Proof. The first statement is proved in the previous theorems. For the second statement we consider the following function with four matrices as input. The function is the parity of the MP function on the first two matrices and the complement of MP on the other two matrices.

A fair probabilistic formula can compute the function obviously with length $O(n^2)$ following the construction in Theorem 3.11. Assume we have a one-sided error formula, then fix the first two input matrices once in a way so that their product is the 0 matrix and then so that their product is something else. In this way one gets one-sided error formulas for both MP and its complement. Then one can use both formulas on the same input and combine their results to get a Las Vegas formula, which leads to the desired lower bound with Theorem 3.12.

For the construction of a Las Vegas formula let F be the one-sided error formula for MP and G be the one-sided error formula for $\neg MP$. Then F and $\neg G$ are formulas for MP, so that F never erroneously accepts and is correct with probability 1/2, and $\neg G$ never erroneously rejects and is correct with probability 1/2. Assuming the function value is 0, then F rejects. With probability 1/2, $\neg G$ also rejects; otherwise, we may give up. Assuming the function value is 1, then $\neg G$ accepts. With probability 1/2, F also accepts; otherwise, we may give up. The other way around, if both formulas accept or both reject we can safely use this result, and this result comes up with probability 1/2; the only other possible result is that F rejects and $\neg G$ accepts, in which case we have to give up. □

The formula described in the proof of Theorem 3.11 has the interesting property that each input is read exactly once, while the random inputs are read often. MP cannot be computed by a deterministic formula reading the inputs only once, since this contradicts the size bound of Theorem 3.12. Later we will show that MP cannot be computed substantially more efficiently by a fair probabilistic formula reading its random inputs only once than by deterministic formulas. This follows from a lower bound for the size of such formulas given by the Nečiporuk function divided by $\log n$ (Corollary 6.7). Hence for the MP function read-once random inputs are of little use.

4. Background on quantum computing and information.

In this section we define more technical notions and describe results we will need. We start with information theory, then define the model of quantum formulas, and give results from quantum information theory. We also discuss programmable quantum gates. These results are used in the following section to give lower bounds for one-way communication complexity. Then we proceed to apply these to derive more formula size bounds.

4.1. Information theory.

We now define a few notions from classical information theory; see, e.g., [10].

DEFINITION 4.1. *Let X be a random variable with values in $S = \{x_1, \dots, x_n\}$.*

The entropy of X is $H(X) = -\sum_{x \in S} \Pr(X = x) \log \Pr(X = x)$.

The entropy of X given an event E is $H(X|E) = -\sum_{x \in S} \Pr(X = x|E) \log \Pr(X = x|E)$.

The conditional entropy of X given a random variable Y is $H(X|Y) = \sum_y \Pr(Y = y) H(X|Y = y)$, where the sum is over the values of Y. Note that $H(X|Y) = H(XY) - H(Y)$.

The information between X and Y is $I(X : Y) = H(X) - H(X|Y)$.

The conditional information between X and Y, given Z, is $I(X : Y|Z) = H(XZ) + H(YZ) - H(Z) - H(XYZ)$.

For $\alpha \in [0, 1]$ we define $H(\alpha) = -\alpha \log \alpha - (1 - \alpha) \log(1 - \alpha)$.

All of the above definitions use the convention $0 \log 0 = 0$.

The following result is a simplified version of Fano's inequality; see [10].

FACT 4.2. *If X, Y are Boolean random variables with $\Pr(X \neq Y) \leq \epsilon$, then $I(X : Y) \geq H(X) - H(\epsilon)$.*

Proof. Let $Z = 1 \iff X = Y$ and $Z = 0 \iff X \neq Y$. Then $H(X|Y) = H(XY) - H(Y) = H(ZY) - H(Y) \leq H(Z) \leq H(\epsilon)$. □

The next lemma is similar in the sense of a "Las Vegas variant."

LEMMA 4.3. *Let X be a random variable with a finite range of values S, and let Y be a random variable with range $S \cup \{x_?\}$, so that $\Pr(Y = x|X = x) \geq 1 - \epsilon$ for all $x \in S$, $\Pr(Y = x|X \neq x) = 0$ for all $x \neq x_?$, and $\Pr(Y = x_?|X = x) \leq \epsilon$ for all $x \in S$. Then $I(X : Y) \geq (1 - \epsilon) H(X)$.*

Proof. $I(X : Y) = H(X) - H(X|Y)$. Let $\delta = \Pr(Y = x_?) \leq \epsilon$, $\epsilon_x = \Pr(Y = x_?|X = x) \leq \epsilon$, $p_x = \Pr(X = x)$.

$$\begin{aligned} H(X|Y) &\leq (1 - \delta) H(X|Y \neq x_?) + \delta H(X|Y = x_?) \\ &= \delta H(X|Y = x_?) \\ &= -\delta \sum_x \Pr(X = x|Y = x_?) \log(\Pr(X = x|Y = x_?)) \\ &= -\delta \sum_x (\epsilon_x p_x / \delta) \log(\epsilon_x p_x / \delta) \\ &\leq -\epsilon \sum_x p_x \log p_x + \delta \sum_x (\epsilon_x p_x / \delta) \log(\delta / \epsilon_x) \\ &\leq \epsilon H(X) + \delta \log \sum_x p_x \text{ with Jensen's inequality} \\ &\leq \epsilon H(X). \qquad \square \end{aligned}$$

4.2. Quantum computation. We refer to [35] for a thorough introduction into the field. Let us briefly mention that pure quantum states are unit vectors in a Hilbert space written $|\psi\rangle$, inner products are denoted $\langle\psi|\phi\rangle$, and the standard norm is $\| \, |\psi\rangle \, \| = \sqrt{\langle\psi|\psi\rangle}$. Outer products $|\psi\rangle\langle\phi|$ are matrix valued.

In the space $\mathbb{C}^4$ we will consider not only the standard basis $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$ but also the Bell basis consisting of

$$|\Phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle), \quad |\Phi^-\rangle = \frac{1}{\sqrt{2}}(|00\rangle - |11\rangle),$$

$$|\Psi^+\rangle = \frac{1}{\sqrt{2}}(|01\rangle + |10\rangle), \quad |\Psi^-\rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle).$$

The dynamics of a discrete time quantum system is described by unitary operations. We give some examples of such operations. A very useful operation is the Hadamard transform:

$$H_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

Then $H_n = \underbrace{H_2 \otimes \cdots \otimes H_2}_{n}$ is the n-wise tensor product of H_2.

The CNOT operation is defined by $CNOT : |x, y\rangle \to |x, x \oplus y\rangle$ on Boolean values x, y.

Furthermore measurements are fundamental operations. Measuring as well as tracing out subsystems leads to probabilistic mixtures of pure states.

Definition 4.4. *An ensemble of pure states is a set $\{(p_i, |\phi_i\rangle) | 1 \le i \le k\}$. Here the p_i are the probabilities of the pure states $|\phi_i\rangle$. Such an ensemble is called a mixed state.*

The density matrix of a pure state $|\phi\rangle$ is the matrix $|\phi\rangle\langle\phi|$; the density matrix of a mixed state $\{(p_i, |\phi_i\rangle) | 1 \le i \le k\}$ is

$$\sum_{i=1}^{k} p_i |\phi_i\rangle\langle\phi_i|.$$

A density matrix is always Hermitian, positive semidefinite, and has trace 1. Thus a density matrix has nonnegative eigenvalues that sum to 1. The results of all measurements of a mixed state are determined by the density matrix.

A pure state in a Hilbert space $H = H_A \otimes H_B$ cannot in general be expressed as a tensor product of pure states in the subsystems.

Definition 4.5. *A mixed state $\{(p_i, |\phi_i\rangle) | 1 \le i \le k\}$ in a Hilbert space $H_1 \otimes H_2$ is called separable if it has the same density matrix as a mixed state $\{(q_i, |\psi_i^1\rangle \otimes |\psi_i^2\rangle) | i = 1, \ldots, k'\}$ for pure states $|\psi_i^1\rangle$ from H_1 and $|\psi_i^2\rangle$ from H_2 with $\sum_i q_i = 1$ and $q_i \ge 0$. Otherwise, the state is called entangled.*

Consider, e.g., the state $|\Phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ in $\mathbb{C}^2 \otimes \mathbb{C}^2$. The state is entangled and is usually called an EPR pair. This name refers to Einstein, Podolsky, and Rosen, who first considered such states [13].

Linear transformations on density matrices are called superoperators. Not all superoperators are physically allowed.

Definition 4.6. *A superoperator T is positive if it sends positive semidefinite Hermitian matrices to positive semidefinite Hermitian matrices. A superoperator is trace preserving if it maps matrices with trace 1 to matrices with trace 1.*

A superoperator T is completely positive if every superoperator $T \otimes I_F$ is positive, where I_F is the identity superoperator on a finite dimensional extensional F of the underlying Hilbert space.

A superoperator is physically allowed iff it is completely positive and trace preserving.

The following theorem characterizes physically allowed superoperators in terms of unitary operation, adding qubits, and tracing out [35].

FACT 4.7. *The following statements are equivalent:*

1. *A superoperator T sending density matrices over a Hilbert space H_1 to density matrices over a Hilbert space H_2 is physically allowed.*
2. *There is a Hilbert space H_3 with $\dim(H_3) \leq \dim(H_1)$ and a unitary map U, so that for all density matrices ρ over H_1:*

$$T\rho = trace_{H_1 \otimes H_3}[U(\rho \otimes |0_{H_3 \otimes H_2}\rangle\langle 0_{H_3 \otimes H_2}|)U^\dagger].$$

4.3. Quantum information theory. In this section we describe notions and results from quantum information theory.

DEFINITION 4.8. *The von Neumann entropy of a density matrix ρ_X is $S(X) = S(\rho_X) = -trace(\rho_X \log \rho_X)$.*

The conditional von Neumann entropy $S(X|Y)$ of a bipartite system with density matrix ρ_{XY} is defined as $S(XY) - S(Y)$, where the state ρ_Y of the Y system is the result of a partial trace over X.

The von Neumann information between two parts of a bipartite system in a state ρ_{XY} is $S(X:Y) = S(X) + S(Y) - S(XY)$ (ρ_X and ρ_Y are the results of partial traces).

The conditional von Neumann information of a system in state ρ_{XYZ} is $S(X : Y|Z) = S(XZ) + S(YZ) - S(Z) - S(XYZ)$.

Let $\mathcal{E} = \{(p_i, \rho_i)|i = 1, \dots, k\}$ be an ensemble of density matrices. The Holevo information of the ensemble is $\chi(\mathcal{E}) = S(\sum_i p_i\rho_i) - \sum_i p_i S(\rho_i)$.

The von Neumann entropy of a density matrix depends on the eigenvalues only, so it is invariant under unitary transformations. If the underlying Hilbert space has dimension d, then the von Neumann entropy of a density matrix is bounded by $\log d$. A fundamental result is the so-called Holevo bound [16], which states an upper bound on the amount of classical information in a quantum state.

FACT 4.9. *Let X be a classical random variable with $\Pr(X = x) = p_x$. Assume for each x that a quantum state with density matrix ρ_x is prepared; i.e., there is an ensemble $\mathcal{E} = \{(p_x, \rho_x)|x = 0, \dots, k\}$. Let $\rho_{XZ} = \sum_{x=0}^{k} p_x|x\rangle\langle x| \otimes \rho_x$. Let Y be a classical random variable which indicates the result of a measurement on the quantum state with density matrix $\rho_Z = \sum_x p_x\rho_x$. Then*

$$I(X : Y) \leq \chi(\mathcal{E}) = S(X : Z).$$

We will also need the following lemma.

LEMMA 4.10. *Let $\mathcal{E} = \{(p_x, \sigma_x)|x = 0, \dots, k\}$ be an ensemble of density matrices, and let $\sigma = \sum_x p_x\sigma_x$ be the density matrix of the mixed state of the ensemble. Assume that there is an observable with possible measurement results x and "?", so that for all x measuring the observable on σ_x yields x with probability at least $1 - \epsilon$, the result "?" with probability at most ϵ, and a result $x' \neq x$ with probability 0; then*

$$S(\sigma) \geq \sum_x p_x S(\sigma_x) + (1 - \epsilon)H(X), \quad \textit{i.e.,}\ \chi(\mathcal{E}) \geq (1 - \epsilon)H(X).$$

Proof. The proof proceeds similar to the information theoretic arguments in [2]. States x of a classical random variable X are coded as quantum states σ_x, where x and σ_x have probability p_x. The density matrix of the overall mixed state is σ and has von Neumann entropy $S(\sigma)$. σ corresponds to the "code" of a random x.

According to Holevo's theorem (Fact 4.9) the information on X one can access by measuring σ with result Y is bounded by $I(X:Y) \leq S(\sigma) - \sum_x p_x S(\sigma_x)$. But there is such a measurement as assumed in the lemma, and with Lemma 4.3 $I(X:Y) \geq (1-\epsilon)H(X)$. Thus the lemma follows. □

Not all of the relations that are valid in classical information theory hold in quantum information theory. The following fact states a notable exception, the so-called Araki–Lieb inequality and one of its consequences; see [35].

FACT 4.11. $S(XY) \geq |S(X) - S(Y)|$.

$S(X:Y|Z) \leq 2S(X)$.

The reason for this behavior is entanglement.

LEMMA 4.12. *If σ_{XY} is separable, then $S(XY) \geq S(X)$ and $S(X:Y) \leq S(X)$.*

4.4. The quantum communication model. Now we define quantum one-way protocols.

DEFINITION 4.13. *In a two-player quantum one-way protocol players Alice and Bob each possess a private set of qubits. Some of the qubits are initialized to the Boolean inputs of the players; all other qubits are in some fixed basis state $|0\rangle$.*

Alice then performs some quantum operation on her qubits and sends a set of these qubits to Bob. The latter action changes the possession of qubits rather than the global state. We can assume that Alice sends the same number of qubits for all inputs. After Bob has received the qubits he can perform any quantum operation on the qubits in his possession, and afterwards he announces the result of the computation. The complexity of a protocol is the number of qubits sent.

In an exact quantum protocol the result has to be correct with certainty. $Q_E(f)$ is the minimal complexity of an exact quantum protocol for a function f.

In a bounded error protocol the output has to be correct with probability $1-\epsilon$ (for $1/2 > \epsilon > 0$). The bounded error quantum one-way communication complexity of a function f is $Q_\epsilon(f)$, the minimal complexity of a bounded error quantum one-way protocol for f, and we set $Q(f) = Q_{1/3}(f)$.

Quantum Las Vegas protocols are defined in a manner similar to their probabilistic counterparts; the complexity measure notation is $Q_{0,\epsilon}(f)$.

Cleve and Buhrman [9] *consider a different model of quantum communication: Before the start of the protocol Alice and Bob own a set of qubits whose state may be entangled but must be independent of the inputs. Then as above a quantum communication protocol is used. We use the superscript* pub *to denote the complexity in this model.*

It is possible to simulate the model with entangled qubits by allowing first an arbitrary finite communication independent of the inputs, followed by an ordinary protocol. By measuring distributed EPR pairs it is possible to simulate classical public randomness. The technique of superdense coding of [5] allows one in the model with prior entanglement to send n bits of classical information with $\lceil n/2 \rceil$ qubits.

4.5. Quantum circuits and formulas. Besides quantum Turing machines quantum circuits [11] are a universal model of quantum computation (see [41]) and are generally easier to handle in descriptions of quantum algorithms. A more general model of quantum circuits in which superoperator gates work on density matrices is described in [1]. We begin with the basic model.

DEFINITION 4.14. *A unitary quantum gate with k inputs and k outputs is specified by a unitary operator $U : \mathbb{C}^{2^k} \to \mathbb{C}^{2^k}$.*

A quantum circuit consists of unitary quantum gates with $O(1)$ inputs and outputs each, plus a set of inputs to the circuits, which are connected to an acyclic directed graph, in which the inputs are sources. Sources are labeled by Boolean constants or by input variables. Edges correspond to qubits; the circuit uses as many qubits as it has sources. One designated qubit is the output qubit. A quantum circuit computes a unitary transformation on the source qubits in the obvious way. In the end the output qubit is measured in the standard basis.

The size of a quantum circuit is the number of its gates; the depth is the length of the longest path from an input to the output.

A quantum circuit computes a function with a bounded error if it gives the right output with probability at least $2/3$ for all inputs.

A quantum circuit computes a Boolean function with a one-sided error if it has a bounded error and furthermore never erroneously accepts.

A pair of quantum circuits computes a Boolean function f in the Las Vegas sense, if the first is a one-sided error circuit for f and the second is a one-sided error circuit for $\neg f$.

A quantum circuit computes a function exactly if it makes no error.

The definition of Las Vegas circuits is motivated by the fact that we can easily verify the computation of a pair of one-sided error circuits for f and $\neg f$ as in the classical case; see the proof of Corollary 3.13.

We are interested in restricted types of circuits, namely, quantum formulas [41].

DEFINITION 4.15. *A quantum formula is a quantum circuit with the following additional property: For each source there is at most one path connecting it to the output. The length or size of a quantum formula is the number of its sources.*

Apart from the Boolean input variables a quantum formula is allowed to read Boolean constants only. There is only one final measurement. We also call the model from [41] *pure* quantum formulas. Compare also the definitions in [37].

In [1] a more general model of quantum circuits is studied, in which superoperators work on density matrices.

DEFINITION 4.16. *A superoperator gate g of order (k, l) is a trace-preserving, completely positive map from the density matrices on k qubits to the density matrices on l qubits.*

A quantum superoperator circuit is a directed acyclic graph with inner vertices marked by superoperator gates with fitting fan-in and fan-out. The sources are marked with input variables or Boolean constants. One gate is designated as the output.

A function is computed as follows. In the beginning the sources are each assigned a density matrix corresponding to the Boolean values determined by the input or by a constant. The Boolean value 0 corresponds to $|0\rangle\langle 0|$, 1 to $|1\rangle\langle 1|$. The overall state of the qubits involved is the tensor product of these density matrices.

Then the gates are applied in an arbitrary topological order. Applying a gate means applying the superoperator composed of the gate's superoperator on the chosen qubits for the gate and the identity superoperator on the remaining qubits.

In the end the state of the output qubit is supposed to be a classical probability distribution on $|0\rangle$ and $|1\rangle$.

The following fact from [1] allows one to apply gates in an arbitrary topological ordering.

FACT 4.17. *Let C be a quantum superoperator circuit, and let C_1 and C_2 be two sets of gates working on different sets of qubits. Then for all density matrices ρ on* *the qubits in the circuit the result of C_1 applied to the result of C_2 on ρ is the same as the result of C_2 applied to the result of C_1 on ρ.*

Let two arbitrary topological orderings of the gates in a quantum superoperator circuit be given. The result of applying the gates in one ordering is the same as the result of applying the gates in the other ordering for any input density matrix.

One more aspect is interesting in the definition of quantum formulas: We want to allow quantum formulas to access multiple read random inputs, just as fair probabilistic formulas. This makes it possible to simulate the latter model. Instead of random variables we allow the quantum formulas to read an arbitrary nonentangled state. A pure state on k qubits is called nonentangled if it is the tensor product of k states on one qubit each. A mixed state is nonentangled if it can be expressed as a probabilistic ensemble of nonentangled pure states. Note that a classical random variable read k times can be modeled as $|1^k\rangle$ with probability $1/2$ and $|0^k\rangle$ with probability $1/2$.

We restrict our definition to gates with fan-in 2; the set of quantum gates with fan-in 2 is known to be universal [4].

Definition 4.18. *A generalized quantum formula is a quantum superoperator circuit with fan-out 1/fan-in 2 gates together with a fixed nonentangled mixed state. The sources of the circuit are either labeled by input variables or may access a qubit of the state. Each qubit of this state may be accessed only by one gate.*

As proved in [1] Fact 4.7 implies that quantum superoperator circuits with constant fan-in are asymptotically as efficient as quantum circuits with constant fan-in. The same holds for quantum formulas. The essential difference between pure and generalized quantum formulas is the availability of multiple read random bits.

4.6. Programmable quantum gates. For simulations of quantum mechanical formulas by communication protocols we will need a programmable quantum gate. Such a gate allows Alice to communicate a unitary operation as a program stored in some qubits to Bob, who then applies this operation to some of his qubits.

Formally we have to look for a unitary operator G, with

$$G(|d\rangle \otimes |P_U\rangle) = U(|d\rangle) \otimes |P'_U\rangle.$$

Here $|P_U\rangle$ is the "code" of a unitary operator U and $|P'_U\rangle$ some leftover of the code.

The bad news is that such a programmable gate does not exist, as proved in [34]. Note that in the classical case such gates are easy to construct.

Fact 4.19. *If N different unitary operators (pairwise different by more than a global phase) can be implemented by a programmable quantum gate, then the gate needs a program of length $\log N$.*

Since there are infinitely many unitary operators on just one qubit there is no programmable qubit with finite program length implementing them all. The proof uses the fact that the gate works deterministically, and actually a probabilistic solution to the problem exists.

We now sketch a construction of Nielsen and Chuang [34]. For the sake of simplicity we describe just the construction for unitary operations on one qubit.

The program of a unitary operator U is

$$|P_U\rangle = \frac{1}{\sqrt{2}}(|0\rangle U|0\rangle + |1\rangle U|1\rangle).$$

The gate receives as input $|d\rangle \otimes |P_U\rangle$. The gate then measures the first and second qubits in the basis $\{|\Phi^+\rangle, |\Phi^-\rangle, |\Psi^+\rangle, |\Psi^-\rangle\}$. Then the third qubit is used as a result.

For a state $|d\rangle = a|0\rangle + b|1\rangle$ the input to the gate is

$$[a|0\rangle + b|1\rangle]\frac{|0\rangle U|0\rangle + |1\rangle U|1\rangle}{\sqrt{2}} = \frac{1}{2}\left[|\Phi^+\rangle(aU|0\rangle + bU|1\rangle) + |\Phi^-\rangle(aU|0\rangle - bU|1\rangle)\right.$$
$$\left. + |\Psi^+\rangle(aU|1\rangle + bU|0\rangle) + |\Psi^-\rangle(aU|1\rangle - bU|0\rangle)\right].$$

Thus the measurement produces the correct state with probability 1/4, and moreover the result of the measurement indicates whether the computation was done correctly. Also, given this measurement result we know exactly which unitary "error" operation has been applied before the desired operation. We now state Nielsen and Chuang's result.

FACT 4.20. *There is a probabilistic programmable quantum gate with m input qubits for the state plus $2m$ input qubits for the program, which implements every unitary operation on m qubits and succeeds with probability $1/2^{2m}$. The result of a measurement done by the gate indicates whether the computation was done correctly and which unitary error operation has been performed.*

Also note that it is easy to construct an approximate programmable quantum gate in the following sense. For any error parameter ϵ we may discretize the set of superoperators to a finite set so that for each superoperator T there is an operator T' from the finite set, such that for each density matrix ρ we have that $T\rho$ is ϵ-close to $T'\rho$. Then we can construct a gate that receives the classical description of one of these finitely many superoperators as a program.

5. One-way communication complexity: The nondeterministic and the quantum cases.

5.1. A lower bound for limited nondeterminism. In this section we investigate nondeterministic one-way communication with a limited number of nondeterministic bits. Analogous problems for many-round communication complexity have been addressed in [18], but in this section we again consider asymmetric problems, for which the one-way restriction is essential.

It is easy to see that if player Bob has m input bits, then m nondeterministic bits are the maximum player Alice needs. Since the nondeterministic communication complexity without any limitation on the number of available nondeterministic bits is at most m, Alice can just guess the communication and send it to Bob in case it is correct with respect to her input and leads to acceptance. Bob can then check the same for his input. Thus an optimal protocol can be simulated.

For the application to lower bounds on formula size we are again interested in functions with an asymmetric input partition; i.e., Alice receives much more inputs than Bob. For nontrivial results thus the number of nondeterministic bits must be smaller than the number of Bob's inputs.

A second observation is that using s nondeterministic bits can reduce the communication complexity from the deterministic one-way communication complexity d to $d/2^s$ in the best case. If s is sublogarithmic, strong lower bounds follow already from the deterministic lower bounds, e.g., $N_{\epsilon \log n}(\neg EQ) \geq n^{1-\epsilon}$, while $N_{\log n}(\neg EQ) = O(\log n)$. On the other hand, we have the following.

LEMMA 5.1.

$$N_s(f) = c \Rightarrow N_c(f) \leq c.$$

Proof. In a protocol with communication c at most 2^c different messages can be sent (for all inputs). To guess such a message c nondeterministic bits are sufficient. □

Hence it is unnecessary for a nondeterministic protocol to use more nondeterministic bits than communication. We are interested in determining how large the difference between nondeterministic one-way communication complexity with s nondeterministic bits and unrestricted nondeterministic communication complexity may be. Therefore we consider the maximal such gap as a function G.

Corollary 5.2. *Let $f : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}$ be a Boolean function and $G : \mathbb{N} \to \mathbb{N}$ a monotone increasing function, with $N(f) = c$ and $N_s(f) = G(c)$ for some s.*

Then $N_{G^{-1}(n)}(f) \leq c$ and hence $s \leq G^{-1}(n)$, where $G^{-1}(x) = \min\{y | G(y) \geq x\}$.

Proof. $G(c) \leq n$ and hence $c \leq G^{-1}(n)$. □

The range of values of s for which a gap G between $N(f)$ and $N_s(f)$ is possible is thus limited. If, e.g., an exponential difference $G(x) = 2^x$ holds, then $s \leq \log n$. If $G(x) = r \cdot x$, then $s \leq n/r$.

We now show a gap between nondeterministic one-way communication complexity with s nondeterministic bits and unlimited nondeterministic communication complexity. First we define the family of functions exhibiting this gap. Denote by $\mathcal{P}(a, b)$ the set of size b subsets of a size a universe.

Definition 5.3. *Let $DI_{n,s}$ be the following Boolean function for $1 \leq s \leq n$:*

$$\begin{aligned} DI_{n,s}(x_1, \dots, x_n; x_{n+1}) = 1 \iff & \forall i : x_i \in \mathcal{P}(n^3, s) \\ & \wedge \exists i : |\{j | j \neq i; x_i \cap x_j \neq \emptyset\}| \geq s. \end{aligned}$$

Note that the function has $\Theta(sn \log n)$ input bits in a standard encoding. We consider the partition of inputs in which Bob receives the set x_{n+1} and Alice all other sets. The upper bounds in the following lemma are trivial, since Bob receives only $O(s \log n)$ input bits.

Lemma 5.4.

$$\begin{aligned} N_{O(s \log n)}(DI_{n,s}) &= O(s \log n). \\ D^B(DI_{n,s}) &= O(s \log n). \end{aligned}$$

The lower bound we present now results in a near optimal difference between nondeterministic (one-way) communication and limited nondeterministic one-way communication. Limited nondeterministic one-way communication has also been studied subsequently to this work in [17]. There a tradeoff between the consumption of nondeterministic bits and the one-way communication is demonstrated (i.e., with more nondeterminism the communication gradually decreases). Here we describe a fundamentally different phenomenon of a threshold type: Nondeterministic bits do not help much, until a certain number of them are available, when quite quickly the optimal complexity is attained. For more results of this type see [22].

Theorem 5.5. *There is a constant $\epsilon > 0$, so that for $s \leq n$*

$$N_{\epsilon s}(DI_{n,s}) = \Omega(ns \log n).$$

Proof. We have to show that all nondeterministic one-way protocols computing $DI_{n,s}$ with ϵs nondeterministic bits need much communication.

A nondeterministic one-way protocol with ϵs nondeterministic bits and communication c induces a cover of the communication matrix with $2^{\epsilon s}$ Boolean matrices having the following properties: Each 1-entry of the communication matrix is a 1-entry in at least one of the Boolean matrices, no 0-entry of the communication matrix is a 1-entry in any of the Boolean matrices, and furthermore the set of rows appearing in those matrices has size at most 2^c. This set of matrices is obtained by fixing the nondeterministic bits and taking the communication matrices of the resulting deterministic protocols. Note that the rows of the communication matrices of the deterministic protocols correspond to messages. We will deduce the lower bound from the weaker property that *each* of the Boolean matrices covering the communication matrix uses at most 2^c different rows. This can be used to show that the lower bound holds even for protocols with limited, but public, nondeterminism.

We start by constructing a submatrix of the communication matrix with some useful properties and then show the theorem for this "easier" problem.

Partition the universe $\{1, \dots, n^3\}$ in n disjoint sets $U_1, \dots, U_n$, with $|U_i| = n^2 = m$. Then choose vectors of n size s subsets of the universe, so that the ith subset is from U_i. Thus the n subsets of a vector are pairwise disjoint. Now the protocol has to determine whether the set of Bob intersects nontrivially with s of the sets given to Alice.

We restrict the set of inputs further. There are $\binom{m}{s}$ different size s subsets of U_i. We choose a set of such subsets so that each pair of them has no more than $s/2$ common elements. To do so we start with any subset and remove all subsets having more than $s/2$ common elements with any already chosen subset. This process can be repeated until all size s subsets are either chosen or discarded. We end with a set of size s subsets of U_i, whose elements have pairwise no more than $s/2$ common elements. In every step at most $\binom{s}{s/2}\binom{m}{s/2}$ subsets are discarded; thus we choose at least

$$\frac{\binom{m}{s}}{\binom{s}{s/2}\binom{m}{s/2}} \geq \left(\frac{m}{s}\right)^{s/2} / 2^{3s/2} \tag{5.1}$$

sets.

As described we draw Alice's inputs as vectors of sets, where the set at position i is drawn from the set of subsets of U_i we have just constructed. These inputs are identified with the rows of the submatrix of the communication matrix. The columns of the submatrix are restricted to elements of $U_1 \cup \{\top\} \times \cdots \times U_n \cup \{\top\}$, for which s positions are occupied; i.e., $n - s$ positions carry the extra symbol $\top$ which stands for "no element." Call the constructed submatrix M.

Now assume there is a protocol computing the restricted problem with communication matrix M. Fixing the nondeterministic bits gives us a deterministic protocol. If a nondeterministic protocol uses r nondeterministic bits, then there are 2^r such deterministic protocols, and at least one of them accepts a fraction of $1/2^r$ of the ones in M, where $r = \epsilon s$. We now show that such a matrix must have many different rows, which corresponds to a large amount of communication.

Each row of M (being a vector of zeros and ones) also corresponds to a vector of n sets, the associated input of Alice. A position i is called a *difference position* for a pair of such sequences if they have different sets at position i. According to our construction these sets have no more than $s/2$ elements in common.

We say a set of rows has k difference positions if there are k positions $i_1, \dots, i_k$, so that for each i_l there are two rows in the set for which i_l is a difference position.

We now show that each row of M' containing "many" ones does not "fit" on many rows of M, i.e., contains ones these do not have. Since M' has a one-sided error, the rows of M' are either sparse or cover only a few rows of M. Observe that each row of M has exactly $\binom{n}{s}s^s$ ones.

LEMMA 5.6. *Let z be a row of M', appearing several times in M'. The rows of M, in whose place in M the row z appears in M', may have δn difference positions. Then z contains at most $2\binom{n}{s}s^s/2^{\delta s/6}$ ones.*

Proof. Several rows of M having δn difference positions are given, and the ones of z occur in all of these rows. Let C be the set of $\binom{n}{s}s^s$ columns/sets being the ones in the first such row. All other columns are forbidden and may not be ones in z.

A column in C is chosen randomly by choosing s out of n positions and then one of s elements for each position. Let $k = \delta s$. We have to show an upper bound on the number of ones in z, and we analyze this number as the probability of getting a one when choosing a column in C. The probability of getting a one is at most the probability that the chosen positions have a nontrivial intersection with less than $k/2$ sets U_i at difference positions i (call this event E) plus the probability of getting a one under the condition of event $\overline{E}$, following the general formula $\mathrm{Prob}(A) \leq \mathrm{Prob}(A|E) + \mathrm{Prob}(\overline{E})$.

We first count the columns in C, which have a nontrivial intersection with at most $k/2$ of the sets U_i at difference positions i. Consider the slightly different experiment in which s times independently one of n positions is chosen; hence positions may be chosen more than one time. Now expected $\delta s = k$ difference positions are chosen. Applying Chernov's inequality yields that, with probability at most

$$e^{-\frac{1}{4\cdot 2}\cdot k} \leq 2^{-\delta s/6},$$

at most $k/2$ difference positions occur. When choosing a random column in C instead, this probability is even smaller, since now positions are chosen without repetitions. Thus the columns in C, which "hit" less than $k/2$ difference positions, contribute at most $2^{-\delta s/6}\binom{n}{s}s^s$ ones to z.

Now consider the columns/sets in C, which intersect at least $k/2$ of the U_i at difference positions i. Such a column/set fits on all of the rows, if the element at each position not bearing a $\top$ lies in the intersection of all sets in the rows at position i. At each difference position there are two rows, which hold different sets at that position, and those sets have no more than $s/2$ common elements.

Fix an arbitrary set of positions such that at least $k/2$ difference positions are included. The next step of choosing a column in C consists of choosing one of s elements for each position. But if a position is a difference position, then at most $s/2$ elements satisfy the condition of lying in the sets held by all of the rows at that position. Thus the probability of fitting on all of the rows is at most $2^{-k/2}$, and at most $\binom{n}{s}s^s/2^{k/2}$ such columns can be a one in z.

Overall only a fraction of $2^{-\delta s/6+1}$ of all columns in C can be ones in z. □

At least one-half of all ones in M' lie in rows containing at least $\geq \binom{n}{s}s^s/2^{r+1}$ ones. Lemma 5.6 tells us that such a row fits only on a set of rows of M having no more than δn difference positions, where $r + 1 = \delta s/6 - 1$. Hence such a row can cover at most all of the ones in $\binom{m}{s}^{\delta n}$ rows of M and therefore only $\binom{m}{s}^{\delta n}\binom{n}{s}s^s$ ones.

According to (5.1) at least $(m/s)^{sn/2}\binom{n}{s}s^s/(2^{3sn/2}2^{r+1})$ ones are covered by such rows; hence

$$\frac{(m/s)^{sn/2}\binom{n}{s}s^s}{\binom{m}{s}^{\delta n}\binom{n}{s}s^s 2^{3sn/2}2^{r+1}} \geq \frac{(m/s)^{sn/2}}{(em/s)^{6\epsilon sn+12n}2^{3sn/2}2^{\epsilon s+1}}$$
$$= 2^{\Omega(sn\log n)}$$

rows are necessary (for $\epsilon = 1/20$ and $n \geq s \geq 400$). □

5.2. Quantum one-way communication. Our first goal in this section is to prove that the VC-dimension lower bound for randomized one-way protocols (Fact 2.9) can be extended to the quantum case. To achieve this we first prove a linear lower bound on the bounded error quantum communication complexity of the index function IX_n and then describe a reduction from the index function IX_d to any function with VC dimension d, thus transferring the lower bound. It is easy to see that $VC(IX_n) = n$, and thus the bounded error probabilistic one-way communication complexity is large for that function.

The problem of *random access quantum coding* has been considered in [2]. In a n, m, ϵ-random access quantum code all Boolean n-bit words x have to be mapped to states of m qubits each, so that for $i = 1, \ldots, n$ there is an observable, so that measuring the quantum code with that observable yields the bit x_i with probability $1 - \epsilon$. The quantum code is allowed to be a mixed state. The following is a result from [2].

FACT 5.7. *For every n, m, ϵ-random access quantum coding $m \geq (1 - H(\epsilon))n$.*

It is easy to see that the problem of random access quantum coding is equivalent to the construction of a quantum one-way protocol for the index function. If there is such a protocol, then the messages can serve as mixed state codes, and if there is such a code, the codewords can be used as messages. We can thus deduce a lower bound for IX_n in the model of one-way quantum communication complexity without prior entanglement.

We now give a proof that can also be adapted to the case of allowed prior entanglement. The proof follows Nayak's idea, who also obtained the generalization to the case of prior entanglement in his thesis [31].

THEOREM 5.8. *$Q_\epsilon(IX_n) \geq (1 - H(\epsilon))n$.*

$Q_\epsilon^{pub}(IX_n) \geq (1 - H(\epsilon))n/2$.

Proof. Let M be the register containing the message sent by Alice, and let X be a register holding a uniformly random input to Alice. Then σ_{XM} denotes the state of Alice's qubits directly before the message is sent. σ_M is the state of a random message. Now every bit is decodable with probability $1 - \epsilon$, and thus $S(X_i : M) \geq 1 - H(\epsilon)$ for all i. To see this consider $S(X_i : M)$ as the Holevo information of the following ensemble:

$$\sigma_{i,0} = \sum_{x:x_i=0} \frac{1}{2^{n-1}} \sigma_M^x$$

with probability 1/2 and

$$\sigma_{i,1} = \sum_{x:x_i=1} \frac{1}{2^{n-1}} \sigma_M^x$$

with probability 1/2, where σ_M^x is the density matrix of the message on input x. The information obtainable on x_i by measuring σ_M must be at $1 - H(\epsilon)$ due to Fano's inequality (Fact 4.2), and thus the Holevo information of the ensemble is at least $1 - H(\epsilon)$; hence $S(X_i : M) \geq 1 - H(\epsilon)$.

But then $S(X : M) \geq (1 - H(\epsilon)n$ (since all X_i are mutually independent). $S(X : M) \leq S(M)$ using Lemma 4.12, since X and M are not entangled. Thus the number of qubits in M is at least $(1 - H(\epsilon))n$.

Now we analyze the complexity of IX_n in the one-way communication model with entanglement.

The density matrix of the state induced by a uniformly random input on X, the message M, and the qubits E_A, E_B containing the prior entanglement in the possession of Alice and Bob is $\sigma_{XME_AE_B}$. Here E_A contains those qubits of the entangled state Alice keeps; note that some of the entangled qubits will usually belong to M. Tracing out X and E_A we receive a state σ_{ME_B}, which is accessible to Bob. Now every bit of the string in X is decodable; thus $S(X_i : ME_B) \geq 1 - H(\epsilon)$ for all i as before. But then also $S(X : ME_B) \geq (1 - H(\epsilon)n$, since all of the X_i are mutually independent.

$S(X : ME_B) = S(X : E_B) + S(X : M|E_B) \leq 2S(M)$ by an application of the Araki–Lieb inequality; see Fact 4.11. Note that $S(X : E_B) = 0$. So the number of qubits in M must be at least $(1 - H(\epsilon))n/2$. □

Note that the lower bound shows that two-round deterministic communication complexity can be exponentially smaller than one-way quantum communication complexity. For a more general quantum communication round hierarchy see [25].

THEOREM 5.9. *For all functions f : $Q_\epsilon(f) \geq (1 - H(\epsilon))VC(f)$ and $Q^{pub}_\epsilon(f) \geq (1 - H(\epsilon))VC(f)/2$.*

Proof. We now describe a reduction from the index function to f. Assume $VC(f) = d$; i.e., there is a set $S = \{s_1, \ldots, s_d\}$ of inputs for Bob, which is shattered by the set of functions $f(x, .)$. The reduction then goes from IX_d to f.

For each $R \subseteq S$ let c_R be the incidence vector of R (having length d). c_R is a possible input for Alice when computing the index function IX_d. For each R choose some x_R, which separates this subset from the rest of S, i.e., so that $f(x_R, y) = 1$ for all $y \in R$ and $f(x_R, y) = 0$ for all $y \in S - R$.

Assume a protocol for f is given. To compute the index function the players do the following. Alice maps c_R to x_R. Bob's inputs i are mapped to the s_i. Then $f(x_R, s_i) = 1 \iff s_i \in R \iff c_R(i) = 1$.

In this manner a quantum protocol for f must implicitly compute IX_d. According to Theorem 5.8 the lower bounds follow. □

As an application of the previous theorem we get lower bounds for the disjointness problem in the model of quantum one-way communication complexity.

COROLLARY 5.10. *$Q_\epsilon(DISJ_n) \geq (1 - H(\epsilon))n$.*

$Q^{pub}_\epsilon(DISJ_n) \geq (1 - H(\epsilon))n/2$.

The first result has independently been obtained by Buhrman and de Wolf [8]. Note that the obtained lower bound method is not tight in general. There are functions for which an unbounded gap exists between the VC dimension and the quantum one-way communication complexity [24].

Now we turn to the exact and Las Vegas quantum one-way communication complexity. For classical one-way protocols it is known that Las Vegas communication complexity is at most a factor 1/2 better than deterministic communication for total functions; see Fact 2.10.

THEOREM 5.11. *For all total functions f:*

$Q_E(f) = D(f)$,

$Q_{0,\epsilon}(f) \geq (1 - \epsilon)D(f)$.

Proof. Let $row(f)$ be the number of different rows in the communication matrix of $f(x, y)$. According to Fact 2.7, $D(f) = \lceil \log row(f) \rceil$. We assume in the following that the communication matrix consists of pairwise different rows only.

We will show that any Las Vegas one-way protocol which gives up with probability at most $\epsilon \geq 0$ for some function f having $row(f) = R$ must use messages with von Neumann entropy at least $(1 - \epsilon) \log R$, when started on a uniformly random input. Inputs for Alice are identified with rows of the communication matrix. We then conclude that the Hilbert space of the messages must have dimension at least $R^{1-\epsilon}$, and hence at least $(1-\epsilon)\log R$ qubits have to be sent. This gives us the second lower bound of the theorem. The upper bound of the first statement is trivial; the lower bound of the first statement follows by taking $\epsilon = 0$.

We now describe a process in which rows of the communication matrix are chosen randomly bit per bit. Let p be the probability of having a 0 in column 1 (i.e., the number of 0s in column 1 divided by the number of rows). Then a 0 is chosen with probability p, a 1 with probability $1-p$. Afterwards the set of rows is partitioned into the set I_0 of rows starting with a 0 and the set I_1 of rows starting with a 1. When $x_1 = b$ is chosen, the process continues with I_b and the next column.

Let ρ_y be the density matrix of the following mixed state: The (possibly mixed) message corresponding to a row starting with y is chosen uniformly over all such rows.

The probability that a 0 is chosen after y is called p_y, and the number of different rows beginning with y is called row_y.

We want to show via induction that $S(\rho_y) \geq (1-\epsilon)\log row_y$. Surely $S(\rho_y) \geq 0$ for all y.

Recall that Bob can determine the function value for an arbitrary column with the correctness guarantee of the protocol.

Then with Lemma 4.10, $S(\rho_y) \geq p_y S(\rho_{y0}) + (1-p_y)S(\rho_{y1}) + (1-\epsilon)H(p_y)$, and via induction

$$\begin{aligned} S(\rho_y) &\geq p_y((1-\epsilon)\log row_{y0}) \\ &\quad + (1-p_y)((1-\epsilon)\log row_{y1}) + (1-\epsilon)H(p_y) \\ &= (1-\epsilon)[p_y \log(p_y row_y) \\ &\quad + (1-p_y)\log((1-p_y)row_y) + H(p_y)] \\ &= (1-\epsilon)\log row_y. \end{aligned}$$

We conclude that $S(\rho) \geq (1-\epsilon)\log row(f)$ for the density matrix ρ of a message to a uniformly random row. Hence the lower bound on the number of qubits holds. □

We now again consider the model with prior entanglement.

THEOREM 5.12. *For all total functions f:*
$Q_E^{pub}(f) = \lceil D(f)/2 \rceil$,
$Q_{0,\epsilon}^{pub}(f) \geq D(f)(1-\epsilon)/2$.

The upper bound follows from superdense coding [5]. Instead of the lower bounds of the theorem we prove a stronger statement. We consider an extended model of quantum one-way communication that will be useful later.

In a *nonstandard* one-way quantum protocol Alice and Bob are allowed to communicate in arbitrarily many rounds; i.e., they can exchange many messages. But Bob is not allowed to send Alice a message, so that the von Neumann information between Bob's input and all of Alice's qubits is larger than 0. The communication complexity of a protocol is the number of qubits sent by Alice in the worst case. The model is at least as powerful as the model with prior entanglement, since Bob may, e.g., generate some EPR pairs and send one qubit of each pair to Alice, and then Alice may send a message as in a protocol with prior entanglement.

LEMMA 5.13. *For all functions f a nonstandard quantum one-way protocol with a bounded error must communicate at least $(1-H(\epsilon))VC(f)/2$ qubits from Alice to Bob.*

For all total functions f a nonstandard quantum one-way protocol

1. *with exact acceptance must communicate at least $\lceil D(f)/2 \rceil$ qubits from Alice to Bob;*

2. *with Las Vegas acceptance and success probability* $1-\epsilon$ *must communicate at least* $(1-\epsilon)D(f)/2$ *qubits from Alice to Bob.*

Proof. In this proof we always call the qubits available to Alice P and the qubits available to Bob Q for simplicity disregarding that these registers change during the course of the protocol. We assume that the inputs are in registers X, Y and are never erased or changed in the protocol. Furthermore we assume that for all fixed values x, y of the inputs the remaining global state is pure.

For the first statement it is again sufficient to investigate the complexity of the index function.

Let σ_{XYPQ} be the state for random inputs in X, Y for Alice and Bob, with qubits P and Q in the possession of Alice and Bob, respectively. Since Bob determines the result, it must be true that in the end of the protocol $S(X_Y : YQ) \geq 1 - H(\epsilon)$, since the value X_Y can be determined from Bob's qubits with probability $1-\epsilon$. It is always true in the protocol that $S(XP : Y) = 0$. Let $\rho_P^{X=x,Y=y}$ be the density matrix of P for fixed inputs $X = x$ and $Y = y$. Then we have that for all x, y, y': $\rho_P^{X=x,Y=y} = \rho_P^{X=x,Y=y'}$.

$\rho_{PQ}^{X=x,Y=y}$ purifies $\rho_P^{X=x,Y=y}$. Then the following fact from [29] and [28] tells us that all y and corresponding states of Q are "equivalent" from the perspective of Alice.

FACT 5.14. *Assume* $|\phi_1\rangle$ *and* $|\phi_2\rangle$ *are pure states in a Hilbert space* $H \otimes K$, *so that* $\mathrm{Tr}_K|\phi_1\rangle\langle\phi_1| = \mathrm{Tr}_K|\phi_2\rangle\langle\phi_2|$.

Then there is a unitary transformation U *acting on* K, *so that* $I \otimes U|\phi_1\rangle = |\phi_2\rangle$ *(for the identity operator* I *on* H*).*

Thus there is a local unitary transformation applicable by Bob alone, so that $\rho_{PQ}^{X=x,Y=y}$ can be changed to $\rho_{PQ}^{X=x,Y=y'}$. Hence for all i we have $S(QY : X_i) \geq 1 - H(\epsilon)$, and thus $S(X : QY) \geq (1 - H(\epsilon))n$.

In the beginning $S(X : QY) = 0$. Then the protocol proceeds w.l.o.g. so that each player applies a unitary transformation on his qubits and then sends a qubit to the other player. Since the information cannot increase by local operations, it is sufficient to analyze what happens if qubits are sent. When Bob sends a qubit to Alice, $S(X : QY)$ is not increased. When Alice sends a qubit to Bob, then Q is augmented by a qubit M, and $S(X : QMY) \leq S(X : QY) + S(XQY : M) \leq S(X : QY) + 2S(M) \leq S(X : QY) + 2$ due to Fact 4.11. Thus the information can increase only when Alice sends a qubit and always by at most 2. The lower bound follows.

Now we turn to the second part. We consider the same situation as in the proof of Theorem 5.11. Let σ_P^{rc} denote the density matrix of the qubits P in Alice's possession under the condition that the input row is r and the input column is c. Clearly σ_{PQ}^{rc} (containing also Bob's qubits) is a purification of σ_P^{rc}. Again $\sigma_P^{rc} = \sigma_P^{rc'}$ for all r, c, c', and according to Fact 5.14 for all c and all corresponding states of Q, it is true that Bob can switch locally between them. Hence it is possible for Bob to compute the function for an arbitrary column.

The probability of choosing a 0 after a prefix y of a row is again called p_y, and the number of different rows beginning with y is called row_y. ρ_y contains the state of Bob's qubits at the end of the protocol if a random row starting with y is chosen uniformly (and some fixed column c is chosen). Surely $S(\rho_y) \geq 0$ for all y. Since Bob can change his column (and the corresponding state of Q) by a local unitary transformation, he is able to compute the function for an arbitrary column, always with the success probability of the protocol, at the end. With Lemma 4.10 $S(\rho_y) \geq p_y S(\rho_{y0}) + (1-p_y)S(\rho_{y1}) + (1-\epsilon)H(p_y)$.

At the end of the protocol thus $S(\sigma_Q^c) = S(\rho) \geq (1-\epsilon)\log row(f) + \sum_r \frac{1}{row(f)} S(\sigma_Q^{rc})$ for all c. Thus the Holevo information of the ensemble, in which $\rho_r = \sigma_Q^{rc}$ is chosen with probability $1/row(f)$, is at least $(1-\epsilon)\log row(f)$. Let σ_{RPQ} be the density matrix of rows, qubits of Alice and Bob. It follows that $S(R:Q) \geq (1-\epsilon)\log row(f)$, and as before at least half that many qubits have to be sent from Alice to Bob. □

6. More lower bounds on formula size.

6.1. Nondeterminism and formula size. Let us first mention that any nondeterministic circuit can easily be transformed into an equivalent nondeterministic formula without increasing size by more than a constant factor. To do so one simply guesses the values of all internal gates and then verifies that all of these guesses are correct and that the circuit accepts. This is a big AND over test involving $O(1)$ variables, which can be implemented by a Boolean formula in conjunctive normal form. Hence large lower bounds for nondeterministic formula size are very hard to prove, since even nonlinear lower bounds for the size of deterministic circuits computing some explicit functions are unknown. We now show that formulas with limited nondeterminism are more approachable. We start by introducing a variant of the Nečiporuk method, this time in terms of nondeterministic communication:

Definition 6.1. *Let f be a Boolean function with n input variables and $y_1 \dots y_k$ be a partition of the inputs in k blocks.*

Player Bob receives the inputs in y_i, and player Alice receives all other inputs. The nondeterministic one-way communication complexity of with s nondeterministic bits of f under this input partition is called $N_s(f_i)$. Define the s-nondeterministic Nečiporuk function as $1/4\sum_{i=1}^k N_s(f_i)$.

Lemma 6.2. *The s-nondeterministic Nečiporuk function is a lower bound for the length of nondeterministic Boolean formulas with s nondeterministic bits.*

The proof is analogous to the proof of Theorem 3.5. Again protocols simulate the formula in k communication games. This time Alice fixes the nondeterministic bits by herself, and no probability distribution on formulas is present.

We will apply the above methodology to the following language.

Definition 6.3. *Let $AD_{n,s}$ denote the following language (for $1 \leq s \leq n$):*

$$\begin{aligned} AD_{n,s} = \{(x_1, \dots, x_{n+1}) | \forall i : x_i \in \mathcal{P}(n^3, s),& \\ x_i \textit{ is written in sorted order}& \\ \wedge \exists i : |\{j | j \neq i; x_i \cap x_j \neq \emptyset\}| \geq s\}.& \end{aligned}$$

Theorem 6.4. *Every nondeterministic formula with s nondeterministic bits for $AD_{n,20s}$ has length at least $\Omega(n^2 s \log n)$.*

$AD_{n,s}$ can be computed by a nondeterministic formula of length $O(ns^2 \log n)$, which uses $O(s \log n)$ nondeterministic bits (for $s \geq \log n$).

Proof. For the lower bound we use the methodology we have just described. We consider the $n+1$ partitions of the inputs, in which Bob receives the set x_i and Alice all other sets. The function they have to compute now is the function $DI_{n,s}$ from Definition 5.3. In Theorem 5.5 a lower bound of $\Omega(ns \log n)$ is shown for this problem; hence the length of the formula is $\Omega(n \cdot ns \log n)$.

For the upper bound we proceed as follows: The formula guesses (in binary) a number i with $1 \leq i \leq n+1$ and pairs $(j_1, w_1), \dots, (j_s, w_s)$, where $1 \leq j_k \leq n+1$ and $1 \leq w_k \leq n^3$ for all $k = 1, \dots, s$. The number i indicates a set, and the pairs are witnesses that set i and set j_k intersect on element w_k.

The formula does the following tests. First there is a test of whether all sets consist of s sorted elements. For this ns comparisons of the form $x_i^j < x_i^{j+1}$ suffice, which can be realized with $O(\log^2 n)$ gates each. Since $s \geq \log n$ overall $O(ns^2 \log n)$ gates are enough.

The next test is whether $j_1 < \cdots < j_s$. This makes sure that witnesses for s different sets have been guessed. Also $i \neq j_k$ for all k must be tested.

Then the formula tests whether for all $1 \leq l \leq n+1$ the following holds: If $l = i$, then all guessed elements are in x_l; if $1 \leq l \leq n+1$ and $1 \leq k \leq s$, the formula also tests, whether $l = j_k$ implies, that $w_k \in x_l$.

All of these tests can be done simultaneously by a formula of length $O(ns^2 \log n)$. □

For $0 < \epsilon \leq 1/2$ let $s = n^{\frac{\epsilon}{1-\epsilon}}$; then the lower bound for limited nondeterministic formulas is $\Omega(N^{2-\epsilon}/\log^{1-\epsilon} N)$, with $N^\epsilon/\log^\epsilon N$ nondeterministic bits allowed. $O(N^\epsilon \log^{1-\epsilon} N)$ nondeterministic bits suffice to construct a formula having length $O(N^{1+\epsilon}/\log^\epsilon N)$. Hence the threshold for constructing an efficient formula is polynomially large, allowing an exponential number of computations on each input.

6.2. Quantum formulas. Now we derive the lower bound for generalized quantum formulas. Roychowdhury and Vatan [37] consider pure quantum formulas (recall these are quantum formulas which may not access multiply readable random bits). Their result is as follows.

FACT 6.5. *Every pure quantum formula computing a function f with a bounded error has length*

$$\Omega\left(\sum_i D(f_i)/\log D(f_i)\right)$$

for the Nečiporuk function $\sum_i D(f_i)$; see Fact 3.1 *and Definition* 3.4.

Furthermore in [37] it is shown that pure quantum formulas can be simulated efficiently by deterministic circuits.

Now we know from section 3.2 that the Boolean function MP with $O(n^2)$ inputs (the matrix product function) has fair probabilistic formulas of linear size $O(n^2)$, while the Nečiporuk bound is cubic (Theorems 3.11 and 3.12). Thus we get the following.

COROLLARY 6.6. *There is a Boolean function MP with N inputs, which can be computed by fair one-sided error formulas of length $O(N)$, while every pure quantum formula with a bounded error for MP has size $\Omega(N^{3/2}/\log N)$.*

We conclude that pure quantum formulas are not a proper generalization of classical formulas. A fair probabilistic formula can be simulated efficiently by a generalized quantum formula, on the other hand. We now derive a lower bound method for generalized quantum formulas. First we give again a lower bound in terms of one-way communication complexity, and then we show that the VC–Nečiporuk bound is a lower bound, too.

This implies with Theorem 3.9 that the maximal difference between the sizes of deterministic formulas and generalized bounded error quantum formulas provable with the Nečiporuk method is at most $O(\sqrt{n})$.

But first let us conclude the following corollary, which states that fair probabilistic formulas reading their random bits only once are sometimes inefficient.

COROLLARY 6.7. *The (standard) Nečiporuk function divided by* $\log n$ *is an asymptotical lower bound for the size for fair probabilistic formulas reading their random inputs only once.*

Proof. We have to show that pure quantum formulas can simulate these special probabilistic formulas. For each random input we use two qubits in the state $|00\rangle$. These are transformed into the state $|\Phi^+\rangle$ by a Hadamard gate. One of the qubits is never used again; then the other qubit has the density matrix of a random bit. Then the probabilistic formula can be simulated. For the simulation of gates unitary transformations on three qubits are used. These get the usual inputs of the gate simulated plus one empty qubit as input, which after the application of the gate carries the output. These gates are easily constructed unitarily. According to [4] each 3-qubits gate can be composed of $O(1)$ unitary gates on two qubits only. □

We will need the following observation [1].

FACT 6.8. *If the density matrix of two qubits in a circuit (with nonentangled inputs) is not the tensor product of their density matrices, then there is a gate so that both qubits are reachable on a path from that gate.*

Since the above situation is impossible in a formula, the inputs to a gate are never entangled.

The first lower bound is stated in terms of one-way communication complexity. It is interesting that actually randomized complexity suffices for a lower bound on quantum formulas.

THEOREM 6.9. *Let f be a Boolean function on n inputs and $y_1 \dots y_k$ a partition of the input variables in k blocks. Player Bob knows the inputs in y_i, and player Alice knows all other inputs. The randomized (private coin) one-way communication complexity of f (with a bounded error) under this input partition is called $R(f_i)$.*

Every generalized quantum formula for f with a bounded error has length

$$\Omega\left(\sum_i \frac{R(f_i)}{\log R(f_i)}\right).$$

Proof. For a given partition of the input we show how a generalized quantum formula F can be simulated in the k communication games, so that the randomized one-way communication in game i is bounded by a function of the number of leaves in a subtree F_i of F. F_i contains exactly the variables belonging to Bob as leaves, and its root is the root of F. Furthermore F_i contains all gates on paths from these leaves to the root. Note that the additional nonentangled mixed state which the formula may access is given to Alice.

F is a tree of fan-in 2 fan-out 1 superoperators (recall that superoperators are not necessarily reversible). "Wires" between the gates carry one qubit each. F_i is a formula that Bob wants to evaluate, the remaining parts of the formula F belong to Alice, and she can easily compute the density matrices for all qubits on any wire in her part of the formula by a classical computation, as well as the density matrices for the qubits crossing to Bob's formula F_i. Note that none of the qubits on wires crossing to F_i is entangled with another, so the state of these qubits is a probabilistic ensemble of pure nonentangled states. Hence Alice may fix a pure nonentangled state from this ensemble with a randomized choice.

In all communication games Bob evaluates the formula as far as possible without the help of Alice. By an argument as in other Nečiporuk methods (e.g., [7, 37] or the previous sections) it is sufficient to send a few bits from Alice to Bob to evaluate a path with the following property: All gates on the path have one input from Alice and one input from its predecessor, except for the first gate, which has one input from Alice and one (already known) input from Bob. With standard arguments the number of such paths is a lower bound on the number of leaves in the subformula; see section 3.1.

Hence we have to consider some path $g_1, \ldots, g_m$ in F, where g_1 has one input or a gate from Alice as predecessor and an input or gate from Bob as the other predecessor, and all gates g_i have the previous gate g_{i-1} and an input or gate from Alice's part of the formula as predecessors. The density matrix of Bob's input to g_1 is called ρ, and the density matrix of the other m inputs is called σ. The circuit computing σ works on different qubits than the circuit computing ρ.

Thus the density matrix of all inputs to the path is $\rho \otimes \sigma$; see Fact 6.8. The path maps $\rho \otimes \sigma$ with a superoperator T to a density matrix μ on one qubit; alternatively we may view σ as determining a superoperator T_σ on one qubit that has to be applied to ρ. Now Alice can compute this superoperator by herself, classically.

Bob knows ρ. Bob wants to know the state $T_\sigma \rho$. Since this operator works on a single qubit only, it can be described within a precision $1/poly(k)$ by a constant size matrix containing numbers of size $O(\log k)$ for any integer k. Thus Alice may communicate T_σ to Bob within this precision using $O(\log k)$ bits.

In this way Alice and Bob may evaluate the formula, and the error of the formula is changed only by $size_i/poly(k)$ compared to the error of the quantum formula, where $size_i$ denotes the number of gates in F_i. Thus choosing $k = poly(size_i)$ the communication is bounded $R(f_i) \leq O(size_i \log size_i)$. This implies $size_i \geq \Omega(R(f_i)/\log R(f_i))$. Summation over all i yields the theorem. □

The above construction loses a logarithmic factor, but in the combinatorial bounds we actually apply, we can avoid this, by using quantum communication and the programmable quantum gate from Fact 4.20.

THEOREM 6.10. *The VC–Nečiporuk function is an asymptotical lower bound for the length of generalized quantum formulas with a bounded error.*

The Nečiporuk function is an asymptotical lower bound for the length of generalized quantum Las Vegas formulas.

Proof. We proceed similar to the above construction, but Alice and Bob use quantum computers. Instead of communicating a superoperator in matrix form with some precision, we use the programmable quantum gate.

Alice and Bob cooperatively evaluate the formulas F_i in a communication game as before. As before, for certain paths Alice wants to help Bob to apply a superoperator T_σ on a state ρ of his. Using Fact 4.7 we can assume that this is a unitary operator on $O(1)$ qubits (one of them ρ, the others blank) followed by throwing away all but one of the qubits.

This time Alice sends to Bob the program corresponding to the unitary operation in T_σ. Bob feeds this program into the programmable quantum gate, which tries to apply the transformation, and if this is successful, the formula evaluation can continue after discarding the unnecessary qubits. This happens with probability $\Omega(1)$. If Alice could get some notification from Bob saying whether the gate has operated successfully, and if not, what kind of error occurred, then Alice could send him another program that both undoes the error and the previous operator and then makes another attempt to compute the desired operator.

Note that the error that resulted by an application of the programmable quantum gate is determined by the classical measurement outcome resulting in its application. Furthermore this error can be described by a unitary transformation itself. If the error function is E, the desired is unitary is U, and the state it has to be applied to is ρ, then Bob now holds $UE\rho E^\dagger U^\dagger$. Once Alice knows E (which is determined by Bob's measurement outcome), Alice can produce a program for $UE^\dagger U^\dagger$. If Bob applies this transformation successfully, they are done; otherwise, they can iterate. Note that only an expected number of $O(1)$ such iterations are necessary, and hence the expected quantum communication in this process is $O(1)$, too.

So the expected communication can be reduced to $O(size_i)$. But Alice needs some communication from Bob. Luckily this communication does not reveal any information about Bob's input: Bob's measurement outcomes are random numbers without correlation with his input.

So we consider the nonstandard one-way communication model from Lemma 5.13, in which Bob may talk to Alice but without revealing any information about his input. Using this model in the construction and letting Bob always ask explicitly for more programs reduces the communication in game i to $O(size_i)$ in the expected sense.

With Lemma 5.13 we get the lower bounds for a bounded error and Las Vegas communication. □

Now we can give a lower bound for ISA showing that even generalized quantum formulas compute the function not significantly more efficient than deterministic formulas.

Corollary 6.11. *Every generalized quantum formula which computes ISA with a bounded error has length $\Omega(n^2/\log n)$.*

Considering the matrix multiplication function MP, we get the following.

Corollary 6.12. *There is a function, which can be computed by a generalized quantum formula with a bounded error as well as by a fair probabilistic formula with a bounded error, with size $O(N)$. Every generalized quantum Las Vegas formula needs size $\Omega(N^{3/2})$ for this task. Hence there is a size gap of $\Omega(N^{1/2})$ between the Las Vegas formula length and the length of the bounded error formulas.*

Since the VC–Nečiporuk function is a lower bound for generalized quantum formulas, Theorem 3.9 implies that the maximal size gap between deterministic formulas and generalized quantum formulas with a bounded error provable by the (standard) Nečiporuk method is $O(\sqrt{n})$ for input length n. Such a gap actually already lies between generalized quantum Las Vegas formulas and fair probabilistic formulas with a bounded error.

7. Conclusions.

In this paper we have derived lower bounds for the sizes of probabilistic, nondeterministic, and quantum formulas. These lower bounds follow the general approach of reinterpreting the Nečiporuk bound in terms of one-way communication complexity. This is nontrivial in the case of quantum formulas, where we had to use a programmable quantum gate. Nevertheless we have obtained the same combinatorial lower bound for quantum and probabilistic formulas based on the VC dimension.

Using the lower bound methods we have derived a general $\sqrt{n}$ gap between the bounded error and Las Vegas formula size. Another result is a threshold phenomenon for the amount of nondeterminism needed to compute a function, which gives a near-quadratic size gap for a polynomial threshold on the number of nondeterministic bits.

To derive our results we needed lower bounds for one-way communication complexity. These results give gaps between two-round and one-way communication complexity in these models. Those gaps have been generalized to round hierarchies for larger number of rounds in [22] and [25] for the nondeterministic and the quantum cases, respectively. Furthermore we have shown that quantum Las Vegas one-way protocols for total functions are not much more efficient than deterministic one-way protocols. The lower bounds for quantum one-way communication complexity are also useful to give lower bounds for quantum automata and for establishing that only bounded error quantum finite automata can be exponentially smaller than deterministic finite automata [23]. A generalization of the VC-dimension bound on quantum one-way communication complexity is given in [24].

The following problems remain open:

1. Give a better separation between deterministic and probabilistic/quantum formula size (see [21] for a candidate function).
2. Separate the size complexities of generalized quantum and probabilistic formulas for some function.
3. Investigate the power of quantum formulas that can access an entangled state as an additional input, thus introducing entanglement into the model.
4. Separate quantum and probabilistic one-way communication complexity for some total function or show that both are related.
5. Prove superquadratic lower bounds for formulas over the basis of all fan-in 2 gates.

Acknowledgments. The author thanks Gregor Gramlich for a talk on the Nečiporuk method, which inspired this research, Georg Schnitger for stimulating discussions, and the anonymous referees for their detailed suggestions and pointing out an error in an earlier version.

OPTIMAL EXPECTED-CASE PLANAR POINT LOCATION[*]

SUNIL ARYA[†], THEOCHARIS MALAMATOS[‡], DAVID M. MOUNT[§], AND KA CHUN WONG[†]

Abstract. Point location is the problem of preprocessing a planar polygonal subdivision S of size n into a data structure in order to determine efficiently the cell of the subdivision that contains a given query point. We consider this problem from the perspective of expected query time. We are given the probabilities p_z that the query point lies within each cell $z \in S$. The entropy H of the resulting discrete probability distribution is the dominant term in the lower bound on the expected-case query time. We show that it is possible to achieve query time $H + O(\sqrt{H} + 1)$ with space $O(n)$, which is optimal up to lower order terms in the query time. We extend this result to subdivisions with convex cells, assuming a uniform query distribution within each cell. In order to achieve space efficiency, we introduce the concept of entropy-preserving cuttings.

Key words. point location, polygonal subdivision, expected-case complexity, entropy, trapezoidal maps, entropy-preserving cuttings

1. Introduction.

A planar straight-line graph defines a subdivision of the plane into (possibly unbounded) polygonal regions called *cells*. Planar point location is the problem of preprocessing such a polygonal subdivision S so that, given any query point q, the cell containing q can be computed efficiently. Throughout, we let n denote the total *size* of S, defined to be the total number of vertices, edges, and faces of S.

The point-location problem has a considerable history. The first asymptotically worst-case optimal result in the area was Kirkpatrick's elegant method based on hierarchical triangulations [19], which supported query processing in $O(\log n)$ time using $O(n)$ space. This was followed by a number of other optimal methods with better practical performance including the layered directed acyclic graph of Edelsbrunner, Guibas, and Stolfi [13], searching in similar lists by Cole [8], the method based on persistent search trees by Sarnak and Tarjan [25], and the randomized incremental algorithms of Mulmuley [23] and Seidel [26]. The important question of determining the exact constant factor in query time was raised in work by Goodrich, Orletsky, and Ramaiyer [16] and was solved subsequently by Seidel and Adamy [27], who showed

that point-location queries can be answered in $\log_2 n + 2\sqrt{\log_2 n} + o(\sqrt{\log n})$ time and $O(n)$ space. They also provided a nearly matching lower bound.

Adamy and Seidel's results were based on a model of computation, called the *trapezoidal search graph model*, in which the result of the query is based entirely on binary tests called *primitive comparisons*. There are two types of primitive comparisons. The first determines whether the query point q lies to the left or right of a vertical line passing through a vertex of the subdivision. (See Figure 1(a).) The other determines whether the query point lies above or below an edge of the subdivision. This latter comparison is performed only after we have already determined that the x-coordinates of the point lie between the x-coordinates of the endpoints of the edge. (See Figure 1(b).) Note that both comparisons can be expressed as standard *orientation tests* [11] (in 1 or 2 dimensions). Orientation tests form the basis of many algorithms in discrete computational geometry [14]. In particular, all of the point-location algorithms mentioned above are easily formulated in this model. Our main result (Theorem 1 below) assumes this same model of computation.

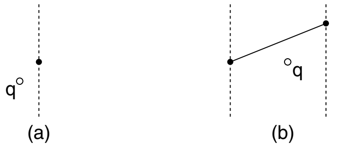

FIG. 1. *Primitive comparisons.*

All the previous results on point location were considered in the context of worst-case query times. In many applications, point-location queries tend to be clustered in regions of greater interest. This raises the question of whether it is possible to use knowledge of the query distribution to achieve better query times in the expected case. We model this by assuming that, for each cell $z \in S$, we are given the probability p_z that a query point lies in z. We call the result a *weighted subdivision.* Unless otherwise stated we make no assumptions about the probability distribution within each cell. To avoid dealing with many special cases, we assume that the probability that the query point lies on an edge or vertex of the subdivision is zero, but this restriction can be overcome, for example, by treating edges and vertices of nonzero probability as cells that have infinitesimal width or extent.

An important concept in characterizing the complexity of the search is the *entropy* of S, denoted throughout as H:

$$entropy(S) \ = \ H \ = \ \sum_{z \in S} p_z \log(1/p_z).$$

(Unless otherwise stated all logarithms are taken in base 2.) It is well known that entropy is maximized when all of the cells have equal probability [10], in which case $H = \log n_2$, where n_2 denotes the number of cells (faces of dimension 2) of S. Conversely, entropy decreases as the disparity among the probabilities increases. Note that entropy may be arbitrarily close to 0. Unlike n, when stating asymptotic bounds, we cannot assume that H is larger than a fixed constant. For this reason, throughout the paper we will follow the convention that the expression "f is $O(g)$" means that there exists a constant c (independent of n and H) such that $f \leq c \cdot g$. Furthermore, we assume throughout that $n \geq n_0$ for some constant n_0.

For the 1-dimensional restriction of this problem, a classical result due to Shannon implies that the expected number of binary comparisons needed to answer such queries is at least as large as the entropy of the probability distribution [20, 28], and clearly this lower bound applies to the 2-dimensional case as well. Mehlhorn [22] showed that it is possible to build a binary search tree whose expected search time is at most $H + 2$. The related problem of computing the binary search tree that minimizes the expected search time is considered in [17, 20].

The idea of using the entropy of the query distribution as the basis for an analysis for geometric data structures is a recent development in computational geometry. Arya and Fu [2] first applied this approach to analyzing the complexity of approximate nearest neighbor queries. Arya et al. [1] then applied this to point location in subdivisions having convex cells. They assumed that the x- and y-coordinates of the query point were chosen independently from some probability distribution. They showed that $O(H + 1)$ expected query time was achievable, where the multiplicative constant factor was a function of the amount of space used. Arya, Malamatos, and Mount [5] presented a simple and practical randomized algorithm that answers queries in $O(H + 1)$ expected time with $O(n)$ space, and Iacono [18] presented a similar deterministic method achieving the same bounds.

In the spirit of prior work on optimal search structures [16, 22, 27], a fundamental question is whether it is possible to achieve the expected query time of H including only additive lower order terms. In our earlier work on this problem [3,4] we presented such data structures, but the space was linear only in special cases, for example, if the cells are axis-parallel rectangles. Otherwise, the space requirements were superlinear, ranging from $O(n \log^* n)$ up to $O(n^{1+\epsilon})$ depending on the nature of the subdivision and assumptions about the probability distribution.

All of the existing solutions fall short of the goal of producing a point-location structure of linear space whose expected query time matches the information-theoretic lower bound of H (up to lower order terms) and which makes no restrictions on the probability distribution within each cell. In this paper we present such a solution. Here is our main result.

Theorem 1. *Consider a polygonal subdivision S of size n consisting of cells of constant combinatorial complexity and a query distribution presented as a weight assignment to the cells of S. In time $O(n \log n)$ it is possible to construct a search structure of space $O(n)$ that answers point-location queries (in the trapezoidal search graph model) in expected time $H + O(\sqrt{H} + 1)$, where $H = entropy(S)$.*

Recall that H may generally be arbitrarily close to 0, which is why the extra "+1" is added to the asymptotic term. Due to our reliance on geometric cuttings of line segments in the plane [7, 16], our construction is randomized, and so the $O(n \log n)$ construction time holds in expectation. Otherwise, our construction runs in $O(n \log n)$ time and is deterministic. Throughout, we make the usual general-position assumption that no two vertices have the same x-coordinate, and thus no edge is vertical. This assumption can be overcome, for example, by standard perturbation methods [14].

The requirement that cells have constant complexity applies only to cells of nonzero probability, since cells of zero probability can be triangulated without affecting the entropy of the subdivision. (This applies to the unbounded external cell of the subdivision as well.) If no assumptions are made about the query distribution, then the assumption that cells have constant cell complexity seems to be critical. In the next section, for example, we show that if the query distribution is arbitrary, then even determining whether a query point lies within a single n-sided convex polygon requires expected time $\Omega(\log n)$, irrespective of entropy. Nonetheless, we show (in

Theorem 2 below) that if we are given a *convex subdivision* (that is, one whose faces are convex) and assume that the query distribution within each cell is *uniform*, then it is possible to answer point-location queries just as efficiently even if the cells have an arbitrary number of sides. In order to handle convex cells it will be necessary to refine the subdivision through the insertion of new edges. For this reason we define the *extended trapezoidal search graph model* to include primitive comparisons involving line segments that are not necessarily part of the original subdivision, but that join two vertices of the original subdivision.

THEOREM 2. *The complexity bounds of Theorem* 1 *apply as well (in the extended trapezoidal search graph model) if S is a weighted convex planar polygonal subdivision such that the query distribution within each cell is uniform.*

In order to provide a formal definition of expected query time in the (standard or extended) trapezoidal search graph model, we begin with a brief discussion of binary space partition trees. Observe that any point-location algorithm that is based on binary comparisons can be modeled abstractly as a decision-tree structure called a *binary space partition* (BSP) [11]. (The search structure that we present is not a proper binary tree, since it allows sharing of substructures, but this affects only the space requirements and not the query time.) For our purposes, a BSP is a rooted binary tree in which each internal node is associated with a line. This line subdivides the plane into two half-planes, one open and one closed, which are then associated with the node's two children. (Since we assume that query points do not fall on edges, the question of which is open and which is closed is not significant.) Each node of a BSP is implicitly associated with a (possibly unbounded) convex polygon, called its *region*, which is the intersection of the half-planes corresponding to the path from the root to this node.

Given a BSP, point-location queries are answered by performing a simple descent in the tree. At each internal node we visit the child corresponding to the half-plane that contains the query point until arriving at a leaf. It is easy to see that the query point lies within the regions associated with each of the nodes along the search path. It follows that the BSP correctly solves the point-location problem if and only if the region associated with every leaf of the tree lies entirely within a single cell of the subdivision. (If the region were to overlap two or more cells, we could not unambiguously determine which of these cells contains the query point.) When the search arrives at a leaf, the associated cell is returned as the answer. Given a query distribution, each leaf of the BSP is associated with the probability that the query point lies within this leaf's region. The *weighted external path length* of a BSP is the weighted average of the depths of all its leaves, where the weight is this probability [20]. We define the *expected query time* of a BSP to be this weighted external path length. An example is shown in Figure 2, where (a) shows the original subdivision, (b) shows the binary space partition induced by three lines L_1, L_2, and L_3 and the associated probabilities with each region, and (c) shows the associated tree. In this case the weighted external path length is $1 \cdot p_1 + 2 \cdot p_2 + 3(p_3 + p_4)$.

The rest of the paper is organized as follows. The next section presents mathematical preliminaries and provides an overview of our approach. In section 3 we present an algorithm for answering point-location queries that is optimal in expected time (up to lower order terms) but suboptimal in space. It answers queries in expected time $H + O(\sqrt{H} + 1)$ and space $O(n^{1+\epsilon})$ for any $\epsilon > 0$. In section 4 we show how to reduce this to $O(n)$ space. We first introduce the notion of entropy-preserving cuttings, and in section 4.1 and section 4.2 we show how to apply this concept to complete the space bound of Theorem 1. Finally, in section 5, we show that these

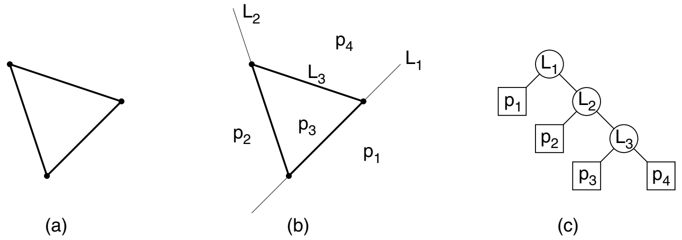

FIG. 2. *BSP and the associated search tree.*

methods can be generalized to convex subdivisions with uniform query distributions within each cell in order to prove Theorem 2.

2. Preliminaries. Consider a weighted subdivision S. Viewing S as a planar graph, let n denote the total numbers of its vertices, edges, and faces (cells), respectively. The (unbounded) external face is also considered a cell. A well-known consequence of Euler's formula is that if this graph is connected, then n is asymptotically bounded by the number of edges of S (see, e.g., [11]). Since the number of edges is clearly a lower bound on the space complexity of any point-location structure, any $O(n)$ space structure is asymptotically optimal with respect to space.

2.1. On subdivisions of unbounded cell complexity. Throughout much of the paper we will concentrate on the case where the cells of S are bounded by a constant number of sides. We will show here why this assumption seems to be critical in the context of achieving query-time bounds based on entropy. Note that this assumption is not required for worst-case optimal planar point location, since it is possible to refine any planar polygonal subdivision into one whose cells have a constant number of sides while increasing the size of the subdivision by just a constant factor. However, we show that if cells have unbounded complexity, even if they are convex, there exist query distributions such that any search structure based on point-line comparisons performs arbitrarily worse than the entropy bound in the expected case.

LEMMA 1. *Given any convex polygon Z with n sides, there exists a discrete query probability distribution such that the probability that a query point lies within Z is $1/2$, and the expected number of point-line comparisons needed to determine whether a point lies within Z is $\Omega(\log n)$.*

Proof. The probability distribution is defined as follows. Let the vertices of Z be $\{v_1, \ldots, v_n\}$. For each vertex v_i we consider two points a_i and b_i placed very close to v_i. The point a_i lies just inside of Z, and b_i lies just outside of Z. The points a_i and b_i all carry a query probability of $1/(2n)$. (See Figure 3.) Observe that the probabilities sum to 1.

Now let Ψ be any BSP that correctly determines membership in Z. Clearly for Ψ to be correct, for each vertex v_i there must be some node of Ψ whose associated line stabs the line segment $\overline{a_i b_i}$, since otherwise both a_i and b_i would lie in the same leaf region, implying that we cannot distinguish between inside and outside in this case. Because Z is convex, we can place the points a_i and b_i sufficiently close to each vertex so that any line can stab at most two such segments. Now consider any node of Ψ. In order to minimize the expected search time, the best that we can hope to accomplish is that the remaining probability in the region is evenly split between the left and right children, implying that, other than the at most two vertices whose

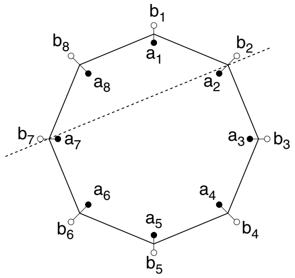

FIG. 3. *The proof of Lemma* 1 *and a stabbing line.*

segments were stabbed, half of the remaining vertices lie on one side of the line and half on the other. It follows easily that $\Omega(\log n)$ such comparisons are needed along any search path of the optimum BSP. □

A convex polygon defines a trivial subdivision consisting of two cells (inside and outside). Irrespective of n, the entropy of the subdivision described in Lemma 1 is easily seen to be 1. Since the query time grows as $\Omega(\log n)$, it is not possible to bound the expected query time purely as a function of entropy. Thus we have the following theorem.

THEOREM 3. *If no restrictions are placed on cell complexity or query distribution, then no search structure based on point-line comparisons can guarantee an expected-case query time that is bounded purely by a function of entropy, even for convex subdivisions.*

2.2. Conditioning the subdivision. If the cells of the subdivision all have constant combinatorial complexity, then we claim that it is possible to condition the problem to bring it into a simpler form without adversely affecting the expected-case query time. Many point-location data structures assume that the subdivision is presented in some canonical subdivision, e.g., a triangulation [19], a monotone subdivision [13], or a trapezoidal map [23,26]. If the cells of S have constant combinatorial complexity, then any of these canonical subdivisions can be realized by refining each cell into at most a constant number of subcells. The most convenient canonical structure for our purposes is a *trapezoidal map.* This is a planar subdivision in which each cell is a trapezoid with vertical parallel sides. These are trapezoids in a general sense and may be unbounded or degenerate to triangles. (To avoid the complexities of unbounded cells, it is common to enclose the entire subdivision in a large bounding rectangle, which contains all the query points.) Any polygonal subdivision can be converted into a trapezoidal map by adding two vertical segments between each vertex and the edges lying immediately above and below it. (See Figure 4.) This can be done in $O(n \log n)$ time either by a straightforward modification of plane sweep [6,11] or through a simple randomized incremental construction [23,26]. (Recall that by our general-position assumption, no segment of the original subdivision is vertical.)

In this section we show that if the initial subdivision has cells of constant complexity, then it is possible to condition the input without significantly affecting the expected-case query time so that it is a trapezoidal map. (The method can be applied to produce any of the other canonical subdivision forms, but this is the one that will be most relevant to our construction.) Before giving a formal statement of the result, we first present a few definitions. Given a planar subdivision S, a *refinement* S^* is a planar subdivision such that each cell of S^* is contained within some cell of

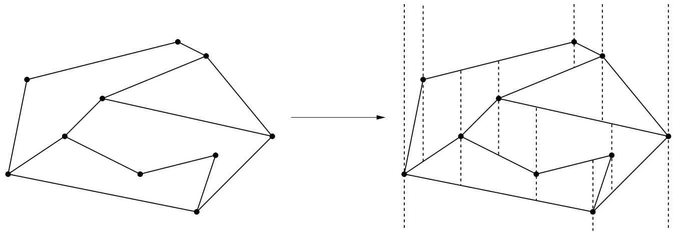

FIG. 4. *A subdivision (left) and its trapezoidal map (right).*

S. Given S and S^*, for each cell $z \in S$, we let $\mathcal{F}_z$ denote the subset of cells of S^* that are contained within z, called its *fragments*. Let $f_z = |\mathcal{F}_z|$ be the number of fragments. We say that S^* has *fragmentation* f if $f_z \leq f$ for all cells z. Clearly answering point-location queries for S can be reduced to answering queries of S^*.

Given a function $g : \mathbb{R}^+ \to \mathbb{R}^+$, we say that a point-location structure Ψ is *g-efficient* for a weighted subdivision S with entropy H if Ψ answers point location queries for S in expected time at most $H + g(H)$. For example, Theorem 1 asserts that it is possible to construct an $O(\sqrt{H} + 1)$-efficient point-location structure. Since the function g is designed to capture the lower order terms of the query-time complexity, it should grow at an asymptotic rate that is less than linear. To make this more formal, we say that a positive function g is *admissible* if for all reals $x, y \geq 0$

- g is subadditive, that is, $g(x + y) \leq g(x) + g(y)$, and
- $g(x)$ is $O(x + 1)$.

It is easy to see that, for any positive constant c, the function $g(H) = c \cdot (\sqrt{H} + 1)$ is admissible.

An important observation about the point-location construction described in Theorem 1 is that it is only given the probability p_z that a query point lies within each cell and knows nothing of the probability distribution within each cell. We say that such a construction is *distribution-oblivious*. It follows that any structure produced by such an algorithm must satisfy its expected-case query-time bound for any choice of the probability distribution within each cell, provided of course that the probability that a point lies within cell z is indeed p_z. This issue arises because in the process of computing the point-location structure we compute a refinement of the original subdivision. We do not know what the query distribution is within the cells of the refined subdivision, and so we cannot compute its expected query time. However, we know that entropy is maximized when all cells have the same probability. Thus, we invent a query distribution by splitting the probabilities evenly among the fragments of each refined cell. We then build an efficient structure for the resulting weighted subdivision using any distribution-oblivious construction. The following result shows formally that this strategy leads to an efficient solution to the original problem, irrespective of the actual query distribution.

LEMMA 2. *Consider a subdivision S and a query distribution on S. Let H denote its entropy. Let S^* be any refinement of S of fragmentation $O(1)$. In $O(n)$ time it is possible to assign nonnegative weights to the cells of S^*, thus producing a weighted subdivision $\widehat{S}$ with the following property. Let Ψ be any g-efficient point-location structure for $\widehat{S}$ produced by a distribution-oblivious construction for an admissible function g. Then Ψ is an $O(g + 1)$-efficient point-location structure for the original subdivision S.*

Before presenting the proof, we show how to apply this result to achieve the desired conditioning. Consider any weighted subdivision S of constant cell complexity and of total size n. In $O(n \log n)$ time we convert this subdivision into a trapezoidal map $\widehat{S}$ through a refinement of fragmentation $O(1)$. Clearly the resulting refinement also has size $O(n)$. Now, we apply the above result to assign weights to this trapezoidal map. Assuming that Theorem 1 holds for trapezoidal maps, it follows that in $O(n \log n)$ time we can construct an $O(\sqrt{H}+1)$-efficient point-location structure Ψ for $\widehat{S}$. By the above result, Ψ can be used as an $O(\sqrt{H}+1)$-efficient point-location structure for the original subdivision S, albeit with a higher constant factor hidden by the "O"-notation.

We devote the remainder of this section to proving Lemma 2. Let S denote the original subdivision of entropy H. Let S^* be a refinement of S of fragmentation f. For each cell z of S, recall that p_z is the probability that the query point lies within z. Also recall that $\mathcal{F}_z$ denotes the set of f_z fragments into which z has been subdivided. For each fragment $y \in \mathcal{F}_z$ there is some probability p_y that the query point lies within y, but the algorithm does not know this probability. Clearly $\sum_{y \in \mathcal{F}_z} p_y = p_z$. Let $H^* = \sum_{z \in S} \sum_{y \in \mathcal{F}_z} p_y \log(1/p_y)$ denote the entropy of this (unknown) distribution.

For the purposes of the proof we need to assign probabilities to the fragments. Since we know that entropy is maximized when probabilities are distributed as evenly as possible, let us split the weight evenly among the fragments by setting $w_y = p_z/f_z$ for each fragment $y \in \mathcal{F}_z$. Since $p_y \le p_z$, and since S^* has fragmentation f, we have $w_y \ge p_y/f$. Clearly $\sum_{y \in \mathcal{F}_z} w_y = p_z$. Let $\widehat{S}$ denote the resulting weighted subdivision, and let

$$\widehat{H} = \sum_{z \in S} \sum_{y \in \mathcal{F}_z} w_y \log \frac{1}{w_y}$$

denote its entropy based on this weight assignment. The assignment can easily be computed in $O(n)$ time. The following lemma asserts that the entropies of all these subdivisions are related to each other, up to an additive term of $\log f$.

Lemma 3. *Given the weighted subdivisions S, S^*, and $\widehat{S}$ defined above, their respective entropies satisfy*

$$H \;\le\; H^* \;\le\; \widehat{H} \;\le\; H + \log f.$$

Proof. To prove the first inequality we observe that if y is a fragment of z, then $p_y \le p_z$ and thus

$$H \;=\; \sum_{z \in S} p_z \log \frac{1}{p_z} \;=\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} p_y \log \frac{1}{p_z} \;\le\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} p_y \log \frac{1}{p_y} \;=\; H^*.$$

The second inequality is an immediate consequence of the fact that entropy is maximized when the probabilities (weights) are equal to each other [10], which is clearly the case for the weight assignment defining $\widehat{H}$. Finally, to prove the last inequality we use the facts that $f_z = |\mathcal{F}_z|$, $\sum_z p_z = 1$, and $f_z \le f$ to obtain

$$\begin{aligned}\widehat{H} = \sum_{z \in S} \sum_{y \in \mathcal{F}_z} w_y \log \frac{1}{w_y} \;&=\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} \frac{p_z}{f_z} \log \frac{f_z}{p_z} \;=\; \sum_{z \in S} p_z \left(\log \frac{1}{p_z} + \log f_z \right) \\ &\le \left(\sum_{z \in S} p_z \log \frac{1}{p_z} \right) + \log f \;=\; H + \log f. \qquad \square\end{aligned}$$

Returning now to the proof of Lemma 2, recall that $\widehat{S}$ is our uniformly weighted refined subdivision. Let Ψ be a g-efficient point-location structure for $\widehat{S}$, which results from a distribution-oblivious construction. Let $\widehat{E}_\Psi$ denote the expected query time for Ψ assuming the weight assignment w_y given above for each cell y of $\widehat{S}$. (Technically, $\widehat{E}_\Psi$ can only be defined relative to a particular probability distribution such that the probability that a query point lies within y is w_y. However, given that the construction is distribution-oblivious, we know that for any choice of such a probability distribution we will have $\widehat{E}_\Psi \leq \widehat{H} + g(\widehat{H})$. Since this is the only assumption we will make about $\widehat{E}_\Psi$ we will tolerate this abuse.)

Because Ψ can be viewed abstractly as a BSP and by the remarks made in section 2.1 on the correctness of BSPs for point location, it follows that the region associated with each leaf cell of Ψ lies within some cell y of $\widehat{S}$. Thus, each fragment y is further decomposed by Ψ into subfragments. Let $\mathcal{F}_y$ denote the subfragments of y, each associated with a leaf of Ψ. (See Figure 5.)

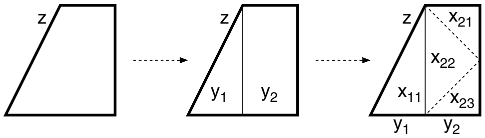

FIG. 5. *Fragments ($\mathcal{F}_z = \{y_1, y_2\}$) and subfragments ($\mathcal{F}_{y_2} = \{x_{21}, x_{22}, x_{23}\}$).*

For each $x \in \mathcal{F}_y$, let p_x denote the (unknown) probability that the query point lies within this subfragment, and let d_x denote its search depth in Ψ, that is, the number of primitive comparisons needed to provide an answer for any query point in x. Since subfragments may have different search depths, we then define the (true) expected search depth for a fragment y of S^* to be

$$D_y = \frac{1}{p_y} \sum_{x \in \mathcal{F}_y} p_x d_x.$$

It follows easily that if we apply Ψ as a point-location structure for the original subdivision S, the expected search time, denoted E_Ψ, is given by summing up the contributions from all the subfragments:

$$E_\Psi \;=\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} \sum_{x \in \mathcal{F}_y} p_x d_x \;=\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} p_y D_y.$$

The values of the p_y's are not known to us, and so we cannot compute D_y. But because Ψ is constructed by a distribution-oblivious algorithm, we know that the upper bound on the expected query time for $\widehat{S}$ holds irrespective of the choice of probability distribution within each of the fragments. We define such a probability distribution for $\widehat{S}$ by allocating weights among the subfragments in exactly the same proportions as their true values. Of course, this is done subject to the constraint that they sum to w_y. We also define the expected depth analogously:

$$w_x \;=\; \frac{p_x}{p_y} w_y \qquad \text{and} \qquad \widehat{D}_y \;=\; \frac{1}{w_y} \sum_{x \in \mathcal{F}_y} w_x d_x.$$

We observe that $\widehat{D}_y$ is equal to its counterpart in the true distribution:

$$\widehat{D}_y \;=\; \frac{1}{w_y} \sum_{x \in \mathcal{F}_y} w_x d_x \;=\; \frac{1}{w_y} \sum_{x \in \mathcal{F}_y} \frac{p_x}{p_y} w_y d_x \;=\; \frac{1}{p_y} \sum_{x \in \mathcal{F}_y} p_x d_x \;=\; D_y.$$

The expected search time $\widehat{E}_\Psi$ under our constructed distribution is

$$\widehat{E}_\Psi \;=\; \sum_{z\in S}\sum_{y\in\mathcal{F}_z}\sum_{x\in\mathcal{F}_y} w_x d_x \;=\; \sum_{z\in S}\sum_{y\in\mathcal{F}_z} w_y \widehat{D}_y.$$

By the obliviousness of Ψ's construction and g-efficiency we have

$$\begin{aligned} g(\widehat{H}) \geq \widehat{E}_\Psi - \widehat{H} \;&=\; \sum_{z\in S}\sum_{y\in\mathcal{F}_z} w_y\widehat{D}_y - \sum_{z\in S}\sum_{y\in\mathcal{F}_z} w_y \log\frac{1}{w_y} \\ &= \sum_{z\in S}\sum_{y\in\mathcal{F}_z} w_y\left(\widehat{D}_y - \log\frac{1}{w_y}\right). \end{aligned}$$

From the observation made prior to Lemma 3 that $w_y \geq p_y/f$ and the fact that the probabilities sum to 1, we have

$$\begin{aligned} g(\widehat{H}) &\geq \sum_{z\in S}\sum_{y\in\mathcal{F}_z} \frac{p_y}{f}\left(\widehat{D}_y - \log\frac{f}{p_y}\right) = \frac{1}{f}\sum_{z\in S}\sum_{y\in\mathcal{F}_z} p_y\left(\widehat{D}_y - \log\frac{1}{p_y} - \log f\right) \\ &= \frac{1}{f}\left(\left(\sum_{z\in S}\sum_{y\in\mathcal{F}_z} p_y\left(\widehat{D}_y - \log\frac{1}{p_y}\right)\right) - \log f\right). \end{aligned}$$

Next, we multiply both sides by f and add $\log f$, and then apply the substitution $\widehat{D}_y = D_y$ and the definitions of E_Ψ and H^* to obtain

$$f\cdot g(\widehat{H}) + \log f \;\geq\; \sum_{z\in S}\sum_{y\in\mathcal{F}_z} p_y\left(D_y - \log\frac{1}{p_y}\right) \;=\; E_\Psi - H^*.$$

Now, from Lemma 3 we know that $H^* \leq \widehat{H} \leq H + \log f$. Since g is admissible, it is also subadditive. Combining this with the fact that the fragmentation f is a constant, we obtain

$$\begin{aligned} E_\Psi - H \leq E_\Psi - H^* + \log f \;&\leq\; f\cdot g(H+\log f) + 2\log f \\ &\leq f(g(H) + g(\log f)) + 2\log f \qquad \text{(by subadditivity)} \\ &\leq f(g(H) + O(\log f + 1)) + 2\log f \qquad \text{(by admissibility)} \\ &= O(g(H)+1). \end{aligned}$$

This implies that Ψ is $O(g+1)$-efficient as a point-location structure for S, and so completes the proof of Lemma 2.

In conclusion, we can condition our input subdivision into a trapezoidal map so that the impact of this conditioning on the expected-case query time is to increase the constant factor of the lower order terms. This conditioning has a nice side benefit. Recall from the introduction that the entropy H of the input subdivision may generally be arbitrarily close to zero, but it does not make sense to talk about query times that are smaller than 1. As mentioned after the statement of Theorem 1, we therefore suffer the notational inconvenience of carrying an extra term of "$+1$" in all our complexity bounds. We claim that we can avoid this inconvenience henceforth because the entropy $\widehat{H}$ of the trapezoidal map is at least 1. To see this, observe that every bounded cell of the initial subdivision has at least three sides and thus will be subdivided by a vertical line into at least two trapezoids. Our construction distributes the probability evenly among the fragments of a cell, and so it follows that for all fragments z in the final subdivision we have $w_z \leq 1/2$. Therefore, because the sum of fragment weights is 1, the entropy of the resulting trapezoidal map is

$$\widehat{H} \;=\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} w_y \log(1/w_y) \;\geq\; \sum_{z \in S} \sum_{y \in \mathcal{F}_z} w_y \;=\; 1,$$

as desired.

2.3. Overview of our methods. Before presenting our algorithms we provide an overview of our methods. Our point-location data structure is based on many of the same methods used in the construction of worst-case efficient point-location structures, particularly the methods given by Preparata [24] and Seidel and Adamy [27]. Establishing efficient expected query time involves considerably different techniques from worst-case query time. As mentioned above, a point-location data structure that is based on linear comparisons can be viewed abstractly as a BSP. What properties must the associated partition tree possess in order to answer point-location queries efficiently on average? Observe that since the expected query time is the tree's weighted external path length, the contribution of each leaf to the expected query time is its tree depth times its probability. The probability that the query point lies in the region associated with a leaf is not known exactly, since we are not given the query distribution within each cell. Our strategy will be to construct a tree in which the depth of any leaf generated from a cell $z \in S$ is close to $\log(1/p_z)$.

As we shall see this will lead to a method, which while optimal with respect to expected-case query time, is not optimal with respect to space. In particular our best upper bound on space is superlinear in n. (See Theorem 4 below.) To reduce the storage further we employ a common strategy in computational geometry, called cuttings. Given a subdivision S with m edges, and a parameter $r \geq 1$, a $(1/r)$-*cutting* [7] is a partition of the plane into $O(r)$ trapezoids such that the interior of each trapezoid is intersected by at most m/r edges of S. If numeric weights are assigned to the edges, then this can be generalized to a *weighted* $(1/r)$-*cutting*, where now the total weight of edges intersecting any trapezoid is at most W/r, where W is the total weight of all the edges. Goodrich, Orletsky, and Ramaiyer [16] and later Seidel and Adamy [27] applied cuttings in a divide-and-conquer manner to produce the most space-efficient data structure.

Cuttings cannot be applied directly in our case, however, since the partitioning process may refine the subdivision in a way that significantly increases its entropy, and this increases the expected query time. An important contribution of this paper is the notion of an *entropy-preserving cutting*, which additionally ensures that the entropy of the subdivision is increased by at most an additive constant. This will be presented in section 4. Our approach will be to apply entropy-preserving cuttings to build a two-level search structure. For the first level we construct an entropy-preserving cutting of an appropriately chosen size and build the initial point-location structure described in section 3 for the cutting. This achieves good expected-case query time but leaves a number of regions to search. We show that the probability that the query point lies within any of these remaining regions is so small that a relatively sloppy worst-case optimal point-location algorithm suffices to achieve our desired results.

Extending these results to convex subdivisions with uniform query distributions involves a simple refinement step. Each convex cell is triangulated by a process that extracts a triangle whose area is a constant fraction of the total area, and then recurses on each of the three resulting fragments. We show that if the query distribution is uniform, then the increase in entropy in the resulting refined subdivision is at most an additive constant.

3. Initial solution.

In this section we present an algorithm for answering point-location queries that is optimal in expected time but suboptimal in space. Recall that from the results of section 2 we may assume that the subdivision S is presented as a weighted trapezoidal map of nonvertical segments and its entropy H is at least 1.

THEOREM 4. *Given a trapezoidal map S of size n, together with probabilities p_z that a query point lies within each cell z, we can build a data structure that answers point-location queries in expected query time*

$$H + 2\sqrt{2H} + \frac{1}{2}\log H + O(1),$$

where H is the entropy of S. The space for the data structure is

$$O\left(n2^{\sqrt{2H}}\frac{1}{\sqrt{H}}\log n\right).$$

Other than the probabilities p_z we make no assumptions about the query probability distribution within each cell. Recall that $1 \leq H \leq \log n$. It is easy to verify that $2^{\sqrt{2H}}/\sqrt{H}$ increases monotonically for $H \geq 1/(\sqrt{2}\ln 2)^2 \approx 1.04$, and so the space is maximized when $H = \log n$. Thus, the space is at most $O(n2^{\sqrt{2\log n}}\sqrt{\log n})$, which is $O(n^{1+\epsilon})$ for any $\epsilon > 0$. The preprocessing time is $O(N + n\log n)$, where N is the total space of the data structure. Thus the asymptotic preprocessing time is dominated by the above space bound.

3.1. Construction of the search tree.

As mentioned earlier, our data structure is based on constructing a BSP Ψ for S. Before building the tree we map the cell probabilities to an assignment of *weights* to the vertices of the subdivision as follows. Recall that n is the combinatorial complexity of S. For each trapezoid $z \in S$, we assign a weight of $w_z/4$ to each of its (at most four) corner vertices, where

$$w_z = \frac{1}{2}\max\left(p_z, \frac{1}{n}\right).$$

(See Figure 6.) If a vertex is a corner of multiple trapezoids, then its weight is the sum of the contributions from all such trapezoids. It is easy to see that the total weight of all the trapezoids is at most 1, and this holds as well for the total weight of all the vertices. The $1/n$ term in the definition of the weight will be important in limiting the fragmentation of cells of very small probability. This in turn will be needed to establish our space bounds.

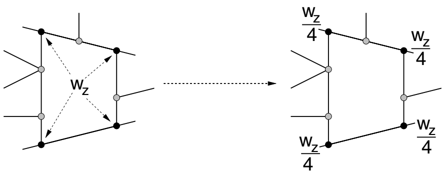

FIG. 6. *Assignment of weights.*

The tree Ψ is built recursively in a top-down fashion. Each node u of Ψ will be associated with a trapezoidal region, denoted Δ_u. We define the *weight* of a region to be the sum of the weights of the subdivision vertices in the interior of the region, and we define the *weight* of a node u to be the weight of Δ_u. The construction is based on a recursive process, which is broken into *stages*. Each stage replaces an existing leaf node whose associated region overlaps two or more cells of S with a new subtree. Let us consider one such stage. Suppose that we are working on the subdivision contained within a trapezoid Δ_u associated with some node u. (Initially u is the root of the tree and Δ_u is the entire space.) Let w_u denote u's weight. (For example, in the upper left of Figure 7(a) w_u is the sum of the weights of the black and gray vertices lying in the interior of the trapezoid Δ_u.) We split Δ_u into two vertical *slabs*, by passing a vertical line through a subdivision segment endpoint, such that the weight of each slab is at most $w_u/2$. We repeat this for t levels, where $t \geq 1$ is a suitable parameter (to be fixed later), each time ensuring that the sum of the weights is halved. This partitioning can be represented in a natural way by a balanced tree having up to 2^t leaves, representing the 2^t vertical slabs. (There may in fact be fewer, since some slabs may contain no interior vertices before the splitting process ends.)

After this, each slab is further partitioned into trapezoids by the segments of the subdivision that completely cross it. (See Figure 7(b).) Following Seidel and Adamy [27], we build a weighted search tree [22] for each slab. There is a technical difficulty, however. A trapezoid that contains no vertices in its interior (called an *empty trapezoid*) has a weight of 0, and so we cannot reasonably bound its depth in the tree. To handle this the weighted search tree is based on the following set of *adjusted weights*. The adjusted weight of a nonempty trapezoid is just its weight, that is, the sum of weights of its interior vertices. The adjusted weight of an empty trapezoid cell is defined to be $w_z/(h2^t)$, where z is the trapezoid of S that contains this cell, and where $h \geq 1$ is a suitable parameter (to be fixed later). (See Figure 7(b).) After building the weighted search tree for the trapezoids of each slab, we recurse on each of the nonempty trapezoids. The process ends when there are no nonempty trapezoids.

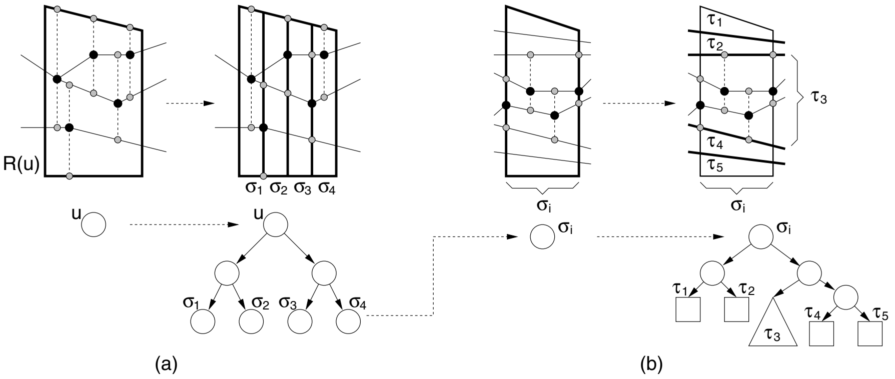

FIG. 7. *Construction of the initial search structure for $t = 2$.*

For the purpose of analysis, it is convenient to view this partitioning scheme as a *multiway tree* as follows. Each stage involves splitting a trapezoid u into 2^t vertical slabs, each of which is then partitioned into smaller trapezoids. In the multiway tree, there is a node representing trapezoid u, which is made the parent of the nodes representing these smaller trapezoids. Let Ψ' denote this multiway tree. Note that each node of Ψ' corresponds to a unique node of Ψ and represents the same region.

This construction can be implemented efficiently as follows. We assume that we maintain the following for each node u:

(i) $S_u = S \cap \Delta_u$ (i.e., the original subdivision S clipped to within Δ_u), and

(ii) a list of the vertices of S that lie within the interior of Δ_u and their associated weights, sorted according to their x-coordinates.

We assume that S_u is represented in a manner that supports efficient processing and traversal, say as a *doubly connected edge list* (DCEL) [11]. We also assume that there are cross links between each vertex of the sorted list and its corresponding vertex of the DCEL. This information can be computed for the root of the tree in $O(n \log n)$ time. Let us also define T_u to be the set of (unclipped) trapezoids of S that intersect the interior of Δ_u. Thus each (clipped) trapezoid $z' \in S_u$ arises by intersecting some (unclipped) trapezoid $z \in T_u$ with Δ_u.

Now consider the single-stage construction for a fixed internal node u of the multiway tree. Let n_u denote the combinatorial complexity of S_u. Let m_u denote the total number of empty and nonempty trapezoids that result from one stage of the construction or, equivalently, the total number of nodes in all the weighted trees for all of u's slabs. In $O(n_u)$ time it is possible to scan the sorted vertex list from left to right, to generate the (up to) 2^t slabs with the desired weights. We then cut S_u into slabs by tracing along each of the $2^t - 1$ vertical lines that define the slab boundaries. Because each cell of S_u is of constant combinatorial complexity, by standard results on DCELs [11] we can do this in $O(1)$ time for each intersection between a segment of S_u and a cutting line. The overall time is $O(m_u)$. As we are cutting out each slab, we note which of the segments of S cut clear through the slab. From this information we can determine which of the resulting trapezoids are empty and which are nonempty. Then, for each nonempty trapezoid, we can construct the DCEL representation of the subdivisions lying within the trapezoid in time proportional to its size. This takes time $O(n_u)$ when summed over all the nonempty trapezoids. After this the subdivisions are ready for the next recursive step.

Next we consider how to update the sorted vertex list. Consider each nonempty trapezoid τ_i. We traverse the associated subdivision and, for each vertex lying in the interior of the trapezoid, we access the cross link to the sorted list and label the associated list entry with the integer i. Through the use of any stable integer sorting algorithm (e.g., counting sort [9]) we sort these labels in $O(n_u)$ time. By collecting adjacent entries with the same label, we can partition the sorted vertex lists among the various nonempty trapezoids, while maintaining the sorted order, all in $O(n_u)$ time.

Thus, the total processing time for node u is $O(n_u + m_u)$. The sum of the m_u terms over all the nodes is essentially equal to the number of nodes of Ψ', which is bounded above by the total number of nodes of Ψ. Because each subdivision vertex appears in the region associated with at most one node at each level of Ψ', the sum of the n_u terms for each level is $O(n)$. In Lemma 4 below we show that the number of levels in Ψ' is at most $(1/t)\log n + 5$. Therefore the overall construction time is $O(N + n \log n)$, where N is the total number of nodes in the tree. We will bound N later in Lemma 5.

3.2. Analysis of the space and query time. We now analyze the space and expected query time as a function of the parameters t and h. For a node u of Ψ, let p_u denote the probability of the query point lying in its associated region Δ_u (or, equivalently, the probability of visiting u during point location). Recall that w_u denotes the weight of all the vertices in the interior of Δ_u. The following lemma bounds the number of levels in multiway tree Ψ'.

LEMMA 4. *The number of levels in* Ψ' *is at most* $(1/t)\log n + 5$.

Proof. Consider any path in the multiway tree Ψ' descending from the root to a leaf. Along any edge that leads from one internal node to another the weight decreases by a factor of at least 2^t. Since the weight of the root is at most 1, the weight of any internal node u at level i of Ψ' is at most $1/2^{t(i-1)}$. Since u is internal, it must contain the corner vertex of some trapezoid z in its interior. Recall that the weight of each of the corner vertices of trapezoid z is at least $w_z/4$ (more if it is a corner of multiple trapezoids). It follows that

$$\frac{1}{2^{t(i-1)}} \geq \frac{w_z}{4}.$$

Simplifying this gives

$$i \;\leq\; \frac{1}{t}\left(\log\frac{1}{w_z} + \log 4\right) + 1 \;\leq\; \frac{1}{t}\log\frac{1}{w_z} + 3.$$

Since $w_z \geq 1/(2n)$ it follows that the level of any internal node is at most $(1/t)\log n + 4$, and the number of levels is higher by 1. ◻

Using this, we can bound the total size of the tree.

LEMMA 5. *The total number of nodes of* Ψ *is at most* $O(n2^t((\log n)/t + 1))$.

Proof. Consider any trapezoid z of S. We first show that the number of leaves of Ψ generated by z is at most

$$4 \cdot 2^t \left(\frac{1}{t}\log n + 4\right).$$

It follows from our construction that any internal node of the multiway tree Ψ' that overlaps the interior of z must contain at least one of the four corner vertices of z. Thus, there are at most four such internal nodes at any level of Ψ'. (In fact, a more careful analysis shows that there are at most two such nodes, one for the left side and one for the right side.) From the proof of Lemma 4 it follows that the total number of internal nodes of Ψ' that overlap the interior of z is at most $4((1/t)\log n + 4)$. Since any node of Ψ' can have at most 2^t children that overlap the interior of z, the above bound follows.

By summing this bound over all $O(n)$ trapezoids, the total number of leaves of Ψ is at most $O(n2^t((\log n)/t + 1))$. Since Ψ is binary, the number of internal nodes cannot be larger. ◻

In Lemma 7, we bound the depth of a leaf generated from a trapezoid $z \in S$. To this end, we need the following technical result.

LEMMA 6. *Let* u *be an internal node in the multiway tree* Ψ'. *Let* σ *be any of the* 2^t *vertical slabs into which* Δ_u *is partitioned. Then the total adjusted weight of the weighted search tree corresponding to* σ *is at most* $(w_u/2^t)(1 + 4/h)$.

Proof. Recall that the segments of S partition σ into empty and nonempty trapezoids. Since the weight associated with σ is at most $w_u/2^t$, the total adjusted weight of all the nonempty trapezoids is at most $w_u/2^t$. We will show that the total adjusted weight of the empty trapezoids is at most $4w_u/(2^t h)$, which will complete the proof.

Recall that T_u denotes the set of (unclipped) trapezoids of S that intersect the interior of Δ_u. The construction implies that the trapezoids of T_u have at least one of their four corner vertices in the interior of Δ_u. Since w_u is the sum of the weights of all the vertices in the interior of Δ_u, it follows that $w_u \geq \sum_{z \in T_u} w_z/4$.

Next observe that a trapezoid of T_u can generate at most one empty trapezoid in slab σ. Recall that the adjusted weight of an empty trapezoid generated by trapezoid $z \in S$ is $w_z/(2^t h)$. Thus the total adjusted weight of the empty trapezoids in σ is at most $\sum_{z \in T_u} w_z/(2^t h)$. By the bound on w_u from the previous paragraph, this is at most $4w_u/(2^t h)$. □

The following lemma establishes the essential property given in section 2.3, by showing that the depth of any leaf associated with a cell is proportional to the logarithm of its reciprocal probability.

LEMMA 7. *Let u be a leaf of Ψ generated by any trapezoid $z \in S$. Then the depth of u in Ψ is at most*

$$\log \frac{1}{w_z} + t + \left(2 + \frac{6}{h}\right) \frac{1}{t} \log \frac{1}{w_z} + \log h + O(1).$$

Proof. Let $P = u_1, u_2, \ldots, u_\ell$ be the path from the root to the leaf $u = u_\ell$ in the multiway tree Ψ'. Recall that each node of Ψ' corresponds to a unique node of Ψ. Consider a fixed i, $1 \le i < \ell$. Let σ denote the vertical slab in Δ_{u_i} that contains the trapezoid associated with u_{i+1}, and let v denote the node of Ψ corresponding to σ. To prove the lemma, we will separately bound the length of the paths in Ψ from u_i to v and from v to u_{i+1}. By construction, the length of the path in Ψ from u_i to v is at most t.

To bound the length of the path in Ψ from v to u_{i+1}, recall that u_{i+1} is a leaf in the weighted search tree for slab σ. By standard results on weighted search trees [22], the length of the path in Ψ from v to u_{i+1} is at most $\log(W/w) + 2$, where W is the total adjusted weight of all the trapezoids in slab σ and w is the adjusted weight of the trapezoid associated with u_{i+1}. By Lemma 6, $W \le (w_{u_i}/2^t)(1 + 4/h)$. We now consider two cases: (i) $1 \le i \le \ell - 2$ and (ii) $i = \ell - 1$. In the first case, u_{i+1} is a nonempty trapezoid, so its adjusted weight w is the same as its weight $w_{u_{i+1}}$. Thus, the length of the path in Ψ from v to u_{i+1} is at most

$$\log\left(\frac{(w_{u_i}/2^t)(1+4/h)}{w_{u_{i+1}}}\right) + 2 \;=\; (\log w_{u_i} - \log w_{u_{i+1}}) - t + \log\left(1 + \frac{4}{h}\right) + 2.$$

In the second case, $u_{i+1} = u_\ell$ is an empty trapezoid, so its adjusted weight w is $w_z/(2^t h)$. Thus, the length of the path in Ψ from v to u_ℓ is at most

$$\log\left(\frac{(w_{u_{\ell-1}}/2^t)(1+4/h)}{w_z/(2^t h)}\right) + 2 \;=\; (\log w_{u_{\ell-1}} - \log w_z) + \log h + \log\left(1 + \frac{4}{h}\right) + 2.$$

By using the above claim to bound the lengths of the paths in Ψ between adjacent pairs of vertices in P, the fact that $w_{u_1} \le 1$, and summing and cancelling the telescoping probability terms, it is easy to see that the depth of u in Ψ is at most

$$\log \frac{1}{w_z} + t + \left(2 + \log\left(1 + \frac{4}{h}\right)\right)(\ell - 1) + \log h. \tag{1}$$

Recall the trapezoid z in the statement of the lemma. Since $u_{\ell-1}$ must contain at least one of the corner vertices of trapezoid z, it follows that $w_{u_{\ell-1}} \ge w_z/4$. Also, since the weight of a node at level i is at most $1/2^{t(i-1)}$, we have $w_{u_{\ell-1}} \le 1/2^{t(\ell-2)}$. Thus,

$$\ell - 2 \;\le\; \frac{1}{t} \log \frac{1}{w_{u_{\ell-1}}} \;\le\; \frac{1}{t}\left(\log \frac{1}{w_z} + \log 4\right) \;\le\; \frac{1}{t}\left(\log \frac{1}{w_z} + 2\right).$$

Substituting this value of ℓ into (1) and using the facts that $\log(1 + 4/h) < 6/h$, $h \geq 1$, and $t \geq 1$, we obtain the bound on the depth of u given in the statement of the lemma. $\square$

We can now bound the expected query time.

LEMMA 8. *The expected query time using the BSP Ψ is at most*

$$H + t + \left(2 + \frac{6}{h}\right)\frac{H}{t} + \log h + O(1).$$

Proof. For any trapezoid $z \in S$, let $\mathcal{L}_z$ denote the set of leaves generated by z. The expected query time is given by

$$\sum_{z\in S}\sum_{u\in\mathcal{L}_z} p_u d_u,$$

where p_u denotes the probability that the query point lies in the region associated with node u, and d_u denotes the depth of u. By applying Lemma 7 it follows that this sum is at most

$$\sum_{z\in S}\sum_{u\in\mathcal{L}_z} p_u \left[\log\frac{1}{w_z} + t + \left(2 + \frac{6}{h}\right)\frac{1}{t}\log\frac{1}{w_z} + \log h + O(1)\right].$$

Using the facts that $\sum_{u\in\mathcal{L}_z} p_u = p_z$ and $\sum_{z\in S} p_z = 1$, this is at most

$$\left(\sum_{z\in S} p_z \log\frac{1}{w_z}\right) + t + \left(2 + \frac{6}{h}\right)\frac{1}{t}\left(\sum_{z\in S} p_z \log\frac{1}{w_z}\right) + \log h + O(1).$$

Noting that $w_z \geq p_z/2$, $h \geq 1$, and $t \geq 1$, we obtain the desired bound. $\square$

In order to obtain the best bound on the expected query time, we choose $t = \lceil\sqrt{2H}\rceil$ and $h = \sqrt{H}$ in Lemma 8. This yields an expected query time of at most

$$H + 2\sqrt{2H} + \frac{1}{2}\log H + O(1).$$

Using Lemma 5 and noting that t is at most $O(\sqrt{\log n})$, we obtain a bound on the space of

$$O\left(n2^{\sqrt{2H}}\frac{\log n}{\sqrt{H}}\right).$$

This completes the proof of Theorem 4.

Remark. By setting $t = \lceil\sqrt{2H}\rceil + c$, where c is a fixed positive integer and $h = \sqrt{H}$, it is easy to see from Lemma 7 that the maximum depth in the search tree, that is, the worst-case query time, is $(1 + O(1/c))\log n$. Simultaneously, the bound on expected performance given by Theorem 4 also holds.

Remark. For the next section on entropy-preserving cuttings, it will be necessary to derive a bound on query times that is sensitive to the cell containing the query point. The following lemma establishes this for us.

LEMMA 9. *We are given a trapezoidal map S of size n, together with a nonnegative weight w_z for each cell $z \in S$, such that $\sum_{z\in S} w_z \leq 1$, and a real parameter* $1 \leq B \leq$

$\sqrt{\log n}$. Then we can build a data structure that answers point-location queries for each cell $z \in S$ in time

$$\left[1 + O\left(\frac{1}{B}\right)\right] \log \frac{1}{w_z} + O(B).$$

The space and preprocessing time for the data structure are $O(n2^{\sqrt{2\log n}}\sqrt{\log n})$.

Proof. Let $h = B$ and $t = \lceil B\sqrt{2}\rceil$. From Lemma 7 it follows that the time to locate a query point in any cell z of S is at most

$$\begin{aligned}\log \frac{1}{w_z} + t + \left(2 + \frac{6}{h}\right)\frac{1}{t}\log\frac{1}{w_z} + \log h + O(1)\\ &= \left[1 + \frac{1}{t}\left(2 + \frac{6}{h}\right)\right]\log\frac{1}{w_z} + (t + \log h + O(1))\\ &= \left[1 + O\left(\frac{1}{B}\right)\right]\log\frac{1}{w_z} + O(B),\end{aligned}$$

as desired.

From Lemma 5, the total number of nodes of Ψ is at most

$$O\left(n2^t\left(\frac{\log n}{t} + 1\right)\right) \;=\; O\left(n2^{B\sqrt{2}}\left(\frac{\log n}{B} + 1\right)\right).$$

For $B \geq 1/(\sqrt{2}\ln 2) \approx 1.02$, it is easy to verify that $2^{B\sqrt{2}}/B$ is an increasing function of B, and since $B \leq \sqrt{\log n}$, it follows that the space is at most

$$O\left(n2^{\sqrt{2\log n}}\left(\frac{\log n}{\sqrt{\log n}} + 1\right)\right) \;=\; O\left(n2^{\sqrt{2\log n}}\sqrt{\log n}\right).$$

Recall that the preprocessing time is $O(N + n\log n)$, where N is the total space of the data structure. Thus the preprocessing time is dominated by the above space bound. This completes the proof. □

4. Entropy-preserving cuttings.

Although the query time given in Theorem 4 is as desired, the space bound is still superlinear in n. In this section we introduce the notion of an entropy-preserving cutting, that is, a cutting that ensures that the entropy of the subdivision is increased by at most an additive constant. Then, in sections 4.1 and 4.2 we will see how to apply this idea to reduce the space to linear.

Recall that we are given a subdivision S, presented to us as a weighted trapezoidal map of a set X of nonvertical segments, whose entropy H is at least 1. The results of the previous section provide optimal expected query time (up to lower order terms), but the space required is superlinear in n. In this section we show how to apply the well-known notion of cuttings in the expected-case setting to produce a structure of linear space. Suppose that each $x \in X$ is associated with a positive weight w_x. Let $W = \sum_{x\in X} w_x$ denote the total weight. Consider a positive parameter r. For our purposes we define a $(1/r)$-*cutting* of X to be a partition of the plane into trapezoids (in general these are canonical shapes of constant combinatorial complexity) such that the total weight of the segments of X that intersect the interior of any trapezoid is at most W/r. It is known that it is possible to compute such a cutting of size $O(r)$ in $O(n\log n)$ time by a randomized algorithm, and it can be computed deterministically in polynomial time [7, 16]. The construction also provides for each trapezoid of the cutting the set of segments that intersect this trapezoid. Furthermore, this construction has the property that each trapezoid in this cutting is bounded from above and below by a subsegment of some segment of X. (See Figure 8.)

The point-location construction of the previous section was based primarily on an assignment of weights to the vertices of S. Our approach here will involve a similar assignment of weights to the segments of X. For each cell $z \in S$, recall that p_z denotes the probability that the query point lies within z, and that we make no other assumptions about the query distribution within a cell.

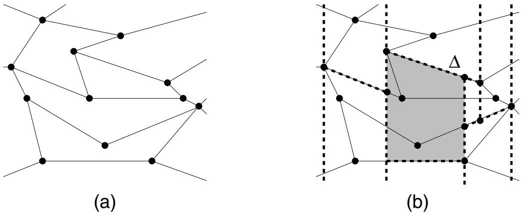

FIG. 8. *A set X of segments* (a) *and a cutting of X (shown with broken lines) and a cell of the cutting (shaded)* (b).

Each trapezoid of S can be associated by a subset of at most four *defining segments* of X, which together define its four sides. These are the segments defining the trapezoid's upper and lower sides, any segment whose endpoint lies on its left vertical side, and any segment whose endpoint lies on its right vertical side. (These segments are indicated with an asterisk in Figure 9.) We begin by assigning weights to the segments of X as follows. For each trapezoid $z \in S$, we assign a weight of $w_z/4$ to each of its defining segments, where

$$w_z = \frac{1}{2}\max\left(p_z, \frac{1}{n}\right).$$

If a segment is a defining segment of multiple trapezoids, then its weight is the sum of the contributions from all such trapezoids. Note that the total weight of all the segments is at most 1.

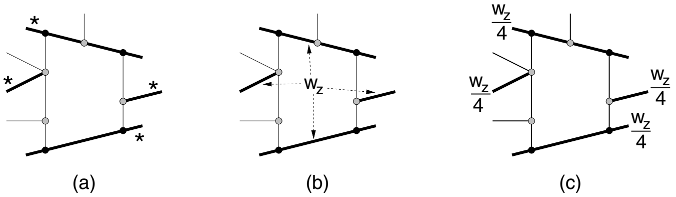

FIG. 9. *Defining segments* (a) *and the weight distribution (*(b) *and* (c)*).*

We next present our construction of entropy-preserving cuttings. Using the weight assignment w_x defined above, we compute a standard weighted $(1/r)$-cutting for X. As mentioned at the start of this section, such a cutting has size $O(r)$ and can be computed in $O(n \log n)$ time. Furthermore, each trapezoid of this cutting is bounded from above and below by a subsegment of some segment of X. Let $\mathcal{C}^*$ denote this cutting.

We modify the cutting $\mathcal{C}^*$ by applying the following procedure on each trapezoid $z \in S$. If a trapezoid of the cutting lies within z, then by the properties of the cutting, this trapezoid is bounded from above and below by the same segments that bound z from above and below. Thus, any adjacent trapezoids of the cutting that are contained within z must be separated from each other by a vertical line segment, and hence a collection of adjacent cutting trapezoids within z occurs as a contiguous sequence. If z contains such a contiguous sequence of trapezoids of $\mathcal{C}^*$, we merge each such maximal subsequence into a single trapezoid. (See Figure 10.) Since no segment of X intersects the interior of the merged trapezoid, it follows that $\mathcal{C}$ also satisfies the properties of a weighted $(1/r)$-cutting. Let $\mathcal{C}$ denote this new cutting, and let S^* denote the subdivision formed by superimposing $\mathcal{C}$ on S. In Lemma 11, we will establish the key properties enjoyed by $\mathcal{C}$. In particular, we will show that $\mathcal{C}$ is entropy-preserving; that is, the entropy of S^* exceeds the entropy of S by at most a constant.

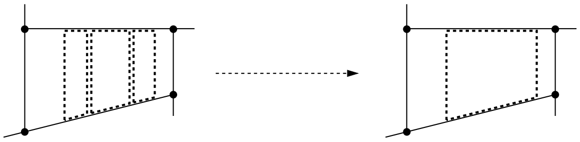

FIG. 10. *Merging contiguous trapezoids of the cutting.*

Clearly, the cells of S^* are trapezoids; we use the term *fragments* to refer to these cells. We distinguish between two types of fragments. Consider a fragment u that arises from the intersection of a cutting cell Δ and a subdivision cell z. If $\Delta \subseteq z$, we call it a *type*-1 *fragment*; otherwise it is a *type*-2 *fragment*. Let $\mathcal{F}_z, \mathcal{F}'_z$, and $\mathcal{F}''_z$ denote the set of all fragments, type-1 fragments, and type-2 fragments, respectively, that are contained within z. Let $\mathcal{F}' = \cup_{z \in S} \mathcal{F}'_z$ denote the set of all type-1 fragments and $\mathcal{F}'' = \cup_{z \in S} \mathcal{F}''_z$ denote the set of all type-2 fragments. Finally, let $\mathcal{C}'$ denote the set of trapezoids of $\mathcal{C}$ that are contained within a single cell of S, and let $\mathcal{C}''$ denote the rest of the trapezoids of $\mathcal{C}$. Note that type-1 fragments are contained inside the trapezoids of $\mathcal{C}'$ (in fact, $\mathcal{F}' = \mathcal{C}'$), while type-2 fragments are contained inside the trapezoids of $\mathcal{C}''$.

For any trapezoid Δ (not necessarily in $\mathcal{C}$), we define the following items. We let $S_\Delta = S \cap \Delta$ (i.e., the original subdivision S clipped to within Δ). We let p_Δ be the probability that the query point lies within Δ. We will use X_Δ to denote the set of segments in X that intersect the interior of Δ, and T_Δ to denote the set of trapezoids of S that intersect the interior of Δ. Observe that S_Δ and T_Δ are exactly analogous to S_u and T_u introduced in section 3.1. In particular, each (clipped) trapezoid $z' \in S_\Delta$ arises by intersecting some (unclipped) trapezoid $z \in T_\Delta$ with Δ.

The following technical lemma will be useful in proving Lemma 11.

LEMMA 10. *Let Δ be any trapezoid of $\mathcal{C}''$. Then*

(i) $\sum_{z \in T_\Delta} p_z = O(1/r)$,

(ii) $p_\Delta = O(1/r)$,

(iii) $|X_\Delta| = O(n/r)$.

Proof. Consider a trapezoid Δ in $\mathcal{C}''$ and any trapezoid z in T_Δ. We claim that at least one of the defining segments of z belongs to X_Δ. To prove this claim, recall that Δ is bounded from above and below by some segment of X. Since S is a trapezoidal map of X, it follows that z cannot cross the segments of X that bound Δ from above and below. We consider two cases. First, suppose either that the segment bounding z from above differs from the segment bounding Δ from above or that the segment bounding z from below differs from the segment bounding Δ from below. (See Figure

11(a).) Then clearly the differing segment must intersect the interior of Δ and thus belongs to X_Δ. Since the segments bounding z from above and below are defining segments of z, the claim holds. Otherwise, it follows that the segments of X bounding Δ from above and below also bound z from above and below. (See Figure 11(b).) In this case, one of the two vertical sides of z must intersect the interior of Δ (because otherwise Δ would be a subset of z, and then Δ would belong to $\mathcal{C}'$). It follows that the segment of X that defines this vertical side of z must belong to X_Δ. This proves the claim.

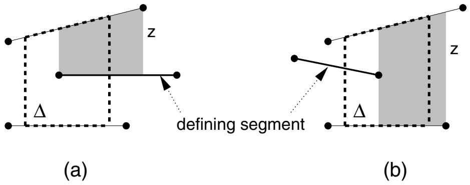

FIG. 11. *Proof of Lemma* 10.

Recall that trapezoid z assigns a weight of at least $p_z/8$ to each of its defining segments. It follows from the above claim that z assigns a weight of at least $p_z/8$ to some segment in X_Δ. Therefore,

$$\sum_{z \in T_\Delta} \frac{p_z}{8} \;\leq\; \sum_{x \in X_\Delta} w_x.$$

Since $\mathcal{C}$ is a weighted $(1/r)$-cutting for X, we have $\sum_{x \in X_\Delta} w_x = O(1/r)$. Thus, $\sum_{z \in T_\Delta} p_z = O(1/r)$, which implies (i). Recalling that each (clipped) trapezoid $z' \in S_\Delta$ is a subset of some (unclipped) trapezoid of $z \in T_\Delta$, we have $p_{z'} \leq p_z$ and so

$$p_\Delta \;=\; \sum_{z' \in S_\Delta} p_{z'} \leq \sum_{z \in T_\Delta} p_z \;=\; O(1/r),$$

which implies (ii). Finally, since the weight of each segment of X is at least $1/(8n)$ and $\sum_{x \in X_\Delta} w_x = O(1/r)$, it follows that there can be at most $O(n/r)$ segments in X_Δ. ▯

LEMMA 11 (entropy-preserving cuttings). *For any $r \geq 1$, in time $O(n \log n)$ we can partition the plane into $O(r)$ trapezoids satisfying the following properties. Let $\mathcal{C}$ denote the cutting formed by these $O(r)$ trapezoids, S^* denote the subdivision formed by superimposing $\mathcal{C}$ on S, and Δ denote any trapezoid of $\mathcal{C}$.*

(i) *If $\Delta \in \mathcal{C}''$, then the probability p_Δ that the query point lies within Δ is $O(1/r)$.*

(ii) *The number of segments, $|X_\Delta|$, intersecting the interior of Δ is $O(n/r)$.*

(iii) $\sum_{\Delta \in \mathcal{C}} \sum_{z \in T_\Delta} p_z = O(1)$.

(iv) *Let $H_S = \sum_{z \in S} p_z \log \frac{1}{p_z}$ and $H_{S^*} = \sum_{u \in S^*} p_u \log \frac{1}{p_u}$ be the respective entropies of these subdivisions. Then the increase in entropy, $H_{S^*} - H_S$, is at most a constant.*

The construction also provides for each trapezoid of the cutting the set of segments that intersect this trapezoid.

Proof. We claim that the cutting $\mathcal{C}$ described above satisfies the four properties given in the statement of the lemma. Let Δ denote any trapezoid of $\mathcal{C}$. If $\Delta \in \mathcal{C}'$, then, by definition, Δ is contained within a trapezoid of S, and so (ii) obviously holds.

Otherwise $\Delta \in \mathcal{C}''$, and, by applying Lemma 10(ii) and (iii), we have $p_\Delta = O(1/r)$ and $|X_\Delta| = O(n/r)$. This proves (i) and (ii).

We next prove (iii). For any trapezoid $z \in S$, let f_z, f'_z, and f''_z denote the number of all fragments, type-1 fragments, and type-2 fragments, respectively, that are contained within z. Observe that $\sum_{\Delta \in \mathcal{C}} \sum_{z \in T_\Delta} p_z$ is the same as $\sum_{z \in S} p_z f_z$. We will show that the latter quantity is $O(1)$, which will prove (iii).

In view of the merging process (recall Figure 10), it is clear that there must be a fragment of type 2 between any two fragments of type 1, and so $f'_z \leq f''_z + 1$. Thus

$$\sum_{z \in S} p_z f_z \;=\; \sum_{z \in S} p_z (f'_z + f''_z) \;\leq\; \sum_{z \in S} p_z (2f''_z + 1) \;=\; 1 + 2 \sum_{z \in S} p_z f''_z. \tag{2}$$

Note that $\sum_{z \in S} p_z f''_z$ is the same as $\sum_{\Delta \in \mathcal{C}''} \sum_{z \in T_\Delta} p_z$. By Lemma 10(i), for each $\Delta \in \mathcal{C}''$, $\sum_{z \in T_\Delta} p_z = O(1/r)$. Since $|\mathcal{C}''| \leq |\mathcal{C}| = O(r)$, it follows that $\sum_{z \in S} p_z f''_z = O(1)$. Substituting into (2), we have $\sum_{z \in S} p_z f_z = O(1)$, which completes the proof of (iii).

For convenience we express part (iv) of the lemma as

$$\sum_{u \in S^*} p_u \log \frac{1}{p_u} - \sum_{z \in S} p_z \log \frac{1}{p_z} \;=\; O(1). \tag{3}$$

The left-hand side of (3) can be written as

$$\sum_{z \in S} \left[\left(\sum_{u \in \mathcal{F}_z} p_u \log \frac{1}{p_u} \right) - p_z \log \frac{1}{p_z} \right].$$

Since $\sum_{u \in \mathcal{F}_z} p_u = p_z$, it follows from basic properties of entropy (see, e.g., [10]) that $\sum_{u \in \mathcal{F}_z} p_u \log(1/p_u)$ is maximized when the probability of all the fragments $u \in \mathcal{F}_z$ is equal, i.e., p_z/f_z. Thus

$$\begin{aligned}\sum_{u \in S^*} p_u \log \frac{1}{p_u} - \sum_{z \in S} p_z \log \frac{1}{p_z} &\leq \sum_{z \in S} \left[f_z \cdot \frac{p_z}{f_z} \log \frac{f_z}{p_z} - p_z \log \frac{1}{p_z} \right] \\ &= \sum_{z \in S} p_z \log f_z \;\leq\; \sum_{z \in S} p_z f_z.\end{aligned}$$

In proving (iii) above, we showed that $\sum_{z \in S} p_z f_z = O(1)$, which establishes (3).

Finally, standard cutting construction already provides the set of segments that intersect each trapezoid, and so it is trivial to adapt our construction to do so as well. □

4.1. Space reduction through entropy-preserving cuttings. We are now ready to describe our space-efficient data structure. We set the parameter r to the value $n/(2^{\sqrt{2 \log n}}\sqrt{\log n})$ and construct the entropy-preserving cutting $\mathcal{C}$ described in Lemma 11. In $O(n \log n)$ time, we obtain $\mathcal{C}$ along with X_Δ for each cutting trapezoid Δ. Let $c = \sum_{\Delta \in \mathcal{C}} \sum_{z \in T_\Delta} p_z$, which by Lemma 11(iii) is $O(1)$. For each trapezoid $\Delta \in \mathcal{C}$, we assign it a weight w_Δ proportional to the sum of probabilities of the overlapping trapezoids, that is, $w_\Delta = \sum_{z \in T_\Delta} p_z / c$. By our choice of c we have $\sum_{\Delta \in \mathcal{C}} w_\Delta = 1$. From our initial conditioning, we know that $H_S \geq 1$. So using these weights, and setting $B = \sqrt{H_S}$, we can now apply Lemma 9 to build a point-location data structure for $\mathcal{C}$. Since $|\mathcal{C}| = O(n/(2^{\sqrt{2 \log n}}\sqrt{\log n}))$, it follows that the space and preprocessing time for this data structure are $O(n)$.

Additionally, for each trapezoid $\Delta \in \mathcal{C}''$, we build any standard worst-case point-location data structure for the subdivision S_Δ. This data structure uses $O(|X_\Delta|)$ space and answers queries in time $O(\log |X_\Delta|)$. Each such structure can be computed in $O(|X_\Delta| \log |X_\Delta|)$ time by standard algorithms [11]. By Lemma 11(ii) we know that $|X_\Delta|$ is $O(2^{\sqrt{2\log n}}\sqrt{\log n})$. Since the number of trapezoids in $\mathcal{C}''$ is $O(n/(2^{\sqrt{2\log n}}\sqrt{\log n}))$, the total space and preprocessing time for all the point location structures corresponding to the trapezoids $\Delta \in \mathcal{C}''$ are $O(n)$ and $O(n\sqrt{\log n})$, respectively.

Together with the space used by the point-location structure for $\mathcal{C}$, it follows that the total space used is $O(n)$. The preprocessing time is $O(n \log n)$ and is dominated by the time to construct the cutting and determine the segments of X intersecting each cutting trapezoid. In the next section we discuss how the data structure is used to answer queries and analyze the expected query time, which is the last step needed to establish Theorem 1.

4.2. Query processing. In order to locate the cell containing a query point q, we use the point-location structure for $\mathcal{C}$ to identify the trapezoid $\Delta \in \mathcal{C}$ that contains q. If $\Delta \in \mathcal{C}'$, then we can directly output the cell of S that contains q. Otherwise $\Delta \in \mathcal{C}''$, and we use the point location structure for S_Δ to locate the cell of S_Δ (and hence of S) that contains q.

To analyze the query time, suppose that q lies in a fragment u that arises from the intersection of a trapezoid $\Delta \in \mathcal{C}$ with a cell $z \in S$. Let t_1 denote the time it takes to determine the trapezoid $\Delta \in \mathcal{C}$ that contains q. By Lemma 9 and using the facts that $B = \sqrt{H_S}$ and $w_\Delta \geq p_z/c$ (where c is the constant defined in the first paragraph of section 4.1), we have

$$\begin{aligned} t_1 &\leq \left[1 + O\left(\frac{1}{\sqrt{H_S}}\right)\right] \log \frac{c}{p_z} + O\left(\sqrt{H_S}\right) \\ &\leq \left[1 + O\left(\frac{1}{\sqrt{H_S}}\right)\right] \log \frac{1}{p_z} + O\left(\sqrt{H_S}\right). \end{aligned}$$

If $\Delta \in \mathcal{C}'$ (that is, $u \in \mathcal{F}'_z$), then we are done after finding Δ, and so the query time is t_1. Otherwise $\Delta \in \mathcal{C}''$ (that is, $u \in \mathcal{F}''_z$), and we need an additional time $t_2 = O(\log |X_\Delta|)$ to search S_Δ and determine u. By Lemma 11(ii), $|X_\Delta| = O(2^{2\sqrt{\log n}}\sqrt{\log n})$, so $t_2 = O(\sqrt{\log n})$. Putting it all together, we have shown that the expected query time is

$$\sum_{z\in S}\left[\sum_{u\in\mathcal{F}_z} p_u \left(\left[1 + O\left(\frac{1}{\sqrt{H_S}}\right)\right] \log\frac{1}{p_z} + O\left(\sqrt{H_S}\right)\right) + \sum_{u\in\mathcal{F}''_z} p_u O\left(\sqrt{\log n}\right)\right].$$

Using the facts that $\sum_{u\in\mathcal{F}_z} p_u = p_z$ and $\sum_{z\in S} p_z = 1$ and substituting H_S for $\sum_{z\in S} p_z \log(1/p_z)$, this simplifies to

$$H_S + O\left(\sqrt{H_S}\right) + O\left(p''\sqrt{\log n}\right), \tag{4}$$

where $p'' = \sum_{z\in S}\sum_{u\in\mathcal{F}''_z} p_u = \sum_{u\in\mathcal{F}''} p_u$.

To complete the analysis we need to establish a relationship between p'' and the entropy H_S. Intuitively, the following lemma shows that p'' is small when the entropy H_S is small.

LEMMA 12. *Let p'' be the probability that the query point falls in a fragment $u \in \mathcal{F}''$. Then $p'' = O(H_S/\log n)$.*

Proof. We first compute a lower bound on H_{S^*}. Clearly

$$H_{S^*} \; = \; \sum_{u \in S^*} p_u \log(1/p_u) \; \geq \; \sum_{u \in \mathcal{F}''} p_u \log(1/p_u).$$

By Lemma 11(i), for each $\Delta \in \mathcal{C}''$, $p_\Delta = O(2^{\sqrt{2\log n}}\sqrt{\log n}/n)$. Let $p_m = \max_{u \in \mathcal{F}''} p_u$. Since any fragment in $\mathcal{F}''$ is a subset of some $\Delta \in \mathcal{C}''$, it follows directly that $p_m = O(2^{\sqrt{2\log n}}\sqrt{\log n}/n)$. Recall that $p'' = \sum_{u \in \mathcal{F}''} p_u$. By basic properties of entropy [10], the entropy is minimized by maximizing the disparity among the probabilities. This is done by setting as many of the p_u's to p_m as possible, subject to the condition that they sum to p''. Thus, we obtain a lower bound on $\sum_{u \in \mathcal{F}''} p_u \log(1/p_u)$ by assuming that $\lfloor p''/p_m \rfloor$ of the fragments $u \in \mathcal{F}''$ have $p_u = p_m$, one fragment $u \in \mathcal{F}''$ has the leftover probability $p_u = p'' - \lfloor p''/p_m \rfloor p_m$, and all remaining fragments $u \in \mathcal{F}''$ have $p_u = 0$. Thus

$$H_{S^*} \; \geq \; \left(\frac{p''}{p_m} - 1\right) p_m \log \frac{1}{p_m} \; \geq \; p'' \log \frac{1}{p_m} - O(1) \; \geq \; \Omega(p'' \log n - 1).$$

Also, by Lemma 11(iv), $H_{S^*} \leq H_S + O(1)$. Combining the lower and upper bound on H_{S^*}, we obtain $H_S + O(1) = \Omega(p'' \log n - 1)$. Recalling that $H_S \geq 1$, the lemma follows. ☐

Applying Lemma 12 to (4), we see that the expected query time is

$$H_S + O\left(\sqrt{H_S}\right) + O\left(H_S/\sqrt{\log n}\right) \; \leq \; H_S + O\left(\sqrt{H_S}\right),$$

where we have used the fact that $H_S = O(\log n)$.

This completes the proof of our main result, Theorem 1.

5. Convex polygons with uniform distribution. In this section we establish Theorem 2. We are given a planar convex subdivision and assume that the query distribution within each cell is uniform. We prove the following lemma, which states that it is possible to triangulate this subdivision so that the entropy increases by only a additive constant. Theorem 2 follows by applying Theorem 1 to the resulting triangulation.

LEMMA 13. *Let S be a planar subdivision of size n whose cells are convex polygons, and assume that the query distribution within each polygon is uniform. We can triangulate each polygon such that the entropy of the resulting subdivision exceeds the entropy of S by at most an additive constant. The new subdivision can be constructed in $O(n \log n)$ time.*

The proof of this lemma relies on the straightforward observation that, given a convex polygon P, in linear time it is possible to compute a triangle whose area is at least $1/4$ the area of P. This is easy to prove by considering the triangle formed by the endpoints of the line segment defining P's diameter and the vertex of P that is farthest from this segment. (Although we do not need it, a better bound can be obtained by combining Tóth's bound of $3\sqrt{3}/4\pi \approx 0.41$ on the fraction of area of the largest triangle in a convex polygon [15] with Dobkin and Snyder's linear-time algorithm for computing the largest triangle contained in a convex polygon [12].)

Proof of Lemma 13. We triangulate each convex cell of S as follows. Let z denote any convex polygon. By the above observation we can find a triangle contained within z whose area is at least $1/4$ the area of z. We insert this triangle into the triangulation. This partitions the remainder of z into at most three convex polygons, which we triangulate recursively.

We bound the entropy of this triangulation. Let $\mathcal{F}_z$ denote the set of triangles in the triangulation of z, constructed by the above procedure. Define Φ_z to be $\sum_{x \in \mathcal{F}_z} p_x \log(1/p_x)$. We claim that

$$\Phi_z \leq p_z \log \frac{1}{p_z} + 8p_z. \tag{5}$$

The proof of this claim is by induction on the number of sides of z. For the basis case, z has three sides, and the claim is trivially true. Suppose that the claim holds for any convex polygon with at most i sides for some $i \geq 3$. We will establish the claim for any convex polygon z with $i+1$ sides.

Let y denote the first triangle added to the triangulation of z. Since the area of y is at least $1/4$ the area of z and the query distribution within z is uniform, $p_y \geq p_z/4$. Note that the remainder $z \setminus y$ consists of (at most) three convex polygons, denoted z_1, z_2, and z_3. By the induction hypothesis, $\Phi_{z_i} \leq p_{z_i} \log(1/p_{z_i}) + 8p_{z_i}$ for $1 \leq i \leq 3$. Thus Φ_z can be written as

$$\begin{aligned} p_y \log \frac{1}{p_y} + \sum_{i=1}^{3} \Phi_{z_i} &\leq p_y \log \frac{1}{p_y} + \sum_{i=1}^{3} \left(p_{z_i} \log \frac{1}{p_{z_i}} + 8p_{z_i} \right) \\ &= \left(p_y \log \frac{1}{p_y} + \sum_{i=1}^{3} p_{z_i} \log \frac{1}{p_{z_i}} \right) + 8 \sum_{i=1}^{3} p_{z_i}. \end{aligned} \tag{6}$$

Obviously $p_y + \sum_{i=1}^{3} p_{z_i} = p_z$. Since $p_y \geq p_z/4$, it follows that $\sum_{i=1}^{3} p_{z_i} \leq 3p_z/4$. Also, by basic properties of entropy [10], the maximum value of

$$p_y \log \frac{1}{p_y} + \sum_{i=1}^{3} p_{z_i} \log \frac{1}{p_{z_i}}$$

subject to the constraint that $p_y + \sum_{i=1}^{3} p_{z_i} = p_z$ occurs when $p_y = p_{z_1} = p_{z_2} = p_{z_3} = p_z/4$, and is given by $p_z \log(4/p_z)$. Using these bounds in (6), we obtain

$$\Phi_z \leq p_z \log \frac{4}{p_z} + 8 \left(\frac{3}{4} p_z \right) = p_z \log \frac{1}{p_z} + 8p_z,$$

which completes the proof by induction.

