangle + |11\rangle$ in qubits z_1, z_2. She sends the second qubit z_2 to Bob.
2. If they both have a $|0\rangle$ (i.e., $z_1 = z_2 = 0$), they compute in the qubits X, Y the superposition $\sum_{x,y}\mu_{x,y}|x,y\rangle$ (this can be done at no cost, as μ is a product distribution), and if they have a 1, they compute ϕ (using $\lceil\log(K_\epsilon)\rceil$ qubits).
3. Now Bob returns the qubit z_2 to Alice. Alice does a unitary transformation over z_1, z_2 that sends $|00\rangle$ to $\frac{1}{\sqrt{2}}(|00\rangle + |01\rangle)$ and $|11\rangle$ to $\frac{1}{\sqrt{2}}(|00\rangle - |01\rangle)$.
4. Finally, both players measure all their qubits.

Now, suppose for the moment that the protocol was run with $\phi = \psi$. In that case after step 2 the two players are in the superposition

$$\sum_{x,y}\mu_{x,y}[|00,x,y\rangle + (-1)^{f(x,y)}|11,x,y\rangle].$$

It can then be easily verified that after step 3 the resulting superposition is

$$\sum_{x,y}\mu_{x,y}|0,f(x,y),x,y\rangle,$$

and thus when Alice and Bob measure their qubits, they actually sample f according to $\mathcal{D}$ with no error.

Now, in the actual protocol the two players compute ϕ, which is not quite ψ but close to it, namely, $|\langle\phi|\psi\rangle| \geq 1-\epsilon$. By Fact 3.1 we know that the resulting distribution is $2\sqrt{1-|\langle\phi|\psi\rangle|^2} \leq 2\sqrt{1-(1-\epsilon)^2} \leq 2\sqrt{2\epsilon}$ close (in the l_1 norm) to the right one, and the lemma follows. □

5.2. q–generating vs. computing. Suppose that we can compute f, and that we want to q–generate it according to a product distribution μ. Since μ is product, we can enter the superposition $\sum_{x,y} \mu_{x,y}|x,y\rangle$. Then we can compute f. However, this does not give a q–generating protocol because we might use some auxiliary qubits for the computation and thus have garbage entangled with the result. The following proof follows ideas from Cleve et al. [7], who showed how to remove such garbage. The proof is given here for completeness.

LEMMA 5.2. *For any function f and any l_2 product distribution μ, $\overset{\bullet}{Q}_{2\epsilon}(f,\mu) \leq 2Q_\epsilon(f)$.*

Proof. Let T be a small error protocol for computing f. We use the safe storage principle, and each time the protocol wants to measure a qubit we simply copy it to a new qubit that is left untouched. Now, say that $T|x,0,y,0\rangle = |x,y\rangle \otimes [\alpha^0_{x,y}|f(x,y),g^0_{x,y}\rangle + \alpha^1_{x,y}|1-f(x,y),g^1_{x,y}\rangle]$, where $g^0_{x,y}$ (and $g^1_{x,y}$) is the correlated garbage that is produced during the computation and is divided between the two players; i.e., the right answer $f(x,y)$ is computed with amplitude $\alpha^0_{x,y}$ and is accompanied by $g^0_{x,y}$ in the garbage qubits.

The two players get into the superposition $\sum_{x,y} \mu_{x,y}|x,y\rangle$. Since μ is a product distribution, this is done at no cost. We run the following three-step protocol:

Compute f. This results in

$$\phi_1 = \sum_{x,y} \mu_{x,y}\ |x,y\rangle \otimes [\alpha^0_{x,y}|f(x,y),g^0_{x,y}\rangle + \alpha^1_{x,y}|1-f(x,y),g^1_{x,y}\rangle].$$

As T has only ϵ error on average, we know that $\sum_{x,y}\ |\mu_{x,y}|^2\ |\alpha^0_{x,y}|^2 \geq 1-\epsilon$.

Lift the result. Next, we lift the result $f(x,y)$ to the amplitude; i.e., the player with the result qubit R changes the amplitude by $(-1)^R$. The resulting superposition is

$$\phi_2 = \sum_{x,y} \mu_{x,y}(-1)^{f(x,y)}|x,y\rangle \otimes [\alpha^0_{x,y}|f(x,y),g^0_{x,y}\rangle - \alpha^1_{x,y}|1-f(x,y),g^1_{x,y}\rangle].$$

Notice the sign change in the garbage belonging to the wrong answer. We do not like this sign change, and we notice that this sign change is immaterial. Namely, if we define

$$\psi_2 = \sum_{x,y} \mu_{x,y}(-1)^{f(x,y)}|x,y\rangle \otimes [\alpha^0_{x,y}|f(x,y),g^0_{x,y}\rangle + \alpha^1_{x,y}|1-f(x,y),g^1_{x,y}\rangle],$$

then $|\langle\phi_2|\psi_2\rangle| \geq \sum_{x,y} |\mu_{x,y}|^2(|\alpha^0_{x,y}|^2 - |\alpha^1_{x,y}|^2)$, which is at least $1-2\epsilon$.

Reverse the computation. Finally, we would like to get rid of the garbage, and so we reverse T; this at most doubles the number of communication qubits transferred. Because of the sign change in ϕ_2, the resulting superposition is ugly and depends on the actual computation. However, had the reversing step been applied to ψ_2, we would have received the ideal superposition $\psi = \sum_{x,y} \mu_{x,y}(-1)^{f(x,y)}|x,y\rangle$. Now $|\langle\phi_2|\psi_2\rangle| \geq 1-2\epsilon$, and reversing T is just a unitary transformation. We conclude that $|\langle\phi_3|\psi\rangle| \geq 1-2\epsilon$. □

6. The $DISJ_k$ function. The $DISJ_k(x,y)$ function gets as input two subsets $S,T \subseteq \{1,\ldots,n\}$, each of cardinality k, and outputs 1 iff $S \cap T = \emptyset$. We bound the quantum sampling complexity of the function under the l_2 uniform distribution $\mu_{x,y} = 1/N$. We then prove the following result.

THEOREM 6.1. *For $k = \Theta(\sqrt{n})$, $\overset{\circ}{Q}_\epsilon(DISJ_k) = O(\log(n)\log(\frac{1}{\epsilon}))$. The result is true even when Alice has an input S and Bob wants to sample a subset T disjoint from S.*

By Theorem 4.1 we need to analyze the spectrum of $M = M_{DISJ_k,\mu}$. Indeed, notice that $M[x,y]$ depends only on the intersection size of x and y. It is not too difficult to see that all matrices that are indexed by k-subsets and depend only on the intersection size commute. In particular, they share the same eigenspaces. Lovasz [13] analyzed the spectrum of these matrices, and we give a slightly different description of the eigenspaces of M than he obtains.

LEMMA 6.2 (a different presentation of [13]). *M has $k+1$ eigenspaces $E_0,\ldots,E_k$. E_0 is of dimension 1 and contains the all 1's vector. E_i has dimension $\binom{n}{i} - \binom{n}{i-1}$. The typical eigenvector in E_i is indexed by $x_1,x_2,\ldots,x_{2i-1},x_{2i} \in \{1,\ldots,n\}$. The corresponding eigenvector e (unnormalized) is given by $e_S = 0$ if there is an index $j : |S \cap \{x_{2j-1},x_{2j}\}| \neq 1$, and otherwise by $e_S = \Pi_j(-1)^{|S\cap\{x_{2j}\}|}$. The corresponding eigenvalues are*

$$\lambda_0 = \frac{2\binom{n-k}{k} - \binom{n}{k}}{\binom{n}{k}} \quad \textit{and} \quad \lambda_i = \frac{2\binom{n-k-i}{k-i}}{\binom{n}{k}}$$

for $i > 0$.

The eigenvalues in the spectrum of M decay rapidly. Let $q_i = \sum_{w_i \in E_i} |\lambda_i|^2$ so that $\sum_{i=0}^k q_i = 1$. Then the following holds.

CLAIM 6.1. *For $k = \Theta(\sqrt{n})$, $\frac{q_{i+1}}{q_i} = O(\frac{1}{i+1})$.*

Proof. To calculate q_{i+1}/q_i, we first bound λ_{i+1}/λ_i. We get that $\frac{-\lambda_{i+1}}{\lambda_i} = \frac{k-i}{n-k-i} \leq \frac{2k}{n}$. The number of eigenvalues is $\binom{n}{i} - \binom{n}{i-1}$ for E_i and $\binom{n}{i+1} - \binom{n}{i}$ for E_{i+1}, and

$$\frac{\binom{n}{i+1} - \binom{n}{i}}{\binom{n}{i} - \binom{n}{i-1}} \leq \frac{2n}{i+1}.$$

Hence

$$\frac{q_{i+1}}{q_i} = \frac{(\binom{n}{i+1} - \binom{n}{i})\lambda_{i+1}^2}{(\binom{n}{i} - \binom{n}{i-1})\lambda_i^2} \leq \frac{2n}{i+1} \cdot \frac{4k^2}{n^2} = \Omega\left(\frac{1}{i+1}\right). \qquad \square$$

Therefore $q_t \leq \frac{c^t}{t!}$. Now we are set to prove the following.

LEMMA 6.3. $\log K_\epsilon \leq O(\log(n)\frac{\log 1/\epsilon}{\log\log 1/\epsilon})$.

Proof. We set $t = O(\frac{\log 1/\epsilon}{\log\log 1/\epsilon})$ and take $\Lambda = E_0 \cup E_1 \cup \cdots \cup E_t$. We have

$$\sum_{i\in\Lambda} |\lambda_i|^2 = 1 - \sum_{i\notin\Lambda} |\lambda_i|^2 \;=\; 1 - \sum_{i=t+1}^{k} q_i$$
$$\geq 1 - \sum_{i=t+1}^{k} \frac{c^i}{i!} \geq 1 - O\left(\frac{c^t}{t!}\right) \geq 1 - \epsilon.$$

Hence $K_\epsilon \le |E_0 \cup \cdots \cup E_t| \le t \cdot \binom{n}{t} \le n^{t+1}$, and $\log K_\epsilon \le (t+1)\log(n)$, as required. □

By Theorem 4.1, $\overset{\bullet}{Q}_\epsilon(\psi) \le \lceil \log K_\epsilon \rceil \le O(t\log(n)) = O(\log(n)\log 1/\epsilon)$, and a similar upper bound on $\overset{\circ}{Q}_\epsilon$ $(DISJ_k)$ follows from Lemma 5.1. This gives the first part of Theorem 6.1. This, in particular, shows that it is easy for Alice and Bob to sample a uniform pair of subsets x and y, along with the knowledge as to whether x and y intersect.

In the next two subsections we prove the second part of the theorem. We want to show two things. One is that the result holds even when Alice and Bob want to sample only *disjoint* subsets, and second that the result holds even when Alice is given an input x and Bob is asked to sample a subset y *disjoint* with x.

6.1. Generating disjoint subsets. Alice and Bob want to ϵ-approximate a sample of disjoint k-subsets x and y. This amounts to sampling the disjointness function according to the distribution $\mathcal{D}$ that is uniform over all pairs of disjoint subsets. (Notice that $\mathcal{D}$ is *not* a product distribution.) Clearly, it is enough for Alice and Bob to approximate the normalized superposition $\psi = \sum_{x,y:x\cap y=\emptyset} \frac{1}{\sqrt{\Delta_0 N}}|x,y\rangle$, for once they do that they can measure x and y and get the desired sample. The normalizing factor Δ_0 is the number of values y in a row x s.t. $x \cap y = \emptyset$ and does not depend on x.

Denote by M_{f_0} the normalized matrix

$$M_{f_0}[x,y] = \frac{1}{\sqrt{\Delta_0 N}} \begin{cases} 1, & x \cap y = \emptyset, \\ 0, & \text{otherwise.} \end{cases}$$

M_{f_0} is symmetric and has full spectrum $\zeta_1, \ldots, \zeta_N$, $|\zeta_1|^2 \ge \cdots |\zeta_N|^2$. We say K^0_ϵ is the first K s.t. $\sum_{i\le K} |\zeta_i|^2 \ge 1-\epsilon$. By Theorem 4.1 (which applies to any superposition), Alice and Bob can ϵ-approximate ψ using only $O(\log(K^0_\epsilon))$ communication qubits.

Since $k = \Theta(\sqrt{N})$, $\Delta_0 \ge \frac{N}{c}$ for some constant c. It is left to show that $O(\log(K^0_\epsilon)) = O(\log(n)\log(1/\epsilon))$. One way to show this is to compute the eigenvalues of M_{f_0}. However, there is an easier way. We show that $K^0_\epsilon \le K_{\epsilon/c} + 1$ and then Lemma 6.3 implies the bound. We are left with the following.

CLAIM 6.2. $K^0_\epsilon \le K_{\epsilon/c} + 1$.

Proof. Denote $M_f[x,y] = \frac{1}{N}(-1^{f(x,y)}))$. M_f and M_{f_0} share the same eigenspaces (as they commute). We now express M_f and M_{f_0} in terms of each other. Let us define $B = \sqrt{N\Delta_0}M_{f_0}$, so that B is a 0,1 matrix. It can easily be verified that

$$NM_f = B - (J - B) = 2B - J,$$

where J is the all 1's matrix. Hence, $M_{f_0} = N/2\sqrt{N\Delta_0}M_f + dJ$ for some value d. In particular, for any eigenvector $w_i \ne (1,\ldots,1)$, $Jw_i = 0$ and $\zeta_i = \frac{1}{2}\sqrt{N/\Delta_0}\lambda_i$. Thus,

$$|\zeta_i| = \frac{1}{2}\sqrt{\frac{N}{\Delta_0}}|\lambda_i| \le \sqrt{c}|\lambda_i|, \quad i > 1.$$

Therefore, suppose $\sum_{i\in S}|\lambda_i|^2 \ge 1 - \epsilon/c$. Denote $S' = S \cup \{(1,\ldots,1)\}$. Clearly, $\sum_{i\notin S'}|\zeta_i|^2 \le \sum_{i\notin S'} c|\lambda_i|^2 \le \epsilon$. Hence $K^0_\epsilon \le K_{\epsilon/c} + 1$. □

6.2. Sampling for a given input x. Alice is given an input $z \in X$, and the goal is that Bob samples $y \in Y$ s.t. $z \cap y = \emptyset$. We follow a protocol similar to that in the upper bound of Theorem 4.1. Given an input $z \in X$ and an $\epsilon > 0$, define

$M = M_{f_0}$ as in the previous subsection. Let W be the eigenvector basis of M (which is symmetric). Let $\Lambda = \Lambda_\epsilon$ be the union of the first eigenspaces E_i (defined in Lemma 6.2) that contain the first K_ϵ heavy eigenvectors of M. Let Π be the projection operator over Λ.

We now describe the protocol. Alice gets into the normalized superposition $v_z = \frac{1}{\sqrt{\Delta_0}} \sum_{y:y\cap z=\emptyset} |y\rangle$. In the eigenvector basis W, $v_z = \sum_i \gamma_i |w_i\rangle$. Alice then projects v_z onto Λ to get $\overline{v_z} = \sum_{i\in\Lambda} \gamma_i |w_i\rangle$ and sends $\overline{v_z}$ to Bob. Bob returns $\overline{v_z}$ to the original basis and measures to get some y. To prove correctness we show the following.

LEMMA 6.4. $|\langle v_z|\overline{v_z}\rangle| \geq 1 - \epsilon$.

Proof. $\langle v_z|\overline{v_z}\rangle = \sum_{i\in\Lambda} |\gamma_i|^2$, i.e., it is the length of the projection of v_z onto Λ. We show that this quantity is the same for all z. If we know that, we can define $\psi = \frac{1}{\sqrt{N}} \sum_z |z, v_z\rangle$ and $\overline{\psi} = \frac{1}{\sqrt{N}} \sum_z |z, \overline{v_z}\rangle$ (so ψ and $\overline{\psi}$ are normalized). Then, from the proof of Theorem 4.1 we know that

$$|\langle \psi|\overline{\psi}\rangle| \geq 1 - \epsilon.$$

However,

$$\langle \psi|\overline{\psi}\rangle = \frac{1}{N} \sum_z \langle v_z|\overline{v_z}\rangle = \langle v_z|\overline{v_z}\rangle,$$

which together implies that $\langle v_z|\overline{v_z}\rangle = \langle \psi|\overline{\psi}\rangle \geq 1-\epsilon$, as required. Indeed, the following claim holds.

CLAIM 6.3. *For any eigenspace E_j, $|\langle v_z|E_j\rangle|^2$, which is the length of the projection of v_z on E_j, does not depend on z.*

Proof. Let $z_1, z_2 \in X$ be two k-subsets; i.e., $z_1, z_2 \subset [1, \ldots, n]$ and $|z_1| = |z_2| = k$. There is a permutation $\pi \in S_n$ s.t. $\pi(z_1) = z_2$, where for a set A, $\pi(A) = \{\pi(a)|a \in A\}$.

The operation of the permutation π can be thought of as a unitary transformation permuting the basis vectors $|x\rangle$ for $x \in X$. In other words, given a superposition $\phi = \sum_{i\in X} a_i|i\rangle$, $\pi(\phi)$ is defined to be $\sum_{i\in X} a_i|\pi(i)\rangle$. In particular, for any two superpositions ϕ_1, ϕ_2, $\langle \pi(\phi_1)|\pi(\phi_2)\rangle = \langle \phi_1|\phi_2\rangle$. As a result, $\langle v_{z_1}|E_j\rangle = \langle \pi(v_{z_1})|\pi(E_j)\rangle$, where $\pi(E_j) = Span\{\pi(w)|w \in E_j\}$. However, we observe that

$$\begin{aligned}
\pi(v_{z_1}) &= \sum_{y:y\cap z_1=\emptyset} |\pi(y)\rangle \\
&= \sum_{w:\pi^{-1}(w)\cap z_1=\emptyset} |w\rangle \\
&= \sum_{w:w\cap\pi(z_1)=\emptyset} |w\rangle \;=\; v_{z_2}.
\end{aligned}$$

Finally, because of the symmetries of the eigenspaces E_j, $\pi(E_j) = E_j$. The lemma follows. □ □

7. A lower bound on classical sampling. In contrast we prove that classically sampling $DISJ_k$ is hard. We begin with the observation that classical sampling protocols can always be made to have just one message at no cost. We then prove the following result.

LEMMA 7.1. *Given any sampling protocol P with k communication bits and ϵ error, there is an optimal one message sampling protocol that samples from the desired distribution with the same complexity.*

Proof. The protocol goes as follows:

- Alice simulates the protocol P, playing the role of both players. She then announces the resulting sequence of messages M to Bob.[1]
- Alice and Bob pick inputs S and T according to the respective conditional distributions for the protocol P given the messages M.

The crucial observation is that, conditioned on the sequence of messages exchanged, the distribution from which Alice and Bob sample is a product distribution. □

We are now ready to prove the next result.

THEOREM 7.2. *Let $k = \sqrt{n}$. There is a constant $\epsilon > 0$ s.t. $\overset{\circ}{R}_\epsilon(DISJ_k) = \Omega(\sqrt{n})$.*

Proof. Let P be the distribution on $X \times Y$ that Alice and Bob sample from (X and Y is the set of all k-sets). By Lemma 7.1, P is a convex combination of L *product* distributions D_M, $P = \sum p_i D_i$, where L is the size of the message space from which Alice chooses her message to Bob (i.e., $\log L$ is the number of bits transmitted during the protocol). We say that a distribution D on rectangle R is *smooth* if for any pair of elements $u, v \in R$, $\frac{D(u)}{D(v)} \leq 4$. We soon show that any product distribution can be very closely approximated by a convex combination of a small number of smooth distributions on rectangles; namely, we have the following.

CLAIM 7.1. *Let D be a product distribution on $X \times Y$. Then there are rectangles $R_1, \ldots, R_{9n^2}$, and smooth distributions D_i on R_i, such that D is within (total variation distance) 2^{-2n+1} of a convex combination of D_i.*

In particular, P is 2^{-n+1} close to a convex combination $\sum_{i=1}^{9n^2 L} p_i P_i$, where P_i is some smooth distribution over some rectangle R_i. Intuitively, the proof shows that large rectangles R_i introduce large error, while small rectangles provide very slow progress. For that we use the following combinatorial lemma of Babai, Frankl, and Simon.

LEMMA 7.3 (see [4]). *There exist a constant $\epsilon_0 > 0$ and $\delta = 2^{-\Omega(\sqrt{n})}$ such that, for any rectangle $R = U \times V$ with $\frac{|R|}{|X||Y|} \geq \delta$, at least ϵ_0 fraction of the pairs of subsets in R intersect (are not disjoint).*

Let us call a rectangle R_i large if $\frac{|R_i|}{|X||Y|} \geq \delta$. By the lemma, any large rectangle must contain at least ϵ_0 fraction of intersecting pairs. Thus, any smooth distribution P_i on a large rectangle R_i must have at least $\frac{\epsilon_0}{4}$ weight on intersecting pairs. Let h denote the total weight of heavy rectangles in the convex combination (i.e., $h = \sum_{i:R_i \text{ is heavy}} p_i$). We see that intersecting pairs get at least weight $\frac{h\epsilon_0}{4}$. We conclude that $\frac{h\epsilon_0}{4} \leq \epsilon$ and $h \leq \frac{4\epsilon}{\epsilon_0} = O(\epsilon)$.

We now concentrate on the nonheavy rectangles P_i. We say we *touch* a pair (x, y) if some nonheavy rectangle R_i contains it. Let I be the set of all disjoint pairs. We see that we must touch at least $(1 - (\epsilon + h))|I|$ pairs in I, or else there are $(\epsilon + h)|I|$ elements that get weight $\epsilon + h$ in the uniform distribution over disjoint pairs and only weight h in P. As every nonheavy rectangle R_i can touch at most $|R_i| \leq \delta|X| \cdot |Y|$ elements, we must have that $9n^2 L\delta|X| \cdot |Y| \geq (1 - \epsilon - h)|I| \geq (1 - O(\epsilon))|I|$.

For $k = \sqrt{n}$ the number of disjoint pairs is some $c_0|X| \cdot |Y|$ for some constant c_0. Thus, $L \geq (1 - O(\epsilon))c_0/9n^2 \cdot 2^{\Omega(\sqrt{n})}$. It follows that for some small enough constant $\epsilon > 0$ we must have $L \geq 2^{\Omega(\sqrt{n})}$, as desired.

We are left with the proof of Claim 7.1, which we give now.

[1] We assume that all messages belonging to the same round have the same length. If this is not the case, Alice has to send a special sign at the end of each message, which may, at most, increase the number of communication bits by a constant factor.

Proof of Claim 7.1. We partition X to sets $X_0, \ldots, X_{3n-1}$ and X_{Bad}, where $X_i = \{x | \frac{1}{2^{i+1}} \leq D(x) \leq \frac{1}{2^i}\}$ and X_{Bad} is all other strings. We similarly partition Y. We define the distribution $D_{i,j}$ to be the distribution that D induces on the rectangle $X_i \times Y_j$ $(0 \leq i, j \leq 3n-1)$. It is clear that $D_{i,j}$ is almost uniform. Let us denote by $\overline{D}$ the appropriate linear combination of the distributions $D_{i,j}$, $\overline{D} = \sum_{i,j} p_{i,j} D_{i,j}$ (where $p_{i,j}$ is the weight of the rectangle $X_i \times Y_j$ under D). It is clear that $\overline{D}(a,b) = D(a,b)$ for any (a,b) that belongs to some rectangle $X_i \times X_j$. Thus, $|\overline{D} - D|_1$ is bounded by the total weight (under D) of entries in $X_{Bad} \times Y$ and $X \times Y_{Bad}$, and so it is bounded by $2 \cdot 2^n \cdot 2^{-3n} = 2^{-2n+1}$. The lemma follows. □ □

8. Zero error sampling and the log-rank conjecture. Theorem 4.1 characterizes the q–generating complexity $\overset{\bullet}{Q}$. However, it is still possible that sampling is much easier (even in the quantum world) than q–generating. For the special case of *zero error* sampling, we supply a lower bound even for the easier task of sampling, using a method similar to that used in Theorem 4.1.

THEOREM 8.1. *For every function f and any distribution $\mathcal{D}$, $\overset{\circ}{Q}_0(f, \mathcal{D}) \geq \frac{\log(\mathrm{rank}(M_{f,\mathcal{D}}))}{2} - 1$.*

Proof. Given a protocol P for sampling f, we define the $|X| \times |Y|$ matrix M_P^0 by letting $M_P^0[x,y]$ be the probability that P samples (x,y) with the answer 0. We similarly define M_P^1. We let $M_P = M_P^0 - M_P^1$. Note that M_P does not necessarily correspond to the probability that the protocol will answer with a yes or no to an instance (x,y).

LEMMA 8.2 (see [12]). *Suppose that P uses only l communication qubits. Then* $\mathrm{rank}(M_P^0), \mathrm{rank}(M_P^1) \leq 2^{2l}$.

Proof. Let P be a quantum protocol for sampling f using l qubits. Suppose by the end of the protocol that the superposition is ϕ, and w_l, the last qubit communicated, contains the answer (0 or 1). By Claim 4.2,

$$\phi = \sum_{w \in \{0,1\}^l} \sum_{x \in X, y \in Y} |x, U_x(w), w_l, y, V_y(w)\rangle.$$

Define $Y_0 = \{w \in \{0,1\}^l | w_l = 0\}$ and $\phi_{x,y}^0 = \sum_{w \in Y_0} |x, U_x(w), w_l, y, V_y(w)\rangle$. Then

$$\begin{aligned} M_P^0[x,y] &= \langle \phi_{x,y}^0 | \phi_{x,y}^0 \rangle \\ &= \sum_{w,z \in Y_0} \langle U_x(w) | U_x(z) \rangle \langle V_y(w) | V_y(z) \rangle. \end{aligned}$$

If we define a matrix A of dimension $|X| \times |Y_0|^2$ by $A[x,(w,z)] = \langle U_x(w) | U_x(z) \rangle$, and a matrix B of dimension $|Y_0|^2 \times |Y|$ by $B[(w,z),y] = \langle V_y(w) | V_y(z) \rangle$, then we see that $M_P^0[x,y] = (AB)[x,y]$. That is, $M_P^0 = AB$. In particular, $\mathrm{rank}(M_P^0) = \mathrm{rank}(AB) \leq \mathrm{rank}(A) \leq |Y_0|^2 \leq 2^{2l}$. A similar argument shows that $\mathrm{rank}(M_P^1) \leq 2^{2l}$. □

We remind the reader that for $f : X \times Y \mapsto \{0,1\}$ the matrix $M_{f,\mathcal{D}}$ has dimensions $|X| \times |Y|$ and is defined by $M_{f,\mathcal{D}}[x,y] = (-1)^{f(x,y)} \mathcal{D}_{x,y}$. ($M_{f,\mathcal{D}}$ is not normalized, i.e., $||M_{f,\mathcal{D}}||_2$ is not necessarily 1.) We notice that if P samples f with zero error using l qubits, then $M_P = M_{f,\mathcal{D}}$. Moreover, $\mathrm{rank}(M_{f,\mathcal{D}}) = \mathrm{rank}(M_P) \leq \mathrm{rank}(M_P^0) + \mathrm{rank}(M_P^1) \leq 2^{2l} + 2^{2l} = 2^{2l+1}$. In particular, $2l + 1 \geq \log(\mathrm{rank}(M_{f,\mathcal{D}}))$. Hence $\overset{\circ}{Q}_0(f, \mathcal{D}) \geq \log(\mathrm{rank}(M_{f,\mathcal{D}}))/2 - 1$, and Theorem 8.1 follows. □

We see in particular that for the uniform distribution ($\mathcal{D}(x,y) = 1/N^2$ and $\mu(x,y) = 1/N$), $M_{f,\mathcal{D}}$ and $M_{f,\mu}$ differ only by a constant factor and so have the same

rank. By Theorem 4.1, $\overset{\circ}{Q}_0(f) \leq \lceil \log \operatorname{rank}(M_f M_f^\dagger) \rceil + O(1) = \lceil \log \operatorname{rank}(M_f) \rceil + O(1)$. Theorem 8.1 gives a matching lower bound. Together we get the following tight characterization for zero error sampling.

COROLLARY 8.3. *For any* $f : X \times Y \mapsto \{0,1\}$, $\overset{\circ}{Q}_0(f) = \Theta(\log \operatorname{rank}(M_f))$.

8.1. Zero error classical computing is almost as easy as sampling.

THEOREM 8.4. $\sqrt{D(f)} \leq \overset{\circ}{R}_0(f) \leq D(f)$.

Proof. Given the matrix M_f, a monochromatic cover is a set of monochromatic rectangles in M_f that together cover the whole matrix. Define $C(f)$ as the smallest number of monochromatic rectangles needed to cover M_f. Define $C^D(f)$ as the smallest number of disjoint monochromatic rectangles needed to cover M_f. It is well known (see [16, Chapter 2]) that

$$\sqrt{D(f)} \leq N(f) = \log_2 C(f) \leq \log_2 C^D(f) \leq D(f),$$

where $N(f)$ is the nondeterministic communication complexity. We show that

$$\log_2 C(f) \leq \overset{\circ}{R}_0(f) \leq \log_2 C^D(f),$$

and in particular we get that $\sqrt{D(f)} \leq N(f) \leq \overset{\circ}{R}_0(f) \leq D(f)$, as required.

We first show that $\log_2 C(f) \leq \overset{\circ}{R}_0(f)$. Indeed, by Lemma 7.1 there is a one message zero error sampling protocol whose complexity is $k = \overset{\circ}{R}_0(f)$. In the one message protocol a message M is chosen (out of the 2^k possible messages) according to some probability distribution, and, given the message M, Alice (Bob) chooses a message $x \in X$ ($y \in Y$) according to some probability distribution that depends on M. Let us say that X_M (Y_M) is the set of elements in X that have nonzero probability of being selected by Alice (Bob), given the message M. As the protocol has zero error, the rectangle $X_M \times Y_M$ must be monochromatic. As Alice and Bob sample inputs according to the uniform distribution, every $(x,y) \in X \times Y$ must be covered. Hence the protocol gives rise to a monochromatic cover of M_f with only 2^k rectangles, and hence $C(f) \leq 2^k$.

Next we show that $\overset{\circ}{R}_0(f) \leq \log_2 C^D(f)$. Suppose that a disjoint monochromatic cover of M_f with 2^k rectangles exists. Say that the cover contains the rectangles $R_1, \ldots, R_{2^k}$ and $R_i = X_i \times Y_i$. We build a sampling protocol. A message $i \in \{1, \ldots, 2^k\}$ is picked with probability proportional to the area of R_i. Given the message i, Alice picks a random element $x \in X_i$, and Bob picks a random element $y \in Y_i$. It is easy to verify that, as the cover is disjoint, this results in the uniform distribution over $X \times Y$ along with the value of $f(x,y)$. Hence $\overset{\circ}{R}_0(f) \leq k$. ∎

THE EXPECTED NUMBER OF 3D VISIBILITY EVENTS IS LINEAR*

OLIVIER DEVILLERS†, VIDA DUJMOVIĆ‡, HAZEL EVERETT§, XAVIER GOAOC§, SYLVAIN LAZARD§, HYEON-SUK NA¶, AND SYLVAIN PETITJEAN§

Abstract. In this paper, we show that, amongst n uniformly distributed unit balls in $\mathbb{R}^3$, the expected number of maximal nonoccluded line segments tangent to four balls is linear. Using our techniques we show a linear bound on the expected size of the visibility complex, a data structure encoding the visibility information of a scene, providing evidence that the storage requirement for this data structure is not necessarily prohibitive. These results significantly improve the best previously known bounds of $O(n^{8/3})$ [F. Durand, G. Drettakis, and C. Puech, *ACM Transactions on Graphics*, 21 (2002), pp. 176–206].

Our results generalize in various directions. We show that the linear bound on the expected number of maximal nonoccluded line segments that are not too close to the boundary of the scene and tangent to four unit balls extends to balls of various but bounded radii, to polyhedra of bounded aspect ratio, and even to nonfat three-dimensional objects such as polygons of bounded aspect ratio. We also prove that our results extend to other distributions such as the Poisson distribution. Finally, we indicate how our probabilistic analysis provides new insight on the expected size of other global visibility data structures, notably the aspect graph.

1. Introduction.

Visibility computations are central in computer graphics applications. Computing the limits of the umbra and penumbra cast by an area light source, identifying the set of blockers between any two polygons, and determining the view from a given point are examples of visibility queries that are essential for the realistic rendering of three-dimensional (3D) scenes. In global illumination algorithms, where the flow of light in a scene is simulated according to the laws of geometrical optics, visibility computations are excessively costly. In fact, more than half of the overall computation time can routinely be spent on visibility queries in radiosity simulations [11].

One approach to speeding up rendering is to store global visibility information in a data structure which can then be efficiently queried. The visibility complex, a partition of the set of maximal-free line segments, has been proposed as a unified data structure encoding the visibility information of a scene [21] and has been used for

rendering purposes [9]. Other related data structures include Pellegrini's ray-shooting structure [18], the aspect graph [20], and the visual hull [12]; see [7] for a recent survey.

One problem with these types of data structures which may prevent their application in practice is their potentially enormous size; the size of the visibility complex of a set of n triangles in $\mathbb{R}^3$ is $\Theta(n^4)$ in the worst case [9], which is prohibitive even for scenes of relatively modest size. Worst-case examples are somewhat artificial, and indeed Durand, Drettakis, and Puech [8] provide empirical evidence indicating that these worst-case upper bounds are largely pessimistic in practical situations; they observe a quadratic growth rate, albeit for rather small scenes. In two dimensions, while the worst-case complexity of the visibility complex is quadratic, experimental results strongly suggest that the size of the visibility complex of a scene consisting of scattered triangles is linear [4].

Our goal is to provide theoretical evidence to support these observations. To this end we investigate the *expected size* of the visibility complex or, equivalently, the expected number of visibility events occurring in scenes in $\mathbb{R}^3$. A visibility event is a combinatorial change in the view of a moving observer; such an event occurs when the viewing direction becomes tangent to some objects. For sets of convex objects in general position in $\mathbb{R}^3$, the viewing direction can be tangent to at most four objects. Visibility events thus correspond to maximal nonoccluded line segments tangent to at most four objects; combinatorially different visibility events correspond to the faces of the visibility complex.

In this paper we prove that the expected number of maximal nonoccluded line segments tangent to four balls, amongst n uniformly distributed unit balls in $\mathbb{R}^3$, is linear. This improves the previously known upper bound of $O(n^{8/3})$ by Durand et al., who proved the more general result that the expected number of (possibly occluded) lines tangent to four balls is $O(n^{8/3})$ for the same model [9]. The intuition behind our proof is that, given a line segment tangent to four balls, the probability that this segment is not occluded by any other ball is the probability that a cylinder-like volume of radius 1 about the segment is free from the centers of the other balls. This probability decays roughly exponentially fast with the length of the segment, yielding the result. Using our techniques we then show a linear bound on the expected size of the visibility complex of n uniformly distributed unit balls in $\mathbb{R}^3$. A simple computation then provides us with the same result for the Poisson distribution.

Our results generalize in the following ways. We show that, for certain types of visibility events, the linear bound also applies to balls of various but bounded radii, to polyhedral objects enclosed between two concentric balls of fixed radius, and even to nonfat objects such as polygons, enclosed between two concentric circles of fixed radius, whose centers and normals are uniformly distributed. For the remaining types of visibility events (namely those occurring close to the boundary of the scene; see section 7.3 for the details), we prove only an $O(n^2)$ bound, which is still an improvement over the bound by Durand, Drettakis, and Puech [9].

Of course, objects in graphics scenes are seldom distributed uniformly or according to a Poisson point process. We chose this model because it allows tractable proofs of theoretical results. This is important in a context where there are few rigorous results, either theoretical or experimental. The same model, albeit with significant simplifying assumptions, has also been used to study the average complexity of ray shooting [23, 24] and occlusion culling for two-dimensional urban scenes [16]. It is interesting to note that Szirmay-Kalos et al. [23], after establishing bounds on the average complexity of ray shooting in scenes consisting of unit balls distributed

TABLE 1.1

Known bounds on the complexity of the set of lines, free lines, or maximal-free line segments tangent to 4 amongst n objects. The expected complexities are calculated for the uniform distribution. The results referenced by ⋆ are established in this paper.

	Worst-case	Expected
Possibly occluded lines amongst unit balls	$\Theta(n^4)$	$O(n^{\frac{8}{3}})$ [9]
Free lines amongst unit balls	$\Omega(n^2)$ [⋆], $O(n^{3+\epsilon})$ [1]	$\Theta(n)$ [⋆]
Free lines amongst disjoint homothetic polytopes	$\Omega(n^3)$ [3]	?
Free segments amongst unit balls	$\Omega(n^2)$ [⋆], $O(n^4)$	$\Theta(n)$[⋆]
Free segments amongst arbitrary sized balls	$\Omega(n^3)$ [6], $O(n^4)$	?
Visibility complex of unit balls	$\Omega(n^2)$ [⋆], $O(n^4)$	$\Theta(n)$ [⋆]

according to a Poisson point process, tested their algorithms on a small number of realistic scenes. The results they obtain are consistent with those predicted by the theoretical results, thus providing some evidence that the model is helpful. No other model has been widely accepted by the graphics community, and, in fact, generating meaningful random scenes usable for testing algorithms is a major problem. (Note that rather than attempting to generate random scenes, an alternative approach, which has been used to study the average complexity of ray shooting, is to fix the scene and randomly distribute the rays; see, for example, [2].)

Previous results on this topic include those that bound the number of lines and the number of free (i.e., nonoccluded) lines amongst different sets of objects. They are summarized in Table 1.1. Agarwal, Aronov, and Sharir [1] showed an upper bound of $O(n^{3+\epsilon})$ on the complexity of the space of line transversals of n balls by studying the lower envelope of a set of functions. A study of the upper envelope of the same set of functions yields the same upper bound on the number of free lines tangent to four balls [6]. Agarwal, Aronov, and Sharir [1] also showed a lower bound on the complexity of the space of line transversals of n balls of $\Omega(n^3)$ for arbitrarily sized balls and $\Omega(n^2)$ for unit sized balls. De Berg, Everett, and Guibas [3] showed a $\Omega(n^3)$ lower bound on the number of free lines (and thus free segments) tangent to 4 amongst n disjoint homothetic convex polyhedra. Recently, Devillers and Ramos [6] presented a simple $\Omega(n^3)$ lower bound on the number of free segments tangent to 4 amongst n arbitrarily sized balls, which also holds for nonintersecting balls. We also present a simple $\Omega(n^2)$ lower bound on the number of free segments tangent to 4 amongst n unit balls.

In the next section we carefully define the problem and state our main results. In section 3 and section 4 we prove the expected upper and lower linear bounds on the number of free segments tangent to four balls. In section 5 we extend this result to the visibility complex. We present in section 6 a $\Omega(n^2)$ worst-case lower bound. In section 7 we discuss extensions of our results to some other models. We conclude in section 8.

2. Our model and results. We first describe our objects and their distribution. Let $n \in \mathbb{N}$ and μ be a positive constant. A sample scene consists of n unit radius balls $B_1, \ldots, B_n$ whose centers $p_1, \ldots, p_n$ are independently chosen from the uniform distribution over a universal ball $\mathcal{U}$ of radius R centered at O. Since we distribute the centers p_i over $\mathcal{U}$, the balls B_i may intersect each other and are contained in the ball, denoted $\mathcal{U}^+$, whose radius is $R+1$ and whose center is that of $\mathcal{U}$.

We define the radius R of the universal ball $\mathcal{U}$ to be a function of n satisfying

$$R^3 = n/\mu. \tag{2.1}$$

The constant μ reflects the density of the balls in the sense that the expected number of centers lying in any given solid of volume V in the universe is $\frac{3}{4\pi}\mu V$. (The model is interesting only if n is asymptotically proportional to R^3. Indeed, if $\frac{n}{R^3}$ tends to infinity when n tends to infinity, then the universe gets entirely filled up with balls, and visibility events occur only in $\mathcal{U}^+ \setminus \mathcal{U}$. Conversely, if $\frac{n}{R^3}$ tends to zero when n tends to infinity, then the balls get scattered so far apart that the probability that any four (or three) balls have a common tangent goes to zero.)

We now define the *visibility complex* of a set of objects [21]. A *free* or *nonoccluded* segment is a line segment that does not intersect the interior of any object. A free segment is maximal if it is not properly contained in another one. Thus, the endpoints of a maximal-free segment are either on an object or at infinity. We say that two maximal-free segments are similar if their endpoints lie on the same objects (possibly at infinity). The visibility complex of a collection of objects is roughly defined as the partition of the space of maximal-free segments into connected components of similar segments.[1] Its faces have dimension between 0 and 4; when the objects are in adequate general position, a k-dimensional face corresponds to a connected set of similar maximal nonoccluded line segments tangent to $4-k$ objects.

In order to bound the total number of faces of the visibility complex, we first bound the number of 0-faces. To do this, we count the $T4$-*segments*, which are the free segments tangent to four balls with endpoints on two of those balls. Since there is a one-to-one correspondence between 0-faces and $T4$-segments when the objects are in adequate general position, this yields a bound on the expected number of vertices of the visibility complex. Note that since the balls are contained in $\mathcal{U}^+$, the $T4$-segments are also contained in $\mathcal{U}^+$.

Our main result is the following.

THEOREM 2.1. *The expected number of $T4$-segments amongst n uniformly distributed unit balls is $\Theta(n)$.*

We extend this result to the higher-dimensional faces of the complex.

THEOREM 2.2. *The expected size of the visibility complex of n uniformly distributed unit balls is $\Theta(n)$.*

We also present an $\Omega(n^2)$ worst-case lower bound on the number of $T4$-segments amongst n unit balls in $\mathbb{R}^3$ (see Proposition 6.1). In fact the lower bound holds for the number of k-faces of the visibility complex for all k between 0 and 4.

3. The expected number of $T4$-segments is at most linear. The general idea behind the proof of the upper bound of Theorem 2.1 is the following. For any ordered choice of four balls, we bound from above the probability that a line is tangent to these balls in the given order and is not occluded in between its contact points with the balls. Then we sum these probabilities over all ordered quadruples of balls and all potential tangent lines to these balls.

For any two points p and q, and positive real number α, let $\mathcal{H}(p,q,\alpha)$ denote the union of all the balls of radius α centered on the line segment pq (see Figure 3.1). We first show that a line is tangent to four balls B_i, B_j, B_k, and B_l in that order only if p_j and p_k are in $\mathcal{H}(p_i,p_l,2)$. Thus the volume of $\mathcal{H}(p_i,p_l,2) \cap \mathcal{U}$ gives an upper bound on the probability that a line tangent to the four balls in the given order exists.

[1] Formally, we consider the space of free segments quotiented by the equivalence relation that is the transitive and reflexive closure of the inclusion. In other words, two free segments are identified if they are both contained in the same maximal-free segment. This allows the cells of the partition to be connected.

We next show that a segment tangent to four balls B_i, B_j, B_k, and B_l in that order at points t_i, t_j, t_k, and t_l, respectively, is not occluded if and only if the centers of all remaining balls are outside or on the boundary of $\mathcal{H}(t_i, t_l, 1)$. The volume of $\mathcal{U} \setminus \mathcal{H}(t_i, t_l, 1)$ gives an upper bound on the probability that the tangent segment is not occluded. Thus, to get an upper bound on that probability, we need a lower bound on the volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$.

To bound the probability that a $T4$-segment exists, we integrate over the distance between p_i and p_l, and over the distance from p_i to the boundary of the universe $\mathcal{U}$. This integral is split into three parts covering the cases where

(i) B_i and B_l are close to one another,

(ii) at least one of B_i and B_l is entirely inside the universe,

(iii) B_i and B_l are not close to one another and both are partially outside the universe.

In each case we overestimate the volume of $\mathcal{H}(p_i, p_l, 2) \cap \mathcal{U}$ and underestimate the volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$. We apply the same general proof technique in each of the three cases. While case (ii) illustrates the main idea behind the proof (case (i) being a simplified version), extending this idea to case (iii) is technically challenging because of the difficulties caused by the boundary of the universe.

3.1. Definitions. Let $\mathcal{N}$ be the set of ordered 4-tuples (i, j, k, l) chosen from $\{1, 2, \ldots, n\}$ such that i, j, k, l are pairwise distinct. In our model, the probability that four centers are collinear is zero, so we may assume that any set of four balls admits at most 12 real common tangent lines [5, 13]. Moreover, the real common tangent lines correspond to the real solutions of a degree 12 system of equations. For any set of four balls we order arbitrarily the 12 solutions of the associated system.

Given four balls B_i, B_j, B_k, and B_l, we denote by $\mathcal{L}^{\omega}_{i,j,k,l}$, for ω in $\{1, \ldots, 12\}$, the event that the ωth solution of the system is real, that the corresponding real tangent line is tangent to the four balls B_i, B_j, B_k, and B_l in that order, and that p_i is not closer than p_l to the boundary of $\mathcal{U}$. Whenever $\mathcal{L}^{\omega}_{i,j,k,l}$ occurs, we denote the points of tangency of that line on B_i, B_j, B_k, B_l by t_i, t_j, t_k, t_l, respectively. Let $\delta^{\omega}_{i,j,k,l}$ be the event that $\mathcal{L}^{\omega}_{i,j,k,l}$ occurs and the line segment $t_i t_l$ is not occluded. Notice that if $\delta^{\omega}_{i,j,k,l}$ occurs, the balls B_i, B_j, B_k, B_l define a $T4$-segment, and that a $T4$-segment corresponds to a unique $\delta^{\omega}_{i,j,k,l}$.

Let $\mathbf{x}_{i,l}$ be the random variable representing the distance from p_i to p_l, and let $\mathbf{y}_i$ (resp., $\mathbf{y}_l$) be the random variable denoting the distance from p_i (resp., p_l) to the boundary of the universe.

In what follows, a random point p denotes a point chosen from the uniform distribution over $\mathcal{U}$.

3.2. The proof. There is a one-to-one correspondence between the $T4$-segments and the events $\delta^{\omega}_{i,j,k,l}$ that occur. We thus have the following straightforward lemma.

LEMMA 3.1. *The expected number of $T4$-segments amongst n uniformly distributed unit balls is*

$$\sum_{(i,j,k,l)\in\mathcal{N}} \sum_{\omega=1}^{12} \Pr(\delta^{\omega}_{i,j,k,l}).$$

We bound the probability $\Pr(\delta^{\omega}_{i,j,k,l})$ by integrating over the distance x between p_i and p_l and over the distance y from p_i to the boundary of the universe $\mathcal{U}$. The integral is split into three parts, covering the cases where (i) the balls B_i and B_l are close to one another, (ii) p_i is at distance at least 1 from the boundary of $\mathcal{U}$, and

(iii) the balls B_i and B_l are not close to one another and p_i is at distance less than 1 from the boundary of $\mathcal{U}$. Note that in the last case, if $\delta^{\omega}_{i,j,k,l}$ occurs, then both ball centers p_i and p_l are within distance 1 from the boundary of $\mathcal{U}$. Two balls are considered close to one another if their centers are closer than some sufficiently large constant; for technical reasons which are embedded in the proof of Proposition A.1, we actually define *close* to mean distance at most 6.

LEMMA 3.2. $\Pr(\delta^{\omega}_{i,j,k,l}) \leqslant I_{x\leqslant 6} + I_{y\geqslant 1} + I_{x>6,y<1}$, *where*

$$
\begin{aligned}
I_{x\leqslant 6} &= \int_{x=0}^{6} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x) \cdot \Pr(x \leqslant \mathbf{x}_{i,l} < x + dx),\\
I_{y\geqslant 1} &= \int_{x=0}^{2R} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i \geqslant 1) \cdot \Pr(x \leqslant \mathbf{x}_{i,l} < x + dx \mid \mathbf{y}_i \geqslant 1),\\
I_{x>6,y<1} &= \int_{x=6}^{2R} \int_{y=0}^{1} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i)\\
&\qquad \cdot \Pr((x \leqslant \mathbf{x}_{i,l} < x + dx) \cap (\mathbf{y}_l \leqslant \mathbf{y}_i) \mid \mathbf{y}_i = y)\\
&\qquad \cdot \Pr(y \leqslant \mathbf{y}_i < y + dy).
\end{aligned}
$$

Proof. By the total probability theorem (see [17]),

$$
\Pr(\delta^{\omega}_{i,j,k,l}) = \int_{x=0}^{2R} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x) \cdot \Pr(x \leqslant \mathbf{x}_{i,l} < x + dx).
$$

The integral can be split at $x = 6$, giving $I_{x\leqslant 6}$. Then applying the total probability theorem on what remains, we get

$$
\begin{aligned}
\int_{x=6}^{2R} \int_{y=0}^{R} &\Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y) \cdot \Pr((x \leqslant \mathbf{x}_{i,l} < x + dx) \mid \mathbf{y}_i = y)\\
&\cdot \Pr(y \leqslant \mathbf{y}_i < y + dy),
\end{aligned}
\tag{3.1}
$$

which can be split at $y = 1$. The part corresponding to y between 1 and R is equal to

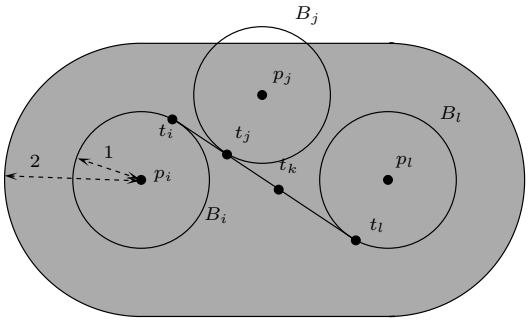
$$
\begin{aligned}
&\int_{x=6}^{2R} \int_{y=1}^{R} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_i \geqslant 1)\\
&\qquad \cdot \Pr((x \leqslant \mathbf{x}_{i,l} < x + dx) \mid \mathbf{y}_i = y,\ \mathbf{y}_i \geqslant 1) \cdot \Pr(y \leqslant \mathbf{y}_i < y + dy)\\
&\leqslant \int_{x=6}^{2R} \int_{y=0}^{R} \Pr(\delta^{\omega}_{i,j,k,l} \cap (x \leqslant \mathbf{x}_{i,l} < x + dx) \mid \mathbf{y}_i = y,\ \mathbf{y}_i \geqslant 1) \cdot \Pr(y \leqslant \mathbf{y}_i < y + dy).
\end{aligned}
$$

Applying the total probability theorem again, we get

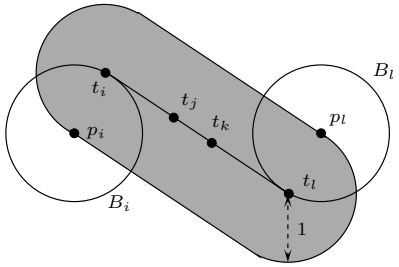
$$
\int_{x=6}^{2R} \Pr(\delta^{\omega}_{i,j,k,l} \cap (x \leqslant \mathbf{x}_{i,l} < x + dx) \mid \mathbf{y}_i \geqslant 1),
$$

which is less than $I_{y\geqslant 1}$. Consider now the part of (3.1) for y between 0 and 1. If $\mathbf{y}_l > \mathbf{y}_i$, then $\delta^{\omega}_{i,j,k,l}$ does not occur (by definition of $\mathcal{L}^{\omega}_{i,j,k,l}$); thus we have

$$
\begin{aligned}
&\Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y) \cdot \Pr((x \leqslant \mathbf{x}_{i,l} < x + dx) \mid \mathbf{y}_i = y)\\
&= \Pr(\delta^{\omega}_{i,j,k,l} \cap (x \leqslant \mathbf{x}_{i,l} < x + dx) \mid \mathbf{y}_i = y)\\
&= \Pr(\delta^{\omega}_{i,j,k,l} \cap (x \leqslant \mathbf{x}_{i,l} < x + dx) \cap (\mathbf{y}_l \leqslant \mathbf{y}_i) \mid \mathbf{y}_i = y)\\
&= \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i)\\
&\quad \cdot \Pr((x \leqslant \mathbf{x}_{i,l} < x + dx) \cap (\mathbf{y}_l \leqslant \mathbf{y}_i) \mid \mathbf{y}_i = y).
\end{aligned}
$$



(a) $\mathcal{H}(p_i, p_l, 2)$



(b) $\mathcal{H}(t_i, t_l, 1)$

FIG. 3.1. *$\mathcal{H}(p_i, p_l, 2)$ and $\mathcal{H}(t_i, t_l, 1)$ are shown shaded.*

Thus, the part of (3.1) for y between 0 and 1 is equal to $I_{x>6,y<1}$. □

Let Ξ denote any of the following events: $(\mathbf{x}_{i,l} = x)$, $(\mathbf{x}_{i,l} = x, \mathbf{y}_i \geqslant 1)$, $(\mathbf{x}_{i,l} = x, \mathbf{y}_i = y, \mathbf{y}_l \leqslant \mathbf{y}_i)$. The next three lemmas are used to bound $\Pr(\delta^{\omega}_{i,j,k,l} \mid \Xi)$ appearing in the three integrals $I_{x\leqslant 6}$, $I_{y\geqslant 1}$, and $I_{x>6,y<1}$.

LEMMA 3.3. *If a line is tangent to four balls B_i, B_j, B_k, B_l in that order at t_i, t_j, t_k, t_l, respectively, then $p_j, p_k \in \mathcal{H}(p_i, p_l, 2)$. Also, the segment $t_i t_l$ is not occluded if and only if the interior of $\mathcal{H}(t_i, t_l, 1)$ does not contain the center of any other ball.*

Proof. Segment $t_i t_l$ is contained in $\mathcal{H}(p_i, p_l, 1)$. Since t_j and t_k belong to that segment, t_j and t_k are also in $\mathcal{H}(p_i, p_l, 1)$. Thus p_j, p_k are both in $\mathcal{H}(p_i, p_l, 2)$. See Figure 3.1(a).

The segment $t_i t_l$ is occluded if and only if some ball B_γ, $\gamma \neq i, j, k, l$, properly intersects it; that is, the center of B_γ lies in the interior of $\mathcal{H}(t_i, t_l, 1)$. See Figure 3.1(b). □

LEMMA 3.4. $\Pr(p \in \mathcal{H}(p_i, p_l, 2) \mid \Xi) \leqslant \frac{(3x+8)}{R^3}$.

Proof.

$$\Pr(p \in \mathcal{H}(p_i, p_l, 2) \mid \Xi) = \frac{\text{Volume of } \mathcal{H}(p_i, p_l, 2) \cap \mathcal{U}}{\text{Volume of } \mathcal{U}} \mid_{\Xi} \leqslant \frac{\text{Volume of } \mathcal{H}(p_i, p_l, 2)}{\text{Volume of } \mathcal{U}} \mid_{\Xi}.$$

When Ξ occurs, $\mathbf{x}_{i,l} = x$ and the volumes of $\mathcal{H}(p_i, p_l, 2)$ and $\mathcal{U}$ are $\frac{4\pi}{3}(3x + 8)$ and $\frac{4\pi}{3}R^3$, respectively. Thus

$$\Pr(p \in \mathcal{H}(p_i, p_l, 2) \mid \Xi) \leqslant \frac{3x + 8}{R^3}. \qquad \square$$

LEMMA 3.5. $\Pr(\delta^{\omega}_{i,j,k,l} \mid \Xi) \leqslant \frac{(3x+8)^2}{R^6} \cdot \Pr(p \notin \mathcal{H}(t_i, t_l, 1) \mid \mathcal{L}^{\omega}_{i,j,k,l},\ \Xi)^{n-4}$.

Proof. If $\delta^{\omega}_{i,j,k,l}$ occurs, then $\mathcal{L}^{\omega}_{i,j,k,l}$ necessarily occurs; thus

$$\Pr(\delta^{\omega}_{i,j,k,l} \mid \Xi) = \Pr(\delta^{\omega}_{i,j,k,l} \cap \mathcal{L}^{\omega}_{i,j,k,l} \mid \Xi) = \Pr(\mathcal{L}^{\omega}_{i,j,k,l} \mid \Xi) \cdot \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathcal{L}^{\omega}_{i,j,k,l},\ \Xi).$$

By Lemma 3.3, $\Pr(\mathcal{L}^{\omega}_{i,j,k,l} \mid \Xi)$ is bounded by the probability that p_j and p_k belong to $\mathcal{H}(p_i, p_l, 2)$, given Ξ, and $\Pr(\delta^{\omega}_{i,j,k,l} \mid \mathcal{L}^{\omega}_{i,j,k,l})$ is equal to the probability that for all $\gamma \neq i, j, k, l$, point p_γ is outside $\mathcal{H}(t_i, t_l, 1)$, given Ξ. Since all the points are independently and identically drawn from the uniform distribution over $\mathcal{U}$, Lemma 3.4 yields the result. ∎

We consider the three integrals $I_{x\leqslant 6}$, $I_{y\geqslant 1}$, and $I_{x>6,y<1}$ in the following subsections and prove that each is bounded by $O\left(\frac{1}{n^3}\right)$. This will complete the proof of the upper bound of Theorem 2.1 since, by Lemmas 3.1 and 3.2, the expected number of $T4$-segments is less than $12\binom{n}{4}(I_{x\leqslant 6} + I_{y\geqslant 1} + I_{x>6,y<1})$.

3.2.1. B_i and B_l are close to one another. We prove here that $I_{x\leqslant 6}$ is $O\left(\frac{1}{n^3}\right)$. When B_i and B_l are close to one another, the probability that there exist two other balls, B_j and B_k, defining a line tangent to B_i, B_j, B_k, B_l in that order is small enough that we do not need to consider occlusions in order to get the bound we want.

We first bound the term $\Pr(x \leqslant \mathbf{x}_{i,l} < x + dx)$ appearing in the integral $I_{x\leqslant 6}$.

LEMMA 3.6. $\Pr(x \leqslant \mathbf{x}_{i,l} < x + dx) \leqslant \frac{3x^2}{R^3} dx$.

Proof. When p_i is given, p_l must belong to a spherical shell between two spheres of center p_i and radii x and $x + dx$. The probability $\Pr(x \leqslant \mathbf{x}_{i,l} < x + dx)$, if p_i is known, is exactly the volume of the part of the spherical shell inside $\mathcal{U}$ divided by the volume of $\mathcal{U}$. The volume of the part of the spherical shell inside $\mathcal{U}$ is bounded from above by the volume of the spherical shell, which is $4\pi x^2 dx$. Since the volume of $\mathcal{U}$ is $\frac{4}{3}\pi R^3$ we get the claimed bound. (The exact value of $\Pr(x \leqslant \mathbf{x}_{i,l} < x + dx)$ is actually given in [15, 22], but the above approximate bound is enough for our purposes.) ∎

PROPOSITION 3.7. *$I_{x\leqslant 6}$ is $O\left(\frac{1}{n^3}\right)$.*

Proof. Recall that (see Lemma 3.2)

$$I_{x\leqslant 6} = \int_{x=0}^{6} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x) \cdot \Pr(x \leqslant \mathbf{x}_{i,l} < x + dx).$$

By Lemma 3.5,

$$\begin{aligned}\Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x) &\leqslant \frac{(3x+8)^2}{R^6} \cdot \Pr(p \notin \mathcal{H}(t_i, t_l, 1) \mid \mathbf{x}_{i,l} = x,\ \mathcal{L}^{\omega}_{i,j,k,l})^{n-4} \\ &\leqslant \frac{(3x+8)^2}{R^6}.\end{aligned}$$

It thus follows from Lemma 3.6 that

$$I_{x\leqslant 6} \leqslant \int_{x=0}^{6} \frac{(3x+8)^2}{R^6} \cdot \frac{3x^2}{R^3} dx = \frac{\mu^3}{n^3} \int_{x=0}^{6} 3x^2(3x+8)^2 dx = O\left(\frac{1}{n^3}\right). \quad ∎$$

3.2.2. B_i is entirely inside $\mathcal{U}$. For the integral $I_{y\geqslant 1}$, occlusions must be taken into account. To this aim, we bound from below the volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ in the following lemma.

LEMMA 3.8. *When $\mathcal{L}^{\omega}_{i,j,k,l}$ occurs and $\mathbf{y}_i \geqslant 1$, the volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ is greater than $\frac{\pi}{12}\mathbf{x}_{i,l}$.*

Proof. Let K be the ball having diameter p_it_i. Note that K and p_l are both contained in $\mathcal{U}$ and in $\mathcal{H}(t_i,t_l,1)$. The convex hull of p_l and K is thus contained in $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$, and its volume is larger than half the volume of the ball K, $\frac{\pi}{12}$, plus the volume of a cone of apex p_l, of base a disk whose boundary is a great circle of K, and of height greater than $\mathbf{x}_{i,l}-1$. The volume of that cone is at least $\frac{1}{3}\frac{\pi}{2^2}(\mathbf{x}_{i,l}-1)=\frac{\pi}{12}\mathbf{x}_{i,l}-\frac{\pi}{12}$. □

We now bound the probability that a tangent line segment t_it_l is not occluded by any of the other $n-4$ balls, given that the line segment t_it_l exists and the ball B_i is entirely contained in $\mathcal{U}$.

LEMMA 3.9. $\Pr\left(p\notin\mathcal{H}(t_i,t_l,1)\mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i\geqslant 1,\ \mathcal{L}^{\omega}_{i,j,k,l}\right)^{n-4}<55\exp\left(-\frac{\mu\,x}{16}\right)$.

Proof. First notice that

$$\Pr\left(p\notin\mathcal{H}(t_i,t_l,1)\mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i\geqslant 1,\ \mathcal{L}^{\omega}_{i,j,k,l}\right) = 1-\frac{\text{Volume of }\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}}{\text{Volume of }\mathcal{U}}\Big|_{\mathbf{x}_{i,l}=x,\ \mathbf{y}_i\geqslant 1,\ \mathcal{L}^{\omega}_{i,j,k,l}}.$$

By Lemma 3.8, the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ is bounded from below by $\frac{\pi}{12}x$. Since the volume of $\mathcal{U}$ is $\frac{4}{3}\pi R^3$, we get

$$\Pr\left(p\notin\mathcal{H}(t_i,t_l,1)\mid \mathbf{x}_{i,l}=x,\mathbf{y}_i\geqslant 1,\ \mathcal{L}^{\omega}_{i,j,k,l}\right)^{n-4}<\left(1-\frac{x}{16R^3}\right)^{n-4}.$$

For any $0\leqslant t\leqslant 1$, we have $(1-t)\leqslant e^{-t}$; thus

$$(1-t)^{n-4}\leqslant e^{-t(n-4)}=e^{-tn}e^{4t}\leqslant e^4e^{-tn}<55\,e^{-tn}.$$

Now $0\leqslant x\leqslant 2R$ and $R\geqslant 1$ since B_i is entirely inside $\mathcal{U}$. Thus $0\leqslant\frac{x}{16R^3}\leqslant\frac{1}{8R^2}\leqslant 1$ and

$$\Pr\left(p\notin\mathcal{H}(t_i,t_l,1)\mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i\geqslant 1,\ \mathcal{L}^{\omega}_{i,j,k,l}\right)^{n-4}<55\exp\left(-\frac{n\,x}{16R^3}\right) = 55\exp\left(-\frac{\mu\,x}{16}\right).$$ □

The following proposition now bounds the integral $I_{y\geqslant 1}$.

PROPOSITION 3.10. *$I_{y\geqslant 1}$ is $O\left(\frac{1}{n^3}\right)$.*

Proof. Recall that

$$I_{y\geqslant 1}=\int_{x=0}^{2R}\Pr(\delta^{\omega}_{i,j,k,l}\mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i\geqslant 1)\cdot\Pr(x\leqslant\mathbf{x}_{i,l}<x+dx\mid \mathbf{y}_i\geqslant 1).$$

By Lemmas 3.5 and 3.9 we have

$$\Pr(\delta^{\omega}_{i,j,k,l}\mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i\geqslant 1)\leqslant\frac{(3x+8)^2}{R^6}\cdot 55\exp\left(-\frac{\mu\,x}{16}\right).$$

Similarly as in Lemma 3.6 we have

$$\Pr(x\leqslant\mathbf{x}_{i,l}<x+dx\mid \mathbf{y}_i\geqslant 1)\leqslant\frac{3x^2}{R^3}dx.$$

Thus we get

$$\begin{aligned} I_{y\geqslant 1} &\leqslant\int_{x=0}^{2R}\frac{(3x+8)^2}{R^6}\cdot 55\exp\left(-\frac{\mu\,x}{16}\right)\cdot\frac{3x^2}{R^3}dx\\ &\leqslant\frac{\mu^3}{n^3}\int_{x=0}^{+\infty}3x^2(3x+8)^2\cdot 55\exp\left(-\frac{\mu\,x}{16}\right)dx. \end{aligned}$$

Changing $\frac{\mu x}{16}$ by z we get integrals of the kind

$$\int_0^\infty z^r \exp(-z)dz,$$

which is bounded by a constant, and thus $I_{y\geqslant 1}$ is $O\left(\frac{1}{n^3}\right)$. □

3.2.3. B_i and B_l are not close to one another and B_i is partially outside $\mathcal{U}$. The only remaining task is to bound the integral $I_{x>6,y<1}$. As in the previous case, we need to bound from below the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$. Here, however, the tangent t_it_l can be entirely outside $\mathcal{U}$, so the bound of Lemma 3.8 does not apply, and a more intricate proof is needed. We need to distinguish two cases depending on the distance of segment t_it_l from O, the center of $\mathcal{U}$.

To this aim, we introduce two new types of events. For any $s\in\mathbb{R}$, let $\mathcal{F}^\omega_{i,j,k,l}(s)$ (resp., $\mathcal{N}^\omega_{i,j,k,l}(s)$) be the event that $\mathcal{L}^\omega_{i,j,k,l}$ occurs and the line segment t_it_l is at distance greater (resp., less) than $R+1-s$ from O. For reasons that will become clear in the proof of Lemma 3.13, we consider $s=y^{\frac{2}{3}}$.

The next five lemmas are used to bound the first term of the integral $I_{x>6,y<1}$.

LEMMA 3.11. *For any random point p in $\mathcal{U}$,* $\Pr(\delta^\omega_{i,j,k,l} \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i)$ *is equal to*

$$\begin{aligned}
&\Pr\left(\mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i\right)\\
&\cdot\Pr\left(p\notin\mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i,\ \mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4}\\
&+\Pr\left(\mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i\right)\\
&\cdot\Pr\left(p\notin\mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i,\ \mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4}.
\end{aligned}$$

Proof. $\delta^\omega_{i,j,k,l}$ implies $\mathcal{L}^\omega_{i,j,k,l}$, which can be split into $\mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}})$, $\mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}})$, and the event that $\mathcal{L}^\omega_{i,j,k,l}$ occurs and the line segment t_it_l is at distance exactly $R+1-y^{\frac{2}{3}}$ from O. This later event occurs with probability 0; thus

$$\begin{aligned}
\Pr(\delta^\omega_{i,j,k,l} \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i)&\\
&=\Pr(\delta^\omega_{i,j,k,l}\cap\mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i)\\
&\quad+\Pr(\delta^\omega_{i,j,k,l}\cap\mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i),
\end{aligned}$$

which can be expanded into

$$\begin{aligned}
&\Pr(\mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i)\\
&\cdot\Pr(\delta^\omega_{i,j,k,l} \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i,\ \mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}}))\\
&+\Pr(\mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i)\\
&\cdot\Pr(\delta^\omega_{i,j,k,l} \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i,\ \mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}})).
\end{aligned}$$

When $\mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}})$ occurs, the probability

$$\Pr(\delta^\omega_{i,j,k,l} \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i,\ \mathcal{F}^\omega_{i,j,k,l}(y^{\frac{2}{3}}))$$

is the probability that the tangent is not occluded; that is, p_γ does not belong to $\mathcal{H}(t_i,t_l,1)$ for all the $n-4$ values of $\gamma\neq i,j,k,l$. The same argument holds for $\mathcal{N}^\omega_{i,j,k,l}(y^{\frac{2}{3}})$. Since the p_γ are independent, we get the result. □

In order to bound the two terms in Lemma 3.11,

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4}$$

and

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4},$$

we need to bound the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ from below.

LEMMA 3.12. *When $\mathbf{x}_{i,l} \geqslant 6$, $\mathbf{y}_l \leqslant \mathbf{y}_i \leqslant 1$, $\mathcal{L}^{\omega}_{i,j,k,l}$ occurs and segment t_it_l is at distance less than $R+1-s$, $0 \leqslant s \leqslant 1$, from the center of $\mathcal{U}$, then the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ is larger than $\frac{1}{6\sqrt{2}}\,(\mathbf{x}_{i,l}-5)\,s\,\sqrt{s}$.*

Proof. We give here the idea of the proof; full details can be found in Appendix A. Let t be the closest point on segment t_it_l from O, and let D be a unit radius disk centered at t in a plane containing O, the center of $\mathcal{U}$. We define a quadrilateral with vertices a,b,a',b' such that a and a' are the closest and the farthest points, respectively, in $D\cap\mathcal{U}$ from O, and b and b' are the points of intersection of ∂D and the perpendicular bisector of segment aa' (see Figure 3.2). Let v be equal to $R+1$ minus the distance from O to segment t_it_l. We prove that the convex hull of a,b,a',b', and p_l, which is included in $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$, has volume greater than $\frac{1}{6\sqrt{2}}\,(\mathbf{x}_{i,l}-5)\,\min(2\sqrt{2},v\sqrt{v})$. It follows that, for any $0\leqslant s\leqslant 1$, if segment t_it_l is at distance less than $R+1-s$ from O, then $v\geqslant s$, and the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ is greater than $\frac{1}{6\sqrt{2}}\,(\mathbf{x}_{i,l}-5)\,s\,\sqrt{s}$. ∎

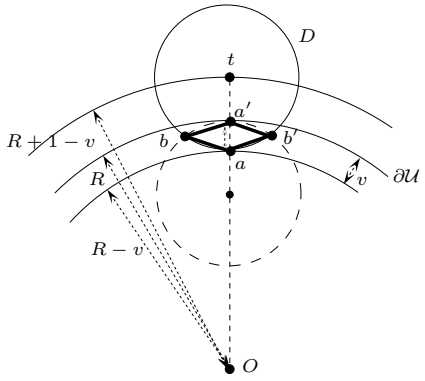


FIG. 3.2. *For the sketch of the proof of Lemma 3.12 ($v\in(0,1)$).*

LEMMA 3.13. *For any random point p in $\mathcal{U}$, $x\geqslant 6$ and $0\leqslant y\leqslant 1$,*

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} < 55\exp\left(-\frac{\mu\,(x-5)\,y^2}{8\sqrt{2}\,\pi}\right)$$

and

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} < 55\exp\left(-\frac{\mu\,(x-5)\,y}{8\sqrt{2}\,\pi}\right).$$

Furthermore, if $x \geqslant 6\sqrt{R}$, *then*

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} < 55\exp\left(-\frac{\mu\,(x-5)}{8\,\sqrt{2}\,\pi}\right).$$

Proof. Let $\mathbf{x}_{i,l}=x$, $\mathbf{y}_i=y$, and suppose first that event $\mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})$ occurs. Since p_i is at distance $R-y$ from O, the segment t_it_l is at distance less than $R+1-y$ from O, and thus, by Lemma 3.12, the volume of $\mathcal{H}\,(t_i,t_l,1)\cap\mathcal{U}$ is greater than $\frac{1}{6\sqrt{2}}\,(x-5)\,y\,\sqrt{y}$, which is bigger than $\frac{1}{6\sqrt{2}}\,(x-5)\,y^2$ since $0\leqslant y\leqslant 1$ (we bound $y\sqrt{y}$ from below by y^2 only so that we can actually compute the integral $\mathcal{I}_1$ in the proof of Proposition 3.18). We now follow the proof of Lemma 3.9, except that the volume of $\mathcal{H}\,(t_i,t_l,1)\cap\mathcal{U}$ is now bounded from below by $\frac{1}{6\sqrt{2}}\,(x-5)\,y^2$ instead of $\frac{\pi}{12}\,x$. We get

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} < 55\exp\left(-\frac{\mu\,(x-5)\,y^2}{8\,\sqrt{2}\,\pi}\right).$$

When $\mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})$ occurs, the segment t_it_l is at distance less than $R+1-y^{\frac{2}{3}}$ from O, and thus, by Lemma 3.12, the volume of $\mathcal{H}\,(t_i,t_l,1)\cap\mathcal{U}$ is bounded from below by $\frac{1}{6\sqrt{2}}\,(x-5)\,y^{\frac{2}{3}}\,\sqrt{y^{\frac{2}{3}}}=\frac{1}{6\sqrt{2}}\,(x-5)\,y$. Then, as before, we get

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} < 55\exp\left(-\frac{\mu\,(x-5)\,y}{8\,\sqrt{2}\,\pi}\right).$$

Now, if $x \geqslant 6\sqrt{R}$, the length of the tangent t_it_l is at least $6\sqrt{R}-2$. Since $x\geqslant 6$, $R>3$ and a simple computation show that $6\sqrt{R}-2$ is bigger than $2\sqrt{2R+1}$, which is the length of the longest line segment that may entirely lie inside $\mathcal{U}^+\setminus\mathcal{U}$. Thus $dist(O,t_it_l)\leqslant R = R+1-s$ with $s=1$, and, by Lemma 3.12, the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ is greater than $\frac{1}{6\sqrt{2}}\,(x-5)$. Then, as before, we get

$$\Pr\left(p \notin \mathcal{H}(t_i,t_l,1) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} < 55\exp\left(-\frac{\mu\,(x-5)}{8\,\sqrt{2}\,\pi}\right). \qquad \square$$

LEMMA 3.14. $\Pr(\mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i) \leqslant \frac{(3x+8)^2}{R^6}$.

Proof. The event $\mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})$ occurs only if $\mathcal{L}^{\omega}_{i,j,k,l}$ occurs. The result thus follows since, by Lemmas 3.3 and 3.4, $\Pr(\mathcal{L}^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y,\ \mathbf{y}_l\leqslant\mathbf{y}_i) \leqslant \frac{(3x+8)^2}{R^6}$. $\square$

LEMMA 3.15. *If* $y<1$, *then*

$$\Pr\left(\mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l}=x,\ \mathbf{y}_i=y\right) \leqslant 81\,\pi^2\,\frac{(x+6)^2y^2}{R^6}.$$

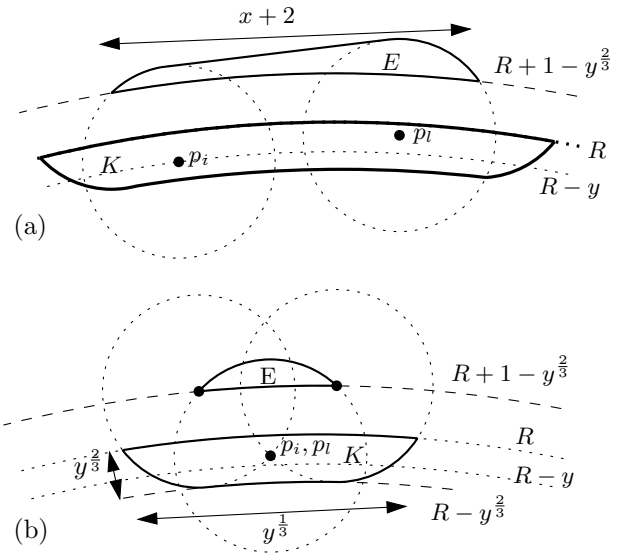

FIG. 3.3. *For the sketch of the proof of Lemma* 3.15.

Proof. A "far" tangent $t_i t_l$ is at distance at least $R+1-y^{\frac{2}{3}}$ from the center O of $\mathcal{U}$. Such a segment also lies in $\mathcal{H}(p_i, p_l, 1)$. Let E be the part of $\mathcal{H}(p_i, p_l, 1)$ lying outside of the sphere of radius $R+1-y^{\frac{2}{3}}$ and center O. See Figure 3.3(a). Now, both p_j and p_k must be in the region inside $\mathcal{U}$ and within distance 1 from E. Denote this region by K. Then

$$\Pr\left(\mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i\right) \leqslant \left(\frac{\text{Volume of } K}{\text{Volume of } \mathcal{U}}\right)^2.$$

By Proposition B.1, which we prove in Appendix B, the volume of K is bounded from above by $12\,\pi^2\,(x+6)\,y$, which yields the result. Here we give the intuition of the proof. Refer to Figure 3.3. First notice that the "length" of K is at most $x+4$. Since K is enclosed in between a sphere of radius R and one of radius $R-y^{\frac{2}{3}}$, its "height" is at most $y^{\frac{2}{3}}$. For the "width," consider Figure 3.3(b), which shows a cross-section of K taken with a plane through O and perpendicular to $p_i p_l$. The "width" of K is no more than two times the "width" of E. The "height" of E can be bounded by some constant times $y^{\frac{2}{3}}$; thus its "width" can be bounded by some constant times $\sqrt{y^{\frac{2}{3}}} = y^{\frac{1}{3}}$. Thus, intuitively, the volume of K is smaller than $(x+4)y^{\frac{2}{3}}y^{\frac{1}{3}} = (x+4)y$, up to a constant, and the result follows. ∎

We now bound the two last terms of the integral $I_{x>6,y<1}$.

LEMMA 3.16. $\Pr(y \leqslant \mathbf{y}_i < y+dy) \leqslant \frac{3\,dy}{R}$.

Proof. The event $(y \leqslant \mathbf{y}_i < y+dy)$ occurs only if p_i lies in the spherical shell delimited by the two spheres centered at O of radii $R-y$ and $R-y-dy$ whose volume is smaller than $4\,\pi\,R^2\,dy$. Dividing by the volume of $\mathcal{U}$ proves the result. ∎

LEMMA 3.17. *For* $6 \leqslant x \leqslant 2R$ *and* $y \leqslant 1$, *we have*

$$\Pr((x \leqslant \mathbf{x}_{i,l} < x+dx) \cap (\mathbf{y}_l \leqslant \mathbf{y}_i) \mid \mathbf{y}_i = y) \leqslant \frac{6\,x\,y\,dx}{R^3}.$$

Proof. The probability $\Pr((x \leqslant \mathbf{x}_{i,l} < x+dx) \cap (\mathbf{y}_l \leqslant \mathbf{y}_i) \mid \mathbf{y}_i = y)$ is equal to the volume of the region (shown in grey in Figure 3.4), which is the intersection of the

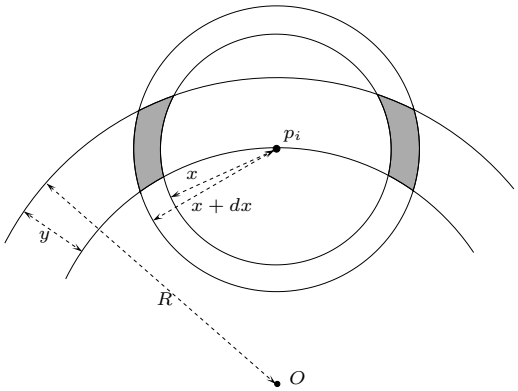

FIG. 3.4. *For the proof of Lemma* 3.17.

region in between the two spheres centered at p_i and of radii x and $x + dx$, and the region in between the two spheres centered at O and of radii R and $R - y$, divided by the volume of $\mathcal{U}$. We prove in Proposition C.1 in Appendix C that the volume of that region is at most $8\,\pi\,x\,y\,dx$. Roughly speaking, the volume bounded by the four spheres is at most $8\,\pi\,x\,y\,dx$ because its "thickness" is dx, its "height" is y, and its "radius" is x. Dividing by the volume of $\mathcal{U}$ proves the result. □

We can now bound the integral $I_{x>6,y<1}$ of Lemma 3.2.