Summing both sides of (5) over all the polygons of S, it follows that the entropy of the triangulation exceeds the entropy of S by at most 8.

Finally, we discuss the time it takes to construct the triangulation. Let m denote the size of a convex polygon $z \in S$. By the observation made just prior to the proof of Lemma 13, it takes $O(m)$ time to find the first triangle y in z and decompose the remainder $z \setminus y$ into (at most) three convex polygons z_1, z_2, and z_3. If $z \setminus y$ consists of just one polygon with $m-1$ vertices, then continuing in this way, it may take $O(m^2)$ time to complete the triangulation of z. To reduce this to $O(m \log m)$, we make a small change to the construction. At each step in the recursion, we partition the current polygon into two polygons with roughly equal numbers of vertices, and then find a triangle with large area in each of these two polygons. This reduces the depth of the recursion to $O(\log m)$, and since the time taken for each level of the recursion is $O(m)$, the total time becomes $O(m \log m)$. It is now a simple exercise to extend the above proof to show that this modified triangulation algorithm also preserves the entropy (only the constant 8 increases). ◻

6. Concluding remarks. We have shown that, given a polygonal subdivision S of size n consisting of cells of constant combinatorial complexity and a query distribution presented as a weight assignment to the cells of S, it is possible to answer point location queries $H + O(\sqrt{H} + 1)$, where H is the entropy of the subdivision. Our data structure requires $O(n)$ space, and it can be constructed in $O(n \log n)$ time by a randomized algorithm. We make no assumptions about the distribution of query points within each cell of the subdivision. We have also shown that this result can be extended to convex subdivisions of arbitrary combinatorial complexity, assuming that the query distribution is uniform within each cell.

There are a number of open problems suggested here. If point location is based on the results of primitive comparisons, it is known that the entropy is a lower bound on the expected running time, and so our results are optimal up to lower order terms. Assuming that the query distribution within the cells is unknown, a stronger lower bound of $H + \sqrt{H} - O(1)$ is known in the trapezoidal search graph model [21]. Can the lower-bound analysis be refined to justify the presence of the $O(\sqrt{H})$ term, when information on the query distribution within the cells is available? Taking this in a different direction, suppose that the query distribution is not known at all. That is, the probabilities that the query point lies within the various cells of the subdivision are unknown. In the 1-dimensional case it is known that there exist self-adjusting data structures, such as splay trees [29], that achieve good expected query time in the limit. Do such self-adjusting structures exist for planar point location?

A related observation is that, in the case of worst-case query time, Seidel and Adamy [27] showed an analogous lower order term of $2\sqrt{\log n}$. An interesting question along these lines is whether it is possible to reduce the lower order term in Theorem 4, say to $2\sqrt{H}$. Another interesting question is the computational complexity of computing the BSP that minimizes the expected search time, assuming, say, the extended trapezoidal search graph model and an oracle that can answer questions about the query distribution.

As mentioned earlier, our results are based on the trapezoidal search graph model used by Seidel and Adamy [27]. The two comparison primitives used in the trapezoidal search graph model have significantly different computation times. (One is a 1-dimensional orientation test, and the other is a 2-dimensional orientation test.) This raises the question of the computational complexity of point location in even more primitive models of computation, for example, the number of arithmetic operations on coordinates.

Acknowledgments. We would like to thank Siu-Wing Cheng, Ramesh Hariharan, and Raimund Seidel for helpful discussions. We would also like to thank the anonymous referees for their careful reading and many helpful suggestions.

SELF-TESTING OF UNIVERSAL AND FAULT-TOLERANT SETS OF QUANTUM GATES*

WIM VAN DAM[†], FRÉDÉRIC MAGNIEZ[‡], MICHELE MOSCA[§], AND MIKLOS SANTHA[‡]

Abstract. We consider the design of self-testers for quantum gates. A self-tester for the gates $\boldsymbol{F}_1, \dots, \boldsymbol{F}_m$ is a procedure that, given any gates $\boldsymbol{G}_1, \dots, \boldsymbol{G}_m$, decides with high probability if each $\boldsymbol{G}_i$ is close to $\boldsymbol{F}_i$. This decision has to rely only on measuring in the computational basis the effect of iterating the gates on the classical states. It turns out that, instead of individual gates, we can design only procedures for families of gates. To achieve our goal we borrow some elegant ideas of the theory of program testing: We characterize the gate families by specific properties, develop a theory of robustness for them, and show that they lead to self-testers. In particular we prove that the universal and fault-tolerant set of gates consisting of a Hadamard gate, a c-NOT gate, and a phase rotation gate of angle $\pi/4$ is self-testable.

Key words. self-testing, quantum circuit, fault-tolerance, robustness

1. Introduction.

As experimentalists attempt to realize quantum computers, we need some way to test whether the desired quantum operations are actually being implemented. Our motivation is to derive sufficient and self-contained tests for verifying the action of specific finite sets of quantum gates. One of the most important features of our work is that our tests do not rely on the use of some other trusted quantum operations that have somehow already been characterized and tested.

Inspired by classical work on self-testing programs [8, 26, 21, 15] (see section 1.1), our approach is to characterize quantum gates by testable properties. For example, one testable property of the Hadamard gate $\boldsymbol{H}$ is that if one starts with input $|0\rangle$, applies $\boldsymbol{H}$, and then measures, one should measure $|0\rangle$ with probability $\frac{1}{2}$. This of course does not uniquely characterize the Hadamard gate; for instance, there are many nonunitary quantum gates with the same property. If a gate is known to be unitary, then it is quite easy to find a set of testable properties that characterize it. So one of our key techniques for characterizing gates is a test for unitarity. Since any reasonable test could verify only that the probability of outputting $|0\rangle$ is likely very close to $\frac{1}{2}$, we need *robust* properties. Informally, a property is robust if, whenever a function satisfies the property approximately, it is close to a function that satisfies it exactly.

Our tests are in the quantum circuit model of computation, which corresponds most naturally to what experimentalists are implementing. The quantum circuit model and the quantum Turing machine are the first formal models of quantum computing that were defined by Deutsch [11, 12]. Yao has shown [31] that these two models have polynomially equivalent computational power when the circuits are uniform.

A quantum circuit operates on n quantum bits (qubits), where n is some integer. The actual computation takes place in the Hilbert space $\mathbb{C}^{\{0,1\}^n}$, whose computational basis consists of the 2^n orthonormal vectors $|i\rangle$ for $i \in \{0,1\}^n$. According to the standard model, during the computation the state of the system is a unit length linear combination, or a superposition, of the basis states. The computational steps of the system are done by quantum gates, which perform unitary operations and are local in the sense that they involve only a constant number of qubits. At the end of the computation a measurement takes place on one of the qubits. This is a probabilistic experiment whose outcome can be 0 or 1, and the probability of measuring the bit b is the squared length of the projection of the superposition to the subspace spanned by the basis states that are compatible with the outcome. As a result of a measurement, the state of the system becomes this projected state.

The most convenient way to describe all possible operations on a quantum register is in the formalism of "density matrices." In this approach, which differs from the Dirac notation, the quantum operations are described by completely positive superoperators (CPSOs) that act on matrices. These density matrices describe mixed states (that is, classical probability distributions over pure quantum states), and the CPSOs correspond exactly to all of the physically allowed transformations on them. Such a model of quantum circuits with mixed states was described by Aharonov, Kitaev, and Nisan [3], and we will adopt it here. The unitary quantum gates of the standard model and measurements are special CPSOs. CPSOs can be simulated by unitary quantum gates on a larger number of qubits, and in [3] it was shown that the computational powers of the two models are polynomially equivalent.

Unitary quantum gates for a small number of qubits have been extensively studied. One reason is that, although quantum gates for up to three qubits have already been realized (e.g., in [20]), constructing gates for large numbers seems to be elusive. Another reason is that universal sets of gates can be built from them, which means that they can simulate (approximately) any unitary transformation on an arbitrary number of qubits. The first universal quantum gate which operates on three qubits was identified by Deutsch [12]. After a long sequence of work on universal quantum gates [14, 4, 13, 22, 6, 30, 18, 17], Boykin et al. [7] have recently shown that the set consisting of a Hadamard gate, a c-NOT gate, and a phase rotation gate of angle $\pi/4$ is universal. In order to form a practical basis for quantum computation, a universal set must also be able to operate in a noisy environment, and therefore there has to be an implementation of fault-tolerant quantum computation using this set of gates [30, 2, 17, 19]. The above set of three gates has the additional advantage of also being fault-tolerant in this sense.

In this paper we develop the theory of self-testing of quantum gates by classical procedures. Given a CPSO $\boldsymbol{G}$ for n qubits, and a family $\mathcal{F}$ of unitary CPSOs, we would like to decide if $\boldsymbol{G}$ belongs to $\mathcal{F}$. Intuitively, a self-tester is a procedure that answers the question "$\boldsymbol{G} \in \mathcal{F}$?" by interacting with the CPSO $\boldsymbol{G}$ in a purely classical way. More precisely, it will be a probabilistic algorithm that is able to access $\boldsymbol{G}$ as a black box in the following sense: It can prepare the classical states $w \in \{0,1\}^n$, iterate $\boldsymbol{G}$ on these states, and, afterwards, measure in the computational basis. The access must be seen as a whole, performed by a specific, experimental oracle for $\boldsymbol{G}$: Once the basis state w and the number of iterations k have been specified, the program in one step gets back one of the possible probabilistic outcomes of measuring the state of the system after $\boldsymbol{G}$ is iterated k times on w. The intermediate quantum states of this process cannot be used by the program, which cannot perform any other quantum operations either. For $0 \le \delta_1 \le \delta_2$, such an algorithm will be a (δ_1, δ_2)-tester for $\mathcal{F}$ if for every CPSO $\boldsymbol{G}$, whenever the distance of $\boldsymbol{G}$ and $\mathcal{F}$ is at most δ_1 (in some norm), it accepts with high probability, and whenever the same distance is greater than δ_2, it rejects with high probability, where the probability is taken over the measurements performed by the oracle and by the coin tosses of the algorithm. Finally we will say that $\mathcal{F}$ is *testable* if for every $\delta_2 > 0$, there exists $0 < \delta_1 \le \delta_2$ such that there exists a (δ_1, δ_2)-tester for $\mathcal{F}$. These definitions can be extended to several classes of CPSOs.

We note in section 2 that for any real φ the states $|1\rangle$ and $e^{i\varphi}|1\rangle$ are experimentally indistinguishable. This implies that if we start by distinguishing only the classical states 0 and 1, then there are families of CPSOs which are indistinguishable as well. For example, let $\boldsymbol{H}$ be the well-known Hadamard gate, and let $\boldsymbol{H}_\varphi$ be the same gate expressed in the basis $(|0\rangle, e^{i\varphi}|1\rangle)$ for $\varphi \in [0, 2\pi)$. Any experiment that starts in state 0 or 1 and uses only $\boldsymbol{H}$ will produce outcomes 0 and 1 with the same probabilities as the same experiment with $\boldsymbol{H}_{\boldsymbol{\varphi}}$. Thus no experiment that uses this quantum gate alone can distinguish it from all of the other Hadamard gates. Indeed, a family $\mathcal{F}$ containing $\boldsymbol{H}$ can be tested only if the entire Hadamard family $\mathcal{H} = \{\boldsymbol{H}_\varphi : \varphi \in [0, 2\pi)\}$ is included in $\mathcal{F}$. This degree of freedom is formalized generally for any gate in Fact 4.1.

It might seem at first sight that not being able to get rid of this degree of freedom is a serious handicap. Nonetheless, it remains coherent when we test several gates simultaneously. Thus, for example, if we define $\mathbf{NOT}_\varphi$ similarly to $\boldsymbol{H}_\varphi$, we are able to test the family of couples $\{(\mathbf{NOT}_\varphi, \boldsymbol{H}_\varphi) : \varphi \in [0, 2\pi)\}$.

The main result of this paper is Theorem 6.5, which states that for several sets of unitary CPSOs, in particular, the Hadamard gates family, Hadamard gates together with c-NOT gates, and Hadamard gates with c-NOT and phase rotation gates of angle $\pm\pi/4$, are testable. This last family is of particular importance since every triplet in the family forms a universal and fault-tolerant set of gates for quantum computation [7].

For the proof we will define the notion of experimental equations which are functional equations for CPSOs corresponding to the properties of the quantum gate that a self-tester can approximately test. These tests are done via the interaction with the experimental oracle. The proof itself contains three parts. In Theorems 4.2, 4.4, and 4.5 we will exhibit experimental equations for the families of unitary CPSOs that we want to characterize. In Theorem 5.2 we will show that actually all experimental equations are robust; in fact, the distance of a CPSO from the target family is polynomially related to the error tolerated in the experimental equations. Finally Theorem 6.3 gives self-testers for CPSO families which are characterized by a finite set of robust experimental equations.

In some cases, we are able to calculate explicitly the polynomial bound in the robustness of experimental equations. Such a result will be illustrated in Theorem 5.4 for the equations characterizing the Hadamard family $\mathcal{H}$.

Technically, these results will be based on the representation of one-qubit states and CPSOs in $\mathbb{R}^3$, where they are, respectively, vectors in the unit ball of $\mathbb{R}^3$ and particular affine transformations. This correspondence is known as the Bloch ball representation.

1.1. Related prior work. Experimental procedures for determining the properties of quantum "black boxes" were given by Chuang and Nielsen [10] and Poyatos, Cirac, and Zoller [24]; however, these procedures implicitly require an apparatus that has already been tested and characterized.

The idea of self-testing in quantum devices is implicit in the work of Adleman, Demarrais, and Huang [1]. They have developed a procedure by which a quantum Turing machine is able to estimate its internal angle by its own means under the hypothesis that the machine is unitary. In the context of quantum cryptography Mayers and Yao [23] have designed tests for deciding if a photon source is perfect. These tests guarantee that if a source passes them, then it is adequate for the security of the Bennett-Brassard [5] quantum key distribution protocol.

The study of self-testing programs is a well-established research area which was initiated by the work of Blum, Luby, and Rubinfeld [8], Rubinfeld [26], Lipton [21], and Gemmel et al. [15]. The purpose of a self-tester for a function family is to detect by simple means if a program which is accessible as an oracle computes a function from the given family. This clearly inspired the definition of our self-testers, which have the particular feature that they should test quantum objects that they can access only in some particular way. The analogy with self-testing does not stop with the definition. One of the main tools in self-testing of function families is the characterization of these families by robust properties. The concept of robustness was introduced and its implication for self-testing was first studied by Rubinfeld and Sudan [27] and by Rubinfeld [28]. It will play a crucial role in our case.

2. Preliminaries.

2.1. The quantum state. A *pure state* in a quantum physical system is described by a unit vector in a Hilbert space. In the *Dirac* notation it is denoted by $|\psi\rangle$. In particular a *qubit* (a quantum two-state system) is an element of the Hilbert space $\mathbb{C}^{\{0,1\}}$. The orthonormal basis containing $|0\rangle$ and $|1\rangle$ is called the *computational basis* of $\mathbb{C}^{\{0,1\}}$. Therefore a pure state $|\psi\rangle \in \mathbb{C}^{\{0,1\}}$ is a linear combination, or a *superposition*, of the computational basis states, that is, $|\psi\rangle = c_0|0\rangle + c_1|1\rangle$, with $|c_0|^2 + |c_1|^2 = 1$. A physical system which deals with n qubits is described mathematically by the 2^n-dimensional Hilbert space which is by definition $\mathbb{C}^{\{0,1\}} \otimes \cdots \otimes \mathbb{C}^{\{0,1\}}$, that is, the n^{th} tensor power of $\mathbb{C}^{\{0,1\}}$. Let $N = 2^n$. The computational basis of this space consists of the N orthonormal states $|i\rangle$ for $0 \leq i < N$. If i is in binary notation $i_1 i_2 \ldots i_n$, then $|i_1 \ldots i_n\rangle = |i_1\rangle \ldots |i_n\rangle$, where this is a short notation for $|i_1\rangle \otimes \cdots \otimes |i_n\rangle$. All vectors and matrices will be expressed in the computational basis. The transposed complex conjugate $|\psi\rangle^\dagger$ of $|\psi\rangle$ is denoted by $\langle\psi|$. The inner product between $|\psi\rangle$ and $|\psi'\rangle$ is denoted by $\langle\psi|\psi'\rangle$ and their outer product by $|\psi\rangle\langle\psi'|$.

Quantum systems can also be in more general states than what can be described by pure states. The most general states are *mixed states*, described by a probability distribution over pure states. Such a mixture can be denoted by $\{(p_k, |\psi_k\rangle) : k \in \mathbb{N}\}$, where the system is in the pure state $|\psi_k\rangle$ with probability p_k.

Different mixtures (even different pure states $|\psi\rangle$) can represent the same physical system. This notational redundancy can be avoided if we use the formalism of the density matrices. A *density matrix* that represents an n-qubit state is an $N \times N$ Hermitian semipositive matrix with trace 1. The pure state $|\psi\rangle$ in this representation is described by the density matrix $\psi = |\psi\rangle\langle\psi|$ and a mixture $\{(p_k, |\psi_k\rangle) : \ k \in \mathbb{N}\}$ by the density matrix $\psi = \sum_{k\in\mathbb{N}} p_k |\psi_k\rangle\langle\psi_k|$. For example, the pure states $e^{i\gamma}|\psi\rangle$, for $\gamma \in [0, 2\pi)$, or the mixtures $\{(\frac{1}{2}, |0\rangle), (\frac{1}{2}, |1\rangle)\}$ and $\{(\frac{1}{2}, \frac{|0\rangle+|1\rangle}{\sqrt{2}}), (\frac{1}{2}, \frac{|0\rangle-|1\rangle}{\sqrt{2}})\}$ have, respectively, the same density matrix.

Since a density matrix is Hermitian semipositive, its eigenvectors are orthogonal and its eigenvalues are nonnegative. Because the density matrix has trace 1, its eigenvalues sum to 1. Therefore a density matrix represents the mixture of its orthonormal eigenvectors, where the probabilities are the respective eigenvalues. Note that diagonal density matrices correspond to a mixture over pure states $|i\rangle$ for $0 \leq i < N$. Density matrices that represent pure states have a simple algebraic characterization: ρ is a pure state if and only if it has two eigenvalues: 0 with multiplicity $N-1$ and 1 with multiplicity 1; equivalently, ρ is a pure state exactly when $\rho^2 = \rho$.

A 2×2 Hermitian matrix of unit trace is semipositive if and only if its determinant is between 0 and 1/4. Therefore in the case of one qubit, any density matrix ρ can be written as $\rho = p|0\rangle\langle 0| + (1-p)|1\rangle\langle 1| + \alpha|1\rangle\langle 0| + \alpha^*|0\rangle\langle 1|$, where $p \in [0,1]$, and α is a complex number such that $|\alpha|^2 \leq p(1-p)$. This density matrix will be denoted by $\rho(p,\alpha)$. Remark that $\rho(p,\alpha)$ is a pure state exactly when $|\alpha|^2 = p(1-p)$; that is, its determinant is 0.

2.2. Superoperators. The evolution of physical systems is described by specific transformations on density matrices, that is, on operators. A *superoperator* for n qubits is a linear transformation on $\mathbb{C}^{N\times N}$. A *positive* superoperator (PSO) is a superoperator that maps density matrices to density matrices. A *completely positive* superoperator (CPSO) $\boldsymbol{G}$ is a PSO such that, for all positive integers M, $\boldsymbol{G} \otimes \boldsymbol{I}_M$ is also a PSO, where $\boldsymbol{I}_M$ is the identity on $\mathbb{C}^{M\times M}$. CPSOs are exactly the physically allowed transformations on density matrices. An example of a PSO for one qubit that is not a CPSO is the transpose superoperator $\boldsymbol{T}$ defined by $\boldsymbol{T}(|i\rangle\langle j|) = |j\rangle\langle i|$ for $0 \leq i,j \leq 1$.

Quantum computation is traditionally based on the possibility of constructing some particular CPSOs, *unitary* superoperators, which preserve the set of pure states. These operators are characterized by transformations from $\mathrm{U}(N)$, the set of $N \times N$ unitary matrices. For any $A \in \mathrm{U}(N)$, we define a CPSO which maps a density matrix ρ into $A\rho A^\dagger$. When the underlying unitary transformation A is clear from the context, by a slight abuse of notation we will denote this CPSO simply by $\boldsymbol{A}$. If $|\psi'\rangle$ denotes $A|\psi\rangle$, then the unitary superoperator $\boldsymbol{A}$ maps the pure state ψ to the pure state ψ'. As was the case in the Dirac representation of states, there is the same phase redundancy in the set of unitary transformations $\mathrm{U}(N)$. If $A \in \mathrm{U}(N)$, then for all $\gamma \in [0, 2\pi)$ the transformations $e^{i\gamma}A$ are different; however, the corresponding superoperators are identical. We will therefore focus on $\mathrm{U}(N)/\mathrm{U}(1)$.

Conversely, CPSOs can be defined using unitary transformations. For every CPSO $\boldsymbol{G}$ for n qubits, there exists a unitary transformation $A \in \mathrm{U}(2^{3n})$ for $3n$ qubits such that $\boldsymbol{G}$ corresponds to the application of A after tracing out the additional n qubits [3]: G maps a density matrix ρ into $\boldsymbol{G}(\rho) = \mathrm{Tr}_2(A(\rho \otimes I_{2^{2n}})A^\dagger)$, where Tr_2 denotes the trace out over the last $2n$ qubits.

2.3. Measurements. Measurements form another important class of (nonunitary) CPSOs. They describe physical transformations corresponding to the observation of the system. We will now formally define one of the simplest classes of measurements which correspond to the projections to elements of the computational basis.

A *von Neumann measurement in the computational basis* of n qubits is the n-qubit CPSO $\boldsymbol{M}$ that, for every density matrix ρ, satisfies $\boldsymbol{M}(\rho)_{i,i} = \rho_{i,i}$ and $\boldsymbol{M}(\rho)_{i,j} = 0$ for $i \neq j$.

In the case of one qubit, the von Neumann measurement in the computational basis maps the density matrix $\rho(p,\alpha)$ into $\rho(p,0)$. We will say that $p = \langle 0|\rho|0\rangle$ is the *probability of measuring* $|0\rangle\langle 0|$, and we will denote it by $\Pr^0[\rho]$.

In general, a *von Neumann measurement* of n qubits in any basis can be viewed as the von Neumann measurement in the computational basis preceded by some unitary superoperator.

2.4. The Bloch ball representation. Specific for the one-qubit case, there is an isomorphism between the group $\mathrm{U}(2)/\mathrm{U}(1)$ and the special rotation group $\mathrm{SO}(3)$, the set of 3×3 orthogonal matrices with determinant 1. This allows us to represent one-qubit states as vectors in the unit ball of $\mathbb{R}^3$ and unitary superoperators as rotations on $\mathbb{R}^3$. We will now describe exactly this correspondence.

The *Bloch ball* $\mathcal{B}$ (respectively, *Bloch sphere* $\mathcal{S}$) is the unit ball (respectively, unit sphere) of the Euclidean affine space $\mathbb{R}^3$. Any point $\overline{u} \in \mathbb{R}^3$ determines a vector with the same coordinates which we will also denote by $\overline{u}$. The inner product of $\overline{u}$ and $\overline{v}$ will be denoted by $(\overline{u}, \overline{v})$ and their Euclidean norm by $\|\overline{u}\|$.

Each point $\overline{u} \in \mathbb{R}^3$ can be also characterized by its norm $r \geq 0$, its latitude $\theta \in [0, \pi]$, and its longitude $\varphi \in [0, 2\pi)$. The *latitude* is the angle between the z-axis and the vector $\overline{u}$, and the *longitude* is the angle between the x-axis and the orthogonal projection of $\overline{u}$ in the plane defined by $z = 0$. If $\overline{u} = (x, y, z)$, then these parameters satisfy $x = r \sin\theta \cos\varphi$, $y = r \sin\theta \sin\varphi$, and $z = r\cos\theta$.

For every density matrix ρ for one qubit there exists a unique point $\overline{\rho} = (x, y, z) \in \mathcal{B}$ such that

$$\rho = \frac{1}{2}\begin{pmatrix} 1+z & x-iy \\ x+iy & 1-z \end{pmatrix}.$$

This mapping is a bijection that also obeys

$$\overline{\rho(p,\alpha)} = (2\mathrm{Re}(\alpha), 2\mathrm{Im}(\alpha), 2p-1).$$

In this formalism, the pure states are nicely characterized in $\mathcal{B}$ by their norm.

FACT 2.1. *A density matrix ρ represents a pure state if and only if $\overline{\rho} \in \mathcal{S}$; that is, $\|\overline{\rho}\| = 1$.*

Also, if $\theta \in [0, \pi]$ and $\varphi \in [0, 2\pi)$ are, respectively, the latitude and the longitude of $\overline{\psi} \in \mathcal{S}$, then the corresponding density matrix represents a pure state and satisfies $|\psi\rangle = \cos(\theta/2)|0\rangle + \sin(\theta/2)e^{i\varphi}|1\rangle$ (see Figure 2.1). Observe that the pure states $|\psi\rangle$ and $|\psi^\perp\rangle$ are orthogonal if and only if $\overline{\psi} = -\overline{\psi^\perp}$. We will use the following notation for the six pure states along the x, y, and z axes: $|\zeta_x^\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$, $|\zeta_y^\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm i|1\rangle)$, $|\zeta_z^+\rangle = |0\rangle$, and $|\zeta_z^-\rangle = |1\rangle$, with the respective coordinates $(\pm 1, 0, 0)$, $(0, \pm 1, 0)$, and $(0, 0, \pm 1)$ in $\mathbb{R}^3$. Recall that for every density matrix ρ for one qubit there exists two orthogonal pure states $|\psi\rangle$ and $|\psi^\perp\rangle$ such that $\rho = p|\psi\rangle\langle\psi| + (1{-}p)|\psi^\perp\rangle\langle\psi^\perp|$, where $0 \leq p \leq 1$. Thus $\overline{\rho}$ is just the barycenter of $\overline{\psi}$ and $\overline{\psi^\perp}$ with respective weights p and $(1{-}p)$ (see Figure 2.2).

For each CPSO $\boldsymbol{G}$, there exists a unique affine transformation $\overline{\boldsymbol{G}}$ over $\mathbb{R}^3$, which maps the ball $\mathcal{B}$ into $\mathcal{B}$ and is such that, for all density matrices ρ, $\overline{\boldsymbol{G}}(\overline{\rho}) = \overline{\boldsymbol{G}(\rho)}$. Unitary superoperators have a nice characterization in $\mathcal{B}$.

FACT 2.2. *The map between* $\mathrm{U}(2)/\mathrm{U}(1)$ *and* $\mathrm{SO}(3)$*, which sends A to $\overline{\boldsymbol{A}}$, is an isomorphism.*

For $\alpha \in (-\pi, \pi]$, $\theta \in [0, \frac{\pi}{2}]$, and $\varphi \in [0, 2\pi)$, we will define the unitary transformation $R_{\alpha,\theta,\varphi}$ over $\mathbb{C}^2$. If $|\psi\rangle = \cos(\theta/2)|0\rangle + e^{i\varphi}\sin(\theta/2)|1\rangle$ and $|\psi^\perp\rangle = \sin(\theta/2)|0\rangle - e^{i\varphi}\cos(\theta/2)|1\rangle$, then by definition $R_{\alpha,\theta,\varphi}|\psi\rangle = |\psi\rangle$ and $R_{\alpha,\theta,\varphi}|\psi^\perp\rangle = e^{i\alpha}|\psi^\perp\rangle$. If $\boldsymbol{A}$ is a unitary superoperator, then we have $\boldsymbol{A} = \boldsymbol{R}_{\alpha,\theta,\varphi}$ for some α, θ, and φ. In $\mathbb{R}^3$ the transformation $\overline{\boldsymbol{R}}_{\alpha,\theta,\varphi}$ is the rotation of angle α whose axis cuts the sphere $\mathcal{S}$ in the

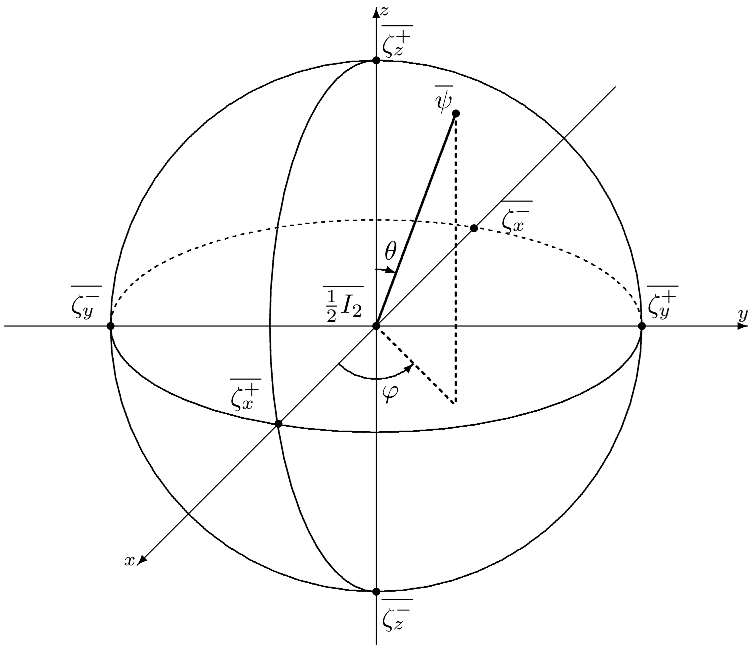

FIG. 2.1. *Bloch ball representation of a pure state.*

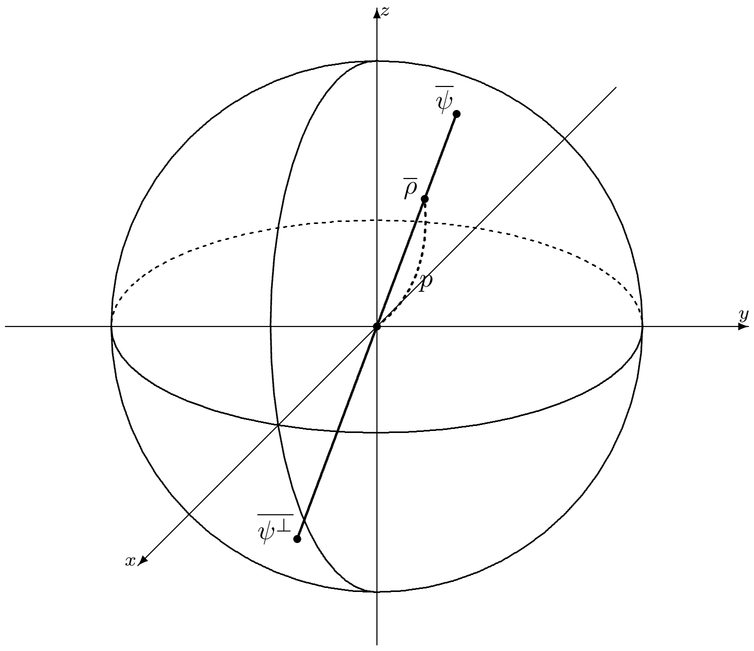

FIG. 2.2. *Bloch ball representation of a density matrix.*

points $\overline{\psi}$ and $\overline{\psi^\perp}$. Note that for $\theta = 0$ the CPSO $\boldsymbol{R}_{\alpha,0,\varphi}$ does not depend on φ. We will denote this phase rotation by $\boldsymbol{R}_\alpha$.

The affine transformation in $\mathcal{B}$ which corresponds to the von Neumann measurement in the computational basis is the orthogonal projection to the z-axis. Therefore it maps $\overline{\rho} = (x, y, z)$ into $(0, 0, z)$, the point which corresponds to the density matrix $\frac{1+z}{2}|0\rangle\langle 0| + \frac{1-z}{2}|1\rangle\langle 1|$. Thus $\Pr^0[\rho] = \frac{1+z}{2}$.

2.5. Norm and distance. Let $N = 2^n$. We will consider the *trace norm* on $\mathbb{C}^{N\times N}$ which is defined as follows: For all $V \in \mathbb{C}^{N\times N}$, $\|V\|_1 = \mathrm{Tr}\sqrt{V^\dagger V}$. This norm has several advantages when we consider the difference of density matrices. Given a von Neumann measurement, a density matrix induces a probability distribution over the basis of the measurement. The trace norm of the difference of two density matrices is the maximal variation distance between the two induced probability distributions, over all von Neumann measurements. It also satisfies the following properties.

FACT 2.3. *For all density matrices $\rho(p, \alpha)$ and $\rho(q, \beta)$ for one qubit, we have*

$$\begin{aligned}\|\rho(p,\alpha) - \rho(q,\beta)\|_1 &= \|\overline{\rho(p,\alpha)} - \overline{\rho(q,\beta)}\| \\ &= 2\sqrt{(p-q)^2 + |\alpha - \beta|^2}.\end{aligned}$$

FACT 2.4. *For all $V \in \mathbb{C}^{N\times N}$ and $W \in \mathbb{C}^{M\times M}$, we have $\|V \otimes W\|_1 = \|V\|_1\|W\|_1$ and $\sqrt{\mathrm{Tr}(V^\dagger V)} \leq \|V\|_1$. For density matrices ρ it holds that $\|\rho\|_1 = 1$.*

For n-qubit superoperators, the superoperator norm associated to the trace norm is defined as

$$\|\boldsymbol{G}\|_\infty = \sup\{\|\boldsymbol{G}(V)\|_1 : \|V\|_1 = 1\}.$$

This norm is always 1 when $\boldsymbol{G}$ is a CPSO (see, e.g., [3, Lem. 12]). The norm $\| \|_\infty$ can be easily generalized for k-tuples of superoperators by $\|(\boldsymbol{G}_1, \ldots, \boldsymbol{G}_k)\|_\infty = \max(\|\boldsymbol{G}_1\|_\infty, \ldots, \|\boldsymbol{G}_k\|_\infty)$. We will denote by dist_∞ the natural distance induced by the norm $\| \|_\infty$.

For our purposes we could have considered any other norm on superoperators since our results are motivated by the testability of universal sets of gates which act on a constant number of qubits. Indeed, it is a well-known fact that in fixed dimension all of the norms are equivalent. As stated in Fact 6.2, the testability remains invariant under changing norms.

3. Properties of CPSOs.

Here we will establish the properties of CPSOs that we will need for the characterization of our CPSO families. The first lemma does not use the complete positivity; thus, it is stated in general for PSOs for one qubit. Note that in the Bloch ball formalism PSOs for one qubit are exactly affine maps that preserve $\mathcal{B}$.

LEMMA 3.1. *Let $\boldsymbol{G}$ be a PSO for one qubit, and let ρ and τ be density matrices for one qubit.*

(a) $\|\boldsymbol{G}(\rho) - \boldsymbol{G}(\tau)\|_1 \leq \|\rho - \tau\|_1$.

(b) *If $\boldsymbol{G}$ is not constant and $\boldsymbol{G}(\rho)$ is a pure state, then ρ is a pure state.*

The first property is clear when $\boldsymbol{G}$ is a CPSO since $\|\boldsymbol{G}\|_\infty = 1$ and $\boldsymbol{G}$ is linear. Moreover, the second property does not hold for PSOs (and even for CPSOs) that act on more than one qubit. For example, the CPSO on two qubits that is the identity on the first qubit and constant to some pure state on the second qubit is a counterexample (take, for instance, $\rho = \psi \otimes (\frac{1}{2}I_2)$, where ψ is any pure state).

Proof. We prove the lemma using the Bloch ball formalism.

(a) Let $\overline{\rho}, \overline{\tau} \in \mathcal{B}$ be two distinct elements. Let $\overline{\boldsymbol{L}}$ and $\overline{u}$ be, respectively, the linear part and the constant part of the affine map $\overline{\boldsymbol{G}}$; that is, $\overline{\boldsymbol{G}} = \overline{\boldsymbol{L}} + \overline{u}$. Then we have

$$\overline{\boldsymbol{G}}(\overline{\rho}) - \overline{\boldsymbol{G}}(\overline{\tau}) = \|\overline{\rho} - \overline{\tau}\|\overline{\boldsymbol{L}}\left(\frac{\overline{\rho} - \overline{\tau}}{\|\overline{\rho} - \overline{\tau}\|}\right).$$

Note that $\overline{v} = \frac{\overline{\rho}-\overline{\tau}}{\|\overline{\rho}-\overline{\tau}\|}$ has norm 1. To conclude the proof, we now show that $\|\overline{\boldsymbol{L}}(\overline{v})\| \leq 1$. Observe that

$$\begin{aligned}\|\overline{\boldsymbol{G}}(\overline{v})\|^2 + \|\overline{\boldsymbol{G}}(-\overline{v})\|^2 &= \|\overline{\boldsymbol{L}}(\overline{v}) + \overline{u}\|^2 + \|-\overline{\boldsymbol{L}}(\overline{v}) + \overline{u}\|^2\\ &= 2(\|\overline{\boldsymbol{L}}(\overline{v})\|^2 + \|\overline{u}\|^2).\end{aligned}$$

Since $\overline{\boldsymbol{G}}$ preserves $\mathcal{B}$ and $\pm\overline{v} \in \mathcal{B}$, the images $\overline{\boldsymbol{G}}(\pm\overline{v})$ are also in $\mathcal{B}$. Therefore $\|\overline{\boldsymbol{G}}(\pm\overline{v})\| \leq 1$, and then $\|\overline{\boldsymbol{L}}(\overline{v})\| \leq 1$.

(b) We prove the second property by contradiction. Let us recall that $\mathcal{S}$ denotes the Bloch sphere. Suppose that there exists $\overline{\rho} \in \mathcal{B} - \mathcal{S}$ such that $\overline{\boldsymbol{G}}(\overline{\rho}) \in \mathcal{S}$. Since $\overline{\boldsymbol{G}}$ is not constant, there exists an element $\overline{\tau} \in \mathcal{B}$ such that $\overline{\boldsymbol{G}}(\overline{\tau}) \neq \overline{\boldsymbol{G}}(\overline{\rho})$. For every real $\varepsilon > 0$, let $\overline{w}_\varepsilon = \overline{\rho} + \varepsilon(\overline{\rho} - \overline{\tau})$. Fix some $\varepsilon > 0$ such that $\overline{w}_\varepsilon \in \mathcal{B}$. Such an ε exists since, by hypothesis, $\overline{\rho} \in \mathcal{B} - \mathcal{S}$. Moreover $\overline{\boldsymbol{G}}$ is affine; thus

$$\overline{\boldsymbol{G}}(\overline{w}_\varepsilon) = \overline{\boldsymbol{G}}(\overline{\rho}) + \varepsilon(\overline{\boldsymbol{G}}(\overline{\rho}) - \overline{\boldsymbol{G}}(\overline{\tau})).$$

Therefore, using $\|\overline{\boldsymbol{G}}(\rho)\| = 1$, the norm of $\overline{\boldsymbol{G}}(\overline{w}_\varepsilon)$ satisfies

$$\begin{aligned}\|\overline{\boldsymbol{G}}(\overline{w}_\varepsilon)\|^2 &= 1 + 2\varepsilon\big((\overline{\boldsymbol{G}}(\overline{\rho}) - \overline{\boldsymbol{G}}(\overline{\tau})), \overline{\boldsymbol{G}}(\overline{\rho})\big) + \varepsilon^2\|\overline{\boldsymbol{G}}(\overline{\rho}) - \overline{\boldsymbol{G}}(\overline{\tau})\|^2\\ &= 1 + 2\varepsilon\Big(1 - \big(\overline{\boldsymbol{G}}(\overline{\tau}), \overline{\boldsymbol{G}}(\overline{\rho})\big)\Big) + \varepsilon^2\|\overline{\boldsymbol{G}}(\overline{\rho}) - \overline{\boldsymbol{G}}(\overline{\tau})\|^2\\ &\geq 1 + \varepsilon^2\|\overline{\boldsymbol{G}}(\overline{\rho}) - \overline{\boldsymbol{G}}(\overline{\tau})\|^2\\ &> 1.\end{aligned}$$

Therefore there exists some element $\overline{w}_\varepsilon \in \mathcal{B}$ such that $\overline{\boldsymbol{G}}(\overline{w}_\varepsilon) \notin \mathcal{B}$, which contradicts $\overline{\boldsymbol{G}}(\mathcal{B}) \subseteq \mathcal{B}$. □

An affine transformation of $\mathbb{R}^3$ is uniquely defined by the images of four noncoplanar points. Surprisingly, if the transformation is a CPSO for one qubit, the images of three points are sometimes sufficient. The following will make this precise more generally for n qubits.

LEMMA 3.2. *Let $n \geq 1$ be an integer, and let ρ_1, ρ_2, and ρ_3 be three distinct one-qubit density matrices representing pure states, such that the plane in $\mathbb{R}^3$ containing the points $\overline{\rho_1}, \overline{\rho_2}, \overline{\rho_3}$ goes through the center of $\mathcal{B}$. If $\boldsymbol{G}$ is a CPSO for n qubits that acts as the identity on the set $\{\rho_1, \rho_2, \rho_3\}^{\otimes n}$, then $\boldsymbol{G}$ is the identity mapping.*

Proof. Let P be the plane defined in $\mathbb{R}^3$ by $\overline{\rho_1}$, $\overline{\rho_2}$, and $\overline{\rho_3}$. To simplify the discussion, we suppose without loss of generality (w.l.o.g.) that $\overline{\zeta_z^\pm}$ and $\overline{\zeta_x^\pm}$ are in P. Every one-qubit ρ satisfying $\overline{\rho} \in P$ is a linear combination of ρ_1, ρ_2 and ρ_3. Therefore by linearity of $\boldsymbol{G}$ we get that it acts as the identity on $\{\rho : \overline{\rho} \in P\}^{\otimes n}$. Moreover it is sufficient to show that $\boldsymbol{G}$ is the identity on density matrices representing nonentangled pure states, since they form a basis for all density matrices. To see this fact, note that any 2×2 complex matrix can be expressed as a linear combination of pure state density matrices. For example, the elementary matrix $|0\rangle\langle 1|$ can be written as

$$2|0\rangle\langle 1| = (|0\rangle + |1\rangle)(\langle 0| + \langle 1|) + i(|0\rangle + i|1\rangle)(\langle 0| - i\langle 1|) - (1+i)|0\rangle\langle 0| - (1+i)|1\rangle\langle 1|.$$

Thus any tensor product of 2×2 matrices can be expanded as a linear combination of the tensor product of single qubit pure state density matrices. Since a $2^n \times 2^n$ density matrix can be written as a linear combination of tensor products of 2×2 matrices (see, e.g., section 3.1 of [29]), it follows that any such density matrix can be expressed as a linear combination of the density matrices representing nonentangled pure states.

Using the fact that $\boldsymbol{G}$ is the identity on both the computational basis and the diagonal basis, that is, on $\{\zeta_x^\pm,\zeta_z^\pm\}^{\otimes n}$, we would like to derive that $\boldsymbol{G}$ acts as the identity everywhere. One way of proving this is to use the correspondence between unitary transformations and CPSOs. Let A be a unitary matrix such that $\boldsymbol{G}(\rho)=\mathrm{Tr}_2(A(\rho\otimes I_{2^n})A^\dagger)$ for every n-qubit state ρ (recall that Tr_2 denotes the trace out over half of the last qubits). By assumption, for every n-qubit pure state $|\psi\rangle\in\{\zeta_x^\pm,\zeta_z^\pm\}^{\otimes n}$, there exists a n-qubit pure state $|\varphi_\psi\rangle$ such that $A|\psi\rangle|0^n\rangle=|\psi\rangle|\varphi_\psi\rangle$. Therefore, by the linearity of A, we get that $|\varphi_\psi\rangle$ does not depend on $|\psi\rangle$, which implies by again the linearity of A that for every n-qubit pure state $|\psi\rangle$, $A|\psi\rangle|0^n\rangle=|\psi\rangle|\varphi\rangle$ for some n-qubit pure state $|\varphi\rangle$. Then we directly conclude that $\boldsymbol{G}$ is the identity.

For the sake of completeness, we now prove the result in more detail by induction using our first definition of CPSOs. For this, for every k, let E_k be the set of density matrices representing k-qubit nonentangled pure states, and let $F_k=\{\zeta_x^\pm,\zeta_z^\pm\}^{\otimes k}$. We will show by induction on k that, for every $0\le k\le n$, the CPSO $\boldsymbol{G}$ acts as the identity on $E_k\otimes F_{n-k}$. The case $k=0$ follows by the hypothesis of the lemma.

Suppose the statement is true for some k. Fix $\sigma\in E_k$ and $\tau\in F_{n-k-1}$. For every one-qubit density matrix ρ, let $\tilde\rho$ denote the n-qubit density matrix $\sigma\otimes\rho\otimes\tau$.

We now prove that $G(\tilde\rho)=\tilde\rho$ for every $\rho\in E_1$. For this, we use the fact that the density matrix Ψ^+ representing the entangled EPR state $(|00\rangle+|11\rangle)/\sqrt{2}$ can be written in terms of tensor products of the ζ states:

$$\Psi^+=\tfrac12(\zeta_x^+\otimes\zeta_x^++\zeta_x^-\otimes\zeta_x^-+\zeta_z^+\otimes\zeta_z^++\zeta_z^-\otimes\zeta_z^-)-\tfrac12(\zeta_y^+\otimes\zeta_y^++\zeta_y^-\otimes\zeta_y^-).$$

This can be generalized for the pure state $|\mu\rangle=(|\tilde0\rangle|\tilde0\rangle+|\tilde1\rangle|\tilde1\rangle)/\sqrt{2}$:

$$\mu=\tfrac12(\tilde\zeta_x^+\otimes\tilde\zeta_x^++\tilde\zeta_x^-\otimes\tilde\zeta_x^-+\tilde\zeta_z^+\otimes\tilde\zeta_z^++\tilde\zeta_z^-\otimes\tilde\zeta_z^-)-\tfrac12(\tilde\zeta_y^+\otimes\tilde\zeta_y^++\tilde\zeta_y^-\otimes\tilde\zeta_y^-).$$

If we apply the CPSO $\boldsymbol{I}_{2^n}\otimes\boldsymbol{G}$ to the state μ, we get

$$\begin{aligned}&(\boldsymbol{I}_{2^n}\otimes\boldsymbol{G})(\mu)\\&=\tfrac12[\tilde\zeta_x^+\otimes\tilde\zeta_x^++\tilde\zeta_x^-\otimes\tilde\zeta_x^-+\tilde\zeta_z^+\otimes\tilde\zeta_z^++\tilde\zeta_z^-\otimes\tilde\zeta_z^--\tilde\zeta_y^+\otimes\boldsymbol{G}(\tilde\zeta_y^+)-\tilde\zeta_y^-\otimes\boldsymbol{G}(\tilde\zeta_y^-)].\end{aligned}$$

If $|\varphi\rangle$ and $|\varphi'\rangle$ are orthogonal n-qubit pure states, then let $\Phi^-_{\varphi\varphi'}=(|\varphi\rangle|\varphi'\rangle-|\varphi'\rangle|\varphi\rangle)/\sqrt{2}$. Since $\Phi^-_{\varphi\varphi'}$ is orthogonal to all symmetric $2n$-qubit pure states of the form $\psi\otimes\psi$, by projecting $(\boldsymbol{I}_{2^n}\otimes\boldsymbol{G})(\mu)$ to $\Phi^-_{\varphi\varphi'}$ we obtain

$$\langle\Phi^-_{\varphi\varphi'}|(\boldsymbol{I}_{2^n}\otimes\boldsymbol{G})(\mu)|\Phi^-_{\varphi\varphi'}\rangle=-\tfrac12\langle\Phi^-_{\varphi\varphi'}|\tilde\zeta_y^+\otimes\boldsymbol{G}(\tilde\zeta_y^+)|\Phi^-_{\varphi\varphi'}\rangle-\tfrac12\langle\Phi^-_{\varphi\varphi'}|\tilde\zeta_y^-\otimes\boldsymbol{G}(\tilde\zeta_y^-)|\Phi^-_{\varphi\varphi'}\rangle.$$

Since $\boldsymbol{G}$ is a CPSO, the left-hand side of this equality is nonnegative, and in the right-hand side both terms are nonpositive. Therefore for every orthogonal n-qubit pure states $|\varphi\rangle$ and $|\varphi'\rangle$, we get

$$\langle\Phi^-_{\varphi\varphi'}|\tilde\zeta_y^+\otimes\boldsymbol{G}(\tilde{\zeta_y}^+)|\Phi^-_{\varphi\varphi'}\rangle=\langle\Phi^-_{\varphi\varphi'}|\tilde\zeta_y^-\otimes\boldsymbol{G}(\tilde{\zeta_y}^-)|\Phi^-_{\varphi\varphi'}\rangle=0.$$

A straightforward calculation then shows that $\boldsymbol{G}(\tilde{\zeta_y}^\pm)=\tilde\zeta_y^\pm$. Therefore $\boldsymbol{G}$ acts as the identity on density matrices $\tilde\zeta_z^\pm$, $\tilde\zeta_x^+$, and $\tilde\zeta_y^+$, which generate all density matrices, and thus $\boldsymbol{G}(\tilde\rho)=\tilde\rho$. □

We also use the property that for CPSOs unitarity and invertibility are equivalent (see, e.g., [25, Chap. 3, sect. 8]).

LEMMA 3.3. *Let $\boldsymbol{G}$ be a CPSO for n qubits. If there exists a CPSO $\boldsymbol{H}$ for n qubits such that $\boldsymbol{H} \circ \boldsymbol{G}$ is the identity mapping, then $\boldsymbol{G}$ is a unitary superoperator.*

Using the following lemma, we can give a version of Lemma 3.2 in the approximate context.

LEMMA 3.4. *Let $\boldsymbol{G}$ be a superoperator for one qubit. Let $0 \leq \varepsilon \leq 1$ be such that $\|\boldsymbol{G}(\zeta_x^\pm) - \zeta_x^\pm\|_1$, $\|\boldsymbol{G}(\zeta_y^\pm) - \zeta_y^\pm\|_1$, $\|\boldsymbol{G}(\zeta_z^\pm) - \zeta_z^\pm\|_1 \leq \varepsilon$. Then $\|\boldsymbol{G} - \boldsymbol{I}_2\|_\infty \leq \sqrt{10}\varepsilon$.*

Proof. Every 2×2 complex matrix V can be decomposed as

$$V = \begin{pmatrix} a & b \\ c & d \end{pmatrix} = a\zeta_z^+ + d\zeta_z^- + \frac{b+c}{2}\left(\zeta_x^+ - \frac{1}{2}(\zeta_z^+ + \zeta_z^-)\right) + i\frac{b-c}{2}\left(\zeta_y^+ - \frac{1}{2}(\zeta_z^+ + \zeta_z^-)\right).$$

All norms $\|\zeta_\cdot^\pm\|_1$ are 1; therefore, the hypotheses on G imply

$$\|\boldsymbol{G}(V) - V\|_1 \leq \varepsilon(|a| + 2|b| + 2|c| + |d|).$$

From Fact 2.4 we also have that $\sqrt{\mathrm{Tr}(V^\dagger V)} \leq \|V\|_1$. Moreover $\mathrm{Tr}(V^\dagger V) = |a|^2 + |b|^2 + |c|^2 + |d|^2$. Then we conclude the proof by the Cauchy–Schwarz inequality $|a| + 2|b| + 2|c| + |d| \leq \sqrt{10}\sqrt{|a|^2 + |b|^2 + |c|^2 + |d|^2}$. □

LEMMA 3.5. *Let $\overline{u}$ and $\overline{v}$ be two orthonormal vectors in $\mathbb{R}^3$, and let $0 \leq \varepsilon \leq 1$ be a constant. If $\boldsymbol{G}$ is a CPSO for one qubit such that $\|\overline{\boldsymbol{G}}(\pm\overline{u}) - \pm\overline{u}\| \leq \varepsilon$ and $\|\overline{\boldsymbol{G}}(\pm\overline{v}) - \pm\overline{v}\| \leq \varepsilon$, then $\|\boldsymbol{G} - \boldsymbol{I}_2\|_\infty \leq 96\varepsilon$.*

Proof. We can suppose w.l.o.g. that $u = \zeta_x^+$ and $v = \zeta_z^+$. Let $\rho = \boldsymbol{G}(\zeta_y^+)$, where $\overline{\rho} = (x, y, z)$. From Lemma 3.1 it follows that $\|\boldsymbol{G}(\zeta_z^+) - \rho\|_1 \leq \|\zeta_z^+ - \zeta_y^+\|_1 = \sqrt{2}$. By the assumption of this lemma we have that $\|\boldsymbol{G}(\zeta_z^+) - \zeta_z^+\|_1 \leq \varepsilon$, and hence $\|\zeta_z^+ - \rho\|_1 \leq \sqrt{2} + \varepsilon$. The same relation holds also for the other three fixed points ζ_z^-, ζ_x^+, and ζ_x^-. As a result, the three coordinates of $\overline{\rho}$ have to obey the four inequalities

$$\begin{aligned} & x^2 + y^2 + (z \pm 1)^2 \leq (\sqrt{2} + \varepsilon)^2 \leq 2 + 4\varepsilon \\ \text{and} \quad & (x \pm 1)^2 + y^2 + z^2 \leq (\sqrt{2} + \varepsilon)^2 \leq 2 + 4\varepsilon. \end{aligned} \tag{3.1}$$

A second set of restrictions on (x, y, z) comes from the complete positivity of $\boldsymbol{G}$. Again we use the decomposition of the EPR state Ψ^+ to analyze the two-qubit state:

$$\begin{aligned} (\boldsymbol{I}_2 \otimes \boldsymbol{G})(\Psi^+) = {} & \tfrac{1}{2}(\zeta_x^+ \otimes \boldsymbol{G}(\zeta_x^+) + \zeta_x^- \otimes \boldsymbol{G}(\zeta_x^-)) \\ & + \tfrac{1}{2}(\zeta_z^+ \otimes \boldsymbol{G}(\zeta_z^+) + \zeta_z^- \otimes \boldsymbol{G}(\zeta_z^-)) \\ & - \tfrac{1}{2}(\zeta_y^+ \otimes \boldsymbol{G}(\zeta_y^+) + \zeta_y^- \otimes \boldsymbol{G}(\zeta_y^-)). \end{aligned}$$

Using the hypothesis, the projection of this state onto the antisymmetrical entangled qubit pair $|\Phi^-\rangle = (|01\rangle - |10\rangle)/\sqrt{2}$ yields

$$\langle\Phi^-|(\boldsymbol{I}_2 \otimes \boldsymbol{G})(\Psi^+)|\Phi^-\rangle \leq 2\varepsilon - \tfrac{1}{2}\langle\Phi^-|\zeta_y^+ \otimes \boldsymbol{G}(\zeta_y^+)|\Phi^-\rangle - \tfrac{1}{2}\langle\Phi^-|\zeta_y^- \otimes \boldsymbol{G}(\zeta_y^-)|\Phi^-\rangle.$$

Since $\boldsymbol{G}$ is a CPSO, as in Lemma 3.2 we get $\langle\Phi^-|\zeta_y^+ \otimes \rho|\Phi^-\rangle \leq 4\varepsilon$. A straightforward calculation shows that this last relation is equivalent with a restriction on the y coordinate: $y \geq 1 - 16\varepsilon$.

This last inequality implies $y^2 \geq 1 - 32\varepsilon$, which combined with the restrictions of (3.1) leads to the conclusion that $(x \pm 1)^2 \leq 2 + 4\varepsilon - y^2 - z^2 \leq 1 + 36\varepsilon$, and similarly $(z \pm 1)^2 \leq 1 + 36\varepsilon$. The x and z coordinates of $\overline{\rho}$ satisfy $|x|, |z| \leq 18\varepsilon$.

These bounds imply

$$\|\boldsymbol{G}(\zeta_y^+) - \zeta_y^+\|_1 = \sqrt{x^2 + (y-1)^2 + z^2} \leq \sqrt{904}\varepsilon.$$

The same result can be proved for ζ_y^-. Therefore by Lemma 3.4 we can conclude the proof. □

4. Characterization.

4.1. One-qubit CPSO families.

In this section, every CPSO will be for one qubit. First we define the notion of experimental equations, and then we show that several important CPSO families are characterizable by them.

An *experimental equation* in one variable is a CPSO equation of the form

$$\mathrm{Pr}^0[\boldsymbol{G}^k(|b\rangle\langle b|)] = r, \tag{4.1}$$

where k is a nonnegative integer, $b \in \{0,1\}$, and $0 \le r \le 1$. We will call the left-hand side of the equation the *probability term* and the right-hand side the *constant term.* The *size* of this equation is k. A CPSO $\boldsymbol{G}$ will "almost" satisfy the equations if, for example, it is the result of adding small systematic and random errors (independent of time) to a CPSO that does satisfy them. For $\varepsilon \ge 0$, the CPSO $\boldsymbol{G}$ *ε-satisfies* (4.1) if $|\mathrm{Pr}^0[\boldsymbol{G}^k(|b\rangle\langle b|)] - r| \le \varepsilon$, and when $\varepsilon = 0$ we will just say that $\boldsymbol{G}$ *satisfies* (4.1). Let (E) be a finite set of experimental equations. If $\boldsymbol{G}$ ε-satisfies all equations in (E), we say that $\boldsymbol{G}$ ε-satisfies (E). If some $\boldsymbol{G}$ satisfies (E), then (E) is *satisfiable.* The set $\{\boldsymbol{G} : \boldsymbol{G} \text{ satisfies } (E)\}$ will be denoted by $\mathcal{F}_{(E)}$. A family $\mathcal{F}$ of CPSOs is *characterizable* if it is $\mathcal{F}_{(E)}$ for some finite set (E) of experimental equations. In this case we say that (E) *characterizes* $\mathcal{F}$.

All of these definitions generalize naturally for m-tuples of CPSOs for $m \ge 2$. In what follows we will need only the case $m = 2$. An *experimental equation* in two CPSO variables is an equation of the form

$$\mathrm{Pr}^0[\boldsymbol{F}^{k_1} \circ \boldsymbol{G}^{l_1} \circ \cdots \circ \boldsymbol{F}^{k_t} \circ \boldsymbol{G}^{l_t}(|b\rangle\langle b|)] = r, \tag{4.2}$$

where $k_1, \ldots, k_t, l_1, \ldots, l_t$ are nonnegative integers, $b \in \{0,1\}$, and $0 \le r \le 1$.

We discuss now the existence of finite sets of experimental equations in one variable that characterize unitary superoperators, that is, the operators $\boldsymbol{R}_{\alpha,\theta,\varphi}$, for $\alpha \in (-\pi,\pi]$, $\theta \in [0,\pi/2]$, and $\varphi \in [0,2\pi)$. First observe that, due to the restrictions of experimental equations, there are unitary superoperators that they cannot distinguish.

FACT 4.1. *Let $\alpha \in [0,\pi]$, $\theta \in [0,\pi/2]$, and $\varphi_1, \varphi_2 \in [0,2\pi)$ such that $\varphi_1 \ne \varphi_2$. Let (E) be a finite set of experimental equations in m variables. If $(\boldsymbol{R}_{\alpha,\theta,\varphi_1}, \boldsymbol{G}_2, \ldots, \boldsymbol{G}_m)$ satisfies (E), then there exist $\boldsymbol{G}'_2, \ldots, \boldsymbol{G}'_m$ and $\boldsymbol{G}''_2, \ldots, \boldsymbol{G}''_m$ such that $(\boldsymbol{R}_{-\alpha,\theta,\varphi_1}, \boldsymbol{G}'_2, \ldots, \boldsymbol{G}'_m)$ and $(\boldsymbol{R}_{\alpha,\theta,\varphi_2}, \boldsymbol{G}''_2, \ldots, \boldsymbol{G}''_m)$ both satisfy (E).*

In the Bloch ball formalism this corresponds to the following degrees of freedom in the choice of the orthonormal basis of $\mathbb{R}^3$. Since experimental equations contain exactly the states $|0\rangle\langle 0|$ and $|1\rangle\langle 1|$, there is no freedom in the choice of the z-axis, but there is complete freedom in the choice of the x and y axes. The indistinguishability of the latitude φ corresponds to the freedom of choosing the oriented x-axis, and the indistinguishability of the sign of α corresponds to the freedom of choosing the orientation of the y-axis.

We introduce the following notations. Let $\mathcal{R}_{\alpha,\theta}$ denote the superoperator family $\{\boldsymbol{R}_{\pm\alpha,\theta,\varphi} : \varphi \in [0,2\pi)\}$. For $\varphi \in [0,2\pi)$, let the NOT_φ transformation be defined by $\mathrm{NOT}_\varphi|0\rangle = e^{i\varphi}|1\rangle$ and $\mathrm{NOT}_\varphi(e^{i\varphi}|1\rangle) = |0\rangle$, and recall that the Hadamard transformation H_φ obeys $H_\varphi|0\rangle = (|0\rangle + e^{i\varphi}|1\rangle)/\sqrt{2}$ and $H_\varphi(e^{i\varphi}|1\rangle) = (|0\rangle - e^{i\varphi}|1\rangle)/\sqrt{2}$. Observe that $\boldsymbol{H}_\varphi = \boldsymbol{R}_{\pi,\pi/4,\varphi}$ and $\mathbf{NOT}_\varphi = \boldsymbol{R}_{\pi,\pi/2,\varphi}$ for $\varphi \in [0,2\pi)$. Finally let $\mathcal{H} = \{\boldsymbol{H}_\varphi : \varphi \in [0,2\pi)\}$, and $\mathcal{N} = \{\mathbf{NOT}_\varphi : \varphi \in [0,2\pi)\}$.

Since the sign of α cannot be determined, we will assume that α is in the interval $[0,\pi]$. We will also consider only unitary superoperators such that α/π is rational. This is a reasonable choice, since these superoperators form a dense subset of all unitary superoperators. For such a unitary superoperator, let n_α be the smallest positive integer n for which $n\alpha = 0 \mod 2\pi$. Then either $n_\alpha = 1$ or $n_\alpha \geq 2$, and there exists $t \geq 1$ which is coprime with n_α such that $\alpha = (t/n_\alpha)2\pi$. Observe that the case $n_\alpha = 1$ corresponds to the identity superoperator.

Our first theorem shows that almost all families $\mathcal{R}_{\alpha,\theta}$ are characterizable by some finite set of experimental equations.

Theorem 4.2. *Let $(\alpha,\theta) \in (0,\pi] \times (0,\pi/2]\backslash\{(\pi,\pi/2)\}$ be such that α/π is rational. Let $z_k(\alpha,\theta) = \cos^2\theta + \sin^2\theta\cos(k\alpha)$. Then the following experimental equations characterize $\mathcal{R}_{\alpha,\theta}$:*

$$\Pr{}^0[\boldsymbol{G}^{n_\alpha}(|1\rangle\langle 1|)] = 0, \tag{4.3}$$

$$\Pr{}^0[\boldsymbol{G}^{k}(|0\rangle\langle 0|)] = (1+z_k(\alpha,\theta))/2,\ k \in \{1,2,\ldots,n_\alpha\}. \tag{4.4}$$

In particular, since $\mathcal{H} = \mathcal{R}_{\pi,\pi/4}$, the family $\mathcal{H}$ is characterized by

$$\begin{aligned}&\Pr{}^0[\boldsymbol{G}^2(|1\rangle\langle 1|)] = 0, \quad \Pr{}^0[\boldsymbol{G}^2(|0\rangle\langle 0|)] = 1,\\ &\Pr{}^0[\boldsymbol{G}(|0\rangle\langle 0|)] = 1/2.\end{aligned}$$

Proof. First observe that every CPSO in $\mathcal{R}_{\alpha,\theta}$ satisfies the experimental equations of the theorem since the z-coordinate of $\overline{\boldsymbol{R}^k_{\alpha,\theta,\varphi}(|0\rangle\langle 0|)}$ is $z_k(\alpha,\theta)$ for every $\varphi \in [0,2\pi)$. Let $\boldsymbol{G}$ be a CPSO that satisfies these equations. We will prove that $\boldsymbol{G}$ is a unitary superoperator. Then, Fact 4.3 implies that $\boldsymbol{G} \in \mathcal{R}_{\alpha,\theta}$.

Since $z_1(\alpha,\theta) \neq \pm 1$, $\boldsymbol{G}(|0\rangle\langle 0|) \notin \{|0\rangle\langle 0|, |1\rangle\langle 1|\}$. Observing that $\boldsymbol{G}^{n_\alpha}(|0\rangle\langle 0|) = |0\rangle\langle 0|$, Lemma 3.1(b) implies that $\boldsymbol{G}(|0\rangle\langle 0|)$ is a pure state. Thus $|0\rangle\langle 0|$, $|1\rangle\langle 1|$, and $\boldsymbol{G}(|0\rangle\langle 0|)$ are distinct pure states, and since $\boldsymbol{G}^{n_\alpha}$ acts as the identity on them, by Lemma 3.2 it is the identity mapping. Hence, by Lemma 3.3, $\boldsymbol{G}$ is a unitary superoperator. □

Fact 4.3. *Let $\alpha \in (0,\pi]$, $\theta \in (0,\pi/2]$, $\alpha' \in (-\pi,\pi]$, $\theta' \in (0,\pi/2]$ be such that α/π is rational. If $z_k(\alpha,\theta) = z_k(\alpha',\theta')$ for $k \in \{1,2,\ldots,n_\alpha\}$, then $|\alpha'| = \alpha$ and $\theta' = \theta$.*

The remaining families $\mathcal{R}_{\alpha,\theta}$ for which α/π is rational are $\{\boldsymbol{R}_{-\alpha},\boldsymbol{R}_\alpha\}$, for $\alpha \in [0,\pi]$, and $\mathcal{N}$. Let us recall that $\boldsymbol{M}$ is the CPSO that represents the von Neumann measurement in the computational basis. Since $\boldsymbol{M}$ satisfies exactly the same equations as $\boldsymbol{R}_{\pm\alpha}$, and $\mathbf{NOT}_0 \circ \boldsymbol{M}$ satisfies exactly the same equations as $\mathbf{NOT}_\varphi$, for any $\varphi \in [0,2\pi)$, these families are not characterizable by experimental equations in one variable. Nevertheless it turns out that together with the family $\mathcal{H}$ they become characterizable. This is stated in the following theorem.

Theorem 4.4. *The family $\{(\boldsymbol{H}_\varphi,\mathbf{NOT}_\varphi) : \varphi \in [0,2\pi)\} \subset \mathcal{H}\times\mathcal{N}$ is characterized by the experimental equations in two variables $(\boldsymbol{F},\boldsymbol{G})$:*

$$\begin{aligned}&\Pr{}^0[\boldsymbol{F}(|0\rangle\langle 0|)] = 1/2, \quad \Pr{}^0[\boldsymbol{F}^2(|0\rangle\langle 0|)] = 1, \quad \Pr{}^0[\boldsymbol{F}^2(|1\rangle\langle 1|)] = 0,\\ &\Pr{}^0[\boldsymbol{G}(|0\rangle\langle 0|)] = 0, \qquad \Pr{}^0[\boldsymbol{G}(|1\rangle\langle 1|)] = 1,\\ &\Pr{}^0[\boldsymbol{F}\circ\boldsymbol{G}^2\circ\boldsymbol{F}(|0\rangle\langle 0|)] = 1, \quad \Pr{}^0[\boldsymbol{F}\circ\boldsymbol{G}\circ\boldsymbol{F}(|0\rangle\langle 0|)] = 1.\end{aligned}$$

If α/π is rational, then the family $\mathcal{H}\times\{\boldsymbol{R}_{\pm\alpha}\}$ is characterized by the experimental *equations in two variables* $(\boldsymbol{F}, \boldsymbol{G})$*:*

$$\begin{array}{lll} \Pr^0[\boldsymbol{F}(|0\rangle\langle 0|)] = 1/2, & \Pr^0[\boldsymbol{F}^2(|0\rangle\langle 0|)] = 1, & \Pr^0[\boldsymbol{F}^2(|1\rangle\langle 1|)] = 0, \\ \Pr^0[\boldsymbol{G}(|0\rangle\langle 0|)] = 1, & \Pr^0[\boldsymbol{G}(|1\rangle\langle 1|)] = 0, & \\ \Pr^0[\boldsymbol{F} \circ \boldsymbol{G}^{n_\alpha} \circ \boldsymbol{F}(|0\rangle\langle 0|)] = 1, & \Pr^0[\boldsymbol{F} \circ \boldsymbol{G} \circ \boldsymbol{F}(|0\rangle\langle 0|)] = (1 + \cos\alpha)/2. & \end{array}$$

In particular, since $\boldsymbol{I}_2 = \boldsymbol{R}_0$, the identity transformation on 1 qubit is characterizable; namely, the family $\mathcal{H} \times \{\boldsymbol{I}_2\}$ is characterized by

$$\begin{array}{lll} \Pr^0[\boldsymbol{F}(|0\rangle\langle 0|)] = 1/2, & \Pr^0[\boldsymbol{F}^2(|0\rangle\langle 0|)] = 1, & \Pr^0[\boldsymbol{F}^2(|1\rangle\langle 1|)] = 0, \\ \Pr^0[\boldsymbol{G}(|0\rangle\langle 0|)] = 1, & \Pr^0[\boldsymbol{G}(|1\rangle\langle 1|)] = 0, & \\ \Pr^0[\boldsymbol{F} \circ \boldsymbol{G} \circ \boldsymbol{F}(|0\rangle\langle 0|)] = 1. & & \end{array}$$

Proof. Let us consider the first characterization. Observe that every couple $(\boldsymbol{F}, \boldsymbol{G})$ of $\{(\boldsymbol{H}_\varphi, \mathbf{NOT}_\varphi) : \varphi \in [0, 2\pi)\}$ satisfies the system of experimental equations.

Let now $\boldsymbol{F}$ and $\boldsymbol{G}$ be two CPSOs that satisfy the system. The CPSO $\boldsymbol{F}$ satisfies also the system in (4.3) for $\alpha = \pi$ and $\theta = \pi/4$; thus, from Theorem 4.2 there exists $0 \leq \varphi < 2\pi$ such that $\boldsymbol{F} = \boldsymbol{H}_\varphi$. By hypothesis, $\boldsymbol{G}^2$ acts as the identity on $|0\rangle\langle 0|$ and $|1\rangle\langle 1|$. Moreover $\boldsymbol{H}_\varphi \circ \boldsymbol{G}^2 \circ \boldsymbol{H}_\varphi(|0\rangle\langle 0|) = |0\rangle\langle 0|$. Let us apply $\boldsymbol{H}_\varphi$ on both sides of the previous equality. Since $\boldsymbol{H}_\varphi^2 = \boldsymbol{I}_2$, the CPSO $\boldsymbol{G}^2$ acts also as the identity on $\boldsymbol{H}_\varphi(|0\rangle\langle 0|)$. Therefore using Lemma 3.2 we get that $\boldsymbol{G}^2$ is the identity; then, by Lemma 3.3, $\boldsymbol{G}$ is a unitary CPSO. Since $\overline{|0\rangle\langle 0|}$ and $\overline{|1\rangle\langle 1|}$ are exchanged together under the action of $\overline{\boldsymbol{G}}$, the rotation axis of $\overline{\boldsymbol{G}}$ is necessarily in the plane with equation $z = 0$. Moreover this axis goes through $\overline{\boldsymbol{H}_\varphi(|0\rangle\langle 0|)}$ because from the last experimental equation $\boldsymbol{G}$ acts as the identity on $\boldsymbol{H}_\varphi(|0\rangle\langle 0|)$. We conclude that the CPSO $\boldsymbol{G}$ is $\mathbf{NOT}_\varphi$.

We now consider the second characterization. The system is clearly satisfied by every pair $(\boldsymbol{F}, \boldsymbol{G})$ in $\mathcal{H} \times \{\boldsymbol{R}_{\pm\alpha}\}$.

Let now $\boldsymbol{F}$ and $\boldsymbol{G}$ be two CPSOs that satisfy the system of experimental equations. Like in the previous characterization, there exists a real $0 \leq \varphi < 2\pi$ such that $\boldsymbol{F} = \boldsymbol{H}_\varphi$, and $\boldsymbol{G}^{n_\alpha}$ is the identity. Therefore $\boldsymbol{G}$ is a unitary CPSO. Since $\boldsymbol{G}$ acts as the identity on $|0\rangle\langle 0|$ and $|1\rangle\langle 1|$, the rotation axis of $\overline{\boldsymbol{G}}$ is the z-axis. The last experimental equation implies that the angle $\alpha' \in (-\pi, \pi]$ of the rotation $\overline{\boldsymbol{G}}$ satisfies $\cos\alpha' = \cos\alpha$; that is, $\alpha' = \pm\alpha$. □

4.2. Characterization of c-NOT gates. In this section we will extend our theory of characterization of CPSO families for several qubits. In particular, we will show that the family of **c-NOT** gates together with the family $\mathcal{H}$ is characterizable. First we need some definitions.

For every $\varphi \in [0, 2\pi)$, we define c-NOT$_\varphi$ as the only unitary transformation over $\mathbb{C}^4$ satisfying c-NOT$_\varphi(|0\rangle|\psi\rangle) = |0\rangle|\psi\rangle$ and c-NOT$_\varphi|1\rangle|\psi\rangle = |1\rangle$NOT$_\varphi|\psi\rangle$ for all $|\psi\rangle \in \mathbb{C}^2$.

We extend the definition of the experimental equation for CPSOs given in (4.2) for n qubits. When variables denote CPSOs for n qubits, it is an equation of the form

$$\Pr^v[\boldsymbol{F}^{k_1} \circ \boldsymbol{G}^{l_1} \circ \cdots \circ \boldsymbol{F}^{k_t} \circ \boldsymbol{G}^{l_t}(|w\rangle\langle w|)] = r, \tag{4.5}$$

where, in addition to the notation of (4.2), $v, w \in \{0,1\}^n$, and $\Pr^v$ is the probability of measuring $|v\rangle\langle v|$. When variables denote CPSOs for less than n qubits, we also allow both the tensor product of two CPSO variables and the tensor product of a CPSO variable with the identity. We now state the characterization.

THEOREM 4.5. *The family* $\{(\boldsymbol{H}_\varphi, \textbf{c-NOT}_\varphi) : \varphi \in [0, 2\pi)\}$ *is characterized by the experimental equations in two variables* $(\boldsymbol{F}, \boldsymbol{G})$*:*

$$\begin{aligned}
&\Pr{}^0[\boldsymbol{F}(|0\rangle\langle 0|)] = 1/2, \quad \Pr{}^0[\boldsymbol{F}^2(|0\rangle\langle 0|)] = 1, \quad \Pr{}^0[\boldsymbol{F}^2(|1\rangle\langle 1|)] = 0,\\
&\Pr{}^{00}[\boldsymbol{G}(|00\rangle\langle 00|)] = 1, \quad \Pr{}^{01}[\boldsymbol{G}(|01\rangle\langle 01|)] = 1,\\
&\Pr{}^{11}[\boldsymbol{G}(|10\rangle\langle 10|)] = 1, \quad \Pr{}^{10}[\boldsymbol{G}(|11\rangle\langle 11|)] = 1,\\
&\Pr{}^{00}[(\boldsymbol{I}_2 \otimes \boldsymbol{F}) \circ \boldsymbol{G} \circ (\boldsymbol{I}_2 \otimes \boldsymbol{F})(|00\rangle\langle 00|)] = 1,\\
&\Pr{}^{10}[(\boldsymbol{I}_2 \otimes \boldsymbol{F}) \circ \boldsymbol{G} \circ (\boldsymbol{I}_2 \otimes \boldsymbol{F})(|10\rangle\langle 10|)] = 1,\\
&\Pr{}^{00}[(\boldsymbol{F} \otimes \boldsymbol{I}_2) \circ \boldsymbol{G}^2 \circ (\boldsymbol{F} \otimes \boldsymbol{I}_2)(|00\rangle\langle 00|)] = 1,\\
&\Pr{}^{01}[(\boldsymbol{F} \otimes \boldsymbol{I}_2) \circ \boldsymbol{G}^2 \circ (\boldsymbol{F} \otimes \boldsymbol{I}_2)(|01\rangle\langle 01|)] = 1,\\
&\Pr{}^{00}[(\boldsymbol{F} \otimes \boldsymbol{F}) \circ \boldsymbol{G} \circ (\boldsymbol{F} \otimes \boldsymbol{F})(|00\rangle\langle 00|)] = 1.
\end{aligned}$$

Proof. First observe that every pair $(\boldsymbol{F}, \boldsymbol{G})$ in $\{(\boldsymbol{H}_\varphi, \textbf{c-NOT}_\varphi) : \varphi \in [0, 2\pi)\}$ satisfies the experimental equations of the theorem.

Let $\boldsymbol{F}$ and $\boldsymbol{G}$ satisfy these equations. By Theorem 4.2, with $\alpha = \pi$ and $\theta = \pi/4$, the first three equations imply that $\boldsymbol{F} = \boldsymbol{H}_\varphi$ for some $\varphi \in [0, 2\pi)$. Let $\rho = \boldsymbol{H}_\varphi(|0\rangle\langle 0|)$. The remaining equations imply that $\boldsymbol{G}^2$ acts as the identity on $\{|0\rangle\langle 0|, |1\rangle\langle 1|, \rho\}^{\otimes^2}$. Then Lemma 3.2 implies that $\boldsymbol{G}^2 = \boldsymbol{I}_4$, and it follows from Lemma 3.3 that $\boldsymbol{G}$ is a unitary CPSO.

We now show that indeed $\boldsymbol{G} = \textbf{c-NOT}_\varphi$. To simplify we will suppose that $\varphi = 0$, since one can replace $|1\rangle$ by $|1'\rangle = e^{i\varphi}|1\rangle$. Let $G \in \mathrm{U}(4)$ be a unitary transformation such that $\boldsymbol{G}$ is the corresponding CPSO. Then, since $\boldsymbol{G}$ acts as the identity on $|00\rangle\langle 00|$, there exists a real $0 \le \gamma < 2\pi$ such that $G|00\rangle = e^{i\gamma}|00\rangle$. Since $\boldsymbol{G}$ is also the corresponding CPSO of the unitary transformation $e^{-i\gamma}G$, we can suppose that $\gamma = 0$ w.l.o.g.. By hypothesis $\boldsymbol{G}$ acts as the identity on the density matrices $|01\rangle\langle 01|$ and $|0\rangle\langle 0| \otimes \rho$. Therefore the linearity of G necessarily implies that $G|01\rangle = |01\rangle$.

Using a similar argument, since $\boldsymbol{G}$ acts as $\textbf{c-NOT}_0$ on the density matrices $|10\rangle\langle 10|$, $|11\rangle\langle 11|$, and $|1\rangle\langle 1| \otimes \rho$, there exists a real $0 \le \gamma' < 2\pi$ such that $G|10\rangle = e^{i\gamma'}|11\rangle$ and $G|11\rangle = e^{i\gamma'}|10\rangle$.

Then the last experimental equation, which states that $\boldsymbol{G}$ acts as the identity on $\rho \otimes \rho$, implies

$$G(|00\rangle + |01\rangle + |10\rangle + |11\rangle) = e^{i\gamma''}(|00\rangle + |01\rangle + |10\rangle + |11\rangle)$$

for some $0 \le \gamma'' < 2\pi$. We now conclude the proof by observing that the linearity of G implies $\gamma' = 0$, $\gamma'' = 0$, and therefore $G = \text{c-NOT}_0$. □

5. Robustness. In this section we introduce the notion of robustness for experimental equations which will be the crucial ingredient for proving self-testability. For simplicity we will deal only with the case of experimental equations for one qubit and in one variable. From now on (E) will always denote a set of such equations. Similar results can be obtained for several qubits and several variables.

DEFINITION 5.1. *Let* $\varepsilon, \delta \ge 0$*, and let* (E) *be a finite satisfiable set of experimental equations. We say that* (E) *is* (ε, δ)-robust *if whenever a CPSO* $\boldsymbol{G}$ ε*-satisfies* (E)*, we have* $\mathrm{dist}_\infty(\boldsymbol{G}, \mathcal{F}_{(E)}) \le \delta$*.*

When a CPSO family is characterized by a finite set of experimental equations (E), one would like to prove that (E) is robust. The next theorem shows that this is always the case.

Theorem 5.2. *Let (E) be a finite satisfiable set of experimental equations. Then there exists an integer $k \geq 1$ and a real $C > 0$ such that, for all $\varepsilon \geq 0$, (E) is $(\varepsilon, C\varepsilon^{1/k})$-robust.*

The proof uses the structure of semialgebraic sets. Therefore we introduce a few notions of algebraic geometry over reals for which the reader can refer, for example, to [9]. A (real) *semialgebraic* set is a subset of $\mathbb{R}^m$ such that $X = \{x \in \mathbb{R}^m : Q(x)\}$, where Q a finite Boolean combination of expressions of type $P(x) > 0$, $P(x) < 0$, or $P(x) = 0$ for any real polynomial P. Finite unions, finite intersections, and complements of such sets remain semialgebraic sets. One of the main results on these sets is that their projections also remain semialgebraic sets. This is Tarski-Seidenberg's theorem (see, e.g., [9, Thm. 2.3.4]). A consequence of that theorem is that we can also use quantifiers $\exists y \in Y$ and $\forall y \in Y$, where Y is a semialgebraic set, for defining semialgebraic sets.

Let $X \subseteq \mathbb{R}^m$. A function $f : X \to \mathbb{R}^{m'}$ is *semialgebraic* if its graph representation is a semialgebraic set. The composition of two semialgebraic functions is also semialgebraic. Tarski-Seidenberg's theorem implies that every real function defined over $X \subseteq \mathbb{R}^m$ by $x \mapsto \inf\{f(x, y) : (x, y) \in X'\}$ (respectively, $x \mapsto \sup\{f(x, y) : (x, y) \in X'\}$), where $X' \subseteq \mathbb{R}^{m'}$ and $f : X' \to \mathbb{R}$ are semialgebraic, is also semialgebraic (see, e.g., [16, Cor. A.2.4]). In particular, the function that maps an element toward its distance to a compact semialgebraic set is a continuous semialgebraic function. Another fundamental consequence of Tarski-Seidenberg's theorem for continuous semialgebraic functions is Lojasiewicz's inequality. For a proof of the following fact, see, for example, [9, Prop. 2.3.11].

Fact 5.3 (Lojasiewicz's inequality). *Let $X \subseteq \mathbb{R}^m$ be a compact semialgebraic set. Let $f, g : X \to \mathbb{R}$ be continuous semialgebraic functions. Assume that for all $x \in X$ if $f(x) = 0$, then $g(x) = 0$. Then there exists an integer $k \geq 1$ and a real $C > 0$ such that, for all $x \in X$, $|g(x)|^k \leq C|f(x)|$.*

We can now prove Theorem 5.2, that is, the generic robustness for experimental equations.

Proof. In the proof, $\mathbb{C}$ is identified with $\mathbb{R}^2$. Then the set K of CPSOs for one qubit is a real compact semialgebraic set. Indeed we prove that, for every n, the set K_n of all CPSOs for n qubits is a real compact semialgebraic set using one of the Kraus representations for CPSOs. For that, let Tr_2 be the *partial trace* operator. Namely, Tr_2 is the unique linear map $\mathbb{C}^{N^2} \otimes \mathbb{C}^{N^2}$, where $N = 2^n$, such that, for every $i, j = 1, \ldots, N^2$ and every $V \in \mathbb{C}^{N^2}$,

$$\mathrm{Tr}_2(V \otimes |i\rangle\langle j|) = \begin{cases} V & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases}$$

Then the set K_n satisfies the following (see, e.g., [25, Chap. 3, sect. 3]):

$$K_n = \{\boldsymbol{G} : \exists A \in \mathrm{U}(N^2), \quad \forall V \in \mathbb{C}^{N \times N},\ \boldsymbol{G}(V) = \mathrm{Tr}_2(A(V \otimes I_N)A^\dagger)\}.$$

Since $\mathrm{U}(N^2)$ is a compact semialgebraic set, K_n is also a compact semialgebraic set.

Suppose now that in (E) there are d equations. Let $f : K \to \mathbb{R}$ be the function that maps the CPSO $\boldsymbol{G}$ to the maximum of the magnitudes of the difference between the probability term and the constant term of the ith equation in (E) for $i = 1, \ldots, d$. By definition of f, we get $f^{-1}(0) = \mathcal{F}_{(E)}$. Moreover, f is a continuous semialgebraic function, since it is the maximum of the magnitudes of polynomial functions in the (real) coefficients of $\boldsymbol{G}$.

Let $g : K \to \mathbb{R}$ be defined in $\boldsymbol{G}$ by $g(\boldsymbol{G}) = \mathrm{dist}_\infty(\boldsymbol{G}, \mathcal{F}_{(E)})$. Since K is a compact semialgebraic set, g is a continuous semialgebraic function. Moreover, for all $\boldsymbol{G} \in K$, we have $f(\boldsymbol{G}) = 0$ if and only if $g(\boldsymbol{G}) = 0$. Then Fact 5.3 concludes the proof. □

In some cases we can explicitly compute the constants C and k of Theorem 5.2. We will illustrate these techniques with the equations in Theorem 4.2 for the case $\alpha = \pi$ and $\theta = \pi/4$. Let us recall that these equations characterize the set $\mathcal{H}$.

THEOREM 5.4. *For every $0 \le \varepsilon \le 1$, the following equations are $(\varepsilon, 1824\sqrt{\varepsilon})$-robust:*

$$\begin{aligned}&\Pr{}^0[\boldsymbol{G}(|0\rangle\langle 0|)] = 1/2, \quad \Pr{}^0[\boldsymbol{G}^2(|0\rangle\langle 0|)] = 1,\\ &\Pr{}^0[\boldsymbol{G}^2(|1\rangle\langle 1|)] = 0.\end{aligned}$$

Proof. Let $\boldsymbol{G}$ be a CPSO which ε-satisfies the equations. First we will show that there is a point $\overline{\rho} \in \mathcal{S}$ with z-coordinate 0 whose distance from $\overline{\boldsymbol{G}(|0\rangle\langle 0|)}$ is at most $10\sqrt{\varepsilon}$. The last two equations imply that $\|\boldsymbol{G}^2(|b\rangle\langle b|) - |b\rangle\langle b|\|_1 \le 3\sqrt{\varepsilon}$ for $b = 0, 1$. Therefore $\|\boldsymbol{G}^2(|0\rangle\langle 0|) - \boldsymbol{G}^2(|1\rangle\langle 1|)\|_1 \ge 2 - 6\sqrt{\varepsilon}$, and by Lemma 3.1(a) we have $\|\boldsymbol{G}(|0\rangle\langle 0|) - \boldsymbol{G}(|1\rangle\langle 1|)\|_1 \ge 2 - 6\sqrt{\varepsilon}$. Thus $\|\overline{\boldsymbol{G}(|b\rangle\langle b|)}\| \ge 1 - 6\sqrt{\varepsilon}$ for $b = 0, 1$. Let $\tau = \rho(1/2, \alpha)$, where $\boldsymbol{G}(|0\rangle\langle 0|) = \rho(p, \alpha)$. The first equation implies that $\|\overline{\tau} - \overline{\boldsymbol{G}(|0\rangle\langle 0|)}\| \le 2\varepsilon$. Therefore for $\overline{\rho} = \overline{\tau}/\|\overline{\tau}\|$ we get $\|\boldsymbol{G}(|0\rangle\langle 0|) - \rho\|_1 \le 10\sqrt{\varepsilon}$.

The point $\overline{\rho}$ on $\mathcal{S}$ uniquely defines $\varphi \in [0, 2\pi)$ such that $\overline{\boldsymbol{H}_\varphi(|0\rangle\langle 0|)} = \overline{\rho}$. One can verify that $\boldsymbol{H}_\varphi^{-1} \circ \boldsymbol{G}$ acts as the identity with error at most $19\sqrt{\varepsilon}$ on the four density matrices $|0\rangle\langle 0|$, $|1\rangle\langle 1|$, $\boldsymbol{H}_\varphi(|0\rangle\langle 0|)$, and $\boldsymbol{H}_\varphi(|1\rangle\langle 1|)$. From Lemma 3.5 we conclude that $\|\boldsymbol{G} - \boldsymbol{H}_\varphi\|_\infty \le 1824\sqrt{\varepsilon}$. □

6. Quantum self-testers. In this final section we formally define our testers and establish the relationship between robust equations and testability. Again, we will do it here only for the case of one qubit and one variable. Let $\boldsymbol{G}$ be a CPSO. The *experimental oracle* $\mathcal{O}[\boldsymbol{G}]$ for $\boldsymbol{G}$ is a probabilistic procedure. It takes inputs from $\{0, 1\} \times \mathbb{N}$ and generates outcomes from the set $\{0, 1\}$ such that for every $k \in \mathbb{N}$

$$\Pr[\mathcal{O}[\boldsymbol{G}](b, k) = 0] = \Pr{}^0[\boldsymbol{G}^k(|b\rangle\langle b|)].$$

An oracle program T with an experimental oracle $\mathcal{O}[\boldsymbol{G}]$ is a program denoted by $T^{\mathcal{O}[\boldsymbol{G}]}$ which can ask queries from the experimental oracle in the following sense: When it presents a query (b, k) to the oracle, in one computational step it receives the probabilistic outcome of $\mathcal{O}[\boldsymbol{G}]$ on it.

DEFINITION 6.1. *Let $\mathcal{F}$ be a family of CPSOs, and let $0 \le \delta_1 \le \delta_2 < 1$. A (δ_1, δ_2)-*tester *for $\mathcal{F}$ is a probabilistic oracle program T such that for every CPSO $\boldsymbol{G}$*

- *if $\mathrm{dist}_\infty(\boldsymbol{G}, \mathcal{F}) \le \delta_1$, then $\Pr[T^{\mathcal{O}[\boldsymbol{G}]}$ says $\mathtt{PASS}] \ge 2/3$,*
- *if $\mathrm{dist}_\infty(\boldsymbol{G}, \mathcal{F}) > \delta_2$, then $\Pr[T^{\mathcal{O}[\boldsymbol{G}]}$ says $\mathtt{FAIL}] \ge 2/3$,*

where the probability is taken over the probability distribution of the outcomes of the experimental oracle and the coin tosses of the program.

Since norms are equivalent in fixed dimension, the testability of families of CPSOs acting on a constant number of qubits does not change for any norm. This is stated in the following fact.

FACT 6.2. *Assume that T is a (δ_1, δ_2)-tester for a family $\mathcal{F}$ of CPSOs for k-qubits. Then T is a $(\delta_1/\alpha, \delta_2/\beta)$-tester for $\mathcal{F}$ when dist_∞ is replaced by any distance d such that $\beta\mathrm{d}(\boldsymbol{G}, \boldsymbol{G'}) \le \mathrm{dist}_\infty(\boldsymbol{G}, \boldsymbol{G'}) \le \alpha\mathrm{d}(\boldsymbol{G}, \boldsymbol{G'})$, for all CPSOs $\boldsymbol{G}, \boldsymbol{G'}$ for k-qubits and for $0 < \beta \le \alpha$.*

THEOREM 6.3. *Let $\varepsilon, \delta > 0$, and let (E) be a satisfiable set of d experimental equations such that the size of every equation is at most k. If (E) is (ε, δ)-robust, then there exists an $(\varepsilon/(3k), \delta)$-tester for $\mathcal{F}_{(E)}$ which makes $O(d\ln(d)/\varepsilon^2)$ queries.*

Proof. We will describe a probabilistic oracle program T. Let $\boldsymbol{G}$ be a CPSO. We can suppose that, for every equation in (E), T has a rational number $\tilde{r}$ such that $|\tilde{r} - r| \leq \varepsilon/6$, where r is the constant term of the equation. By sampling the oracle $\mathcal{O}[\boldsymbol{G}]$, for every equation in (E), T obtains a value $\tilde{p}$ such that $|\tilde{p} - p| \leq \varepsilon/6$ with probability at least $1 - 1/(3d)$, where p is the probability term of the equation. A standard Chernoff bound argument shows that this is feasible with $O(\ln(d)/\varepsilon^2)$ queries for each equation. If for every equation $|\tilde{p} - \tilde{r}| \leq 2\varepsilon/3$, then T says `PASS`; otherwise, T says `FAIL`. Using the robustness of (E) and Fact 6.4, one can verify that T is a $(\varepsilon/(3k), \delta)$-tester for $\mathcal{F}_{(E)}$. □

FACT 6.4. *Let (E) be a finite satisfiable set of experimental equations such that the size of every equation is at most k, and let $\boldsymbol{G}$ be a CPSO. For every $\varepsilon \geq 0$, if $\mathrm{dist}_\infty(\boldsymbol{G}, \mathcal{F}_{(E)}) \leq \varepsilon$, then $\boldsymbol{G}$ $(k\varepsilon)$-satisfies (E).*

Our main result is the consequence of Theorems 4.2, 4.4, 4.5, 5.2, 5.4, and 6.3 and the many-qubit generalizations of them.

THEOREM 6.5. *Let $\mathcal{F}$ be one of the following families:*

- $\mathcal{R}_{\alpha,\theta}$ *for* $(\alpha, \theta) \in (0, \pi] \times (0, \pi/2] \backslash \{(\pi, \pi/2)\}$, *where* α/π *is rational,*
- $\{(\boldsymbol{H}_\varphi, \mathbf{NOT}_\varphi) : \varphi \in [0, 2\pi)\}$,
- $\mathcal{H} \times \{\boldsymbol{R}_{\pm\alpha}\}$ *for* α/π *rational,*
- $\{(\boldsymbol{H}_\varphi, \mathbf{c\text{-}NOT}_\varphi) : \varphi \in [0, 2\pi)\}$,
- $\{(\boldsymbol{H}_\varphi, \boldsymbol{R}_{s\pi/4}, \mathbf{c\text{-}NOT}_\varphi) : \varphi \in [0, 2\pi), s = \pm 1\}$.

Then there exists an integer $k \geq 1$ and a real $C > 0$ such that, for all $\varepsilon > 0$, $\mathcal{F}$ has an $(\varepsilon, C\varepsilon^{1/k})$-tester which makes $O(1/\varepsilon^2)$ queries. Moreover, for every $0 < \varepsilon \leq 1$, $\mathcal{H}$ has an $(\varepsilon/6, 4579\sqrt{\varepsilon})$-tester which makes $O(1/\varepsilon^2)$ queries.

Note that each triplet of the last family forms a universal and fault-tolerant set of quantum gates [7].

Acknowledgments. We thank Jean-Benoit Bost, Stéphane Boucheron, Charles Delorme, Stéphane Gonnord, Lucien Hardy, Richard Jozsa, and Vlatko Vedral for several useful discussions and advice. We are very grateful to the anonymous referee for the helpful comments and suggestions.

FASTER AND SIMPLER ALGORITHMS FOR MULTICOMMODITY FLOW AND OTHER FRACTIONAL PACKING PROBLEMS*

NAVEEN GARG† AND JOCHEN KÖNEMANN‡

Abstract. This paper considers the problem of designing fast, approximate, combinatorial algorithms for multicommodity flows and other fractional packing problems. We present new, faster, and much simpler algorithms for these problems.

Key words. multicommodity flow, fractional packing, concurrent flow, approximation algorithms

DOI. 10.1137/S0097539704446232

1. Introduction.

Consider the problem of computing a maximum s-t flow in a graph with unit edge capacities. While there are many different algorithms known for this problem we discuss one which views the problem purely as one of packing s-t paths so that constraints imposed by edge capacities are not violated. The algorithm associates a length with each edge and at any step it routes a unit flow along the shortest s-t path. It then multiplies the length of every edge on this path by $1+\epsilon$ for a fixed ϵ. Thus the longer an edge is the greater the flow through it is. Since we always choose the shortest s-t path to route flow along, we essentially try to balance the flow on all edges in the graph. One can argue that, if, after sufficiently many steps, M is the maximum flow through an edge, then the flow computed is almost M times the maximum s-t flow. Therefore scaling the flow by M gives a feasible flow which is almost maximum.

Note that the length of an edge at any step is exponential in the total flow going through the edge. Such a length function was first proposed by Shahrokhi and Matula [22], who used it to compute the throughput of a given multicommodity flow instance. While this problem (and all other problems considered in this paper) can be formulated as a linear program and solved to optimality using fast matrix multiplication [24], the authors of [22] were mainly interested in providing fast, possibly approximate, combinatorial algorithms. Their procedure, which applied only to the case of uniform edge capacities, computed a $(1+\omega)$-approximation to the maximum throughput in time polynomial in ω^{-1}. The key idea of their procedure, which was adopted in numerous subsequent papers, was to compute an initial flow by disregarding edge capacities and then to reroute this, iteratively, along short paths so as to reduce the maximum congestion on any edge.

The running time of [22] was improved significantly by Klein et al. [17]. It was then extended and refined to the case of arbitrary edge capacities by Leighton et al.

[18], Goldberg [11], and Radzik [21] to obtain better running times; see Table 1 for the current best bound.

Plotkin, Shmoys, and Tardos [20] observed that a similar technique could be applied to solve any fractional packing problem. Their approach to packing problems starts with an infeasible solution. The amount by which a packing constraint is violated is captured by a variable which is exponential in the extent of this violation. At any step the packing is modified by a *fixed amount* in a direction determined by these variables. Hence, the running time of the procedure depends upon the maximum extent to which any constraint could be violated; this is referred to as the *width* of the problem [20]. In [20], the authors propose several width-reduction techniques in order to decrease the (pseudopolynomial) running time of the algorithm.

Grigoriadis and Khachiyan [13] consider block angular packing problems which are problems of the form

$$\min \left\{ \lambda | \sum_{i=1}^{k} f^i(x^i) \leq \lambda e, x^i \in B^i, 1 \leq i \leq k \right\},$$

where B^i is a convex set, $f^i : B^i \to \mathbb{R}^m$ is a nonnegative convex function, and e is the vector of all 1's. They assume the existence of an oracle which, given $i, 1 \leq i \leq k$, nonnegative vector y, and scalar μ, computes $\min \left\{ y^T f^i(x) | f^i(x) \leq \mu e, x \in B^i \right\}$, and they show how to find a $(1+\epsilon)$-approximation to the block angular packing problem with only $k^2 \ln m(\epsilon^{-2} + \ln k)$ calls to this oracle. In [14], Grigoriadis and Khachiyan show that this problem can also be solved in $km(\epsilon^{-2} \ln \epsilon^{-1} + \ln m)$ calls to an oracle which computes $\min \left\{ y^T f^i(x) | x \in B^i \right\}$. Note that both these running times are independent of the width of the problem.

All the problems that we consider in this paper can be formulated as block angular packing problems. This is immediate for the maximum concurrent flow and the min-cost multicommodity flow problems. For these problems, the blocks are single commodity flows. In [13], the oracle corresponds to finding a min-cost single-commodity flow, while in [14], the oracle is a shortest path computation.

The maximum multicommodity flow problem can also be formulated as a block angular packing problem with one block, B, which is the set of all multicommodity flows of total value 1. For a flow $x \in B$, $f(x)$ is a vector denoting the fraction of the capacity utilized by x on the edges. If for a flow x, $f(x) \leq \lambda e$, then the flow x/λ satisfies all capacities and routes $1/\lambda$ units. Thus computing maximum flow is the same as minimizing λ. A similar idea can also be used to formulate fractional packing as a block angular convex program.

In a significant departure from this line of research and motivated by ideas from randomized rounding, Young [25] proposed an *oblivious rounding* approach to packing problems. Young's approach has the essential ingredient of previous approaches—a length function which measures, and is exponential in, the extent to which each constraint is violated by a given solution. However, [25] builds the solution from scratch and at each step adds to the packing a variable which violates only such packing constraints that are not already too violated. In particular, for multicommodity flow, it implies a procedure which does not involve rerouting flow (the flow is scaled only at the end) and which for the case of maximum s-t flow reduces to the algorithm discussed at the beginning of this section.

Our contributions. In this paper we provide a unified framework for multicommodity flow and packing problems which yields significantly simpler and faster algorithms than previously known. Our approach is similar to Young's approach to packing problems. However, we develop a new and simple combinatorial analysis which has the added flexibility that it allows us to make the greatest possible advance at each step. Thus for the setting of maximum s-t flows with integral edge capacities, Young's procedure routes a unit flow at each step, while our procedure would route enough flow so as to saturate the minimum capacity edge on the shortest s-t path. This simple modification is quite powerful and delivers a slightly better running time and a much simpler proof.

Our approach yields a new, very natural, algorithm for maximum concurrent flow (section 5) which extends in a straightforward manner to min-cost multicommodity flows (section 6). These algorithms use a min-cost flow computation as a subroutine and have running times that match the best known. We also provide algorithms for these two problems which use shortest path computations as a subroutine and are faster than previous algorithms. One idea in these algorithms which is key to the faster running times is to organize all computation sequentially and to use the length updates done at one step in the computations done at all subsequent steps. This is, in some ways, similar to the round-robin idea employed by Radzik [21].

This paper first appeared as a technical report in [9] and then as an extended abstract in [10]. Subsequently the approach presented here has been extended and improved results have been obtained for almost all the problems considered here. For the maximum multicommodity flow problem, Fleischer [7] obtained a running time that is independent of the number of commodities. Karakostas [15] obtained a corresponding result for the maximum multicommodity flow and min-cost multicommodity flow problems. We discuss the ideas behind these improvements in the appropriate sections.

Bienstock and Iyengar [4] recently adapted a method by Nesterov [19] in order to obtain a $(1+\omega)$-approximation for generalized packing problems. The ω-dependence of the running time of their algorithm is $O((1/\omega)\cdot\log 1/\omega)$, as opposed to a dependence of $O(1/\omega^2)$ of our algorithms. However, their algorithm needs to solve a convex quadratic program in each iteration, and this is computationally substantially more expensive than the oracle calls necessary in our algorithms. As a result, our algorithms remain faster than the algorithm by Bienstock and Iyengar for a fixed or moderately small ω.

Table 1 summarizes our results. All our algorithms are deterministic and compute a $(1+\omega)$-approximation to the optimum solution. In giving the running times we ignore polylog factors; the $\tilde{O}$ denotes this fact.

TABLE 1

A summary of our results. Here, D denotes the number of nonzero entries in the given constraint matrix and L is the maximum number of nonzero entries in a column.

Problem	Previous best	Our running time	Subseq. improvement
Max. mult. flow	$\tilde{O}(\omega^{-2}km^2)$ [14]	$\tilde{O}(\omega^{-2}km^2)$	$\tilde{O}(\omega^{-2}m^2)$ [7]

Maximum concurrent flow	$\tilde{O}(\omega^{-2}kmn)$ [21]	$\tilde{O}(\omega^{-2}kmn)$	
	$\tilde{O}(\omega^{-2}km^2)$ [14]	$\tilde{O}(\omega^{-2}(k+m)m)$	$\tilde{O}(\omega^{-2}m^2)$ [15]
Max. cost-bd. conc. flow	$\tilde{O}(\omega^{-2}kmn)$ [12]	$\tilde{O}(\omega^{-2}kmn)$	
	$\tilde{O}(\omega^{-2}km^2)$ [14]	$\tilde{O}(\omega^{-2}(k+m)m)$	$\tilde{O}(\omega^{-2}m^2)$ [15]

The framework introduced in this paper for multicommodity flow problems was extended by Fleischer and Wayne [8] to generalized flow. The book by Bienstock [3] is a good survey of the theoretical issues and computational studies done on this topic.

2. Maximum multicommodity flow. Given a graph $G = (V, E)$ with edge capacities $c : E \to \mathbb{R}^+$ and k pairs of terminals $(s_1, t_1), \ldots, (s_k, t_k)$, with one commodity associated with each pair, we want to find a multicommodity flow such that the sum of the flows of all commodities is maximized. Let $\mathcal{P}_j$ be the set of s_j, t_j-paths in G for all $1 \leq j \leq k$, and define $\mathcal{P}$ to be the union of $\mathcal{P}_1, \ldots, \mathcal{P}_k$. Also, let $\mathcal{P}_e$ be the set of paths in $\mathcal{P}$ that use edge e for all $e \in E$. The path-flow linear programming formulation for the maximum multicommodity flow problem has a variable $x(p)$ for the flow sent along each path $p \in \mathcal{P}$:

$$(P_{\text{mmc}}) \qquad \begin{aligned} \max \quad & \sum_{p \in \mathcal{P}} x(p) \\ \text{s.t.} \quad & \sum_{p \in \mathcal{P}_e} x(p) \leq c(e) \quad \forall e \in E, \\ & x \geq 0. \end{aligned}$$

The dual to this linear program associates a length $l(e)$ with each of the edges $e \in E$:

$$(D_{\text{mmc}}) \qquad \begin{aligned} \min \quad & D(l) \overset{\text{def}}{=} \sum_{e \in E} c(e) \cdot l(e) \\ \text{s.t.} \quad & \sum_{e \in p} l(e) \geq 1 \quad \forall p \in \mathcal{P}, \\ & l \geq 0. \end{aligned}$$

Observe that the above two linear programs (P_{mmc}) and (D_{mmc}) have exponential size. Optimal solutions can, however, be found in polynomial time as equivalent polynomial-size edge-flow formulations exist (e.g., see [1]).

In the following let $\texttt{dist}_j(l)$ be the length of the shortest s_j, t_j-path with respect to length l for $1 \leq j \leq k$. Also let $\alpha(l) \overset{\text{def}}{=} \min_j \texttt{dist}_j(l)$ be the minimum length path between any pair of terminals. Then (D_{mmc}) is equivalent to finding a length function $l : E \to \mathbb{R}^+$ such that $\frac{D(l)}{\alpha(l)}$ is minimized. Let $\beta \overset{\text{def}}{=} \min_l D(l)/\alpha(l)$.

The algorithm proceeds in iterations. Let l_{i-1} be the length function at the beginning of the ith iteration and f_{i-1} be the total flow routed in iterations $1 \ldots i-1$. Let P be a path of length $\alpha(l_{i-1})$ between a pair of terminals, and let c be the capacity of the minimum capacity edge on P. In the ith iteration we route c units of flow along P. Thus $f_i = f_{i-1} + c$. The function l_i differs from l_{i-1} only in the lengths of the edges along P; these are modified as $l_i(e) = l_{i-1}(e)(1 + \epsilon c/c(e))$, where ϵ is a constant to be chosen later.

Initially every edge e has length δ, i.e., $l_0(e) = \delta$ for some constant δ to be chosen later. For brevity we denote $\alpha(l_i), D(l_i)$ by $\alpha(i), D(i)$, respectively. The procedure stops after t iterations, where t is the smallest number such that $\alpha(t) \geq 1$.

2.1. Analysis. For every iteration $i \geq 1$

$$\begin{aligned} D(i) &= \sum_e l_i(e)c(e) \\ &= \sum_e l_{i-1}(e)c(e) + \epsilon \sum_{e \in P} l_{i-1}(e)c \\ &= D(i-1) + \epsilon(f_i - f_{i-1})\alpha(i-1), \end{aligned}$$

which implies that

$$D(i) = D(0) + \epsilon \sum_{j=1}^{i} (f_j - f_{j-1})\alpha(j-1). \tag{1}$$

Consider the length function $l_i - l_0$. Note that $D(l_i - l_0) = D(i) - D(0)$ and $\alpha(l_i - l_0) \geq \alpha(i) - \delta L$, where L is the maximum number of edges on any simple path in G. Hence

$$\beta \leq \frac{D(l_i - l_0)}{\alpha(l_i - l_0)} \leq \frac{D(i) - D(0)}{\alpha(i) - \delta L}. \tag{2}$$

Substituting this bound on $D(i) - D(0)$ into (1), we get

$$\alpha(i) \leq \delta L + \frac{\epsilon}{\beta} \sum_{j=1}^{i} (f_j - f_{j-1})\alpha(j-1).$$

To solve the above recurrence we first note that the sequence $x(0), x(1), \ldots x(i), \ldots,$ where $x(i) = \delta L + \frac{\epsilon}{\beta} \sum_{j=1}^{i} (f_j - f_{j-1})x(j-1)$, dominates the sequence

$$\alpha(0), \alpha(1), \ldots, \alpha(i), \ldots,$$

where $x(0) = \alpha(0)$. Now

$$\begin{aligned} x(i) &= \delta L + \frac{\epsilon}{\beta} \sum_{j=1}^{i-1} (f_j - f_{j-1})x(j-1) + \frac{\epsilon}{\beta}(f_j - f_{j-1})x(i-1) \\ &= x(i-1)(1 + \epsilon(f_i - f_{i-1})/\beta) \\ &\leq x(i-1)e^{\epsilon(f_i - f_{i-1})/\beta}. \end{aligned}$$

Since $x(0) = \alpha(0) \leq \delta L$ we have $x(i) \leq \delta L e^{\epsilon f_i/\beta}$, and this implies

$$\alpha(i) \leq \delta L e^{\epsilon f_i/\beta}.$$

By our stopping condition

$$1 \leq \alpha(t) \leq \delta L e^{\epsilon f_t/\beta}, \tag{3}$$

and hence

$$\frac{\beta}{f_t} \leq \frac{\epsilon}{\ln(\delta L)^{-1}}. \tag{4}$$

CLAIM 2.1. *There is a feasible flow of value* $\frac{f_t}{\log_{1+\epsilon}\frac{1+\epsilon}{\delta}}$.

Proof. Consider an edge e. For every $c(e)$ units of flow routed through e the length of e increases by a factor of at least $1 + \epsilon$. The last time its length was increased, e was on a path of length strictly less than 1. Since every increase in edge-length is by a factor of at most $1 + \epsilon$, $l_t(e) < 1 + \epsilon$. Since $l_0(e) = \delta$ it follows that the total flow through e is at most $c(e)\log_{1+\epsilon}\frac{1+\epsilon}{\delta}$. Scaling the flow, f_t, by $\log_{1+\epsilon}\frac{1+\epsilon}{\delta}$ then gives a feasible flow of claimed value. □

Thus the ratio of the values of the optimum dual and the primal solutions, γ, is $\frac{\beta}{f_t}\log_{1+\epsilon}\frac{1+\epsilon}{\delta}$. By substituting the bound on β/f_t from (4) we obtain

$$\gamma \leq \frac{\epsilon \log_{1+\epsilon}\frac{1+\epsilon}{\delta}}{\ln(\delta L)^{-1}} = \frac{\epsilon}{\ln(1+\epsilon)} \frac{\ln\frac{1+\epsilon}{\delta}}{\ln(\delta L)^{-1}}.$$

The ratio $\frac{\ln(1+\epsilon)\delta^{-1}}{\ln(\delta L)^{-1}}$ equals $(1-\epsilon)^{-1}$ for $\delta = (1+\epsilon)((1+\epsilon)L)^{-1/\epsilon}$. Hence with this choice of δ we have

$$\gamma \leq \frac{\epsilon}{(1-\epsilon)\ln(1+\epsilon)} \leq \frac{\epsilon}{(1-\epsilon)(\epsilon-\epsilon^2/2)} \leq (1-\epsilon)^{-2}.$$

Since this quantity should be no more than our approximation ratio $(1+w)$, we choose ϵ appropriately.

2.2. Running time. In the ith iteration we increase the length of the minimum capacity edge along P by a factor of $1+\epsilon$. Since, for any edge e, $l_0(e) = \delta$ and $l_t(e) < 1+\epsilon$, the number of iterations in which e is the minimum capacity edge on the path chosen in that iteration is at most $\lceil \frac{1}{\epsilon}\log_{1+\epsilon} L\rceil$. Using the fact that there are m edges we get the following theorem.

THEOREM 2.1. *There is an algorithm that computes a $(1+\omega)$-approximation to the maximum multicommodity flow in time $O(\omega^{-2}km\log L\cdot T_{sp})$, where L is the maximum number of edges on a path between any source-sink pair and T_{sp} is the time required to compute the shortest s-t path in a graph with nonnegative edge-weights.*

2.3. Subsequent improvements. Fleischer [7] made the interesting observation that it suffices to route flow along an approximate shortest path and that if the path chosen at each step is an a approximation to the shortest path then the approximation guarantee worsens only by a multiplicative factor a. Her algorithm proceeds in phases, each of which is composed of k iterations. If at the start of the ith phase the shortest path between each pair has length at least α, then in the jth iteration of this phase we route the jth commodity along any path of length at most $\alpha(1+\epsilon)$ and move to the next iteration only when the shortest path between s_j, t_j is at least $\alpha(1+\epsilon)$. This ensures that at the end of the ith phase every (s_j, t_j) pair is at least $\alpha(1+\epsilon)$ apart. Hence the number of phases is at most $\log_{1+\epsilon}\delta^{-1}$. The algorithm performs one shortest path computation in each iteration that does not result in flow being routed. Hence the total number of shortest path computations is $(m+k)\lceil\frac{1}{\epsilon}\log_{1+\epsilon} L\rceil$. Since k can be as large as $\mathrm{O}(n^2)$, Fleischer eliminates the dependence of the running time on k by routing all commodities with the same source in an iteration. It is possible to do this without additional effort since Dijkstra's algorithm for computing shortest paths gives the shortest path to every node in the graph.

3. Packing LP.

A packing **LP** is a linear program of the kind

$$\max\left\{c^T x | Ax \leq b, x \geq 0\right\},$$

where A, b, and c are $(m\times n), (m\times 1)$, and $(n\times 1)$ matrices, all of whose entries are positive. We also assume that for all i, j, the (i,j)th entry of A, $A(i,j)$, is at most $b(i)$. The dual of this **LP** is $\min\left\{b^T y | A^T y \geq c, y \geq 0\right\}$.

We view the rows of A as edges and the columns as paths. $b(i)$ is the capacity of edge i, and every unit of flow routed along the jth column consumes $A(i,j)$ units of capacity of edge i while providing a benefit of $c(j)$ units.

The dual variable $y(i)$ corresponds to the length of edge i. Define the *length* of a column j with respect to the dual variables y as $\mathtt{length}_y(j) \overset{\text{def}}{=} \sum_i A(i,j)y(i)/c(j)$. Finding a shortest path now corresponds to finding a column whose length is minimum; define $\alpha(y) \overset{\text{def}}{=} \min_j \mathtt{length}_y(j)$. Also define $D(y) \overset{\text{def}}{=} b^T y$. Then the dual program is equivalent to finding a variable assignment y such that $D(y)/\alpha(y)$ is minimized.

Once again our procedure will be iterative. Let y_{k-1} be the dual variables and f_{k-1} the value of the primal solution at the beginning of the kth iteration. Let q be the minimum length column of A, i.e., $\alpha(y_{k-1}) = \mathtt{length}_{y_{k-1}}(q)$—this corresponds to the path along which we route flow in this iteration. The minimum capacity edge is the row for which $b(i)/A(i,q)$ is minimum; let this be row p. Thus in this iteration we will increase the primal variable $x(q)$ by an amount $b(p)/A(p,q)$ so that $f_k = f_{k-1} + c(q)b(p)/A(p,q)$. The dual variables are modified as

$$y_k(i) = y_{k-1}(i)\left(1 + \epsilon\frac{b(p)/A(p,q)}{b(i)/A(i,q)}\right),$$

where ϵ is a constant to be chosen later.

The initial values of the dual variables are given by $y_0(i) = \delta/b(i)$ for some constant δ to be chosen later. For brevity we denote $\alpha(y_k), D(y_k)$ by $\alpha(k), D(k)$, respectively. Thus $D(0) = m\delta$. The procedure stops at the first iteration t such that $D(t) \geq 1$.

3.1. Analysis. The analysis here proceeds almost exactly as in the case of maximum multicommodity flow. For every iteration $k \geq 1$

$$\begin{aligned} D(k) &= \sum_i b(i)y_k(i) \\ &= \sum_i b(i)y_{k-1}(i) + \epsilon\frac{b(p)}{A(p,q)}\sum_i A(i,q)y_{k-1}(i) \\ &= D(k-1) + \epsilon(f_k - f_{k-1})\alpha(k-1), \end{aligned} \tag{5}$$

which, as before, implies that

$$D(k) = D(0) + \epsilon\sum_{l=1}^{k}(f_l - f_{l-1})\alpha(l-1).$$

Let $\beta \overset{\text{def}}{=} \min_y D(y)/\alpha(y)$. Then $\beta \leq D(l-1)/\alpha(l-1)$, and so

$$D(k) \leq m\delta + \frac{\epsilon}{\beta}\sum_{l=1}^{k}(f_l - f_{l-1})D(l-1).$$

In order to solve this recurrence, we first define

$$x(i) = m\delta + \frac{\epsilon}{\beta}\sum_{l=1}^{k}(f_l - f_{l-1})x(l-1)$$

for all $i \geq 0$. We note that the sequence $(x(i))_{i\geq 0}$ dominates the sequence $(D(i))_{i\geq 0}$. Now

$$\begin{aligned} x(k) &= m\delta + \frac{\epsilon}{\beta}\sum_{l=1}^{k-1}(f_l - f_{l-1})x(l-1) + \frac{\epsilon}{\beta}(f_k - f_{k-1})x(k-1) \\ &= \left(1 + \frac{\epsilon}{\beta}(f_k - f_{k-1})\right)x(k-1) \\ &\leq e^{\epsilon(f_k - f_{k-1})/\beta}x(k-1) \\ &\leq e^{\epsilon f_k/\beta}x(0) = m\delta \cdot e^{\epsilon f_k/\beta}. \end{aligned}$$

Using $D(k) \leq x(k)$ we therefore obtain

$$D(k) \leq m\delta e^{\epsilon f_k/\beta},$$

and by our stopping condition

$$1 \leq D(t) \leq m\delta e^{\epsilon f_t/\beta}, \tag{6}$$

and hence

$$\frac{\beta}{f_t} \leq \frac{\epsilon}{\ln(m\delta)^{-1}}.$$

CLAIM 3.1. *There is a feasible solution to the packing* **LP** *of value* $\frac{f_t}{\log_{1+\epsilon}\frac{1+\epsilon}{\delta}}$.

Proof. The primal solution x we constructed has value f_t. However, it may not be feasible since some packing constraint $(\sum_j A(i,j)x(j))/b(i) \leq 1$ may be violated. When we pick column q and increase $x(q)$ by $b(p)/A(p,q)$ we increase the left-hand side (LHS) of the ith constraint by $\frac{A(i,q)b(p)}{b(i)A(p,q)}$ ($= z$, say). Simultaneously we increase the dual variable $y(i)$ by a multiplicative factor of $1 + \epsilon z$. By our definition of p it follows that $z \leq 1$, and hence increasing the LHS of the ith constraint by 1 causes an increase in $y(i)$ by a multiplicative factor of at least $1+\epsilon$. Note that $y_{t-1}(i) < 1/b(i)$, and so $y_t(i) < (1+\epsilon)/b(i)$. Since $y_0(i) = \delta/b(i)$ it follows that the final value of the LHS of the ith constraint is no more than $\log_{1+\epsilon}\frac{1+\epsilon}{\delta}$. Since this is true for every i, scaling the primal solution by $\log_{1+\epsilon}\frac{1+\epsilon}{\delta}$ gives a feasible solution of value as in the claim. ☐

The rest of the analysis is exactly the same as in section 2.1 with m replacing L. Thus $\delta = (1+\epsilon)((1+\epsilon)m)^{-1/\epsilon}$.

3.2. Running time. In the kth iteration we increase the dual variable of the "minimum capacity" row by a factor of $(1+\epsilon)$. Since for any row i, $y_0(i) = \delta/b(i)$ and $y_t(i) < (1+\epsilon)/b(i)$ and there are m rows in all, the total number of iterations is at most $m\lceil\frac{1}{\epsilon}\log_{1+\epsilon} m\rceil$. For explicitly given packing programs one requires $\mathrm{O}(D)$ time to compute the minimum length column, where D is the number of nonzero entries in the matrix A. This implies a running time of $mD\lceil\frac{1}{\epsilon}\log_{1+\epsilon} m\rceil$ for computing a $(1-\epsilon)^{-2}$-approximation to the packing **LP**.

THEOREM 3.1. *There is an algorithm that computes a* $(1+\omega)$*-approximation to the packing* **LP** *in time* $O(\omega^{-2}mD\log m)$*, where* m *is the number of rows and* D *is the number of nonzero entries in the given constraint matrix.*

3.3. Subsequent improvements. Young [26] observed that with Fleischer's technique this running time improves to $\tilde{O}(\omega^{-2}(mL + D))$, where L is the maximum number of nonzero entries in a column and D is the number of nonzero entries in the constraint matrix.

4. Spreading metrics. Given a graph $G = (V, E)$ with edge costs $c : E \rightarrow \mathbb{R}^+$, a spreading metric is an assignment of lengths to the edges, $l : E \rightarrow \mathbb{R}^+$, so as to minimize $\sum_e l(e)c(e)$ subject to the constraint that for any set $S \subseteq V$ and vertex $r \in S$, $\sum_{v \in S} \texttt{dist}_{r,v}(l) \geq f(S)$, where $\texttt{dist}_{r,v}(l)$ is the distance from r to v under the length function l and $f()$ is a function only of the size of S. For the linear arrangement problem $f(S) = (|S| - 1)(|S| - 3)/4$ [6], while for the problem of computing a ρ-separator[1] $f(S)$ is defined as $|S| - \rho|V|$ [5].

Since the length function l is positive, the shortest paths from r to the other vertices in S form a tree—the shortest path tree rooted at r. Thus the above constraints can be equivalently stated as follows: for any tree T, for any subset S of vertices in T, and for any vertex $r \in S$

$$\sum_{v \in S} \texttt{dist}_{r,v}(l, T) \geq f(S),$$

where $\texttt{dist}_{r,v}(l, T)$ denotes the distance from r to v in tree T under the length function l.

Let $u_e(T, S, r)$ be the number of vertices of S in the subtree below edge e when T is rooted at r. Then the above constraint can be rewritten again to obtain the **LP**

$$\begin{aligned} \min \quad & \sum_e l(e)c(e) \\ \text{s.t.} \quad & \sum_{e \in T} l(e)u_e(T, S, r) \geq f(S) \quad \forall T, \forall S \subseteq T, \forall r \in S, \\ & l \geq 0. \end{aligned}$$

The dual of this program, which is a packing **LP**, has a nonnegative variable $x(T, S, r)$ for every tree T, subset $S \subseteq T$, and vertex $r \in S$ and is as follows:

$$\begin{aligned} \max \quad & \sum_{T,S,r} x(T, S, r)f(S) \\ \text{s.t.} \quad & \sum_{T: e \in T} x(T, S, r)u_e(T, S, r) \leq c(e) \quad \forall e \in E, \\ & x \geq 0. \end{aligned}$$

Note that the packing **LP** has exponentially many variables. However, the $(1+w)$-approximation to the optimum fractional solution, in the previous section, needed an oracle that returned only the "most violated constraint" of the dual **LP**. In this setting, this oracle is a subroutine, which, given a length function l, finds a triple (T, S, r) for which $(\sum_{e \in T} l(e)u_e(T, S, r))/f(S)$ or, equivalently, $(\sum_{v \in S} \texttt{dist}_{r,v}(l, T))/f(S)$ is minimum.

[1] A minimum cost set of edges whose removal disconnects the graph into connected components, each of which has at most $\rho|V|$ vertices.

Our subroutine will try out all n choices for vertex r and for each of these it will determine the best choice of T, S. For a given r and every subset S, the expression $\sum_{v\in S} \mathtt{dist}_{r,v}(l,T)$ is minimized when T is the tree of shortest paths from r and under the length function l. Therefore, for a given r, our choice of T will be the shortest path tree rooted at r. Since $f(S)$ depends only on $|S|$, given that $|S| = k$, the ratio $(\sum_{v\in S} \mathtt{dist}_{r,v}(l,T))/f(S)$ is minimized when S is the set of k nearest vertices to r. Amongst the n different choices for k, and hence for S, we choose the set for which the above ratio is minimum. Having found the best triple (T, S, r), we now determine the extent to which $x(T, S, r)$ is increased by considering all edges in T and finding the edge for which $c(e)/u_e(T, S, r)$ is minimum.

The subroutine thus requires n single-source shortest path computations. The running time of the procedure is obtained by noting that the subroutine is invoked once in each of the $m\lceil \frac{1}{\epsilon} \log_{1+\epsilon} m\rceil$ iterations.

Theorem 4.1. *There is an algorithm that computes a* $(1+\omega)$*-approximation to spreading metrics in time* $O(\omega^{-2} mn \log m \cdot T_{\mathrm{sp}})$*, where* T_{sp} *is the time required to compute single-source shortest paths in a graph with nonnegative edge-weights.*

It is easy to improve the running time by a factor n by using Fleischer's idea. After computing the shortest path tree from a certain root vertex and finding the best set S we continue with the same root vertex until the ratio is at least $(1+\epsilon)$ times the ratio at the start of the phase. Our analysis is now almost exactly the same as for the maximum multicommodity flow problem and leads to a running time of $\tilde{O}(\omega^{-2} m^2)$.

5. Maximum concurrent flow.

Once again we are given a graph with edge capacities $c : E \to \mathbb{R}^+$ and k commodities with s_j, t_j being the source and sink, respectively, for commodity j. Now each commodity has a demand $d(j)$ associated with it, and we want to find the largest λ such that there is a multicommodity flow which routes $\lambda d(j)$ units of commodity j.

In the following, let $\mathcal{F}_j$ be the set of flows that transport $d(j)$ units of flow from s_j to t_j for all $1 \le j \le k$. Similar to section 2, we use $\mathcal{F}$ to denote the union of $\mathcal{F}_1, \dots, \mathcal{F}_k$. For a flow $f \in \mathcal{F}$ and an edge $e \in E$, we let f_e be the amount of flow sent across e. We can then formulate the maximum concurrent flow problem as the following LP:

$$(P_{\mathrm{mcf}}) \qquad \begin{aligned} \max \quad & \lambda \\ \text{s.t.} \quad & \sum_{f\in\mathcal{F}} f_e \cdot x(f) \le c(e) \quad \forall e \in E, \\ & \sum_{f\in\mathcal{F}_j} x(f) \ge \lambda \quad \forall 1 \le j \le k, \\ & x \ge 0, \lambda \ge 0. \end{aligned}$$

Its dual has a length $l(e)$ for each edge $e \in E$, and a variable $z(j)$ for each commodity

$1 \le j \le k$:

$$(D_{\mathrm{mcf}}) \qquad \min \quad D(l) \overset{\mathrm{def}}{=} \sum_{e \in E} c(e) l(e)$$

$$\text{s.t.} \quad \sum_{e \in E} f_e \cdot l(e) \ge z(j) \quad \forall 1 \le j \le k, \forall f \in \mathcal{F}_j,$$

$$\sum_{j=1}^{k} z(j) \ge 1,$$

$$l, z \ge 0.$$

For a given $l : E \rightarrow \mathbb{R}^+$, $z(j)$ is the minimum cost of shipping $d(j)$ units of flow from s_j to t_j under cost function l, henceforth denoted by $\mathtt{min\_cost}_j(l)$. Let

$$\alpha(l) \overset{\mathrm{def}}{=} \sum_{j=1}^{k} \mathtt{min\_cost}_j(l).$$

LP (D_{mcf}) can now be recast as finding an assignment of lengths to the edges, $l : E \rightarrow \mathbb{R}^+$, such that $D(l)/\alpha(l)$ is minimized. Let β be this minimum. For now we assume that $\beta \ge 1$ and shall remove this assumption later.

The algorithm now proceeds in phases; each phase is composed of k iterations. Consider the jth iteration of the ith phase and let $l_{i,j-1}$ be the length function before this iteration. In this iteration we route $d(j)$ units of commodity j along the paths given by $\mathtt{min\_cost}_j(l_{i,j-1})$. Let $f_{i,j}(e)$ be the flow through edge e. The length function is modified as $l_{i,j}(e) = l_{i,j-1}(e)(1 + \epsilon f_{i,j}(e)/c(e))$. Then

$$\begin{aligned} D(l_{i,j}) &= \sum_e l_{i,j}(e) c(e) \\ &= D(l_{i,j-1}) + \epsilon \sum_e l_{i,j-1}(e) f_{i,j}(e) \\ &= D(l_{i,j-1}) + \epsilon \cdot \mathtt{min\_cost}_j(l_{i,j-1}). \end{aligned}$$

The lengths at the start of the $(i+1)$th phase are the same as those at the end of the ith phase, i.e., $l_{i+1,0} = l_{i,k}$. Initially, for any edge e, $l_{1,0}(e) = \delta/c(e) = l_{0,k}(e)$.

5.1. The analysis. We shall be interested in the values of the functions $D(), \alpha()$ only for the length functions $l_{i,k}, i \ge 0$. For brevity we denote $D(l_{i,k}), \alpha(l_{i,k})$ by $D(i), \alpha(i)$, respectively. With this new notation we have for $i \ge 1$

$$D(i) = D(l_{i,k}) = D(l_{i,0}) + \epsilon \sum_{j=1}^{k} \mathtt{min\_cost}_j(l_{i,j-1}).$$

Since the edge-lengths are monotonically increasing, $\mathtt{min\_cost}_j(l_{i,j-1}) \le \mathtt{min\_cost}_j(l_{i,k})$, and hence

$$D(i) \le D(l_{i,0}) + \epsilon \sum_{j=1}^{k} \mathtt{min\_cost}_j(l_{i,k}) = D(i-1) + \epsilon\alpha(i). \tag{7}$$

Since $\frac{D(i)}{\alpha(i)} \geq \beta$ we have

$$D(i) \leq \frac{D(i-1)}{1-\epsilon/\beta}.$$

Since $D(0) = m\delta$ we have for $i \geq 1$

$$\begin{aligned} D(i) &\leq \frac{m\delta}{(1-\epsilon/\beta)^i} \\ &= \frac{m\delta}{1-\epsilon/\beta}\left(1+\frac{\epsilon}{\beta-\epsilon}\right)^{i-1} \\ &\leq \frac{m\delta}{1-\epsilon/\beta} e^{\frac{\epsilon(i-1)}{\beta-\epsilon}} \\ &\leq \frac{m\delta}{1-\epsilon} e^{\frac{\epsilon(i-1)}{\beta(1-\epsilon)}}, \end{aligned}$$

where the last inequality uses our assumption that $\beta \geq 1$.

The procedure stops at the first phase t for which $D(t) \geq 1$. Therefore,

$$1 \leq D(t) \leq \frac{m\delta}{1-\epsilon} e^{\frac{\epsilon(t-1)}{\beta(1-\epsilon)}},$$

which implies

$$\frac{\beta}{t-1} \leq \frac{\epsilon}{(1-\epsilon)\ln\frac{1-\epsilon}{m\delta}}. \tag{8}$$

In the first $t-1$ phases, for every commodity j, we have routed $(t-1)d(j)$ units. However, this flow may violate capacity constraints.

CLAIM 5.1. $\lambda > \frac{t-1}{\log_{1+\epsilon} 1/\delta}$.

Proof. Consider an edge e. For every $c(e)$ units of flow routed through e, we increase its length by at least a factor $1+\epsilon$. Initially, its length is $\delta/c(e)$, and after $t-1$ phases, since $D(t-1) < 1$, the length of e satisfies $l_{t-1,k}(e) < 1/c(e)$. Therefore the total amount of flow through e in the first $t-1$ phases is strictly less than $\log_{1+\epsilon}\frac{1/c(e)}{\delta/c(e)} = \log_{1+\epsilon} 1/\delta$ times its capacity. Scaling the flow by $\log_{1+\epsilon} 1/\delta$ implies the claim. □

Thus the ratio of the values of the dual and primal solutions, γ, is strictly less than $\frac{\beta}{t-1}\log_{1+\epsilon} 1/\delta$. Substituting the bound on $\beta/(t-1)$ from (8), we get

$$\gamma < \frac{\epsilon \log_{1+\epsilon} 1/\delta}{(1-\epsilon)\ln\frac{1-\epsilon}{m\delta}} = \frac{\epsilon}{(1-\epsilon)\ln(1+\epsilon)} \frac{\ln 1/\delta}{\ln\frac{1-\epsilon}{m\delta}}.$$

For $\delta = (m/(1-\epsilon))^{-1/\epsilon}$ the ratio $\frac{\ln 1/\delta}{\ln\frac{1-\epsilon}{m\delta}}$ equals $(1-\epsilon)^{-1}$, and hence

$$\gamma \leq \frac{\epsilon}{(1-\epsilon)^2\ln(1+\epsilon)} \leq \frac{\epsilon}{(1-\epsilon)^2(\epsilon-\epsilon^2/2)} \leq (1-\epsilon)^{-3}.$$

Now it remains to choose ϵ suitably so that $(1-\epsilon)^{-3}$ is at most our desired approximation ratio $1+w$.

5.2. Running time. By weak-duality we have

$$1 \leq \gamma < \frac{\beta}{t-1} \log_{1+\epsilon} \frac{1}{\delta},$$

and hence the number of phases in the above procedure, t, is strictly less than $1 + \beta \log_{1+\epsilon} 1/\delta$, which implies that $t = \lceil \frac{\beta}{\epsilon} \log_{1+\epsilon} \frac{m}{1-\epsilon} \rceil$.

The running time of our computation depends on β, which can be reduced/increased by multiplying the demands/capacities appropriately. Let z_i be the maximum possible flow of commodity i, and let $z \overset{\text{def}}{=} \min_i z_i/d(i)$. Then z denotes the maximum fraction of the demands that can be routed independently, and hence $z/k \leq \beta \leq z$. We scale the capacities/demands so that $z/k = 1$ thus satisfying our assumption that $\beta \geq 1$. Note, however, that β could now be as large as k.

If our procedure does not stop within $2\lceil \frac{1}{\epsilon} \log_{1+\epsilon} \frac{m}{1-\epsilon} \rceil$ ($= T$, say) phases, then we know that $\beta \geq 2$. We double the demands of all commodities and continue the procedure. Note that β is now half its value in the previous phase and is at least 1. We run the procedure for an additional T phases and if it does not halt we again double demands. Since we halve the value of β after every T phases, the total number of phases is at most $T \log k$.

THEOREM 5.1. *There is an algorithm that computes a $(1+\omega)$-approximation to the maximum concurrent flow in time $O(\omega^{-2} k \log k \log m \cdot T_{\text{mcf}})$, where T_{mcf} is the time required to compute a minimum cost s-t flow in a graph with nonnegative edge-costs.*

The number of phases can be reduced further using an idea from [20]. We first compute a 2-approximation to β using the procedure outlined above. This requires $O(\log k \log m)$ phases and returns $\hat{\beta}$, $\beta \leq \hat{\beta} \leq 2\beta$. Now create a new instance by multiplying demands by $\hat{\beta}/2$; this instance has $1 \leq \beta \leq 2$. Therefore, we need at most an additional T phases to obtain a $(1+w)$-approximation. Thus the number of phases is $O(\log m(\log k + (\epsilon \ln 1 + \epsilon)^{-1}))$, which multiplied by k gives the number of single-commodity min-cost flow computations required.

5.3. Avoiding min-cost flow computations. We now show how min-cost flow computations can be avoided in the above algorithm for the maximum concurrent flow problem. Using the notation introduced in section 2, an alternate path-flow LP formulation of the maximum concurrent flow problem is as follows:

$$(P^2_{\text{mcf}}) \qquad \begin{aligned} \max \quad & \lambda \\ \text{s.t.} \quad & \sum_{p \in \mathcal{P}_e} x(p) \leq c(e) \quad \forall e \in E, \\ & \sum_{p \in \mathcal{P}_j} x(p) \geq \lambda \cdot d(j) \quad \forall 1 \leq j \leq k, \\ & x \geq 0, \lambda \geq 0. \end{aligned}$$

Its linear programming dual has a length $l(e)$ for each edge $e \in E$ and a variable $z(j)$ for each commodity j:

$$(D^2_{\mathrm{mcf}}) \qquad \begin{aligned} \min \quad & D(l) \overset{\mathrm{def}}{=} \sum_{e \in E} c(e) l(e) \\ \text{s.t.} \quad & \sum_{e \in p} l(e) \geq z(j) \quad \forall 1 \leq j \leq k, \forall p \in \mathcal{P}_j, \\ & \sum_{j=1}^{k} d(j) \cdot z(j) \geq 1, \\ & l, z \geq 0. \end{aligned}$$

For a given $l : E \rightarrow \mathbb{R}^+$, $z(j)$ is the shortest path between s_j and t_j under length function l. Define

$$\alpha(l) \overset{\mathrm{def}}{=} \sum_{j} d(j) \mathtt{dist}_j(l),$$

where $\mathtt{dist}_j(l)$ denotes the shortest path distance between s_j and t_j under the length function l. The dual (D^2_{mcf}) can then be viewed as an assignment of lengths to edges, $l : E \rightarrow \mathbb{R}^+$, such that $D(l)/\alpha(l)$ is minimized. Let β be this minimum.

The structure of this new algorithm is similar to that in the previous section. Thus the algorithm runs in phases, each of which is composed of k iterations. In the jth iteration of the ith phase, we route $d(j)$ units of commodity j in a sequence of steps. Let $l^{s-1}_{i,j}$ be the length function before the sth step, and let $P^s_{i,j}$ be the shortest path between s_j and t_j; i.e., $P^s_{i,j}$ has length $\mathtt{dist}_j(l^{s-1}_{i,j})$. In this step we route $f^s_{i,j} = \min\left\{c, d^{s-1}_{i,j}\right\}$ units of flow along $P^s_{i,j}$, where c is the capacity of the minimum capacity edge on this path. We now set $d^s_{i,j}$ to $d^{s-1}_{i,j} - f^s_{i,j}$; the iteration ends after p steps, where $d^p_{i,j} = 0$.

Thus at each step we perform a shortest path computation instead of a min-cost flow computation as in section 6. The length functions are modified in exactly the same manner as before and the analysis is almost exactly the same. Thus after routing all flow of commodity j we have

$$D(l^p_{i,j}) \leq D(l^0_{i,j}) + \epsilon \cdot d(j) \mathtt{dist}_j(l^p_{i,j}),$$

and after routing all commodities in the ith phase we have

$$D(l_{i,k}) \leq D(l_{i,0}) + \epsilon \sum_{j=1}^{k} d(j) \mathtt{dist}_j(l_{i,k}).$$

Using the same abbreviations as before we again obtain

$$D(i) \leq D(i-1) + \epsilon \alpha(i).$$

Beyond this point we follow the analysis of section 5.1 to argue that we have a $(1+\omega)$-approximation for the same choice of ϵ and δ.

For the running time we again note that in each step, except the last one in an iteration, we increase the length of at least one edge by a factor $1+\epsilon$. Since each edge has an initial length of δ and a final length less than $1+\epsilon$, the number of steps exceeds the number of iterations by at most $m \log_{1+\epsilon} \frac{1+\epsilon}{\delta}$. Thus the total number of steps is at most $(2k \log k + m)\lceil \frac{1}{\epsilon} \log_{1+\epsilon} \frac{m}{1-\epsilon} \rceil$ and each of these involves one shortest path computation.

Recall from the previous section that we needed k initial maximum flow computations to compute an approximate interval for the optimum throughput. We now describe a technique introduced by Grigoriadis and Khachiyan [14] to compute a slightly larger interval using k shortest path computations.

Define a length $l(e) = 1/c(e)$ for each edge $e \in E$. For $1 \leq i \leq k$, let P_i be a shortest s_i, t_i-path with respect to this length. Then let f be the flow obtained by sending $d(i)$ units of flow along path P_i for all $1 \leq i \leq k$ concurrently. Let f^* be an optimum concurrent flow that feasibly routes $\beta \cdot d(i)$ units of flow from s_i to t_i for each commodity i and define $\bar{f}$ as $(1/\beta)f^*$. Flow $\bar{f}$ routes the full demand of $d(i)$ units of flow between s_i and t_i for each $1 \leq i \leq k$ while sending at most $(1/\beta) \cdot c(e)$ of flow on each edge $e \in E$. The total length of flow $\bar{f}$ under l is

$$\sum_{e \in E} \frac{1}{c(e)} \cdot \bar{f}_e \leq \frac{m}{\beta}.$$

It is not hard to see that the total length of flow f is at most that of $\bar{f}$, and hence

$$\frac{1}{c(\bar{e})} \cdot f_{\bar{e}} \leq \sum_{e \in E} \frac{f_e}{c(e)} \leq \frac{m}{\beta}$$

for all edges $\bar{e} \in E$. Equivalently, the flow $f \cdot (\beta/m)$ is feasible. The maximum congestion of f is given by

$$\lambda = \max_{e \in E} \frac{f_e}{c(e)} \leq \frac{m}{\beta}.$$

Thus, the flow f/λ is feasible and has a throughput of at least β/m, i.e., $\beta \in [1/\lambda, m/\lambda]$. Using this interval for β, the total number of phases used in our algorithm becomes $T \log m$.

THEOREM 5.2. *There is an algorithm that computes a $(1+\omega)$-approximation to the maximum concurrent flow in time $O(\omega^{-2}(k \log m + m) \log m \cdot T_{\text{sp}})$ where T_{sp} is the time required to compute the shortest s-t path in a graph with nonnegative edge-weights.*

5.4. Subsequent improvements. Karakostas [15] improved the running time of the above algorithm by removing the dependence on k. This was done in a manner similar to the approach followed for maximum multicommodity flow. Thus in an iteration all commodities with the same source are considered together. The shortest path to all sinks are computed with one call to Dijkstra's algorithm and flow is routed along these paths in ratio of the demands of the various commodities. As before, in each step of the iteration, except the last, the length of at least one edge increases by a factor $1+\epsilon$. However, the number of iterations in a phase is now at most $\min(k,n)$, and hence the overall running time is $\tilde{O}(\omega^{-2}m^2)$.

6. Minimum cost multicommodity flow. Given an instance of the multicommodity flow problem, as in the previous section, edge costs $b : E \to \mathbb{R}^+$, where $b(e)$ represents the cost incurred in shipping one unit of flow along edge e, and a bound B, we consider the problem of maximizing λ subject to the additional constraint that the cost of the flow is no more than B. In the following LP formulation we use the notation introduced in section 5 and we let $b(f)$ denote the cost of a flow $f \in \mathcal{F}$ under cost function b:

$$(P_{\rm mcmcf}) \qquad \begin{aligned} \max \quad & \lambda \\ \text{s.t.} \quad & \sum_{f \in \mathcal{F}} f_e \cdot x(f) \le c(e) \quad \forall e \in E, \\ & \sum_{f \in \mathcal{F}_j} x(f) \ge \lambda \quad \forall 1 \le j \le k, \\ & \sum_{f \in \mathcal{F}} b(f) \cdot x(f) \le B, \\ & x \ge 0, \lambda \ge 0. \end{aligned}$$

Its dual has a length $l(e)$ for each edge $e \in E$, variables $z(1), \dots, z(k)$ for the throughput constraints, and a variable ϕ for the cost constraint. We will view ϕ as the *length* of the cost constraint.

$$(D_{\rm mcmcf}) \qquad \begin{aligned} \min \quad & D(l,\phi) \overset{\rm def}{=} \sum_{e \in E} c(e) l(e) + B \cdot \phi \\ \text{s.t.} \quad & \sum_{e \in E} f_e \cdot (l(e) + b(e)\phi) \ge z(j) \quad \forall 1 \le j \le k, \forall f \in \mathcal{F}_j, \\ & \sum_{j=1}^{k} z(j) \ge 1, \\ & l, z \ge 0. \end{aligned}$$

For a given $l : E \to \mathbb{R}^+$, $z(j)$ is the minimum cost of shipping $d(j)$ units of flow from s_j to t_j under cost function $l + b\phi$. Define $\alpha(l,\phi) \overset{\rm def}{=} \sum_j \texttt{min\_cost}_j(l + \phi b)$. Then $(D_{\rm mcmcf})$ can be restated as finding a length function (l, ϕ) such that $D(l,\phi)/\alpha(l,\phi)$ is minimum; let β denote this minimum value. As in the case of maximum concurrent flow we begin by assuming that $\beta \ge 1$.

Once again the algorithm proceeds in phases, each of which is composed of k iterations. In the jth iteration of the ith phase we begin with length functions $(l_{i,j-1}, \phi_{i,j-1})$ and route $d(j)$ units of commodity j. As before, for all edges e, define $l_{i+1,0}(e) = l_{i,k}(e)$ and $l_{1,0}(e) = l_{0,k}(e) = \delta/c(e)$. Similarly, $\phi_{i+1,0} = \phi_{i,k}$ and $\phi_{1,0} = \delta/B$.

The flow in each iteration is routed in a sequence of steps; in each step we route only so much flow that its cost does not exceed the bound B. Let $(l_{i,j}^{s-1}, \phi_{i,j}^{s-1})$ be the length functions at the start of the sth step (see Figure 1); the lengths at the start of the first step are given by $l_{i,j}^0 = l_{i,j-1}$ and $\phi_{i,j}^0 = \phi_{i,j-1}$. Further, let $d_{i,j}^{s-1}$ be the flow of commodity j that remains to be routed in this iteration. We compute $f_{i,j}^s \overset{\rm def}{=} \texttt{min\_cost}_j(l_{i,j}^{s-1} + b\phi_{i,j}^{s-1})$, which routes $d(j)$ units of flow of commodity j. Since we need to route only $d_{i,j}^{s-1}$ units of flow, we multiply the flow function $f_{i,j}^s$ by $d_{i,j}^{s-1}/d(j)$. If $B_{i,j}^s$ is the cost of flow $f_{i,j}^s$, then the cost of the scaled flow is

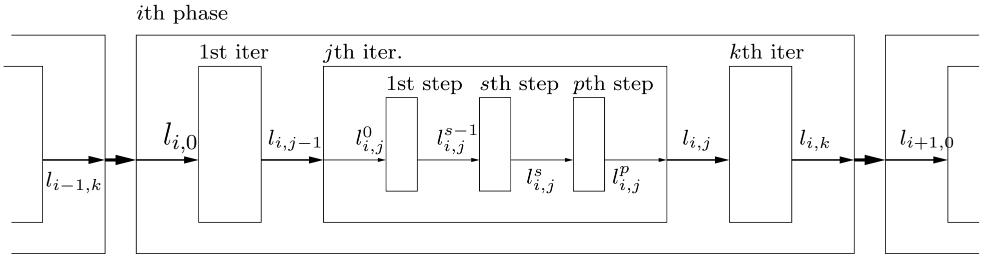

FIG. 1. *The notation used in section* 6. *The length functions above the central axis are the lengths* before *the box on the right, and the ones below are the lengths* after *the box on the left.*

$B^s_{i,j}d^{s-1}_{i,j}/d(j)$. If this quantity exceeds B, then we multiply the original flow function $f^s_{i,j}$ by $B^s_{i,j}/B$. We reuse notation and denote the final scaled flow and its cost by $f^s_{i,j}, B^s_{i,j}$, respectively. Now $f^s_{i,j}$ routes at most $d^{s-1}_{i,j}$ units of flow at cost $B^s_{i,j} \leq B$.

The length functions are modified in a similar manner as before. Thus $l^s_{i,j} = l^{s-1}_{i,j}(1+\epsilon f^s_{i,j}(e)/c(e))$ and $\phi^s_{i,j} = \phi^{s-1}_{i,j}(1+\epsilon B^s_{i,j}/B)$. Further, only $d^s_{i,j} = d^{s-1}_{i,j} - f^s_{i,j}$ more units of commodity j remain to be routed in this iteration. The iteration ends at the step p for which $d^p_{i,j} = 0$. The procedure stops at the first step at which $D()$ exceeds 1; let this happen in the tth phase.

6.1. Analysis. Note that now

$$\begin{aligned} &D(l^s_{i,j}, \phi^s_{i,j}) \\ &= D(l^{s-1}_{i,j}, \phi^{s-1}_{i,j}) + \epsilon \cdot \texttt{min\_cost}_j(l^{s-1}_{i,j} + b\phi^{s-1}_{i,j}) f^s_{i,j}/d(j) \\ &\leq D(l^{s-1}_{i,j}, \phi^{s-1}_{i,j}) + \epsilon \cdot \texttt{min\_cost}_j(l^{p}_{i,j} + b\phi^{p}_{i,j}) f^s_{i,j}/d(j), \end{aligned}$$

where the last inequality holds because the edge-lengths are monotonically increasing over steps. The total flow routed in the p steps equals the demand of commodity j, i.e., $\sum_{s=1}^p f^s_{i,j} = d(j)$. Summing over all p steps, we get

$$D(l^p_{i,j}, \phi^p_{i,j}) \leq D(l^0_{i,j}, \phi^0_{i,j}) + \epsilon \cdot \texttt{min\_cost}_j(l^p_{i,j} + b\phi^p_{i,j}).$$

The length functions at the start of the $(j+1)$th iteration are given by $l_{i,j} = l^p_{i,j}$ and $\phi_{i,j} = \phi^p_{i,j}$. Moving from steps to iterations we have

$$\begin{aligned} &D(l_{i,j}, \phi_{i,j}) \\ &\leq D(l_{i,j-1}, \phi_{i,j-1}) + \epsilon \cdot \texttt{min\_cost}_j(l_{i,j} + b\phi_{i,j}) \\ &\leq D(l_{i,j-1}, \phi_{i,j-1}) + \epsilon \cdot \texttt{min\_cost}_j(l_{i,k} + b\phi_{i,k}), \end{aligned}$$

where the last inequality uses the fact that the edge-lengths are monotonically increasing over iterations. Summing over all iterations in the ith phase, we have

$$\begin{aligned} D(l_{i,k}, \phi_{i,k}) &\leq D(l_{i,0}, \phi_{i,0}) + \epsilon \sum_{j=1}^{k} \texttt{min\_cost}_j(l_{i,k} + b\phi_{i,k}) \\ &= D(l_{i-1,k}, \phi_{i-1,k}) + \epsilon\alpha(l_{i,k}, \phi_{i,k}). \end{aligned}$$

As before we abbreviate $D(l_{i,k}, \phi_{i,k}), \alpha(l_{i,k}, \phi_{i,k})$ to $D(i), \alpha(i)$, respectively, to obtain

$$D(i) \leq D(i-1) + \epsilon\alpha(i).$$

The remainder of the analysis is exactly as in section 5.1. The only modification is in the claim about the throughput of the flow routed. Now we need to argue that the cost of the flow after we scale it by $\log_{1+\epsilon} 1/\delta$ is at most B or, equivalently, that the cost of the flow routed in the first $t-1$ iterations is at most $B \log_{1+\epsilon} 1/\delta$. This follows from the facts that $\phi_{t-1,k} < 1/B$ (since $D(t-1) < 1$), that $\phi_{1,0} = \delta/B$, and that in our procedure every time we route flow whose total cost is B we increase ϕ by at least a factor $1+\epsilon$.

6.2. Running time.

Note that except for the last step in each iteration, in all other steps we increase the length function ϕ by a factor $1+\epsilon$. This implies that the total number of steps exceeds the number of iterations by at most $\log_{1+\epsilon} 1/\delta$.

Now define z_i as the maximum possible flow of commodity i of cost no more than B. Again $z \stackrel{\text{def}}{=} \min_i z_i/d(i)$ denotes the maximum fraction of the demands that can be routed if the capacity constraints and the bound B on the cost of the flow are applied independently to each commodity. Thus $z/k \leq \beta \leq z$, and we multiply demands suitably so that for the new instance $1 \leq \beta \leq k$. As before we double the demands, thereby halving β, after every $T = 2\lceil \frac{1}{\epsilon} \log_{1+\epsilon} \frac{m}{1-\epsilon} \rceil$ phases. Thus the number of iterations is $kT \log k$, and our procedure for minimum cost multicommodity flow needs at most $(2k \log k + 1)\lceil \frac{1}{\epsilon} \log_{1+\epsilon} \frac{m}{1-\epsilon} \rceil$ single-commodity min-cost flow computations.

THEOREM 6.1. *There is an algorithm that computes a $(1+\omega)$-approximation to the maximum cost-bounded concurrent flow in time $O(\omega^{-2} k \log k \log m \cdot T_{\text{mcf}} + kT_{\text{mcbf}})$, where T_{mcf} is the time required to compute a minimum-cost s-t flow in a graph with nonnegative edge-costs and T_{mcbf} is the time required to compute the maximum s-t flow of cost at most B in a capacitated network with nonnegative edge costs.*

6.3. Avoiding min-cost flow computations.

Much like in section 5.3 we can give an alternate path-flow formulation for the minimum-cost multicommodity flow problem. In the following we let $b(p)$ denote the cost of path $p \in \mathcal{P}$:

$$(P^2_{\text{mcmcf}}) \qquad \max \quad \lambda$$

$$\text{s.t.} \quad \sum_{p \in \mathcal{P}_e} x(p) \leq c(e) \quad \forall e \in E,$$

$$\sum_{p \in \mathcal{P}_j} x(p) \geq \lambda \cdot d(j) \quad \forall 1 \leq j \leq k,$$

$$\sum_{p \in \mathcal{P}} b(p) \cdot x(p) \leq B,$$

$$x \geq 0, \lambda \geq 0.$$

Its linear programming dual has a length $l(e)$ for each edge $e \in E$, a length ϕ for the cost constraint, and a variable $z(j)$ for each commodity j:

$$(D^2_{\mathrm{mcmcf}}) \qquad \begin{aligned} \min \quad & D(l,\phi) \stackrel{\mathrm{def}}{=} \sum_{e \in E} c(e)l(e) + B \cdot \phi \\ \text{s.t.} \quad & \sum_{e \in p} (l(e) + b(e)\phi) \geq z(j) \quad \forall 1 \leq j \leq k, \forall p \in \mathcal{P}_j, \\ & \sum_{j=1}^{k} d(j) \cdot z(j) \geq 1, \\ & l, z \geq 0. \end{aligned}$$

For a given $l : E \to \mathbb{R}^+$, $z(j)$ is the shortest path between s_j and t_j under length function $l + b\phi$. We now define $\alpha(l,\phi) \stackrel{\mathrm{def}}{=} \sum_j d(j)\mathtt{dist}_j(l + b\phi)$. The dual to the min-cost multicommodity flow problem is an assignment of lengths to edges, $l : E \to \mathbb{R}^+$, and a scalar ϕ such that $D(l)/\alpha(l)$ is minimized. Let β be this minimum.

The algorithm differs from the one developed in section 6 in that at any step we route flow along only one path, which, if this is the sth step of the jth phase of the ith iteration, is the shortest path between s_j and t_j under the length function $l^{s-1}_{i,j} + b\phi^{s-1}_{i,j}$. If the minimum capacity edge on this path has capacity c, then the flow function at this step, $f^s_{i,j}$, corresponds to routing c units of flow along this path. If $c \leq d^{s-1}_{i,j}$ and the cost of this flow is less than B, we route this flow completely. Else we scale it so that the flow routed in this step has cost no more than B and the total flow routed in this iteration does not exceed $d(j)$.

The analysis of the algorithm proceeds as in section 6.1 with the only modification that $\mathtt{min\_cost}_j(.)$ is replaced with $d(j)\mathtt{dist}_j(.)$. For the running time we need only observe that in each step, except the last step in an iteration, we increase either the length of some edge or the value of ϕ by a factor $1+\epsilon$. The lengths of the edges and ϕ can each be increased by a factor $1+\epsilon$ at most $\log_{1+\epsilon} \frac{1+\epsilon}{\delta}$ times. Hence the number of steps exceeds the number of iterations by at most $(m+1)\lceil \frac{1}{\epsilon} \log_{1+\epsilon} \frac{m}{1-\epsilon} \rceil$.

Similar to section 5.3, we now describe how an idea proposed by Grigoriadis and Khachiyan [14] can be adapted to find a good estimate on the maximum throughput β subject to capacity and cost bounds. Once again, we define the length l_e of each edge $e \in E$ as $b(e)/B + 1/c(e)$. For each $1 \leq i \leq k$, let P_i be the shortest s_i, t_i-path for this length. Then define f to be the flow obtained by routing $d(i)$ units of flow along P_i for all commodities i simultaneously. As before, let f^* be an optimum cost-bounded flow with throughput β and define $\bar{f}$ as $f^* \cdot (1/\beta)$. The flow $\bar{f}$ routes $d(i)$ units of flow between the terminals of each of the k commodities.

The total length of flow $\bar{f}$ under length l is

$$\sum_{e \in E} (b(e)/B + 1/c(e)) \cdot \bar{f}_e \leq \frac{m+1}{\beta}.$$

The total length of flow f is at most that of $\bar{f}$, and hence

$$\frac{1}{c(e)} \cdot f_e \leq \frac{m+1}{\beta}$$

for all edges $e \in E$ and

$$\frac{1}{B} \cdot \sum_{e \in E} b(e) f_e \leq \frac{m+1}{\beta}.$$

The flow $(\beta/(m+1))f$ is therefore a feasible cost-bounded flow with throughput $\beta/(m+1)$.

Define the congestion of f as

$$\lambda = \max \left\{ \frac{\sum_{e \in E} b(e) f_e}{B}, \max_{e \in E} \frac{f_e}{c(e)} \right\} \leq \frac{m+1}{\beta}.$$

From the above we conclude that the optimal throughput β must be in the interval $[1/\lambda, (m+1)/\lambda]$. Using this interval for β, the total number of phases used in the algorithm becomes $T \log(m+1)$.

Theorem 6.2. *There is an algorithm that computes a $(1+\omega)$-approximation to the maximum concurrent flow in time $O(\omega^{-2}(m + k \log m) \log m \cdot T_{\text{sp}})$, where T_{sp} is the time required to compute the shortest s-t path in a graph with nonnegative edge-weights.*

6.4. Subsequent improvements. Karakostas [15] showed how to remove the dependence of the running time on k by grouping commodities with a common source. The shortest paths are now computed with respect to the length function $l + \phi b$ and only so much flow is routed that the cost of flow routed is no more than B. This leads to a $(1+\omega)$-approximation algorithm for computing the maximum cost-bounded concurrent flow in time $\tilde{O}(\omega^{-2} m^2)$.

7. Integrality. A multicommodity flow has integrality q if the flow of every commodity on every edge is a nonnegative integer multiple of q. In this section we show how small modifications to the algorithms discussed in previous sections lead to flows that have small integrality.

Our algorithm for maximum multicommodity flow routes flow along a path P in the ith iteration. If c is the minimum capacity of an edge on P, then we require that the flow routed in this iteration be no more than c. However, note that if we route $q < c$ units along P and increase the length of an edge e on P by a factor $(1+\epsilon q/c(e))$, then the algorithm still delivers a $(1-\epsilon)^{-2}$-approximation to the maximum multicommodity flow, albeit with a worse running time. To obtain a feasible flow we eventually scale the flow constructed in this manner by $\log_{1+\epsilon} 1/\delta$. Thus if we were routing q units in a certain iteration, then only $\frac{q}{\log_{1+\epsilon} 1/\delta}$ units would "appear" in the feasible solution.

Theorem 7.1. *Let e be the minimum capacity edge in G and $q \leq c(e)$. Then one can in polynomial time compute a flow f which is a $(1-\epsilon)^{-2}$-approximation to the maximum multicommodity flow and has integrality $\frac{q\epsilon}{\log_{1+\epsilon} L}$.*

Corollary 7.2. *If all edges in G have capacity at least $\frac{1}{\epsilon} \log_{1+\epsilon} L$, then there is an integral flow which is a $(1-\epsilon)^{-2}$-approximation to the maximum multicommodity flow.*

For maximum concurrent flow we use the algorithm from section 5.3. Recall that in the sth step of the jth iteration in the ith phase we route $f_{i,j}^s = \min\{c, d_{i,j}^{s-1}\}$ units of flow along path $P_{i,j}^s$, where c is the minimum capacity of an edge on this path and $d_{i,j}^{s-1}$ is the residual demand of the jth commodity. As in the case of maximum multicommodity flow we route $q < f_{i,j}^s$ units of flow in this step and increase the length of an edge e on P by a factor $(1+\epsilon q/c(e))$. To ensure that exactly q units of flow can be routed in each step of the jth iteration we require that $d(j)$ be an integral multiple of q. To obtain a feasible flow we scale the flow constructed by $\log_{1+\epsilon} 1/\delta$. Hence in the final solution the flow appears in units of $\frac{q\epsilon}{\log_{1+\epsilon} m/(1-\epsilon)}$.

THEOREM 7.3. *Let e be the minimum capacity edge in G and $q \leq c(e)$. If all demands are integral multiples of q, then one can, in polynomial time, compute a flow f which is a $(1-\epsilon)^{-3}$-approximation to the maximum concurrent flow and f has integrality $\frac{q\epsilon}{\log_{1+\epsilon} m/(1-\epsilon)}$.*

COROLLARY 7.4. *If all edges in G have capacity at least $\frac{1}{\epsilon}\log_{1+\epsilon}\frac{m}{1-\epsilon}$ and all demands are integral multiples of $\frac{1}{\epsilon}\log_{1+\epsilon}\frac{m}{1-\epsilon}$, then there is an integral flow which is a $(1-\epsilon)^{-3}$-approximation to the maximum concurrent flow.*

The above theorem and its corollary also hold for the setting of min-cost multicommodity flows.

8. Improvements in practice. In this section we propose a heuristic for our algorithms that turns out to improve running times greatly in practice. The idea is best explained with the example of the maximum multicommodity algorithm from section 2. To route $(f_i - f_{i-1})$ units of flow in iteration i, we computed k shortest paths which was later improved to one shortest path computation by Fleischer.

The idea now is to allow flow to be routed along paths which have lengths greater than the shortest path. More precisely, let l be the vector of current edge lengths and let f be the total flow routed so far. Let $\widehat{\beta}$ be an upper bound on β. We allow flow to be routed along a path P if its length is at most $L\delta e^{\epsilon f/\widehat{\beta}}$, where L, ϵ, and δ are defined as in section 2. The amount of flow routed along P equals the minimum capacity of an edge on P. The edge-lengths are updated in the same manner as before. The procedure stops when

$$1 \leq L\delta e^{\epsilon f/\widehat{\beta}}.$$

We first show that in the modified algorithm we can always find a path whose length is at most the given bound. Observe that the $\alpha(j-1)$ on the right side of (1) really denotes the length of the path along which flow was routed in the jth iteration. As our induction hypothesis we assume that this quantity is at most $\delta L e^{\epsilon f_{j-1}/\widehat{\beta}}$, which in turn is at most $\delta L e^{\epsilon f_{j-1}/\beta}$; we denote this last expression by $y(j-1)$. This implies that the length of the shortest path at the ith iteration, $\alpha(i)$, is bounded as

$$\alpha(i) \leq \delta L + \frac{\epsilon}{\beta}\sum_{j=1}^{i}(f_j - f_{j-1})y(j-1).$$

Recall the solution of the recurrence for the sequence x in section 2.1. It follows that the expression on the right is at most $\delta L e^{\epsilon f_i/\beta}$, which shows that the shortest path between any pair has length less than the specified bound.

In the original algorithm in section 5 we used the stopping condition in two ways. We argued that the length of any edge is no more than $1+\epsilon$ and that $\delta L e^{\epsilon f_t/\beta} \geq 1$. The termination condition of the modified algorithm is the same as the second property. The first property also holds since all paths along which flow was ever routed had length at most 1.

This modification to the algorithm allows one to continue sending flow on a path until its length exceeds the specified bound. Thus we can now route more flow for every shortest path computation performed. This same heuristic can be adapted to the other problems considered in this paper to obtain better running times in practice.

APPROXIMATION ALGORITHMS FOR ORIENTEERING AND DISCOUNTED-REWARD TSP[*]

AVRIM BLUM[†], SHUCHI CHAWLA[‡], DAVID R. KARGER[§], TERRAN LANE[¶], ADAM MEYERSON[‖], AND MARIA MINKOFF[**]

Abstract. In this paper, we give the first constant-factor approximation algorithm for the rooted ORIENTEERING problem, as well as a new problem that we call the DISCOUNTED-REWARD traveling salesman problem (TSP), motivated by robot navigation. In both problems, we are given a graph with lengths on edges and rewards on nodes, and a start node s. In the ORIENTEERING problem, the goal is to find a path starting at s that maximizes the reward collected, subject to a hard limit on the total length of the path. In the DISCOUNTED-REWARD TSP, instead of a length limit we are given a discount factor γ, and the goal is to maximize the total discounted reward collected, where the reward for a node reached at time t is discounted by γ^t. This problem is motivated by an approximation to a planning problem in the Markov decision process (MDP) framework under the commonly employed infinite horizon discounted reward optimality criterion. The approximation arises from a need to deal with exponentially large state spaces that emerge when trying to model one-time events and nonrepeatable rewards (such as for package deliveries). We also consider tree and multiple-path variants of these problems and provide approximations for those as well. Although the unrooted ORIENTEERING problem, where there is no fixed start node s, has been known to be approximable using algorithms for related problems such as k-TSP (in which the amount of reward to be collected is fixed and the total length is approximately minimized), ours is the first to approximate the rooted question, solving an open problem in [E. M. Arkin, J. S. B. Mitchell, and G. Narasimhan, *Proceedings of the* 14*th ACM Symposium on Computational Geometry*, 1998, pp. 307–316] and [B. Awerbuch, Y. Azar, A. Blum, and S. Vempala, *SIAM J. Comput.*, 28 (1998), pp. 254–262]. We complement our approximation result for ORIENTEERING by showing that the problem is APX-hard.

1. Introduction.

Consider a robot with a map of its environment that needs to visit a number of sites to drop off packages, collect samples, search for a lost item, etc. One classic model of such a scenario is the traveling salesman problem (TSP), in which we ask for the tour that visits all the sites and whose length is as short as possible.

However, what if this robot cannot visit everything? For example, it might have a limited supply of battery power. In that case, a natural problem is to find the tour that visits the maximum total reward of sites (where the reward might correspond to the value of a package being delivered or the probability that some lost item we are searching for is located there), subject to a constraint that the total length is at most some given bound B. This is called the (rooted) ORIENTEERING problem ("rooted" because we are fixing the starting location of the robot). Interestingly, while there have been a number of algorithms that given a desired reward can approximately minimize the distance traveled (which yield approximations to the unrooted ORIENTEERING problem), approximating the reward for the case of a *fixed* starting location and *fixed* hard length limit has been an open problem.

Alternatively, suppose that battery power is not the limiting consideration, but we simply want to give the robot a penalty for taking too long to visit high-value sites. For example, if we are searching for a lost item, and at each time step there is some possibility the item will be taken (or, if we are searching for a trapped individual in a dangerous environment, and at each time step there is some probability the individual might die), then we would want to discount the reward for a site reached at time t by γ^t, where γ is a known discount factor. We call this the DISCOUNTED-REWARD TSP. This problem is motivated by an approximation to a planning problem in the *Markov decision process* (MDP) framework [26, 25] under the commonly employed *infinite horizon discounted reward* optimality criterion. The approximation arises from a need to deal with exponentially large state spaces that emerge when trying to model one-time events and nonrepeatable rewards (such as for package deliveries).

In this paper, we provide the first constant-factor approximations to both the (rooted) ORIENTEERING and the DISCOUNTED-REWARD TSP problems, as well as a number of variants that we discuss below. We also prove that ORIENTEERING is APX-hard, or NP-hard to approximate within an arbitrarily small constant factor.

1.1. Motivation and background. Robot navigation and path planning problems can be modeled in many ways. In the theoretical computer science and optimization communities, these are typically modeled as kinds of prize-collecting TSPs [19, 4, 17, 3]. In the artificial intelligence community, problems of this sort are often modeled as MDPs [6, 7, 21, 25, 26]. Below we give some background and motivation for our work from each perspective.

1.1.1. MDPs and time-dependent rewards. An MDP consists of a state space S, a set of actions A, a probabilistic transition function T, and a reward function R. For this work, it is sufficient to consider discrete, finite S and A. At any given time step, an agent (such as a robot) acting in an MDP will be located at some state $s \in S$, where it can choose an action $a \in A$. The agent is subsequently relocated to a new state s' drawn from the transition probability distribution $T(s'|s,a) \equiv \Pr[q_{t+1} = s'|q_t = s, a]$, where q_t is a random variable indicating the agent's state at time step t. The transition function captures both the agent's stochastic dynamics (e.g., unreliable actuators) and structure and characteristics of the environment such as walls, pits, friction of the surface, etc. Associated with each state is a real-valued reward, given by the function $R(s)$, which the agent receives upon entering state s.[1] For example, a

[1] It is also possible to model rewards associated with actions or transitions by writing more general reward functions such as $R(s,a)$ or $R(s,a,s')$, but such extensions do not fundamentally change the nature of the MDP. Any such functions can be rewritten into a model of the form we give here with an appropriate modification to the state and action sets.

package-delivery robot might get a reward every time it correctly delivers a package.

The goal of planning in an MDP framework is to formulate a policy, $\psi : S \rightarrow A$, that guides the agent to optimal long-term aggregate reward. In order to encourage the agent to perform the tasks that we want, and to do so in a timely manner, a commonly employed aggregate reward objective function is the *infinite horizon discounted reward* [21, 25, 26]. Specifically, for a given *discount factor* $\gamma \in (0, 1)$, the value of the reward collected at time t is discounted by a factor γ^t. Thus the total discounted reward, which we aim to maximize, is $R_{tot} = \sum_{t=0}^{\infty} R(s_t)\gamma^t$. Because the agent's actions are stochastic, in practice we must settle for optimizing the expected value of this quantity, $V^{\psi}(s) = \mathbf{E}_{\psi}[R_{tot}|q_0 = s]$, where the expectation is taken with respect to all possible trajectories through the state space rooted at state s, weighted by their probability of occurring under policy ψ. Note that because a fixed (s, a) pair yields a fixed probability distribution over next states, the combination of an MDP with a fixed policy produces a Markov chain over S. The expectation, therefore, is simply the expected discounted reward accumulated by a random walk on the corresponding Markov chain. This optimality criterion guides the agent to accumulate as much reward as possible as early as possible, and produces what in practice turns out to be good behavior.

One can also motivate exponential discounting by imagining that, at each time step, there is some fixed probability the game will end (the robot loses power, a catastrophic failure occurs, the objectives change, etc.). The quantity $V^{\psi}(s)$ then gives the expected (undiscounted) reward collected by the robot before the game ends. Exponential discounting also has the nice mathematical property that it is *time-independent*, meaning that an optimal strategy is *stationary* and can be completely described by the mapping from states to actions given by ψ.[2] The overall goal of planning, then, is to locate ψ^*, the policy that maximizes $V^{\psi}(s)$, the expected infinite horizon discounted reward. A fundamental theorem of MDP planning states that for this optimality criterion, there is guaranteed to be a stationary ψ^* that dominates all other policies at all states: $V^{\psi^*}(s) \geq V^{\psi}(s)$ for all $s \in S$ and all ψ [25].

There are well-known algorithms for solving MDPs in time polynomial in the cardinality of the state space [6, 25, 26]. However, one drawback of the MDP model is that the agent receives $R(s)$ every time that state s is visited. Thus, in order to model a package-delivery or search-and-rescue robot, one would need a state representing not only the current location of the robot but also a record of all packages (victims) it has already delivered (rescued). For example, one could write $S = L \times 2^d$, where L is a set of discrete locations that the robot could occupy, and the list of d bits tracks whether the agent has achieved each of d subgoals (packages or rescues). Then the reward function can be $R(\langle l, b_1, \ldots, b_d\rangle) = 1$ iff l is a location containing subgoal i and $b_i = 0$, or $R(s) = 0$ otherwise. When the robot reaches the location containing subgoal i, b_i is set to 1 and remains so thereafter. This formulation yields an exponential increase in the size of the state space over the raw cardinality of L and prevents a direct, exact solution of the MDP. Instead, it would be preferable to directly model the case of rewards that are given only the *first* time a state is visited [22, 23].

As a first step towards tackling this general problem, we abandon the stochastic element and restrict the model to deterministic, reversible actions. This model is a reasonable approximation to many robot-navigation style MDP domains, in which we can formulate subpolicies for navigating between pairs of locations in the environ-

[2] Under other objective functions, an optimal policy could require dependence on the number of steps remaining in the game or other functions of the history of states encountered to date.

ment. Often, such subpolicies, or macros, can be "nearly deterministic" (failing with probability $\leq \epsilon$) because they average out the stochasticity of atomic actions over many steps [23]. We can to a good approximation, therefore, treat such a domain as a deterministic planning problem over the set of subgoal locations (nodes) and location-to-location macros (arcs). This leads us to study the DISCOUNTED-REWARD TSP, in which we assume we have an undirected weighted graph (edge weights represent the time to traverse a given edge), with a reward value π_v on each vertex v, and our goal is to find a path visiting each vertex v at time t_v so as to maximize $\sum \pi_v \gamma^{t_v}$.

1.1.2. Prize-collecting TSP and ORIENTEERING problems. A different way to model the goal of collecting as much reward as possible as early as possible is to impose a hard deadline on the time the robot may spend delivering its packages. The robot gets a reward equal to the value of the package on a delivery but only if the delivery is made before a deadline D. If the deadline is exceeded, he gets no reward. This problem has been studied previously as the ORIENTEERING problem [19] or bank robber problem [3].

ORIENTEERING belongs to the family of the prize-collecting traveling salesman problems (PCTSPs). Given a set of cities with nonnegative "prize" values associated with them and a table of pairwise distances, a salesman needs to pick a subset of the cities to visit so as to minimize the total distance traveled while maximizing the total amount of prize collected. Note that there is a trade-off between the cost of a tour and how much prize it spans. The original version of the PCTSP introduced by Balas [4] deals with these two conflicting objectives by combining them: one seeks a tour that minimizes the *sum* of the total distance traveled and the penalties (prizes) on cities skipped, while collecting at least a given quota amount of prize. Bienstock et al. [8] subsequently focused on a special case of this problem in which the quota requirement is dropped, and provided a constant-factor approximation for it. This was further improved to a 2-approximation via a primal-dual approach by Goemans and Williamson [18].

An alternative approach to the bicriterion optimization is to optimize just one of the objectives while enforcing a fixed bound on the other. For example, in a quota-driven version of the PCTSP, called k-TSP, every node has a prize of one unit and the goal is to minimize the total length of the tour, while visiting at least k nodes. Similarly, ORIENTEERING can be viewed as a budget-driven version of the PCTSP, since we are maximizing the total amount of prize collected, while keeping the distance traveled below a certain threshold.[3]

There are several constant-factor approximations known for the k-TSP problem [2, 15, 9, 3], the best being a recent 2-approximation due to Garg [16]. Most of these results are based on a classic primal-dual algorithm for the PCTSP due to Goemans and Williamson [18] (mentioned above).

The algorithms for k-TSP extend easily to the *unrooted* version of the ORIENTEERING problem in which we do not fix the starting location [3, 16]. In particular, suppose that we want to find a tour (cycle) of length D that spans value Π, and using a c-approximation to the k-TSP, for some $c > 1$, we obtain a cycle of length cD spanning value Π. Then we can just break this cycle into $2c$ pieces of length at most $D/2$ each, take the piece spanning the most value, and convert it into a cycle of length at most D (by traversing the path forward and then back). Noting that the cycle

[3] Strictly speaking, a budget-driven version of the PCTSP would require a tour, e.g., a path that ends at the start node, whereas the ORIENTEERING problem is content with a path that ends at an arbitrary node. We consider both versions of the problem.

spans at least $\Pi/2c$ value, we get a $2c$-approximation to unrooted ORIENTEERING. However, this does not work for the rooted problem because the "best piece" in the above reduction might be far from the start. In contrast to this simple result, there is no previously known $O(1)$-approximation algorithm for the rooted ORIENTEERING problem in general graphs. Arkin, Mitchell, and Narasimhan [1] give a constant-factor approximation to the rooted ORIENTEERING problem for the special case of points in the plane.

1.2. Summary of results. In this paper, we give the first constant-factor approximation algorithms for both of the above problems. A key contribution of our work is the introduction of the *min-excess* objective. The excess of a path is defined to be the difference between the length of a prize-collecting s-t path and the length of the shortest path between the two endpoints. Informally, any path must spend a minimum amount of time equal to the shortest distance between s and t, just to get to the destination t; the excess of the path is the extra time spent by it to gather reward along the way. We consider the following MIN-EXCESS-PATH problem: given a weighted graph with rewards, endpoints s and t, and a reward quota k, find a minimum excess path from s to t collecting reward at least k.

Approximating the excess of a path turns out to be a crucial component in our algorithms for ORIENTEERING and DISCOUNTED-REWARD TSP. Note that an approximation for the excess is a strictly better guarantee than what is implied by an approximation algorithm for the k-TSP; the latter would return a path that has length at most a constant multiple times the *total* optimal length from s to t.

Our algorithm for approximating MIN-EXCESS-PATH uses as a subroutine an approximation to a variant of the k-TSP, the min-cost s-t path problem (k-PATH problem in [10]). In particular, an α_{CP}-approximation to the k-PATH, when used as a subroutine in our algorithm, implies an ($\alpha_{EP} = \frac{3}{2}\alpha_{CP} - \frac{1}{2}$)-approximation for the MIN-EXCESS-PATH problem. The best currently known approximation for the k-PATH problem is a $(2+\delta)$-approximation (for any fixed $\delta > 0$), which follows from a $(2+\delta)$-approximation to the k-TSP due to Chaudhuri et al. [10].[4] Then via our reduction, this implies a $(2.5+\delta)$-approximation to excess, for any fixed $\delta > 0$. We also present an improved analysis of our algorithm based on the Chaudhuri et al. k-TSP algorithm obtaining a $(2+\delta)$-approximation for the MIN-EXCESS-PATH problem.

An α_{EP}-approximation to MIN-EXCESS-PATH further implies a $(1 + \lceil\alpha_{EP}\rceil)$-approximation for ORIENTEERING and a roughly $e(\alpha_{EP} + 1)$-approximation for DISCOUNTED-REWARD TSP. Our final approximation factors for the latter two problems are 4 and $6.75 + \delta$, respectively.

Finally, using the APX-hardness of the TSP on bounded metrics [14], we prove that MIN-EXCESS-PATH and ORIENTEERING are APX-hard.

1.3. Subsequent work. Following the initial publication of our work, Bansal et al. [5] obtained a 3-approximation for a stronger version of ORIENTEERING called "point-to-point ORIENTEERING," in which the starting location s as well as the terminal location t are fixed. They also consider the vehicle routing problem with time-windows, a generalization of ORIENTEERING in which each reward has a time-window ("release time" and "deadline") associated with it, and reward is earned only if the location is visited within the corresponding time-window. Bansal et al. obtain an

[4] Garg's 2-approximation algorithm for the k-TSP, although better that Chaudhuri et al.'s $(2+\delta)$-approximation, implies only a 5-approximation to the k-PATH problem.

$O(\log^2 n)$-approximation for this problem, as well as an $O(\log n)$-approximation when all the release times are zero.

Organization. The rest of this paper is organized as follows. We begin with some definitions in section 2. Then we give an algorithm for MIN-EXCESS-PATH in section 3, followed by algorithms for DISCOUNTED-REWARD TSP and ORIENTEERING in sections 4 and 5, respectively. In section 6, we extend some of the algorithms to tree and multiple-path versions of the problems. We present some hardness of approximation results in section 7 and conclude in section 8.

2. Notation and definitions.

Our work encompasses a variety of problems. In this section, we introduce the notation to be used throughout the paper, provide formal problem statements, and describe a uniform naming scheme for them.

Let $G = (V, E)$ be a weighted undirected graph, with a distance function on edges, $d : E \to \Re^+$, and a *prize* or *reward* function on nodes, $\pi : V \to \Re^+$. Let $\pi_v = \pi(v)$ be the reward on node v. Let $s \in V$ denote a special node called the *start* or *root*.

For a path P visiting u before v, let $d^P(u, v)$ denote the length along P from u to v. Let $d(u, v)$ denote the length of the *shortest* path from node u to node v. For ease of notation, let $d_v = d(s, v)$ and $d^P(v) = d^P(s, v)$. For a set of nodes $V' \subseteq V$, let $\Pi(V') = \sum_{v \in V'} \pi_v$. For a set of edges $E' \subseteq E$, let $d(E') = \sum_{e \in E'} d(e)$.

Our problems aim to construct a certain subgraph—a path, tree, or cycle, possibly with additional constraints. Most of the problems attempt a trade-off between two objective functions: the *cost* (distance) of the path (or tree, or cycle), and the *total prize* spanned by it. From the point of view of exact algorithms, we need simply to specify the cost we are willing to tolerate and the prize we wish to span. Most variants of this problem, however, are $\mathcal{NP}$-hard, and so we focus on approximation algorithms. We must then specify our willingness to approximate the two distinct objectives. We refer to a *min-cost* problem when our goal is to *approximately* minimize the cost of our objective subject to a fixed lower bound on prize (thus, prize is a feasibility constraint, while our approximated objective is cost). Conversely, we refer to a *max-prize* problem when our goal is to *approximately* maximize the prize collected subject to a fixed upper bound on cost (thus, cost is a feasibility constraint, while our approximated objective is prize). For example, the min-cost tree problem is the traditional k-MST: it requires spanning k units of prize and aims to minimize the cost of doing so. Both the rooted and unrooted min-cost tree problems have constant-factor approximations [20, 2, 15, 9, 3]. The max-prize path problem, which aims to find a path of length at most D from the start node s that visits a maximum amount of prize, is the ORIENTEERING problem.

The main subroutine in our algorithms also requires introducing a variation on approximate cost. Define the *excess* of a path P from s to t to be $d^P(s, t) - d(s, t)$, that is, the difference between that path's length and the distance between s and t in the graph. Obviously, the minimum excess path of total prize Π is also the minimum *cost* path of total prize Π; however, a path of a constant factor times minimum cost may have more than a constant factor times the minimum excess. We therefore consider separately the *minimum excess path* problem. Note that an (s, t) path approximating the optimum excess ϵ by a factor α will have length $d(s, t) + \alpha\epsilon \leq \alpha(d(s, t) + \epsilon)$ and therefore approximates the minimum cost path by a factor α as well. Achieving a good approximation to this MIN-EXCESS-PATH problem will turn out to be a key ingredient in our approximation algorithms.

Finally, as discussed earlier, we consider a different means of combining length and cost motivated by applications of MDPs. We introduce a *discount factor* $\gamma < 1$.

Table 2.1
Approximation factors and reductions for our problems.

Problem	Best approx.	Source/Reduction	Hardness of approx.
min-cost s-t path (k-Path)	$\alpha_{CP} = 2 + \delta$	[10]	1.0046
min-excess path (Min-Excess-Path)	$\alpha_{EP} = 2.5 + \delta$ $\alpha_{EP} = 2 + \delta$	$\frac{3}{2}(\alpha_{CP}) - \frac{1}{2}$ algo. based on [10]	1.0046
max-discounted-prize path (Disctd-Reward TSP)	$\alpha_{DP} = 6.75 + \delta$	$\alpha_{EP}^{-\alpha_{EP}}(1 + \alpha_{EP})^{1+\alpha_{EP}}$	?
max-prize path (Orienteering)	$\alpha_{PP} = 4$	$1 + \lceil \alpha_{EP} \rceil$	1.00068
max-prize tree	$\alpha_{PT} = 8$	$2\alpha_{PP}$	?
max-prize cycle	$\alpha_{PC} = 8$	$2\alpha_{PP}$	1.00068
max-prize multiple-path	$\alpha_{kPP} = 5$	$\alpha_{PP} + 1$	1.00068

Given a path P rooted at s, let the *discounted reward* collected at node v by path P be defined as $\rho_v^P = \pi_v \gamma^{d^P(s,v)}$. That is, the prize gets discounted exponentially by the amount of time it takes for the path to reach node v. The *max-discounted-reward* problem is to find a path P rooted at s that maximizes $\rho^P = \sum_{v \in P} \rho_v^P$. We call this the Discounted-Reward TSP. Note that the length of the path is not specifically bounded in this problem, though of course shorter paths produce less discounting.

2.1. Reductions and approximation factors. We present a constant-factor approximation algorithm for the max-prize path (rooted Orienteering) problem, solving an open problem of [3, 1], as well as the Discounted-Reward TSP. Central to our results is a constant-factor approximation for the Min-Excess-Path problem defined above, which uses an algorithm for the min-cost s-t path problem as a subroutine. We also give constant-factor approximations to several related problems, including the max-prize tree problem—the "dual" to the k-MST (min-cost tree) problem—and max-prize cycle. Specific constants are given in Table 2.1. For the Min-Excess-Path problem, we derive a tighter analysis and an improved approximation of $2+\delta$ in section 3.2, based on the min-cost s-t path algorithm of [10]. This improvement gives a better approximation factor of $6.75 + \delta$ for the Discounted-Reward TSP.

Our approximation algorithms reflect a series of reductions from one approximation problem to another. Improvements in the approximations for various problems will propagate through. We state approximation factors in the form α_{XY}, where XY denotes the problem being approximated; the first letter denotes the objective (cost, prize, excess, or discounted prize denoted by C, P, E, and D, respectively), and the second letter denotes the structure (path, cycle, or tree denoted by P, C, or T, respectively).

2.2. Preliminaries. To support dynamic programming in the max-prize variants, we assume that all prizes are integers in the range $\{1, \ldots, n^2\}$—this allows us to "guess" the reward collected by the optimal solution by trying out all integer values less than n^3. We can make this assumption by scaling the values such that the maximum value is exactly n^2 (this guarantees that the optimal solution gets at least n^2 reward). We then round each value down to its nearest integer, losing an additive amount of at most n, which is a negligible multiplicative factor. This negligible factor does mean that an approximation algorithm for a max-prize problem with guarantee c on polynomially bounded inputs has (weaker) guarantee "arbitrarily close to c" on arbitrary inputs. For the MIN-EXCESS-PATH problem, we do not make this bounded-value assumption. This implies that the running time of our algorithm is linear in the total value in the graph (with all the values in the graph being integral). Note, however, that in our algorithms for the max-prize problems, we may use a bicriteria version of MIN-EXCESS-PATH in which we approximate the value obtained to within a $(1 + O(1/n))$ factor and excess to within an α_{EP} factor. We may then use the bounded value assumption, and our running time is again bounded by a polynomial in n.

3. MIN-EXCESS-PATH.

Let P^* be the shortest path from s to t with $\Pi(P^*) \geq k$. Let $\epsilon(P^*) = d(P^*) - d(s,t)$. Our algorithm returns a path P with $\Pi(P) \geq k$ and length $d(P) = d(s,t) + \alpha_{EP}\epsilon(P^*)$, where $\alpha_{EP} = \frac{3}{2}\alpha_{CP} - \frac{1}{2}$. Thus we obtain a $(2.5 + \delta)$-approximation to MIN-EXCESS-PATH using an algorithm of Chaudhuri et al. [10] for min-cost s-t path (MCP) with $\alpha_{CP} = 2 + \delta$.

We begin with a brief description of the min-cost path algorithm and approximation. In their paper, Chaudhuri et al. provide a subroutine for constructing a tree containing nodes s and t that spans at least k vertices[5] and has cost at most $(1 + \frac{1}{2}\delta)$ times the cost of the shortest s-t path with k vertices, for any fixed constant δ. To construct an s-t path from the tree obtained by the algorithm of Chaudhuri et al., we can double all the edges, except those along the tree path from s to t. This gives us a partial "Euler tour" of the tree that starts at s and ends at t. Clearly, the cost of such a path is at most $(2 + \delta)$ times the cost of the shortest s-t path spanning prize k, for any fixed constant δ.

Now we return to the harder MIN-EXCESS-PATH problem. The idea for our algorithm for MIN-EXCESS-PATH is as follows. Suppose that the optimum solution path encounters all its vertices in increasing order of distance from s. We call such a path *monotonic*. We can find this optimum monotonic path via a simple dynamic program: for each possible prize value p and for each vertex i in increasing order of distance from s, we compute the minimum excess path that starts at vertex s, ends at i, and collects prize at least p.

We solve the general case by breaking the optimum path into *segments* that are either monotonic (and thus can be found optimally as just described) or "wiggly" (generating a large amount of excess). We show that the total length of the wiggly portions is comparable to the excess of the optimum path; our solution uses the optimum monotonic paths and approximates the length of the wiggly portions by a constant factor, yielding an overall increase proportional to the excess.

Consider the optimal path P^* from s to t. We divide it into segments in the following manner. For any real d, define $f(d)$ as the number of edges on P^* with one endpoint at distance less than d from s and the other endpoint at distance at least d from s. Note that $f(d) \geq 1$ for all $0 \leq t \leq d_t$ (it may also be nonzero for some $d \geq d_t$). Note also that f is piecewise constant, changing only at distances equal to vertex distances. We break the real line into intervals according to f: the *type* 1 *intervals* are the maximal intervals on which $f(d) = 1$; the *type* 2 *intervals* are the maximal intervals on which $f(d) \geq 2$. These intervals partition the real line (out to the maximum distance reached by the optimum solution) and alternate between types 1 and 2. Let the interval boundaries be labeled $0 = b_1 < b_2 \cdots b_m$, where b_m is the maximum distance of any vertex on the path, so that the ith interval is (b_i, b_{i+1}).

[5] The algorithm can be transformed easily to obtain a tree spanning a given target *prize value*—to each node v with a prize π_v, we attach $\pi_v - 1$ leaves and run the algorithm on this new graph.

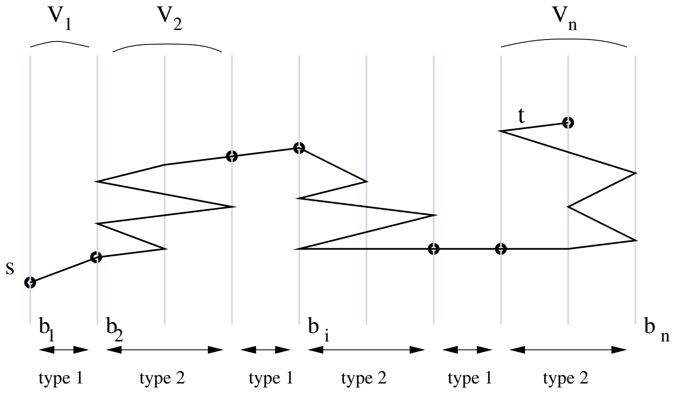

FIG. 3.1. *Segment partition of a path in graph G. Vertices are laid out in order of their distances from s. The vertical dotted lines indicate distances from s.*

Note that each b_i is the distance label for some vertex. Let V_i be the set of vertices whose distance from s falls in the ith interval. Note that the optimum path traverses each set V_i exactly once—once it leaves some V_i, it does not return. One of any two adjacent intervals is of type 1; if the path left this interval and returned to it, then $f(d)$ would exceed 1 within the interval. Thus, the vertices of P^* in set V_i form a contiguous *segment* of the optimum path that we label as $S_i = P^* \cap V_i$.

A segment partition is shown in Figure 3.1.

Note that for each i, there may be (at most) 1 edge crossing from V_i to V_{i+1}. To simplify the next two lemmas, let us split that edge into two with a vertex at distance b_i from s, so that every edge is completely contained in one of the segments (this can be done since one endpoint of the edge has distance exceeding b_i and the other endpoint has distance less than b_i).

LEMMA 3.1. *A segment S_i of type 1 has length at least $b_{i+1} - b_i$. A segment S_i of type 2 has length at least $3(b_{i+1} - b_i)$, unless it is the segment containing t, in which case it has length at least $3(d_t - b_i)$.*

Proof. The length of segment S_i is lower bounded by the integral of $f(d)$ over the ith interval. In a type 1 interval, the result is immediate. For a type 2 interval, note that $f(d) \geq 1$ actually implies that $f(d) \geq 3$ by a parity argument—if the path crosses distance d twice only, it must end up at distance less than d. □

COROLLARY 3.2. *The total length of type 2 segments is at most $3\epsilon(P^*)/2$.*

Proof. Let ℓ_i denote the length of segment i. We know that the length of P^* is $d_t + \epsilon(P^*) = \sum \ell_i$. At the same time, we can write

$$d_t \leq b_m = \sum_{i=1}^{m-1} (b_{i+1} - b_i) \leq \sum_{i \text{ type } 1} \ell_i + \sum_{i \text{ type } 2} \ell_i/3.$$

It follows that

$$\epsilon(P^*) = \sum \ell_i - d_t \geq \sum_{i \text{ type } 2} 2\ell_i/3.$$

Multiplying both sides by 3/2 completes the proof. □

Having completed this analysis, we note that the corollary remains true even if we do not introduce extra vertices on edges crossing interval boundaries. The crossing edges are no longer counted as parts of segments, but this decreases only the total length of type 2 segments.

3.1. A dynamic program. Our algorithm computes, for each interval that might be an interval of the optimum solution, a segment corresponding to the optimum solution in that interval. It then uses a dynamic program to paste these fragments together using (and paying for) edges that cross between segments. The segments we compute are defined by four vertices: the closest-to-s and farthest-from-s vertices, c and f, in the interval (which define the start- and endpoints of the interval: our computation is limited to vertices within that interval), and the first and last vertices, x and y, on the segment within that interval. They are also defined by the amount p of prize we are required to collect within the segment. There are therefore $O(\Pi n^4)$ distinct segments to compute, where Π is the total prize in the graph. For each segment, we find an optimum solution for a type 1 and a type 2 interval. For a type 1 interval, the optimum path is monotonic; we can therefore compute (in linear time) an optimum (shortest) monotonic path from x to y that collects prize p. If the interval is of type 2, the optimum path need not be monotonic. Instead, we use the MCP routine to approximate to within a constant factor the minimum length of a path that starts at x, finishes at y, stays within the boundaries of the interval defined by c and f, and collects prize at least p. Let $A_1(x, y, p)$ and $A_2(x, y, c, f, p)$ denote the lengths of the type 1 and type 2 segments computed above for each interval. (Note that for type 1 segments, $c = x$ and $f = y$.)

Given the optimum type 1 and near-optimum type 2 segment determined for each set of four vertices and prize value, we can find the optimal way to paste some subset of them together monotonically using a dynamic program. Let $B_1(y, p)$ denote the length of the path starting at s, ending at y, spanning value p, and ending in a type 1 segment that is found by our algorithm. Likewise, let $B_2(y, f, p)$ denote the length of a corresponding path ending in a type 2 segment found by our algorithm. Then the following recurrences determine $B_1(y, p)$ and $B_2(y, f, p)$:

$$\begin{aligned}
B_1(y,p) &= \min_{x,z,f,p':d_z<d_f<d_x<d_y,p'<p} \{B_2(z,f,p') + d(z,x) + A_1(x,y,p-p')\},\\
B_2(y,f,p) &= \min_{x,c,f,p':d_z<d_c<d_x<d_y,p'<p} \{B_1(z,p') + d(z,x) + A_2(x,y,c,f,p-p')\}.
\end{aligned}$$

Note that the segments corresponding to the optimum path are considered in this dynamic program, and so our solution will be at least as good as the one we get by using the segments corresponding to the ones on the optimum path (i.e., using the optimum type 1 segments and using the approximately optimum type 2 segments). We need to show only that this solution is good.

We focus on the segments corresponding to the optimum path P^*. Consider the segments S_i of length ℓ_i on the optimum path. If S_i is of type 1, our algorithm will find a (monotonic) segment with the same endpoints collecting the same amount of prize of no greater length. If S_i is of type 2, our algorithm (through its use of subroutine MCP) will find a path with the same endpoints collecting the same prize over length at most $\alpha_{CP}\ell_i$. Let L_1 denote the total length of the optimum type 1 segments, together with the lengths of the edges used to connect between segments. Let L_2 denote the total length of the optimum type 2 segments. Recall that $L_1 + L_2 = d_t + \epsilon(P^*)$ and that (by Corollary 3.2) $L_2 \leq \frac{3}{2}\epsilon(P^*)$. By concatenating the optimum type 1 segments and the approximately optimum type 2 segments, the dynamic program can (and therefore will) find a path collecting the same total prize as P^* of total length at most

$$\begin{aligned} L_1 + \alpha_{CP} L_2 &= L_1 + L_2 + (\alpha_{CP} - 1) L_2 \\ &\leq d_t + \epsilon(P^*) + (\alpha_{CP} - 1)\left(\frac{3}{2}\epsilon(P^*)\right) \\ &= d_t + \left(\frac{3}{2}\alpha_{CP} - \frac{1}{2}\right)\epsilon(P^*). \end{aligned}$$

In other words, we approximate the minimum excess to within a factor of $\frac{3}{2}\alpha_{CP} - \frac{1}{2}$.

3.2. An improved approximation for Min-Excess-Path. Our approximation guarantee for Min-Excess-Path derived above is based on treating the k-path subroutine as a "black box." In this section, we show how to slightly improve our approximation guarantee for the Min-Excess-Path problem by exploiting the details of the min-cost path algorithm derived from the work of Chaudhuri et al. [10].

Recall that Chaudhuri et al. provide an algorithm for constructing a tree containing two nodes s and t that spans at least k reward and has cost at most $(1 + \frac{1}{2}\delta)$ times the cost of the optimal k-path P^* from s to t. Doubling the edges of this tree, we obtain an approximation to the k-path problem with $\alpha_{CP} = (2 + \delta)$.

In fact, if the optimal path P^* has length $\ell = d(s,t) + \epsilon^*$, then the tree has length at most $(1 + \frac{1}{2}\delta)(d(s,t) + \epsilon^*)$. We convert this tree into a path from s to t by doubling all edges, except for the ones on the tree path from s to t. Noting that the total cost of "nondoubled" edges is at least $d(s,t)$, we get a path from s to t of length at most $(2+\delta)(d(s,t)+\epsilon^*) - d(s,t) = (1+\delta)(d(s,t)+\epsilon^*) + \epsilon^* = (1+\delta)\ell + \epsilon^*$. This stronger guarantee gives us an improved guarantee on the performance of the Min-Excess-Path algorithm described above.

In particular, suppose that we apply the k-path algorithm to a segment of type 2 with endpoints u and v, and having an optimum min-excess path with length $\ell = d(u,v) + \epsilon$. Then we get a path from u to v with the same value and length at most $(1+\delta)\ell + \epsilon$, for any fixed small constant δ.

In order to combine the lengths of all the type 2 segments, we rewrite this expression in terms of the excess of the path P^* at u and v. Let $\epsilon_u = d^{P^*}(u) - d_u$ denote the excess of P^* from s to u, and $\epsilon_v = d^{P^*}(v) - d_v$ the excess of P^* from s to v. Note that the ϵ in the above expression is not necessarily equal to $\epsilon_v - \epsilon_u$, but we can relate the two quantities via the triangle inequality—the distance along P^* from u to v can be written as $\ell = (d_v + \epsilon_v) - (d_u + \epsilon_u) \leq d(u,v) + \epsilon_v - \epsilon_u$; therefore, $\epsilon \leq \epsilon_v - \epsilon_u$. This implies that the Chaudhuri et al. algorithm returns a path of length at most $(1+\delta)\ell + \epsilon_v - \epsilon_u$ between u and v.

We can now apply Corollary 3.2 as before, to obtain an approximation in terms of the excess. The dynamic program finds a path collecting the same total value as P^* and of total length at most

$$\begin{aligned} L_1 + (1+\delta)L_2 + \sum_{\text{type 2 segments}} (\epsilon_v - \epsilon_u) &\leq L_1 + (1+\delta)L_2 + \epsilon(P^*) \\ &= d_t + 2\epsilon(P^*) + \delta L_2 \\ &\leq d_t + 2\epsilon(P^*) + \frac{3\delta}{2}\epsilon(P^*), \end{aligned}$$

where the last statement follows from Corollary 3.2. Therefore, we get an approximation ratio of $2 + \delta'$ for the Min-Excess-Path problem, for any small constant δ'.

4. Maximum discounted-prize path. In this section, we present an approximation algorithm for the Discounted-Reward TSP which builds upon our Min-Excess-Path algorithm. Recall that we aim to optimize $\rho(P) = \sum \gamma^{d_v^P} \pi_v$. Assume without loss of generality that the discount factor is $\gamma = 1/2$—we simply rescale each length ℓ to ℓ' such that $\gamma^\ell = (\frac{1}{2})^{\ell'}$, i.e., $\ell' = \ell \log_2(1/\gamma)$.

We first establish a property of an optimal solution that we make use of in our algorithm. Define the *scaled prize* π' of a node v to be the (discounted) reward that a path gets at node v if it follows a shortest path from the root to v. That is, $\pi'_v = \pi_v \gamma^{d_v}$. Let $\Pi'(P) = \sum_{v \in P} \pi'_v$. Note that for any path P, the discounted reward obtained by P is at most $\Pi'(P)$.

Now consider an optimal solution P^*. Fix a parameter ϵ that we will set later. Let t be the last node on the path P^* for which $d_t^{P^*} - d_t \leq \epsilon$; i.e., the excess of path P^* at t is at most ϵ. Consider the portion of P^* from root s to t. Call this path P_t^*.

Lemma 4.1. *Let P_t^* be the part of P^* from s to t. Then, $\rho(P_t^*) \geq \rho(P^*)(1 - \frac{1}{2^\epsilon})$.*

Proof. Assume otherwise. Suppose we shortcut P^* by taking a shortest path from s to the next node visited by P^* after t. This new path collects (discounted) rewards from the vertices of $P^* - P_t^*$, which form more than a $\frac{1}{2^\epsilon}$ fraction of the total discounted reward by assumption. The shortcutting procedure decreases the distance on each of these vertices by at least ϵ, meaning these rewards are "undiscounted" by a factor of at least 2^ϵ over what they would be in path P^*. Thus, the total reward on this path exceeds the optimum, a contradiction. ∎

It follows that we can approximate $\rho(P^*)$ by approximating $\rho(P_t^*)$. Based on the above observation, we give the algorithm of Figure 4.1 for finding an approximately optimal solution. Note that "guess t" and "guess k" are implemented by exhausting all polynomially many possibilities.

```
Algorithm for Discounted-Reward TSP
    1. Rescale all edge lengths so that $\gamma = 1/2$.
    2. Replace the prize value of each node with the prize discounted by the shortest
       path to that node: $\pi'_v = \gamma^{d_v} \pi_v$. Call this modified graph $G'$.
    3. Guess $t$—the last node on optimal path $P^*$ with excess less than $\epsilon$.
    4. Guess $k$—the value of $\Pi'(P_t^*)$.
    5. Apply our Min-Excess-Path approximation algorithm to find a path $P$
       collecting scaled prize $k$ with small excess.
    6. Return this path as the solution.
```

Fig. 4.1. *Approximation for maximum discounted-prize path (*Discounted-Reward *TSP).*

Our analysis below proceeds in terms of $\alpha = \alpha_{EP}$, the approximation factor for our Min-Excess-Path algorithm.

Lemma 4.2. *Our approximation algorithm finds a path P that collects discounted reward $\rho(P) \geq \Pi'(P_t^*)/2^{\alpha\epsilon}$.*

Proof. The prefix P_t^* of the optimum path shows that it is possible to collect scaled prize $k = \Pi'(P_t^*)$ on a path with excess ϵ. Thus, our approximation algorithm finds a path collecting the same scaled prize with excess at most $\alpha\epsilon$. In particular, the excess of any vertex v in P is at most $\alpha\epsilon$. Thus, the discounted reward collected at v is at least

$$\rho(v) \geq \pi_v \left(\frac{1}{2}\right)^{d_v+\alpha\epsilon} = \pi_v \left(\frac{1}{2}\right)^{d_v} \left(\frac{1}{2}\right)^{\alpha\epsilon} = \pi'_v \left(\frac{1}{2}\right)^{\alpha\epsilon}.$$

Summing over all $v \in P$ and observing $\Pi'(P) \geq \Pi'(P^*) \geq \Pi'(P^*_t)$ completes the proof. □

Combining Lemmas 4.2 and 4.1, we get the following.

THEOREM 4.3. *The solution returned by the above algorithm has* $\rho(P) \geq (1 - \frac{1}{2^\epsilon})\rho(P^*)/2^{\alpha\epsilon}$.

Proof.

$$\begin{aligned} \rho(P) &\geq \Pi'(P^*)/2^{\alpha\epsilon} && \text{by Lemma 4.2} \\ &\geq \rho(P^*_t)/2^{\alpha\epsilon} && \text{by definition of } \pi' \\ &\geq \left(1 - \tfrac{1}{2^\epsilon}\right)\rho(P^*)/2^{\alpha\epsilon} && \text{by Lemma 4.1.} \quad \square \end{aligned}$$

We can now set ϵ as we like. Writing $x = 2^{-\epsilon}$, we optimize our approximation factor by maximizing $(1-x)x^\alpha$ to deduce $x = \alpha/(\alpha+1)$. Plugging this into x yields an approximation ratio of $(1+\alpha_{EP})(1+1/\alpha_{EP})^{\alpha_{EP}}$.

5. Orienteering.

In this section, we present an algorithm for computing an approximately max-prize path of length at most D that starts at a specified vertex s. We will use the algorithm for MIN-EXCESS-PATH given in section 3 as a subroutine. Our algorithm for the max-prize problem is given in Figure 5.1. As before, "guess k" is implemented by performing exhaustive enumeration.

```
Algorithm for max-prize path (ORIENTEERING)
    1. Guess $k$, the amount of prize collected by an optimum ORIENTEERING solution. Let $\alpha = \lceil \alpha_{EP} \rceil + 1$.
    2. For each vertex $v$, compute the min-excess path from $s$ to $v$ collecting prize $k/\alpha$.
    3. There exists a $v$ such that the min-excess path returned has length at most $D$; return the corresponding path.
```

FIG. 5.1. *Algorithm for max-prize path (*ORIENTEERING*).*

We analyze this algorithm by showing that any optimum ORIENTEERING solution contains a low-excess path which, in turn, is an approximately optimum ORIENTEERING solution. More precisely, we prove that for some vertex v, there exists a path from s to v with excess at most $\frac{D-d_v}{\alpha_{EP}}$ that collects prize at least $\frac{\Pi^*}{\alpha_{PP}}$, where α_{EP} is the approximation ratio for MIN-EXCESS-PATH, α_{PP} is the desired approximation ratio for max-prize path, and Π^* is the prize of the optimum max-prize path. Assuming this path exists, our min-excess path computation on this vertex v will find a path with total length at most $d_v + \alpha_{EP}\frac{D-d_v}{\alpha_{EP}} = D$ and prize at least $\frac{\Pi^*}{\alpha_{PP}}$, providing an α_{PP}-approximation for ORIENTEERING.

Let t be the last vertex on the optimum ORIENTEERING path. We first consider the case where t is the vertex at maximum distance from s on the optimum path.

LEMMA 5.1. *If there is a path from s to t of length at most D that collects prize Π, such that t is the furthest point from s along this path, then there is a path from s to some node v with excess at most $\frac{D-d_v}{r}$ and prize at least $\frac{\Pi}{r}$ (for any integer $r \geq 1$).*

Proof. For each point a along the original path P, let $\epsilon(a) = d^P_a - d_a$; in other words, $\epsilon(a)$ is the excess in the length of the path to a over the shortest-path distance.

We have $\epsilon(t) \le D - d_t$. Consider mapping the points on the path to a line from 0 to $\epsilon(t)$ according to their excess (we observe that excess can only increase as we traverse path P). Divide this line into r intervals with length $\frac{\epsilon(t)}{r}$. Some such interval must contain at least $\frac{\Pi}{r}$ prize, since otherwise the entire interval from 0 to $\epsilon(t)$ would not be able to collect prize Π. Suppose such an interval starts with node a and ends with node v. We consider a path from s to v that takes the shortest s-a path and then follows path P from a to v. This path collects the prize of the interval from a to v in the original path, which is a prize of at least $\frac{\Pi}{r}$ as desired. The total length of this path is $d_a + d^P(a, v) = d_a + d_v^P - d_a^P = d_v + \epsilon(v) - \epsilon(a) \le d_v + \frac{\epsilon(t)}{r}$. The excess of this path is $\frac{\epsilon(t)}{r} \le \frac{D-d_t}{r} \le \frac{D-d_v}{r}$, where the last inequality follows by using that t is farther from s than v. □

Of course, in general the optimum ORIENTEERING path might have some intermediate node that is farther from s than the terminal node t. We will generalize the above lemma to account for this case.

LEMMA 5.2. *If there is a path from s to t of length at most D that collects prize Π, then there is a path from s to some node v with excess at most $\frac{D-d_v}{r}$ and prize at least $\frac{\Pi}{r+1}$ (for any integer $r \ge 1$).*

Proof. Let f be the furthest point from s along the given path P. We are interested in the case where $f \ne t$. We can break path P into two pieces; first a path from s to f and then a path from f to t. Using the symmetry of our metric, we can produce a second path from s to f by using the shortest path from s to t and then following the portion of our original path from f to t in reverse. We now have two paths from s to f, each of which has length at most D. The total length of these paths is bounded by $D + d_t$. We will call our paths A and B, and let their lengths be $d_f + \delta_A$ and $d_f + \delta_B$, respectively. Note that $\delta_A + \delta_B \le D + d_t - 2d_f < D - d_f$.

We now map path A to the interval from 0 to δ_A according to the excess at each point, much as in Lemma 5.1. We consider dividing this interval into pieces of length $\frac{\delta_A+\delta_B}{r}$ (the last subinterval may have shorter length if δ_A does not divide evenly). We perform the same process on path B. We have created a total of $r + 1$ intervals (this relies on the assumption that r is integral, allowing us to bound the sum of the ceilings of the number of intervals for each path). We conclude that some such interval has prize at least $\frac{\Pi}{r+1}$. We suppose without loss of generality that this interval spans a portion of path A from a to v. We now consider a path that travels from s to a via the shortest path and then from a to v following path A. The length of this path is bounded by $d_v + \frac{\delta_A+\delta_B}{r}$ for an excess of at most $\frac{D-d_f}{r} \le \frac{D-d_v}{r}$ as desired. □

Making use of Lemma 5.2, we can prove that our algorithm for ORIENTEERING obtains a constant approximation. Making use of Chaudhuri et al.'s approximation for min-cost s-t path [10] along with our result on MIN-EXCESS-PATH from section 3, we have a 4-approximation for ORIENTEERING.

THEOREM 5.3. *Our algorithm is an $(\lceil \alpha_{EP} \rceil + 1)$-approximation for the max-prize path (*ORIENTEERING*) problem, where α_{EP} is the approximation factor for* MIN-EXCESS-PATH.

Proof. Lemma 5.2 implies that there exists a path from s to some v with excess $\frac{D-d_v}{\lceil \alpha_{EP} \rceil}$ obtaining prize $\frac{\Pi^*}{\lceil \alpha_{EP} \rceil + 1}$. Such a path has length $d_v + \frac{D-d_v}{\lceil \alpha_{EP} \rceil}$, implying that the approximation algorithm for MIN-EXCESS-PATH will find a path from s to v with length at most $d_v + (D - d_v) = D$ and at least the same prize. The algorithm described will eventually try the proper values of k and v and find such a path in polynomial time. □

6. Extensions.

6.1. Max-prize tree and max-prize cycle.

In this section, we consider the tree and cycle variants of the ORIENTEERING problem. In max-prize tree, given a graph G with root r, prize function Π, and lengths d, we are required to output a tree $\mathcal{T}$ rooted at r with $d(\mathcal{T}) \leq \mathcal{D}$ and maximum possible reward $\Pi(\mathcal{T})$. This problem is also called the budget prize-collecting Steiner tree problem [20]. Although the unrooted version of the problem can be approximated to within a factor of $5 + \epsilon$ via a 3-approximation for k-MST [20], the version of the problem in which a tree is required to contain a specified vertex has remained open until recently.

Let the optimal solution for this problem be a tree $\mathcal{T}^*$. Double the edges of this tree to obtain an Euler tour of length at most $2D$. Now, divide this tour into two paths, each starting from the root r and having length at most D. Among them, let P' be the path that has greater reward. Now consider the max-prize path problem on the same graph with distance limit D. Clearly, the optimal solution P^* to this problem has $\Pi(P^*) \geq \Pi(P') \geq \frac{\Pi(\mathcal{T}^*)}{2}$. Thus, we can use the α_{PP}-approximation for ORIENTEERING to get a $2\alpha_{PP}$-approximation to T^*.

Finally, we note that we can use our algorithm for the ORIENTEERING problem to approximate max-prize cycle. Namely, we can find an approximately max-prize cycle of length at most D that contains a specified vertex s. To this end, we apply our algorithm to an instance of the ORIENTEERING problem with the starting node s and the length constraint $D/2$. To obtain a cycle from the resulting path, we connect its endpoints by a shortest path. Clearly, the length of the resulting cycle is at most D. Now, notice that an optimal max-prize cycle of length D can span at most twice the amount of prize as an optimal max-prize path of length $D/2$. Thus, using α_{PP}-approximation to ORIENTEERING, we get $2\alpha_{PP}$-approximation to the max-prize cycle problem.

6.2. Multiple-path ORIENTEERING.

In this section, we consider a variant of the ORIENTEERING problem in which we are allowed to construct up to k paths, each having length at most D.

We approximate this problem by applying the algorithm in section 4 successively k times, to construct the k paths. At the ith step, we set the prizes of all points visited in the first $i - 1$ paths to 0, and constructed the ith path on the new graph, using the ORIENTEERING algorithm in section 5. Using a set-cover-like argument, we get the following approximation guarantees for the cases when all paths have the same starting point and when different paths have different starts.[6]

THEOREM 6.1. *If all the paths have a common start node, the above algorithm gives a* $1/(1 - e^{-\alpha_{PP}})$*-approximation to multiple-path* ORIENTEERING. *If the paths have different start nodes, the above algorithm gives a* $(\alpha_{PP} + 1)$*-approximation to multiple-path* ORIENTEERING.

Proof. Consider first the case when all the paths have the same starting point. Let the difference in the reward collected by the optimal solution and the reward collected by our solution up to stage i be Π_i. At the beginning, this is the total reward of the optimal solution. At step i, at least one of the paths in the optimal solution collects reward, not collected by the algorithm by stage i, of value at least $\frac{1}{k}\Pi_i$. Then, using the approximation guarantee of the algorithm for ORIENTEERING, our solution collects at least a $\frac{1}{k\alpha_{PP}}$ fraction of this reward. That is, $\Pi_{i+1} \leq (1 - \frac{1}{k\alpha_{PP}})\Pi_i$. By the end of

[6] Subsequent to the initial publication of our work, Chekuri and Kumar [12] independently employed a similar analysis for other "maximum-coverage" problems.

k rounds, the total reward collected by optimal solution, but not collected by us, is at most $(1-\frac{1}{k\alpha_{PP}})^k\Pi(P^*) \le e^{-\alpha_{PP}}\Pi(P^*)$, and the result follows.

Next, consider the case when different paths have different starting locations. Let O_i be the set of points visited by the ith path in the optimal solution and A_i be the corresponding set of points visited by our algorithm. Let Δ_i be the set of points that are visited by the ith path in the optimal solution and some other path in our solution. Let $O = \cup_i O_i$, $A = \cup_i A_i$, and $\Delta = \cup_i \Delta_i$. Now, in the ith stage, there is a valid path starting at the ith source that visits all points in $O_i \setminus \Delta_i$. Thus we have $\Pi(A_i) \ge \frac{1}{\alpha_{PP}}(\Pi(O_i) - \Pi(\Delta_i))$. Summing over i, we get $\alpha_{PP}\Pi(A) \ge (\Pi(O) - \Pi(\Delta))$. But $\Pi(\Delta) \le \Pi(A)$. Thus $\Pi(A) \ge \frac{1}{\alpha_{PP}+1}\Pi(O)$. □

7. Hardness of approximation. All the problems discussed in this paper are NP-hard, as they are generalizations of the TSP. In this section, we show that the Min-Excess-Path problem and Orienteering are APX-hard; that is, it is NP-hard to approximate these problems to within an arbitrary constant factor.

The hardness of approximating the Min-Excess-Path problem follows from the APX-hardness of the TSP [24]. In particular, we can reduce the TSP to an instance of Min-Excess-Path on the same graph, with any one vertex as the start and the end point, and a reward quota of n. Then an α-approximation to Min-Excess-Path on this instance is also an α-approximation to the TSP. We therefore get the following theorem.

Theorem 7.1. *The* Min-Excess-Path *problem is NP-hard to approximate to within a factor of* $\frac{220}{219}$.

Theorem 7.2. Orienteering *is NP-hard to approximate to within a factor of* $\frac{1481}{1480}$.

Proof. We reduce the TSP on $\{1,2\}$-metrics to Orienteering. In particular, let $G = (V, E)$ be a complete graph on n nodes, with edges lengths in the set $\{1,2\}$. Engebretsen and Karpinski [14] show that the TSP is NP-hard to approximate within a factor of $1+\alpha = \frac{741}{740}$ on such graphs.

Our reduction is as follows. Let the length of the optimal TSP solution be $L = n + \delta n$. (We simply try all values of L between n and $2n$.) Suppose that there is an algorithm that approximates Orienteering within a factor of $1+\beta$, where $\beta \le \frac{\alpha}{2} = \frac{1}{1480}$. We apply this algorithm to the graph G with distance limit L. Note that the optimal solution (which is the optimal TSP path) collects $n-1$ nodes within distance L (all nodes, except the start, assuming a reward of 0 on the start node). Therefore, the solution returned by our algorithm collects $\frac{1}{1+\beta}(n-1)$ nodes. We augment this solution to a tour containing all the nodes by using $(1-\frac{1}{1+\beta})(n-1)+1$ edges of length at most 2. Therefore, the length of our solution is at most

$$\begin{aligned} L + 2(1-\tfrac{1}{1+\beta})(n-1)+2 &= L + \tfrac{2\beta}{1+\beta}(n-1)+2 \\ &< L + 2\beta n \\ &= L + \alpha n \le (1+\alpha)L, \end{aligned}$$

where the second inequality follows from assuming that $n > \frac{1}{\beta^2}$.

Therefore, we get a $(1+\alpha)$-approximation to the TSP on G, contradicting the fact that TSP is NP-hard to approximate to within a $(1+\alpha)$ factor on $\{1,2\}$-metrics. □

Using a similar argument as for Orienteering, we get a $\frac{1481}{1480}$ hardness of approximation for the max-prize cycle problem as well.

8. Conclusions. In this paper, we give constant-factor algorithms for the Orienteering problem, Discounted-Reward TSP, and some of their variants. We also prove that it is NP-hard to obtain a polynomial time approximation scheme (PTAS) for the Orienteering and Min-Excess-Path problems. An interesting open problem is to obtain better approximations, or even a PTAS, for these problems when the underlying metric is planar. Another interesting open problem is to consider the directed versions of the problems, although we believe that it may be hard to approximate these to within constant or even logarithmic factors. Some recent progress has been made in this direction by Chekuri and Pál [13], who developed quasi-polynomial time log-approximation algorithms for Orienteering and several related problems on directed graphs.

Even more ambitiously, returning to the MDP motivation for this work, one would like to generalize these results to probabilistic transition functions. However, this has the additional complication that the optimum solution may not even have a short description (it is no longer just a path). Still, perhaps some sort of nontrivial approximation bound, or a result holding in important special cases, can be found. The Ph.D. thesis of the second author [11] contains preliminary results in this direction.

EFFECTIVE STRONG DIMENSION IN ALGORITHMIC INFORMATION AND COMPUTATIONAL COMPLEXITY*

KRISHNA B. ATHREYA[†], JOHN M. HITCHCOCK[‡], JACK H. LUTZ[§], AND ELVIRA MAYORDOMO[¶]

Abstract. The two most important notions of fractal dimension are *Hausdorff dimension*, developed by Hausdorff [*Math. Ann.*, 79 (1919), pp. 157–179], and *packing dimension*, developed independently by Tricot [*Math. Proc. Cambridge Philos. Soc.*, 91 (1982), pp. 57–74] and Sullivan [*Acta Math.*, 153 (1984), pp. 259–277]. Both dimensions have the mathematical advantage of being defined from measures, and both have yielded extensive applications in fractal geometry and dynamical systems. Lutz [*Proceedings of the* 15*th IEEE Conference on Computational Complexity*, Florence, Italy, 2000, IEEE Computer Society Press, Piscataway, NJ, 2000, pp. 158–169] has recently proven a simple characterization of Hausdorff dimension in terms of *gales*, which are betting strategies that generalize martingales. Imposing various computability and complexity constraints on these gales produces a spectrum of effective versions of Hausdorff dimension, including constructive, computable, polynomial-space, polynomial-time, and finite-state dimensions. Work by several investigators has already used these effective dimensions to shed significant new light on a variety of topics in theoretical computer science. In this paper we show that packing dimension can also be characterized in terms of gales. Moreover, even though the usual definition of packing dimension is considerably more complex than that of Hausdorff dimension, our gale characterization of packing dimension is an exact dual of—and every bit as simple as—the gale characterization of Hausdorff dimension. Effectivizing our gale characterization of packing dimension produces a variety of *effective strong dimensions*, which are exact duals of the effective dimensions mentioned above. In general (and in analogy with the classical fractal dimensions), the effective strong dimension of a set or sequence is at least as great as its effective dimension, with equality for sets or sequences that are sufficiently regular. We develop the basic properties of effective strong dimensions and prove a number of results relating them to fundamental aspects of randomness, Kolmogorov complexity, prediction, Boolean circuit-size complexity, polynomial-time degrees, and data compression. Aside from the above characterization of packing dimension, our two main theorems are the following. 1. If $\vec{\beta} = (\beta_0, \beta_1, \dots)$ is a computable sequence of biases that are bounded away from 0 and R is random with respect to $\vec{\beta}$, then the dimension and strong dimension of R are the lower and upper average entropies, respectively, of $\vec{\beta}$. 2. For each pair of Δ^0_2-computable real numbers $0 < \alpha \leq \beta \leq 1$, there exists $A \in \mathrm{E}$ such that the polynomial-time many-one degree of A has dimension α in E and strong dimension β in E. Our proofs of these theorems use a new large deviation theorem for self-information with respect to a bias sequence $\vec{\beta}$ that need not be convergent.

Key words. effective dimension, packing dimension, Hausdorff dimension, Kolmogorov complexity, computational complexity, Martin-Löf randomness

1. Introduction.

Hausdorff dimension—a powerful tool of fractal geometry developed by Hausdorff [12] in 1919—was effectivized in 2000 by Lutz [22, 23, 24]. This has led to a spectrum of effective versions of Hausdorff dimension, including constructive, computable, polynomial-space, polynomial-time, and finite-state dimensions. Work by several investigators has already used these effective dimensions to illuminate a variety of topics in algorithmic information theory and computational complexity [23, 24, 1, 7, 27, 13, 16, 11, 14, 15, 10]. (See [28] for a survey of some of these results.) This work has also underscored and renewed the importance of earlier work by Ryabko [29, 30, 31, 32], Staiger [38, 39, 40], and Cai and Hartmanis [5] relating Kolmogorov complexity to classical Hausdorff dimension. (See section 6 of [24] for a discussion of this work.)

The key to all these effective dimensions is a simple characterization of classical Hausdorff dimension in terms of *gales*, which are betting strategies that generalize martingales. (Martingales, introduced by Lévy [18] and Ville [46], have been used extensively by Schnorr [33, 34, 35] and others in the investigation of randomness and by Lutz [20, 21] and others in the development of resource-bounded measure.) Given this characterization, it is a simple matter to impose computability and complexity constraints on the gales to produce the above-mentioned spectrum of effective dimensions.

In the 1980s, a new concept of fractal dimension, called the packing dimension, was introduced independently by Tricot [43] and Sullivan [41]. Packing dimension shares with Hausdorff dimension the mathematical advantage of being based on a measure. Over the past two decades, despite its greater complexity (requiring an extra optimization over all countable decompositions of a set in its definition), packing dimension has become, next to Hausdorff dimension, the most important notion of fractal dimensions, yielding extensive applications in fractal geometry and dynamical systems [9, 8].

The main result of this paper is a proof that packing dimension can also be characterized in terms of gales. Moreover, notwithstanding the greater complexity of packing dimension's definition (and the greater complexity of its behavior on compact sets, as established by Mattila and Mauldin [26]), our gale characterization of packing dimension is an exact dual of—and every bit as simple as—the gale characterization of Hausdorff dimension. (This duality and simplicity are in the *statement* of our gale characterization; its proof is perforce more involved than its counterpart for Hausdorff dimension.)

Effectivizing our gale characterization of packing dimension produces for each of the effective dimensions above an *effective strong dimension* that is its exact dual. Just as the Hausdorff dimension of a set is bounded above by its packing dimension, the effective dimension of a set is bounded above by its effective strong dimension. Moreover, just as in the classical case, the effective dimension coincides with the strong effective dimension for sets that are sufficiently regular.

After proving our gale characterization and developing the effective strong dimensions and some of their basic properties, we prove a number of results relating them to fundamental aspects of randomness, Kolmogorov complexity, prediction, Boolean circuit-size complexity, polynomial-time degrees, and data compression. Our two main theorems along these lines are the following.

1. If $\delta > 0$ and $\vec{\beta} = (\beta_0, \beta_1, \dots)$ is a computable sequence of biases with each

$\beta_i \in [\delta, \frac{1}{2}]$, then every sequence R that is random with respect to $\vec{\beta}$ has dimension

$$\dim(R) = \liminf_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} \mathcal{H}(\beta_i)$$

and strong dimension

$$\mathrm{Dim}(R) = \limsup_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} \mathcal{H}(\beta_i),$$

where $\mathcal{H}(\beta_i)$ is the Shannon entropy of β_i.

2. For every pair of Δ^0_2-computable real numbers $0 < \alpha \leq \beta \leq 1$ there is a decision problem $A \in \mathrm{E}$ such that the polynomial-time many-one degree of A has dimension α in E and strong dimension β in E.

In order to prove these theorems, we prove a new large deviation theorem for the self-information $\log \frac{1}{\mu^{\vec{\beta}}(w)}$, where $\vec{\beta}$ is as in 1 above. Note that $\vec{\beta}$ need not be convergent here.

A corollary of theorem 1 above is that, if the average entropies $\frac{1}{n}\sum_{i=0}^{n-1} \mathcal{H}(\beta_i)$ converge to a limit $\overline{H}(\vec{\beta})$ as $n \to \infty$, then $\dim(R) = \mathrm{Dim}(R) = \overline{H}(\vec{\beta})$. Since the convergence of these average entropies is a much weaker condition than the convergence of the biases β_n as $n \to \infty$, this corollary substantially strengthens Theorem 7.7 of [24].

Our remaining results are much easier to prove, but their breadth makes a strong prima facie case for the utility of effective strong dimension. They in some cases explain dual concepts that had been curiously neglected in earlier work, and they are likely to be useful in future applications. It is to be hoped that we are on the verge of seeing the full force of fractal geometry applied fruitfully to difficult problems in the theory of computing.

2. Preliminaries.

We use the set $\mathbb{Z}$ of integers, the set $\mathbb{Z}^+$ of (strictly) positive integers, the set $\mathbb{N}$ of natural numbers (i.e., nonnegative integers), the set $\mathbb{Q}$ of rational numbers, the set $\mathbb{R}$ of real numbers, and the set $[0, \infty)$ of nonnegative reals. All logarithms in this paper are base 2. We use the slow-growing function $\log^* n = \min\{j \in \mathbb{N} \mid t_j \geq n\}$, where $t_0 = 0$ and $t_{j+1} = 2^{t_j}$, and Shannon's binary entropy function $\mathcal{H} : [0,1] \to [0,1]$ defined by

$$\mathcal{H}(\beta) = \beta \log \frac{1}{\beta} + (1-\beta) \log \frac{1}{1-\beta},$$

where $0 \log \frac{1}{0} = 0$.

A *string* is a finite, binary string $w \in \{0,1\}^*$. We write $|w|$ for the length of a string w and λ for the empty string. For $i, j \in \{0, \ldots, |w|-1\}$, we write $w[i..j]$ for the string consisting of the ith through the jth bits of w, and $w[i]$ for $w[i..i]$, the ith bit of w. Note that the 0th bit $w[0]$ is the leftmost bit of w and that $w[i..j] = \lambda$ if $i > j$. A *sequence* is an infinite binary sequence. If S is a sequence and $i, j \in \mathbb{N}$, then the notations $S[i..j]$ and $S[i]$ are defined exactly as for strings. We work in the *Cantor space* $\mathbf{C}$ consisting of all sequences. A string $w \in \{0,1\}^*$ is a *prefix* of a sequence $S \in \mathbf{C}$, and we write $w \sqsubseteq S$, if $S[0..|w|-1] = w$. The *cylinder generated by* a string $w \in \{0,1\}^*$ is $\mathbf{C}_w = \{S \in \mathbf{C} | w \sqsubseteq S\}$. Note that $\mathbf{C}_\lambda = \mathbf{C}$.

A *language*, or *decision problem*, is a set $A \subseteq \{0,1\}^*$. We usually identify a language A with its characteristic sequence $\chi_A \in \mathbf{C}$ defined by $\chi_A[n] = \textbf{if } s_n \in A \textbf{ then } 1 \textbf{ else } 0$, where $s_0 = \lambda$, $s_1 = 0$, $s_2 = 1$, $s_3 = 00, \ldots$ is the standard enumeration of $\{0,1\}^*$. That is, we usually (but not always) use A to denote both the set $A \subseteq \{0,1\}^*$ and the sequence $A = \chi_A \in \mathbf{C}$.

Given a set $A \subseteq \{0,1\}^*$ and $n \in \mathbb{N}$, we use the abbreviations $A_{=n} = A \cap \{0,1\}^n$ and $A_{\leq n} = A \cap \{0,1\}^{\leq n}$. A *prefix set* is a set $A \subseteq \{0,1\}^*$ such that no element of A is a prefix of another element of A.

For each $i \in \mathbb{N}$ we define a class G_i of functions from $\mathbb{N}$ into $\mathbb{N}$ as follows.

$$\begin{aligned} G_0 &= \{f \mid (\exists k)(\forall^\infty n) f(n) \leq kn\}, \\ G_{i+1} &= 2^{G_i(\log n)} = \{f \mid (\exists g \in G_i)(\forall^\infty n) f(n) \leq 2^{g(\log n)}\}. \end{aligned}$$

We also define the functions $\hat{g}_i \in G_i$ by $\hat{g}_0(n) = 2n$, $\hat{g}_{i+1}(n) = 2^{\hat{g}_i(\log n)}$. We regard the functions in these classes as growth rates. In particular, G_0 contains the linearly bounded growth rates, and G_1 contains the polynomially bounded growth rates. It is easy to show that each G_i is closed under composition, that each $f \in G_i$ is $o(\hat{g}_{i+1})$, and that each $\hat{g}_i$ is $o(2^n)$. Thus G_i contains superpolynomial growth rates for all $i > 1$, but all growth rates in the G_i-hierarchy are subexponential.

Let CE be the class of computably enumerable languages. Within the class DEC of all decidable languages, we are interested in the exponential complexity classes $\mathrm{E}_i = \mathrm{DTIME}(2^{G_{i-1}})$ and $\mathrm{E}_i\mathrm{SPACE} = \mathrm{DSPACE}(2^{G_{i-1}})$ for $i \geq 1$. The much-studied classes $\mathrm{E} = \mathrm{E}_1 = \mathrm{DTIME}(2^{\mathrm{linear}})$, $\mathrm{E}_2 = \mathrm{DTIME}(2^{\mathrm{polynomial}})$, and $\mathrm{ESPACE} = \mathrm{E}_1\mathrm{SPACE} = \mathrm{DSPACE}(2^{\mathrm{linear}})$ are of particular interest.

We use the following classes of functions:

$$\begin{aligned} \mathrm{all} &= \{f \mid f : \{0,1\}^* \to \{0,1\}^*\}, \\ \mathrm{comp} &= \{f \in \mathrm{all} \mid f \text{ is computable}\}, \\ \mathrm{p}_i &= \{f \in \mathrm{all} \mid f \text{ is computable in } G_i \text{ time}\} \ (i \geq 1), \\ \mathrm{p}_i\mathrm{space} &= \{f \in \mathrm{all} \mid f \text{ is computable in } G_i \text{ space}\} \ (i \geq 1). \end{aligned}$$

(The length of the output *is* included as part of the space used in computing f.) We write p for p_1 and pspace for $\mathrm{p}_1$space.

A *constructor* is a function $\delta : \{0,1\}^* \to \{0,1\}^*$ that satisfies $x \sqsubsetneq \delta(x)$ for all x. The *result* of a constructor δ (i.e., the language *constructed* by δ) is the unique language $R(\delta)$ such that $\delta^n(\lambda) \sqsubseteq R(\delta)$ for all $n \in \mathbb{N}$. Intuitively, δ constructs $R(\delta)$ by starting with λ and then iteratively generating successively longer prefixes of $R(\delta)$. We write $R(\Delta)$ for the set of languages $R(\delta)$ such that δ is a constructor in Δ. The following facts are the reason for our interest in the above-defined classes of functions:

$R(\mathrm{all}) = \mathbf{C}$.
$R(\mathrm{comp}) = \mathrm{DEC}$.
For $i \geq 1$, $R(\mathrm{p}_i) = \mathrm{E}_i$.
For $i \geq 1$, $R(\mathrm{p}_i\mathrm{space}) = \mathrm{E}_i\mathrm{SPACE}$.

If D is a discrete domain (such as $\mathbb{N}, \{0,1\}^*, \mathbb{N} \times \{0,1\}^*$, etc.), then a function $f : D \longrightarrow [0,\infty)$ is *Δ-computable* if there is a function $\hat{f} : \mathbb{N} \times D \longrightarrow \mathbb{Q} \cap [0,\infty)$ such that $|\hat{f}(r,x) - f(x)| \leq 2^{-r}$ for all $r \in \mathbb{N}$ and $x \in D$ and $\hat{f} \in \Delta$ (with r coded in unary and the output coded in binary). We say that f is *exactly Δ-computable* if $f : D \longrightarrow \mathbb{Q} \cap [0,\infty)$ and $f \in \Delta$. We say that f is *lower semicomputable* if there is a computable function $\hat{f} : D \times \mathbb{N} \to \mathbb{Q}$ such that

(a) for all $(x,t) \in D \times \mathbb{N}$, $\hat{f}(x,t) \leq \hat{f}(x,t+1) < f(x)$, and

(b) for all $x \in D$, $\lim_{t\to\infty} \hat{f}(x,t) = f(x)$.

Finally, we say that f is Δ^0_2-computable if f is computable (i.e., comp-computable) relative to the halting oracle.

A real number $\alpha \in [0,\infty)$ is *computable* (respectively, Δ^0_2-*computable*) if the function $f : \{0\} \to [0,\infty)$ defined by $f(0) = \alpha$ is computable (respectively, Δ^0_2-computable).

Let k be a positive integer. A *k-account finite-state gambler (k-account FSG)* is a tuple $G = (Q, \delta, \beta, q_0, \vec{c_0})$, where

- Q is a nonempty, finite set of states,
- $\delta : Q \times \{0,1\} \to Q$ is the transition function,
- $\beta : \{1,\ldots,k\} \times Q \times \{0,1\} \to \mathbb{Q} \cap [0,1]$ is the betting function,
- $q_0 \in Q$ is the initial state, and
- $\vec{c_0}$ is the initial capital vector, a sequence of k nonnegative rational numbers.

The betting function satisfies $\beta(i,q,0) + \beta(i,q,1) = 1$ for each $q \in Q$ and $1 \leq i \leq k$. We use the standard extension $\delta^* : \Sigma^* \to Q$ of δ defined recursively by $\delta^*(\lambda) = q_0$ and $\delta^*(wb) = \delta(\delta^*(w), b)$ for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$.

3. Fractal dimensions. In this section we briefly review the classical definitions of some fractal dimensions and the relationships among them. Since we are primarily interested in binary sequences and (equivalently) decision problems, we focus on fractal dimension in the Cantor space $\mathbf{C}$.

For each $k \in \mathbb{N}$, we let $\mathcal{A}_k$ be the collection of all prefix sets A such that $A_{<k} = \emptyset$. For each $X \subseteq \mathbf{C}$, we then define the families

$$\mathcal{A}_k(X) = \left\{ A \in \mathcal{A}_k \,\middle|\, X \subseteq \bigcup_{w\in A} \mathbf{C}_w \right\},$$
$$\mathcal{B}_k(X) = \{ A \in \mathcal{A}_k \,|(\forall w \in A)\mathbf{C}_w \cap X \neq \emptyset \}.$$

If $A \in \mathcal{A}_k(X)$, then we say that the prefix set A *covers* the set X. If $A \in \mathcal{B}_k(X)$, then we call the prefix set A a *packing* of X. For $X \subseteq \mathbf{C}$, $s \in [0,\infty)$, and $k \in \mathbb{N}$, we then define

$$H^s_k(X) = \inf_{A\in\mathcal{A}_k(X)} \sum_{w\in A} 2^{-s|w|},$$
$$P^s_k(X) = \sup_{A\in\mathcal{B}_k(X)} \sum_{w\in A} 2^{-s|w|}.$$

Since $H^s_k(X)$ and $P^s_k(X)$ are monotone in k, the limits

$$H^s(X) = \lim_{k\to\infty} H^s_k(X),$$
$$P^s_\infty(X) = \lim_{k\to\infty} P^s_k(X)$$

exist, though they may be infinite. We then define

$$P^s(X) = \inf \left\{ \sum_{i=0}^{\infty} P^s_\infty(X_i) \,\middle|\, X \subseteq \bigcup_{i=0}^{\infty} X_i \right\}. \tag{3.1}$$

The set functions H^s and P^s have the technical properties of an outer measure [9], and the (possibly infinite) quantities $H^s(X)$ and $P^s(X)$ are thus known as the *s-dimensional Hausdorff (outer) cylinder measure* of X and the *s-dimensional packing* *(outer) cylinder measure* of X, respectively. The set function P^s_∞ is *not* an outer measure; this is the reason for the extra optimization (3.1) in the definition of the packing measure.

Definition. *Let* $X \subseteq \mathbf{C}$.

1. *The* Hausdorff dimension *of* X *is* $\dim_{\mathrm{H}}(X) = \inf\{s \in [0,\infty) | H^s(X) = 0\}$.
2. *The* packing dimension *of* X *is* $\dim_{\mathrm{P}}(X) = \inf\{s \in [0,\infty) | P^s(X) = 0\}$.

The proof of our main result uses a well-known characterization of packing dimension as a modified box dimension. For each $X \subseteq \mathbf{C}$ and $n \in \mathbb{N}$, let

$$N_n(X) = \Big|\{w \in \{0,1\}^n | (\exists S \in X) w \sqsubseteq S\}\Big|.$$

Then the *upper box dimension* of X is

$$\overline{\dim}_{\mathrm{B}}(X) = \limsup_{n\to\infty} \frac{\log N_n(X)}{n}. \tag{3.2}$$

The lower box dimension $\underline{\dim}_{\mathrm{B}}(X)$, which we do not use here, is obtained by using a limit inferior in place of the limit superior in (3.2). When $\underline{\dim}_{\mathrm{B}}(X) = \overline{\dim}_{\mathrm{B}}(X)$, this quantity, written $\dim_{\mathrm{B}}(X)$, is called the box dimension of X.

Box dimensions are over 60 years old, have been reinvented many times, and have been named many things, including Minkowski dimension, Kolmogorov entropy, Kolmogorov dimension, topological entropy, metric dimension, logarithmic density, and information dimension. Box dimensions are often used in practical applications of fractal geometry because they are easy to estimate, but they are not well-behaved mathematically. The *modified upper box dimension*

$$\overline{\dim}_{\mathrm{MB}}(X) = \inf\left\{\sup_i \overline{\dim}_{\mathrm{B}}(X_i) \,\middle|\, X \subseteq \bigcup_{i=0}^{\infty} X_i\right\} \tag{3.3}$$

is much better behaved. (Note that (3.3), like (3.1), is an optimization over all countable decompositions of X.) In fact, the following relations are well known [9].

Theorem 3.1. *For all* $X \subseteq \mathbf{C}$, $0 \le \dim_{\mathrm{H}}(X) \le \overline{\dim}_{\mathrm{MB}}(X) = \dim_{\mathrm{P}}(X) \le \overline{\dim}_{\mathrm{B}}(X) \le 1$.

The above dimensions are *monotone*, i.e., $X \subseteq Y$ implies $\dim(X) \le \dim(Y)$, and *stable*, i.e., $\dim(X \cup Y) = \max\{\dim(X), \dim(Y)\}$. The Hausdorff and packing dimensions are also *countably stable*, i.e., $\dim(\cup_{i=0}^{\infty} X_i) = \sup\{\dim(X_i) | i \in \mathbb{N}\}$.

4. Gale characterizations.

In this section we review the gale characterization of Hausdorff dimension and prove our main theorem, which is the dual gale characterization of packing dimension.

Definition. *Let* $s \in [0,\infty)$.

1. *An* s-supergale *is a function* $d : \{0,1\}^* \longrightarrow [0,\infty)$ *that satisfies the condition*

$$d(w) \ge 2^{-s}[d(w0) + d(w1)] \tag{4.1}$$

for all $w \in \{0,1\}^*$.

2. *An* s-gale *is an* s*-supergale that satisfies* (4.1) *with equality for all* $w \in \{0,1\}^*$.
3. *A* supermartingale *is a* 1*-supergale.*
4. *A* martingale *is a* 1*-gale.*

Intuitively, we regard a supergale d as a strategy for betting on the successive bits of a sequence $S \in \mathbf{C}$. More specifically $d(w)$ is the amount of capital that d has after betting on the prefix w of S. If $s = 1$, then the right-hand side of (4.1) is the conditional expectation of $d(wb)$, given that w has occurred (when b is a uniformly distributed binary random variable). Thus a martingale models a gambler's capital when the payoffs are fair. (The expected capital after the bet is the actual capital before the bet.) In the case of an s-gale, if $s < 1$, the payoffs are less than fair; if $s > 1$, the payoffs are more than fair.

We use the following known generalization of the Kraft inequality.

Lemma 4.1 (Lutz [23]). *Let $s \in [0, \infty)$. If d is an s-supergale and $B \subseteq \{0, 1\}^*$ is a prefix set, then for all $w \in \{0, 1\}^*$, $\sum_{u \in B} 2^{-s|u|} d(wu) \leq d(w)$.*

We now define two criteria for the success of a gale or supergale.

Definition. *Let d be an s-supergale, where $s \in [0, \infty)$.*

1. *We say that d* succeeds *on a sequence $S \in \mathbf{C}$ if*

$$\limsup_{n \to \infty} d(S[0..n-1]) = \infty. \tag{4.2}$$

The success set *of d is $S^\infty[d] = \{S \in \mathbf{C} | d \text{ succeeds on } S\}$.*

2. *We say that d* succeeds strongly *on a sequence $S \in \mathbf{C}$ if*

$$\liminf_{n \to \infty} d(S[0..n-1]) = \infty. \tag{4.3}$$

The strong success set *of d is $S^\infty_{\mathrm{str}}[d] = \{S \in \mathbf{C} | d \text{ succeeds strongly on } S\}$.*

We have written conditions (4.2) and (4.3) in a fashion that emphasizes their duality. Condition (4.2) says simply that the set of values $d(S[0..n-1])$ is unbounded, while condition (4.3) says that $d(S[0..n-1]) \to \infty$ as $n \to \infty$.

Notation. Let $X \subseteq \mathbf{C}$.

1. $\mathcal{G}(X)$ is the set of all $s \in [0, \infty)$ for which there exists an s-gale d such that $X \subseteq S^\infty[d]$.
2. $\mathcal{G}^{\mathrm{str}}(X)$ is the set of all $s \in [0, \infty)$ for which there exists an s-gale d such that $X \subseteq S^\infty_{\mathrm{str}}[d]$.
3. $\widehat{\mathcal{G}}(X)$ is the set of all $s \in [0, \infty)$ for which there exists an s-supergale d such that $X \subseteq S^\infty[d]$.
4. $\widehat{\mathcal{G}}^{\mathrm{str}}(X)$ is the set of all $s \in [0, \infty)$ for which there exists an s-supergale d such that $X \subseteq S^\infty_{\mathrm{str}}[d]$.

Note that $s' \geq s \in \mathcal{G}(X)$ implies that $s' \in \mathcal{G}(X)$, and similarly for the classes $\mathcal{G}^{\mathrm{str}}(X)$, $\widehat{\mathcal{G}}(X)$, and $\widehat{\mathcal{G}}^{\mathrm{str}}(X)$. The following fact is also clear.

Observation 4.2. *For all $X \subseteq \mathbf{C}$, $\mathcal{G}(X) = \widehat{\mathcal{G}}(X)$ and $\mathcal{G}^{\mathrm{str}}(X) = \widehat{\mathcal{G}}^{\mathrm{str}}(X)$.*

For Hausdorff dimension, we have the following known fact.

Theorem 4.3 (gale characterization of Hausdorff dimension; see Lutz [23]). *For all $X \subseteq \mathbf{C}$, $\dim_{\mathrm{H}}(X) = \inf \mathcal{G}(X)$.*

Our main result is the following dual of Theorem 4.3.

Theorem 4.4 (gale characterization of packing dimension). *For all $X \subseteq \mathbf{C}$, $\dim_{\mathrm{P}}(X) = \inf \mathcal{G}^{\mathrm{str}}(X)$.*

By Observation 4.2, we could equivalently use $\widehat{\mathcal{G}}(X)$ and $\widehat{\mathcal{G}}^{\mathrm{str}}(X)$ in Theorems 4.3 and 4.4, respectively. We will use the following lemma to prove Theorem 4.4.

Lemma 4.5. *For each family of sets $\{X_k \subseteq \mathbf{C} \,|\, k \in \mathbb{N}\}$, $\inf \mathcal{G}^{\mathrm{str}}\left(\bigcup_k X_k\right) = \sup_k \inf \mathcal{G}^{\mathrm{str}}(X_k)$.*

Proof. The inequality $\inf \mathcal{G}^{\mathrm{str}}(\bigcup_k X_k) \geq \sup_k \inf \mathcal{G}^{\mathrm{str}}(X_k)$ holds trivially.

To prove that $\inf \mathcal{G}^{\rm str}(\bigcup_k X_k) \le \sup_k \inf \mathcal{G}^{\rm str}(X_k)$, let $s > \sup_k \inf \mathcal{G}^{\rm str}(X_k)$. Then for each $k \in \mathbb{N}$ there is an s-gale d_k such that $X_k \subseteq S^{\infty}_{\rm str}[d_k]$. We define an s-gale d by

$$d(w) = \sum_{k\in\mathbb{N}} \frac{2^{-k}}{d_k(\lambda)} \cdot d_k(w)$$

for all $w \in \{0,1\}^*$. Then for each k, for any $S \in X_k$, we have

$$d(S[0..n-1]) \ge \frac{2^{-k}}{d_k(\lambda)} \cdot d_k(S[0..n-1])$$

for all n, so $S \in S^{\infty}_{\rm str}[d]$. Therefore $\bigcup_k X_k \subseteq S^{\infty}_{\rm str}[d]$, and the lemma follows. □

Proof of Theorem 4.4. Let $X \subseteq \mathbf{C}$. By Theorem 3.1, it suffices to show that $\overline{\dim}_{\rm MB}(X) = \inf \mathcal{G}^{\rm str}(X)$.

To see that $\overline{\dim}_{\rm MB}(X) \le \inf \mathcal{G}^{\rm str}(X)$, let $s > \inf \mathcal{G}^{\rm str}(X)$. It suffices to show that $\overline{\dim}_{\rm MB}(X) \le s$.

By our choice of s, there is an s-gale d such that $X \subseteq S^{\infty}_{\rm str}[d]$. For each $n \in \mathbb{N}$, let

$$B_n = \{w \in \{0,1\}^n | d(w) > d(\lambda)\}$$

and

$$Y_n = \{S \in \mathbf{C} | S[0..n-1] \in B_n\}.$$

For each $i \in \mathbb{N}$, let

$$X_i = \bigcap_{n=i}^{\infty} Y_n,$$

and note that

$$X \subseteq \bigcup_{i=0}^{\infty} X_i. \tag{4.4}$$

For all $n \ge i \in \mathbb{N}$, we have $X_i \subseteq Y_n$, whence the generalized Kraft inequality (Lemma 4.1) tells us that

$$N_n(X_i) \le N_n(Y_n) = |B_n| < 2^{sn}.$$

It follows that, for all $i \in \mathbb{N}$,

$$\overline{\dim}_{\rm B}(X_i) = \limsup_{n\to\infty} \frac{\log N_n(X_i)}{n} \le s,$$

whence by (4.4),

$$\overline{\dim}_{\rm MB}(X) \le \sup_{i\in\mathbb{N}} \overline{\dim}_{\rm B}(X_i) \le s.$$

To see that $\inf \mathcal{G}^{\rm str}(X) \le \overline{\dim}_{\rm MB}(X)$, let $s > s' > s'' > \overline{\dim}_{\rm MB}(X)$. It suffices to show that $\inf \mathcal{G}^{\rm str}(X) \le s$. Since $s'' > \overline{\dim}_{\rm MB}(X)$, there exist sets $X_0, X_1, \ldots \subseteq \mathbf{C}$ such that $X = \bigcup_{i=0}^{\infty} X_i$ and $\overline{\dim}_{\rm B}(X_i) < s''$ for all $i \in \mathbb{N}$. By Lemma 4.5, it suffices to show that $s \in \mathcal{G}^{\rm str}(X_i)$ for all $i \in \mathbb{N}$.

Fix $i \in \mathbb{N}$. Since $\overline{\dim}_{\mathrm{B}}(X_i) < s''$, there exists $n_0 \in \mathbb{N}$ such that, for all $n \geq n_0$, $\frac{\log N_n(X_i)}{n} < s''$, i.e., $N_n(X_i) < 2^{s''n}$. For each $n \geq n_0$, let

$$A_n = \{S[0..n-1] | S \in X_i\}$$

(noting that $|A_n| = N_n(X_i)$), and define $d_n : \{0,1\}^* \to [0,\infty)$ by

$$d_n(w) = \begin{cases} 2^{(s-s')|w|} \displaystyle\sum_{\substack{u \\ wu \in A_n}} 2^{-s'|u|} & \text{if } |w| \leq n, \\ 2^{(s-1)(|w|-n)} d_n(w[0..n-1]) & \text{if } |w| > n. \end{cases}$$

It is routine to verify that d_n is an s-gale for each $n \geq n_0$. Note also that $d_n(w) = 2^{(s-s')n}$ for all $n \geq n_0$ and $w \in A_n$. Let $d = \sum_{n=n_0}^{\infty} d_n$. Then

$$\begin{aligned} d(\lambda) = \sum_{n=n_0}^{\infty} d_n(\lambda) &= \sum_{n=n_0}^{\infty} |A_n| 2^{-s'n} = \sum_{n=n_0}^{\infty} N_n(X_i) 2^{-s'n} \\ &< \sum_{n=n_0}^{\infty} 2^{(s''-s')n} < \infty, \end{aligned}$$

so d is an s-gale by linearity. Let $S \in X_i$. Then, for all $n \geq n_0$, $S[0..n-1] \in A_n$, so

$$d(S[0..n-1]) \geq d_n(S[0..n-1]) \geq 2^{(s-s')n}.$$

Thus $S \in S_{\mathrm{str}}^{\infty}[d]$. This shows that $X_i \subseteq S_{\mathrm{str}}^{\infty}[d]$, whence $s \in \mathcal{G}^{\mathrm{str}}(X_i)$. □

5. Effective strong dimensions. Theorem 4.3 has been used to effectivize Hausdorff dimension at a variety of levels. In this section we review these effective dimensions while using Theorem 4.4 to develop the dual effective strong dimensions.

We define a gale or supergale to be *constructive* if it is lower semicomputable. For any $s \in [0,\infty)$ and any k-account FSG G an s-gale $d_G^{(s)}$ is defined as follows [11]. (Recall that finite-state gamblers were defined in section 2.) For each $1 \leq i \leq k$ we define an s-gale $d_{G,i}^{(s)}$ by the recursion

$$d_{G,i}^{(s)}(\lambda) = c_{0,i},$$

$$d_{G,i}^{(s)}(wb) = 2^s d_{G,i}^{(s)}(w) \beta(i, \delta^*(w), b)$$

for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$. Then

$$d_G^{(s)} = \sum_{i=1}^{k} d_{G,i}^{(s)}.$$

We define an s-gale d to be *finite-state* if there is an FSG G such that $d_G^{(s)} = d$. For the rest of this paper, Δ denotes one of the classes all, comp, p, pspace, p_2, $\mathrm{p}_2$space, etc., defined in section 2.

For each $\Gamma \in \{\mathrm{constr}, \Delta, \mathrm{FS}\}$ and $X \subseteq \mathbf{C}$, we define the sets $\mathcal{G}_\Gamma(X)$, $\mathcal{G}_\Gamma^{\mathrm{str}}(X)$, $\widehat{\mathcal{G}}_\Gamma(X)$, and $\widehat{\mathcal{G}}_\Gamma^{\mathrm{str}}(X)$ just as the classes $\mathcal{G}(X)$, $\mathcal{G}^{\mathrm{str}}(X)$, $\widehat{\mathcal{G}}(X)$, and $\widehat{\mathcal{G}}^{\mathrm{str}}(X)$ were defined in section 4, but with the following modifications:

(i) If $\Gamma = \mathrm{constr}$, then d is required to be constructive.

(ii) If $\Gamma = \Delta$, then d is required to be Δ-computable.

(iii) In $\mathcal{G}_{\mathrm{FS}}(X)$ and $\mathcal{G}^{\mathrm{str}}_{\mathrm{FS}}(X)$, d is required to be finite-state.

(iv) $\widehat{\mathcal{G}}_{\mathrm{FS}}(X)$ and $\widehat{\mathcal{G}}^{\mathrm{str}}_{\mathrm{FS}}(X)$ are not defined.

The following effectivizations of Hausdorff and packing dimension are motivated by Theorems 4.3 and 4.4.

Definition. *Let* $X \subseteq \mathbf{C}$ *and* $S \in \mathbf{C}$*.*

1. [24] *The* constructive dimension *of* X *is* $\mathrm{cdim}(X) = \inf \mathcal{G}_{\mathrm{constr}}(X)$*.*
2. *The* constructive strong dimension *of* X *is* $\mathrm{cDim}(X) = \inf \mathcal{G}^{\mathrm{str}}_{\mathrm{constr}}(X)$*.*
3. [24] *The* dimension *of* S *is* $\dim(S) = \mathrm{cdim}(\{S\})$*.*
4. *The* strong dimension *of* S *is* $\mathrm{Dim}(S) = \mathrm{cDim}(\{S\})$*.*
5. [23] *The* Δ-dimension *of* X *is* $\dim_{\Delta}(X) = \inf \mathcal{G}_{\Delta}(X)$*.*
6. *The* Δ-strong dimension *of* X *is* $\mathrm{Dim}_{\Delta}(X) = \inf \mathcal{G}^{\mathrm{str}}_{\Delta}(X)$*.*
7. [23] *The* dimension *of* X in $R(\Delta)$ *is* $\dim(X|R(\Delta)) = \dim_{\Delta}(X \cap R(\Delta))$*.*
8. *The* strong dimension *of* X in $R(\Delta)$ *is* $\mathrm{Dim}(X|R(\Delta)) = \mathrm{Dim}_{\Delta}(X \cap R(\Delta))$*.*
9. [11] *The* finite-state dimension *of* X *is* $\dim_{\mathrm{FS}}(X) = \inf \mathcal{G}_{\mathrm{FS}}(X)$*.*
10. *The* finite-state strong dimension *of* X *is* $\mathrm{Dim}_{\mathrm{FS}}(X) = \inf \mathcal{G}^{\mathrm{str}}_{\mathrm{FS}}(X)$*.*
11. [11] *The* finite-state dimension *of* S *is* $\dim_{\mathrm{FS}}(S) = \dim_{\mathrm{FS}}(\{S\})$*.*
12. *The* finite-state strong dimension *of* S *is* $\mathrm{Dim}_{\mathrm{FS}}(S) = \mathrm{Dim}_{\mathrm{FS}}(\{S\})$*.*

In parts 1, 2, 5, and 6 of the above definition, we could equivalently use the "hatted" sets $\widehat{\mathcal{G}}_{\mathrm{constr}}(X)$, $\widehat{\mathcal{G}}^{\mathrm{str}}_{\mathrm{constr}}(X)$, $\widehat{\mathcal{G}}_{\Delta}(X)$, and $\widehat{\mathcal{G}}^{\mathrm{str}}_{\Delta}(X)$ in place of their unhatted counterparts. In the case of parts 5 and 6, this follows from Lemma 4.7 of [23]. In the case of parts 1 and 2, it follows from the main theorem in [15] (which answered an open question in [24], where $\widehat{\mathcal{G}}_{\mathrm{constr}}(X)$ was in fact used in defining $\mathrm{cdim}(X)$).

The polynomial-time dimensions $\dim_{\mathrm{p}}(X)$ and $\mathrm{Dim}_{\mathrm{p}}(X)$ are also called the feasible dimension and the feasible strong dimension, respectively. The notation $\dim_{\mathrm{p}}(X)$ for the p-dimension is all too similar to the notation $\dim_{\mathrm{P}}(X)$ for the classical packing dimension, but confusion is unlikely because these dimensions typically arise in quite different contexts.

Note that the classical Hausdorff and packing dimensions can each now be written in three different ways, i.e.,

$$\dim_{\mathrm{H}}(X) = \dim_{\mathrm{all}}(X) = \dim(X|\mathbf{C})$$

and

$$\dim_{\mathrm{P}}(X) = \mathrm{Dim}_{\mathrm{all}}(X) = \mathrm{Dim}(X|\mathbf{C}).$$

Observations 5.1.

1. *Each of the dimensions that we have defined is* monotone *(e.g.,* $X \subseteq Y$ *implies* $\mathrm{cdim}(X) \leq \mathrm{cdim}(Y)$*).*
2. *Each of the effective strong dimensions is bounded below by the corresponding effective dimension (e.g.,* $\mathrm{cdim}(X) \leq \mathrm{cDim}(X)$*).*
3. *Each of the dimensions that we have defined is nonincreasing as the effectivity constraint is relaxed (e.g.,* $\dim_{\mathrm{H}}(X) \leq \mathrm{cdim}(X) \leq \dim_{\mathrm{pspace}}(X) \leq \dim_{\mathrm{FS}}(X)$*).*
4. *Each of the dimensions that we have defined is nonnegative and assigns* $\mathbf{C}$ *the dimension* 1*.*

Lemma 5.2. *The finite-state dimensions are* stable*; i.e., for all* $X, Y \subseteq \mathbf{C}$*,*

$$\dim_{\mathrm{FS}}(X \cup Y) = \max\{\dim_{\mathrm{FS}}(X), \dim_{\mathrm{FS}}(Y)\}$$

and

$$\mathrm{Dim}_{\mathrm{FS}}(X \cup Y) = \max\{\mathrm{Dim}_{\mathrm{FS}}(X), \mathrm{Dim}_{\mathrm{FS}}(Y)\}.$$

Proof. The stability of finite-state dimension was proved in [11]. The same arguments establish stability for finite-state strong dimension. □

DEFINITION. *Let $X, X_0, X_1, X_2, \ldots \subseteq \mathbf{C}$.*

1. *We say that X is a* Δ-union of the Δ-dimensioned sets $\{X_k | k \in \mathbb{N}\}$ *if $X = \bigcup_{k=0}^{\infty} X_k$ and for each $s > \sup_{k\in\mathbb{N}} \dim_\Delta(X_k)$ with 2^s rational there is a function $d : \mathbb{N} \times \{0,1\}^* \to [0,\infty)$ with the following three properties:*
   - (i) *d is Δ-computable.*
   - (ii) *For each $k \in \mathbb{N}$, if we write $d_k(w) = d(k, w)$, then the function d_k is an s-gale.*
   - (iii) *For each $k \in \mathbb{N}$, $X_k \subseteq S^\infty[d_k]$.*

   Analogously, X is a Δ-union of the Δ-strong dimensioned sets $\{X_k | k \in \mathbb{N}\}$ *if there is a d with the above properties that also satisfies*
   - (iv) *For each $k \in \mathbb{N}$, $X_k \subseteq S^\infty_{\mathrm{str}}[d_k]$.*
2. *We say that X is a* Δ-union of the sets $\{X_k | k \in \mathbb{N}\}$ dimensioned in $R(\Delta)$ *if $X = \bigcup_{k=0}^{\infty} X_k$ and $X \cap R(\Delta)$ is a Δ-union of the Δ-dimensioned sets $\{X_k \cap R(\Delta) | k \in \mathbb{N}\}$.*

   Analogously, X is a Δ-union of the sets $\{X_k | k \in \mathbb{N}\}$ strong dimensioned in $R(\Delta)$ *if $X = \bigcup_{k=0}^{\infty} X_k$ and $X \cap R(\Delta)$ is an Δ-union of the Δ-strong dimensioned sets $\{X_k \cap R(\Delta) | k \in \mathbb{N}\}$.*

LEMMA 5.3. *The dimensions defined from Δ are* Δ-countably stable*; i.e., if X is a Δ-union of the Δ-dimensioned sets $X_0, X_1, X_2, \ldots,$ then*

$$\dim_\Delta(X) = \sup_{k\in\mathbb{N}} \dim_\Delta(X_k),$$

and if X is a Δ-union of the Δ-strong dimensioned sets $X_0, X_1, X_2, \ldots,$ then

$$\mathrm{Dim}_\Delta(X) = \sup_{k\in\mathbb{N}} \mathrm{Dim}_\Delta(X_k),$$

and similarly for dimension and strong dimension in $R(\Delta)$.

Proof. The stability of $\dim_\Delta$ over Δ-unions was proven in [23]. The proof for strong dimension is analogous. □

LEMMA 5.4. *The constructive dimensions are* absolutely stable*; i.e., for all $X \subseteq \mathbf{C}$,*

$$\mathrm{cdim}(X) = \sup_{S\in X} \dim(S)$$

and

$$\mathrm{cDim}(X) = \sup_{S\in X} \mathrm{Dim}(S).$$

Proof. The absolute stability of constructive dimension was proven in [24] using optimal constructive supergales. The same argument works for constructive strong dimension. □

In the following two sections, we use Martin-Löf's definition of randomness [25] as reformulated in terms of martingales by Schnorr [33] as follows.

A *probability measure* on $\mathbf{C}$ is a function $\nu : \{0,1\}^* \to [0,\infty)$ such that $\nu(\lambda) = 1$ and $\nu(w) = \nu(w0) + \nu(w1)$ for all $w \in \{0,1\}^*$. (Intuitively, $\nu(w)$ is the probability that $w \sqsubseteq S$ when the sequence S is "chosen according to ν.")

A *bias* is a real number $\beta \in [0,1]$. Intuitively, if we toss a 0/1-valued coin with bias β, then β is the probability of the outcome 1. A *bias sequence* is a sequence $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ of biases. If $\vec{\beta}$ is a bias sequence, then the *$\vec{\beta}$-coin-toss probability measure* is the probability $\mu^{\vec{\beta}}$ on $\mathbf{C}$ defined by

$$\mu^{\vec{\beta}}(w) = \prod_{i=0}^{|w|-1} \beta_i(w), \tag{5.1}$$

where $\beta_i(w) = (2\beta_i - 1)w[i] + (1-\beta_i)$, i.e., $\beta_i(w) = \textbf{if } w[i] \textbf{ then } \beta_i \textbf{ else } 1 - \beta_i$. That is, $\mu^{\vec{\beta}}$ is the probability that $S \in \mathbf{C}_w$ when $S \in \mathbf{C}$ is chosen according to a random experiment in which for each i, independently of all other j, the ith bit of S is decided by tossing a 0/1-valued coin whose probability of 1 is β_i. In the case where the biases β_i are all the same, i.e., $\vec{\beta} = (\beta, \beta, \beta, \dots)$ for some $\beta \in [0,1]$, we write μ^{β} for $\mu^{\vec{\beta}}$, and (5.1) simplifies to

$$\mu^{\beta}(w) = (1-\beta)^{\#(0,w)}\beta^{\#(1,w)}, \tag{5.2}$$

where $\#(b,w)$ is the number of times the bit b appears in the string w. The *uniform probability measure* on $\mathbf{C}$ is the probability measure $\mu = \mu^{\frac{1}{2}}$, for which (5.2) simplifies to

$$\mu(w) = 2^{-|w|}$$

for all $w \in \{0,1\}^*$.

DEFINITION. *Let ν be a probability measure on $\mathbf{C}$.*

1. *A* ν-martingale *is a function $d : \{0,1\}^* \to [0,\infty)$ that satisfies the condition*

$$d(w)\nu(w) = d(w0)\nu(w0) + d(w1)\nu(w1)$$

for all $w \in \{0,1\}^*$.

2. *A ν-martingale is* constructive *if it is lower semicomputable.*

Note that a μ-martingale is a martingale. If $\vec{\beta}$ is a bias sequence, then we call a $\mu^{\vec{\beta}}$-martingale simply a $\vec{\beta}$-martingale.

DEFINITION. *Let ν be a probability measure on $\mathbf{C}$, and let $X \subseteq \mathbf{C}$.*

1. *X has* constructive ν-measure 0*, and we write $\nu_{\text{constr}}(X) = 0$ if there is a constructive ν-martingale d such that $X \subseteq S^{\infty}[d]$.*
2. *X has* constructive ν-measure 1*, and we write $\nu_{\text{constr}}(X) = 1$ if $\nu_{\text{constr}}(\mathbf{C} - X) = 0$.*

DEFINITION. *If ν is a probability measure on $\mathbf{C}$, then a sequence $R \in \mathbf{C}$ is* ν-random*, and we write $R \in \mathrm{RAND}^{\nu}$ if the singleton set $\{R\}$ does not have constructive ν-measure 0 (i.e., there is no constructive ν-martingale that succeeds on R).*

It is well known (and easy to see) that $\nu_{\text{constr}}(\mathrm{RAND}^{\nu}) = 1$.

We write $\mathrm{RAND}^{\vec{\beta}}$ for $\mathrm{RAND}^{\mu^{\vec{\beta}}}$ and RAND for RAND^{μ}.

We also use resource-bounded notions of randomness that have been investigated by Schnorr [34], Lutz [20], Ambos-Spies, Terwijn, and Zheng [2], and others.

DEFINITION. *Let ν be a probability measure on $\mathbf{C}$, and let $t : \mathbb{N} \to \mathbb{N}$.*

1. *A sequence* $R \in \mathbf{C}$ *is* Δ-ν-random, *and we write* $R \in \mathrm{RAND}^{\nu}(\Delta)$, *if there is no* Δ*-computable* ν*-martingale that succeeds on* R*.*
2. *A sequence* $R \in \mathbf{C}$ *is* $t(n)$-ν-random, *and we write* $R \in \mathrm{RAND}^{\nu}(t(n))$, *if there is no* $O(t(n))$*-time-computable* ν*-martingale that succeeds on* R*.*

We write $\mathrm{RAND}^{\vec{\beta}}(t(n))$ for $\mathrm{RAND}^{\mu^{\vec{\beta}}}(t(n))$.

6. Algorithmic information. In this section we present a variety of results and observations in which constructive and computable strong dimensions illuminate or clarify various aspects of algorithmic information theory. Included is our second main theorem, which says that every sequence that is random with respect to a computable sequence of biases $\beta_i \in [\delta, 1/2]$ has the lower and upper average entropies of $(\beta_0, \beta_1, \dots)$ as its dimension and strong dimension, respectively. We also present a result in which finite-state strong dimension clarifies an issue in data compression.

Mayordomo [27] proved that for all $S \in \mathbf{C}$,

$$\dim(S) = \liminf_{n\to\infty} \frac{K(S[0..n-1])}{n}, \tag{6.1}$$

where $K(w)$ is the Kolmogorov complexity of w. (Note: Here and below, $K(w)$ is the "self-delimiting" or "prefix" version of Kolmogorov complexity, as opposed to the "plain" complexity $C(w)$ [19].) Subsequently, Lutz [24] used termgales to define the dimension $\dim(w)$ of each (finite!) string $w \in \{0,1\}^*$ and proved that

$$\dim(S) = \liminf_{n\to\infty} \dim(S[0..n-1]) \tag{6.2}$$

for all $S \in \mathbf{C}$ and

$$K(w) = |w|\dim(w) \pm O(1) \tag{6.3}$$

for all $w \in \{0,1\}^*$, thereby giving a second proof of (6.1). The following theorem is a dual of (6.2) that yields a dual of (6.1) as a corollary.

THEOREM 6.1. *For all* $S \in \mathbf{C}$,

$$\mathrm{Dim}(S) = \limsup_{n\to\infty} \dim(S[0..n-1]).$$

Proof. This proof is analogous to the one for the dual statement (6.2) given in [24]. □

COROLLARY 6.2. *For all* $S \in \mathbf{C}$,

$$\mathrm{Dim}(S) = \limsup_{n\to\infty} \frac{K(S[0..n-1])}{n}.$$

By Corollary 6.2, the "upper algorithmic dimension" defined by Tadaki [42] is precisely the constructive strong dimension.

The rate at which a gambler can increase its capital when betting in a given situation is a fundamental concern of classical and algorithmic information and computational learning theories. In the setting of constructive gamblers, the following quantities are of particular relevance.

DEFINITION. *Let* d *be a supermartingale, let* $S \in \mathbf{C}$*, and let* $X \subseteq \mathbf{C}$*.*

1. *The* lower d-Lyapunov exponent *of* S *is* $\lambda_d(S) = \liminf_{n\to\infty} \frac{\log d(S[0..n-1])}{n}$.
2. *The* upper d-Lyapunov exponent *of* S *is* $\Lambda_d(S) = \limsup_{n\to\infty} \frac{\log d(S[0..n-1])}{n}$.

3. *The* lower Lyapunov exponent *of S is* $\lambda(S) = \sup\{\lambda_d(S) | d$ *is a constructive supermartingale*$\}$.
4. *The* upper Lyapunov exponent *of S is* $\Lambda(S) = \sup\{\Lambda_d(S) | d$ *is a constructive supermartingale*$\}$.
5. *The* lower Lyapunov exponent *of X is* $\lambda(X) = \inf_{S \in X} \lambda(S)$.
6. *The* upper Lyapunov exponent *of X is* $\Lambda(X) = \inf_{S \in X} \Lambda(S)$.

Lyapunov exponents such as these were investigated by Schnorr [34, 36], Ryabko [32], and Staiger [39, 40] (using slightly different notation) prior to the effectivization of Hausdorff dimension. The quantities $\lambda_d(S)$ and $\Lambda_d(S)$ are also called "exponents of increase" of d on S. It is implicit in Staiger's paper [39] that

$$\Lambda_{\text{comp}}(S) = 1 - \dim_{\text{comp}}(S)$$

for all $S \in \mathbf{C}$, where $\Lambda_{\text{comp}}(S)$ is defined like $\Lambda(S)$ above, but with d required to be a computable martingale. Similar reasoning leads to the following characterizations of the Lyapunov exponents.

Theorem 6.3. *Let $S \in \mathbf{C}$ and $X \subseteq \mathbf{C}$. Then $\Lambda(S) = 1 - \dim(S)$, $\lambda(S) = 1 - \mathrm{Dim}(S)$, $\Lambda(X) = 1 - \mathrm{cdim}(X)$, and $\lambda(X) = 1 - \mathrm{cDim}(X)$.*

Proof. We show that $\Lambda(S) = 1 - \dim(S)$. A similar argument shows that $\lambda(S) = 1 - \mathrm{Dim}(S)$. By Lemma 5.4, $\Lambda(X) = 1 - \mathrm{cdim}(X)$ and $\lambda(X) = 1 - \mathrm{cDim}(X)$ follow from the statements about sequences.

Let $t < s < \Lambda(S)$ with t computable, and let d be a constructive supermartingale for which $\Lambda_d(S) > s$. Then for infinitely many n, $d(S[0..n-1]) > 2^{sn}$. Define a constructive $(1-t)$-supergale d' by $d'(w) = 2^{-t|w|}d(w)$ for all $w \in \{0,1\}^*$. Then for infinitely many n, we have $d'(S[0..n-1]) = 2^{-tn}d(S[0..n-1]) > 2^{(s-t)n}$, so $S \in S^\infty[d]$. Therefore $\dim(S) \leq 1 - t$. This holds for all computable $t < \Lambda(S)$, so $\dim(S) \leq 1 - \Lambda(S)$.

Let $s > \dim(S)$ be computable, and let d be a constructive s-gale with $S \in S^\infty[d]$. Define a constructive martingale d' by $d'(w) = 2^{(1-s)|w|}d(w)$ for all $w \in \{0,1\}^*$. For infinitely many n, we have $d(S[0..n-1]) > 1$, and for each of these n, $d'(S[0..n-1]) > 2^{(1-s)n}$. Therefore $\Lambda_{d'}(S) \geq 1 - s$, so $\Lambda(S) \geq 1 - s$. This holds for all $s > \dim(S)$, so $\Lambda(S) \geq 1 - \dim(S)$. □

Constructive strong dimension can also be used to characterize entropy rates of the type investigated by Staiger [38, 39] and Hitchcock [16].

Definition. *Let $A \subseteq \{0,1\}^*$.*

1. *The* entropy rate *of $A \subseteq \{0,1\}^*$ is* $H_A = \limsup_{n \to \infty} \frac{\log |A_{=n}|}{n}$.
2. *We define the sets of sequences*

$$A^{\text{i.o.}} = \{S \in \mathbf{C} | (\exists^\infty n) S[0..n-1] \in A\}$$

and

$$A^{\text{a.e.}} = \{S \in \mathbf{C} | (\forall^\infty n) S[0..n-1] \in A\}.$$

Definition. *Let $X \subseteq \mathbf{C}$. The* constructive entropy rate *of X is*

$$\mathcal{H}_{\text{CE}}(X) = \inf\{H_A | X \subseteq A^{\text{i.o.}} \textit{ and } A \in \text{CE}\},$$

and the constructive strong entropy rate *of X is*

$$\mathcal{H}^{\text{str}}_{\text{CE}}(X) = \inf\{H_A | X \subseteq A^{\text{a.e.}} \textit{ and } A \in \text{CE}\}.$$

Hitchcock [16] proved that

$$\mathcal{H}_{\mathrm{CE}}(X) = \mathrm{cdim}(X) \tag{6.4}$$

for all $X \subseteq \mathbf{C}$. We have the following dual of (6.4).

THEOREM 6.4. *For any $X \subseteq \mathbf{C}$, $\mathcal{H}^{\mathrm{str}}_{\mathrm{CE}}(X) = \mathrm{cDim}(X)$.*

Proof. This proof is analogous to the proof of (6.4) given in [16]. □

In the classical case, Tricot [43] has defined a set to be *regular* if its Hausdorff and packing dimensions coincide, and defined its *irregularity* to be the difference between these two fractal dimensions. Analogously, we define the c-*irregularity* (i.e., constructive irregularity) of a sequence $S \in \mathbf{C}$ to be $\mathrm{Dim}(S) - \dim(S)$, and we define the c-*irregularity* of a set $X \subseteq \mathbf{C}$ to be $\mathrm{cDim}(X) - \mathrm{cdim}(X)$. We define a sequence or set to be c-*regular* (i.e., *constructively regular*) if its c-irregularity is 0.

As the following result shows, the c-irregularity of a sequence may be any real number in $[0, 1]$.

THEOREM 6.5. *For any two real numbers $0 \leq \alpha \leq \beta \leq 1$, there is a sequence $S \in \mathbf{C}$ such that $\dim(S) = \alpha$ and $\mathrm{Dim}(S) = \beta$.*

Proof. Let $R \in \mathrm{RAND}$ be a random sequence. It is well known that

$$K(R[0..n-1]) \geq n - O(1). \tag{6.5}$$

Write $R = r_1 r_2 r_3 \ldots$, where $|r_n| = 2n - 1$ for all n. Note that $|r_1 \cdots r_n| = n^2$.

For each n, define

$$\gamma_n = \begin{cases} \frac{1-\alpha}{\alpha} & \text{if } \log^* n \text{ is odd,} \\ \frac{1-\beta}{\beta} & \text{if } \log^* n \text{ is even,} \end{cases}$$

and let

$$k_n = \lceil |r_n| \gamma_n \rceil .$$

We now define $S \in \mathbf{C}$ as

$$S = r_1 0^{k_1} r_2 0^{k_2} \cdots r_n 0^{k_n} \cdots \ .$$

Note that for all n,

$$\begin{aligned} |r_n 0^{k_n}| &= \lceil |r_n|(1 + \gamma_n) \rceil \\ &= \begin{cases} \left\lceil \frac{1}{\alpha} |r_n| \right\rceil & \text{if } \log^* n \text{ is odd,} \\ \left\lceil \frac{1}{\beta} |r_n| \right\rceil & \text{if } \log^* n \text{ is even.} \end{cases} \end{aligned}$$

Let $w \sqsubseteq S$. Then for some n,

$$w = r_1 0^{k_1} \cdots r_{n-1} 0^{k_{n-1}} r'_n 0^j,$$

where $r'_n \sqsubseteq r_n$ and $0 \leq j \leq k_n$. We have

$$\begin{aligned} K(w) &\leq K(r_1 \cdots r_{n-1} r'_n) + K(k_1) + \cdots + K(k_{n-1}) + K(j) + O(1) \\ &\leq |r_1 \cdots r_{n-1} r'_n| + O(n \log n) \\ &\leq (n-1)^2 + O(n \log n). \end{aligned} \tag{6.6}$$

Also,

$$\begin{aligned} K(r_1 \cdots r_{n-1} r'_n) &\le K(w) + K(k_1) + \cdots + K(k_{n-1}) + K(j) + O(1) \\ &\le K(w) + O(n \log n), \end{aligned}$$

and so by (6.5),

$$\begin{aligned} K(w) &\ge K(r_1 \cdots r_{n-1} r'_n) - O(n \log n) \\ &\ge |r_1 \cdots r_{n-1} r'_n| - O(n \log n) \\ &\ge (n-1)^2 - O(n \log n). \end{aligned} \tag{6.7}$$

We bound the length of w in terms of n as

$$\begin{aligned} |w| &\ge |r_1|(1+\gamma_1) + \cdots + |r_{n-1}|(1+\gamma_{n-1}) + |r'_n| \\ &\ge \frac{|r_1 \cdots r_{n-1}|}{\beta} \\ &= \frac{1}{\beta}(n-1)^2 \end{aligned} \tag{6.8}$$

and

$$\begin{aligned} |w| &\le |r_1|(1+\gamma_1) + \cdots + |r_{n-1}|(1+\gamma_{n-1}) + |r_n|(1+\gamma_n) + n \\ &\le \frac{|r_1 \cdots r_{n-1} r_n|}{\alpha} + n \\ &\le \frac{1}{\alpha}(n+1)^2. \end{aligned} \tag{6.9}$$

From (6.6) and (6.8), we have

$$\limsup_{m\to\infty} \frac{K(S[0..m-1])}{m} \le \limsup_{n\to\infty} \frac{(n-1)^2 + O(n \log n)}{\frac{1}{\beta}(n-1)^2} = \beta, \tag{6.10}$$

and (6.7) and (6.9) yield

$$\liminf_{m\to\infty} \frac{K(S[0..m-1])}{m} \ge \liminf_{n\to\infty} \frac{(n-1)^2 - O(n \log n)}{\frac{1}{\alpha}(n+1)^2} = \alpha. \tag{6.11}$$

For each n, let

$$w_n = r_1 0^{k_1} \cdots r_n 0^{k_n}.$$

Recall the sequence of *towers* defined by t_j by $t_0 = 1$ and $t_{j+1} = 2^{t_j}$. If j is even, then for all $t_{j-1} < i \le t_j$, $\gamma_i = \frac{1-\beta}{\beta}$. Then

$$\begin{aligned} |w_{t_j}| &\le t_j + \sum_{i=1}^{t_j} |r_i|(1+\gamma_i) \\ &= t_j + \sum_{i=1}^{t_{j-1}} |r_i|(1+\gamma_i) + \frac{1}{\beta} \sum_{i=t_{j-1}+1}^{t_j} |r_i| \\ &\le t_j + \frac{1}{\alpha} t_{j-1}^2 + \frac{1}{\beta}(t_j^2 - t_{j-1}^2) \\ &\le \frac{1}{\beta} t_j^2 + t_j + O((\log t_j)^2). \end{aligned} \tag{6.12}$$

Similarly, if j is odd, we have

$$
\begin{aligned}
|w_{t_j}| &\geq \sum_{i=1}^{t_j} |r_i|(1+\gamma_i) \\
&= \sum_{i=1}^{t_{j-1}} |r_i|(1+\gamma_i) + \frac{1}{\alpha} \sum_{i=t_{j-1}+1}^{t_j} |r_i| \\
&\geq \frac{1}{\beta} {t_{j-1}}^2 + \frac{1}{\alpha}(t_j^2 - t_{j-1}^2) \\
&\geq \frac{1}{\alpha} t_j^2 - O((\log t_j)^2).
\end{aligned} \tag{6.13}
$$

Combining (6.7) and (6.12), we have

$$
\limsup_{m\to\infty} \frac{K(S[0..m-1])}{m} \geq \limsup_{n\to\infty} \frac{K(w_{t_{2n}})}{|w_{t_{2n}}|} \geq \beta. \tag{6.14}
$$

Putting (6.6) together with (6.13) yields

$$
\liminf_{m\to\infty} \frac{K(S[0..m-1])}{m} \leq \liminf_{n\to\infty} \frac{K(w_{t_{2n+1}})}{|w_{t_{2n+1}}|} \leq \alpha. \tag{6.15}
$$

By (6.1), (6.11), and (6.15), we have $\dim(S) = \alpha$. By Corollary 6.2, (6.10), and (6.14), we have $\mathrm{Dim}(S) = \beta$. □

We now come to the main theorem of this section. The following notation simplifies its statement and proof.

Notation. Given a bias sequence $\vec{\beta} = (\beta_0, \beta_1, \dots)$, $n \in \mathbb{N}$, and $S \in \mathbf{C}$, let

$$
\begin{aligned}
H_n(\vec{\beta}) &= \frac{1}{n}\sum_{i=0}^{n-1} \mathcal{H}(\beta_i), \\
H^-(\vec{\beta}) &= \liminf_{n\to\infty} H_n(\vec{\beta}), \\
H^+(\vec{\beta}) &= \limsup_{n\to\infty} H_n(\vec{\beta}).
\end{aligned}
$$

We call $H^-(\vec{\beta})$ and $H^+(\vec{\beta})$ the *lower* and *upper average entropies*, respectively, of $\vec{\beta}$.

THEOREM 6.6. *If $\delta \in (0, \frac{1}{2}]$ and $\vec{\beta}$ is a computable bias sequence with each $\beta_i \in [\delta, \frac{1}{2}]$, then for every sequence $R \in \mathrm{RAND}^{\vec{\beta}}$,*

$$
\dim(R) = H^-(\vec{\beta}) \quad \textit{and} \quad \mathrm{Dim}(R) = H^+(\vec{\beta}).
$$

Theorem 6.6 says that every sequence that is random with respect to a suitable bias sequence $\vec{\beta}$ has the lower and upper average entropies of $\vec{\beta}$ as its dimension and strong dimension, respectively. Since there exist $\vec{\beta}$-random sequences in Δ_2^0 when $\vec{\beta}$ is computable, this gives a powerful and flexible method for constructing Δ_2^0 sequences with given (Δ_2^0-computable) dimensions and strong dimensions.

Note that Theorem 6.6 also gives an alternative, though less constructive, proof of Theorem 6.5.

We now develop a sequence of results that are used in our proof of Theorem 6.6.

LEMMA 6.7. *Assume that $\delta > 0$, $\epsilon > 0$, and that, for each $\beta \in [\delta, 1-\delta]$, η_β is a bounded random variable with expectation $\mathrm{E}\eta_\beta \leq -\epsilon$ and $\mathrm{E}e^{t\eta_\beta}$ is, uniformly in t, a continuous function of β. Then there exists $\theta > 0$ such that, for all $\beta \in [\delta, 1-\delta]$ and $t \in (0, \theta]$,*

$$\mathrm{E}e^{t\eta_\beta} < 1 - \frac{t\epsilon}{2}.$$

Proof. Assume the hypothesis. Then the dominated convergence theorem [3] tells us that, for all $\beta \in [\delta, 1-\delta]$,

$$\begin{aligned}\lim_{t\to 0^+} \frac{\mathrm{E}e^{t\eta_\beta} - 1}{t} &= \lim_{t\to 0^+} \mathrm{E}\frac{e^{t\eta_\beta} - 1}{t} \\ &= \mathrm{E}\left(\lim_{t\to 0^+} \frac{e^{t\eta_\beta} - 1}{t}\right) \\ &= \mathrm{E}\left(\eta_\beta \lim_{t\to 0^+} \frac{e^{t\eta_\beta} - 1}{t\eta_\beta}\right) \\ &= \mathrm{E}\eta_\beta \\ &\leq -\epsilon.\end{aligned}$$

Hence, for each $\beta \in [\delta, 1-\delta]$, there exists $t_\beta > 0$ such that, for all $t \in (0, t_\beta]$,

$$\frac{\mathrm{E}e^{t\eta_\beta} - 1}{t} < -\frac{3\epsilon}{4}.$$

It follows by our continuity hypothesis that, for each $\beta \in [\delta, 1-\delta]$, there is an open neighborhood N_β of β such that, for all $t \in (0, t_\beta]$ and $\gamma \in N_\beta \cap [\delta, 1-\delta]$,

$$\frac{\mathrm{E}e^{t\eta_\gamma} - 1}{t} < -\frac{\epsilon}{2}.$$

The family $\mathcal{G} = \{N_\beta \mid \beta \in [\delta, 1-\delta]\}$ is an open cover of the compact set $[\delta, 1-\delta]$, so there is a finite set $B \subseteq [\delta, 1-\delta]$ such that the subcollection $\mathcal{G}' = \{N_\beta \mid \beta \in B\}$ is also a cover of $[\delta, 1-\delta]$. Let

$$\theta = \min\{t_\beta \mid \beta \in B\}.$$

Then $\theta > 0$ and, for all $\beta \in [\delta, 1-\delta]$ and $t \in (0, \theta]$,

$$\frac{\mathrm{E}e^{t\eta_\beta} - 1}{t} < -\frac{\epsilon}{2},$$

whence

$$\mathrm{E}e^{t\eta_\beta} < 1 - \frac{t\epsilon}{2}. \qquad \square$$

COROLLARY 6.8. *For each $\delta > 0$ and $\epsilon > 0$, there exists $\theta > 0$ such that, for all $\beta \in [\delta, 1-\delta]$, if we choose $a \in \{0, 1\}$ with $\mathrm{Prob}[a = 1] = \beta$, and if*

$$\eta = \xi - \mathcal{H}(\beta) - \epsilon$$

or

$$\eta = \mathcal{H}(\beta) - \xi - \epsilon,$$

where

$$\xi = (1-a)\log\frac{1}{1-\beta} + a\log\frac{1}{\beta},$$

then

$$\mathrm{E}e^{\theta\eta} < 1 - \frac{\theta\epsilon}{2}.$$

Proof. The random variables

$$\eta_{1,\beta} = \xi - \mathcal{H}(\beta) - \epsilon,$$
$$\eta_{2,\beta} = \mathcal{H}(\beta) - \xi - \epsilon$$

satisfy the hypothesis of Lemma 6.7 with $\mathrm{E}\eta_{1,\beta} = \mathrm{E}\eta_{2,\beta} = -\epsilon$, so we can choose $\theta_1 > 0$ for $\eta_{1,\beta}$ and $\theta_2 > 0$ for $\eta_{2,\beta}$ as in that lemma. Letting $\theta = \min\{\theta_1, \theta_2\}$ establishes the corollary. □

Notation. Given a bias sequence $\vec{\beta} = (\beta_0, \beta_1, \dots)$, $n \in \mathbb{N}$, and $S \in \mathbf{C}$, let

$$L_n(\vec{\beta})(S) = \log\frac{1}{\mu^{\vec{\beta}}(S[0..n-1])} = \sum_{i=0}^{n-1}\xi_i(S),$$

where

$$\xi_i(S) = (1 - S[i])\log\frac{1}{1-\beta_i} + S[i]\log\frac{1}{\beta_i}$$

for $0 \le i < n$.

Note that $L_n(\vec{\beta}), \xi_0, \dots, \xi_{n-1}$ are random variables with

$$\mathrm{E}L_n(\vec{\beta}) = \sum_{i=0}^{n-1}\mathrm{E}\xi_i = \sum_{i=0}^{n-1}\mathcal{H}(\beta_i) = nH_n(\vec{\beta}).$$

The following large deviation theorem tells us that $L_n(\vec{\beta})$ is very unlikely to deviate significantly from this expected value.

THEOREM 6.9. *For each $\delta > 0$ and $\epsilon > 0$, there exists $\alpha \in (0,1)$ such that, for all bias sequences $\vec{\beta} = (\beta_0, \beta_1, \dots)$ with each $\beta_i \in [\delta, 1-\delta]$ and all $n \in \mathbb{Z}^+$, if $L_n(\vec{\beta})$ and $H_n(\vec{\beta})$ are defined as above, then*

$$\mathrm{P}\left[|L_n(\vec{\beta}) - nH_n(\vec{\beta})| \ge \epsilon n\right] < 2\alpha^n,$$

where the probability is computed according to $\mu^{\vec{\beta}}$.

Proof. Let $\delta > 0$ and $\epsilon > 0$, and choose $\theta > 0$ as in Corollary 6.8. Let $\alpha = 1 - \frac{\theta\epsilon}{2}$, noting that $\alpha \in (0,1)$. Let $\vec{\beta}$ be as given, and let $n \in \mathbb{Z}^+$. Let $L = L_n(\vec{\beta})$, $H = H_n(\vec{\beta})$, and $\xi_0, \xi_1, \dots$ be as above. The proof is in two parts.