PROPOSITION 3.18. *$I_{x>6,y<1}$ is $O\left(\frac{1}{n^3}\right)$.*

Proof. Recall that

$$\begin{aligned} I_{x>6,y<1} = \int_{x=6}^{2R}\int_{y=0}^{1} & \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i) \\ & \cdot \Pr((x \leqslant \mathbf{x}_{i,l} < x + dx) \cap (\mathbf{y}_l \leqslant \mathbf{y}_i) \mid \mathbf{y}_i = y) \\ & \cdot \Pr(y \leqslant \mathbf{y}_i < y + dy). \end{aligned}$$

By Lemmas 3.16 and 3.17, we get

$$I_{x>6,y<1} \leqslant \int_{x=6}^{2R}\int_{y=0}^{1} \Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i) \cdot \frac{6\,x\,y\,dx}{R^3} \cdot \frac{3\,dy}{R}.$$

By Lemma 3.11, $\Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i)$ is equal to

$$\begin{aligned} & \Pr\left(\mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i\right) \\ & \cdot \Pr\left(p \notin \mathcal{H}(t_i, t_l, 1) \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4} \\ & + \Pr\left(\mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i\right) \\ & \cdot \Pr\left(p \notin \mathcal{H}(t_i, t_l, 1) \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i,\ \mathcal{N}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}})\right)^{n-4}. \end{aligned}$$

We split the integral at $x = 6\sqrt{R}$. When $x \geqslant 6\sqrt{R}$, the distance from O to the tangent $t_i t_l$ is less than R (see the proof of Lemma 3.13), which is less than $R + 1 - y^{\frac{2}{3}}$ for any y in $(0, 1)$. Thus, for any $x \geqslant 6\sqrt{R}$ and $y \in (0, 1)$, the probability $\Pr\left(\mathcal{F}^{\omega}_{i,j,k,l}(y^{\frac{2}{3}}) \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i\right)$ is equal to 0. It then follows from Lemmas

3.13, 3.14, and 3.15 that $I_{x>6,y<1} \leqslant \mathcal{I}_1 + \mathcal{I}_2 + \mathcal{I}_3$ with

$$\mathcal{I}_1 = \int_{x=6}^{6\sqrt{R}} \int_{y=0}^{1} 81\,\pi^2 \frac{(x+6)^2 y^2}{R^6} \cdot 55 \exp\left(-\frac{\mu\,(x-5)\,y^2}{8\sqrt{2}\,\pi}\right) \cdot \frac{6\,x\,y\,dx}{R^3} \cdot \frac{3\,dy}{R},$$

$$\mathcal{I}_2 = \int_{x=6}^{6\sqrt{R}} \int_{y=0}^{1} \frac{(3x+8)^2}{R^6} \cdot 55 \exp\left(-\frac{\mu\,(x-5)\,y}{8\sqrt{2}\,\pi}\right) \cdot \frac{6\,x\,y\,dx}{R^3} \cdot \frac{3\,dy}{R},$$

$$\mathcal{I}_3 = \int_{x=6\sqrt{R}}^{2R} \int_{y=0}^{1} \frac{(3x+8)^2}{R^6} \cdot 55 \exp\left(-\frac{\mu\,(x-5)}{8\sqrt{2}\,\pi}\right) \cdot \frac{6\,x\,y\,dx}{R^3} \cdot \frac{3\,dy}{R}.$$

Changing $\frac{\mu\,(x-5)}{8\sqrt{2}\,\pi}$ by z in the three integrals and y^2 by y' in $\mathcal{I}_1$, we get

$$\mathcal{I}_1 \leqslant \frac{K}{R^{10}} \sum_{u=0}^{u=3} \int_{z=0}^{c\sqrt{R}} \int_{y'=0}^{1} z^u\, y'\, \exp(-z\,y')\,dz\,dy',$$

$$\mathcal{I}_2 \leqslant \frac{K}{R^{10}} \sum_{u=0}^{u=3} \int_{z=0}^{c\sqrt{R}} \int_{y=0}^{1} z^u\, y\, \exp(-z\,y)\,dz\,dy,$$

$$\mathcal{I}_3 \leqslant \frac{K}{R^{10}} \sum_{u=0}^{u=3} \int_{z=0}^{\infty} \int_{y=0}^{1} z^u\, y\, \exp(-z)\,dz\,dy,$$

where K and c are some positive constants.

Note first that $\mathcal{I}_3$ is bounded from above by $\frac{K}{R^{10}} \sum_{u=0}^{u=3} \int_{z=0}^{\infty} z^u \exp(-z)\,dz$. These integrals are bounded by a constant; thus $\mathcal{I}_3$ is $O\left(\frac{1}{R^{10}}\right)$.

To bound the integrals $\mathcal{I}_1$ and $\mathcal{I}_2$, we now compute the integral

$$\int_{z=0}^{A} \int_{y=0}^{1} z^u\, y\, \exp(-z\,y)\,dz\,dy \tag{3.2}$$

for $u \in \{0, \ldots, 3\}$ and $A > 0$, for example with Maple [14]. For $u = 0$ it is equal to

$$\frac{\exp(-A) + A - 1}{A}. \tag{3.3}$$

For $u = 1$, the integral (3.2) is equal to

$$\exp(-A) + \ln A + Ei(1, A) + \gamma - 1, \tag{3.4}$$

where $Ei(1, A)$ denotes the exponential integral $\int_{t=1}^{\infty} \frac{\exp(-A\,t)}{t}\,dt$ and γ denotes Euler's constant. Finally, for $u = 2$ or 3, the integral (3.2) is equal to

$$\exp(-A)\,P_1(A, u-1) + P_2(A, u-1), \tag{3.5}$$

where $P_i(A, u-1)$ denotes a polynomial of degree $u-1$ in A.

When A tends to ∞, (3.3) tends to 1, (3.4) is equivalent to $\ln A$ (since $Ei(1, A)$ tends to 0), and (3.5) is equivalent to the leading monomial of $P_2(A, u-1)$, which is of degree $u - 1 \leqslant 2$. This guarantees that for $A = c\sqrt{R}$ and $u \in \{0, \ldots, 3\}$, the integral (3.2) is $O(R)$. It follows that $\mathcal{I}_1$ and $\mathcal{I}_2$ are $O\left(\frac{1}{R^9}\right)$.

Since $R^3 = n/\mu$, we get that $I_{x>6,y<1} \leqslant \mathcal{I}_1 + \mathcal{I}_2 + \mathcal{I}_3 = O\left(\frac{1}{R^9}\right) = O\left(\frac{1}{n^3}\right)$. □

We can now conclude the proof that the expected number of $T4$-segments is $O(n)$, because, by Lemmas 3.1 and 3.2, and Propositions 3.7, 3.10, and 3.18, the expected number of $T4$-segments is smaller than

$$\sum_{(i,j,k,l)\in\mathcal{N}} \sum_{\omega=1}^{12} \left(O\left(\frac{1}{n^3}\right) + O\left(\frac{1}{n^3}\right) + O\left(\frac{1}{n^3}\right)\right) = O\left(n\right).$$

4. The expected number of $T4$-segments is at least linear. In this section, we prove that the expected number of $T4$-segments amongst n uniformly distributed unit balls is $\Omega(n)$. To do this, we bound from below the probability that four given balls have a given $T4$-segment. The key step is to give a condition on the relative positions of four unit balls that guarantees that they have exactly 12 common tangent lines. We use here the notation as defined in section 3.1.

LEMMA 4.1. *Let e be a real number satisfying $\frac{4\sqrt{2}}{3} < e < 2$, and let the radius R of $\mathcal{U}$ be strictly greater than e. There exists an $\epsilon > 0$ such that for any point $p \in \mathcal{U}$, there exist three balls $\Gamma_1(p)$, $\Gamma_2(p)$, $\Gamma_3(p)$ of radius ϵ contained in $\mathcal{U}$ and satisfying the following conditions:*

- *p and the centers of the $\Gamma_i(p)$ form a regular tetrahedron with edges of length e, and*
- *for any triple of points (p_1, p_2, p_3), p_i taken from $\Gamma_i(p)$, the four unit balls centered at p, p_1, p_2, and p_3 have exactly 12 distinct tangent lines.*

Proof. Macdonald, Pach, and Theobald proved [13, Lemma 3] that four unit balls centered on the vertices of a regular tetrahedron with edges of length e, $\frac{4\sqrt{2}}{3} < e < 2$, have exactly 12 distinct real common tangent lines. Moreover, these 12 tangent lines correspond to the 12 real roots of a system of equations of degree 12; thus each tangent line corresponds to a *simple* root of that system of equations. It thus follows that for any sufficiently small perturbation of the four ball centers, the four perturbed balls still have 12 real common tangent lines. Let $\epsilon > 0$ be such that the four ball centers can move distance ϵ in any direction while keeping 12 distinct common tangents.

Now, for any point $p \in \mathcal{U}$, consider a regular tetrahedron with edge length e having p as a vertex and such that the other vertices are at distance at least ϵ from the boundary of $\mathcal{U}$; for example, we can choose the other three vertices on a plane perpendicular to the segment Op. Let $\Gamma_1(p)$, $\Gamma_2(p)$, and $\Gamma_3(p)$ be the balls of radius ϵ centered at the vertices, distinct from p, of that tetrahedron. By the previous reasoning, for any $q \in \Gamma_1(p)$, $r \in \Gamma_2(p)$, and $s \in \Gamma_3(p)$, the four unit balls centered at p, q, r, and s have exactly 12 tangents. ∎

Now, by Lemma 3.1, the expected number of $T4$-segments is

$$\sum_{(i,j,k,l)\in\mathcal{N}} \sum_{\omega=1}^{12} \Pr(\delta^{\omega}_{i,j,k,l}).$$

Thus we need only to bound from below the probability that the event $\delta^{\omega}_{i,j,k,l}$ occurs.

LEMMA 4.2. $\Pr(\delta^{\omega}_{i,j,k,l})$ *is* $\Omega\left(\frac{1}{n^3}\right)$.

Proof. Assume that $n > 8\mu$ so that the radius $R = \sqrt[3]{n/\mu}$ of $\mathcal{U}$ is larger than 2, and let $T(p)$ be the set $\Gamma_1(p) \times \Gamma_2(p) \times \Gamma_3(p)$, where $\Gamma_i(p)$ and e are defined as in Lemma 4.1. First, note that

$$\begin{aligned}\Pr(\delta^{\omega}_{i,j,k,l}) &\geqslant \Pr(\delta^{\omega}_{i,j,k,l} \cap (p_i, p_j, p_k) \in T(p_l)) \\ &= \Pr((p_i, p_j, p_k) \in T(p_l)) \cdot \Pr(\delta^{\omega}_{i,j,k,l} \mid (p_i, p_j, p_k) \in T(p_l)).\end{aligned}$$

Since $\Gamma_1(p_l)$, $\Gamma_2(p_l)$, and $\Gamma_3(p_l)$ are three balls of radius ϵ entirely contained in $\mathcal{U}$, we have

$$\Pr((p_i,p_j,p_k)\in T(p_l)) = \left(\frac{\frac{4}{3}\pi\epsilon^3}{\frac{4}{3}\pi R^3}\right)^3 = \frac{\mu^3\epsilon^9}{n^3}.$$

By Lemmas 3.3 and 4.1, the event $(\delta^{\omega}_{i,j,k,l} \mid (p_i,p_j,p_k)\in T(p_l))$ occurs if and only if the interior of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ does not contain the center of any ball. Note that the volume of $\mathcal{H}(t_i,t_l,1)\cap\mathcal{U}$ is at most the volume of $\mathcal{H}(t_i,t_l,1)$, which is at most $\frac{4}{3}\pi+\pi(2+e+2\epsilon)$ since the length of t_it_l is at most $e+2+2\epsilon$. It follows that

$$\Pr(\delta^{\omega}_{i,j,k,l} \mid (p_i,p_j,p_k)\in T(p_l)) \geqslant \left(1-\frac{\pi(\frac{4}{3}+2+e+2\epsilon)}{\text{Volume}(\mathcal{U})}\right)^{n-4}.$$

Since $e<2$, we get, after some elementary calculations, that

$$\Pr(\delta^{\omega}_{i,j,k,l} \mid (p_i,p_j,p_k)\in T(p_l)) \geqslant \left(1-\frac{(6+2\epsilon)\mu}{n}\right)^{n-4}. \tag{4.1}$$

We thus have

$$\Pr(\delta^{\omega}_{i,j,k,l}) \geqslant \frac{\mu^3\epsilon^9}{n^3}\left(1-\frac{(6+2\epsilon)\mu}{n}\right)^{n-4}.$$

Since $\left(1-\frac{(6+2\epsilon)\mu}{n}\right)^{n-4}$ tends to $e^{-(6+2\epsilon)\mu}$ when n tends to infinity, we get

$$\Pr(\delta^{\omega}_{i,j,k,l}) = \Omega\left(\frac{1}{n^3}\right). \qquad \square$$

This completes the proof of the lower bound of Theorem 2.1 since the expected number of $T4$-segments amongst n uniformly distributed unit balls is, by Lemmas 3.1 and 4.2,

$$\sum_{(i,j,k,l)\in\mathcal{N}}\sum_{\omega=1}^{12}\Pr(\delta^{\omega}_{i,j,k,l}) = \sum_{(i,j,k,l)\in\mathcal{N}}\sum_{\omega=1}^{12}\Omega\left(\frac{1}{n^3}\right) = \Omega(n).$$

5. The expected size of the visibility complex is linear. In this section we prove Theorem 2.2, that the expected size of the visibility complex of a set of n uniformly distributed unit balls is linear.

We say that the balls are in general position if any k-dimensional face of the visibility complex is a connected set of maximal-free segments tangent to exactly $4-k$ balls. We can assume that the balls are in general position since this occurs with probability 1. We give a bound on the expected number of k-faces for $k=0,\ldots,4$.

LEMMA 5.1. *The expected number of* 0*-faces is* $\Theta(n)$.

Proof. A 0-face of the visibility complex is a maximal-free line segment tangent to four balls. Each maximal-free line segment tangent to four balls contains a $T4$-segment, and each $T4$-segment is contained in one maximal-free line segment. Thus, by Theorem 2.1, the expected number of 0-faces is linear. $\square$

To deal with the faces of dimension $k\geqslant 1$, we divide them into two classes. A k-face is *open* if it is incident to at least one $(k-1)$-face; otherwise, it is *closed*. When the balls are in general position, the number of k-faces incident to a particular

$(k-1)$-face is constant. In the proof of the following lemmas, any constant can be used. However, for completeness, we will use the exact values but without justifying them.

LEMMA 5.2. *The expected number of* 1*-faces is* $\Theta(n)$.

Proof. Note that a 0-face corresponds to a maximal-free segment tangent to four balls, and it is incident to those 1-faces corresponding to free segments tangent to three amongst those four balls. So a 0-face is incident to exactly six 1-faces, which implies that the number of open 1-faces is six times the number of 0-faces, and is thus $\Theta(n)$ by the previous lemma.

Proving that the expected number of closed 1-faces is $O(n)$ can be done in a way very similar to the proof of the upper bound in Theorem 2.1. The difference is that we consider now only three balls, and thus in all proofs we forget ball B_k. We have to consider only $\binom{n}{3}$ triples of balls instead of $\binom{n}{4}$ quadruples, but we remove from the integral the probability $\Pr(p_k \in \mathcal{H}(p_i, p_l, 2) | \mathbf{x}_{i,l} = x) \leqslant \frac{3x+8}{R^3}$. Since $\frac{n}{R^3} = \mu$, this amounts to dividing the terms over which we integrate by $\mu(3x+8)$, which does not change the general shape of the integrals (a polynomial multiplied by an exponential) which are convergent. Notice that B_i, B_j, B_l, and ω now define a set of segments $t_i t_l$, rather than just a single segment. However, those segments define a closed 1-face only if none of them is occluded by one of the $n-3$ remaining balls. Any particular choice of a tangent $t_i t_l$ in the 1-face will give a relevant cylinder $\mathcal{H}(t_i, t_l, 1)$ to use in the proofs. □

LEMMA 5.3. *The expected number of* 2*-faces is* $\Theta(n)$.

Proof. Since a 1-face has five incident 2-faces, the tight linear bound on the number of 1-faces gives a tight linear bound on the number of open 2-faces. The closed case is solved similarly to the proof of the upper bound in Theorem 2.1. We now consider $\binom{n}{2}$ pairs of balls B_i, B_l, and we remove from the integrals the probability $\Pr(p_j, p_k \in \mathcal{H}(p_i, p_l, 2) | \mathbf{x}_{i,l} = x) \leqslant \left(\frac{3x+8}{R^3}\right)^2$, which gives an $O(n)$ bound on the number of closed 2-faces. □

LEMMA 5.4. *The expected numbers of* 3*-faces and* 4*-faces are* $\Theta(n)$.

Proof. A 3-face, corresponding to lines tangent to a ball, can be closed only if $n = 1$. The number of open 3-faces is linear by the fact that in general position a 2-face is incident to four 3-faces. The number of 4-faces is linear since a 3-face is incident to three 4-faces. □

6. Worst-case lower bound. We provide here a $\Omega(n^2)$ lower bound on the number of k-faces in the visibility complex. Recall that for the case of n arbitrarily sized balls, Devillers and Ramos [6] presented a simple $\Omega(n^3)$ lower bound on the number of free segments tangent to four balls, which is also the number of vertices in the visibility complex. Their lower bound (see Figure 6.1) consists of (i) $\frac{n}{3}$ balls such that the view from the origin consists of $\frac{n}{3}$ disjoint disks centered on a circle, (ii) $\frac{n}{3}$ balls such that the view from the origin consists of $\frac{n}{3}$ disks whose boundaries are concentric circles intersecting (in projection) all the disks of (i), and (iii) $\frac{n}{3}$ tiny balls centered around the origin such that from any point on these $\frac{n}{3}$ tiny balls the view of the balls in (i) and (ii) is topologically invariant. Note that finding a $\Omega(n^3)$ lower bound on the number of free segments tangent to four balls, amongst n balls of bounded radii, is to the best of our knowledge open.

PROPOSITION 6.1. *The number of* k*-faces in the visibility complex of* n *disjoint unit balls in* $\mathbb{R}^3$ *is* $\Omega(n^2)$ *for all* k *between* 0 *and* 4.

Proof. We first observe that the size of the visibility complex of n unit balls can trivially be quadratic by having the balls sparsely distributed in the space such that

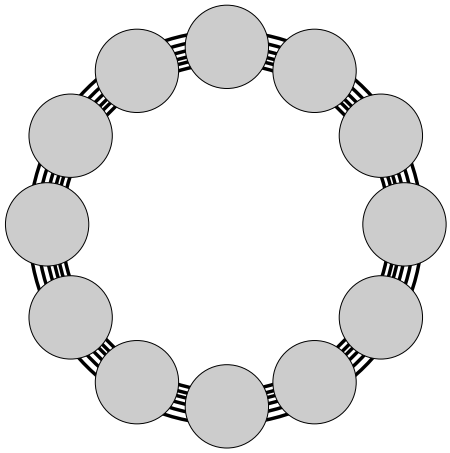

FIG. 6.1. *Quadratic view from the origin* [6].

any pair of balls defines a closed 2-face.

Getting a quadratic number of free lines tangent to four balls amongst a set of n unit balls can be done by taking balls B_i centered at $(2i, 0, 0)$ for $1 \leqslant i \leqslant \frac{n}{2}$ and balls B'_j centered at $(2j, 10, 0)$ for $1 \leqslant j \leqslant \frac{n}{2}$. Then, for any i and j, the line through the points $(2i+1, 0, 1)$ and $(2j+1, 10, 1)$ is free and can be moved down so that it comes into contact with the four balls B_i, B_{i+1}, B'_j, and B'_{j+1}. This argument proves that the number of k-faces, for $0 \leqslant k \leqslant 2$, can be quadratic.

The free segment $(2i, 1, 0)(2j, 9, 0)$ belongs to the 4-face consisting of maximal-free segments with endpoints on B_i and B'_j. Thus there is a quadratic number of 4-faces. The bound also applies to 3-faces by considering lines tangent to B_i and stabbing B'_j.

In the above construction, the balls can be pushed together (they will intersect) so that they fit inside a spherical universe of radius $\sqrt[3]{n/\mu}$ without changing the result. Note also that the above construction can be slightly perturbed to obtain the same result for a set of n unit balls, disjoint or not, with no four centers coplanar. ∎

7. Generalizations. In this section we provide several generalizations of our results.

7.1. Poisson distribution. Consider a set of unit balls whose centers are drawn by a 3D Poisson point process of parameter μ in the universe $\mathcal{U}$. By a *Poisson point process of parameter μ in $\mathcal{U}$* [10], we mean that we generate X random points inside $\mathcal{U}$ so that

$$Pr(X = k) = \frac{(\mu \cdot \text{Volume}(\mathcal{U}))^k \cdot \exp(-\mu \cdot \text{Volume}(\mathcal{U}))}{k!} \tag{7.1}$$

and for any disjoint subsets M and M' of $\mathcal{U}$, the number of the points inside M and the number of points inside M' are independent random variables. Note that (7.1) yields that the expected number of points inside $\mathcal{U}$ is $\mu \cdot \text{Volume}(\mathcal{U}) = \frac{4\pi}{3}n$.

The following simple argument shows that our results extend to this distribution. Let X be the random variable representing the number of centers of unit balls generated by a Poisson point process with parameter μ in $\mathcal{U}$, and let Y be the random variable representing the number of $T4$-segments amongst those balls. The expected

number of $T4$-segments is

$$E(Y) = \sum_{k=0}^{\infty} E(Y|X = k) \cdot \Pr(X = k).$$

Theorem 2.1 gives $E(Y|X = k) = \Theta(k)$ and

$$\Pr(X = k) = \frac{(\frac{4}{3}\pi\ n)^k \cdot \exp(-\frac{4}{3}\pi\ n)}{k!}.$$

Thus

$$\begin{aligned} E(Y) &= \Theta\left(\tfrac{4}{3}\pi\ n\ \exp(-\tfrac{4}{3}\pi\ n)\ \textstyle\sum_{k=1}^{\infty} \frac{(\frac{4}{3}\pi\ n)^{k-1}}{(k-1)!}\right) \\ &= \Theta(n\ \exp(-\tfrac{4}{3}\pi\ n)\ \exp(\tfrac{4}{3}\pi\ n)) = \Theta(n). \end{aligned}$$

Therefore the expected number of $T4$-segments amongst n balls whose centers are generated by a Poisson point process with parameter μ in $\mathcal{U}$ is $\Theta(n)$. Similarly, this bound extends to the expected size of the visibility complex.

We now investigate various models in which we change the shape of the universe or the nature of the objects.

7.2. Smooth convex universe. Our results can be generalized to the case where the universe is no longer a ball but a homothet of a smooth convex set with homothety factor proportional to $\sqrt[3]{n}$. This can be achieved by considering the radius of curvature of the boundary of the universe, instead of R, in the proofs of the lemmas dealing with tangents outside the universe.

7.3. Other objects. Let r_{min} and r_{max} be two strictly positive real constants. In the following, we bound the expected number of $T4$-segments amongst balls whose radii vary in the interval $[r_{min}, r_{max}]$, amongst polyhedra each enclosed between two concentric balls of radii r_{min} and r_{max}, and amongst polygons each enclosed between two concentric circles of radii r_{min} and r_{max}. The centers of the concentric balls or circles are called the centers of the polyhedra or polygons, respectively. In each case a $T4$-segment is called *outer* if the centers of the two extremal objects it is tangent to are farther apart than $6r_{max}$ and are both at distance less than $2r_{max}$ from the boundary of $\mathcal{U}$. Otherwise, the $T4$-segment is called *inner*.

For these models, the proof of the $\Omega(n)$ lower bound on the expected number of $T4$-segments (section 4) generalizes directly because, for the kind of objects we consider, there always exist placements of four of them such that they admit at least one common tangent line with multiplicity one.

7.3.1. Balls of various radii. We have considered a model where all the balls have the same radius. If we allow the radii to vary in the interval $[r_{min}, r_{max}]$, then the proof of the linear upper bound on the expected number of inner $T4$-segments generalizes almost immediately by considering the volumes $\mathcal{H}(p_i, p_l, 2r_{max})$ and $\mathcal{H}(t_i, t_l, r_{min})$ instead of $\mathcal{H}(p_i, p_l, 2)$ and $\mathcal{H}(t_i, t_l, 1)$.

Section 3.2.1 generalizes immediately to prove that the expected number of $T4$-segments tangent to four balls B_i, B_j, B_k, and B_l in that order such that p_i and p_l are closer to one another than $6r_{max}$ is $O(n)$. The only difficult task for extending section 3.2.2 is the proof of the following analogue of Lemma 3.8.

LEMMA 7.1. *When* $\mathbf{x}_{i,l} \geqslant 6r_{max}$, $\mathbf{y}_i \geqslant 2r_{max}$, *and* $\mathcal{L}^{\omega}_{i,j,k,l}$ *occurs, the volume of* $\mathcal{H}(t_i, t_l, r_{min}) \cap \mathcal{U}$ *is greater than* $\frac{\pi}{24} r^2_{min}(\mathbf{x}_{i,l} - 6r_{max})$.

Proof. The proof is similar to the proof of Lemma 3.8. Refer to Figure 7.1. Let m be the midpoint of segment t_it_l and K be the sphere of diameter r_{min} centered on the point c lying on segment t_ip_i at distance $\frac{1}{2}r_{min}$ from t_i. The sphere K is entirely inside $\mathcal{H}(t_i, t_l, r_{min}) \cap \mathcal{U}$, m lies in $\mathcal{H}(t_i, t_l, r_{min})$, and a straightforward computation shows that m is in $\mathcal{U}$ since t_i is in $\mathcal{U}$ at distance at least r_{max} from its boundary and t_l is at distance at most r_{max} from $\mathcal{U}$. Thus $\mathcal{H}(t_i, t_l, r_{min}) \cap \mathcal{U}$ contains the convex hull of K and m, which contains the cone of apex m, of base a disk whose boundary is a great circle of K, and of height the distance from m to the center c of K. Now

$$\begin{aligned}\mathbf{x}_{i,l} = |p_ip_l| &\leqslant |p_ic| + |cm| + |mt_l| + |t_lp_l| \\ &\leqslant r_{max} + |cm| + \frac{1}{2}|t_it_l| + r_{max} \\ &\leqslant 2r_{max} + |cm| + \frac{1}{2}(\mathbf{x}_{i,l} + 2r_{max}).\end{aligned}$$

Thus $|cm| \geqslant \frac{1}{2}\mathbf{x}_{i,l} - 3r_{max}$, and the volume of the cone is at least $\frac{1}{3}\pi(\frac{r_{min}}{2})^2(\frac{1}{2}\mathbf{x}_{i,l} - 3r_{max}) = \frac{\pi}{24}r_{min}^2(\mathbf{x}_{i,l} - 6r_{max})$. □

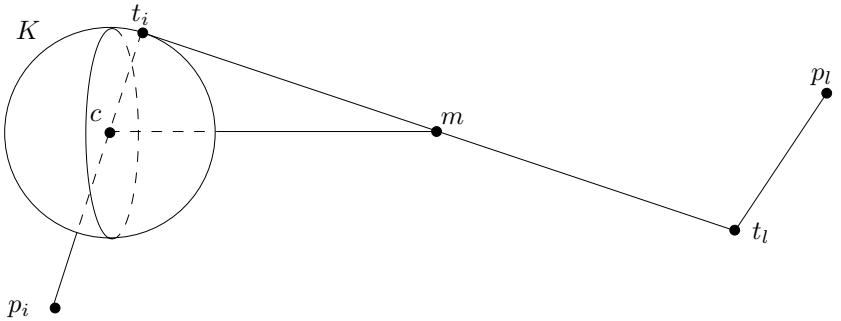

FIG. 7.1. *For the proof of Lemma* 7.1.

The rest of section 3.2.2 generalizes easily for proving that the expected number of $T4$-segments tangent to four balls B_i, B_j, B_k, and B_l in that order such that p_i and p_l are farther apart than $6r_{max}$ and p_i is farther than $2r_{max}$ from the boundary of $\mathcal{U}$ is $O(n)$. Hence the expected number of inner $T4$-segments is $O(n)$.

Our proof cannot be extended to provide a linear upper bound on the expected number of outer $T4$-segments. This is because, if balls B_i and B_l are of radius r_{max}, then a line segment t_it_l tangent to B_i and B_l might be outside $\mathcal{U}$ and at distance greater than r_{min} from its boundary. Then $\mathcal{H}(t_i, t_l, r_{min})$ does not intersect $\mathcal{U}$, and we cannot bound $\mathcal{H}(t_i, t_l, r_{min}) \cap \mathcal{U}$ from below by a positive constant as in Lemma 3.12, which is crucial for the proof of Lemma 3.13 and thus for Proposition 3.18.

However, by not taking into account the occlusion in the proof of Proposition 3.18, we get that the expected number of outer $T4$-segments is $O(n^2)$. Refer to the proof of Proposition 3.18, and consider $I_{x>6r_{max}, y<2r_{max}}$, the analogue of $I_{x>6,y<1}$ for this case. The analogues of Lemmas 3.4 and 3.5 yield that

$$\Pr(\delta^{\omega}_{i,j,k,l} \mid \mathbf{x}_{i,l} = x,\ \mathbf{y}_i = y,\ \mathbf{y}_l \leqslant \mathbf{y}_i) \leqslant \frac{(3\,x\,r_{max}^2 + 8\,r_{max}^3)^2}{R^6}.$$

Lemma 3.16 still holds, and we can easily prove the analogue of Lemma 3.17. Both

results imply that

$$I_{x>6r_{max},y<2r_{max}} \leqslant \int_{x=6r_{max}}^{2R} \int_{y=0}^{2r_{max}} \frac{(3\,x\,r_{max}^2 + 8\,r_{max}^3)^2}{R^6} \cdot \frac{6\,x\,y\,dx}{R^3} \cdot \frac{3\,dy}{R}$$
$$\in O\left(\frac{1}{R^6}\right) = O\left(\frac{1}{n^2}\right).$$

Hence the expected number of inner $T4$-segments is $O(n)$, and the expected number of outer $T4$-segments is $O(n^2)$. This still improves the result of Durand, Drettakis, and Puech [9], who proved a bound of $O(n^{8/3})$ for the same model.

In this section we have assumed that the sphere centers are uniformly distributed, but we have made no assumption on the distribution of the radii of the spheres in the interval $[r_{min}, r_{max}]$, which are thus assumed to be worst-case. The addition of some hypothesis on the radii distribution may yield better results on the number of outer $T4$-segments.

7.3.2. Polyhedra of bounded aspect ratio. Consider polyhedra of constant complexity, each enclosed between two concentric balls of radii r_{min} and r_{max} whose centers are uniformly distributed in $\mathcal{U}$. In such a case, as for balls of various radii, the $O(n)$ bound on the expected number of inner $T4$-segments immediately applies, as well as the $O(n^2)$ bound on the expected number of outer $T4$-segments.

7.3.3. Polygons of bounded aspect ratio. Our proof technique can also be generalized to nonfat 3D objects such as polygons. Consider polygons of constant complexity enclosed between two coplanar concentric circles of radii r_{min} and r_{max} and whose centers and normals are independently chosen from the uniform distributions over $\mathbb{R}^3$ and $\mathbb{S}^2$. Let $T_1, \ldots, T_n$ be such polygons with respective normals $\mathbf{n}_1, \ldots, \mathbf{n}_n$ and centers $p_1, \ldots, p_n$.

Four polygons T_i, T_j, T_k, and T_l have a common tangent line that meet them in that order only if p_j and p_k lie in $\mathcal{H}(p_i, p_l, 2r_{max})$. This implies, as in section 3.2.1, that the expected number of $T4$-segments tangent to four polygons T_i, T_j, T_k, and T_l in that order such that p_i and p_l are closer to one another than some constant, say $6r_{max}$, is $O(n)$.

When such a tangent, denoted t_it_l, exists, it is not occluded only if, for any $\gamma \neq i, j, k, l$, point p_γ does not lie in the interior of $\mathcal{H}(t_i, t_l, r_{min}\cos\theta_\gamma)$, where θ_γ denotes the angle between $\mathbf{n}_\gamma$ and the supporting line of t_it_l (see Figure 7.2(a) and Lemma 3.3). Let γ be an integer distinct from i, j, k, and l. By the total probability theorem, the probability that T_γ does not occlude the tangent line segment t_it_l is bounded from above by

$$\int_{\theta=0}^{\pi/2} \Pr\left(p_\gamma \notin \mathcal{H}(t_i, t_l, r_{min}\cos\theta_\gamma) \mid \theta_\gamma = \theta\right) \cdot \Pr(\theta \leqslant \theta_\gamma < \theta + d\theta).$$

Similarly as in Lemma 7.1, when the tangent t_it_l exists, $\mathbf{x}_{i,l} \geqslant 6r_{max}$ and $\mathbf{y}_i \geqslant 2r_{max}$, and the volume of $\mathcal{H}(t_i, t_l, r_{min}) \cap \mathcal{U}$ is greater than $\frac{\pi}{24}(r_{min}\cos\theta_\gamma)^2(\mathbf{x}_{i,l} - 6r_{max})$. Thus

$$\Pr\left(p_\gamma \notin \mathcal{H}(t_i, t_l, r_{min}\cos\theta_\gamma) \mid \theta_\gamma = \theta\right) \leqslant 1 - \frac{(r_{min}\cos\theta_\gamma)^2(\mathbf{x}_{i,l} - 6r_{max})}{32R^3}.$$

The probability that θ_γ is in between θ and $\theta + d\theta$ is $\sin\theta\,d\theta$, which corresponds to twice the area of the spherical shell between the latitudes θ and $\theta + d\theta$ on the unit

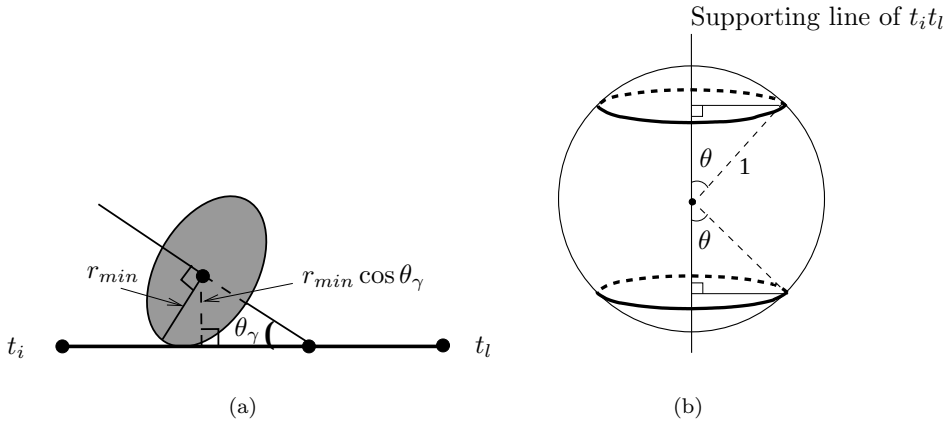

FIG. 7.2. *Illustration for the case of polygons of bounded aspect ratio.*

sphere, divided by the area of the unit sphere (see Figure 7.2(b)). Thus when p_i is at distance greater than $6r_{max}$ from p_l and at distance greater than $2r_{max}$ from the boundary of $\mathcal{U}$, the probability that T_γ does not occlude the tangent line segment $t_i t_l$ is bounded from above by

$$\int_{\theta=0}^{\pi/2} \left(1 - \frac{(r_{min}\cos\theta_\gamma)^2(\mathbf{x}_{i,l} - 6r_{max})}{32R^3}\right) \sin\theta \, d\theta = 1 - \frac{r_{min}^2\,(\mathbf{x}_{i,l} - 6r_{max})}{96\,R^3}.$$

Then, similarly as in Lemma 3.9, the probability that the tangent line segment $t_i t_l$ is not occluded, when p_i is at distance greater than $6r_{max}$ from p_l and at distance greater than $2r_{max}$ from the boundary of $\mathcal{U}$, is at most

$$55\exp\left(-\frac{\mu\, r_{min}^2\,(\mathbf{x}_{i,l} - 6r_{max})}{96}\right).$$

We thus get the analogue of Proposition 3.10 for the model considered here, which implies that the expected number of $T4$-segments tangent to four polygons T_i, T_j, T_k, and T_l in that order such that p_i and p_l are farther apart than $6r_{max}$ and p_i is farther than $2r_{max}$ from the boundary of $\mathcal{U}$ is $O(n)$.

We thus get that the expected number of inner $T4$-segments is $O(n)$. Moreover, as for balls of various radii, the expected number of outer $T4$-segments is $O(n^2)$.

8. Conclusion. In this paper, we proved that the expected number of $T4$-segments amongst n uniformly distributed unit balls in $\mathbb{R}^3$ is $\Theta(n)$. We also proved that the expected size of the visibility complex of n uniformly distributed unit balls is $\Theta(n)$. Equivalently, the expected number of combinatorially different visibility events amongst n uniformly distributed unit balls is $\Theta(n)$. We then proved that $\Theta(n)$ also bounds the expected number of $T4$-segments occurring not too close to the boundary of the universe for various other models such as n uniformly distributed polyhedra, or polygons, of bounded aspect ratio and constant complexity. For these models, we also provided a $O(n^2)$ bound on the expected number of all the $T4$-segments.

This paper is an attempt to analyze the average-case behavior of the size of visibility structures. The distribution models of scene objects investigated here are theoretical in nature since objects in graphics scenes are seldom distributed uniformly

or by a Poisson process. However, our results are important in a context where there are few rigorous results, either theoretical or experimental. They provide theoretical ground to support the empirical evidence indicating that the worst-case upper bound on the number of visibility events is largely pessimistic in practical situations. As a consequence, there is reason to believe that an output-sensitive algorithm for computing all visibility events may work in practice.

Practitioners will be concerned about the size of the constant hidden in the Θ notation. We have calculated (in the proofs of section 3) this constant to be no larger than $2^{16}\,\mu^3 + 2^{31}\,\mu + 2^{37}\,e^{-\mu/3}\,(\mu^2 + 1/\mu^2)$. Of course this is shocking. We suppose that the constant is actually much smaller. However, estimating it in practice is a difficult problem which is still to be solved. After solving this problem, an interesting experiment will be to compare the number of visibility events occurring in a realistic graphic scene with the theoretical bound for uniformly distributed objects.

The results proved here also provide new insight on the complexity of other visibility structures. Consider, for instance, the aspect graph, a partition of viewpoint space into maximal connected regions by surfaces along which visibility events are observed. As explained in [19], the complexity of the aspect graph is dominated by δ^m, where δ is the degree of the surface corresponding to lines "tangent" to three objects and m the dimension of the viewpoint space. For a scene composed of n disjoint spheres, δ is trivially $O(n^3)$, so the aspect graph has $O(n^6)$ orthographic views and $O(n^9)$ perspective views. However, the results of this paper show that the expected value of δ is $\Theta(n)$ since the expected number of families of lines tangent to three objects (related to the 1-faces of the visibility complex) is linear and the degree of each family is bounded. It would thus be interesting to get a good bound on the expected value of δ^2 and δ^3, which is related to bounding the expected value of the square and the cube of the number of combinatorially different visibility events. Note that the former would also give the standard deviation of the expected number of combinatorially different visibility events. Similar observations hold for the polyhedral case.

Appendix A. Volume of the intersection of a 3D hippodrome with a ball. Recall that $\mathcal{U}$ is a ball of radius R centered at O. Let B_i and B_l be two unit balls whose centers p_i and p_l are in $\mathcal{U}$, within distance 1 from its boundary, and distance $x \geqslant 6$ apart. Let t_it_l be a line segment tangent to B_i and B_l at its endpoints. The section is devoted to the proof of the following proposition, which leads directly to Lemma 3.12.

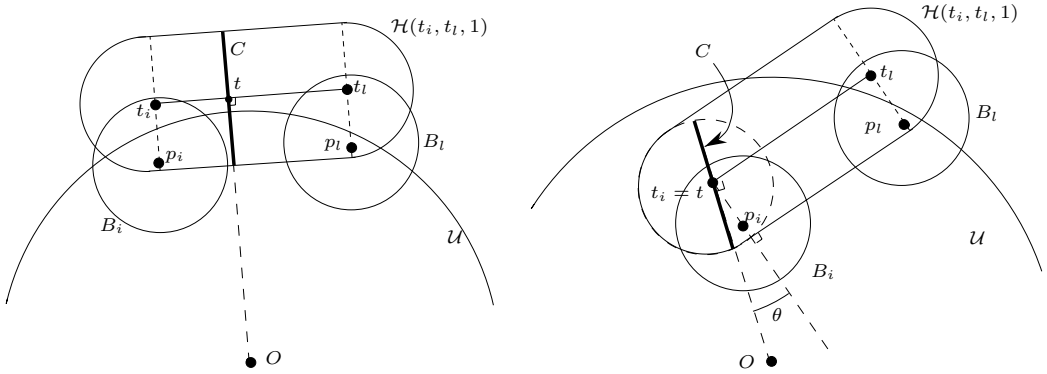
PROPOSITION A.1. *For any $0 \leqslant s \leqslant 1$ such that segment t_it_l is at distance less than $R+1-s$ from O, the volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ is larger than $\frac{1}{6\sqrt{2}}\,(x-5)\,s\,\sqrt{s}$.*

We proceed as follows. Let v be such that the distance from O to the segment t_it_l is $R+1-v$, and let t be the point on segment t_it_l closest to O (see Figure A.1). Assume without loss of generality that t is closer to t_i than to t_l. Let C (resp., D) be the unit radius circle (resp., disk) centered at t in the plane, denoted $\mathcal{P}$, containing the vectors $\overrightarrow{Ot}$ and the cross-product of $\overrightarrow{Ot}$ and $\overrightarrow{t_it_l}$. Let θ be the angle between the plane orthogonal to t_it_l and $\mathcal{P}$. We first prove the following lemma.