1. For each $i \in \mathbb{N}$, let $\eta_i = \xi_i - \mathcal{H}(\beta_i) - \epsilon$. Then Markov's inequality, indepen-

dence, and Corollary 6.8 tell us that

$$\begin{aligned}\mathrm{P}[L - nH \geq \epsilon n] &= P[e^{\theta(L-nH)} \geq e^{\theta \epsilon n}] \\ &\leq e^{-\theta\epsilon n}\mathrm{E}e^{\theta(L-nH)} \\ &= \mathrm{E}e^{\theta(L-nH)-\epsilon\theta n} \\ &= \mathrm{E}e^{\theta\sum_{i=0}^{n-1}\eta_i} \\ &= \mathrm{E}\prod_{i=0}^{n-1} e^{\theta\eta_i} \\ &= \prod_{i=0}^{n-1}\mathrm{E}e^{\theta\eta_i} \\ &< \alpha^n.\end{aligned}$$

2. Arguing as in part 1 with $\eta_i = \mathcal{H}(\beta_i) - \xi_i - \epsilon$ shows that $\mathrm{P}[nH - L \geq \epsilon n] < \alpha^n$. By parts 1 and 2 of this proof, we now have

$$\mathrm{P}[|L - nH| \geq \epsilon n] < 2\alpha^n. \qquad \square$$

Some of our arguments are simplified by the following constructive version of a classical theorem of Kakutani [17]. Say that two bias sequences $\vec{\beta}$ and $\vec{\beta}'$ are *square-summably equivalent*, and write $\vec{\beta} \approx^2 \vec{\beta}'$ if $\sum_{i=0}^{\infty}(\beta_i - \beta_i')^2 < \infty$.

THEOREM 6.10 (van Lambalgen [44, 45], Vovk [47]). *Let $\delta > 0$, and let $\vec{\beta}$ and $\vec{\beta}'$ be computable bias sequences with $\beta_i, \beta_i' \in [\delta, 1-\delta]$ for all $i \in \mathbb{N}$.*

1. *If $\vec{\beta} \approx^2 \vec{\beta}'$, then $\mathrm{RAND}^{\vec{\beta}} = \mathrm{RAND}^{\vec{\beta}'}$.*
2. *If $\vec{\beta} \not\approx^2 \vec{\beta}'$, then $\mathrm{RAND}^{\vec{\beta}} \bigcap \mathrm{RAND}^{\vec{\beta}'} = \emptyset$.*

COROLLARY 6.11. *If $\delta > 0$ and $\vec{\beta}$ is a computable bias sequence with each $\beta_i \in [\delta, 1-\delta]$, then there is an exactly computable bias sequence $\vec{\beta}'$ with each $\beta_i' \in [\frac{\delta}{2}, \beta_i]$ satisfying $\mathrm{RAND}^{\vec{\beta}'} = \mathrm{RAND}^{\vec{\beta}}$.*

Proof. Assume the hypothesis. Then there is a computable function $g : \mathbb{N}\times\mathbb{N} \to \mathbb{Q}$ such that $|g(i,r) - \beta_i| \leq 2^{-r}$ for all $i, r \in \mathbb{N}$. Let $m = 2 + \lceil \log \frac{1}{\delta} \rceil$, and let

$$\beta_i' = g(i, m+i) - 2^{-(m+i)}$$

for all $i \in \mathbb{N}$. It is easily verified that $\vec{\beta}'$ is exactly computable, each $\beta_i' \in [\frac{\delta}{2}, \beta_i]$, and $\vec{\beta}' \approx^2 \vec{\beta}$, whence Theorem 6.10 tells us that $\mathrm{RAND}^{\vec{\beta}'} = \mathrm{RAND}^{\vec{\beta}}$. $\square$

LEMMA 6.12. *If $\delta > 0$ and $\vec{\beta}$ is a computable bias sequence with each $\beta_i \in [\delta, 1-\delta]$, then every sequence $R \in \mathrm{RAND}^{\vec{\beta}}$ satisfies*

$$L_n(\vec{\beta})(R) = nH_n(\vec{\beta}) + o(n)$$

as $n \to \infty$.

Proof. Assume the hypothesis. By Corollary 6.11, we can assume that $\vec{\beta}$ is exactly computable. Let $\epsilon > 0$. For each $n \in \mathbb{N}$, define the set

$$Y_n = \left\{ S \in \mathbf{C} \;\middle|\; |L_n(\vec{\beta})(S) - nH_n(\vec{\beta})| \geq \epsilon n \right\},$$

and let

$$X_\epsilon = \{S \in \mathbf{C} \mid (\exists^\infty n) S \in Y_n\}.$$

It suffices to show that $\mu^{\vec{\beta}}_{\text{comp}}(X_\epsilon) = 0$.

For each $n \in \mathbb{N}$ and $w \in \{0,1\}^*$, let

$$d_n(w) = \begin{cases} \mu^{\vec{\beta}}(Y_n | \mathbf{C}_w) & \text{if } |w| \leq n, \\ d_n(w[0..n-1]) & \text{if } |w| > n. \end{cases}$$

It is easily verified that each d_n is a $\vec{\beta}$-martingale and that the function $(n, w) \mapsto d_n(w)$ is computable. It is clear that $Y_n \subseteq S^1[d_n]$ for all $n \in \mathbb{N}$, where $S^1[d_n] = \bigcup_{d_n(w) \geq 1} \mathbf{C}_w$. Finally, by Theorem 6.9, the series $\sum_{n=0}^{\infty} d_n(\lambda)$ is computably convergent, so the computable first Borel–Cantelli lemma [20] (extended to $\vec{\beta}$ as indicated in [4]) tells us that $\mu^{\vec{\beta}}_{\text{comp}}(X_\epsilon) = 0$. □

LEMMA 6.13. *If $\delta > 0$ and $\vec{\beta}$ is a computable bias sequence with each $\beta_i \in [\delta, \frac{1}{2}]$, then* $\text{cdim}(\text{RAND}^{\vec{\beta}}) \leq H^-(\vec{\beta})$ *and* $\text{cDim}(\text{RAND}^{\vec{\beta}}) \leq H^+(\vec{\beta})$.

Proof. Assume the hypothesis. By Corollary 6.11, we can assume that $\vec{\beta}$ is exactly computable. Let $s \in [0, \infty)$ be computable.

Define $d : \{0,1\}^* \to [0, \infty)$ by

$$d(w) = 2^{s|w|} \mu^{\vec{\beta}}(w)$$

for all $w \in \{0,1\}^*$. Then d is a constructive (in fact, computable) s-gale. For each $R \in \mathbf{C}$ and $n \in \mathbb{N}$, if we write $z_n = R[0..n-1]$, then

$$\log d(z_n) = sn + \log \mu^{\vec{\beta}}(z_n)$$

for all n. In particular, if $R \in \text{RAND}^{\vec{\beta}}$, if follows by Lemma 6.12 that

$$\log d(z_n) = n[s - H_n(\vec{\beta})] + o(n) \tag{6.16}$$

as $n \to \infty$. We now verify the two parts of the lemma. For both parts, we let

$$I_\epsilon = \{n \in \mathbb{N} \mid H_n(\vec{\beta}) < s - \epsilon\}.$$

To see that $\text{cdim}(\text{RAND}^{\vec{\beta}}) \leq H^-(\vec{\beta})$, let $s > H^-(\vec{\beta})$, and let $\epsilon = \frac{s - H^-(\vec{\beta})}{2}$. Then the set I_ϵ is infinite, so (6.16) tells us that $\text{RAND}^{\vec{\beta}} \subseteq S^\infty[d]$, whence $\text{cdim}(\text{RAND}^{\vec{\beta}}) \leq s$.

To see that $\text{cDim}(\text{RAND}^{\vec{\beta}}) \leq H^+(\vec{\beta})$, let $s > H^+(\vec{\beta})$, and let $\epsilon = \frac{s - H^+(\vec{\beta})}{2}$. Then the set I_ϵ is cofinite, so (6.16) tells us that $\text{RAND}^{\vec{\beta}} \subseteq S^\infty_{\text{str}}[d]$, whence $\text{cDim}(\text{RAND}^{\vec{\beta}}) \leq s$. □

LEMMA 6.14. *Assume that $\delta > 0$, $\vec{\beta}$ is a computable bias sequence with each $\beta_i \in [\delta, 1 - \delta]$, $s \in [0, \infty)$ is computable, and d is a constructive s-gale.*

1. *If $s < H^-(\vec{\beta})$, then $S^\infty[d] \bigcap \text{RAND}^{\vec{\beta}} = \emptyset$.*
2. *If $s < H^+(\vec{\beta})$, then $S^\infty_{\text{str}}[d] \bigcap \text{RAND}^{\vec{\beta}} = \emptyset$.*

Proof. Assume the hypothesis. Define $d' : \{0,1\}^* \to [0, \infty)$ by

$$d'(w) = \frac{d(w)}{2^{s|w|} \mu^{\vec{\beta}}(w)}$$

for all $w \in \{0,1\}^*$. Then d' is a $\vec{\beta}$-martingale, and d' is clearly constructive.

Let $R \in \mathrm{RAND}^{\vec{\beta}}$. Then d' does not succeed on R, so there is a constant $c > 0$ such that, for all $n \in \mathbb{N}$, if we write $z_n = R[0..n-1]$, then $d'(z_n) \le 2^c$, whence

$$\log d(z_n) \le c + sn + \log \mu^{\vec{\beta}}(z_n).$$

It follows by Lemma 6.12 that

$$\log d(z_n) \le c + n[s - H_n(\vec{\beta})] + o(n)$$

as $n \to \infty$. Hence, for any $\epsilon > 0$, if we let

$$I_\epsilon = \{n \in \mathbb{Z}^+ \mid s < H_n(\vec{\beta}) - \epsilon\},$$

then $\log d(z_n) < c$ for all sufficiently large $n \in I_\epsilon$. We now verify the two parts of the lemma.

1. If $s < H^-(\vec{\beta})$, let $\epsilon = \frac{H^-(\vec{\beta})-s}{2}$. Then I_ϵ is cofinite, so $\log d(z_n) < c$ for all sufficiently large $n \in \mathbb{Z}^+$, so $R \notin S^\infty[d]$.
2. If $s < H^+(\vec{\beta})$, let $\epsilon = \frac{H^+(\vec{\beta})-s}{2}$. Then I_ϵ is infinite, so $\log d(z_n) < c$ for infinitely many $n \in \mathbb{Z}^+$, so $R \notin S^\infty_{\mathrm{str}}[d]$. □

We now have all we need to prove the main theorem of this section.

Proof of Theorem 6.6. Assume the hypothesis, and let $R \in \mathrm{RAND}^{\vec{\beta}}$. By Lemma 6.13, $\dim(R) \le H^-(\vec{\beta})$ and $\mathrm{Dim}(R) \le H^+(\vec{\beta})$. To see that $\dim(R) \ge H^-(\vec{\beta})$ and $\mathrm{Dim}(R) \ge H^+(\vec{\beta})$, let $s, t \in [0, \infty)$ be computable with $s < H^-(\vec{\beta})$ and $t < H^+(\vec{\beta})$, let d^- be a constructive s-gale, and let d^+ be a constructive t-gale. It suffices to show that $R \notin S^\infty[d^-]$ and $R \notin S^\infty_{\mathrm{str}}[d^+]$. But these follow immediately from Lemma 6.14 and the $\vec{\beta}$-randomness of R. □

Corollary 6.15. *If $\vec{\beta}$ is a computable sequence of coin-toss biases such that $\overline{H}(\vec{\beta}) = \lim_{n\to\infty} H_n(\vec{\beta}) \in (0,1)$, then every sequence $R \in \mathbf{C}$ that is random with respect to $\vec{\beta}$ is c-regular, with* $\dim(R) = \mathrm{Dim}(R) = \overline{H}(\vec{\beta})$.

Note that Corollary 6.15 strengthens Theorem 7.6 of [24] because the convergence of $H_n(\vec{\beta})$ is a weaker hypothesis than the convergence of $\vec{\beta}$.

Generalizing the construction of Chaitin's random real number Ω [6], Mayordomo [27] and, independently, Tadaki [42] defined for each $s \in (0,1]$ and each infinite computably enumerable set $A \subseteq \{0,1\}^*$ the real number

$$\theta^s_A = \sum \left\{ 2^{-\frac{|\pi|}{s}} \,\middle|\, \pi \in \{0,1\}^* \text{ and } U(\pi) \in A \right\},$$

where U is a universal self-delimiting Turing machine. Given (6.1) and Corollary 6.2 above, the following fact is implicit in Tadaki's paper.

Theorem 6.16 (Tadaki [42]). *For each $s \in (0,1]$ and each infinite computably enumerable set $A \subseteq \{0,1\}^*$, the (binary expansion of the) real number θ^s_A is c-regular with* $\dim(\theta^s_A) = \mathrm{Dim}(\theta^s_A) = s$.

We define a set $X \subseteq \mathbf{C}$ to be *self-similar* if it has the form

$$X = A^\infty = \{S \in \mathbf{C} \mid S = w_0 w_1 w_2 \dots \text{ for some } w_0, w_1, w_2, \dots \in A\},$$

where $A \subseteq \{0,1\}^*$ is a finite prefix set. Self-similar sets are examples of c-regular sets.

Theorem 6.17. *Let $X = A^\infty$ be self-similar, where A is a finite prefix set. Then X is c-regular, with* $\mathrm{cdim}(X) = \mathrm{cDim}(X) = \inf\{s \mid \sum_{w\in A} 2^{-s|w|} \le 1\}$.

Proof. We say that a string w is *composite* if there are strings $w_1, \dots, w_k \in A$ such that $w = w_1 \cdots w_k$. Let s be computable such that $\sum_{w\in A} 2^{-s|w|} \le 1$. For any computable $\epsilon > 0$ we define a constructive $(s+\epsilon)$-supergale d as follows. Let $w \in \{0,1\}^*$, and let v be the maximal composite proper prefix of w. Then

$$d(w) = \sum_{u \in A : w \sqsubseteq vu} 2^{\epsilon|w|} 2^{-s(|vu|-|w|)}.$$

For all composite strings w, we have $d(w) = 2^{\epsilon|w|}$. It follows that $A^\infty \subseteq S^\infty_{\mathrm{str}}[d]$, and therefore $\mathrm{cDim}(A^\infty) \leq s + \epsilon$.

Let s be such that $\sum_{w \in A} 2^{-s|w|} > 1$, and let d be an s-gale. To show that $\mathrm{cdim}(A^\infty) > s$, it suffices to construct a sequence $S \in A^\infty - S^\infty[d]$. Initially, we let $w_0 = \lambda$. Assume that w_n has been defined, and let $u \in A$ such that $d(w_n u) \leq d(w_n)$. We know that such a u exists because of our choice of s. Then we let $w_{n+1} = w_n u$. Our sequence S is the unique one that has $w_n \sqsubseteq S$ for all n. □

Dai et al. [7] investigated the *finite-state compression ratio* $\rho_{\mathrm{FS}}(S)$, defined for each sequence $S \in \mathbf{C}$ to be the infimum, taken over all information-lossless finite-state compressors C (a model defined in Shannon's 1948 paper [37]) of the *(lower) compression ratio*

$$\rho_C(S) = \liminf_{n\to\infty} \frac{|C(S[0..n-1])|}{n}.$$

They proved that

$$\rho_{\mathrm{FS}}(S) = \dim_{\mathrm{FS}}(S) \tag{6.17}$$

for all $S \in \mathbf{C}$. However, it has been pointed out that the compression ratio $\rho_{\mathrm{FS}}(S)$ differs from the one investigated by Ziv [48]. Ziv was instead concerned with the ratio $R_{\mathrm{FS}}(S)$ defined by

$$R_{\mathrm{FS}}(S) = \inf_{k\in\mathbb{N}} \limsup_{n\to\infty} \inf_{C\in\mathcal{C}_k} \frac{|C(S[0..n-1])|}{n},$$

where $\mathcal{C}_k$ is the set of all k-state information-lossless finite-state compressors. The following result, together with (6.17), clarifies the relationship between $\rho_{\mathrm{FS}}(S)$ and $R_{\mathrm{FS}}(S)$.

THEOREM 6.18. *For all $S \in \mathbf{C}$, $R_{\mathrm{FS}}(S) = \mathrm{Dim}_{\mathrm{FS}}(S)$.*

The proof of Theorem 6.18 is based on the following lemma.

LEMMA 6.19. *Let $\mathcal{C}$ be the set of all finite-state compressors. For all $S \in \mathbf{C}$,*

$$R_{\mathrm{FS}}(S) = \inf_{C\in\mathcal{C}} \limsup_{n\to\infty} \frac{|C(S[0..n-1])|}{n}.$$

Proof. For each $k \in \mathbb{N}$ let $\mathcal{C}'_k$ be the set of all k-state information-lossless finite-state compressors whose output length per input bit is bounded by k. Notice that $\mathcal{C}'_k$ is a subset of $\mathcal{C}_k$ and that $\mathcal{C}'_k$ is finite. Ziv and Lempel implicitly prove in [49] that the following equality holds:

$$R_{\mathrm{FS}}(S) = \inf_{k\in\mathbb{N}} \limsup_{n\to\infty} \inf_{C\in\mathcal{C}'_k} \frac{|C(S[0..n-1])|}{n}.$$

Let

$$R'_{\mathrm{FS}}(S) = \inf_{C\in\mathcal{C}} \limsup_{n\to\infty} \frac{|C(S[0..n-1])|}{n}.$$

The inequality $R_{\mathrm{FS}}(S) \leq R'_{\mathrm{FS}}(S)$ is trivial. We use several results from [7] to obtain for each $k \in \mathbb{N}$ and $\epsilon > 0$ a finite-state compressor $C_{k,\epsilon}$ that is nearly optimal for all compressors in $\mathcal{C}'_k$. From Lemma 7.7 in [7] we obtain a finite-state gambler for each $C \in \mathcal{C}'_k$. By Lemma 3.7 in [7], we can combine these gamblers into a single finite-state gambler. Theorem 4.5 and Lemma 3.11 in [7] convert this single gambler into a 1-account nonvanishing finite-state gambler, and finally Lemma 7.10 converts this to the finite-state compressor $C_{k,\epsilon}$. Combining the five cited constructions in [7], we obtain that there is a constant $c_{k,\epsilon}$ such that, for all $w \in \{0,1\}^*$ and $C \in \mathcal{C}'_k$,

$$|C_{k,\epsilon}(w)| \leq |C(w)| + \epsilon|w| + c_{k,\epsilon}.$$

Then for all $k \in \mathbb{N}$ and $\epsilon > 0$,

$$\begin{aligned} R'_{\mathrm{FS}}(S) &\leq \limsup_{n\to\infty} \frac{|C_{k,\epsilon}(S[0..n-1])|}{n} \\ &\leq \limsup_{n\to\infty} \inf_{C\in\mathcal{C}'_k} \frac{|C(S[0..n-1])|}{n} + \epsilon, \end{aligned}$$

so $R'_{\mathrm{FS}}(S) \leq R_{\mathrm{FS}}(S)$. □

Proof of Theorem 6.18. The equality

$$\mathrm{Dim}_{\mathrm{FS}}(S) = \inf_{C\in\mathcal{C}} \limsup_{n\to\infty} \frac{|C(S[0..n-1])|}{n}$$

has a proof analogous to that of (6.17) given in [7]. Together with Lemma 6.19, this implies that $R_{\mathrm{FS}}(S) = \mathrm{Dim}_{\mathrm{FS}}(S)$. □

Thus, mathematically, the compression ratios $\rho_{\mathrm{FS}}(S)$ and $R_{\mathrm{FS}}(S)$ are both natural: they are the finite-state effectivizations of the Hausdorff and packing dimensions, respectively.

7. Computational complexity. In this section we prove our third main theorem, which says that the dimensions and strong dimensions of polynomial-time many-one degrees in exponential time are essentially unrestricted. Our proof of this result uses Theorem 6.9 and convenient characterizations of p-dimension and strong p-dimension in terms of feasible unpredictability.

DEFINITION. *A* predictor *is a function* $\pi : \{0,1\}^* \times \{0,1\} \to [0,1]$ *such that, for all* $w \in \{0,1\}^*$, $\pi(w,0) + \pi(w,1) = 1$.

We interpret $\pi(w,b)$ as the predictor's estimate of the probability that the bit b will occur next, given that w has occurred. We write $\Pi(\mathrm{p})$ for the class of all feasible predictors.

DEFINITION. *Let* $w \in \{0,1\}^*$, $S \in \mathbf{C}$, *and* $X \subseteq \mathbf{C}$.

1. *The* cumulative log-loss *of* π *on* w *is*

$$\mathcal{L}^{\log}(\pi, w) = \sum_{i=0}^{|w|-1} \log \frac{1}{\pi(w[0..i-1], w[i])}.$$

2. *The* log-loss rate *of* π *on* S *is*

$$\mathcal{L}^{\log}(\pi, S) = \liminf_{n\to\infty} \frac{\mathcal{L}^{\log}(\pi, S[0..n-1])}{n}.$$

3. *The* strong log-loss rate *of* π *on* S *is*

$$\mathcal{L}^{\log}_{\mathrm{str}}(\pi, S) = \limsup_{n\to\infty} \frac{\mathcal{L}^{\log}(\pi, S[0..n-1])}{n}.$$

4. *The* (worst-case) log-loss *of* π *on* X *is*

$$\mathcal{L}^{\log}(\pi, X) = \sup_{S\in X} \mathcal{L}^{\log}(\pi, S).$$

5. *The* (worst-case) strong log-loss *of* π *on* X *is*

$$\mathcal{L}^{\log}_{\mathrm{str}}(\pi, X) = \sup_{S\in X} \mathcal{L}^{\log}_{\mathrm{str}}(\pi, S).$$

6. *The* feasible log-loss unpredictability *of* X *is*

$$\mathrm{unpred}^{\log}_{\mathrm{p}}(X) = \inf_{\pi\in\Pi(\mathrm{p})} \mathcal{L}^{\log}(\pi, X).$$

7. *The* feasible strong log-loss unpredictability *of* X *is*

$$\mathrm{Unpred}^{\log}_{\mathrm{p}}(X) = \inf_{\pi\in\Pi(\mathrm{p})} \mathcal{L}^{\log}_{\mathrm{str}}(\pi, X).$$

Hitchcock [14] showed that feasible dimension exactly characterizes feasible log-loss unpredictability; that is,

$$\mathrm{unpred}^{\log}_{\mathrm{p}}(X) = \dim_{\mathrm{p}}(X) \tag{7.1}$$

for all $X \subseteq \mathbf{C}$. The same argument proves the following dual result for strong dimension.

THEOREM 7.1. *For all* $X \subseteq \mathbf{C}$*,* $\mathrm{Unpred}^{\log}_{\mathrm{p}}(X) = \mathrm{Dim}_{\mathrm{p}}(X)$*.*

The following theorem is the main result of this section. Recall that the *polynomial-time many-one degree* of a language $A \subseteq \{0,1\}^*$ is

$$\deg^{\mathrm{P}}_{\mathrm{m}}(A) = \mathrm{P}_{\mathrm{m}}(A) \cap \mathrm{P}^{-1}_{\mathrm{m}}(A),$$

where the *lower span* $\mathrm{P}_{\mathrm{m}}(A)$ and the *upper span* $\mathrm{P}^{-1}_{\mathrm{m}}(A)$ are defined by

$$\mathrm{P}_{\mathrm{m}}(A) = \{B \mid B \leq^{\mathrm{P}}_{\mathrm{m}} A\}, \quad \mathrm{P}^{-1}_{\mathrm{m}}(A) = \{B \mid A \leq^{\mathrm{P}}_{\mathrm{m}} B\}.$$

THEOREM 7.2. *For every pair of* Δ^0_2*-computable real numbers* x, y *with* $0 < x \leq y \leq 1$*, there exists* $A \in \mathrm{E}$ *such that*

$$\dim_{\mathrm{p}}(\deg^{\mathrm{P}}_{\mathrm{m}}(A)) = \dim(\deg^{\mathrm{P}}_{\mathrm{m}}(A)|\mathrm{E}) = x$$

and

$$\mathrm{Dim}_{\mathrm{p}}(\deg^{\mathrm{P}}_{\mathrm{m}}(A)) = \mathrm{Dim}(\deg^{\mathrm{P}}_{\mathrm{m}}(A)|\mathrm{E}) = y.$$

Most of this section is devoted to proving Theorem 7.2. Our proof is motivated by analogous, but simpler, arguments by Ambos-Spies et al. [1]. Like most dimension calculations, our proof consists of separate lower and upper bound arguments. The results from here through Lemma 7.7 are used for the lower bound. Lemma 7.8 uses Theorem 7.1 to establish the upper bound. The proof of Theorem 7.2 follows Lemma 7.8.

The first part of the following theorem is due to Ambos-Spies et al. [1]. The second part is an exact dual of the first part.

THEOREM 7.3. *Let* $A \in \mathrm{E}$*.*

1. $\dim_{\mathrm{p}}(\deg_{\mathrm{m}}^{\mathrm{P}}(A)) = \dim_{\mathrm{p}}(\mathrm{P}_{\mathrm{m}}(A))$ *and* $\dim(\deg_{\mathrm{m}}^{\mathrm{P}}(A)|\mathrm{E}) = \dim(\mathrm{P}_{\mathrm{m}}(A)|\mathrm{E})$.
2. $\mathrm{Dim}_{\mathrm{p}}(\deg_{\mathrm{m}}^{\mathrm{P}}(A)) = \mathrm{Dim}_{\mathrm{p}}(\mathrm{P}_{\mathrm{m}}(A))$ *and* $\mathrm{Dim}(\deg_{\mathrm{m}}^{\mathrm{P}}(A)|\mathrm{E}) = \mathrm{Dim}(\mathrm{P}_{\mathrm{m}}(A)|\mathrm{E})$.

The following lemma is a time-bounded version of Lemma 6.14.

Lemma 7.4. *Assume that* $k, l \in \mathbb{Z}^+$, $\delta > 0$, $\vec{\beta}$ *is an exactly* n^l*-time-computable bias sequence with each* $\beta_i \in \mathbb{Q} \cap [\delta, 1-\delta]$, $s \in \mathbb{Q} \cap [0, \infty)$, *and* d *is an* n^k*-time-computable* s*-gale.*

1. *If* $s < H^-(\vec{\beta})$, *then* $S^\infty[d] \bigcap \mathrm{RAND}^{\vec{\beta}}(n^{k+2l+1}) = \emptyset$.
2. *If* $s < H^+(\vec{\beta})$, *then* $S^\infty_{\mathrm{str}}[d] \bigcap \mathrm{RAND}^{\vec{\beta}}(n^{k+2l+1}) = \emptyset$.

Proof. We proceed exactly as in the proof of Lemma 6.14, noting that our present hypothesis implies that the $\vec{\beta}$-martingale d' is $O(n^{k+2l+1})$-time-computable. □

Our proof of Theorem 7.2 also uses the *martingale dilation technique*, which was introduced by Ambos-Spies, Terwijn, and Zheng [2] and extended by Breutzmann and Lutz [4]. Recall the standard enumeration $s_0, s_1, s_2, \ldots$ of $\{0,1\}^*$, defined in section 2.

Definition. *The* restriction *of a string* $w \in \{0,1\}^*$ *to a language* $A \subseteq \{0,1\}^*$ *is the string* $w \restriction A$ *defined by the following recursion:*

1. $\lambda \restriction A = \lambda$.
2. *For* $w \in \{0,1\}^*$ *and* $b \in \{0,1\}$,

$$(wb) \restriction A = \begin{cases} (w \restriction A)b & \text{if } s_{|w|} \in A, \\ w \restriction A & \text{if } s_{|w|} \notin A. \end{cases}$$

(That is, $w \restriction A$ *is the concatenation of the successive bits* $w[i]$ *for which* $s_i \in A$*.)*

Definition. *A function* $f : \{0,1\}^* \longrightarrow \{0,1\}^*$ *is* strictly increasing *if, for all* $x, y \in \{0,1\}^*$,

$$x < y \Longrightarrow f(x) < f(y),$$

where $<$ *is the standard ordering of* $\{0,1\}^*$.

Notation. If $f : \{0,1\}^* \longrightarrow \{0,1\}^*$, then for each $n \in \mathbb{N}$, let n_f be the unique integer such that $f(s_n) = s_{n_f}$.

Definition. *If* $f : \{0,1\}^* \longrightarrow \{0,1\}^*$ *is strictly increasing and* $\vec{\beta}$ *is a bias sequence, then the* f-dilation *of* $\vec{\beta}$ *is the bias sequence* $\vec{\beta}^f$ *given by* $\beta^f_n = \beta_{n_f}$ *for all* $n \in \mathbb{N}$.

Observation 7.5. *If* $f : \{0,1\}^* \longrightarrow \{0,1\}^*$ *is strictly increasing and* $A \subseteq \{0,1\}^*$, *then for all* $n \in \mathbb{N}$,

$$\chi_{f^{-1}(A)}[0..n-1] = \chi_A[0..n_f - 1] \restriction \mathrm{range}(f).$$

Definition. *If* $f : \{0,1\}^* \longrightarrow \{0,1\}^*$ *is strictly increasing and* d *is a martingale, then the* f-dilation *of* d *is the function* $f\hat{}d : \{0,1\}^* \longrightarrow [0,\infty)$,

$$f\hat{}d(w) = d(w \restriction \mathrm{range}(f)).$$

Intuitively, the f-dilation of d is a strategy for betting on a language A, assuming that d itself is a good betting strategy for betting on the language $f^{-1}(A)$. Given an opportunity to bet on the membership of a string $y = f(x)$ in A, $f\hat{}d$ bets exactly as d would bet on the membership or nonmembership of x in $f^{-1}(A)$.

The following result is a special case of Theorem 6.3 in [4].

Theorem 7.6 (martingale dilation theorem; see Breutzmann and Lutz [4]). *Assume that* $\vec{\beta}$ *is a bias sequence with each* $\beta_i \in (0,1)$, $f : \{0,1\}^* \longrightarrow \{0,1\}^*$ *is strictly* *increasing, and d is a $\vec{\beta}^f$-martingale. Then $f\hat{\ }d$ is a $\vec{\beta}$-martingale and, for every language $A \subseteq \{0,1\}^*$, if d succeeds on $f^{-1}(A)$, then $f\hat{\ }d$ succeeds on A.*

Notation. For each $k \in \mathbb{Z}^+$, define $g_k : \{0,1\}^* \longrightarrow \{0,1\}^*$ by $g_k(x) = 0^{k|x|}1x$. Note that each g_k is strictly increasing and computable in polynomial time.

LEMMA 7.7. *Assume that $\vec{\beta}$ is a bias sequence with each $\beta_i \in (0,1)$, and $R \in \mathrm{RAND}^{\vec{\beta}}(n^2)$. Then, for each $k \geq 2$, $g_k^{-1}(R) \in \mathrm{RAND}^{\vec{\alpha}}(n^k)$, where $\vec{\alpha} = \vec{\beta}^{g_k}$.*

Proof. Let $\vec{\beta}$, k, and $\vec{\alpha}$ be as given, and assume that $g_k^{-1}(R) \notin \mathrm{RAND}^{\vec{\alpha}}(n^k)$. Then there is an n^k-time-computable $\vec{\alpha}$-martingale d that succeeds on $g_k^{-1}(R)$. It follows by Theorem 7.6 that $g_k\hat{\ }d$ is a $\vec{\beta}$-martingale that succeeds on R. The time required to compute $g_k\hat{\ }d(w)$ is $O(|w|^2 + |w'|^k)$ steps, where $w' = w \upharpoonright \mathrm{range}(g_k)$. (This allows $O(|w|^2)$ steps to compute w' and then $O(|w'|^k)$ steps to compute $d(w')$.) Now $|w'|$ is bounded above by the number of strings x such that $k|x| + |x| + 1 \leq |s_{|w|}| = \lfloor \log(1 + |w|) \rfloor$. Therefore $|w'| \leq 2^{1+\log(1+|w|)/k}$, which implies $|w'|^k = O(|w|)$. Thus $g_k\hat{\ }d(w)$ is an $O(n^2)$-time computable $\vec{\beta}$-martingale, so $R \notin \mathrm{RAND}^{\vec{\beta}}(n^2)$. □

Notation. From here through the proof of Theorem 7.2, we assume that α and β are Δ_2^0-computable real numbers with $0 < \alpha \leq \beta \leq 1/2$. It is well known that a real number is Δ_2^0-computable if and only if there is a computable sequence of rationals that converge to it. Slowing down this construction gives polynomial-time functions $\hat{\alpha}, \hat{\beta} : \mathbb{N} \to \mathbb{Q}$ such that

$$\lim_{n\to\infty} \hat{\alpha}(n) = \alpha, \qquad \lim_{n\to\infty} \hat{\beta}(n) = \beta.$$

We assume that for some $\delta > 0$, $\hat{\alpha}(n) > \delta$ for all n. We place the analogous assumption on $\hat{\beta}(n)$. For each n, we let

$$\kappa(n) = \begin{cases} \hat{\alpha}(n) & \text{if } n \text{ is even,} \\ \hat{\beta}(n) & \text{if } n \text{ is odd,} \end{cases}$$

and define a special-purpose bias sequence $\vec{\gamma}$ by

$$\gamma_n = \kappa(\log^* n).$$

Note that $\vec{\gamma}$ is $O(n)$-time-computable, $H^-(\vec{\gamma}) = \mathcal{H}(\alpha)$, and $H^+(\vec{\gamma}) = \mathcal{H}(\beta)$.

We now use the unpredictability characterizations from the beginning of this section to establish upper bounds on the dimensions and strong dimensions of lower spans of sequences random relative to $\vec{\gamma}$.

LEMMA 7.8. *For each $R \in \mathrm{RAND}^{\vec{\gamma}}(n^5)$,*

$$\dim_{\mathrm{p}}(\mathrm{P_m}(R)) \leq \mathcal{H}(\alpha)$$

and

$$\mathrm{Dim}_{\mathrm{p}}(\mathrm{P_m}(R)) \leq \mathcal{H}(\beta).$$

Proof. Fix a polynomial-time function $f : \{0,1\}^* \to \{0,1\}^*$. The *collision set* of f is

$$C_f = \{j \mid (\exists i < j) f(s_i) = f(s_j)\}.$$

For each $n \in \mathbb{N}$, let

$$\#C_f(n) = |C_f \cap \{0, \ldots, n-1\}|.$$

We use f to define the predictors

$$\pi_0^f(w,b) = \begin{cases} \frac{1}{2} & \text{if } |w| \notin C_f, \\ w[i] & \text{if } |w| \in C_f,\ i = \min\{j \mid f(s_j) = f(s_{|w|})\}, \text{ and } b = 1\ , \\ 1 - w[i] & \text{if } |w| \in C_f,\ i = \min\{j \mid f(s_j) = f(s_{|w|})\}, \text{ and } b = 0\ , \end{cases}$$

and

$$\pi_1^f(w,b) = \begin{cases} \gamma_{|w|}^f & \text{if } |w| \notin C_f \text{ and } b = 1, \\ 1 - \gamma_{|w|}^f & \text{if } |w| \notin C_f \text{ and } b = 0, \\ w[i] & \text{if } |w| \in C_f,\ i = \min\{j \mid f(s_j) = f(s_{|w|})\}, \text{ and } b = 1\ , \\ 1 - w[i] & \text{if } |w| \in C_f,\ i = \min\{j \mid f(s_j) = f(s_{|w|})\}, \text{ and } b = 0\ , \end{cases}$$

for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$.

For each $S \in \mathbf{C}$, we now define several objects to facilitate the proof. First, we let

$$A^f(S) = f^{-1}(S);$$

that is, $A^f(S)$ is the language $\leq_{\mathrm{m}}^{\mathrm{P}}$-reduced to S by f. Observe that for all $w \sqsubseteq A^f(S)$,

$$\mathcal{L}^{\log}(\pi_0^f, w) = |w| - \#C_f(|w|). \tag{7.2}$$

Recall the sequence of towers defined by t_j by $t_0 = 1$ and $t_{j+1} = 2^{t_j}$. For any $j \in \mathbb{N}$ and $t_j < n \leq t_{j+1}$, define the entropy quantity

$$H_n^f = \sum_{\substack{i<n \\ i \notin C_f \text{ and } i_f > t_{j-1}}} \mathcal{H}(\gamma_n^f)$$

and the random variable

$$L_n^f(S) = \sum_{\substack{i<n \\ i \notin C_f \text{ and } i_f > t_{j-1}}} \log \frac{1}{\pi_1^f(A^f(S)[0..i-1], A^f(S)[i])}.$$

(Recall that i_f is the unique number such that $f(s_i) = s_{i_f}$.) We have

$$\begin{aligned} \mathcal{L}^{\log}(\pi_1^f, A^f(S)[0..n-1]) &= \sum_{i<n} \log \frac{1}{\pi_1^f(A^f(S)[0..i-1], A^f(S)[i])} \\ &= \sum_{\substack{i<n \\ i \notin C_f}} \log \frac{1}{\pi_1^f(A^f(S)[0..i-1], A^f(S)[i])} \\ &= L_n^f(S) + \sum_{\substack{i<n \\ i \notin C_f \text{ and } i_f \leq t_{j-1}}} \log \frac{1}{\pi_1^f(A^f(S)[0..i-1], A^f(S)[i])} \\ &\leq L_n^f(S) + (1 + t_{j-1}) \log \tfrac{1}{\delta}, \end{aligned}$$

so the bound

$$\mathcal{L}^{\log}(\pi_1^f, A^f(S)[0..n-1]) \leq L_n^f(S) + (1 + \log n) \log \tfrac{1}{\delta} \tag{7.3}$$

holds for all n. Finally, for any $\epsilon > 0$ and $\theta \in (0, 1)$, define the set

$$J^f_{\theta,\epsilon}(S) = \{n \mid \#C_f(n) < (1-\theta)n \text{ and } L^f_n(S) \geq H^f_n + \epsilon n\}$$

of natural numbers.

Claim. *For any rational $\theta \in (0,1)$ and $\epsilon > 0$,*

$$\mu^{\vec{\gamma}}_{n^5}\left(\{S \mid J^f_{\theta,\epsilon}(S) \textit{ is finite}\}\right) = 1.$$

Proof of claim. The argument is similar to the proof of Lemma 6.12. For each $n \in \mathbb{N}$, define the set

$$Y_n = \begin{cases} \{S \mid L^f_n(S) \geq H^f_n + \epsilon n\} & \text{if } \#C_f(n) < (1-\theta)n, \\ \emptyset & \text{otherwise,} \end{cases}$$

and let

$$X_\epsilon = \{S \in \mathbf{C} | (\exists^\infty n) S \in Y_n\}.$$

To prove the claim, we will show that $\mu^{\vec{\gamma}}_{n^5}(X_\epsilon) = 0$.

For each $n \in \mathbb{N}$ and $w \in \{0,1\}^*$, let

$$d_n(w) = \begin{cases} \mu^{\vec{\gamma}}(Y_n | \mathbf{C}_w) & \text{if } |w| \leq n, \\ d_n(w[0..n-1]) & \text{if } |w| > n. \end{cases}$$

It is clear that each d_n is a $\vec{\gamma}$-martingale and that $Y_n \subseteq S^1[d_n]$ for all $n \in \mathbb{N}$.

Let $S \in \mathbf{C}$. For each $n, j \in \mathbb{N}$, let

$$I^n_j = \{i_f \mid i < n, i \notin C_f, \text{ and } \log^* i_f = j\}.$$

Also, define $S^+ = \{i \mid S[i] = 1\}$ and $S^- = \{i \mid S[i] = 0\}$. Then, if n is large enough to ensure that $\log^* i_f \leq 1 + \log^* n$ for all $i < n$, we have

$$L^f_n(S) = \sum_{k=(\log^* n)-1}^{(\log^* n)+1} \left|I^n_k \cap S^+\right| \log \frac{1}{\kappa(k)} + \left|I^n_k \cap S^-\right| \log \frac{1}{1-\kappa(k)}.$$

For any n and k, write $i(n,k) = |I^n_k|$. Let T_n be the set of all tuples (l_{-1}, l_0, l_1) satisfying $0 \leq l_r \leq i(n, j+r)$ for $-1 \leq r \leq 1$ and

$$\sum_{r=-1}^{1} l_r \log \frac{1}{\kappa(j+r)} + (i(n,j+r) - l_r) \log \frac{1}{1-\kappa(j+r)} \geq H^f_n + \epsilon n,$$

where $j = \log^* n$. Then we have

$$\mu^{\vec{\gamma}}(Y_n) = \sum_{(l_{-1},l_0,l_1) \in T_n} \prod_{r=-1}^{1} \binom{i(n,j+r)}{l_r} \kappa(j+r)^{l_r} (1-\kappa(j+r))^{i(n,j+r)-l_r}.$$

We can write a similar formula for $\mu^{\vec{\gamma}}(Y_n|\mathbf{C}_w)$ when $w \neq \lambda$. From this it follows that the mapping $(n,w) \mapsto d_n(w)$ is exactly computable in $O(n^3)$ time.

Since $\hat{\gamma}$ is bounded away from 0 and 1, we can apply Theorem 6.9 to conclude that there exists $\rho \in (0,1)$ such that for all $n \in \mathbb{N}$ with $Y_n \neq \emptyset$ we have

$$\mu^{\vec{\gamma}}(Y_n) < 2\rho^{n-\#C_f(n)} < 2\rho^{\theta n}.$$

It follows that the series $\sum_{n=0}^{\infty} d_n(\lambda)$ is p-convergent, so the polynomial-time first Borel–Cantelli lemma [20] (extended to $\vec{\gamma}$ as indicated in [4]) tells us that $\mu^{\vec{\gamma}}_{n^5}(X_\epsilon) = 0$. □

Let $R \in \mathrm{RAND}^{\vec{\gamma}}(n^5)$. Let $\epsilon > 0$ and $\theta < \mathcal{H}(\alpha)+\epsilon$ be rational. Then by the above claim, $J^f_{\theta,\epsilon}(R)$ is finite. That is, for all but finitely many n,

$$\#C_f(n) \geq (1-\theta)n \quad \text{or} \quad L^f_n(R) < H^f_n + \epsilon n. \tag{7.4}$$

Writing $w_n = A^f(R)[0..n-1]$, (7.4) combined with (7.2) and (7.3) implies that for all but finitely many n,

$$\mathcal{L}^{\log}(\pi^f_0, w_n) \leq \theta n < (\mathcal{H}(\alpha)+\epsilon)n \tag{7.5}$$

or

$$\mathcal{L}^{\log}(\pi^f_1, w_n) < H^f_n + \epsilon n + (1+\log n)\log\tfrac{1}{\delta}. \tag{7.6}$$

As

$$\limsup_{n\to\infty} \frac{H^f_n}{n} \leq \mathcal{H}(\beta),$$

it follows that

$$\limsup_{n\to\infty} \frac{\min\{\mathcal{L}^{\log}(\pi^f_0, w_n), \mathcal{L}^{\log}(\pi^f_1, w_n)\}}{n} \leq \mathcal{H}(\beta)+\epsilon. \tag{7.7}$$

If (7.5) holds for infinitely many n, then

$$\mathcal{L}^{\log}(\pi^f_0, A^f(R)) \leq \mathcal{H}(\alpha)+\epsilon. \tag{7.8}$$

Otherwise, (7.6) holds for almost all n. Assuming

$$\liminf_{n\to\infty} \frac{H^f_n}{n} \leq \mathcal{H}(\alpha), \tag{7.9}$$

in this case we have

$$\mathcal{L}^{\log}(\pi^f_1, A^f(R)) \leq \mathcal{H}(\alpha)+\epsilon. \tag{7.10}$$

We now verify (7.9). For each n, let $m(n) = t_n^2$. Then for sufficiently large n, we have $i_f < t_{n+1}$ for all $i < m(n)$. Using the sets I^k_n from the proof of the claim, we then have

$$\begin{aligned} H^f_{m(n)} &= \left|I^{m(n)}_n\right| \mathcal{H}(\kappa(n)) + \left|I^{m(n)}_{n+1}\right| \mathcal{H}(\kappa(n+1)) \\ &\leq (t_n+1)\mathcal{H}(\kappa(n)) + m(n)\mathcal{H}(\kappa(n+1)). \end{aligned}$$

As $t_n = o(m(n))$ and $\kappa(2n) \to \alpha$ as $n \to \infty$, we have

$$\liminf_{n\to\infty} \frac{H^f_n}{n} \leq \liminf_{n\to\infty} \frac{H^f_{m(2n+1)}}{m(2n+1)} \leq \mathcal{H}(\alpha).$$

For each polynomial-time reduction f, we have defined and analyzed two predictors π_0^f and π_1^f. We now show how to combine all these predictors into a single predictor that will establish the lemma.

Let $\{f_j \mid j \in \mathbb{N}\}$ be a uniform enumeration of all polynomial-time functions $f_j : \{0,1\}^* \to \{0,1\}^*$ such that $f_j(x)$ is computable in $O(2^{|x|} + j)$ steps. For any predictor ρ, define a probability measure $\mu[\rho]$ by

$$\mu[\rho](w) = \prod_{i=0}^{|w|-1} \rho(w[0..i-1], w[i])$$

for all $w \in \{0,1\}^*$. For each $m \in \mathbb{N}$ and $w \in \{0,1\}^m$, let

$$\mu_m(w) = 2^{-(2m+1)} + \sum_{j=0}^{m-1} 2^{-(2j+3)} \left(\mu[\pi_0^{f_j}](w) + \frac{1}{2}\mu[\pi_1^{f_j}](w) \right).$$

Then

$$\begin{aligned}
\mu_{m+1}(w0) + \mu_{m+1}(w1) &= 2^{-(2m+3)} + \sum_{j=0}^{m} 2^{-(2j+3)} \left(\mu[\pi_0^{f_j}](w0) + \frac{1}{2}\mu[\pi_1^{f_j}](w0) \right) \\
&\quad + 2^{-(2m+3)} + \sum_{j=0}^{m} 2^{-(2j+3)} \left(\mu[\pi_0^{f_j}](w1) + \frac{1}{2}\mu[\pi_1^{f_j}](w1) \right) \\
&= 2^{-(2m+2)} + \sum_{j=0}^{m} 2^{-(2j+3)} \left(\mu[\pi_0^{f_j}](w) + \frac{1}{2}\mu[\pi_1^{f_j}](w) \right) \\
&= 2^{-(2m+3)} \left(2 + \mu[\pi_0^{f_m}](w) + \frac{1}{2}\mu[\pi_1^{f_m}](w) \right) \\
&\quad + \mu_m(w) - 2^{-(2m+1)} \\
&\le \mu_m(w) + 2^{-(2m+3)} \left(3 + \frac{1}{2} \right) - 2^{-(2m+1)} \\
&< \mu_m(w).
\end{aligned}$$

Now define a predictor π by

$$\begin{aligned}
\pi(w,1) &= \frac{\mu_{|w|+1}(w1)}{\mu_{|w|}(w)}, \\
\pi(w,0) &= 1 - \pi(w,1).
\end{aligned}$$

Then for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$,

$$\pi(w,b) \ge \frac{\mu_{|w|+1}(wb)}{\mu_{|w|}(w)}.$$

For all $w \in \{0,1\}^*$, $k \in \{0,1\}$, and $j < |w|$, we have

$$\begin{aligned}\mathcal{L}^{\log}(\pi, w) &= \sum_{i=0}^{|w|-1} \log \frac{1}{\pi(w[0..i-1], w[i])} \\ &\le \sum_{i=0}^{|w|-1} \log \frac{\mu_i(w[0..i-1])}{\mu_{i+1}(w[0..i])} \\ &= \log \frac{\mu_0(\lambda)}{\mu_{|w|}(w)} \\ &\le \log \frac{2^{2j+3+k}}{\mu[\pi_k^{f_j}](w)} \\ &= 2j + 3 + k + \mathcal{L}^{\log}(\pi_k^{f_j}, w).\end{aligned}$$

For any $j \in \mathbb{N}$, it follows that

$$\mathcal{L}^{\log}_{\mathrm{str}}(\pi, A^{f_j}(R)) \le \mathcal{H}(\beta) + \epsilon$$

by using $f = f_j$ in (7.7). Also, since either (7.8) or (7.10) holds for $f = f_j$, we have

$$\mathcal{L}^{\log}(\pi, A^{f_j}(R)) \le \mathcal{H}(\alpha) + \epsilon.$$

As π is (exactly) polynomial-time computable, this establishes that

$$\mathrm{P_m}(R) = \{A^{f_j}(R) \mid j \in \mathbb{N}\}$$

has p-dimension at most $\mathcal{H}(\alpha) + \epsilon$ by (7.1) and strong p-dimension at most $\mathcal{H}(\beta) + \epsilon$ by Theorem 7.1. As $\epsilon > 0$ was arbitrary, the statement of the lemma follows. □

We now have the machinery we need to prove the main result of this section.

Proof of Theorem 7.2. Let x and y be Δ^0_2-computable real numbers with $0 < x \le y \le 1$. Then there exist Δ^0_2-computable real numbers α and β with $0 < \alpha \le \beta \le \frac{1}{2}$, $\mathcal{H}(\alpha) = x$, and $\mathcal{H}(\beta) = y$. Let $\vec{\gamma}$ be the bias sequence defined from α and β above (just prior to Lemma 7.8). It is well known [20, 2] that almost every language in E is n^5-$\vec{\gamma}$-random. In particular, there exists a language $A \in \mathrm{RAND}^{\vec{\gamma}}(n^5) \cap \mathrm{E}$. By Theorem 7.3, it suffices to prove that

$$\dim_{\mathrm{p}}(\mathrm{P_m}(A)) = \dim(\mathrm{P_m}(A)|\mathrm{E}) = \mathcal{H}(\alpha)$$

and

$$\mathrm{Dim}_{\mathrm{p}}(\mathrm{P_m}(A)) = \mathrm{Dim}(\mathrm{P_m}(A)|\mathrm{E}) = \mathcal{H}(\beta).$$

By Lemma 7.8, then, it suffices to prove that

$$\dim(\mathrm{P_m}(A)|\mathrm{E}) \ge \mathcal{H}(\alpha) \tag{7.11}$$

and

$$\mathrm{Dim}(\mathrm{P_m}(A)|\mathrm{E}) \ge \mathcal{H}(\beta). \tag{7.12}$$

Let $s \in [0, \mathcal{H}(\alpha)) \cap \mathbb{Q}$, and let d^- be an n^k-time computable s-gale. Similarly, let $t \in [0, \mathcal{H}(\beta)) \cap \mathbb{Q}$, and let d^+ be an n^k-time computable t-gale. It suffices to show that

$$\mathrm{P_m}(A) \cap \mathrm{E} \not\subseteq S^\infty[d^-] \tag{7.13}$$

and

$$\mathrm{P_m}(A) \cap \mathrm{E} \not\subseteq S^{\infty}_{\mathrm{str}}[d^+]. \tag{7.14}$$

Let $B = g^{-1}_{k+3}(A)$. It is clear that $B \in \mathrm{P_m}(A) \cap \mathrm{E}$. Also, by Lemma 7.7, we have $B \in \mathrm{RAND}^{\vec{\gamma}'}(n^k)$, where $\vec{\gamma}' = \vec{\gamma}^{g_{k+3}}$. Since

$$s < \mathcal{H}(\alpha) = H^-(\vec{\gamma}) = H^-(\vec{\gamma}'),$$

$$t < \mathcal{H}(\beta) = H^+(\vec{\gamma}) = H^+(\vec{\gamma}'),$$

and $\vec{\gamma}'$ is $O(n)$-time-computable, Lemma 7.4 tells us that $B \notin S^{\infty}[d^-]$ and $B \notin S^{\infty}_{\mathrm{str}}[d^+]$. Thus (7.13) and (7.14) hold. □

In light of Theorem 7.2, the following question concerning the relativized feasible dimension of NP is natural.

Open Question 7.9. *For which pairs of real numbers* $\alpha, \beta \in [0,1]$ *does there exist an oracle* A *such that* $\dim_{\mathrm{p}^A}(\mathrm{NP}^A) = \alpha$ *and* $\mathrm{Dim}_{\mathrm{p}^A}(\mathrm{NP}^A) = \beta$*?*

We conclude this section with two brief observations.

Fortnow and Lutz [11] have recently established a tight quantitative relationship between p-dimension and feasible predictability. Specifically, for each $X \subseteq \mathbf{C}$, they investigated the quantity $\mathrm{Pred_p}(X)$, which is the supremum, for all feasible predictors π, of the *(worst-case, upper) success rate*

$$\pi^+(S) = \inf_{S \in X} \limsup_{n \to \infty} \pi^+(S[0..n-1]), \tag{7.15}$$

where

$$\pi^+(w) = \frac{1}{|w|} \sum_{i=0}^{|w|-1} \pi(w[0..i-1], w[i])$$

is the expected fraction of correct predictions that π will make on w. They proved that $\mathrm{Pred_p}(X)$ is related to the p-dimension of X by

$$2(1 - \mathrm{Pred_p}(X)) \le \dim_{\mathrm{p}}(X) \le \mathcal{H}(\mathrm{Pred_p}(X)) \tag{7.16}$$

(where $\mathcal{H}(\alpha)$ is the Shannon entropy of α) and that these bounds are tight. If we call $\mathrm{Pred_p}(X)$ the *upper feasible predictability* of X and define the *lower feasible predictability* of X, $\mathrm{pred_p}(X)$, in the same fashion, but with the limit superior in (7.15) replaced by a limit inferior, then we have the following dual of (7.16).

Theorem 7.10. *For all* $X \subseteq \mathbf{C}$*,*

$$2(1 - \mathrm{pred_p}(X)) \le \mathrm{Dim_p}(X) \le \mathcal{H}(\mathrm{pred_p}(X)).$$

For each $s : \mathbb{N} \to \mathbb{N}$, let $\mathrm{SIZE}(s(n))$ be the class of all (characteristic sequences of) languages $A \subseteq \{0,1\}^*$ such that, for each $n \in \mathbb{N}$, $A_{=n}$ is decided by a Boolean circuit consisting of at most $s(n)$ gates.

Theorem 7.11. *For each* $\alpha \in [0,1]$*, the class* $X_\alpha = \mathrm{SIZE}(\alpha \cdot \frac{2^n}{n})$ *is pspace-regular, with* $\dim_{\mathrm{pspace}}(X_\alpha) = \mathrm{Dim}_{\mathrm{pspace}}(X_\alpha) = \dim(X_\alpha|\mathrm{ESPACE}) = \mathrm{Dim}(X_\alpha|\mathrm{ESPACE}) = \alpha$*.*

Proof. It was shown in [23] that $\dim_{\mathrm{pspace}}(X_\alpha) = \dim(X_\alpha|\mathrm{ESPACE}) = \alpha$. This proof also shows that the strong dimensions are α. □

Acknowledgments. The third author thanks Dan Mauldin for extremely useful discussions. We all thank two very thorough referees for many helpful suggestions. We also thank Dave Doty for pointing out a problem with an earlier version of our proof of Theorem 6.18.

NEW APPROACHES FOR VIRTUAL PRIVATE NETWORK DESIGN*

FRIEDRICH EISENBRAND†, FABRIZIO GRANDONI‡, GIANPAOLO ORIOLO§, AND MARTIN SKUTELLA¶

Abstract. *Virtual private network design* is the following NP-hard problem. We are given a communication network represented as a weighted graph with thresholds on the nodes which represent the amount of flow that a node can send to and receive from the network. The task is to reserve capacities at minimum cost and to specify paths between every ordered pair of nodes such that all valid traffic-matrices can be routed along the corresponding paths. Recently, this network design problem has received considerable attention in the literature. It is motivated by the fact that the exact amount of flow which is exchanged between terminals is not known in advance and prediction is often elusive. The main contributions of this paper are as follows: (1) Using Hu's 2-commodity flow theorem, we provide a new and considerably stronger lower bound on the cost of an optimum solution. With this lower bound we reanalyze a simple routing scheme which has been described in the literature many times, and provide an improved upper bound on its approximation ratio. (2) We present a new randomized approximation algorithm. In contrast to earlier approaches from the literature, the resulting solution does not have tree structure. A combination of our new algorithm with the simple routing scheme yields an expected performance ratio of 3.79 for virtual private network design. This is a considerable improvement of the previously best known 5.55-approximation result [A. Gupta, A. Kumar, and T. Roughgarden, *Simpler and better approximation algorithms for network design*, in Proceedings of the ACM Symposium on Theory of Computing, ACM, New York, 2003, pp. 365–372]. (3) Our VPND algorithm uses a Steiner tree approximation algorithm as a subroutine. It is known that an optimum Steiner tree can be computed in polynomial time if the number of terminals is logarithmic. Replacing the approximate Steiner tree computation with an exact one whenever the number of terminals is sufficiently small, we finally reduce the approximation ratio to 3.55. To the best of our knowledge, this is the first time that a nontrivial result from exact (exponential) algorithms leads to an improved polynomial-time approximation algorithm.

Key words. approximation algorithms, randomized algorithms, network design

1. Introduction.

Consider a communication network which is represented by an undirected graph $G = (V, E)$ with edge-weights $c : E \to \mathbb{R}_+$. Within this network there is a set of terminals $T \subseteq V$ which want to communicate with each other. However, the exact amount of traffic between pairs of terminals is not known in advance. Instead, each terminal $v \in T$ has associated input and output thresholds $b_{in}(v) \in \mathbb{Z}_{\geq 0}$ and $b_{out}(v) \in \mathbb{Z}_{\geq 0}$. A *traffic-matrix* $D \in \mathbb{Q}_{\geq 0}^{TT}$ is *valid* if it respects the lower and upper bounds on the incoming and outgoing traffic of the terminals, i.e., if

the following holds for each terminal $i \in T$:

$$\sum_{j \in T, j \neq i} D(i,j) \leq b_{out}(i) \quad \text{and} \quad \sum_{j \in T, j \neq i} D(j,i) \leq b_{in}(i).$$

The *(asymmetric) virtual private network design (VPND)* problem defined by G, c, and T consists of finding capacities $u(e)$, $e \in E$ and paths P_{ij} for each ordered pair $(i,j) \in TT$ such that the following conditions hold:

(i) All valid traffic-matrices can be routed without exceeding the installed capacities where all traffic from terminal i to terminal j is routed along path P_{ij}.

(ii) The total cost of the reservation $\sum_{e \in E} u(e)\, c(e)$ is minimal.

A reservation of capacities $u : E \to \mathbb{R}_+$ is a *tree reservation* if the subgraph of G induced by the edges $e \in E$ with $u(e) > 0$ is a tree. A general reservation is sometimes referred to as a *graph reservation*.

The virtual private network design problem is NP-hard by the following reduction from the Steiner tree problem [11]. Given an instance of the Steiner tree problem, pick a terminal which has to be connected with the other terminals in a Steiner tree. This terminal has thresholds $b_{in}(v) = 0$ and $b_{out}(v) = 1$. All other terminals u of the Steiner tree instance have $b_{in}(u) = 1$ and $b_{out}(u) = 0$. A minimum cost Steiner tree also yields an optimum reservation for this VPND instance.

The virtual private network design problem was independently defined by Fingerhut, Suri, and Turner [10] and by Duffield et al. [6] and has since then been studied by various authors in several variations which we next discuss. In the following list, the last one ($AsymG$) is the one which we refer to as VPND.

($SymT$) Symmetric thresholds, tree reservation: In this variant, each terminal $i \in T$ has only one threshold $b(i)$, which is an upper bound on the cumulative amount of traffic that terminal i can send or receive. The task is to find an optimal tree reservation which supports all valid traffic-matrices. Gupta et al. [11] show that ($SymT$) is polynomially solvable.

($SymG$) Symmetric thresholds, graph reservation: This variant is defined in the same way as ($SymT$), except that the capacity reservation can be arbitrary and not necessarily a tree. Gupta et al. [11] present a 2-approximation for ($SymG$). It is not known whether $SymG$ is NP-hard.

($BalT$) Balanced thresholds, tree reservation: The thresholds are *balanced*, which means that $\sum_{v \in T} b_{in}(v) = \sum_{v \in T} b_{out}(v)$. The reservation has to be a tree. Italiano, Leonardi, and Oriolo [15] show that this variant can be solved in polynomial time.

($BalG$) Balanced thresholds, graph reservation: The same as ($BalT$), except that an arbitrary graph reservation is allowed.

($AsymT$) Asymmetric thresholds, tree reservation: This problem is NP-hard [11]. Constant approximation algorithms are presented in [11, 12]. Interestingly, while the algorithm in [11] is deterministic, the algorithm in [12] is randomized and seems difficult to derandomize.

($AsymG$) Asymmetric thresholds, graph reservation: This is the VPND problem defined above. We have seen that this problem is NP-hard. The randomized 5.55-approximation result presented in [12] in fact compares the computed tree solution to an optimal graph reservation.

Simplifying assumptions and a lower bound. Following [12], we make some simplifying assumptions without loss of generality. By duplicating nodes, we can assume that each terminal is either a *sender* s, with $b_{out}(s) = 1$ and $b_{in}(s) = 0$, or a *receiver* r, with $b_{out}(r) = 0$ and $b_{in}(r) = 1$. This simplifying assumption is feasible as long as we make sure that the selected paths in our solution between copies of a terminal v and copies of a terminal u are all equal. The algorithms presented in this paper can easily be adapted to run in polynomial time even when the thresholds are not polynomially bounded and to satisfy the consistence property described above. Let $\mathcal{S}$ and $\mathcal{R}$ be the set of senders and the set of receivers, respectively. By $S = |\mathcal{S}|$ and $R = |\mathcal{R}|$ we denote the corresponding cardinalities. For symmetry reasons, we always assume $R \geq S$.

We can now interpret VPND as follows. Let $B = (\mathcal{S} \cup \mathcal{R}, E^B)$ be the complete bipartite graph with nodes partitioned into senders and receivers. We have to reserve capacities on the edges of G and we have to specify a set of paths $\mathcal{P}$ in graph G containing one path P_{sr} for each edge $sr \in E^B$ such that each bipartite matching of B can be routed along these paths. In other words, for each edge $e \in E$, the reservation $u(e)$ has to satisfy the following condition:

$$(1) \qquad \left|\{P_{rs} \in \mathcal{P} \mid e \in P_{rs} \text{ and } rs \in M\}\right| \leq u(e) \quad \text{for each matching } M \text{ in } B.$$

Notice that for a fixed set of paths $\mathcal{P}$, an optimal reservation of capacity is the componentwise minimal u satisfying (1). (In particular, given $\mathcal{P}$, the integral capacity $u(e)$ of edge e can be obtained by a maximum bipartite matching computation.) Thus, a solution to VPND can be encoded by specifying only a set of paths $\mathcal{P}$ in G.

The cost of a bipartite matching between senders and receivers in the metric closure of G is obviously a lower bound on OPT, the value of an optimum solution to the VPND instance. We denote the shortest path distance between nodes u and v of G by $\ell(u, v)$. Thus, if edges (r, s) in B are assigned weights $\ell(r, s)$, then the cost of any matching in B is a lower bound on OPT. This lower bound is used in the analysis of all previous constant-factor approximation algorithms for VPND.

Lemma 1 (see [12]). *Let $B = (\mathcal{S} + \mathcal{R}, E^B)$ be the complete bipartite graph on the senders and receivers with edge-weights $\ell : E^B \to \mathbb{R}_+$ given by the shortest path distances in the graph G. Then, the weight of any matching in B is a lower bound on OPT.*

Contribution of this paper. The design of good approximation results usually requires two main ingredients—cleverly constructed algorithms and thoroughly chosen lower bounds on the optimum such that the quality of the computed solutions can be assessed in terms of the lower bounds. We considerably advance the state of the art of approximating VPND by making contributions to both ingredients.

In section 2 we present a new lower bound which strengthens the one stated in Lemma 1. We prove that the weight of *any matching* (not necessarily bipartite) on the union of the senders and at most S receivers is at most OPT. The edge-weights in the matching are again the shortest path distances in G. This new lower bound relies on an interesting interrelation between a special case of VPND and 2-commodity flows. Its proof is based on an application of Hu's 2-commodity flow theorem [13].

In section 3 we employ the new lower bound in order to show that the following simple algorithm achieves performance ratio $1 + R/S$: Find a vertex $v \in V$ which minimizes the sum of the shortest path distances between v and the union of senders and receivers; cumulatively install a capacity of one on each such shortest path. One interesting consequence of this result is that ($BalG$), VPND with balanced thresholds and graph reservation, has a 2-approximation. Thus our result improves upon the 3-approximation of Italiano, Leonardi, and Oriolo [15] for this problem and generalizes the 2-approximation for ($SymG$) by Gupta et al. [11].

In section 4 we present a new randomized algorithm for VPND. The algorithm chooses a random subset of receivers and connects each sender via its own Steiner tree to this subset. The remaining receivers are then connected to the randomly chosen subset of receivers by shortest paths. Due to the Steiner trees for each individual sender, the resulting solution has in general no tree structure. In contrast to our new approach, the previous algorithm by Gupta, Kumar, and Roughgarden [12] constructs only one random "high-bandwidth core" which is a Steiner tree with high capacity. All previous approximation algorithms for VPND produce tree solutions.

In section 4 we show also that our new algorithm in combination with the simple algorithm from above yields a 3.79 randomized approximation algorithm. The previously best known algorithm [12] achieves performance ratio 5.55.

Our VPND algorithm uses a Steiner tree approximation algorithm as a subroutine. Dreyfus and Wagner [5] showed how to compute optimum Steiner trees in polynomial time when the number of terminals is logarithmic. In section 5, by replacing the approximate Steiner tree computation with an exact one whenever the number of terminals is sufficiently small, we eventually obtain a 3.55-approximation algorithm. To the best of our knowledge, this is the first time a result from exact (exponential) algorithms leads to an improved polynomial-time approximation algorithm, which might be of independent interest.

Related work. We have seen that the Steiner tree problem is a special case of VPND. The current best approximation ratio for the Steiner tree problem is $\rho_{st} < 1.55$ [18]. A related problem is *buy-at-bulk* network design (see, e.g., [1, 2]). Here, there is a fixed demand $d_{i,j}$ between each pair of nodes in the graph, specifying the amount of flow which has to be sent from i to j. The costs of the capacities however is a concave function on the amount purchased, which reflects "economies of scale." Gupta, Kumar, and Roughgarden [12] consider the single source buy-at-bulk network design problem and present a simple constant-factor approximation algorithm.

Another important issue in this context is to cope with arc failures in the network [3, 4]. Italiano, Rastogi, and Yener [16] consider the problem of restoring the network, when at most one arc in a tree solution to VPND might fail and provide a constant-factor approximation algorithm.

It is conjectured that $(SymG)$ can be solved in polynomial time. It is in fact conjectured that an optimal solution to $(SymT)$ is also an optimal solution to $(SymG)$. Hurkens, Keijsper, and Stougie [14] show that this conjecture holds for rings. The authors also describe an integer programming formulation for VPND, which proves that a fractional version can be solved in polynomial time. This fractional version allows us to specify several paths for each sender-receiver pair and requires the fraction for each of these paths, which describes how the commodity has to be split.

2. A new lower bound via Hu's 2-commodity flow theorem.

This section is devoted to proving a new lower bound on the cost of an optimal solution to VPND. Generalizing Lemma 1, we prove that the cost of an arbitrary (not necessarily bipartite) matching between terminals in $\mathcal{S} \cup \mathcal{R}'$ is at most OPT for any subset of receivers $\mathcal{R}' \subseteq \mathcal{R}$ of cardinality $|\mathcal{R}'| = S$. The proof of this result is based on Hu's classical 2-commodity flow theorem [13].

THEOREM 1 (Hu's 2-commodity flow theorem). *Let $G = (V, E)$ be a graph and let s_1, r_1, s_2, r_2 be pairs of vertices of G; let $u : E \to \mathbb{R}_+$ be a capacity function on the edges and let $d_1, d_2 \in \mathbb{R}_+$. There exists a (fractional) 2-commodity flow of value d_1, d_2 if and only if the* cut condition *is satisfied, i.e., if and only if $u(\delta(U)) \geq$*

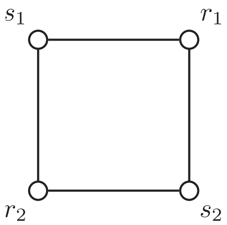

FIG. 1. *An undirected graph with unit capacities on the edges. While there exist integral* 2*-commodity flows satisfying unit demands for terminal pairs* $\{s_1, r_1\}, \{s_2, r_2\}$ *and for terminal pairs* $\{s_1, r_2\}, \{s_2, r_1\}$*, there is only a half-integral* 2*-commodity flow for terminal pairs* $\{s_1, s_2\}, \{r_1, r_2\}$*.*

$d_1\,\chi_1(U)+d_2\,\chi_2(U)$ *for each* $U \subseteq V$*. Here* $\delta(U)$ *denotes the cut induced by* U *and, for* $i \in \{1, 2\}$*,* $\chi_i(U) = 1$ *if the cut* $\delta(U)$ *separates* s_i *from* r_i*, and* $\chi_i(U) = 0$ *otherwise.*

Hu's theorem immediately implies the following corollary.

COROLLARY 1. *Let* $G = (V, E)$ *be an undirected graph with edge capacity function* $u : E \to \mathbb{R}_+$ *and* $s_1, s_2, r_1, r_2 \in V$*. In the following, all demand values are equal to* 1*. If there exists a feasible* 2*-commodity flow for terminal pairs* $\{s_1, r_1\}, \{s_2, r_2\}$ *and for terminal pairs* $\{s_1, r_2\}, \{s_2, r_1\}$*, then there also exists a feasible* 2*-commodity flow for terminal pairs* $\{s_1, s_2\}, \{r_1, r_2\}$*.*

Proof. Hu's 2-commodity flow theorem states that there exists a feasible 2-commodity flow if and only if the "cut condition" is satisfied. In the case of unit demands, the cut condition says that, for all $U \subseteq V$, the capacity $u(\delta(U))$ of the cut induced by U must be at least the number of terminal pairs which are separated by the cut.

It thus remains to show that the cut condition holds for terminal pairs $\{s_1, s_2\}$, $\{r_1, r_2\}$ if it holds for $\{s_1, r_1\}$, $\{s_2, r_2\}$ and for $\{s_1, r_2\}$, $\{s_2, r_1\}$. Consider an arbitrary $U \subseteq V$. If the corresponding cut separates neither $\{s_1, s_2\}$ nor $\{r_1, r_2\}$, nothing needs to be shown. If $\delta(U)$ separates one terminal pair, say, $\{s_1, s_2\}$, then it separates either $\{s_1, r_1\}$ or $\{s_2, r_1\}$ since s_1 and s_2 lie on different sides of the cut. In particular, the capacity of the cut is at least 1. Finally, if $\delta(U)$ separates both terminal pairs $\{s_1, s_2\}, \{r_1, r_2\}$, then it must separate either $\{s_1, r_1\}$ and $\{s_2, r_2\}$ or $\{s_1, r_2\}$ and $\{s_2, r_1\}$. In both cases the capacity of the cut is at least 2. □

We remark that Corollary 1 is no longer true if we replace "2-commodity flow" by "integral 2-commodity flow." A counterexample is given in Figure 1. Even, Itai, and Shamir show that finding an integer 2-commodity flow is NP-hard [9]. On the other hand, Hu's result states that there always exists a half-integral flow in this case. For a more detailed account of results we refer the reader to Schrijver's book [19, Chapter 71].

The next lemma shows that a partition of the senders and receivers into k-subsets each and the "addition" of the optimal solutions of the k subproblems induced by the pairs of subsets provide a lower bound on the optimal solution.

LEMMA 2. *Suppose that* $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_k$ *is a partition of* $\mathcal{S}$ *and that* $\mathcal{R}_1, \mathcal{R}_2, \ldots, \mathcal{R}_k$ *is a partition of* $\mathcal{R}$*. Let* I_i *be the* VPND *instance on graph* G *with senders* $\mathcal{S}_i$ *and receivers* $\mathcal{R}_i$*, and let* OPT_i *be the value of an optimal solution to instance* I_i*. Then the following holds:*

$$\sum_{i=1}^{k} OPT_i \le OPT.$$

Proof. Let $\mathcal{P}$ be an optimal set of paths for the original VPND instance with resulting capacity reservation $u : E \to \mathbb{R}_+$. The subset $\mathcal{P}_i \subseteq \mathcal{P}$ of paths with endpoints in $\mathcal{S}_i \cup \mathcal{R}_i$ defines a solution to subinstances I_i with capacity reservation $u_i : E \to \mathbb{R}_+$. It suffices to show that $u(e) \geq \sum_{i=1}^{k} u_i(e)$ for each edge $e \in E$.

It follows from (1) that for each $i = 1, 2, \ldots, k$

$$u_i(e) = \max_{M_i} |\{P_{rs} \in \mathcal{P}_i \mid e \in P_{rs} \text{ and } rs \in M_i\}|,$$

where M_i ranges over all bipartite matchings between senders $\mathcal{S}_i$ and receivers $\mathcal{R}_i$. We denote the matching for which the maximum is attained by $\tilde{M}_i$. Then, the disjoint union $\tilde{M} := \bigcup_{i=1}^{k} \tilde{M}_i$ is a bipartite matching between senders $\mathcal{S}$ and receivers $\mathcal{R}$. It thus follows from (1) that

$$\begin{aligned} u(e) &\geq |\{P_{rs} \in \mathcal{P} \mid e \in P_{rs} \text{ and } rs \in \tilde{M}\}| \\ &= \sum_{I=1}^{k} |\{P_{rs} \in \mathcal{P}_i \mid e \in P_{rs} \text{ and } rs \in \tilde{M}_i\}| = \sum_{i=1}^{k} u_i(e) \end{aligned}$$

for each edge $e \in E$. This concludes the proof. □

We are now ready to prove the following theorem which gives a new lower bound on the cost of an optimal VPND solution.

THEOREM 2. *Consider an arbitrary subset $\mathcal{R}' \subseteq \mathcal{R}$ of S receivers. Let M be a matching in the complete graph on $\mathcal{S} \cup \mathcal{R}'$. Then*

$$\sum_{vw \in M} \ell(v, w) \leq OPT.$$

Proof. Let $\mathcal{S} = \{s_1, s_2, \ldots, s_S\}$ and $\mathcal{R}' = \{r_1, r_2, \ldots, r_S\}$. It suffices to prove the claim for perfect matchings. Suppose that the matching consists of the edges

$$s_1s_2,\ s_3s_4, \ldots, s_{2k-1}s_{2k} \quad \text{and} \quad r_1r_2,\ r_3r_4, \ldots, r_{2k-1}r_{2k},$$
$$\text{and} \quad s_{2k+1}r_{2k+1},\ s_{2k+2}r_{2k+2}, \ldots, s_Sr_S.$$

Consider the following partition of $\mathcal{S}$ and $\mathcal{R}'$ into $S - k$ subsets $\mathcal{S}_i$ and $\mathcal{R}'_i$:

$$\begin{aligned} &\mathcal{S}_i = \{s_{2\,i-1}, s_{2\,i}\},\ \mathcal{R}'_i = \{r_{2\,i-1}, r_{2\,i}\}, && 1 \leq i \leq k, \\ &\mathcal{S}_i = \{s_i\},\ \mathcal{R}'_i = \{r_i\}, && 2\,k+1 \leq i \leq S. \end{aligned}$$

By Lemma 2, the sum of the optimum solutions OPT_i of the VPND subinstances I_i with senders $\mathcal{S}_i$ and receivers $\mathcal{R}'_i$ is a lower bound on OPT. Thus we need only to prove that $\ell(s_{2\,i-1}, s_{2\,i}) + \ell(r_{2\,i-1}, r_{2\,i}) \leq OPT_i$ for each $1 \leq i \leq k$.

An optimum solution to the subproblem I_i, $1 \leq i \leq k$, is a reservation of capacities that supports 2-commodity flows with unit demands for the terminal pairs $\{s_{2\,i-1}, r_{2\,i-1}\}$, $\{s_{2\,i}, r_{2\,i}\}$ and for the terminal pairs $\{s_{2\,i-1}, r_{2\,i}\}$, $\{s_{2\,i}, r_{2\,i-1}\}$. By Corollary 1, it must also support a 2-commodity flow for the terminal pairs $\{s_{2\,i-1}, s_{2\,i}\}$, $\{r_{2\,i-1}, r_{2\,i}\}$. Therefore, the cost of this solution is at least $\ell(s_{2\,i-1}, s_{2\,i}) + \ell(r_{2\,i-1}, r_{2\,i})$. This concludes the proof. □

3. The quality of a simple routing scheme. Consider the following simple VPND algorithm.

Algorithm 1 (simple routing scheme).

(1) *Compute a vertex $v \in V$ such that $\sum_{s \in \mathcal{S}} \ell(s, v) + \sum_{r \in \mathcal{R}} \ell(r, v)$ is minimal.*

(2) *Add one unit of capacity along the shortest path between each $u \in \mathcal{R} \cup \mathcal{S}$ and v.*

Algorithm 1 selects the vertex $v \in V$ which minimizes the sum of the distances from v to the union of the senders and receivers, and reserves one unit of capacity along each of the shortest paths. Note that the effects of installing capacities along the shortest paths is cumulative. In other words, if k shortest paths share the same edge, the algorithm adds k units of capacity to that edge. Moreover, we assume the shortest paths are computed with a consistent tie-breaking rule. This way, the edges with nonzero capacity form a tree.

Algorithm 1 produces an optimal tree reservation in the symmetric case (*SymT*) [11] and in the balanced case (*BalT*) [15]. In the symmetric case, Gupta et al. [11] showed that the tree produced by the algorithm is a 2-approximate solution to the optimum graph reservation. Italiano, Leonardi, and Oriolo [15] show that, in the balanced case, the produced tree is a 3-approximate solution to the optimum graph reservation.

In this section, we apply our new lower-bound result to show that the algorithm produces a tree solution which is within $1 + R/S$ from the optimum graph reservation. Thus (*BalG*) can also be approximated within a factor of two. We first need the following simple lower bound on OPT. Let $\ell(E') := \sum_{uv \in E'} \ell(u, v)$ for any subset of edges E'.

Lemma 3. *The sum of the distances between each sender-receiver pair is at most R times the optimum:*

$$\sum_{s \in \mathcal{S}} \sum_{r \in \mathcal{R}} \ell(s, r) \leq R \cdot OPT. \tag{2}$$

Proof. Let $B = (\mathcal{S} + \mathcal{R}, E^B)$ be the complete bipartite graph on the senders and receivers with edge-weights $\ell : E^B \to \mathbb{R}_+$ given by the shortest path distances in the graph G. The edges of B can be partitioned into a set $\mathcal{M}$ of R matchings. By Lemma 1, the cost $\ell(M)$ of each $M \in \mathcal{M}$ is at most OPT. Hence

$$\sum_{s \in \mathcal{S}} \sum_{r \in \mathcal{R}} \ell(s, r) = \sum_{M \in \mathcal{M}} \ell(M) \leq R \cdot OPT.$$

We are now ready to bound the approximation ratio provided by Algorithm 1.

Theorem 3. *Algorithm 1 is a $(1 + R/S)$-approximation algorithm for* VPND.

Proof. Let $G^m = (\mathcal{R} \cup \mathcal{S}, E^m)$ be the metric closure of $\mathcal{R} \cup \mathcal{S}$, i.e., the complete graph on $\mathcal{R} \cup \mathcal{S}$ with edge-weight $\ell(u, v)$ given by the shortest path distance between u and v in G. We show that there exists a node $u \in \mathcal{R} \cup \mathcal{S}$ such that the cost of the complete star centered at u satisfies

$$\sum_{v \in \mathcal{R} \cup \mathcal{S}} \ell(u, v) \leq (1 + R/S)\, OPT.$$

If $R = S$, the edges of E^m can be partitioned into $2S - 1$ perfect matchings. By Theorem 2, the weight of each matching is a lower bound on OPT. Since each edge is contained in exactly two stars of G^m,

$$\sum_{v\in\mathcal{R}\cup\mathcal{S}} \sum_{u\in\mathcal{R}\cup\mathcal{S}} \ell(v,\,u) = 2\ell(E^m) \leq 2(2S-1)\,OPT.$$

Thus there must exist one star, whose weight is at most $2(2S-1)\,OPT/(2S) < 2\,OPT$.

Suppose for the remainder of the proof that $R > S$. In the following we denote by $\mathcal{M}_\mathcal{S}$ and $\mathcal{M}_\mathcal{R}$ the set of matchings of cardinality at most $\lfloor S/2 \rfloor$ involving only senders and only receivers, respectively. Theorem 2 implies the inequality

$$\ell(M_\mathcal{S}) + \ell(M_\mathcal{R}) \;\leq\; OPT \qquad \text{for each } M_\mathcal{S} \in \mathcal{M}_\mathcal{S},\, M_\mathcal{R} \in \mathcal{M}_\mathcal{R}. \tag{3}$$

In consideration of (3), we distinguish two cases.

(A) $\ell(M_\mathcal{S}) \leq OPT/2$ *for each* $M_\mathcal{S} \in \mathcal{M}_\mathcal{S}$. Consider the subgraph $G^m_\mathcal{S}$ of G^m which is induced by the senders. The edges $E^m_\mathcal{S}$ of $G^m_\mathcal{S}$ can be partitioned into S matchings. Therefore

$$\sum_{s'\in\mathcal{S}} \sum_{s\in\mathcal{S}} \ell(s',s) \;=\; 2\,\ell(E^m_\mathcal{S}) \leq 2\,S\frac{OPT}{2} = S\,OPT. \tag{4}$$

Combining (4) and (2), one obtains

$$\sum_{s'\in\,\mathcal{S}} \left(\sum_{s\in\,\mathcal{S}} \ell(s',s) + \sum_{r\in\,\mathcal{R}} \ell(s',r) \right) \;\leq\; (S+R)\,OPT.$$

Therefore there is a sender s^* such that

$$\sum_{v\in\,\mathcal{S}\,\cup\mathcal{R}} \ell(s^*,\,v) \leq (1+R/S)OPT.$$

(B) $\ell(M_\mathcal{S}) > OPT/2$ *for some maximum weight matching* $M_\mathcal{S} \in \mathcal{M}_\mathcal{S}$. Let $G^m_\mathcal{R}$ denote the subgraph of G^m which is induced by the receivers. We will show below that, for any maximal matching $\tilde{M}$ in $G^m_\mathcal{R}$,

$$\ell(\tilde{M}) \leq (R/S)\,OPT/2. \tag{5}$$

Since the edges of $G^m_\mathcal{R}$ can be partitioned into at most R maximal matchings, we can then argue in a similar manner as in case (A) that

$$\sum_{r'\in\,\mathcal{R}} \sum_{r\in\,\mathcal{R}} \ell(r,\,r') \;\leq\; 2\,R\,\frac{R}{S}\,\frac{OPT}{2} \;=\; (R^2/S)\,OPT.$$

Together with (2) this implies

$$\sum_{r'\in\,\mathcal{R}} \left(\sum_{s\in\,\mathcal{S}} \ell(s,r') + \sum_{r\in\,\mathcal{R}} \ell(r,r') \right) \;\leq\; (R + R^2/S)\,OPT,$$

from which we conclude that there is a receiver r^* satisfying

$$\sum_{v\in\,\mathcal{S}\,\cup\mathcal{R}} \ell(v,\,r^*) \leq (1+R/S)OPT.$$

It remains to prove (5). We distinguish between the two subcases in which S is even and S is odd.

(B.1) *S is even.* Theorem 2, together with the assumption $\ell(M_{\mathcal{S}}) > OPT/2$, implies $\ell(M_{\mathcal{R}}) \leq OPT/2$ for each matching $M_{\mathcal{R}} \in \mathcal{M}_{\mathcal{R}}$. Note that $|\tilde{M}| = \lfloor R/2 \rfloor \geq S/2$. Consider the $S/2$ most expensive edges M' of $\tilde{M}$. Since $M' \in \mathcal{M}_{\mathcal{R}}$, $\ell(M') \leq OPT/2$. Hence the average cost of one edge of $\tilde{M}$ is upper bounded by $(OPT/2)/(S/2) = OPT/S$. Since $\tilde{M}$ has at most $R/2$ edges, we get

$$\ell(\tilde{M}) \leq |\tilde{M}| \frac{OPT}{S} \leq \frac{R}{2}\,\frac{OPT}{S} = (R/S)OPT/2.$$

(B.2) *S is odd.* There is a sender s^* which is missed by the maximum cost matching $M_{\mathcal{S}}$ of $G^m_{\mathcal{S}}$. For each matching $M_{\mathcal{R}} \in \mathcal{M}_{\mathcal{R}}$ and $r_1^* \in \mathcal{R}$ which is not matched by $M_{\mathcal{R}}$, Theorem 2 yields

$$\ell(M_{\mathcal{S}}) + \ell(M_{\mathcal{R}}) + \ell(s^*, r_1^*) \;\leq\; OPT,$$

and hence

$$\ell(M_{\mathcal{R}}) + \ell(s^*, r_1^*) \;\leq\; OPT/2.$$

Consider any other receiver r_2^* which is not matched by $M_{\mathcal{R}}$. This receiver must exist since $R > S$. By the triangle inequality one has $\ell(r_1^*, r_2^*) \leq \ell(s^*, r_1^*) + \ell(s^*, r_2^*)$. As a result we get

$$\ell(M_{\mathcal{R}}) + 1/2\,\ell(r_1^*, r_2^*) \;\leq\; OPT/2 \tag{6}$$

for each matching $M_{\mathcal{R}} \in \mathcal{M}_{\mathcal{R}}$ and receivers r_1^*, r_2^* which are missed by $M_{\mathcal{R}}$.

Now consider the $(S-1)/2$ most expensive edges M' of $\tilde{M}$, and let e' be the next most expensive edge of $\tilde{M}$. Since $M' \in \mathcal{M}_{\mathcal{R}}$, by (6),

$$\ell(M') + 1/2\,\ell(e') \leq OPT/2.$$

It follows that half the average cost of one edge of $\tilde{M}$ is upper bounded by $(OPT/2)/(S-1+1) = OPT/(2\,S)$, from which we conclude

$$\ell(\tilde{M}) \leq 2\,|\tilde{M}| \frac{OPT}{2\,S} \leq 2\frac{R}{2}\frac{OPT}{2\,S} = (R/S)\,OPT/2.$$

4. A new algorithm for VPND.

In section 3 we described an algorithm which guarantees a good approximation ratio for R close to S. Here we present a better approximation algorithm in case R is sufficiently larger than S.

The algorithm by Gupta et al. [12] constructs one random "high-bandwidth core," i.e., a small Steiner tree with high capacity, where the terminals are a random sender and a random subset of receivers. Such a Steiner tree collects and distributes the demands from outside, and routes them along its high capacity paths. Our algorithm is also based on Steiner tree computations, but we proceed by connecting each sender to a previously sampled subset of receivers via S distinct Steiner trees of low capacity, and by connecting the other receivers along their shortest paths to the sampled subset (see Figure 2). More precisely, our algorithm works as follows.

Algorithm 2.

(1) *Partition $\mathcal{R}$ into S subsets uniformly at random. Select one subset $\mathcal{R}'$ uniformly at random, among the nonempty subsets in the partition.*

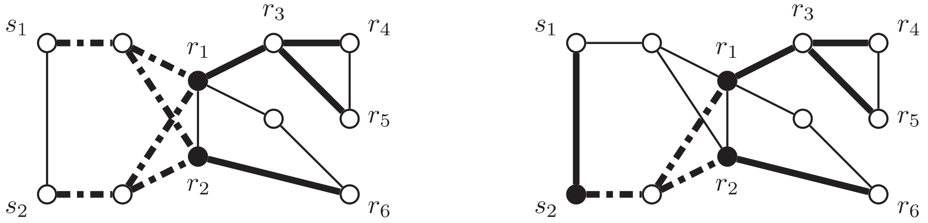

FIG. 2. *Intuitive comparison between Algorithm* 2 *(on the left) and the algorithm in* [12]. *Black nodes form the randomly sampled subsets. Positive capacity is reserved on thick edges only: Dashed thick edges correspond to Steiner trees, while full ones correspond to shortest paths.*

(2) *For each sender $s \in \mathcal{S}$, compute a ρ_{st}-approximate Steiner tree $T(s)$ on $\{s\} \cup \mathcal{R}'$, and add one unit of capacity to each edge of $T(s)$.*

(3) *Add one unit of capacity along the shortest path between each receiver $r \in \mathcal{R}$ and $\mathcal{R}'$.*

It remains to specify the path between each sender-receiver pair (s, r). Assume that the shortest paths are computed with a consistent tie-breaking rule. Let r^* be the receiver in $\mathcal{R}'$ which is closest to r. The path P_{sr} between s and r is obtained by concatenating the (simple) path between s and r^* in $T(s)$, with the shortest path between r^* and r.

The thereby produced solution is not a tree solution. Though an optimal tree solution is a constant-factor approximation to an optimal graph solution, it is known [11] that an optimal solution to $(AsymT)$ is not an optimal solution to VPND. All previous constant-factor approximation algorithms for VPND, however [12, 7], produce tree reservations.

Before we proceed with the analysis of Algorithm 2, we state a corollary of Lemma 2. Here, given a subset V' of nodes, we denote the cost of the optimum Steiner tree on V' by $st(V')$.

COROLLARY 2 (see [12]). *Let $\mathcal{R}_1, \mathcal{R}_2, \ldots, \mathcal{R}_s$ be a partition of $\mathcal{R}$ into S (disjoint) subsets. Consider an arbitrary perfect matching between $\mathcal{S}$ and this family of subsets. Let $\mathcal{R}(s)$ be the subset matched with sender s. The sum over $\mathcal{S}$ of the costs of the optimum Steiner trees on $\{s\} \cup \mathcal{R}(s)$ is a lower bound on OPT:*

$$\sum_{s \in \mathcal{S}} st(\{s\} \cup \mathcal{R}(s)) \leq OPT.$$

Proof. This follows from Lemma 2 since a solution of a subinstance $\{s\}, \mathcal{R}(s)$ contains a Steiner tree with terminals $\{s\} \cup \mathcal{R}(s)$. ▯

THEOREM 4. *Algorithm* 2 *is a $(2 + \rho_{st})/(1 - e^{-R/S})$-approximation algorithm for* VPND.

Theorem 4 is a straightforward consequence of the following lemmas.

LEMMA 4. *For a uniformly chosen random sender s',*

$$E[st(\{s'\} \cup \mathcal{R}')] \leq \frac{OPT}{S(1 - e^{-R/S})}.$$

Proof. Consider the following random process. For each receiver r, we *assign* r to a sender s chosen uniformly at random. Let $\mathcal{R}(s)$ be the subset of receivers assigned to s. Note that the subsets $\mathcal{R}(s)$ partition $\mathcal{R}$ into S (possibly empty) subsets. Thus, by Corollary 2,

$$\sum_{s\in\mathcal{S}} st(\{s\}\cup\mathcal{R}(s)) \le OPT.$$

This means that, for the random sender s',

$$E[st(\{s'\}\cup\mathcal{R}(s'))] \le OPT/S.$$

Let A denote the event that $\mathcal{R}(s')$ is empty. By elementary probability theory,

$$E[st(\{s'\}\cup\mathcal{R}(s'))] = P(A)\, E[st(\{s'\}\cup\mathcal{R}(s')) \mid A] + P(\overline{A})\, E[st(\{s'\}\cup\mathcal{R}(s')) \mid \overline{A}].$$

Now observe that

$$P(\overline{A}) = 1-(1-1/S)^R \ge 1-e^{-R/S}.$$

Moreover

$$E[st(\{s'\}\cup\mathcal{R}(s')) \mid A] = E[st(\{s'\})] = 0.$$

Thus

$$E[st(\{s'\}\cup\mathcal{R}(s')) \mid \overline{A}] = \frac{E[st(\{s'\}\cup\mathcal{R}(s'))]}{P(\overline{A})} \le \frac{OPT}{S(1-e^{-R/S})}.$$

The claim follows by observing that, given $\overline{A}$, $\mathcal{R}(s')$ and $\mathcal{R}'$ are identically distributed. Thus

$$E[st(\{s'\}\cup\mathcal{R}')] = E[st(\{s'\}\cup\mathcal{R}(s')) \mid \overline{A}] \le \frac{OPT}{S(1-e^{-R/S})}.$$

Lemma 5. *The expected cost of the capacity installed in the second step of Algorithm* 2 *is at most*

$$\rho_{st}\, OPT/(1-e^{-R/S}).$$

Proof. The expected cost considered is

$$E\left[\sum_{s\in\mathcal{S}} c(T(s))\right],$$

where $c(T(s))$ is the cost of the Steiner tree $T(s)$. Of course

$$c(T(s)) \le \rho_{st}\, st(\{s\}\cup\mathcal{R}').$$

Let s' be a sender chosen uniformly at random. By Lemma 4,

$$E\left[\sum_{s\in\mathcal{S}} c(T(s))\right] \le \rho_{st}\, E\left[\sum_{s\in\mathcal{S}} st(\{s\}\cup\mathcal{R}')\right] = \rho_{st}\, S\, E[st(\{s'\}\cup\mathcal{R}')]$$

$$\le \rho_{st}\, S\, \frac{OPT}{S(1-e^{-R/S})} = \frac{\rho_{st}\, OPT}{1-e^{-R/S}}.$$

LEMMA 6. *The expected cost of the capacity installed in the third step of Algorithm* 2 *is at most*

$$2\,OPT/(1-e^{-R/S}).$$

Proof. Let r' be an arbitrary receiver in $\mathcal{R}'$. Observe that the probability of any other receiver r'' being in $\mathcal{R}'$, given that r' is in $\mathcal{R}'$, is $1/S$. In fact, let $\mathcal{R}^*$ be a random (possibly empty) partition element. Then

$$P(r' \in \mathcal{R}') = P(r' \in \mathcal{R}^* \mid \mathcal{R}^* \neq \emptyset) = \frac{P(r' \in \mathcal{R}^* \cap \mathcal{R}^* \neq \emptyset)}{P(\mathcal{R}^* \neq \emptyset)}$$
$$= \frac{P(r' \in \mathcal{R}^*)}{P(\mathcal{R}^* \neq \emptyset)} = \frac{1/S}{1-(1-1/S)^R}.$$

By basically the same argument

$$P(r' \in \mathcal{R}' \cap r'' \in \mathcal{R}') = \frac{(1/S)^2}{1-(1-1/S)^R}.$$

Thus

$$P(r'' \in \mathcal{R}' \mid r' \in \mathcal{R}') = \frac{P(r'' \in \mathcal{R}' \cap r' \in \mathcal{R}')}{P(r' \in \mathcal{R}')} = \frac{(1/S)^2/(1-(1-1/S)^R)}{(1/S)/(1-(1-1/S)^R)} = \frac{1}{S}.$$

Now consider the following random process. In step t, let $\mathcal{A}_t$ be the subset of receivers considered so far, and let $\mathcal{B}_t$ be the bought receivers in $\mathcal{A}_t$. Initially $\mathcal{A}_1 = \mathcal{B}_1 = \{r'\}$, where r' is a random receiver. In step t, we consider the receiver $r_t \in \mathcal{R} \setminus \mathcal{A}_t$ which is closest to $\mathcal{B}_t$, and we set $\mathcal{A}_{t+1} = \mathcal{A}_t \cup \{r_t\}$. Then, with probability $1/S$, we *buy* r_t; that is,

- we add S units of capacity along the shortest path from r_t to $\mathcal{B}_t$, and
- we set $\mathcal{B}_{t+1} = \mathcal{B}_t \cup \{r_t\}$.

Otherwise, we *rent* r_t; that is,

- we add one unit of capacity along the shortest path from r_t to $\mathcal{B}_t$, and
- we set $\mathcal{B}_{t+1} = \mathcal{B}_t$.

Note that, at the end of the process, the set of bought receivers $\mathcal{B}'$ has the same distribution as the set $\mathcal{R}'$ of selected receivers. Let $\ell(v, V') = \min_{v' \in V'}\{\ell(v, v')\}$ denote the minimum distance between a node v and a subset of nodes V'. The expected cost of the third step of the algorithm is upper bounded by the expected cost c_{rent} of renting receivers

$$E\left[\sum_{r \in \mathcal{R}\setminus\mathcal{R}'} \ell(r, \mathcal{R}')\right] = E\left[\sum_{r_t \in \mathcal{R}\setminus\mathcal{B}'} \ell(r_t, \mathcal{B}')\right] \leq E\left[\sum_{r_t \in \mathcal{R}\setminus\mathcal{B}'} \ell(r_t, \mathcal{B}_t)\right]$$
$$= E\left[\sum_{r_t \in \mathcal{R}} \left(1-\frac{1}{S}\right) \ell(r_t, \mathcal{B}_t)\right] = c_{rent},$$

where the inequality comes from the fact that $\mathcal{B}_t \subseteq \mathcal{B}'$ for any t.

The expected cost c_{buy} of buying receivers is an upper bound on c_{rent}:

$$c_{rent} = E\left[\sum_{r_t\in\mathcal{R}}\left(1-\frac{1}{S}\right)\ell(r_t,\,\mathcal{B}_t)\right] \le E\left[\sum_{r_t\in\mathcal{R}}\left(\frac{1}{S}\right)S\,\ell(r_t,\,\mathcal{B}_t)\right]$$
$$= E\left[\sum_{r_t\in\mathcal{B}'} S\,\ell(r_t,\,\mathcal{B}_t)\right] = c_{buy}\,.$$

Note that c_{buy} is equal to S times the expected cost of the Steiner tree on $\mathcal{B}'$ which is obtained via the minimum spanning tree heuristic (starting Prim's algorithm from node r'). It is well known that this heuristic provides a 2-approximate solution [17]. Thus

$$c_{buy} \le 2\,S\,E[st(\mathcal{B}')] = 2\,S\,E[st(\mathcal{R}')].$$

For a random sender s', by Lemma 4,

$$E[st(\mathcal{R}')] \le E[st(\{s'\}\cup\mathcal{R}')] \le \frac{OPT}{S(1-e^{-R/S})}.$$

Altogether,

$$E\left[\sum_{r\in\mathcal{R}}\ell(r,\mathcal{R}')\right] \le c_{rent} \le c_{buy} \le 2\,S\,\frac{OPT}{S(1-e^{-R/S})} = \frac{2\,OPT}{1-e^{-R/S}}.$$

In section 3 we described a $(1+R/S)$-approximation algorithm. The factors $1+R/S$ and $(2+\rho_{st})/(1-e^{-R/S})$ are equal for $R/S = 2.78\ldots < 2.79$. Note that $1+R/S$ is increasing in R/S and $(2+\rho_{st})/(1-e^{-R/S})$ is decreasing in R/S. It follows that a combination (taking the minimum cost solution) of Algorithms 1 and 2 has an expected approximation guarantee of 3.79, which is a considerable improvement compared to the 5.55-approximation ratio achieved by Gupta, Kumar, and Roughgarden [12].

Theorem 5. *The combination (taking the cheaper solution) of Algorithms* 1 *and* 2 *is an expected* 3.79*-approximation algorithm for* VPND.

5. Computing optimum Steiner trees. The performance ratios of Algorithms 1 and 2 meet roughly at $R/S \simeq 2.78$. In this case, the sampled set $\mathcal{R}'$ of receivers has expected constant size. An optimum Steiner tree on a graph with n nodes and t terminals can be computed in $O(3^t\,n + 2^t\,n^2 + n^3)$ time with the Dreyfus–Wagner algorithm [5]. This suggests the following variant of Algorithm 2, which computes optimal Steiner trees in step (2), instead of ρ_{st}-approximate ones, whenever $|\mathcal{R}'| \le \log n$. Here n is the number of nodes in the original graph G. Without loss of generality, we assume n is sufficiently large.

Algorithm 3.

(1) *Partition $\mathcal{R}$ into S subsets uniformly at random. Select one subset $\mathcal{R}'$ uniformly at random, among the nonempty subsets in the partition.*

(2) *For each sender $s \in \mathcal{S}$, compute a ρ_{st}-approximate Steiner tree $T(s)$ on $\{s\}\cup\mathcal{R}'$ if $|\mathcal{R}'| > \log n$. Otherwise, compute an optimum Steiner tree $T(s)$ on $\{s\}\cup\mathcal{R}'$. In both cases, add one unit of capacity to each edge of $T(s)$.*

(3) *Add one unit of capacity along the shortest path between each receiver $r \in \mathcal{R}$ and $\mathcal{R}'$.*

Clearly, Algorithm 3 is a polynomial-time algorithm whose expected approximation guarantee is not worse than the one of Algorithm 2. In particular, if R/S is very large, say, $R/S \geq \log\log n$, the approximation achieved is

$$\frac{2+\rho_{st}}{1-e^{-R/S}} \leq \frac{2+\rho_{st}}{1-1/\log n} = 2+\rho_{st}+o(1) < 3.55.$$

What can be said about the approximation guarantee if $R/S \leq \log\log n$? In that case, the expected size of $\mathcal{R}'$ is $1+(R-1)/S < 1+\log\log n$. The probability that the size of $\mathcal{R}'$ exceeds $\log n$ is at most $(1+\log\log n)/\log n$ by Markov's inequality. Thus with high probability Algorithm 3 computes optimum Steiner trees. When this happens, the approximation ratio is bounded by $3.325\ldots < 3.326$. In the very unlikely event that Algorithm 3 computes ρ_{st}-approximate Steiner trees, the approximation guaranteed by Algorithm 1 alone is $O(\log\log n)$. Hence this event contributes to the expected approximation ratio with $o(1)$ only. This is the intuition behind the following theorem.

THEOREM 6. *For a sufficiently large n, the combination (taking the cheaper solution) of Algorithms* 1 *and* 3 *is an expected* 3.55*-approximation algorithm for* VPND.

Proof. Following the discussion above, if $R/S > \log\log n$, the expected approximation ratio achieved is $2+\rho_{st}+o(1) < 3.55$. Then we can restrict our analysis to the case $R/S \leq \log\log n$. Let APX denote the expected cost of the solution computed. One has

$$APX \leq E\left[\min\left\{(1+R/S)\,OPT, \sum_{s\in\mathcal{S}} c(T(s)) + \sum_{r\in\mathcal{R}} \ell(r,\mathcal{R}')\right\}\right].$$

Of course,

$$APX \leq (1+R/S)OPT, \tag{7}$$

and

$$APX \leq E\left[\sum_{r\in\mathcal{R}} \ell(r,\mathcal{R}')\right] + E\left[\min\left\{(1+R/S)\,OPT, \sum_{s\in\mathcal{S}} c(T(s))\right\}\right].$$

By Lemma 6,

$$E\left[\sum_{r\in\mathcal{R}} \ell(r,\mathcal{R}')\right] \leq \frac{2\,OPT}{1-e^{-R/S}}. \tag{8}$$

Let A denote the event that $R' = |\mathcal{R}'| \leq \log n$. By elementary probability theory one has

$$\begin{aligned} E\left[\min\left\{(1+R/S)OPT, \sum_{s\in\mathcal{S}} c(T(s))\right\}\right] &\leq P(\overline{A})\, E\left[(1+R/S)\,OPT \mid \overline{A}\right] \\ &\quad + P(A)\, E\left[\sum_{s\in\mathcal{S}} c(T(s)) \mid A\right]. \end{aligned} \tag{9}$$

We now consider both terms separately. By Markov's inequality one has $P(\overline{A}) \leq (1 + \log\log n)/\log n$. Thus

$$\begin{aligned} P(\overline{A})E\big[(1 + R/S)\,OPT \mid \overline{A}\big] &\leq P(\overline{A})E\big[(1 + \log\log n)\,OPT \mid \overline{A}\big] \\ &\leq \frac{(1 + \log\log n)^2}{\log n} OPT. \end{aligned}$$

Given A, Algorithm 3 computes optimal Steiner trees $T(s)$ of cost $st(\{s\} \cup \mathcal{R}')$. Also $E\big[st(\{s\} \cup \mathcal{R}') \mid R' \leq h\big]$ is a nondecreasing function of h. Thus, from the proof of Lemma 5, the second term on the right of (9) can be bounded by

$$P(A)\,E\left[\sum_{s \in \mathcal{S}} c(T(s)) \mid A\right] \leq E\left[\sum_{s \in \mathcal{S}} st(\{s\} \cup \mathcal{R}')\right] \leq \frac{OPT}{1 - e^{-R/S}}.$$

One therefore has

$$\begin{aligned} E\left[\min\left\{(1 + R/S)\,OPT, \sum_{s \in \mathcal{S}} c(T(s))\right\}\right] &\leq \frac{(1 + \log\log n)^2}{\log n} OPT + \frac{OPT}{1 - e^{-R/S}} \\ &\leq \left(1 + \frac{(1 + \log\log n)^2}{\log n}\right) \frac{OPT}{1 - e^{-R/S}}. \qquad (10) \end{aligned}$$

Combining (7), (8), and (10), we conclude that

$$APX \leq \min\left\{(1 + R/S)\,OPT, \left(3 + \frac{(1 + \log\log n)^2}{\log n}\right) \frac{OPT}{1 - e^{-R/S}}\right\}.$$

Thus, for a sufficiently large n, the expected approximation ratio for $R/S \leq \log\log n$ is upper bounded by $3.325\ldots < 3.326$. Altogether, the approximation ratio is

$$\min\{3.326,\ 2 + \rho_{st} + o(1)\} < 3.55.$$

COROLLARY 3. *There is an expected* 3.55*-approximation algorithm for* VPND.

Proof. When n is upper bounded by a constant, the optimum solution can be computed in polynomial time by trivial enumeration. The claim follows from Theorem 6. □

THE TIME-COMPLEXITY OF LOCAL DECISION IN DISTRIBUTED AGREEMENT*

PARTHA DUTTA[†], RACHID GUERRAOUI[‡], AND BASTIAN POCHON[‡]

Abstract. Agreement is at the heart of distributed computing. In its simple form, it requires a set of processes to decide on a common value out of the values they propose. The time-complexity of distributed agreement problems is generally measured in terms of the number of communication rounds needed to achieve a global decision, i.e., for *all* nonfaulty (correct) processes to reach a decision. This paper studies the time-complexity of *local* decisions in agreement problems, which we define as the number of communication rounds needed for *at least one* correct process to decide. We explore bounds for *early* local decision that depend on the number f of actual failures (that occur in a given run of an algorithm), out of the maximum number t of failures tolerated (by the algorithm). We first consider the synchronous message-passing model where we give tight local decision bounds for three variants of agreement: consensus, uniform consensus, and (nonblocking) atomic commit. We use these results to (1) show that, for consensus, local decision bounds are not compatible with global decision bounds (roughly speaking, they cannot be reached by the same algorithm), and (2) draw the first sharp line between the time-complexity of uniform consensus and atomic commit. Then we consider the eventually synchronous model, where we give tight local decision bounds for synchronous runs of uniform consensus. (In this model, consensus and uniform consensus are similar, atomic commit is impossible, and one cannot bound the number of rounds to reach a decision in nonsynchronous runs of consensus algorithms.) We prove a counterintuitive result that the early local decision bound is the same as the early global decision bound. We also give a matching early deciding consensus algorithm that is significantly better than previous eventually synchronous consensus algorithms.

Key words. distributed systems, agreement problems, lower bounds

1. Introduction.

Local versus global agreement decisions. Determining how long it takes to reach agreement among a set of processes is an important question in distributed computing. For instance, the performance of a replicated system is impacted by the performance of the underlying consensus service used to ensure that the replica processes agree on the same order to deliver client requests [20]. Similarly, the performance of a distributed transactional system is impacted by the performance of the underlying atomic commit service used to ensure that the database servers agree on a transaction outcome [15].

Traditionally, lower bounds on the time-complexity of distributed agreement have been stated in terms of the number of communication rounds (also called communication steps) needed for *all* correct processes to decide [21] (i.e., *global decision*), or

even *halt* [6], possibly as a function of the number of failures f that actually occur in a given run of an algorithm, out of the total number of failures t that are tolerated by the algorithm. (In this paper we consider only crash-stop failures.)

From a practical perspective, what we might sometimes want to measure and optimize is the number of rounds needed for *at least one* correct process to decide, i.e., for a *local decision.* Indeed, a replicated service can respond to its clients as soon as a single replica decides on a reply (and knows that other replicas will reach the same decision). Similarly, the client of an atomic commit service might be happy to know the outcome of a transaction once the outcome has been determined, even if some database servers have yet to be informed of the outcome.

Motivations. Surprisingly, despite the large body of work on the performance of agreement, so far, no study on local decision lower bounds has appeared in the literature. To get an intuition of some of the specific ramifications underlying such a study, consider the consensus problem [27, 22] in the synchronous model, where a set of processes, $\{p_1, p_2, \ldots, p_n\}$, proceeds by exchanging messages in a round by round manner, and t out of the n processes may fail by crashing [23].

In this problem, the processes must decide on a common final value, out of the values they initially proposed, such that all correct processes eventually decide and agree on a common decision. The following algorithm (from [16]) conveys the fact that there can indeed be a difference between local and global decision lower bounds. (Round numbers start from 1.) At the beginning of round 1, process p_1 decides on its proposal value and then sends its decision value to all processes. At the end of every round $i \geq 1$, process p_{i+1} decides on the value contained in the last received message, and if p_{i+1} has not received any message, p_{i+1} decides on its proposal value. Process p_{i+1} then sends its decision value to all processes in round $i+1$. (The correct process with the lowest id, say, p_j, succeeds in sending its decision value to all processes in round j. Subsequently, all processes with higher ids decide and propagate the decision value of p_j.) If there are no failures, i.e., $f = 0$, then p_1 decides before sending any message in round 1, and we say that p_1 decides in round 0. In runs of this algorithm with at most $1 \leq f \leq t$ failures, at least one correct process decides by round f. Hence, if we denote by l_f the tight local decision lower bound for consensus in runs of the synchronous model with f failures, the very existence of the algorithm means that $l_f \leq f$. In fact, a closer look reveals that l_f is exactly f. However, if we denote by g_f the tight global decision lower bound, we know from [21] that g_f is exactly $f + 1$. This observation opens several questions.

1. Can we match both lower bounds with the *same* algorithm? The synchronous consensus algorithm we just sketched matches the lower bound $l_f = f$ but clearly does not match the lower bound $g_f = f + 1$. Is there any other algorithm that does so? Otherwise, we would be highlighting a rather interesting trade-off in the design of consensus algorithms.

2. What is the impact of the very nature of the agreement?

(i) Consider, for instance, the *uniform* variant of consensus [18], where no process disagrees with any other process, even one that crashed. Clearly, the algorithm sketched above needs to be revisited. We can easily exhibit a uniform consensus algorithm in which at least one correct process decides by round $f + 1$, in runs with at most f failures; i.e., $l_f \leq f + 1$. Additionally, we know from [4, 19] that, for most values of f, $g_f = f + 2$. Is $g_f = l_f + 1$?

(ii) Similarly, consider the nonblocking atomic commit problem [29, 18], where the processes have to decide 0 if some process proposes 0, and have to decide 1 if no process proposes 0 or crashes. We know that the tight global decision lower bound for atomic commit is the same as for uniform consensus [3, 10]. But, do the two problems have the same tight local decision bounds as well?

3. What is the impact of the model? Consider consensus, for instance, in the eventually synchronous model [11]. If we compare (a) the number of rounds g_f^{es} needed for all correct processes to decide in *synchronous* runs with f process crashes, and (b) the number of rounds l_f^{es} needed for at least one correct process to decide in such runs, is $g_f^{es} = l_f^{es} + 1$?

Contributions. 1.We show in the synchronous model that, except for some specific values of f (which we make precise in the paper), $g_f = l_f + 1$ for consensus, uniform consensus, and nonblocking atomic commit. (In fact, to exhibit a matching algorithm for uniform consensus and nonblocking atomic commit, we give an algorithm for the "stronger" interactive consistency problem [27].) Furthermore, we highlight an interesting trade-off in the design of consensus algorithms by showing that no consensus algorithm can match both global and local decision bounds. More precisely, no consensus algorithm can match both l_{f+1} and g_f. In addition, we show that, for the failure-free case (i.e., $f = 0$) of nonblocking atomic commit, the local decision bound is higher than that of uniform consensus. Since both problems have identical global decision lower bounds [3, 10], we draw the first line between their time-complexity.

2. We also consider uniform consensus in the eventually synchronous model. (In this model, nonblocking atomic commit is not solvable when $t \geq 1$, and consensus is equivalent to uniform consensus [16].) We determine a local decision lower bound of $f + 2$ rounds for synchronous runs of the model, with f failures (for $f \leq t - 3$). Then we present an algorithm that, in synchronous runs with f failures, globally (and hence locally) decides in $f + 2$ rounds. In addition to matching the local decision bound, to our knowledge, our algorithm is the first to match the $f + 2$ rounds global decision lower bound presented in [4, 19, 9]. In other words, we show that, for synchronous runs of the eventually synchronous model, tight local decision bounds are the same as for global decision; i.e., $g_f^{es} = l_f^{es} = f + 2$.

Related work. The consensus problem was introduced in [27, 22] and (nonblocking) atomic commit was defined in [15, 29]. The distinction between consensus and uniform consensus, and the relationship with the atomic commit problem were discussed in [18, 16]. Initial lower bound results on the time-complexity of agreement problems were proved in [13] and studied further in [21, 7, 25, 12, 1]. The eventually synchronous model was introduced in [5, 11].

In the synchronous model, one of the initial early halting agreement algorithms was presented in [21]. The early halting lower bound for consensus was proved in [6]. The early decision lower bound for uniform consensus and its difference from the nonuniform case were studied in [4, 19].

In the eventually synchronous model, the first consensus algorithm was presented in [11]. The equivalence between consensus and uniform consensus in the eventually synchronous model was shown in [16]. Tight bounds for synchronous runs of the eventually synchronous model in the failure-free case ($f = 0$) were shown in [19, 28, 26] and in the worst-case ($f = t$) were shown in [9]. Techniques that use forward inductions to prove lower bounds on agreement problems were introduced in [24, 1].

Roadmap. Section 2 recalls the models we consider. Section 3 recalls the definitions of the agreement problems we study. In section 4, we introduce the definition of our local decision metric, and we recall other time-complexity metrics. We also devise a compact notation for presenting various lower bound results on agreement problems. Section 5 recalls the layering technique of [24], also used in [19], which we slightly extend to prove local decisions results. Sections 6 and 7 present our lower bound results and matching algorithms in the synchronous model, respectively. The lower bound results for the eventually synchronous model and the matching algorithm are presented in sections 8 and 9, respectively. Section 10 concludes the paper.

2. Models. The distributed system we consider consists of a set of $n \geq 3$ processes, denoted by $\Pi = \{p_1, p_2, \ldots, p_n\}$, that communicate by message-passing: every pair of processes is connected by a bidirectional communication channel that does not create, duplicate, or alter messages. However, messages may be lost or reordered. The processes may fail by crashing and do not recover from a crash. The computation proceeds in rounds of message-exchange with round numbers starting from 1 and increasing by 1 in every round. A distributed algorithm A is a collection of deterministic automata, where the automaton for each process executes the following two phases in every round: (a) in the *send phase*, the processes send messages to all processes; (b) in the *receive phase*, the processes receive some messages sent in the send phase (of the current round or of a lower round) and update local states (which might include a decision event). A *run* of algorithm A is an infinite sequence of rounds of A. A *partial run* is a finite prefix of some run. A (partial) run r *extends* some partial run pr if pr is a prefix of r. A process that does not crash in a run is said to be *correct* in that run; otherwise the process is *faulty.* We say that a message m sent in a run is *lost* (in that run) if m is never received in that run.

In the distributed system described above, a *model* is a set of runs selected by restricting when processes can crash and specifying which messages are received. A *submodel* of a model M is a model that is a subset of M. We consider the following models.

- For every t such that $0 \leq t \leq n-1$, we define the t-resilient synchronous crash-stop model [23], denoted SCS_t, as follows. In every given run of SCS_t, the following properties hold: (1) if a process starts some round k then it either completes that round or crashes; (2) at most t processes crash; and (3) in round k, if p_i completes the send phase of the round, then every process that completes the receive phase of the round receives in that phase the round k message sent by p_i. (If p_i crashes in the send phase of round k, then there are no delivery guarantees—an arbitrary subset of messages sent by p_i in round k may be lost.)
- For every t such that $0 \leq t \leq n-1$, we define $\mathrm{SCS1}_t$ as the submodel of SCS_t that contains those runs of SCS_t in which at most one process crashes in a round.
- For every t such that $0 \leq t \leq n-1$, we define the t-resilient eventually synchronous crash-stop model, denoted ES_t, as follows. In ES_t, the runs may be "asynchronous" for an arbitrary yet finite number of rounds but eventually become "synchronous." A message sent in the "asynchronous period" may be *delayed* for a finite number of rounds, i.e., received in a round higher than the round in which it was sent. More precisely, in every given run of ES_t, the following properties hold: (1) if a process starts some round k then it either completes that round or crashes; (2) (*t-resilience*) at most t processes crash, and every process that completes any round k receives in that round the round k messages from at least $n-t$ processes; (3) (*reliable channels*) every message sent by a correct process to a correct process in any round k

is received in round k or in a higher round; (4) (*eventual synchrony*) there is an unknown but finite round number GSR (global stabilization round) such that, in every round $k \geq GSR$, if p_i completes the send phase of the round k, then every process that completes the receive phase of the round receives in that phase the round k message sent by p_i. (If p_i crashes in the send phase of round k, then, similar to SCS_t, there are no delivery guarantees; an arbitrary subset of messages sent by p_i in round k may be lost.) Also, we say that the run is *synchronous from round GSR*.

Observe that, for every $0 \leq f \leq t \leq n-1$, SCS_f is a submodel of SCS_t, and ES_f is a submodel of ES_t. Furthermore, every run of SCS_t is a run of ES_t with $GSR = 1$. Thus, SCS_t is a submodel of ES_t.

Hereafter, we make a slight change in terminology: instead of saying that there is a unique synchronous model, we say that each of the $2n$ models SCS_t and $SCS1_t$ $(0 \leq t \leq n-1)$ is a different synchronous model (i.e., there is no unique synchronous model). Similarly, we say that each of the n models ES_t $(0 \leq t \leq n-1)$ is a different eventually synchronous model.

3. Agreement problems. We consider three agreement problems: consensus, uniform consensus, and nonblocking atomic commit.

- In the (nonuniform) *consensus* problem [22], denoted NC, the processes start with a proposal value and eventually decide on a final value such that the following properties are satisfied: (validity) if a process decides v, then some process has proposed v; (agreement) no two correct processes decide differently; and (termination) every correct process eventually decides.
- *Uniform consensus* [18], denoted UC, is a variant of consensus in which the agreement property is replaced by the following *uniform agreement* property: no two processes decide differently.
- In the *nonblocking atomic commit* problem [15, 29], denoted NBAC, each process casts a vote of whether to abort or commit a transaction, and eventually decides. The termination and the uniform agreement properties are the same as that for uniform consensus. Validity is defined in two parts: (abort validity) abort can be decided only if some process proposes to abort or fails, and (commit validity) commit can be decided only if all processes propose to commit. For presentation uniformity, we make the following changes in notation: (1) we say that a process proposes 0 (resp., 1) if the process votes abort (resp., commit), and (2) we say that a process decides 0 (resp., 1) if the process decides to abort (resp., to commit).

To prove our lower bounds, we consider variants of consensus and uniform consensus. We define the *weak binary agreement* problem, denoted WA, where the processes are allowed to propose either 0 or 1. WA satisfies the agreement and termination properties of consensus, and the following weak validity property (from [19]): for every value $v \in \{0, 1\}$, there is a failure-free run in which correct processes decide v. The *weak binary uniform agreement* problem, denoted UA, is identical to WA except that it also satisfies uniform agreement (no two processes decide differently).

Clearly, any NC, UC, or NBAC algorithm can solve WA without any additional communication. Thus, our time-complexity lower bounds on WA immediately apply to the three agreement problems. Similarly, any UC or NBAC algorithm can solve UA without any additional communication, and hence, our time-complexity lower bounds on UA immediately apply to UC and NBAC problems.

In the synchronous models, we present the matching algorithms for uniform consensus and nonblocking atomic commit by first devising an interactive consistency algorithm, which we then transform to consensus and nonblocking atomic commit algorithms. In the *interactive consistency* problem [27], denoted IC, each process proposes an initial value and eventually decides on a vector of values. Termination and agreement properties are the same as for uniform consensus. Validity is defined as follows: for every decision vector V, the jth component of V is either the value proposed by p_j or $\perp$, and may be $\perp$ only if p_j fails.

4. Time complexity metrics. Let r be any run of an algorithm that solves one of the agreement problems described in section 3. We say that a process p_i *decides* in round $k \geq 1$ in r if p_i decides in the receive phase of round k, and a process decides at round 0 if it decides before sending any message in round 1. We say that a process *halts* in round k in r if it does not crash by round k, and does not take any step after round k.

We distinguish four different time complexity metrics for runs of agreement algorithms: *global decision*, *global halting*, *local decision*, and *local halting.* Consider any run r of an algorithm that solves an agreement problem.

- We say that run r *globally decides* (resp., *globally halts*) in round k if all correct processes decide (resp., halt) in round k, or in a *lower* round, and some correct process decides (resp., halts) in round k [13, 6, 4, 19].
- We say that run r *locally decides* (resp., *locally halts*) in round k if all correct processes decide (resp., halt) in round k, or in a *higher* round, and some correct process decides (resp., halts) in round k.

We introduce the following notation. If a run r globally decides at round k, we write $(r, gd) = k$. Similarly, the round at which run r globally halts, locally decides, and locally halts are denoted by (r, gh), (r, ld), and (r, lh), respectively. Note that, since every correct process decides before it halts, $(r, ld) \leq (r, lh)$, and $(r, ld) \leq (r, gd) \leq (r, gh)$. Given a model M1, a submodel M2 of M1, an agreement problem P, and a time complexity metric T, we denote by the ordered tuple (M1, M2, P, T) the following tight bound. (M1, M2, P, T) is the round number k such that (1) (lower bound) every algorithm that solves P in M1 has a run r in M2 such that $(r, T) \geq k$, and (2) (matching algorithm) there is an algorithm *Alg* that solves P in M1 such that every run r of *Alg* in M2 has $(r, T) \leq k$.

In other words, for algorithms that solve problem P in model M1, (M1, M2, P, T) is the tight bound for achieving T in submodel M2. The notation captures the common time-complexity tight bounds for agreement problems, where submodel M2 denotes the set of runs (e.g., failure-free runs) for which we want to optimize the algorithms in M1. If we set M2 = M1, the tuple denotes the worst-case bound in M1.

Before delving into our lower bounds, we recall some known results on consensus (NC) and uniform consensus (UC) using our notation. (For every pair of reals $a \leq b$, $[a, b]$ denotes the set of integers x such that $a \leq x \leq b$; when $a > b$, $[a, b]$ denotes the emptyset.)

- $\forall t \in [0, n-2]$, $(SCS_t$, SCS_t, NC, $gd) = t + 1$. Every consensus algorithm in SCS_t has a run (in SCS_t) in which some correct process decides in round $t+1$ or in a higher round, and there is a consensus algorithm A in SCS_t such that, in every run of A (in SCS_t), every correct process decides by round $t+1$ [13, 23].
- $\forall t \in [2, n-2]$, $\forall f \in [0, t-1]$, $(SCS_t$, SCS_f, NC, $gh) = f+2$. Every consensus algorithm in SCS_t has a run in SCS_f in which some correct process halts in

round $f+2$ or in a higher round, and there is a consensus algorithm A in SCS_t such that, in every run of A in SCS_f, every correct process halts by round $f+2$ [6].

- $\forall t \in [2, n-1]$, $\forall f \in [0, t-2]$, (SCS_t, SCS_f, UC, gd) $= f+2$. Every uniform consensus algorithm in SCS_t has a run in SCS_f in which some correct process decides in round $f+2$ or in a higher round, and there is a uniform consensus algorithm A in SCS_t such that, in every run of A in SCS_f every correct process decides by round $f+2$ [4, 19].
- $\forall t \in [1, (n-1)/2]$, ($ES_t$, SCS_t, NC, gd) $= t+2$. Every consensus algorithm in ES_t has a run in SCS_t in which some correct process decides in round $t+2$ or in a higher round, and there is a consensus algorithm A in ES_t such that, in every run of A in SCS_t every correct process decides by round $t+2$ [9].

Roughly speaking, in this paper we investigate tight bounds when the time-complexity metric is local decision (ld). In particular, we determine (SCS_t, SCS_f, UC, ld), (SCS_t, SCS_f, NC, ld), and (ES_t, SCS_f, UC, ld).

5. Layering.

Our lower bound proofs are devised following the layering technique of [24], which is also used in [19]. We first introduce some definitions and then recall the notion of layering from [24, 19]. We then present two lemmas (that are slightly modified from [19]) from which we derive our lower bound results. (In the following, we point out when our notions differ from those in [19].)

5.1. Configurations and extensions.

Consider a model M and an agreement algorithm A devised in M. For each run r of algorithm A in model M, we denote by $val(r)$ the decision value of any correct process in r. (This definition is unambiguous because, in every agreement problem we consider, no two correct processes decide differently.) For a run r of A in M we define the *configuration* C at the end of round k (also called *round k configuration*), as an ordered tuple of size $n+n^2$, where the element i, for $1 \leq i \leq n$, is the state of process p_i at the end of round k in run r, and the rest of the elements contain the set of delayed messages in the n^2 communication channels at the end of round k in run r. (Since there are no delayed messages in synchronous models, the channels are empty at the end of every round. Hence, in a synchronous model, we ignore state of channels in configurations at the end of a round.) The state of a process that has crashed is denoted by the special symbol $\perp$. We say that a process p_i is *alive* in a configuration if p_i has not crashed in that configuration. In the *initial configuration* (which we also call round 0 configuration) of run r, the state of each process is its proposal value, and the state of every communication channel is the emptyset $\emptyset$.

Given a round k configuration C of algorithm A in model M, we define the following concepts. A run r of algorithm A in model M is an *extension* of the round k configuration C if the round k configuration of run r is C. A round k_1 configuration C′ of algorithm A in model M is an *extension* of the round k configuration C if $k \leq k_1$ and there is a run r of A in M such that the round k configuration of r is C and round k_1 configuration of r is C′. If M is a synchronous model, we denote by $r(C)$ the run which is an extension of C such that no process crashes after round k. We define $val(C)$ as $val(r(C))$. Observe that a process p_i is alive in C if and only if p_i is correct in $r(C)$.

5.2. Layering in synchronous models.

In this subsection, we consider any given weak binary agreement (WA) algorithm A in model $SCS1_t$. (See section 2 and section 3 for a definition of SCS1$_t$ and WA, respectively.)

Extensions in $\mathbf{SCS1_t}$. A run of algorithm A is completely defined by its initial configuration and its failure pattern. (The failure pattern for a run in $SCS1_t$ consists, for each round k, of the process p_i that crashes in round k and the set of processes that did not receive the round k message from p_i.) In model $SCS1_t$, we denote an *extension by one round*, of a round k configuration C, as follows: for $1 \leq i \leq n$ and $S \subseteq \Pi$, $C.(i, S)$ denotes the round $k+1$ configuration reached by crashing p_i in round $k+1$ such that a process p_j *does not* receive a round $k+1$ message from p_i if at least one of the following holds: (1) $p_j = p_i$, (2) p_j is crashed in C, or (3) $p_j \in S$. Configuration $C.(0, \emptyset)$ denotes the one round extension of C in which no process crashes. Clearly, $C.(i, S)$ for $i > 0$ and $S \subseteq \Pi$ is a possible extension of C if at most $t - 1$ processes have crashed in C and p_i is alive in C. We then say that (i, S) is *applicable* to C. Configuration $C.(0, \emptyset)$ is always applicable to C.

Layers. A layer $L(C)$ is the set of configurations defined as $\{C.(i, S) | i \in \Pi, S \subseteq \Pi, (i, S) \text{ is applicable to } C\}$. (In other words, if C is a round k configuration, then $L(C)$ is the set of all round $k+1$ configurations that extend C in $SCS1_t$.) For a set of round k configurations SC, $L(SC)$ is a set of round $k+1$ configurations defined as $\cup_{C \in SC} L(C)$. $L^k(SC)$ is recursively defined as follows: $L^0(SC) = SC$ and for $k > 0$, $L^k(SC) = L(L^{k-1}(SC))$. (In other words, if SC is a set of round l configurations then $L^k(SC)$ is the set of all round $(l + k)$ configurations that extend any configuration in SC.)

Similar configurations. Consider a set of round k configurations SC. Two configurations C and D in SC are *similar*, denoted $C \sim D$, if they are identical or they differ at exactly one process. A pair of configurations C and D in SC is *similarity connected* if there are configurations $C = C_0, \ldots, C_m = D$ in SC such that $C_i \sim C_{i+1}$ for every i such that $0 \leq i \leq m - 1$. The set SC is *similarity connected* if every pair of configurations in SC is similarity connected. (Our definition of *similarity* does not include the second requirement in the original definition of [19]: there exists a process that is alive in both C and D and has identical states in C and D. When this property is required in our lower bound proofs, we derive it directly from our assumption on t and n.)

We now revisit Lemma 2.3 of [19]. Roughly speaking, this lemma says that, in $SCS1_t$, if we start with a similarity connected set SC of configurations, we can keep the set of extensions from SC similarity connected, provided we can crash one process in every round.

LEMMA 5.1. *In $SCS1_t$, let $SC = L^0(SC)$ be a similarity connected set of configurations such that in every configuration of SC no process has crashed. Then for all $k \in [1, t]$, $L^k(SC)$ is a similarity connected set of configurations in which no more than k processes have crashed in any configuration.*

Proof. The proof is by induction on round number k. The base case $k = 0$ is immediate. For the inductive step, assume that $L^{k-1}(SC)$ is similarity connected and in every configuration of $L^{k-1}(SC)$ at most $k-1$ processes have crashed. Notice that, in every extension by one round that is applicable to a configuration in $L^{k-1}(SC)$, at most one more process can crash. Therefore, in every configuration in $L^k(SC)$ at most k processes have crashed. We now show that $L^k(SC)$ is similarity connected through the following three claims.

1. *For every configuration $C \in L^{k-1}(\text{SC})$, $L(C)$ is similarity connected.* Consider any configuration in $L(C)$ that is different from $C.(0, \emptyset)$, say, $C1 = C.(i, Q)$, where $Q \subseteq \Pi$, and p_i is alive in C. We claim that $C1$ and $C.(0, \emptyset)$ are similarity connected. Since $C1$ is arbitrarily selected from $L(C)$, our claim implies that every

configuration in $L(C)$ is similarity connected to $C.(0, \emptyset)$, and hence, $L(C)$ is similarity connected.

Now we prove our claim. $C.(i, \emptyset) \sim C.(0, \emptyset)$ since the configurations differ only at p_i. If $Q = \emptyset$ then we are done. Hence, let $Q = \{q_1, q_2, \ldots, q_m\}$. For every l in $[1, m]$, let $Q_l = \{q_1, \ldots, q_l\}$, and $Q_0 = \emptyset$. For every l in $[0, m-1]$, $C.(i, Q_l) \sim C.(i, Q_{l+1})$ because the two configurations differ only at q_{l+1}. Thus, $C(i, \emptyset) = C.(i, Q_0)$ and $C1 = C.(i, Q_m)$ are similarity connected.

2. *For every pair of configurations* $C, D \in L^{k-1}(\mathrm{SC})$*, if* $C \sim D$ *then* $L(C) \cup L(D)$ *is similarity connected.* If C and D are identical then the claim immediately follows from claim 1. So consider the case where C and D are distinct. As $C \sim D$, there is a process p_i such that C and D are different only at p_i. Then, configurations $C.(i, \Pi)$ and $D.(i, \Pi)$ are identical because no process receives message from p_i in round k, and p_i has crashed. Hence, $C.(i, \Pi) \sim D.(i, \Pi)$. We know from claim 1 that $L(C)$ and $L(D)$ are each similarity connected. Thus every configuration in $L(C)$ is similarity connected to $C.(i, \Pi)$ and every configuration in $L(D)$ is similarity connected to $D.(i, \Pi)$. As, $C.(i, \Pi) \sim D.(i, \Pi)$, so every configuration in $L(C)$ is similarity connected to every configuration in $L(D)$. Thus, $L(C) \cup L(D)$ is similarity connected.

3. $L^k(\mathrm{SC})$ *is similarity connected.* Consider any pair of configurations $C', D' \in L^k(SC)$. Thus, there are configurations $C, D \in L^{k-1}(SC)$ such that $C' \in L(C)$ and $D' \in L(D)$. As $L^{k-1}(SC)$ is similarity connected, there is a chain of configurations $C = C_0, \ldots, C_m = D$ such that, for every $l \in [0, m-1]$, $C_l \sim C_{l+1}$. Thus, from claim 2, $L(C_l) \cup L(C_{l+1})$ is similarity connected. A simple induction shows that $L(C_1) \cup \ldots \cup L(C_m)$ is similarity connected. Thus $C' \in L(C = C_0)$ is similarity connected to $D' \in L(D = C_m)$. As C' and D' are arbitrarily selected from $L^k(SC)$, $L^k(SC)$ is similarity connected. □

Remarks. The above lemma is a simple generalization of Lemma 2.3 of [19]. The statement of the lemma is similar; however, the proof is slightly different because our model $SCS1_t$ is slightly different from that of [19]. Their model is actually a submodel of $SCS1_t$. Consider any crashed process p_i, and the set of processes J to which messages from p_i were lost in the round in which p_i crashed. Then, in the model of [19], J is allowed only to be a prefix of processes $\{p_1, \ldots, p_k\}$, whereas in $\mathrm{SCS1}_t$, J is allowed to be any subset of Π.

Informally, the next lemma says that, for any WA algorithm in $SCS1_t$, there are two round f configurations that are almost identical (they differ at only one process) but have different decision values in failure-free extensions.

Recall that, for any configuration y in a synchronous model, $val(y)$ is the decision value of correct processes in a run which extends y and has no crashes after y.

LEMMA 5.2. *Consider any WA algorithm A in* SCS_t *such that* $t \in [1, n-1]$*. For every* $f \in [0, t]$*, there are two runs of A in* $SCS1_t$ *such that their round* f *configurations,* y *and* y'*, satisfy the following:* (1) *at most* f *processes have crashed in each configuration,* (2) *the configurations differ at exactly one process, and* (3) $val(y) = 0$*, whereas* $val(y') = 1$*.*

Proof. Consider any WA algorithm A in SCS_t. We claim that A solves WA in $SCS1_t$ as well. A maintains the agreement and termination properties in all runs of $SCS1_t$ because every run in $SCS1_t$ is also a run in SCS_t. The weak validity property is bit different—it is a condition on the set of failure-free runs. However, observe that the SCS_t and $SCS1_t$ have the same set of failure-free runs. It follows that if A satisfies the weak validity property in SCS_t, then A also satisfies the property in $SCS1_t$. Thus, A solves WA in $SCS1_t$.

Now consider WA algorithm A in $SCS1_t$. Let C$'$ be any initial configuration of algorithm A and C be the initial configuration in which all processes propose 0. Consider the following $n-1$ (not necessarily distinct) initial configurations: for every i in $[1, n-1]$, in configuration C_i, processes p_1 to p_i propose the same value as in C', and the remaining processes propose 0. Notice that, for every i in $[1, n-2]$, C_i and C_{i+1} may differ only at p_{i+1}. Furthermore, C_1 and C may differ only at p_1, and C' and C_{n-1} may differ only at p_n. Thus C and C' are connected through a chain of configurations, such that any two adjacent configurations in the chain are similar. Since C' was arbitrarily selected, the set of initial configurations of A in $SCS1_t$ is similarity connected. From Lemma 5.1 it follows that the set of round f configurations of A in $SCS1_t$ is similarity connected.

Consider any failure-free run $r0$ of algorithm A in which correct processes decide 0. (From the validity property of WA, such a run of A exists.) We denote by z the round f configuration of $r0$. Similarly, consider any failure-free run $r1$ of A in which correct processes decide 1. We denote by z' the round f configuration of $r1$. Obviously, $val(z) = 0$ and $val(z') = 1$.

As the set of round f configurations of A in $SCS1_t$ is similarity connected, there are some round f configurations of A in $SCS1_t$, $z = y_0, y_1, \ldots, y_m = z'$, such that $y_j \sim y_{j+1}$ for every j in $[0, m-1]$. Clearly, there is some $y_i \in \{y_0, \ldots, y_{m-1}\}$ such that $val(y_0) = \cdots = val(y_i) \neq val(y_{i+1})$. (Otherwise, $val(z) = val(y_0) = val(y_1) = \cdots = val(y_m) = val(z')$, which is a contradiction.)

As $val(y_i) = val(y_0)$ and $y = y_0$, $val(y_i) = 0$. Therefore, $val(y_{i+1}) = 1$. Since both y_i and y_{i+1} are round f configurations in $SCS1_t$, at most f processes have crashed in each configuration. As $y_i \sim y_{i+1}$, the two configurations either are identical or differ at exactly one process. Since $val(y_i) \neq val(y_{i+1})$, the configurations cannot be identical; i.e., they differ at exactly one process. □

6. Synchronous lower bounds.

6.1. Consensus. In the following we show a local decision lower bound for weak binary agreement (WA) in synchronous models (SCS_t with $1 \leq t \leq n-1$). We then show the impossibility of simultaneously matching both local decision and global decision lower bounds of WA. Since any consensus (NC) algorithm solves WA, the results immediately apply to consensus.

We observe that every run of an algorithm in $SCS1_t$ is also a run in SCS_t. Thus, Lemma 5.2 holds when $SCS1_t$ is replaced by SCS_t.

Local decision. The following proposition states that any WA algorithm in SCS_t has a run in SCS_f (i.e., a run with at most f crashes) in which every correct process decides in round f or in a higher round.

PROPOSITION 6.1. *For all* $t \in [1, n-1]$, *for all* $f \in [0, t]$, (SCS_t, SCS_f, WA, *ld*) $\geq f$.

Proof. Suppose by contradiction that there is a WA algorithm A in SCS_t and an integer f in $[0, t]$ such that, in every run of A with f failures, some correct process decides by round $f-1$. Notice that the contradiction is immediate for the case $f = 0$: no process can decide by round -1. So we consider the case $f \in [1, t]$. (Also recall that we define deciding at round 0 as deciding before sending any message in round 1.)

It follows from Lemma 5.2 that there are two runs of A in SCS_t such that their round $f-1$ configurations, y and y', satisfy the following: (1) at most $f-1$ processes have crashed in each configuration, (2) the configurations differ at exactly one process, say, p_i, and (3) $val(y) = 0$ and $val(y') = 1$.

As $r(y)$ is a run with at most $f-1$ crashes, it follows from our assumption on A that, in $r(y)$, there is a correct process q_1 that has decided $val(y) = 0$ by round $f-1$. As all correct processes in $r(y)$ are alive in y, it follows that, in y, q_1 is alive and has decided $val(y) = 0$.

We now show that no alive process distinct from p_i has decided in y (which implies $p_i = q_1$). Suppose by contradiction that some alive process distinct from p_i, say, q_2, has decided in y. Since q_2 is alive in y, it is correct in $r(y)$, and hence, q_2 has decided $val(y) = 0$ in y. As y and y' differ only at p_i, and p_i is distinct from q_2, q_2 is alive and has decided 0 in y'. Thus, in $r(y')$, q_2 is a correct process and decides 0. However, every correct process in $r(y')$ decides $val(y') = 1$, which is a contradiction.

Thus, p_i is the only alive process that has decided in y. Consider any run r' that extends y and in which only process p_i crashes after round $f-1$. At most f processes crash in r'. At the end of round $f-1$ in r', the only alive process that has decided is p_i, but p_i is a faulty process in r'. Thus, r' is a run with f failures in which no correct process decides by round $f-1$, which is a contradiction. □

Incompatibility. It is easy to design a consensus algorithm that matches either the early local decision or the early global decision lower bound. We now show that, maybe surprisingly, no consensus algorithm can match both the early local decision and the early global decision lower bounds, even for two consecutive values of f. This is in contrast to uniform consensus, where a single algorithm can match both local decision and global decision lower bounds (as we show in section 7).

PROPOSITION 6.2. *For all $t \in [1, n-2]$, for all $f \in [0, t-1]$, there is no WA algorithm in SCS_t that matches the following two conditions:* (a) *in every run with at most f crashes, every correct process decides by round $f+1$, and* (b) *in every run with at most $f+1$ crashes, some correct process decides by round $f+1$.*

Remarks. Condition (a) is for matching the global decision lower bound for f crashes, and condition (b) is for matching the local decision lower bound for $f+1$ crashes. Note that, we do not consider the case $f = t$, because when $f = t$, (a) implies (b), as there is no run in SCS_t with $t+1$ crashes.

Proof. Suppose by contradiction that there is a WA algorithm A in SCS_t and an integer f in $[0, t-1]$ such that (a) by round $f+1$ of every run with at most f failures, every correct process decides, and (b) by round $f+1$ of every run with at most $f+1$ failures, some correct process decides.

It follows from Lemma 5.2 that, at the end of round f there are two configurations y_0 and y_1 such that (a) at most f processes have crashed in each configuration, (b) the configurations differ at exactly one process, say, p_i, and (c) $val(y_0) = 0$ and $val(y_1) = 1$.

Consider run $r(y_0)$. Obviously, $r(y_0)$ is a run with at most f failures, and from our initial assumption, every correct process decides $val(y_0) = 0$ at the end of round $f+1$. Similarly, we construct run $r(y_1)$, which is a failure-free extension of y_1, and every correct process decides $val(y_1) = 1$ at the end of round $f+1$. There are two cases to consider.

Case 1. Process p_i is alive in y_0 and y_1. Consider the extension of y_0 to a run $r'(y_0)$ such that p_i crashes in round $f+1$ before sending any message, and no process crashes thereafter. (Recall that $f \leq t-1$.) Notice that $r'(y_0)$ is a run with at most $f+1$ failures and p_i is a faulty process in $r'(y_0)$. Thus, from our initial assumption about A, it follows that there is a correct process $p_j(\neq p_i)$ in $r'(y_0)$ which decides some value $v \in \{0, 1\}$ at round $f+1$. (Notice that, since $p_j \neq p_i$, p_j cannot decide before round $f+1$: as y_0 and y_1 differ only at p_i, if p_j decides by round f, then p_j

decides identical values in y_0 and y_1.) Also, as $f \leq n-3$, there is a process p_l distinct from p_i and p_j such that p_l decides 0 and 1 at the end of round $f+1$ in $r(y_0)$ and $r(y_1)$, respectively.

Now we construct a run r'' by extending configuration y_{1-v}: process p_i crashes in the send phase of round $f+1$ such that, in round $f+1$, p_l receives a message from p_i but p_j does not receive any message from p_i. No process distinct from p_i crashes in round $f+1$ or a higher round. Obviously, p_j and p_l are correct in r''. At the end of round $f+1$ in run r'', p_j cannot distinguish r'' from $r'(y_0)$ because the round f configurations of the two runs differ only at p_i, and p_j does not receive any round $f+1$ message from p_i in both runs. Therefore, p_j decides v at the end of round $f+1$ in r''. However, since p_l receives a message from p_i in round $f+1$, at the end of round $f+1$, p_l cannot distinguish r'' from $r(y_{1-v})$, and therefore, decides $1-v$ at the end of round $f+1$, which is a contradiction to the agreement property of WA.

Case 2. Process p_i has crashed in either y_0 or y_1. Without loss of generality, we can assume that p_i has crashed in y_0, and hence, p_i is alive in y_1. (Recall that p_i has different states in the two configurations.) As at most f processes, including p_i, have crashed in y_0, and p_i has not crashed in y_1, it follows that at most $f-1$ processes have crashed in y_1. Since $f \leq n-3$ and at most $f-1$ processes have crashed in y_1, there are at least two correct process p_j and p_l (both distinct from p_i) in $r(y_1)$. Consider the run r' which extends y_1 such that process p_i crashes in round $f+1$ and the only alive process that *does not* receive the round $f+1$ message from p_i is p_l, and no process crashes after round $f+1$. Obviously p_j and p_l are correct in r'. At the end of round $f+1$, p_l cannot distinguish $r(y_0)$ from r' because p_l does not receive the round $f+1$ message from p_i in both runs. Thus, p_l decides 0 at the end of round $f+1$ in r'. At the end of round $f+1$, p_j cannot distinguish $r(y_1)$ from r' because both runs extend y_1 and p_j receives round $f+1$ message from p_i in both runs. Thus, p_j decides 1 at the end of round $f+1$ in r', which is a contradiction to the agreement property of WA. □

6.2. Uniform consensus. In the following, we show a local decision lower bound for weak binary uniform agreement (UA) in the synchronous models (SCS_t with $1 \leq t \leq n-1$). Since any uniform consensus (UC) and nonblocking atomic commit (NBAC) algorithm solves UA, the lower bound immediately applies to UC and NBAC. In section 6.3, we show that the lower bound holds for IC as well.