LEMMA A.2. *The volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ is greater than*

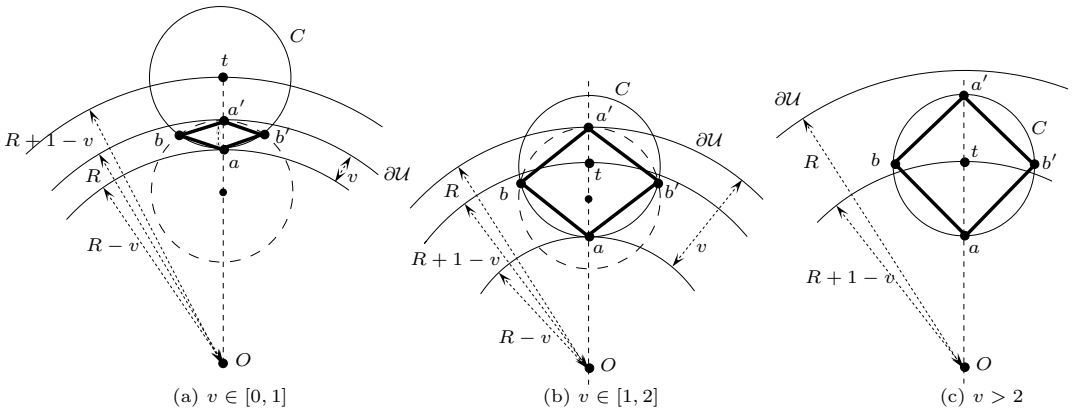
$$\frac{1}{3}\min\left(2, \frac{v\sqrt{v}}{\sqrt{2}}\right) \cdot \min\left(\frac{x-2}{2}, (x-2)\cos\theta - 1\right).$$

Proof. Let a denote the closest point on C from O, a' the farthest point in $D \cap \mathcal{U}$



(a) t is not equal to t_i or t_l; $\theta = 0$. (b) t is equal to t_i.

FIG. A.1. *For the definition of t and C (C is shown from the side view).*



(a) $v \in [0, 1]$ (b) $v \in [1, 2]$ (c) $v > 2$

FIG. A.2. *For the definition of a, a', b, b'.*

from O, and b and b' the two points of intersection of C and the perpendicular bisector of segment aa' (see Figure A.2).

The volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ is greater than the volume of the convex hull of a, b, a', b', and p_l because $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ is convex and contains these five points. The volume of this polyhedron is equal to one third of the area of its base, the quadrilateral with vertices a, b, a', b' times its height, the distance from p_l to the plane $\mathcal{P}$ containing a, b, a', b'.

We first compute a lower bound on the area of the quadrilateral with vertices a, b, a', b'. If $v \leqslant 2$ (see Figure A.2(a) and (b)), then the length of aa' is equal to v, and a simple calculation gives that the length of bb' is equal to $2\sqrt{v - \frac{v^2}{4}} \geqslant \sqrt{2v}$. Thus the area of the quadrilateral a, b, a', b' is greater than $\frac{v\sqrt{v}}{\sqrt{2}}$. If $v > 2$ (see Figure A.2(c)), then C is entirely contained in $\mathcal{U}$, and the area of the quadrilateral a, b, a', b' is equal to 2. Thus, the area of the quadrilateral is at least $\min(2, \frac{v\sqrt{v}}{\sqrt{2}})$.

The volume of the polyhedron is thus greater than $\frac{1}{3}\min(2, \frac{v\sqrt{v}}{\sqrt{2}})$ times the distance from p_l to the plane $\mathcal{P}$. We consider two cases.

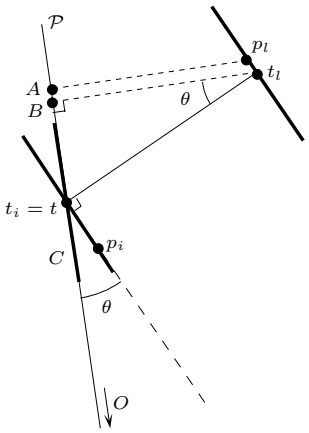


FIG. A.3. *The height from p_l to $\mathcal{P}$ is greater than $|t_i t_l| \cos\theta - 1$.*

First, suppose that t belongs to the interior of the segment $t_i t_l$ (see Figure A.1(a)). Then the height is equal to the distance from t_l to t since p_l and a, b, a', b' belong, respectively, to the two planes, orthogonal to $t_i t_l$ and passing through t_l and t, respectively. Since t_i and t_l belong to B_i and B_l, they are at least distance $x-2$ apart; thus t and t_l are at least distance $\frac{x-2}{2}$ apart. Thus, the height from p_l to $\mathcal{P}$ is at least $\frac{x-2}{2}$.

Second, suppose that $t = t_i$ (see Figure A.1(b)); $t \neq t_l$ since we assumed that t is closer to t_i than to t_l. Refer to Figure A.3. Let A and B be the orthogonal projections of p_l and t_l onto $\mathcal{P}$, respectively. Note that the lengths of Ap_l and Bt_l are the distances from p_l and t_l to the plane $\mathcal{P}$, respectively.

Considering the triangle $\triangle Ap_l t_l$ and that the distance between t_l and p_l is 1, we obtain that $|Ap_l| \geqslant |At_l| - |t_l p_l| = |At_l| - 1$, where $|ab|$ denotes the length of segment ab. Since $A \in \mathcal{P}$ and the length of Bt_l is the distance from t_l to the plane $\mathcal{P}$, the length of At_l is greater than that of Bt_l; thus $|Ap_l| \geqslant |Bt_l| - 1$.

To bound the length of Bt_l, we now consider the triangle $\triangle Bt_l t$. The angle $\angle Bt_l t$ is the angle between the normal of the plane $\mathcal{P}$ and $t_i t_l$, that is, by definition, θ. So the length of Bt_l is the length of $t_i t_l$ times $\cos\theta$, and, since $|t_i t_l|$ is at least $x-2$, $|Bt_l|$ is greater than $(x-2)\cos\theta$. Thus the length of Ap_l is greater than $(x-2)\cos\theta - 1$.

Hence the distance from p_l to the plane $\mathcal{P}$ is greater than $\min(\frac{x-2}{2}, (x-2)\cos\theta - 1)$, and thus the volume of $\mathcal{H}(t_i, t_l, 1) \cap \mathcal{U}$ is greater than $\frac{1}{3}\min(2, \frac{v\sqrt{v}}{\sqrt{2}}) \cdot \min(\frac{x-2}{2}, (x-2)\cos\theta - 1)$. ∎

The following lemma bounds $\cos\theta$.

LEMMA A.3. *The angle θ is such that $\cos\theta \geqslant \frac{\sqrt{7}}{4}$.*

Proof. Note first that this lemma is intuitively obvious. Indeed (see Figure A.1(b)), if x is sufficiently large and if t_i is the closest point on segment $t_i t_l$ to O, then the angle between the plane supporting C and the segment $t_i t_l$ is necessarily close to $\pi/2$, which implies that θ is close to 0. We now prove the lemma.

Refer to Figure A.3, and consider the triangle $\triangle Ot_i t_l$. Let $|ab|$ denote the length of segment ab. Then the law of cosines yields

$$\begin{aligned} |Ot_l|^2 &= |Ot_i|^2 + |t_i t_l|^2 - 2 \cdot |Ot_i| \cdot |t_i t_l| \cdot \cos(\tfrac{\pi}{2} + \theta) \\ &= |Ot_i|^2 + |t_i t_l|^2 + 2 \cdot |Ot_i| \cdot |t_i t_l| \cdot \sin\theta, \end{aligned}$$

which gives that

$$\sin\theta = \frac{|Ot_l|^2 - |Ot_i|^2 - |t_it_l|^2}{2 \cdot |Ot_i| \cdot |t_it_l|}.$$

The centers p_i and p_l of balls B_i and B_l are distance $x \geqslant 6$ apart and at distance less than 1 from the boundary of $\mathcal{U}$, so $|t_it_l| \geqslant 4$, $|Ot_i| \geqslant R-2$ and $|Ot_l| \leqslant R+1$. Hence

$$\sin\theta \leqslant \frac{(R+1)^2 - (R-2)^2 - 4^2}{2 \cdot (R-2) \cdot 4} \leqslant \frac{6(R-2)}{8(R-2)} = \frac{3}{4}.$$

Using $\cos\theta = \sqrt{1-(\sin\theta)^2}$ proves that $\cos\theta \geqslant \frac{\sqrt{7}}{4}$. □

We can now conclude the proof of Proposition A.1. For any $0 \leqslant s \leqslant 1$, if segment t_it_l is at distance $R+1-v \leqslant R+1-s$ from the center of $\mathcal{U}$, then $v \geqslant s$. By Lemma A.3, $(x-2)\cos\theta - 1 \geqslant \frac{x-5}{2}$, which means that $\min(\frac{x-2}{2}, (x-2)\cos\theta - 1) \geqslant \frac{x-5}{2}$. Thus Lemma A.2 gives that the volume of $\mathcal{H}(t_i,t_l,1) \cap \mathcal{U}$ is greater than $\frac{1}{6\sqrt{2}}(x-5)\min(2\sqrt{2}, v\sqrt{v}) \geqslant \frac{1}{6\sqrt{2}}(x-5)\min(2\sqrt{2}, s\sqrt{s}) = \frac{1}{6\sqrt{2}}\, s\sqrt{s}\,(x-5)$ since $s \leqslant 1$. Hence the volume of $\mathcal{H}(t_i,t_l,1) \cap \mathcal{U}$ is greater than $\frac{1}{6\sqrt{2}}\, s\sqrt{s}\,(x-5)$.

Appendix B. Volume of K. Recall that $\mathcal{U}$ is a ball of radius R centered at O, and let p_i and p_l be two points in $\mathcal{U}$ within distance 1 of its boundary and distance x apart. Let y be a real number such that $0 \leqslant y < 1$. Let F be the open ball with center O and radius $R+1-y^{\frac{2}{3}}$ and ∂F its frontier. Let E be the part of $\mathcal{H}(p_i,p_l,1)$ that is outside F, and let K be the intersection of $\mathcal{U}$ with the union of all unit balls centered on points in E (see Figure B.1). This section is devoted to the proof of the following proposition used in the proof of Lemma 3.15.

PROPOSITION B.1. *The volume of K is bounded from above by $12\,\pi^2\,(x+6)\,y$.*

LEMMA B.2. *If $z \in \mathcal{U}$ is at distance less than 1 from E, then z is at distance less than 1 from $E \cap \partial F$.*

Proof. Let $z \in \mathcal{U}$ and $w \in E$ be two points at distance less than 1, and refer to Figure B.1. Let w' be the point of intersection of ∂F and the ray from O through w. For any ball B centered in $\mathcal{U}$, $B \setminus F$ lies in the cone of center O and base $B \cap \partial F$. Thus $E = \mathcal{H}(p_i,p_l,1) \setminus F$ lies in the cone of center O and base $E \cap \partial F$. Hence the ray from O through w lies in this cone and $w' \in E \cap \partial F$. On the other hand, $|zw'| \leqslant |zw|$ since $z \in F$, $w' \in \partial F$, and w lies outside F on the ray from O through w'. Thus, since $w' \in E \cap \partial F$ and $|zw| < 1$ by hypothesis, the distance from z to $E \cap \partial F$ is less than 1. □

The above lemma implies that K is the intersection of $\mathcal{U}$ with the union of all unit balls centered on $E \cap \partial F$. To bound the volume of K, we enclose $E \cap \partial F$ in a subset of ∂F that will be easier to deal with.

Let $B(p)$ denote the ball of unit radius centered at p. Let $\pi(p)$ be the point that maximizes (under inclusion) the intersection $\partial F \cap B(q)$ for all q on the ray from O through p. A simple computation yields that the distance between $\pi(p)$ and O is

$$R_y = \sqrt{(R+1-y^{\frac{2}{3}})^2 - 1}.$$

Thus π is the orthogonal projection onto the sphere centered at O of radius R_y. Now let $\pi'(p)$ be the point that maximizes (under inclusion) the intersection $\partial F \cap B(q)$ for all q on the radius of $\mathcal{U}$ through p (that is the part inside $\mathcal{U}$ of the ray from O through p). Similarly, π' is the orthogonal projection onto the sphere centered at O of radius

$$R' = \min(R, R_y).$$

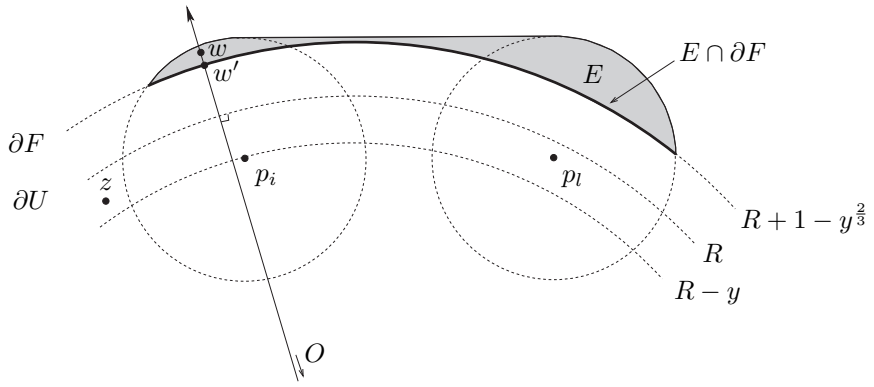

FIG. B.1. *The part E of $\mathcal{H}(p_i, p_l, 1)$ outside F.*

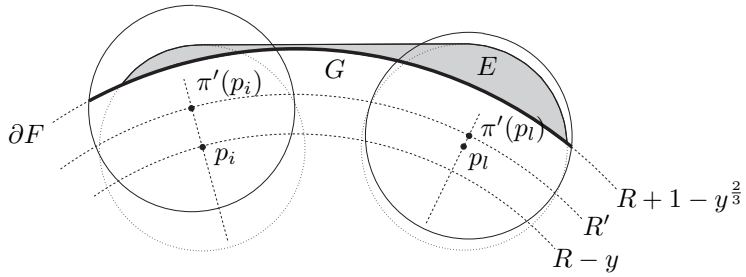

FIG. B.2. *G, a part of ∂F enclosing $E \cap \partial F$.*

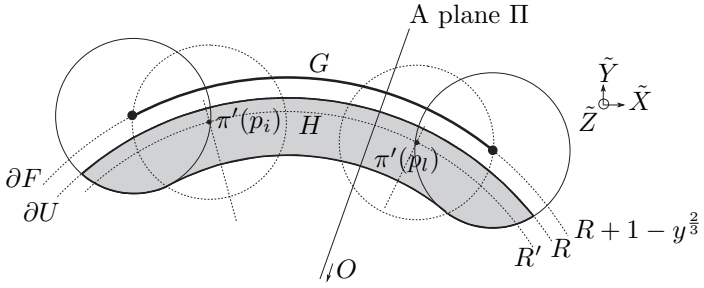

FIG. B.3. *The region H and a plane* Π.

Let G be the union of the spherical caps $\partial F \cap B(\pi'(p))$ for all p on the segment from p_i to p_l (see Figure B.2). Let H denote the points of $\mathcal{U}$ at distance less than or equal to 1 from G (see Figure B.3).

LEMMA B.3. $K \subseteq H$.

Proof. $E \cap \partial F$ is the union of $\partial F \cap B(p)$ for all p on the segment $p_i p_l$. Furthermore, for any such p, $\partial F \cap B(p) \subseteq \partial F \cap B(\pi'(p))$ by definition of π' since $p \in \mathcal{U}$. Thus $E \cap \partial F$ is contained in G.

By Lemma B.2, K is the intersection of $\mathcal{U}$ with the union of all unit balls centered on $E \cap \partial F$. Thus K is contained in H, with the union of all unit balls centered in G. ∎

To bound the volume of H from above, we first bound the area of its section by planes Π that contain O and are orthogonal to the plane, denoted (O, p_i, p_l),

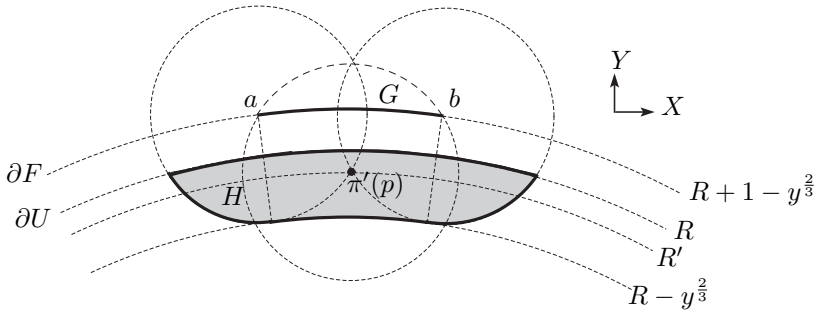

FIG. B.4. *Section of H by a plane Π intersecting segment p_ip_l at p.*

containing O, p_i, and p_l (see Figures B.3 and B.4).

LEMMA B.4. *The area of $\Pi \cap H$ is less than $12\,\pi\, y$.*

Proof. The section of G by a plane Π is a circular arc on ∂F. If Π intersects the segment p_ip_l, let p denote the point of intersection; then the circular arc is the intersection of ∂F and the disk $B(\pi'(p))\cap\Pi$ (refer to Figures B.2 and B.4). Otherwise, the circular arc is the intersection of ∂F and the disk $B(\pi'(p_i)) \cap \Pi$ or $B(\pi'(p_l)) \cap \Pi$ (see Figure B.2). The disk has radius 1 in the former case and radius less than one in the latter case. In both cases the center of the disk is at distance R' from O. Thus the length of the circular arc $G\cap\Pi$ is maximal if and only if Π intersects the segment p_ip_l. Thus the area of $\Pi\cap H$ is maximal if and only if Π intersects the segment p_ip_l. Hence we can assume that Π is such a plane. Let p denote its intersection with segment p_ip_l.

Let a and b denote the endpoints of $G\cap\Pi$, and refer to Figure B.4. Points a and b are the intersection of ∂F and the circle in Π of radius 1 centered at $\pi'(p)$. The lines (Oa) and (Ob) split $\Pi\cap H$ into three parts: a left, a central, and a right part. Symmetries with respect to the lines (Oa) and (Ob) send the left and right parts into the central one. Hence, the area of $\Pi \cap H$ is bounded by three times the area of its central part. This part is delimited by the two rays from O through a and b, and the two circles in Π with center O and radii R and $R - y^{\frac{2}{3}}$. So, if α denotes the length of the circular arc ab, the area A of the central part is

$$A = \frac{\alpha}{2\pi(R+1-y^{\frac{2}{3}})} \cdot \pi(R^2 - (R-y^{\frac{2}{3}})^2) = \alpha\,\frac{2Ry^{\frac{2}{3}} - y^{\frac{4}{3}}}{2(R+1-y^{\frac{2}{3}})} \leqslant \alpha\, y^{\frac{2}{3}}.$$

We now bound the length α of the arc ab. We choose an orthonormal frame $(\pi'(p), X, Y)$ in Π such that O has coordinates $(0, -R')$ (see Figure B.4). Recall that a is one of the intersection points of the circle centered at $\pi'(p)$ of radius 1 and the circle centered at O of radius $R + 1 - y^{\frac{2}{3}}$. A simple computation yields that the coordinates (X_a, Y_a) of a are equal to

$$Y_a = \frac{(R+1-y^{\frac{2}{3}})^2 - 1 - R'^2}{2R'}, \qquad |X_a| = \sqrt{1 - Y_a^2}.$$

If $R' = R$, then

$$Y_a = \frac{y^{\frac{4}{3}} + 2R - 2Ry^{\frac{2}{3}} - 2y^{\frac{2}{3}}}{2R} = 1 - y^{\frac{2}{3}}\left(1 + \frac{2 - y^{\frac{2}{3}}}{2R}\right) \geqslant 1 - 2y^{\frac{2}{3}},$$

which implies that

$$|X_a| \leqslant \sqrt{1 - (1-2y^{\frac{2}{3}})^2} = \sqrt{4y^{\frac{2}{3}} - 4y^{\frac{4}{3}}} \leqslant 2y^{\frac{1}{3}}.$$

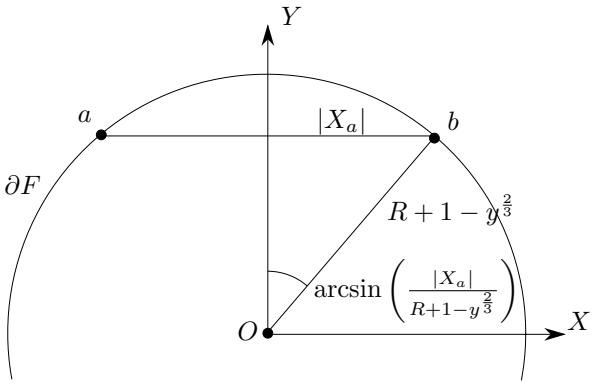

FIG. B.5. *The length of the circular arcs ab.*

Now, if $R' \neq R$, then $(R+1-y^{\frac{2}{3}})^2 - 1 \leqslant R^2$ by definition. Expanding this inequality yields

$$y^{\frac{4}{3}} + 2R - 2Ry^{\frac{2}{3}} - 2y^{\frac{2}{3}} \leqslant 0,$$

$$y^{\frac{2}{3}} \geqslant \frac{y^{\frac{4}{3}} + 2R}{2(R+1)} \geqslant \frac{R}{R+1} \geqslant \frac{1}{2}.$$

Thus $\sqrt{2y^{\frac{2}{3}}} \geqslant 1$, and since $|X_a| = \sqrt{1-Y_a^2} \leqslant 1$ we get $|X_a| \leqslant \sqrt{2}y^{\frac{1}{3}}$. Hence, in both cases,

$$|X_a| \leqslant 2y^{\frac{1}{3}}.$$

Thus the length of the circular arc ab is (see Figure B.5)

$$\alpha = (R+1-y^{\frac{2}{3}}) \cdot 2\arcsin\left(\frac{|X_a|}{R+1-y^{\frac{2}{3}}}\right) \leqslant (R+1-y^{\frac{2}{3}}) \cdot 2\arcsin\left(\frac{2y^{\frac{1}{3}}}{R+1-y^{\frac{2}{3}}}\right).$$

A straightforward computation shows that $\arcsin(x) - \pi\, x \leqslant 0$ for any $x \in [0,1]$. Thus

$$\alpha \leqslant (R+1-y^{\frac{2}{3}}) \cdot 2\,\pi \frac{2y^{\frac{1}{3}}}{R+1-y^{\frac{2}{3}}} = 4\,\pi\, y^{\frac{1}{3}}.$$

Since the area A of the middle part is less than or equal to $\alpha\, y^{\frac{2}{3}}$,

$$A \leqslant 4\,\pi\, y^{\frac{1}{3}}\, y^{\frac{2}{3}} = 4\,\pi\, y.$$

This implies that the area of $\Pi \cap H$ is less than or equal to $12\,\pi\, y$. □

LEMMA B.5. *The volume of H is bounded from above by $12\,\pi^2\,(x+6)\,y$.*

Proof. We express the volume of H by an integral using spherical coordinates (r,θ,ϕ) in an orthogonal frame $(O,\tilde{X},\tilde{Y},\tilde{Z})$ such that the plane $(O,\tilde{X},\tilde{Y})$ contains p_i and p_l (see Figure B.3). A plane $\theta =$ constant contains the $\tilde{Z}$-axis and thus is a plane Π. Let $1_H(r,\theta,\phi)$ denote the indicator function of H; $1_H(r,\theta,\phi)$ is equal to 1 if the point of coordinates (r,θ,ϕ) belongs to H and to 0 otherwise. Then

$$\text{Volume of } H = \int_\phi \int_r \int_\theta 1_H(r,\theta,\phi) \cdot r^2 \sin\phi\, dr\, d\theta\, d\phi.$$

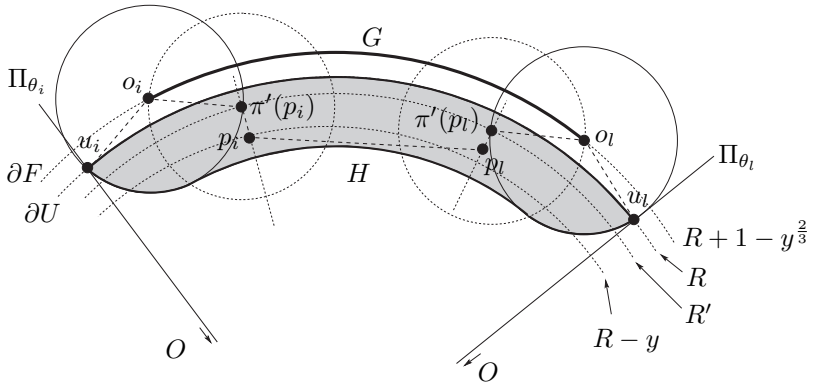

FIG. B.6. *For computing a bound on* $\Delta\theta$.

Since H is inside $\mathcal{U}$, $r \cdot 1_H(r,\theta,\phi) \leqslant R \cdot 1_H(r,\theta,\phi)$. Moreover, $\sin\phi \leqslant 1$; thus

$$\text{Volume of } H \leqslant R \int_\theta \left(\int_\phi \int_r 1_H(r,\theta,\phi) \cdot r \, dr \, d\phi \right) d\theta.$$

The double integral in parentheses is equal to the area of the section of H by a plane $\Pi_\theta : \theta = \text{constant}$. By Lemma B.4, this area is less than $12\,\pi\,y$, which is independent of θ. Moreover, the area is equal to 0 when Π_θ does not intersect H. Let $\Delta\theta$ denote the angle between the two extreme planes Π_θ that intersect H. Thus we have

$$\text{Volume of } H \leqslant R \cdot 12\,\pi\,y \cdot \Delta\theta.$$

We now bound $\Delta\theta$. Refer to Figure B.6. Let Π_{θ_i} and Π_{θ_l} be the two extreme planes that intersect H. Let u_i and u_l be the two points of intersection of H with Π_{θ_i} and Π_{θ_l}, respectively; u_i and u_l lie on $\partial\mathcal{U}$. Let o_i and o_l be the two points in G at distance 1 from u_i and u_l, respectively. $\pi'(p_i)$ and $\pi'(p_l)$ are at distance 1 from o_i and o_l, respectively.

The angle between the two extreme planes Π_{θ_i} and Π_{θ_l} is, as before,

$$\Delta\theta = 2\arcsin\frac{|u_iu_l|/2}{R} \leqslant 2\,\pi\frac{|u_iu_l|/2}{R} = \pi\frac{|u_iu_l|}{R}.$$

Now we bound $|u_iu_l|$ by the length of the polygonal line shown in Figure B.6.

$$\begin{aligned}|u_iu_l| &\leqslant |u_io_i| + |o_i\pi'(p_i)| + |\pi'(p_i)p_i| + |p_ip_l| + |p_l\pi'(p_l)| + |\pi'(p_l)o_l| + |o_lu_l| \\ &= 1 + 1 + |\pi'(p_i)p_i| + x + |p_l\pi'(p_l)| + 1 + 1.\end{aligned}$$

We show that $|\pi'(p_i)p_i|$ and $|p_l\pi'(p_l)|$ are less than 1. $\pi'(p_i)$ is inside $\mathcal{U}$ at distance less than 1 from ∂F, which lies outside $\mathcal{U}$. Thus $\pi'(p_i)$ is inside $\mathcal{U}$ at distance less than 1 from its frontier. Point p_i is also inside $\mathcal{U}$ at distance less than 1 from its frontier. Since p_i and $\pi'(p_i)$ are on the same ray starting from O, they are at distance less than 1 apart and similarly for $\pi'(p_l)$ and p_l. Hence

$$\Delta\theta \leqslant \pi\frac{|u_iu_l|}{R} \leqslant \pi\frac{x+6}{R}.$$

Therefore

$$\text{Volume of } H \leqslant R \cdot 12\,\pi\,y \cdot \Delta\theta \leqslant 12\,\pi^2\,y\,(x+6). \qquad \square$$

Proposition B.1 follows from Lemmas B.3 and B.5.

Appendix C. Volume of the intersection of two spherical shells.

We prove in this section the following proposition used in the proof of Lemma 3.17.

PROPOSITION C.1. *Let $R > 0$, $x \in [6, 2R]$, $y \in [0, 1]$, and let p be a point at distance $R - y$ from O. The volume of the intersection of the region in between the two spheres centered at p and of radii x and $x + dx$, and the region in between the two spheres centered at O and of radii R and $R - y$ (see Figure* C.1*), is bounded from above by $8\,\pi\,x\,y\,dx$.*

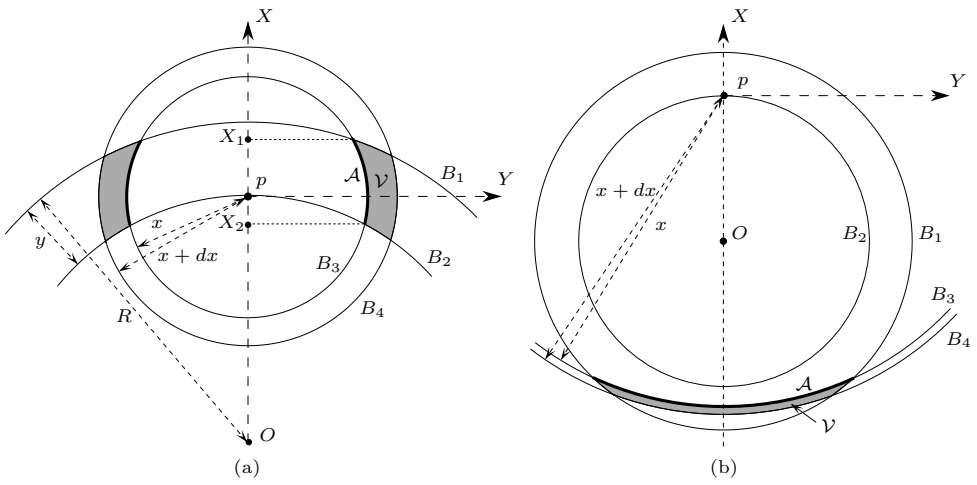

FIG. C.1. *For the proof of Proposition* C.1.

Proof. Define the balls B_1 with center O and radius R, B_2 with center O and radius $R - y$, B_3 with center p and radius x, and, finally, B_4 with center p and radius $x + dx$. Let $\mathcal{V}$ denote the intersection of $(B_1 \setminus B_2)$ and $(B_4 \setminus B_3)$. We prove that the volume of $\mathcal{V}$ is less than $8\,\pi\,x\,y\,dx$.

Since dx is infinitesimally small, the volume of $\mathcal{V}$ is $\mathcal{A}dx$, where $\mathcal{A}$ is the area of the intersection of the sphere ∂B_3 with $B_1 \setminus B_2$.

Let (p, X, Y, Z) be an orthogonal reference frame whose center is p and whose X-axis is oriented along $\overrightarrow{Op}$ (see Figure C.1). Notice that all spheres are centered on that axis. Let C_1 (resp., C_2, C_3) denote the circle that is the boundary of the intersection of B_1 (resp., B_2, B_3) and the plane (p, X, Y) in which Figure C.1 is drawn. The equations of these circles are, in the frame (p, X, Y),

$$\begin{aligned} C_1 : &\quad (X + R - y)^2 + Y^2 = R^2, \\ C_2 : &\quad (X + R - y)^2 + Y^2 = (R - y)^2, \\ C_3 : &\quad X^2 + Y^2 = x^2. \end{aligned}$$

Since C_3 is centered at a point on C_2 and has radius $x \geqslant 6 > 1 \geqslant y$, C_3 intersects or encloses C_1 and C_2. In fact, C_3 intersects or encloses C_1 and C_2 in one of the three following ways.

Case 1. If $6 \leqslant x \leqslant 2R - 2y$, then C_3 intersects both C_1 and C_2 (see Figure C.1(a)).

Case 2. If $2R - 2y < x \leqslant 2R - y$, then C_3 intersects C_1 and encloses C_2 (see Figure C.1(b)).

Case 3. If $2R - y < x$, then C_3 encloses both C_1 and C_2. In that case, $\mathcal{V}$ is empty and the volume is 0.

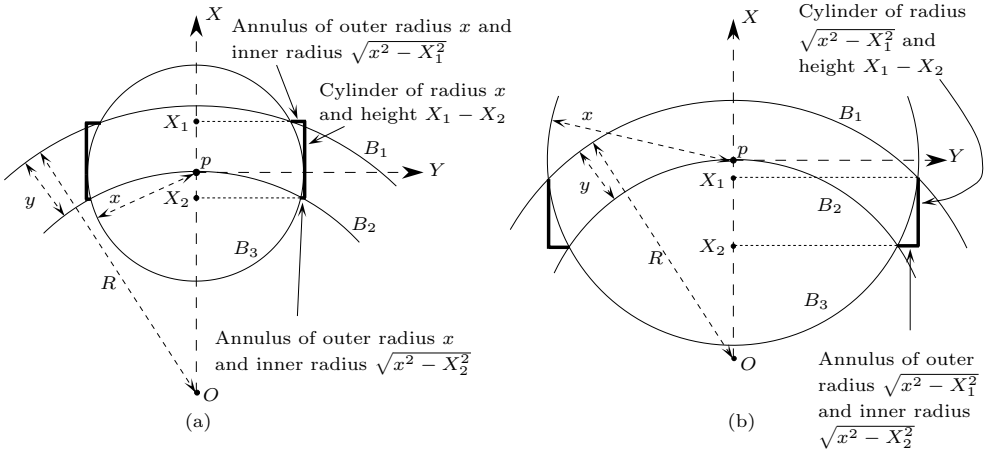

FIG. C.2. *For the proof of Proposition* C.1*, Case* 1.

In the first case, let X_1 (resp., X_2) be the abscissa of the points of intersection of circles C_1 (resp., C_2) and C_3. Note that $X_1 \geqslant X_2$, and their values can be computed directly from the equations of the circles C_1, C_2, and C_3:

$$X_1 = \frac{R^2 - x^2 - (R-y)^2}{2R - 2y}, \qquad X_2 = \frac{-x^2}{2R - 2y}.$$

Using the fact that $y \leqslant x \leqslant 2R - 2y$ we get

$$X_1 - X_2 = \frac{y(2R-y)}{2R-2y} = y\left(1 + \frac{y}{2R-2y}\right) \leqslant 2y,$$
$$-X_1 - X_2 = \frac{2x^2 - y(2R-y)}{2R-2y} \leqslant 2x\frac{x}{2R-2y} \leqslant 2x.$$

We now bound from above the area $\mathcal{A}$ of the surface $\partial B_3 \cap (B_1 \setminus B_2)$ by the area of a larger surface which depends on the sign of X_1. If $X_1 \geqslant 0$, the surface consists of a cylinder of axis, the X-axis, of radius x and height $X_1 - X_2$, and of two annuli in the planes $X = X_1$ and $X = X_2$, of inner radius $\sqrt{x^2 - X_1^2}$ and $\sqrt{x^2 - X_2^2}$, respectively, and outer radius x (see Figure C.2(a)). If $X_1 \leqslant 0$, the surface consists of a cylinder of axis, the X-axis, of radius $\sqrt{x^2 - X_1^2}$ and height $X_1 - X_2$, and of an annulus in the plane $X = X_2$, of inner radius $\sqrt{x^2 - X_2^2}$ and outer radius $\sqrt{x^2 - X_1^2}$ (see Figure C.2(b)). In both cases that surface is larger than $\partial B_3 \cap (B_1 \setminus B_2)$ by convexity.

If $X_1 \geqslant 0$, the area of the cylinder is $2\pi x(X_1 - X_2) \leqslant 4\pi xy$, and the area of the annuli are $\pi x^2 - \pi(x^2 - X_i^2) = \pi X_i^2$, $i = 1, 2$. Since $X_1 \geqslant 0$, $X_1 \leqslant y \leqslant x$, and thus $\pi X_1^2 \leqslant \pi xy$. We also have from the expression of X_1 that $R^2 - x^2 - (R-y)^2 \geqslant 0$, and thus $x^2 \leqslant y(2R - y)$. Thus

$$\pi X_2^2 = \pi \frac{x^2}{2R-2y}\frac{x^2}{2R-2y} \leqslant \pi x \frac{x}{2R-2y} y \frac{2R-y}{2R-2y} = \pi xy \frac{x}{2R-2y}\left(1+\frac{y}{2R-2y}\right).$$

It thus follows from $y \leqslant x \leqslant 2R-2y$ that $\pi X_2^2 \leqslant 2\pi xy$. Hence $\mathcal{A} \leqslant 7\pi xy$.

If $X_1 \leqslant 0$, the area of the cylinder is $2\pi\sqrt{x^2-X_1^2}(X_1-X_2) \leqslant 2\pi x(2y)$, and the area of the annulus is $\pi(x^2-X_1^2)-\pi(x^2-X_2^2) = \pi(X_1-X_2)(-X_2-X_1) \leqslant 4\pi xy$. Thus $\mathcal{A} \leqslant 8\pi xy$.

Consider now the second case $2R-2y < x \leqslant 2R-y$ (see Figure C.1(b)). For a fixed value of y, $\mathcal{A}$ is the area of a spherical cap whose perimeter and curvature decreases as x increases. Thus $\mathcal{A}$ is a decreasing function of x. Since the bound $\mathcal{A} \leqslant 8\pi xy$ is valid for $x = 2R-2y$ and $8\pi xy$ is an increasing function of x, $\mathcal{A} \leqslant 8\pi xy$ for any $x \geqslant 2R-2y$. □

Acknowledgments. The authors would like to thank Helmut Alt, who led us to the lower bound proof of section 4, and Luc Devroye for useful discussions.

PSEUDOTRIANGULATIONS FROM SURFACES AND A NOVEL TYPE OF EDGE FLIP*

OSWIN AICHHOLZER†, FRANZ AURENHAMMER‡, HANNES KRASSER‡, AND PETER BRASS§

Abstract. We prove that planar pseudotriangulations have realizations as polyhedral surfaces in three-space. Two main implications are presented. The spatial embedding leads to a novel flip operation that allows for a drastic reduction of flip distances, especially between (full) triangulations. Moreover, several key results for triangulations, like flipping to optimality, (constrained) Delaunay-hood, and a convex polytope representation, are extended to pseudotriangulations in a natural way.

Key words. pseudotriangulation, flip distance, surface realization, locally convex function, constrained regular complex, polytope representation

1. Introduction.

In geometric data processing, structures that partition the geometric input, as well as connectivity structures for geometric objects, play an important role. A versatile tool in this context is triangular meshes, often called triangulations; see, e.g., the survey articles [14, 26, 11]. A *triangulation* of a finite set S of points in the plane is a maximal planar straight-line graph that uses exactly the points in S as its vertices. Each face in a triangulation is a triangle spanned by S.

In recent years, a relaxation of triangulations, called *pseudotriangulation* (or geodesic triangulation), has received considerable attention. Here, faces bounded by three concave chains, rather than by three line segments, are allowed. Interest in these structures originates from applications to ray shooting [18, 29] and visibility [42, 43]. Meanwhile, their usefulness as an efficient data structure in many other areas has been discovered, including kinetic collision detection [1, 36, 37], rigidity [51, 47, 30], and guarding [44, 49].

Concerning the combinatorial and geometric properties of pseudotriangulations, knowledge is comparatively sparse. Beside the structural rigidity results mentioned above, certain results on the vertex and face degree [35], on the number of possible pseudotriangulations [45, 5], and on edge flipping operations in pseudotriangulations [16, 47] have been obtained recently. An interesting geometric result, in [47] and generalized in [41], addresses polytope representations of pseudotriangulations.

The present paper intends to show that pseudotriangulations possess rich geometric properties. This provides a deeper understanding of their combinatorial properties

and of the interrelation of pseudotriangulations of different levels of edge rank. One of our main results asserts that pseudotriangulations have realizations as polyhedral surfaces in three-space. This insight leads to a novel edge flip operation, which has a three-dimensional interpretation in the surface, as well as a consistent geodesics interpretation in the plane. Inclusion of the new flip type allows us to transform arbitrary pseudotriangulations into each other without changing the underlying set of vertices. A tool for rapidly adapting pseudotriangulations (in particular, triangulations) and their realizing surfaces becomes possible, using a near-linear number of constant-size combinatorial changes. Pseudotriangulations that are realizable as locally convex surfaces project to unique constrained regular complexes, a concept which has not been rigorously defined before. We further solve the optimization problem of finding maximal locally convex surfaces over polygonal domains, by bounding the length of (improving) flip sequences that reach the global optimum of local convexity. Finally, we provide a polytope representation of constrained regular pseudotriangulations.

Subsection 1.1 gives a more detailed overview of our results. We expect various applications in areas where (pseudo)triangulations and polyhedral surfaces play a role, such as surface modeling and terrain fitting. Related concepts, which may be affected by our results, are power diagrams [8] (a generalization of Voronoi diagrams, dual to regular triangulations), weighted alpha shapes [24] and dual complexes [23] (certain subcomplexes of regular triangulations), reflex-free hulls [2] (polyhedral surfaces avoiding cavities), and roofs [3] (surface representations of straight skeletons). The focus of the present paper, though, is on providing new and fundamental properties of pseudotriangulations, rather than on a particular application.