The following proposition says that any UA algorithm in SCS_t has a run in SCS_f (i.e., a run with at most f crashes) in which every correct process decides in round $f+1$ or in a higher round.

We observe that any UA algorithm also solves WA, and every run of an algorithm in $SCS1_t$ is also a run in SCS_t. Thus, Lemma 5.2 holds when WA and $SCS1_t$ are replaced by UA and SCS_t, respectively.

Proposition 6.3. *For all* $t \in [1, n-1]$*, for all* $f \in [0, t-1]$*,* (SCS_t*,* SCS_f*, UA, ld*) $\geq f+1$.

Proof. Suppose by contradiction that there is a UA algorithm A in SCS_t and an integer f in $[0, t-1]$ such that, in every run of A with f failures, some correct process decides by round f.

As every UA algorithm solves WA, it follows from Lemma 5.2 that there are two runs of A in SCS_t such that their round f configurations, y and y', satisfy the following: (1) at most f processes have crashed in each configuration, (2) the configurations differ at exactly one process, say, p_i, and (3) $val(y) = 0$ and $val(y') = 1$.

From our initial assumption about algorithm A, it follows that there is an alive process q_1 in y that has already decided. (Otherwise, since every correct process in $r(y)$ is an alive process in y, $r(y)$ is a run with at most f crashes in which no correct process decides by round f.) Furthermore, q_1 has decided $val(y) = 0$ in $r(y)$ (and hence, in y) because q_1 is a correct process in $r(y)$. Similarly, in y', there is an alive process q_2 that has decided $val(y') = 1$. There are two cases to consider.

(1) $q_1 \neq p_i$: As y and y' are identical at all processes different from p_i, in y', q_1 is alive and has decided 0. Thus in $r(y')$, q_1 is a correct process and decides 0. However, in $r(y')$ every correct process decides $val(y') = 1$, which is a contradiction.

(2) $q_1 = p_i$: We distinguish two subcases:

- $q_2 = p_i$: Thus $p_i = q_1 = q_2$, and hence, p_i is alive in y and y'. Consider a run $r1$ that extends y and in which p_i crashes in round $f + 1$ before sending any message. (Recall that $f \leq t-1$.) As p_i has decided 0 in y, it follows from the uniform agreement property that every correct process decides 0 in $r1$. Since $t < n$, there is at least one correct process, say, p_l, in $r1$. Now consider a run $r2$ that extends y' and in which p_i crashes in round $f + 1$ before sending any message. Notice that no correct process can distinguish $r1$ from $r2$: at the end of round f no alive process that is distinct from p_i can distinguish y from y', and p_i crashes before sending any message in round $f + 1$. Thus every correct process decides the same value in $r1$ and $r2$; in particular, p_l decides 0 in $r2$. However, $p_i = q_2$ decides 1 in $r2$, which is a contradiction to uniform agreement.
- $q_2 \neq p_i$: Then, q_2 has the same state in y and y'. Thus in y, q_2 is alive and has decided 1. In any run that extends y, $p_i = q_1$ has decided 0 and q_2 has decided 1, which is a contradiction to uniform agreement. □

6.3. Nonblocking atomic commit and interactive consistency. Recall that the local decision lower bound presented in section 6.2 holds for UC and NBAC. In the following, we show that for NBAC and IC, the local decision lower bound for the failure-free case ($f = 0$) can be shifted to 2. However, this result does not hold for UC: in section 7.4 we exhibit a UC algorithm that locally decides in 1 round in failure-free runs.

PROPOSITION 6.4. *For all* $t \in [2, n-1]$, $(\text{SCS}_t, \text{SCS}_0, \textit{NBAC, ld}) \geq 2$.

Proof. Suppose by contradiction that there is an NBAC algorithm A such that, in every failure-free run, some process decides in round 1. Let $C1$ be the initial configuration in which all processes propose 1. Consider the failure-free run $R1$ starting from $C1$; i.e., $R1 = r(C1)$. Suppose that some process p_i decides at the end of round 1. From the abort validity property of NBAC, we know that p_i cannot decide 0 (and hence, p_i decides 1) in $R1$.

Consider another run $R2$ starting from $C1$, but some process p_j ($\neq p_i$) crashes in round 1 and only p_i receives the round 1 message from p_j. Also, process p_i crashes in round 2, before sending the round 2 message to any process, and no process crashes thereafter. At the end of round 1, p_i cannot distinguish $R1$ from $R2$. Thus, p_i decides 1 in $R2$. From uniform agreement, we know that every process distinct from p_i and p_j decides 1. There exists at least one such process, say, p_l, because $t \leq n - 1$.

Let $C0$ be the initial configuration in which p_j proposes 0 and all other processes propose 1. Consider a run $R3$ starting from $C0$ with the same failure pattern as $R2$; i.e., p_j crashes in round 1 and only p_i receives the round 1 message from p_j, p_i crashes in round 2 before sending the round 2 message to any process, and no process crashes thereafter. No process distinct from p_i and p_j can distinguish $R2$ from $R3$: at the end of round 1, only p_i receives the message from p_j, but p_i crashes before sending any message in round 2. Therefore, every process distinct from p_i and p_j decides 1 (as in $R2$), particularly p_l. But the commit validity property of NBAC requires that no process decides 1 in $R3$ because some process p_j has proposed 0, which is a contradiction. □

The above proposition highlights a fundamental difference between the time-complexity of NBAC and UC in synchronous models. However, the proposition extends to IC. In fact, any IC algorithm can be easily transformed to an NBAC algorithm (without any additional rounds) as follows. Let $V1$ denote an ordered n-tuple in which every component is 1. Suppose we have an IC algorithm with IC-propose() primitive. We implement the NBAC-propose() primitive of the NBAC specification in the following way. When a process NBAC-proposes $v \in \{0, 1\}$, then if IC-proposes v. If a process IC-decides $V1$, then it NBAC-decides 1; if the process IC-decides an n-tuple different from $V1$, then it NBAC-decides 0. Note that the transformation by itself does not require any additional communication and hence can be performed even in an asynchronous model. Thus, this transformation immediately implies that the bound in section 6.2 and Proposition 6.4 applies to IC.

In a related work [10], we show for NBAC algorithms, an incompatibility between globally deciding by round 2 in the failure-free run where all processes propose 1 and globally deciding by round 1 in every run where some process proposes 0. However, that paper does not consider local decisions.

7. A matching synchronous algorithm. In [21], an NC algorithm was proposed that matches the global decision and global halting lower bounds. The algorithm can be easily modified to derive another algorithm that matches corresponding bounds for UC. However, we knew of no UC algorithm that matches the local decision lower bounds.

In this section, we present an algorithm for IC that *simultaneously* matches the local decision, global decision, and global halting lower bounds for most values of f and t. (We do not match the bounds in some boundary cases when f, t, and n are close to each other.) From our IC algorithm, we then derive matching algorithms for UC and NBAC. (Algorithms that match either the local decision or the global decision of NC are straightforward, but, as we showed in Proposition 6.2, no single NC algorithm can match both local and global decision lower bounds.)

7.1. IC algorithm overview. Our IC algorithm (Figure 7.1) is inspired by the Byzantine Generals algorithm of [21]. The algorithm runs for at most $t + 1$ rounds. Process p_i maintains two primary variables: (1) an ordered n-tuple est_i, component j of which contains the proposal value of p_j, provided p_i has received that value (either directly from p_j or relayed by some other process), and $\perp$ otherwise, and (2) a set of processes $halt_i$ that p_i knows to have either crashed or halted. In each round, the processes exchange estimate (EST) messages containing their *est* values. If the *halt* set at a process does not change in round k, then (1) if the *est* does not change in round k as well, the process decides on its *est* in round k, and otherwise, (2) the process decides on its *est* in round $k + 1$. Before halting, a process sends a special decision (DEC) message to all processes, so that the processes can distinguish a halt from a crash.

Roughly speaking, if the *halt* set at a process p_i does not change in some round k, then at the end of round k, no *alive* process has seen more proposal values than p_i. Thus, p_i can decide on its current est_i value, provided p_i ensures that all other processes see its current est_i. So p_i sends its *est* to all processes in round $k + 1$ and

```
at process $p_i$:
 1: propose($v_i$)
 2: Ordered $n$-tuples $est_i$ and $newest_i$: element $i$ initialized to $v_i$ and all other elements initialized to $\bot$
 3: Set $halt_i \leftarrow newhalt_i \leftarrow \emptyset$
 4: Boolean $decided_i \leftarrow lastRound_i \leftarrow false$
 5: for $1 \le r \le t+1$ do Multiset $S_i^r \leftarrow \emptyset$

 6: for round $r$ from 1 to $t+1$ do
 7:     $halt_i \leftarrow newhalt_i$
 8:     $est_i \leftarrow newest_i$

 9:     Send phase
10:     if $lastRound_i$ then
11:         send($r$, DEC, $est_i$) to all
12:     else
13:         send($r$, EST, $est_i$) to all

14:     Receive phase
15:     $S_i^r \leftarrow \{est_j \mid (r, \text{EST}, est_j)$ was received$\}$
16:     if $lastRound_i$ then
17:         if not $decided_i$ then
18:             decide($est_i$)                                                    {decision}
19:         return                                                                 {halt}
20:     if received any $(r, \text{DEC}, est_j)$ then
21:         $newest_i \leftarrow est_j$
22:         $lastRound_i \leftarrow true$
23:     else
24:         $newhalt_i \leftarrow \Pi \backslash$sender($S_i^r$)      {processes from which $p_i$ did not receive any message}
25:         for $1 \le j \le n$ do
26:             if there is any $est' \in S_i^r$ s.t. $est'[j] \ne \bot$ then $newest_i[j] \leftarrow est'[j]$ else $newest_i[j] \leftarrow \bot$
27:         if $newhalt_i = halt_i$ then
28:             if $est_i = newest_i$ then
29:                 decide($est_i$); $decided_i \leftarrow true$                  {decision}
30:             $lastRound_i \leftarrow true$
31:     if $r = t+1$ then
32:         if not $decided_i$ then
33:             decide($newest_i$)                                                 {decision}
34:         return                                                                 {halt}
```

FIG. 7.1. *An early deciding (and halting) interactive consistency algorithm.*

then decides. However, if the *est* of p_i does not change in round k, then p_i has already sent that *est* to all processes in round k; so p_i can decide at the end of that round.

7.2. Correctness.

In the following, a variable *var* at a process p_i is denoted var_i, and if p_i reaches the end of any round r, the value of var_i at the end of round r is denoted var_i^r; var_i^0 denotes the value of the variable at the end of line 5. (We omit the subscript of the variable when we make a statement that applies to multiple processes.) For $1 \le r \le t+1$, $faulty^r$ denotes the set of processes that have crashed by round r, and $faulty^0$ equals $\emptyset$. For any pair of ordered n-tuples d and d', we say that (1) $d = d'$ if for all $j \in [1, n]$, $d[j] = d'[j]$, (2) $d \preceq d'$ if for all $j \in [1, n]$, either $d[j] = \bot$ or $d[j] = d'[j]$, and (3) $d \not\preceq d'$ if $d \preceq d'$ is false.

First, we make the following simple observations that we frequently use: (1) (*Observation* O1) For the *est* value at every process and every $j \in [1, n]$, $est[j]$ is either the proposal value of p_j or $\bot$. (2) (*Observation* O2) If, before deciding, p_j receives an EST message from some process p_l in round k, then $newest_l^{k-1} \preceq newest_j^k$. (It follows that $newest_j^{k-1} \preceq newest_j^k$.)

Every process decides on some *est* value; thus, validity immediately follows from Observation O1. Termination follows from the simple observations that no process halts without deciding and no process completes round $t+1$ without halting (lines 31 to 34). Thus we detail only the proof of uniform agreement. We start with some general lemmas about the algorithm.

LEMMA 7.1. *If for some* $r \in [1, t]$ *no process decides by round* r*, then the following holds for every process* p_i *that completes round* r*. If* $lastRound_i^r = true$*, then every process* p_j *that completes round* r *has* $newest_j^r \preceq newest_i^r$*.*

Proof. We prove the lemma by induction on round number r, such that $r \in [1, t]$.

Base case $r = 1$. Suppose $lastRound_i^r = true$ and no process decides in round 1. Then p_i has executed either line 22 or line 30 of round 1. Observe that p_i executes line 22 only if some process sends DEC message to p_i. Since *lastRound* is initialized to false and the processes send DEC messages only when $lastRound = true$, no process has sent a DEC message in round 1. Thus p_i has executed line 30. So $newhalt_i^1 = halt_i^1 = \emptyset$, and hence, $newest_i^1$ contains proposal values of all processes. Thus, every process p_j that completes round 1 has $newest_j^1 \preceq newest_i^1$.

Induction hypothesis $r = k$. If no process decides by round k, then the following holds for every process p_i that completes round k. If $lastRound_i^k = true$, then every process p_j that completes round k has $newest_j^k \preceq newest_i^k$.

Induction step $r = k + 1 \leq t$. Suppose by contradiction that (1) no process decides by round $r = k + 1$, (2) there is a process p_i that completes round $k + 1$ such that $lastRound_i^{k+1} = true$ and $newest_i^{k+1} = d'$, and (3) another process p_j completes round $k + 1$ with $newest_j^{k+1} = d$ such that $d \not\preceq d'$. Process p_i has executed either line 22 or line 30. If p_i executed line 22, then p_i has received a ($k + 1$, DEC, d') message from some process p_l. To send a DEC message in round $k + 1$, p_l must have set $lastRound_l$ to *true* in round k. Thus, from the induction hypothesis, every process that completes round k has $newest^k \preceq d'$. Since $d \not\preceq d'$, process p_j receives a round $k + 1$ message from some process with an n-tuple d'' such that $d'' \not\preceq d'$, which is a contradiction because, for all processes that complete round k, we have $newest^k \preceq d'$. Hence, p_i executed line 30, and $halt_i^{k+1} = newhalt_i^{k+1}$. Since p_j completes round $k + 1$, p_i received the round $k + 1$ message from p_j containing $newest_j^k$, and hence, $newest_j^k \preceq newest_i^{k+1} = d'$. As $newest_j^{k+1} = d \not\preceq d'$, it follows that p_j received ($k+1$, $*$, d'') from some process p_m such that $d'' \not\preceq d'$, and p_i did not receive ($k + 1$, $*$, d'') from p_m (otherwise, $d'' \preceq newest_i^{k+1} = d'$). Thus $p_m \in newhalt_i^{k+1}$. However, as p_m completed round k, $p_m \notin newhalt_i^k = halt_i^{k+1}$. Thus, $halt_i^{k+1} \neq newhalt_i^{k+1}$, which is a contradiction. □

LEMMA 7.2. *If a process* p_i *does not halt or crash by round* $r \in [0, t]$*, then* p_i *has* $halt_i^k \neq newhalt_i^k$ *for all* $k \in [1, r - 1]$*.*

Proof. The proof is obvious from the algorithm. □

LEMMA 7.3. *If no correct process halts by some round* $r - 1 \in [0, t - 1]$*, and if there is a process* p_i *such that, for every round number* $r' \in [1, r]$*,* $halt_i^{r'} \neq newhalt_i^{r'}$*, then* $|faulty^r| \geq r$*.*

Proof (for uniformity of presentation, we slightly abuse the terminology and say that *for all runs, no process halts or crashes by round* 0). Suppose there is a round r such that no correct process halts by round $r - 1$ and there exists a process p_i such that, for every round number $r' \in [1, r]$, $halt_i^{r'} \neq newhalt_i^{r'}$. Clearly, $halt_i^{r'} = newhalt_i^{r'-1} \subseteq newhalt_i^{r'}$. Thus $|newhalt_i^r| \geq r$. Every process in $newhalt_i^r$ has either halted by round $r - 1$ or crashed by round r. Since no correct process halts by round $r - 1$, $newhalt_i^r \subseteq faulty^r$, and hence, $|faulty^r| \geq r$. □

LEMMA 7.4. *If no correct process halts by round* $r+1 \in [1, t]$*, then* $|faulty^r| \geq r$*.*

Proof. The proof is trivial for $r + 1 = 1$. So we consider the case $r + 1 \in [2, t]$. Suppose that no correct process halts by round $r + 1$. Consider any correct process p_i. Since p_i does not halt by round $r + 1 \leq t$, it follows from Lemma 7.2 that for

$r' \in [1, r]$, $halt_i^{r'} \neq newhalt_i^{r'}$. Since no correct process halts by round $r - 1 \leq t - 1$, applying Lemma 7.3, we have $|faulty^r| \geq r$. □

LEMMA 7.5. *If every process that decides decides in line* 29 *of round* $t + 1$ *or line* 33 *of round* $t + 1$*, then* $|faulty^t| = t$.

Proof. The proof is trivial when $t = 0$. Thus we consider the case $t \geq 1$. Suppose that every process that decides decides in line 29 of round $t+1$ or line 33 of round $t+1$. Consider any correct process p_i. Since p_i does not decide in line 18 of round $t + 1$, $lastRound_i^t = false$. Thus $newhalt_i^t \neq halt_i^t$ (from lines 27 and 30). Furthermore, as p_i does not halt by round t, from Lemma 7.2 it follows that for every $g \in [1, t - 1]$, $newhalt_i^g \neq halt_i^g$. Thus for every $g \in [1, t]$, $newhalt_i^g \neq halt_i^g$. Since no process decides (and hence, halts) by round t, by applying Lemma 7.3 (with $r - 1 = t - 1$), we have $|faulty^t| \geq t$. As at most t processes can crash in a run, $|faulty^t| = t$. □

LEMMA 7.6 (uniform agreement). *No two processes decide differently.*

Proof. If no process decides, then the lemma trivially holds. Suppose some process decides. Consider the lowest round number r in which some process decides. Let p_i be a process that decides in round r, say, on some n-tuple d. We divide the proof into two parts: (a) p_i does not decide in line 33 of round $t + 1$, and (b) $r = t + 1$ and p_i decides in line 33 of round $t + 1$.

(a) p_i *does not decide in line* 33 *of round* $t + 1$: Thus, process p_i decides either in (1) line 18 or in (2) line 29 of round $r \leq t + 1$. In both cases, we show the following: no process can decide an n-tuple different from d in round r, and any process that completes round r without deciding in line 18 and line 29 does so with $newest^r = d$. This implies uniform agreement because every process that decides in round r has decision value the same as its $newest^r$, and in subsequent rounds, d is the only surviving *newest* and *est* value. (Note that, even if $r = t + 1$, and another process p_j decides in line 33 of round r, p_j decides on $newest_j^r = d$.)

Process p_i *decides in line* 18 *of round* r: Notice that $r > 1$ because no process can decide at line 18 in round 1 (as $lastRound^0 = false$). Since p_i decides in line 18, $lastRound_i^{r-1} = true$ and p_i sends a DEC message in round r. We claim that every DEC message sent in round r is (r, DEC, d). Suppose that another process p_j sends a (r, DEC, $d1$) message. Then $lastRound_j^{r-1} = true$. Since no process decides by round $r - 1$, applying Lemma 7.1 twice we have $d1 = newest_j^{r-1} \preceq newest_i^{r-1} = d$ and $d = newest_i^{r-1} \preceq newest_j^{r-1} = d1$, i.e., $d1 = d$. As p_i completes the send phase of round r, every process receives at least one (r, DEC, d) message and either decides d in line 18 or adopts d as *newest* in line 21.

Process p_i *decides in line* 29 *of round* r: Thus $est_i = newest_i$ is d in line 28 of round r, and p_i sent (r, EST, d) in round r. We claim that no process decides a value different from d in round r. Clearly, p_i does not receive any DEC message in round r (otherwise, p_i would not have executed line 29). Suppose some process p_j decides $d1$ in round r. If process p_j decides in line 18, then p_j sends a DEC message in round r, and p_i receives that message (as p_j completes the send phase of round r, none of its messages are lost), which is a contradiction. Suppose that p_j decides in line 29. Thus $est_j = newest_j$ is $d1$ in line 28 of round r, and p_i sent (r, EST, $d1$) in round r. Since p_i receives a round r message from p_j and vice versa, $d1 \preceq d$ and $d \preceq d1$; i.e., $d = d1$. If p_j decides in line 33, then it decides on the *newest* value adopted in round $t + 1$. We show below that every process that updates its *newest* in round k updates it to d.

We now show that any process that completes round r without deciding in line 18 or line 29 does so with $newest = d$. Suppose by contradiction that some process p_j completes round r with $newest = d2 \neq d$ and without deciding in line 18 and line 29.

Process p_j updates its variable *newest* in line 21 or line 26. Suppose p_j updates its *newest* in line 21. Then p_j has received a DEC message from some process p_m. Since p_i decides at line 29, it does not receive any DEC message in round r. Thus $p_m \in \mathit{newhalt}_i^r$. Since p_m completes round $r-1$, $p_m \notin \mathit{newhalt}_i^{r-1} = \mathit{halt}_i^r$. (If $r = 1$ then obviously $p_m \notin \mathit{halt}_i^r = \emptyset$.) Hence, the predicate in line 27 evaluates to false at p_i, and p_i cannot decide in line 29, which is a contradiction. Thus, p_j updates its *newest* in line 26. Since p_i completes round r by deciding d and evaluates the condition in line 28 to true, p_i sends a (r, EST, d) message in round r. Thus p_j receives (r, EST, d) from p_i, and hence, $d \preceq d2$. As $d2 \neq d$, it follows that $d2 \npreceq d$. Consequently, there is a process p_m such that p_j receives $d3 \npreceq d$ from p_m, and p_i does not receive any message from p_m in round r. Thus, $p_m \in \mathit{newhalt}_i^r$. However, p_m completes round $r-1$ and hence, $p_m \notin \mathit{newhalt}_i^{r-1} = \mathit{halt}_i^r$. (If $r = 1$ then obviously $p_m \notin \mathit{halt}_i^r = \emptyset$.) Hence, the predicate in line 27 evaluates to false at p_i, and p_i cannot decide in line 29, which is a contradiction.

(b) $r = t+1$ *and* p_i *decides in line* 33 *of round* $r = t+1$: From the definition of r, every process that decides decides in round $t+1$. We have shown above that if any process decides in line 18 or line 29 of round $t+1$ then every process that decides in round $t+1$, decides the same value. Therefore, we need only to consider the case where every process that decides does so at line 33 of round $t+1$. From Lemma 7.5, we have $|\mathit{faulty}^t| = t$. Hence, every process that enters round $t+1$ is a correct process. Consequently, every process that enters round $t+1$ receives the same set of messages in round $t+1$. Observe that no process sends a DEC message in round $t+1$ (otherwise, that process decides in line 18 of round $t+1$ or line 29 of round t, which is a contradiction). Thus every process that enters round $t+1$ updates *newest* to the same value in line 26 and decides on identical values in line 33. □

7.3. Time-complexity. We now discuss the time-complexity of our IC algorithm. We show through the following lemma that, in runs with at most $f \geq 1$ failures, the algorithm achieves local decision in $f+1$ rounds and global decision in $f+2$ rounds. However, when $f = 0$, the local decision takes the same number of rounds as the global decision (2 rounds); recall that we showed in Proposition 6.4 that NBAC (and hence, IC) algorithms require 2 rounds for local decision when $f = 0$. (In section 7.4, we show a UC algorithm that achieves local decision in round 1 when $f = 0$.)

We say that a process p_i *learns* index $l \in [1,n]\backslash\{i\}$ in round k if $\mathit{newest}_i^{k-1}[l] = \bot$ and $\mathit{newest}_i^k[l] \neq \bot$. (In other words, p_i learns about the proposal value of p_l in round k.) We say that p_i learns index i in round 0. Also, we say that p_i learns index l from p_j in round k if $\mathit{newest}_i^{k-1}[l] = \bot$ and p_i receives a round k message from p_j containing an *est* such that $\mathit{est}[l] \neq \bot$. On the other hand, if p_j sends an *est* such that $\mathit{est}[l] \neq \bot$ in round k, then we say that p_j propagates index l in round k. (Note that there may be more than one process from which a process learns the same index in a round.) Clearly, if p_i propagates l in round k, then p_i learns l in a lower round.

LEMMA 7.7. *In every run with at most f faulty processes, the following properties hold:*

(a) *If $f \in [1,t]$, then there is a correct process that decides by round $f+1$.*

(b) *If $f \in [0, t-2]$, then any process that halts halts by round $f+2$.*

(c) *Any process that halts does so by round $t+1$.*

Proof. (a) For $f = t$, the proof is trivial because every correct process decides by round $t+1$. Consider a run in which at most $f \in [1, t-1]$ processes crash, and suppose by contradiction that no correct process decides by round $f+1$. Thus, no process halts by round $f+1 \leq t$. It follows from Lemma 7.4 that $|\mathit{faulty}^f| \geq f$. Since at most f processes crash in the run, $|\mathit{faulty}^f| = f$ and every process that enters round $f+1$ is correct. Furthermore, since no correct process halts by round f, Lemma 7.4 implies that $|\mathit{faulty}^{f-1}| \geq f-1$. Since $|\mathit{faulty}^f| = f$, *at most* one process crashes in round f.

Let S be the set of processes that enter round $f+1$. Since every process in S is correct, all of them complete round $f+1$. We establish a contradiction by showing that some process in S decides in line 29 of round $f+1$. We demonstrate this fact indirectly by showing the following four claims for processes in S in round $f+1$: (1) every process has $\mathit{lastRound} = \mathit{false}$ in line 16, (2) no process receives a DEC message in round $f+1$, (3) every process evaluates the predicate in line 27 to true, and (4) some process evaluates the predicate in line 28 to true.

Claim 1. Suppose by contradiction that, at some process in S, $\mathit{lastRound} = \mathit{true}$ in line 16 of round $f+1$. Then that process halts in round $f+1$. This leads to a contradiction because we know that every process in S is correct, and (from our initial assumption) correct processes do not decide (and hence, do not halt) by round $f+1$.

Claim 2. Suppose by contradiction that some process $p_i \in S$ receives a DEC message from some process p_j in round $f+1$. Since every process that enters round $f+1$ is correct, p_j is a correct process, and hence, p_j decides in line 18 of round $f+1$ or line 29 of round f, which is a contradiction. Thus no process in S receives a DEC message in round $f+1$.

Claim 3. Suppose by contradiction that some process $p_i \in S$ evaluates the predicate at line 27 to false; i.e., $\mathit{halt}_i^{f+1} \neq \mathit{newhalt}_i^{f+1}$. Since p_i does not halt by round $f+1 \leq t$, from Lemma 7.2 we have $\mathit{halt}_i^k \neq \mathit{newhalt}_i^k$ for every k in $[1, f]$. Thus $\mathit{halt}_i^k \neq \mathit{newhalt}_i^k$ for every k in $[1, f+1]$. As no correct process halts by round $f+1$, from Lemma 7.3 (with $r-1 = f \leq t-1$) it follows that $|\mathit{faulty}^{f+1}| \geq f+1$, which is a contradiction.

Claim 4. Suppose by contradiction that every process in S evaluates the predicate in line 28 to false. It follows that, in round $f+1$, every process in S learns an index. (Recall that every process that enters round $f+1$ is correct and is in set S.)

Consider any process $p_i \in S$ which learns index $l1$ in round $f+1$ from some process p_x. Suppose p_x learns index $l2$ in round $f+1$ from process p_y. Since p_i learns from p_x and p_x learns from p_y, $p_i \neq p_x$ and $p_x \neq p_y$. (Note that p_i and p_y may not be distinct.) Since p_x propagates $l1$ and learns $l2$, $l1 \neq l2$.

Since p_x is a correct process, p_x learns $l1$ in round f (otherwise, if p_x learned $l1$ in a round lower than f, p_x would have propagated $l1$ to p_i by round f). Similarly, p_y learns $l2$ in round f. Consider the process p'_x from which p_x learns $l1$ in round f. Process p'_x must have crashed in round f; otherwise, on receiving the round f message from p'_x, p_i would have learned $l1$ in round f. Similarly, the process p'_y from which p_y learns $l2$ in round f must have crashed in round f; otherwise, p_x would have learned $l2$ from p'_y in round f. We claim that p'_x and p'_y are distinct processes. Otherwise, if $p'_x = p'_y$, then p'_x propagates both $l1$ and $l2$ in round f, and when p_x receives a message from p'_x in round f, p_x learns both $l1$ and $l2$ in round f, which is a contradiction. (Recall that we assumed p_x learned $l2$ in round $f+1$.)

Thus two processes, p'_x and p'_y, crash in round f. However, recall that we have already shown (in the first paragraph of this proof) that *at most* one process crashes in round f, which is a contradiction.

(b) Consider a run in which at most $f \in [0, t-2]$ processes crash, and suppose by contradiction that a process p_i completes round $f+2$ without halting. Observe that if any process p_j halts at round $k \leq f+1$, then p_j sends a DEC message in round k. Since p_j completes round k, p_i receives the DEC message, sets *lastRound* to *true* in round k, and halts in round $k+1 \leq f+2$. Thus no process halts by $f+1$. As p_i does not halt by round $f+2 \leq t$, from Lemma 7.2, for every $g \in [1, f+1]$, we have $newhalt_i^g \neq halt_i^g$. Applying Lemma 7.3 (with $r-1 = f \leq t-1$) we have $|faulty^{f+1}| \geq f+1$, which is a contradiction.

(c) This part of the proof is obvious from the algorithm. □

7.4. Deriving NBAC and UC algorithms. In section 6.3, we showed how to transform any IC algorithm to an NBAC algorithm without any additional communication. An equally straightforward transformation generates a UC algorithm from an IC algorithm: on UC-propose(v), a process invokes IC-propose(v), and if a process IC-decides an n-tuple d, then it UC-decides $d[l]$, where l is the lowest index such that $d[l] \neq \perp$.

The IC algorithm of Figure 7.1 does not locally decide in round 1 in a failure-free run ($f = 0$). Therefore, to match the local decision lower bound for UC when $f = 0$, we modify the UC algorithm obtained from our IC algorithm by adding the following: p_1 UC-decides on its proposal value v_1 in the receive phase of round 1. This modification does not violate UC agreement because, if p_1 completes the send phase of round 1, then every process that completes round 1 has $newest[1] = v_1$ at the end of round 1. At the beginning of round 2, the processes set *est* to *newest*. Subsequently, at all processes, $newest[1]$ and $est[1]$ are always v_1. Thus, in our transformation of IC algorithm to UC algorithm, no process can UC-decide a value different from v_1.

7.5. Synchronous results summary. Combining our lower bound results with the time-complexity of the IC algorithm, the derived NBAC and UC algorithms, and the simple NC algorithm sketched in the introduction, we get the following tight bounds:

1. $\forall t \in [1, n-1]$, $\forall f \in [0, t]$, (SCS_t, SCS_f, NC, ld) $= f$. Local decision bound for consensus.
2. $\forall t \in [1, n-1]$, $\forall f \in [0, t-1]$, (SCS_t, SCS_f, UC, ld) $= f+1$. Local decision bound for uniform consensus.
3. (a) $\forall t \in [1, n-1]$, $\forall f \in [1, t-1]$, $\forall P \in$ {NBAC, IC}, (SCS_t, SCS_f, P, ld) $= f+1$. (b) $\forall t \in [1, n-1]$, $\forall P \in$ {NBAC, IC}, (SCS_t, SCS_0, P, ld) $= 2$. Local decision bounds for nonblocking atomic commit and interactive consistency.

8. Eventually synchronous lower bound. In this section we investigate lower bounds for UC in eventually synchronous models ES_t. We do not consider lower bounds for NBAC and IC in ES_t because they are impossible to solve in ES_t if $t \geq 1$. Furthermore, any algorithm that solves consensus also solves uniform consensus in ES_t [16]. Thus, in ES_t, we investigate only lower bounds for uniform consensus.

We know from [14] that every UC algorithm in ES_t has a run that requires an arbitrary number of rounds for any correct process to decide (because a run may remain "asynchronous" for an arbitrary number of rounds). Thus, we focus on *synchronous* runs of ES_t, i.e., runs in which $GSR = 1$. (In other words, a run of ES_t is synchronous if it is also a run of SCS_t.)

As all runs of SCS_t are synchronous runs of ES_t, the local and global decision lower bounds for UC in SCS_t also hold for synchronous runs of ES_t; i.e., roughly speaking, the local decision lower bound is $f+1$ and the global decision lower bound is $f+2$. However, we knew of no algorithm that showed that the bounds are tight, except when $f = 0$ and $f = t$ (the best and the worst case): the global decision tight bound is 2 rounds in runs with $f = 0$ crashes [19, 28, 26], and $t+2$ rounds in runs with at most $f = t$ crashes [9].

In the following proposition, we show that, for most values of f, the local decision lower bound is $f+2$ rounds, which is the same as the lower bound for global decision. (We give a matching algorithm in section 9.) The proposition states that every UC algorithm in ES_t has a run in SCS_f (i.e., a synchronous run with at most f crashes) in which every correct process decides in round $f+2$ or a higher round.

PROPOSITION 8.1. *For all t s.t. $1 \leq t < n/2$, for all $f \in [0, t-3]$,* (ES_t*,* SCS_f*, UC, ld*) $\geq f+2$.

Remarks. We exclude the following two cases. (1) $t = 0$: In this case, processes can decide after exchanging proposal values in the very first round in synchronous runs (e.g., decide always on the proposal value of p_1). (2) $t \geq n/2$: In this case, we know that there is no UC algorithm in ES_t.

Proof. Suppose by contradiction that there is a UC algorithm A in ES_t and an integer f in $[0, t-3]$ such that in every synchronous run of A with f crashes some correct process decides by round $f+1$. Since SCS_t is a submodel of ES_t, A solves UC in SCS_t as well. We also observe that any UC algorithm also solves WA. Thus A solves WA in SCS_t. Thus from Lemma 5.2 we know that there are two runs of A in SCS_t such that their round f configurations, y and y', satisfy the following: (1) at most f processes have crashed in each configuration, (2) the configurations differ at exactly one process, say, p_i, and (3) $val(y) = 0$ and $val(y') = 1$. (Recall that, given a configuration C, $r(C)$ and $val(C)$ are defined only if C is a configuration of a run in a synchronous model.)

We note that in y or y', any alive process p_j that is distinct from p_i has not yet decided. Otherwise, as y and y' differ only at p_i, process p_j would decide the same value v in y and y', and hence, p_j is a correct process that decides v in both $r(y)$ and $r(y')$, which is a contradiction.

Let z and z' denote the configurations at the end of round $f+1$ of $r(y)$ and $r(y')$, respectively. Runs $r(y)$ and $r(y')$ are runs of A in SCS_t and hence synchronous runs of A in ES_t. As at most f processes crash in each run, $r(y)$ and $r(y')$, it follows from our assumption about algorithm A that some correct process decides by round $f+1$ in each run. Thus, there is at least one alive process in z, say, q_1, that has decided 0. Similarly, there is at least one alive process in z', say, q_3, that has decided 1. There are three cases to consider. (We now consider runs of A in ES_t.)

Case 1. $p_i \notin \{q_1, q_3\}$. Thus we have (1) a round $f+1$ configuration z and a process q_1 such that at most f processes have crashed in z, and q_1 is alive and has decided 0 in z, (2) a round $f+1$ configuration z' and a process q_3 such that at most f processes have crashed in z', and q_3 is alive and has decided 1 in z', and (3) process p_i is distinct from both q_1 and q_3. (Processes q_1 and q_3 might not be distinct.) There are two subcases to consider.

Case 1a. Process p_i is alive in y and y'. Consider the following two synchronous runs of A.

$R1$ is a run such that (1) the round f configuration is y, (2) p_i crashes in the send phase of round $f+1$ such that only q_1 and q_3 receive the message from p_i, (3) q_1 and q_3 crash in round $f+2$ before sending any message, and (4) no process distinct from p_i, q_1, and q_3 crashes after round f. Notice that q_1 cannot distinguish the round $f+1$ configuration of $R1$ from z and therefore decides 0 at the end of round $f+1$ in $R1$. By uniform agreement, every correct process decides 0. Since $t \leq n-1$, there is at least one correct process in $R1$, say, p_l.

$R2$ is a run such that (1) the round f configuration is y', (2) p_i crashes in the send phase of round $f+1$ such that only q_1 and q_3 receive the message from p_i, (3) q_1

and q_3 crash in round $f+2$ before sending any message, and (4) no process distinct from p_i, q_1, and q_3 crashes after round f. Notice that q_3 cannot distinguish the round $f+1$ configuration of $R2$ from z' and therefore decides 1 at the end of round $f+1$ in $R2$. However, p_l cannot distinguish $R1$ from $R2$: at the end of round $f+1$, the two runs are different only at p_i, q_1, and q_3, and none of the three processes sends messages after round $f+1$ in both runs. Thus (as in $R1$) p_l decides 0 in $R2$, which is a contradiction to uniform agreement.

Case 1b. Process p_i has crashed in either y or y'. (Process p_i has not crashed in both y and y' because p_i has different states in y and y'.) Without loss of generality, we can assume that p_i has crashed in y, and hence, p_i is alive in y'. Consider the following two synchronous runs of A.

$R12$ is a run such that (1) the round f configuration is y (and hence, p_i has crashed before round $f+1$), (2) no process crashes in round $f+1$, (3) q_1, and q_3 crash in round $f+2$ before sending any message, and (4) no process distinct from p_i, q_1, and q_3 crashes after round f. Observe that the round $f+1$ configuration of $R12$ is z, and hence, q_1 decides 0 at the end of round $f+1$ in $R12$. Due to uniform agreement, every correct process decides 0 in $R12$. Since $t \leq n-1$, there is at least one correct process in $R12$, say, p_l.

$R21$ is a run such that (1) the round f configuration is y', (2) p_i crashes in the send phase of round $f+1$ such that only q_1 and q_3 receive the message from p_i, (3) q_1 and q_3 crash in round $f+2$ before sending any message, and (4) no process distinct from p_i, q_1, and q_3 crashes after round f. Notice that q_3 cannot distinguish the round $f+1$ configuration of $R21$ from z' because it receives the round $f+1$ message from p_i in both runs. Thus (as in z') q_3 decides 1 at the end of round $f+1$ in $R21$. However, p_l cannot distinguish $R12$ from $R21$: at the end of round $f+1$, the two runs are different only at p_i, q_1, and q_3, and none of them sends messages after round $f+1$ in both runs. Thus (as in $R12$), p_l decides 0 in $R21$, which is a contradiction to uniform agreement.

Case 2. $p_i \in \{q_1, q_3\}$ and p_i is alive in both y and y'.

Remark. To see why we cannot reuse the proof of Case 1, observe that if $p_i = q_1$, then run $R1$ is not a valid run of A in SCS_t: in SCS_t, p_i cannot decide in the receive phase of round $f+1$ while some of its messages from that round are lost. Similarly, if $p_i = q_3$, then run $R2$ is not a valid run in SCS_t. Hence, in this case, we construct some runs of A in ES_t that are not in SCS_t (i.e., nonsynchronous runs) to derive a contradiction.

Without loss of generality we can assume that $p_i = q_1$. (Note that the proof holds even if $p_i = q_1 = q_3$.) Consider the following three runs ($R3$ is a synchronous run, whereas $R4$ and $R5$ are nonsynchronous runs. We would like to point out that, as required by the properties of ES_t, in all nonsynchronous runs that we construct, we ensure that in every round, processes received at least $n-t$ messages of the current round, and channels are reliable):

$R3$ is a run such that (1) the round f configuration is y, (2) p_i crashes in round $f+1$ before sending any message, (3) if $q_3 \neq p_i$ then q_3 crashes in round $f+2$ before sending any message, and every message sent by q_3 in round $f+1$ is received in round $f+1$, (4) no process distinct from p_i and q_3 crashes in round $f+1$ or in a higher round, and (5) no message is delayed. Since $t < n/2 < n-1$, there is at least one correct process in $R3$, say, p_l. Suppose p_l decides $v \in \{0,1\}$ in some round $K1 \geq f+1$. (To see why p_l cannot decide before round $f+1$ in $R3$, notice that the state of p_l at the end of round f is the same in runs $r(y)$, $r(y')$, and $R3$, because $p_l \neq p_i$. If p_l

decides v before round $f+1$ in $R3$, then it also decides v in $r(y)$ and $r(y')$. However, $val(y) \neq val(y')$.)

$R4$ is a run such that (1) the round f configuration is y, (2) p_i and q_3 crash in round $f+2$ before sending any message, and only p_i and q_3 receive the round $f+1$ message from p_i (all other round $f+1$ messages from p_i are lost[1]), (3) if $q_3 \neq p_i$, every process that completes round $f+1$ receives a round $f+1$ message from q_3, (4) no process distinct from p_i and q_3 crashes in round $f+1$ or in a higher round, and (5) no message is delayed. Notice that p_i cannot distinguish the configuration at the end of round $f+1$ in $R4$ from z, and thus, p_i decides 0 at the end of round $f+1$ in $R4$ (because $p_i = q_1$ decides 0 in z). However, p_l cannot distinguish the round $K1$ configuration of $R4$ from that of $R3$ because (a) at the end of round f, the two runs are different only at p_i, (b) all round $f+1$ messages sent by p_i to processes distinct from p_i and q_3 are lost, and (c) p_i and q_3 do not send messages after round $f+1$. Thus (as in $R3$) p_l decides v in round $K1$.

$R5$ extends y' in the same way as $R4$ extends y. Namely, $R5$ is a run such that (1) the round f configuration is y', (2) p_i and q_3 crash in round $f+2$ before sending any message, and only p_i and q_3 receive the round $f+1$ message from p_i (all other round $f+1$ messages from p_i are lost), (3) if $q_3 \neq p_i$, then every process that completes round $f+1$ receives the round $f+1$ message from q_3, (4) no process distinct from p_i and q_3 crashes in round $f+1$ or in a higher round, and (5) no message is delayed. Notice that q_3 cannot distinguish the configuration at the end of round $f+1$ in $R5$ from z' (because in both runs, q_3 receives the round $f+1$ message from p_i), and thus, q_3 decides 1 at the end of round $f+1$ in $R5$. However, p_l cannot distinguish the round $K1$ configuration of $R5$ from that of $R3$ because, (a) at the end of round f the two runs are different only at p_i, (b) all round $f+1$ messages sent by p_i to processes distinct from p_i and q_3 are lost, and (c) p_i and q_3 do not send messages after round $f+1$. Thus (as in $R3$) p_l decides v in round $K1$.

Clearly, either $R4$ or $R5$ violates uniform agreement: p_l decides v in both runs; however, p_i decides 0 in $R4$ and q_3 decides 1 in $R5$.

Case 3. $p_i \in \{q_1, q_3\}$ and p_i has crashed in either y or y'. (Process p_i has not crashed in both y and y' because p_i has different states in y and y'.) Notice that the case $p_i = q_1 = q_3$ is not possible because, in that case, p_i is alive in both z and z' and hence in y and y'. We show the contradiction for the case when $p_i = q_1 \neq q_3$. (The contradiction for $p_i = q_3 \neq q_1$ is symmetric.)

Since, $p_i = q_1$, p_i is alive in z and hence alive in y. Thus p_i has crashed in y'. Consider the following nonsynchronous run.

$R6$ is a run such that (1) the round f configuration is y, (2) in round $f+1$, only p_i receives the round $f+1$ message from itself (all other messages sent by p_i in round $f+1$ are lost), (3) p_i crashes in round $f+2$ before sending any message, (4) no process distinct from p_i crashes in round $f+1$ or in a higher round, and (5) no message is delayed. At the end of round $f+1$ in $R6$, p_i cannot distinguish the configuration from z and therefore decides 0 (because $p_i = q_1$ decides 0 in z). However, q_3 does not receive the round $f+1$ message from p_i in $R6$, and hence, q_3 cannot distinguish the configuration at the end of round $f+1$ in $R6$ from z'. (Observe that, in z', q_3 does not receive the round $f+1$ message from p_i because p_i has crashed in y'.) Consequently, q_3 decides 1 in $R6$, which is a contradiction to uniform agreement. □

Remark. A closer look at the proof of Proposition 8.1 reveals that the non-

[1] From the definition of ES_t, messages sent by a faulty process (p_i) may be lost in a nonsynchronous run.

synchronous runs we construct ($R4$, $R5$, and $R6$) require only a small amount of nonsynchrony in the model. The three runs are valid in a weakened synchronous model where the following holds: even if some message from process p_i is lost in round $f+1$, then p_i might complete round $f+1$. (Recall that, in a synchronous model, if some message from p_i is lost in round $f+1$, then p_i has necessarily crashed in the send phase of round $f+1$.) It is easy to see that such runs are also valid in the synchronous send-omission model [17] as well as in an asynchronous round based model enriched with a *Perfect* failure detector [2]. Thus the $f+2$ local decision lower bound in synchronous runs also extends to these two models.

9. A matching eventually synchronous algorithm.

In this section, we present a UC algorithm in ES_t that matches the local and global decision lower bounds in synchronous runs. We assume that $t < n/2$, as UC is impossible to solve in ES_t if $t \geq n/2$ [11]. As we pointed out earlier, [19, 28, 26] give a UC algorithm in ES_t that matches the global decision bound for synchronous runs with $f = 0$ crashes, and [9] gives a UC algorithm in ES_t that matches the global decision bound for synchronous runs with $f = t$ crashes. We knew of no UC algorithm that matches the bounds for $1 \leq f \leq t-1$.

Figure 9.1 presents a uniform consensus algorithm A_{es} in ES_t that globally decides (and hence, locally decides) within $f+2$ rounds in every synchronous run with at most f crashes for $0 \leq f \leq t$. In other words, our algorithm matches the $f+2$ round global (and local) decision lower bound for synchronous runs of UC algorithms in ES_t.

9.1. Overview.

Algorithm A_{es} is a generalization of the UC algorithm of [9] modified for early decision. A_{es} assumes the following: (1) the model ES_t with $0 \leq t < n/2$ (i.e., a majority of processes are correct), (2) any message sent by a process p_i to itself in any round k is received in round k, or p_i crashes in round k, and (3) the set of proposal values in a run is a totally ordered set, e.g., every process p_i can tag its proposal value with its index i and then the values can be ordered based on this tag. (A matching algorithm that does not rely on each process receiving at least $n-t$ messages in every round is described in [8].)

The algorithm A_{es} proceeds in sessions, where each session is composed of $t+2$ rounds of message exchange. A run globally decides within $f+2$ rounds in a "synchronous" session, provided at most f processes crash in the run. In each round of a session, processes exchange their estimate (of the decision value), and, roughly speaking, adopt the minimum estimate value seen in the round as the estimate for the next round. In this respect, a session of A_{es} is similar to the IC algorithm presented in section 7: if the model was synchronous, then a process p_i could simply monitor the set of processes from which p_i did not receive any message (set $Halt_i$), and then, p_i could decide on its own estimate when $Halt_i$ did not change for a round. Basically, p_i could do so because, in a synchronous model, $Halt_i$ would be equal to the set of crashed processes, and hence, if $Halt_i$ did not change for a round, then p_i would have the smallest estimate among all alive processes.

However, in ES_t, even if p_i does not receive a message from some process p_j, p_j might not have crashed, and p_j can continue sending messages in subsequent rounds. Thus, even if $Halt_i$ does not change for a round, p_i might not have the lowest estimate among all alive processes. Therefore, in A_{es}, in addition to the estimate values, processes also exchange the $Halt$ sets to detect whether the current session is synchronous. Furthermore, to ensure early decision, p_i maintains and exchanges a variable STATE_i which indicates if p_i considers the current session to be synchronous ($\text{SYNC}1$), or if p_i

FIG. 9.1. *A uniform consensus algorithm A_{es} in ES_t.*

considers the session to be synchronous with the possibility of a decision in the next round (SYNC2), or whether p_i considers the session to be asynchronous (NSYNC).

9.2. Description. The processes invoke propose($*$) with their respective proposal values as a parameter, and the propose procedure progresses in *sessions*: a session consists of $t+2$ rounds, and session sn contains rounds from $((sn-1)*(t+2))+1$ to $sn*(t+2)$. We call the kth round in a session sn (i.e., round $((sn-1)*(t+2))+k$) *step k* of session sn. Recall that, for every run R in ES_t, there is an unknown round number GSR from which the system is *synchronous* (eventual synchrony property of ES_t). We say that a session is synchronous if the session starts in round GSR or in a higher round.

Every process p_i maintains the following variables:

k_i is the current round number;

STATE$_i$ at p_i reflects its view on how much progress is made toward achieving a decision in the current session: (1) if STATE$_i$ is updated to NSYNC then p_i considers the current session to be asynchronous, (2) if STATE$_i$ is updated to SYNC1 then p_i considers the session to be synchronous but p_i cannot decide in the next round, (3) if STATE$_i$ is updated to SYNC2 then p_i considers the session to be synchronous with the possibility of a decision in the next round, and (4) p_i updates STATE$_i$ to DECIDE upon decision;

est_i is the estimate of the possible decision value, and, roughly speaking, the minimum value seen by p_i;

$Halt_i$ is a set of processes p_j such that, in the current round or a lower round of this session, at least one of the following occurred: p_i received STATE = NSYNC from p_j, p_i did not receive a message from p_j, or p_i received a messages from p_j with $p_i \in Halt_j$;

$msgSet_i$ is a set of messages received by p_i from processes that are not in $Halt_i$.

The variables are initialized as follows. Round number s_i starts from 1 and est_i is initialized to the proposal value of p_i. Variables STATE_i and $Halt_i$ are initialized to SYNC1 and $\emptyset$, respectively and, if p_i has not yet decided, are reset to their initial values at the beginning of each session. In each round, processes exchange est, STATE, and $Halt$ variables, update their own variables depending upon the messages received, and possibly decide. In step k, p_i updates its variables as follows.

1. If p_i receives a DECIDE message, then p_i decides on the decision value received.
2. If STATE_i is SYNC1 or SYNC2, then the following hold:
   - p_i updates $Halt_i$ to include all processes already in $Halt_i$ and also includes the set of processes p_j such that (a) p_i has received an NSYNC message from p_j in step k, (b) p_i has received a message from p_j with $p_i \in Halt_j$ in step k, or (c) p_i has not received any message from p_j in step k.
   - p_i includes in $msgSet_i$ every message received in step k whose sender is not in $Halt_i$, and p_i computes est_i to be the minimum est value among messages in $msgSet_i$.
   - If STATE_i is SYNC2, $Halt_i$ is of size at most t, and all messages in $msgSet_i$ contain STATE = SYNC2, then p_i decides on its estimate.
   - Depending on the size h of the set $Halt_i$, p_i updates STATE_i as follows: if h is lower than the current step number, then STATE_i is set to SYNC2; else if h is at most t, then STATE_i is set to SYNC1; otherwise, STATE_i is set to NSYNC.
3. If STATE = NSYNC and p_i receives a message with STATE = SYNC2, then p_i adopts the estimate contained in that message.
4. Upon decision in round k, p_i sends the decision value to all processes in round $k + 1$ and then halts.

9.3. Correctness. The validity property of the algorithm follows from the following three simple observations: (1) the est value of a process is initialized to the proposal value of the process, (2) the est value of a process at the beginning of round $s \geq 2$ is the est value of some process at the beginning of round $s - 1$, and (3) every process decides on the est value of some process. In the rest of the section, we prove the uniform agreement property of the algorithm. We defer the proof of the termination property to the next subsection, where we prove termination along with the time-complexity property of the algorithm.

For a given session, we introduce the following notation. For every variable val_i at process p_i, we denote by $val_i[k]$ ($k \geq 1$) the value of the variable val_i immediately after the completion of step k; $val_i[0]$ denotes the value of val_i immediately before sending messages in step 1. We assume that there is a symbol *undefined* that is distinct from any possible value of the variables in the algorithm. If p_i crashes before completing step k, then $val_i[k] =$ *undefined*; if p_i crashes before sending messages in step 1, then $val_i[0] =$ *undefined*. For every process p_l that completes step k with $\text{STATE}_l[k] \in \{\text{SYNC1, SYNC2}\}$, let $senderMS_l[k]$ denote the set of processes that have sent the messages in $msgSet_l[k]$. We first prove the following lemma.

LEMMA 9.1. *Consider any session and a process p_l that completes step k with $\text{STATE}_l[k] \in \{\text{SYNC1, SYNC2}\}$. Then, $senderMS_l[k] = \Pi - Halt_l[k]$.*

Proof. Process p_l completes step k with STATE = SYNC1 or STATE = SYNC2 and hence updates $Halt$ and $msgSet$ at line 17 and line 18 of step k, respectively. Consider any process $p_m \in \Pi$. There are two cases concerning the message from p_m to p_l in step k.

- If p_l does not receive the messages from p_m in step k, then from the third condition in line 17, $p_m \in \mathit{Halt}_l[k]$, and from line 18, $p_m \notin \mathit{senderMS}_l[k]$.
- If p_l receives the step k message from p_m, then from line 18, $p_m \in \mathit{senderMS}_l[k]$ if and only if $p_m \notin \mathit{Halt}_l[k]$. □

LEMMA 9.2 (uniform agreement). *No two processes decide differently.*

Proof. If no process ever decides, then the lemma is trivially true. Thus, consider the lowest session sn in which some process decides. In session sn, consider the lowest step in which some process decides, say, step $k' + 1 \geq 2$. (It is easy to see that no process can decide in step 1 of sn.) If some process decides in line 15, then some other process has decided in a lower step of sn or in a lower session, which is a contradiction to the definition of $k' + 1$ and sn. Thus some process decides in line 21 of step $k' + 1$. We claim the following.

CLAIM 9.3 (elimination). *Consider the lowest session sn in which some process decides. If $k' + 1 \geq 2$ is the lowest step in sn in which some process decides, then, if there are two processes p_x and p_y such that* $\text{STATE}_x[k'] \in \{\text{SYNC1},\text{SYNC2}\}$ *and* $\text{STATE}_y[k'] = \text{SYNC2}$*, then* $est_x[k'] \geq est_y[k']$*.*

Proof of Lemma 9.2 *continued.* For now, we assume the above claim and prove uniform agreement. We later give a proof of Claim 9.3. Suppose that some process p_w decides d at line 21 of step $k' + 1$. From lines 19 and 20 it follows that there is a message in $\mathit{msgSet}_w[k' + 1]$ that has $\text{STATE} = \text{SYNC2}$ and $est = d$, say, from process p_v. Consider another process p_u that completes step k' with $\text{STATE} = \text{SYNC2}$ and $est = d'$. Applying Claim 9.3 twice with $p_x = p_v$ and $p_y = p_u$, and vice-versa, we get $d' = d$. It follows that, every process that completes step k' with $\text{STATE} = \text{SYNC2}$ does so with $est = d$. Notice that every process that decides at line 21 in step $k' + 1$ (that includes p_w) has only messages with $\text{STATE} = \text{SYNC2}$ in the $\mathit{msgSet}[k' + 1]$, and hence, all these messages have $est = d$. Consequently, every process that decides in line 21 of step $k' + 1$ sets its est to d in line 19 and then decides on its $est = d$ in line 21. Thus, every process that decides in step $k' + 1$ decides d. (Recall that no process can decide in line 15 of step $k' + 1$.) It remains to be shown that no process decides a different value in a higher step of sn or in a higher session.

From line 20 we have $|\mathit{Halt}_w[k' + 1]| \leq t$, and hence, Lemma 9.1 implies that $\mathit{msgSet}_w[k' + 1]$ contains at least $n - t$ messages, i.e., messages from a majority of processes. Furthermore, the last condition in line 20 requires that every message in $\mathit{msgSet}_w[k'+1]$ has $\text{STATE} = \text{SYNC2}$. Thus, a majority of the processes sent a message with $\text{STATE} = \text{SYNC2}$ in step $k' + 1$. As the round $k' + 1$ message from process p_v has $\text{STATE} = \text{SYNC2}$ and $est = d$, by applying Claim 9.3, it follows that for messages in round $k' + 1$, (1) every message with $\text{STATE} = \text{SYNC2}$ in round $k' + 1$ has $est = d$, and (2) every message with $\text{STATE} = \text{SYNC1}$ has $est \geq d$.

Now consider the est value of any process p_i at the end of step $k'+1$. If $\text{STATE}_i[k'+1] = \text{NSYNC}$, then p_i has received at least one message with $\text{STATE} = \text{SYNC2}$ and $est = d$ (because a majority of processes have sent such messages and, in every step, p_i receives messages from at least $n - t$ processes, a majority) and therefore updates its est to d (line 28). On the other hand, if $\text{STATE}_i[k' + 1] \in \{\text{SYNC1}, \text{SYNC2}\}$ then $\mathit{Halt}_i[k' + 1] \leq t$ (line 22 and line 24). Therefore, $\mathit{msgSet}_i[k' + 1]$ contains at least $n - t$ messages (Lemma 9.1). Furthermore, $\mathit{msgSet}_i[k' + 1]$ contains no message with $\text{STATE}_i[k'+1] = \text{NSYNC}$ (line 17 and line 18). Therefore, from Claim 9.3, every message in $\mathit{msgSet}_i[k' + 1]$ has $est \geq d$ and there is at least one message with $\text{STATE} = \text{SYNC2}$

and $est = d$ (because, in step $k' + 1$, a majority of processes sent messages with $\text{STATE} = \text{SYNC2}$ and $est = d$). Therefore, in line 19, p_i updates est to d.

Thus every process that completes step $k' + 1$ updates its est to d, and every process that decides in step $k' + 1$ decides d. Suppose by contradiction that some process decides a value different from d in a higher step of sn or in a higher session. Consider the lowest session sn'' and the lowest step k'' in sn'' in which some process p_j decides a value different from d, say, d''. Observe that if p_j decides in line 15 of step k'', then from line 14 it follows that some process has decided d'' in a lower step of sn'' or in a lower session. Thus p_j has decided on its est in line 21. Again observe that, given a session sn', the est value of a process at the end of some step $k \geq 2$ is the est value of some process at the end of step $k - 1$, and the est value of a process at the end of the step $k = 1$ is the est value of some process at the end of step $t + 2$ of the previous session $sn' - 1$. Therefore, the est value of any process in a step higher than $k' + 1$ in session sn, or in a higher session, cannot be different from d. Thus p_j cannot decide d'' in step k'' of sn'', which is a contradiction. □

CLAIM 9.3. *Consider the lowest session sn in which some process decides. If* $k' + 1 \geq 2$ *is the lowest step in sn in which some process decides, then, if there are two processes* p_x *and* p_y *such that* $\text{STATE}_x[k'] \in \{\text{SYNC1}, \text{SYNC2}\}$ *and* $\text{STATE}_y[k'] = \text{SYNC2}$*, then* $est_x[k'] \geq est_y[k']$.

Proof. Suppose by contradiction that there are two processes p_x and p_y such that the following holds.

Assumption A1. $\text{STATE}_x[k'] \in \{\text{SYNC1}, \text{SYNC2}\}$, $\text{STATE}_y[k'] = \text{SYNC2}$, $est_x[k'] = c$, $est_y[k'] = d$, and $c < d$.

In the context of session sn, we show Claims 9.3.1–9.3.7 based on the definition of k' and the Assumption A1. Claim 9.3.4 contradicts Claim 9.3.7, which completes the proof of Claim 9.3 by contradiction. □

Let us define the following sets for $k \in [1, k' + 1]$:

- $C[k] = \{p_i | est_i[k] \leq c\}$ (the set of processes that complete step k with $est \leq c$).
- $crashed[k]$ = the set of processes that crashed before completing step k.
- $NSYN[k] = \{p_i | \text{STATE}_i[k] = \text{NSYNC}\}$.
- $Z[k] = C[k] \cup crashed[k] \cup NSYN[k]$.

Additionally, let us define $C[0]$ to be the set of processes that start step 1 with est less than or equal to c, $crashed[0]$ to be the set of processes that crash before sending any message in step 1, $NSYN[0] = \emptyset$, and $Z[0] = C[0] \cup crashed[0] \cup NSYN[0]$. We make the following observation.

Observation A2. $|C[0]| \geq 1$, and hence, $|Z[0]| \geq 1$. Otherwise, if every process starts step 1 with a value greater than c, then $est_x[k'] > c$ (which contradicts Assumption A1).

Proof sketch. Before presenting Claims 9.3.1–9.3.7, we give a rough sketch of the overall proof. Recall that Z is the set of processes that crashed, entered state NSYNC, or have estimate less than or equal to c at the end of a step. $Z[k]$ denotes the set Z at the end of step k. We derive a contradiction on the size of set Z by showing that (1) for p_y to complete step k' with $\text{STATE} = \text{SYNC2}$ and $est = d$, we need $|Z[k' - 1]| \leq k' - 1$, but (2) for Assumption A1 to be satisfied, $|Z|$ should increase in every step, and hence, $|Z[k' - 1]| > k' - 1$.

We first note that, if a process is in set $Z[k]$, then it remains in that set in all higher steps. To see why, note that once a process crashes or enters state NSYNC, it stays in those states. In addition, if a process has $est \leq c$, then, unless it crashes or enters state NSYNC, the process updates its estimate to the lowest estimate seen in that step, which cannot be more than c.

Now, from Assumption A1, process p_y completes step k' with state SYNC2. From the algorithm, this requires that $Halt_y$ set of p_y at the end of step k' is of size at most $k'-1$. Now consider the message from a process p_j in $Z[k'-1]$ to p_y in step k'. Either p_y does not receive a message from p_j or it receives one with state NSYNC, or with $est \leq c$. In the first two cases, p_y puts p_j in its $Halt_y$ set, and the last case is not possible because it requires p_y to update its est to a value lower than d. Thus the set $Z[k'-1]$ is a subset of $Halt_y$ at the end of step k', and hence, $|Z[k'-1]| \leq k'-1$.

From the definition of Z and Assumption A1, process p_x is in $Z[k']$. We also show that p_x is not in $Z[k'-2]$. To see why, assume otherwise. Then p_x sends step $k'-1$ messages with $est \leq c$, and therefore, processes in $\Pi - Z[k'-1]$ do not receive any message from p_x (otherwise, they would update their estimate to a value at most c and hence be in set $Z[k'-1]$). Note that the number of processes that are in $\Pi - Z[k'-1]$ is more than t as we have already shown $|Z[k'-1]| \leq k'-1 \leq t < n/2$. Thus, in step k', more than t processes send messages with $p_x \in Halt$. From the algorithm, p_x puts all such processes in its $Halt_x$ set. However, a $Halt_x$ set of size more than t requires p_x to enter state NSYNC, which is a contradiction.

We next show that at least one process enters the set Z in every step (until step $k'-2$). For ease of presentation, in this proof sketch, we ignore crashed processes and processes with state NSYNC. Suppose by contradiction that no process enters the set Z in some step g; i.e., $Z[g] = Z[g+1]$. Then, arguing as above, processes in $\Pi - Z[g+1]$ do not receive any message from processes in $Z[g]$ (otherwise, they would update their estimate to a value at most c, and hence be in set $Z[g+1]$). It follows from the algorithm that, in subsequent steps, every process in $\Pi - Z[g+1] = \Pi - Z[g]$ ignores estimate values received from any process in $Z[g]$. Thus no process in $\Pi - Z[g]$ adopts an est less than or equal to c. Thus set Z does not change after round g. This contradicts our earlier observation that p_x is in $Z[k']$ but not in $Z[k'-2]$. (The actual proof of this claim is bit involved because we need to consider crashed processes and processes with state NSYNC.)

As $|Z|$ increases by at least 1 in every step until step $k'-2$, we have $|Z[k'-2]| \geq k'-1$. Using a slightly different argument we can show that $|Z|$ increases by 1 in step $k'-1$ as well. Thus, $|Z[k'-1] > k'-1$, which contradicts our earlier observation. We now give the detailed proof of the claims.

CLAIM 9.3.1. (1) For all $k \in [0, k'-1]$, $(crashed[k] \cup NSYN[k]) \subseteq (crashed[k+1] \cup NSYN[k+1])$. (2) For all $k \in [1, k']$, if $p_i \notin (NSYN[k] \cup crashed[k])$ then p_i sends messages with STATE $\in \{$SYNC1, SYNC2$\}$ in step k, and in all steps lower than k, of this session.

Proof. (1) Suppose by contradiction that there is a process p_i such that $p_i \in crashed[k] \cup NSYN[k]$ and $p_i \notin crashed[k+1] \cup NSYN[k+1]$. Since a crashed process does not recover, $crashed[k] \subseteq crashed[k+1]$, and hence, $p_i \notin crashed[k+1] \cup NSYN[k+1]$ implies that $p_i \notin crashed[k]$. Thus, $p_i \in crashed[k] \cup NSYN[k]$ implies that $p_i \in NSYN[k]$; i.e., p_i completes step k with STATE $=$ NSYNC. Notice that by the definition of k' (i.e., $k'+1$ is the lowest step in which some process decides), the conditions of line 12 and line 14 cannot be true in step $k+1 < k'+1$ for any process. Thus the STATE of p_i remains NSYNC at the end of step $k+1$, i.e., $p_i \in NSYN[k+1]$, which is a contradiction.

(2) If $p_i \notin (NSYN[k] \cup crashed[k])$, then, from Claim 9.3.1.1, it follows that $p_i \notin (NSYN[k_1] \cup crashed[k_1])$ for all $k_1 \leq k$; i.e., p_i completes every step lower than or equal to k with STATE $\neq$ NSYNC. Thus p_i has not sent any message with

STATE = NSYNC in step k or in a lower step. □

CLAIM 9.3.2. For all $k \in [0, k'-1]$, $Z[k] \subseteq Z[k+1]$.

Proof. Suppose by contradiction that there is a process p_i and some $k \in [0, k'-1]$ such that $p_i \in Z[k]$ and $p_i \notin Z[k+1]$. Since $p_i \notin Z[k+1]$, then $p_i \notin \mathit{crashed}[k+1] \cup \mathit{NSYN}[k+1]$. Applying Claim 9.3.1(1), we get $p_i \notin \mathit{crashed}[k] \cup \mathit{NSYN}[k]$. However, $p_i \in Z[k] = C[k] \cup \mathit{crashed}[k] \cup \mathit{NSYN}[k]$, and hence, $p_i \in C[k]$.

We first observe that p_i sends messages with STATE ≠ NSYNC in the first $k+1$ steps: this follows from $p_i \notin \mathit{crashed}[k+1] \cup \mathit{NSYN}[k+1]$ and Claim 9.3.1(2). As p_i always receives messages from itself and does not send any message with STATE ≠ NSYNC in the first $k+1$ steps, it follows that $p_i \notin \mathit{Halt}_i[k+1]$ (line 17). Furthermore, $p_i \notin \mathit{crashed}[k+1] \cup \mathit{NSYN}[k+1]$ implies that p_i completes step $k+1$ with STATE = SYNC1 or STATE = SYNC2. Applying Lemma 9.1 we have $p_i \in \mathit{senderMS}_i[k+1]$. Thus, the step $k+1$ message from p_i is in $\mathit{msgSet}_i[k+1]$. However, as $p_i \in C[k]$, the step $k+1$ message from p_i contains $\mathit{est}_i[k] \leq c$. Thus, when p_i evaluates *est* in line 19 of step $k+1$, p_i considers its own message with $\mathit{est}_i[k] \leq c$ and hence adopts a value less than or equal to c as $\mathit{est}_i[k+1]$. Thus $p_i \in C[k+1] \subseteq Z[k+1]$, which is a contradiction. □

CLAIM 9.3.3. For all $k \in [0, k'-1]$, for all $p_i \notin Z[k+1]$, $Z[k] \subseteq \mathit{Halt}_i[k+1]$.

Proof. Consider a process $p_j \in Z[k]$ and a process $p_i \notin Z[k+1]$. In step $k+1$, $\mathit{msgSet}_i[k+1]$ either contains a message from p_j or does not contain any message from p_j. In the second case, Lemma 9.1 implies that $p_j \in \mathit{Halt}_i[k+1]$. Consider the case where $\mathit{msgSet}_i[k+1]$ contains a message m from p_j. From line 17 and line 18, it follows that m contains STATE ≠ NSYNC, and hence, $p_j \notin \mathit{NSYN}[k]$. Furthermore, p_j has sent a message in step $k+1$, and so, $p_j \notin \mathit{crashed}[k]$. Thus $p_j \notin \mathit{crashed}[k] \cup \mathit{NSYN}[k]$, but we have assumed $p_j \in Z[k]$. So, $p_j \in C[k]$, and hence, message m from p_j contains an *est* less than or equal to c. Since $m \in \mathit{msgSet}_i[k+1]$, in step $k+1$, p_i evaluates *est* to a value less than or equal to c. Thus $p_i \in C[k+1] \subseteq Z[k+1]$, which is a contradiction. Thus $\mathit{msgSet}_i[k+1]$ does not contain any message from p_j. □

CLAIM 9.3.4. $|Z[k'-1]| \leq k'-1$.

Proof. From Assumption A1, it follows that $p_y \notin Z[k']$. Therefore, from Claim 9.3.3, $Z[k'-1] \subseteq \mathit{Halt}_y[k']$. On the other hand, $\text{STATE}_y[k'] = \text{SYNC2}$ implies that $|\mathit{Halt}_y[k']| \leq k'-1$ (line 22 and line 23). Thus, $|Z[k'-1]| \leq k'-1$. □

CLAIM 9.3.5. $p_x \in Z[k']$ and $p_x \notin Z[k'-2]$.

Proof. As $\mathit{est}_x[k'] = c$, we have $p_x \in C[k'] \subseteq Z[k']$.

For the second part of the claim, suppose by contradiction that $p_x \in Z[k'-2]$. Then, from Claim 9.3.3, for every process $p_i \notin Z[k'-1]$, $p_x \in \mathit{Halt}_i[k'-1]$. Therefore, in step k', if any process in $\Pi - Z[k'-1]$ sends a message m, then $p_x \in m.\mathit{Halt}$ (where $m.\mathit{Halt}$ denotes the *Halt* field of m). If p_x receives m in step k', then it includes the sender of m in Halt_x (because of condition 2 in line 17), and if p_i does not receive m in step k', then p_i includes the sender of m in Halt_x (because of condition 3 in line 17). Thus $\Pi - Z[k'-1] \subseteq \mathit{Halt}_x[k']$. Using Claim 9.3.4, $|\mathit{Halt}_x[k']| \geq |\Pi - Z[k'-1]| \geq n - (k'-1)$. Since $k'+1 \leq t+2$ and $t < n/2$, we have $|\mathit{Halt}_x[k']| \geq n - t > t$. However, $|\mathit{Halt}_x[k']| > t$ implies that $\text{STATE}_x[k'] = \text{NSYNC}$ (line 26 and line 27), which is a contradiction. □

CLAIM 9.3.6. (1) For all $k \in [0, k'-3]$, $Z[k] \subset Z[k+1]$. ($Z[k]$ is a proper subset of $Z[k+1]$.) (2) $|Z[k'-2]| \geq k'-1$.

Proof. (1) From Claim 9.3.2, $Z[k] \subseteq Z[k+1]$ ($k \in [0, k'-1]$). Suppose by contradiction that there is some $g \in [0, k'-3]$ such that $Z[g] = Z[g+1]$.

We first show by induction on the step number k that, for all $k \in [g+1, k'-1]$, $C[k] - (\mathit{NSYN}[k] \cup \mathit{crashed}[k]) \supseteq C[k+1] - (\mathit{NSYN}[k+1] \cup \mathit{crashed}[k+1])$. (This statement corresponds to the brief argument presented in the proof sketch where we showed that if we ignore crashed processes and processes with NSYNC state, then the set Z does not increase after step g.)

Base case $(k = g+1)$. $C[g+1] - (NSYN[g+1] \cup crashed[g+1]) \supseteq C[g+2] - (NSYN[g+2] \cup crashed[g+2])$. Suppose by contradiction that there is a process p_i such that $p_i \in C[g+2] - (NSYN[g+2] \cup crashed[g+2])$ (*Assumption* A3) and $p_i \notin C[g+1] - (NSYN[g+1] \cup crashed[g+1])$ (*Assumption* A4).

Assumption A3 implies that $p_i \notin NSYN[g+2] \cup crashed[g+2]$. Applying Claim 9.3.1.1, we have $p_i \notin NSYN[g+1] \cup crashed[g+1]$, and therefore, from Assumption A4, it follows that $p_i \notin C[g+1]$. Thus p_i completes step $g+1$ with $est > c$ and STATE $\neq$ NSYNC. Furthermore, Assumption A3 implies that p_i completes step $g+2$ with $est \leq c$ and STATE $\neq$ NSYNC. So, $msgSet_i[g+2]$ contains a message with $est \leq c$ from some process p_j, i.e., $p_j \in senderMS_i[g+2]$ (*Observation* A5). As p_j sends a message with $est \leq c$ in step $g+2$, it follows that $p_j \in C[g+1] \subseteq Z[g+1]$.

As $p_i \notin NSYN[g+1] \cup crashed[g+1]$ and $p_i \notin C[g+1]$, from the definition of $Z[g+1]$ we have $p_i \notin Z[g+1]$. Claim 9.3.3 implies that $Z[g] \subseteq Halt_i[g+1]$. Recall that we assumed $Z[g] = Z[g+1]$ and, from line 17, $Halt_i[g+1] \subseteq Halt_i[g+2]$. Therefore, $Z[g+1] \subseteq Halt_i[g+2]$. Thus $p_j \in C[g+1] \subseteq Z[g+1]$ implies that $p_j \in Halt_i[g+2]$. From Observation A5, $p_j \in senderMS_i[g+2] \cap Halt_i[g+2]$.

As $p_i \notin NSYN[g+2] \cup crashed[g+2]$, it follows that p_i completed step $g+2$ with STATE = SYNC1 or STATE = SYNC2. From Lemma 9.1 it follows that $senderMS_i[g+2] \cap Halt_i[g+2] = \emptyset$. However, $p_j \in senderMS_i[g+2] \cap Halt_i[g+2]$, which is a contradiction.

Induction hypothesis $(k \in [g+1, r])$. $C[k] - (NSYN[k] \cup crashed[k]) \supseteq C[k+1] - (NSYN[k+1] \cup crashed[k+1])$ for some $r < k' - 1$.

Induction step $(k = r+1)$. $C[r+1] - (NSYN[r+1] \cup crashed[r+1]) \supseteq C[r+2] - (NSYN[r+2] \cup crashed[r+2])$. Suppose by contradiction that there is a process p_i such that $p_i \in C[r+2] - (NSYN[r+2] \cup crashed[r+2])$ (*Assumption* A6) and $p_i \notin C[r+1] - (NSYN[r+1] \cup crashed[r+1])$ (*Assumption* A7).

Similar to the base case, applying Assumptions A6 and A7, and Claim 9.3.1 gives us $p_i \notin NSYN[r+2] \cup crashed[r+2]$, $p_i \notin NSYN[r+1] \cup crashed[r+1]$, and $p_i \notin C[r+1]$. Thus $p_i \notin Z[r+1]$. Since $g+1 < r+1$, from Claim 9.3.2, we have $Z[g+1] \subseteq Z[r+1]$, and therefore, $p_i \notin Z[g+1]$.

Applying Claim 9.3.3 on $p_i \notin Z[g+1]$ implies that $Z[g] \subseteq Halt_i[g+1]$. Recall that we assumed $Z[g] = Z[g+1]$, and from line 17 and $g+1 < r+2$, $Halt_i[g+1] \subseteq Halt_i[r+2]$. Therefore, $Z[g+1] \subseteq Halt_i[r+2]$ (*Observation* A8).

From the induction hypothesis, we have $(C[g+1] - (NSYN[g+1] \cup crashed[g+1])) \supseteq (C[r+1] - (NSYN[r+1] \cup crashed[r+1]))$. From the definition of $Z[g+1]$, $C[g+1] - (NSYN[g+1] \cup crashed[g+1]) \subseteq C[g+1] \subseteq Z[g+1]$, and therefore, $C[r+1] - (NSYN[r+1] \cup crashed[r+1]) \subseteq Z[g+1]$. Applying Observation A8, we have $(C[r+1] - (NSYN[r+1] \cup crashed[r+1])) \subseteq Halt_i[r+2]$ (*Observation* A9).

As $p_i \notin Z[r+1]$, p_i completes step $r+1$ with $est > c$ and STATE $\neq$ NSYNC. Furthermore, Assumption A6 implies that p_i completes step $r+2$ with $est \leq c$ and STATE $\neq$ NSYNC. Therefore, $msgSet_i[r+2]$ contains a message with $est \leq c$ from some process p_j, i.e., $p_j \in senderMS_i[r+2]$ (*Observation* A10). As p_j sends a message with $est \leq c$ in step $r+2$, $p_j \in C[r+1] \subseteq Z[r+1]$.

As the step $r+2$ message of p_j is in $msgSet_i[r+2]$, from line 17 it follows that the message sent by p_j had STATE $\neq$ NSYNC. Therefore, $p_j \notin NSYN[r+1]$, and clearly, $p_j \notin crashed[r+1]$. Therefore, $p_j \in C[r+1] - (NSYN[r+1] \cup crashed[r+1])$.

From Observation A9 it follows that $p_j \in Halt_i[r+2]$. From Observation A10, $p_j \in senderMS_i[r+2] \cap Halt_i[r+2]$.

As $p_i \notin NSYN[r+2] \cup crashed[r+2]$ (from Assumption A6), p_i completed step $r+2$ with STATE = SYNC1 or STATE = SYNC2. Lemma 9.1 implies that $senderMS_i[r+2] \cap Halt_i[r+2] = \emptyset$. However, $p_j \in senderMS_i[r+2] \cap Halt_i[r+2]$, which is a contradiction.

From the above result (that we proved by induction), we have $C[k'-2]-(NSYN[k'-2] \cup crashed[k'-2]) \supseteq C[k'] - (NSYN[k'] \cup crashed[k'])$. From Assumption A1, $p_x \in C[k'] - (NSYN[k'] \cup crashed[k']))$. From Claim 9.3.5, we have $p_x \notin Z[k'-2] \supseteq (C[k'-2] - (NSYN[k'-2] \cup crashed[k'-2])$. In other words, p_x is in $C[k'] - (NSYN[k'] \cup crashed[k'])$ but not in $C[k'-2]-(NSYN[k'-2] \cup crashed[k'-2])$, which is a contradiction.

(2) Part (1) of this claim implies that for every $k \in [0, k'-3]$, $|Z[k+1]|-|Z[k]| \geq 1$. From Observation A2, $|Z[0]| \geq 1$. Therefore, $|Z[k'-2]| \geq k'-1$. □

CLAIM 9.3.7. $|Z[k'-1]| > k'-1$.

Proof. Suppose by contradiction that $|Z[k'-1]| \leq k'-1$. Since $Z[k'-2] \subseteq Z[k'-1]$ (Claim 9.3.2) and $|Z[k'-2]| \geq k'-1$ (Claim 9.3.6.2), we have $Z[k'-2] = Z[k'-1]$ and $|Z[k'-2]| = |Z[k'-1]| = k'-1$ (*Assumption* A11).

From Claim 9.3.5, we know that $p_x \notin Z[k'-2] = Z[k'-1]$. Applying Claim 9.3.3, we have $Z[k'-2] \subseteq Halt_x[k'-1]$. As $Z[k'-2] = Z[k'-1]$ (from Assumption A11), it follows that $Z[k'-1] \subseteq Halt_x[k'-1]$.

Since $p_x \notin Z[k'-1]$, p_x completes step $k'-1$ with $est > c$ and STATE $\neq$ NSYNC. From Assumption A1, we also know that p_x completes step k' with $est \leq c$ and STATE $\neq$ NSYNC. Therefore, $msgSet_x[k']$ contains a message, say, from process p_j, with $est \leq c$, i.e., $p_j \in senderMS_x[k']$. From the definition of $C[k'-1]$, $p_j \in C[k'-1] \subseteq Z[k'-1]$. However, we showed earlier that $Z[k'-1] \subseteq Halt_x[k'-1]$, and from line 17, it follows that $Halt_x[k'-1] \subseteq Halt_x[k']$. Thus $Z[k'-1] \subseteq Halt_x[k']$ and $p_j \in Halt_x[k']$.

From Assumption A1, we know that p_x completed step k' with STATE = SYNC1 or STATE = SYNC2. Therefore, Lemma 9.1 implies that $senderMS_x[k'] \cap Halt_x[k'] = \emptyset$. However, $p_j \in senderMS_x[k'] \cap Halt_x[k']$, which is a contradiction. □

9.4. Time-complexity. We now discuss the termination and the time-complexity of the algorithm. From the definition of ES_t, for every run R in ES_t, there is an unknown round number GSR from which the system is *synchronous* (eventual synchrony property of ES_t). Define a *synchronous session* as a session that starts in round GSR or in a higher round. Let sn be the lowest synchronous session, and let f be the number of processes that crash in R.

LEMMA 9.4. *Consider any process p_i that completes step $k \in [1, t+2]$ of session sn. If no correct process decides before step k, then every process in $Halt_i[k]$ has crashed by step k.*

Proof. Suppose no correct process decides before step k in session sn. For every step $l \in [0, k]$ in sn, let $H[l]$ be the union of all $Halt_j[l]$ such that $Halt_j[l] \neq$ *undefined*. We claim the following, which immediately implies the lemma: *Every process in $H[l]$ (for all $l \in [0, k]$) crashes by step l.*

We prove the claim by induction on step number l. For $l = 0$, the claim is trivially true, because $H[0] = \emptyset$ (base case). Suppose that the claim is true for $l \in [0, l'-1]$ (for some $l'-1 \leq k-1$): every process in $H[l]$ crashes by step l (induction hypothesis). Consider the set $H[l']$ (induction step). If $H[l']-H[l'-1] = \emptyset$ then the induction step is trivial. Suppose by contradiction that there is a process $p_j \in H[l']-H[l'-1]$ such that

p_j has not crashed by step l'. Thus there is a process p_a such that $p_j \notin Halt_a[l'-1]$ and $p_j \in Halt_a[l']$.

As p_j has not crashed by step l', no correct process has decided before round k, and sn is a synchronous session, so p_a must have received the step l' message m of p_j. Since, $p_j \in Halt_a[l']$, m contains either (a) STATE = NSYNC or (b) set $Halt_j$ such that $p_a \in Halt_j$. Now, we show both cases to be impossible and thus prove the induction step by contradiction.

From our induction hypothesis, for every step $l'' < l'$, every process in $Halt_j[l'']$ has crashed by step l''. Since no more than t processes can crash in a run, in rounds lower than l', $|Halt_j|$ is never higher than t. Thus p_j cannot update its STATE to NSYNC in rounds lower than l' (line 26). Thus the round l' message from p_j does not contain STATE = NSYNC.

If the round l' message from p_j contains $Halt_j$, such that $p_a \in Halt_j$, then $p_a \in Halt_j[l'-1] \subseteq H[l'-1]$. However, from our induction hypothesis, every process in $H[l'-1]$ has crashed before completing round $l'-1$, which implies that p_a has crashed before completing round $l'-1$, which is a contradiction. □

LEMMA 9.5 (time-complexity). *In every run of the algorithm in SCS_f (for any $f \in [0,t]$), every process that decides does so by round $f+2$.*

Proof. Consider any run R of the algorithm in SCS_f. (Note that, for a run in SCS_f, the first session is synchronous.) If some correct process decides by round $f+1$, then every process receives a DECIDE message (and decides) by round $f+2$. Therefore, suppose by contradiction that no correct process decides by round $f+1$ in R, and some correct process p_i completes round $f+2$ without deciding.

Since at most f processes may crash in R, from Lemma 9.4, in every round, $|Halt|$ at every alive process is less than or equal to f. As p_i does not decide in round $f+2$ and $|Halt_i[f+2]| \leq f$, one of the following is true: (1) STATE$_i[f+1]$ = NSYNC, (2) STATE$_i[f+1]$ = SYNC1, or (3) some other process p_j sent a message in round $f+2$ with STATE = SYNC1. Case 1 requires $|Halt_i| > t$ in round $f+1$ or in a lower round (line 26), which is a contradiction. Cases 2 and 3 are not possible because $|Halt[f+1]| \leq f$ at p_i and p_j, and therefore, p_i and p_j set STATE to SYNC2 in round $f+1$. □

LEMMA 9.6 (termination). *Every correct process eventually decides.*

Proof. Suppose by contradiction that some correct process p_i does not decide in a run R. If some correct process decides, then every correct process receives a DECIDE message and decides. Thus, no correct process decides. Consider the lowest synchronous session sn. Since no correct process decides in R, from Lemma 9.4, in every step, $|Halt|$ at every alive process in session sn is less than or equal to t (as t is the maximum number of processes that may crash in R).

As p_i does not decide by step $t+2$ of session sn, from line 20, one of the following is true: (1) STATE$_i[t+1]$ = NSYNC, (2) STATE$_i[t+1]$ = SYNC1, or (3) some other process p_j sent a message in step $t+2$ with STATE = SYNC1. Case 1 requires $|Halt_i| > t$ in step $t+1$ or in a lower step (line 26),which is a contradiction. Cases 2 and 3 are not possible because $|Halt[t+1]| \leq t$ at p_i and p_j, and therefore, p_i and p_j set STATE to SYNC2 in round $t+1$. □

9.5. Eventually synchronous results summary. Combining Proposition 8.1, the global decision lower bounds in [19, 9], and the time-complexity of algorithm A_{es}, we get the following tight bounds in eventually synchronous models:

1. $\forall t \in [1,(n-1)/2]$, $\forall f \in [0, t-3]$, $(ES_t,\ SCS_f,\ \text{UC},\ ld) = f+2$. Local decision bound for uniform consensus.

2. $\forall t \in [1, (n-1)/2]$, $\forall f \in [0, t]$, $(ES_t,\ SCS_f,\ \text{UC},\ gd) = f + 2$. Global decision bound for uniform consensus.

10. Concluding remarks.

The time-complexity of local decisions is a natural measure in many agreement-based distributed systems. As pointed out in the introduction, in a replication or a transactional system, it may be sufficient for a client to receive the decision value from any process executing the agreement algorithm. Besides, studying the local decision metric helps uncover fundamental differences between problems and between models that were not apparent with other metrics. For example, in a synchronous model, uniform consensus and nonblocking atomic commit have the same tight bound in terms of global decision but have different bounds when we consider local decision. Similarly, considering a local decision metric allows us to infer that early deciding uniform consensus algorithms are faster in a synchronous model than in synchronous runs of an eventually synchronous model.

A NEARLY LINEAR-TIME APPROXIMATION SCHEME FOR THE EUCLIDEAN *k*-MEDIAN PROBLEM*

STAVROS G. KOLLIOPOULOS[†] AND SATISH RAO[‡]

Abstract. This paper provides a randomized approximation scheme for the k-median problem when the input points lie in the d-dimensional Euclidean space. The worst-case running time is $O(2^{O((\log(1/\epsilon)/\varepsilon)^{d-1})} n \log^{d+6} n)$, which is nearly linear for any fixed ε and d. Moreover, our method provides the first polynomial-time approximation scheme for k-median and uncapacitated facility location instances in d-dimensional Euclidean space for any fixed $d > 2$. Our work extends techniques introduced originally by Arora for the Euclidean traveling salesman problem (TSP). To obtain the improvement we develop a structure theorem to describe hierarchical decomposition of solutions. The theorem is based on an *adaptive decomposition* scheme, which guesses at every level of the hierarchy the structure of the optimal solution and accordingly modifies the parameters of the decomposition. We believe that our methodology is of independent interest and may find applications to further geometric problems.

Key words. approximation algorithms, approximation schemes, k-median, facility location, Euclidean space, linear time

1. Introduction.

In the *k-median* problem we are given a set N of n points in a metric space and a positive integer k. The objective is to locate k *medians* (facilities) among the points so that the sum of the distances from each point in N to its closest median is minimized. The version of the problem we study is sometimes called the discrete k-median: the facilities must be located at input points. In the continuous version facilities may be located anywhere in the underlying space. The k-median problem is a well-studied, NP-hard problem which falls into the general class of *clustering* problems: partition a set of points into clusters so that the points within a cluster are close to each other with respect to some appropriate measure. Moreover, k-median is closely related to *uncapacitated facility location,* a basic problem in the operations research literature (see, e.g., [13]). In the latter problem, in addition to the set N of points, we are given also a cost c_i for *opening* a facility at point i. The objective is to open an unspecified number of facilities at a subset of N so as to minimize the sum of the cost to open the facilities (*facility cost*) plus the cost of assigning each point to the nearest open facility (*service cost*). In this paper we provide a fast approximation scheme for the problem when the input lies in a Euclidean space.

A *ρ-approximation algorithm* for a minimization problem, $\rho > 1$, computes in time polynomial in the input size a feasible solution of cost at most ρ times the optimum. An *approximation scheme* computes, for any fixed $\varepsilon > 0$, a $(1+\varepsilon)$-approximate feasible solution in time polynomial in the input size and $1/\varepsilon$.

1.1. Previous work. The succession of results for k-median is as follows. Lin and Vitter [23] used their filtering technique to obtain a solution of cost at most $(1+\varepsilon)$ times the optimum but using $(1+1/\varepsilon)(\ln n+1)k$ medians. They later refined their technique to obtain a solution of cost $2(1+\varepsilon)$ while using at most $(1+1/\varepsilon)k$ medians [22]. The first nontrivial approximation algorithm that achieves feasibility as well, i.e., uses k medians, combined the powerful randomized algorithm by Bartal for approximation of metric spaces by trees [5, 6] with an approximation algorithm by Hochbaum for k-median on trees [19]. The ratio thus achieved is $O(\log n \log\log n)$. This algorithm was subsequently refined and derandomized by Charikar et al. [8] to obtain a guarantee of $O(\log k \log\log k)$. Charikar and Guha and independently Tardos and Shmoys reported the first constant-factor approximations [10]. In contrast, the uncapacitated facility location problem, in which there is no a priori constraint on the number of facilities, seems to be better understood. Shmoys, Tardos, and Aardal [27] gave a 3.16 approximation algorithm. This was later improved by Guha and Khuller [16] to 2.408 and to 1.736 by Chudak [12]. After a preliminary, and by now obsolete, abstract[1] of this work appeared in [21] some additional results on k-median and facility location appeared by Charikar and Guha [9] and Jain and Vazirani [20] and on the local search approach by Arya et al. [4]. Follow-up work on the Euclidean case includes that by Har-Peled and Mazumdar [18], and work focusing on improving the dependence on the dimension includes that by Chen [11].

In this paper we focus on the case when the underlying metric is Euclidean. Until the work of Arora, Raghavan, and Rao [3], this case was not known to be any easier to approximate than a general metric. These authors gave a randomized polynomial-time approximation scheme for k-median when the points lie on the Euclidean plane [3]. For any fixed $\varepsilon > 0$, their algorithm outputs a $(1+\varepsilon)$-approximation with probability $1-o(1)$ and runs in $O(nkn^{O(1/\varepsilon)}\log n)$ time in the worst case. For facility location they gave an approximation scheme with running time $O(n^{1+O(1/\varepsilon)}\log n)$. This development followed the breakthrough approximation schemes of Arora [2] for the traveling salesman problem (TSP) and other geometric problems. While the work in [3] used techniques from the TSP approximation scheme, the different structure of the optimal solutions for k-median and TSP necessitated the development of a new structure theorem to hierarchically decompose solutions. We elaborate further on this issue during the exposition of our results in the next paragraph. The dependence of the running time achieved by the methods of Arora, Raghavan, and Rao on $1/\varepsilon$ is particularly high. For example, the approximation scheme can be extended to higher-dimensional instances but runs in quasi-polynomial time $O(n^{(\log n/\varepsilon)^{d-2}})$ for a set of points in R^d with fixed $d > 2$.

1.2. Results and techniques. Results. We provide a randomized approximation scheme for k-median on the Euclidean plane. For any fixed $\varepsilon > 0$, our scheme outputs in expectation a $(1+\varepsilon)$-approximate solution, in time

$$O\left(2^{O\left(\frac{\log(1/\varepsilon)}{\varepsilon}\right)} n \log^8 n\right)$$

in the worst case.[2] Our time bound represents a drastic improvement on the result in [3]. For any fixed accuracy ε desired, the dependence of the running time on $1/\varepsilon$

[1] In the conference version [21] we had erroneously claimed a running time of $O(2^{1/\varepsilon^d} n \log n \log k)$.

[2] For large ε, the term $\frac{\log(1/\varepsilon)}{\varepsilon}$ should be interpreted throughout the paper as $\frac{\max\{\log(1/\varepsilon),\Theta(1)\}}{\varepsilon}$. We omit the $\Theta(1)$ factor to avoid cumbersome notation.

translates to a (large) constant hidden in the near-linear asymptotic bound $O(n \log^8 n)$ compared to the exponent of a term polynomial in n in the bound of Arora, Raghavan, and Rao. Moreover, for inputs in R^d, our algorithm extends to yield a running time of

$$O\left(2^{O\left(\left(\frac{\log(1/\varepsilon)}{\varepsilon}\right)^{d-1}\right)} n \log^{d+6} n\right),$$

which yields for the first time a polynomial-time approximation scheme for any fixed $d > 2$. The ideas behind the new k-median algorithm yield also improved, nearly linear-time, approximation schemes for uncapacitated facility location. Our time bounds for the latter problem hold under the assumption that a polynomial in n-approximation is available for the value of the service cost. An example of such a case is when all the interpoint distances are polynomially related. We now elaborate on the techniques we use to obtain our results.

Techniques. Our main motivation for improving the running times of [3] was to gain a better understanding of approximation schemes for geometric problems and in particular the issues arising from Euclidean facility location problems. The actual running time we obtain is mainly of theoretical interest. We believe that the main contribution of the present paper lies in the new ideas we introduce to overcome the limitations of the approach employed by Arora, Raghavan, and Rao in [3]. To describe these ideas we sketch first some previous developments, starting with the breakthrough results by Arora [2] (see also the work of Mitchell [24] for a different approximation scheme for the Euclidean TSP).

A basic building block for Arora's results on TSP [2] was a structure theorem providing insight into how much the cost of an optimal tour could be affected in the following situation. Roughly speaking, the plane is recursively dissected into a collection of rectangles of geometrically decreasing area, represented by a quadtree data structure. For every box in the dissection one places a fixed number, dependent on the desired accuracy ε, of equidistant *portals* on the boundary of the box. The optimal TSP tour can cross between adjacent rectangles any number of times; a *portal-respecting* tour is allowed to cross only at portals. How bad can the cost of a deflected, portal-respecting tour be compared to the optimum? Implicitly, Arora used a charging argument on the edges in an optimal solution to show that the edges could be made to be portal-respecting. We now sketch his approach, which was made explicit and applied to k-median in [3].

Given a set of at most k open facilities, a k-median solution is a set of edges assigning every point to an open facility. A portal-respecting solution is one in which the assignment edges are actually paths that cross rectangle boundaries only at portals. We can assume that the input is surrounded by a rectangle with sidelength polynomial in n (cf. section 2). At level i of the dissection, the rectangles at this level with sidelength 2^i are cut by vertical and horizontal lines into rectangles of sidelength 2^{i-1}. The x- and y-coordinates of the dissection are randomly shifted at the beginning so that the probability that an edge e in a solution is cut at level i is $O(\text{length}(e)/2^i)$. Let m denote the number of portals along the dissection lines. If e is cut at level i, it must be deflected through a portal, paying additional cost $O(2^i/m)$. Summing over all the $O(\log n)$ levels of the decomposition, the expected deflection cost of edge e in a portal-respecting solution is at most

$$\sum_{i=1}^{O(\log n)} O\left(\frac{\text{length}(e)}{2^i}(2^i/m)\right). \tag{1}$$

Selecting $m = \Theta(\log n/\varepsilon)$ and applying the dissection to the optimal solution, we obtain the existence of a portal-respecting solution of cost $(1+\varepsilon)OPT$. Once the existence has been shown, dynamic programming can be used to compute the best portal-respecting solution. The running time of the dynamic programming contains a $k2^{O(m)}$ term; hence we have the $kn^{1/\varepsilon}$ term in the overall running time.

Arora additionally used a "patching lemma" argument to show that the TSP tour could be made to cross each box boundary $O(1/\epsilon)$ times. This yielded an $O(n(\log n)^{O(1/\varepsilon)})$ time algorithm for the TSP. (This running time was subsequently improved by Rao and Smith to $O(2^{O(1/\varepsilon^2)} + n \log n)$ [25] while still using $\Theta(\log n/\varepsilon)$ portals.) The k-median method did not, however, succumb to a patching lemma argument; thus the running time for the algorithms in [3] remained $O(kn^{O(1/\epsilon)})$.

Our method reduces the number m of portals to $O(\log(1/\epsilon)/\epsilon)$. *That is, we remove the* $\log n$ *factor in the number of portals that appears to be inherent in Arora, Raghavan, and Rao's charging based methods and even in Arora's charging plus patching based methods.*

Adaptive dissection. We outline some of the ideas behind the reduced value for m. The computation in (1) exploits linearity of expectation by showing that the "average" dissection line cutting an edge is short enough. The complicated dependencies among the dissection lines across all $O(\log n)$ levels seem too complicated to reason about directly. On the other hand, when summing the expectations across all levels an $O(\log n)$ factor creeps in, which apparently has to be offset by setting m to $\log n/\varepsilon$. We provide a new structure theorem to characterize the structure of near-optimal solutions. In contrast to previous approaches, given a rectangle at some level in the decomposition, it seems a good idea to choose several possible "cuts" hoping that one of them will hit a small number of segments from the optimum solution. This approach gives rise to the *adaptive dissection* idea, in which the algorithm "guesses" the structure of the part of the solution contained in a given rectangle and tunes accordingly the generation of the subrectangles created for the next level of the dissection. In the k-median problem the guess consists of the area of the rectangle which is empty of facilities. Let L be the maximum sidelength of the subrectangle containing facilities. Cutting close to the middle of this subrectangle with a line of length L should, in a probabilistic sense, mostly dissect segments from the optimal solution of length $\Omega(L)$, forcing them to deflect by $L/m = \varepsilon L$. A number of complications arise by the fact that a segment may be cut by both horizontal and vertical dissection lines. We note that the cost of "guessing" the empty area is incorporated into the size of the dynamic programming lookup table by trying all possible configurations. Given the preeminence of recursive dissection in approximation schemes for Euclidean problems [2, 3, 25] we believe that the adaptive dissection technique is of independent interest and may prove useful in other geometric problems as well.

Although the adaptive dissection technique succeeds in reducing the required number of portals to $\Theta(\log(1/\varepsilon)/\varepsilon)$ and thus asymptotically improves the dependence of the running time on $1/\varepsilon$, the dynamic program has still to enumerate all possible rectangles. Compared to the algorithm in [3], we apparently have to enumerate even more rectangles due to the "guess" for the areas without facilities and some amount of randomization we introduce in the choice of subrectangle boundaries. We bound the size of the lookup table by showing that the boundaries of the possible rectangles can be appropriately spaced and still capture the structure of a near-optimal solution.

The outline of the paper is as follows. In section 2 we give definitions and preprocessing steps. In section 3 we prove the new structure theorem and obtain the reduced number of portals. In section 4 we provide a modified structure theorem which yields a small size for the dynamic program table. In section 5 we present the dynamic program and some extensions of the main result.

2. Preliminaries. An *edge* (u, v) is a line segment connecting input points u and v. Given a selection of open facilities, an *assignment edge* is an edge (u, v) such that exactly one of u or v is an open facility. An *assignment* is a set E of assignment edges such that every point which does not host a facility appears exactly once as an endpoint. In order to minimize the cost every point must of course be assigned to its closest open facility. The *sidelength* of a rectangle with sides parallel to the axes is the length of its largest side. For any two points p, p' their Euclidean distance is denoted by $d(p, p')$.

We assume that the input points are on a unit grid of size polynomial in the number of input points. This assumption is enforced by a preprocessing phase described in [3]; the preprocessing incurs an additive error of $O(1/n^c)$ times the optimal value for some constant $c > 0$. The assumption is needed to ensure the depth of the recursive dissection is $O(\log n)$. Within the same additive error we can assume that no two input points lie on the same vertical grid line. The latter assumption simplifies the presentation.

In [3] it is shown that if a polynomial-factor approximation is available for the value of the service cost, i.e., a range $[D, n^c D]$ where this value must lie, then the above assumptions on the points can be enforced by a simple plane sweep. An algorithm to compute this range for the k-median problem is the 2-approximation minmax clustering algorithm of Gonzalez [15]. A faster algorithm for the same problem was given by Feder and Greene [14]. The latter runs in $O(n \log k)$ time on the plane. The total preprocessing time for $d = 2$ is $O(n \log n)$. For general dimension d the preprocessing time is $O(dn \log n + kd^d \log(kd^d))$ [14]. A faster 2-approximation algorithm that runs in $O(n + k \log k)$ with high probability was given by Har-Peled in [17].

3. The Structure Theorem. In this section we prove our basic Structure Theorem that shows the existence of approximately optimal solutions with a simple structure. This theorem can yield directly a dynamic programming algorithm whose running time dependence on ε is no worse than $2^{O(\log(1/\varepsilon)/\varepsilon)}$. Our exposition focuses on 2-dimensional Euclidean instances. It is easy to generalize to d dimensions. Given a set of points N and a set of facilities $F \subset N$, we define the *greedy cost under* F to be the cost of assigning each point to its closest facility. If F is the set of facilities open in the optimal solution, the greedy cost under F is the optimal cost.

We proceed to define a recursive randomized decomposition. The decomposition uses two processes: the Subrectangle process, and the Cutrectangle process.

Subrectangle:
Input: a rectangle B containing at least one facility.
Process: Find the minimal rectangle B' containing all the facilities. Let its maximum sidelength be s. Grow the rectangle by $s/3$ in each dimension. We call the grown rectangle B''.
Output: $B_s = B'' \cap B$.

Notice that $B - B_s$ contains no facilities. If $B_s \neq B$, we call B_s a *proper subrectangle.*

Cutrectangle:
Input: a rectangle B containing at least one facility.
Process: Randomly cut the rectangle into two rectangles with a line that is orthogonal

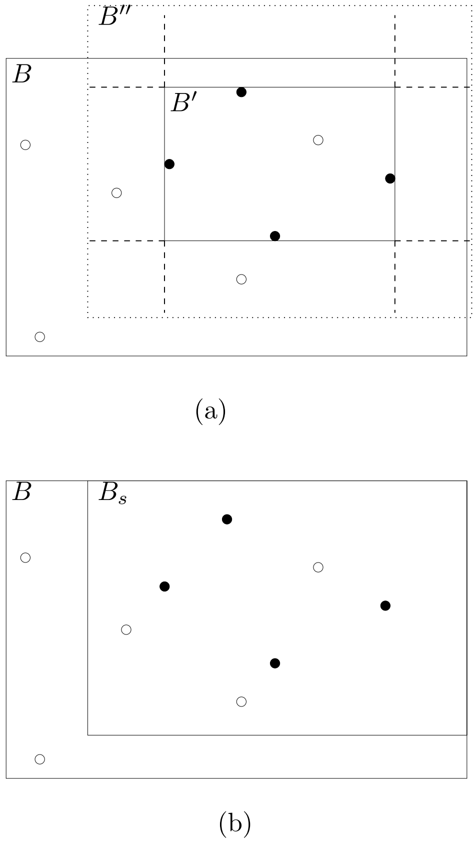

Fig. 1. *Illustration of the* Subrectangle *process. The circles are input points. The solid black ones indicate points with open facilities.* (a) *The intermediate rectangles created.* (b) *The input B and the output B_s of the process.*

to the middle third of the maximal side of the rectangle.

Output: The two created rectangles.

Remark 1. Given as input a rectangle with constant aspect ratio, both processes output rectangles with constant aspect ratio. This remark will be useful in section 4.

See Figure 1 for an illustration of the Subrectangle process. The recursive method alternately applies the Subrectangle and Cutrectangle processes to produce a decomposition of the original rectangle containing the input. The method stops when either the current rectangle contains one point or the current rectangle contains no facilities—whichever happens earlier. We emphasize that in this section we do not use an a priori random shift of the coordinate system as Arora does in [2]. The Subrectangle process would diminish any randomization introduced at the beginning of the dissection. The randomization required by the upcoming Facts 1 and 2 is introduced by Cutrectangle. We also observe that the original rectangle is not necessarily covered by leaf rectangles in the decomposition, due to the subrectangle steps.

We place $m+1$ evenly spaced points on each side of each rectangle in the dissection, where m will be defined later and depends on the accuracy ε of the sought approximation. We call these points *portals.* We define a *portal-respecting path* between two points to be a path between the two points that crosses only rectangles that enclose one of the points at portals. We define the *portal-respecting distance* between two points to be the length of the shortest portal-respecting path between the points. We begin by giving three technical lemmas which will be of use in the main Structure Theorem. Lemma 1 has a straightforward proof and gives the motivation behind the decomposition. We want short assignment edges in a given solution to be separated by rectangles of small sidelength.

LEMMA 1. *If the first rectangle R in the dissection to separate points v and w has sidelength D, the difference between the portal-respecting distance and the geometric distance between v and w is $O(D/m)$.*

We define a *cutting* line segment in the decomposition to be either (i) a line segment l that is used in the CUTRECTANGLE process to divide a rectangle R into two rectangles or (ii) a line segment l used to form the boundary of a proper subrectangle R in the SUBRECTANGLE procedure. In both cases we say that l *cuts* R. We define the *sidelength* of a cutting line l as the sidelength of the rectangle cut by l. Observe that the length of a cutting line is upperbounded by its sidelength.

LEMMA 2. *If any two parallel cutting line segments produced by the application of* CUTRECTANGLE *are within distance L, one of the line segments has sidelength at most $3L$.*

Proof. Let l_1, l_2 be the two cutting segments at distance L. Assume without loss of generality that they are both vertical, l_1 is the longer of the two lines, and l_1 is on the left of l_2 and cuts a rectangle R of sidelength greater than $3L$ into R_1 and R_2. Then l_1 is produced first in the decomposition. Thus l_2 is contained within R_2 (see Figure 2) and since it comes second can only cut a rectangle R'_2 contained within R_2. By the definition of CUTRECTANGLE, if s is the sidelength of R'_2, l_2 is drawn at least $s/3$ away from the left boundary of R'_2, which implies $s/3 \leq L$. Thus $s < 3L$. □

The next lemma relates the length of a cutting line segment produced by SUBRECTANGLE to the length of any assignment edges it intersects. We slightly abuse terminology and say that an edge (v, f) is *separated* when a cutting line separates v and f.

LEMMA 3. *Let f be a facility and (v, f) an assignment edge of length D. If a cutting line segment σ produced by* SUBRECTANGLE *separates v and f for the first time, then σ has sidelength at most $5D$.*

Proof. Let B_s be the rectangle cut by σ; let s be its sidelength. Assume without loss of generality that σ is a vertical line and that the horizontal dimension of B_s is maximal. Let B_s be produced by a SUBRECTANGLE process with input B. We use the notation of the process for the intermediate rectangles produced. Let $y \leq s$ be the sidelength of the rectangle B'. Then the sidelength of B'' is $(5/3)y > s$. The two vertical strips at the side of B'' are empty of facilities. Part of those strips may lie outside B; see Figure 3. The intersection of the vertical strip which is crossed by (v, f) with B must be a rectangle whose projection on the x-axis has length $y/3$. Therefore, $y/3 < D$, which implies that $s < 5D$. □

Consider the optimal solution with k given medians among the points. In the Structure Theorem we will prove the existence of a near-optimal solution in which a point v is always assigned to its closest or second-closest median. The *modified cost* of an assignment E is the sum over all the points of the portal-respecting distances to their respective assigned facilities. Since the Structure Theorem assumes that the set of open facilities is given, it applies more generally to uncapacitated facility location.

We first provide two calculations that will be of use in the proof of the theorem.

FACT 1. *Let $\mathcal{E}(\Delta, Z)$ denote the event that an edge of length Δ is separated by a*

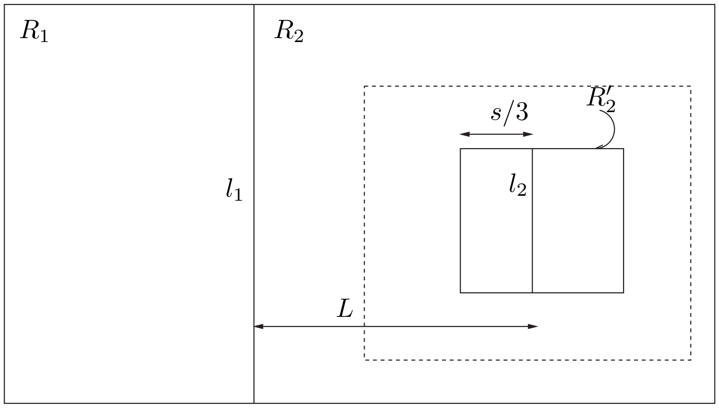

FIG. 2. *Illustration of the proof of Lemma* 2. *Rectangle R_2' is a descendant but not necessarily a child of R_2 in the decomposition.*

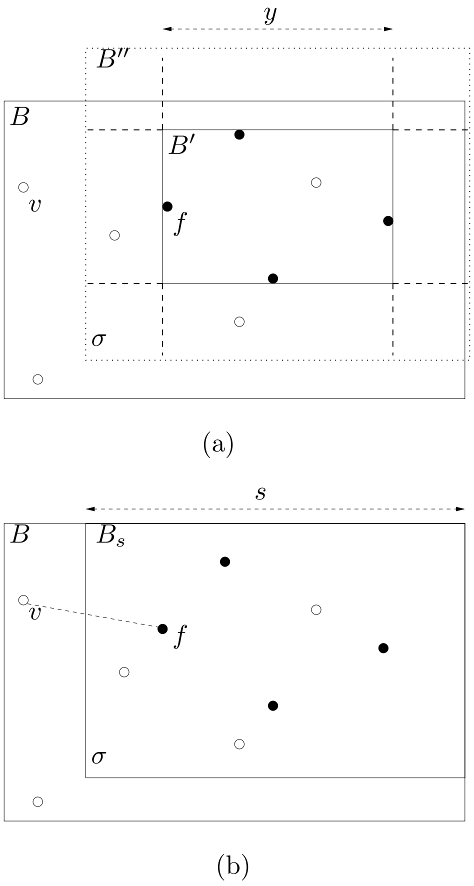

FIG. 3. *Illustration of the proof of Lemma* 3. *The circles are input points. The solid black ones indicate points with open facilities.* (a) *The intermediate rectangles created by* SUBRECTANGLE. (b) *The input B and the output B_s of the process.*

cutting line of sidelength Z that is produced by Cutrectangle. *We have that*

$$Pr[\mathcal{E}(\Delta, Z)] \leq 3\Delta/Z.$$

Intuitively, sidelengths increase geometrically in the dissection. Therefore, a consequence of Fact 1 is that the probability that an edge of length Δ is separated by a cutting line of sidelength Z or more that is produced by Cutrectangle is at most $O((\Delta/Z))$.

Fact 2. *Let $\mathcal{E}_{\geq}(\Delta, Z)$ denote the event that an edge of length Δ is separated by a cutting line of sidelength Z or more that is produced by* Cutrectangle. *Then*

$$Pr[\mathcal{E}_{\geq}(\Delta, Z)] = O(\Delta/Z).$$

The following lemma will also be of use.

Lemma 4. *Let the distance from a point v to its closest open facility f be D and the distance from v to its second closest open facility l be L. In the decomposition, v and f are separated for the first time by a cutting line that has sidelength either* (i) *larger than $L/2$ or* (ii) *smaller than $8D$.*

Proof. We know that v and l are separated by the time the sidelength of any enclosing rectangle is at most L. Observe that by Lemma 3, a cutting line of sidelength $> 5D$ separating v and f can only be produced by Cutrectangle. We will show that Cutrectangle cannot produce such a cutting line with sidelength in $(8D, L/2)$.

Without loss of generality we assume the relative positioning of v, f, l given above. See Figure 4 for an illustration. For any rectangle of sidelength $L/2$ containing v, there are no facilities to the left of v. Thus, by the Subrectangle process on input of sidelength $s < L/2$, the left boundary of any rectangle of sidelength $s < L/2$ that contains v is within a distance of at most $s/5$ of v. This is because in Subrectangle the maximal rectangle empty of facilities is grown by at most a third in each direction. By the Cutrectangle process on input of sidelength s, any cutting line for a rectangle box is at least $s/3$ to the right of its left boundary, which implies that the cutting line is at least $s/3 - s/5 = 2s/15$ to the right of v. Thus, the length D line segment cannot be cut until the sidelength of the enclosing rectangle is at most $(15/2)D$. □

Theorem 1 (Structure Theorem). *Let $m > 0$ be any integer and $F \subset N$ be a set of open facilities. There is an assignment E such that the expected difference between the modified cost of E and the greedy cost C under F is $O(C \max\{1, \log(m)\}/m)$.*

Proof. By linearity of expectation, it suffices to bound the expected cost increase for a given assignment edge. For a point v we define $f \in F$ as v's closest facility and assume f to be to the right of v (without loss of generality). We define $l \in F$ as the closest facility to the left of v. We denote the distance from v to f by D, and the distance from v to l by L. The idea behind the analysis of the portal-respecting solution is that assigning v to either f or l (a decision based on the amount by which the decomposition distorts each distance) will be enough to show near-optimal modified cost. The proof of the theorem shows how to actually construct the assignment E.

We assume without loss of generality that v and f are separated for the first time by a vertical cutting line. We can turn the configuration on its side and use the same argument if this condition does not hold.

The semicircle of diameter $2L$ centered at v and lying entirely to the left of the vertical line passing through v is empty in its interior. Therefore Lemma 4 applies.

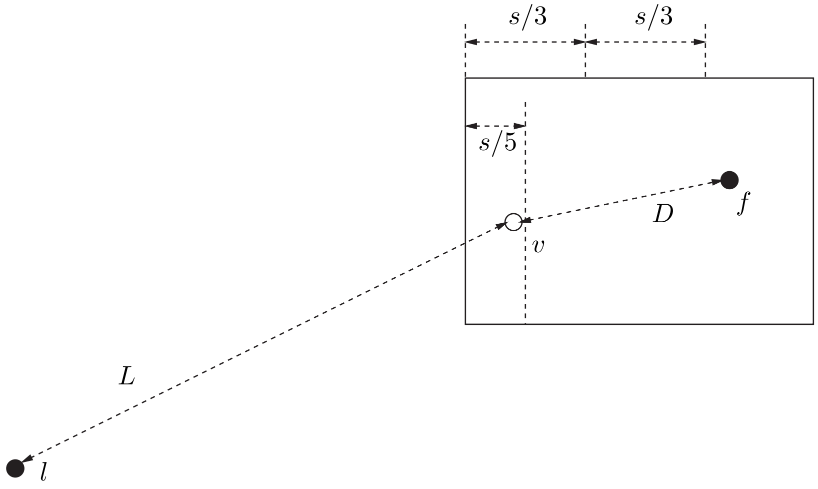

FIG. 4. *Illustration of the proof of Lemma* 4. *In this case we depict* $s < 2D$.

We proceed to a case analysis based on which of the two edges (v, l) or (v, f) is separated first by the decomposition. Observe that (v, l) can be separated for the first time by either a vertical or a horizontal line. If v and f are separated for the first time by a line produced by SUBRECTANGLE, we assign v to f in E and the increase in cost is $5D/m$ by Lemma 3. Therefore we can assume for the remainder of the proof that v and f are first separated by a vertical cutting line produced by CUTRECTANGLE. Let μ, ξ denote the lines separating for the first time (v, l) and (v, f), respectively.

CASE A. *Edge* (v, l) *is separated before* (v, f).

We will now calculate the expectation of the cost increase for the two possible subcases.

CASE A1. *Edge* (v, l) *is separated for the first time by a vertical cutting line.* We assign v to f in E. With some probability p, ξ has sidelength $L/2$ or more. By Lemma 4, ξ has sidelength at most $8D$ with probability $(1 - p)$. Therefore, by Lemma 1, the cost increase is $O(D/m)$ with probability $(1 - p)$. Now we turn to the case in which ξ has length $L/2$ or more. If μ is produced by SUBRECTANGLE, by Lemma 3, μ has sidelength at most $5L$. If μ is produced by CUTRECTANGLE, by Lemma 2 either ξ or μ has length at most $6L$. Moreover, ξ always has length smaller than μ since it is produced second in the dissection. By Lemma 1 the cost increase is $O(L/m)$ regardless of the operation producing μ. By Fact 2, probability p is $O(D/L)$. Therefore, the expected cost increase for CASE A1 is at most

$$(1 - p)O(D/m) + pO(L/m) = O(D/m) + O((D/L)(L/m)) = O(D/m).$$

Remark 2. The probability calculation for Case A1 depended only on the choice of which vertical line first cuts (v, f). This will be useful in section 4, when we restrict our choices for vertical cutting lines.

CASE A2. *Edge* (v, l) *is separated for the first time by a horizontal cutting line.* We assign v to f in E. We compute first the expectation of the cost increase conditioned upon the sidelength X of line μ. See Figure 5. By Fact 1, (v, f) is cut by a line of sidelength Y with probability at most $3D/Y$. Observe that this is true regardless of the value of X. Moreover, $L/2 \leq Y \leq X$ or, by Lemma 4, $Y \leq 8D$. The upper bound of X holds since (v, f) is contained in the rectangle cut by μ. For some constant c,

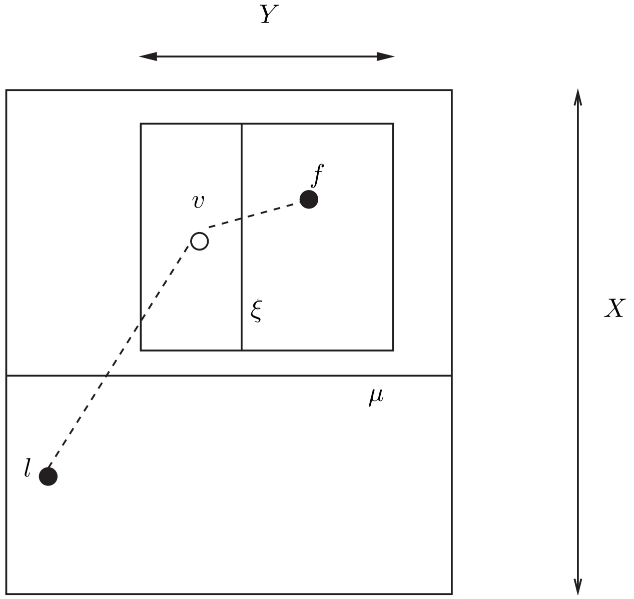

FIG. 5. *Case* A2 *in the proof of Theorem* 1.

the conditional expected cost increase is bounded by

$$\sum_{L/2\leq Y\leq X|\exists i, Y=2^i} (cD/Y)(Y/m) = O\left((D/m)\log(X/L)\right).$$

We now remove the conditioning on X. If line μ was produced by SUBRECTANGLE, by Lemma 3 it has length at most $5L$. No matter how large the probability of this event is, by the sum above the cost increase is $O(D/m)$. If line μ is produced by CUTRECTANGLE, by Fact 1 it has sidelength X with probability at most $3L/X$. The expectation of the cost increase is at most

$$\sum_{X\geq L|\exists i, X=2^i} 3(L/X)\log(X/L)O(D/m) = O(D/m).$$

Remark 3. To compute the probability of the event B that ξ has a given sidelength Y, we used only the total probability theorem. We partitioned the event space into the possible events $A_1, A_2, \ldots$ based on the different possible values of X and then applied $Pr[B] = \sum_i Pr[B|A_i]Pr[A_i]$. This remark will be useful in section 4.

CASE B. *Edge* (v, f) *is separated before* (v, l).

CASE B1. *Edge* (v, l) *is separated for the first time by a vertical cutting line.* The difference from CASE A1 is that we cannot argue that ξ has smaller sidelength than μ; therefore, we follow a different strategy. If the sidelength of ξ is at most mL we assign v to f; else we assign v to l in E.

By Lemma 4, if the cost increase exceeds $8D/m$ the sidelength of ξ is $L/2$ or higher. By Fact 1, there is a constant c such that assigning v to f yields an expected cost increase of

$$c[(2D/L)(L/2m) + (D/L)(L/m) + (D/2L)(2L/m) + \cdots + (D/mL)(mL/m)]$$
$$= O(D\log(m)/m).$$

By Fact 2, the probability that ξ has a sidelength of mL or more and hence that we assign v to l is $O(\frac{D}{mL})$. In this case Lemma 2 gives that the sidelength of μ is at most $3(L + D)$. Therefore, when v is assigned to l, the expected assignment cost (and not just the increase) is

$$O\left(\frac{D}{mL}(L + L/m)\right) = O(D/m + D/m^2).$$

Therefore, regardless of whether v is assigned to f or l the expected cost increase is $O(D \log(m)/m)$.

CASE B2. *Edge* (v, l) *is separated for the first time by a horizontal cutting line.* We follow the same strategy as in Case B1: if the sidelength of ξ is at most mL we assign v to f; else we assign v to l in E.

By the same argument as in Case B1, if v is assigned to f the expected cost increase is $O(D \log(m)/m)$. Consider the case where v is assigned to l. If μ is produced by SUBRECTANGLE by Lemma 3 it has sidelength at most $5L$ and hence the expected assignment cost is $O(D/m + D/m^2)$ by a calculation similar to Case B1.

If μ is produced by CUTRECTANGLE it cannot have sidelength less than L. Moreover, by Fact 1 it has sidelength X with probability at most $3L/X$. X cannot exceed the sidelength Y of ξ but for every possible X in the range $[L, Y]$, the conditional probability that μ has sidelength X is still at most $3L/X$. Therefore, we obtain that the expected assignment cost for v is

$$O\left(\sum_{mL \le Y | \exists i, Y = 2^i} \frac{D}{mL} \sum_{L \le X \le Y | \exists i, X = 2^i} (L/X)(X + X/m)\right)$$
$$= O\left(\frac{D}{mL}(L + L/m)\right) = O(D/m + D/m^2).$$

Remark 4. To compute the probability of the event B that μ has a given sidelength X, we used only the total probability theorem. We partitioned the event space into the possible events $A_1, A_2, \ldots$ based on the different possible values of Y and then applied $Pr[B] = \sum_i Pr[B|A_i]Pr[A_i]$. This remark will be useful in section 4.

This is the end of the proof of the Structure Theorem. □

4. Modifying the Structure Theorem.

The Structure Theorem in the previous section demonstrates that a portal-respecting $(1 + O(\log(m)/m))$-approximate solution exists while only placing m portals on the boundary of the decomposition rectangles. The randomization introduced by CUTRECTANGLE is essential for the Structure Theorem. However, it does pose the problem of how to enumerate all possible outputs of CUTRECTANGLE in the context of a dynamic program such as the one in [3]. In this section we show how to effectively bound the number of rectangles to be enumerated by the dynamic program and in the process obtain a nearly linear-time algorithm. To this end we introduce some discretization on the possible outcomes of SUBRECTANGLE and CUTRECTANGLE.

We first give some definitions. Consider the square of sidelength T that surrounds the original input. We know from section 2 that $T = O(n^c)$ for some constant $c > 0$. We assume that $T = m2^\rho$ for some integer ρ and that the leftmost lower corner of the square lies at the origin of the axes. Call the vertical (horizontal) lines whose x-coordinate (y-coordinate) is an integral multiple of m *eligible.* Then, we call the vertical (horizontal) eligible lines with x-coordinate (y-coordinate) congruent to 0 mod2^i, $1 \leq i \leq \rho$, *i-allowable.* Note that the top- and leftmost eligible lines are ρ-allowable, and that any j-allowable line is i-allowable for all $i < j$. A rectangle R of sidelength s is *t-allowable* if t is the maximum value such that any two parallel sides of R of length s lie on t-allowable lines and $s \geq 2^t m$. Observe that when a rectangle is t-allowable, the aspect ratio is not bounded. The definition guarantees only that the smallest side has length $2^t m$. A rectangle which is t-allowable for some t and whose sides have length within a factor of $5 + 1/2m$ of each other is called *allowable.*

We modify the SUBRECTANGLE and CUTRECTANGLE processes as follows.

SUBRECTANGLE-NEW:
Input: An allowable rectangle containing at least one facility.
Process: Perform the SUBRECTANGLE process of the previous section. Let B_s be the computed rectangle.
Output: The minimal allowable rectangle that contains B_s.

CUTRECTANGLE-NEW:
Input: An allowable rectangle containing at least one facility.
Process: Choose a cutting line in the middle third of the maximal side of the rectangle, uniformly at random among all lines that produce two allowable subrectangles.
Output: The two allowable subrectangles.

To illuminate further CUTRECTANGLE-NEW consider an example that takes as input a t-allowable rectangle with sidelength $m2^t$. This implies that the rectangle is a square. Let us consider the horizontal side as maximal. The middle third of the maximal side has $\lfloor m/3 \rfloor$ candidate t-allowable cutting lines. Choosing one yields two subrectangles for which the horizontal side has length at least $(m/3)2^t$ and at most $(2/3)m2^t$. Accordingly the two subrectangles are each i-allowable for $i \geq t-2$.

Before proving the Modified Structure Theorem we examine the validity of the deterministic lemmas from section 3 in the new setting. Clearly Lemma 2 continues to hold. We have to be more careful with Lemmas 3 and 4 due to the extra requirement that the output of SUBRECTANGLE-NEW should be allowable. This might cause the rectangle output by SUBRECTANGLE to be "stretched." We first show that this stretch is small.

LEMMA 5. *Each side of the rectangle output by* SUBRECTANGLE-NEW *has length at most $1 + 2/m$ the length of the corresponding side of the rectangle B_s computed during the process.*

Proof. Within the SUBRECTANGLE process, the rectangle B' of sidelength s is grown by $s/3$ in each dimension. It follows that the lengths of the sides of B_s are within a factor of $(s + 2s/3)/(2s/3) = 5$ of each other. To meet the definition of an allowable rectangle, we have only to move the boundaries of B_s so that they fall on t-allowable lines. Here t is the maximum integer so that each side of B_s has length at least $2^t m$. To achieve this, we have to extend each side by at most 2^t in each direction for a total increase of a $1 + 2/m$ factor. □

Lemma 4 continues to hold with the modified decomposition. In fact it becomes slightly stronger since (cf. proof of Lemma 4) the left boundary of any allowable rectangle produced by SUBRECTANGLE-NEW that has sidelength $s < L/2$ and contains v is within a distance of at most $s(1/5 + 1/m)$ from v. We now give the equivalent to Lemma 3 in the modified setting.

LEMMA 6. *Let f be a facility and (v, f) be an assignment edge of length D. If a cutting line segment σ produced by* SUBRECTANGLE-NEW *separates v and f for the* *first time, then σ has sidelength at most* $(5 + 6/m)D$.

Proof. We outline only the changes from the proof of Lemma 3. Keeping the same notation, by Lemma 5 $(5/3)y \leq s \leq (5/3 + 2/m)y$. Since $y/3 < D$, we obtain $s < (5 + 6/m)D$. □

The difference between Lemmas 3 and 6 is negligible from the point of view of the Modified Structure Theorem since it introduces only an additive $O(D/m^2)$ error term. We can now focus on the probabilistic part of the modified decomposition.

The new dissection is similar to the one from section 3. The primary difference is that the randomization in the CUTRECTANGLE process has been diminished. If we add back some randomization up front by shifting the original rectangle containing the input, we can get the same result as in the Structure Theorem on the expected increased cost of a portal-respecting solution. We define an (a, b)*-shifted* coordinate system, $0 \leq a, b \leq T$, as one in which the x and y coordinates are shifted by a and b, respectively. The shifting uses wraparound as in [2]: a vertical line which had x-coordinate x_1 before the shifting has coordinate $x_1 + a \bmod T$ after. If a and b are chosen at random, any vertical or horizontal line is equally likely to be i-allowable. The *new modified cost* of an assignment is defined with respect to the new dissection given above.

THEOREM 2 (Modified Structure Theorem). *Let $m > 0$ be any integer and $F \subset N$ be a set of open facilities. If the coordinate system is randomly shifted by (a, b), where a and b are chosen independently in $[0, T]$, then there is an assignment E such that the expected difference between the new modified cost of E and the greedy cost C under F is $O(C \max\{1, \log(m)\}/m)$.*

Proof. As mentioned, minor variations of the deterministic lemmas from section 3 continue to hold in the restricted version of the dissection. The randomized portion in the proof of Theorem 1 reasons only about two types of events. Moreover, it reasons about each event in isolation (cf. Cases A1 and A2 in the proof; the rest are similar). Thus, we need only be concerned with the probability of each event. The random shift up front of the coordinate system along with the randomization inside the process will ensure that these two types of events occur in our decomposition into allowable rectangles with approximately the same probability as in the previous decomposition.

The first event (cf. Case A1) is that a line produced by CUTRECTANGLE-NEW of length X cuts a line segment of length D. The probability of this event is required to be at most $3D/X$ in the proof of the Structure Theorem. We show that this continues to hold albeit with a constant larger than 3.

We assume for simplicity that the line segment is in a rectangle R of sidelength exactly $X = m2^i$ at some point. (This will be true to within a constant factor.) If $D < 2^i$, we know that the segment is cut by at most one i-allowable line. The probability of this event is at most $D/2^i$ due to the random shift. The CUTRECTANGLE-NEW process chooses from $m/3$ i-allowable lines uniformly at random. Thus, the line segment is cut with probability $1/(m/3)$ times $D/2^i$, which is $3D/X$ as required. If $D > 2^i$, we notice that D intersects at most $\lceil D/2^i \rceil < 2D/2^i$ i-allowable lines. By the union bound the probability that this line segment is cut during CUTRECTANGLE-NEW on R is upperbounded by $2D/2^i$ times $3/m$, i.e., $6D/X$.

The second event (cf. Case A2) is the intersection of two events; a horizontal line of length X cuts a segment of length L and a vertical line of length Y cuts a segment of length D. In the proof of the Structure Theorem, the probability was shown by the total probability theorem to be upperbounded by the product of the probability bounds of the two events, i.e., $3L/X$ times $3D/Y$. The second term represented the conditional probability that edge (v, f) is cut by a line of sidelength Y given that (v, l) was cut by a horizontal line of sidelength X. We argued that the conditional probability does not depend on X.

For our restricted decomposition, the probability of each event in isolation can be bounded by $6L/X$ and $6D/Y$ as argued above. Moreover, we chose the horizontal and vertical shifts independently and we choose the horizontal and vertical cut-lines in different processes. Thus, we can also argue that the probability of the intersection of the two events is at most $6L/X$ times $6D/Y$. □

We now prove a lemma bounding the number of allowable rectangles.

Lemma 7. *The number of allowable rectangles that contain l or more points from the input set N is $O(m^4(n/l)\log n)$.*

Proof. Our proof uses a charging argument. Let R_l be a rectangle on the plane that has minimum sidelength, say, L, and contains l points. We bound the cardinality of the set S_l of allowable rectangles, which are distinct from R_l, contain at least l points and have at least one point in common with R_l. Let R_a be such a rectangle. Then R_a has sidelength at least L; otherwise it would have been chosen instead of R_l.

We bound the number of allowable rectangles in S_l with sidelength $X \in [2^{i-1}, 2^i]m$ by $O(m^4)$ as follows. The corners must fall on the intersection of two t-allowable lines that are within distance X from some side of R_l. Since allowable rectangles have bounded aspect ratio, the possible values for t are 2^{i-k}, $k = 0, 1, 2, 3$.

The number of j-allowable lines that are within distance X from some side of R_l is $O(X/2^{j-1})$ since $X \geq L$. Thus, the number of corner choices is $O(m^2)$. Two corners must be chosen, so the number of rectangles in S_l of sidelength $X \in [2^{i-1}, 2^i]m$ is $O(m^4)$. Since there are $O(\log n)$ values of i, $|S_l| = O(m^4 \log n)$.

Now, we remove R_l and its points from the decomposition and repeat the argument on the remaining $n - l$ points. The number of repetitions until no points are left is $O(n/l)$; therefore, by induction, we get a bound of $O(m^4(n/l)\log n)$ on the number of allowable rectangles that contain at least l points. □

5. The dynamic program. We have structural theorems relative to a particular decomposition. Unfortunately, the decompositions are defined with respect to the facility locations. However, in reality they use only the facility locations in the Subrectangle steps. Moreover, the number of subrectangles is at most polynomial in the size of the original rectangle. Indeed, the number of allowable subrectangles is polynomial in m and n. Thus, we can perform dynamic programming to find the optimal solution. The structure of the lookup table is similar to the one used in [3]. We exploit our Structure Theorem and the analysis on the total number of allowable rectangles to obtain a smaller number of entries.

We will develop two versions of our dynamic program, in order of increasing sophistication, each with a somewhat different time complexity. Our dynamic programs have much in common with the one in [3]. For the sake of completeness we include here all the relevant definitions from [3].

5.1. The table definition. In all our approaches the table will consist of a set of entries for each allowable rectangle that contains at least one point. There is a one-to-one correspondence between entries of the table and subproblems on the corresponding rectangle. Subproblems on a given rectangle are generated by what amounts to a guessing (enumeration) of the location of facilities that serve the points in the rectangle. These facilities could be either inside the rectangle or outside. In either case, since by the Structure Theorem it suffices to consider portal-respecting solutions, we store only the *interaction pattern* (defined by items 2 and 3 below) of the portals to the facilities. For each allowable rectangle, we will enumerate the following:

1. the number of facilities in the rectangle,
2. a distance for each portal p to the nearest facility in the rectangle, and
3. a distance for each portal p to the nearest facility outside the rectangle, if one exists that is nearer to p than all facilities inside the rectangle.

Every triple of this sort defines a subproblem. Given a subproblem which is indexed by f for the number of facilities and is defined on a rectangle R, a solution will be a set of f facilities among the points in R and a portal-respecting path from each point in R to one of the facilities in R or to a portal on the boundary. The table entry corresponding to the subproblem will store the minimum service cost under the given constraints. Recall from section 3 that the decomposition stops as soon as a rectangle is produced that contains no facilities. Formally, a *leaf* of the decomposition is a rectangle R which has been produced by the decomposition, such that either (i) R contains one point and this point is an open facility or (ii) R is a rectangle that contains at least one point and no facilities.

The enumeration of the distances happens by using the *inside* and *closest* functions on the portals as defined in [3]. In order to save on the size of the table the definitions of the two functions follow three rules, as in [3]. We present them first, establish their validity, and then provide the definitions that implement them.

Rule 1. We will only approximate the distances to the nearest facility inside and outside of a rectangle R to a precision of s/m for a rectangle of sidelength s.

Rule 2. As far as the distance from a portal p to the closest facility is concerned we do not consider distances of more than $6s$. Clearly the distance from a portal p on the boundary of R to the nearest facility within R cannot exceed $2s$. Therefore this rule affects only assignments to the outside of R, i.e., the upcoming definition of the *closest* function. We want to ensure that no assignments are lost for the dynamic program. A key remark is that a portal p is assigned to a facility η outside R *only if all* facilities within R (if such exist) are further from p than η. Therefore if R contains some facility, any facility outside R at a distance of more than $2s$ is of no interest to the points in R. If R contains no facilities, it is a leaf of the decomposition. This leaf rectangle must have been produced by CUTRECTANGLE-NEW. Let R' be the parent rectangle that was cut. $R' - R$ must contain some facility, or else R' itself must have been a leaf. The sidelength s of R is at least one third the sidelength of R'. Hence by a generous estimate there is a facility at distance at most $6s$ from every portal of R.

Rule 3. It suffices for neighboring portals to represent distances as offsets from the previous distance. This is o.k. because the distance value at a portal changes only by a constant from the distance value at an adjacent portal.

We are now ready to give the definitions of the *inside* and *closest* functions as in [3]. Let Π be a subproblem defined on rectangle R, and let Π be indexed by a number of facilities $f \in [0, k]$. For a portal p, *inside* (*closest*) encodes the distance to the nearest facility to p within (outside) R, subject to Rules 1, 2, and 3.

- If $f = 0$, we set $inside(p) = \infty$ for every portal p on the boundary of R. This should happen for all R that are leaves of the decomposition.
- If $f > 0$, we define an assignment *inside* of numbers $[1, \ldots, 4m]$ to the portals of R, such that $|inside(p) - inside(p')| \leq 1$ if portals p and p' are successive along the boundary of R. The domain of the assignment expresses Rule 1, i.e., the precision of the distances. The condition on the difference expresses Rule 3; i.e., we represent distances as offsets from the previous distance.

- If $f < k$, we define an assignment *closest* of numbers $[1, \ldots, 4m]$ to the portals of R, such that (i) $|closest(p) - closest(p')| \leq 1$ if portals p and p' are successive along the boundary of R and (ii) $closest(p) < inside(p)$. Since by Rule 2 above, we can always assume that there is a facility within distance $6s$ from p, the definition can fail only if one such facility within R is the nearest to p, i.e., when condition (ii) fails. In this case we set $closest(p) = \infty$.
- If $f = k$, we set $closest(p) = \infty$ for every portal p on the boundary of R.

By the three rules above, as far as the distances are concerned we need only to guess $O(m)$ bits per entry. Taking into account the guess for the number of facilities the total number of table entries (subproblems) corresponding to each allowable rectangle is bounded by $k2^{O(m)}$. We bound the table size by noting that the total number of allowable rectangles is, by Lemma 7, at most $O(m^4 n \log n)$. Thus, we can bound the total number of entries in the table by $k2^{O(m)} n \log n$.

5.2. Computing the table entries. With respect to the recursive decomposition defined by the Modified Structure Theorem every subproblem defined on a rectangle R has one or two *children* subproblems, the number depending on which process, Cutrectangle-new or Subrectangle-new, is applied. The solution for a subproblem Π defined on rectangle R is computed by looking at children subproblems whose interaction patterns match with the interaction pattern of Π. The *recursion height* of any subproblem defined on R is equal to the maximum length of a path leading to a leaf of the decomposition in the tree representing the dissection defined by the Modified Structure Theorem. The maximum recursion height is obviously $O(\log n)$. Based on which process is applied, we are looking for either (i) a pair of subproblems defined on two allowable subrectangles that cover R and whose total number of facilities equals that of Π or (ii) a subproblem defined on a single allowable subrectangle of R whose number of facilities equals that of R. Among the matching combinations we select the one of minimum cost, where the cost is computed as follows. After fixing the values of the *inside* and *closest* functions on the portals of Π, for every point in R, we know the location of the nearest facility, either within R or outside. For a portal p on the boundary of R let $n(p)$ be the total number of points assigned to p, i.e., the total number of points that are served by a facility on the outside via p. Similarly to [3], the *cost* of Π equals the total assignment cost within R plus

$$\sum_{\text{portals } p} closest(p) n(p) (s/m).$$

An important difference of our scheme from [3] is that we cannot a priori compute the randomly shifted dissection and then apply dynamic programming on the rectangles of the dissection. Because of the Subrectangle-new process, for any given subproblem we have to enumerate all possible outputs of either the Subrectangle-new process or all different cuttings of the Cutrectangle-new process. This gives rise to two different types of algorithmic steps, one for each case. Fortunately, by Lemma 7 the total number of rectangles to be enumerated throughout the dynamic program is $O(m^4 n \log n)$.

Let R be a rectangle of sidelength s at height i of the recursion, and assume inductively that the algorithm has solved all subproblems at height $i-1$. Consider a subproblem Π defined on R and let Π be indexed by a number f of facilities. We now give the details of the algorithm's steps.

Application of SUBRECTANGLE-NEW. To capture the outcome of SUBRECTANGLE-NEW the algorithm enumerates all possible subproblems on allowable subrectangles R_u of R such that the following hold.

S1. The number of facilities open in R and R_u is equal to f.
S2. For each portal p of R there is a portal p' of R_u such that $d(p,p')+inside(p')(s_u/m) \leq inside(p)(s/m)$. Here s_u denotes the sidelength of R_u, with $s_u \leq s$.
S3. For each portal p of R_u there is a portal p' of R such that $d(p,p')+(s/m)closest(p') \leq closest(p)(s_u/m)$.

There does not seem to be a way to look up the cost of R, say, as a function of the cost of the chosen R_u. Moreover, the number of possible candidates for R_u could be large; we need to consider candidates of arbitrarily small sidelength. We take the inverse view and enumerate the work done for each allowable rectangle S when it is considered as a subrectangle of some R. The argument that follows is due to J. Remy.

For fixed t, any rectangle S is contained in $O(1)$ t-allowable rectangles of constant aspect ratio. Therefore, a fixed S is considered as a subrectangle $O(\log n)$ times. Therefore, by Lemma 7 the total number of subrectangles, not necessarily distinct, that the dynamic program needs to enumerate is $O(m^4 n \log^2 n)$. For every such occurrence of S in the dynamic program we enumerate all the interaction patterns and the possible number of facilities, which yields $k2^{O(m)}$ subproblems. We proceed to bound the running time for each subproblem involving a rectangle R containing S.

A subproblem defined on S specifies the positions of facilities within R (up to an additive $sidelength(S)/m$ factor). We want to assign the points in R to the closest facility within S or outside R without paying time proportional to the number of points in R. The intuition behind the proof is that a higher additive error on the assignment can be tolerated for points in $R \setminus S$ that are “far” from S. The adaptive dissection suggests at a high level guessing the rectangle S and accordingly the location of facilities within R. To assign the points efficiently, the algorithm will be also adaptive at a much lower level and tune the accuracy of the assignment for the different points.

LEMMA 8 (due to J. Remy). *Let Π_R and Π_S be two subproblems defined on rectangles R and S where S is contained in R. The two subproblems agree as in* S1–S3 *above. Let G be the assignment of every point in R to its closest facility where the locations of facilities are specified by Π_R and Π_S. We can compute an assignment G' such that the service cost of each point p has an additive error of $O(1/m)$ times the modified service cost of p in G. G' and its total cost can be computed in $O(m^4 \log^2 n)$ time worst-case.*

Proof. The construction uses some ideas similar to the ones in [26]. We partition the area of $R \setminus S$ into rectangular *moats* $M_1, M_2, \ldots$. Moat M_1 is a $2d$-shape created by surrounding S by a rectangle S' that strictly contains S and then removes S. Moat M_{i+1} is the area remaining from a rectangle surrounding moat M_i after $(\bigcup_{j \leq i} M_j) \cup S$ has been removed. The *radius* r_i of moat M_i is the maximum distance of an outer vertical (or horizontal) side from the nearest vertical (horizontal) side of S. The radii are set to be geometrically increasing with $r_i = sidelength(S)(1+1/m)^i$, $i = 1, 2, \ldots$. Any outer vertical (horizontal) side of M_i is at the maximum distance that does not exceed r_i from the closest vertical (horizontal) side of S. Hence a side at a distance less than r_i will fall on the boundary of R. See Figure 6 for an illustration. If the area left uncovered in R at some point of the process is not wide enough to become a moat by itself, we append it to the last moat produced and terminate. The number of moats is $O\left(m \log(sidelength(R) - sidelength(S))\right) = O(m \log n)$.

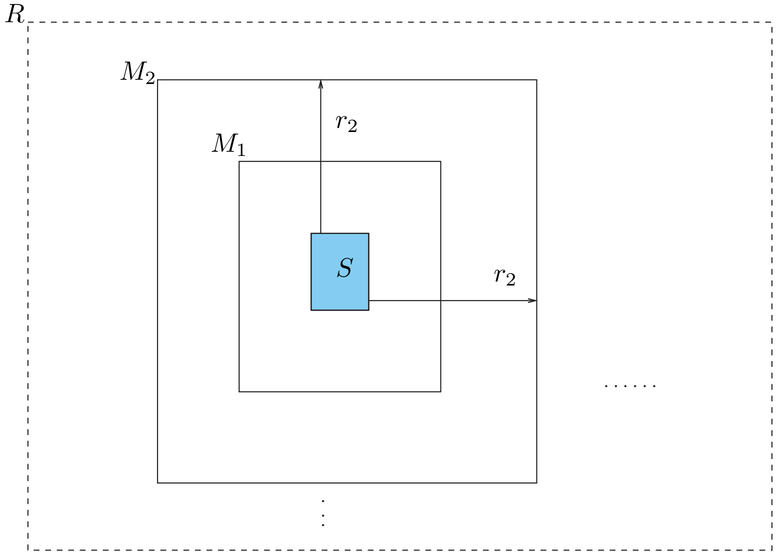

Fig. 6. *Illustration of the moat construction process. If all sides of S are equidistant from the sides of R, each of the moats will be topologically equivalent to an annulus.*

Each moat M_i is divided into $O(m^2)$ rectangular cells whose sides are each $\Theta(r_i/m)$ long. See Figure 7. The total number of cells across all moats is $O(m^3 \log n)$. For every point in $R \setminus S$ we have to try $O(m)$ portals on the boundaries of S and R to find the closest facility. The algorithm identifies *all points within a cell* C with the center of the cell and assigns them to the same portal. We calculate now the error induced by this collapsing of points. For a point p in cell C of moat M_l, let d_1 be its distance from the nearest portal on the boundary of S. The estimated distance d_1' for all points in the cell to the closest portal on the boundary of S will be at most

$$d_1 + O(sidelength(C)) \leq d_1 + O\left(\frac{\max\{(1+1/m)d_1, (1+1/m)sidelength(S)\}}{m}\right)$$

$$= d_1 + O(1/m)\max\{d_1, sidelength(S)\}.$$

The second term in the max expression above is needed for points in M_1. For the same point p let d_2 be its distance from the nearest portal on the boundary of R. In the worst case the distortion is maximized when M_l is the outer moat, i.e., the one touching the boundary of R. The estimated distance after collapsing p will be at most $d_2 + O(sidelength(C)) \leq d_2 + O(sidelength(R)/m)$ which is fine since the modified service cost through a portal on the boundary of R is already distorted by $O(sidelength(R)/m)$.

The total cost of assigning the points in $R \backslash S$ is the weighted sum of the assignment costs of the cells where the cost for each cell is weighted by the number of points in the cell. Computing this number can be done by orthogonal range searching techniques in $O(\log n)$ time per cell (see [1]) after an $O(n \log n)$ global preprocessing. Therefore, the total running time is $O(m^4 \log^2 n)$. □

Remark 5. The analogue of Lemma 8 holds in d-dimensional space. The number of cells is $O(M^{d+1} \log n)$, where M is the number of portals maintained on each face of a parallelepiped. The range searching query time increases by a multiplicative $O(\log^{d-2} n)$ factor [1]. The running time becomes $O(M^{d+2} \log^d n)$.

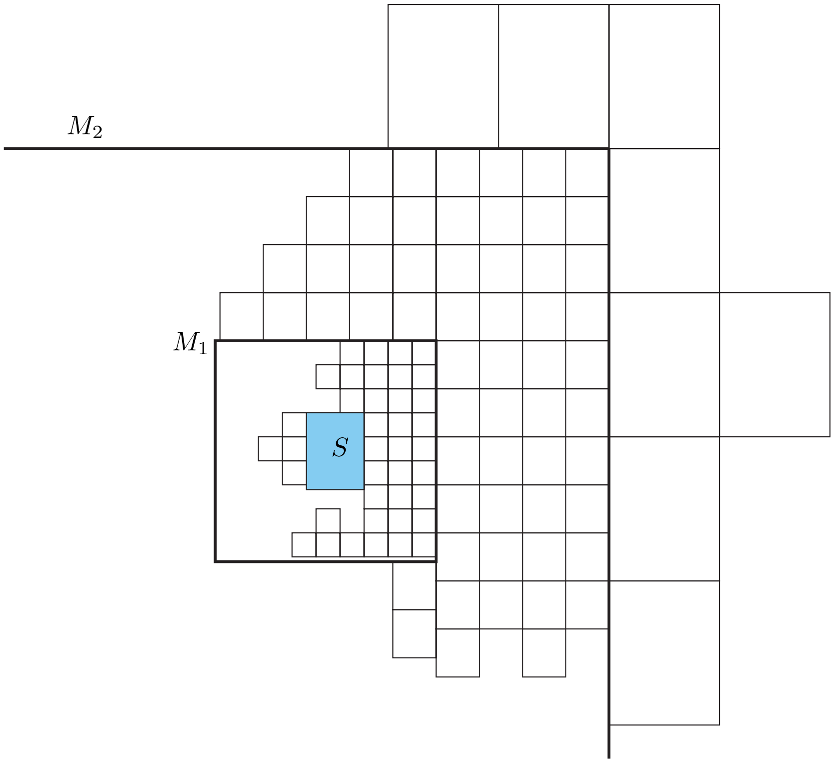

FIG. 7. *Illustration of the cell construction process.*

By Lemma 8 and the previous discussion the total computation time of the dynamic program due to SUBRECTANGLE-NEW is

$$\begin{aligned} &\text{Total time due to SUBRECTANGLE-NEW} \\ &\quad = (\text{Time per entry}) \ \times \ (\text{number of entries}) \\ &\quad = O(m^4 \log^2 n) \times k2^{O(m)} n \log^2 n = O(k2^{O(m)} n \log^4 n). \end{aligned} \tag{2}$$

This bound can be improved by amortization. By Lemma 7, the number of allowable rectangles that contain k or more points is $O(m^4 (n/k) \log n)$. If an allowable rectangle S contains fewer than $l < k$ points from N, we need only to keep $l2^{O(m)}$ table entries for it, since at most l facilities can be placed inside it. Moreover, the number of allowable rectangles containing between l and $2l$ points is shown by Lemma 7 to be $O(m^4 (n/l) \log n)$. We can now bound the total time due to SUBRECTANGLE-NEW by

$$\begin{aligned} &O(m^4 \log^2 n) \times \left(k2^{O(m)} (n/k) \log^2 n + \sum_{l=2^i}^{l<k} l2^{O(m)} (n/l) \log^2 n \right) \\ &\quad = 2^{O(m)} n \log^4 n \log k. \end{aligned} \tag{3}$$

Application of CUTRECTANGLE-NEW. The algorithm enumerates also all possible cuttings of R according to the CUTRECTANGLE-NEW process. It looks for combinations of subrectangles R_1, R_2 of R whose interaction patterns match those of Π. The details are similar to the method outlined in [3], where four children rectangles are considered instead of two. In particular, the algorithm enumerates pairs of subproblems defined on allowable rectangles R_1, R_2 that partition R, fulfill the sidelength requirements of CUTRECTANGLE-NEW, and in addition fulfill the following.

C1. The sum of the number of facilities in R_1 and R_2 equals f.

C2. For each portal p of R there is a portal p' on one of R_1, R_2 (call it R') such that $d(p,p') + \mathit{inside}(p')(s'/m) \leq \mathit{inside}(p)(s/m)$. Here s' is the sidelength of R', with $s' \geq s/3$.

C3. For each portal p of R_j, $j = 1, 2$, there is either (i) a portal p' on one of R_1, R_2 (call it R') such that $d(p,p') + \mathit{inside}(p')(s'/m) \leq \mathit{closest}(p)(s(j)/m)$ or (ii) a portal p' of R such that $d(p,p') + \mathit{closest}(p')(s/m) \leq \mathit{closest}(p)(s(j)/m)$. Here $s(j)$ is the sidelength of R_j.

The total number of combinations of subrectangles and interaction patterns to consider for Π, due to CUTRECTANGLE-NEW, is $2^{O(m)}$. We also need to search over all possible splits of the facilities across pairs of subrectangles which gives an additional k factor. Therefore, the total number of subproblems needed to determine the value for the entry of subproblem Π is $k2^{O(m)}$. In contrast to the SUBRECTANGLE-NEW case, computing the cost of every combination can be done via lookup. For every pair of children subproblems that fulfill C1–C3, the cost of Π is equal to the sum of the two costs. We have that

$$\begin{aligned} &\text{Total time due to CUTRECTANGLE-NEW} \\ &\quad = \text{(Time per entry)} \times \text{(number of entries)} \\ &\quad = k2^{O(m)} \times k2^{O(m)} n \log n = O(k^2 2^{O(m)} n \log n). \end{aligned} \tag{4}$$

Again we can improve the total time to $O(k2^{O(m)} n \log k \log n)$ by amortization. By Lemma 7, the number of allowable rectangles that contain k or more points is $O(m^4 (n/k) \log n)$. If an allowable rectangle contains fewer than $l < k$ points from N, we need only to keep $l2^{O(m)}$ entries for it, since at most l facilities can be placed inside it. Moreover, the number of allowable rectangles containing between l and $2l$ points is shown by Lemma 7 to be $O(m^4(n/l) \log n)$. We can now bound the total number of table entries by

$$k2^{O(m)} O(m^4 (n/k) \log n) + \sum_{l=2^i}^{l<k} 2^{O(m)} O(m^4 (n/l) \log n) l = O(2^{O(m)} n \log k \log n). \tag{5}$$

By (4), (5) the total running time due to CUTRECTANGLE-NEW is

$$O(k2^{O(m)} n \log^2 n). \tag{6}$$

By (3) and (6) the total running time of the algorithm is $O(\max\{k, \log^3 n\} 2^{O(m)} n \log^2 n)$ in the worst case.

5.3. Improving the dependence on *k*. In a second approach, we can further replace the factor of k with a factor that depends only on m and $\log n$. The idea is to use indexing according to approximate cost. In this approach, the table entries are indexed by

1. the total cost of the solution corresponding to the service cost required by the clients (points) of the rectangle (this cost includes the possible assignments of points to facilities outside the rectangle via the appropriate portals),

2. a distance for each portal p to the nearest facility in the rectangle, and
3. a distance for each portal p to the nearest facility outside the rectangle if one exists that is nearer to p than all facilities inside the rectangle.

The value of a table entry is the minimum number of facilities required inside the rectangle to find a solution with the corresponding cost and interaction pattern. Naturally, we disregard subproblems indexed by cost values that are too small to be attainable with no more than k facilities.

How many different cost indexes are there? Given our initial assumption about the points lying on a grid of polynomial size, the total number of interesting cost values is polynomial in n. We quantize them further by considering only cost values that are powers of $(1+\delta)$. Then the number of distinct cost values becomes $\Theta(\log_{1+\delta} n)$. The effect of this quantizing is that for a single subproblem we approximate only its cost value to within a factor of $(1+\delta)$. These approximations pile up multiplicatively over the $O(\log n)$ levels of the decomposition. To offset this effect we choose δ to be $\Theta(m^{-1}/\log n)$. The total number of cost indexes is then $\Theta(m \log^2 n)$. Accordingly, the total number of table entries is $(\log^2 n)2^{O(m)} n \log n = 2^{O(m)} n \log^3 n$.

Under the cost quantizing, the intended meaning of the table values is the following. Let an entry be indexed by cost $C = (1+\delta)^y$ and some interaction pattern. Let this entry correspond to height i of the recursion. The value f in the entry means that the minimum number of facilities to achieve cost at most $C/(1+\delta)^i$ is at least $f+1$. In Lemma 9 below we will show that this intention can indeed be achieved. Computing an entry involves searching over combinations of subrectangles, matching interaction patterns, and cost splits, and choosing the combination that requires the minimum number of facilities in order to be realized. As before, the number of matching interaction patterns and subrectangles to be considered is $2^{O(m)}$ per table entry. The dynamic program computes entries defined on the same rectangle and with the same interaction pattern by increasing order of cost index.

For the number of cost splits we reason as follows. Given a subproblem on a rectangle R indexed by interaction pattern P and cost C one needs to consider all three cases that follow. *Cost-Split Case* (i): All subproblems on R indexed by the same interaction pattern P and with costs less than C. *Cost-Split Case* (ii): Due to the SUBRECTANGLE-NEW process, all subproblems defined on subrectangles of R with matching interaction pattern and costs less than or equal to C. Note that we might also consider cost equal to C if the subrectangle might contain all the points of R. *Cost-Split Case* (iii): Due to the CUTRECTANGLE-NEW, all cost splits C_1, C_2, across a pair of rectangles with appropriate interaction patterns, such that $C_1 + C_2 = C$. The minimum number of facilities between (i), (ii), and (iii) will give the value for the entry. Because everything is quantized at powers of $(1+\delta)$, sums get distorted. Therefore, for (iii), instead of considering all cost splits such that $C_1 + C_2 = C$, we consider C_1, C_2 such that

$$C/(1+\delta) < C_1 + C_2 \leq C.$$

The number of such splits is proportional to the total number of distinct cost values, i.e., $O(m \log^2 n)$.

To obtain the new running times we make the necessary changes to (2) and (4). In (4) the k factor is replaced throughout with $O(m \log^2 n)$, yielding time $O(2^{O(m)} n \log^5 n)$. In (2) the corresponding number of entries is proportional to the square of the total number of cost values. Therefore the total time due to SUBRECTANGLE-NEW is $O(2^{O(m)} n \log^8 n)$. Taking the maximum over the SUBRECTANGLE-NEW and the CUTRECTANGLE-NEW processes yields a worst-case running time of $O(2^{O(m)} n \log^8 n)$.

Now, we should argue that at each level the table entry corresponds to the minimum number of facilities that achieve the specified connection cost or better. This follows easily from the following lemma.

LEMMA 9. *If the table entry for a subproblem* Π, *which is indexed by cost* C, *is filled with the number* f, *then there exists a set of* f *facilities within the corresponding rectangle and a portal-respecting assignment of points to facilities that satisfies the interaction patterns such that the total cost is no more than* C. *Furthermore, there is no portal-respecting solution for* Π *that* (i) *uses fewer facilities and* (ii) *has actual service cost less than or equal to* $C/(1+\delta)^i$, *where* i *is the recursion height of the subproblem* Π.

Proof. We use induction on i. It is easy to compute table entries for rectangles that are leaves of the decomposition. Then, we inductively assume the lemma and note that the first part holds by construction. For the second part we consider the way the dynamic program computed the entry for Π. Let R be the corresponding rectangle. For the sake of contradiction assume that there is a better solution for Π, i.e., one with $g < f$ facilities and cost $C^* \le C/(1+\delta)^i$. Among these solutions, choose the one that minimizes g. By our (Modified) Structure Theorem it must be decomposable either via SUBRECTANGLE-NEW into a subproblem Π_u or via CUTRECTANGLE-NEW into two subproblems Π_1, Π_2.

In the first case, let R_u be the subrectangle of R on which Π_u is defined, and let $C_u \le C$ be the minimum cost for which Π_u admits a solution with g facilities. The cost C^* equals C_u plus the assignment cost of the points in $R - R_u$. By induction there is a computed entry for Π_u filled with the value g and indexed by cost $C'_u \le (1+\delta)^{i-1}C_u \le (1+\delta)^{i-1}C^* \le C/(1+\delta)$. Π_u will be examined by the dynamic program as per Cost-Split Case (ii) above. This contradicts the fact that the dynamic program missed the solution with the g facilities.

In the second case, this better solution is defined by combining the solutions to the two subproblems Π_1 and Π_2. Then, by induction we have solutions with the correct number of facilities in the entries for Π_1 and Π_2 which are indexed by the appropriate approximate cost; i.e., the table entries are indexed by costs C_1 and C_2 that are at most $(1+\delta)^{i-1}$ times the actual assignment cost for each subproblem. We show that at combination one can further lose an additional factor of at most $(1+\delta)$. Let Γ be the smallest power of $(1+\delta)$ such that $C_1 + C_2 \le \Gamma$. The idea is that this combination of Π_1 and Π_2 with actual service cost at most $C_1 + C_2$ will be considered by *any* subproblem, with appropriate interaction pattern, defined on R at recursion height i and whose cost index is at least Γ. In particular, we have that

$$\Gamma \le (1+\delta)(C_1 + C_2) \le (1+\delta)^i C^* \le C.$$

If $\Gamma < C$ (recall that C is also a power of $(1+\delta)$), the induction step gives us that the combination was examined as per Cost-Split Case (iii) when filling out the entry of the subproblem on R, with the same interaction pattern as Π but indexed by cost Γ. Therefore, it will be available when filling out the entry for Π and will be examined as per Cost-Split Case (i), which is a contradiction.

If $\Gamma = C$, we have that $C/(1+\delta) < C_1 + C_2 \le C$. Therefore, the combination will be examined when filling out the entry for Π as per Cost-Split Case (iii). Again this contradicts the fact that the dynamic program missed this solution. □

We are now ready to state the main result of the paper.

THEOREM 3. *Given an instance of the* k*-median problem in the* 2*-dimensional Euclidean space, and any fixed* $m > 0$, *there are randomized algorithms that compute* *a* $(1 + O(\log(m)/m))$*-approximation, in expectation, with worst-case running times* $O(2^{O(m)} n \log^8 n)$ *and* $O(2^{O(m)} \max\{k, \log^3 n\} n \log^2 n)$*, respectively.*

Repeating the algorithm $O(m \log n)$ times gives a $(1 + O(\log(m)/m))$ approximation guarantee with probability $1 - o(1)$. The algorithm can be easily extended to instances in the d-dimensional Euclidean space. The main difference is that now we work with rectangular parallelepipeds whose faces lie on i-allowable hyperplanes. As a consequence the bound given in Lemma 7 increases by an $O(m^{2d-4})$ factor and in the dynamic program we have to maintain data for each of the $2d$ faces of each parallelepiped where each face contains m^{d-1} portals. Moreover, the increased cost for range searching in Lemma 8 has to be taken into account. Following the same steps as in the proof of Theorem 3, we obtain the following.

THEOREM 4. *Given an instance of the* k*-median problem in the* d*-dimensional Euclidean space, and any fixed* $m > 0$*, there are randomized algorithms that compute a* $(1 + O(\log(m)/m))$*-approximation, in expectation, with worst-case running times* $O(2^{O(m^{d-1})} n \log^{d+6} n)$ *and* $O(2^{O(m^{d-1})} \max\{k, \log^{d+1} n\} n \log^2 n)$*, respectively.*

For any given accuracy $\varepsilon > 0$, we want $\ln(m)/m \le c\varepsilon$, where m is the number of portals and c an appropriately small constant. Let us assume $c = 1$, since we can always decrease the given value of ε. Using the computer algebra package Maple [7] we obtain that for $m = \ln(1/\varepsilon)/(0.5\varepsilon)$, $\ln(m)/m \le \varepsilon$ for any $\varepsilon \in (0, 0.5)$, while at the same time $m > 2$. On the other hand, setting $m = 3$ always yields an error less than 0.5. Therefore, the asymptotic number of portals required for an accuracy of ε in the objective is

$$O(\log(1/\varepsilon)/\varepsilon).$$

We obtain the following reinterpretation of Theorem 4.

THEOREM 5. *Given an instance of the* k*-median problem in the* d*-dimensional Euclidean space, and any fixed* $\varepsilon > 0$*, there are randomized algorithms that compute a* $(1 + \varepsilon)$*-approximation, in expectation, with worst-case running times*

$$O\left(2^{O\left((\frac{\log(1/\varepsilon)}{\varepsilon})^{d-1}\right)} n \log^{d+6} n\right) \text{ and } O\left(2^{O\left((\frac{\log(1/\varepsilon)}{\varepsilon})^{d-1}\right)} \max\{k, \log^{d+1} n\} n \log^2 n\right).$$

5.4. Uncapacitated facility location. In this section we extend the results to uncapacitated facility location. Our structure theorems clearly hold as far as the service cost is concerned. We need to implement a dynamic programming algorithm that also keeps track of the facility cost. In order to be able to preprocess the points so that they lie on a polynomial-size grid, we need the existence of a polynomial-factor approximation for the service cost as explained in section 2. *The discussion below is predicated on such an estimate being available.*

The second approach for the k-median problem enumerated the service cost and computed for each service cost value the corresponding minimum number of facilities. The analogue here is to compute the minimum facility cost. This yields an algorithm that computes a $(1 + \varepsilon)$-approximation in expectation with worst-case running time

$$O\left(2^{O\left((\frac{\log(1/\varepsilon)}{\varepsilon})^{d-1}\right)} n \log^{d+6} n\right).$$

Note that the latter time bound holds without any assumption on the range of the facility costs.

Acknowledgments. Many thanks to Sariel Har-Peled for valuable comments on a draft of this paper. The authors are grateful to Jan Remy for identifying a gap in the dynamic program and allowing us to include in the paper the fix he proposed.

HAMMING CODES, HYPERCUBE EMBEDDINGS, AND FAULT TOLERANCE*

WILLIAM AIELLO[†] AND F. T. LEIGHTON[‡]

Abstract. In this paper, we devise a special 1-error-correcting code that enables us to embed the graph product of an $N/\log N$-node hypercube and a $\log N$-node complete graph into in an N-node hypercube with constant load, dilation, and congestion. We apply the result to construct improved embeddings of trees and other structures in a hypercube, and to design more efficient and robust algorithms for reconfiguring a hypercube around random or worst-case faults. The result has also been used subsequently by others to show that the N-node hypercube can emulate all N-node planar graphs with constant slowdown.

Key words. hypercube, graph embeddings, fault tolerance, reconfiguration, tree compression, tree embedding, emulation, worst-case faults, random faults

1. Introduction.

In this paper, we use the notion of a graph product to define a graph called the *hypercube of cliques* which is the product of an $N/\log N$-node hypercube and a $\log N$-node clique (also known as a complete graph). We then show that an N-node hypercube of cliques can be embedded into an N-node hypercube with load 1 and constant dilation and congestion. As a consequence, we find that the hypercube has even stronger structural, algorithmic, and fault-tolerant properties than previously realized.

To clarify terminology, an embedding σ of a network F into a network G is a mapping of nodes of F to nodes of G and edges of F to paths in G such that the endpoints of the path $\sigma(e)$ for any edge $e = (u, v)$ in F are $\sigma(u)$ and $\sigma(v)$. The *load* of an embedding is the maximum number of nodes of F assigned to any one node of G. The *dilation* is the maximum length in G of the image of an edge of F. The *congestion of an edge* of G is the number of edges of F whose image passes through the edge of G. The *congestion* of the embedding is the maximum congestion of any edge.

We denote the N-node (or n-dimensional) hypercube by H_N where $N = 2^n$ throughout. We denote the S-node clique by K_S. We define the N-node *hypercube of cliques* P_N as the product of $H_{N/2^s}$ with K_{2^s}, where $s = \lfloor \log(n + 1)\rfloor$. Formally, this is written as $P_N = H_{N/2^s} \otimes K_{2^s}$. The $\otimes$ operator will be defined in the next section. For the purposes of the introduction, P_N can be formed from H_N by inserting an edge between any pair of nodes whose first $n - s$ bits of address are the same. Note that for any $(n - s)$-bit binary string there are 2^s such nodes which are completely connected.

Obviously, H_N is a subgraph of P_N. But can P_N be nicely embedded into H_N? From the above characterization of P_N, it is clear that one could embed P_N into H_N with constant load given a constant-load embedding of a 2^s-node clique into a 2^s-node hypercube.

But, of course, any constant-load embedding of K_{2^s} into H_{2^s} must have congestion at least $\Omega(2^s/s) = \Omega(n/\log n)$ and dilation at least $\Omega(s) = \Omega(\log n)$.

In spite of this, we show that it is possible to construct an embedding of P_N in H_N with load 1, dilation $O(1)$, and congestion $O(1)$. The embedding is described in section 2 and makes use of 1-error-correcting codes in order to map the cliques of P_N to "stars" in H_N. Roughly speaking, a *star* consists of a node u whose binary address is a codeword together with its neighbors in the hypercube. The fact that hypercubes can be partitioned into stars corresponding to codewords is well known and has been exploited in many previous papers [2, 14, 18, 20].

In addition to mapping the cliques of P_N to the stars of H_N, we must find paths between the stars in H_N such that the stars have the connectivity of a lower dimensional hypercube. In order to find the paths, we devise an algorithm to find 1-error-correcting codes with two properties: (1) any one bit of the cleartext affects only a constant number of bits of the codeword (i.e., the codes are length preserving), and (2) any one bit of the codeword is a function of only a constant number of bits of the cleartext. It is well known how to generate codes with the first property. This property ensures that our embedding has constant dilation. The second property is novel to this paper, and it guarantees that the embedding has constant congestion. To the best of our knowledge, codes satisfying the latter property were not previously studied prior to the preliminary version of this paper [1].

As a consequence of proving that P_N can be nicely embedded in H_N, we can resolve several problems concerning hypercube embeddings and robustness. For example, an immediate corollary is the fact that an $O(\log N)$-dilated N-node butterfly can be embedded in an N-node hypercube with constant load, congestion, and dilation. (A network is said to be *k-dilated* if every edge is replaced with k parallel edges.[1]) The $O(\log N)$-dilated butterfly is a powerful network for circuit-switched routing [2], and packet-switched routing [16]. The best previously known embeddings of this network in H_N have dilation $\Omega(\log N)$ [2, 12] or congestion $\Omega(\log N)$.

In section 3, we give several algorithms for embedding trees in hypercubes. First, in section 3.1, we prove a general tree compression lemma. A similar lemma using different techniques can be found in [10]. Then in section 3.2 we use the tree compression lemma and the embedding of P_N into H_N to improve the results of Bhatt et al. [6], and Greenberg and Bhatt [12]. In particular, we show how to (off-line) embed any $O(\log N)$-dilated M-node binary tree into an N-node hypercube with $O((M/N)+1)$ load and $O(1)$ congestion and dilation. Embedding a $O(\log N)$-dilated tree into a hypercube is useful for simulating tree algorithms on a hypercube. If the interprocessor messages of the tree algorithm are large, say of $\Omega(\log^2 N)$ length, then one might be able to achieve an $O(\log N)$ speedup by breaking up the messages into $O(\log N)$ pieces and sending each piece on a different path. Alternatively, by using Reed–Solomon codes to break up the messages into $O(\log N)$ packets and sending each packet along a different path, as done by Rabin [22] for hypercube routing, one may be able to simulate the tree algorithm in the presence of edge faults. The off-line embeddings of Bhatt et al. [6] apply only to undilated trees and require $M = O(N)$

[1] Note that k-dilated and $O(k)$ dilation sound similar but have very different meanings. An embedding has $O(k)$ dilation if every edge of the embedded graph is stretched across at most $O(k)$ edges by the embedding.

in order to achieve constant load and congestion. While Greenberg and Bhatt [12] are able to embed $\log N$-dilated grids into the hypercube with constant load, dilation, and congestion, their embedding of $\log N$-dilated trees has dilation $\Theta(\log\log N)$ and requires $M = O(N)$ to achieve constant load and $\Theta(\log\log N)$ congestion.

In section 3.3 we show how to dynamically (on-line) embed any M-node binary tree in an N-node hypercube with $O((M/N) + 1)$ load, $O((M/N \log N) + 1)$ congestion, and $O(1)$ dilation. Dynamic embeddings are important since, for many parallel algorithms with tree structure, the growth pattern and eventual shape of the tree are dependent on the input and are not known at compile-time. Our dynamic embedding improves upon the on-line embedding of Leighton et al. [18] which has the same (optimal) load and dilation but congestion $\Theta((M/N) + 1)$ which is only optimal for $M = O(N)$.

In section 4 we apply our embedding of P_N into H_N to the problem of reconfiguring a hypercube around faults. Previously, Hastad, Leighton, and Newman [14] showed that if each component of H_N fails independently with any constant probability $p < 1$, then the functioning parts of the hypercube can be reconfigured using only local control to simulate the original hypercube with constant slowdown. The reconfiguration algorithm of [14] is probabilistic and runs in polylogarithmic time. In section 4.1, we show how to embed P_N in H_N with constant load, congestion, and dilation, even if the nodes and edges of H_N fail with some small constant probability $p \le p_0$. Since H_N is a subgraph of P_N, this effectively reconfigures H_N. Our embedding algorithm is deterministic and uses only $O(\log N)$ rounds of communication.

In section 4.2 we extend the reconfiguration algorithm to work for any faulty hypercube containing up to $\log^{O(1)} N$ worst-case faults. Previously, Bruck, Cypher, and Soroker [9] had shown that an N-node hypercube with $\log^{O(1)} N$ worst-case faults can implement certain restricted hypercube computations with constant slowdown. The best previous general simulations were by Becker and Simon [4] and Livingston et al. [11] and can tolerate only $O(\log\log N)$ worst-case faults. To obtain the $\log^{O(1)} N$-fault bound we define the r-fold hypercube of cliques, $P_{N,r}$, as

$$P_{N,r} = H_{N/2^{sr}} \otimes \overbrace{K_{2^s} \otimes \cdots \otimes K_{2^s}}^{r},$$

where $s = \Theta(\log n)$ is defined in the next section. For constant r, we show that $P_{N,r}$ can be embedded in H_N with constant load, dilation, and congestion. We then prove that $P_{N,r}$ can tolerate $O(\log^{r-1} N)$ faults. No upperbound is known on the number of worst-case faults that a hypercube can reconfigure around. We leave tight bounds on the number of worst-case faults as an interesting subject for future research.

Subsequent to [1], Kaklamanis, Krizanc, and Rao [15] have used the fact that $P_{N,r}$ can be embedded into H_N with constant load, dilation, and congestion to show that H_N can emulate any constant-degree planar graph with constant slowdown.

2. Embedding $H_{N/2^s} \otimes K_{2^s}$ into H_N.

The main result of this section is an embedding of the N-node hypercube of cliques $P_N = H_{N/2^s} \otimes K_{2^s}$, $s = \lfloor \log(\log N + 1) \rfloor$ into the N-node hypercube. The embedding has load 1 and constant congestion and dilation. Hence, H_N can simulate the P_N with a constant factor slowdown.

By virtue of the embedding, the hypercube of cliques is no more powerful than the hypercube. Nonetheless, several routing, embedding, and robustness problems are conceptually easier to solve when viewed on the hypercube of cliques. These will be dealt with in later sections.

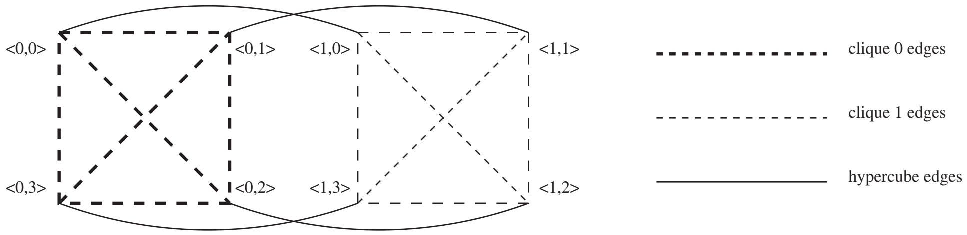

FIG. 1. $H_2 \otimes K_4 = P_8$.

Before we can state our main theorems, we need the following notation. Given two graphs, $G = (V, E)$ and $G' = (V', E')$, define the product graph $G \otimes G'$ to have a vertex set which is the cartesian product of V and V' and to have an edge set which is the union of "G edges"

$$\{(\langle v, s'\rangle, \langle u, s'\rangle) \mid (v, u) \in E,\ s' \in V'\}$$

and "G' edges"

$$\{(\langle s, v'\rangle, \langle s, u'\rangle) \mid s \in V,\ (v', u') \in E'\}.$$

$G^{(2)}$ will denote $G \otimes G$, and more generally, $G^{(r)}$ is G taken as a product with itself r times, $r \geq 1$.

We will denote the interval of consecutive integers from a to b inclusive by $[a,\ b]$. Let $N = 2^n$. The *complete graph* on S vertices K_S has vertex set $[0,\ S-1]$ and edge set $\{(i, j) \mid 0 \leq i \neq j \leq S-1\}$. The N-node *hypercube* H_N is a network with vertex set $\{0,1\}^n$. The edges of the network are between nodes whose labels differ by one bit. In what follows we will use the notation $u(j)$ to denote the jth bit of $u \in \{0,1\}^n$, $j \in [1,\ n]$. For $A \subset [1,\ n]$ we define u^A to be the node such that $u^A(k) = 1 - u(k)$ for $k \in A$ and $u^A(k) = u(k)$ for $k \notin A$. Define $A \Delta B$ to be the symmetric difference of A and B, i.e., $A \Delta B = A \cup B - A \cap B$. Then $(u^A)^B$ is equivalent to $u^{A \Delta B}$. When A has small cardinality we will often omit its brackets, e.g., $u^{\{j\}}$ will be written as u^j and denotes the node adjacent to u across the jth dimension of the hypercube. Since bit positions of a hypercube address start at 1, u^0 will mean u^ϕ which, of course, is just u. The hypercube edges are the set $\{(u, u^j)\}$, where $u \in \{0,1\}^n$ and $j \in [1,\ n]$. It is well known that $H_{2^n} = H_2^{(n)}$.

Define the *hypercube of cliques* with $N = 2^n$ nodes, P_N, as the product graph $H_{2^{n-s}} \otimes K_{2^s}$, where $s = \lfloor \log(n+1) \rfloor$. Note that if $n = 2^k - 1$ for some positive integer k, then $s = k$. Furthermore, $s = k$ for the 2^k values of n in the range $2^k - 1 \leq n < 2^{k+1} - 1$. The edges of P_N are the union of the "complete graph edges" $\{(\langle v, i\rangle, \langle v, j\rangle) \mid v \in \{0,1\}^{n-s},\ 0 \leq i \neq j \leq 2^s - 1\}$ and the "hypercube edges" $\{(\langle v, i\rangle, \langle v^j, i\rangle) \mid v \in \{0,1\}^{n-s},\ i \in [0,\ 2^s - 1],\ j \in [1,\ n-s]\}$. The hypercube of cliques for $n = 3 = 2^2 - 1$ is shown in Figure 1.

In addition to embedding the hypercube of cliques into a hypercube of the same size, we will also embed the *r-fold hypercube of cliques*, defined below, into a hypercube of the same size. The r-fold hypercube of cliques with $N = 2^n$ nodes, $P_{N,r}$, is defined as $H_{N/2^{rs}} \otimes K_{2^s}^{(r)}$, where s is the largest integer such that $2^s - 1 + (r-1)s \leq n$.

The embedding of P_N into H_N relies crucially on the notion of a star partition. This in turn relies on perfect 1-error-correcting codes which were first constructed by Hamming [13] for binary strings of length $2^k - k - 1$ for some integer k. More specifically, Hamming showed that there is a mapping g from words m of length $2^k - k - 1$ to codewords $g(m)$ of length $2^k - 1$ such that every string of length $2^k - 1$ is either a codeword or Hamming distance 1 from exactly one codeword.

To describe the mapping g, define C_k to be the k by $2^k - 1$ matrix where the columns are all the binary strings of length k except for the all-zero string. Consider strings of length l as column vectors in the vector space $GF(2)^l$. That is, vector addition is simply bitwise exclusive-or, and matrix-vector multiplication occurs with the vector on the right. It is a property of perfect 1-error-correcting codes that $C_k \cdot y = 0$ iff y is a codeword, i.e., iff $y = g(m)$ for some m. That is, the nullspace of C_k consists precisely of the codewords. It is well known that the nullspace of C_k has dimension $2^k - k - 1$ and so has a basis set $B = \{v_1, \ldots, v_{2^k-k-1}\}$ of $2^k - k - 1$ basis vectors. We will also let B denote the natural $2^k - 1$ by $2^k - k - 1$ matrix formed by the column vectors v_i. Given a basis B, the following mapping g clearly generates all the codewords of length $2^k - 1$ from strings m of length $2^k - k - 1$:

$$g(m) = B \cdot m.$$

Consider the following measures of a basis. Let the *weight* of a vector (column) be the number of 1's in the vector. Define the *height* of the basis as the maximum weight of any vector in the basis. Let the *width* of a dimension (row) be the number of basis vectors with a 1 in that dimension. Define the *width of the basis* as the maximum width of any dimension.

The lemma below shows that a basis with small height and width yields a good embedding of P_N into H_N. After proving this lemma we will show how to find such a basis.

LEMMA 1. *Given a basis of the nullspace of C_k with height h and width w for some $k \geq 2$, there is an embedding of $H_{2^{n-k}} \otimes K_{2^k}$ into H_{2^n} with load 1, dilation h, and congestion $2w + 2$ for all $n \geq 2^k - 1$.*

Proof. Assume we are given a basis B for the nullspace of C_k with height h and width w for some $k \geq 2$, and let g be the the encoding from strings of length $\eta - k$ to η defined by B. We will first describe the embedding of $H_{2^{\eta-k}} \otimes K_{2^k} = P_{2^\eta}$ into H_{2^η}, where $\eta = 2^k - 1$. We will then show that this embedding can be easily extended to an embedding of $H_{2^{n-k}} \otimes K_{2^k}$ into H_{2^n} for all $n \geq \eta$. For simplicity we will treat both H_{2^η} and P_{2^η} as directed graphs where each simple edge is replaced by two directed edges, one in each direction.

Call a node u in H_{2^η} a *star center* if u is a codeword, i.e., if $u \in \{g(m) | m \in \{0,1\}^{\eta-k}\}$. Define a *star* to be a star center together with all of its neighbors. Since g is a perfect 1-error-correcting code, every node in the hypercube is in exactly one star. That is, the stars partition the nodes of H_{2^η}: there are $2^{\eta-k}$ stars each with $\eta + 1 = 2^k$ nodes.

The $2^{\eta-k}$ cliques of size 2^k in $P_{2^\eta} = H_{2^{\eta-k}} \otimes K_{2^k}$ will be mapped to the $2^{\eta-k}$ stars of size 2^k in H_{2^η}. Furthermore, cliques which differ in one dimension in P_{2^η} will be mapped to stars which are "close" in H_{2^η}.

Our map from nodes of P_{2^η} to nodes of H_{2^η} is defined as follows:

$$\langle m, i \rangle \mapsto g(m)^i$$

for $m \in \{0, 1\}^{\eta-k}$ and $i \in [0, \eta]$. Observe that each clique is mapped to a unique star and that each node in a clique is mapped to a unique node in the corresponding star. Since the stars partition H_{2^η}, the embedding is one-to-one and onto.

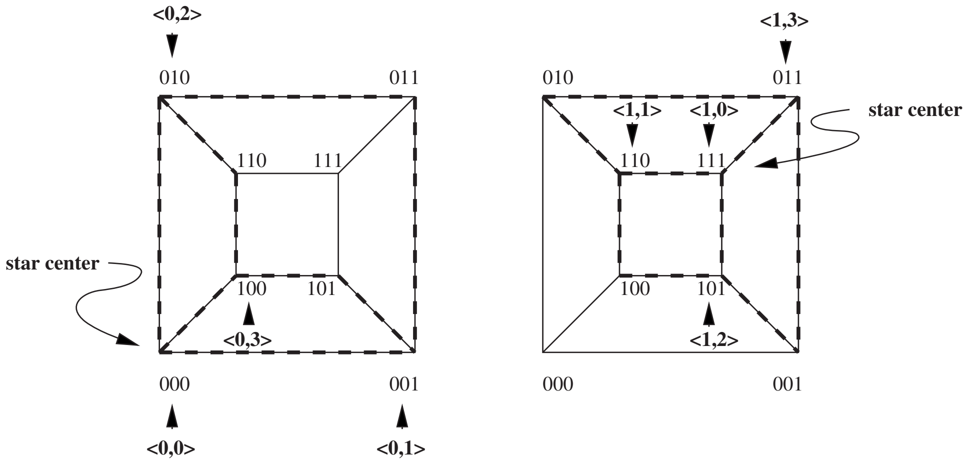

FIG. 2. *The embedding of clique* 0 *of* $H_2 \otimes K_4$ *into* H_8 *on the left, and the embedding of clique* 1 *into* H_8 *on the right.*

Embedding the clique edges of P_{2^η} is easy. The edge $\langle m, 0\rangle \rightarrow \langle m, j\rangle$, $j \in [1,\, \eta]$, is mapped to the edge $g(m) \rightarrow g(m)^j$ in H_{2^η}. The edge $\langle m, i\rangle \rightarrow \langle m, j\rangle$, $1 \le i \ne j \le \eta$, is mapped to the path $g(m)^i \rightarrow g(m)^{i,j} \rightarrow g(m)^j$. It is easy to verify that a directed edge of H_{2^η} is used at most once as the first edge of these paths and at most once as the second edge. Hence, the directed congestion due to the clique edges of P_{2^η} is at most 2. The mapping of the nodes and clique edges of P_8 to H_8 is shown in Figure 2.

To embed the hypercube edges of P_{2^η}, $\{\langle m, j\rangle \rightarrow \langle m^i, j\rangle \mid j \in [0,\, \eta],\, i \in [1,\, \eta - k]\}$, observe that $g(m^i) = g(m) \oplus v_i$ since

$$g(m^i) = B \cdot m^i = (B \cdot m) \oplus v_i = g(m) \oplus v_i.$$

This can also be written as $g(m^i) = g(m)^{V_i}$ if we let V_i be the indicies of the bits of v_i which are 1. The edge $\langle m, j\rangle \rightarrow \langle m^i, j\rangle$ is mapped to the path which starts at $g(m)^j$ and goes to $g(m^i)^j$ by changing the bits indicated by V_i. More formally, let $V_i = \{l_{i_1},\, l_{i_2}, \ldots, l_{i_{h'}}\}$, where $l_{i_1} < l_{i_2} < \cdots < l_{i_{h'}}$. Then the edge $\langle m, j\rangle \leftrightarrow \langle m^i, j\rangle$ is mapped to the path

$$g(m)^{\{j\}} \leftrightarrow g(m)^{\{l_{i_1}\}\Delta\{j\}} \leftrightarrow g(m)^{\{l_{i_1}, l_{i_2}\}\Delta\{j\}} \leftrightarrow \cdots \leftrightarrow g(m)^{V_i \Delta \{j\}} = g(m^i)^j.$$

That the dilation for embedding the hypercube edges of P_{2^η} is h follows directly from the embedding above and from the definitions of dilation and height. Note that h is an upper bound on the dilation for the entire embedding since Hamming codes must have height at least 3 and the dilation due to the embedding of the clique edges is just 2.

To bound the congestion in H_{2^η} due to the hypercube edges of P_{2^η}, consider a hypercube edge $u \leftrightarrow u^j$ across dimension j. Let v be a basis vector with a 1 in dimension j, and further suppose v has 1's in dimensions $V = \{l_1, \ldots, l_d,\, j,\, l_{d+2}, \ldots, l_{h'}\}$, where $l_1 < l_2 < \cdots < l_d < j < l_{d+2} < \cdots < l_{h'}$. If we start at node $s = u^{\{l_1, \ldots, l_d\}}$ and take a path defined by changing the dimensions of V in increasing order, we will pass through the edge $u \rightarrow u^j$ and end up at the node $t = u^{\{j, l_{d+2}, \ldots, l_{h'}\}}$. The above path may be a path of the embedding which passes through $u \leftrightarrow u^j$ if the appropriate nodes of P_{2^η} have been mapped to s and t. Note that a path, which starts at s^j, traverses the dimension of V in increasing order, and ends at t^j, traverses the edge $u^j \to u$. If the appropriate nodes of P_{2^η} have been mapped to s^j and t^j, then this latter path will also pass through $u \leftrightarrow u^j$. Hence, every basis vector with a 1 in dimension j may contribute congestion 2 to the edge $u \leftrightarrow u^j$. Obviously paths based on basis vectors which don't have a 1 in dimension j cannot cause congestion to $u \leftrightarrow u^j$ since these paths do not even cross dimension j. Hence, the congestion in H_{2^η} due to hypercube edges of P_{2^η} is at most $2w$.

This completes the embedding of $H_{2^{n-k}} \otimes K_{2^k}$ into H_{2^n} for the special case $n = \eta$. To get an embedding of all $n \geq \eta$ the following lemma will be useful.

LEMMA 2. *Given an embedding $\mathcal{E}$ of F into G with load l, congestion c, and dilation d and an embedding $\mathcal{E}'$ of F' into G' with load l', congestion c', and dilation d', there is a natural embedding of $F \otimes F'$ into $G \otimes G'$, called the product embedding, which achieves load equal to ll', congestion equal to* $\max\{cl', c'l\}$*, and dilation equal to* $\max\{d, d'\}$.

Proof. The product embedding maps nodes $\langle u, u' \rangle$ to $\langle \mathcal{E}(u), \mathcal{E}'(u') \rangle$. If an edge (u, v) of F is mapped to a path $(\mathcal{E}(u), w_1, \ldots, w_k, \mathcal{E}(v))$ in G, then the F edge $(\langle u, u' \rangle, \langle v, u' \rangle)$ of $F \otimes F'$ is mapped to the path

$$(\langle \mathcal{E}(u), \mathcal{E}'(u') \rangle, \langle w_1, \mathcal{E}'(u') \rangle, \ldots, \langle w_k, \mathcal{E}'(u') \rangle, \langle \mathcal{E}(v), \mathcal{E}'(u') \rangle)$$

in $G \otimes G'$. F' edges are mapped similarly. The claimed bounds follow easily from these mappings. □

Since H_{2^n} is equivalent to H_2 taken as a product with itself n times, it follows that H_{2^n} can be written as the product of two smaller hypercubes. Hence we can write H_{2^n} as $H_{2^{n-\eta}} \otimes H_{2^\eta}$ and $H_{2^{n-k}} \otimes K_{2^k}$ as $H_{2^{n-\eta}} \otimes H_{2^{\eta-k}} \otimes K_{2^k}$ which is just $H_{2^{n-\eta}} \otimes P_{2^\eta}$. (Recall that we are assuming that $n \geq \eta$ and $k \geq 2$ so that $\eta - k > 0$.) Now we use the product embedding consisting of the identity embedding of $H_{2^{n-\eta}}$ into itself along with the previously described embedding of P_{2^η} into H_{2^η}. This finishes the proof of Lemma 1. □

Lemma 1 along with a basis B for the nullspace of C_k with constant height and width for all k would yield an embedding P_{2^n} into H_{2^n} with load 1 and constant dilation and congestion for all n. We describe an algorithm for constructing such a basis in Appendix A where we prove the following.

LEMMA 3. *A basis of the nullspace of C_k with height* 6 *and width* 9 *can be found in time polynomial in* 2^k.

Our original bounds in [1] were height 6 and width 28. The width was improved in [17] to 11 before being further improved to 9 as presented here. Subsequently, Pritikin [21] improved both the height and the width to 3 and 5, respectively.

For many values of k one can do even better. For example, it is well known that cyclic codes based on primitive polynomials for $GF(2)[x]$ with degree k and t nonzero coefficients give a basis for the nullspace of C_k with height t. In Appendix A we give an easy proof that the width of the basis is also bounded by t. Empirical work has shown that for most degrees up to 137, the primitive polynomials have three nonzero coefficients [23]. This means that for most practical values of k, the height and width are both 3.

Finally, we can state our main theorem.

THEOREM 1. *There is an embedding of $H_{2^{n-k}} \otimes K_{2^k}$ into H_{2^n} with load* 1*, dilation* 3*, and congestion* 12 *for all $k \geq 2$ and $n \geq 2^k - 1$. For most $n \in [3, 2^{137} - 1]$ the congestion can be reduced to* 8.

As an obvious corollary, P_{2^n} can be embedded into H_{2^n} with the stated bounds for $n \geq 3$.

The above theorem can also be used as a base case to yield an embedding for the r-fold hypercube of cliques.

Theorem 2. *There is an embedding of $H_{2^{n-rk}} \otimes K_{2^k}^{(r)}$ into H_{2^n} with load* 1*, dilation* 3^r*, and congestion* 12^r *for all $k \geq 2$ and $n \geq 2^k - 1 + (r-1)k$.*

Proof. The proof will proceed by induction on r. The base case $r = 1$ is simply Theorem 1 above. Assume Theorem 2 is true for $r \leq t - 1$. Now given an $n \geq 2^k - 1 + (t-1)k$ we will embed $H_{2^{n-tk}} \otimes K_{2^k}^{(t)}$ into H_{2^n}. Note that $H_{2^{n-tk}} \otimes K_{2^k}^{(t)}$ can be written as $H_{2^{(n-k)-(t-1)k}} \otimes K_{2^k}^{(t-1)} \otimes K_{2^k}$. The first two terms in this product can be embedded into $H_{2^{n-k}}$ by induction since $n - k \geq 2^k - 1 + ((t-1)-1)k$ follows immediately from the assumption that $n \geq 2^k - 1 + (t-1)k$. The embedding has load 1, dilation 3^{t-1}, and congestion 12^{t-1}. Hence, $H_{2^{n-tk}} \otimes K_{2^k}^{(t-1)} \otimes K_{2^k}$ can be embedded into $H_{2^{n-k}} \otimes K_{2^k}$ with load 1, dilation 3^{t-1}, and congestion 12^{t-1} using the product embedding. The latter can now be embedded into H_{2^n} using the base case. This multiplies the dilation and congestion by 3 and 12, respectively. □

It follows immediately that $P_{N,r}$ can be embedded into H_N with load 1 and constant load and congestion for constant r.

3. Embedding trees into hypercubes.

3.1. The tree compression lemma. This section describes several results on embedding binary trees into the hypercube. A main tool for these embeddings will be the following lemma which is proved in Appendix B. A similar lemma using different techniques appears in [10].

Lemma 4 (the tree compression lemma). *For any M-node binary tree T and any positive integer $N < M$, it is possible to partition T into N subtrees by removing $N - 1$ edges so that every subtree has at most $\frac{12M}{N} + 1$ nodes. Furthermore, if each subtree is considered a single supernode, then the $N - 1$ removed edges and the N supernodes form a binary tree.*

As our first application of the tree compression lemma, we will generalize the result of Bhatt et al. [6] who show that any binary tree of size N can be embedded into H_N with load 1, congestion $O(1)$, dilation $O(1)$, and node congestion $O(1)$. By *node congestion* we mean the maximum number of paths of the embedding that pass through a hypercube node.[2]

Theorem 3. *Any M-node binary tree can be embedded into H_N with load $O(\frac{M}{N} + 1)$, congestion $O(1)$, dilation $O(1)$, and node congestion $O(1)$.*

Proof. Given an M-node tree T, $M > N$, use the tree compression lemma to get a tree T' with N supernodes, each consisting of subtrees of size $O(M/N)$. Now use the theorem of [6] to embed T' into H_N. This clearly gives $O(1)$ dilation, congestion, and node congestion. It also maps one supernode onto each hypercube node which gives the desired bounds on the load. □

3.2. Embedding dilated trees in a hypercube. As our second application of the tree compression lemma, we will show how to embed $O(\log N)$-dilated binary trees in a hypercube with constant dilation and congestion. A tree is said to be k-dilated if every edge is replaced with k edges.

Greenberg and Bhatt [12] studied the problem of embedding N-node, $O(\log N)$-dilated grids, and $O(\log N)$-dilated trees into H_N. Their motivation was as follows. If

[2] We do not count paths where both endpoints are mapped to the same node. Using such a definition, one cannot do better than $O(M/N)$ node congestion. Counting paths where one endpoint is mapped to a node does not change the stated results.

one is simulating a tree or grid algorithm on a hypercube in which the interprocessor messages are large, say of $\Omega(\log^2 N)$ length, then one might be able to achieve an $O(\log N)$ speedup by breaking up the messages into $O(\log N)$ pieces and sending each piece on a path which is short and has low congestion. They were able to embed the $O(\log N)$-dilated grid into H_N with $O(1)$ load, congestion, and dilation, but they were able to achieve only $O(\log\log N)$ dilation and congestion for $O(\log N)$-dilated binary trees. In what follows, we show how to achieve $O(1)$ dilation and congestion for $O(\log N)$-dilated binary trees.

Theorem 4. *Any N-node $O(\log N)$-dilated binary tree can be embedded into H_N with $O(1)$ congestion, dilation, and load.*

Proof. Let T be an $O(\log N)$-dilated tree with $N = 2^n$ nodes. Apply the tree compression lemma to get an $O(\log N)$-dilated binary tree T' with $N/2^s$ supernodes, where as before $s = \lfloor \log(n+1) \rfloor$. Each supernode is an $O(\log N)$-dilated subtree of size $O(2^s)$. Let T'' be the binary tree derived from T' by converting supernodes to nodes and dilated edges to edges. Below we will embed T' into $T'' \otimes K_{2^s}$ with dilation 3 and constant load and congestion. This will imply the theorem as follows. T'' can be embedded into $H_{N/2^s}$ with $O(1)$ load, dilation, and congestion by [6]. Hence $T'' \otimes K_{2^s}$ can be embedded into $H_{N/2^s} \otimes K_{2^s} = P_N$ with constant load, dilation, and congestion by Lemma 2. P_N is then embedded into H_N by Theorem 1.

Our embedding of T' into $T'' \otimes K_{2^s}$ is as follows. Each supernode v of T' is embedded into the clique labeled v in $T'' \otimes K_{2^s}$. The $O(2^s)$ nodes of a supernode v are assigned evenly to the 2^s nodes of clique v to achieve constant load. To analyze the dilation and congestion we'll analyze the dilated edges within a supernode and between supernodes separately.

If two neighbors within supernode v of T' are mapped to different nodes of clique v, then the $O(\log N)$ edges in the dilated edge between them are mapped evenly to the $2^s - 1$ paths of length 1 or 2 between the endpoints in clique v. Note that a pair of neighbors within supernode v that are mapped to the pair of nodes $\{x, y\}$ or the pair $\{x, z\}$ or the pair $\{w, y\}$ in clique v contribute $O(1)$ congestion to the edge (x, y) of clique v. Since $O(1)$ nodes of supernode v are mapped to any one node of clique v and since each node of supernode v has at most three neighbors, it follows that the congestion due to neighbors within supernodes of T' is $O(1)$.

Suppose supernodes u and v are neighbors in T' by virtue of the fact that nodes $U \in u$ and $V \in v$ are neighbors in T. U and V are mapped to nodes in neighboring cliques u and v in $T'' \otimes K_{2^s}$. Between any two nodes, one each in neighboring cliques in $T'' \otimes K_{2^s}$, there are 2^s paths of length at most 3. Hence, the $O(\log N)$ edges in the dilated edge between U and V can be evenly distributed among 2^s paths of length at most 3. These paths contribute at most $O(1)$ congestion to the clique edges of $T'' \otimes K_{2^s}$ and $O(1)$ congestion to the T'' edges of $T'' \otimes K_{2^s}$. □

Corollary 1. *Any M-node, $O(\log N)$-dilated binary tree can be embedded into H_N with load $O(\lceil M/N \rceil)$, congestion $O(1)$, and dilation $O(1)$.*

Proof. Apply the tree compression lemma to get a dilated tree with supernodes of size $O(\lceil M/N \rceil)$. Now apply Theorem 4 treating each supernode as a node. □

3.3. Embedding dynamic trees. The previous section dealt with off-line embeddings of arbitrary trees. However, for many parallel algorithms with a tree structure, the growth pattern and eventual shape of the tree are dependent on the input. Bhatt and Cai [5] were the first to examine whether dynamic trees could be efficiently simulated on the hypercube. Their results were improved by Leighton et al. [18] who gave a probabilistic embedding of a dynamic tree of size M into H_N which achieved, with high probability, $O(\frac{M}{N}+1)$ load, $O(1)$ dilation, and $O(\frac{M}{N}+1)$ congestion. Their bounds for load and dilation are clearly optimal (and, in fact, they show that a deterministic algorithm cannot simultaneously achieve optimal load and dilation). Using an algorithm similar to theirs we improve the congestion to $O(\frac{M}{N\log N}+1)$, which is a $\log N$ factor improvement. This is within a $\log(M/N)$ factor of the lower bound $\Omega(M/N\log N\log(M/N))$ on congestion for on-line algorithms implied in the work of Bhatt et al. [7].

THEOREM 5. *An arbitrary binary tree T with M vertices can be dynamically grown on an N-processor hypercube with constant dilation such that with high probability the maximum load per processor is $O(\frac{M}{N}+1)$ and the maximum congestion on any edge is $O(\frac{M}{N\log N}+1)$.*

Proof. The starting point of our proof is an algorithm by Leighton et al. [18] which dynamically embeds an M-node binary tree into an N-input, $\log N$-depth butterfly B_N with dilation 2 such that with high probability the number of tree nodes per column is $O(\frac{M}{N}+\log N)$ and the load is $O(\frac{M}{N\log N}+\log N)$.

The essential idea will be to use the algorithm of [18] on a butterfly $B_{N/2^s}$ of size $N/2^s$ by $\log N-s$ and then adapt this algorithm to run on $P_N=H_{N/2^s}\otimes K_{2^s}$ (where as before, $N=2^n$ and $s=\lfloor\log(n+1)\rfloor$). Observe that the algorithm of [18] will dynamically embed an M-node tree on $B_{N/2^s}$ with dilation 2 such that with high probability there are $O(\frac{M}{N/\log N}+\log N)$ nodes per column and $O(\frac{M}{N}+\log N)$ load. Call this algorithm A. Algorithm A' will be the adapted version of this algorithm which runs on P_N.

We will rely on the following simple combinatorial lemma to help distribute load and congestion.

LEMMA 5. *Assume a total of m balls are placed into n boxes one at a time. If at each step a ball is placed in any one of the $\lceil\alpha n\rceil$ least occupied boxes, $0<\alpha<1$, then after all balls have been assigned, at most $\frac{m}{n(1-\alpha)}+1$ balls are in any box.*

Proof. Let $\lceil\alpha n\rceil=k$. Let b_i be the number of balls in box i, where the boxes are sorted by increasing size after each ball is added. We first argue by induction that $b_n-1\le b_k\le b_n$. After the first ball has been added, $b_n=1$ and $b_k=0$. Now assume the statement is true after many balls have been added. When the next ball is added, the algorithm requires that it be added to a box i with $b_i<b_k$ or a box j with $b_j=b_k$. In the former case the inductive hypothesis clearly remains true. In the latter case, there are two cases. If $b_k=b_n$, then adding a ball to any box j with $b_j=b_k$ and resorting will result in $b_n=b_k+1$. If $b_k=b_n-1$, then adding a ball to any box j with $b_j=b_k$ and resorting will result in $b_k=b_n$ or $b_k=b_n-1$ depending on the configuration of boxes before the ball is added.

Now suppose to the contrary of the lemma that more than $\frac{m}{n(1-\alpha)}+1$ balls are in one box. The fact that $b_n-1\le b_k\le b_n$ is an invariant implies that there are at least $n-\lceil\alpha n\rceil+1$ boxes with more than $\frac{m}{n(1-\alpha)}$ balls. Since $n-\lceil\alpha n\rceil+1$ is strictly greater than $n-\alpha n$, this implies that there are more than m balls. □

If A embeds a tree node in column v in $B_{N/2^s}$, then A' will embed the same tree node in clique v in P_N. If A embeds a root u into column v, then A' will map u to one of the $\lceil\frac{4}{5}2^s\rceil$ least loaded nodes of clique v. We will now describe how the children of an arbitrary node u are embedded. To begin, assume that A has embedded u to some node $\langle v,i\rangle$ of $B_{N/2^s}$ and that A' has embedded u into $\langle v,j\rangle$ in P_N for some j. Algorithm A will only embed the children of u in column v, v^{i+1}, or v^{i+2} of $B_{N/2^s}$ (i.e., in $\langle v,i+1\rangle$, $\langle v^{i+1},i+1\rangle$, $\langle v,i+2\rangle$, or $\langle v^{i+2},i+2\rangle$). A' will handle these three cases as follows. In the first case, A' will map the child to $\langle v, k\rangle$ such that $\langle v, k\rangle$ is among the $\lceil \frac{4}{5} 2^s \rceil$ least loaded nodes of clique v and $\langle v, j\rangle \rightarrow \langle v, k\rangle$ is among the $\lceil \frac{4}{5} 2^s \rceil$ least congested edges with endpoint $\langle v, j\rangle$. Note that such an embedding can always be found.

Now suppose that A embeds the child in column v^{i+1}. A' embeds the node across a path of length 2:

$$\langle v, j\rangle \rightarrow \langle v, k\rangle \rightarrow \langle v^{i+1}, k\rangle$$

such that the first edge is among the $\lceil \frac{4}{5} 2^s \rceil$ least congested edges with endpoint $\langle v, j\rangle$, the second edge is among the $\lceil \frac{4}{5} 2^s \rceil$ least congested edges between clique v and clique v^{i+1}, and $\langle v^{i+1}, k\rangle$ is among the $\lceil \frac{4}{5} 2^s \rceil$ least loaded nodes in clique v^{i+1}. Note that such a path can always be found.

When A embeds a child in column v^{i+2}, A' embeds the node across a path of length 3:

$$\langle v, j\rangle \rightarrow \langle v, k\rangle \rightarrow \langle v^{i+1}, k\rangle \rightarrow \langle v^{i+2}, k\rangle$$

such that the first edge is among the $\lceil \frac{4}{5} 2^s \rceil$ least congested edges with endpoint $\langle v, j\rangle$, the second edge is among the $\lceil \frac{4}{5} 2^s \rceil$ least congested edges across dimension $i+1$, the third edge is among the $\lceil \frac{4}{5} 2^s \rceil$ least congested edges across dimension $i+2$, and $\langle v^{i+2}, k\rangle$ is among the $\lceil \frac{4}{5} 2^s \rceil$ least loaded nodes in clique v^{i+2}. As before, such a path can always be found.

That the load is $O(\lceil M/N \rceil)$ with high probability easily follows from Lemma 5 and the fact that the number of tree nodes per column in A is $O(\frac{M}{N} \log N + \log N)$ with high probability. To bound the congestion on clique edges of P_N use the fact that the load of A' is $O(\lceil M/N \rceil)$ with high probability. By the fact that each tree node has at most two children and by Lemma 5, the congestion is $O(\lceil \frac{M}{N \log N} \rceil)$. To bound the congestion on the hypercube edges of P_N, first note that the congestion on the butterfly edges due to A is at most $O(\frac{M}{N} + \log N)$ with high probability. This follows from the fact that the load due to A is $O(\frac{M}{N} + \log N)$ with high probability and the fact that each tree node has at most two children. That the congestion on hypercube edges of P_N is $O(\lceil \frac{M}{N \log N} \rceil)$ with high probability follows from Lemma 5 and the fact that each embedding by A' uses at most two hypercube edges when A uses a butterfly crossedge. □

In the model just analyzed only one node is expanded at a time. It is more natural to allow many tree nodes to expand in one time step. Because the algorithm embeds nodes locally, it is not difficult to adapt the algorithm to run in an on-line fashion with a polylogarithmic slowdown on the hypercube, even when many nodes are expanded simultaneously.

4. Reconfiguring hypercubes around faults.

In this section, we show how to apply the techniques developed in sections 2 and 3 to devise improved algorithms for using faulty hypercubes to simulate fault-free hypercubes. We will consider the case of random faults in section 4.1 and the case of worst-case faults in section 4.2.

4.1. Random faults.

Consider an N-node hypercube H_N in which every edge and node is faulty with some constant probability $p < 1$. We will assume that each fault is independent of the location of other faults and that if a node is faulty, then it cannot be used for any purpose (i.e., no communication can pass through it). In what follows, we will prove that if p is a sufficiently small constant, then with high probability we can embed P_N into H_N with constant load, dilation, and congestion so that every node of P_N is mapped to a live node of H_N and so that every edge of P_N is mapped to a path of live nodes and edges of H_N. Since H_N is a subgraph of P_N, we will have thus shown how a faulty hypercube can simulate a functioning hypercube of the same size with constant slowdown.

The result is similar to that proved by Hastad, Leighton, and Newman [14], except that the reconfiguration algorithm in [14] is probabilistic and uses a polylogarithmic number of communication steps to achieve the reconfiguration. The only previously known deterministic reconfiguration algorithm requires $\Omega(N)$ steps [3]. The algorithm described in this section is simple and deterministic and uses only $O(\log N)$ local communication steps. The algorithm is limited by the fact that the probability of component failure p must be a small constant, but it should be possible to extend the result to work for all $p < 1$ using the methods of [14] and section 4.2 of this paper.

THEOREM 6. *There is a deterministic embedding algorithm using $O(\log N)$ local communication rounds such that if the components of H_N fail independently with probability $p \leq p_0$ (for some fixed constant p_0), then P_N can be embedded in the faulty H_N with $O(1)$ load, dilation, and congestion with probability $1 - 1/N^{O(1)}$.*

Proof. The algorithm for embedding P_N into a faulty hypercube is very similar to the fault-free embedding described in section 2. To economize on space, we will only sketch the additional steps needed to tolerate faults in what follows. We will assume that $N = 2^n$, where $n = 2^k - 1$ for some integer k, so that $P_N = H_{2^{n-k}} \otimes K_{2^k}$. As in section 2 the extension of the result to general n is straightforward.

The first step of the embedding is to map the nodes of each clique of P_N to the nodes of the corresponding star in H_N. For ease of exposition we will assume that every star center is faulty. It is easy to show that, for any $\beta > 0$ and any $\epsilon_1 > 0$, there exists a sufficiently small p (e.g., $p \leq 2^{-1-\beta/\epsilon_1}$) such that with probability at least $1 - 1/N^\beta$, at least $(1-\epsilon_1)n$ nodes of each star are alive. Hence, we will map the ith node of a clique to the ith live node of the corresponding star, using wraparound as necessary. In particular, if $\epsilon_1 \leq 1/2$, then at most two nodes of any clique will be mapped to any star node by this process.

We next show how to interconnect the live nodes of each star into a clique. Given any two live nodes v^i, v^j in a star centered at v, we will connect them with the path $v^i \to v^{ij} \to v^j$ provided that the path is fault-free. Note that the probability that such a path is faulty is $1 - (1-p)^3 < 3p$ and that the path for $v^i \to v^j$ is disjoint from the path for $v^{i'} \to v^{j'}$ whenever $\{i, j\} \neq \{i', j'\}$. Hence, we can use a simple probabilistic argument to show that, with high probability, every live node of every star is connected to at least $(1 - \epsilon_2)n$ live nodes in the same star with live disjoint paths of length 2. These connections can be made in constant time on the hypercube.

We next show how to connect a pair of live nodes in a star v^i, v^j for which the path $v^i \to v^{ij} \to v^j$ contains a fault. For each such pair we will find a third live node v^s for which the paths $v^i \to v^{is} \to v^s$ and $v^s \to v^{sj} \to v^j$ are functioning. There are at least $(1-2\epsilon_2)n$ choices for s since both v^i and v^j are connected to at least $(1-\epsilon_2)n$ other live nodes with paths of length 2. In order to avoid congestion problems, we will choose intermediate nodes in rounds as follows. In the first round, we will find intermediate nodes for disconnected live pairs v^i, v^j, where $j \equiv i + 1 \pmod{n}$. In particular, the processors at node v^i will select a value of s such that both $v^i \to v^{is} \to v^s$ and $v^s \to v^{sj} \to v^j$ are live where $j = i + 1$. This step can be accomplished with $O(1)$ communication steps (where we allow $\log N$ bits to traverse each edge during a step) and can increase the congestion of every edge by at most 2 (due to reconfiguring this star). (Note that every edge in a path of length 4 is involved in reconfiguring at most two stars.) In the rth round $(1 \leq r \leq n)$, we will find intermediate nodes for live pairs

v^i, v^j, where $j \equiv i + r \pmod{n}$. In particular, the processor at node v^i will select a value of s such that every component along the path $v^i \to v^{is} \to v^s \to v^{sj} \to v^j$ is alive and so that every edge along the path has congestion (due to reconfiguring this star) at most C, where C is a predetermined, sufficiently large constant. We can always find such an s since at most $2\epsilon_2 n$ values of s are eliminated due to faults and since at most $2n/C$ values are eliminated due to edge congestion. (Hence, it suffices to choose $C > 2/(1 - 2\epsilon_2)$.) Information about whether or not edges are congested can be transmitted in $O(1)$ communication steps, where we allow $O(\log N)$ bits of data to be transmitted at each step. Note that we don't need to coordinate among selections being made in a given round since the congestion of any edge can go up by at most 2 in a single round.

After n rounds, the previous algorithm will have connected every pair of live nodes in a star with a live path of length at most 4. Moreover, the congestion is bounded by $O(1)$. This completes the embedding of the cliques of P_N into the faulty H_N. We next show how to embed the hypercube edges of P_N into the faulty H_N.

By Theorem 1, the hypercube edges of P_N are mapped to paths of constant length in H_N. For every pair of neighboring cliques in P_N there are n paths in H_N between the stars corresponding to the cliques (excluding the path between the star centers). For example, clique u and clique u^t are neighbors across hypercube dimension t in P_N. Let $\mathcal{P}(u, u^t)$ be the paths (nodes and edges, including endpoints) in H_N between $g(u)^i$ and $g(u^t)^i$, $1 \leq i \leq n$, given by the embedding. It can be shown that at most three paths in $\mathcal{P}(u, u^t)$ can intersect in a single node of H_N. Hence, these paths collectively use $\Theta(n)$ nodes and edges of H_N. If p is a sufficiently small constant, then with high probability, at most $\epsilon_3 n$ of the nodes or edges in $\mathcal{P}(u, u^t)$ will be faulty for any pair u, u^t and $\epsilon_3 > 0$. Since each faulty node or edge in $\mathcal{P}(u, u^t)$ can destroy at most three of the paths in $\mathcal{P}(u, u^t)$, this means that with high probability, at least $(1 - 3\epsilon_3)n$ of the paths in $\mathcal{P}(u, u^t)$ will be live. Hence, we embed the ith path along the ith live path (counted with wraparound). Provided that $\epsilon_3 \leq 1/6$, this results in at most a factor of 2 increase in congestion.

Of course, we still have to hook up the endpoints of the live paths to the appropriate endpoints in each star. This is easily accomplished in the following manner. If e is a dimension t edge of $H_{2^{n-k}}$ whose path ends at v^j in the star centered at v but whose clique endpoint has been embedded at v^i, we make the connection by routing the path through the path of length at most 4 from v^j to the tth live node of the star and then through the path of length at most 4 from this node to v^i. We use a similar path at the other endpoint. Because each v^i contains at most $O(1)$ clique nodes and each v^j contains at most $O(1)$ path endpoints for e in dimension t, this embedding results in only constant congestion. This completes the proof of Theorem 6. □

4.2. Worst-case faults. In this section we prove the following theorem.

THEOREM 7. *An N-node hypercube with $\log^{O(1)} N$ worst-case faults contains an embedding of a fully functioning N-node hypercube with constant load, dilation, and congestion.*

Proof. Below we will show that, for every constant r, the r-fold hypercube of cliques $P_{N,r}$ with $O(n^r)$ faults contains an embedding of a fault-free $P_{N,r}$ with constant load, dilation, and congestion. This implies Theorem 7 as follows. Let the number of faults that an r-fold hypercube of cliques can tolerate (i.e., still reconfigure to run with constant slowdown) be $a_r n^r$ for some constant $a_r > 0$. Suppose we embed $P_{N,r}$ into an N-node hypercube with F faults. Consider nodes or edges of $P_{N,r}$ that are embedded in a fault of H_N to be faulty. Since one node fault in H_N induces n edge faults in H_N, by Theorem 2 at most bnF nodes or edges of $P_{N,r}$ are faulty for some constant b that is independent of N. If $F \le \frac{a_r n^{r-1}}{b}$, then we can reconfigure $P_{N,r}$ within itself so as to avoid these faults, thereby obtaining an embedding of $P_{N,r}$ into H_N that avoids the faulty components of H_N. Since $P_{N,r}$ contains H_N as a subgraph, this means that an N-node hypercube can be reconfigured around $\frac{a_r n^{r-1}}{b}$ faults with $O(1)$ load, dilation, and congestion for any constant r. Hence, the N-node hypercube can tolerate $\log^{O(1)} N$ faults, as claimed.

For simplicity we will assume that all the faults in $P_{N,r}$ are node faults. This affects the bounds by only constant factors since for any set E of edge faults in $P_{N,r}$ there is a set F of node faults of size at most $2|E|$ such that the set of edge faults induced by the node faults contains E. We will show that a fault-free $P_{N,r}$ can be embedded into a $P_{N,r}$ with $c_r 2^{sr} = \Theta(n^r)$ faults, for some constant $c_r > 0$ (and s as defined previously), with constant load, dilation, and congestion for a fixed r. Recall that

$$P_{N,r} = H_{N/2^{sr}} \otimes \overbrace{K_{2^s} \otimes \cdots \otimes K_{2^s}}^{r} = H_{N/2^{sr}} \otimes K_{2^s}^{(r)},$$

where for convenience we will denote $K_{2^s}^{(r)}$ as the r-dimensional mesh of cliques. The key to the reconfiguration of $P_{N,r}$ is the reconfiguration of the r-dimensional mesh of cliques $K_{2^s}^{(r)}$ around $c_r 2^{sr}$ faults. This is established in the following lemma. To state the lemma let us define an M-relation on a set of nodes A to be a set of origin-destination pairs such that any node in A is the origin in at most M pairs and the destination in at most M pairs.

LEMMA 6. *Define $c_r = 2^{-(r+1)^2}$ for $r \ge 1$, and set $d_1 = \frac{15}{16}$ and $d_r = \left(1 - \frac{c_r}{c_{r-1}}\right) d_{r-1}$ for $r > 1$. Then if $K_M^{(r)}$ has at most $c_r M^r$ worst-case node faults, there exists a set Γ of $d_r M^r$ nonfaulty nodes in $K_M^{(r)}$ for which the paths for any M-relation on Γ can be routed in a fault-avoiding fashion through $K_M^{(r)}$ using constant dilation and congestion (where the constant depends on r but not on M). Moreover, there exists a fault-free embedding of $K_M^{(r)}$ in the faulty graph with constant load, dilation, and congestion (where the constant depends on r but not on M) for which every node of the fault-free $K_M^{(r)}$ is mapped to a node in Γ.*

Proof. The proof is by induction on r. The base case when $r = 1$ is easy since $K_M^{(1)} = K_M$ and $c_1 = \frac{1}{16}$. Then the set Γ will consist of the $\frac{15}{16}M$ fault-free nodes. To route any M-relation on $K_{15M/16}$, we use the well-known fact that any M-relation can be partitioned into M 1-relations [17]. A pair (i, j) in the tth 1-relation is then routed along the path $i \to t \to j$ in $K_{15M/16}$, where t is computed modulo $15M/16$. It is easy to check that these paths have dilation 2 and congestion $O(1)$. We can also use any $M/2$ of the $15M/16$ nodes in Γ to simulate the fault-free K_M with load 2, dilation 1, and congestion 4.

We now assume that the lemma is true for $r - 1$ dimensions, and we consider the case for r dimensions. We start by showing how to find the set Γ.

By definition, $K_M^{(r)} = K_M \otimes K_M^{(r-1)}$. Hence, we can partition $K_M^{(r)}$ into M copies of $K_M^{(r-1)}$. At least $(1 - \frac{c_r}{c_{r-1}})M$ of these copies contain at most $c_{r-1}M^{r-1}$ faults each. (Otherwise, we would have more than $c_r M^r$ faults overall, which is not possible.) Define these copies as the *useful* copies. The useful copies will be used for Γ and for reconfiguring $K_M^{(r)}$.

The set of nodes Γ will be the union of $\Gamma_1, \Gamma_2, \ldots, \Gamma_{(1-c_r/(c_{r-1}))M}$, where Γ_i is the corresponding set of $d_{r-1}M^{r-1}$ nodes in the ith useful copy of $K_M^{(r-1)}$ (which exist by induction). Hence

$$|\Gamma| = d_{r-1}M^{r-1}\left(1 - \frac{c_r}{c_{r-1}}\right)M = d_r M^r$$

as desired.

We next show how to route any M-relation on Γ using constant dilation and congestion. Given any M-relation on Γ, we will first consider the congestion and dilation necessary to route paths to the correct copy of $K_M^{(r-1)}$. If G is the subgraph of $K_M^{(r)}$ restricted to the useful copies of $K_M^{(r-1)}$ and G' is derived from G by viewing each $K_M^{(r-1)}$ as a supernode, then this part of the routing corresponds to an M^r-relation on G'. The M^r-relation can be factored into M^r 1-relations which can then be coalesced into M M^{r-1}-relations. A pair (i, j), i and j in G', in the tth M^{r-1}-relation will be routed in two parts: first from the ith useful copy of $K_M^{(r-1)}$ to the tth useful copy, and then from the tth useful copy to the jth useful copy. Overall, at most $O(M^{r-1})$ paths will have to be routed between any pair of copies of $K_M^{(r-1)}$.

By definition, each useful copy of $K_M^{(r-1)}$ contains $d_{r-1}M^{r-1}$ nodes which can be used for routing any M-relation. By definition, $d_{r-1} \geq 2/3$. Hence, for any pair of useful copies there must be at least $(2d_{r-1} - 1)M^{r-1} > M^{r-1}/3$ of these nodes which are common to both. These nodes will be used to interconnect the two copies. A total of $O(M^{r-1})$ paths need to be routed between the two copies, and we will use the $M^{r-1}/3$ available edges in an arbitrary fashion. Hence, we can route the paths between each pair of $K_M^{(r-1)}$ with constant dilation and congestion. Thus, all the paths for any M-relation on Γ can be routed to the correct copy of $K_M^{(r-1)}$ with constant dilation and congestion. The remainder of the routing is handled within each useful copy of $K_M^{(r-1)}$ by induction.

We next show how to reconfigure $K_M^{(r)}$ within Γ. Since $c_r < \frac{c_{r-1}}{2}$, there will be at least $\frac{M}{2}$ useful copies of $K_M^{(r-1)}$, each of which (by induction) can be reconfigured to embed two fault-free copies of $K_M^{(r-1)}$ (within the appropriate subsets of Γ) with constant load, dilation, and congestion. It remains to hook up these M copies of $K_M^{(r-1)}$ to each other to produce a single copy of $K_M^{(r)} = K_M \otimes K_M^{(r-1)}$.

To hook up any pair of copies of $K_M^{(r-1)}$, we need to route an edge connecting the ith node of one copy to the ith node of the other copy for each i, $1 \leq i \leq M^{r-1}$. These edges are routed using the same method as before. In particular, we know that there are at least $M^{r-1}/3$ edges connecting each pair of copies with endpoints in Γ. These edges will be used to interconnect a pair of copies with congestion 3. The connection is completed by routing a 3-relation in each copy.

To make connections between all pairs, we will load the edges between the useful copies of $K_M^{(r-1)}$ by a factor of at most 12 (4 pairs, each with load 3), and we will need to embed a $6M$-relation in each copy (4 pairs for each of $\frac{M}{2}$ faulty copies, each needing a 3-relation). By the inductive hypothesis, this can be accomplished with constant dilation and congestion. This concludes the proof that $K_M^{(r)}$ can be reconfigured around $c_r M^r$ faults. □

To complete the reconfiguration of $P_{N,r}$ we need to embed the hypercube edges of $P_{N,r}$ into the faulty $P_{N,r}$. This is shown with an argument similar to that used in Lemma 6 for routing edges between two copies of $K_{2^s}^{(r-1)}$ in $K_{2^s}^{(r)}$. By the lemma, each mesh of cliques of the faulty $P_{N,r}$ has a set Γ of $d_r 2^{sr}$ nodes through which to route a 2^s-relation. Since $d_r > 2/3$, any pair of meshes of cliques, $\mathcal{M}$ and $\mathcal{N}$, which are neighbors across a hypercube dimension must share at least 1/3 of these nodes. A total of 2^{sr} edges will be routed between $\mathcal{M}$ and $\mathcal{N}$ using the $2^{sr}/3$ available edges. The connection between the ith node of $\mathcal{M}$ and the ith node of $\mathcal{N}$, for each i, is completed by routing a 3-relation in each mesh of cliques. This embedding yields only constant congestion on the hypercube edges of the faulty $P_{N,r}$. Since each hypercube dimension requires only the set Γ of each mesh of cliques to route an $O(1)$-relation and there are $n - rs = \Theta(2^s)$ dimensions, this routing adds another $O(2^s)$-relation for each Γ of each mesh of cliques to route. Hence, the additional load and congestion on the nodes and edges, respectively, of the meshes of cliques in the faulty $P_{N,r}$ is increased by at most a constant factor. □

4.3. Remarks. We have shown how to embed $P_{N,r}$ into H_N with load 1, dilation $O(1)$, and congestion $O(1)$ for any constant $r \geq 1$, and we have demonstrated several applications of this embedding. Subsequent to [1], Kaklamanis, Krizanc and Rao have used the result to show that the hypercube can emulate any bounded degree planar graph with constant slowdown [15]. In addition the constants in the embedding have been improved by finding Hamming codes with smaller height and width: first in [17], then in the present paper, then in [21] in which a height 3, width 5 code is claimed. Determining whether a height 3 Hamming code with width less than 5 can be constructed is an interesting open problem.

Characterizing the height and width of other linear codes may yield other applications for hypercube routing, embedding, and emulation algorithms. Such characterizations may also be of interest in their own right. Note that the height and width are not parameters of the codewords themselves but rather of the particular mapping of input strings to codewords. The height is the maximum distance between codewords whose inverses differ by one bit. The width is equivalent to the number of input bits needed to compute one bit of the codeword. Hence, linear codes with n-bit codewords and width w can be computed by bounded degree circuits of depth $O(\log w)$ and size $O(nw)$.

Appendix A. Constructing a good basis for the codewords.

Proof of Lemma 3. Finding a basis with the above bounds for C_1 and C_2 is trivial. Henceforth, assume that $k \geq 3$. The basic approach is to take a well-defined basis of height 3 but large width and manipulate it to get a basis with height 6 and width 9. We will first need some definitions.

Let c_i denote the ith column of C_k. For concreteness assume that the columns of C_k are fixed as follows: the first k columns, $c_1, \ldots, c_k$, are all the strings of length k with weight 1; the next $\binom{k}{2}$ columns are all the strings of weight 2; and so on. So, e.g.,

$$C_3 = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix}.$$

Suppose a vector in the nullspace is nonzero in bit positions $i_1, \ldots, i_h$, then columns $c_{i_1}, \ldots, c_{i_h}$ when added up in $GF(2)^k$ yield the all zero vector of length k. Conversely, any subset of columns $c_{i_1}, \ldots, c_{i_h}$ which add up to zero correspond to a vector in the nullspace of C_k. Henceforth, we will assume that vectors in the nullspace of C_k and subsets of columns of C_k which add up to zero are synonymous.

Let S be the set of all vectors of weight 3 which are in the nullspace of C_k. An easy counting argument shows that there are $\frac{1}{3}\binom{n}{2}$ such vectors, where $n \equiv 2^k - 1$. Let $S(i)$ be all the vectors in S which have a 1 in the ith dimension. Observe that the size of $S(i)$ is $(n-1)/2$ for all i.

Our starting basis B will be composed of $n-k$ vectors from S. Obviously this basis will have height 3. However, the width may be unbounded. The basis is constructed as follows. For each column c_i in C_k of weight 2 or more we will find two more columns which when added to c_i yield zero. This will obviously give us $n-k$ vectors provided that no triple of columns is chosen more than once. To do this, we need the following definition. Recall that for a string s, $s(i)$ denotes the ith bit of s. A k bit string s *contains* another k bit string s' if $s(i) \geq s'(i)$ for all $i \in [1, k]$. For each column c of weight $l \geq 2$, we will choose one of the l columns of weight $l-1$ which are contained by c. Call this c'. Obviously, there will be a unique vector of weight 1 which when added to c and c' will yield zero. We will pick c' carefully among the l choices as follows. It is well known that there is a surjection, f, from strings of weight l to strings of weight $l-1$ such that s contains $f(s)$ for $1 \leq l \leq \lceil k/2 \rceil$ [8]. There is also an injection, g, from strings of length l to strings of length $l-1$ such that s contains $g(s)$ for $\lfloor k/2 \rfloor + 1 \leq l \leq k$. For $2 \leq l \leq \lceil k/2 \rceil$, let $c' = f(c)$. For $\lceil k/2 \rceil + 1 \leq l \leq k$, let $c' = g(c)$.

B as defined above contains $n-k$ vectors. Since this is the dimension of the nullspace, to show that B is a basis, we need show only that it spans.

LEMMA 7. *B spans the nullspace of C_k.*

Proof. Consider a nonzero vector y, and let $\sigma(y)$ be the largest nonzero dimension of y, i.e., $\sigma(y) = i$ when $y(i) = 1$ and $y(j) = 0$ for $j > i$. We will prove by induction on l that all vectors in the nullspace with $k \leq \sigma \leq l$ are spanned by B. The base case is trivial since there are no vectors with $\sigma = k$ in the nullspace of C_k. This is because the columns 1 through k of C_k are a permutation of the k by k identity matrix and so no subset of them can add up to zero.

Suppose by induction that all vectors in the nullspace with $k \leq \sigma \leq l$ are spanned by B. Let y be a vector in the nullspace with $\sigma(y) = l+1$. Let v be the unique vector in B with $\sigma(v) = l+1$. The vector $y' = y \oplus v$ is in the nullspace since y and v are. Furthermore, $\sigma(y') \leq l$. Hence, by the induction hypothesis, y' is spanned by B. Since $y = y' \oplus v$, y is spanned by B as well. □

Before we begin manipulating B, let us first show that B is not too bad to begin with. Define $W(i)$ to be the set of basis vectors with a 1 in dimension i, and define $w(i) = |W(i)|$ to be the width of dimension i. Define D_q as the set of dimensions i with $w(i) = q$ and $D_{>q} \equiv D_{\geq q+1}$ as the set of dimensions i with $w(i) > q$. Define $M_{>q} \equiv M_{\geq q+1}$ as

$$\sum_{i \in D_{>q}} w(i) - q.$$

This is the mass of 1's causing dimensions to have width more than q.

LEMMA 8. *The basis B given above has $M_{\geq 3} \leq (3/2)n - 3k$ for $k \geq 3$.*

Proof. First observe that the total number of 1's in B is $3(n-k)$ since it is composed of $n-k$ vectors each of weight 3. It follows that $|D_1| + 2|D_{\geq 2}| + M_{\geq 3} = 3(n-k)$. Every dimension of B has width at least 1 so that $|D_1| + |D_{\geq 2}| = n$. Hence, $M_{\geq 3} = n - 3k + |D_1|$. To bound $|D_1|$ recall that f is a surjection and g is an injection. This implies that the highest $\sum_{i=\lceil k/2 \rceil}^{k} \binom{k}{i}$ dimensions have width 1 or 2 (and only these dimensions can have width 1). It further implies that, of these, $\sum_{i=\lceil k/2 \rceil+1}^{k} \binom{k}{i}$ have width 2. So, $|D_1| = \binom{k}{\lceil k/2 \rceil}$ which is at most $n/2$ for $k \geq 3$. □

Now we will start the process of manipulating B to achieve bounded width. Our main tool for doing this is the lemma below, for which we will need the following definition. Given a basis $B = \{v_1, \ldots, v_{n-k}\}$ and vectors z and z_B such that $z = B \cdot z_B$, we say that v_j *contributes* to z if $z_B(j) = 1$; otherwise, we say that it does not contribute.

LEMMA 9. *Given any z, any v in B which contributes to z, and any other basis vector x, the following holds. If x does not contribute to z, then $B' = (B - \{v, x\}) \cup \{z, z \oplus x\}$ is a new basis. If x contributes to z, then $B' = (B - \{v, x\}) \cup \{z \oplus v, z\}$ is a new basis.*

Proof. Let us examine the first case. Since B' has $n - k$ vectors, we need argue only that B' spans. To do this we need show only how to produce v and x from B'. We can produce x from B' simply by adding z and $z \oplus x$. To produce v, note that by assumption $z = v \oplus a$, where a is in the span of $B - \{v, x\}$. Hence, v is produced from B' simply by adding the basis vector z and the vector a.

The proof for the second case follows identical reasoning. □

We will use Lemma 9 in the following way. Suppose i is a dimension with large width, i.e., $W(i)$ is a large set. Let z be any vector in $S(i)$. Since B spans, there must be at least one vector in B which contributes to z and is also in $W(i)$ (otherwise z could not have a 1 in dimension i). Call this vector v. Let x be any other vector in $W(i)$. If we use the above lemma, then the width of dimension i of B' is $w(i) - 1$. Of course, in the process we have increased the width of two other dimensions (since the weight of z was 3). These must be dimensions which had small width. We will ensure that this is the case as follows.

Let $D_{\geq g+2}$ be the *bad* dimensions where g will be determined below. Let the dimensions with width less than g be the *good* dimensions. Below we will show that for sufficiently large g, if i is a bad dimension, there is a $z \in S(i)$ such that z's other two 1's are in good dimensions (say j and k). Now when we apply Lemma 9, since dimensions j and k increase their width by at most 2, they cannot become bad dimensions.

Suppose we have just one more application of Lemma 9 left to make. That is, there is one dimension, i, with width $g+2$, and the remainder of the dimensions have width at most $g+1$. Recall that D_{g+1} is the set of dimensions which have width exactly $g+1$ and that the size of $S(i)$ is $(n-1)/2$. Moreover, for any dimension other than i there is a unique vector in $S(i)$ with a 1 in that dimension. In order to be able to guarantee that we can pick a z in $S(i)$ with its other two 1's in good dimensions, we need

$$\frac{n-1}{2} - |D_{g+1}| - |D_g| \geq 1$$

(every dimension with width g or $g+1$ may eliminate one vector from $S(i)$).

To check that we can satisfy the above inequality we need to calculate an upper bound on the size of $D_g \cup D_{g+1}$. This is maximized when the dimensions not in $D_g \cup D_{g+1}$ (other than dimension i which has width $g+2$) have minimum width, i.e., width 1. That is,

$$(g+2) + |D_{g+1}|(g+1) + |D_g|g + n - (|D_{g+1}| + |D_g| + 1) \leq T,$$

where T is the total number of 1's in the basis before the last step.

T is bounded by the number of 1's at the start $(3(n-k))$ plus the number of 1's added to the basis before the last step. To bound this latter quantity first note that we add at most 1 to our basis with each application of Lemma 9. This follows from the fact that z has weight 3, $z \oplus x$ has weight at most the weight of x plus 1, $z \oplus v$ has weight at most the weight of v plus 1, and the weights of x and v are at least 3 since they are basis vectors. The number of applications of Lemma 9 is bounded by $M_{\geq g+2}-1$, where $M_{\geq g+2}$ is the mass of 1's contributing to width $\geq g+2$ in our original basis. But $M_{\geq g+2} \leq M_{\geq 3} \leq (3/2)n-3k$. Putting this all together we find

$$|D_g|+|D_{g+1}| \leq \frac{\frac{7}{2}n-6k-g-2}{g-1}.$$

Substituting this into $\frac{n-1}{2}-|D_{g+1}|-|D_g| \geq 1$ and doing some algebra, we find that we require

$$(g-8)n+12k+7-g \geq 0.$$

Hence, $g=8$ suffices which bounds the width of our final basis by 9.

We have achieved a basis with the desired width, but let us check that we have not unduly increased the height. When we eliminated a 1 in a vector in a bad dimension, we added at most two 1's in good dimensions. Since there were at most three 1's in bad dimensions at the start, the resulting vector has weight at most 6.

The algorithm for constructing the original B is polynomial in n (f and g are efficiently constructable), and the manipulations to reduce the width of B require only polynomial in n time. This completes the proof of Lemma 3. □

An alternate construction. In what follows, we will describe a relationship between the well-known cyclic codes and good bases. This will lead to a good basis for C_k for k up to 137. This in turn gives us an alternative method for obtaining good embeddings for hypercubes up to size $2^{2^{137}}$.

Let p be a primitive polynomial of degree k in $GF(2)[x]$. By definition, x^i mod p, $0 \leq i \leq 2^k-1$, generates all polynomials of degree $k-1$ or less except for the zero polynomial. For convenience, in this section we will assume that the dimensions (bit positions) of a vector (string) of length n are labeled from 0 to $n-1$. There is a one-to-one correspondence between all polynomials of degree $k-1$ or less and strings of length k when the strings are regarded as a sequence of coefficients. Let the weight of a polynomial be the weight of its associated string.

LEMMA 10. *If there exists a primitive polynomial of degree k in $GF(2)[x]$ of weight s, then there is a basis for the nullspace of C_k of height and width s.*

Proof. Let column i, c_i, of C_k be x^i reduced modulo p for $0 \leq i \leq 2^k-1$. Now suppose for simplicity that p has weight 3: $p = x^k + x^j + 1$, where $k > j$. It will be clear how the proof generalizes to primitive polynomials of arbitrary weight. Define v_l to be a vector of length 2^k which is zero everywhere except for a 1 in the lth position, a 1 in the $(l+j)$th position, and a 1 in the $l+k$th position. Let $\mathcal{V}$ be the set of all v_l with $0 \leq l \leq n-k-1$. This is the well-known cyclic code.

CLAIM 1. *$\mathcal{V}$ is in the nullspace of C_k.*

Proof. $C_k \cdot v_l$ is just the sum $c_l \oplus c_{l+j} \oplus c_{l+k}$, where addition is in $GF(2)^k$. By definition of c_i this is equivalent to

$$x^l(\text{mod} p) + x^{l+j}(\text{mod} p) + x^{l+k}(\text{mod} p),$$

where addition is in $GF(2)[x]$. But this is just $x^l(1+x^j+x^k) \pmod p$ which is 0. □

CLAIM 2. *$\mathcal{V}$ is a basis for the nullspace of C_k.*

Proof. Since $\mathcal{V}$ has the correct cardinality, it is enough to show that it spans. The proof that $\mathcal{V}$ spans is nearly identical to the proof of Lemma 7 that B spans and so we omit it. □

To finish the proof of the lemma observe that the number of 1's in each $v_l \in \mathcal{V}$ is at most s, the weight of the primitive polynomial, and that the number of v_l's with a 1 in a given dimension is at most s as well. □

It is not known whether there is a c such that for all degrees there is a primitive polynomial of weight at most c. Nonetheless, small primitive polynomials of degree k in $GF(2)[x]$ have been tabulated for k up to 137 [23]. For each of these degrees there is a polynomial of weight 3 or 5.

Appendix B. Proof of the tree compression lemma.

Proof of Lemma 4. The proof makes use of the following two simple lemmas. The first is a well-known result which first appeared in [19].

Lemma 11. *Given any M-node binary tree T, it is possible to partition T into two subtrees, each with at least $\frac{M-1}{3}$ nodes, by removing a single edge from T.*

Lemma 12. *Let T be a weighted M-node binary tree for which $d_i + w_i \leq 3$ and $w_i \in \{0, 1, 2\}$ for each $i(1 \leq i \leq M)$, where d_i and w_i are the degree and weight, respectively, of the ith node in T. Then if $\sum_{i=1}^{M} w_i = 4$, it is possible to partition T into two subtrees each having total weight 2 by removing a single edge from T.*

Proof. If T contains a node with weight 2, then this node has degree 1, and we can form the desired partition by removing the edge incident to this node.

If T does not contain a node with weight 2, then it contains precisely four nodes with weight 1. Define T' to be the subtree of T consisting of the simple paths that interconnect the four weight-1 nodes. Since the weight-1 nodes can have degree at most 2 in T, there are only three possibilities for the homeomorphic structure of T', and it is easy to find the desired partition of T for each possibility. □

We are now ready to prove Lemma 4. The partition is constructed by repeatedly applying Lemma 11 to split T into smaller and smaller subtrees. However, we must be careful not to remove too many edges from the same subtree. In order to keep everything balanced, we will apply the following splitting process to subtrees in the partially formed partition.

Let T_1 be an M_1-node subtree in the partially formed partition of T. We will assume for now that T_1 is incident to at most three previously removed edges of T. We start by using Lemma 11 to split T_1 into two subtrees, each having at least $\frac{M_1-1}{3}$ nodes. Since T_1 is incident to at most three removed edges, the two newly formed subtrees are incident to two and three removed edges, respectively, or to one and four removed edges, respectively. In the former case, we quit and repeat the entire process on another subtree in the partially formed partition. In the latter case, we apply Lemma 12 to further split the subtree that is incident to four removed edges. As a consequence, we will have split T_1 into three subtrees, each incident to at most three removed edges and at least two of which have at least $\frac{M_1-1}{6}$ nodes.

In order to split T into N subtrees, we repeatedly apply the process just described to the largest remaining subtree until a total of $N-2$ or $N-1$ edges of T have been removed. If $N-2$ edges have been removed, then we apply Lemma 12 once more to a subtree to produce a partition with precisely N subtrees.

By construction, we know that each of the subtrees in the partition is incident to at most three removed edges. In what follows, we show that every subtree has at most $\frac{12M}{N} + 1$ nodes. The proof is not difficult. Each time that we apply the splitting process, we remove at most two edges from T, and we replace the largest current subtree with two or three subtrees, at least two of which have size at least $\frac{M_1-1}{6}$, where M_1 is the size of the subtree being split. Thus, after the splitting process is applied s times, at least $s+1$ of the subtrees will have size at least $\frac{x-1}{6}$, where x is the size of the largest subtree at that point in the algorithm. Since the splitting process is applied at least $\frac{N}{2} - 1$ times during the formation of the partition, this means that the largest subtree in the partition can have size at most x where

$$\frac{N}{2}\frac{(x-1)}{6} \leq M.$$

Hence the largest subtree can have size at most $\frac{12M}{N} + 1$, as claimed. This concludes the proof of Lemma 4. □

PLANAR EARTHMOVER IS NOT IN L_1*

ASSAF NAOR† AND GIDEON SCHECHTMAN‡

Abstract. We show that any L_1 embedding of the transportation cost (a.k.a. Earthmover) metric on probability measures supported on the grid $\{0,1,\dots,n\}^2 \subseteq \mathbb{R}^2$ incurs distortion $\Omega\left(\sqrt{\log n}\right)$. We also use Fourier analytic techniques to construct a simple L_1 embedding of this space which has distortion $O(\log n)$.

Key words. Earthmover metric, nearest neighbor search, metric embeddings

AMS subject classifications. 51F99, 65D18, 46B99

1. Introduction.

For a finite metric space (X, d_X) we denote by $\mathscr{P}_X$ the space of all probability measures on X. The transportation cost distance (also known as the Earthmover distance in the computer vision/graphics literature) between two probability measures $\mu, \nu \in \mathscr{P}_X$ is defined by

$$\tau(\mu,\nu) := \min\left\{ \sum_{x,y\in X} d_X(x,y)\pi(x,y) :\ \forall x,y \in X,\ \pi(x,y) \ge 0, \right.$$
$$\left. \sum_{z\in X} \pi(x,z) = \mu(x),\ \sum_{z\in X}\pi(z,y) = \nu(y) \right\}.$$

Observe that if μ and ν are the uniform probability distribution over k-point subsets $A \subseteq X$ and $B \subseteq X$, respectively, then by the fact that all the extreme points of the $k \times k$ doubly stochastic matrices are permutation matrices,

$$\tau(\mu,\nu) = \min\left\{ \frac{1}{k}\sum_{a\in A} d_X(a, f(a)) :\ f : A \to B \text{ is a bijection} \right\}. \tag{1.1}$$

This quantity is also known as the *minimum weight matching* between A and B, corresponding to the weight function $d_X(\cdot,\cdot)$ (see [42]). Thus, the Earthmover distance is a natural measure of similarity between images [42, 15, 14]—the distance is the optimal way to match various features, where the cost of such a matching corresponds to the sum of the distances between the features that were matched. Indeed, such metrics occur in various contexts in computer science. Apart from being a popular distance measure in graphics and vision [42, 15, 14, 26], they are used as LP relaxations for classification problems such as 0-extension and metric labeling [9, 8, 2]. Transportation cost metrics are also prevalent in several areas of analysis and PDEs (see the book [53] and the references therein).

Following extensive work on nearest neighbor search and data stream computations for L_1 metrics (see [24, 20, 19, 10, 22]), it became of great interest to obtain low distortion embeddings of useful metrics into L_1 (here, and in what follows, L_1 denotes the space of all Lebesgue measurable functions $f : [0, 1] \to \mathbb{R}$ such that $\|f\|_1 := \int_0^1 |f(t)|dt < \infty$). Indeed, such embeddings can be used to construct approximate nearest neighbor databases, with an approximation guarantee depending on the *distortion* of the embedding (we are emphasizing here only one aspect of the algorithmic applications of low distortion embeddings into L_1—they are also crucial for the study of various cut problems in graphs, and we refer the reader to [36, 23, 21] for a discussion of these issues).

In the context of the Earthmover distance, nearest neighbor search (a.k.a. similarity search in the vision literature) is of particular importance. It was therefore asked (see, e.g., [35]) whether the Earthmover distance embeds into L_1 with constant distortion (the best known upper bounds on the L_1 distortion were obtained in [8, 26] and will be discussed further below). In [30] the case of the Hamming cube was settled negatively: It is shown there that any embedding of the Earthmover distance on $\{0, 1\}^d$ (equipped with the L_1 metric) incurs distortion $\Omega(d)$. However, the most interesting case is that of the Earthmover distance on the Euclidean plane, as this corresponds to a natural similarity measure between images [14] (indeed, the case of the L_1 embeddability of planar Earthmover distance was explicitly asked about in [35]). Here we settle this problem negatively by obtaining the first superconstant lower bound on the L_1 distortion of the planar Earthmover distance. To state it we first recall some definitions.

Given two metric spaces (X, d_X) and (Y, d_Y), and a mapping $f : X \to Y$, we denote its Lipschitz constant by

$$\|f\|_{\mathrm{Lip}} := \mathrm{supp}_{\substack{x,y\in X\\ x\neq y}} \frac{d_Y(f(x), f(y))}{d_X(x, y)}.$$

If f is one to one, then its distortion is defined as

$$\mathrm{dist}(f) := \|f\|_{\mathrm{Lip}} \cdot \|f^{-1}\|_{\mathrm{Lip}} = \mathrm{supp}_{\substack{x,y\in X\\ x\neq y}} \frac{d_Y(f(x), f(y))}{d_X(x, y)} \cdot \mathrm{supp}_{\substack{x,y\in X\\ x\neq y}} \frac{d_X(x, y)}{d_Y(f(x), f(y))}.$$

The smallest distortion with which X can be embedded into Y is denoted $c_Y(X)$, i.e.,

$$c_Y(X) := \inf \{\mathrm{dist}(f) : \ f : X \hookrightarrow Y \text{ is one to one}\}.$$

When $Y = L_p$ we use the shorter notation $c_Y(X) = c_p(X)$. Thus, the parameter $c_2(X)$ is the Euclidean distortion of X, and $c_1(X)$ is the L_1 distortion of X.

Our main result bounds from below the L_1 distortion of the space of probability measures on the n by n grid, equipped with the transportation cost distance.

THEOREM 1.1. $c_1\left(\mathscr{P}_{\{0,1,\ldots,n\}^2}, \tau\right) = \Omega\left(\sqrt{\log n}\right)$.

We note that the best known upper bound for $c_1\left(\mathscr{P}_{\{0,1,\ldots,n\}^2}, \tau\right)$ is $O(\log n)$, as proved in [8, 26]. Later on (see Theorem 1.4) we will show a new embedding which achieves this bound.

After reducing the problem to a functional analytic question, our proof of Theorem 1.1 is a discretization of a theorem of Kislyakov from 1975 [32]. We attempted to make the presentation self-contained by presenting here appropriate versions of the various functional analytic lemmas that are used in the proof.

For readers who are more interested in the minimum cost matching metric (1.1), we also prove the following lower bound.

Theorem 1.2 (discretization). *For arbitrarily large integers n there is a family $\mathscr{Y}$ of n-point subsets of $\left\{0,1\ldots,O\left(\sqrt{n\log\log n}\right)\right\}^2$, with $|\mathscr{Y}|\le n^{O(\log\log n)}$, such that any L_1 embedding of $\mathscr{Y}$, equipped with the minimum weight matching metric τ, incurs distortion:*

$$\Omega\left(\sqrt{\log\log\log n}\right)=\Omega\left(\sqrt{\log\log\log|\mathscr{Y}|}\right).$$

A metric space (X,d_X) is said to embed into squared L_2, or to be of negative type, if the metric space $\left(X,\sqrt{d_X}\right)$ is isometric to a subset of L_2. Squared L_2 metrics are important in various algorithmic applications since it is possible to efficiently solve certain optimization problems on them using semidefinite programming (see the discussion in [3, 31]). It turns out that planar Earthmover does not embed into any squared L_2 metric (see Remark 3.3 for a more general result).

Theorem 1.3 (nonembeddability into squared L_2). $\lim_{n\to\infty}c_2\left(\mathscr{P}_{\{0,\ldots,n\}^2},\sqrt{\tau}\right)=\infty$.

Motivated by the proof of Theorem 1.1, we also construct simple low-distortion embeddings of the space $\left(\mathscr{P}_{\{0,1,\ldots,n\}^2},\tau\right)$ into L_1. It is convenient to work with probability measures on the torus $\mathbb{Z}_n^2$ instead of the grid $\{0,1,\ldots,n\}^2$. One easily checks that $\{0,\ldots,n\}^2$ embeds with constant distortion into $\mathbb{Z}_{2n}^2$ (see, e.g., Lemma 6.12 in [37]). Every $\mu\in\mathscr{P}_{\mathbb{Z}_n^2}$ can be written in the Fourier basis as

$$\mu=\sum_{(u,v)\in\mathbb{Z}_n^2}\widehat{\mu}(u,v)e_{uv},\tag{1.2}$$

where

$$\forall(a,b),(u,v)\in\mathbb{Z}_n^2,\ e_{uv}(a,b):=e^{\frac{2\pi i(au+bv)}{n}}$$

and

$$\forall(u,v)\in\mathbb{Z}_n^2,\quad\widehat{\mu}(u,v):=\frac{1}{n^2}\sum_{(a,b)\in\mathbb{Z}_n^2}\mu(a,b)e_{uv}(-a,-b).$$

Observe that for $n=2^k+1$, $k\in\mathbb{N}$, the decomposition (1.2) can be computed in time $O\left(n^2\log n\right)$ using the fast Fourier transform [45]. Motivated in part by the results of [40] (see also [5, 41]), we define

$$A\mu=\sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}}\frac{e^{\frac{2\pi iu}{n}}-1}{\left|e^{\frac{2\pi iu}{n}}-1\right|^2+\left|e^{\frac{2\pi iv}{n}}-1\right|^2}\cdot\widehat{\mu}(u,v)\cdot e_{uv}\tag{1.3}$$

and

$$B\mu=\sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}}\frac{e^{\frac{2\pi iv}{n}}-1}{\left|e^{\frac{2\pi iu}{n}}-1\right|^2+\left|e^{\frac{2\pi iv}{n}}-1\right|^2}\cdot\widehat{\mu}(u,v)\cdot e_{uv}.\tag{1.4}$$

Theorem 1.4. *The mapping $\mu\mapsto(A\mu,B\mu)$ from $\left(\mathscr{P}_{\mathbb{Z}_n^2},\tau\right)$ to $L_1\left(\mathbb{Z}_n^2\right)\oplus L_1\left(\mathbb{Z}_n^2\right)$ has distortion $O(\log n)$.*

The $O(\log n)$ distortion in Theorem 1.4 matches the best known distortion guarantee proved in [26, 8]. Our embedding has various nice features. First of all, it is a simple closed-form linear mapping into a low dimensional L_1 space, which is based on the computation of the Fourier transform. It is thus very fast to compute, and it is versatile in the sense that it might behave better on images whose Fourier transform is sparse (we do not study this issue here). Thus there is scope to apply the embedding on certain subsets of the frequencies, and this might improve the performance in practice. This is an interesting "applied" question which should be investigated further (see section 5).

2. Preliminaries and notation. For the necessary background on measure theory, we refer the reader to the book [46]; however, in the setting of the present paper, our main results will deal with finitely supported measures, in which case no background and measurabilty assumptions are necessary. We also refer the reader to the book [53] for background on the theory of optimal transportation of measures. Let (X, d_X) be a metric space. We denote by $\mathscr{M}_X$ the space of all Borel measures on X with bounded total variation and by $\mathscr{P}_X \subseteq \mathscr{M}_X$ the set of all Borel *probability* measures on X. We also let $\mathscr{M}_X^+ \subseteq \mathscr{M}_X$ be the space of *nonnegative* measures on X with finite total mass, and we denote by $\mathscr{M}_X^0 \subseteq \mathscr{M}_X$ the space of all measures $\mu \in \mathscr{M}_X$ with $\mu(X) = 0$. Given a measure $\mu \in \mathscr{M}_X$, we can decompose it in a unique way as $\mu = \mu^+ - \mu^-$, where $\mu^+, \mu^- \in \mathscr{M}_X^+$ are disjointly supported. If $\mu, \nu \in \mathscr{M}_X^+$ have the same total mass, i.e., $\mu(X) = \nu(X) < \infty$, then we let $\Pi(\mu, \nu)$ be the space of all *couplings* of μ and ν, i.e., all nonnegative Borel measures π on $X \times X$, such that for every measurable bounded $f : X \to \mathbb{R}$,

$$\int_{X\times X} f(x)d\pi(x,y) = \int_X f(x)d\mu(x) \quad \text{and} \quad \int_{X\times X} f(y)d\pi(x,y) = \int_X f(y)d\nu(y).$$

Observe that in the case of finitely supported measures, this condition translates to the standard formulation, in which we require that the marginals of π are μ and ν, i.e.,

$$\forall x, y \in X,\ \sum_{z\in X} \pi(x,z) = \mu(x) \quad \text{and} \quad \sum_{z\in X} \pi(z,y) = \nu(y).$$

The *transportation cost distance* between μ and ν, denoted here by $\tau(\mu,\nu) = \tau_{(X,d_X)}(\mu,\nu)$ (and also referred to in the literature as the Wasserstein 1 distance, Monge–Kantorovich distance, or the Earthmover distance), is

$$\tau(\mu,\nu) := \inf\left\{\int_{X\times X} d_X(x,y)\, d\pi(x,y) :\ \pi \in \Pi(\mu,\nu)\right\}. \tag{2.1}$$

For $\mu \in \mathscr{M}_X^0$, $\mu^+(X) = \mu^-(X)$, and so we may write $\|\mu\|_\tau := \tau(\mu^+, \mu^-)$. This is easily seen to be a norm on the vector space $\mathscr{M}_{X,\tau}^0 := \left\{\mu \in \mathscr{M}_X^0 :\ \|\mu\|_\tau < \infty\right\}$. It is easy to check that for any two nonnegative measures μ, ν with the same total mass, and for every nonnegative measure σ, we have $\tau(\mu + \sigma,\ \nu + \sigma) = \tau(\mu, \nu)$. It follows that

$$\begin{aligned} \|\mu - \nu\|_\tau &= \tau\left((\mu-\nu)^+, (\mu-\nu)^-\right) \\ &= \tau\left((\mu-\nu)^+ + \min\{\mu,\nu\}, (\mu-\nu)^- + \min\{\mu,\nu\}\right) \\ &= \tau(\mu,\nu). \end{aligned} \tag{2.2}$$

Fix some $x_0 \in X$, and let $\mathrm{Lip}_0(X) = \mathrm{Lip}_{x_0}(X)$ be the linear space of all Lipschitz mappings $f : X \to \mathbb{R}$ with $f(x_0) = 0$, equipped with the norm $\|\cdot\|_{\mathrm{Lip}}$ (i.e., the norm of a function equals its Lipschitz constant). Any $\mu \in \mathscr{M}^0_{X,\tau}$ can be thought of as a bounded linear functional on $\mathrm{Lip}_0(X)$, given by $f \mapsto \int_X f d\mu$. The famous *Kantorovich duality theorem* (see Theorem 1.14 in [53]) implies that $\mathrm{Lip}_0(X)^* = \mathscr{M}^0_{X,\tau}$, in the sense that every bounded linear functional on $\mathrm{Lip}_0(X)$ is obtained in this way, and for every $\mu \in \mathscr{M}^0_{X,\tau}$,

$$\|\mu\|_\tau = \|\mu\|_{\mathrm{Lip}_0(X)^*} := \mathrm{supp}\left\{\int_X f d\mu : \ f \in \mathrm{Lip}_0(X), \ \|f\|_{\mathrm{Lip}} \le 1\right\}.$$

(We note that this identity amounts to duality of linear programming.)

3. Proof of Theorem 1.1. Fix an integer $n \ge 2$, and denote $X = \{0, 1, \dots, n-1\}^2$, equipped with the standard Euclidean metric. In what follows, for concreteness, $\mathrm{Lip}_0 := \mathrm{Lip}_0(X)$ is defined using the base point $x_0 = (0, 0)$. Also, for ease of notation we denote $\mathscr{M} = \mathscr{M}^0_{X,\tau}$. Observe that Lip_0 and $\mathscr{M}$ are vector spaces of dimension $n^2 - 1$, and by Kantorovich duality, $\mathrm{Lip}_0^* = \mathscr{M}$ and $\mathscr{M}^* = \mathrm{Lip}_0$.

Assume that $F : \mathscr{P}_X \to L_1$ is a bi-Lipschitz embedding satisfying, for any two probability measures $\mu, \nu \in \mathscr{P}_X$,

$$\tau(\mu, \nu) \le \|F(\mu) - F(\nu)\|_1 \le L \cdot \tau(\mu, \nu). \tag{3.1}$$

Our goal is to bound L from below. We begin by reducing the problem to the case of *linear mappings*. Recall that given two normed spaces $(Z, \|\cdot\|_Z)$ and $(W, \|\cdot\|_W)$, the norm of a linear mapping $T : Z \to W$ is defined as $\|T\| = \mathrm{supp}_{z \in Z\setminus\{0\}} \frac{\|Tz\|_W}{\|z\|_Z}$ (observe that in this case $\|T\| = \|T\|_{\mathrm{Lip}}$).

Lemma 3.1 (reduction to a linear embedding of $\mathscr{M}$ into ℓ_1^N). *Under the assumption of an existence of an embedding $F : \mathscr{P}_X \to L_1$ satisfying* (3.1)*, there exists an integer N, and an invertible linear operator $T : \mathscr{M} \to \ell_1^N$, with $\|T\| \le 2L$ and $\|T(\mu)\|_1 \ge \|\mu\|_\tau$ for all $\mu \in \mathscr{M}$ (the factor 2 can be replaced by $1 + \epsilon$ for every $\epsilon > 0$, but this is irrelevant for us here).*

Proof. By translation we may assume that F maps the uniform measure on X to 0. For $\mu \in \mathscr{M}$ denote $\|\mu\|_\infty := \max_{x\in X} |\mu(x)|$. Observe that it is always the case that $\|\mu\|_\infty \le \|\mu\|_\tau$. Indeed, if $\pi \in \Pi(\mu^+, \mu^-)$, then

$$\int_{X\times X} \|x - y\|_2 d\pi(x, y) \ge \int_{X\times X} d\pi(x, y) = \mu^+(X) = \mu^-(X) \ge \|\mu\|_\infty.$$

Let B_{M} denote the unit ball of $\mathscr{M}$. Define for $\mu \in B_{\mathrm{M}}$ a probability measure $\psi(\mu) \in \mathscr{P}_X$ by $\psi(\mu)(x) := \frac{\mu(x)+1}{n^2}$. It is clear that for every $\mu, \nu \in \mathscr{M}$, $\|\mu - \nu\|_\tau = n^2\|\psi(\mu) - \psi(\nu)\|_\tau$. The mapping $h := \frac{1}{n^2} \cdot F \circ \psi : B_{\mathrm{M}} \to L_1$ satisfies $h(0) = 0$, $\|h\|_{\mathrm{Lip}} \le L$, and $\|h(\mu) - h(\nu)\|_1 \ge \|\mu - \nu\|_\tau$, where we have used (3.1) and (2.2). This implies that there exists a map $\tilde{h} : \mathscr{M} \to L_1$ satisfying the same inequalities. We shall present two arguments establishing this fact: The first is a soft nonconstructive proof, using the notion of ultraproducts, and the second argument is more elementary but does not preserve the Lipschitz constant.

Let $\mathscr{U}$ be a free ultrafilter on $\mathbb{N}$, and denote by $(L_1)_{\mathrm{U}}$ the corresponding ultrapower of L_1. (See [16] for the necessary background on ultrapowers of Banach spaces. In particular, it is shown there that $(L_1)_{\mathrm{U}}$ is isometric to an $L_1(\sigma)$ space for some measure σ.) Define for $\mu \in \mathscr{M}$, $\tilde{h}(\mu) = (j \cdot h(\mu/j))_{j=1}^\infty / \mathscr{U}$, where we set, say, $h(\nu) = 0$ for $\nu \in \mathscr{M} \setminus B_{\mathrm{M}}$. Then, by standard arguments, $\|\tilde{h}\|_{\mathrm{Lip}} \le L$ and $\|\tilde{h}^{-1}\|_{\mathrm{Lip}} \le 1$. Moreover, $\tilde{h}(\mathscr{M})$ spans a separable subspace of $(L_1)_{\mathrm{U}}$, and thus we may assume without loss of generality that $\tilde{h}$ takes values in L_1.

An alternative proof (for those of us who do not mind losing a constant factor) proceeds as follows. For every $f \in L_1$ let $\chi(f) : [0,1]\times\mathbb{R} \to \{-1,0,1\}$ be the function given by

$$\chi(f)(s,t) = \operatorname{sign}(f(s))\cdot \mathbf{1}_{\left[0,|f(s)|\right]}(t) = \begin{cases} 1, & f(s)>0,\ 0\le t\le f(s),\\ -1, & f(s)<0,\ 0\le t\le -f(s),\\ 0 & \text{otherwise.}\end{cases}$$

It is straightforward to check that $\|\chi(f)-\chi(g)\|_{L_1([0,1]\times\mathbb{R})} = \|f-g\|_1$ for every $f,g\in L_1$. (We note here that the space $L_1([0,1]\times\mathbb{R})$ is isometric to L_1.) Define $\tilde{h} : \mathscr{M} \to L_1([0,1]\times\mathbb{R})$ by setting $\tilde{h}(\mu) = \|\mu\|_\tau \cdot \chi\circ h(\mu/\|\mu\|_\tau)$ for $\mu\in\mathscr{M}\setminus\{0\}$, and $\tilde{h}(0)=0$. Since for every $f\in L_1$, $\chi(f)$ takes values in $\{-1,0,1\}$, we have the following pointwise identity for every $\mu,\nu\in\mathscr{M}$ with $\|\mu\|_\tau\ge\|\nu\|_\tau$:

$$\begin{aligned}\left|\tilde{h}(\mu)-\tilde{h}(\nu)\right| &= \|\nu\|_\tau\cdot\left|\chi\circ h\left(\frac{\mu}{\|\mu\|_\tau}\right)-\chi\circ h\left(\frac{\nu}{\|\nu\|_\tau}\right)\right|\\ &\quad+(\|\mu\|_\tau-\|\nu\|_\tau)\cdot\left|\chi\circ h\left(\frac{\mu}{\|\mu\|_\tau}\right)\right|.\end{aligned}$$

Thus

$$\begin{aligned}\left\|\tilde{h}(\mu)-\tilde{h}(\nu)\right\|_{L_1([0,1]\times\mathbb{R})} &= \|\nu\|_\tau\cdot\left\|h\left(\frac{\mu}{\|\mu\|_\tau}\right)-h\left(\frac{\nu}{\|\nu\|_\tau}\right)\right\|_1\\ &\quad+(\|\mu\|_\tau-\|\nu\|_\tau)\cdot\left\|h\left(\frac{\mu}{\|\mu\|_\tau}\right)\right\|_1\\ &\ge \|\nu\|_\tau\cdot\left\|\frac{\mu}{\|\mu\|_\tau}-\frac{\nu}{\|\nu\|_\tau}\right\|_\tau+\|\mu\|_\tau-\|\nu\|_\tau\\ &\ge \|\nu-\mu\|_\tau-\left\|\mu-\frac{\|\nu\|_\tau}{\|\mu\|_\tau}\mu\right\|_\tau+\|\mu\|_\tau-\|\nu\|_\tau\\ &= \|\nu-\mu\|_\tau.\end{aligned}\tag{3.2}$$

It also follows from the identity (3.2) that

$$\begin{aligned}\left\|\tilde{h}(\mu)-\tilde{h}(\nu)\right\|_{L_1([0,1]\times\mathbb{R})} &\le L\|\nu\|_\tau\cdot\left\|\frac{\mu}{\|\mu\|_\tau}-\frac{\nu}{\|\nu\|_\tau}\right\|_\tau+L\|\mu-\nu\|_\tau\\ &\le L\|\mu-\nu\|_\tau+L\|\nu\|_\tau\|\mu\|_\tau\cdot\left|\frac{1}{\|\mu\|_\tau}-\frac{1}{\|\nu\|_\tau}\right|+L\|\mu-\nu\|_\tau\\ &\le 3L\|\mu-\nu\|_\tau.\end{aligned}$$

We are now in position to use a theorem of Ribe [44] (see also [17], and Corollary 7.10 in [4], for softer proofs), which implies that there is an into linear isomorphism $S:\mathscr{M}\to L_1^{**}$ satisfying $\|S\|\le L$ and $\|S^{-1}\|\le 1$. Since $\mathscr{M}$ is finite dimensional, by the principle of local reflexivity [33] (alternatively by Kakutani's representation theorem [27, 34]), and a simple approximation argument, we get that there exists an integer N and an into linear isomorphism $T:\mathscr{M}\to\ell_1^N$ satisfying $\|T\|\le 2L$ and $\|T^{-1}\|\le 1$. (The value of N is irrelevant for us here, and indeed it is possible to conclude the proof without passing to a finite dimensional L_1 space, but this slightly simplifies some of the ensuing arguments. For completeness we note here that using a theorem of Talagrand [50] we can ensure that $N=O(n^2\log n)$.) □

Remark 3.1. The first argument above is not special for L_1 and can be generalized to show that for every finite dimensional Banach space Y, if the unit ball of Y admits a bi-Lipschitz embedding into a Banach space Z, then Y embeds linearly with the same distortion into Z.

From now on let $T : \mathscr{M} \to \ell_1^N$ be the linear operator guaranteed by Lemma 3.1. Since T is an isomorphism, the adjoint operator $T^* : \ell_\infty^N \to \mathscr{M}^* = \mathrm{Lip}_0$ is a quotient mapping, i.e., $\|T^*\| \le 2L$, and the image of the unit ball of ℓ_∞^N under T^* contains the unit ball of Lip_0.

The rest of the proof follows that of Kislyakov [32] and is a discretization of his argument. The idea is to compose T^* with a map $\mathscr{F}$ which is the imaginary part of the discrete two dimensional Fourier transform (see the exact definition below), seen as a map from Lip_0 to $\ell_2(X)$, and to prove two properties of the composed map: Using the fact that $\|T^*\| \le 2L$, we shall show that $\mathscr{F} \circ T^*$ is *order bounded* with good bound, that is,

$$\mathscr{F}\left(T^*\left(B_{\ell_\infty^N}\right)\right) \subseteq \{y \in \ell_2(X) : \ |y| \le x\},$$

for some $x \in \ell_2(X)$ such that $\|x\|_2 \le 4Ln$. Then, using the quotient property of T^*, we find a family of functions $\{\phi_i \in B_{\ell_\infty^N}\}_{i\in I}$ such that if $\mathscr{F}(T^*(\phi_i))) \le x$ for all $i \in I$, then necessarily $\|x\|_2 \ge cn\sqrt{\log n}$ for some universal $c > 0$.

We now define two more auxiliary linear operators. The first is the formal identity $\mathrm{Id} : \mathrm{Lip}_0 \to W$, where W is the space of all functions $f : X \to \mathbb{R}$ with $f(0) = 0$, equipped with the (discrete Sobolev) norm

$$\begin{aligned}\|f\|_W := \sum_{i=0}^{n-1}\sum_{j=0}^{n-2} |f(i,j+1) - f(i,j)| + \sum_{j=0}^{n-1}\sum_{i=0}^{n-2} |f(i+1,j) - f(i,j)| \\ + n\sum_{i=0}^{n-2} |f(i+1,0) - f(i,0)| + n\sum_{j=0}^{n-2} |f(0,j+1) - f(0,j)|.\end{aligned}$$

The second operator is also a formal identity (discrete Sobolev embedding) $S : W \to \ell_2(X)$, where the Euclidean norm on $\ell_2(X)$ is taken with respect to the counting measure on X. The final operator that we will use is the imaginary part of the Fourier operator, already referred to above, which we denote by $\mathscr{F} : \ell_2(X) \to \ell_2(X)$. It is defined for $f : X \to \mathbb{R}$ by

$$\mathscr{F}(f)(u,v) := \Im\left(\frac{1}{n^2}\sum_{(k,\ell)\in X} f(k,\ell)e^{\frac{2\pi i(uk+v\ell)}{n}}\right) = \frac{1}{n^2}\sum_{(k,\ell)\in X} f(k,\ell)\sin\left(\frac{2\pi(uk+v\ell)}{n}\right).$$

The following lemma summarizes known estimates on the norms of these operators.

Lemma 3.2 (operator norm bounds). *The following operator norm bounds hold true:*

- $\|\mathrm{Id}\| \le 4n(n-1)$.
- $\|S\| \le \frac{1}{2}$.
- $\|\mathscr{F}\| \le \frac{1}{n}$.

Proof. The first statement means that for every $f : X \to \mathbb{R}$ with $f(0) = 0$, $\|f\|_W \le 4n(n-1)\|f\|_{\mathrm{Lip}}$, which is obvious from the definitions. The second assertion is that $\|f\|_2 \le \frac{1}{2}\|f\|_W$. This is a discrete version of Sobolev's inequality [41] (with nonoptimal constant), which can be proved as follows. First of all, since $f(0) = 0$, for every $(u, v) \in X$,

$$\begin{aligned}|f(u,v)| &= \left|\sum_{k=0}^{u-1}[f(k+1,v)-f(k,v)] + \sum_{\ell=0}^{v-1}[f(0,\ell+1)-f(0,\ell)]\right| \\ &\le \sum_{k=0}^{n-2}|f(k+1,v)-f(k,v)| + \sum_{\ell=0}^{n-2}|f(0,\ell+1)-f(0,\ell)| := A(v). \qquad (3.3)\end{aligned}$$

Analogously,

$$|f(u,v)| \le \sum_{\ell=0}^{n-2}|f(u,\ell+1)-f(u,\ell)| + \sum_{k=0}^{n-2}|f(k+1,0)-f(k,0)| := B(u). \qquad (3.4)$$

Multiplying (3.3) and (3.4), and summing over X, we see that

$$\begin{aligned}\|f\|_2^2 &\le \sum_{(u,v)\in X} A(v)B(u) = \left(\sum_{v=0}^{n-1}A(v)\right)\cdot\left(\sum_{u=0}^{n-1}B(u)\right) \\ &\le \frac{1}{4}\left(\sum_{v=0}^{n-1}A(v) + \sum_{u=0}^{n-1}B(u)\right)^2 = \frac{1}{4}\|f\|_W^2.\end{aligned}$$

The final assertion follows since the system of functions $\{(k,\ell) \mapsto e^{\frac{2\pi i(uk+v\ell)}{n}}\}_{(u,v)\in X}$ are orthogonal in $\ell_2^{\mathbb{C}}(X)$ (the space of complex-valued functions on X) and have norms bounded by n. □

We now recall some facts related to absolutely summing operators on Banach spaces (we refer the interested reader to [51, 54] for more information on this topic). Given two Banach spaces Y and Z, the π_1 norm of an operator $A : Y \to Z$, denoted $\pi_1(A)$, is defined to be the smallest constant $K > 0$ such that for every $m \in \mathbb{N}$ and every $y_1, \ldots, y_m \in Y$ there exists a norm 1 linear functional $y^* \in Y^*$ satisfying

$$\sum_{j=1}^{m}\|Ay_j\|_Z \le K\sum_{j=1}^{m}|y^*(y_j)|. \qquad (3.5)$$

This defines an *ideal norm* in the sense that it is a norm, and for every two operators $P : W \to Y$ and $Q : Z \to V$ we have $\pi_1(QAP) \le \|Q\| \cdot \pi_1(A) \cdot \|P\|$. Observe that it is always the case that $\pi_1(A) \ge \|A\|$.

LEMMA 3.3. *Using the above notation,* $\pi_1(\mathrm{Id}) \le 4n(n-1)$. *Therefore, Lemma* 3.2 *implies that*

$$\pi_1(\mathscr{F} \circ S \circ \mathrm{Id} \circ T^*) \le 4nL.$$

Proof. Fix $f_1, \ldots, f_m : X \to \mathbb{R}$ with $f_1(0) = \cdots = f_m(0) = 0$. Then

$$\begin{aligned}
\sum_{j=1}^{m} \|f_j\|_W &= \sum_{s=1}^{n-1}\sum_{t=0}^{n-2}\sum_{j=1}^{m}\big(|f_j(s,t+1) - f_j(s,t)| + |f_j(t+1,s) - f_j(t,s)|\big) \\
&\quad + (n+1)\sum_{t=0}^{n-2}\sum_{j=1}^{m}\big(|f_j(0,t+1) - f_j(0,t)| + |f_j(t+1,0) - f_j(t,0)|\big) \\
&\le 4n(n-1)\max\Bigg\{\max_{\substack{0\le s\le n-1\\ 0\le t\le n-2}}\sum_{j=1}^{m}|f_j(s,t+1) - f_j(s,t)|, \\
&\qquad\qquad \max_{\substack{0\le s\le n-1\\ 0\le t\le n-2}}\sum_{j=1}^{m}|f_j(t+1,s) - f_j(t,s)|\Bigg\}.
\end{aligned}$$

Assume without loss of generality that the maximum above equals $\sum_{j=1}^{m}|f_j(s_0, t_0 + 1) - f_j(s_0, t_0)|$ for some $0 \le s_0 \le n-1$ and $0 \le t_0 \le n-2$. Consider the measure $\mu = \delta_{(s_0,t_0+1)} - \delta_{(s_0,t_0)} \in \mathscr{M} = \mathrm{Lip}_0^*$. One checks that $\|\mu\|_\tau = 1$, and $\sum_{j=1}^{m}|f_j(s_0, t_0 + 1) - f_j(s_0, t_0)| = \sum_{j=1}^{m}|\mu(f_j)|$, implying the required result. □

The fundamental property of the π_1 norm is the Pietsch factorization theorem (see [51]), a special (particularly easy) case of which is the following lemma. We present a proof for the sake of completeness.

Lemma 3.4 (Pietsch factorization). *Let Y be a Banach space, and fix a linear operator $A : \ell_\infty^N \to Y$. Then there exists a probability measure σ on $\{1, \ldots, N\}$ and a linear operator $R : L_1(\sigma) \to Y$ such that $A = R \circ I$, where I is the formal identity from ℓ_∞^N to $L_1(\sigma)$, and $\|R\| = \pi_1(A)$.*

Proof. Recall that $A : \ell_\infty^N \to Y$ satisfies, for all $x_1, \ldots, x_m \in \ell_\infty^N$,

$$\sum_{j=1}^{m}\|Ax_j\| \le \pi_1(A)\cdot \mathrm{supp}_{\substack{x^*\in(\ell_\infty^N)^*\\ \|x^*\|=1}}\sum_{j=1}^{m}|x^*(x_j)| = \pi_1(A)\cdot\max_{1\le k\le N}\sum_{j=1}^{m}|x_j(k)|, \tag{3.6}$$

where the last equality follows from the fact that the evaluation functionals $x \mapsto x(k)$ are the extreme points of the unit ball of $\ell_1^N = \left(\ell_\infty^N\right)^*$.

Denoting by $e_1, \ldots, e_N$ the standard basis of $\mathbb{R}^N$, we deduce from (3.6) that $\pi_1(A) \ge \sum_{j=1}^{N}\|Ae_j\|$. Define a probability measure σ on $\{1, \ldots, N\}$ by $\sigma(k) = \frac{\|Ae_k\|}{\sum_{j=1}^{N}\|Ae_j\|}$. Then for every $x \in \ell_\infty^N$ we see that

$$\begin{aligned}
\|Ax\| = \left\|\sum_{k=1}^{N}x(k)Ae_k\right\| &\le \sum_{k=1}^{N}|x(k)|\cdot\|Ae_k\| \\
&= \left(\sum_{j=1}^{N}\|Ae_j\|\right)\int_{\{1,\ldots,N\}}|x(k)|d\sigma(k) \le \pi_1(A)\int_{\{1,\ldots,N\}}|x(k)|d\sigma(k).
\end{aligned}$$

Defining $Rx = Ax$, this implies the required result. □

From now on let R and σ be the operator and probability measure corresponding to $A = \mathscr{F} \circ S \circ \mathrm{Id} \circ T^*$ in Lemma 3.4. Thus $R \circ I = \mathscr{F} \circ S \circ \mathrm{Id} \circ T^*$ and $\|R\| \le 4nL$.

Schematically, we have the following commuting diagram:

$$\begin{tikzcd}
\ell_\infty^N \arrow[r, "T^*"] \arrow[dr, "I"] & \mathrm{Lip}_0 \arrow[r, "\mathrm{Id}"] & W \arrow[r, "S"] & \ell_2(X) \arrow[r, "\mathscr{F}"] & \ell_2(X) \\
& L_1(\sigma) \arrow[urrr, "R"] & & &
\end{tikzcd}$$

We need only one more simple result from classical Banach space theory. This result can be generalized to the case in which the target space ℓ_2 is replaced by a more general Banach lattice. For the sake of simplicity we shall prove here only what is needed to conclude the proof of Theorem 1.1.

LEMMA 3.5. *Let $R : L_1(\sigma) \to \ell_2$ be a linear operator. Fix $f : \{0,\dots,N\} \to [0,\infty)$. Then there is $x \in \ell_2$ with nonnegative coordinates such that*

$$R\left(\{g : \{0,\dots,N\} \to \mathbb{R} : \ \forall j,\ |g(j)| \le f(j)\}\right) \subseteq \{y \in \ell_2 : \ \forall j,\ |y_j| \le x_j\},$$

and $\|x\|_2 \le \|R\| \cdot \|f\|_{L_1(\sigma)}$.

Proof. R is given by a matrix $(R_{ij} : i = 1,\dots,N,\ j \in \mathbb{N})$. In other words, for every j, $(Rf)_j = \sum_{i=1}^N R_{ij} f(i)$. Observe that using this notation,

$$\|R\| = \max_{1\le i\le N} \left(\frac{1}{\sigma(i)^2} \sum_{j=1}^{\infty} R_{ij}^2 \right)^{1/2}. \tag{3.7}$$

Fix $g \in L_1(\sigma)$ such that for all $i \in \{1,\dots,N\}$, $|g(i)| \le f(i)$. Then for all j,

$$|(Rg)_j| \le \sum_{i=1}^N |R_{ij}| f(i) := x_j.$$

Now

$$\begin{aligned}
\|x\|_2 = \left[\sum_{j=1}^{\infty} \left(\sum_{i=1}^N |R_{ij}| f(i) \right)^2 \right]^{1/2} &\le \sum_{i=1}^N \left(\sum_{j=1}^{\infty} |R_{ij}|^2 f(i)^2 \right)^{1/2} \\
&= \sum_{i=1}^n \sigma(i) f(i) \left(\frac{1}{\sigma(i)^2} \sum_{j=1}^{\infty} R_{ij}^2 \right)^{1/2} \le \|R\| \cdot \|f\|_{L_1(\sigma)},
\end{aligned}$$

where we have used (3.7). □

We are now in position to conclude the proof of Theorem 1.1.

Proof of Theorem 1.1. For $(u,v) \in \{1,\dots,n-1\}^2$ define $\varphi_{u,v} : X \to \mathbb{R}$ by

$$\varphi_{u,v}(k,\ell) := \frac{1}{u+v} \cdot \sin\left(\frac{2\pi(uk + v\ell)}{n} \right).$$

Then $\varphi_{u,v}(0) = 0$, and one computes that $\|\varphi_{u,v}\|_{\mathrm{Lip}} < \frac{4\pi}{n}$. By the fact that T^* maps the unit ball of ℓ_∞^N onto the unit ball of Lip_0, it follows that there is $\phi_{u,v} \in \ell_\infty^N$ with $\|\phi_{u,v}\|_\infty \le \frac{4\pi}{n}$ and $T^*\phi_{u,v} = \varphi_{u,v}$. Now the functions $|I(\phi_{u,v})| \in L_1(\sigma)$ are pointwise bounded by the constant $\frac{4\pi}{n}$, and so by Lemma 3.5 there exists $x \in \ell_2(X)$ of norm at most $\frac{4\pi}{n}\|R\| \le 16\pi L$ such that $|R(I(\phi_{u,v}))|$ is bounded pointwise by x.

Note that

$$\begin{aligned}
&R \circ I(\phi_{u,v})(u,v)\\
&= \mathscr{F} \circ S \circ \mathrm{Id} \circ T^*(\phi_{u,v})(u,v)\\
&= \mathscr{F}(\varphi_{u,v})(u,v)\\
&= \frac{1}{n^2} \sum_{(k,\ell)\in X} \frac{1}{u+v} \cdot \sin^2\left(\frac{2\pi(uk+v\ell)}{n}\right)\\
&= \frac{1}{n^2(u+v)} \sum_{k=0}^{n-1}\sum_{\ell=0}^{n-1} \left(\frac{1}{2} - \frac{1}{4}\cdot e^{2\pi i\cdot\frac{2uk}{n}} \cdot e^{2\pi i\cdot\frac{2v\ell}{n}} - \frac{1}{4}\cdot e^{-2\pi i\cdot\frac{2uk}{n}} \cdot e^{-2\pi i\cdot\frac{2v\ell}{n}}\right)\\
&= \begin{cases} \frac{1}{2(u+v)}, & (u,v) \neq \left(\frac{n}{2},\frac{n}{2}\right),\\ 0, & (u,v) = \left(\frac{n}{2},\frac{n}{2}\right). \end{cases}
\end{aligned}$$

But

$$(16\pi L)^2 \ge \|x\|_2^2 \ge \sum_{u,v=1}^{n-1} x_{u,v}^2 \ge \sum_{u,v=1}^{n-1} \Big[R \circ I(\phi_{u,v})(u,v)\Big]^2 \ge \frac{1}{8}\sum_{u,v=1}^{n-1} \frac{1}{(u+v)^2} \ge \frac{\log n}{16},$$

where the last bound follows from comparison with the appropriate integrals. The proof of Theorem 1.1 is complete. □

3.1. Discretization and minimum weight matching. In this section we deduce Theorem 1.2 from Theorem 1.1. The main tool is the following theorem of Bourgain [6], which gives a quantitative version of Ribe's theorem [44].

THEOREM 3.6 (Bourgain's quantitative version of Ribe's theorem [6]). *There exists a universal constant C with the following property. Let Y and Z be Banach spaces,* $\dim(Y) = d$. *Assume that $\mathscr{Y}$ is an ϵ-net in the unit ball of Y, that $f : \mathscr{Y} \to Z$ satisfies* $\mathrm{dist}(f) \le D$, *and that* $\log\log\frac{1}{\epsilon} \ge Cd\log D$. *Then there exists an invertible linear operator $T : Y \to Z$ satisfying $\|T\| \cdot \|T^{-1}\| \le C \cdot D$.*

Proof of Theorem 1.2. Observe that for every $\mu \in \mathscr{M}$, the measure $\frac{1}{\mu^+(X)} \cdot (\mu^+ \otimes \mu^-)$ is in $\Pi(\mu^+,\mu^-)$. Thus

$$\begin{aligned}
\|\mu\|_\tau &\le \frac{1}{\mu^+(X)}\int_{X\times X} \|x-y\|_2 d\mu^+(x)d\mu^-(y)\\
&\le \sqrt{2}\cdot(n-1)\cdot\mu^+(X)\\
&\le 2n \cdot |\mathrm{supp}(\mu^+)| \cdot \|\mu\|_\infty\\
&\le 2n^3\|\mu\|_\infty.
\end{aligned}$$

On the other hand, as we have seen in the proof of Lemma 3.1, for every $\mu \in \mathscr{M}$, $\|\mu\|_\infty \le \|\mu\|_\tau$. It follows from these considerations, and Theorems 1.1 and 3.6, that for every integer $N \ge e^{e^{C'n^2\log\log n}}$, the set of probability measures $\mathscr{Y} \subseteq \mathscr{P}_X$ consisting of measures $\mu \in \mathscr{P}_X$ such that for all $x \in X$, $\mu(x) = k/N$ for some $k \in \{0,\dots,N\}$, satisfies $c_1(\mathscr{Y},\tau) = \Omega\left(\sqrt{\log n}\right)$. We pass to a family of subsets as follows. Let M be an integer which will be determined later. For every $\mu \in \mathscr{Y}$ we assign a subset $S_\mu \subseteq \{0,\dots,nM\}^2$ as follows. For every $(u,v) \in X = \{0,\dots,n-1\}^2$, if $\mu(u,v) = k/N$, where $k \in \{0,\dots,N\}$, then S_μ will contain arbitrary k distinct points from the set $(uM, vM) + \{0, \ldots, \lceil\sqrt{N}\rceil\}^2$. Provided $M \geq 4\sqrt{N}$, the sets $\{S_\mu\}_{\mu\in\mathrm{Y}}$ thus obtained are N point subsets of $\{0, \ldots, nM\}^2$, and it is straightforward to check that the minimum weight matching metric on $\{S_\mu\}_{\mu\in\mathrm{Y}}$ is bi-Lipschitz equivalent to $(\mathscr{Y}, \tau)$ with constant distortion. □

3.2. Uniform and coarse nonembeddability into Hilbert space. In this section we prove Theorem 1.3. We shall prove, in fact, that the space $\mathscr{M}_{[0,1]^2,\tau}$ does not embed uniformly or coarsely into L_2. We first recall the definitions of these important notions (see [4, 37] and the references therein for background on these concepts). Let (X, d_X) and (Y, d_Y) be metric spaces. For $f : X \to Y$ and $t > 0$ we define

$$\Omega_f(t) = \operatorname{supp}\{d_Y(f(x), f(y));\ d_X(x, y) \leq t\}$$

and

$$\omega_f(t) = \inf\{d_Y(f(x), f(y));\ d_N(x, y) \geq t\}.$$

Clearly, Ω_f and ω_f are nondecreasing, and for every $x, y \in X$,

$$\omega_f\left(d_X(x, y)\right) \leq d_Y(f(x), f(y)) \leq \Omega_f\left(d_X(x, y)\right).$$

With these definitions, f is uniformly continuous if $\lim_{t\to 0} \Omega_f(t) = 0$, and f is said to be a uniform embedding if f is injective and both f and f^{-1} are uniformly continuous. Also, f is said to be a coarse embedding if $\Omega_f(t) < \infty$ for all $t > 0$ and $\lim_{t\to\infty} \omega_f(t) = \infty$.

In what follows we will use the following standard notation: Given a sequence of Banach spaces $\left\{(Z_j, \|\cdot\|_{Z_j})\right\}_{j=1}^\infty$, the Banach space $(\bigoplus_{j=1}^\infty Z_j)_1$ is the space of all sequences $\overline{z} = (z_j)_{j=1}^\infty \in \prod_{j=1}^\infty Z_j$ such that $\|\overline{z}\| := \sum_{j=1}^\infty \|z_j\|_{Z_j} < \infty$. If for every $j \in \mathbb{N}$, $Z_j = Z_1$, we write $\ell_1(Z_1) = (\bigoplus_{j=1}^\infty Z_j)_1$.

Theorem 3.7. *The spaces $\{\mathscr{M}^0_{\{0,\ldots,n\}^2,\tau}\}_{n=1}^\infty$ do not admit a uniform or coarse embedding into L_2 with moduli uniformly bounded in n; i.e., there do not exist increasing functions $\omega, \Omega : [0, \infty) \to [0, \infty)$ which either satisfy $\lim_{t\to 0} \omega(t) = \lim_{t\to 0} \Omega(t) = 0$, or $\lim_{t\to\infty} \omega(t) = \infty$, and mappings $f_n : \mathscr{M}^0_{\{0,\ldots,n\}^2} \to L_2$, such that $\omega(\|\mu - \nu\|_\tau) \leq \|f_n(\mu) - f_n(\nu)\|_2 \leq \Omega(\|\mu - \nu\|_\tau)$ for all $\mu, \nu \in \mathscr{M}^0_{\{0,\ldots,n\}^2}$ and all n.*

Proof. If this is not the case, then by passing to a limit along an ultrafilter we easily deduce that $\mathscr{M}^0_{[0,1]^2,\tau}$ uniformly or coarsely embeds into an ultraproduct of Hilbert spaces and thus into L_2 (see [16, 17]). By a theorem of Aharoni, Maurey, and Mityagin [1] in the case of uniform embeddings, and a result of Randrianarivony [43] in the case of coarse embeddings, this implies that $\mathscr{M}^0_{[0,1]^2}$ is linearly isomorphic to a subspace of L_0. By a theorem of Nikišin [39], it follows that $\mathscr{M}^0_{[0,1]^2}$ is isomorphic to a subspace of $L_{1-\epsilon}$ for any $\epsilon \in (0, 1)$. We recall that it is an open problem posed by Kwapien (see the discussion in [28, 4]) whether a Banach space which linearly embeds into L_0 is linearly isomorphic to a subspace of L_1. If this were the case, we would have finished by Theorem 1.1. Since the solution of Kwapien's problem is unknown, we proceed as follows.