1.1. Overview of results. We start by revisiting edge flipping operations in pseudotriangulations, in section 2. A new type, the edge-removing flip, is introduced, and its relationship to existing flip types is discussed. Section 3 shows that, when using the edge-removing flip, the flip distance between any two pseudotriangulations (and especially, triangulations) of a set of n points is reduced to $O(n \log n)$. This is a substantial improvement over the situation without the new flip type, where an $\Omega(n^2)$ lower bound holds for triangulations [31, 34]. We further derive an $O(n \log^2 n)$ bound for minimum pseudotriangulations, *without* using edge-removing flips. This improves the previous bounds of $O(n^2)$ in [16, 47] and shows that the diameter of the high-dimensional polytope in [47] is $O(n \log^2 n)$. For special settings, even some linear flip distance bounds are achieved. The results above partially rely on new partitioning results for pseudotriangulations in section 4, which may be of separate interest.

Section 5 describes realizations of pseudotriangulations as polyhedral surfaces. We introduce the concept of complete vertices, to distinguish among the vertices those whose heights in the surface can be predetermined. We characterize the class of pseudotriangulations which are projective, in the sense that their internal edges exactly correspond to the set of nonlinearity of a polyhedral surface. This generalizes the situation for triangulations, which are trivially projective. Section 6 gives a surface interpretation of all the admissible flip types from section 2. Surface flips, while being constant-size combinatorial changes, are geometrically nonlocal; a single flip may change the surface heights for $\Theta(n)$ vertices. Special cases are tetrahedral surface flips, which are well known from flipping in convex hulls; see, e.g., [38, 25].

Section 7 puts the above results to use, by solving the optimization problem of finding maximal locally convex functions on polygonal domains (with n vertices, some possibly internal). We prove that every triangular surface can be made locally convex, by performing surface flips which are convexifying or planarizing. The resulting pro-

jection is a pseudotriangulation. If the underlying domain is convex, or if this domain contains no internal vertices, then $O(n^2)$ flips suffice. The former result strengthens a result in [25], which shows that incrementally inserting the vertices, and flipping away all reflex edges in the special (triangular) surface that arises from each insertion, is capable of generating the optimum. For convex domains, the optimum is a lower convex hull, and a regular triangulation in the projection. It is well known [25] that the optimum cannot be reached *within* the class of triangulations, in general. This explains the need for edge-removing (i.e., planarizing) flips and substantiates the usefulness of pseudotriangulations. Our results can also be viewed as a generalization of a well-known fact, namely, that every triangulation of a planar point set can be transformed into the Delaunay triangulation, using so-called Delaunay flips; see, e.g., [26].

Extending the scenario, by fixing a set of edges which are not to be flipped, we arrive at the concept of constrained regular complexes, in subsection 8.2. These are projections of unique maximal surfaces that are locally convex with respect to a constraining planar straight-line graph. If this graph is connected, then pseudotriangulations are obtained. In contrast, constrained regular *triangulations* do not always exist [13, 50] (or are ambiguous structures, depending on the definition), apart from special cases like the constrained Delaunay triangulation [40, 19]. The algorithmic results from section 7 carry over to the constrained setting. In section 9, we show the existence of a convex polytope in n dimensions, whose vertices correspond to all the regular pseudotriangulations constrained by a given graph. The edges of this polytope represent flips of the admissible types. This implies that the set of constrained regular pseudotriangulations is connected under admissible flip operations, and generalizes the polytope constructions in [39, 28, 15] (the so-called associahedron, or secondary polytope) for regular triangulations. As a consequence, locally convex surfaces can be deformed into each other in a controlled way using surface flips.

1.2. Basic properties of pseudotriangulations. We first review some basic notions concerning and properties of pseudotriangulations. For more details, we refer to, e.g., [35, 16, 47]. A *(simple) polygon* is a subset of the plane, homeomorphic to a disk and with piecewise-linear boundary. We denote with $vert(P)$ the set of vertices of a polygon P. A *corner* of P is a vertex with internal angle less than π. The other vertices of P are called *noncorners*. A *side chain* of P is the chain of edges between two consecutive corners of P. The *geodesic* between two points $x, y \in P$ is the shortest curve that connects x and y and lies inside P. A *pseudotriangle* ∇ is a polygon with exactly three corners. Note that the corners of ∇ are the vertices of the convex hull $conv(\nabla)$ of ∇. Moreover, for each pair of corners of ∇, the geodesic between them entirely lies on ∇'s boundary and defines a side chain of ∇.

Let S be a finite set of points in the plane. We will assume throughout this paper that S is in general position (i.e., no three points in S are collinear). A *pseudotriangulation* of S is a partition of $conv(S)$ into pseudotriangles whose vertex set is exactly S. A pseudotriangulation is a face-to-face two-dimensional cell complex; see Figure 1.1 for an illustration. Two faces (pseudotriangles) may be adjacent at one or two edges. In case of such *double-adjacencies*, the union of the two pseudotriangles is a pseudotriangle itself.

Let $\mathcal{PT}$ be some pseudotriangulation of S. A vertex of $\mathcal{PT}$ is called *pointed* if its incident edges lie in an angle smaller than π. Note that all vertices of $conv(S)$ are pointed. The more pointed vertices there are in $\mathcal{PT}$, the less edges and faces it has. More precisely, $\mathcal{PT}$ contains exactly $3n - p - 3$ edges and $2n - p - 2$ pseudotriangles

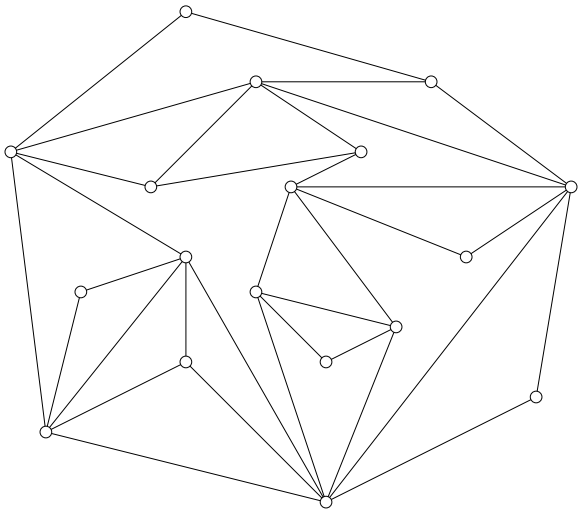

FIG. 1.1. *A pseudotriangulation for* 18 *points.*

if $|S| = n$ and there are $p \leq n$ pointed vertices in $\mathcal{PT}$.

We define the *edge rank* of $\mathcal{PT}$ as $n - p$. The minimum edge rank is zero, where $\mathcal{PT}$ is commonly called a *minimum* (or a *pointed*) pseudotriangulation. $\mathcal{PT}$ then is a maximal planar straight-line graph on S where all vertices are pointed; see, e.g., [51]. It contains exactly $2n - 3$ edges and $n - 2$ pseudotriangles. The edge rank expresses the excess in edges, compared to a minimum pseudotriangulation. Its value is at most $n - |vert(conv(S))|$, which is attained if and only if $\mathcal{PT}$ is a triangulation. The reader may verify that the pseudotriangulation in Figure 1.1 has edge rank 1.

2. Flips in pseudotriangulations revisited. So-called *flips* are operations of constant combinatorial complexity which are commonly used to modify triangulations [4, 25, 26, 31, 34, 38] and, as of late, pseudotriangulations [43, 36, 16, 47]. The purpose of the present section is to introduce a novel flip operation and to show its natural relationship to existing flip types.

2.1. Classical flips. The standard edge flip, also called the *Lawson flip* [38], takes two triangles Δ_1 and Δ_2 whose union is a convex quadrilateral and exchanges the diagonals e and e' of this quadrilateral. To generalize to pseudotriangulations, a different view of this edge flip is advantageous: Take the vertex of Δ_1 and Δ_2, respectively, that lies opposite to e, and replace e by the geodesic between these two vertices. The geodesic is just a line segment e' in this case.

The geodesics interpretation above has been used in [42, 51] to define flips in minimum pseudotriangulations. Let ∇_1 and ∇_2 be two adjacent pseudotriangles, and let e be an edge they have in common. A flip replaces e by the part of the geodesic interior to $\nabla_1 \cup \nabla_2$ that connects the two corners of ∇_1 and ∇_2 opposite to e. In a minimum pseudotriangulation each vertex is pointed, and thus the geodesic indeed contributes a line segment e' which is no edge of ∇_1 or ∇_2.

See Figure 2.1(a) and (b), where the edge e to be flipped is shown in bold and the obtained geodesic is drawn dashed. Note that the flipping partners e and e' may cross or not. In either case, the flip creates two valid pseudotriangles. We refer to such flips as *exchanging* flips. In a minimum pseudotriangulation, each internal

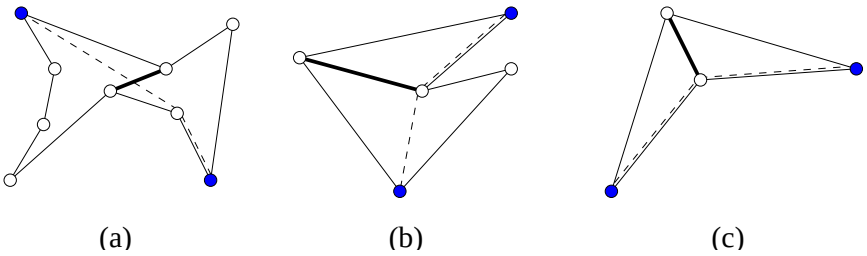

FIG. 2.1. *Exchanging flips and nonflippable edge.*

edge can be flipped to a unique different edge. In a pseudotriangulation of nonzero edge rank, however, edges incident to nonpointed vertices may be *nonflippable* in this sense. In particular, in a full triangulation, an internal edge is nonflippable if and only if its two incident triangles form a nonconvex quadrilateral; see Figure 2.1(c). Nonflippable edges have been the source for the theoretically poor behavior of certain flipping algorithms, concerning the flip distance [31, 34] as well as the nonexistence of flip sequences [25].

2.2. A novel flip type. We wish to generalize the edge flip so as to cover the situation in Figure 2.1(c) as well. In fact, when being consistent with the geodesics rule above, flipping a nonflippable edge $e = \nabla_1 \cap \nabla_2$ means removing e because its substitute does not exist. A pseudotriangle $\nabla_1 \cup \nabla_2$ is obtained. We include this *edge-removing* flip (and its inverse, the *edge-inserting* flip) into the repertoire of admissible flips. By definition, an edge-removing flip is applicable only if a valid pseudotriangle is created. That is, a single nonpointed vertex of the pseudotriangulation is made pointed by the flip.

This simple modification makes each internal edge in every pseudotriangulation (and, in particular, in every triangulation) flippable. Note that each edge-removing flip decreases the edge rank by one, whereas each edge-inserting flip increases it by one. This allows for "surfing" between pseudotriangulations of different edge ranks. Various interesting consequences will be discussed, including a reduction of flip distances, in section 3, and a three-dimensional interpretation of the new flip type, in section 6.

2.3. Relation to other types. The new flip type can be used to simulate certain other flip types. For instance, the exchanging flip in Figure 2.1(b) can be simulated by an edge-inserting flip followed by an edge-removing flip. Of particular relevance is a type of flip that arises in the context of Delaunay and regular triangulations; see [46, 25]. This flip inserts a new vertex v into the interior of a triangle Δ and connects v by edges to the three vertices of Δ. Vertex insertion is meaningful for pseudotriangulations as well [51, 5]. Connect v by geodesics to (at least two) corners of the pseudotriangle ∇ in which v lies. Each geodesic contributes one edge incident to v, and ∇ is partitioned into (two or three) pseudotriangles.

Let us simulate the inverse operation, the removal of a degree-3 vertex v, using the new flip type; see Figure 2.2. Apply an edge-removing flip to one of v's edges first, which leaves a partition of ∇ into two pseudotriangles in double-adjacency. Then, carry out two edge-removing flips simultaneously. This deletes v and leaves ∇ empty, because no edges are created by the geodesics rule. We consider the simultaneous operation as a single flip—the *vertex-removing* flip. By definition, vertex-removing

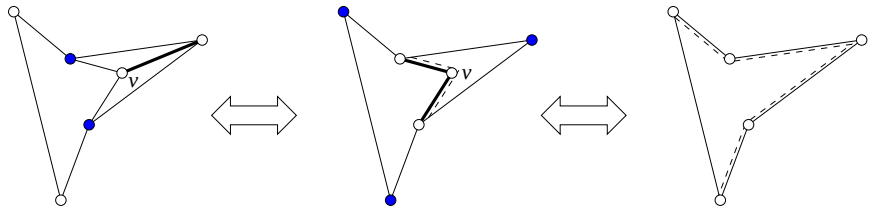

FIG. 2.2. *Edge-removing and vertex-removing flips.*

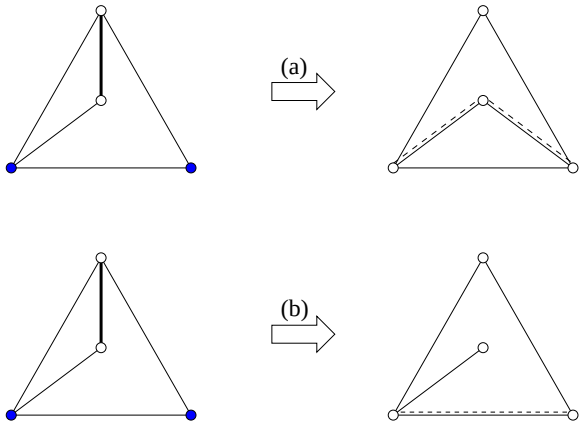

FIG. 2.3. *Ambiguous geodesics interpretation.*

flips can be applied to vertices of degree 2 only.

In summary, the repertoire of flip operations we are going to use contains the (classical) exchanging flips, the edge-removing and the vertex-removing flip, and their inverses, the inserting flips.

Remarks. Edge-removing flips arise implicitly in a greedy flip algorithm for pseudotriangulations of *convex objects*, in [43]. Certain flips that exchange bitangents of such objects cause an edge removal (or insertion) in the corresponding pseudotriangulation for the object centers.[1]

Instead of the vertex-removing flip, a different version—namely, the exchanging flip in Figure 2.3(a)—has been commonly used. It also leads to a valid pseudotriangulation (which now does contain the vertex v). However, care has to be taken not to misinterpret this version as in Figure 2.3(b), where the geodesic still lies inside the union of the two pseudotriangles involved. Also, this version conflicts with a three-dimensional interpretation of flips in surfaces, in section 6. When change in edge rank is conceded, we may circumvent the flip in Figure 2.3(a) by performing two consecutive flips of the new type, namely, an edge-inserting flip followed by an edge-removing flip.

The vertex-inserting flip together with the exchanging flips are the constituting operations of the so-called Henneberg construction, which is capable of generating every minimum pseudotriangulation of a point set S; see, e.g., [51]. With our reper-

[1] We recently learned that edge-removing flips have been introduced independently (and at about the same time) in [41], to generalize the polytope representation in [47] to pseudotriangulations of arbitrary edge rank. In fact, Theorem 3.4 in section 3 implies a bound of $O(n \log n)$ on the diameter of their polytope.

toire, arbitrary pseudotriangulations of S can be derived from each other without ever changing S. We will elaborate on this issue in detail in section 3.

3. Reducing the flip distance. Let S be a set of n points in the plane. It is well known that $\Theta(n^2)$ Lawson flips may be necessary, and are also sufficient, to transform two given triangulations of S into each other; see, e.g., [31, 34]. The upper bound also applies to exchanging flips in minimum pseudotriangulations (see [16, 47]), but no nontrivial lower bounds are known in this case. This section presents a series of improved upper bounds on flip distances, partially even without using the new flip type.

3.1. Simple polygons. We start with proving that flip distances become linear between pseudotriangulations of (simple) polygons when edge-removing flips and their inverses are allowed. Consider a polygon P in the plane. The *shortest-path tree* of P with root $v \in vert(P)$ is the union of all geodesics in P from $vert(P)$ to v. Let $\pi_v(P)$ denote this structure. It is well known [32] that $\pi_v(P)$ is a tree that partitions P into pseudotriangles in a unique way.

LEMMA 3.1. *Let P be a polygon with n vertices, and let $v \in vert(P)$. The shortest-path tree $\pi_v(P)$ can be constructed by triangulating P arbitrarily and applying at most $n-3$ exchanging or edge-removing flips.*

Proof. Fix some triangulation $\mathcal{T}$ of P. We prove the assertion by induction on the number of triangles of $\mathcal{T}$. As an induction base, let Q be the union of all triangles of $\mathcal{T}$ incident to the vertex v. Clearly, the restriction of $\mathcal{T}$ to Q just gives $\pi_v(Q)$. We show that this invariant can be maintained by flipping, when an adjacent triangle Δ of $\mathcal{T}$ is added to Q.

Let u be the vertex of Δ that does not belong to Q. Consider the unique edge $e = Q \cap \Delta$ (which is a diagonal of P). If e belongs to $\pi_v(Q \cup \Delta)$, then an edge of Δ connects u to $\pi_v(Q)$, and $\pi_v(Q \cup \Delta)$ is already complete. No flip is performed. Else let ∇ denote the unique pseudotriangle in $\pi_v(Q)$ that is adjacent to Δ at e. There are two cases. If $\nabla \cup \Delta$ is a pseudotriangle, then, again, u is connected to $\pi_v(Q)$ by Δ. Perform a flip that removes e, which restores $\pi_v(Q \cup \Delta)$. Otherwise, let w be the corner of ∇ opposite to e. Apply an exchanging flip to e. The new edge e' lies on the geodesic between u and w. Thus e' connects u to $\pi_v(Q)$, which constructs $\pi_v(Q \cup \Delta)$ in this case.

The total number of flips is at most $n-3$, because each flip can be charged to the triangle of $\mathcal{T}$ that is added. □

COROLLARY 3.2. *Any two triangulations of a polygon P with n vertices can be flipped into each other by at most $2n-6$ exchanging, edge-removing, or edge-inserting flips.*

Proof. Let $\mathcal{T}_1$ and $\mathcal{T}_2$ be two triangulations of P. Choose some vertex $v \in vert(P)$ and flip $\mathcal{T}_1$ to $\pi_v(P)$. Then flip $\pi_v(P)$ to $\mathcal{T}_2$ by reversing the sequence of flips that transforms $\mathcal{T}_2$ to $\pi_v(P)$. This is possible and takes at most $2n-6$ flips of the types above, by Lemma 3.1. □

Corollary 3.2 implies a flip distance of $O(n)$ between any two *pseudotriangulations* $\mathcal{PT}_1$ and $\mathcal{PT}_2$ of a polygon P, because $\mathcal{PT}_1$ and $\mathcal{PT}_2$ can be completed to form a triangulation of P with $O(n)$ edge-inserting flips.

3.2. Planar point sets. We continue with pseudotriangulations of planar point sets. In fact, we choose a slightly more general scenario, namely, a point set enclosed by an arbitrary simple polygon (a so-called augmented polygon). This setting will turn out to be more appropriate for our developments, as it arises naturally from

constraining the pseudotriangulated domain. We will show how to flip any given pseudotriangulation into a canonical one by splitting the underlying augmented polygon in a balanced way until empty polygons are obtained and Corollary 3.2 applies.

Let P be a polygon, and consider a finite point set $S \subset P$ with $vert(P) \subseteq S$. We call the pair (P, S) an *augmented polygon*. A pseudotriangulation $\mathcal{PT}$ of (P, S) is a partition of P into pseudotriangles whose vertex set is exactly S. It contains exactly $3n - m + k - p - 3$ edges and $2n - m + k - p - 2$ pseudotriangles if $|S| = n$, P is an m-gon with k corners, and p counts the pointed vertices of $\mathcal{PT}$. The maximum edge rank of $\mathcal{PT}$ is $n - k$, in which case $\mathcal{PT}$ is a triangulation. In the special case $P = conv(S)$, we have $m = k$ and deal with pseudotriangulations of the point set S. Below is another corollary of Lemma 3.1.

COROLLARY 3.3. *Let $\mathcal{T}$ be a (full) triangulation of an augmented polygon (P, S). Let e be some line segment spanned by S, which lies inside P and crosses $\mathcal{T}$ at $j \geq 1$ edges. Then $\mathcal{T}$ can be modified to a triangulation that contains e by applying $O(j)$ exchanging, edge-removing, or edge-inserting flips.*

Proof. Let Q be the union of the triangles of $\mathcal{T}$ that are crossed by e. Note that Q may contain points of S in its interior or even may contain holes, namely if Q contains internal edges which do not cross e. In this case, we cut Q along these edges and move Q apart infinitesimally at the cuts, to obtain a simple polygon empty of points in S. This is possible because a general position is assumed for S. Now choose any triangulation $\mathcal{T}_e$ of Q which includes the edge e to be integrated. By Corollary 3.2, the part of $\mathcal{T}$ inside Q can be flipped to $\mathcal{T}_e$ by $O(j)$ flips. □

We are now prepared to prove the following general assertion on flip distances.

THEOREM 3.4. *Any two pseudotriangulations of a given planar point set S (or more generally, of a given augmented polygon (P, S)) can be transformed into each other by applying $O(n \log n)$ flips of the types exchanging, edge-removing, and edge-inserting, for $n = |S|$. No vertex-removing flips are used.*

Proof. The two pseudotriangulations of the augmented polygon (P, S) in question can be completed to form a triangulation by applying $O(n)$ edge-inserting flips. We show how to transform two arbitrary triangulations $\mathcal{T}_1$ and $\mathcal{T}_2$ of (P, S) into the same, using $O(n \log n)$ flips. Let P be an m-gon. If $m = n$, then $O(n)$ flips suffice, by Corollary 3.2. Else we partition P into subpolygons, each containing at most $\frac{2}{3}(n - m)$ points of $S \setminus vert(P)$. A constant number of line segments spanned by S suffice for this purpose, by Theorem 4.4(1) below. Incorporate these segments into $\mathcal{T}_1$ and $\mathcal{T}_2$, respectively, in $O(n)$ flips, which is possible by Corollary 3.3. Treat the obtained $O(1)$ augmented polygons recursively. This yields a polygonal partition of P whose vertex set is exactly S, and two triangulations thereof, in $O(n \log n)$ flips. By Corollary 3.2, another $O(n)$ flips let these two triangulations coincide. □

Remarks. Theorem 3.4 demonstrates that flip distances are substantially reduced when using the new flip type. "Shortcuts" via pseudotriangulations with varying edge rank become possible. The interested reader may check that the constant involved in the $O(n \log n)$ term is small (less than 6). We conjecture that Theorem 3.4 can be improved to $O(n)$ flips, because the $\Omega(n^2)$ worst-case examples for Lawson flips in triangulations are based on (nonconvex) polygons without internal points [34], an instance covered by Corollary 3.2 in $O(n)$ flips.

All flips used in Theorem 3.4 are constant-size combinatorial operations, which can be carried out in $O(\log m)$ time each if the size of the two pseudotriangles involved is at most m; see, e.g., [27]. This implies that any two (pseudo)triangulations of a given set of n points can be adapted by local operations in $O(n \log^2 n)$ time—a result

we expect to have various applications.

3.3. Two linear bounds. For the sake of completeness, we include here two more implications that come from using our extended repertoire of flips.

Recall that vertex-removing and vertex-inserting flips have been excluded in Theorem 3.4. Dropping this restriction makes things easy, because every pseudotriangulation contains some vertex of constant degree, which can be removed with $O(1)$ flips. A flip distance of $O(n)$ is obvious in this setting. However, removing a vertex not only changes the vertex set S, but also changes the underlying domain (the polygon P) if removal was for a boundary vertex. In contrast, in the setting in Theorem 3.4, both S and P remain unchanged. The situation where S but not P is allowed to change is of some interest, because no internal vertex of constant degree might exist in a pseudotriangulation.

LEMMA 3.5. *Let S be a planar n-point set. Any two pseudotriangulations of S can be flipped into each other in $O(n)$ flips, without changing the underlying domain $conv(S)$, if the entire repertoire of flips from section 2 is used.*

It suffices to prove Lemma 3.5 for full triangulations. Let $\mathcal{T}^*$ be the *star triangulation* of $conv(S)$ with respect to a fixed boundary vertex v. In $\mathcal{T}^*$, each vertex of $conv(S)$ different from v is connected to v by an edge. We show that any triangulation $\mathcal{T}$ of S can be flipped into $\mathcal{T}^*$ with $O(n)$ flips. To this end, consider a particular order for the triangles of $\mathcal{T}$.

LEMMA 3.6. *Let v be some boundary vertex of $\mathcal{T}$. There exists an order $\Delta_1, \ldots, \Delta_t$ for $\mathcal{T}$'s triangles such that $\bigcup_{i \le j} \Delta_j$ is star-shaped as seen from v, for $j = 1, \ldots, t$.*

Proof. Set $Q_j = \bigcup_{i \le j} \Delta_j$. To apply induction, assume that Q_j is star-shaped as seen from v, for some j; this assumption is obviously true for $Q_t = conv(S)$. Let Δ be a triangle of T in Q_j that is not incident to v. The part of Δ on the boundary of Q_j (if existent) defines a visibility angle $\alpha(\Delta)$ at v. Because Q_j is star-shaped and v is a boundary vertex of Q_j, there exists some triangle Δ which lies within $\alpha(e)$. Thus $Q_j \setminus \Delta = Q_{j-1}$ is star-shaped too. □

We now visit $\Delta_1, \ldots, \Delta_t$ in the order given by Lemma 3.6, and maintain the star triangulation T_j^* of Q_j with respect to v by flipping. If the current triangle Δ_j is incident to v, then no flip is performed. Otherwise, Δ_j shares either one or two edges with Q_{j-1}. Let e be such an edge. In the former case, the exchanging flip for e restores T_j^*. To obtain T_j^* in the latter case, the flip removing e is applied first, followed by a flip that removes the unique vertex w internal to Q_j. (Note that the degree of w has been lowered to 2 by the removal of e.) This yields $T_t^* = \mathcal{T}^*$ after less than $2t = O(n)$ flips and proves Lemma 3.5.

The next linear bound concerns minimum pseudotriangulations. It is well known that not every pseudotriangulation can be made minimum by removing edges. It can only be made *minimal* in edge rank, and is termed accordingly in [1, 35, 48]. In particular, a minimal pseudotriangulation may be a full triangulation, even when its vertices are not in convex position [48]. We can show the following result.

LEMMA 3.7. *Let $\mathcal{PT}$ be any pseudotriangulation of a planar n-point set S. Then $\mathcal{PT}$ can be transformed into a minimum pseudotriangulation of S with $O(n)$ exchanging, edge-removing, or edge-inserting flips. No vertex-removing flips are used.*

Proof. Consider some spanning tree B of $\mathcal{PT}$. We construct a connected graph Z with vertex set S, which does not cross B and where each vertex is pointed. Let $v_1, \ldots, v_n$ be the vertices of S in some depth-first order for B such that, for each v_i, the edges of B incident to v_i are visited in clockwise order. To obtain Z, connect v_i

and v_{i+1} for $i = 1, \ldots, n$ and $v_{n+1} = v_1$, as follows. If $v_i v_{i+1}$ is an edge of B, then use this edge. Otherwise, use the geodesic that comes from "stretching" the unique path in B between v_i and v_{i+1} to the shortest path in the plane that does not cross B. By construction, each vertex v_i either has degree 2 in Z or some geodesics run via v_i, in which case v_i is pointed in Z as well.

In general, $\mathcal{PT}$ will not contain Z as a subgraph. We flip $\mathcal{PT}$ into a pseudotriangulation $\mathcal{PT}'$ that contains Z (and B) as follows. Imagine cutting $conv(S)$ along B and moving it apart at the cuts infinitesimally. This yields a partition of $conv(S)$ into simple polygons. Within each such polygon, $\mathcal{PT}$ can be flipped to contain the relevant part of Z, in a total of $O(n)$ flips for all polygons; see subsection 3.1. Finally, we flip $\mathcal{PT}'$ to a minimum pseudotriangulation that contains Z, by cutting $conv(S)$ along Z and adapting the pseudotriangulations within these polygons, using $O(n)$ additional flips. □

Remarks. The order in Lemma 3.6 is called a shelling order (or a translation order) for $\mathcal{T}$ with respect to v. It is well known that such an order does not exist for every triangulation if v is an *internal* vertex. Exceptions are Delaunay triangulations [21] and regular triangulations [22].

Lemma 3.7 does not imply a linear flip distance between any two pseudotriangulations of S, because which minimum pseudotriangulations can be reached depends on $\mathcal{PT}$. The pointed graph Z arises in a classical factor-2 approximation for the travelling salesman tour for S. We raise the question of whether every triangulation of a point set S contains a pointed spanning tree.

3.4. Minimum pseudotriangulations. Our next aim is to provide a stronger version of Theorem 3.4, namely for minimum pseudotriangulations and when using the exchanging flip type exclusively. That is, we restrict ourselves to staying within the class of minimum pseudotriangulations. We apply arguments similar to those of subsections 3.1 and 3.2.

Let P be a polygon with k corners. The *minimum shortest-path tree* $\mu_c(P)$, for a fixed corner c of P, is the union of all geodesics inside P that lead from c to the *corners* of P. Observe that $\mu_c(P)$ defines a minimum pseudotriangulation for P, which is a subset of the shortest-path tree $\pi_c(P)$ defined in subsection 3.1. The proof of Lemma 3.1 now can be adapted to show that every minimum pseudotriangulation of P can be transformed into $\mu_c(P)$ by at most $k-3$ exchanging flips. The new flip type is not used here, because each internal edge is flippable in the classical sense. We obtain the following.

LEMMA 3.8. *Let P be a polygon with k corners. Any two minimum pseudotriangulations of P are transformable into each other by applying at most $2k-6$ exchanging flips.*

The next lemma is a variant of Corollary 3.3 for minimum pseudotriangulations.

LEMMA 3.9. *Let $\mathcal{MPT}$ be a minimum pseudotriangulation of an augmented polygon (P, S), and let G be some pointed planar straight-line graph on S and in P. Then $\mathcal{MPT}$ can be modified to contain G by applying $O(nj)$ exchanging flips if S has n vertices and $G \setminus P$ has j edges.*

Proof. Let uv be some edge of $G \setminus P$. We prove that uv can be incorporated into $\mathcal{MPT}$ using $O(n)$ exchanging flips, and without altering previously incorporated edges of G.

If vertex u is not pointed in $\mathcal{MPT} \cup \{uv\}$, we flip edges of $\mathcal{MPT}$ incident to u to restore the pointedness of u, as follows. Let $m(u)$ denote the angle formed by u's edges in the current minimum pseudotriangulation, and let $g(u)$ be the angle

formed by those edges among them which also belong to G (if there are any). We have $g(u) < m(u) < \pi$. Rotate $m(u)$, by flipping the unique edge e that bounds $m(u)$ but not $g(u)$ and such that e and $g(u)$ lie on different sides of uv, until $uv \in m(u)$. The condition is necessarily met as soon as e does not exist. This process does not alter any edge of G in $\mathcal{MPT}$, takes $O(n)$ exchanging flips, and transforms $\mathcal{MPT}$ into a minimum pseudotriangulation $\mathcal{MPT}'$. Note that the vertex v may be nonpointed in $\mathcal{MPT}' \cup \{uv\}$.

We next flip the edges of $\mathcal{MPT}'$ which cross uv (if there are any), in the order from u to v. For the current edge e to be flipped, the following invariants hold. Edge e bounds a face ∇ incident to u. Denote with c the corner of ∇ opposite to e. ($c = u$ is possible.) The edge f obtained by flipping e lies on some geodesic to c. Thus f leaves u pointed. Moreover, as the line segment uv also lies on a geodesic to c, edge f does not cross uv. After $O(n)$ flips, a minimum pseudotriangulation $\mathcal{MPT}''$ results, where no edge crosses uv and such that u is still pointed in $\mathcal{MPT}'' \cup \{uv\}$.

Now either $uv \in \mathcal{MPT}''$ (and we are done) or v is not pointed in $\mathcal{MPT}'' \cup \{uv\}$. In the latter case, there is a unique face ∇'' of $\mathcal{MPT}''$ which contains uv in its interior, and v is a noncorner of ∇''. Consider the side chain of ∇'' that contains v, and let c'' be the corner of ∇'' opposite to this side chain. Flip an edge of ∇'' which is incident to v and which does not lie in the pointed angle of v in G. The obtained edge f'' lies on a geodesic to the corner c''. Therefore, f'' neither crosses uv nor destroys the pointedness of u. If $f'' = uv$, the construction is complete. Otherwise, the degree of v has been decremented in the flip, and we repeat the step above for the face that now contains uv in its interior, until uv becomes part of the current pseudotriangulation. This takes another $O(n)$ flips. □

Lemma 3.9 directly implies an $O(n^2)$ bound on the (exchanging) flip distance in minimum pseudotriangulations: Take for G the minimum pseudotriangulation into which $\mathcal{MPT}$ is to be transformed. The proof of the theorem below shows that Lemma 3.9 can be used in a more sophisticated way.

THEOREM 3.10. *Let S be a set of n points in the plane, and let $\mathcal{MPT}_1$ and $\mathcal{MPT}_2$ be two minimum pseudotriangulations of S. Then $\mathcal{MPT}_1$ can be transformed into $\mathcal{MPT}_2$ by applying $O(n \log^2 n)$ exchanging flips. No other flip types are used. The same result holds for augmented polygons (P, S).*

Proof. Consider an augmented polygon (P, S). We recursively split (P, S) in a balanced way, by applying Theorem 4.4(2) from section 4. This constructs a polygonal partition Π of P, whose vertex set is S and where all vertices are pointed. Π is obtained by introducing $O(\log n)$ line segments spanned by S in each recursive step, and the number of recursive steps is $O(\log n)$.

By Lemma 3.9, $O(n \log^2 n)$ exchanging flips are sufficient to make $\mathcal{MPT}_1$ and $\mathcal{MPT}_2$ contain all the edges of Π. Finally, Lemma 3.8 allows for adapting pseudotriangles within the polygons of Π in $O(n)$ such flips. □

Remarks. Theorem 3.10 improves the recent bound of $O(n^2)$ in [16] for minimum pseudotriangulations of point sets. Again, we conjecture that the truth is $O(n)$ flips.[2]

In [47], the polytope $\mathcal{M}(S)$ of minimum pseudotriangulations of a point set S was introduced. $\mathcal{M}(S)$ is a high-dimensional convex polytope. Its vertices correspond to all the minimum pseudotriangulations of S, and its edges represent all possible exchanging flips. By Theorem 3.10, the diameter of $\mathcal{M}(S)$ is bounded by $O(n \log^2 n)$.

[2] By a very recent result in [12], a flip distance of $O(n \log n)$ for minimum pseudotriangulations of point sets is obtainable, using a different divide-and-conquer approach. However, this approach does not carry over to the more general case of augmented polygons.

As a somewhat counterintuitive fact, the transformation between two given minimum pseudotriangulations may be speeded up by using edge-inserting and edge-removing flips intermediately. There exist examples where $n-3$ exchanging flips are necessary, a third of which are saved when performing a single edge-inserting and edge-removing flip, respectively, in the beginning and at the end; see [33]. This indicates that flexibility of pseudotriangulations not only comes from low edge rank, but also stems from the ability to change this parameter, using the new flip type.

A *constrained* pseudotriangulation of a point set S is one that is required to contain a given planar straight-line graph G on S. It is well known that, for any choice of G, the set of constrained *triangulations* of S is connected by Lawson flips: Every triangulation constrained by G can be flipped into the constrained Delaunay triangulation for G and S; see [40]. The following related result holds, by arguments in the proof of Lemma 3.9.

COROLLARY 3.11. *Any two minimum pseudotriangulations of a point set S constrained by a given (pointed) planar straight-line graph G on S can be flipped into each other using $O(n^2)$ exchanging flips.*

In case G partitions $conv(S)$ into augmented polygons (as in Figure 8.1 below), the $O(n \log^2 n)$ exchanging flip distance bound from Theorem 3.10 applies. Moreover, for such graphs G, the flip distance between constrained pseudotriangulations of arbitrary edge rank is $O(n \log n)$ when edge-inserting flips and their reverses are admitted, by Theorem 3.4. The concept of constrained pseudotriangulations plays an important role in the context of regularity; see sections 8 and 9.

4. Partitioning results. This section presents some partitioning results concerning pseudotriangulations that were referred to in section 3. Subsections 4.1 and 4.3 give two technical lemmas. The assertions in subsections 4.2 and 4.4 might be of separate interest.

4.1. Pseudoconvex polygons. Let P be a simple polygon. Consider a pseudotriangle $\nabla \subset P$ with vertices from $vert(P)$. ∇ is called *nice* if its three corners are corners of P. We define the *cut* of ∇ as the number of diagonals of P on ∇'s boundary.

A polygon P is *pseudoconvex* if every geodesic inside P is a convex chain. A *corner tangent* is an inner tangent of P incident to at least one corner of P. A pseudoconvex polygon P is *strongly pseudoconvex* if no corner tangent exists for P.

LEMMA 4.1. *Let P be a strongly pseudoconvex polygon with k corners. There exists a nice pseudotriangle for P with cut $O(\log k)$.*

Proof. Observe first that there always exists *some* nice pseudotriangle ∇ for P. Select a corner w of P. Since P is strongly pseudoconvex, w "sees" a unique side chain of P. Together with w, the two corners that define this side chain span a nice pseudotriangle ∇. If ∇ has cut $O(\log k)$, then we are done. Otherwise, we apply induction by constructing a pseudotriangle whose cut is strictly smaller, as follows.

We will prove the following:

(*) at each edge d of ∇ which is a diagonal of P there exists an adjacent pseudotriangle ∇', spanned by d and some corner c of P, such that ∇' has cut at most $1 + \log_2 k$.

Property (*) is used as follows. Set $x = \log_2 k$, and assume that some side chain of ∇ contains at least $2x + 5$ diagonals of P. Choose a middlemost diagonal d, and generate an adjacent pseudotriangle ∇' as above. Flip edge d, which creates two pseudotriangles. Each of them avoids at least $x + 2$ diagonals that bound ∇ and contains at most $x + 1$ diagonals that bound ∇'. So for both, the cut is strictly

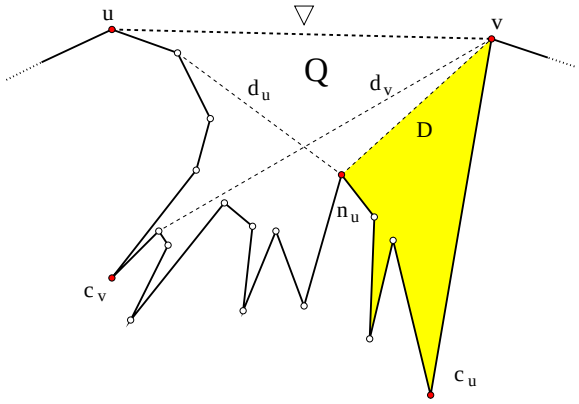

FIG. 4.1. *Constructing* ∇'.

smaller than the cut of ∇. Moreover, because P is strongly pseudoconvex, exactly one created pseudotriangle is nice.

It remains to prove (*). We construct the desired pseudotriangle ∇' as follows; see Figure 4.1. Let $d = uv$, and denote with Q the part of P cut off by d and not containing ∇. Note that u and v are corners of Q. Consider the minimum shortest-path tree of Q with root u, as defined in subsection 3.4. Let ∇_u be the unique face of this tree incident to uv. (Here and below, define things for v analogously.)

Case 1. Q contains only one corner $c \neq u, v$. Then $\nabla_u = \nabla_v$, and we take this face for the pseudotriangle ∇' in question. No diagonals of P lie on the side chains uc and vc of ∇'.

Case 2. Q contains at least two corners $\neq u, v$. Then ∇_u and ∇_v differ in their third corner, call it c_u and c_v, respectively, and thus have diagonals of P on their boundaries. Let d_u be the first diagonal on the side chain uc_u of ∇_u, and let d_u end at the vertex n_u. P is strongly pseudoconvex, and thus n_u is a noncorner of Q, because d_u would be a corner tangent, otherwise. Also, n_u does not lie on the side chain of Q that starts at v and is different from uv, because nonconvex geodesics inside P and via u and n_u would exist otherwise. Therefore, the geodesic from n_u to v starts with a diagonal D of P. Observe next that, by $\nabla_u \neq \nabla_v$, their side chains uc_u and vc_v cross. Hence the two diagonals d_u and d_v cross unless $n_u = n_v$. In both cases at least one diagonal, say d_u, cuts off from Q at least half of its corners. Therefore the diagonal D above, which is adjacent to d_u at vertex n_u, cuts off $k' \leq \frac{k}{2}$ corners. Clearly, $k' \geq 1$, and we treat the polygon cut off by D (shaded in Figure 4.1) recursively. The diagonal d_u lies on the boundary of the pseudotriangle ∇' being constructed.