Let $\{S_j\}_{j=1}^\infty$ be a sequence of disjoint squares in $[0, 1]^2$ with

$$d(S_j, S_k) = \min_{a\in S_j,\ b\in S_k} \|a - b\|_2 > \max\left\{\operatorname{diam} S_j, \operatorname{diam} S_k\right\}. \tag{3.8}$$

Consider the linear subspace Y of $\mathscr{M}^0_{[0,1]^2}$ consisting of all measures μ satisfying $\operatorname{supp}(\mu) \subseteq \bigcup_{j=1}^\infty S_j$ and $\mu(S_j) = 0$ for all j. It is intuitively clear that in the computation of $\|\mu\|_\tau$ for $\mu \in Y$ the best transportation leaves each of the S_j invariant; i.e., it is enough to take the infimum in (2.1) only over measures $\pi \in \Pi(\mu, \nu)$ which are supported on $\bigcup_{j=1}^{\infty}(S_j \times S_j)$. This is proved formally as follows: Fix $\mu \in Y$, and write $\mu = \sum_{j=1}^{\infty} \mu_j$, where $\mathrm{supp}(\mu_j) \subseteq S_j$ and $\mu_j(S_j) = 0$ for all $j \in \mathbb{N}$. We claim that

$$\|\mu\|_{[0,1]^2,\tau} = \sum_{j=1}^{\infty} \|\mu_j\|_{S_j,\tau}. \tag{3.9}$$

If $\pi_j \in \Pi(\mu_j^+, \mu_j^-)$, then $\pi := \sum_{j=1}^{\infty} \pi_j \in \Pi(\mu^+, \mu^-)$. Thus $\|\mu\|_{[0,1]^2,\tau} \le \sum_{j=1}^{\infty} \|\mu_j\|_{S_j,\tau}$. To prove the reverse inequality take $\pi \in \Pi(\mu^+, \mu^-)$. For every $j = 1, 2, \ldots$ define a measure σ_j on S_j as follows: For $A \subseteq S_j$ set $\sigma_j(A) := \pi(A \times \bigcup_{k \neq j} S_k)$. Thus, in particular, by our assumption (3.8) for every $y \in S_j$,

$$\int_{S_j} \|x - y\|_2 d\sigma_j(x) = \int_{S_j \times \bigcup_{k \neq j} S_k} \|x - y\|_2 d\pi(x, z) \le \int_{S_j \times \bigcup_{k \neq j} S_k} \|x - z\|_2 d\pi(x, z). \tag{3.10}$$

Writing

$$\begin{aligned} \widetilde{\pi} &:= \pi \cdot \mathbf{1}_{\bigcup_{j=1}^{\infty}(S_j \times S_j)} + \sum_{j=1}^{\infty} \frac{1}{\sigma_j(S_j)} \cdot \sigma_j \otimes \sigma_j \\ &= \pi \cdot \mathbf{1}_{\bigcup_{j=1}^{\infty}(S_j \times S_j)} + \sum_{j=1}^{\infty} \frac{1}{\pi\left(S_j \times \bigcup_{k \neq j} S_k\right)} \cdot \sigma_j \otimes \sigma_j, \end{aligned}$$

it follows from our definitions that $\widetilde{\pi} \in \Pi(\mu^+, \mu^-)$ and $\widetilde{\pi}$ is supported on $\bigcup_{j=1}^{\infty}(S_j \times S_j)$. Moreover, for each j, $\widetilde{\pi}_j := \widetilde{\pi}|_{S_j} \in \Pi(\mu_j^+, \mu_j^-)$, so that

$$\begin{aligned} \sum_{j=1}^{\infty} \|\mu_j\|_{S_j,\tau} &\le \sum_{j=1}^{\infty} \int_{S_j \times S_j} \|x - y\|_2 d\widetilde{\pi}_j(x, y) \\ &= \int_{\bigcup_{j=1}^{\infty}(S_j \times S_j)} \|x - y\|_2 d\pi(x, y) \\ &\quad + \sum_{j=1}^{\infty} \frac{1}{\pi\left(S_j \times \bigcup_{k \neq j} S_k\right)} \cdot \int_{S_j \times S_j} \|x - y\|_2 d\sigma_j(x) d\sigma_j(y) \\ &\overset{(3.10)}{\le} \int_{\bigcup_{j=1}^{\infty}(S_j \times S_j)} \|x - y\|_2 d\pi(x, y) + \sum_{j=1}^{\infty} \int_{S_j \times \bigcup_{k \neq j} S_k} \|x - z\|_2 d\pi(x, z) \\ &= \int_{\left(\bigcup_{j=1}^{\infty} S_j\right) \times \left(\bigcup_{j=1}^{\infty} S_j\right)} \|x - y\|_2 d\pi(x, y). \end{aligned}$$

This concludes the proof of (3.9). It follows that Y is isometric to $(\bigoplus_{n=1}^{\infty} \mathscr{M}_{S_n,\tau}^0)_1$, which in turn is isometric to $\ell_1(\mathscr{M}_{[0,1]^2,\tau}^0)$. Now Kalton proved in [28] that if for some Banach space X, $\ell_1(X)$ is isomorphic to a subspace of L_0, then X is isomorphic to a subspace of L_1, and we finish by Theorem 1.1. □

Proof of Theorem 1.3. Assume for the sake of contradiction that there exists $C < \infty$ such that for all $n \in \mathbb{N}$, $c_2\left(\mathscr{P}_{\{0,\ldots,n\}^2}, \sqrt{\tau}\right) < C$. By the proof of Lemma 3.1, we know that the unit ball of $\mathscr{M}_{\{0,\ldots,n\}^2,\tau}$ is isometric to a subset of $(\mathscr{P}_{\{0,\ldots,n\}^2}, \tau)$. Thus by our assumption there exist mappings $f_n : \mathscr{M}_{\{0,\ldots,n\}^2} \to L_2$ such that for every $\mu, \nu \in \mathscr{M}_{\{0,\dots,n\}^2}$ with $\|\mu\|_\tau, \|\nu\|_\tau \le 1$,

$$\sqrt{\|\mu-\nu\|_\tau} \le \|f_n(\mu) - f_n(\nu)\|_2 \le C \cdot \sqrt{\|\mu-\nu\|_\tau}\ . \tag{3.11}$$

Let $\mathscr{U}$ be a free ultrafilter on $\mathbb{N}$. Define $\widetilde{f}_n : \mathscr{M}_{\{0,\dots,n\}^2} \to (L_2)_{\mathrm{U}}$ by $\widetilde{f}_n(\mu) = \left(\sqrt{j} \cdot f_n(\mu/j)\right)_{j=1}^{\infty}/\mathscr{U}$. Inequalities (3.11) imply that all $\mu, \nu \in \mathscr{M}_{\{0,\dots,n\}^2}$ satisfy $\sqrt{\|\mu-\nu\|_\tau} \le \|\widetilde{f}_n(\mu) - \widetilde{f}_n(\nu)\|_{(L_2)_{\mathrm{U}}} \le C \cdot \sqrt{\|\mu-\nu\|_\tau}$. Since the ultrapower $(L_2)_{\mathrm{U}}$ is isometric to a Hilbert space (see [16]), we arrive at a contradiction with Theorem 3.7. □

Remark 3.2. We believe that Theorem 1.3 can be made quantitative; i.e., one can give explicit quantitative estimates on the rate with which $c_2\left(\mathscr{P}_{\{0,\dots,n\}^2}, \sqrt{\tau}\right)$ tends to infinity. This would involve obtaining quantitative versions of the proofs in [1, 28, 43], which seems easy but somewhat tedious. We did not attempt to obtain such bounds.

Remark 3.3. We do not know whether $\left(\mathscr{P}_{[0,1]^2}, \tau\right)$ admits a uniform embedding into Hilbert space. The proof above actually gives that for all $\alpha \in (0,1]$, $\left(\mathscr{P}_{[0,1]^2,\tau}, \tau^\alpha\right)$ does not embed bi-Lipschitzly into Hilbert space. But, our proof exploits the homogeneity of the function $t \mapsto t^\alpha$ in an essential way, and so it does not apply to the case of more general moduli.

4. Upper bounds via Fourier analysis. In this section we prove Theorem 1.4 and discuss some related upper bounds. Given a measure μ on $\mathbb{Z}_n^2$, we decompose it as in (1.2), and we consider the linear operators A and B, from $\mathscr{M}_{\mathbb{Z}_n^2}$ to $L_1\left(\mathbb{Z}_n^2\right)$, defined in (1.3) and (1.4), respectively. One checks that the duals of these operators, $A^*, B^* : L_\infty\left(\mathbb{Z}_n^2\right) \to \mathscr{M}_{\mathbb{Z}_n^2}^* = \mathrm{Lip}_0\left(\mathbb{Z}_n^2\right)$, are given by

$$A^* f = \sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \frac{e^{-\frac{2\pi i u}{n}} - 1}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2} \cdot \widehat{f}(u,v) \cdot (e_{uv} - 1) \tag{4.1}$$

and

$$B^* f = \sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \frac{e^{-\frac{2\pi i v}{n}} - 1}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2} \cdot \widehat{f}(u,v) \cdot (e_{uv} - 1). \tag{4.2}$$

To check these identities the reader should verify that for all $\mu \in \mathscr{M}_{\mathbb{Z}_n^2}$, $\int_{\mathbb{Z}_n^2} f d(A\mu) = \int_{\mathbb{Z}_n^2} (A^* f) d\mu$, and similarly for B. (To this end, recall that $\mu\left(\mathbb{Z}_n^2\right) = 0$, so that $\widehat{\mu}(0,0) = 0$. This explains the subtraction of 1 in the identities (4.1) and (4.2).)

We claim that for every $\mu \in \mathscr{M}_{Z_n^2}$,

$$\|\mu\|_\tau \le \|A\mu\|_{L_1(\mathbb{Z}_n^2)} + \|B\mu\|_{L_1(\mathbb{Z}_n^2)} \le C \log n \cdot \|\mu\|_\tau, \tag{4.3}$$

where C is a universal constant. This will imply Theorem 1.4 since the mapping $\mu \mapsto \mu - U$, where U is the uniform probability measure on Z_n^2, is an isometric embedding of $\mathscr{P}_{\mathbb{Z}_n^2}$ into $\mathscr{M}_{\mathbb{Z}_2^n}$.

By duality, (4.3) is equivalent to the fact that the mapping $(f,g) \mapsto A^* f + B^* g$ from $L_\infty\left(\mathbb{Z}_n^2\right) \oplus L_\infty\left(\mathbb{Z}_n^2\right)$ to $\mathrm{Lip}_0\left(\mathbb{Z}_n^2\right)$ is a $C \log n$ quotient map; i.e., for every $(f,g) \in L_\infty\left(\mathbb{Z}_n^2\right) \oplus L_\infty\left(\mathbb{Z}_n^2\right)$,

$$\|A^* f + B^* g\|_{\mathrm{Lip}} \le C \log n \cdot \max\left\{\|f\|_\infty, \|g\|_\infty\right\}, \tag{4.4}$$

and for every $h \in \mathrm{Lip}_0\left(\mathbb{Z}_n^2\right)$, there is some $(f,g) \in L_\infty\left(\mathbb{Z}_n^2\right) \oplus L_\infty\left(\mathbb{Z}_n^2\right)$ satisfying $A^*f + B^*g = h$ and $\max\{\|f\|_\infty, \|g\|_\infty\} \le \|h\|_{\mathrm{Lip}}$. The second assertion is proved as follows: Take $f = \partial_1 h$ and $g = \partial_2 h$, where for $j = 1,2$, $\partial_j h(x) = h(x+e_j) - h(x)$ (here $e_1 = (1,0)$ and $e_2 = (0,1)$). Clearly, $\|f\|_\infty, \|g\|_\infty \le \|h\|_{\mathrm{Lip}}$, and

$$
\begin{aligned}
&A^*f + B^*g\\
&\quad= \sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \left(\frac{\left(e^{-\frac{2\pi i u}{n}} - 1\right)\cdot \widehat{\partial_1 h}(u,v) + \left(e^{-\frac{2\pi i v}{n}} - 1\right)\cdot \widehat{\partial_2 h}(u,v)}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2}\right)(e_{uv} - 1)\\
&\quad= \sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \left(\frac{\left(e^{-\frac{2\pi i u}{n}} - 1\right)\cdot\left(e^{\frac{2\pi i u}{n}} - 1\right) + \left(e^{-\frac{2\pi i v}{n}} - 1\right)\cdot\left(e^{\frac{2\pi i v}{n}} - 1\right)}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2}\right)\\
&\qquad\cdot \widehat{h}(u,v)(e_{uv} - 1)\\
&\quad= \sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \widehat{h}(u,v)e_{uv} - \sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \widehat{h}(u,v)\\
&\quad= \sum_{(u,v)\in\mathbb{Z}_n^2} \widehat{h}(u,v)e_{uv} = h,
\end{aligned}
$$

where we used the fact that $h(0) = 0$.

It remains to prove (4.4). To this end, it is enough to show that $\|A^*f\|_{\mathrm{Lip}} \le O(\log n)\cdot\|f\|_\infty$ and $\|B^*g\|_{\mathrm{Lip}} \le O(\log n)\cdot\|g\|_\infty$. We will establish this for A^*—the case of B^* is entirely analogous. Observe that

$$\|A^*f\|_{\mathrm{Lip}} \le \|\partial_1 A^*f\|_\infty + \|\partial_2 A^*f\|_\infty,$$

and so it is enough to establish the following two inequalities:

$$\left\|\sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \frac{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2}\cdot \widehat{f}(u,v)e_{uv}\right\|_\infty \le O(\log n)\cdot\|f\|_\infty \tag{4.5}$$

and

$$\left\|\sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \frac{\left(e^{-\frac{2\pi i u}{n}} - 1\right)\cdot\left(e^{\frac{2\pi i v}{n}} - 1\right)}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2}\cdot \widehat{f}(u,v)e_{uv}\right\|_\infty \le O(\log n)\cdot\|f\|_\infty. \tag{4.6}$$

Since for $p > 0$ the norms on $L_\infty\left(\mathbb{Z}_n^2\right)$ and $L_p\left(\mathbb{Z}_n^2\right)$ are equivalent with constant $n^{2/p}$ (by Hölder's inequality), it is enough to show that for $p \ge 2$,

$$\left\|\sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \frac{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2}\cdot \widehat{f}(u,v)e_{uv}\right\|_p \le O(p)\cdot\|f\|_p \tag{4.7}$$

and

$$\left\|\sum_{(u,v)\in\mathbb{Z}_n^2\setminus\{(0,0)\}} \frac{\left(e^{-\frac{2\pi i u}{n}} - 1\right)\cdot\left(e^{\frac{2\pi i v}{n}} - 1\right)}{\left|e^{\frac{2\pi i u}{n}} - 1\right|^2 + \left|e^{\frac{2\pi i v}{n}} - 1\right|^2}\cdot \widehat{f}(u,v)e_{uv}\right\|_p \le O(p)\cdot\|f\|_p. \tag{4.8}$$

To prove inequalities (4.7) and (4.8) we will assume that n is odd (all of our results are valid for even n as well, and the proofs in this case require minor modifications). We think of $\mathbb{Z}_n^2$ as $[-(n-1)/2,\ (n-1)/2]^2 \cap \mathbb{Z}^2$. As before, given $m : \mathbb{Z}_n^2 \to \mathbb{C}$, we denote

$$\partial_1 m(x,y) = m(x+1,y) - m(x,y) \quad \text{and} \quad \partial_2 m(x,y) = m(x,y+1) - m(x,y).$$

Thus

$$\begin{aligned} &\partial_1^2 m(x,y) = m(x+2,y) - 2m(x+1,y) + m(x,y) \quad \text{and} \\ &\partial_2^2 m(x,y) = m(x,y+2) - 2m(x,y+1) + m(x,y), \end{aligned}$$

and

$$\partial_1\partial_2 m(x,y) = \partial_2\partial_1 m(x,y) = m(x+1,y+1) - m(x+1,y) - m(x,y+1) + m(x,y).$$

In what follows we think of m as a *Fourier multiplier* in the sense that it corresponds to a translation invariant operator T_m on $L_2\left(\mathbb{Z}_n^2\right)$ given by

$$T_m(f) := \sum_{(u,v)\in\mathbb{Z}_n^2} m(u,v) \cdot \widehat{f}(u,v) \cdot e_{uv}. \tag{4.9}$$

Recall that an operator $T : L_1\left(\mathbb{Z}_n^2\right) \to L_1\left(\mathbb{Z}_n^2\right)$ is said to be weak $(1,1)$ with constant K if for every $f : \mathbb{Z}_n^2 \to \mathbb{C}$ and every $a > 0$,

$$\left|\left\{((u,v) \in \mathbb{Z}_n^2 :\ |Tf(u,v)| \geq a\right\}\right| \leq \frac{K}{a} \cdot \|f\|_1 = \frac{K}{a} \cdot \sum_{(u,v)\in\mathbb{Z}_n^2} |f(u,v)|.$$

We will use the following discrete version of the Hörmander–Mihlin multiplier theorem [38, 18].

THEOREM 4.1 (Hörmander–Mihlin multiplier criterion on $\mathbb{Z}_n^2$). *For $j \in \mathbb{N}$ denote $Q_j = [-2^j, 2^j] \times [-2^j, 2^j]$. Fix $B > 0$ and $m : \mathbb{Z}_n^2 \to \mathbb{C}$ with $m(0,0) = 0$, and assume that for all $j = 0, 1, \ldots, \lfloor \log_2(n-1) \rfloor - 1$,*

$$\begin{aligned} \sum_{(u,v)\in(Q_j\setminus Q_{j-1})\cap\mathbb{Z}_n^2} &\big[2^{-2j}|m(u,v)|^2 + |\partial_1 m(u,v)|^2 + |\partial_2 m(u,v)|^2 \\ &+2^{2j}|\partial_1^2 m(u,v)|^2 + 2^{2j}|\partial_2^2 m(u,v)|^2 + 2^{2j}|\partial_1\partial_2 m(u,v)|^2\big] \leq B^2. \end{aligned}$$

Then the translation invariant operator T_m corresponding to m is weak $(1,1)$ with constant $O(B)$.

While the continuous version of the Hörmander–Mihlin multiplier theorem is a powerful tool which appears in several texts (e.g., in the books [12, 48, 52]), we could not locate a statement of the above discrete version in the literature. It is, however, possible to prove it using several minor modifications of the existing proofs. The standard proof of the Hörmander–Mihlin criterion is usually split into two parts. The first part, which is based on the Calderón–Zygmund decomposition, transfers virtually verbatim to the discrete setting—see Theorem 3 in Chapter 1 of [48] and Remark 8.1 there, which explains how this part of the proof transfers from $\mathbb{R}^n$ to the setting of finitely generated groups of polynomial growth (in fact, the Calderón–Zygmund decomposition itself, as presented in Theorem 2 in Chapter 1 of [48], is valid in the setting of general metric spaces equipped with a doubling measure). The second part of the proof of the Hörmander–Mihlin theorem, as presented in Theorem 2.5 of [18], requires several straightforward modifications in order to pass to the discrete setting. We leave the simple details to the reader. For the sake of readers that are not familiar with these aspects of Fourier analysis, we will later present a complete reduction to a continuous problem whose proof appears in print, which yields slightly worse bounds on the distortion guarantee.

In order to apply Theorem 4.1, we consider the following two multipliers,

(4.10)
$$m_1(u,v) := \frac{\left|e^{\frac{2\pi iu}{n}}-1\right|^2}{\left|e^{\frac{2\pi iu}{n}}-1\right|^2+\left|e^{\frac{2\pi iv}{n}}-1\right|^2} \quad \text{and} \quad m_2(u,v) := \frac{\left(e^{-\frac{2\pi iu}{n}}-1\right)\cdot\left(e^{\frac{2\pi iv}{n}}-1\right)}{\left|e^{\frac{2\pi iu}{n}}-1\right|^2+\left|e^{\frac{2\pi iv}{n}}-1\right|^2},$$

where we set $m_1(0,0) = m_2(0,0) = 0$. A direct (albeit tedious!) computation shows that m_1 and m_2 satisfy the conditions of Theorem 4.1 with $B = O(1)$. Thus, the operators T_{m_1} and T_{m_2} are weak $(1,1)$ with constant $O(1)$. Since m_1 and m_2 are bounded functions, the operator norms $\|T_{m_1}\|_{L_2(\mathbb{Z}_n^2)\to L_2(\mathbb{Z}_n^2)}$ and $\|T_{m_2}\|_{L_2(\mathbb{Z}_n^2)\to L_2(\mathbb{Z}_n^2)}$ are $O(1)$. Since these operators are self-adjoint, by the Marcinkiewicz interpolation theorem (see [56]) it follows that for $p \ge 2$, the operator norms $\|T_{m_1}\|_{L_p(\mathbb{Z}_n^2)\to L_p(\mathbb{Z}_n^2)}$ and $\|T_{m_2}\|_{L_p(\mathbb{Z}_n^2)\to L_p(\mathbb{Z}_n^2)}$ are $O(p)$. This is precisely (4.7) and (4.8).

The above argument is based on Theorem 4.1, which does not appear exactly as stated in the literature, but its proof is a straightforward adaptation of existing proofs (which is too simple to justify rewriting the lengthy argument here). However, making the necessary changes easily does require some familiarity with Calderón–Zygmund theory. We therefore now present another argument which gives a polylog(n) bound on the distortion but uses only statements which appear in the literature. This alternative approach appears to be quite versatile and might be useful elsewhere.

The following lemma reduces the problem of proving inequalities such as (4.7) and (4.8) (with perhaps a different dependence on p) to a continuous inequality. The argument is based on the proof of a theorem of Marcinkiewicz from [56] (see Theorem 7.5 in Chapter X there). In what follows we denote by $\mathbb{T}$ the Euclidean unit circle in the plane.

Proposition 4.2 (transferring multipliers from the torus to $\mathbb{Z}_n^2$). *Fix an odd integer n. Let $\{\lambda(u,v)\}_{u,v=0}^{\infty}$ be complex numbers such that $\lambda(u,v) = 0$ for $\max\{u,v\} \ge n$. Consider the operators $M : L_p\left(\mathbb{T}^2\right) \to L_p\left(\mathbb{T}^2\right)$ and $M_n : L_p\left(\mathbb{Z}_n^2\right) \to L_p\left(\mathbb{Z}_n^2\right)$ given by*

$$M\left(\sum_{u,v=-\infty}^{\infty} \widehat{f}(u,v)e^{2\pi i(ux+vy)}\right) = \sum_{u,v=0}^{\infty} \lambda(u,v)\widehat{f}(u,v)e^{2\pi i(ux+vy)}$$

and

$$M_n\left(\sum_{u,v=0}^{n-1} \widehat{f}(u,v)e^{\frac{2\pi i}{n}(ua+vb)}\right) = \sum_{u,v=0}^{n-1} \lambda(u,v)\widehat{f}(u,v)e^{\frac{2\pi i}{n}(ua+vb)}.$$

Then

$$\|M_n\|_{L_p(\mathbb{Z}_n^2)\to L_p(\mathbb{Z}_n^2)} \le 81\cdot\|M\|_{L_p(\mathbb{T}^2)\to L_p(\mathbb{T}^2)}.$$

Proof. The proof is a variant of the first part of the proof of Theorem 7.5 in Chapter X in [56] and a small twist on the second part. Since the terminology in [56] is different from ours, we repeat the proof of the first part as well. Recall that the Dirichlet kernels $D_\ell : [0,1] \to \mathbb{C}$ are defined as

$$D_\ell(x) = \sum_{j=-\ell}^{\ell} e^{2\pi i j x},$$

and the Fejér kernels $K_m : [0,1] \to \mathbb{C}$ are

$$K_m(x) = \frac{1}{m+1}\sum_{\ell=0}^{m} D_\ell x = \sum_{j=-m}^{m}\left(1 - \frac{|j|}{m+1}\right)e^{2\pi i j x}.$$

A basic property of D_ℓ is that for any trigonometric polynomial $S(x)$ of degree at most ℓ, namely $S(x) = \sum_{j=-\ell}^{\ell} a_j e^{2\pi i j x}$, we have that $S(x) = S * D_\ell(x) = \int_0^1 S(t)D_\ell(x-t)dt$. The same is true with any other function all of whose jth Fourier coefficients for j between $-\ell$ and ℓ are 1, in particular for the de la Vallée Poussin kernel $2K_{2\ell-1} - K_{\ell-1}$ (see [29]). The well-known advantage of the Fejér kernel over the Dirichlet kernel is that it is everywhere (real and) nonnegative. Note also that $\int_0^1 K_m(t)dt = 1$ for all m. Thus, by convexity of the function t^p, for any trigonometric polynomial S of degree at most ℓ, and for all $x \in [0,1]$,

$$\begin{aligned} |S(x)|^p &= |2S * K_{2\ell-1}(x) - S * K_\ell(x)|^p \\ &\le 3^p\left(\frac{2}{3}\int_0^1 |S(t)|^p K_{2\ell-1}(x-t)dt + \frac{1}{3}\int_0^1 |S(t)|^p K_{\ell-1}(x-t)dt\right). \end{aligned} \tag{4.11}$$

Now let $\omega_{2\ell+1}$ be the measure which assigns mass $\frac{1}{2\ell+1}$ to each of $2\ell+1$ equally spaced points on $[0,1]$. Then it is easy to check that

$$\int_0^1 K_m(x-t)d\omega_{2\ell+1}(x) = \int_0^1 K_m(x-t)dx = 1$$

for all $m \le 2\ell$ and for all $t \in [0,1]$. Integrating (4.11) with respect to $\omega_{2\ell+1}$, we get that for any trigonometric polynomial S of degree at most ℓ

$$\int_0^1 |S(x)|^p d\omega_{2\ell+1}(x) \le 3^p \int_0^1 |S(x)|^p dx. \tag{4.12}$$

It follows that if $S(x,y)$ is a two-variable trigonometric polynomial of degree at most ℓ in each of the variables, i.e., $S(x,y) = \sum_{u,v=-\ell}^{\ell} a_{uv} e^{2\pi i(ux+vy)}$, then

$$\int_{[0,1]^2} |S(x,y)|^p d\omega_{2\ell+1}(x)d\omega_{2\ell+1}(y) \le 9^p \int_{[0,1]^2} |S(x,y)|^p dxdy.$$

It follows from this that, since n is odd, for every $f \in L_p\left(\mathbb{T}^2\right)$,

$$\left\|M_n\left(\sum_{u,v=0}^{n-1}\widehat{f}(u,v)e^{\frac{2\pi i}{n}(ua+vb)}\right)\right\|_{L_p(\mathbb{Z}_n^2)} \le 9\left\|M\left(\sum_{u,v=-\infty}^{\infty}\widehat{f}(u,v)e^{2\pi i(ux+vy)}\right)\right\|_{L_p(\mathbb{T}^2)}.$$

For each trigonometric polynomial of the form $P(x,y) = \sum_{u,v=-n+1}^{n-1} a_{uv} e^{2\pi i(ux+vy)}$, note that

$$\int_{[0,1]^2} P(x,y)d\omega_n(x)d\omega_n(y) = a_0 = \int_{[0,1]^2} P(x,y)dxdy.$$

Fix $f \in L_p\left(\mathbb{Z}_n^2\right)$, $1 < p < \infty$. By the first part of the proof and duality, there is $g \in L_{p^*}(\mathbb{T}^2)$ $(p^* = p/(p-1))$ with $\|g\|_{p^*} = 1$ such that

$$
\begin{aligned}
&\|M_n f\|_{L_p(\mathbb{Z}_n^2)} \\
&\quad \le 9 \int_{[0,1]^2} \left(\sum_{u,v=0}^{n-1} \lambda_j \widehat{f}(u,v) e^{2\pi i(ux+vy)} \right) \overline{g(x,y)} dxdy \\
&\quad = 9 \int_{[0,1]^2} \left(\sum_{u,v=0}^{n-1} \lambda(u,v) \widehat{f}(u,v) e^{2\pi i(ux+vy)} \right) \left(\sum_{u,v=0}^{n-1} \overline{\widehat{g}(u,v)} e^{-2\pi i(ux+vy)} \right) dxdy \\
&\quad = 9 \int_{[0,1]^2} \left(\sum_{u,v=0}^{n-1} \lambda(u,v) \widehat{f}(u,v) e^{2\pi i(ux+vy)} \right) \left(\sum_{u,v=0}^{n-1} \overline{\widehat{g}(u,v)} e^{-2\pi i(ux+vy)} \right) d\omega_n(x) d\omega_n(y) \\
&\quad = 9 \int_{[0,1]^2} \left(\sum_{u,v=0}^{n-1} \widehat{f}(u,v) e^{2\pi i(ux+vy)} \right) \left(\sum_{u,v=0}^{n-1} \lambda(u,v) \overline{\widehat{g}(u,v)} e^{-2\pi i(ux+vy)} \right) d\omega_n(x) d\omega_n(y) \\
&\quad \le 9 \left(\int_{[0,1]^2} \left| \sum_{u,v=0}^{n-1} \widehat{f}(u,v) e^{2\pi i(ux+vy)} \right|^p d\omega_n(x) d\omega_n(y) \right)^{1/p} \\
&\qquad \cdot \left(\int_{[0,1]^2} \left| \sum_{u,v=0}^{n-1} \lambda(u,v) \overline{\widehat{g}(u,v)} e^{-2\pi i(ux+vy)} \right|^{p^*} d\omega_n(x) \omega_n(y) \right)^{1/p^*} \\
&\quad \le 81 \cdot \|f\|_{L_p(\mathbb{Z}_n^2)} \left(\int_{[0,1]^2} \left| \sum_{u,v=0}^{n-1} \overline{\lambda(u,v)} \widehat{g}(u,v) e^{2\pi i(ux+vy)} \right|^{p^*} dx \right)^{1/p^*} \\
&\quad \le 81 \cdot \|f\|_{L_p(\mathbb{Z}_n^2)} \cdot \|M\|_{L_p(\mathbb{T}^2) \to L_p(\mathbb{T}^2)},
\end{aligned}
$$

where the second to last inequality follows from (4.12) and the last inequality (that is, the fact that the norm of a multiplier in $L_p\left(\mathbb{T}^2\right)$ is the same as the norm of the conjugate multiplier in $L_{p^*}\left(\mathbb{T}^2\right)$) follows from duality. The case $p = 1$ (and also a similar inequality for the ∞ norm) follows easily from the L_p cases. □

Proposition 4.2 implies that it is enough to obtain L_p to L_p bounds for the operators T_{m_1} and T_{m_2}, where m_1, m_2 are as in (4.10), as operators on functions on the torus $\mathbb{T}^2$. By a theorem of de Leeuw [11], it is enough to obtain such bounds when we think of T_{m_1} and T_{m_2} as operators on functions on $\mathbb{R}^2$ (see [55] for the respective result in the case of weak $(1,1)$ bounds). The continuous version of the Hörmander–Mihlin multiplier theorem now applies, but unfortunately its conditions are not satisfied. However, a (once again tedious) computation shows it is possible to apply the Marcinkiewicz multiplier theorem (see [47, 52]), in combination with bounds on the Hilbert transform [47, 52], to obtain bounds similar to (4.7) and (4.8) with $O(p)$ replaced by $O(\text{poly}(p))$. (It is quite easy to obtain a bound of $O(p^3)$, and with more work this can be reduced to $O(p^2)$. However, we do not see a simple way to obtain $O(p)$ using this approach.)

Remark 4.1. Consider the mapping $S : \mathscr{P}_{\mathbb{Z}_n^2} \to L_1\left(\mathbb{Z}_n^2\right)$ given by

$$
S\mu := \sum_{(u,v) \in \mathbb{Z}_n^2 \setminus \{(0,0)\}} \left(\left| e^{\frac{2\pi i u}{n}} - 1 \right| + \left| e^{\frac{2\pi i v}{n}} - 1 \right| \right) \cdot \widehat{\mu}(u,v) e_{uv}.
$$

Using considerations similar to the above (see Proposition III.A.3 in [54] for a continuous counterpart), it is possible to show that S has distortion $O(\text{polylog}(n))$. However, we were unable to get this bound down to $O(\log n)$ as in Theorem 1.4. Nevertheless, this embedding might be of interest since it reduces the dimension of the ambient L_1 space by a factor of 2.

5. Discussion and open problems. There are several interesting problems that arise from the results presented in this paper—we shall discuss some of them in the list below.

1. The most natural problem that is left open is to determine the asymptotic behavior of $c_1\left(\{0,1\ldots,n\}^2,\tau\right)$. It seems hard to use the ideas in section 4 to obtain an embedding of distortion $O\left(\sqrt{\log n}\right)$, as the known bounds on multipliers usually give a weak $(1,1)$ inequality at best. We do not know the actual distortion of the embedding in Theorem 1.4.
2. Remark 4.1 implies that the Banach–Mazur distance between the (n^2-1)-dimensional normed space $\mathscr{M}_{\mathbb{Z}_n^2,\tau}$ and $\ell_1^{n^2-1}$ is $O(\text{polylog}(n))$. It would be interesting to determine the asymptotic behavior of this distance. In particular, it is not clear whether the L_1 (embedding) distortion of $\mathscr{M}_{\mathbb{Z}_n^2,\tau}$ behaves differently from its Banach–Mazur distance from $\ell_1^{n^2-1}$.
3. We did not attempt to study the L_1 distortion of $\mathscr{M}_{\{0,1,\ldots,n\}^d,\tau}$ for $d \geq 3$. Observe that this space contains $\mathscr{M}_{\{0,1,\ldots,n\}^2,\tau}$, and so the $\Omega\left(\sqrt{\log n}\right)$ lower bound still applies. But the result of [30] shows that the transportation cost metric on the Hamming cube $\{0,1\}^d$ has distortion $\Theta(d)$, and so some improvements are still possible. Note that in higher dimensions it becomes interesting to study the transportation cost distance when $\mathbb{R}^d$ is equipped with other norms. The Banach–Mazur distance between ℓ_1^d and arbitrary d-dimensional norms has been studied in [7, 49, 13]. In particular, the result of [13] states that any d-dimensional Banach space is at distance $O\left(d^{5/6}\right)$ from ℓ_1^d. Combining this fact with the lower bound on the L_1 distortion of the transportation cost distance on the Hamming (ℓ_1) cube cited above, we see that for any norm $\|\cdot\|$ on $\mathbb{R}^d$, $c_1\left(\mathscr{P}_{(\mathbb{R}^d,\|\cdot\|),\tau}\right) = \Omega\left(d^{1/6}\right)$. It would be interesting to study the dependence on d for general norms on $\mathbb{R}^d$.
4. As stated in Remark 3.2, it would be interesting to study the rate with which the Euclidean distortion $c_2\left(\mathscr{P}_{\{0,\ldots,n\}^2},\sqrt{\tau}\right)$ tends to infinity.
5. As stated in Remark 3.3, we do not know whether $\left(\mathscr{P}_{[0,1]^2},\tau\right)$ admits a uniform embedding into Hilbert space.
6. The present paper rules out the "low distortion approach" to nearest neighbor search in the Earthmover metric via embeddings into L_1. However, it might still be possible to find *nearest neighbor preserving embeddings* into L_1 in the sense of [25].
7. On the more "applied side," as stated in the introduction, there is a possibility that the embedding of Theorem 1.4 behaves better than the theoretical distortion guarantee of $O(\log n)$ in "real life" situations, since it is often the case that the bulk of the Fourier spectrum is concentrated on a sparse set of frequencies. Additionally, it might be worthwhile to "thin out" some frequencies of the given set of images before embedding into L_1 (and then using the known L_1 nearest neighbor search databases). It would be interesting to carry out such "tweaking" of our algorithm in a more experimental setting.

Acknowledgments. We are grateful to David Jerison and Terence Tao for several helpful suggestions. The first author wishes to thank Piotr Indyk for his encouragement to work on the planar Earthmover problem. We also thank Guillaume Aubrun for correcting several mistakes in our original manuscript.

LEARNING MONOTONE DECISION TREES IN POLYNOMIAL TIME*

RYAN O'DONNELL[†] AND ROCCO A. SERVEDIO[‡]

Abstract. We give an algorithm that learns any monotone Boolean function $f\colon \{-1,1\}^n \to \{-1,1\}$ to any constant accuracy, under the uniform distribution, in time polynomial in n and in the decision tree size of f. This is the first algorithm that can learn arbitrary monotone Boolean functions to high accuracy, using random examples only, in time polynomial in a reasonable measure of the complexity of f. A key ingredient of the result is a new bound showing that the average sensitivity of any monotone function computed by a decision tree of size s must be at most $\sqrt{\log s}$. This bound has proved to be of independent utility in the study of decision tree complexity [O. Schramm, R. O'Donnell, M. Saks, and R. Servedio, *Every decision tree has an influential variable*, in Proceedings of the 46th Annual IEEE Symposium on Foundations of Computer Science, IEEE Computer Society, Los Alamitos, CA, 2005, pp. 31–39]. We generalize the basic inequality and learning result described above in various ways—specifically, to partition size (a stronger complexity measure than decision tree size), p-biased measures over the Boolean cube (rather than just the uniform distribution), and real-valued (rather than just Boolean-valued) functions.

1. Introduction.

1.1. Computationally efficient learning from random examples.

In the two decades since Valiant introduced the probably approximately correct (PAC) learning model [31], a major goal in computational learning theory has been the design of computationally efficient algorithms for learning Boolean functions from random examples. The original distribution-free PAC learning model of Valiant required that for *any* distribution $\mathcal{D}$ over the domain of examples (which throughout this paper is $\{-1,1\}^n$), the learning algorithm must with high probability succeed in generating a hypothesis for the unknown target function which is highly accurate relative to $\mathcal{D}$. Despite much effort over a twenty year span, very few efficient learning algorithms have been obtained in this demanding model. Thus the focus of much work has shifted to the natural *uniform distribution* PAC learning model, in which the examples used for learning are uniformly distributed over $\{-1,1\}^n$ (we give a precise definition of this learning model in section 2).

An easy information-theoretic argument shows that no poly(n)-time algorithm can learn arbitrary Boolean functions $f : \{-1,1\}^n \to \{-1,1\}$ to accuracy nonnegligibly better than 1/2. Consequently, the most ambitious conceivable goal in uniform

distribution learning is to obtain an algorithm that can learn any Boolean function $f : \{-1,1\}^n \to \{-1,1\}$ in time polynomial in n and in a reasonable measure of the "size" or complexity of f. Different complexity measures for Boolean functions thus give rise to different notions of efficient learnability; for example, one might hope for an algorithm that can learn any Boolean function f in time polynomial in n and $DT(f)$ the number of leaves in the smallest Boolean decision tree that computes f (this is the well-studied—and notoriously difficult—problem of "learning decision trees under the uniform distribution"). A more ambitious goal would be to learn in time polynomial in $DNF(f)$, the number of terms in the smallest disjunctive normal form formula for f, or $AC^0_d(f)$, the size of the smallest depth-d AND/OR/NOT circuit for f.

Unfortunately, learning arbitrary Boolean functions in polynomial time in this sense has proved to be intractably difficult for all "reasonable" size measures. For the strongest reasonable size measure (Boolean circuit size), Valiant already observed in [31] that the existence of cryptographic pseudorandom functions [11] implies the nonexistence of uniform distribution algorithms that can learn any function f in time polynomial in the Boolean circuit size of f. This negative result was strengthened by Kharitonov [20], who showed that (under a strong but plausible assumption on the hardness of integer factorization) no uniform distribution algorithm can learn every f in time polynomial in $AC^0_d(f)$ for some fixed constant d. In fact, despite intensive research, no algorithm is currently known that learns arbitrary Boolean functions in time polynomial in *any* reasonable size measure; such an algorithm would constitute a tremendous breakthrough in computational learning theory; see, e.g., [2]. (We stress that simple arguments such as those in [5] show that there is no *information-theoretic* impediment to learning from a polynomial number of examples; the apparent difficulty is in designing a *polynomial-time* algorithm.)

1.2. Background: Learning monotone functions. Confronted with the difficulties described above, researchers have tried to learn various restricted classes of Boolean functions. The most natural and intensively studied such class is the class of all *monotone* functions $f : \{-1,1\}^n \to \{-1,1\}$, i.e., functions that satisfy $f(x) \geq f(y)$ whenever $x \geq y$ in the partial order on $\{-1,1\}^n$.

Many partial results on learning restricted subclasses of monotone functions under the uniform distribution have been obtained. Sakai and Maruoka [27] gave a poly(n)-time algorithm that can learn any monotone size-$O(\log n)$ disjunctive normal form (DNF) under the uniform distribution; this result was subsequently generalized by Bshouty [6] to a somewhat broader class than the $O(\log n)$-term DNF. The main result of Bshouty and Tamon in [7] is a proof that any monotone function can be learned to accuracy ϵ in $2^{\tilde{O}(\sqrt{n}/\epsilon)}$ time; they used this result to obtain a poly(n)-time algorithm (for ϵ constant) that can learn a class of functions that includes monotone $O(\log^2 n/(\log\log n)^3)$-term DNF. More recently, Servedio [30] showed that monotone $2^{O(\sqrt{\log n})}$-term DNF can be learned to constant accuracy ϵ in poly(n) time. Other researchers have also studied the problem of learning monotone functions under the uniform distribution (see, e.g., [18, 3, 34, 12, 21]), but prior to the current work no algorithms were known for learning arbitrary monotone functions in time polynomial in a reasonable size measure.

1.3. The main learning result. We give the first algorithm that learns any monotone Boolean function f, under the uniform distribution, in time polynomial in a reasonable measure of the size of f. Given a Boolean function $f : \{-1,1\}^n \to \{-1,1\}$, the *partition size* $P(f)$ of f is the minimum size partition of the Boolean cube $\{-1,1\}^n$

into disjoint subcubes such that f is constant on each subcube. Note that this is a strictly stronger measure of complexity than decision tree size; i.e., $P(f) \leq DT(f)$. Our main learning result is the following.

THEOREM 1. *There is an algorithm that (with confidence $1 - \delta$) can learn any monotone Boolean function $f : \{-1,1\}^n \to \{-1,1\}$ to accuracy ϵ, given uniform random examples $(x, f(x))$, in time poly$(n, P(f)^{1/\epsilon^2}) \cdot \log(1/\delta)$.*

For any constant accuracy $\epsilon = \Theta(1)$, the algorithm runs in time polynomial in the partition size of f and hence also in the decision tree size of f. We feel that this constitutes progress toward learning monotone functions in time polynomial in their DNF size, an open problem in computational learning theory (see, e.g., the open questions posed in [15, 3, 1]).

1.4. The approach: Bounding average sensitivity of monotone functions. The main ingredient of our learning algorithm is a new inequality bounding the average sensitivity (sum of influences of all coordinates) of monotone Boolean functions. We give here a simplified version of the theorem (the full result is given in Theorem 3).

THEOREM 2. *Every monotone Boolean function f has average sensitivity at most $\sqrt{\log P(f)}$.*[1]

This edge-isoperimetric-type result is of independent interest; indeed, our most general version of it, Theorem 7, recently played a critical role in a new lower bound on the randomized decision tree complexity of monotone graph properties—see [29].

Combining this new inequality with a result of Friedgut [8] that says that Boolean functions with low average sensitivity essentially depend on only a small number of coordinates, we can show that (i) there is a set of $P(f)^{O(1/\epsilon^2)}$ many Fourier coefficients of f which contain all but ϵ of the "Fourier weight" of f, and (ii) this set of Fourier coefficients can be efficiently identified from uniform random examples only. Applying standard machinery on approximating Boolean functions via their Fourier representations, we obtain Theorem 1.

Our approach seems quite robust. We generalize the basic scenario described above by (i) considering *real-valued* monotone functions that map $\{-1,1\}^n$ into the continuous interval $[-1,1]$ rather than the discrete range $\{-1,1\}$, and (ii) considering general p-biased product measures over $\{-1,1\}^n$ rather than the uniform distribution. We show that suitable variants of all of our intermediate results hold and that our main learning result holds exactly as before (i.e., runs in time $P(f)^{O(1/\epsilon^2)}$) in these generalized scenarios.

2. Preliminaries.

2.1. Boolean functions and complexity measures. As is standard in complexity theory and learning theory, we will be interested in complexity measures for Boolean functions f given by the syntactic size of the smallest representation of f under various natural representation schemes. We will chiefly be concerned with partition size and decision tree size, two complexity measures that we now define.

Given a Boolean function $f : \{-1,1\}^n \to \{-1,1\}$, the *decision tree size* of f, denoted $DT(f)$, is the number of leaves in the smallest Boolean decision tree (with variables $x_1, \dots, x_n$ at the internal nodes and bits -1, 1 at the leaves) that computes f. The *partition size* $P(f)$ of f is the minimum number of disjoint subcubes that the Boolean cube $\{-1,1\}^n$ can be partitioned into such that f is constant on each subcube.

[1] Here and throughout the paper "log" denotes logarithm to the base two.

Since any s-leaf decision tree induces a partition of $\{-1,1\}^n$ into s disjoint subcubes (corresponding to the root-to-leaf paths in the tree), we have that $P(f) \leq DT(f)$ for all f. In fact, $P(\cdot)$ is known to be a superpolynomially stronger measure than $DT(\cdot)$ even for monotone functions; Savický [28] has given a monotone Boolean function $g : \{-1,1\}^n \to \{-1,1\}$ which has $P(g) = \mathrm{poly}(n)$ and $DT(g) = 2^{\Omega(\log^{1.26}(n))}$.

2.2. Background: Uniform distribution learning. A *concept class* $\mathcal{F}$ is a collection $\cup_{n\geq 1}\mathcal{F}_n$ of Boolean functions where each $f \in \mathcal{F}_n$ is a function from $\{-1,1\}^n$ to $\{-1,1\}$. Throughout this paper we consider the concept class consisting of all monotone Boolean functions.

The uniform distribution probably approximately correct (PAC) learning model has been studied by many authors; see, e.g., [4, 7, 13, 14, 20, 22, 24, 27, 30, 33]. In this framework a learning algorithm has access to an *example oracle* $EX(f)$, where $f \in \mathcal{F}_n$ is the unknown *target function* the algorithm is trying to learn. The oracle $EX(f)$ takes no inputs and, when queried, in one time step outputs a labeled example $(x, f(x))$, where x is drawn from the uniform distribution $\mathcal{U}$ over $\{-1,1\}^n$.

We say that a Boolean function $h\colon \{-1,1\}^n \to \{-1,1\}$ is an *ϵ-approximator for f* if it satisfies $\Pr_{x\in\mathcal{U}}[h(x) = f(x)] \geq 1-\epsilon$. The goal of a uniform distribution PAC learning algorithm is to generate an ϵ-approximator for the unknown target function f. More precisely, an algorithm A is a *learning algorithm for concept class $\mathcal{F}$* if the following condition holds: for all $n \geq 1$, all $f \in \mathcal{F}_n$, and all $0 < \epsilon, \delta < 1$, if A is given ϵ and δ as input and has access to $EX(f)$, then with probability at least $1-\delta$ algorithm A outputs an ϵ-approximator for f. We further say that *A PAC learns $\mathcal{F}$ in time t* if A runs for at most t time steps and outputs a hypothesis h which can be evaluated on any point $x \in \{-1,1\}^n$ in time t. Here t will depend on the dimension n and the size s of f under some complexity measure, as well as on ϵ and δ. We note that for the learning algorithm presented and analyzed in this paper, the dominant ingredient in the running time t is collecting a sample of essentially t labeled examples using the oracle $EX(f)$; the computation that is performed after this sample has been obtained is relatively simple and inexpensive.

2.3. Fourier representation. Fourier techniques have proven to be a powerful tool for obtaining uniform distribution learning algorithms; see the survey of Mansour [23] for an overview.

Except in section 5, we will always view $\{-1,1\}^n$ as a probability space under the uniform distribution which we denote by $\mathcal{U}$. Let $f : \{-1,1\}^n \to \mathbf{R}$ be a real-valued function. Recall that the *Fourier expansion* of f is

$$f(x) = \sum_{S\subseteq[n]} \hat{f}(S)\chi_S(x),$$

where $\chi_S(x)$ denotes $\prod_{i\in S} x_i$ and $\hat{f}(S)$ denotes $\mathbf{E}_{x\in\mathcal{U}}[f(x)\chi_S(x)]$. It is well known that every f has a unique Fourier expansion. Parseval's theorem states that for any $f : \{-1,1\}^n \to \mathbf{R}$ we have $\sum_{S\subseteq[n]} \hat{f}(S)^2 = \mathbf{E}_{x\in\mathcal{U}}[f(x)^2]$, which is clearly 1 if f's range is $\{-1,1\}$.

For Boolean-valued functions $f\colon \{-1,1\}^n \to \{-1,1\}$, the *influence of coordinate i on f* is defined as $\mathrm{Inf}_i(f) = \Pr_{x\in\mathcal{U}}[f(x) \neq f(x^{(\oplus i)})]$, where $x^{(\oplus i)}$ denotes x with the ith bit flipped. In general we have $\mathrm{Inf}_i(f) = \sum_{S\ni i} \hat{f}(S)^2$; it is also well known (see, e.g., [17]) that if f is monotone then $\mathrm{Inf}_i(f) = \hat{f}(\{i\})$. For notational ease we will henceforth write $\hat{f}(i)$ in place of $\hat{f}(\{i\})$. The *average sensitivity* of a Boolean function

f is $\mathrm{I}(f) = \sum_{i=1}^n \mathrm{Inf}_i(f)$; this is the expected number of sensitive coordinates for a random input $x \in \{-1,1\}^n$. Note that $\mathrm{I}(f) = \sum_{i=1}^n \hat{f}(i)$ for monotone f.

3. The average sensitivity of monotone functions.

A well-known, folkloric edge-isoperimetric inequality for the Boolean cube states that for any monotone function $f\colon \{-1,1\}^n \to \{-1,1\}$, we have $\mathrm{I}(f) \le I(\mathsf{Maj}_n) = \Theta(\sqrt{n})$. (This follows from, e.g., the Kruskal–Katona theorem; see [9] for an explicit proof.) This bound $\mathrm{I}(f) \le O(\sqrt{n})$ is the key to the main result of [7] that any monotone Boolean function can be learned to accuracy ϵ in time $2^{\tilde{O}(\sqrt{n}/\epsilon)}$.

In this section we give a more refined bound on $\mathrm{I}(f)$ that depends on $P(f)$, the partition size of f. Our new bound states that $\mathrm{I}(f) \le \sqrt{\log P(f)}$ for any monotone f. This yields the usual isoperimetric inequality mentioned as a special case but is much stronger for functions f which have partition size $P(f) = 2^{o(n)}$.

3.1. Subcube partitions.

Let $f\colon \{-1,1\}^n \to \{-1,1\}$ be a Boolean function and let $\mathcal{C} = \{C^1, \dots, C^s\}$ be a subcube partition for f, so $C^1, \dots, C^s$ partition $\{-1,1\}^n$ into s subcubes on each of which f is constant. By abuse of notation we will also identify a cube C^t with a length-n vector over $\{-1,0,1\}$ in the obvious way; i.e., the ith coordinate of the string C^t is

$$(C^t)_i = \begin{cases} 1 & \text{if } x_i = 1 \text{ for all } x \in C^t, \\ -1 & \text{if } x_i = -1 \text{ for all } x \in C^t, \\ 0 & \text{otherwise.} \end{cases}$$

Let us also introduce notation for the sets of coordinates which cubes fix:

$$\mathrm{pluses}(C^t) = \{i : (C^t)_i = 1\}, \qquad \mathrm{minuses}(C^t) = \{i : (C^t)_i = -1\},$$

$$\mathrm{fixed}(C^t) = \mathrm{pluses}(C^t) \cup \mathrm{minuses}(C^t).$$

Given an input $x \in \{-1,1\}^n$, we write $C(x)$ to denote the subcube C^t in $\mathcal{C}$ to which x belongs. We also write δ_i to denote $\Pr_{x \in \mathcal{U}}[i \in \mathrm{fixed}(C(x))]$, the probability that the subcube partition "queries" x_i. Note that $\sum_{i=1}^n \delta_i$ equals $\mathbf{E}_{x \in \mathcal{U}}[|\mathrm{fixed}(C(x))|]$, the average number of coordinates $\mathcal{C}$ "queries."

When we draw $x \in \mathcal{U}$, this determines $C(x)$. However, we can equally well view the random determination of $(x, C(x))$ the other way around. Indeed, we will almost always consider choosing a uniformly random string x as follows:

1. Pick a random subcube R from $\mathcal{C}$ by choosing each C^t with probability $2^{-|\mathrm{fixed}(C^t)|}$. In general we will write $R \in \mathcal{C}$ to indicate that R is a random variable given by choosing a subcube from among $C^1, \dots, C^s$ according to this natural probability distribution on subcubes.
2. Now choose x uniformly at random from the strings in R. We will write $x \in R$ to indicate that x is chosen randomly in this way.

After this procedure, x indeed has the uniform distribution. Furthermore, note that the value $f(x)$ is determined as soon as R is chosen; thus we may abuse notation and write $f(R)$ for this quantity.

We will require the following very easy lemmas.

LEMMA 1. *Let R be any subcube and let $i \ne j$ be in $[n]$. Then $\mathbf{E}_{x \in R}[x_i] = R_i$ and $\mathbf{E}_{x \in R}[x_i x_j] = R_i R_j$.*

Proof. The proof is immediate from the definitions. □

LEMMA 2. *Let $i \neq j$ be in $[n]$. Then $\mathbf{E}_{R\in\mathcal{C}}[R_i] = 0$ and $\mathbf{E}_{R\in\mathcal{C}}[R_iR_j] = 0$.*

Proof. We prove the second statement, with the first being even easier:

$$0 = \mathop{\mathbf{E}}_{x\in\mathcal{U}}[x_ix_j] = \mathop{\mathbf{E}}_{R\in\mathcal{C}}\mathop{\mathbf{E}}_{x\in R}[x_ix_j] = \mathop{\mathbf{E}}_{R\in\mathcal{C}}[R_iR_j],$$

where in the last step we used Lemma 1. □

3.2. Proof of the main inequality. The proof requires one basic lemma.

LEMMA 3. *Let $f\colon \{-1,1\}^n \to \{-1,1\}$ be a Boolean function with a subcube partition $\mathcal{C} = \{C^1,\dots,C^s\}$. Then for each $i = 1,\dots,n$ we have $\hat{f}(i) = \mathbf{E}_{R\in\mathcal{C}}[f(R)R_i]$, and hence we have $\sum_{i=1}^n \hat{f}(i) = \mathbf{E}_{R\in\mathcal{C}}[f(R)\cdot\sum_{i=1}^n R_i]$.*

Proof. Fix any i in $\{1,\dots,n\}$. We have

$$\hat{f}(i) = \mathop{\mathbf{E}}_{x\in\mathcal{U}}[f(x)x_i] = \mathop{\mathbf{E}}_{R\in\mathcal{C}}\mathop{\mathbf{E}}_{x\in R}[f(x)x_i] = \mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[f(R)\mathop{\mathbf{E}}_{x\in R}[x_i]\right] = \mathop{\mathbf{E}}_{R\in\mathcal{C}}[f(R)R_i],$$

where in the last step we used Lemma 1. □

With this lemma in hand we can give the proof that $\mathrm{I}(f) \le \sqrt{\log P(f)}$ for monotone f.

THEOREM 3. *Let $f\colon \{-1,1\}^n \to \{-1,1\}$ be a Boolean function with a subcube partition $\mathcal{C} = \{C^1,\dots,C^s\}$. Then we have*

$$\sum_{i=1}^n \hat{f}(i) \le \sqrt{\sum_{i=1}^n \delta_i} \le \sqrt{\log s},$$

and if f is monotone we may thus write $\mathrm{I}(f) \le \sqrt{\log s}$.

Proof. Since f is ± 1-valued, from Lemma 3 we have

$$\sum_{i=1}^n \hat{f}(i) \le \mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[\left|\sum_{i=1}^n R_i\right|\right] \tag{1}$$

with equality iff $f(x) = \mathrm{sgn}(\sum_{i=1}^n C(x)_i)$ for all x, i.e., $f(x)$ is the majority of the bits that are set in $C(x)$. Applying Cauchy–Schwarz, we have

$$\begin{aligned}\mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[\left|\sum_{i=1}^n R_i\right|\right] \le \sqrt{\mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[\left(\sum_{i=1}^n R_i\right)^2\right]} &= \sqrt{\mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[\sum_{i=1}^n R_i^2 + 2\sum_{i<j} R_iR_j\right]}\\ &= \sqrt{\mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[|\mathrm{fixed}(R)|\right]} \qquad (2)\\ &= \sqrt{\mathop{\mathbf{E}}_{x\in\mathcal{U}}\left[|\mathrm{fixed}(C(x))|\right]} = \sqrt{\sum_{i=1}^n \delta_i},\end{aligned}$$

where (2) uses Lemma 2.

This proves the first inequality; to finish the proof we must show that $\sum_{i=1}^n \delta_i \le \log s$. We have

$$\sum_{i=1}^n \delta_i = \mathop{\mathbf{E}}_{R\in\mathcal{C}}[|\mathrm{fixed}(R)|] = \sum_{t=1}^s 2^{-|\mathrm{fixed}(C^t)|}\cdot|\mathrm{fixed}(C^t)| = H(R),$$

where $H(R)$ denotes the binary entropy of the random variable $R \in \mathcal{C}$. Since $\mathcal{C}$, the support of R, is of cardinality s, this entropy is at most $\log s$. □

Remarks.

1. We note that our proof can easily be used to recover the standard upper bound $\mathrm{I}(f) \le \mathrm{I}(\mathsf{Maj}_n)$ for any monotone Boolean function f on n variables. (Recall that $\mathrm{I}(\mathsf{Maj}_n) \sim \sqrt{\frac{2}{\pi}}\sqrt{n}$.) This is because in upper-bounding $\mathbf{E}_{R\in\mathcal{C}}[|\sum_{i=1}^{n} R_i|]$, we may assume without loss of generality that each subcube $C^t \in \mathcal{C}$ fixes exactly n bits. (To see this, suppose that C^t fixes $n' < n$ bits and we subdivide C^t into two subcubes each fixing one more bit. If $\sum_{i=1}^{n}(C^t)_i \neq 0$ then the contribution of C^t to $\mathbf{E}_{R\in\mathcal{C}}[|\sum_{i=1}^{n} R_i|]$ is unchanged by this subdivision, and if $\sum_{i=1}^{n}(C^t)_i = 0$ then the contribution increases.) But now observe that equality occurs in inequality (1), as noted above, if $f(x)$ always equals the majority of the bits set in $C(x)$, i.e., if $f(x) = \mathsf{Maj}_n(x)$ for all x.
2. The bound $\mathrm{I}(f) \le \sqrt{\log P(f)}$ need not hold for nonmonotone f; an easy example is the parity function on n variables for which $I(f) = \log P(f) = n$.

4. Learning monotone Boolean functions.

4.1. Spectral concentration. In this subsection we show that any monotone Boolean function has all but ϵ of its Fourier spectrum concentrated on a set of $P(f)^{O(1/\epsilon^2)}$ many Fourier coefficients.

In [8] Friedgut showed that any Boolean function with "low" average sensitivity is well approximated by a function that depends only on a "small" number of coordinates. In particular, the proof of Corollary 3.2 in [8] yields the following.

THEOREM 4. *There is a universal constant $K < \infty$ such that for all $f\colon \{-1,1\}^n \to \{-1,1\}$ and $\epsilon > 0$, if*

$$t = 2\mathrm{I}(f)/\epsilon, \quad J = \{i : \mathrm{Inf}_i(f) \ge K^{-t}\}, \quad \mathcal{S} = \{S : \ S \subseteq J, \ |S| \le t\},$$

then $\sum_{S\notin\mathcal{S}} \hat{f}(S)^2 \le \epsilon$.

Combining this result with Theorem 3, we obtain the following theorem.

THEOREM 5. *Let $f\colon \{-1,1\}^n \to \{-1,1\}$ be a monotone function, $\epsilon > 0$, and $t = 2\sqrt{\log P(f)}/\epsilon$. Let J and $\mathcal{S}$ be as in Theorem 4. Then $|\mathcal{S}| = P(f)^{O(1/\epsilon^2)}$ and $\sum_{S\notin\mathcal{S}} \hat{f}(S)^2 \le \epsilon$.*

Proof. The second part of the conclusion follows immediately from combining Theorems 3 and 4. As for bounding $|\mathcal{S}|$, we have $|\mathcal{S}| = \sum_{i=0}^{t}\binom{|J|}{i} \le O(|J|^t)$. But we also have $|J| \le \mathrm{I}(f)K^t \le tK^t$ using Theorem 3, and so $|J|^t \le 2^{O(t^2)} = P(f)^{O(1/\epsilon^2)}$, as claimed. □

4.2. Approximating Boolean functions with spectral concentration. The following proposition is a straightforward generalization of the "low-degree" algorithm of Linial, Mansour, and Nisan [22].

PROPOSITION 4. *There is an algorithm A with the following property: Let $f : \{-1,1\}^n \to [-1,1]$ and let $\mathcal{S} \subseteq 2^{[n]}$ be a collection of subsets of $[n]$ with the property that $\sum_{S\in\mathcal{S}} \hat{f}(S)^2 \ge 1-\epsilon$. Then if A is given $\mathcal{S}$, access to $EX(f)$, and parameters $\delta, \theta > 0$, it runs in poly$(n, |\mathcal{S}|, 1/\theta)\cdot\log(1/\delta)$ time and with probability $1-\delta$ outputs a real-valued function $g : \{-1,1\}^n \to \mathbf{R}$ of the form $g(x) = \sum_{S\in\mathcal{S}} c_S\chi_S(x)$ such that $\mathbf{E}_{x\in\mathcal{U}}[(f(x)-g(x))^2] \le \epsilon + \theta$.*

Proof sketch. Algorithm A draws a sample of m labeled examples from $EX(f)$ and uses them to empirically estimate each of the Fourier coefficients $\hat{f}(S)$ for $S \in \mathcal{S}$, using the fact that $\hat{f}(S) = E[f(x)\chi_S(x)]$; the coefficients c_S are the empirical estimates thus obtained. A standard analysis (see, e.g., Theorem 4.3 of [23]) shows that $m = \mathrm{poly}(|\mathcal{S}|, 1/\theta)\cdot\log(1/\delta)$ suffices to give the proposition. □

We remark that if $f : \{-1,1\}^n \to \{-1,1\}$ is Boolean-valued, and $g : \{-1,1\}^n \to \mathbf{R}$ satisfies $\mathbf{E}_{x\in\mathcal{U}}[(f(x) - g(x))^2] \le \epsilon'$, then defining $h : \{-1,1\}^n \to \{-1,1\}$ by $h(x) = \mathrm{sgn}(g(x))$, it is easily seen that $\Pr_{x\in\mathcal{U}}[h(x) \ne f(x)] \le \epsilon'$ (see, e.g., [22, 23]).

4.3. Learning monotone Boolean functions in polynomial time. We now give the proof of Theorem 1. Given Theorem 5 and Proposition 4, the idea behind our main learning algorithm is obvious: Given uniform examples from a target function f, identify all coordinates with influence at least $2^{-O(\sqrt{\log P(f)}/\epsilon)}$, and then run the algorithm from Proposition 4 using the set $\mathcal{S}$ from Theorem 5. (We note that a similar algorithm is used by Servedio in [30], though the analysis is completely different.)

By a standard doubling argument, we may assume the partition size $P(f)$ is known to the learner (see Exercise 1.5 of [19]). We now show that the learner can actually identify the sufficiently influential coordinates. This is because f is monotone, and consequently $\mathrm{Inf}_i(f) = \hat{f}(i) = \mathbf{E}_{x\in U}[f(x)x_i]$. Since the learner can empirically estimate this latter quantity to within $\pm\theta$ in time $\mathrm{poly}(n, 1/\theta) \cdot \log(1/\delta)$ (with confidence $1 - \delta$) by sampling, the learner can determine each influence $\mathrm{Inf}_i(f)$ of f to within an additive $2^{-O(\sqrt{\log P(f)}/\epsilon)}$ in $\mathrm{poly}(n, 2^{O(\sqrt{\log P(f)}/\epsilon)})$ time steps, and it is easy to see this is sufficient to maintain correctness and the same time bounds. Complete details can be found in a more general setting in Appendix B.

5. Generalizations: Real-valued functions and p-biased measures.

In this section we extend our learning result to real-valued functions $f : \{-1,1\}^n \to [-1,1]$ on the p-biased discrete cube. As in the Boolean case, we say a real-valued function f is monotone if $f(x) \ge f(y)$ whenever $x \ge y$. The partition size $P(f)$ of $f : \{-1,1\}^n \to [-1,1]$ is still defined as the minimum number of disjoint subcubes that $\{-1,1\}^n$ can be partitioned into such that f is constant on each subcube.

The p-biased measure on $\{-1,1\}^n$ is the probability distribution assigning probability $p^{|\mathrm{pluses}(x)|}q^{|\mathrm{minuses}(x)|}$ to the input $x \in \{-1,1\}^n$. (Here and throughout q denotes $1-p$.) We will write $\{-1,1\}^n_{(p)}$ to indicate that $\{-1,1\}^n$ is endowed with the p-biased measure and write $\Pr_p[\cdot]$ and $\mathbf{E}_p[\cdot]$ to denote probabilities and expectations over $x \in \{-1,1\}^n_{(p)}$.

We use standard notions of PAC learning for functions $f : \{-1,1\}^n_{(p)} \to [-1,1]$. This involves only slightly altering the definitions from section 2.2. Specifically, examples are now from the p-biased distribution $\{-1,1\}^n_{(p)}$ instead of the uniform distribution;[2] and, the definition of an ϵ-approximator is a function $h : \{-1,1\}^n_{(p)} \to \mathbf{R}$ satisfying $\mathbf{E}_p[(h - f)^2] \le \epsilon$ (note that we use the "square loss" as is common in learning or approximating real-valued functions). For other work studying PAC learning under the p-biased distribution, see, e.g., [10, 12, 25, 30].

Our main learning theorem completely extends to the p-biased, real-valued case, as follows.

THEOREM 6. *There is an algorithm that (with confidence $1 - \delta$) can learn any monotone Boolean function $f : \{-1,1\}^n_{(p)} \to [-1,1]$ to accuracy ϵ, given p-biased random examples $(x, f(x))$, in time poly$(n, P(f)^{1/\epsilon^2}) \cdot \log(1/\delta)$.*

Again, note that for any constant accuracy $\epsilon = \Theta(1)$, the algorithm runs in polynomial time in the partition size of f. Further note that unlike some p-biased PAC learning algorithms such as [10, 30], our algorithm's running time has no dependence

[2] There is a question as to whether or not the learning algorithm "knows" the value of p in advance. We show in Appendix B that we may assume without loss of generality that the learning algorithm knows p.

on p and thus we have the claimed runtime bound even if p depends on n or $P(f)$, such as $p = 1/\sqrt{n}$.

5.1. Background: Fourier analysis under *p*-biased measures. Given two functions $f, g : \{-1,1\}^n_{(p)} \to \mathbf{R}$, the p-biased inner product is defined as $\langle f, g\rangle_p = \mathbf{E}_p[f(x)g(x)]$. For $S \subseteq [n]$ the function $\phi_S(x) : \{-1,1\}^n_{(p)} \to \mathbf{R}$ is defined by

$$\phi_S(x) = \prod_{i\in S} \phi(x_i), \qquad \text{where } \phi(x_i) = \begin{cases} \sqrt{q/p} & \text{if } x_i = 1, \\ -\sqrt{p/q} & \text{if } x_i = -1. \end{cases}$$

The functions $\{\phi_S\}_{S\subseteq[n]}$ form an orthonormal basis with respect to $\langle \cdot, \cdot \rangle_p$. The *p-biased Fourier expansion* of $f : \{-1,1\}^n_{(p)} \to \mathbf{R}$ is $f(x) = \sum_{S\subseteq[n]} \tilde{f}(S)\phi_S(x)$, where $\tilde{f}(S) = \mathbf{E}_p[f(x)\phi_S(x)]$; note that we write $\tilde{f}$ rather than $\hat{f}$ to denote p-biased Fourier coefficients. Parseval's identity continues to hold: $\mathbf{E}_p[f^2] = \sum_S \tilde{f}(S)^2$.

We define the operator D_i on functions $f : \{-1,1\}^n_{(p)} \to \mathbf{R}$ by $(D_i f)(x) = \sqrt{pq}\ (f(x^{(i=1)}) - f(x^{(i=-1)}))$, where $x^{(i=b)}$ denotes x with the ith bit set to b. It is not difficult to verify that $(D_i f)(x) = \sum_{S\ni i} \tilde{f}(S)\phi_{S\setminus i}(x)$. We now give the definition of p-biased influence.

DEFINITION 1. *The* p-biased influence of the ith coordinate on $f : \{-1,1\}^n_{(p)} \to \mathbf{R}$ *is*

$$\mathrm{Inf}_i^{(p)}(f) = \mathbf{E}_p[(D_i f)^2] = \sum_{S\ni i} \tilde{f}(S)^2.$$

Note that if $f : \{-1,1\}^n_{(p)} \to \{-1,1\}$, *then* $\mathrm{Inf}_i^{(p)}(f) = 4pq \Pr_p[f(x) \neq f(x^{\oplus i})]$.

We remark that this definition differs from the ones in [8, 9] by a multiplicative factor of $4pq$. We define the *p-biased average sensitivity* to be $\mathrm{I}^{(p)}(f) = \sum_{i=1}^n \mathrm{Inf}_i^{(p)}(f) = \sum_{S\subseteq[n]} |S|\tilde{f}(S)^2$. Note that in the case when $p = 1/2$ and f's range is $\{-1,1\}$, these definitions agree with the standard uniform distribution definitions from section 2.3.

We conclude this section with a useful relationship in the p-biased case between influences of monotone real-valued functions and singleton Fourier coefficients.

FACT 5. *For any monotone* $f : \{-1,1\}^n \to [-1,1]$ *we have* $\mathrm{Inf}_i^{(p)}(f) \leq 2\sqrt{pq}\cdot\tilde{f}(i)$, *with equality iff the range of* f *is* $\{-1,1\}$.

Proof. We have $\mathrm{Inf}_i^{(p)}(f) = \mathbf{E}_p[(D_i f)^2]$. Since f is monotone and has range $[-1,1]$ it is easy to see that $0 \leq (D_i f)(x) \leq 2\sqrt{pq}$ for all x. Thus $(D_i f)^2 \leq 2\sqrt{pq} \cdot (D_i f)$ with equality iff f's range is $\{-1,1\}$, and hence $\mathrm{Inf}_i^{(p)}(f) \leq 2\sqrt{pq} \cdot \mathbf{E}_p[D_i f] = 2\sqrt{pq} \cdot \tilde{f}(i)$. ☐

5.2. Bounding influence in monotone real-valued functions under *p*-biased measures. In this section we describe our analogue of Theorem 3 for real functions under p-biased measures. We first set up some p-biased preliminaries before proving the theorem. Let $\mathcal{C} = \{C^1, \ldots, C^s\}$ be a subcube partition of $\{-1,1\}^n$. We now identify the C^t's with length-n vectors in a way compatible with the ϕ-basis, i.e.,

$$(C^t)_i = \begin{cases} \phi(1) = \sqrt{q/p} & \text{if } x_i = 1 \text{ for all } x \in C^t, \\ \phi(-1) = -\sqrt{p/q} & \text{if } x_i = -1 \text{ for all } x \in C^t, \\ 0 & \text{otherwise.} \end{cases}$$

The definitions of pluses(C^t), minuses(C^t), and fixed(C^t) are as before. We now define $\delta_i^{(p)}$ to be the p-biased version of δ_i:

$$\delta_i^{(p)} = \Pr_{x \in \{-1,1\}^n_{(p)}} [i \in \text{fixed}(C(x))].$$

The observation that choosing $x \in \{-1,1\}^n_{(p)}$ and considering $(x, C(x))$ can be viewed as choosing $R \in \mathcal{C}$ and then $x \in R$ still holds with the obvious p-biased interpretation. Specifically, the random choice $R \in \mathcal{C}$ means selecting the cube C^t with probability $p^{|\text{pluses}(C^t)|} q^{|\text{minuses}(C^t)|}$; then the choice $x \in R$ means picking the unfixed coordinates according to the p-biased distribution.

The analogue of Lemma 2 and the analogue of Lemma 3 (for functions $f : \{-1,1\}^n_{(p)} \to \mathbf{R}$) now hold with no changes in the statements. To prove them we simply repeat their proofs and also the statement and proof of Lemma 1, everywhere replacing x_i and x_j with $\phi(x_i)$ and $\phi(x_j)$. As a consequence, we have the following additional lemma.

Lemma 6. *Given $\alpha, \beta \in \mathbf{R}$, the quantity $\mathbf{E}_{R \in \mathcal{C}}[\alpha \cdot |\text{pluses}(R)| + \beta \cdot |\text{minuses}(R)|]$ depends only on $p\alpha + q\beta$.*

Proof. Sum the first statement of the p-biased analogue of Lemma 2 over all i, and then expand the definition of R_i; one gets

$$\mathop{\mathbf{E}}_{R \in \mathcal{C}}\Big[\sqrt{q/p} \cdot |\text{pluses}(R)| - \sqrt{p/q} \cdot |\text{minuses}(R)|\Big] = 0$$

$$\Rightarrow \mathop{\mathbf{E}}_{R \in \mathcal{C}}[|\text{minuses}(R)|] = (q/p) \cdot \mathop{\mathbf{E}}_{R \in \mathcal{C}}[|\text{pluses}(R)|]. \tag{3}$$

So substituting this in, we get

$$\begin{aligned}\mathop{\mathbf{E}}_{R \in \mathcal{C}}[\alpha \cdot |\text{pluses}(R)| + \beta \cdot |\text{minuses}(R)|] &= \mathop{\mathbf{E}}_{R \in \mathcal{C}}[\alpha \cdot |\text{pluses}(R)| + (q/p)\beta \cdot |\text{pluses}(R)|] \\ &= (1/p) \mathop{\mathbf{E}}_{R \in \mathcal{C}}[(p\alpha + q\beta) \cdot |\text{pluses}(R)|],\end{aligned}$$

completing the proof. □

With this preparation in hand, we now give our p-biased, real-valued generalization of Theorem 3.

Theorem 7. *Let $f : \{-1,1\}^n_{(p)} \to \mathbf{R}$ be a function with subcube partition $\mathcal{C} = \{C^1, \dots, C^s\}$. Then we have*

$$\sum_{i=1}^n \tilde{f}(i) \le \|f\|_2 \cdot \sqrt{\sum_{i=1}^n \delta_i^{(p)}} \le \|f\|_2 \cdot \sqrt{\log s} / \sqrt{H(p)},$$

where $H(p) = p\log(1/p) + q\log(1/q)$. If $f : \{-1,1\}^n_{(p)} \to [-1,1]$ is monotone then by Fact 5 we may write $\mathrm{I}^{(p)}(f) \le \sqrt{4pq/H(p)}\sqrt{\log s}$.

Proof. Applying Cauchy–Schwarz directly to the analogue of Lemma 3, we have

$$\sum_{i=1}^n \tilde{f}(i) \le \sqrt{\mathop{\mathbf{E}}_{R \in \mathcal{C}}\Big[f(R)^2\Big]} \cdot \sqrt{\mathop{\mathbf{E}}_{R \in \mathcal{C}}\Big[\Big(\sum_{i=1}^n R_i\Big)^2\Big]} = \|f\|_2 \cdot \sqrt{\mathop{\mathbf{E}}_{R \in \mathcal{C}}\Big[\sum_{i=1}^n R_i^2\Big]},$$

where we used the p-biased analogue of the second statement of Lemma 2 in the equality, just as in the proof of Theorem 3. Let us now consider the quantity inside the square root. By definition,

$$\mathop{\mathbf{E}}_{R\in\mathcal{C}}\Big[\sum_{i=1}^{n} R_i^2\Big] = \mathop{\mathbf{E}}_{R\in\mathcal{C}}\Big[(q/p)\cdot \mathrm{pluses}(R) + (p/q)\cdot \mathrm{minuses}(R)\Big]. \tag{4}$$

Using (3) twice, we have

$$\begin{aligned}\mathop{\mathbf{E}}_{R\in\mathcal{C}}\Big[(q/p)\cdot \mathrm{pluses}(R) + (p/q)\cdot \mathrm{minuses}(R)\Big] &= \mathop{\mathbf{E}}_{R\in\mathcal{C}}[\mathrm{pluses}(R) + \mathrm{minuses}(R)]\\ &= \mathop{\mathbf{E}}_{R\in\mathcal{C}}[|\mathrm{fixed}(R)|] = \sum_{i=1}^{n} \delta_i^{(p)},\end{aligned}$$

completing the proof of the first inequality. As for the second inequality, note that the binary entropy $H(R)$ of the random variable $R \in \mathcal{C}$ is

$$\begin{aligned}H(R) &= \mathop{\mathbf{E}}_{R\in\mathcal{C}}\Big[\log(1/\Pr[R])\Big]\\ &= \mathop{\mathbf{E}}_{R\in\mathcal{C}}\Big[\log(1/p)\cdot \mathrm{pluses}(R) + \log(1/q)\cdot \mathrm{minuses}(R)\Big]\\ &= H(p)\cdot \mathop{\mathbf{E}}_{R\in\mathcal{C}}\left[\frac{\log(1/p)}{H(p)}\cdot \mathrm{pluses}(R) + \frac{\log(1/q)}{H(p)}\cdot \mathrm{minuses}(R)\right].\end{aligned}$$

But since $p\frac{\log(1/p)}{H(p)} + q\frac{\log(1/q)}{H(p)} = 1$ as well, applying Lemma 6 again yields

$$(4) = H(R)/H(p).$$

But $H(R) \le \log s$ as observed in the proof of Theorem 3, and the proof is complete. □

Using the bound $pq\log(1/pq) \le H(p)$, we have the following corollary.

COROLLARY 7. *If* $f : \{-1,1\}^n_{(p)} \to [-1,1]$ *is monotone then* $\mathrm{I}^{(p)}(f) \le 2\sqrt{\log P(f)}/\sqrt{\log(1/pq)}$.

5.3. Spectral concentration under p-biased measures. We now need to extend Friedgut's result to the p-biased, real-valued case. There are some difficulties involved. In [8], Friedgut gave a p-biased version of Theorem 4; however, he left the quantitative details of the dependence on p unspecified. More seriously, Friedgut's theorem is simply not true for $[-1,1]$-valued functions, even in the $p = 1/2$ case. (See Appendix A for an example demonstrating this.)

However, we are able to circumvent this problem. The necessary insight is the following: A real-valued function with small average sensitivity depends on only a small number of coordinates *if its range is sufficiently "discrete."* And for the purposes of learning an unknown function to some prescribed accuracy, we do not lose much by "rounding" the function's values to a discrete range.

For $\gamma > 0$, let $\gamma\mathbf{Z}$ denote the set of real numbers of the form γm, where m is an integer. By making some small changes to Friedgut's proof we can derive the following result (the proof is in Appendix A).

THEOREM 8. *There is a universal constant $K < \infty$ such that for all $0 < \epsilon, \gamma < 1/2$ and all $f : \{-1,1\}^n_{(p)} \to [-1,1] \cap (\gamma\mathbf{Z})$, if*

$$t = 2\mathrm{I}^{(p)}(f)/\epsilon, \quad \tau = \gamma^K (pq)^{Kt}, \quad J = \{i : \mathrm{Inf}_i^{(p)}(f) \geq \tau\}, \quad \mathcal{S} = \{S : S \subseteq J, |S| \leq t\},$$

then $\sum_{S \notin \mathcal{S}} \tilde{f}(S)^2 \leq \epsilon$.

We now combine Theorem 8 with Corollary 7, exactly in the manner of Theorem 5. The $\sqrt{\log(1/pq)}$ saved in Corollary 7 cancels with the pq paid in the τ from Theorem 8, and the factor of $\gamma^{O(1)}$ becomes negligible if we take $\gamma = \epsilon$ (indeed, even $\gamma = 2^{-O(1/\epsilon)}$ would be negligible). We get the following theorem.

THEOREM 9. *Let $\epsilon > 0$, $f : \{-1,1\}^n_{(p)} \to [-1,1] \cap (\epsilon\mathbf{Z})$ be a monotone function, and let $t = 4\sqrt{\log P(f)}/(\epsilon\sqrt{\log(1/pq)})$. Let $J = \{i : \mathrm{Inf}_i(f) \geq (K')^{-t\log(1/pq)}\}$, where $K' < \infty$ is a universal constant, and let $\mathcal{S} = \{S : S \subseteq J, |S| \leq t\}$. Then $|\mathcal{S}| = P(f)^{O(1/\epsilon^2)}$ and $\sum_{S \notin \mathcal{S}} \tilde{f}(S)^2 \leq \epsilon$.*

5.4. Learning monotone real-valued functions under *p*-biased measures. With Theorem 9 in hand, the proof of our main learning result Theorem 6 is now not very difficult. Given an unknown target function $f : \{-1,1\}^n_{(p)} \to [-1,1]$ and $\epsilon > 0$, let f_ϵ denote f with its values "rounded" to the nearest integer multiples of ϵ. Clearly, given examples from $EX(f,p)$, we can simulate examples from $EX(f_\epsilon, p)$. We now simply try to learn f_ϵ. It is easy to check that an ϵ-approximator hypothesis for f_ϵ is also an $O(\epsilon)$-approximator for f. Further, we have $P(f_\epsilon) \leq P(f)$ so a $P(f_\epsilon)^{O(1/\epsilon^2)}$ runtime is also $P(f)^{O(1/\epsilon^2)}$ as desired. The p-biased analogue of Proposition 4 holds with essentially the same proof. The only new difficulty is that we cannot exactly estimate the quantities $\mathrm{Inf}_i(f_\epsilon)$. However from Fact 5, the quantities $\tilde{f}(i)$—which we can estimate empirically—are upper bounds on the influences; so by taking all the coordinates i with $\tilde{f}(i) \geq \tau$, we get all the sufficiently influential coordinates. There cannot be too many coordinates with large $\tilde{f}(i)$, since $\sum_{i=1}^n \tilde{f}(i)^2 \leq 1$.

For completeness, we give all the details of the proof of Theorem 6 in Appendix B.

6. Extension to stronger complexity measures? It is natural to wonder whether our results can be extended to stronger complexity measures than decision tree size and partition size. An obvious next complexity measure to consider is the minimum number of (not necessarily disjoint) subcubes that cover $\{-1,1\}^n$ and are such that f is constant on each subcube. We refer to this as the *subcube covering complexity* of f and denote it by $CDNF(f)$, since it is equal to the minimum number of terms in any DNF formula for f plus the minimum number of clauses in any CNF formula for f.

The following theorem shows that Theorem 3 does not hold for subcube covering complexity.

THEOREM 10. *There is a monotone Boolean function $g : \{-1,1\}^n \to \{-1,1\}$ for which $\mathrm{I}(g) = \Omega(n^{\log_4(6-2\sqrt{5})}) = \Omega(n^{0.305})$ but $\sqrt{\log CDNF(g)} = O(n^{1/4})$.*

The proof is by the probabilistic method. We define a distribution $\mathcal{D}$ over monotone Boolean functions and show that some function g that is assigned nonzero weight under $\mathcal{D}$ must satisfy the bounds of the theorem. See Appendix C.

7. Conclusion. In this paper we established a new bound on average sensitivity of monotone functions and used this bound to give the first algorithm that uses random examples to learn any monotone function to high accuracy in time polynomial in the function's decision tree or partition size.

A natural goal for future work is to obtain even stronger learning results for monotone functions. Can the boosting methods used by Jackson in his harmonic sieve algorithm [13] be applied here? We note that while the harmonic sieve algorithm makes essential use of membership queries, related algorithms that combine boosting with Fourier techniques have been successfully developed for the framework of learning from random examples only [14].

Appendix A. Proof of Theorem 8 and a counterexample.

Proof of Theorem 8. Recall that we have

$$D_i f(x) = \sqrt{pq}(f(x^{(i=1)}) - f(x^{(i=-1)})) = \sum_{S:\ i \in S} \tilde{f}(S)\phi_{S\setminus i}(x)$$

and that $\mathrm{Inf}_i^{(p)}(f) = \mathbf{E}_p[(D_i f)^2] = \|D_i f\|_2^2$, where throughout this section $\|\cdot\|$ denotes the norm induced by the p-biased measure.

Since $\mathrm{I}^{(p)}(f) = \sum_S |S|\tilde{f}(S)^2$, Markov's inequality immediately gives that $\sum_{S:\ |S|>t} \tilde{f}(S)^2 < \epsilon/2$. Let $J' = [n] \setminus J$. It now suffices to show that

$$\sum_{S:\ S\cap J' \neq \emptyset, |S| \le t} \tilde{f}(S)^2 \le \epsilon/2. \tag{5}$$

Certainly the left side of (5) is at most

$$\sum_{i \in J'} \sum_{S:\ i \in S, |S| \le t} \tilde{f}(S)^2 = \sum_{i \in J'} \|D_i f^{\le t}\|_2^2 = \sum_{i \in J'} \langle D_i f^{\le t}, D_i f\rangle, \tag{6}$$

where we use the notation $f^{\le t}$ to denote the function $f^{\le t}(x) = \sum_{|S| \le t} \tilde{f}(S)\phi_S$. Now we have

$$\langle D_i f^{\le t}, D_i \rangle \le \|D_i f^{\le t}\|_4 \, \|D_i f\|_{4/3} \tag{7}$$

$$\le (1 + 1/\sqrt{pq})^{t/2} \, \|D_i f^{\le t}\|_2 \, \|D_i f\|_{4/3} \tag{8}$$

$$\le (1/pq)^t \, \mathrm{Inf}_i^{(p)}(f)^{1/2} \, \mathbf{E}[|D_i f|^{4/3}]^{3/4}. \tag{9}$$

Here (7) is Hölder's inequality, inequality (8) follows from a p-biased version of Bonami–Beckner (here with the best bounds provided by [26]), and inequality (9) uses the generous bound $(1 + 1/\sqrt{pq})^{1/2} < (1/pq)$ and also $\|D_i f^{\le t}\|_2 \le \|D_i f\|_2 = \mathrm{Inf}_i^{(p)}(f)^{1/2}$.

We now observe that by virtue of the assumption that f's range is contained in $\gamma\mathbf{Z}$, we have that $|D_i f(x)|$ is always either 0 or at least $\gamma\sqrt{pq}$. This implies that (9) is at most

$$(1/pq)^t \, \mathrm{Inf}_i^{(p)}(f)^{1/2} \, \mathbf{E}_p[(\gamma\sqrt{pq})^{-2/3} \cdot |D_i f|^2]^{3/4} = (1/pq)^{t+1/4} \, \gamma^{-1/2} \, \mathrm{Inf}_i^{(p)}(f)^{5/4}$$

$$\le (1/pq)^{t+1/4} \, \gamma^{-1/2} \, \mathrm{Inf}_i^{(p)}(f) \, \tau^{1/4}, \tag{10}$$

where we have used the definitions of $\mathrm{Inf}_i^{(p)}(f)$ and τ. Using the fact that $\sum_{i \in J'} \mathrm{Inf}_i^{(p)}(f) \le \mathrm{I}^{(p)}(f)$, we can sum (10) and conclude that (6) is at most

$$(1/pq)^{t+1/4} \, \gamma^{-1/2} \, \mathrm{I}^{(p)}(f) \, \tau^{1/4}.$$

Thus to ensure (5) holds we need only

$$t(1/pq)^{t+1/4}\,\gamma^{-1/2}\,\tau^{1/4} \leq 1;$$

upper-bounding $t(1/pq)^{t+1/4}$ by $(1/pq)^{O(t)}$ (acceptable for all $t \geq 0$), we see that $\tau = \gamma^{O(1)}(pq)^{O(t)}$ suffices. Thus the choice of τ given in the definition of Theorem 8 suffices and the proof of this theorem is complete. □

We now justify the remark from section 5.3 indicating that Friedgut's theorem does not in general hold for real-valued functions; in other words, the condition that f's range is contained in $\gamma\mathbf{Z}$ cannot be removed.

To see this, consider (in the uniform measure case) the function $f : \{-1,1\}^n \to [-1,1]$ defined by

$$f(x) = \begin{cases} \operatorname{sgn}(\sum_{i=1}^n x_i) & \text{if } |\sum_{i=1}^n x_i| > \sqrt{n}, \\ \frac{1}{\sqrt{n}}\sum_{i=1}^n x_i & \text{if } |\sum_{i=1}^n x_i| \leq \sqrt{n}. \end{cases}$$

It is easy to see that for each $i = 1,\dots,n$, $D_i f(x)$ is always either 0 or $1/\sqrt{n}$ and is $1/\sqrt{n}$ for a $\Theta(1)$ fraction of all x's. Consequently we have $\mathrm{Inf}_i(f) = \Theta(1/n)$ and thus $\mathrm{I}(f) = \Theta(1)$. In addition, it is clear that both $\mathbf{E}[f(x)] = 0$ and $|f(x)| \geq 1/2$ for a $\Theta(1)$ fraction of all x's; hence we have $\sum_{|S|>0}\hat{f}(S)^2 \geq \Omega(1)$. But now if we take ϵ to be any constant smaller than this $\Omega(1)$, then we get a contradiction, since the choice of τ in Theorem 8 will be a constant, and so J and hence $\mathcal{S}$ will be empty (for all n sufficiently large).

Appendix B. Technical details for learning. We begin with some basic learning details for the p-biased measure. First, as mentioned earlier, we may assume without loss of generality that the learning algorithm "knows" p. The proof is quite similar to the proof that a noise-tolerant learning algorithm can be assumed to know the exact noise rate (see [19]). The basic idea is that we can run the learning algorithm repeatedly using successively finer estimates (easily obtained from sampling) for the value of p. If the original algorithm runs for T time steps, then if the guessed value for p is within Δ/T of the true value, the statistical distance between the algorithm's output when run with the guessed value versus the true value will be at most Δ. It can be shown that at most a polynomial factor runtime overhead is incurred in coming up with a sufficiently accurate guess.

Next, we remark that low-degree algorithm of Linial, Mansour, and Nisan, Proposition 4, easily carries over to the real-valued p-biased case with essentially the same proof.

PROPOSITION 8. *There is an algorithm A with the following property: Let $f : \{-1,1\}^n_{(p)} \to [-1,1]$ and let $\mathcal{S} \subseteq 2^{[n]}$ be a collection of subsets of $[n]$ with the property that $\sum_{S:S\notin\mathcal{S}}\tilde{f}(S)^2 \leq \epsilon$. Then if A is given p, $\mathcal{S}$, access to a source $EX(f,p)$ of p-biased random examples, and parameters $\delta, \theta > 0$, it runs in poly$(n, |\mathcal{S}|, 1/\theta)\cdot\log(1/\delta)$ time and with probability $1-\delta$ outputs a real-valued function $g : \{-1,1\}^n \to \mathbf{R}$ of the form $g(x) = \sum_{S\in\mathcal{S}} c_S\phi_S(x)$ such that $\mathbf{E}_p[(f-g)^2] \leq \epsilon + \tau$.*

We now proceed to discuss the proof of Theorem 6. Let $f : \{-1,1\}^n_{(p)} \to [-1,1]$ be the target function. Given $\epsilon > 0$, let f_ϵ denote the "rounded" version of f in which each of its values is rounded to the nearest integer multiple of ϵ. It is clear that given access to $EX(p,f)$ we can simulate access to $EX(p,f_\epsilon)$. Our algorithm will use $EX(p,f_\epsilon)$ to learn f_ϵ in time $\mathrm{poly}(n, P(f_\epsilon)^{O(1/\epsilon^2)})\cdot\log(1/\delta)$. This is sufficient for learning f in the same time bound, because $P(f_\epsilon) \leq P(f)$ and because if $\mathbf{E}_p[(h - f_\epsilon)^2] \leq \epsilon$ then

$$\mathbf{E}_p[(h-f)^2] = \mathbf{E}_p[((h-f_\epsilon)+(f_\epsilon - f))^2] \leq 2\mathbf{E}_p[(h-f_\epsilon)^2] + 2\mathbf{E}_p[(f_\epsilon - f)^2]$$
$$\leq 2\epsilon + \epsilon^2/2 = O(\epsilon).$$

Our goal is now essentially to use Proposition 8 given Theorem 9. As mentioned in section 5.4, unlike in the algorithm for Boolean-valued functions, we cannot estimate the influences of f_ϵ directly since the relationship $\mathrm{Inf}_i^{(p)}(f_\epsilon) = \tilde{f}_\epsilon(i)$ does not hold in the real-valued case. We may, however, use Fact 5 which says that $\tilde{f}_\epsilon(i)$—a quantity we can empirically estimate—is an upper bound on $\mathrm{Inf}_i^{(p)}(f_\epsilon)$.

We now describe the algorithm to learn f_ϵ using $EX(p, f_\epsilon)$. As in section 4.3 we may assume that the partition size $P(f_\epsilon)$ is known. The algorithm is as follows:

1. For $i = 1, \ldots, n$ empirically estimate $\tilde{f}_\epsilon(i) = \mathbf{E}_p[f_\epsilon(x)\phi_i(x)]$ to within an additive $\pm\tau/4$ (with confidence $1-\delta$), where $\tau = (C')^{-t\log(1/pq)}$ and t is defined in Theorem 9. Let $J \subseteq [n]$ be the set of those i for which the obtained estimate is greater than $\tau/2$.
2. Now run algorithm A from Proposition 8 with $\mathcal{S} = \{S : \ S \subseteq J, \ |S| \leq t\}$ and $\theta = \epsilon$, outputting its hypothesis g.

Let us first confirm the running time of this algorithm. In step 1, standard sampling bounds ensure that $\mathrm{poly}(n, 1/\tau) \cdot \log(1/\delta)$ samples suffice. We may then conclude that $|J| \leq O(1/\tau^2)$, since $\sum_{i=1}^n \tilde{f}_\epsilon(S)^2 \leq 1$. It follows that $|\mathcal{S}| \leq \mathrm{poly}(1/\tau^t) = P(f_\epsilon)^{O(1/\epsilon^2)}$, as necessary to bound the running time. Finally, we still have $\sum_{S \notin \mathcal{S}} \tilde{f}_\epsilon(S)^2 \leq \epsilon$ because (with confidence $1-\delta$) the J the algorithm finds is a superset of the J from Theorem 9. Hence the algorithm correctly gives an $O(\epsilon)$-approximator hypothesis g with confidence $1 - O(\delta)$, and the proof of Theorem 6 is complete.

Appendix C. Proof of Theorem 10. Let $n = 4^k$. Let $f_1(a,b,c,d)$ be the "AND/OR" function on four Boolean variables $f_1(a,b,c,d) = (a \wedge b) \vee (c \wedge d)$. An important property of f_1 is that if each of its four arguments is independently set to be 1 (true) with probability p, then $\Pr[f_1 = 1]$ equals $2p^2 - p^4$. For $i = 2, 3, \ldots$, we define the function f_i on 4^i variables to be $f_i = f_1(f_{i-1}^1, f_{i-1}^2, f_{i-1}^3, f_{i-1}^4)$, where the superscripts indicate distinct copies of f_{i-1} on disjoint sets of variables. Thus f_k is a function on n variables computed by a read-once Boolean formula that is a tree of ANDs and ORs at alternating levels.

We now define distributions $\mathcal{D}_1, \ldots, \mathcal{D}_k$ over monotone Boolean functions, where $\mathcal{D}_i$ is a distribution over functions from $\{-1,1\}^{4^i}$ to $\{-1,1\}$. The distribution $\mathcal{D}_i$ is defined in the following way: a random draw from $\mathcal{D}_i$ is obtained by independently substituting 1 for each of the 4^i Boolean arguments to f_i with probability α, where $\alpha = \sqrt{5} - 2 \approx 0.236$. (This construction and some of the subsequent analysis are reminiscent of [32].) Note that for a random g drawn from $\mathcal{D}_1$ and a random x drawn uniformly from $\{-1,1\}^4$, we have that each of the four arguments to f_1 is independently 1 with probability $\frac{1}{2} + \frac{\alpha}{2} = \frac{\sqrt{5}-1}{2}$; we denote this value by ρ. Consequently we have $\Pr_{g \in \mathcal{D}_1, x \in \{-1,1\}^4}[g(x) = 1] = 2\rho^2 - \rho^4$, but this is easily seen to equal ρ. It follows from the recursive definition of f_i that for all $i = 1, 2, \ldots$ we have $\Pr_{g \in \mathcal{D}_i, x \in \{-1,1\}^{4^i}}[g(x) = 1] = \rho$.

It is not difficult to show (see Theorem 2.4 of [16]) that $CDNF(f_k) \leq 2^{2^k+1}$; as an immediate consequence we have that $CDNF(g) \leq 2^{2^k+1}$ (and thus $\sqrt{\log CDNF(g)} = O(2^{k/2}) = O(n^{1/4})$) for every g that is in the support of $\mathcal{D}_k$. But by Lemma 9 below we have that $\mathbf{E}_{g\in\mathcal{D}_k}[\mathrm{I}(g)] = \Theta((6-2\sqrt{5})^k)$; clearly this implies that there is some g in the support of $\mathcal{D}_k$ for which $\mathrm{I}(g)$ is $\Omega((6-2\sqrt{5})^k) = \Omega(n^{\log_4(6-2\sqrt{5})})$. This proves Theorem 10.

LEMMA 9. *For $i = 1, 2, \ldots$ we have $\mathbf{E}_{g\in\mathcal{D}_i}[\mathrm{I}(g)] = (3-\sqrt{5})(6-2\sqrt{5})^i$.*

Proof. It is clear from symmetry that $\mathbf{E}_{g\in\mathcal{D}_i}[\mathrm{I}(g)] = 4^i \cdot \mathbf{E}_{g\in\mathcal{D}_i}[\mathrm{Inf}_1(g)]$. We have

$$\mathbf{E}_{g\in\mathcal{D}_i}[\mathrm{Inf}_1(g)] = \mathbf{E}_{g\in\mathcal{D}_i, x\in\{-1,1\}^{4^i}}[\Pr[g(1,x_2,\ldots,x_{4^i}) \neq g(-1,x_2,\ldots,x_{4^i})]]$$

$$= \Pr_{g\in\mathcal{D}_i, x\in\{-1,1\}^{4^i}}[g(1,x_2,\ldots,x_{4^i}) \neq g(-1,x_2,\ldots,x_{4^i})].$$

From the definition of $\mathcal{D}_i$, we have that with probability $\alpha = \sqrt{5}-2$ the constant 1 is substituted for the first argument of f_i in g; if this occurs, then clearly $g(1,x_2,\ldots,x_{4^i}) = g(-1,x_2,\ldots,x_{4^i})$ for all x since g does not depend on its first argument. If this does not occur, then we have (for a random $g \in \mathcal{D}_i$ and a uniform $x \in \{-1,1\}^{4^i}$) that each of the other 4^{i-1} arguments to f_i independently takes value 1 with probability $\rho = \frac{\sqrt{5}-1}{2}$.

Under the distribution on inputs to f_i described in the previous paragraph, if $i = 1$ it is easy to see that flipping the first argument of f_1 flips the value of f_1 iff the second argument is 1 (probability ρ) and the AND of the third and fourth arguments is 0 (probability $1-\rho^2$). Thus flipping the first argument of f_1 flips the value of f_1 with probability precisely $\rho(1-\rho^2)$ which is easily seen to equal $1-\rho$, using the fact that $2\rho^2-\rho^4 = \rho$. Similarly, if $i = 2$, then flipping the first of the 16 arguments to $f_2 = f_1(f_1^1, f_1^2, f_1^3, f_1^4)$ (again under the distribution of inputs to f_i described above) will flip the value of f_2 iff the value of f_1^1 flips (probability $1-\rho$ as shown above), f_1^2 equals 1 (probability ρ), and $f_1^3 \wedge f_1^4$ equals 0 (probability $1-\rho^2$). We thus have that flipping the first argument of f_2 flips the value of f_2 with probability $(1-\rho)\rho(1-\rho^2) = (1-\rho)^2$. An easy induction in this fashion shows that for all i, under the distribution of inputs described above flipping the first argument of f_i causes f_i to flip with probability $(1-\rho)^i$.

We thus have that

$$\Pr_{g\in\mathcal{D}_i, x\in\{-1,1\}^{4^i}}[g(1,x_2,\ldots,x_{4^i}) \neq g(-1,x_2,\ldots,x_{4^i})] = (1-\alpha)(1-\rho)^i$$

$$= (3-\sqrt{5})\left(\frac{3-\sqrt{5}}{2}\right)^i,$$

which proves the lemma. □

Acknowledgment. We are grateful to an anonymous referee for several suggestions for simplifications of the proof of Theorem 3.

LOWER BOUNDS FOR LOVÁSZ–SCHRIJVER SYSTEMS AND BEYOND FOLLOW FROM MULTIPARTY COMMUNICATION COMPLEXITY*

PAUL BEAME†, TONIANN PITASSI‡, AND NATHAN SEGERLIND§

Abstract. We prove that an $\omega(\log^4 n)$ lower bound for the three-party number-on-the-forehead (NOF) communication complexity of the set-disjointness function implies an $n^{\omega(1)}$ size lower bound for treelike Lovász–Schrijver systems that refute unsatisfiable formulas in conjunctive normal form (CNFs). More generally, we prove that an $n^{\Omega(1)}$ lower bound for the $(k+1)$-party NOF communication complexity of set disjointness implies a $2^{n^{\Omega(1)}}$ size lower bound for all treelike proof systems whose formulas are degree k polynomial inequalities.

Key words. propositional proof complexity, zero-one programming, communication complexity, lower bounds

1. Introduction.

Zero-one programming is the problem of optimizing a linear objective function over the zero-one points of a polytope. It is a useful framework for expressing optimization problems. In particular, Boolean conjunctive normal form (CNF) satisfiability can be easily recast as a zero-one programming problem, and for this reason zero-one programming was among the first discrete optimization problems proved to be NP-complete. In contrast, linear programming, the problem of optimizing a linear objective function over all points of a polytope, is polynomial-time solvable [19]. Many attempts have been made to transfer efficient techniques from linear programming to zero-one programming, and among them are the Lovász–Schrijver "lift-and-project" methods. In this paper we establish limitations on using such methods to prove unsatisfiability for CNFs, modulo a conjecture in communication complexity.

Techniques for zero-one programming often come from the slightly more general realm of optimizing over the integral points of a polytope. One approach for reducing these integer programming problems to linear programming problems is to begin with the polytope defined by the original linear program without integrality constraints and systematically pare down the polytope by repeatedly refining the linear program with "cutting planes" that remove only nonintegral solutions until we are left with the convex hull of the integral solutions. These are local methods in which an initial polytope Q is transformed by a sequence of local operations to smaller and smaller subpolytopes until the integral hull of Q is reached. At this point, rational linear

programming finds the correct solution. Note that, for decision problems, this procedure terminates with the empty polytope if and only if the initial polytope contains no integral points. A well-known method of this kind is the use of Gomory–Chvátal cuts [10] which derive each new cutting plane as a linear combination and shift of existing facet constraints.

For zero-one programming, there are more subtle methods available. Lovász and Schrijver [21] introduced a variety of cutting planes methods that derive new cutting planes by first "lifting" the inequalities to higher degree polynomial inequalities (in particular, quadratic inequalities) and then "projecting" them down to linear inequalities using polynomial identities and the fact that $x^2 = x$ for $x \in \{0, 1\}$.

The Lovász–Schrijver methods for solving zero-one programs can be naturally used for propositional proof systems. Consider the problem of proving that a CNF is unsatisfiable (equivalently, proving that a formula in disjunctive normal form (DNF) is a tautology). Each clause is mapped to an equivalent linear inequality; for example, $x \vee \neg y \vee z$ is mapped to $x + 1 - y + z \geq 1$. By repeated application of the lift-and-project rules and elementary linear algebra, inequalities of quadratic polynomials are derived from the translated clauses, and we can arrive at the inconsistent inequality $1 \geq 0$ if and only if the CNF is unsatisfiable.[1] In this way, we obtain propositional proof systems for CNF unsatisfiability in which the formulas are quadratic inequalities, and the rules of inference are the algebraic manipulations coming from the lift-and-project steps and elementary linear algebra. Collectively, these propositional proof systems are known as *Lovász–Schrijver (LS) systems*. An important feature of the LS systems is that they can provide exponentially smaller proofs for certain tautologies, such as the pigeonhole principle, than the ones possible with systems such as resolution or constant-depth Frege systems.

There are two complexity measures that are commonly studied for cutting-planes-based proof systems such as the LS and the Gomory–Chvatal cutting planes system: *size* and *rank*. Intuitively, rank is the number of intermediate polytopes that must be passed through before arriving at the integral hull. In [21] it was shown that for any (relaxed) polytope P, if the rank of P is d, then the optimization and decision problems for P can be solved exactly deterministically in time $n^{O(d)}$. This makes LS systems especially appealing for solving or approximating NP-hard optimization problems via semidefinite programming. A variety of rank lower bounds for the exact solution are known, even for the case of unsatisfiable systems [4, 11, 14, 9, 15]. Moreover, interesting bounds on the rank required to obtain good approximations to the problems of finding a minimum sized vertex cover for a graph and finding an assignment that satisfies a maximum number of clauses in a CNF. This, in turn, implies inapproximability results for these problems for *any* polynomial-time algorithm based on rank.

While there is a rich and growing body of results concerning rank, very little is known about the size of LS proofs. From the proof theoretic perspective, the size of a proof is defined in the usual manner, but from an informal geometric perspective, the size of a LS procedure with respect to some polytope P is the smallest number of hyperplanes defining all of the polytopes that we need to pass through before arriving at the integral hull. Clearly size lower bounds imply rank lower bounds, and indeed, size lower bounds for treelike proofs[2] imply rank lower bounds, but whether the converse holds is open.

[1] The proof systems are made more precise in subsection 2.2.

[2] A proof is treelike if each formula is used at most once as an antecedent to an inference. That is, each time a formula is reused, it must be rederived. For many proof systems, there are CNFs for which the smallest treelike proofs of unsatisfiability are exponentially larger than the smallest unrestricted proofs of unsatisfiability, but it is open whether or not this holds for LS proofs.

At the time of this writing, it is unknown whether or not every unsatisfiable CNF Φ possesses a treelike LS proof of unsatisfiability whose size is bounded by a polynomial in the number of symbols in Φ. Of course, if every unsatisfiable CNF has such a small refutation, then $\mathsf{NP} = \mathsf{coNP}$, so one might say that because this is unlikely, the problem is "resolved modulo a plausible complexity theoretic conjecture." However, this is really begging the question as one would expect that establishing limitations for specific proof methods is prerequisite to establishing limitations for *all* propositional proof systems. Moreover, there are several similar results and conditional lower bounds based on weaker assumptions:

1. The results of Pudlák [25], extended by Dash [12], establish that certain formulations of the LS refutation systems possess "effective interpolation." Therefore, under the conjecture that there are disjoint NP pairs that are not separable by a polynomial-size circuit, these systems require superpolynomial size to refute some CNFs. The hypothesis that some NP disjoint pairs cannot be separated by polynomial-size circuits is not known to imply $\mathsf{NP} \neq \mathsf{coNP}$, so these results provide further evidence that LS proofs require superpolynomial size to refute some CNFs.
2. Grigoriev, Hirsch, and Pasechnik showed that there are unconditional superpolynomial size lower bounds known for treelike LS proofs that certain "non-CNF" polytopes contain no zero-one points [15].
3. Several unconditional lower bounds are known for similar systems that are incomparable with or apparently weaker than treelike LS systems with respect to proof size. An exciting series of papers, culminating in the celebrated result of Pudlák, unconditionally showed that the cutting planes proof system (a kind of logic whose formulas are linear inequalities and whose inference rules are based on Gomory–Chvatal cuts) requires superpolynomial size to refute certain CNFs [16, 5, 24]. Dash has extended this work and proved unconditionally that a restricted form of the LS system (one that makes only "noncommutative cuts") requires superpolynomial size to refute certain CNFs [12].

In this paper, we develop a new method for approaching size lower bounds for treelike LS and for systems that generalize treelike LS. Our main result is that lower bounds on the three-party communication complexity of set disjointness (in the number-on-the-forehead (NOF) model) imply lower bounds on the size of treelike LS proofs for a particular family of unsatisfiable CNF formulas. We also generalize this result to a much more general family of proof systems known as semantic $\mathbf{Th(k)}$, where lines are now degree k polynomial inequalities. All versions of LS are special cases of $\mathbf{Th(2)}$, and Chvátal's cutting planes proof system is a special case of $\mathbf{Th(1)}$.

More generally, we show that proving lower bounds on the $(k+1)$-party communication complexity of set disjointness implies lower bounds on the size of treelike semantic $\mathbf{Th(k)}$ proofs. A lower bound showing that $\textsc{Disj}_k$ is not in $(k+1)$-RP^{cc} would give excellent lower bounds for $\mathbf{Th(k)}$ proofs.

Admittedly, this is another conditional result towards proving size lower bounds for treelike LS proofs. However, we feel that there is a significant difference between an approach that is based on the conjecture "set disjointness requires $\omega(\log^4 n)$ bits of communication in the three-player number-on-the-forehead model" and assumptions such as "$\mathsf{NP} \neq \mathsf{coNP}$" or "there exists an NP disjoint pair that cannot be separated by a polynomial size circuit." The latter problems both imply that $\mathsf{P} \neq \mathsf{NP}$, one of the most famous and difficult problems in contemporary computer science and mathematics, with few persons making serious claims of substantial progress towards its resolution, and the task of establishing proof-size lower bounds can be viewed as establishing partial evidence in support of these conjectures. On the other hand, NOF communication complexity is an area in which there has been substantial progress in the decades since its introduction in 1983 [8]. There are specific, concrete functions on n-bit inputs for which the three-player NOF communication complexity is known to require $\Omega(n)$ bits of communication, so the problem is one of establishing the bound for the set-disjointness function in particular. Moreover, in the two-player model, set disjointness is known to require $\Omega(n)$ bits of communication. Finally, the authors of this paper with Avi Wigderson have established $n^{\Omega(1)}$ lower bounds for the computation of the set-disjointness function by certain restricted protocols in the NOF model.

Our proof can be seen as a generalization of [16] to arbitrary k, but the extension requires a number of new ideas and a substantially more complicated argument that includes a detailed analysis of large sets of vertex-disjoint paths in expander graphs.

Our work is incomparable to the interpolation-based results of Pudlák and Dash. While our bound is conditional, based upon what seems to be a more earthly conjecture than strengthenings of $\mathsf{P} \neq \mathsf{NP}$, our bounds apply only for the treelike case, whereas the results of Pudlák and Dash apply to the DAG-like case as well. On the other hand, their interpolation theorems depend highly on the form of the cuts used, whereas our semantic approach allows the result to apply to almost any system for manipulating polynomial inequalities with reasonable inference rules.

While the results of Grigoriev, Hirsch, and Pasechnik [15] are unconditional, they do not apply to systems of inequalities that arise from the translation of CNFs. Rather, an exponential size lower bound was proved for all treelike LS refutations of the equality $x_1 + \cdots + x_n = \alpha$, where α is a noninteger in the range $(\lceil n/4 \rceil, \lfloor 3n/4 \rfloor)$. As this equality cannot arise as the translation of a CNF into inequalities, their bound says nothing about the LS systems for propositional unsatisfiability. Indeed, proving treelike size lower bounds for CNF polytopes was given as one of the main problems left open in their paper.

Recently Kojevnikov and Itsykson [17] have released a proof of a $2^{\Omega(n)}$ size lower bound for treelike LS_+ refutations of the Tseitin principles over a constant degree expander. This is result is incomparable to ours because while their proof is unconditional, it does not apply to systems that use inference rules besides those of LS_+, nor does it clearly generalize to systems that take inequalities of degree higher than two.

2. Definitions.

2.1. Multiparty communication complexity and set disjointness.

The *k-party NOF model of communication complexity* computes functions (or relations) of input vectors $(x_1, \ldots, x_k) \in X_1 \times \cdots \times X_k$ distributed among k parties such that party $i \in [k]$ sees all x_j for all $j \in [k]$, $j \neq i$. It is as if player i has the ith input on his forehead, hence the name. The players communicate by transmitting bits over a channel shared by all players. The communication complexity of a protocol is the number of bits exchanged. For a function $f : X_1 \times \cdots \times X_k \to \{0,1\}$, we define $R^k_\epsilon(f)$ to be the minimum cost of a randomized protocol that computes f with a probability of error at most ϵ. For a more thorough treatment of communication complexity, see the monograph by Kushilevitz and Nisan [20].

The *k-party set-disjointness problem* $\textsc{Disj}_{k,m} : (\{0,1\}^m)^k \to \{0,1\}$ is defined by $\textsc{Disj}_{k,m}(\vec{x}) = 1$ if and only if there is some $j \in [n]$ such that $x_{i,j} = 1$ for all $i \in [k]$. Although it might be more appropriate to call this function set intersection rather than disjointness, we follow standard terminology. A *$(0,\epsilon)$-error k-party NOF communication protocol* for set disjointness is a protocol that for every disjoint input produces output 0 and for intersecting inputs outputs 1 with probability at least $1-\epsilon$.

It is conjectured that for all constants $k \geq 2$ the k-party set-disjointness problem of length n requires randomized NOF communication complexity that is $\Omega(n/2^k)$ [3]. This conjecture is equivalent to showing that nondeterministic k-party communication complexity can be almost optimally separated from randomized k-party communication complexity. The conjecture is proven for $k = 2$ [18], but the best known lower bound for $k \geq 3$ is $\Omega(\log n)$ for general models and $\Omega(n^{1/k})$ for more restricted models [3].

2.2. Threshold logics. The best known classes of threshold logics are Gomory–Chvátal cutting planes [10], the matrix cuts of Lovász and Schrijver [21], and the lift-and-project relaxations of Sherali and Adams [27]. First we briefly describe Gomory–Chvátal cutting planes, which is referred to in the literature as simply cutting planes (CP). A CP proof of unsatisfiability of a set of integer linear inequalities $f = \{\vec{a}_1 \cdot \vec{x} \geq b_1, \ldots \vec{a}_m \cdot \vec{x} \geq b_m\}$ is a sequence of integer linear inequalities $\vec{c}_1 \cdot \vec{x} \geq t_1, \ldots, \vec{c}_q \cdot \vec{x} \geq t_q$ such that each $\vec{c}_i \cdot \vec{x} \geq t_i$ is either an inequality from f, an axiom ($x \geq 0$ or $1-x \geq 0$), or is obtained by one of the two rules: (i) $\vec{c}_i \cdot \vec{x} \geq t_i$ is a positive integer linear combination of some previously derived inequalities, or (ii) $\vec{c}_i \cdot \vec{x} \geq t_i$ is obtained from a previous inequality $d\vec{c_i} \cdot \vec{x} \geq t_i$ by rounding (to obtain $\vec{c}_i \cdot \vec{x} \geq \lceil t_i/d \rceil$).

There are several cutting planes proof systems defined by Lovász and Schrijver [21], collectively referred to as matrix cuts. These systems allow one to "lift" the linear inequalities to degree-two polynomials and then project back to degree one, using the fact that $x^2 = x$ for $x \in \{0,1\}$. To see that the definitions below are equivalent to the original definitions of Lovász and Schrijver, see [12].

Definition 2.1. *Given a polytope $P \subseteq \mathbb{Q}^n$ defined by $\vec{a}_i \cdot \vec{x} \geq b_i$ for $i = 1, 2, \ldots, m$:*

(1) *An inequality $d - \vec{c} \cdot \vec{x} \geq 0$ is called an N-cut for P if*

$$d - \vec{c} \cdot \vec{x} = \sum_{i,j} \alpha_{ij}(b_i - \vec{a}_i \cdot \vec{x})x_j + \sum_{ij} \beta_{ij}(b_i - \vec{a}_i \cdot \vec{x})(1-x_j) + \sum_j \lambda_j(x_j^2 - x_j),$$

where $\alpha_{ij}, \beta_{ij} \geq 0$ and $\lambda_j \in R$ for $i = 1, \ldots, m$, $j = 1, \ldots, n$.

(2) *A weakening of N-cuts, called N_0-cuts, can be obtained if, when simplifying to the term $d - \vec{c} \cdot \vec{x}$, we view $x_i x_j$ as distinct from $x_j x_i$.*

(3) *An inequality $d - \vec{c} \cdot \vec{x}$ is called an N_+-cut if*

$$d - \vec{c} \cdot \vec{x} = \sum_{i,j} \alpha_{ij}(b_i - \vec{a}_i \cdot \vec{x})x_j + \sum_{ij} \beta_{ij}(b_i - \vec{a}_i \cdot \vec{x})(1-x_j) + \sum_j \lambda_j(x_j^2 - x_j) + \sum_k (g_k + \vec{h}_k \cdot \vec{x})^2,$$

where again $\alpha_{ij}, \beta_{ij} \geq 0$, $\lambda_j \in R$ for $i = 1, \ldots, m$, $j = 1, \ldots, n$, and $g_k + \vec{h}_k \cdot \vec{x}$ is an affine function for $k = 1, \ldots, n+1$.

The operators N, N_0, and N_+ are called the *commutative*, *noncommutative*, and *semidefinite* operators, respectively. All three are collectively called *matrix-cut* operators.

Definition 2.2. *A LS refutation for f is a sequence of inequalities $g_1, \ldots, g_q$ such that each g_i is either an inequality from f or follows from previous inequalities* *by an N-cut as defined above and such that the final inequality is* $0 \geq 1$. *Similarly, a LS_0 refutation uses N_0-cuts and LS_+ uses N_+-cuts.*

DEFINITION 2.3. *Let $\mathcal{P}$ be one of the proof systems CP, LS, LS_0, or LS_+. Let S be an $\mathcal{P}$-refutation of f, viewed as a directed acyclic graph. If the underlying directed acyclic graph is a tree, then S is a treelike $\mathcal{P}$-refutation of f. The inequalities in S are represented with all coefficients in binary notation. The size of S is the sum of the sizes of all inequalities in S; the rank of S is the depth of the underlying directed acyclic graph. For a set of Boolean inequalities f, the $\mathcal{P}$-size of f is the minimal size over all $\mathcal{P}$ refutations of f. Similarly the $\mathcal{P}$-treesize of f is the minimal size over all treelike $\mathcal{P}$-refutations of f.*

The inference rules and axioms for the CP, LS, LS_0, and LS_+ systems are easily seen to be sound. Furthermore, it has been shown that, in their treelike forms, each of CP, LS, LS_0, and LS_+ can p-simulate treelike resolution (cf. [3]). Therefore, by the completeness of treelike resolution, the treelike systems CP, LS, LS_0, and LS_+ can refute every unsatisfiable CNF.

All of the above proof systems are special cases of the more general *semantic* threshold logic proof systems which we define now. A *k-threshold formula* over Boolean variables $x_1, \ldots, x_n$ is a formula of the form $\sum_j \gamma_j m_j \geq t$, where γ_j, t are integers, and for all j, m_j is a multilinear monomial of degree at most k. The *size* of a k-threshold formula is the sum of the sizes of γ_j and t, written in binary notation. Let f_1, f_2, g be k-threshold formulas in the variables $\vec{x}$. We say that g *is semantically entailed* by f_1 and f_2 if, for every $0/1$ assignment to $\vec{x}$ that satisfies both f_1 and f_2, g is also satisfied.

Let f be an unsatisfiable CNF formula over $x_1, \ldots, x_n$, and let $t_1, \ldots, t_m$ be the underlying set of clauses of f, written as 1-threshold inequalities. A **Th(k)** *refutation of* f, $\mathcal{P}$, is a sequence of k-threshold formulas $L_1, \ldots, L_q$, where each L_j is one of the inequalities t_i, $i \in [m]$, or is semantically entailed by two formulas L_i and $L_{i'}$, with $i, i' < j$, and the final formula L_q is $0 \geq 1$. The *size* of $\mathcal{P}$ is the sum of the sizes of all k-threshold formulas occurring in $\mathcal{P}$. The proof is *treelike* if the underlying directed acyclic graph, representing the implication structure of the proof, is a tree. (That is, every formula in the proof is used at most once as an antecedent of an implication. It is allowed, and quite often necessary, that $L_i = L_j$, and L_i and L_j are used as antecedents for two different inferences. In this way, a formula must be rederived each time it is used.)

Note that, in our definition of these cutting planes systems, we can derive a new inequality from any number of previous inequalities in one step, whereas in the $\mathbf{Th(k)}$ proof system, we are restricted to fan-in two. Because the vector space of degree-at-most-one inequalities has dimension at most $n+1$, in light of Caratheodory's theorem, every inequality derived by purely linear operations in a CP refutation can be derived from at most $n+2$ many previous equations. Therefore, we can assume without loss of generality that the fan-in is at most $n+2$ in CP and, similarly, at most $\binom{n}{2} + n + 2$ in LS, LS_0, and LS_+. Because of this bound on fan-in, refutation size increases by at most an $O(n^2)$ factor when the sums are taken by fan-in two inferences of the form "from $f \geq a$ and $g \geq b$ infer $f + g \geq a + b$." Thus, superpolynomial size lower bounds for treelike **Th(2)** semantic refutations imply superpolynomial size lower bounds for all treelike LS systems.

Because the inference rule in $\mathbf{Th(k)}$ is semantic entailment, lower bounds for the $\mathbf{Th(k)}$ system apply to almost any treelike system for deriving polynomial inequalities with reasonable axioms and inference rules, not only the LS systems. For example, division operators such as "from $\vec{c} \cdot \vec{x} > 0$ and $(b - \vec{a} \cdot \vec{x})\vec{c} \cdot \vec{x} \geq 0$ infer $\vec{a} \cdot \vec{x} \geq b$"

are semantically valid inference rules of fan-in two, and variants of the LS system incorporating such rules fall under our analysis. Furthermore, CP refutations are a special case of $\mathbf{Th(1)}$ semantic refutations, and thus lower bounds for treelike $\mathbf{Th(1)}$ semantic refutations imply similar lower bounds for treelike CP. This connection was exploited to prove lower bounds for treelike CP [16].

2.3. Miscellaneous notation. We use the standard asymptotic notation of Ω, O, ω, and o that is found in theoretical computer science and discrete mathematics. We use the ± notation in the following nonstandard way: When we write $x = a \pm b$, we mean that $x \in [a - b, a + b]$. We use this in the asymptotic sense as well. When we write $x = (1 \pm o(1))M$, we mean that there is a value t with $|t| = o(1)$ so that $x \in [(1 - t)M, (1 + t)M]$.

3. Relating the size of threshold logic refutations to the communication complexity of search problems. Let f be an unsatisfiable CNF formula. We will be interested in the following search problem, Search_f associated with f: Given a truth assignment α, find a clause from f which is falsified by α. The model for this computation is a decision tree whose nodes evaluate polynomial threshold functions.

A *k-threshold decision tree* is a rooted, directed tree whose vertices are labeled with k-threshold functions and edges are labeled with either 0 or 1. The leaves of the tree are labeled with clauses of f. A k-threshold decision tree solves Search_f in the obvious way: Start at the root and evaluate the threshold function; follow the edge that is consistent with the value of the threshold function; continue until the computation reaches a leaf and output the associated clause. The size S of a k-threshold decision tree is the sum of the sizes of all threshold formulas in the tree, where the coefficients are written in binary. The depth of a k-threshold decision tree is the depth of the underlying tree.

The following lemma, similar to the degree 1 case in [16], shows that from a small treelike $\mathbf{Th(k)}$ refutation of an unsatisfiable formula f a small-size, small-depth k-threshold decision tree for Search_f can be extracted.

LEMMA 3.1. *Let $\mathcal{P}$ be a treelike $\mathbf{Th(k)}$ refutation of f of size S. Then there is a k-threshold decision tree for Search_f of depth $O(\log S)$ and size $O(S)$. Furthermore, every threshold formula labeling a node of the decision tree is either a formula in the refutation $\mathcal{P}$ or the vacuously true inequality $0 \geq 0$.*

Proof. Assume that $\mathcal{P}$ is a size S treelike $\mathbf{Th(k)}$ refutation of f. We will describe a depth $O(\log S)$, size $O(S)$, k-threshold decision tree which computes the search problem associated with f. The proof is by induction on S; clearly if $S = 1$, then the unsatisfiable formula is a single, false threshold formula, so the lemma holds. For the inductive statement, assume that the size of $\mathcal{P}$ is $S > 1$. Because the DAG of the proof is a binary tree, there is an intermediate formula f in $\mathcal{P}$ such that the number of formulas above f (ancestors in the tree) is at least $S/3$ and at most $2S/3$. Let the subtree of $\mathcal{P}$ with root formula f be denoted by $\mathcal{A}$, and write $\mathcal{B}$ for the remainder of $\mathcal{P}$, that is, all formulas of $\mathcal{P}$ that are not in $\mathcal{A}$ and with f replaced by $0 \geq 0$. In the decision tree, the root is labeled with f. Beneath the edge labeled 0, we inductively apply the lemma to the subtree $\mathcal{A}$, and beneath the edge labeled 1, we inductively apply the lemma on the subtree $\mathcal{B}$. Both $\mathcal{A}$ and $\mathcal{B}$ have size at most $2S/3$, so we may apply the induction hypothesis and conclude that the height of the decision tree obtained will be at most $\log_{3/2}(S) + 1$, which is $O(\log S)$. To see that the decision tree computes the search function, notice that if f evaluates to false on a given truth assignment ϕ, then we proceed on the subproof $\mathcal{A}$. By soundness of the proof, at least one of the leaf formulas of $\mathcal{A}$ must be falsified by ϕ. A similar argument holds when f evaluates to true. □

The next lemmas, adapted from arguments in [23], show that any relation computed by a shallow k-threshold decision tree can also be efficiently computed by a $k+1$ player communication complexity protocol in the NOF model, over any partition of the variables.

LEMMA 3.2. *Suppose that a relation $R(x_1, \ldots, x_{kn})$ is computed by a depth d k-threshold decision tree in which all coefficients are bounded by $N \geq n$. For any partition of the inputs into k sets, there is a $k+1$-party deterministic NOF communication complexity protocol for R in which $O(d \log N)$ bits are communicated in total.*

Proof. Fix a partition of $x_1, \ldots x_{kn}$. Observe that for each monomial in each k-threshold formula there is at least one party that can evaluate the monomial. Let $\alpha_1 m_1 + \cdots + \alpha_q m_q \geq t$ be the k-threshold formula queried at the root of the k-threshold decision tree for f. The set of monomials m_j can be partitioned into $k+1$ groups, where group i contains monomials that can be "seen" by the ith player. Each player (in turn) communicates the weighted linear combination of their monomials to the other players. After all players have spoken, each player can simply add up the total sum and see if it is greater than the target t, in order to evaluate the k-threshold formula. The $k+1$ players then continue on the half of the decision tree which agrees with the value of this formula. The protocol terminates after d rounds, and each round requires $O(\log N)$ bits of communication. □

In order to prove the randomized version of the above lemma we use a standard randomized protocol for testing linear inequalities. The protocol works in the *number-in-hand* model which is more restricted than the NOF model. In the number-in-the-hand model, each player $i = 1, \ldots k$ has private access to the input x_i (whereas in the NOF model, player i sees inputs $x_1, \ldots x_{i-1}, x_{i+1}, \ldots x_k$).

LEMMA 3.3. *Let $y_1, \ldots, y_{k+1}$ be (signed) integers with n-bit binary representations, and let $c > 0$. Then there is an $O(k \log^2 n)$-bit $(k+1)$-player number-in-hand probabilistic protocol with an error less than $1/n^c$ for determining whether $y_1 + \cdots + y_{k+1} \geq 0$.*

Proof. The players follow a binary search strategy on the bits of the y_i.

Suppose $n \geq 2$. (If $n \leq 2$, the parties simply send their inputs.) Let y_i^H be the high order $\lceil n/2 \rceil$ bits that underapproximate $y_i/2^{\lfloor n/2 \rfloor}$ and y_i^L be the corresponding low order bits for $1 \leq i \leq k+1$. (Some of the y_i may be negative, but then the y_i^L will all be positive.) If $\sum_i y_i^H > 0$, then $\sum_i y_i > 0$; similarly, if $\sum_i y_i^H < -k$, then $\sum_i y_i < 0$. Thus, unless $\sum_i y_i^H \in \{-k, \ldots, 0\}$, the answer can be found by determining whether $y_1^H + \cdots + y_{k+1}^H \geq 0$. If $\sum_i y_i^H = -j \in \{-k, \ldots, 0\}$, then the answer can be found by comparing $y_1^L + \cdots + y_k^L + y_{k+1}^L - j \cdot 2^{\lfloor n/2 \rfloor}$ to 0.

Player 1 randomly selects a prime number $p \in [n^{c+2} \log n, 2n^{c+2} \log n]$ and sends $(p, y_1^H \bmod p)$. For $i = 2$ to k, player i sends $y_i^H \bmod p$. Then, using these values and his own private input, player $k+1$ computes $z = \sum_{i=1}^{k+1} y_i^H \bmod p$.

If $z \not\equiv -j \pmod p$ for $j \in \{0, \ldots, k\}$, then player $k+1$ sends the bit 1, and the protocol continues recursively, using $y_1^H, \ldots, y_{k+1}^H$ instead of $y_1, \ldots, y_{k+1}$.

If $z \equiv -j \pmod p$ for $j \in \{0, \ldots, k\}$, then player $k+1$ sends the bit 0 and j, and the protocol continues recursively with players 1 to j using $(y_1^L - 2^{\lfloor n/2 \rfloor}), \ldots, (y_j^L - 2^{\lfloor n/2 \rfloor})$ instead of $y_1, \ldots, y_j$ and players $j+1$ to $k+1$ using $y_{j+1}^L, \ldots, y_{k+1}^L$ instead of $y_{j+1}, \ldots, y_{k+1}$.

In both of the recursive calls the integers each have at most $\lfloor n/2 \rfloor + 1$ bits. At each stage, we send $O(\log n)$ bits, and the total number of stages is $O(\log n)$ for a total of $O(\log n)^2$ bits sent. The probability of error at each stage is $O(1/n^{c+1})$, and therefore the total error is less than $1/n^c$ (for sufficiently large n). □

LEMMA 3.4. *Suppose that a relation $R(x_1, \dots, x_{kn})$ is computed by a depth d k-threshold decision tree in which all coefficients are bounded by $N \geq n$. For any partition of the inputs into k sets, there is a $(k+1)$-party randomized NOF communication complexity protocol for R in which $O(d(\log \log N)^2)$ bits are communicated in total, which is correct with probability at least $1 - 1/n$.*

Proof. As in the proof of Lemma 3.2, the players proceed in d rounds, at each step evaluating the threshold formula and proceeding on the consistent subtree. Let $p(\vec{x}) \geq t$ be the threshold formula at the root of the decision tree. As before, partition the monomials of $p(\vec{x})$ into $k+1$ groups where the ith player can "see" the monomials in group i. Each of the $k+1$ players computes the weighted sum of their respective monomials. Call these sums $y_1, \dots, y_{k+1}$, respectively. Player $k+1$ uses $y'_{k+1} = y_{k+1} - t$, and by applying Lemma 3.3 with $n = \log_2 N$ and c such that $1/n^c < 1/(dn)$, there is a probabilistic protocol allowing the players to determine with an error at most $1/(dn)$ whether the sum of the y_i's is at least t, where $O((\log \log N)^2)$ bits are exchanged. After evaluating $p(\vec{x}) \geq t$, the players then continue on the branch of the decision tree which agrees with the value of $p(\vec{x}) \geq t$. The protocol terminates after d rounds, for a total of $O(d(\log \log N)^2)$ bits of communication. By the union bound, the probability of encountering an error at some level of the recursion is at most $d \cdot 1/(dn) = 1/n$. □

The following theorem is an easy corollary of the above lemmas.

THEOREM 3.5. *Suppose that f has a treelike* **Th(k)** *refutation of size S. Then there exists a $(k+1)$-party randomized NOF communication complexity protocol for $Search_f$ (over any partition of the variables into k groups) that communicates $O(\log^3 S)$ bits and has an error probability at most $1/n$.*

Further, if all k-threshold formulas in the **Th(k)** *refutation have coefficients bounded by a polynomial in n, then there is a randomized protocol using $O(\log S(\log \log n)^2)$ many bits and an error probability at most $1/n$ and a deterministic protocol using $O(\log S \log n)$ bits.*

Proof. We apply Lemma 3.1 to produce a k-threshold decision tree for $Search_f$ of depth $O(\log S)$ and size $O(S)$. Because every label of a node of the decision tree is a formula of the refutation, or the triviality $0 \geq 0$, N is no larger than the maximum absolute value of a coefficient in the refutation.

For the first claim, set N to be the maximum absolute value of any coefficient appearing in the decision tree; by the definition of the size of a proof, $N = 2^{O(S)}$. For the second claim, we find by hypothesis that $N = n^{O(1)}$. We apply Lemmas 3.2 and 3.4 to this decision tree to yield the claimed size and error bounds. □

4. The difficult CNFs, their search problems, and an outline of the lower bound proof.

Our hard examples are based on the well-known Tseitin graph formulas. Let $G = (V, E)$ be any connected, undirected graph, and let $\vec{c} \in \{0,1\}^V$. The *Tseitin formula for G with respect to charge vector $\vec{c}$, $TS(G, \vec{c})$*, has variables $\mathrm{Vars}(G) = \{y_e \mid e \in E\}$. The formula states that, for every vertex $v \in V$, the parity of the edges incident with v is equal to the charge c_v at node v. It is expressed propositionally as the conjunction of the clauses obtained by expanding $\oplus_{e \ni v} y_e = c_v$ for each $v \in V$. Note that, for a graph with maximum degree d, each clause is of width at most d and the number of clauses is at most $|V|2^d$.

Notice that $TS(G,\vec{c})$ is satisfiable if and only if $\sum_{v\in V} c_v$ is even. For odd $\vec{c}$, the search problem $Search_{TS(G,\vec{c})}$ takes a 0/1 assignment α to Vars(G) and outputs a clause of $TS(G,\vec{c})$ that is unsatisfied. In other words, a solution to $Search_{TS(G,\vec{c})}$ on input α is a vertex v such that a parity equation at the vertex v is violated by α.

To make the search problem hard for k-party NOF communication protocols and, by Theorem 3.5, hard for $(k-1)$-threshold decision trees, we modify $TS(G,\vec{c})$ by replacing each variable y_e by the conjunction of k variables $\bigwedge_{i=1}^{k} y_e^i$ and expanding the result into clauses by use of deMorgan's law. We call the resulting *k-fold Tseitin formula* $TS^k(G,\vec{c})$ and its variable set $\text{Vars}^k(G) = \{y_e^i \mid e \in E, i \in [k]\}$.

For a fixed graph G and different odd-charge vectors $\vec{c} \in \{0,1\}^{V(G)}$, the problems $Search_{TS^k(G,\vec{c})}$ are very closely related. Define $\text{OddCharge}^k(G)$ to be the k-party NOF communication search problem which takes as input an odd charge vector $\vec{c} \in \{0,1\}^{V(G)}$, seen by all players, and an assignment α to $\text{Vars}^k(G)$, in which player i sees all values but the assignment α_e^i to y_e^i for $e \in E(G)$, and requires that the players output a vertex v that is a solution to $Search_{TS^k(G,\vec{c})}$.

The communication complexity of $\text{OddCharge}^k(G)$ depends on the graph G, and we use a carefully modified expander to obtain our lower bounds. We use a family of graphs H_n such that each H_n is the union of two edge-disjoint graphs on the same set of n vertices $[n]$, G_n, and T_n. G_n is a Δ-regular expander graph of the form defined by Lubotzky, Phillips, and Sarnak [22] for $\Delta = \Theta(\log n)$. Since $\overline{G_n}$ has degree $> n/2$, there is a spanning tree T_n of maximum degree 2 (one can take the Hamiltonian path guaranteed by Dirac's theorem; cf. [13]) in $\overline{G_n}$. Clearly H_n also has maximum degree $\Theta(\log n)$, and thus $TS^k(H_n,\vec{c})$ has size $n^{O(k)}$. (Notice that the graph H_n has degree $O(\log n)$, so the CNF $TS^k(H_n,\vec{c})$ has size $n^{O(1)}$ and width $O(\log n)$.)

Now we are ready to describe the sequence of reductions to show that an efficient k-party NOF communication complexity protocol for $\text{OddCharge}^k(H_n)$ will imply an efficient 1-sided error randomized k-party NOF protocol for the set-disjointness relation. The reduction passes through two intermediate problems: a search problem called $\text{EvenCharge}^k(H_n)$ and set disjointness with the promise that, for every input under consideration, the size of the intersection is either zero or one. Reducing the general set-disjointness problem to this *zero/one set-disjointness* problem is a standard application of Valiant–Vazirani isolation (Lemma 5.4, after [28]). Our reduction from zero/one set disjointness to $\text{OddCharge}^k(H_n)$ goes via an intermediate problem $\text{EvenCharge}^k(H_n)$, which is the exact analog of $\text{OddCharge}^k(H_n)$ except that the input charge vector $\vec{c}$ is even rather than odd and the task is either to find a charge violation or to determine that no charge violation exists. For an assignment α and a charge vector $\vec{c}$, we define $\text{Err}(\alpha,\vec{c})$ to be the set of vertices at which the parity constraints are violated by α.

THEOREM 4.1. *Let $k \geq 2$ and $m = n^{1/3}/\log n$. For each n there is an odd charge vector $\vec{c} \in \{0,1\}^n$ such that for any $\epsilon < 1/2$ the size of any treelike* **Th(k-1)** *refutation of $TS^k(H_n,\vec{c})$ is at least $2^{\Omega((R_\epsilon^k(\text{Disj}_{k,m})/\log n)^{1/3})}$. Further, if the coefficients in the* **Th(k-1)** *refutations are bounded by a polynomial in n, then the refutation size must be at least $2^{\Omega(R_\epsilon^k(\text{Disj}_{k,m})/(\log n(\log\log n)^2))}$.*

The proof of Theorem 4.1 is presented at the end of section 5. Here we provide a high-level outline of the proof and its component lemmas. In the sketch, quantities are left out, and definitions are not precise.

Proof sketch. Suppose for the sake of contradiction that there is a small $\mathbf{Th(k-1)}$ refutation of $TS^k(H_n,\vec{c})$.

1. We apply the refutation-to-search conversion of Theorem 3.5 to obtain a low-communication k-player NOF protocol for the ODDCHARGE$^k(H_n)$ search problem.
2. Using Lemma 5.1, we convert the search protocol for ODDCHARGE$^k(G)$ to a search protocol for EVENCHARGE$^k(H_n)$ that correctly solves "most" EVENCHARGE$^k(H_n)$ instances. "Most" is measured by a distribution $\mathcal{D}_t$ on the EVENCHARGE$^k(H_n)$ instances in which there are exactly $2t$ nodes at which the parity constraints are violated. The distribution is $\mathcal{D}_t$ defined in Definition 5.2 of section 5.
3. In Lemma 5.2 we show that the 0/1 set-disjointness problem randomly reduces to EVENCHARGE$^k(H_n)$ in the following sense: For each set-disjointness instance $\vec{x}$, there is a distribution $R(\vec{x})$ on EVENCHARGE$^k(H_n)$ instances so that if $|\cap\vec{x}| = 0$, the instance generated satisfies all parity constraints, and if $|\cap\vec{x}| = 1$, the instance generated has exactly two nodes at which the parity constraints are violated.
4. The distributions $R(\vec{x})$ and $\mathcal{D}_t$ do not coincide, but they are close enough. In Lemma 5.3, it is shown that when $|\cap\vec{x}| = 0$, $R(\vec{x})$ and $\mathcal{D}_0$ are ϵ-close in l_1 distance, and similarly, when $|\cap\vec{x}| = 1$, $R(\vec{x})$ and $\mathcal{D}_1$ are ϵ-close in l_1 distance. Therefore, using the protocol of Lemma 5.1 on inputs generated by $R(\vec{x})$ correctly solves 0/1 set disjointness with an added probability of error at most ϵ. Lemma 5.3 is the most delicate part of the argument, and it is where most of the work is invested.

A simple argument shows that the lower bound of Theorem 4.1 holds for all odd charge vectors.

THEOREM 4.2. *The same lower bounds as Theorem* 4.1 *hold for* every *odd charge vector* $\vec{c} \in \{0,1\}^n$.

Proof. Observe that distributions $\mathcal{D}_t$ and $R(\vec{x})$ on the assignments to Vars$^k(H_n)$ both have the property that for each edge e of T_n, $\alpha_e^1 = \cdots = \alpha_e^k$. Therefore in the proof of Theorem 4.1 observe that we can replace $TS^k(H_n,\vec{c})$ by $\widetilde{TS}^k(H_n,\vec{c}) = TS^k(H_n,\vec{c}) \wedge EQ(T_n)$, where $EQ(T_n)$ is the conjunction of $(\neg y_e^i \vee y_e^j)$ for every $i \neq j \in [k]$ and every $e \in T_n$. The size of any **Th(k-1)** refutation of $TS^k(H_n,\vec{c})$ is at least that of $\widetilde{TS}^k(H_n,\vec{c})$. Moreover, it is not hard to see that, for any odd weight vectors $\vec{c},\vec{d} \in \{0,1\}^n$, $\widetilde{TS}^k(H_n,\vec{c})$ and $\widetilde{TS}^k(H_n,\vec{d})$ have proof sizes that differ by at most a polynomial additive term: Given a small proof of $\widetilde{TS}^k(H_n,\vec{d})$, let $S \subset [n]$ be the set of vertices v for which $c_v \neq d_v$. Since both c and d are odd weight vectors, $|S|$ is even. Let $M \subset E(T_n)$ be the set of edges of corresponding to $|S|/2$ disjoint subpaths in T_n that match the elements in S.

Applying the substitution of $y_e^i = \neg y_e^i$ for each $e \in M$ and $i \in [k]$ *almost* converts a refutation of $\widetilde{TS}^k(H_n,\vec{d})$ into a refutation of $\widetilde{TS}^k(H_n,\vec{c})$. A positive literal y_e^i in a clause from $TS^k(H_n,\vec{c})$, with e on a toggled path, becomes $\neg y_e^i$ rather than $\neg y_e^1 \vee \cdots \vee \neg y_e^k$, which is the proper form for negative literals in clauses of $TS^k(H_n,\vec{d})$. This is corrected by application of the subsumption rule. A disjunction of negative literals $\neg y_e^1 \vee \cdots \vee \neg y_e^k$ in a clause from $TS^k(H_n,\vec{c})$, with e on a toggled path, becomes $y_e^1 \vee \cdots \vee y_e^k$ rather than one of $y_e^1,\ldots,y_e^k$, as is the proper form for positive literals in clauses of $TS^k(H_n,\vec{d})$. Application of the axioms $\neg y_e^j \vee y_e^i$, with resolution steps, corrects this. These corrections increase the size of the proof by at most an $O(k)$ factor. □

5. Reduction from set disjointness to OddCharge. The reduction from EvenCharge$^k(H_n)$ to OddCharge$^k(H_n)$ works by planting a single randomly chosen additional charge violation. This yields a protocol for EvenCharge$^k(H_n)$ that works well on average for each class of inputs with a given number of charge violations. This is similar in spirit to a reduction by Raz and Wigderson [26], and the reader might profit by first becoming familiar with that argument.

The difficult part of our argument is the reduction from zero/one set disjointness to EvenCharge$^k(H_n)$. The key idea is that for even $\vec{c}$, charge violations of $TS^k(H_n, \vec{c})$ come in pairs: Given an instance $\vec{x} \in (\{0,1\}^m)^k$ of zero/one set disjointness, using the public coins, the players randomly choose an even charge vector $\vec{c}$ and m vertex-disjoint paths in H_n, $p_1, \ldots, p_m$, for each $j \in [m]$, the players plant the $x_{1,j}, \ldots, x_{k,j}$ as the assignment along each edge of path p_j, in a random solution that otherwise meets the chosen charge constraint. By construction, a charge violation can occur only at the end points of a path and only if there is an intersection in the set-disjointness problem.

The challenges arise when we would like to apply the average case properties of the EvenCharge$^k(H_n)$ protocol to the instances created by the above distribution. Unfortunately, this distribution is not quite uniform, and we need the distribution to be close to uniform. The bulk of the work is in using the properties of H_n, rapid mixing, modest degree, and high girth, to show that the distribution generated by the reduction is sufficiently close to uniform.

Distributions on labeled graphs. Let n be given, let H_n be the graph described in section 4, and let $\vec{c}$ be an even charge vector.

Definition 5.1. *We define $Sol(H_n, \vec{c})$ to be the set of all $0/1$ assignments to the edges of H_n so that, for each vertex $v \in [n]$, the parity of edges incident with v is equal to c_v. A uniform random distribution over $Sol(H_n, \vec{c})$ can be obtained by first selecting $0/1$ values uniformly at random for all edges in G_n and then choosing the unique assignment to the edges of T_n that fulfill the charge constraints given by $\vec{c}$.*

Given a bit value b associated with an edge $e \in G_n$, we can define a uniform distribution $\mathcal{L}_k(b)$ over the corresponding variables y_e^i, $i \in [k]$. Such an assignment is chosen randomly from $\mathcal{L}_k$ on input b by the following experiment. If $b = 1$, then set all variables associated with edge e, y_e^i, $i \in [k]$ to 1. Otherwise, if $b = 0$, set the vector $(\vec{y}_e)_{i \in [k]}$ by choosing uniformly at random from the set of $2^k - 1$ not-all-1 vectors (i.e., $\{0,1\}^k \setminus \{0^k\}$).

Definition 5.2. *For any $t \geq 0$ let $\mathcal{D}_t$ be a distribution given by the following experiment on input $H_n = G_n \cup T_n$:*

1. *Choose an even charge vector $\vec{c} \in \{0,1\}^n$ uniformly at random.*
2. *Choose $\beta \in Sol(H_n, \vec{c})$ uniformly at random.*
3. *For each $e \in G_n$, select the values for the vector $(y_e)_{i \in [k]}$ from $\mathcal{L}_k(\beta_e)$, and, for each $e \in T_n$, set $y_e^i = \beta_e$ for all $i \in [k]$.*
4. *Select a random subset $U \subseteq [n]$ of $2t$ vertices, and produce charge vector $\vec{c}^{\,U}$ from $\vec{c}$ by toggling all bits c_v for $v \in U$.*
5. *Return the pair $(\alpha, \vec{c}^{\,U})$, where α is the Boolean assignment to the variables y_e^i, $i \in [k]$, $e \in H_n$.*

Reduction from EvenCharge to OddCharge.