Each occurrence of Case 2 increments the cut of ∇', which initially is 1 because of the diagonal $d = uv$. By the choice of D, Case 2 occurs at most $\log_2 k$ times. This proves (*) and completes the argumentation. ∎

4.2. Pseudotriangulations with small cut. We are now ready to prove the following structural result for minimum pseudotriangulations of simple polygons.

THEOREM 4.2. *For every polygon P with n vertices there exists a minimum pseudotriangulation of P in which each face has cut $O(\log n)$.*

Proof. We first partition P into strongly pseudoconvex polygons. Diagonals on nonconvex geodesics and corner tangents are used, such that each introduced diagonal

is incident to some corner in both polygons that it bounds. (These diagonals will contribute to the cut of the final faces in the minimum pseudotriangulation to be constructed, but their number is at most six per face.) Each strongly pseudoconvex polygon Q with more than three corners is partitioned further as follows.

Integrate a nice pseudotriangle ∇ with small cut for Q, whose existence is guaranteed by Lemma 4.1. Because ∇ is nice, it does not violate the pointedness of any vertex. Moreover, each diagonal of Q on ∇'s boundary is incident to two corners of the polygon it cuts off from Q. These polygons are partitioned recursively.

A minimum pseudotriangulation $\mathcal{MPT}$ of P results. Each face f of $\mathcal{MPT}$ has cut $O(\log n)$: A diagonal on f's boundary comes from Lemma 4.1 or is among the at most six edges incident to some corner of f. □

Remarks. Theorem 4.2 is asymptotically optimal. There exist polygons with n vertices where every possible minimum pseudotriangulation contains some face with cut $\Omega(\log n)$; see [6]. The theorem is related to a result in [35] which shows, for every point set S, the existence of a minimum pseudotriangulation with constant face complexity. Another related result, in [18], shows that every n-gon P admits a minimum pseudotriangulation $\mathcal{MPT}$ such that each line segment internal to P crosses only $O(\log n)$ edges of $\mathcal{MPT}$.

4.3. Splitting pseudotriangles. We continue with a ham-sandwich-type result for pseudotriangles.

LEMMA 4.3. *Let ∇ be a pseudotriangle that contains a set M of i points in its interior. There exists a point $p \in M$ whose geodesics to two corners of ∇ divide M into two subsets of cardinality $\frac{2\,i}{3}$ or less.*

Proof. For each point $p \in M$, the geodesics from p to the three corners of ∇ partition ∇ into three pseudotriangles (faces). Such a face f is called *sparse* if f encloses at most $\frac{2\,i}{3}$ points of M. We claim that, for each pair c, c' of corners of ∇, there exist at least $\frac{2\,i}{3} + 1$ sparse faces: Consider the sorted order of M, as given by the shortest-path tree with root c for M. The jth point of M in this order spans a face that contains strictly fewer than j points.

We conclude that there are at least $2\,i + 3$ sparse faces in total. Thus the mean number of sparse faces per point in M exceeds two, which implies that there exists a point $p \in M$ incident to three sparse faces. Among them, let f be the face that contains the most points, which are at least $\frac{i}{3}$. We take the two geodesics that span f to partition ∇. This yields two parts with at most $\frac{2\,i}{3}$ points each. □

Remarks. The fraction $\frac{2}{3}$ in Lemma 4.3 is optimal, even when ∇ is a triangle. The set M may consist of three groups of $\frac{i}{3}$ points such that, for each choice of $p \in M$, the two groups not containing p end up in the same subset.

4.4. Partition theorem. The results in the preceding subsections combine into the following partition theorem for augmented polygons.

THEOREM 4.4. *Let (P, S) be an augmented polygon, and let $I = S \setminus vert(P)$. There exist polygonal partitions Π_1 and Π_2 of (P, S) such that*

(1) *Π_1 uses $O(1)$ line segments spanned by S and assigns at most $\frac{2}{3} \cdot |I|$ points of I to each polygon;*

(2) *Π_2 uses $O(\log n)$ line segments spanned by S, assigns at most $\frac{2}{3} \cdot |I|$ points of I to each polygon, and guarantees the pointedness of each vertex of S.*

Proof. To construct Π_1, let $\mathcal{T}$ be some triangulation of the polygon P. Call a polygon $Q \subset P$ *sparse* if Q contains at most $\frac{2}{3} \cdot |I|$ points of I. Let ∇ be any face of $\mathcal{T}$. If each part of $P \setminus \nabla$ is sparse, then we are done, because we can partition P

with ∇, and ∇ with two line segments as in Lemma 4.3 if ∇ is nonsparse. Otherwise, we continue with the face of $\mathcal{T}$ adjacent to ∇ in the (unique) nonsparse part of $P \setminus \nabla$ until the first condition is met.

To construct Π_2 we proceed analogously but use a minimum pseudotriangulation $\mathcal{MPT}$ of P with face cuts bounded by $O(\log n)$. The existence of $\mathcal{MPT}$ is given by Theorem 4.2. The $O(\log n)$ edges of ∇ that are used to partition (P, S) retain the pointedness of all vertices, as do the two segments from Lemma 4.3 that may have to be used to split ∇. □

Remarks. Theorem 4.4 is similar in flavor to a result in [17], which asserts that any simple n-gon can be split by a diagonal into two subpolygons with at most $\frac{2}{3}n$ vertices.

5. Surfaces for pseudotriangulations. A *polyhedral surface* is the graph of a continuous and piecewise-linear function whose domain is the plane, or a polygonal subset thereof. Polyhedral surfaces are also known as polyhedral terrains. A two-dimensional cell complex $\mathcal{C}$ is called *projective* if there exists some polyhedral surface whose set of nonlinearity projects exactly to the set of all (internal) edges of $\mathcal{C}$. A subclass consists of the *regular* complexes, which are the projections of *convex* surfaces, i.e., whose defining function is convex. Examples of regular two-dimensional complexes are line arrangements, Voronoi diagrams and power diagrams (even their generalizations to higher order), and Delaunay triangulations; see, e.g., [9] and references therein. Not every triangulation, however, is regular (as Figure 7.3 below shows), but it is trivial that triangulations are projective.

We intend to show, in subsection 5.2, that pseudotriangulations have natural realizations as polyhedral surfaces. We characterize the class of projective pseudotriangulations in subsection 5.3 and discuss regular pseudotriangulations and their constrained variants in later sections.

The underlying domain is—as in previous sections—an augmented polygon, not only to gain generality compared to the point set case, but also because certain questions concerning a three-dimensional realization become more natural and interesting in this setting.

5.1. Complete vertices. We start with introducing a *status* for vertices, which will allow us to determine which vertices can be fixed in height when lifting a given pseudotriangulation to three dimensions.

Consider an augmented polygon (P, S), and let $\mathcal{PT}$ be a pseudotriangulation of (P, S). The status of a vertex v of $\mathcal{PT}$ is *complete* if v is a corner in each of its incident pseudotriangles. The status of v is *incomplete* otherwise. Note that each incomplete vertex uniquely corresponds to a pseudotriangle of $\mathcal{PT}$ where this vertex is a noncorner. Incomplete vertices have to be pointed, whereas complete vertices are pointed if and only if they are corners of P. In a (full) triangulation, all vertices are complete. On the other end of the spectrum, every minimum pseudotriangulation of (P, S) realizes the minimum number of complete vertices.

Observe that no vertex status is affected by an exchanging flip, whereas an edge-removing flip alters the status of exactly one vertex from complete to incomplete. A vertex-removing flip does not alter the status of any remaining vertex. Making all vertices complete by edge-inserting flips always results in a triangulation.

Remarks. We believe that the *completeness* of a vertex is a concept more natural than *pointedness*. For example, the vertices of $conv(S)$, though being pointed, behave like nonpointed vertices in the flipping process, because no geodesic ever runs via them. This effect becomes even more apparent when the underlying domain (P, S) is not convex. Corners as well as noncorners of the boundary polygon P may be pointed

in a pseudotriangulation $\mathcal{PT}$ of (P, S), but the (forced) pointedness of P's corners seems artificial. What actually counts is "(non)pointedness with boundary effects eliminated," that is, the completeness status of a vertex.

The number of incomplete vertices is $i = p - k$ if P has k corners and $\mathcal{PT}$ has p pointed vertices. This relation saves one of the four parameters in the formulas for the number of edges and faces in a pseudotriangulation of (P, S) (see subsection 3.2), another fact in favor of the new concept.

Complete vertices can be distinguished from incomplete ones in any polygonal partition, as they are defined via corners of polygonal faces. In fact, all the results in sections 2, 3, and 4 could have been derived using this terminology. We refrained from doing so only to keep to existing notation in related work. In the three-dimensional setting below, the notion of complete vertices is indispensable, however.

5.2. Surface theorem. In this subsection, we state and prove a main geometric result of this paper.

THEOREM 5.1 (surface theorem). *Let (P, S) be an augmented polygon, and let $\mathcal{PT}$ be any pseudotriangulation thereof. Let $\boldsymbol{h}$ be a vector assigning a height to each complete vertex of $\mathcal{PT}$. For each choice of $\boldsymbol{h}$ there exists a unique polyhedral surface $\mathcal{F}$ above the domain P, which respects $\boldsymbol{h}$ and whose edges project vertically to (a subset of) the edges of $\mathcal{PT}$.*

Proof. Let $v_1, \ldots, v_r$ denote the complete vertices of $\mathcal{PT}$, and let $v_{r+1}, \ldots, v_n$ be the incomplete ones. We set up a system of linear equations for the vertex heights $z_1, \ldots, z_n$ that determines a polygonal surface $\mathcal{F}$ and has a unique solution.

If v_i is a complete vertex, the system contains the equation $z_i = h_i$. Otherwise, its height z_i is constrained as follows. There is a unique pseudotriangle ∇ in $\mathcal{PT}$ where v_i is no corner; an internal angle larger than π occurs in ∇ at v_i. Let v_j, v_k, v_ℓ be the corners of ∇. We have $v_i \in \mathit{conv}(v_j, v_k, v_\ell) = \mathit{conv}(\nabla)$ by definition of a pseudotriangle. Requiring coplanarity of the lifted vertices v_i, v_j, v_k, v_ℓ leads to an equation of the form

$$\alpha(v_j v_k v_\ell) \cdot z_i - \alpha(v_i v_k v_\ell) \cdot z_j - \alpha(v_i v_j v_\ell) \cdot z_k - \alpha(v_i v_j v_k) \cdot z_\ell = 0,$$

where $\alpha(abc)$ denotes the (unsigned) area of a triangle abc. This expresses z_i as a convex combination of z_j, z_k, and z_ℓ.

A linear system $A \cdot \boldsymbol{z} = \boldsymbol{b}$ is obtained, where A is an $n \times n$ matrix whose ith row corresponds to the equation for z_i, and where $\boldsymbol{b}$ is a vector that coincides with $\boldsymbol{h}$ in the first r entries and contains zero entries otherwise. Any solution $\boldsymbol{z}$ defines a valid surface $\mathcal{F}$, because triangular facets of $\mathcal{F}$ are trivially fixed by three heights, and for each pseudotriangular facet of $\mathcal{F}$ its vertices are forced to be coplanar. Thus $\mathcal{F}$ is piecewise-linear and continuous, and each edge of $\mathcal{F}$ projects to an edge of $\mathcal{PT}$.

We now prove that a unique solution $\boldsymbol{z}$ exists, by showing $\mathit{det}(A) \neq 0$. Call an $n \times n$ matrix M *affirmative* if (a) M is positive exactly at its diagonal entries, (b) no row sum in M is negative, and (c) at least one row sum is positive. M is called *strictly affirmative* if each allowable submatrix of M (i.e., which comes from deleting the ith row and the ith column of M for $t < n$ indices i) is affirmative. It is easy to prove $\mathit{det}(M) > 0$ for any strictly affirmative matrix M; see [10].

It remains to show that A is strictly affirmative. Observe first that A is affirmative: The first $r \geq 1$ rows of A are unit rows, and the remaining $n - r$ rows represent convex combinations for the diagonal elements. Let A' be an allowable submatrix of A. Then properties (a) and (b) clearly hold for A'. Property (c) is obvious while unit rows (that correspond to complete vertices) are present in A', and is retained because heights

for complete vertices participate with negative coefficients in remaining rows. We conclude that A is strictly affirmative. □

Remarks. The set of edges of the surface $\mathcal{F}$ in Theorem 5.1 may project to a proper subset of edges of the pseudotriangulation $\mathcal{PT}$ of (P, S). We will discuss this phenomenon in detail in subsection 5.3.

The existence of *some* projection surface is obvious when (P, S) contains no internal vertices, that is, if $S = vert(P)$. Then all internal edges of $\mathcal{PT}$ are diagonals of P. For each pseudotriangle of $\mathcal{PT}$, its three corners define a plane, which can be placed appropriately in space. Note that these planes can be chosen such that the resulting surface is convex at each internal edge; this observation leads to Corollary 9.2 in section 9.

Theorem 5.1 holds for arbitrary (augmented) polygonal domains, including polygons with holes. We will use this generalization in subsections 6.3 and 8.2. Note that the noncorners of holes are corners of the domain and thus are complete vertices.

The vector $\boldsymbol{b}$ is an eigenvector of the transpose A^T with eigenvalue 1, that is, $A^T \cdot \boldsymbol{b} = \boldsymbol{b}$. In fact, A^T (and thus A) has r eigenvalues of 1.

Interestingly, a matrix of a form similar to A arises in the context of power diagrams and Gale transforms [10]. Moreover, the polytope representation of pseudotriangulations, which we are going to describe in section 9, could alternatively be obtained using Gale transform techniques; cf. [15]. A systematic use of Gale transforms may shed additional light on the geometric properties of pseudotriangulations.

By applying allowable row operations to A, it can be shown that its inverse A^{-1} contains only nonnegative entries. This implies a monotonicity property which will be important later.

LEMMA 5.2. *The solution $\boldsymbol{z}$ of the system $A \cdot \boldsymbol{z} = \boldsymbol{b}$ is a monotone (linear) function of $\boldsymbol{b}$ and thus of the height vector $\boldsymbol{h}$.*

The Maxwell–Cremona theorem [20] asserts that, for a given planar straight-line graph G, there exists a (certain) projection surface if and only if G admits a so-called stress, i.e., an assignment of a real-valued tension to each edge of G such that all vertices of G are in equilibrium state. In this projection surface, the outer facet is required to be planar (unlike in the surface in Theorem 5.1). For *convex* augmented polygons (P, S), the Maxwell–Cremona theorem combines with Theorem 5.1, namely, when height zero is chosen for each (necessarily complete) boundary vertex of the convex polygon P. This gives the corollary below, which also follows from recent results in [41].

COROLLARY 5.3. *Let $\mathcal{PT}$ be a pseudotriangulation of a planar point set S. There exists a nontrivial stress for the edges of $\mathcal{PT}$, provided that $\mathcal{PT}$ is not minimum. More generally, the dimension of the space of stresses for $\mathcal{PT}$ equals the number of its complete internal vertices.*

We mention that Theorem 5.1 also implies a variant of Corollary 5.3 for arbitrary augmented polygons (P, S), asserting that every pseudotriangulation of (P, S) admits a nontrivial stress for the set $S \setminus vert(P)$ of *internal* vertices unless P is a pseudotriangle.

5.3. Projective pseudotriangulations. The surface $\mathcal{F}$ in Theorem 5.1 may fail to be strictly convex or reflex for some edges of $\mathcal{PT}$. In this case, $\mathcal{F}$ yields a proper subset of edges of $\mathcal{PT}$ in the projection. One reason for this is that the height vector $\boldsymbol{h}$ is degenerate. For instance, if $\boldsymbol{h} = 0$, then $\mathcal{F}$ contains a single facet that projects to the polygon P in the plane, regardless of the shape of $\mathcal{PT}$. On the other hand, pseudotriangles in double-adjacency give rise to a single pseudotriangular facet

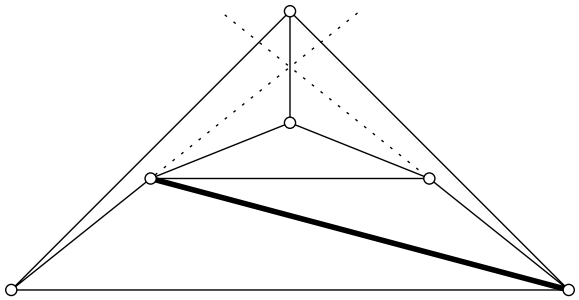

FIG. 5.1. *A stable though nonprojective pseudotriangulation.*

of $\mathcal{F}$ for every choice of $\boldsymbol{h}$.

Let us call a pseudotriangulation $\mathcal{PT}$ of (P, S) *stable* if no subset of incomplete vertices in $S \setminus vert(P)$ can be eliminated (along with their incident edges) such that both a valid pseudotriangulation $\mathcal{PT}'$ remains, and the status of each vertex of $\mathcal{PT}'$ is the same as in $\mathcal{PT}$. In particular, double-adjacencies are ruled out in a stable pseudotriangulation. Trivial stable instances are full triangulations, and pseudotriangulations of (P, S) for $S = vert(P)$. To see an example of a pseudotriangulation which is not stable, omit the three bold edges in Figure 7.3 (below) which do not belong to the internal triangle. Interestingly, no double-adjacencies occur in this example.

THEOREM 5.4. *A pseudotriangulation $\mathcal{PT}$ of (P, S) is projective only if $\mathcal{PT}$ is stable. If $\mathcal{PT}$ is stable, then the point set S can be perturbed (by some arbitrarily small ε) such that $\mathcal{PT}$ becomes projective.*

Proof. Assume first that $\mathcal{PT}$ is not stable. Eliminate some set of incomplete vertices from $S \setminus vert(P)$ such that a pseudotriangulation $\mathcal{PT}'$ of (P, S) is obtained where all vertices agree in status with their counterparts in $\mathcal{PT}$. Fix an arbitrary height vector $\boldsymbol{h}$ for S. By Theorem 5.1, there exist unique surfaces $\mathcal{F}$ for $\mathcal{PT}$ and $\mathcal{F}'$ for $\mathcal{PT}'$. Since only incomplete vertices have been eliminated, and the status of no remaining vertex has been changed, we have $\mathcal{F}' = \mathcal{F}$. Now let ∇ be a pseudotriangle of $\mathcal{PT}'$ but not of $\mathcal{PT}$. The restriction of $\mathcal{F}'$ to ∇ is a pseudotriangular facet. Because $\mathcal{F}' = \mathcal{F}$, the restriction of $\mathcal{F}$ to ∇ is planar, too. This implies that $\mathcal{PT}$ is not projective.

Now let $\mathcal{PT}$ be a stable pseudotriangulation. Let $\boldsymbol{h}$ be a height vector for S with pairwise different entries. Assume that the surface $\mathcal{F}$ for $\mathcal{PT}$ and $\boldsymbol{h}$ is planar at some edge uv. Let c and c' be the two corners opposite to uv in the two pseudotriangular facets of $\mathcal{F}$ adjacent at uv. By assumption, the vertex v lies in the plane through u, c, and c'. Suppose first that v is a complete vertex. As the heights of u, c, and c' also depend on vertices different from v, we can displace v by some arbitrarily small ε in an appropriate direction, such that $\mathcal{F}$ becomes nonplanar at uv. Now suppose that v is incomplete. Because $\mathcal{PT}$ is stable, the height of v does not depend on the same set of (three) vertices as do the heights of u, c, and c'. Otherwise, v could be eliminated (possibly jointly with other vertices) without changing $\mathcal{F}$, a contradiction to the assumed stability of $\mathcal{PT}$. So, again, v can be displaced to make $\mathcal{F}$ nonplanar at uv. This implies that S can be perturbed such that $\mathcal{PT}$ becomes projective. □

Figure 5.1 illustrates a stable pseudotriangulation which fails to be projective. Neither of the two incomplete vertices can be eliminated without changing the status of the upmost internal vertex from complete to incomplete. On the other hand, as the prolongations (shown dotted) of two edges meet at a third edge, the edge drawn

in bold flattens out in all possible surface realizations. Note that a slight movement of any single vertex restores the projectivity in this example.

By Theorem 5.4, we restrict our attention—in the remainder of this paper—to vertex sets where every stable pseudotriangulation is also projective. For such a vertex set S and a pseudotriangulation $\mathcal{PT}$ thereof, a height vector $\boldsymbol{h}$ is called *generic* if $\boldsymbol{h}$ witnesses the projectivity of $\mathcal{PT}$.

Remarks. Note the difference between the concepts of *stable* and *minimum* pseudotriangulation. In the latter, no single edge (but possibly some vertices) can be eliminated such that a valid pseudotriangulation remains. There is no obvious relation between stable and minimum pseudotriangulations, but the following can be observed. If $conv(S)$ is a triangle and S contains vertices internal to P, then no minimum pseudotriangulation $\mathcal{MPT}$ of (P, S) is stable. All internal vertices are incomplete, and their elimination leaves a valid pseudotriangle P without changing the status of any vertex of P. By Theorem 5.4, this implies that $\mathcal{MPT}$ is not projective.

6. Surface interpretation of flips. We next provide a surface interpretation for all the admissible flip operations in section 2. To this end, consider some projective pseudotriangulation $\mathcal{PT}$ of an augmented polygon (P, S). (Recall from subsection 5.3 that "projective" is equivalent to "stable," by our convention on the vertex set S.) Let $\mathcal{PT}'$ be the unique pseudotriangulation obtained from $\mathcal{PT}$ by applying a single admissible flip. Assign height vectors $\boldsymbol{h}$ and $\boldsymbol{h}'$ to $\mathcal{PT}$ and $\mathcal{PT}'$ such that $\boldsymbol{h}$ is generic for $\mathcal{PT}$ and coincides with $\boldsymbol{h}'$ for all vertices being complete in both structures. By Theorem 5.1, there exist two unique projection surfaces $\mathcal{F}$ and $\mathcal{F}'$ for $\mathcal{PT}$ and $\mathcal{PT}'$. We call the operation that transforms $\mathcal{F}$ into $\mathcal{F}'$ a *surface flip*.

In a combinatorial sense, surface flips cause local and constant-size changes. Geometrically, however, these operations are by no means local. A single flip may change the surface heights for many vertices, even "far away" from the region where the combinatorial change takes place. The change in height depends on the structure of the entire surface. Thus general surface flips are *context-sensitive* operations.

For expository reasons, we will first study surface flips in their *context-free* version in the next two subsections. The following notation will be used. Consider an exchanging or an edge-removing flip. ∇_1 and ∇_2 are the two adjacent pseudotriangles involved in the flip, and R denotes their union. We restrict the corresponding surface flip to R such that $\mathcal{PT}$ and $\mathcal{PT}'$ are the two (projective) pseudotriangulations of R before and after the flip, and $\mathcal{F}$ and $\mathcal{F}'$ are the corresponding unique surfaces. The operation that takes $\mathcal{F}$ into $\mathcal{F}'$ constitutes the context-free surface flip. We come back to its context-sensitive version in subsection 6.3.

6.1. Convexifying flips. Suppose the flip in question is an exchanging flip. The following combinatorial change is caused. The flip replaces the edge $e = \nabla_1 \cap \nabla_2$ by the edge e' that is the intersection of the two pseudotriangles that comprise $\mathcal{PT}'$. Note that ∇_1 and ∇_2 are in no double-adjacency, by our assumption that $\mathcal{PT}$ is projective. R has exactly four corners, which are the vertices v_i, complete in both $\mathcal{PT}$ and $\mathcal{PT}'$. Their heights have been fixed as $z_i = h_i$, in a noncoplanar manner. The noncorners of R are incomplete in both of $\mathcal{PT}$ and $\mathcal{PT}'$. If they change incidence to pseudotriangles during the flip, then the planarity conditions for their heights are affected. For such a vertex v_j the change is from $z_j = \gamma_j$ to $z_j = \gamma'_j$, where γ_j and γ'_j are convex combinations of the heights of the corners in the respective pseudotriangles.

To view the change geometrically, see Figure 6.1. Consider the two facets f_1 and f_2 of the surface $\mathcal{F}$ before the flip, and assume that $\mathcal{F}$ is reflex at edge e. Then exactly one corner of f_1 lies below the plane through f_2, and vice versa. As corners

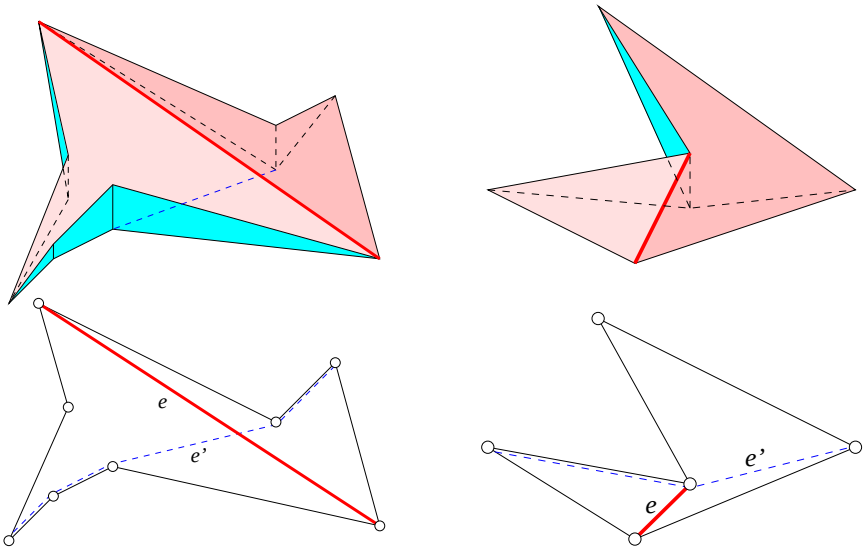

FIG. 6.1. *Two convexifying flips.*

do not change height in the flip, this implies that the obtained surface $\mathcal{F}'$ is convex at edge e'. We will therefore use the term *convexifying* flip. $\mathcal{F}$ and $\mathcal{F}'$ bound a polyhedron from above and below, respectively. This polyhedron is a tetrahedron if f_1 and f_2 are triangles, and the flip degenerates to the Lawson flip for triangulations. In this case, we will also talk of a *tetrahedral* flip—a special case well known from flipping in triangular surfaces; see, e.g., [38].

6.2. Planarizing flips. We discuss the edge-removing flip next. Combinatorially, the following change takes place. $\mathcal{PT}$ consists of two pseudotriangles ∇_1 and ∇_2 in single adjacency. The flip removes their common edge e and joins ∇_1 and ∇_2 to the pseudotriangle R, which thus represents $\mathcal{PT}'$. The three corners of R are complete in both $\mathcal{PT}$ and $\mathcal{PT}'$. Thus their heights are given explicitly. One vertex v_e incident to e changes its status from complete in $\mathcal{PT}$ to incomplete in $\mathcal{PT}'$. The condition for its height changes from $z_e = h_e$ to $z_e = \gamma'_e$, where γ'_e expresses coplanarity with the lifted corners of R. All other vertices v_j of R are incomplete in both $\mathcal{PT}$ and $\mathcal{PT}'$. Their height constraints change from $z_j = \gamma_j$ to $z_j = \gamma'_j$, where γ_j expresses coplanarity with the lifted corners of ∇_1 or ∇_2.

Geometrically, the surface $\mathcal{F}$ (which we assume to be reflex at edge e again) is flipped to $\mathcal{F}'$, as is depicted in Figure 6.2. $\mathcal{F}'$ is a single pseudotriangular facet and thus is planar. We call such a flip a *planarizing* flip. Again, $\mathcal{F}$ and $\mathcal{F}'$ bound a polyhedron from above and below, respectively.

6.3. Context-sensitive view. The context-free flips described in the previous two subsections leave the heights of the complete vertices of $\mathcal{PT}'$ unchanged. The incomplete vertices of $\mathcal{PT}'$ are lowered. Complete vertices may, however, be incomplete when being embedded in a larger pseudotriangulation. A surface flip—in its general context-sensitive form—may alter their heights as well. This alteration is uniquely described by the corresponding two linear systems. No alteration occurs in a convexifying flip that is tetrahedral, because the system remains unchanged.

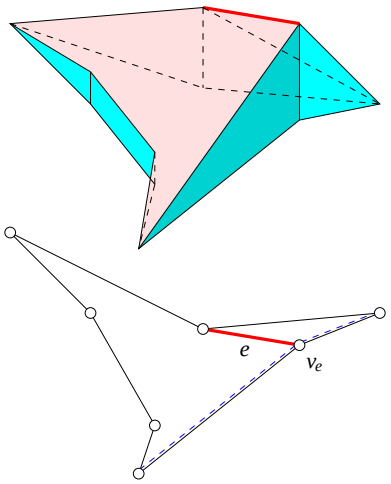

FIG. 6.2. *Planarizing flip.*

LEMMA 6.1. *Let $\mathcal{F}'$ be obtained from the surface $\mathcal{F}$ by applying a (context-sensitive) convexifying or planarizing surface flip φ. Then $\mathcal{F}'$ nowhere lies strictly above $\mathcal{F}$.*

Proof. We show that φ can be simulated by a sequence of flips, each lowering certain parts of the surface. Let (P, S) and $\mathcal{PT}$, respectively, be the augmented polygon and the pseudotriangulation in question. Thus $\mathcal{F}$ is the surface for $\mathcal{PT}$ before flipping. Consider the polygon $R \subseteq P$ to which the context-free version of φ is restricted, and denote this flip by φ_R.

Introduce new edges to $\mathcal{PT}$ such that a pseudotriangulation $\mathcal{PT}_1$ is obtained in which all corners of R are complete vertices. Assign heights as determined by $\mathcal{F}$ to the complete vertices of $\mathcal{PT}_1$. The surface that corresponds to $\mathcal{PT}_1$ and these heights is still $\mathcal{F}$. Now perform the flip φ_R and denote the obtained pseudotriangulation by $\mathcal{PT}_2$ and its surface by $\mathcal{F}_2$. This lowers the noncorners of R (which are incomplete in $\mathcal{PT}_2$) but leaves the heights of R's corners fixed. To see that no other incomplete vertex of $\mathcal{PT}_2$ can gain height, let us cut out the region R from P and consider it as a hole. The restrictions of $\mathcal{PT}_1$ and $\mathcal{PT}_2$, respectively, to $P \setminus R$ have the same set of complete vertices, which now includes all vertices of R. Let $\boldsymbol{h}_1$ and $\boldsymbol{h}_2$ be their height vectors in the linear systems for $\mathcal{F}$ and $\mathcal{F}_2$. We know that $\boldsymbol{h}_2 \leq \boldsymbol{h}_1$ (element-wise) because a subset of R's vertices has been lowered, which implies $\boldsymbol{z}_2 \leq \boldsymbol{z}_1$ by Lemma 5.2. We conclude that $\mathcal{F}_2$ nowhere lies strictly above $\mathcal{F}$.

Observe that pseudotriangles in $\mathcal{PT}_1$ may be incident to R only with their corners. Thus $\mathcal{F}_2$ may be reflex at edges of $\mathcal{PT}_1$ which are not in $\mathcal{PT}$. However, no reflex edge is changed to being convex. If all reflex edges of $\mathcal{F}_2$ have been present as reflex edges in $\mathcal{F}$ already, then the surface flip is complete. That is, $\varphi_R = \varphi$. Otherwise, appropriate context-free flips (convexifying or planarizing) are applied to the new reflex edges in $\mathcal{F}_2$, in the way described above and until all such edges disappear. Note that reflex edges flipped away earlier can reappear, so that the process may oscillate. It converges, though, because each reflex edge is flippable at all times, and there is an obvious lower bound on the heights, as certain vertices (the corners of P, for instance) never change height. This implies that the limit is the unique surface $\mathcal{F}'$ that $\mathcal{F}$ is flipped into by the context-sensitive surface flip φ. □

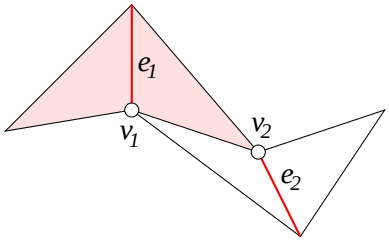

FIG. 6.3. *Oscillating flips.*

Figure 6.3 illustrates two oscillating flips. The edges e_1 and e_2 are both reflex at the beginning. They alternately disappear when context-free planarizing flips are applied. Their endpoints v_1 and v_2 are lowered alternately until the limit is reached, the pseudotriangulation that contains the shaded and the blank pseudotriangles.

6.4. Trivial flips. In a convexifying or a planarizing surface flip, a pseudotriangulation of (P, S) may be created which is not stable. This happens if a subset $B \in S \setminus vert(P)$ of incomplete vertices is generated, such that the removal of B leaves a valid pseudotriangle ∇ without changing the status of vertices. As a special case, a double-adjacency occurs. The obtained pseudotriangulation is not projective, by Theorem 5.4. In fact, the surface flip changes the part of the surface above ∇ to planar. That is, a *trivial* flip takes place implicitly, which eliminates from the surface the edges and vertices that stem from B.

In the pseudotriangulation of (P, S), the removal of B can be realized by a finite sequence of admissible flips (including vertex-removing flips, of course). This restores a projective pseudotriangulation. Surface flips that cause trivial flips are a natural generalization of the degree-3 vertex removal in triangular surfaces, where a single tetrahedron is split off; see, e.g., [38].

Remarks. Each (nontetrahedral) surface flip requires that a system of linear equations be solved; see subsection 5.2. The corresponding matrix has a special structure, however. The first $n-i$ rows are unit rows if i of the n vertices in the current pseudotriangulation are incomplete. Thus the system can be solved in $O(n+i^3)$ time, which covers the geometrical part of the surface flip. The combinatorial part obviously can be done within this complexity.

7. Locally convex functions. Let P be a polygon in the plane. A real-valued function f with domain P is called *locally convex* if f is convex on each line segment internal to P. For convex polygons P, every locally convex function is convex continuable on the exterior of P, but this is not true for arbitrary polygons in general.

Let (P, S) be an augmented polygon, and let $\boldsymbol{h}$ be a vector assigning some real value to each of the n vertices in S. We are interested in the following optimization problem.

Given (P, S) and $\boldsymbol{h}$, find the maximal locally convex function f^* on the domain P which fulfills $f^*(v_i) \leq h_i$ for each $v_i \in S$.

The function f^* is unique, because it is the pointwise maximum of all locally convex functions on P that satisfy the constraints given by $\boldsymbol{h}$. Moreover, f^* is piecewise linear, and nonlinearity occurs only at line segments spanned by the set S. We prove that the graph $\mathcal{F}^*$ of f^* projects to a pseudotriangulation of (P, S') for some $S' \subseteq S$. We further show that $\mathcal{F}^*$ can be constructed by a finite sequence of convexifying or planarizing surface flips.

If (P, S) is convex, then a well-known special case is obtained: $\mathcal{F}^*$ is the lower convex hull of the point set S when being lifted to the heights in $\boldsymbol{h}$. In this case, we succeed in generating the (convex) surface $\mathcal{F}^*$ with $O(n^2)$ surface flips of the kind above. The bound $O(n^2)$ can further be achieved when (P, S) is an arbitrary polygon without internal vertices. Both flip distance results are asymptotically optimal, by known lower bounds; see, e.g., [26].

7.1. Flipping to optimality. Consider some full triangulation $\mathcal{T}$ of the augmented polygon (P, S). All the n vertices of $\mathcal{T}$ are complete vertices, and we assign to $\mathcal{T}$ the height vector $\boldsymbol{h}$ used above to specify the maximal locally convex surface $\mathcal{F}^*$. This defines a unique triangular surface $\mathcal{F}(\mathcal{T}, \boldsymbol{h})$. We state another core result of this paper.

THEOREM 7.1 (optimality theorem). *Let $\mathcal{F}^*(\mathcal{T}, \boldsymbol{h})$ be a surface obtained from $\mathcal{F}(\mathcal{T}, \boldsymbol{h})$ by applying convexifying and planarizing surface flips (in any order) as long as reflex edges do exist. Then $\mathcal{F}^*(\mathcal{T}, \boldsymbol{h}) = \mathcal{F}^*$ for any choice of the initial triangulation $\mathcal{T}$. The optimum $\mathcal{F}^*$ is reached after a finite number of surface flips.*

Proof. By Lemma 6.1, convexifying and planarizing surface flips always generate a sequence of surfaces that is (strictly) totally ordered by decreasing height. As, by the uniqueness result in Theorem 5.1, these surfaces are pairwise different, so are the corresponding pseudotriangulations. An exponential upper bound on the sequence length results, because the number of possible planar straight-line graphs on the vertex set S is exponentially bounded in n; see [7]. The obtained surface $\mathcal{F}^*(\mathcal{T}, \boldsymbol{h})$ contains no reflex edge, as each such edge can be flipped at any time. This implies that $\mathcal{F}^*(\mathcal{T}, \boldsymbol{h})$ is locally convex. Moreover, $\mathcal{F}^*(\mathcal{T}, \boldsymbol{h})$ is maximal, because it fulfills $\boldsymbol{h}$ with equality for all complete vertices. Thus $\mathcal{F}^*(\mathcal{T}, \boldsymbol{h}) = \mathcal{F}^*$ follows from the uniqueness of $\mathcal{F}^*$. □

If the vector $\boldsymbol{h}$ constraining the vertex heights is generic, then all facets in the surfaces generated above are pseudotriangles. That is, only (projective) pseudotriangulations are generated. In particular, $\mathcal{F}^*$ projects to a pseudotriangulation.

$\mathcal{F}^*$ can be alternatively computed by solving a linear program with at most $\binom{n}{4}$ constraints. Each constraint stems from a quadrilateral $Q \subset P$ with vertices from S and postulates convex position for the vertex heights.

Theorem 3.4 implies the existence of a sequence of $O(n \log n)$ surface flips that transforms any given triangular surface $\mathcal{F}(\mathcal{T}, \boldsymbol{h})$ for (P, S) into $\mathcal{F}^*$. This sequence includes convexifying and planarizing flips and, in general, their inverses. Trivial flips may be implicated if vertices of $\mathcal{F}(\mathcal{T}, \boldsymbol{h})$ are missing in $\mathcal{F}^*$. The sequence contains no inverse trivial flips, however. This rules out the reinsertion of vertices and makes the bound substantial. Note that the sequence need not be *improving*, i.e., exclusively consisting of convexifying and planarizing (and trivial) surface flips such as in Theorem 7.1. We summarize in the following.

THEOREM 7.2. *Let (P, S) be an augmented polygon with $|S| = n$, and let $\boldsymbol{h}$ be a height vector for S. Let f^* be the unique maximal locally convex function on P that is bounded from above by $\boldsymbol{h}$.*

(1) *The graph $\mathcal{F}^*$ of f^* projects to a pseudotriangulation in the generic case.*

(2) *$\mathcal{F}^*$ can be constructed from any triangular surface $\mathcal{F}$ for (P, S) and $\boldsymbol{h}$, by applying any improving flip sequence of sufficient length.*

(3) *There exists a sequence of $O(n \log n)$ flips (excluding the inverse trivial type) which transforms $\mathcal{F}$ into $\mathcal{F}^*$ and can be computed in polynomial time if $\mathcal{F}^*$ is known.*

A principal problem, which complicates the construction of improving sequences of polynomial length (as in [26]), is that edges flipped away may reappear. Figure 7.1

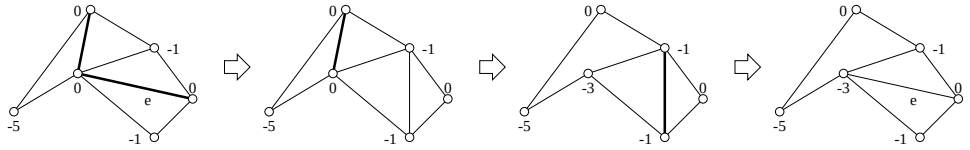

FIG. 7.1. *Edge e reappears.*

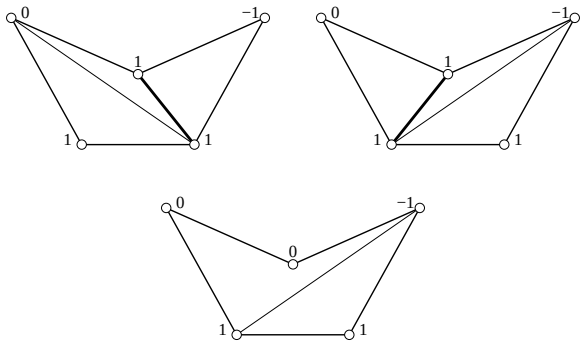

FIG. 7.2. *Local and global optima.*

illustrates this phenomenon. Numbers denote vertex heights, and reflex edges are shown in bold. Edge e is flipped first, and a planarizing flip for the other reflex edge follows. This makes the edge between the two remaining triangles reflex. Flipping this edge next lets e reappear, though as a convex edge. However, an appropriate flip in the neighborhood of e (not shown in the figure) makes e reflex again. Interestingly, a different improving sequence—that does not start with e—avoids this undesirable effect. We show in subsections 7.2 and 7.3 that the reappearance of edges can always be avoided for less general domains (P, S).

Remarks. Flipping to local convexity is not always possible *within* the class of triangulations. Different flip sequences may terminate at different triangular surfaces that contain reflex edges, as Figure 7.2 shows. (Numbers at vertices denote surface heights.) The initial surface contains two reflex edges, connecting vertices of height 1. Flipping either edge yields one of the two triangular surfaces shown in the upper part. Each contains only one reflex edge (shown in bold), which cannot be flipped away without destroying the triangulation. The global optimum $\mathcal{F}^*$ is a pseudotriangular surface, shown in the lower part.

7.2. Convex domains. Suppose that the underlying domain (P, S) is convex. Then $\mathcal{F}^*$ bounds from below the convex hull of a three-dimensional point set. Let us show that reappearance of edges does not take place if improving surface flips are performed in a carefully chosen order. In particular, the following holds.

LEMMA 7.3. *Let (P, S) be an augmented* convex *polygon, and let $\boldsymbol{h}$ be a height vector for S. Then $\mathcal{F}^*$ can be generated, from any given triangular surface for (P, S) and $\boldsymbol{h}$, by $O(n^2)$ improving surface flips, for $n = |S|$.*

Proof. To avoid the discussion of special cases, assume that $\boldsymbol{h}$ is generic. Let $\mathcal{F}$ be the current surface for (P, S), which is triangular at the beginning. For a vertex v of $\mathcal{F}$, denote with $I(v)$ the set of all vertices of $\mathcal{F}$ that share a facet with v. Note that $v \in I(v)$. Let $low(I(v))$ be the lower part of the boundary of $conv(I(v))$. We use the following algorithm to flip $\mathcal{F}$ into $\mathcal{F}^*$.

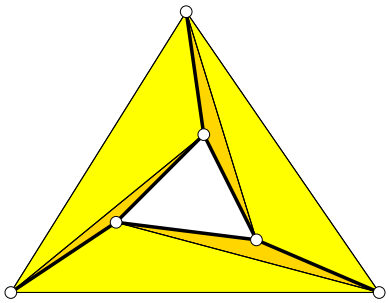

FIG. 7.3. *Local optimum for convex P; adapted from* [25].

Step 1. While there exists a vertex v of $\mathcal{F}$ that lies strictly above $low(I(v))$ do:

Case 1.1. Vertex v is complete. As v lies strictly above $low(I(v))$, there exist reflex edges incident to v. While v is complete, we flip away such edges, using convexifying and planarizing surface flips. We know, from Lemma 6.1, that $low(I(v))$ is lowered in this process, whereas v keeps its height. Thus there always exists some reflex edge incident to v, which can be flipped. Each flip decrements the degree of v. Note that pseudotriangular facets with many vertices may be created, but only if v is a corner there. Obviously, the last flip is planarizing. It either changes the status of v to incomplete, and we continue with Case 1.2, or it implicates a trivial flip that removes v (possibly together with some other vertices in v's neighborhood). In particular, v gets removed if its degree before the flip has been three.

Case 1.2. Vertex v is incomplete. Let f be the unique pseudotriangular facet of $\mathcal{F}$ where v is a noncorner. While v has more than two edges, we flip away reflex edges, according to the following rule. As v lies strictly above $low(I(v))$, either both edges of f incident to v are reflex, or another reflex edge is incident to v. In the latter case, we flip this edge. The former case needs more care. Consider the projections, e_1 and e_2, of these two reflex edges of f in the pseudotriangulation. Between them, there is another edge incident to the projection v' of v. Therefore, for at least one of e_1 and e_2, say e_1, the geodesic between the two corners opposite to e_1 (in the two pseudotriangles adjacent at e_1) does not run via v'. We select e_1 for the edge to be flipped. This flip creates no edge incident to v. Thus either the degree of v is decremented, or v is removed in a trivial flip.

Step 2. Now all vertices v of $\mathcal{F}$ lie on $low(I(v))$. The surface $\mathcal{F}$ therefore is triangular, and all vertices in the corresponding triangulation are complete. While $\mathcal{F}$ is not convex, we apply convexifying (in fact, tetrahedral) flips. No vertex heights change. This yields the convex and triangular surface $\mathcal{F}^*$.

The total number of flips in Cases 1.1 and 1.2 is bounded by $n-1$, the maximum possible degree of the vertex v. Step 1 runs through these cases at most $n-3$ times, because each time one internal vertex is removed. The number of flips needed in Step 2 is at most $\binom{n}{2}$, by well-known arguments [26]. □

Remarks. Even though P is convex such that $\mathcal{F}^*$ is triangular, only a local optimum may be reached when tetrahedral flips are applied exclusively. See Figure 7.3, which is taken from [25]. P has height zero, and the three vertices in $S \setminus vert(P)$ lie in some plane above P. No reflex edge (bold) can be flipped, and no single vertex can be removed, to obtain a valid triangulation. Planarizing (and trivial) flips are needed

to reach the optimum $\mathcal{F}^*$, which is a single triangle P.

It remains unclear whether the algorithm above can be modified to run efficiently for *nonconvex* augmented polygons (P, S). Step 1 may leave noncorners of P incomplete, such that Step 2 is not guaranteed to take $O(n^2)$ flips.

7.3. Vertex-empty domains. Improving flip sequences of (at most) quadratic length also exist for any polygonal domain (P, S) without internal vertices, that is, in the case $vert(P) = S$. Let Δ be an *ear* of the polygon P, that is, a triangle that can be cut off from P by some diagonal. It is well known that every triangulation of P contains at least two ears.

LEMMA 7.4. *Let Δ be an ear of P, and let $\boldsymbol{h}$ be a height vector for $vert(P)$. Denote with $\mathcal{F}^*$ and $\mathcal{F}^*(P \setminus \Delta)$, respectively, the optimal surfaces for P and $P \setminus \Delta$ with respect to $\boldsymbol{h}$. Then $\mathcal{F}^*(P \setminus \Delta)$ can be transformed into $\mathcal{F}^*$ by attaching the triangular facet for Δ and applying $O(n)$ improving flips.*

Proof. Consider the following sequence of flips. Imagine that a triangular facet f with the following properties is attached to $\mathcal{F}^*(P \setminus \Delta)$: The projection of f is Δ, and the corner c of f that does not belong to $\mathcal{F}^*(P \setminus \Delta)$ has some height h_c large enough to make the resulting surface convex at the respective diagonal d of P. This surface is optimum for P and the vector $\boldsymbol{h}$ with c's height replaced by h_c. Now, continuously lower h_c, and maintain the optimum surface by flips as below, until h_c attains the original value as given by $\boldsymbol{h}$ and the surface becomes $\mathcal{F}^*$.

If the diagonal d stays convex throughout, then no flips are performed. Otherwise, right after the surface becomes reflex at d, we flip d. This flip is either planarizing or convexifying. It does not change the convexity of any other edge, though, and thus restores optimality. To describe the generic step, let F_c be the part of the surface modified by flips so far. F_c is separated by diagonals $d_1, \ldots, d_k$ from its complement in the surface. Therefore, when decreasing h_c, all edges of the surface except possibly $d_1, \ldots, d_k$ stay convex. As soon as one of $d_1, \ldots, d_k$ becomes reflex, the next flip is performed. This restores optimality and extends F_c by one facet.

The number of flips is $O(n)$ because each flip extends F_c. It remains to be observed that exactly the same sequence of flips can be applied if the facet f is attached to $\mathcal{F}^*(P \setminus \Delta)$ with c's original height: Each diagonal d flipped above now becomes reflex as soon as d bounds the current locally convex part incident to c. Thus flipping d indeed constitutes an improving flip. ∎

We remark that each edge constructed above corresponds to an edge of the shortest-path tree $\pi_c(P)$ for P and c, defined in subsection 3.1.

LEMMA 7.5. *Let P be a simple polygon with n vertices, and let $\boldsymbol{h}$ be some height vector for $vert(P)$. The optimum $\mathcal{F}^*$ can be constructed by an improving flip sequence of length $O(n^2)$, from any given triangular surface for P and $\boldsymbol{h}$.*

Proof. We construct $\mathcal{F}^*$ by simulating an incremental algorithm. Let $\mathcal{T}$ be the triangulation to which the initial surface projects. Traverse the triangles of $\mathcal{T}$ in some adjacency order. Let Q be the union of the triangles visited so far. We maintain the following invariant for the current surface $\mathcal{F}$. The restriction of $\mathcal{F}$ to the polygon Q is optimum for Q (i.e., maximal and locally convex), and the restriction of $\mathcal{F}$ to $P \setminus Q$ coincides with the initial triangular surface.

The generic step processed a triangle Δ of $\mathcal{T}$ by constructing the optimum surface for the polygon $Q \cup \Delta$. As Δ is an ear of $Q \cup \Delta$, this takes $O(n)$ improving flips by Lemma 7.4. These flips leave the triangular surface for $P \setminus (Q \cup \Delta)$ unaffected, because all its vertices are complete. The number of steps (triangles) is $n - 3$. ∎

8. (Constrained) regular complexes. The concept of local convexity of polyhedral surfaces is closely related to the concept of constrained regularity of polygonal partitions. Let us elaborate on the consequences of the results in section 7 in terms of constrained regularity.

8.1. Regular triangulations. A triangulation $\mathcal{T}$ of a point set S is called *regular* if there exists some convex function on $conv(S)$ whose set of nonlinearity coincides with the set of internal edges of $\mathcal{T}$. Regular triangulations arise as duals of power diagrams [8] (a generalization of Voronoi diagrams) and have several applications [24, 23]. Figure 7.3 shows a well-known example of a nonregular triangulation.

We discuss the implications of section 7 for regular triangulations, that is, for the case $P = conv(S)$. For each height vector $\boldsymbol{h}$, the surface $\mathcal{F}^*$ is convex in this case and is the lower part, $low(S_{\boldsymbol{h}})$, of the boundary of the convex hull of the lifted point set $S_{\boldsymbol{h}}$. A unique regular triangulation $\mathcal{T}(S)_{\boldsymbol{h}}$ for S and $\boldsymbol{h}$ is obtained by projecting $low(S_{\boldsymbol{h}})$. Lemma 7.3 implies the following result.

THEOREM 8.1. *Let $\mathcal{T}$ and $\boldsymbol{h}$ be a given triangulation and a height vector, respectively, for a planar set S of n points. Then $\mathcal{T}$ can be flipped to the regular triangulation $\mathcal{T}(S)_{\boldsymbol{h}}$ using $O(n^2)$ flips, which are improving in the corresponding surfaces.*

Note that the *upper* part of the boundary of the convex hull of $S_{\boldsymbol{h}}$ can be obtained as well, by reflecting $S_{\boldsymbol{h}}$ at the plane $z = 0$ first. This yields another interesting result.

COROLLARY 8.2. *The convex hull of a three-dimensional n-point set M can be constructed by taking an arbitrary triangular surface for M and performing $O(n^2)$ improving surface flips.*

Observe that vertices of S may be absent in $\mathcal{T}(S)_{\boldsymbol{h}}$, namely, if some points of $S_{\boldsymbol{h}}$ lie strictly above $low(S_{\boldsymbol{h}})$. We call $\boldsymbol{h}$ a *convex* height vector (for S) if no point of $S_{\boldsymbol{h}}$ lies strictly above $low(S_{\boldsymbol{h}})$. If $\boldsymbol{h}$ is convex, then no (proper) pseudotriangle is ever created when flipping to regularity: Pseudotriangles stem from planarizing flips, which are never performed because the respective edges are convex already. Therefore all convexifying flips are tetrahedral flips, and all vertices show up in $\mathcal{T}(S)_{\boldsymbol{h}}$. In particular, if $S_{\boldsymbol{h}}$ happens to lie on a paraboloid with a vertical axis of rotation (say, $z = \boldsymbol{x}^2$), then $\mathcal{T}(S)_{\boldsymbol{h}}$ is the Delaunay triangulation $DT(S)$ of S; see, e.g., [26].

Remarks. It is well known that each triangulation of S can be transformed into $DT(S)$ by flips that are convexifying and tetrahedral in the respective surface (so-called Delaunay flips), but not every regular triangulation can be constructed in this way. Theorem 8.1 tells us that pseudotriangulations—rather than triangulations—are the right framework for flipping to regularity.

$O(n^2)$ convexifying flips always suffice for generating $DT(S)$. On the other hand, $\Omega(n^2)$ is a lower bound, even if S is in convex position; see, e.g., [26]. This implies that Theorem 8.1 is optimal in the worst case. Theorem 8.1 is a stronger version of a result in [25], which asserts that incremental insertion of points, and application of tetrahedral flips to the special triangular surface that arises from each insertion, is capable of generating the regular triangulation in $O(n^2)$ flips.

Recently, the quest for a *Delaunay pseudotriangulation* of a point set S has been formulated [47]. If "Delaunay" is interpreted as "convex at each edge of the projection surface," and if the *entire* class of pseudotriangulations for S is taken as the underlying setting (rather than some class of fixed edge rank), then our results imply that $\mathcal{T}(S)_{\boldsymbol{h}}$ (or $DT(S)$, respectively) is the solution. The Delaunay *minimum* pseudotriangulation does not exist in this setting unless S is in convex position: No minimum pseudotriangulation of S is regular if S contains some internal vertex v, because the incompleteness of v forces every surface to be nonconvex in the neighborhood of v.

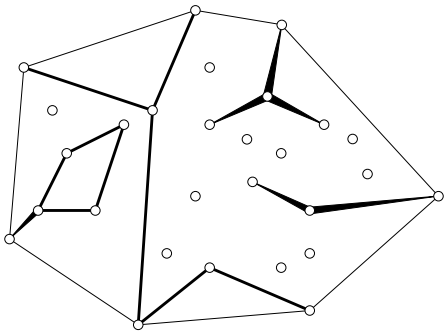

FIG. 8.1. *Cutting conv(S) along G.*

8.2. Constrained regular pseudotriangulations. Let us return to general augmented polygons (P, S). Here the maximal locally convex surface $\mathcal{F}^*$ is not convex continuable on the exterior of P in general. Thus $\mathcal{F}^*$ disagrees with the lower convex hull of the lifted point set $S_{\boldsymbol{h}}$ and contains pseudotriangular facets. The pseudotriangulation that $\mathcal{F}^*$ projects to always contains the edges of P. It can be interpreted as the regular pseudotriangulation for S *constrained* by P. Constrained triangulations, and especially, constrained *Delaunay* triangulations are well-known and versatile concepts; see, e.g., [40, 19, 4]. Very recently, constrained *regular* triangulations have been considered [13, 50]. This structure is not guaranteed to exist for general height vectors $\boldsymbol{h}$, however. We intend to show that our framework allows for a definition of constrained regular pseudotriangulations that always exist and are unique.

To exploit our concepts more generally, let G be a planar straight-line graph with vertex set S. Local convexity of a function f generalizes naturally, by requiring f to be convex on each line segment in $conv(S)$ that does not cross G. We call G *admissible* if, apart from the isolated vertices of G, each component of G is connected to the boundary of $conv(S)$. An admissible graph G defines a partition of $conv(S)$ as follows; see Figure 8.1. Cut $conv(S)$ along G, and move it apart at the cuts infinitesimally. This gives a collection of augmented polygons (Q_i, S_i) with $\bigcup_i S_i = S$.

Theorems 7.1 and 7.2 directly apply to this setting. Let $\mathcal{T}$ be a triangulation of S that includes all the edges of G. For a given height vector $\boldsymbol{h}$ for S, consider the unique triangular surface for $\mathcal{T}$ and $\boldsymbol{h}$. Let $\mathcal{F}_i$ denote the restriction of this surface to the polygon Q_i. Then $\mathcal{F}_i$ can be made locally convex by flipping away all reflex edges that do not belong to G. This gives a unique pseudotriangulation $\mathcal{PT}_i$ for each augmented polygon (Q_i, S_i). Altogether, a unique constrained regular pseudotriangulation $\mathcal{PT}(G)_{\boldsymbol{h}}$ for G and $\boldsymbol{h}$ is obtained.

The corresponding maximal locally convex function $f_{G,\boldsymbol{h}}$ on the domain $conv(S)$ is piecewise linear but, in general, not continuous. Its set of discontinuity is a subset of G and occurs at certain pseudotriangular faces of $\mathcal{PT}(G)_{\boldsymbol{h}}$, namely, where local convexity (with respect to G) and maximality (with respect to $\boldsymbol{h}$) contradict. The graph of $f_{G,\boldsymbol{h}}$ thus is no surface in our sense. We summarize as follows.

THEOREM 8.3. *Let S be a set of n points in the plane, and let G and $\boldsymbol{h}$, respectively, be an admissible straight-line graph and a height vector for S. There exists a unique constrained regular pseudotriangulation $\mathcal{PT}(G)_{\boldsymbol{h}}$ for G and $\boldsymbol{h}$. $\mathcal{PT}(G)_{\boldsymbol{h}}$ can be constructed by improving surface flips, starting from any triangulation of S that conforms with G. Moreover, the $O(n \log n)$ bound in Theorem 7.2 applies.*

Remarks. If G partitions $conv(S)$ into augmented *convex* polygons, then no incomplete vertices occur in $\mathcal{PT}(G)_{\boldsymbol{h}}$, which thus is a triangulation for every $\boldsymbol{h}$. The graph $F_{G,\boldsymbol{h}}$ of $f_{G,\boldsymbol{h}}$ then is a surface, namely, the continuous concatenation of lower convex hulls on top of these convex polygons.

There are other interesting instances of admissible constraining graphs G. For example, G may define a minimum pseudotriangulation $\mathcal{M}$ of S. In this case, $\mathcal{PT}(G)_{\boldsymbol{h}}$ gives ways of canonically refining $\mathcal{M}$. Alternatively, G may define a spanning tree of S, a choice used in [4] to transform crossing-free spanning trees into each other.

If the height vector $\boldsymbol{h}$ is convex, then all vertices of S show up in $\mathcal{PT}(G)_{\boldsymbol{h}}$. Moreover, only triangles are generated in the flipping process. $\mathcal{PT}(G)_{\boldsymbol{h}}$ is a triangulation, and $f_{G,\boldsymbol{h}}$ is continuous. The surface $F_{G,\boldsymbol{h}}$ is reflex only at edges of G, namely, at those that are absent in the regular triangulation $\mathcal{T}(S)_{\boldsymbol{h}}$. In the special case where the lifted point set $S_{\boldsymbol{h}}$ lies on the paraboloid $z = \boldsymbol{x}^2$, the constrained Delaunay triangulation [40] of S and G is obtained.

If the graph G is not admissible, then G splits $conv(S)$ into augmented polygons with possible holes. $\mathcal{PT}(G)_{\boldsymbol{h}}$ is still uniquely defined, because Theorem 5.1 generalizes to augmented polygons with holes in a straightforward way. However, the constrained regular complex $\mathcal{PT}(G)_{\boldsymbol{h}}$ fails to be a pseudotriangulation in general because pseudotriangular facets with holes may arise. It is worth mentioning that the polytope constructed in section 9 generalizes to representing arbitrary constrained regular complexes.

An attempt to define constrained regular complexes as full triangulations results in one of two phenomena: If convexity on all edges different from G is required, then the complex does not always exist; on the other hand, ambiguity occurs if reflex edges not belonging to G are admitted, even if they are all nonflippable (in the classical sense). Their structure depends on the flip sequence rather than on G and $\boldsymbol{h}$ alone. That is, several solutions (local optima) do exist in general. See Figure 7.2, where G delineates a nonconvex polygon.

9. Polytope representation. Let S be a set of n points in the plane. Let G denote an admissible straight-line graph on S, as defined in subsection 8.2. We establish the existence of a convex polytope that represents all the regular pseudotriangulations on S and constrained by G. This generalizes the polytope constructions in [39] (the associahedron) and in [28] (the secondary polytope, see also [15]), which concern the (unconstrained) regular triangulations of a point set S.

Let S' be a subset of S, which includes all the vertices of the (unique) connected component formed by G and the boundary of $conv(S)$. We consider the set $\Pi(G)$ of all pseudotriangulations $\mathcal{PT}$ that live on such subsets S' and conform with G. Clearly, for each height vector $\boldsymbol{h}$ for S, the constrained regular pseudotriangulation $\mathcal{PT}(G)_{\boldsymbol{h}}$ is a member of $\Pi(G)$.

We construct, for each $\mathcal{PT} \in \Pi(G)$ and each $\boldsymbol{h}$, a unique piecewise linear function $f_{\mathcal{PT},\boldsymbol{h}}$ on the domain $conv(S)$. Recall from subsection 8.2 that the admissible graph G defines a partition of $conv(S)$ into polygons Q_i. Let $\mathcal{PT}_i$ denote the part of $\mathcal{PT}$ inside Q_i. Then $\boldsymbol{h}$ assigns a height to each complete vertex of the pseudotriangulation $\mathcal{PT}_i$. Thus, by the surface theorem (Theorem 5.1), there exists a unique polyhedral surface $\mathcal{F}_i$ for $\mathcal{PT}_i$ and $\boldsymbol{h}$. The concatenation of the surfaces $\mathcal{F}_i$ is the graph of the function $f_{\mathcal{PT},\boldsymbol{h}}$ to be constructed. Note that $f_{\mathcal{PT},\boldsymbol{h}}$ is discontinuous in general.

Recall further that $f_{\mathcal{PT},\boldsymbol{h}}$ is locally convex with respect to G exactly if $\mathcal{PT} = \mathcal{PT}(G)_{\boldsymbol{h}}$. The optimality theorem (Theorem 7.1) thus implies $f_{\mathcal{PT},\boldsymbol{h}} \leq f_{\mathcal{PT}',\boldsymbol{h}}$ for all

$\mathcal{PT}' \in \Pi(G)$. Integrating both sides yields

$$\int_{x \in conv(S)} f_{\mathcal{PT},\boldsymbol{h}}(x)\, dx \leq \int_{x \in conv(S)} f_{\mathcal{PT}',\boldsymbol{h}}(x)\, dx. \tag{9.1}$$

Consider the left-hand-side integral in (9.1). The expressed volume is a linear (and homogenous) function of $\boldsymbol{h}$, because $f_{\mathcal{PT},\boldsymbol{h}}$ is piecewise linear and, by Lemma 5.2, the value of $f_{\mathcal{PT},\boldsymbol{h}}$ at each vertex of $\mathcal{PT}$ linearly depends on $\boldsymbol{h}$. Let $\boldsymbol{q}(\mathcal{PT})$ be the coefficient vector of this linear function. As analogous observations hold for the right-hand side in (9.1), we obtain

$$\boldsymbol{q}(\mathcal{PT}) \cdot \boldsymbol{h} \leq \boldsymbol{q}(\mathcal{PT}') \cdot \boldsymbol{h} \quad \text{for all } \mathcal{PT}' \in \Pi(G). \tag{9.2}$$

We now interpret $\boldsymbol{q}(\mathcal{PT})$ as a point in R^n and consider the convex polytope

$$\mathcal{Q}(G) = conv\{\boldsymbol{q}(\mathcal{PT}) \mid \mathcal{PT} \in \Pi(G)\}.$$

Further, we define the following set of height vectors:

$$\mathsf{V}(G, \mathcal{PT}) = \{\boldsymbol{h} \mid \mathcal{PT} = \mathcal{PT}(G)_{\boldsymbol{h}}\}.$$

Inequality (9.2) implies that, for each $\boldsymbol{h} \in \mathsf{V}(G, \mathcal{PT})$, the set $\{\boldsymbol{q}(\mathcal{PT}) \mid \mathcal{PT} \in \Pi(G)\}$ lies in a half-space whose boundary contains $\boldsymbol{q}(\mathcal{PT})$. Thus $\boldsymbol{q}(\mathcal{PT})$ is a vertex of the polytope $\mathcal{Q}(G)$ if and only if $\mathcal{PT} = \mathcal{PT}(G)_{\boldsymbol{h}}$ for some height vector $\boldsymbol{h}$. Note that $\boldsymbol{q}(\mathcal{PT})$ lies in the interior of $\mathcal{Q}(G)$ if $\mathcal{PT}$ is not constrained regular.

The collection of all sets $\mathsf{V}(G, \mathcal{PT})$, for $\mathcal{PT} \in \Pi(G)$, defines a cell complex $\mathcal{C}(G)$ in R^n because $\mathcal{PT}(G)_{\boldsymbol{h}}$ exists and is unique for each $\boldsymbol{h}$, by Theorem 8.3. $\mathsf{V}(G, \mathcal{PT})$ contains, for each member $\boldsymbol{h}$, the vector $\lambda \cdot \boldsymbol{h}$ for $\lambda \geq 0$. Moreover, $\boldsymbol{h}_1, \boldsymbol{h}_2 \in \mathsf{V}(G, \mathcal{PT})$ implies $\lambda \cdot \boldsymbol{h}_1 + (1-\lambda) \cdot \boldsymbol{h}_2 \in \mathsf{V}(G, \mathcal{PT})$ for $0 < \lambda < 1$. That is, $\mathsf{V}(G, \mathcal{PT})$ is a convex polyhedral cone with apex 0.

Consider a facet $g = \mathsf{V}(G, \mathcal{PT}_1) \cap \mathsf{V}(G, \mathcal{PT}_2)$ of the complex $\mathcal{C}(G)$. For $\boldsymbol{h} \in g$ we have $\boldsymbol{h} \cdot (q(\mathcal{PT}_1) - q(\mathcal{PT}_2)) = 0$ by inequality (9.2). Thus the line segment connecting $q(\mathcal{PT}_1)$ and $q(\mathcal{PT}_2)$ is normal to g. This implies that the edges of $\mathcal{Q}(G)$ are dual to the facets of $\mathcal{C}(G)$. For $\boldsymbol{h}$ lying in the relative interior of such a facet, there are exactly two constrained regular pseudotriangulations $\mathcal{PT}_1$ and $\mathcal{PT}_2$ that yield the same function $f_{\mathcal{PT}_1,\boldsymbol{h}} = f_{\mathcal{PT}_2,\boldsymbol{h}}$. Therefore, the graphs of $f_{\mathcal{PT}_1,\boldsymbol{h}_1}$ and $f_{\mathcal{PT}_2,\boldsymbol{h}_2}$, for $\boldsymbol{h}_1 \in \mathsf{V}(G, \mathcal{PT}_1)$ and $\boldsymbol{h}_2 \in \mathsf{V}(G, \mathcal{PT}_2)$, differ by a minimum combinatorial change, which corresponds to a flip that transforms $\mathcal{PT}_1$ and $\mathcal{PT}_2$ into each other. We conclude the following.

THEOREM 9.1. *Let S be a finite set of points in the plane, and let G be an admissible straight-line graph spanned by S. There exists a convex polytope $Q(G)$ for G, whose vertices are in one-to-one correspondence with the regular pseudotriangulations of S constrained by G. Moreover, the edges of this polytope correspond to flips as in section 2.*

Remarks. The existence of $\mathcal{Q}(G)$ implies that any two constrained regular pseudotriangulations $\mathcal{PT}(G)_{\boldsymbol{h}}, \mathcal{PT}(G)_{\boldsymbol{h}'} \in \Pi(G)$ are connected by a sequence of flips that retain constrained regularity. That is, there exists a sequence $\boldsymbol{h} = \boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_k = \boldsymbol{h}'$ of height vectors such that the functions $f_{G,\boldsymbol{h}_i}$ are all locally convex with respect to G. If G is chosen such that $f_{G,\boldsymbol{h}_i}$ is continuous (which, for instance, is the case if G defines a convex partition of $conv(S)$), then a tool for morphing locally convex surfaces is obtained. We raise the question for the maximal length k of the sequence above, that is, for the diameter of $\mathcal{Q}(G)$. The diameter obviously depends on both $n = |S|$ and G.

It is not hard to see that every pseudotriangulation of a simple polygon P (without internal vertices) is constrained regular. The corresponding polytope $\mathcal{Q}(P)$ therefore represents *all* possible pseudotriangulations of P. Moreover, any two pseudotriangulations of P can be transformed into each other with $O(n)$ flips; see subsection 3.1. We obtain the following result.

COROLLARY 9.2. *Let P be a simple polygon with n vertices. There exists a polytope $\mathcal{Q}(P)$ whose vertices and edges, respectively, represent all possible pseudotriangulations of P and the flips between them. The diameter of $\mathcal{Q}(P)$ is $O(n)$.*

Corollary 9.2 shows that, when generalizing from convex to nonconvex polygons, the diameter of the associahedron [39] remains linear.

Is there a polytope representation of all possible pseudotriangulations of an augmented polygon? One does exist for the subclass of all minimum pseudotriangulations of a point set S, by results in [47]. In view of our extended repertoire of flips, the general question arises naturally. We recently learned that an affirmative answer for the point set case has been given in [41], by generalizing the construction in [47]. Our results on flip distances in section 3 imply that the diameters of the polytopes in [47] and [41] are $O(n \log^2 n)$ and $O(n \log n)$, respectively. What is the relation of these polytopes to the polytopes in Theorem 9.1 and Corollary 9.2?

10. Conclusion. We have demonstrated that pseudotriangulations enjoy rich geometric and combinatorial properties, a new contribution to the theory of pseudotriangulations. Several key concepts for triangulations have been generalized to pseudotriangulations. A series of algorithmic implications have been described, which we believe to be of value in practical applications. The three main ingredients have been (1) the derivation of a new type of flip, (2) a proof of the realizability of pseudotriangulations as polyhedral surfaces, and (3) the establishment of a link to locally convex functions. For a better understanding of pseudotriangulations, several notions have been revitalized or introduced for the first time, like the edge rank, the completeness status of vertices, and the stability of pseudotriangulations. Let us conclude this paper with an extension of our results which seems most interesting to us.

The relationship between pseudotriangulations and locally convex functions, expressed in Theorem 7.2, opens a way to define pseudocomplexes in higher dimensions and flips therein. Also, the techniques used to prove the surface theorem (Theorem 5.1) do not depend on the underlying dimension. These tools may finally resolve the "3D pseudotriangulation mystery." We are exploring the consequences of this approach in a separate paper.

A SUBQUADRATIC SEQUENCE ALIGNMENT ALGORITHM FOR UNRESTRICTED SCORING MATRICES*

MAXIME CROCHEMORE†, GAD M. LANDAU‡, AND MICHAL ZIV-UKELSON§

Abstract. Given two strings of size n over a constant alphabet, the classical algorithm for computing the similarity between two sequences [D. Sankoff and J. B. Kruskal, eds., *Time Warps, String Edits, and Macromolecules*; Addison–Wesley, Reading, MA, 1983; T. F. Smith and M. S. Waterman, *J. Molec. Biol.*, 147 (1981), pp. 195–197] uses a dynamic programming matrix and compares the two strings in $O(n^2)$ time. We address the challenge of computing the similarity of two strings in subquadratic time for metrics which use a scoring matrix of unrestricted weights. Our algorithm applies to both *local* and *global* similarity computations. The speed-up is achieved by dividing the dynamic programming matrix into variable sized blocks, as induced by Lempel–Ziv parsing of both strings, and utilizing the inherent periodic nature of both strings. This leads to an $O(n^2/\log n)$, algorithm for an input of constant alphabet size. For most texts, the time complexity is actually $O(hn^2/\log n)$, where $h \leq 1$ is the entropy of the text. We also present an algorithm for comparing two *run-length* encoded strings of length m and n, compressed into m' and n' runs, respectively, in $O(m'n + n'm)$ complexity. This result extends to all distance or similarity scoring schemes that use an additive gap penalty.

1. Introduction.

Rapid progress in large-scale DNA sequencing has opened a new level of computational challenges in storing, organizing, and analyzing the wealth of resulting biological information. One of the most interesting new fields created by the availability of complete genomes is that of genome comparison. (The *genome* is all of the DNA sequence passed from one generation to the next.) Comparing complete genomes can give deep insights about the relationship between organisms, as well as shedding light on the function of specific genes in each single genome. The challenge of comparing complete genomes necessitates the creation of additional, more efficient computational tools.

One of the most common problems in biological comparative analysis is that of aligning two long bio-sequences in order to measure their similarity. The alignment is classically based on the transformation of one sequence into the other via operations

of substitutions, insertions, and deletions (indels). The costs of these transformations are given by a scoring matrix.

DEFINITION 1.1 (see Gusfield [25]). The global alignment problem. *Given a pairwise scoring matrix δ over the alphabet Σ, the similarity of two strings A and B is defined as the value* maxV *of the alignment of A and B that maximizes the total alignment value.*

- The score value $maxV$ is called the *optimal global alignment value* of A and B.
- A description of a $maxV$-scoring transformation of A into B is called a *global alignment trace*.

In many applications, two strings may not be highly similar in their entirety but may contain regions that are highly similar. The task is to find and extract a pair of regions, one from each of the two given strings, that exhibit high similarity. This is called the *local alignment* or *local similarity* and is defined formally below.

DEFINITION 1.2 (see Gusfield [25]). The local alignment problem. *Given two strings A and B, find substrings α and β of A and B, respectively, whose similarity (optimal global alignment value) is maximum over all pairs of substrings from A and B.*

- The score value $maxL$ of the most similar pair of substrings α and β is called the *optimal local alignment value*.
- The description of a $maxL$-scoring transformation of substring α into substring β is called a *local alignment trace*.

Given two strings of size n, both global and local similarity problems can be solved in $O(n^2)$ time by dynamic programming [25], [36], [50]. After the optimal similarity scores have been computed, both global alignment and local alignment traces can be reported in time linear with their size [10], [26], [28].

1.1. Results. In this paper data compression techniques are employed to speed up the alignment of two strings. The compression mechanism enables the algorithm to adapt to the data and to utilize its repetitions. The periodic nature of the sequence is quantified via its *entropy*, denoted by the real number h, $0 < h \leq 1$. Entropy is a measure of how "compressible" a sequence is (see [7], [13]), and is small when there is a lot of order (i.e, the sequence is repetitive and therefore more compressible) and large when there is a lot of disorder (see section 2.2).

Our results include the following algorithms.

1.1.1. Global alignment.

- We present an $O(n^2/\log n)$ algorithm for computing the optimal global alignment value of two strings, each of size n, over a constant alphabet (see section 3). The algorithm is even faster when the sequence is compressible. In fact, for most texts, the complexity of our algorithm is actually $O(hn^2/\log n)$.
- After the optimal score is computed, a single alignment trace corresponding to the optimal score can be recovered in time complexity that is linear with the size of the trace (see section 4).
- For global alignment over "discrete" scoring matrices, we explain how the space complexity can be reduced to $O(h^2n^2/(\log n)^2)$ without impairing the $O(hn^2/\log n)$ time complexity (see section 5).

1.1.2. Local alignment.

- We describe a subquadratic $O(hn^2/\log n)$ algorithm for the computation of the optimal local alignment value of two strings over a constant alphabet (see

section 6.1).
- Given an index on A where substring α ends and an index on B where substring β ends, an *optimal local alignment trace* can be reported in time linear with its size (see section 6.2).

1.1.3. Comparing two run-length encoded strings.
- We give an algorithm for comparing two *run-length* encoded strings of length m and n, compressed to m' and n' runs, respectively, using any distance or similarity scoring scheme with additive gaps, in $O(m'n + n'm)$ complexity (see section 7).

The algorithms described in this paper are the first to approach *fully LZ compressed* string alignment (both source and target strings are compressed). The methods given in this paper can also be used by applications where both input strings are stored or transmitted in the form of an $LZ78$ or LZW compressed sequence, thus providing an efficient solution to the problem of how to compare two strings without having to decompress them first.

Remark. For the sake of simplicity we assume, throughout the description of the global alignment and the local alignment solutions, that both input strings A and B are of the same size n, and that both sequences share the same entropy h. For the case of comparing string A of size m and entropy $0 < h_A \leq 1$ with string B of size n and entropy $0 < h_B \leq 1$, the results of subsections 1.1.1 and 1.1.2 are as follows:
- $O(mn(h_A/\log m + h_B/\log n))$ time and space complexity for both global alignment and local alignment replaces the $O(hn^2/\log n)$ result.
- $O(h_A h_B mn/\log m \log n)$ space complexity for global alignment over "discrete" scoring matrices replaces the $O(h^2n^2/(\log n)^2)$ result.

1.2. Previous results. The only previously known subquadratic global alignment string comparison algorithm, by Masek and Paterson [40], is based on the "Four Russians" paradigm. The Four Russians algorithm divides the dynamic programming table into uniform-sized ($\log n$ by $\log n$) blocks and uses table lookup to obtain an $O(n^2/\log n)$ time complexity string comparison algorithm, based on two assumptions. One assumption is that the sequence elements come from a constant alphabet. The other, which they denote the "discreteness" condition, is that the weights (of substitutions and indels) are all rational numbers.

Our algorithms present a new approach and are better than the above algorithm in two respects. First, the algorithms presented here are faster for compressible sequences. For such sequences, the complexity of our algorithms is $O(hn^2/\log n)$, where $h \leq 1$ is the entropy of the sequence.

Second, our algorithms are general enough to support scoring schemes with real number weights. For many scoring schemes, the rational number weights supported by Masek and Paterson's algorithm do not suffice. For example, the entries of PAM similarity matrices [25], as well as BLOSUM evolutionary distance matrices [25], are defined to be real numbers, computed as log-odds ratios, and therefore could be irrational.

The paper by Masek and Paterson concludes with the following statement: "The most important problem remaining is finding a better algorithm for the finite (in our terms constant) alphabet case without the discreteness condition." Here, more than twenty years later, this important open question will finally be answered!

The advantages of our approach are based on the following facts. First, our algorithm does not require any precomputation of lookup tables and therefore can afford more flexible weight values. Also, instead of dividing the dynamic programming

matrix into uniform-sized blocks as did Masek and Paterson, we employ a variable-sized block partition, as induced by Lempel–Ziv factorization of both source and target. The common denominator between blocks, maximized by the compression technique, is then recycled and used for computing the relevant information for each block, in time which is linear with the length of its sides. In this sense, the approach described in this paper can be viewed as another example of speeding up dynamic programming by keeping and computing only a relevant subset of important values, as demonstrated in [17], [18], [34], and [48]. A similar unbalanced strategy has been successfully used for square detection in strings [12] to speed up the original algorithm based on a divide-and-conquer approach [37].

2. Preliminaries.

2.1. The alignment graph. The dynamic programming solution to the string comparison computation problem can be represented in terms of a weighted alignment graph [25]; see Figure 2.1.

The weight of a given edge can be specified directly on the grid graph or, as is frequently the case in biological applications, is given by a scoring matrix, denoted δ, which specifies the substitution score for each pair of characters and the insertion/deletion scores for each character from the alphabet.

The two widely used classes of scoring schemes are distance scoring, in which the objective is to minimize the total alignment score, and similarity scoring, in which the objective is to maximize the total alignment score. Within these classes, scoring schemes are further characterized by the treatment of gap scores. A *gap* is the result of the deletion of one or more consecutive characters in one of the sequences. *Additive* gap scores assign a constant weight to each of the consecutive characters. For other gap functions which have been found useful for biological sequences, see [25]. The solutions in this paper assume a scoring scheme with additive gap scores.

Global alignment via dynamic programming. The classical dynamic programming algorithm for the global comparison of two strings will set the value at each vertex (i, j) of the alignment graph, row by row in a left to right order, to the score between the first i characters of A and the first j characters of B, using the following recurrence:

$$\begin{aligned} V(i,j) = max[&V(i,j-1) + \delta(\epsilon, B_j),\\ &V(i-1,j) + \delta(A_i, \epsilon),\\ &V(i-1,j-1) + \delta(A_i, B_j)]. \end{aligned}$$

Computing and setting the values of all vertices in the alignment graph, using the above recurrence, takes $O(n^2)$ time and space. After the values at each vertex of the alignment graph have been computed and set, the optimal global alignment value $maxV$ is found at vertex (n, n) of the graph.

If each vertex in the alignment graph stores the operation (insertion, deletion, substitution) selected when its value was set, then a global alignment trace, corresponding to an optimal path in the alignment graph, can be recovered in time linear with its size, starting from vertex (n, n), which contains the maximal score, and tracing the edges back up to vertex $(0, 0)$ in the graph.

Local alignment via dynamic programming. Smith and Waterman [50] (see also [25]) showed that essentially the same $O(|A||B|)$ dynamic programming solution can be used for computing local similarity, provided that the score of the alignment of two empty strings is defined as 0, and only pairs whose alignment scores are above 0 are of interest. The Smith–Waterman algorithm for computing local similarity computes

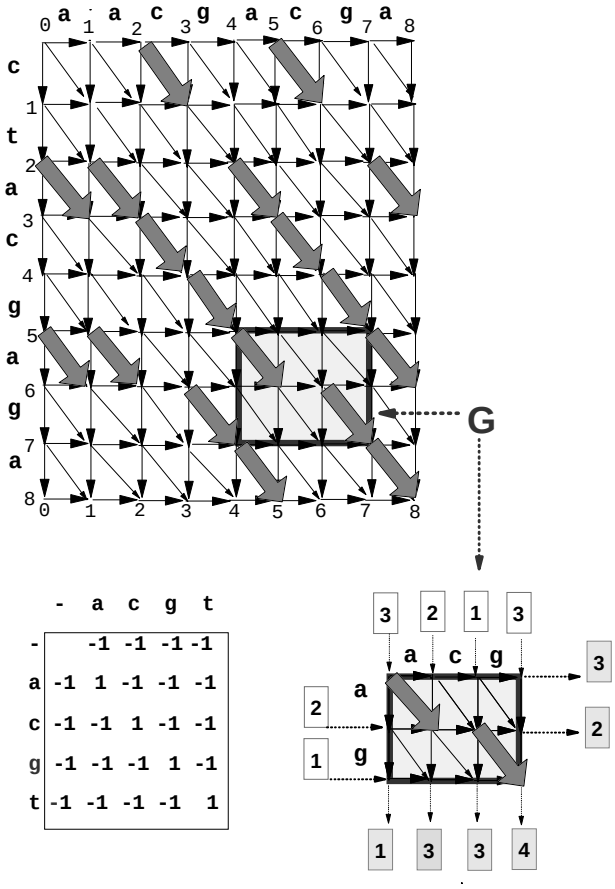

FIG. 2.1. *The alignment graph for comparing strings* A = "*ctacgaga*" *and* B = "*aacgacga*." *The scoring scheme matrix* δ *is shown in the lower left corner of the figure. The highest scoring global alignment paths originate in vertex* (0,0)*, end in vertex* (8,8)*, and have a total weight of* 3*. The highest scoring local alignment path has a total weight of* 5 *and corresponds to the alignment of substrings* a = *"acgaga" and* b = *"acgacga." A subgraph* G *corresponding to the block for comparing substrings* a = "*ag*" *and* b = "*acg*" *is shown in the lower-right corner of the figure. Also specified are the values* I *for the entries of the input border for* G *(in white-shaded rectangles), and the values* O *of the output border of* G *(in grey-shaded rectangles), as set during a local alignment computation.*

the following recurrence, which includes 0 as an additional option, and thus restricts the scores to nonnegative values:

$$\begin{aligned} L(i,j) = max[0, & L(i,j-1) + \delta(\epsilon, B_j), \\ & L(i-1,j) + \delta(A_i, \epsilon), \\ & L(i-1,j-1) + \delta(A_i, B_j)]. \end{aligned}$$

The method for computing the optimal local alignment value $maxL$ is to compute all alignment graph vertex values $L(i,j)$ in $O(n^2)$ time and space, and then find the largest value at *any* vertex on the table, say at vertex (i_{end}, j_{end}).

Given the vertex (i_{end}, j_{end}), which carries the score $maxL$, the corresponding substrings α and β giving the optimal local alignment of A and B are obtained in time

linear with their size, by using the stored operations (insertion, deletion, substitution) to trace back the edges from vertex (i_{end}, j_{end}) until a vertex (i_{start}, j_{start}) is reached that has value zero. Then the optimal local alignment substrings for vertex (i_{end}, j_{end}) are $\alpha = A[i_{start} \dots i_{end}]$ and $\beta = B[j_{start} \dots j_{end}]$ (see [25]).

2.2. A block partition of the alignment graph based on LZ78 factorization. The traditional aim of text compression is the efficient use of resources such as storage and bandwidth. Here, we will compress the sequences in order to speed up the alignment process. Note that this approach, denoted "acceleration by text compression," has been recently applied to a related problem—that of *exact string matching* [31], [39], [49].

It should also be mentioned that another related problem, that of exact string matching in compressed text without decoding it, which is often referred to as "compressed pattern matching," has been studied extensively [4], [19], [45]. Along these lines, string search in compressed text was developed for the compression paradigm of LZ78 [54] and its subsequent variant LZW [52], as described in [32], [46]. A more challenging problem is that of "fully compressed" pattern matching, when both the pattern and text strings are compressed [22], [23].

For the LZ78-LZW paradigm, compressed matching has been extended and generalized to *approximate pattern matching* (finding all occurrences of a short sequence within a long one, allowing up to k changes) in [30], [44].

The LZ compression methods are based on the idea of self–reference: while the text file is scanned, substrings or phrases are identified and stored in a dictionary, and whenever, later in the process, a phrase or concatenation of phrases is encountered again, this is compactly encoded by suitable pointers [35], [53], [54].

Of the several existing versions of the method, we will use those called the $LZ78$ family [52], [54]. The main feature which distinguishes $LZ78$ factorization from previous LZ compression algorithms is the choice of codewords. Instead of allowing pointers to reference any string that has appeared previously, the text seen so far is parsed into phrases, where each phrase is the longest matching phrase seen previously plus one character. For example, the string "S = aacgacg" is divided into fours phrases: a, ac, g, acg. Each phrase is encoded as an index to its prefix, plus the extra character. The new phrase is then added to the list of phrases that may be referenced.

Since each phrase is distinct from others, the following upper bound applies to the possible number of phrases obtained by $LZ78$ factorization.

THEOREM 2.1 (see Lempel and Ziv [35]). *Given a sequence S of size n over a constant alphabet, the maximal number of distinct phrases in S is $O(\frac{n}{\log n})$.*

Even though the upper bound above applies to any possible sequence over a constant alphabet, it has been shown that in many cases we can do better than that.

Intuitively, the $LZ78$ algorithm compresses the sequence because it is able to discover some repeated patterns. Therefore, in order to compute a tighter upper bound on the number of phrases obtained by $LZ78$ factorization for "compressible" sequences, the repetitive nature of the sequence needs to be quantified. One of the fundamental ideas in information theory is that of *entropy*, denoted by the real number h, $0 < h \leq 1$, which measures the amount of disorder or randomness, or inversely, the amount of order or redundancy in a sequence. Entropy is small when there is a lot of order (i.e, the sequence is repetitive) and large when there is a lot of disorder. The entropy of a sequence should ideally reflect the ratio between the size of the sequence after it has been compressed and the length of the uncompressed sequence.

The number of distinct phrases obtained by $LZ78$ factorization has been shown

to be $O(hn/\log n)$ for most texts [7], [13], [35], [51], [54]. Note that, for any text over a constant alphabet, the upper bound above still applies by setting h to 1.

3. Computing the optimal global similarity value.

3.1. Definitions and basic observations. The alignment graph will be partitioned as follows. Strings A and B will be parsed using $LZ78$ factorization. This induces a partition of the alignment graph, for comparing A with B, into variable-sized blocks (see Figure 3.1). Each block will correspond to a comparison of an LZ phrase of A with an LZ phrase of B.

Let xa denote a phrase in A obtained by extending a previous phrase x of A with character a, and yb denote a phrase in B obtained by extending a previous phrase of B with character b.

From now on we will focus on the computations necessary for a single block of the alignment graph.

Consider the block G which corresponds to the comparison of xa and yb. We define *input border* I as the left and top borders of G, and *output border* O as the bottom and right borders of G. (The node entries on the input border are numbered in a clockwise direction, and the node entries on the output border are numbered in a counterclockwise direction.)

Rather than filling in the values of each vertex in G, as does the classical dynamic programming algorithm, the only values computed for each block will be those on its I/O borders (see Figures 2.1 and 6.1A). Intuitively, this is the reason behind the efficiency gain.

Let ℓ_r denote the number of rows in G, $\ell_r = |xa|$. Let ℓ_c denote the number of

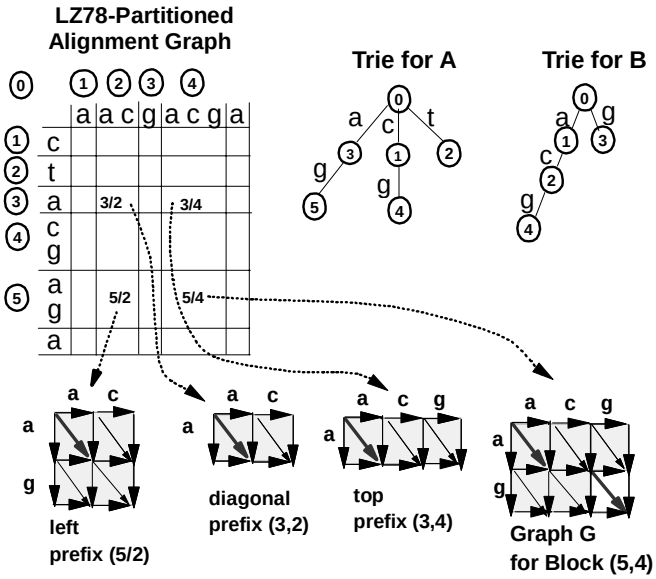

FIG. 3.1. *The block partition of the alignment graph, and the tries corresponding to* LZ78 *parsing of strings* A = "*ctacgaga*" *and* B = "*aacgacga*." *Note that for the block G in this example,* $\alpha =$ "*ag*," $\beta =$ "*acg*," $\ell_r = 2$, $\ell_c = 3$, $i = 5$, *and* $j = 4$. *(The new cell of* G, *which does not appear in any of the prefix blocks, is the rightmost cell at the bottom row of* G *and can be distinguished by its white color.) This figure continues Figure* 2.1.

columns in G, $\ell_c = |yb|$. Let $t = \ell_r + \ell_c$. Clearly, $|I| = |O| = t$.

We define the following three *prefix* blocks of G:

1. The *left prefix* of G denotes the block comparing phrase xa of A and phrase y of B.
2. The *diagonal prefix* of G denotes the block comparing phrase x of A and phrase y of B.
3. The *top prefix* of G denotes the block comparing phrase x of A and phrase yb of B.

Observation 1. When traversing the blocks of an $LZ78$ parsed alignment graph in a left-to-right, top-to-bottom order, the blocks for the left prefix, diagonal prefix, and top prefix of G are encountered prior to block G.

Note that the graph for the left prefix of G is identical to the subgraph of G containing all columns but the last one. More specifically, both the structure and the weights of edges of these two graphs are identical, but the weights to be assigned to vertices during the similarity computation may vary according to the input border values. Similarly, the graph for the top prefix block is identical in structure to a subgraph of G containing all rows but the last one, and the graph for the diagonal prefix block is similar in structure to the last subgraph of G which is obtained by removing both the last column and the last row of G. The only new cell in G, which does not appear in any of its prefix block graphs, is the cell for comparing a and b. This new cell consists of one new vertex and three new edges.

3.2. I/O propagation across G. The work for each block consists of two stages (a similar approach is shown in [8], [29], [34]):

1. *Encoding*: study the structure of G and represent it in an efficient way.
2. *Propagation*: given I and the encoding of G, constructed in the previous stage, compute O for G.

The structure of G is encoded by computing weights of optimal paths connecting each entry of its input border with each entry of its output border. The following $DIST$ matrix is used (see Figure 3.2).

DEFINITION 3.1. *$DIST[i, j]$ stores the weight of the optimal path from entry i of the input border of G to entry j of its output border.*

$DIST$ matrices have also been used in [5], [8], [29], [34], and [48].

Given input row I and the $DIST$ for G, the weight of output row vertex O_j can be computed as the maximum among the sums $I_r + DIST[r, j]$ if there is indeed a path connecting input border entry r with output border entry j.

Vertex O_j is the maximum of column j of the following OUT matrix, which merges the information from input row I and $DIST$. (See Figure 3.2.)

DEFINITION 3.2. $OUT[i, j] = I_i + DIST[i, j]$.

Aggarwal and Park [3] and Schmidt [48] observed that $DIST$ matrices are Monge arrays [43].

DEFINITION 3.3. *A matrix $M[0 \dots m, 0 \dots n]$ is* Monge *if either condition* 1 or 2 *below holds for all $a, b = 0 \dots m; c, d = 0 \dots n$:*

1. convex condition: $M[a, c] + M[b, d] \leq M[b, c] + M[a, d]$ *for all $a < b$ and $c < d$;*
2. concave condition: $M[a, c] + M[b, d] \geq M[b, c] + M[a, d]$ *for all $a < b$ and $c < d$.*

Since $DIST$ is Monge, so is OUT, which is a $DIST$ with constants added to its rows.

An important property of Monge arrays is that of being totally monotone.

***DIST* matrix**

$I_0 = 1$	0	−1	−2	−3	△	△
$I_1 = 2$	−1	−1	−2	−1	−3	△
$I_2 = 3$	−2	0	0	1	−1	−3
$I_3 = 2$	△	−2	−2	0	−2	−2
$I_4 = 1$	△	△	−2	0	−1	−1
$I_5 = 3$	△	△	△	−2	−1	0

FIG. 3.2. *The DIST matrix which corresponds to the subsequences "acg" and "ag"; the OUT matrix obtained by adding the values of* I *to the rows of DIST; and the* O *containing the row maxima of OUT. This figure continues Figures* 2.1 *and* 3.1.

DEFINITION 3.4. *A matrix* $M[0 \dots m, 0 \dots n]$ *is* totally monotone *if either condition* 1 *or* 2 *below holds for all* $a, b = 0 \dots m$; $c, d = 0 \dots n$:

1. convex condition: $M[a, c] \geq M[b, c] \Longrightarrow M[a, d] \geq M[b, d]$ *for all* $a < b$ *and* $c < d$;
2. concave condition: $M[a, c] \leq M[b, c] \Longrightarrow M[a, d] \leq M[b, d]$ *for all* $a < b$ *and* $c < d$.

Note that the Monge property implies total monotonicity, but the converse is not true. Therefore, both *DIST* and *OUT* are totally monotone by the concave condition.

Aggarwal et al. [2] gave a recursive algorithm, nicknamed *SMAWK* in the literature, which can compute in $O(n)$ time all row and column maxima of an $n \times n$ totally monotone matrix, by querying only $O(n)$ elements of the array. Hence, one can use *SMAWK* to compute the output row O by querying only $O(n)$ elements of *OUT*. Clearly, if both the full *DIST* and all entries of I are available, then computing an element of *OUT* is O(1) work.

For various solutions to related problems that also utilize Monge and total monotonicity properties, we refer the interested reader to [15], [16], [20], [21], [24], [33], [34], and [41]. In order to efficiently utilize these properties here, we need to address the following two problems:

1. How to efficiently compute *DIST* and represent it in a format which allows direct access to its entries. This will be done in section 3.4.
2. *SMAWK* is intended for a full, rectangular matrix. However, neither *DIST* nor its corresponding *OUT* is rectangular. Since paths in an alignment graph

can assume only a left-to-right, top-to-bottom direction, connections between some input border vertices and some output border vertices are impossible. Therefore, the matrices are missing both a lower-left triangle and upper-right triangle (see Figure 3.2). This problem is addressed in section 3.3.

3.3. Addressing the rectangle problem. The undefined entries of OUT can be complemented in constant time each, as follows:

(a) The missing upper-right triangle entries can be completed by setting the value of any entry $OUT\,[i,j]$ in this triangle to $-\infty$.

(b) Let k denote the maximal absolute value of a score in δ. The missing lower-left triangle entries can be completed by setting the value of any $OUT\,[i,j]$ in this triangle to $-(n+i+1)*k$.

LEMMA 3.5. *Complementing the undefined entries as described above preserves the concave total monotonicity condition of OUT and does not introduce new row-maxima.*

Proof. (a) *Upper right triangle.* All similarity scores in the alignment graph are finite. Therefore, no new column maxima are introduced. Suppose $OUT\,[a,c] \leq OUT\,[b,c]$, $a < b$, and $OUT\,[a,c]$ have been set to $-\infty$. Due to the shape of the redefined upper-right triangle, once a $-\infty$ value in row a is encountered, all future values in row a are also $-\infty$. The future values of row b could either be finite or $-\infty$. Therefore, $OUT\,[a,d] \leq OUT\,[b,d]$ for all $d > c$.

(b) *Lower left triangle.* The worst score appearing in the alignment graph is lower-bounded by $-nk$. Since i is always greater than or equal to zero, the complemented values in the lower-left triangle are upper-bounded by $-(n+1)*k$, and no new column maxima are introduced. Also, for any complemented entry $OUT\,[b,c]$ in the lower-left triangle, $OUT\,[b,c] < OUT\,[a,c]$ for all $a < b$, and therefore the concave total monotonicity condition holds. □

3.4. Incremental update of the new *DIST* information for *G*. In this section we show how to efficiently compute the new *DIST* information for G, using the *DIST* representations previously computed for its prefix blocks plus the information of its new cell.

When processing a new block G, we compute the scores of t new optimal paths, leading from the input border to the new vertex (ℓ_r, ℓ_c) in the new cell of G in its lowest, rightmost corner. These values correspond to column ℓ_c of the *DIST* matrix for G and can be computed as follows.

Entry $[i]$ in column ℓ_c of the *DIST* for G contains the weight of the optimal path from entry i in the input border of G to vertex (ℓ_r, ℓ_c). This path must go through one of the three vertices $(\ell_r - 1, \ell_c)$, $(\ell_r - 1, \ell_c - 1)$, or $(\ell_r, \ell_c - 1)$. Therefore, the weight of the optimal path from entry i in the input border of G to (ℓ_r, ℓ_c) is equal to the maximum among the following three values:

1. Entry $[i]$ of column $\ell_c - 1$ of the *DIST* for the left prefix of G, plus the weight of the horizontal edge leading into (ℓ_r, ℓ_c);
2. Entry $[i]$ of column $\ell_c - 1$ of the *DIST* for the diagonal prefix of G, plus the weight of the diagonal edge leading into (ℓ_r, ℓ_c);
3. Entry $[i]$ of column ℓ_c of the *DIST* for the top prefix of G, plus the weight of the vertical edge leading into (ℓ_r, ℓ_c).

3.4.1. Maintaining direct access to *DIST* columns. In order to compute an entry of OUT in constant time during the execution of *SMAWK*, direct access to *DIST* entries is necessary. This is not straightforward, since, as shown in the previous

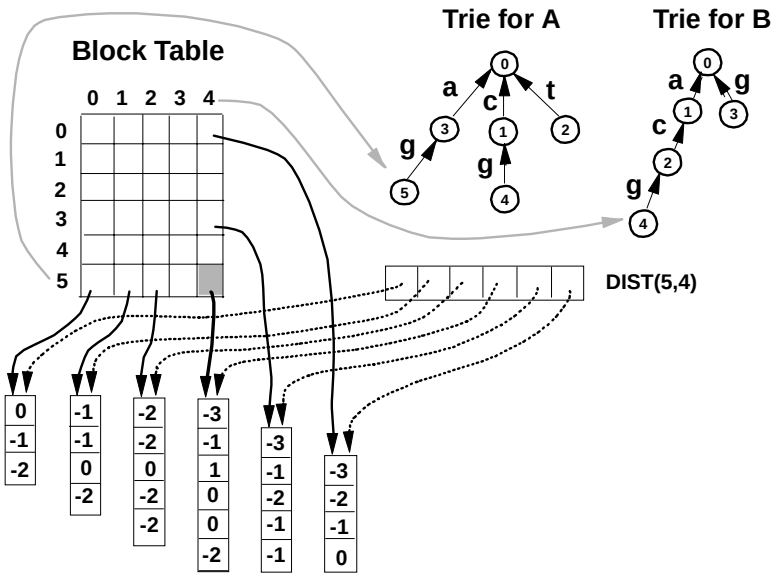

FIG. 3.3. *A table containing an entry for each block of the alignment graph. Entry* (i, j) *of the table represents the block which corresponds to node* i *in the trie for* A *and node* j *in the trie for* B*. The entry for each block in the table points to the start of its new DIST column. Also shown is the vector which contains pointers to all columns of the DIST for block* $(5, 4)$*, as obtained from its ancestor prefix blocks. This figure continues Figures* 2.1*,* 3.1*, and* 3.2*.*

section, for each block only one new *DIST* column has been computed and stored. All other columns besides column ℓ_c of the *DIST* for G need to be obtained from G's prefix ancestor blocks.

Therefore, before the execution of *SMAWK* begins, a vector with pointers to all $t + 1$ columns of the *DIST* for G is constructed (see Figure 3.3). This vector is no longer needed after the computations for G have been completed, and its space can be freed.

The pointers to all columns of the *DIST* for G are assembled as follows. Column ℓ_c is set to the newly constructed vector for G. All columns of indices smaller than ℓ_c are obtained via ℓ_c recursive calls to left prefix blocks of G. All columns of indices greater than ℓ_c are obtained via ℓ_r recursive calls to top prefix blocks of G.

3.4.2. Querying a prefix block and obtaining its *DIST* column in constant time. The *LZ*78 phrases form a trie (see Figure 3.1), and the string to be compressed is encoded as a sequence of names of prefixes of the trie. Each node in the trie contains the serial number of the phrase it represents. Since each block corresponds to a comparison of a phrase from A with a phrase from B, each block will be identified by a pair of numbers, composed of the serial numbers for its corresponding phrases in the tries for A and B.

Another data structure to be constructed is a block table (see Figure 3.3), containing an entry for each partitioned block of the alignment graph. The entry for each block in the table points to the start of its new *DIST* column and can be directly accessed via the block's phrase number index pair.

The left prefix of G can be identified in constant time as a pair of phrase numbers,

the first identical to the serial number of xa, and the second corresponding to the serial number of y, which is the direct ancestor of yb in the trie for B. Similarly, the top prefix of G can be identified in constant time. Given the pair of identification numbers for a block, a pointer to the corresponding *DIST* column can then be obtained directly from the block table.

Time and space analysis. Assuming sequence size n and sequence entropy $h \leq 1$, the $LZ78$ factorization algorithm parses the strings and constructs the tries for A and B in $O(n)$ time. The resulting number of phrases in both A and B is $O(hn/\log n)$. The number of resulting blocks in the alignment graph is equal to the number of phrases in A times number of phrases in B, and is therefore $O(h^2n^2/(\log n)^2)$. For each block G, the following information is computed, in time and space complexity linear with the size of its I/O borders:

1. *Updating the encoding structure for G.* The prefix blocks of G can be accessed in constant time. The vectors of *DIST* column pointers for the prefix blocks have already been freed. However, since each prefix block directly points to its newly computed *DIST* column, all values needed for the computations are still available. Since each entry of the new *DIST* column for G is set to the maximum among up to three sums of pairs, the new *DIST* column for G can be constructed in $O(t)$ time and space.
2. *Maintaining direct access to DIST columns.* Since *prefix* blocks and their *DIST* columns can be accessed in constant time, the vector with pointers to columns of the *DIST* for G can be set in $O(t)$ time.
3. *Propagating I/O values across the block.* Using the information computed for G, and given the I for G obtained from the O vectors for the block above G and the block to its left, the values of O for G are computed via *SMAWK* matrix searching in $O(t)$ time.

Total complexity. Since the work and space for each block is linear with the size of its I/O borders, the total time and space complexity is linear with the total size of the borders of the blocks. The block borders form $O(hn/\log n)$ rows of size $|B|$ each and $O(hn/\log n)$ columns of size $|A|$ each in the alignment graph (see Figure 3.1). Therefore, the total time and space complexity is $O(hn^2/\log n)$.

4. Global similarity optimal alignment trace recovery. The recovery of an optimal global alignment trace between A and B starts at vertex (n, n). The series of block crossing paths is then traced back until vertex $(0, 0)$ is reached. For each block crossed, the internal alignment trace is reported, starting from the output border sink and back to the optimal origin source vertex in the corresponding input border. In order to support the recovery of block-crossing paths in time linear with their size, the computation and storage of the following additional information for a given block G is required:

1. During the propagation stage, for each entry j in the output border of G, the index of the input border entry i, which is the source of the highest scoring path to output border entry j, is saved.
2. During encoding, an additional $O(t)$-sized vector of pointers, the *ancestors* vector, is computed for G. For any output border entry $O[j = 0 \dots t]$, *ancestors*$[j]$ points to the ancestor block of G for which this entry is the new vertex in its new cell. (The value of *ancestors*$[\ell_c]$ is set to G. All columns of indices smaller than ℓ_c are obtained via ℓ_c recursive calls to left prefix blocks of G. All columns of indices greater than ℓ_c are obtained via ℓ_r recursive calls to top prefix blocks of G.)

3. During encoding, G's new vertex (ℓ_r, ℓ_c) is annotated with an additional $O(t)$-sized vector of pointers, denoted *direction*. These pointers are set during the *DIST* column computation described in section 3.4, as follows. The value of *direction*$[i]$ is set according to the direction of the last edge in the optimal path originating at entry i of G's input border and ending at vertex (ℓ_r, ℓ_c).

Given that the optimal path enters through entry j of the output border of G, the trace-back of the part of the path going through G proceeds in two stages. The first stage is a destination and origin initialization stage. This stage includes the fetching of the input row source entry i, which was stored as the origin for the highest scoring path to G's output border entry j (see 1 above). Entry i serves as the destination for the alignment trace-back. In addition, the ancestor prefix block P of G, pointed to by *ancestors*$[j]$ is fetched (see 2 above). The edge recovery begins in block P.

During the second stage, the origin and destination information computed in the first stage is used to trace back the part of the path contained in P, from entry j on P's output border (the new vertex of P) to entry i on its input border. This is done by backtracking through a dynasty of prefix ancestor blocks internal to P, using the *direction* vector computed for each of the traversed blocks (see 3 above). If *direction*$[i]$ of the traversed block specifies a horizontal edge, then the trace-back retreats to the left prefix of P, and an "insertion" operation is reported in the alignment trace. Correspondingly, "substitution" and "deletion" are reported when backtracking to diagonal and top prefix blocks. The recovery continues through a series of prefix blocks of P until the full optimal alignment trace is recovered.

Time and space analysis. The two additional vectors for G, *direction* and *ancestors*, and the input border source entry i, can be computed and stored during the encoding and propagation stages in $O(t)$ time and space.

The work for the first stage in the trace-back can be done in constant time. In the second stage, each edge in the recovered alignment path results in a traversal to a single prefix block. Since prefix blocks and their corresponding direction vectors can be accessed in constant time, a highest scoring global alignment between strings A and B can be recovered in additional time linear in its size, using the $O(hn^2/\log n)$ storage which was allocated during the encoding and propagation stages.

5. Reducing the space complexity. When computing the optimal global alignment value with scoring matrices which follow the "discreteness" condition (see section 1), the *efficient alignment stage algorithm* described in [34] can be extended to support full propagation from the leftmost and upper boundaries to the bottom and rightmost boundaries of G.

This extended propagation algorithm can then be used to compute the values of the global alignment O for G, given the I for G and a minimal encoding of the *DIST* for G. The advantage of this minimal encoding of *DIST* is that, rather than saving an $O(t)$ sized *DIST* column per block, we need to save only a constant number of values per block. The encoding for the new *DIST* column of each block can be computed and stored in constant time and space from the information stored for the left, diagonal, and top prefix blocks of G, using the technique described in section 6 of [48]. This reduces the space complexity to $O(h^2n^2/(\log n)^2)$ while preserving the $O(hn^2/\log n)$ time complexity.

6. The local alignment algorithm.

6.1. Computing the optimal local similarity value. When computing the optimal local similarity value, an optimal path could either be contained entirely in

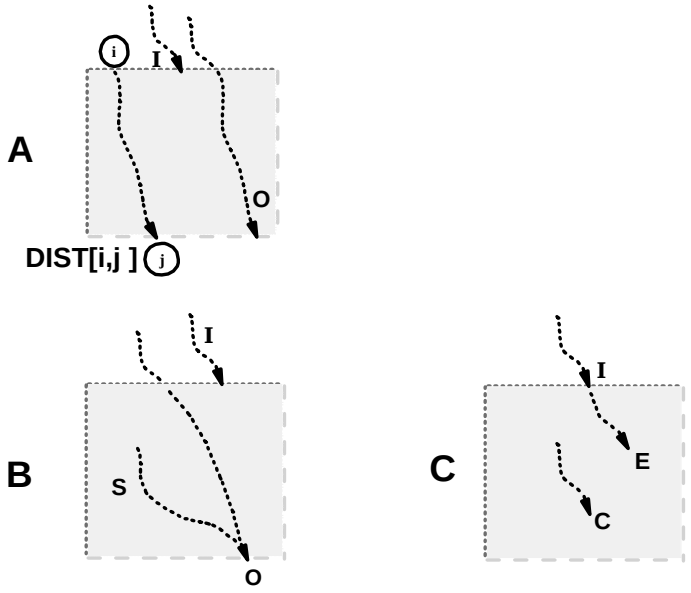

FIG. 6.1. A. *The I/O path weight vectors computed for each block in the global alignment solution. DIST $[i, j]$ will be set to the highest scoring path connecting vertex i in the input border with vertex j in the output border.* B,C. *The vectors of optimal path weights considered for the local alignment computation.*

one block (type C) or be a block-crossing path (see Figure 6.1). A block-crossing path consists of a (possibly empty) S-path, followed by any number of paths leading from the input border of a block to its output border, and ending in an E-path with a highest scoring last vertex. Since an optimal path could begin inside any block, vector O needs to be updated to consider the additional paths originating inside G. Also, since an optimal path could end inside any block, extra bookkeeping is needed in order to keep track of the highest scoring paths ending in each block.

Therefore, in addition to the *DIST* described in section 3, we compute for each block G the following data structures (see Figures 6.1B and 6.1C):

1. E is a vector of size t. $E[i]$ contains the value of the highest scoring path which starts at vertex i of the input border of G and ends inside G. $E[i]$ is computed as the maximum between $E[i]$ for the left prefix of G, $E[i]$ for the top prefix of G, and $DIST\,[i, \ell_c]$.
2. S is a vector of size t. $S[i]$ contains the value of the highest scoring path which starts inside G and ends at vertex i of the output border of G.
   The only new values computed for S are the local alignment scores for the new vertex of G, $S[\ell_c]$. Given the scores $S[\ell_c - 1]$ obtained from the *diagonal prefix*, $S[\ell_c - 1]$ obtained from the *left prefix*, and $S[\ell_c]$ obtained from the *top prefix* of G, as well as the weights of the three edges leading into vertex (ℓ_r, ℓ_c), $S[\ell_c]$ can be computed in $O(1)$ time complexity using the recursion given in section 2.1.
   The values of all other entries of S are then set as follows. The first ℓ_c values of S are copied from the first ℓ_c values of the S computed for the left prefix of G. The last ℓ_r values are copied from the last ℓ_r values of the S vector for the top prefix of G.

3. C is the value of the highest scoring path contained in G, that is, the highest scoring path which originates inside G and ends inside G. C is computed as the maximum between the C value for the left prefix of G, the C value for the top prefix of G, and the newly computed $S[\ell_c]$ as described above.

The S vector computed for G is used to update the values of the output border O, while E and C will be used to compute the weight of the highest scoring path ending in G.

Vector O is first computed from the I and $DIST$ for G as described in section 3.2. At this point, entry $O[i]$ reflects the weight of the optimal path starting anywhere outside G and ending at entry i of the output border. It needs to be updated with the weights of the highest scoring paths starting inside G. This is achieved by resetting $O[i]$ to the maximum between $O[i]$ and $S[i]$.

The weight of the highest scoring path ending in G is computed as $max(Max_{i=0}^{t}\{I[i]+E[i]\},\ C)$.

After the computations for each block have been completed, the overall highest local alignment score for comparing A and B can be computed as the maximum among the values of the highest scoring path ending in each block.

Time and space analysis. Since, as shown in section 3.4.1, each prefix block of G can be accessed in constant time, the values of the S and E vectors for G can be computed and stored in $O(t)$ time and space, and the C value for G can be computed in constant time and space.

Given the S, E, and C vectors for G, the values of O and the weight of the highest scoring path ending in G can be computed in $O(t)$ time each as described above.

The weight of the highest scoring path in the alignment graph can then be computed in an additional $O(h^2n^2/(\log n)^2)$ time as the maximum value among the best values computed for each block.

Since the work and space for each block is linear with the size of its I/O borders, the total time and space complexity of computing the optimal local alignment value is $O(hn^2/\log n)$.

6.2. Optimal alignment trace recovery for the local alignment solution. Similarly to the alignment trace defined in section 4, given a $maxL$ vertex (i_{end}, j_{end}) which was obtained in the previous section, we show how to recover the optimal path ending in this vertex by reporting a trace-back of the edges from vertex (i_{end}, j_{end}) until a start-point vertex (i_{start}, j_{start}) is reached that has value zero.

A block-crossing optimal path consists of a (possibly empty) S-path, followed by any number of paths leading from the input border of a block to its output border and ending in an E-path whose last vertex is (i_{end}, j_{end}).

The recovery starts at vertex (i_{end}, j_{end}) and continues back to the optimal path origin in three stages, as follows:

1. *Recovering the E-path part.* During encoding, whenever the $E[i]$ value of a block is updated by its new vertex, a pointer to the updating block is saved together with the new $E[i]$ value.
   During alignment recovery, given that vertex (i_{end}, j_{end}) ends an $E[i]$ path in G, the corresponding block can be fetched and the path from its new vertex to entry i on its input border recovered, as described in section 4.
2. *Recovering all paths leading from the input border of a block to its output border.* The part of the path contained in each one of these blocks can be recovered as described in section 4.
3. *Recovering the S-path part.* During encoding, when computing the S-score of

the new vertex of each block, the direction of the edge optimizing the score $S[\ell_c]$ of the new vertex of G, denoted $s_{direction}$, is saved with the score.
During the termination of the propagation stage, when setting the score values for each entry in O, a field is set, indicating whether the newly set score value for this entry corresponds to a path originating inside G (an S-path) or a path crossing G. If the score corresponds to an S-path, the recovery of the S-path part utilizes the technique described in section 4, with a slight modification. Instead of the *direction* vector, the $s_{direction}$ field is used for the edge traceback. The recovery halts when an ancestor block is reached whose $S[\ell_c]$ value is zero.

A special case occurs when vertex (i_{end}, j_{end}) is the end point of a C-path. A C-path is, in essence, a halted S-path. During encoding, whenever the C value of a block is updated by its new vertex, a pointer to the updating block is saved together with the new C value. The recovery of the C path in G starts at the new vertex of its corresponding block and continues similarly to the S-path recovery, as described in 3 above.

Time and space analysis. In addition to the values described in section 4, an additional $O(t)$ information (pointers to the $E[i]$ updating blocks) is computed and stored for E-paths, and an additional $O(1)$ information per block is computed and stored for C and S paths. During propagation termination, an additional $O(t)$ information is stored with the O vector.

During recovery, each edge in the recovered alignment path results in a traversal to a single prefix block, for each of the three path parts. Both prefix blocks and their corresponding direction vectors can be accessed in constant time. Therefore, in addition to the basic $O(hn^2/\log n)$ time and space needed for computing the optimal local alignment score $maxL$, an alignment trace ending at a given $maxL$-scoring vertex can be reported in time linear with the size of the trace.

7. Applications to the problem of comparing two run-length encoded strings. A string S is *run-length encoded* if it is described as an ordered sequence of pairs (σ, i), often denoted "σ^i," each consisting of an alphabet symbol σ and an integer i. Each pair corresponds to a *run* in S, consisting of i consecutive occurrences of σ. For example, the string *aabbbbbccc* can be encoded as $a^2b^5c^3$. Such a run-length encoded string can be significantly shorter than the expanded string representation after efficiently encoding the integers (see [14], for example).

Run-length encoding serves as a popular image compression technique, since many classes of images (e.g., binary images in facsimile transmission or for use in optical character recognition) typically contain large patches of identically valued pixels.

Let m and n be the lengths of two run-length encoded strings X and Y, of encoded lengths m' and n', respectively. Previous algorithms for the problem compared two run-length encoded strings using the Levenshtein edit distance [36] and the LCS similarity measure [26]. For the LCS metric, Bunke and Csirik [9] presented an $O(mn' + nm')$ time algorithm, while Apostolico, Landau, and Skiena [6] described an $O(m'n' \log(m'n'))$ time algorithm. Mitchell [42] has obtained an $O((d + m' + n') \log(d + m' + n'))$ time algorithm for a more general string matching problem in run-length encoded strings, where d is the number of matches of compressed characters. Both Arbell, Landau, and Mitchell [1] and Mäkinen, Navarro, and Ukkonen [38] independently obtained an $O(m'n + n'm)$ time algorithm for computing the edit distance between two run-length encoded strings for the Levenshtein distance metric.

Mäkinen, Navarro, and Ukkonen [38] posed as an open problem the challenge of

extending these results to more general scoring schemes, since in those applications which are related to image compression, the change from a pixel value to the next is smooth. Here, we will show how to extend the results to apply them to any distance or similarity scoring scheme with additive gap scores.

In this solution, the alignment graph is also partitioned into blocks. But rather than using the $LZ78$ partition described in section 3.1, each block here consists of two runs—one of X and one of Y. This results in the partition of the alignment graph into $m'n'$ blocks. The algorithm suggested also propagates accumulated scores from the left and upper boundaries of each block to its bottom and right boundaries.

Consider the block R for comparing the run α^i of X with the run β^j of Y. An edge in R could be assigned one of three possible weight values: D(diagonal), H(horizontal), or V(vertical).

Let Δ_h and Δ_w denote the difference in row index values and column index values, respectively, between entry i on the input border of R and entry j on the output border of R.

We show how to compute $DIST\,[i,j]$ (which is the cost of the best scoring path from entry i in the input border of the block to entry j in the output border of the block) in constant time, given Δ_h and Δ_w for the input and output entries, and the values D, H, and V.

- $H + V \leq D$. Clearly, an optimal path from i to j can use all possible diagonal edges and only then the minimal number of remaining H and V edges necessary to reach j.
  Therefore, $DIST\,[i,j]$ obtains one of three values:
  1. If $\Delta_w = \Delta_h$, then $DIST\,[i,j] = D \times \Delta_h$.
  2. If $\Delta_w > \Delta_h$, then $DIST\,[i,j] = D \times \Delta_h + H \times (\Delta_w - \Delta_h)$.
  3. If $\Delta_w < \Delta_h$, then $DIST\,[i,j] = D \times \Delta_w + V \times (\Delta_h - \Delta_w)$.
- $H + V > D$. In this case, an optimal path never uses any diagonal edge. The path includes only the minimal number of H edges, and the minimal number of V edges necessary to reach j from i. In this case, $DIST\,[i,j] = H \times \Delta_w + V \times \Delta_h$.

Therefore, $DIST\,[i,j]$ can be easily computed in constant time when using the general scoring scheme described in section 2.1.

Time and space analysis. The O vector for each block is computed using *SMAWK*. Vector I for block R can easily be obtained from the O vectors for the block above R and the block to its left, in time linear with the sides of R. The "rectangle" problem can be solved as in section 3.2. Therefore, any value $OUT\,[i,j] = I[i] + DIST\,[i,j]$ can be computed in constant time.

Since the work for each block is linear with the size of its I/O borders, the total time complexity is linear with the total size of the borders of the blocks, which is $O(m'n + n'm)$.

Note that alternative methods for achieving linear-time propagation across run-length compressed blocks can be obtained by adapting any of the queue algorithms described in [16], [20], [27], and [34].

Since all relevant $DIST$ entry values are computed "on the fly" and do not need to be stored, Hirschberg's method [26] can be applied to achieve an algorithm with a space complexity that is linear with the size of the uncompressed strings.

Open problems. The subquadratic sequence comparison algorithms presented in this paper are perhaps close to optimal in time complexity. However, an important concern is the space complexity of the algorithms. If only the similarity score

value is required, the classical, quadratic time sequence alignment algorithm can easily be implemented to run in linear space by keeping only two rows of the dynamic programming table alive at each step. If the recovery of either global or local optimal alignment traces is required, quadratic-time and linear-space algorithms can be obtained by applying Hirschberg's refinement to the classical sequence alignment algorithms [10], [26], [28]. We post as an open problem the challenge of further reducing the space requirement of the algorithms described in this paper without impairing their subquadratic time complexity.

Acknowledgment. We are grateful to Dan Gusfield for a helpful discussion.