Lemma 5.1. *Let n be given, and let Δ be the maximum degree of a vertex in H_n. Suppose that Π_{odd} is a randomized k-party NOF protocol for* OddCharge$^k(H_n)$ *that produces a vertex with a probability at least $1 - \epsilon$, is correct whenever it produces a* *vertex, and uses at most s bits of communication. Then there is a randomized k-party NOF protocol Π_{even} for* $\textsc{EvenCharge}^k(H_n)$ *that uses $s + \Delta$ bits of communication and has the following performance:*

$$\Pr_{(\alpha,\vec{c})\in\mathcal{D}_0}[\Pi_{even}(\alpha,\vec{c}) = \text{true}] = 1,$$
$$\Pr_{(\alpha,\vec{c})\in\mathcal{D}_t}[\Pi_{even}(\alpha,\vec{c}) \in \text{Err}(\alpha,\vec{c})] \geq 2/3 - \epsilon \textit{ for } t \geq 1.$$

Proof. Let Π_{odd} be a protocol for $\textsc{OddCharge}^k(H_n)$. We give a protocol Π_{even} for $\textsc{EvenCharge}^k(H_n)$. On input $(\alpha, \vec{c})$ and random public string r, using r, choose a random vertex $v \in [n]$. Check whether the parity equation associated with vertex v is satisfied by α using at most $\Delta(G)$ bits of communication. (This can be done by having player 1 broadcast y_e^2 for each $e \ni v$ and then having player 2 compute whether the constraint at v is obeyed or violated.) If it is not, return v. Otherwise, create an odd charge vector $\vec{c}^{\,\{v\}}$, which is just like $\vec{c}$ except that the value of c_v is replaced by $1 - c_v$. Now run Π_{odd} on input $(\vec{c}^{\,\{v\}}, \alpha)$. If Π_{odd} returns the planted error v or if Π_{odd} does not return a value, then return "true"; if Π_{odd} returns $u \neq v$, output u.

Suppose that $(\alpha, \vec{c}) \in \mathcal{D}_0$. Then α satisfies all charges specified by $\vec{c}$, so when Π_{odd} returns a vertex, the above protocol must output "true" because Π_{odd} has a one-sided error–that is, Π_{odd} will return a vertex u only when there is an error on the parity equation associated with u. Now suppose that $(\alpha, \vec{c}) \in \mathcal{D}_t$, so exactly $2t$ parity equations are violated. If the parity constraint about the vertex v is not satisfied, then the protocol detects this and correctly reports the location of the error. The remaining case is when the parity constraint at v is satisfied, and in this case we call Π_{odd} on a pair $(\alpha, \vec{c}^{\,\{v\}})$ where exactly $2t + 1$ parity equations are violated.

We show the probability bound by conditioning separately on the events $\text{Err}(\alpha, \vec{c}^{\,\{v\}}) = T$ for each $T \in \binom{[n]}{2t+1}$. Because the events $\text{Err}(\alpha, \vec{c'}) = T$ partition the probability space, this proves the claim. By symmetry, for $T \in \binom{[n]}{2t+1}$ and *any* function g whose range is a subset of T, we have that $\Pr_{\alpha,\vec{c},v}[g(\alpha, \vec{c}^{\,\{v\}}) = v \mid \text{Err}(\alpha, \vec{c}^{\,\{v\}}) = T] = 1/(2t+1)$ since it is equally likely for $\vec{c'} = \vec{c}^{\,\{v\}}$ to be generated as $\vec{c}^{\,\{u\}}$ for any $u \in T$. Thus we obtain

$$\begin{aligned}
&\Pr_{\alpha,\vec{c},v}[\Pi_{even}(\alpha, \vec{c}^{\,\{v\}}) \text{ errs} \mid \text{Err}(\alpha, \vec{c}^{\,\{v\}}) = T] \\
&= \Pr_{\alpha,\vec{c},v}[\Pi_{odd}(\alpha, \vec{c}^{\,\{v\}}) = v \text{ or } \Pi_{odd}(\alpha, \vec{c}^{\,\{v\}}) \text{ is not defined } \mid \text{Err}(\alpha, \vec{c}^{\,\{v\}}) = T] \\
&\leq 1/(2t+1) + \epsilon \;\leq\; 1/3 + \epsilon
\end{aligned}$$

for $t \geq 1$. □

Reduction from zero/one set disjointness to EvenCharge. We now show how to use a k-party NOF communication complexity protocol Π_{even} for $\textsc{EvenCharge}^k(H_n)$ as guaranteed by Lemma 5.1 to produce a k-party NOF protocol for the zero/one set-disjointness problem which uses the following definition. In this reduction, we place the set-disjointness variables on the variables labeling some randomly chosen paths in the graph G_n. For the purposes of analyzing the distribution, the paths are chosen to be of length $l = \lceil \frac{\log n}{\log\log n} \rceil$ where $c_1 > 0$ is a constant. The constant c_1 is determined by Proposition 6.6. This is necessary for the proof of Lemma 5.3. For a more thorough discussion of this choice, see section 6.2.

Definition 5.3. *Let $P_l^{(m)}$ be the set of all sequences of m vertex-disjoint length l paths in G_n.*

Lemma 5.2. *Let $m = n^{1/3}/\log n$. For sufficiently large n and for any even charge vector $\vec{c}$, if there is a probabilistic k-party NOF communication complexity protocol Π_{even} for* $\text{EvenCharge}^k(H_n)$ *using s bits, satisfying the conditions in Lemma* 5.1 *for $\mathcal{D}_0$ and $\mathcal{D}_1$, then there is a randomized $(0, 1/3 + \epsilon + o(1))$ error k-party NOF communication complexity protocol Π_{01disj} for zero/one set disjointness on input $\vec{x} \in (\{0,1\}^m)^k$ that uses s bits of communication.*

Proof. Let $\vec{x}$ be an instance of zero/one set disjointness. Protocol Π_{01disj} will call Π_{even} on the graph H_n, on a pair $(\alpha, \vec{c})$ chosen according to the following distribution/experiment:

1. On input $\vec{x}$ with public coins r:
   (a) Using public coins r, choose a random even charge vector $\vec{c} \in \{0,1\}^n$.
   (b) Using public coins r, choose a sequence of m vertex-disjoint length l paths $p_1, \dots p_m$ uniformly at random from $P_l^{(m)}$.
   (c) Using the public coins r, choose $\beta \in Sol(H_n - \bigcup_{j=1}^m p_j, \vec{c})$.
2. For all edges $e \in H_n$, all players other than player i compute α_e^i as follows:
   (a) If $e \in p_j$ for $j \in [m]$, set $\alpha_e^i = x_{i,j}$.
   (b) If $e \in G_n$ and $e \notin \bigcup_{j=1}^m p_j$, choose the vector $\alpha_e^1 \dots \alpha_e^k$ according to the distribution $\mathcal{L}_k(\beta_e)$.
   (c) For the remaining edges $e \in T_n$, set all variables α_e^i for $i \in [k]$ equal to β_e.
3. Return $(\alpha, \vec{c})$.

We write $\mathcal{R}(\vec{x})$ to denote the distribution on assignment/charge pairs produced by reduction Π_{01disj} when given an input $\vec{x}$. The following lemma shows that when $|\cap \vec{x}| = 1$, although $\mathcal{R}(\vec{x})$ is not the same as $\mathcal{D}_1$, $\mathcal{R}(\vec{x})$ is close to the distribution $\mathcal{D}_1$ in the ℓ_1 norm. This is the main technical lemma in the proof. The proof of this lemma can be found in the next section.

Lemma 5.3. *Let $\vec{x} \in (\{0,1\}^m)^k$ and $|\cap \vec{x}| = 1$. Then $||\mathcal{R}(\vec{x}) - \mathcal{D}_1||_1$ is $o(1)$.*

The protocol Π_{01disj} will output 0 if Π_{even} returns "true" and 1 otherwise. If $\cap\vec{x} = \emptyset$, by the above construction, the support of $\mathcal{R}(\vec{x})$ is contained in that of $\mathcal{D}_0$ and thus on $\mathcal{R}(\vec{x})$, Π_{even} must answer "true" and the vector $\vec{x}$ is correctly identified as being disjoint. In the case that $\cap\vec{x}$ contains exactly one element, $\Pr[\Pi_{01disj}(\vec{x}) = 0] \geq 2/3 - \epsilon - o(1)$. This completes the proof of Lemma 5.2. ◻

Reduction from set disjointness to zero/one set disjointness.

Lemma 5.4. *If there is an $(0, \epsilon)$ randomized NOF protocol for the k-party zero-one set-disjointness problem that uses s bits of communication where ϵ is a constant < 1, then there is a $(0, \frac{1}{3})$ randomized NOF protocol for the k-party set-disjointness problem that uses $O(s \log n)$ bits of communication.*

Naturally, our starting point is the well-known result of Valiant and Vazirani [28].

Lemma 5.5 (Valiant–Vazirani). *Let a be a positive integer. Fix a nonempty $S \subseteq \{0,1\}^a$, and choose $w_1, \dots w_a \in \{0,1\}^a$ independently and uniformly. With probability at least $1/4$, there exists $j \in \{0, \dots, a\}$ so that $|\{x \in S \mid \forall i \leq j,\ x \cdot w_i = 0\}| = 1$.*

Proof of Lemma 5.4. Let Π be the protocol for the promise problem. Set $a = \lceil \log n \rceil$. Using public coins, independently and uniformly choose $w_1, \dots w_l \in \{0,1\}^a$. For $j \in \{0, \dots a\}$, the players run the protocol Π, using the following rule for evaluating the input $x_{i,r}$ for $i \in [k], r \in [m]$: Interpret r as a vector in $\{0,1\}^a$, and replace the value of $x_{i,r}$ by zero if for some $j' \leq j$, $w_{j'} \cdot r \neq 0$, and use the value $x_{i,r}$ if for all $j' \leq j$, $w_{j'} \cdot r = 0$. If the protocol Π returns 1, the players halt and output 1; otherwise, the players proceed to round $j + 1$. If no intersection is found after all $a + 1$ rounds, the players announce that the inputs are disjoint.

Clearly, this protocol uses $O(s \log n)$ bits of communication, and by the 0-error property of Π on disjoint inputs, it never outputs 1 when the inputs are disjoint. When the inputs are nondisjoint, the Valiant–Vazirani construction ensures that, with probability at least 1/4, at some round j the protocol Π is used on an input with a unique intersection, and therefore, conditioned on this event, the correct answer is returned with a probability at least $1 - \epsilon$. Therefore, the correct answer is returned with a probability at least $\frac{1}{4} - \frac{\epsilon}{4}$. Because ϵ is bounded away from 1 and the error is one-sided, a constant number of repetitions decreases the probability of error to 1/3. □

Combining the reductions to prove Theorem 4.1.

Proof of Theorem 4.1. By Theorem 3.5 and the definition of $\textsc{OddCharge}^k(H_n)$, if for every $\vec{c} \in \{0,1\}^n$ there is treelike **Th(k-1)** refutation of $TS^k(H_n, \vec{c})$ of size at most S, then there is a $1/n$-error randomized k-party NOF communication complexity protocol for $\textsc{OddCharge}^k(H_n)$ in which at most $O(\log^3 S)$ bits are communicated. By communicating the values of the edges incident to the vertex to be output by this $\textsc{OddCharge}^k(H_n)$ protocol, the players can check that this vertex is indeed in error and not produce a vertex otherwise. This gives a 0-error protocol that outputs the correct answer with a probability at least $1 - 1/n$. By Lemma 5.1 this yields a randomized 0-error k-party NOF protocol Π_{even} for $\textsc{EvenCharge}^k(H_n)$ that uses $O(\log^3 S + \log n)$ bits, produces the correct answer for all inputs in the support of $\mathcal{D}_0$, and for inputs randomly chosen according to $\mathcal{D}_1$ produces a correct answer with a probability at least $2/3 - 1/n$. Applying Lemma 5.2 this yields a $(0, 1/3 + 1/n + o(1))$-error k-party protocol for zero/one set disjointness on $(\{0,1\}^m)^k$ also of complexity $O(\log^3 S + \log n)$. Finally applying Lemma 5.4 yields an error 1/3 randomized k-party NOF protocol for $\textsc{Disj}_{k,m}$ of complexity $O(\log^3 S \log n + \log^2 n)$ bits in total. The deterministic bound is obtained by applying a similar reduction using the other parts of Theorem 3.5. □

6. Proximity of distributions $\mathcal{D}_1$ and $\mathcal{R}(\vec{x})$ when $|\cap \vec{x}| = 1$.

In this section we prove Lemma 5.3, that for $|\cap \vec{x}| = 1$ the distributions $\mathcal{R}(\vec{x})$ and $\mathcal{D}_1$ are close in the ℓ_1 norm. Let $\mu_{\mathcal{D}_1}$ and $\mu_{\mathcal{R}(\vec{x})}$ be their associated probability measures. We will show that, for all but a set of $(\alpha, \vec{c})$ with $\mu_{\mathcal{D}_1}$ measure $o(1)$, $\mu_{\mathcal{D}_1}(\alpha, \vec{c}) = (1 \pm o(1))\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c})$.

Given an instance of the set-disjointness variables $\vec{x} = (\{0,1\}^m)^k$, for $j \in [m]$ we say that the *color* of j is the tuple $(x_{1,j}, \dots, x_{k,j}) \in \{0,1\}^k$. By construction, the assignment $\mathcal{R}(\vec{x})$ has color $(x_{1,j}, \dots, x_{k,j})$ on each edge of the path p_j.

Definition 6.1. *Given an ordered sequence of paths $\vec{p} \in P_l^{(m)}$, an $\vec{x} \in (\{0,1\}^m)^k$, and an assignment α, write $\chi(\alpha_{\vec{p}}) = \vec{x}$ if and only if every edge on path p_j has color $(x_{1,j}, \dots, x_{k,j})$ for every $j \in [m]$.*

We first observe that for any $(\alpha, \vec{c})$ with $|\mathrm{Err}(\alpha, \vec{c})| = 2$ the probability $\mu_{\mathcal{D}_1}(\alpha, \vec{c})$ depends only on the number of edges $e \in G_n$ having color 1^k in α.

Definition 6.2. *Let $\phi(a, b) = 2^{-a}(2^k - 1)^{-(a-b)}$.*

Lemma 6.1. *For any $(\alpha, \vec{c})$ with $|\mathrm{Err}(\alpha, \vec{c})| = 2$ and $m_1 = |\{e \in E(G_n) \mid \alpha_e = 1^k\}|$,*

$$\mu_{\mathcal{D}_1}(\alpha, \vec{c}) = \frac{\phi(|E(G_n)|, m_1)}{2^{n-1}\binom{n}{2}}.$$

Proof. Let $U = \mathrm{Err}(\alpha, \vec{c})$. The probability under $\mathcal{D}_1$ that U is chosen to be flipped is $1/\binom{n}{2}$, and, given U, the probability that the charge vector $\vec{c}$ is produced by the experiment is simply the probability that $\vec{c}^U$ is generated by the uniform distribution over all 2^{n-1} many even charge vectors, that is, $2^{-(n-1)}$. Conditioned on the event that U is chosen to be flipped, and that the charge vector is $\vec{c}$, the chance that α labels the edges for the randomly selected element of $Sol(H_n, \vec{c})$ is $2^{-|E(G_n)|}(2^k-1)^{-(|E(G_n)|-m_1)} = \phi(|E(G_n)|, m_1)$. □

Definition 6.3. *For $U \subset V$, with $|U| = 2$, let $P_l^{(m)}(U)$ be the set of all elements of $P_l^{(m)}$ that have a path whose end points are U.*

Now consider the measure $\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c})$. Let $\{i\} = \cap \vec{x} \subseteq [n]$, $U = \text{Err}(\alpha, \vec{c})$, with $|U| = 2$, and $m_1 = |\{e \in E(G_n) \mid \alpha_e = 1^k\}|$. By the definition of $\mathcal{R}(\vec{x})$,

$$\begin{aligned}\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c}) = &\Pr_{\vec{p} \in P_l^{(m)}}[\text{Ends}(p_i) = \text{Err}(\alpha, \vec{c}) \wedge \chi(\alpha_{\vec{p}}) = \vec{x}] \\ &\cdot \Pr_{\substack{\vec{c'} \in \{0,1\}^n \\ \alpha' \in \mathcal{L}_k(Sol(H_n - \vec{p}, \vec{c'}))}}[\alpha' = \alpha_{G_n - \vec{p}} \text{ and } \vec{c'} = \vec{c}] \\ = &\Pr_{\vec{p} \in P_l^{(m)}}[\text{Ends}(p_i) = \text{Err}(U)] \cdot \Pr_{\vec{p} \in P_l^{(m)}(U)}[\chi(\alpha_{\vec{p}}) = \vec{x}] \\ &\cdot \phi(|E(G_n)| - ml, m_1 - l)/2^{n-1}.\end{aligned}$$

Observe that p_i is a uniformly chosen element of P_l, and we can analyze the first term using the following property of random paths on Lubotzky–Phillips–Sarnak (LPS) expanders proved as part of Lemma 6.9 in section 6.2.2.

Lemma 6.2. *For $u \neq v \in V(G_n)$ and $l \geq c_1 \log n / \log \log n$, $\Pr_{p \in P_l}[\text{Ends}(p) = \{u, v\}] = (1 \pm o(1))/\binom{n}{2}$.*

Thus

$$\begin{aligned}\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c}) &= (1 \pm o(1)) \frac{\phi(|E(G_n)| - ml, m_1 - l)}{\binom{n}{2} 2^{n-1}} \cdot \Pr_{\vec{p} \in P_l^{(m)}(U)}[\chi(\alpha_{\vec{p}}) = \vec{x}] \\ &= (1 \pm o(1)) \frac{\mu_{\mathcal{D}_1}(\alpha, \vec{c})}{\phi(ml, l)} \cdot \Pr_{\vec{p} \in P_l^{(m)}(U)}[\chi(\alpha_{\vec{p}}) = \vec{x}].\end{aligned}$$

It follows that we will obtain the desired result if we can show that, for all but a $o(1)$ measure of $(\alpha, \vec{c})$ under $\mu_{\mathcal{D}_1}$,

$$\Pr_{\vec{p} \in P_l^{(m)}(U)}[\chi(\alpha_{\vec{p}}) = \vec{x}] = (1 \pm o(1))\phi(ml, l) = (1 \pm o(1))2^{-ml}(2^k - 1)^{-(m-1)l},$$

where $U = \text{Err}(\alpha, \vec{c})$. In the case that this happens, we say that $(\alpha, \vec{c})$ is *well-distributed for $\vec{x}$*.

Using the second moment method we prove the following lemma, which shows that, for all but a $o(1)$ measure of $(\alpha, \vec{c})$ under $\mu_{\mathcal{D}_1}$, $(\alpha, \vec{c})$ is indeed well-distributed for $\vec{x}$. The detailed proof is given in section 6.1.

Lemma 6.3. *Let $m \leq n^{1/3}/\log n$, $l = 2\lceil c_1 \log n / \log \log n \rceil$, and $\vec{x} \in (\{0,1\}^m)^k$, with $|\cap \vec{x}| = 1$. For almost all $U \subset [n]$, with $|U| = 2$,*

$$\Pr_{(\alpha, \vec{c}) \in \mathcal{D}_1}[(\alpha, \vec{c}) \textit{ is well-distributed for } \vec{x} \mid \text{Err}(\alpha, \vec{c}) = U] = 1 - o(1).$$

Lemma 5.3 follows from this almost immediately.

Proof of Lemma 5.3. Let $\vec{x} \in (\{0,1\}^m)^k$ and $|\cap \vec{x}| = 1$. By Lemma 6.3 and the preceding argument, for all $U \in \binom{[n]}{2}$ except for a set B that forms an $o(1)$ fraction of $\binom{[n]}{2}$,

$$\Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[\mu_{\mathcal{R}(\vec{x})}(\alpha,\vec{c}) = (1\pm o(1))\mu_{\mathcal{D}_1}(\alpha,\vec{c}) \mid \mathrm{Err}(\alpha,\vec{c}) = U] = 1 - o(1).$$

By Lemma 6.2, $\Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[\mathrm{Err}(\alpha,\vec{c}) \in B] = o(1)$. Therefore by summing over distinct choices of U, we obtain that, with probability $1-o(1)$ over $(\alpha,\vec{c}) \in \mathcal{D}_1$, $\mu_{\mathcal{R}(\vec{x})}(\alpha,\vec{c}) = (1\pm o(1))\mu_{\mathcal{D}_1}(\alpha,\vec{c})$. This is equivalent to the desired conclusion that $||\mathcal{D}_1 - \mathcal{R}(\vec{x})||_1$ is $o(1)$. □

6.1. Most $(\alpha,\vec{c})$ are well-distributed. In this section we use the second moment method to prove Lemma 6.3. For this purpose we will need the following property of the LPS expander graphs G_n, proved in section 6.2, which will allow us to show that the correlations considered in the second moment method are low.

Definition 6.4. *For $\vec{p},\vec{q} \in P_l^{(m)}$ we write $\vec{p} \sim_s \vec{q}$ when $\vec{p}$ and $\vec{q}$ share exactly s edges. Let $\gamma > 0$ be a positive real number. We say that $U \subset V(G_n)$ is* γ-nice *if, for all $s \geq 0$, $\Pr_{\vec{p},\vec{q}\in P_l^{(m)}(U)}[\vec{p} \sim_s \vec{q}] \leq \gamma^s$.*

Theorem 6.4 (proved in section 6.2). *Suppose that $m \leq n^{1/3}/\log n$ and $l = 2\lceil c_1 \log n/\log\log n\rceil$. There are constants $c > 0$ and c' such that, for all but a $o(1)$ fraction of sets $U = \{u,v\} \subset V(G_n)$, for all $\vec{q} \in P_l^{(m)}(U)$ and every integer $s \geq 0$,*

$$\Pr_{\vec{p}\in P_l^{(m)}(U)}[\vec{p} \sim_s \vec{q}] \leq (c'/(\log\log n)^{1/4} + (\log n)^{-c})^s;$$

i.e., almost every $U \in V^{(2)}$ is $(c'/(\log\log n)^{1/4} + 1/\log^c n)$-nice.

We now use this in our application of the second moment method to prove that most $(\alpha,\vec{c})$ pairs are well-distributed:

Lemma 6.5. *Let $m \leq n^{1/3}/\log n$, $l = 2\lceil c_1 \log n/\log\log n\rceil$, $\vec{x} \in (\{0,1\}^m)^k$, with $|\cap \vec{x}| = 1$, and $|U| = 2$. If U is γ-nice, with $\gamma = o(2^{-k})$, then*

$$\Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[(\alpha,\vec{c}) \textit{ is well-distributed for } \vec{x} \mid \mathrm{Err}(\alpha,\vec{c}) = U] = 1 - o(1)$$

Proof. For each $\vec{p} \in P_l^{(m)}(U)$, let $X_{\vec{p}}$ denote the indicator variable for the event that $\chi(\alpha_{\vec{p}}) = \vec{x}$.

We now calculate $E_{(\alpha,\vec{c})\in\mathcal{D}_1}[X_{\vec{p}}]$. For $(\alpha,\vec{c})$ chosen according to $\mathcal{D}_1$, the assignment $\alpha_{\vec{p}}$ is distributed according to $(\mathcal{L}_k)^{ml}$; therefore, since for $\chi(\alpha_{\vec{p}})$ to equal $\vec{x}$, $\alpha_{\vec{p}}$ must have precisely l edges whose color is 1^k and $l(m-1)$ edges whose color is a lift of label 0,

$$E_{(\alpha,\vec{c})\in\mathcal{D}_1}[X_{\vec{p}}] = \Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[X_{\vec{p}} = 1] = \phi(ml,l) = 2^{-ml}(2^k-1)^{-(m-1)l}.$$

Let $X = \sum_{\vec{p}\in P_l^{(m)}(U)} X_{\vec{p}}$. X is the random variable denoting the number of sequences $\vec{p} \in P_l^{(m)}(U)$ for which $\chi(\alpha_{\vec{p}}) = \vec{x}$. By the linearity of expectation, $E_{(\alpha,\vec{c})}[X] = \phi(ml,l)\cdot|P_l^{(m)}(U)|$.

We use the second moment method to show that X is concentrated near its expectation. For $\vec{p},\vec{q} \in P_l^{(m)}(U)$, the random variables $X_{\vec{p}}$ and $X_{\vec{q}}$ are correlated if and only if $\vec{p}$ and $\vec{q}$ share an edge. Because U is γ-nice, $\Pr_{\vec{p},\vec{q}\in P_l^{(m)}(U)}[\vec{p} \sim_s \vec{q}] \leq \gamma^s$.

When $X_{\vec{p}} = 1$, the colors of all edges of $\vec{p}$ are determined. Therefore given $X_{\vec{p}} = 1$, if $\vec{p} \sim \vec{q}$, either some edge that $\vec{p}$ and $\vec{q}$ share ensures that $X_{\vec{q}} = 0$ or the probability that $X_{\vec{p}} = X_{\vec{q}} = 1$ is nonzero. In the latter case consider $G' = \bigcup_{i=1}^{m}(p_i \cup q_i)$, which contains $2ml - s$ edges. Because the marginal distribution of α to the edges of G' independently assigns each e of G' a label using the distribution $\mathcal{L}_k$ (per Definition 5.1), we have that the probability that $\chi(\alpha_{\vec{p}}) = \chi(\alpha_{\vec{q}}) = \vec{x}$ is larger than $[\phi(ml,l)]^2$ by a factor of either 2 or $2(2^k - 1)$ per shared edge depending on whether that edge has a label 1 or 0.

Let $D = \sum_{\vec{p} \sim_s \vec{q}} \Pr_{(\alpha,\vec{c})}[X_{\vec{p}} = X_{\vec{q}} = 1]$.

$$\begin{aligned}
D &= \sum_{s=1}^{ml} \sum_{\vec{p}\sim_s \vec{q}} \Pr_{(\alpha,\vec{c})}[X_{\vec{p}} = X_{\vec{q}} = 1] \\
&\le \sum_{s=1}^{ml} \sum_{\vec{p}\sim_s \vec{q}} (2(2^k-1))^s \Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[X_{\vec{p}} = 1] \Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[X_{\vec{q}} = 1] \\
&= \sum_{s=1}^{ml} \sum_{\vec{p}\sim_s \vec{q}} (2(2^k-1))^s (\phi(ml,l))^2 \\
&= \sum_{s=1}^{ml} |P_l^{(m)}(U)|^2 \Pr_{\vec{p},\vec{q}\in P_l^{(m)}(U)}[\vec{p} \sim_s \vec{q}](2(2^k-1))^s(\phi(ml,l))^2 \\
&= (|P_l^{(m)}(U)| \cdot \phi(ml,l))^2 \sum_{s=1}^{lm} \Pr_{\vec{p},\vec{q}\in P_l^{(m)}(U)}[\vec{p} \sim_s \vec{q}](2(2^k-1))^s \\
&= (E_{(\alpha,\vec{c})\in\mathcal{D}_1}[X])^2 \sum_{s=1}^{ml} \Pr_{\vec{p},\vec{q}\in P_l^{(m)}(U)}[\vec{p} \sim_s \vec{q}](2(2^k-1))^s \\
&\le (E_{(\alpha,\vec{c})\in\mathcal{D}_1}[X])^2 \sum_{s=1}^{ml} \gamma^s (2(2^k-1))^s.
\end{aligned}$$

Since $\gamma = o(2^{-k})$ by hypothesis, $\sum_{s=1}^{\infty} \gamma^s(2(2^k-1))^s$ is $o(1)$, and thus D is $o((E_{(\alpha,\vec{c})\in\mathcal{D}_1}[X])^2)$. Therefore, $E_{(\alpha,\vec{c})}(X^2) = D + E_{(\alpha,\vec{c})}(X) = o((E_{(\alpha,\vec{c})}[X])^2) + E_{(\alpha,\vec{c})}(X)$, and by the second moment method,

$$\Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[|X - E_{(\alpha,\vec{c})\in\mathcal{D}_1}(X)| \ge \epsilon E_{(\alpha,\vec{c})\in\mathcal{D}_1}(X)] \le \frac{D + E_{(\alpha,\vec{c})\in\mathcal{D}_1}[X]}{\epsilon^2 E_{(\alpha,\vec{c})}(X)^2} = o(1).$$

By choosing ϵ as an appropriate function that is $o(1)$, we obtain that, with probability $1 - o(1)$ in the choice of $(\alpha,\vec{c}) \in \mathcal{D}_1$, $X = (1 \pm o(1))\phi(ml,l) \cdot |P_l^{(m)}(U)|$ and therefore, with probability $1 - o(1)$ in $(\alpha,\vec{c})$, $\Pr_{\vec{p}\in P_l^{(m)}(U)}[\chi(\alpha_{\vec{p}}) = \vec{x}] = (1 \pm o(1))\phi(ml,l)$ and thus $(\alpha,\vec{c})$ is well-distributed for $\vec{x}$. □

Proof of Lemma 6.3. Let $\vec{x} \in (\{0,1\}^m)^k$ and $|\cap \vec{x}| = 1$. By Theorem 6.4 there is a $\delta > 0$ so that for all but a $o(1)$ fraction of sets $U \subset V(G_n)$, with $|U| = 2$, U is γ-nice for $\gamma = c''/(\log\log n)^{1/4}$ for some constant c'' and γ is $o(2^{-k})$. Therefore, $\Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[\mathrm{Err}(\alpha,\vec{c}) \text{ is } \gamma\text{-nice}] = 1 - o(1)$, and by Lemma 6.5, $\Pr_{(\alpha,\vec{c})\in\mathcal{D}_1}[(\alpha,\vec{c})$ is well-distributed for $\vec{x} \mid \mathrm{Err}(\alpha,\vec{c}) = U] = 1 - o(1)$. □

6.2. Graph theoretic properties of LPS expanders.

6.2.1. The LPS expanders. In the analysis of $R(\vec{x})$, we want the end points of the random paths in G_n to be almost uniformly distributed. We base our proof of this upon the fact that the end points of random walks in expander graphs are almost uniformly distributed (Proposition 6.6). Since a walk is allowed to repeat vertices but a path does not repeat vertices, the length of the walk is too large with respect to the degree, and it is very likely that a random walk will not be a path. To transfer Proposition 6.6 from walks to paths, we use a graph in which random walks of length l will have their end points almost uniformly distributed, but the walks are short enough with respect to the degree so that a random walk is very likely to be a path. We use the LPS expanders. The crucial properties of the expander graphs G_n constructed in [22] that we need are as follows:

1. G_n is regular of degree $\Delta = \Theta(\log n)$.
2. G_n is connected and nonbipartite.
3. The second eigenvalue of G_n is $O(\sqrt{\log n})$.
4. The girth of G_n is $\Omega(\log n/\log\log n)$.

A walk in G_n is chosen by selecting a start node and repeatedly following one of the Δ edges adjacent to the current node.

Proposition 6.6. *There exists $c_1 > 0$ so that for every $u, v \in V(G_n)$ a random walk in G_n of length $l \geq c_1 \log n/\log\log n$ starting at u ends at vertex v with a probability at least $1/n - 1/n^2$ and at most $1/n + 1/n^2$.*

We consider random walks and random paths in the G_n graphs of a fixed length $l = l(n) = 2\lceil c_1 \log n/\log\log n\rceil$ that is twice the minimum length specified in Proposition 6.6 so that their midpoints are nearly uniformly distributed.

6.2.2. Approximating paths by walks.

Remark 1. In principle one might replace disjoint paths in the definition of Π_{01disj} by disjoint walks of the same length, conditioned on each having distinct end points. However, in that case it would be overwhelmingly likely that many walks will repeat edges, and therefore, as graphs, they would contain different numbers of edges. This would significantly complicate the second moment argument of Lemma 6.5.

We show that, because G_n is expanding and has high girth, random walks in G_n not only mix well but they are paths almost surely as well. We state some folklore properties of random walks and observe how they translate into properties of random paths.

For $v \in V(G_n)$, let $W_l(v)$ be the set of all Δ^l walks of length l in G_n starting at v, and let $P_l(v)$ be the set of all paths of length l in G_n with one end point v. Let $\mu_{W_l(v)}$ be the measure given by a uniform distribution over $W_l(v)$, and let $\mu_{P_l(v)}$ be the measure given by a uniform distribution over $P_l(v)$.

Lemma 6.7. *There exists a universal constant c_3 so that, for every $v \in V(G_n)$ and for each path $p \in P_l(v)$, $(1 - c_3/\log\log n)\mu_{P_l(v)}(p) \leq \mu_{W_l(v)}(p) \leq \mu_{P_l(v)}(p)$. Moreover, for w uniformly chosen from $W_l(v)$ the probability that w is not a path is at most $c_3/\log\log n$.*

Proof. Observe that every $p \in P_l(v)$ has equal measure under $\mu_{W_l(v)}$ so $\mu_{W_l(v)}(p) \leq \mu_{P_l(v)}(p)$, and, moreover, $\mu_{W_l(v)}(p) = \mu_{P_l(v)}(p)\mu_{W_l(v)}(P_l(v))$.

Set $g = girth(G_n)$. By the properties of G_n, $g \geq c_0 \log n/\log\log n$ for some constant $c_0 > 0$ and its degree $\Delta \geq c_2 \log n$ for some constant $c_2 \geq 0$. Notice that for any walk w of length l each vertex in w can have at most $l/(g-3)$ many neighbors also in w. (If u is a vertex in w that has two neighbors u' and u'' in G_n within distance $g-3$ on w, then there is a cycle of length $g-1$ in $w \cup \{(u,u'),(u,u'')\}$ which is a subgraph of G_n.) Therefore

$$\mu_{W_l(v)}(P_l(v)) \geq \left(\frac{\Delta - l/(g-3)}{\Delta}\right)^l \ \geq\ 1 - \frac{l^2}{\Delta(g-3)}$$
$$\geq 1 - \frac{2\lceil c_1 \log n/\log\log n\rceil^2}{c_2 \log n \cdot (c_0 \log n/\log\log n - 3)} \ \geq\ 1 - c_3/\log\log n$$

for some constant c_3. □

The following are folklore properties of random walks in G_n.

PROPOSITION 6.8. *Let W_l be the set of all walks of length l in G_n.*

1. *For each $v \in V(G_n)$, $\Pr_{w\in W_l}[v \in V(w)] \leq (l+1)/n$.*
2. *For each $u \neq v \in V(G_n)$, $\Pr_{w\in W_l}[\text{Ends}(w) = \{u, v\}] = (1 \pm 2/n)/\binom{n}{2}$.*

Proof. There is a sequence of $l+1$ vertices (not necessarily distinct) on each walk w in W_l and precisely Δ^l walks in which v is the ith vertex in w. Therefore, in total there are at most $(l+1)\Delta^l$ walks with $v \in V(w)$. (This is an overcount since v may appear more than once in w.) Since there are precisely $n\Delta^l$ random walks in G_n of length l, $\Pr_{w\in W_l}[v \in V(w)] \leq (l+1)/n$.

By Proposition 6.6 the chance that a particular pair of distinct vertices $\{u, v\}$ appear as end points of w is $\frac{2}{n}(1/n \pm 1/n^2)$, which is $(1 \pm 2/n)/\binom{n}{2}$. □

We obtain the following easy corollary which includes a proof of Lemma 6.2.

LEMMA 6.9. *Let P_l be the set of all paths in G_n of length l.*

1. *Let $V' \subseteq V(G_n)$. There exists a constant c so that*

$$\Pr_{p\in P_l}[V(p) \cap V' \neq \emptyset] \leq (1 + c/\log\log n)\frac{|V'|(l+1)}{n}.$$

2. *Let $u \neq v \in V(G_n)$. Then $\Pr_{p\in P_l}[\text{Ends}(p) = \{u, v\}] = (1 \pm o(1))/\binom{n}{2}$.*

Proof. By Proposition 6.8, for w a randomly chosen walk of length l in G_n,

$$\Pr_{w\in W_l}[V(w) \cap V' \neq \emptyset] \leq \frac{|V'|(l+1)}{n},$$

and by Lemma 6.7, $\Pr_{w\in W_l}[w \text{ is a path}] \geq 1 - c_3/\log\log n$. The random distribution of paths p of length l in G_n is the same as the random distribution of walks w of length l in G_n conditioned on w being a path. Therefore

$$\begin{aligned}\Pr_{p\in P_l}[V \cap V(p) \neq \emptyset] &= \Pr_{w\in W_l}[V \cap V(w) \neq \emptyset \mid w \text{ is a path}]\\ &\leq \frac{|V|(l+1)}{(1 - c_3/\log\log n)n}\\ &\leq (1 + c/\log\log n)\frac{|V|(l+1)}{n}\end{aligned}$$

for some constant c.

For $u \neq v \in V(G_n)$, by Lemma 6.7 $\Pr_{p\in P_l}[\text{Ends}(p) = \{u, v\}]$ is within a $1 \pm o(1)$ factor of $\Pr_{w\in W_l}[\text{Ends}(w) = \{u, v\}]$, and by Proposition 6.8 the latter is $(1 \pm o(1))/\binom{n}{2}$, which yields the desired property. □

6.2.3. The proof of Theorem 6.4. In this subsection we prove Theorem 6.4. We will actually prove a slightly stronger result in which $\vec{q} \in P_l^{(m)}(U)$ is replaced by any subgraph of G_n with at most $m(l+1)$ vertices and a maximum degree at most 2.

It will be convenient to consider sequences of length l paths P_l^m that are not necessarily vertex-disjoint. Let $\mu_{P_l^{(m)}}$ be the uniform measure on $P_l^{(m)}$ and $\mu_{P_l^m}$ be the uniform distribution on P_l^m.

Lemma 6.10. *Suppose that $m \le n^{1/3}/\log n$ and $l = 2\lceil c_1 \log n/\log\log n\rceil$. For any $\vec{p} \in P_l^{(m)}$, $(1-o(1))\mu_{P_l^{(m)}}(\vec{p}) \le \mu_{P_l^m}(\vec{p}) \le \mu_{P_l^{(m)}}(\vec{p})$.*

Proof. Conditioned on the paths in $\vec{p} \in P_l^m$ being vertex-disjoint, $\mu_{P_l^m}$ is uniform over $P_l^{(m)}$. By Lemma 6.9, the probability that the ith path shares a vertex with paths $p_1, \ldots, p_{i-1}$ is at most $(1 + c/\log\log n)(l+1)^2(m-1)/n \le 2l^2m/n$, and the probability that the paths in P_l^m are not vertex-disjoint is at most $2l^2m^2/n \le 1/n^{1/3}$. □

We first observe that if we required only that $\vec{p} \in P_l^{(m)}$ rather than $\vec{p} \in P_l^{(m)}(U)$—i.e., we had no requirement that one path in $\vec{p}$ have its end points in U—then the exponentially decaying bound on intersection size of Theorem 6.4 would be relatively easy.

Lemma 6.11. *Suppose that $m \le n^{1/3}/\log n$ and $l = 2\lceil c_1 \log n/\log\log n\rceil$. There is some constant $c \ge 0$ such that, for all subgraphs G' of G_n with at most $m(l+1)$ vertices and every integer $s \ge 0$,*

$$\Pr_{\vec{p} \in P_l^{(m)}}[|E(\cup\vec{p}) \cap E(G')| \ge s] \le (\log n)^{-cs}.$$

Proof. For $\vec{p} \in P_l^{(m)}$, because each component of $\vec{p}$ is a path of length l, if $|E(\cup\vec{p}) \cap E(G')| \ge s$, then there are at least $\lceil s/l\rceil$ paths p_i in $\vec{p}$ that share an edge (and therefore a vertex) with G'. By Lemma 6.9, the probability that a random p_i from P_l shares a vertex with G' is at most $(1 + c/\log\log n)(l+1)^2m/n < 2l^2m/n$. Therefore for elements of P_l^m, the probability that there are least $r = \lceil s/l\rceil$ such paths is at most $\binom{m}{r}(2l^2m/n)^r < (2l^2m^2/n)^r/2$. By Lemma 6.10, the probability that this happens for elements of $P_l^{(m)}$ is at most $(2l^2m^2/n)^r \le n^{s/(3l)} = (\log n)^{-cs}$ for some constant $c > 0$. □

The major complication of the proof of Theorem 6.4 is the assumption that $\vec{p}$ contains a path with end points u and v for $U = \{u, v\}$, $u \ne v$. We base the analysis of paths with end points U on the analysis of walks with end points U. For some sets U, for example, if u and v are adjacent in G_n, the distributions of random walks and random paths with end points U may not be close to each other.[3] We will see that, for most choices of U, the probabilities under the two distributions are close to each other, and this will be enough to obtain the bound required by Theorem 6.4.

Definition 6.5. *For $U = \{u, v\} \in V(G_n)$ let $W_l(U)$ be the set of all walks in G_n of length n that have end points U.*

Lemma 6.12. *There is a constant c_4 such that, for all but at most a $c_4/\log\log n$ fraction of pairs $u \ne v \in V(G_n)$,*

$$\Pr_{w \in W_l(\{u,v\})}[w \textit{ is a path}] \ge 2/3.$$

Proof. By Lemma 6.7,

$$\Pr_{w \in W_l}[w \text{ is not a path}] \le c_3/\log\log n.$$

[3] Even in these cases the distributions may be sufficiently close, but we do not need to analyze them.

Therefore by definition,

$$\sum_{u\neq v\in V(G_n)} \Pr_{w\in W_l}[\mathrm{Ends}(w)=\{u,v\}] \Pr_{w\in W_l(\{u,v\})}[w \text{ is not a path}] \leq c_3/\log\log n.$$

By Proposition 6.8, $\Pr_{w\in W_l}[\mathrm{Ends}(w)=\{u,v\}] \geq (1-2/n)\binom{n}{2}^{-1}$, and thus

$$(1-2/n)\binom{n}{2}^{-1} \sum_{u\neq v\in V(G_n)} \Pr_{w\in W_l(\{u,v\})}[w \text{ is not a path}] \leq c_3/\log\log n,$$

which says that the expected value

$$E_{u\neq v\in V(G_n)}(\Pr_{w\in W_l(\{u,v\})}[w \text{ is not a path}]) \leq \frac{c_3/\log\log n}{(1-2/n)}.$$

We now apply Markov's inequality to obtain that the fraction of pairs $u \neq v \in V(G_n)$ for which $\Pr_{w\in W_l(\{u,v\})}[w$ is not a path$] \geq 1/3$, is at most $\frac{c_3/\log\log n}{(1-2/n)/3} \leq c_4/\log\log n$ for some constant c_4. ∎

Bounding intersection size of random walks. Lemma 6.12 will allow us to use the following analysis involving a random walk with end points in U rather than a random path.

LEMMA 6.13. *Let G' be a subgraph of G_n with the property that every vertex has a degree at most d in G'. For fixed $v \in V(G_n)$,*

$$\Pr_{w\in W_l(v)}[|E(w)\cap E(G')| \geq s] \leq \binom{l}{s}\left(\frac{d}{\Delta}\right)^s.$$

Proof. There are at most $\binom{l}{s}$ many choices of steps in the random walk in which the first s shared edges can occur. Fix some such set of steps $S \subseteq [l]$. For each $i \in S$ a necessary condition for the ith edge in the walk to lie in $E(G')$ is that the end point u after step $i-1$ must lie in $V(G')$. Since $\deg_{G'}(u) \leq d$, given that $u \in V(G')$, the probability that the ith edge lies in $E(G')$ is then at most d/Δ. That is, conditioned on a shared edge in each of the first j elements in S, the chance of a shared edge in the $j+1$st element in S is at most d/Δ because every vertex has a degree at most d in G'. This yields a total probability at most $\binom{l}{s}(d/\Delta)^s$ as required. ∎

In order to analyze the random walks in $W_l(U)$ we need more than the result of Lemma 6.13, since it constrains only one end point of the random walk rather than both end points. We can view each half of a random walk in which both end points are constrained as two random walks of half the length with only one end point constrained. (Obviously, these two half-length walks are highly correlated.)

LEMMA 6.14. *Let $l = 2\lceil c_1 \log n/\log\log n\rceil$. Let G' be a subgraph of G_n in which every vertex has a degree at most d. For $u \neq v \in V(G_n)$,*

$$\Pr_{w\in W_l(\{u,v\})}[|E(w)\cap E(G')| \geq s] < \left(\frac{2dl}{\Delta}\right)^{s/2}.$$

Proof. Without loss of generality, walk $w \in W_l(\{u,v\})$ starts at u and ends at v. Let $l' = l/2$. Let $w = (w_u, w_v)$, where w_u and w_v each have length l'. We first observe that w_u is nearly uniformly distributed in $W_{l'}(u)$:

Let $w^* \in W_{l'}(u)$, and let v^* be the end of w^*.

$$\begin{aligned}&\Pr_{w \in W_l(\{u,v\})}[w_u = w^* \mid w \text{ starts at } u]\\ &= \frac{\Pr_{w \in W_l(u)}[w_u = w^* \text{ and } w_v, \text{ starts at } v^*, \text{ ends at } v]}{\Pr_{w \in W_l(u)}[w \text{ ends at } v]}\\ &= \frac{\Pr_{w_u \in W_{l'}(u)}[w_u = w^*] \cdot \Pr_{w_v \in W_{l'}(v^*)}[w_v \text{ ends at } v]}{\Pr_{w \in W_l(u)}[w \text{ ends at } v]}.\end{aligned}$$

Clearly $\Pr_{w_u \in W_{l'}(u)}[w_u = w^*] = \Delta^{-l'} = \Delta^{-l/2}$, and since $l > l' \geq c_1 \log n / \log\log n$ by Proposition 6.6, both $\Pr_{w_v \in W_{l'}(v^*)}[w_v \text{ ends at } v]$ and $\Pr_{w \in W_l(u)}[w \text{ ends at } v]$ are $1/n \pm 1/n^2$; thus

$$\Pr_{w \in W_l(\{u,v\})}[w_u = w^* \mid w \text{ starts at } u] = (1 \pm O(1/n))\Delta^{-l/2}.$$

Since G_n is a *regular* undirected graph, a length l random walk from u to v has the same distribution as a length l random walk from v to u. Thus by symmetry with the above argument, within a $1 \pm O(1/n)$ factor, w_v is distributed as a (nearly) uniform random walk of length l' starting at v.

Now if there are a total of s edges in common between w and G', then at least $\lceil s/2 \rceil$ must be shared between G' and one of the two halves of w, w_u and w_v. By Lemma 6.13 and the above argument each of these probabilities is at most $(1 + O(1/n))(\frac{dl'}{\Delta})^{\lceil s/2 \rceil}$, and the total probability is at most $2(1 + O(1/n))(\frac{dl}{2\Delta})^{\lceil s/2 \rceil} \leq (2\frac{dl}{\Delta})^{\lceil s/2 \rceil}$. □

Deriving the bound.

LEMMA 6.15. *Let $l = 2\lceil c_1 \log n / \log\log n \rceil$ and $m \leq n^{1/3}/\log n$. For any fixed subgraph G' of G_n with at most $m(l+1)$ vertices and a maximum degree at most 2, and any set $U = \{u,v\} \subset V(G_n)$,*

$$\Pr_{(w,\vec{p}))\in W_l(U) \times P_l^{m-1}}[|(E(w) \cup E(\vec{p})) \cap E(G')| \geq s] \leq (c''/\log\log n)^{s/4} + (\log n)^{-cs/2}.$$

Proof. If there are s edge intersections between $E(w) \cup E(\vec{p})$ and G', then at least $s/2$ of them occur in either w or $\vec{p}$. Lemma 6.14 implies that $\Pr_{w \in W_l(U)}[|E(w) \cap E(G')| \geq s/2] \leq \left(\frac{4l}{\Delta}\right)^{s/4} \leq (c''/\log\log n)^{s/4}$.

By Lemma 6.11, $\Pr_{\vec{p} \in P_l^{m-1}}[|E(\vec{p}) \cap E(G')| \geq s/2] \leq \Pr_{\vec{p} \in P_l^m}[|E(\vec{p}) \cap E(G')| \geq s/2] \leq (\log n)^{-cs/2}$. □

We now obtain Theorem 6.4.

LEMMA 6.16. *Suppose that $m \leq n^{1/3}/\log n$ and $l = 2\lceil c_1 \log n/\log\log n \rceil$. For all but a $c_4/\log\log n$ fraction of all $U = \{u,v\}$, $u \neq v \in V(G_n)$, there are constants $c, c' > 0$ such that, for all subgraphs G' of G_n with at most $m(l+1)$ vertices and a maximum degree 2 and for every integer $s \geq 0$,*

$$\Pr_{\vec{p} \in P_l^{(m)}(U)}[|E(\cup\vec{p}) \cap E(G')| \geq s] \leq ((c'/\log\log n)^{1/4} + (\log n)^{-c})^s.$$

Proof. By Lemma 6.12, for all but a $c_4/\log\log n$ fraction of U, $\Pr_{w \in W_l(U)}[w \text{ is a path}] \geq 2/3$. For any such U, since the distribution of $w \in W_l(U)$ conditional on w being a path is uniform over $P_l(U)$, the measure of any event on $P_l(U) \times P_l^{m-1}$ is at most $3/2$ times that on $W_l(U) \times P_l^{m-1}$. Further, by the same argument as Lemma 6.10, the probability that the paths in $\vec{p}$ chosen from $P_l(U) \times P_l^{m-1}$ are vertex-disjoint is at least $1-o(1)$ conditioned on being vertex-disjoint the distribution of $\vec{p}$ is uniform over $P_l^{(m)}(U)$. Therefore the measure of any event on $P_l^{(m)}(U)$ is at most $(1+o(1))3/2 \leq 2$ times that on $W_l(U) \times P_l^{m-1}$. Applying Lemma 6.15 and adjusting constants c and c' yields the bound. $\square$

7. Discussion. There are a couple of interesting open problems related to our work beyond the natural problem of the communication complexity of DISJ_k.

The first regards *automatizability* and the existence of *separation oracles*. In [21] it was shown that if a system of 0/1 inequalities has a rank $\leq d$ LS refutation, then the system of inequalities possesses a separation oracle that runs in time $n^{O(d)}$. (A separation oracle is a procedure that takes a polytope P and a point $\vec{x}$ and returns either "true" if $\vec{x} \in P$ or a hyperplane separating $\vec{x}$ and P.) Does semantic $\mathbf{Th(k)}$ have an efficiently computable separation oracle as LS does? A refutation system $\mathcal{R}$ is said to be *automatizable* ([6], cf. [2]) if there is an algorithm that, given unsatisifable CNF Ψ, the algorithm finds a refutation of Ψ in time $S^{O(1)}$, where S is the minimum size of an $\mathcal{R}$ refutation of ψ. The question of the existence of a separation oracle for $\mathbf{Th(k)}$ is closely related to whether or not $\mathbf{Th(k)}$ is automatizable, and we conjecture that the answer to both questions is negative.

The second question is whether or not it is possible to extend our lower bounds to other tautologies that would imply inapproximability results for polynomial-time $\mathbf{Th(k)}$-based algorithms. For example, if we could prove superpolynomial lower bounds for treelike $\mathbf{Th(k)}$ proofs of random 3CNF formulas, this would imply inapproximability results for $\mathbf{Th(k)}$-based linear programming algorithms for MaxSAT [7]. Of course, lower bounds for random 3CNF formulas are open for the $\mathbf{Th(1)}$ systems and even for treelike cutting planes with unary coefficients. A first step towards analyzing random 3CNFs in the $\mathbf{Th(k)}$ systems would be to improve the analysis of this paper to apply to a graph of degree 3 rather than one of degree $\Theta(\log n)$.

Acknowledgment. We are indebted to Avi Wigderson for helpful discussions and insights.

IMPROVED BOUNDS ON NONBLOCKING 3-STAGE CLOS NETWORKS*

JOSÉ R. CORREA† AND MICHEL X. GOEMANS‡

Abstract. We consider a generalization of edge coloring bipartite graphs in which every edge has a weight in $[0, 1]$ and the coloring of the edges must satisfy that the sum of the weights of the edges incident to a vertex v of any color must be at most 1. For unit weights, König's theorem says that the number of colors needed is exactly the maximum degree. For this generalization, we show that $2.557n + o(n)$ colors are sufficient, where n is the maximum total weight adjacent to any vertex, improving the previously best bound of $2.833n + O(1)$ due to Du et al. Our analysis is interesting on its own and involves a novel decomposition result for bipartite graphs and the introduction of an associated continuous one-dimensional bin packing instance which we can prove allows perfect packing. This question is motivated by the question of the rearrangeability of 3-stage Clos networks. In that context, the corresponding parameter n of interest in the edge coloring problem is the maximum over all vertices of the number of unit-sized bins needed to pack the weights of the incident edges. In that setting, we are able to improve the bound to $2.5480n + o(n)$, also improving a bound of $2.5625n + O(1)$ of Du et al. We also consider the online version of this problem in which edges have to be colored as soon as they are revealed. In this context, we can show that $5n$ colors are enough. This contrasts with the best known lower bound of $3n - 2$ by Tsai, Wang, and Hwang but improves upon the previous best upper bound of $5.75n$ obtained by Gao and Hwang. Additionally, we show several improved bounds for more restricted versions of the problem. These online bounds are achieved by simple and easy-to-implement algorithms, inspired by the first fit heuristic for bin packing.

Key words. bipartite edge coloring, rearrangeability of 3-stage Clos networks, bin packing

1. Introduction.

1.1. Clos networks.

Suppose we need to connect a set of inlets $i_1, \dots, i_k$—which may represent telephone calls, parallel machines, or any kind of connection request—to a set of outlets $j_1, \dots, j_k$, through an *interconnection network*, in such a way that any request permutation (i.e., a permutation of $\{1, \dots, k\}$) can be routed simultaneously. More precisely, let us define a connection request as a pair, (i, j), where i is an inlet and j an outlet, and a *request frame* as any collection of requests such that every inlet and every outlet are associated with at most one request. The goal is to design a network that can route any request frame; such a network is called *nonblocking*.

Naturally, the simplest way to achieve this is to directly connect every inlet to every outlet by a different link. This solution, called *crossbar*, was already developed and implemented for telephone communications in the late 1930's by Western Electric (the Bell System). Despite the simplicity and nice properties of crossbar networks,

their main drawback is that they require too many links to achieve their goal: If we have k inlets and k outlets, they require k^2 links. In 1953, Clos [9] introduced a new type of interconnection network with the same property but that requires only $O(k^{3/2})$ links. These networks have been widely used for data communications and parallel computing systems (see, e.g., [3, 16]).

Formally, a 3-stage Clos network $C(n_1, r_1, m, n_2, r_2)$ is an interconnection network where the first stage consists of r_1 crossbars of size $n_1 \times m$, the last stage has r_2 crossbars of size $m \times n_2$, and the middle stage has m crossbars of size $r_1 \times r_2$. Moreover, each of the r_1 input switches is connected to each of the m middle switches. Similarly, the middle stage and the last stage are fully connected. We focus on the case in which $n_1 = n_2 = n$; i.e., the number of *inlets* or inputs of the input stage switches is equal to the number of *outlets* or outputs of the output stage switches. We also assume that $r_1 = r_2 = r$, even though all our results hold independently of what r_1 and r_2 are. The resulting Clos network is denoted by $C(n, m, r)$.

In a Clos network, a request frame is said to be *routable* if all requests can be routed through a middle switch so that no two requests share a link. The main question related to 3-stage Clos networks is to determine the number m of middle switches (crossbars) needed to route any request frame, i.e., for the network to be nonblocking. The answer, however, depends on the model we consider. Essentially there are three settings in which this question has been studied and used:

- *Rearrangeably nonblocking:* An interconnection network is *rearrangeably nonblocking* (or just rearrangeable) if every request frame is routable. This is the relevant question in an offline setting.
- *Strictly nonblocking:* An interconnection network is *strictly nonblocking* if any new connection request, compatible with a request frame, can be routed, independent of how the rest of the request frame is routed (i.e., independent of the state of the network). This is a relevant question in an online setting.
- *Wide-sense nonblocking:* If connection requests are revealed over time, an interconnection network is *wide-sense nonblocking* if any new connection request, compatible with a request frame, can be routed, provided that the rest of the request frame was routed according to a given routing algorithm. This question is the most important in practice, since it is motivated by the online environment, but it is less restrictive than the strictly nonblocking requirement. It is important to mention that several authors consider the more restrictive definition of wide-sense nonblocking in which the algorithm has to be able to route new connection requests even if previous connections terminate (see, e.g., Benes' original book [5]).

Clos himself noted that $C(n, 2n-1, r)$ is strictly nonblocking (which implies that it is wide-sense nonblocking as well), while, shortly after, Slepian [29] (see also [5]) proved that $C(n, n, r)$ is rearrangeable. Moreover, both results are best possible. It is then clear that if the total number of inlets is k and we choose $n = r = \sqrt{k}$, the number of links required in a 3-stage Clos network is $5 \times k^{3/2}$ or $8 \times k^{3/2}$, depending on whether we need it to be rearrangeably or strictly nonblocking.

Although our focus here will be the study of 3-stage Clos networks, let us briefly mention a few results for general interconnection networks. Shannon [27] showed that $\Omega(k \log k)$ links are needed for an interconnection network to even be rearrangeable. Surprisingly, this lower bound was matched by Benes [6] and Beizer [4], who designed rearrangeable networks of size $O(k \log k)$. Later, Bassalygo and Pinsker [2] constructively showed the existence of strictly nonblocking networks of size $O(k \log k)$.

The multirate environment. We just described the *classic* switching environment, in which connection requests fully use a link and have all the same bandwidth. However, in modern communications, different requests may have different bandwidths and may be combined in a given link if the "link capacity" is large enough to carry both requests. This setting is usually called the *multirate* environment. In such a setting, a connection request is a triple (i, j, w), where i is an inlet, j an outlet, and w the weight (thus, the classic environment corresponds to the special case in which all weights are 1). A *request frame* is a collection of requests such that the total weight of all requests in the frame involving a fixed inlet or outlet does not exceed 1. In a Clos network, all $r \times m$ links between the input switches and middle switches and all $m \times r$ links between the middle switches and the output switches also have capacity 1. A request frame is said to be *routable* if all requests can be routed through a middle switch so that none of the link capacities is violated. For a recent survey on multirate Clos networks, we refer the reader to the excellent survey by Turner and Melen [30], who also initiated the research on multirate switching networks [23]. As in the classic environment, the question is to determine the minimum value of m of middle switches such that any request frame can be routed; the network is then said to be multirate nonblocking. Again, the answer depends on whether the problem is considered online or offline. However, the questions are still wide open and need further investigations.

- *Rearrangeably nonblocking (offline):* An interconnection network is said to be *multirate rearrangeably nonblocking* (or just rearrangeable) if every request frame is routable. The question is thus to determine the minimum value of m of middle switches such that $C(n, m, r)$ is multirate rearrangeable, and this minimum value is denoted by $m(n, r)$. It is particularly interesting to obtain bounds that are independent of r.
- *Wide-sense nonblocking (online):* If connection requests are revealed over time (both the inlet-outlet pair and its weight), an interconnection network is said to be *wide-sense nonblocking* if any new connection request, compatible with a request frame, can be routed, provided that all the rest of the request frame was routed according to a given routing algorithm. Thus, the question is again to determine the minimum value m of middle switches such that $C(n, m, r)$ is wide-sense nonblocking, and this value is denoted by $m_W(n, r)$. Let us emphasize again that we assume that the requests never terminate, i.e., that we have no deletions during the execution; this is the same weaker setting as in [13], for example.
- *Strictly nonblocking:* In the multirate environment, we say that an interconnection network is *strictly nonblocking* if any new connection request, compatible with a request frame, can be routed, independent of how the rest of the request frame is routed (i.e., independent of the state of the network).

1.2. Problem definition.

The question of rearrangeability and nonblocking properties of a 3-stage Clos network can be translated in graph-theoretic terms in the following way. We are given a bipartite (multi)graph $G = (V, E)$ with bipartition A, B (say with $|A| = |B| = r$); in what follows, all our graphs will be multigraphs. A and B represent the input and output switches, respectively. Edge $e = (i, j)$ represents a request between input switch i and output switch j and carries a weight $0 \leq w(e) \leq 1$. The assumption of the requests being a request frame can be translated into the assumption that the weights on the edges incident to $v \in V$ can be packed into n unit-sized bins. That is, for all $v \in V$, the set $\delta(v)$ of edges incident to v can be partitioned into n groups C_i^v, $i = 1, \dots, n$, satisfying

$$\sum_{e \in C_i^v} w(e) \leq 1 \qquad \text{for all } i = 1 \dots, n. \tag{1}$$

Following the notation in [24], let $\mathcal{B}_r^n$ be the collection of such edge-weighted bipartite multigraphs.

A Clos network $C(n, m, r)$ is then (multirate) rearrangeable if, for every graph in $\mathcal{B}_r^n$, the edges can be colored with m colors so that the total weight of all edges of the same color incident to a vertex v is at most 1. The question is thus to determine the minimum number $m(n, r)$ of colors needed to properly color every weighted bipartite graph in $\mathcal{B}_r^n$. In the online setting, we know only a priori that the graph belongs to $\mathcal{B}_r^n$, but the edges and their weight are revealed over time. Similar to the rearrangeable case, a Clos network $C(n, m, r)$ is (multirate) wide-sense nonblocking if there exists an online algorithm A such that, for every graph in $\mathcal{B}_r^n$, the edges can be colored with m colors so that the total weight of all edges of the same color incident to a vertex v is at most 1. The question is thus to determine the minimum number $m_W(n, r)$ for which there is an online algorithm that properly colors every weighted bipartite graph in $\mathcal{B}_r^n$ using no more than $m_W(n, r)$ colors. In the same manner, $C(n, m, r)$ is (multirate) strictly nonblocking if, for any $G = (V, E) \in \mathcal{B}_r^n$ and any proper m-coloring of $(V, E \setminus \{e\})$, for any $e \in E$, edge e can be colored without changing the color of any already colored edge and using any extra color. Now $m_S(n, r)$ is the minimum number of colors such that $C(n, m_S(n, r), r)$ is strictly nonblocking.

If all weights are forced to belong to a subset $I \subset [0, 1]$, let $\mathcal{B}_r^n(I)$ denote the natural extension of $\mathcal{B}_r^n$. In this case, $m_I(n, r)$ is the smallest integer such that every graph in $\mathcal{B}_r^n(I)$ admits a proper coloring with $m_I(n, r)$ colors. The quantities $m_{W\,I}(n, r)$ and $m_{S\,I}(n, r)$ are the natural counterparts of $m_I(n, r)$ in the wide-sense and strictly nonblocking setting.

Another special case that has attracted attention is when all edge weights can take only k different values (known, in Clos network terminology, as the bounded rate environment, or k-rate environment). We denote by $m^k(n, r)$ the minimum number of middle switches so that $C(m^k(n, r), n, r)$ is multirate rearrangeable when all request frames have weights with only k different values. Similarly, $m_W^k(n, r)$ is the corresponding counterpart of $m^k(n, r)$.

In section 3, we focus on a generalized bipartite edge-coloring problem, very similar to the one just described, except that we require only the weights incident to any vertex to add up to at most n. That is, condition (1) is replaced by the following weaker condition:

$$\sum_{e \in \delta(v)} w(e) \leq n \qquad \text{for all } v \in V. \tag{2}$$

Here $\mathcal{D}_r^n$ denotes the natural counterpart of $\mathcal{B}_r^n$. As $\mathcal{B}_r^n \subseteq \mathcal{D}_r^n$, the required number of colors in this case, denoted by $M(n, r)$, is clearly greater than or equal to $m(n, r)$. If all weights are forced to belong to a subset $I \subset [0, 1]$, $\mathcal{D}_r^n(I)$ and $M_I(n, r)$ denote the natural counterparts of $\mathcal{B}_r^n(\mathrm{I})$ and $m_I(n, r)$.

1.3. Discussion of previous work.

Let us review some existing results on this problem. We start by giving the most relevant results on rearrangeability, and later we focus on wide-sense and strictly nonblocking properties.

Rearrangeability. The first important result was proved shortly after the introduction of 3-stage Clos networks and is due to Slepian [29] (see also [5]). He used König's edge-coloring theorem [19] (see also [11]) to prove that $m_{[1,1]}(n,r) = n$. Melen and Turner [23] initiated the research on multirate switching networks and proved that $m_{[0,1/2]}(n,r) \leq M_{[0,1/2]}(n,r) \leq 2n-1$. More generally, they proved that

$$m_{[0,B]}(n,r) \leq M_{[0,B]}(n,r) \leq \frac{n}{1-B}.$$

On the other hand, it is easy to prove that $m_{[b,1]}(n,r) \leq n\lfloor \frac{1}{b} \rfloor$ and that $M_{[b,1]}(n,r) \leq \frac{n}{b}$.

Previous to this work, the best bounds known on $m(n,r)$ in the general setting are $\frac{5n}{4} \leq m(n,r) \leq \frac{41n}{16} + O(1)$ and were obtained by Ngo and Vu [24] (lower bound) and Du et al. [12] (upper bound). The latter authors also obtained the previously best bounds for $M(n,r)$, namely $2n-1 \leq M(n,r) \leq \frac{17n}{6} + O(1)$.

In the k-rate environment, better bounds have been proved. For $k=2$, one can actually verify the Chung–Ross conjecture, namely, that the $2n-1$ bound holds in this case [8]. Moreover, Lin et al. [21] proved that

$$m^3(n,r) \leq \frac{9n}{4} + O(1) \quad \text{ and } \quad m^3_{(\frac{1}{5},1]}(n,r) \leq 2n.$$

The first bound is an improvement over the $\frac{7n}{3}$ bound obtained by Lin et al. [20]. Unfortunately, the proofs of all bounds for the finite rate environment rely on rather tedious case analysis.

Wide-sense and strictly nonblocking. Let us now survey some of the most relevant results concerning nonblocking properties of 3-stage Clos networks. In the classical environment, Clos [9] proved that $C(n, 2n-1, r)$ is strictly nonblocking. Unfortunately, as first noted in [23], in the multirate environment, $C(n,m,r)$ cannot be strictly nonblocking unless m is infinity. Indeed, consider the network $C(n,m,1)$ and assume that there is a connection request of weight 1 and $(n-1)/\varepsilon$ connection requests of weight $\varepsilon = (n-1)/m$ between the only input and output switch pair in the network. A possible current state for the network is that each small connection request is routed along a different middle switch, and thus the large request cannot be routed, implying that the network is in a blocking state. However, if connection requests are restricted to have weights within some interval, finite bounds can be obtained. Indeed, Melen and Turner [23] proved that $m_{S[b,1]}(n,r) \leq 2\lfloor (n-1)/b \rfloor + 3$, which was further improved by Chung and Ross [8] to $m_{S[b,1]}(n,r) \leq 2\lfloor 1/b \rfloor (n-1) + 1$. The latter authors also proved that $m_{S(0,B]} \leq 2\lceil \frac{n-B}{1-B} \rceil + 1$.

The bad example above motivated the algorithmic concept of wide-sense nonblocking. Indeed, already in [23] it was noted that $8n$ middle switches are enough to ensure the wide-sense nonblocking condition, i.e., $m_W(n,r) \leq 8n$. Later, Chung and Ross [8] used their bounds on $m_{S[b,1]}(n,r)$ and $m_{S(0,B]}(n,r)$ to improve the bound. Indeed, their algorithm would split connection requests according to their weight: the smaller than or equal to 1/2 and those strictly larger than 1/2. The bound is therefore

$$m_W(n,r) \leq m_{S(1/2,1]}(n,r) + m_{S(0,1/2]}(n,r) \leq 2n-2+1+4n+1 = 6n.$$

The best known bound previous to our result was obtained by Gao and Hwang [13]. They used a *quota scheme*, which consists of reserving some middle switches for large connections while letting the rest carry any connection request. This approach led them to the bound $m_{W[0,1/2]} \leq 3.75n$, implying, in the same manner as above, that

$$m_W(n,r) \leq 5.75n.$$

The study of lower bounds for wide-sense nonblocking properties has been much more recent. Bar-Noy, Motwani, and Naor [1] were the first to prove that in the classical setting $m_{W[1,1]}(n,r) \geq 2n-1$ for exponentially large r. This surprising result essentially says that in the classical single-rate environment the strictly nonblocking and wide-sense nonblocking conditions are the same. Moreover, recent work by Haxell et al. [14] shows that this lower bound holds even for $r = \Omega(n^2)$. In the multirate environment, there is only a recent improvement on the previous bound. Tsai, Wang, and Hwang [31] proved that $m_W(n,r) \geq 3n-2$, and their proof also works in the more restricted 2-rate environment.

1.4. Overview and main results in the paper. The main goal of this paper is to present bounds on $M(n,r)$, $m(n,r)$, and $m_W(n,r)$. Indeed, we will show that $2.557n$, $2.548n$, and $5n$ are, respectively, upper bounds on these numbers.

We start in section 2 by showing a result on balanced decomposition of bipartite graphs into matchings. In the context of Clos networks, this result becomes useful only in section 3; however, we believe it is interesting on its own, and so we have decided to present it in a separate section. The question that is addressed is as follows: Given a bipartite graph G and nonnegative numbers $\gamma_1, \ldots, \gamma_l$ summing to 1, decompose the graph into $F_1, \ldots, F_l$ such that the degree of any vertex v in F_i is approximately γ_i times the degree of v in G. We show that the decomposition can be done such that for all i and all vertices, the degree of v in F_i differs from its required value by an additive constant less than 3. The question whether this constant can be decreased to 1 is to the best of our knowledge open.

Our main contribution in this paper, proved in section 3, is the following result.

THEOREM 1. *The number of colors required to properly color every weighted bipartite graph in $\mathcal{D}_r^n$ is at most $2.557n + o(n)$. In other words,*

$$M(n,r) \leq 2.557n + o(n).$$

Observe that this does not improve only upon Du et al.'s bound of $\frac{17}{6}n + O(1)$ on $M(n,r)$ but even slightly upon their bound of $\frac{41}{16}n+O(1) = 2.5625n+O(1)$ on $m(n,r)$. In fact, our approach can also be applied to bounding $m(n,r)$ directly, and this gives us a slightly improved bound of $m(n,r) \leq 2.5480n + o(n)$. The latter improvement is sketched in section 3.7.

For most of section 3, we consider the generalized bipartite edge coloring problem in which the weights on edges incident to any vertex sum to at most n, i.e., graphs in $\mathcal{D}_r^n$. The approach we consider to attack this problem associates a bin packing instance with every such generalized edge coloring instance. For this purpose, we first decompose the edge weighted bipartite graph $G = (V,E)$ into a union of matchings. We then create a bin packing instance in which all bins have size 1. We create an item of our bin packing instance for each matching in our decomposition, and we set its size to be the maximum weight of any edge in the matching. A packing with k bins immediately leads to a valid k-coloring by simply coloring the edges of all matchings (items) placed in the same bin with the same unique color. As we shall see in section 3.1, this approach needs that we first discard all edges whose weight is less than some parameter α (to be determined). This can be done using the following result implicit in Du et al. [12].

LEMMA 2. *Consider $G = (V,E) \in \mathcal{D}_r^n$ with bipartition $V = A \cup B$ and assume that we have used at least $\frac{2n}{1-\alpha}$ colors to color all edges except some edges e with $w(e) \leq \alpha$. Then we can greedily color these remaining edges without using any additional color. In particular, if $M_{(\alpha,1]}(n,r) \leq \lceil 2n/(1-\alpha) \rceil$, then $M(n,r) \leq \lceil 2n/(1-\alpha) \rceil$.*

Proof. If $e = (u, v) \in E$ with $w(e) \leq \alpha$ cannot be colored then the total weight of edges of a given color i incident to either u or v is greater than $1 - \alpha$. Summing over all $\frac{2n}{1-\alpha}$ colors, we get a contradiction with sum of conditions (2) for u and v. $\square$

Therefore, we can focus on instances in which all weights are in $[\alpha, 1]$, provided that we are willing to use $\lceil \frac{2n}{1-\alpha} \rceil$ colors. As the proof of this last result used only any greedy algorithm, the result also holds in the wide-sense nonblocking setting.

Our main contribution is to show that, for *any* generalized edge coloring problem with weights in $[\alpha, 1]$, we can decompose the bipartite graph into matchings in such a way that the corresponding bin packing instance can be packed into at most $n + o(n)$ bins plus the number of bins required to pack a continuous bin packing instance with density $\frac{n}{x^2}$ for $x \in [\alpha, 1]$ (i.e., the number of items with size in the interval $(x, x + dx)$ is $\frac{n}{x^2} dx$). We should emphasize that our bin packing instance is independent of the given bipartite graph G; it is based only on the fact that $G \in \mathcal{D}_r^n$. Although it is easier to refer in the statements here to the continuous bin packing instance, we actually deal only with an arbitrarily fine discretization of it and consider discrete bin packing instances. Our decomposition of the graph into matchings relies on the result of section 2 and is described in section 3.2, while the construction of our bin packing instance is detailed in section 3.3.

Once the continuous bin packing instance with density $\frac{n}{x^2}$ for $x \in [\alpha, 1]$ is constructed, in sections 3.4, 3.5, and 3.6, we turn to compute the number of bins it requires. First, we observe that all items of size greater than $1 - \alpha$ need to be placed alone in bins; they therefore require $\int_{1-\alpha}^{1} \frac{n}{x^2} dx = \frac{\alpha}{1-\alpha} n$ bins. For the remaining items with density $\frac{n}{x^2}$ for $x \in [\alpha, 1 - \alpha]$, we prove that they can be *perfectly* packed. This means that the number of bins they require is simply their total size, up to lower-order terms (accounting for the discretization). This means that they require $\int_{\alpha}^{1-\alpha} x \frac{n}{x^2} dx = n \ln \frac{1-\alpha}{\alpha}$ additional bins. This relies on a result of Rhee and Talagrand [26]. The total number of bins used is thus $(1 + \frac{\alpha}{1-\alpha} + \ln \frac{1-\alpha}{\alpha})n$, and we choose α so that this equals $\frac{2}{1-\alpha} n$ in order to be able to greedily color the edges with weight lower than α. For $\alpha = 0.217811\ldots$, we obtain that the number of colors needed is less than $2.557n$.

It is worth mentioning that our main result can be done algorithmically. Indeed, the continuous bin packing instance is independent of the input; therefore, a discretization of it can be solved optimally a priori by exhaustive search (or by using any good algorithm for bin packing). The matching decomposition, for edges with weight in $[\alpha, 1]$, can be efficiently done using network flows techniques (see Lemma 5). Finally, the edges with weight in $(0, \alpha)$ can be greedily colored as in Lemma 2.

In section 4, we will use simple adaptations of the first fit (FF) heuristic for the classical bin packing problem to obtain improved bounds on the wide-sense nonblocking properties of 3-stage Clos networks. In the bin packing setting, FF places a new item in the first bin that has space available for it; in our online setting, it will simply color an edge with the smallest possible color (under some arbitrary order on the colors) as long as it does not violate condition (1). Our main result, proved in section 4.1, is to show that $C(n, 5n, r)$ is wide-sense nonblocking, i.e., $m_W(n, r) \leq 5n$. Later, in section 4.2, we show that $m_{W(0,1/2]} \leq 3.601n + 3$. Both bounds improve upon the bounds obtained by Gao and Hwang [13] of $5.75n$ and $3.75n$, respectively.

Additionally, in section 4.3 we are able to show that in the 2-rate environment, there is an online algorithm that uses no more than $3n$ middle switches to schedule any request frame. This not only improves the previous best known bound of $4n$ [13] but also almost matches the lower bound on $m_W(n, r)$ of $3n - 2$ obtained by

Tsai, Wang, and Hwang [31] which is also valid in the 2-rate case. We can therefore conclude that

$$3n-2 \leq m_W^2(n,r) \leq 3n.$$

Finally, in section 5 we prove that using an analogue of the FF decreasing heuristic for bin packing, no more than $\frac{8n}{3}$ middle switches are needed to route any request frame. As sorting is needed, this bound holds only in the offline setting, and it does not improve upon the bound of $m(n,r) \leq 2.548n + o(n)$ given in section 3. However, it has the following advantages: (i) it is a nonasymptotic result; (ii) it is a very simple to implement algorithm; and (iii) it can be implemented to run in time $O(n \log n)$.

2. Balanced decompositions of bipartite graphs. Given a subset of edges F of a graph G and a vertex v, we let $\deg_F(v)$ denote the degree of vertex v in F, that is, $|\delta(v) \cap F|$, where $\delta(v)$ is the set of edges incident to v in the graph. The following result follows easily from network flow theory.

LEMMA 3 (Hoffman [15]). *Consider a bipartite graph $G = (V, E)$ and let $0 \leq \mu_1, \mu_2$ with $\mu_1 + \mu_2 = 1$. Then there exists a partition of E into E_1 and E_2 such that*

$$\lfloor \mu_i \deg_E(v) \rfloor \leq \deg_{E_i}(v) \leq \lceil \mu_i \deg_E(v) \rceil$$

for $i = 1, 2$ and all $v \in V$.

Proof. Let A, B be the bipartition of the bipartite graph G. Orient all edges from A to B. Add a source with arcs to all vertices in A and a sink with arcs from all vertices in B. Set the capacity of all the arcs in E to be 1, and set upper and lower capacities on the arcs adjacent to the source and sink to be $\lceil \mu_1 \deg_E(v) \rceil$ and $\lfloor \mu_1 \deg_E(v) \rfloor$, where v is the corresponding adjacent vertex. As a feasible flow can be obtained by setting the flow on every arc in E to be μ_1, there exists an integer feasible flow, and this flow corresponds to the edge set E_1. The remaining edges E_2 also satisfy the required property. □

The next theorem is an extension of Hoffman's result.

THEOREM 4. *Consider a bipartite graph $G = (V, E)$ and let $\gamma_1, \ldots, \gamma_l \in (0, 1)$ such that $\sum_{i=1}^{l} \gamma_i = 1$. Then there exists a partition $E_1, \ldots, E_l$ of E such that for all $v \in V$ and all $i = 1, \ldots, l$,*

$$\gamma_i \deg_E(v) - e_i(v) < \deg_{E_i}(v) < \gamma_i \deg_E(v) + e_i(v).$$

Here $e_i(v) < 3$, and $\sum_{i=1}^{l} e_i(v) \leq 2(l-1)$.

Proof. Let $L = \{1, \ldots, l\}$. We construct a binary tree T with $l-1$ internal nodes and l leaves, each node being labelled by a subset of L. The root is labelled with L, and the l leaves are labelled by a distinct singleton subset of L. If an internal node is labelled with N, then its two children are labelled with I and $N \setminus I$, where $I, N \setminus I$ is the most balanced number partition of N; i.e., I is such that $\max\{\gamma(I), \gamma(N \setminus I)\}$ is minimized (for a set S, $\gamma(S)$ denotes $\sum_{i \in S} \gamma_i$).

With every node with label I, we also associate an edge set $E(I)$. We first set $E(L) = E$. Given $E(N)$ for an internal node N, we obtain $E(I)$ and $E(N \setminus I)$ for its children by applying Lemma 3 to the graph with edge set $E(N)$ and with $\mu_1 = \gamma(I)/\gamma(N)$ and $\mu_2 = 1 - \mu_1$. The leaves are thus associated with subgraphs $E(\{i\})$ which make a partition of E. We claim that $E(\{i\})$ satisfies the required properties for E_i.

Fix a vertex $v \in V$ (for simplicity, we just drop v when writing $\deg_*(v)$) and an index $i \in L$. Let $\{i\} = A_0 \subset A_1 \subset \cdots \subset A_k = L$ be the labels on the path from the leaf $\{i\}$ to the root. We now derive an upper bound on $\deg_{E_i}(v)$ (and we could proceed similarly for the lower bound). From Lemma 3, we have that

$$\begin{aligned}\deg_{E_i}(v) = \deg_{E(A_0)} &< \frac{\gamma(A_0)}{\gamma(A_1)} \deg_{E(A_1)} +1 \\ &< \frac{\gamma(A_0)}{\gamma(A_1)} \left(\frac{\gamma(A_1)}{\gamma(A_2)} \deg_{E(A_2)} +1 \right) + 1 \\ &< \frac{\gamma(A_0)}{\gamma(A_1)} \left(\frac{\gamma(A_1)}{\gamma(A_2)} \left(\cdots \left(\frac{\gamma(A_{k-1})}{\gamma(A_k)} \deg_E +1 \right) \cdots \right) + 1 \right) + 1 \\ &= \frac{\gamma(A_0)}{\gamma(A_k)} \deg_E +1 + \frac{\gamma(A_0)}{\gamma(A_1)} + \frac{\gamma(A_0)}{\gamma(A_2)} + \cdots + \frac{\gamma(A_0)}{\gamma(A_{k-1})} \\ &= \gamma_i \deg_E + e_i(v),\end{aligned}$$

where $e_i(v) = 1 + \frac{\gamma(A_0)}{\gamma(A_1)} + \frac{\gamma(A_0)}{\gamma(A_2)} + \cdots + \frac{\gamma(A_0)}{\gamma(A_{k-1})}$. Let $\eta = \min_{i \in A_1} \gamma_i$ and let j be the arg min. Let $a = \gamma(A_0) \geq \eta$. Thus we have $\gamma(A_1) \geq a + \eta$. In general, when considering A_k, we split it into A_{k-1} and $A_k \setminus A_{k-1}$, while we could have split it into $A_{k-1} \setminus \{j\}$ and the rest. This implies that $\gamma(A_{k-1}) - \eta \leq \gamma(A_k) - \gamma(A_{k-1})$, i.e., $\gamma(A_k) \geq 2\gamma(A_{k-1}) - \eta$. Using this repeatedly, we get $\gamma(A_2) \geq 2a + \eta$, $\gamma(A_3) \geq 4a + \eta$, and, generally, $\gamma(A_{k-1}) \geq 2^k a + \eta$. Thus the bound becomes

$$\begin{aligned}e_i(v) &\leq 1 + \frac{a}{a+\eta} + \frac{a}{2a+\eta} + \frac{a}{4a+\eta} + \frac{a}{8a+\eta} + \cdots \\ &\leq 1 + \frac{a}{a} + \frac{a}{2a} + \frac{a}{4a} + \frac{a}{8a} + \cdots < 3.\end{aligned}$$

Finally, in order to get a bound on $\sum_i e_i(v)$, observe that

$$\sum_{i=1}^{l} e_i(v) = \sum_{(\text{all labels } N \text{ except the root})} \sum_{i \in N} \frac{\gamma_i}{\gamma(N)} = 2(l-1),$$

since there are $2l-1$ nodes in the binary tree. A proof of the lower bound on $\deg_{E_i}(v)$ is identical. □

We suspect that the bound can be further improved. If $\gamma_i = 1/l$ for every i, de Werra [10] has shown that we can impose $\lfloor \gamma_i \deg_E(v) \rfloor \leq \deg_{E_i}(v) \leq \lceil \gamma_i \deg_E(v) \rceil$ for every i, while Theorem 4 implies $\lfloor \gamma_i \deg_E(v) \rfloor - 2 \leq \deg_{E_i}(v) \leq \lceil \gamma_i \deg_E(v) \rceil + 2$ for every i (without making assumptions on the γ_i's). We do not know whether the tighter condition (without the $+2$) can be imposed in the general case. The proof technique used here, however, cannot even improve the $+2$ term into a $+1$ term. Indeed, for $\gamma_i = 1/13$ for $i = 1, \ldots, 13$, one can see that no partitioning scheme would give a bound on $e_i(v)$ (using the analysis in the proof of Theorem 4) better than $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{5} + \frac{1}{13} = 2 + \frac{7}{260}$ (and this can be shown to be the worst when all γ_i's are equal).

As stated, the proof of Theorem 4 is not algorithmic, since we need to solve number partition as a subroutine. However, we used in the proof only the fact that the partitioning of N used is locally optimum in the sense that no item can be moved to the other side of the partition while making it more balanced. A locally optimum number partition can be obtained in polynomial time in several ways. Brucker, Hurink, and Werne [7] show (in the context of scheduling parallel machines) that iteratively improving the partition until a local optimum is reached takes $O(|N|^2)$ iterations. Schuurman and Vredeveld [28] noted that iteratively finding the best local improvement requires $O(|N|)$ iterations, which implies an overall running time of $O(|N| \log |N|)$. One can also use the differencing method of Karmarkar and Karp [18]. This differencing method, which also runs in $O(|N| \log |N|)$ time, consists of repeatedly replacing the largest two items by one new item whose size (i.e., γ value) equals the difference in sizes of these largest two items until only one item of size say Δ remains. By inverting the process, one can easily obtain a partition $(I, N \setminus I)$ with $\gamma(I) = \gamma(N \setminus I) + \Delta$. A simple inductive argument shows that all items in I have $\gamma_i \geq \Delta$, and therefore the partition obtained is locally optimum. Using any of these algorithms to find a local optimum, a partition of the edge set satisfying the conditions of Theorem 4 can be obtained in polynomial time.

3. Rearrangeably nonblocking Clos networks.

In this section, we consider the generalized bipartite edge coloring problem in which the weights on edges incident to any vertex sum to at most n, i.e., graphs in $\mathcal{D}_r^n$. As described earlier, we associate a bin packing instance with every such generalized edge coloring instance by decomposing the edge weighted bipartite graph $G = (V, E)$ into a union of matchings. We then create a bin packing instance in which all bins have size 1. We create an item of our bin packing instance for each matching in our decomposition, and we set its size to be the maximum weight of any edge in the matching. A packing with k bins immediately leads to a valid k-coloring by simply coloring the edges of all matchings (items) placed in the same bin with the same unique color.

3.1. Limitations.

Consider the following trivial instance of our generalized edge coloring problem. Let X be a finite subset of $(0, 1]$ and create a vertex in A and in B for each element $x \in X$ and $\lfloor \frac{n}{x} \rfloor$ edges between them. In this case, $2n - 1$ colors are sufficient (and needed if $\frac{1}{2} + \epsilon \in X$ for some small ϵ). No matter what decomposition into matchings we consider, our bin packing instance has at least $\lfloor \frac{n}{x} \rfloor$ items (matchings) of size at least x for every $x \in X$. If $X = \{x_0, x_1, \ldots, x_l\}$ with $x_0 > x_1 > \cdots > x_l$, this bin packing instance requires no fewer bins than another bin packing instance with $\lfloor \frac{n}{x_i} \rfloor - \lfloor \frac{n}{x_{i-1}} \rfloor$ items of size x_i for every $i \geq 1$ and $\lfloor \frac{n}{x_i} \rfloor$ items of size x_0. As X gets denser in $(0, 1]$, this bin packing instance tends to a continuous bin packing instance with density $\frac{n}{x^2}$ (i.e., the number of items of size in $(x, x + dx)$ is $\frac{n}{x^2} dx$) after having removed the n items of size 1. Now the number of bins required is at least the total size of all items $n + \int_0^1 x \frac{n}{x^2} dx$, which is unbounded!

To overcome this problem, we first discard all edges whose weight is less than some parameter α (to be determined) by using Lemma 2. This said, we can turn to proving the graph partitioning result in which our work is based.

3.2. Partitioning the graph.

From now on we fix a parameter $0 < \alpha < 1$ and work with graphs in $\mathcal{D}_r^n(\alpha, 1)$. The decomposition we need to construct our bin packing instance is given below.

LEMMA 5. *Consider the sequence $\alpha_0 = 1 > \alpha_1 > \alpha_2 > \cdots > \alpha_p = \alpha \geq 0$. Let $G = (V, E) \in \mathcal{D}_r^n(\alpha, 1)$. Then there exist sets $F_1, \ldots, F_p$ partitioning E such that the following hold:*

(i) $\max_{e \in F_k} w(e) \leq \alpha_{k-1}$.

(ii) *For all vertices* $v \in V$,

$$\deg_{F_k}(v) \le \left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}}\right) n + a_k(v) \quad \text{for all } 2 \le k \le p,$$

$$\deg_{F_1}(v) \le \frac{n}{\alpha_1} + a_1(v),$$

where $a_k(v) \le 3(p-k+1)$.

Proof. Consider an instance $G = (L, R, E)$ with weight function w and let

$$D_i = \{e \in E \ : \ w(e) \in (\alpha_i, \alpha_{i-1}]\}$$

for $i = 1, \dots, p$. From inequality (2) we can easily deduce that for all $v \in L \cup R$,

$$\sum_{i=k}^{p} \alpha_i \deg_{D_i}(v) \le n \qquad \text{for all } k = 1 \dots, p. \tag{3}$$

If we divide the inequality (3) corresponding to $k = 1$ by α_1 and multiply the kth inequality (3) by $(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}})$, we obtain the following set of inequalities:

$$\left(\frac{1}{\alpha_1}\right)\alpha_1 \deg_{D_1}(v) + \left(\frac{1}{\alpha_1}\right)\alpha_2 \deg_{D_2}(v) + \cdots + \left(\frac{1}{\alpha_1}\right)\alpha_p \deg_{D_p}(v) \le \left(\frac{1}{\alpha_1}\right) n$$

$$\left(\frac{1}{\alpha_2} - \frac{1}{\alpha_1}\right)\alpha_2 \deg_{D_2}(v) + \left(\frac{1}{\alpha_2} - \frac{1}{\alpha_1}\right)\alpha_3 \deg_{D_3}(v) + \cdots + \left(\frac{1}{\alpha_2} - \frac{1}{\alpha_1}\right)\alpha_p \deg_{D_p}(v)$$
$$\le \left(\frac{1}{\alpha_2} - \frac{1}{\alpha_1}\right) n$$

$$\vdots$$

$$\left(\frac{1}{\alpha_p} - \frac{1}{\alpha_{p-1}}\right)\alpha_p \deg_{D_p}(v) \le \left(\frac{1}{\alpha_p} - \frac{1}{\alpha_{p-1}}\right) n.$$

Note that, for all $i = 1, \dots, p$, the coefficients in front of $\deg_{D_i}(v)$ over the above inequalities sum to 1. Therefore, for each D_i we can apply Theorem 4 with

$$\gamma_1^i = \frac{1}{\alpha_1}\alpha_i, \gamma_2^i = \left(\frac{1}{\alpha_2} - \frac{1}{\alpha_1}\right)\alpha_i, \dots, \gamma_i^i = \left(\frac{1}{\alpha_i} - \frac{1}{\alpha_{i-1}}\right)\alpha_i$$

to partition D_i into sets $D_i^1, \dots, D_i^i$ such that for all $k = 1, \dots, i$ and all $v \in V$,

$$\gamma_k^i \deg_{D_i}(v) - e_k^i(v) < \deg_{D_i^k}(v) < \gamma_k^i \deg_{D_i}(v) + e_k^i(v),$$

where $e_k^i(v) \le 3$ and $\sum_{k=1}^{i} e_k^i(v) \le 2(i-1)$.

We are now ready to finish the proof. Define $F_k = D_k^k \cup D_{k+1}^k \cup \cdots \cup D_p^k$ for all

$k = 1, \dots, p$. Thus letting $a_k(v) = \sum_{i=k}^{p} e_k^i(v) \le 3(p-k+1)$, we have the following:

$$\begin{aligned}\deg_{F_1}(v) &\le \sum_{i=1}^{p} \left(\gamma_1^i \deg_{D_i}(v) + e_1^i(v)\right)\\ &\le \left(\frac{1}{\alpha_1}\right) n + a_1(v);\\ \deg_{F_k}(v) &\le \sum_{i=k}^{p} \left(\gamma_k^i \deg_{D_i}(v) + e_k^i(v)\right)\\ &\le \left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}}\right) n + a_k(v), \qquad 2 \le k \le p. \qquad \square\end{aligned}$$

3.3. The associated bin packing problem. Let us now consider a bipartite graph $G = (V, E) \in \mathcal{D}_r^n(\alpha, 1)$ and $F_1, \dots, F_p$ as in Lemma 5. By König's theorem, F_k can be decomposed into no more than

$$\left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}}\right) n + \max_{v \in V} a_k(v)$$

matchings, for all $k = 2, \dots, p$ and F_1 can be decomposed into $\frac{n}{\alpha_1} + \max_{v \in V} a_1(v)$ matchings. We now construct an instance of the one-dimensional bin packing problem with unit-sized bins. Arbitrarily select $(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}})n$ matchings (or, more formally, the floor of this quantity) in the decomposition of F_k for $k = 2, \dots, p$ and assign each of them an item of size α_{k-1}. Similarly, arbitrarily select $\frac{n}{\alpha_1}$ matchings in the decomposition of F_1 and assign each of them an item of size α_0. Let $\mathcal{M}$ be those matchings selected in $F_1, \dots, F_p$, and, by construction, we have an item for each element of $\mathcal{M}$. Our bin packing instance is thus the following:

Input: $\frac{n}{\alpha_1}$ items of size 1 and $(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}})n$ items of size α_{k-1} for $k = 2, \dots, p$.

Output: A packing of the items into the minimum number of bins.

Observe that this bin packing instance is *independent* of $G = (V, E) \in \mathcal{D}_r^n(\alpha, 1)$ and depends only on n and the values of α_i selected.

Given any solution to this bin packing instance, say with k opened bins, we can easily obtain a coloring of all the edges in the union of the matchings in $\mathcal{M}$ using just k colors. Indeed, we can simply color an edge belonging to a matching by a color representing the bin in which the corresponding item is packed. In constructing the bin packing instance, we have discarded at most

$$\sum_{k=1}^{p} \max_{v \in V} a_k(v) \le 3 \sum_{k=1}^{p} (p-k+1) = \frac{3}{2} p(p+1)$$

matchings, and they can be colored with a new color for each of them. In summary, the number of colors we need is at most the optimal number of bins of our bin packing instance plus $\frac{3}{2}p(p+1)$. An interesting feature of the results on the previous section is that they do not assume any conditions on p. We will see later that the optimal value for p is $\Theta(n^{1/3})$, which implies that the number of additional colors we need to accommodate the matchings not in $\mathcal{M}$ is $\frac{3}{2}p(p+1) = O(n^{2/3}) = o(n)$ and hence negligible.

As an example of the associated bin packing instance, consider the case with $p = 3$ and $\alpha_1 = \frac{1}{2}$, $\alpha_2 = \frac{1}{3}$, and $\alpha_3 = \alpha = \frac{1}{4}$. The bin packing instance then consists of $2n$ items of size 1, n items of size $\frac{1}{2}$, and n items of size $\frac{1}{3}$, and these items can be packed into $2n + \frac{n}{2} + \frac{n}{3} = \frac{17}{6}n$ bins (plus $O(1)$ bins for fractionally opened bins). The argument above regarding discarded items shows that we need $O(p^2) = O(1)$ additional bins. Using Lemma 2, we then obtain that $M(n, r) \leq \frac{17}{6}n + O(1)$. This derivation is essentially identical to the result of Du et al. [12], and the approach taken here can be viewed as an extension of it.

Our goal now is to focus on our general bin packing instance and analyze the number of bins it requires. Since all items in the bin packing instance have size at least $\alpha = \alpha_p$, it is clear that items whose size is more that $1-\alpha$ are forced to use a full bin in any feasible packing. Hence, without loss of generality, we can let $\alpha_1 = 1 - \alpha$. With this, an optimal packing always needs $n/(1 - \alpha)$ bins to pack items of size 1 plus a certain number of bins to pack the remaining items (of size $\alpha_1, \ldots, \alpha_p$).

3.4. A lower bound. A trivial lower bound on the number of unit bins required to pack our discrete instance is $n/(1-\alpha)$ bins (for the items of size greater than $1-\alpha$) plus the total size of the remaining items:

$$\frac{n}{1-\alpha} + \sum_{k=2}^{p} \alpha_{k-1} \left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}} \right) n.$$

This can be lower bounded in the following way. Let $g : [\alpha, 1 - \alpha] \to \mathbb{R}$ be defined by $g(x) = 1/x^2$. As $n \int_{\alpha_k}^{\alpha_{k-1}} g(x)dx = (\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}})n$ is the number of items of size α_{k-1} and $\alpha_{k-1} \geq x$ for any $x \in [\alpha_k, \alpha_{k-1}]$, we have that

$$\sum_{k=2}^{p} \alpha_{k-1} \left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}} \right) n \geq n \int_{\alpha}^{1-\alpha} x g(x) dx$$

$$= \int_{\alpha}^{1-\alpha} \left(\frac{n}{x} \right) dx = n \ln \frac{1-\alpha}{\alpha}.$$

Therefore, from Lemma 2, we derive that our analysis cannot give an upper bound on $M_{[\alpha,1]}(n, r)$ better than

$$\min_{\alpha \in (0,1]} \max \left\{ \frac{2n}{1-\alpha}, \frac{n}{1-\alpha} + n \ln \frac{1-\alpha}{\alpha} \right\} = M \cdot n,$$

with $2.5569 \leq M \leq 2.5570$. The term $\frac{2n}{1-\alpha}$ comes from Lemma 2, while the other term is the bound just obtained. The value of α for which the minimum is attained is $\alpha \approx 0.2178117$. From now on, we fix α to be the argmin of the above expression. In what follows, we show that this lower bound is actually achievable by relating the number of bins required by our bin packing instance to a continuous bin packing instance and analyzing it. For this purpose, we assume that the α_i's in the definition of our bin packing instance are equally spaced in $[\alpha, 1-\alpha]$, i.e., $\alpha_{k-1} - \alpha_k = \Delta = \frac{1-2\alpha}{p-1}$ with $\alpha_1 = 1 - \alpha$ and $\alpha_p = \alpha$.

3.5. The continuous packing problem. We round our bin packing instance to a continuous bin packing problem for which packing strategies with sublinear waste exist. We first define what we mean by a continuous bin packing instance. Consider a finite positive measure μ with density g defined over $[a, b]$ (with $0 \leq a \leq b \leq 1$) and, for any integer q, consider a uniform discretization $a = x_1 < \cdots < x_q = b$ of the interval $[a, b]$. Let Q_n^q be the optimal number of bins needed to pack the bin packing instance in which, for all $1 \leq i < q$, there are $\lceil n\mu([x_i, x_{i+1}))\rceil$ items of size x_{i+1}. The *value* of our bin packing instance is then defined as $\lim_{q\to\infty} \lim_{n\to\infty} \frac{Q_n^q}{n}$. By simply considering the total size of the items, we see that the value of a continuous instance is never smaller than

$$\int_a^b x d\mu(x) = \int_a^b xg(x)dx.$$

We say that μ admits a perfect packing if we have equality

$$\lim_{q\to\infty} \lim_{n\to\infty} \frac{Q_n^q}{n} = \int_a^b x d\mu(x) = \int_a^b xg(x)dx.$$

The lower bound in the previous section suggests that we consider the continuous bin packing instance with the continuous density $g(x) = \frac{1}{x^2}$ over $x \in [\alpha, 1-\alpha]$. In the next section, we show that a result of Rhee and Talagrand [26] can be applied to prove that g actually admits a perfect packing. What we show now is that the difference between the number of bins we need in our discrete instance and the value of this continuous instance times n is $O(\frac{n}{p})$ and hence sublinear whenever p grows with n. For this purpose, we show that we can discard $O(n/p)$ items in our discrete instance and obtain an instance which is dominated by discrete realizations of our continuous instance. Indeed, as $\int_{\alpha_{k-1}}^{\alpha_{k-2}} g(x)dx = \frac{1}{\alpha_{k-1}} - \frac{1}{\alpha_{k-2}}$, the continuous instance would dominate the discrete instance if we had only $(\frac{1}{\alpha_{k-1}} - \frac{1}{\alpha_{k-2}})n$ items of size α_{k-1}. We therefore need to discard a number of items of size α_{k-1} equal to

$$\begin{aligned}&\left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}}\right)n - \left(\frac{1}{\alpha_{k-1}} - \frac{1}{\alpha_{k-2}}\right)n \\ &= \frac{2\Delta^2}{\alpha_k\alpha_{k-1}\alpha_{k-2}}n \leq \frac{2\Delta^2}{\alpha^3}n.\end{aligned}$$

Over all values of k, this amounts to discarding $p\frac{2\Delta^2}{\alpha^3}n = \Theta(\frac{n}{p})$ items, and they can each be packed in a separate bin.

As announced, we show in the next section that g admits a perfect packing. This implies that the total number of colors needed to color any graph $G \in \mathcal{D}_r^n(\alpha, 1)$ is at most $M \cdot n + O(p^2) + O(n/p)$, which is optimized choosing $p = \Theta(n^{1/3})$. For the optimal choice of α, which is approximately 0.2178117, the previous quantity becomes

$$M \cdot n + O(n^{\frac{2}{3}}) < 2.557 \cdot n + O(n^{\frac{2}{3}}),$$

concluding the proof of Theorem 1.

3.6. Perfect packing.

Consider the positive measure μ defined over the interval $[\alpha, 1-\alpha]$ with density $g(x) = 1/x^2$ for the optimal parameter α just obtained. To show that a perfect packing exists, we decompose g as the sum of three other positive functions, f_1, f_2 and f_3, all of which allow perfect packing. Furthermore, all bins used for the items corresponding to f_i will contain exactly $i+1$ items. With this, μ is a mixture of the corresponding measures μ_1, μ_2 and μ_3. The decomposition is depicted in Figure 1.

Consider the following functions:

1. $f_1(x) = \begin{cases} g(1-x) & \text{if } x \in [\alpha, 1/2), \\ g(x) & \text{if } x \in [1/2, 1-\alpha], \\ 0 & \text{otherwise,} \end{cases}$
2. $f_2(x) = \begin{cases} g(x) - f_1(x) - c & \text{if } x \in [1/4, \beta), \\ d & \text{if } x \in [\beta, \delta), \\ g(x) - f_1(x) & \text{if } x \in [\delta, 1/2), \\ 0 & \text{otherwise,} \end{cases}$
3. $f_3(x) = \begin{cases} g(x) - f_1(x) & \text{if } x \in [\alpha, 1/4), \\ c & \text{if } x \in [1/4, \beta), \\ g(x) - f_1(x) - d & \text{if } x \in [\beta, \delta), \\ 0 & \text{otherwise.} \end{cases}$

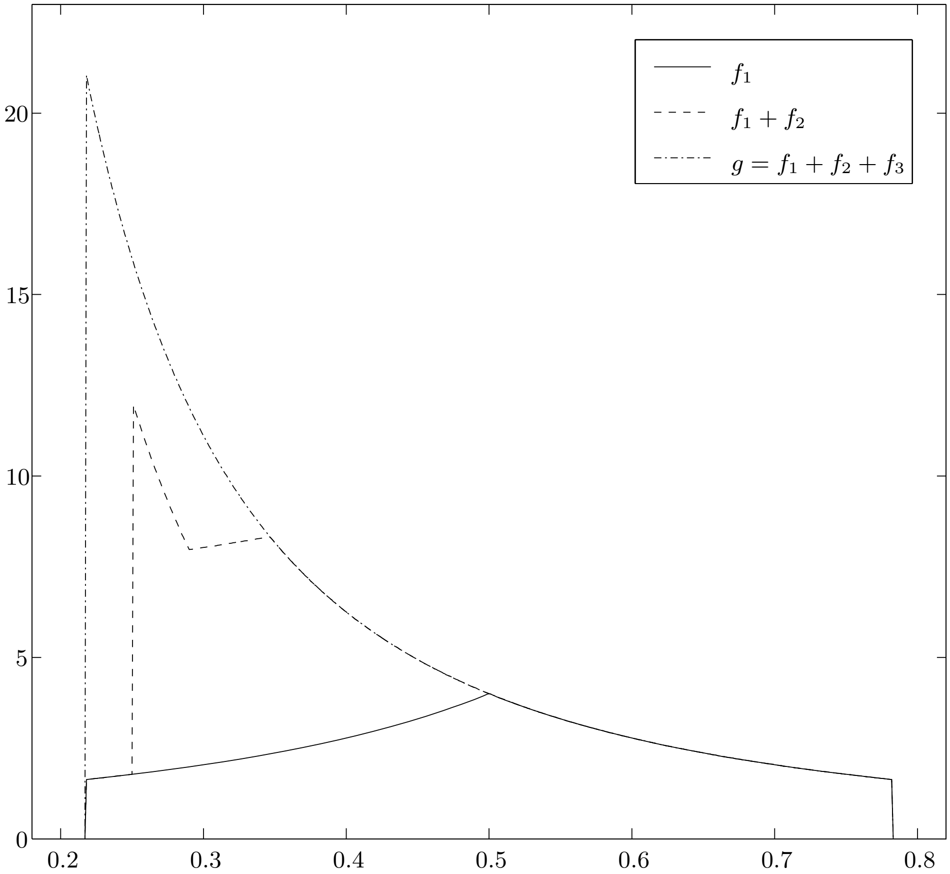

FIG. 1. *Decomposition of g into f_1, f_2, and f_3.*

Here $c = g(\beta) - f_1(\beta) - d$ and $d = g(\delta) - f_1(\delta)$ (so that f_2 is continuous). Clearly, for all $x \in [\alpha, 1-\alpha]$, $g(x) = f_1(x) + f_2(x) + f_3(x)$. The values of β and δ are uniquely determined by imposing that the average value of f_2 is $1/3$ and that of f_3 is $1/4$.

Namely, if $\beta \approx 0.2900708$ and $\delta \approx 0.3465256$, then

$$\frac{\int_{\alpha}^{1-\alpha} x f_1(x)dx}{\int_{\alpha}^{1-\alpha} f_1(x)dx} = \frac{1}{2},$$

$$\frac{\int_{1/4}^{1/2} x f_2(x)dx}{\int_{1/4}^{1/2} f_2(x)dx} = \frac{1}{3},$$

$$\frac{\int_{\alpha}^{\delta} x f_3(x)dx}{\int_{\alpha}^{\delta} f_3(x)dx} = \frac{1}{4}.$$

To prove that all f_1, f_2, and f_3 allow perfect packing, we use a perfect packing result proved by Karmarkar [17] and by Loulou [22] and a powerful theorem by Rhee and Talagrand [26]. The former result says that measures that are symmetric around $1/2^k$ for some integer k allow perfect packing. The latter can be stated as follows.

Theorem 6 (Rhee and Talagrand [26]). *Consider a decreasing measure μ defined over $[a, b]$ (with $0 \leq a \leq b \leq 1$) and an integer $p \geq 3$ such that $1/p \in [a, b]$. Then μ allows perfect packing if the following are satisfied:*

(i) $(p-1)a + b \leq 1$.

(ii) $\int_a^b x d\mu(x) = \frac{1}{p} \int_a^b d\mu(x)$.

In what follows, we briefly outline this result. Let $0 \leq a \leq b \leq c \leq 1$ be such that $(p-1)a + c \leq 1$ and $a + b < 2/p < a + c$. The *L-shaped function*, denoted by $L(a, b, c)$, is the unique (up to a multiplicative constant) nondecreasing real function defined over $[a, c]$, which is constant on $[a, b]$ and constant on $(b, c]$, and whose average value is $1/p$, i.e.,

$$\frac{\int_a^c xL(a, b, c)(x)dx}{\int_a^c L(a, b, c)(x)dx} = \frac{1}{p}.$$

In order to prove Theorem 6, Rhee and Talagrand first showed how to decompose a density satisfying the assumptions of the theorem as the limit of sum of L-shaped functions with the above properties. Then the central part of their work was to show that all such L-shaped functions do allow perfect packing. Unfortunately, they did not find a simple perfect packing strategy, and so they overcame the problem using a perfect packing characterization by Rhee [25], together with a complicated (and implicit) "exhaustion method," that decomposes an L-shaped function into possibly uncountably many perfectly packable functions.

Let us mention, however, that although the previous result was proved in a probabilistic setting (namely, under the following definition: μ allows perfect packing if and only if the expected number of bins needed to pack n independent and identically distributed random variables drawn according to μ divided by n approaches the expected size of an item), the proof also applies to our setting here.

Lemma 7. *The measure μ with density function $g : [\alpha, 1-\alpha] \to \mathbb{R}$ with $g(x) = 1/x^2$ allows perfect packing.*

Proof. As $g = f_1 + f_2 + f_3$, we need only show that each f_i, $i = 1, 2, 3$, allows perfect packing. The result follows immediately for f_1. Indeed, f_1 is symmetric around $1/2$. It remains to prove that both f_2 and f_3 satisfy the conditions of the previous theorem.

(1) The density f_2 is clearly decreasing in $[1/4, 1/2]$. Moreover,

$$\int_{1/4}^{1/2} x f_2(x) dx = \frac{1}{3} \int_{1/4}^{1/2} f_2(x) dx.$$

Finally, $(3-1)\frac{1}{4} + \frac{1}{2} = 1$. Thus all conditions are satisfied.

(2) Again, the density f_3 is decreasing in $[\alpha, \delta]$. In this case,

$$\int_{\alpha}^{\delta} x f_3(x) dx = \frac{1}{4} \int_{\alpha}^{\delta} f_3(x) dx,$$

and $(4-1)\alpha + \delta < 1$ (indeed, $(4-1)\alpha + \delta \approx 0.9999607$). □

3.7. Improved analysis for the rearrangeability of 3-stage Clos networks. In this section, we briefly discuss how a slight improvement of the $2.557n$ bound can be achieved when considering graphs belonging to $\mathcal{B}_r^n$. Specifically, we establish that $m(n, r) \leq 2.5480n + o(n)$. The analysis is essentially the same as the one for the bound on $M(n, r)$; therefore, we give only the main differences.

Let $G = (V, E) \in \mathcal{B}_r^n$. Since the weights satisfy condition (1), we can strengthen the main inequality used in Lemma 5 to be $\sum_{i=k}^{p} \deg_{D_i}(v) \leq 4n$ whenever $\alpha_p > 1/5$ (this is a strengthening only for $\alpha_k \leq 1/4$). This inequality, combined with the ideas in Lemma 5, can be used to prove the following result.

Lemma 8. *Let $G = (V, E) \in \mathcal{B}_r^n(\alpha, 1)$ and consider a sequence $\alpha_0 = 1 > \alpha_1 > \cdots > \alpha_l = 1/4 > \cdots > \alpha_p = \alpha > 1/5$. Then there exist sets $F_1, \dots, F_p$ partitioning E such that the following hold:*

(i) $\max_{e \in F_k} w(e) \leq \alpha_{k-1}$.

(ii) *For all vertices $v \in V$,*

$$\deg_{F_1}(v) \leq \frac{n}{\alpha_1} + a_1(v),$$

$$\deg_{F_k}(v) \leq \left(\frac{1}{\alpha_k} - \frac{1}{\alpha_{k-1}}\right) n + a_k(v), \qquad 2 \leq k \leq l,$$

$$\deg_{F_k}(v) \leq 16\,(\alpha_{k-1} - \alpha_k)\, n + a_k(v), \qquad l+1 \leq k \leq p,$$

where $a_k(v) \leq 3(p - k + 1)$.

By mimicking the analysis in section 3.3, the problem now translates into packing the function $g : [\alpha, 1-\alpha] \to \mathbb{R}$ such that $g(x) = 16$ if $x \in [\alpha, 1/4]$, and $g(x) = 1/x^2$ otherwise. The value of α now has to be taken a bit smaller than it used to be: $\alpha \approx 0.2151$ is the optimal choice. For that value of α, a decomposition of g very similar to that in section 3.6 can be found. Applying again the result in [26], such decomposition amounts to concluding that g allows perfect packing. The total number of colors needed is therefore

$$n \int_{\alpha}^{1-\alpha} x g(x) dx + \frac{n}{1-\alpha} + o(n) = \frac{2n}{1-\alpha} + o(n)$$

$$< 2.5480 \cdot n + o(n),$$

where the inequality comes from the choice of α.

4. Wide-sense nonblocking Clos networks. In what follows, we consider the online coloring formulation of the problem, assuming that edge weights satisfy condition (1). We start by describing two variants of the FF heuristic in the context of wide-sense nonblocking 3-stage Clos networks. Let $G = (V, E)$ be the bipartite graph with bipartition $V = A \cup B$ such that edge weights satisfy (1). Let $\{1, \ldots, M\}$ be the colors with which we attempt to find a valid coloring of G. Assume all edges in $\tilde{E} \subset E$ have been revealed and colored so far, and a new edge $e = (u, v) \notin \tilde{E}$ is revealed. The *first-fit-min (FF-Min)* heuristic assigns $c(e) = j$ (i.e., colors e with color j), where j is the smallest color for which adding e does not violate the valid coloring condition. In other words,

$$c(e) = j = \min \Bigg\{ 1 \leq i \leq M : w(e) + \sum_{f:\, f \in \delta(v) \cap \tilde{E},\, c(f)=i} w(f) \leq 1, \\ w(e) + \sum_{f:\, f \in \delta(u) \cap \tilde{E},\, c(f)=i} w(f) \leq 1 \Bigg\}.$$

In the first-fit-max (FF-Max) heuristic, the above minimization is replaced by a maximization.

The main issue now is to determine the smallest M such that FF-Min can always assign a color to a given edge. In order to establish our main result, we need a preliminary definition regarding the *blocking number* of $\mathcal{B}_r^n([0,1])$ under algorithm FF-Min. For an interval $I \subset [0, 1]$, we define the blocking number of $\mathcal{B}_r^n(I)$ under algorithm A (or simply the blocking number of algorithm A) as the maximum over all vertices $v \in V$ and over any graph $G = (V, E) \in \mathcal{B}_r^n(I)$ of the number of colors whose total weight adjacent to v is more than $1/2$. We denote it by $B_I(A)$:

$$B_I(A) = \max_{G=(V,E) \in \mathcal{B}_r^n(I)} \max_{v \in V} \left\{ \text{number of colors } i : \sum_{f:\, f \in \delta(v)\, c(f)=i} w(f) > \frac{1}{2} \text{ under A} \right\}.$$

By definition of $\mathcal{B}_r^n(I)$, we have that, for any algorithm A and for any $I \subseteq [0, 1]$, $B_I(A) \leq 2n - 1$. This bound, for interval $[0, 1]$, is exactly what we need to establish our main result.

We remark that our results do not hold for the more restrictive definition of wide-sense nonblocking in which the algorithm has to be able to route new connection requests *even if* previous connections terminate. In terms of the graph coloring problem, the more restrictive condition allows not only additions but also deletions of edges over time.

4.1. Wide-sense nonblocking for general connection requests. We now give the main result of this section, namely the bound on $m_W(n, r)$ in the general case.

THEOREM 9. *The number of colors needed to color any graph in $\mathcal{B}_r^n$ using algorithm FF-Min is at most $5n$, i.e.,*

$$m_W(n, r) \leq 5n.$$

Proof. Consider algorithm FF-Min, with $M = 5n$, applied to $G \in \mathcal{B}_r^n$. Let A, B be the bipartition of V, i.e., $V = A \cup B$. Let us say that an edge e is *large* if $w(e) > 1/2$ and *small* if $w(e) \leq 1/2$.

Consider iteration k of the algorithm and assume $e_k = e = (u, v)$ for some $u \in A$, $v \in B$. To see that the algorithm indeed works, we prove that edge e can be colored with some of $5n$ available colors. For this we consider two cases:

- Edge $e = e_k$ is small ($w(e) \leq 1/2$). Since FF-Min is a greedy-type heuristic, by Lemma 2, $\frac{2n}{1-1/2} = 4n$ colors are enough; and thus a color smaller than or equal to $4n$ is assigned to e.
- Edge $e = e_k$ is large ($w(e) > 1/2$). In this case, assume e cannot be colored. Let S^k_{uv} be the set of colors $1 \leq i \leq 5n$ such that there exists an edge e_t with $t < k$ satisfying that
  - e_t is colored with i,
  - $w(e_t) > 1/2$, and
  - e_t is adjacent to either u or v.

  The bound $B_I(A) \leq 2n-1$ for any algorithm implies that $|S^k_{uv}| \leq 2(2n-1) = 4n-2$. Now consider s, the smallest color in S^k_{uv}, such that $i > s$ implies that $i \in S^k_{uv}$. Since $|S^k_{uv}| \leq 4n-2$, we have that $s \geq n+3$. By definition, there is a small edge, say $f = (u, t)$, colored with $s-1$. The fact that f is small amounts to concluding that for all $i < s-1$, either

  $$\sum_{e:\, e\in\delta(u), c(e)=i} w(e) > \frac{1}{2} \quad \text{or} \quad \sum_{e:\, e\in\delta(t), c(e)=i} w(e) > \frac{1}{2}.$$

  The latter can happen for at most $2n-1$ colors (see the bound on the blocking number above), and therefore the former holds for at least $s-2-(2n-1) = s-2n-1$ colors. (As the former can happen only for at most $2n-1$ colors, this actually also implies $s \leq 4n$.) On the other hand, the number of large edges adjacent to u or v which are colored with $j \geq s$ is at least $5n-s+1$. Since, by condition (1), at most n of these can be adjacent to v, at least $5n-s-n+1 = 4n-s+1$ are adjacent to u.

  Overall we have that

  $$\sum_{e:\, e\in\delta(u)} w(e) > \frac{s-2n-1}{2} + \frac{4n-s+1}{2} = n,$$

  which contradicts (1). □

4.2. Improved bounds for the case of small connection requests. We now turn to the case in which all connection requests have weights in $[0, 1/2]$. In terms of our graph coloring problem, this means considering graphs in $\mathcal{B}^n_r([0, 1/2])$. Gao and Hwang [13] have proved that $m_{W[0,1/2]}(n, r) \leq 3.75n$. Let us now see how an improvement of this result can be obtained.

LEMMA 10. *The number of colors needed to color any graph in $\mathcal{B}^n_r([0, 1/2])$ using algorithm FF-Min is at most $3.601n + 3$, i.e.,*

$$m_{W[0,1/2]}(n, r) \leq 3.601n + 3.$$

Proof. Observe first that from Lemma 2, if e is an edge with weight $w(e)$, FF-Min actually assigns to it a color $c(e)$ satisfying $c(e) \leq \frac{2n}{1-w(e)} + 1$, or

$$w(e) \geq 1 - \frac{2n}{c(e)-1}. \tag{4}$$

This immediately implies that edges with weight below $\frac{1}{4}$ are assigned to the first $\lceil \frac{8n}{3} \rceil$ colors.

Let M be the number of colors needed by FF-Min and let $e = (u, v)$ be an edge that could not be assigned to any of the first $M-1$ colors. Consider a color $j \leq M-1$, since e was not assigned to j (and $w(e) \leq 1/2$); then $\sum_{f\colon f\in\delta(u),c(f)=j} w(f) > 1/2$ or $\sum_{f\colon f\in\delta(v),c(f)=j} w(f) > 1/2$. Assume, without loss of generality, that the latter holds. Since all weights are at most $1/2$, at least two edges in $\delta(v)$ are colored j, and thus

$$\sum_{f\colon f\in\delta(v),c(f)=j} w(f) \geq 2\left(1 - \frac{2n}{j-1}\right).$$

We can now compute $\sum_{g\in\delta(v)} w(g) + \sum_{g\in\delta(u)} w(g)$ using the previous equation, the fact that for a color $j \leq \lceil \frac{8n}{3} \rceil$ either $\sum_{f\colon f\in\delta(u),c(f)=j} w(f) > 1/2$ or $\sum_{f\colon f\in\delta(v),c(f)=j}$ $w(f) > 1/2$, and (4):

$$\begin{aligned}
\sum_{g\in\delta(v)} w(g) + \sum_{g\in\delta(u)} w(g) &> 2w(e) + \left\lceil \frac{8n}{3} \right\rceil \frac{1}{2} + \sum_{j=\lceil \frac{8n}{3} \rceil+1}^{M-1} 2\left(1 - \frac{2n}{j-1}\right) \\
&\geq \left\lceil \frac{8n}{3} \right\rceil \frac{1}{2} + \sum_{j=\lceil \frac{8n}{3} \rceil+1}^{M} 2\left(1 - \frac{2n}{j-1}\right) \\
&\geq 2M - \frac{3}{2}\left\lceil \frac{8n}{3} \right\rceil - 4n \int_{\lceil 8n/3 \rceil -1}^{M-1} \frac{1}{x} dx \\
&\geq 2M - 4n - \frac{3}{2} - 4n \int_{8n/3-1}^{M-1} \frac{1}{x} dx \\
&= 2M - 4n - \frac{3}{2} + 4n \ln\left(\frac{8n-3}{3M-3}\right) \\
&= 2M - 4n - \frac{3}{2} + 4n \ln\left(\frac{8n}{3M-9}\right) \\
&\quad + 4n \ln\left(\frac{(3M-9)(8n-3)}{(3M-3)8n}\right).
\end{aligned}$$

However, for $M \geq 3.601n + 3$, the above quantity surpasses $2n$, leading to a contradiction. Indeed, for this choice of M, the last term is greater than -4, and so the previous quantity is greater than $2 \cdot 3.601n - 4n + 4n \ln(8/10.803) > 2n$. □

4.3. The 2-rate environment. We now prove the bound on $m_W(n, r)$ when connection requests can take only two values, which are known beforehand. As mentioned before, this result almost closes the gap with the best known lower bound in this environment. Indeed, the result in this section, together with results in [13, 31], implies that

$$3n - 2 \leq m_W^2(n, r) \leq 3n.$$

In what follows, we denote by b and B the two rates (or edge weights) and assume that $0 < b < B \leq 1$. Gao and Hwang [13] already proved the bound in the case $B \leq 1/2$.

LEMMA 11 (Gao and Hwang [13]). *If $0 < b < B \leq 1/2$ are the two rates, then $m^2_W(n, r) \leq 3n$.*

We complete Gao and Hwang's result by proving a slightly better bound when $B > 1/2$. Of course, we may assume $b \leq 1/2$, for otherwise condition (1) allows us to reason that every vertex has degree at most n, and thus an even stronger bound of $2n$ holds for any online algorithm. Let k be the largest integer such that $B + kb \leq 1$ and ℓ be the largest integer such that $\ell b \leq 1$. Let us associate a *height* of 1 with every edge of weight b and a height of $(\ell - k)$ to every edge of weight B; and denote by $h(e)$ the height of an edge. As at most one item of size B can fit into a bin, (1) implies that the height of edges in any bin is at most l, and thus $\sum_{e\in\delta(v)} h(e) \leq n\ell$.

The algorithm we need to consider is the following.

```
ALGORITHM FF-MIN-MAX

(1) Assume the edges are revealed in the order $\{e_1, \ldots, e_m\}$.
(2) For $p = 1$ to $m$ do:
    (a) If $w(e_p) = B$, assign a color $1 \leq i \leq 3n-1$ to $e_p$ using FF-Max.
    (b) If $w(e_p) = b$:
        * Assign any color $1 \leq i \leq 3n - 1$ to $e_p$ such that at most
          $k - 1$ small edges adjacent to $u$ have been colored $i$, and
          at most $k - 1$ small edges adjacent to $v$ have been colored
          $i$, if one such color exists.
        * Otherwise, assign a color $1 \leq i \leq 3n - 1$ to $e_p$ using FF-
          Min.
```

LEMMA 12. *The number of colors needed to color any graph in $\mathcal{B}^n_r(\{b, B\})$, with $0 < b \leq 1/2 < B \leq 1$, using Algorithm FF-Min-Max is at most $3n - 1$.*

Proof. Consider the graph $G = (V, E) \in \mathcal{B}^n_r(\{b, B\})$ and assume the set of colors is $\{1, \ldots, 3n - 1\}$. For the purpose of this proof, let us say that an edge e is *large* if $w(e) = B$ and *small* if $w(e) = b$.

Consider step (1) of the algorithm and let $e_i = (u, v) \in E$ be the edge currently considered.

Let us first see that in step (2)(b) of the algorithm, FF-Min does not attempt to color e_i using a color larger than $2n - 1$ (assuming thus that no color could be found such that either u or v has at most $k - 1$ edges adjacent to it of that color). Indeed, it is enough to observe that FF-Min is a greedy-type algorithm. With this in mind, assume that FF-Min could not color e_i (which is a small edge) with a color $j \leq 2n-1$. Then, for any color $j \leq 2n - 1$, one of the following is satisfied:

- There are ℓ small edges $f_1 \ldots, f_\ell$ such that $c(f_r) = j$ for all $r = 1, \ldots, \ell$, and either $\{f_1, \ldots, f_\ell\} \subseteq \delta(u)$ or $\{f_1, \ldots, f_\ell\} \subseteq \delta(u)$.
- There are k small edges $f_1, \ldots, f_k$ and one large edge f such that $c(f_r) = c(f) = j$ for all $r = 1 \ldots, k$, and either $\{f_1, \ldots, f_k, f\} \subseteq \delta(u)$ or $\{f_1, \ldots, f_k, f\} \subseteq \delta(u)$.

We can therefore assume that there is a set of n colors $c_1, \ldots, c_n$ such that for each c_r, ℓ small edges or k small and one large edge are colored with c_r and are adjacent to u (otherwise, the property is true with v). Since also e_i is adjacent to u, we obtain that the total height of edges adjacent to u is at least $n\ell + 1 > n\ell$, a contradiction with condition (1).

We conclude that the algorithm will always find a feasible color for a small edge.

Suppose now that the algorithm cannot assign any color to $e_i = (u, v)$ because e_i is a large edge ($w(e_i) = B$). Then Algorithm FF-Min-Max attempted to color e_i in step (2)(a) using FF-Max, but no color was found. We see in what follows that this is impossible.

Let j be the largest color having at least $k + 1$ small edges adjacent to either u or v. From the analysis above, no color i with $i \geq 2n$ has more than k small edges adjacent to it, and thus $j < 2n$. In addition, for any color i with $i > j$, there must already be a large edge colored i adjacent to either u or v, and as this can happen to at most $2n - 2$ edges, we have $j > n$. Thus, $n < j < 2n$. Without loss of generality, assume that at least $k + 1$ small edges of color j are adjacent to u and let $f = (u, t)$ be one of those edges that was colored using FF-min (there is at least one such f, since there are at least $k+1$ edges in total). Since f was colored by FF-min, for every color $1 \leq r \leq 3n - 1$, at least k small edges of color r are adjacent to u or t. Also, by definition of FF-min, for every color $1 \leq r < j$, there is a set of edges colored with r, of total height ℓ, adjacent to u or t (such a set consists of either ℓ small edges or k small and one large edge). Overall we have that

$$\sum_{e \in \delta(u) \cup \delta(t) : w(e) = b} h(e) + \sum_{e \in \delta(u) \cup \delta(t) : w(e) = B \text{ and } c(e) < j} h(e) \geq (3n-1)k + (j-1)(\ell - k) + 1,$$

where the final $+1$ comes from the fact that $k+1$ small edges adjacent to u are colored with j. Thus, since $n\ell$ is the maximum total height of edges adjacent to t,

$$(5) \qquad \sum_{e \in \delta(u) : w(e) = b} h(e) + \sum_{e \in \delta(u) : w(e) = B \text{ and } c(e) < j} h(e) \geq (3n-1)k + (j-1)(\ell - k) + 1 - n\ell.$$

On the other hand, for every color r with $j < r \leq 3n - 1$, there is a large edge of color r adjacent to u or v. Since at most $n - 1$ (already colored) large edges can be adjacent to v, at least $3n - 1 - j - (n - 1) = 2n - j$ large edges of color larger than j are adjacent to u. Thus,

$$\sum_{e \in \delta(u) :\, w(e) = B \text{ and } c(e) > j} h(e) \geq (2n - j)(\ell - k).$$

Combining this with (5) and the fact that e_i is large, we conclude that the total height of edges adjacent to u is at least

$$[\ell - k] + [(3n - 1)k + (j - 1)(\ell - k) + 1 - nl] + [(\ell - k)(2n - j)],$$

where the first term corresponds to the height of e_i, the second to inequality (5), and the third to large edges adjacent to u of color $r > j$. The above quantity equals $(3n - 1)k - n\ell + 2n(\ell - k) + 1 = (n - 1)k + n\ell + 1 > n\ell$, which is impossible. □

5. A simple algorithm for multirate rearrangeability. In this section, we reconsider the offline setting and present a simple algorithm that is multirate rearrangeably nonblocking and that uses no more than $8n/3$ colors. In comparison, the algorithm of section 3 uses $2.548n + o(n)$ colors but is more complex. The algorithm we consider is the following.

```
Algorithm FF-Min-Decreasing

(1) Sort the edges according to their weight such that $w(e_1) \geq w(e_2) \geq \cdots \geq w(e_m)$. Let $k = 1$.
(2) While $k \leq m$ do:
    (a) Assign a color $1 \leq i \leq \lceil 8n/3 \rceil$ to $e_k$ using FF-Min.
    (b) $k = k + 1$.
```

As is the case for FF decreasing for bin packing, Algorithm FF-Min-Decreasing can be implemented in time $O(n \log n)$. As it involves sorting, it is applicable only to the offline setting. We have the following result.

Theorem 13. *The number of colors needed to color any graph in $\mathcal{B}_r^n$ using Algorithm FF-Min-Decreasing is at most $\lceil 8n/3 \rceil$.*

Proof. Consider the graph $G = (V, E) \in \mathcal{B}_r^n$ and let k be the smallest index such that $w(e_k) \leq \frac{1}{4}$. As FF-Min-Decreasing is a greedy algorithm, we know from Lemma 2 that our algorithm will always be able to color $\{e_k, \ldots, e_m\}$. Thus we can assume that $w(e_i) > \frac{1}{4}$ for all $i = 1 \ldots, m$; i.e., we can assume $G = (V, E) \in \mathcal{B}_r^n(]1/4, 1])$.

Let $e = e_\ell = (u, v)$ be the first edge that could not be colored by FF-Min-Decreasing. We distinguish two cases:

(i) $w(e) = \alpha > 1/3$. In this case, we will prove that FF-Min-Decreasing colors e with a color no larger than $2n$. We define the function $g_\alpha : [0, 1] \to [0, 1]$ as

$$g_\alpha(x) = \begin{cases} 1 & \text{if } 1 - \alpha < x, \\ 1/2 & \text{if } \alpha \leq x \leq 1 - \alpha, \\ 0 & \text{if } x < \alpha \end{cases}$$

and consider the modified edge weights $w'(e_i) = g_\alpha(w(e_i))$. We know that $G_\ell = (V, \{e_1, \ldots, e_\ell\})$ together with w satisfies condition (1), and from the sorting step $w(e_i) \geq \alpha$ for all $i = 1, \ldots, \ell$. Thus, G, together with w', also satisfies condition (1). Now, as e could not be colored using the first $2n$ colors, for all $1 \leq i \leq 2n$ either

$$\sum_{e : e \in \delta(u), c(e) = i} w(e) > 1 - \alpha \quad \text{or} \quad \sum_{e : e \in \delta(v), c(e) = i} w(e) > 1 - \alpha.$$

We can then assume that for a set $B \subset \{1, \ldots, 2n\}$ with $|B| \geq n$ the first inequality holds. For $i \in B$, the previous condition implies that the edges in $\delta(u)$ colored with i are either one edge f with $w(f) > 1 - \alpha$ or two edges f, g with $w(f) \geq \alpha$ and $w(g) \geq \alpha$. In both cases,

$$\sum_{e : e \in \delta(u), c(e) = i} w'(e) = 1.$$

It follows that

$$\sum_{e : e \in \delta(u)} w'(e) > \sum_{e : e \in \delta(u), c(e) \in B} w'(e) \geq n,$$

a contradiction with condition (1).

(ii) $1/3 \geq w(e) = \alpha > \frac{1}{4}$. We define the function $f_\alpha : [0,1] \to [0,1]$ as

$$f_\alpha(x) = \begin{cases} 1 & \text{if } 1-\alpha < x, \\ 1/2 & \text{if } \frac{1-\alpha}{2} < x \leq 1-\alpha, \\ 1/4 & \text{if } \alpha \leq x \leq \frac{1-\alpha}{2}, \\ 0 & \text{if } x < \alpha \end{cases}$$

and consider the modified edge weights $w'(e_i) = f_\alpha(w(e_i))$. As in the previous case, $G_\ell = (V, \{e_1, \dots, e_\ell\})$, together with w, satisfies condition (1). Thus, from the sorting step $w(e_i) \geq \alpha$ for all $i = 1, \dots, \ell$, and it is easy to check that G_ℓ, together with w', also satisfies condition (1).
Additionally, as e could not be colored using the $\lceil \frac{8n}{3} \rceil$ colors, for all $1 \leq i \leq \lceil \frac{8n}{3} \rceil$ either

$$\sum_{e: e \in \delta(u), c(e) = i} w(e) > 1 - \alpha \quad \text{or} \quad \sum_{e: e \in \delta(v), c(e) = i} w(e) > 1 - \alpha.$$

We can then assume that for a set $B \subset \{1, \dots, \lceil 8n/3 \rceil\}$ with $|B| \geq 4n/3$ the first inequality holds. For $i \in B$, the previous condition implies that the edges in $\delta(u)$ colored with i are either one edge f with $w(f) > 1 - \alpha$; two edges f, g with at least one of them (the largest), say f, satisfying $w(f) > \frac{1-\alpha}{2}$; or three edges f, g, h (all with weights greater than α). In any case,

$$\sum_{e: e \in \delta(u), c(e) = i} w'(e) \geq \frac{3}{4}.$$

It follows that

$$\sum_{e: e \in \delta(u)} w'(e) > \sum_{e: e \in \delta(u), c(e) \in B} w'(e) \geq |B| \cdot \frac{3}{4} \geq n. \qquad \square$$

THE RESOLUTION COMPLEXITY OF RANDOM CONSTRAINT SATISFACTION PROBLEMS[*]

MICHAEL MOLLOY[†] AND MOHAMMAD R. SALAVATIPOUR[‡]

Abstract. We consider random instances of constraint satisfaction problems where each variable has domain size d and each constraint contains t restrictions on k variables. For each (d, k, t) we determine whether the resolution complexity is a.s. constant, polynomial, or exponential in the number of variables. For a particular range of (d, k, t), we determine a sharp threshold for resolution complexity where the resolution complexity drops from a.s. exponential to a.s. polynomial when the clause density passes a specific value.

Key words. random constraint satisfaction problems, resolution complexity, random k-SAT, phase transition, sharp threshold

1. Introduction.

A constraint satisfaction problem (CSP) is a generalized form of satisfiability which is widely studied in the artificial intelligence community. For example, the journal *Constraints* is devoted to these problems. Roughly speaking, a CSP generalizes SAT[1] in the sense that variables can draw their values from a more general domain than simply $\{T, F\}$, and each clause (also known as a constraint) forms a set of restrictions on the values that the variables in the clause may jointly take.

Random instances of k-SAT have been extremely well studied over the past few decades (see [1] for many references). More recently, the interest in this area has expanded into random instances of various generalizations of k-SAT, such as NAE-SAT [3], XOR-SAT [14, 18, 19], $(2+p)$-SAT [35, 37, 38, 4, 2], and many others. All of these can be expressed as CSPs. It was natural for this interest to eventually spread to random instances of CSPs, rigorously in [5, 15, 33, 20, 31, 32, 40] and experimentally even earlier (see [24] for a good survey).

One of the most important results regarding random k-SAT is that of Chvátal and Szemerédi [13], who showed that for any $k \geq 3$ and $c > 0$ a random instance of k-SAT with n variables and cn clauses will almost surely (a.s.)[2] have no resolution proof of unsatisfiabilty of length less than $2^{\Theta(n)}$. It is easy to show that, for large values of c, such random instances are a.s. unsatisfiable. This immediately implied that, for sufficiently large values of c, any Davis–Putnam-style algorithm will take exponential time on such an input. Furthermore, it provided an astoundingly vast and rich class to the, beforehand rather sparse [26, 39], list of unsatisfiable instances of k-SAT for which there is no polytime resolution proof of unsatisfiability. Such instances are

[1] Instances of SAT are boolean formulas in conjunctive normal form. For k-SAT, all clauses contain k literals.

[2] Formal definitions of these and other terms will appear in the next section.

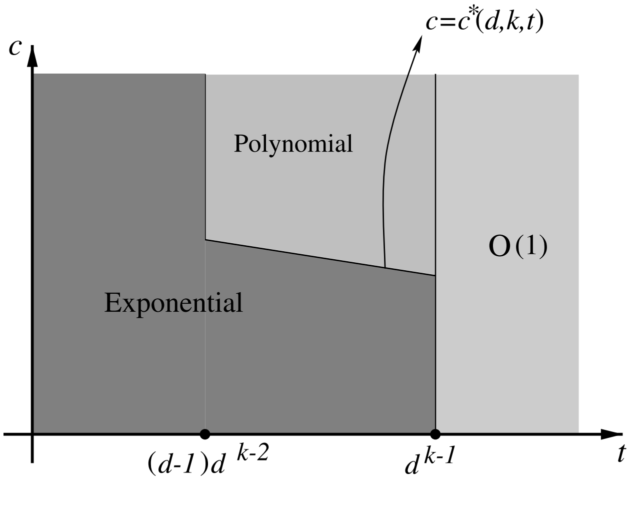

FIG. 1. *Resolution complexities.*

of great interest, since their existence can be viewed as a step toward proving that there are some unsatisfiable instances with no polytime proof of unsatisfiability of any kind, i.e., that $NP \neq co-NP$. Chvátal and Szemerédi's paper spawned numerous extensions and generalizations, e.g., [7, 8, 2, 6], including a general framework for proving lower bounds on resolution complexity by Ben-Sasson and Wigderson [9].

Mitchell [31, 32] extended the framework of Ben-Sasson and Wigderson to the setting of CSPs. He then used this framework to prove exponential lower bounds on the resolution complexity of a very natural class of random CSPs—one where the number of restrictions per constraint is fixed. Specifically, he considered random CSPs with domain size $d \geq 2$ and every constraint containing precisely t restrictions on $k \geq 2$ variables.[3] Note that these CSPs are trivial if either d or k is equal to 1 and that they are the well-studied 2-SAT when $d = k = 2$ and $t = 1$. Mitchell showed that, for $t \leq (d-1)/2, k = 2$, for $t \leq d-1, k \geq 3$, and for any constant $c > 0$, such a random instance with cn constraints will a.s. have no subexponential proof of unsatisfiability.[4] Again, it is easy to see that, for sufficiently large c, these instances are a.s. unsatisfiable (for $t > 0$). In contrast, Achlioptas et al. [5] showed that for $t \geq d^{k-1}$, and any $c > 0$, such a random instance will a.s. have an unsatisfiable subproblem of size $O(1)$ and thus will have a $O(1)$-length resolution proof of unsatisfiability. In this paper, we fill in the gap between $d-1$ and d^{k-1}. Using $\mathcal{F}_{n,M}^{d,k,t}$ to denote such a random CSP with M constraints, we prove the following theorems which are summarized in Figure 1.

THEOREM 1. *For any constants $d, k \geq 2$ and $1 \leq t < (d-1)d^{k-2}$, and for every constant $c > 0$, $\mathcal{F}_{n,M=cn}^{d,k,t}$ a.s. has resolution complexity at least $2^{\Theta(n)}$.*

For $d, k \geq 2$ and $t \geq (d-1)d^{k-2}$, we define

$$c^*(d,k,t) = \tfrac{1}{dk(k-1)}\binom{d^k}{t} \Bigg/ \binom{d^k-(d-1)d^{k-2}}{t-(d-1)d^{k-2}}.$$

[3] This natural model was, historically, one of the first two random models of a random CSP to be studied; the other turned out to be problematic and a.s. has $O(1)$ length resolution proofs of unsatisfiablity for any nontrivial number of constraints. See [33] or [24] for more details; the latter reference contains more than 30 references to the study of the model considered here.

[4] In [31], Mitchell claims to prove that this holds for $t \leq (d-1)(k-1)$ so long as d, k are not both 2. But there is an unfortunate error in his Lemmas 8 and 10, and his proof holds only for $t \leq (d-1)/2, k = 2$ and $t \leq d-1, k \geq 3$.

(An explanation of the derivation of this expression will have to wait until the end of the next section—see Lemma 9.)

THEOREM 2. *For any constants $d, k \geq 2$ and $(d-1)d^{k-2} \leq t < d^{k-1}$, and for every $c < c^*(d,k,t)$, $\mathcal{F}^{d,k,t}_{n,M=cn}$ a.s. has resolution complexity at least $2^{\Theta(n)}$.*

THEOREM 3. *For any constants $d, k \geq 2$ and $(d-1)d^{k-2} \leq t < d^{k-1}$, and for every constant $c > c^*(d,k,t)$, $\mathcal{F}^{d,k,t}_{n,M=cn}$ a.s. has resolution complexity* poly(n).

Trivially, the resolution complexity of a satisfiable CSP is infinite, so Theorem 2 is of no interest if, for all $c < c^*(d,k,t)$, $\mathcal{F}^{d,k,t}_{n,M}$ is a.s. satisfiable. This is, in fact, well known to be the case for $d = 2, k = 2, t = 1$ (i.e., 2-SAT), and we prove here that it is also the case for $d = 2, k = 3, t = 3$ (see Theorem 5 below). We prove that it is not the case for $d = 2, k = 3, t = 2$ and for all other d, k (note that when $d = 2, k = 3$, and t is as in Theorem 2, then $t \in \{2, 3\}$).

THEOREM 4. (a) *For any constants $d, k \geq 2$ and for every $c > \ln d / \ln[d^k/(d^k - t)]$, $\mathcal{F}^{d,k,t}_{n,M=cn}$ is a.s. unsatisfiable.*

(b) *For any constants $d, k \geq 2$, $(d,k) \notin \{(2,2),(2,3)\}$, and $(d-1)d^{k-2} \leq t < d^{k-1}$,*

$$\frac{\ln d}{\ln[d^k/(d^k - t)]} < c^*(d,k,t).$$

(c) *For every $c > 2.114$, $\mathcal{F}^{2,3,2}_{n,M=cn}$ is a.s. unsatisfiable.*

Parts (a) and (b) of Theorem 4 prove that $\mathcal{F}^{d,k,t}_{n,M}$ is a.s. unsatisfiable for some values of $c < c^*(d,k,t)$ for $d, k \geq 2$, $(d,k) \notin \{(2,2),(2,3)\}$, and $(d-1)d^{k-2} \leq t < d^{k-1}$. Part (c) proves the same for the case $d = 2, k = 3, t = 2$ since $c^*(2,3,2) = 7/3 > 2.114$. The next theorem shows that this is not the case for $d = 2, k = 3, t = 3$, and that here, just as in 2-SAT, there are short resolution proofs of unsatisfiability for every value of c above the threshold of satisfiability.

THEOREM 5. *For every $c < 7/9 = c^*(2,3,3)$, $\mathcal{F}^{2,3,3}_{n,M=cn}$ is a.s. satisfiable. Thus, $7/9$ is the (sharp) threshold of satisfiability for $\mathcal{F}^{2,3,3}_{n,M=cn}$.*

As mentioned above, when $t \geq d^{k-1}$, the resolution complexity of $\mathcal{F}^{d,k,t}_{n,M=cn}$ is a.s. $O(1)$. So these theorems completely characterize the resolution complexity of $\mathcal{F}^{d,k,t}_{n,M=cn}$ for every constant d, k, t, c except for $(d-1)d^{k-2} \leq t < d^{k-1}$ and $c = c^*(d,k,t)$. Here we have a sharp threshold for resolution complexity, similar to that found in [2], where the main technical result was the following.

THEOREM 6. *For any $\Delta, \epsilon > 0$, consider a random conjunctive normal form (CNF) formula F on n variables with Δn 3-clauses and $(1-\epsilon)n$ 2-clauses where every such formula is equally likely. F a.s. has resolution complexity at least $2^{\Theta(n)}$.*

(The other side of the "sharp threshold," i.e., that if the number of 2-clauses is $(1+\epsilon)n$ for some $\epsilon > 0$, then a.s. the resolution complexity of F is poly(n), was previously known to follow from the work in [12, 21, 25].)

Theorems 2 and 3 are at heart very similar to Theorem 6. For $(d-1)d^{k-2} \leq t < d^{k-1}$, a certain type of constraint called a *forcer* arises. Forcers play, essentially, the same role that 2-clauses play in random CNF formulas. We show that if $c > c^*$, then the forcers alone provide an unsatisfiable CSP with low resolution complexity, while if $c < c^*$, then, even along with the additional nonforcer constraints, the CSP has high resolution complexity.

Independently, Gao and Culberson [23] proved Theorem 3 for the special case $d = 2$. Essentially, they showed that in this case the forcers imply 2-clauses and for $c > c^*$ these 2-clauses form a random instance of 2-SAT which is above the satisfiability threshold. It is well known that such an instance will have low resolution complexity. We remark more on this at the end of subsection 2.3.

At first, we tried to adapt the lengthy proof of Theorem 6 to the setting of Theorem 2, but we were unsuccessful. Fortunately, we found an alternate proof technique, and to our pleasant surprise, it produced a proof of Theorem 2 which was dramatically shorter than the proof from [2] of Theorem 6. In fact, our technique yields a short proof of Theorem 6 which we provide in Appendix A. This technique looks like it will be of value to those who wish to prove future similar theorems.

We close this section by mentioning that the class of models of random CSPs considered here is a subset of the more general class introduced in [15, 33]. That class contains a much wider range of problems, including XOR-SAT and d-colorability. It would be very nice to characterize which models from that larger class exhibit high resolution complexity, but thus far we are unable to do so.

2. Preliminaries.

Here we give formal definitions of some of the concepts discussed in the introduction, along with other concepts required for the remainder of the paper.

2.1. The random model.

In our setting, the variables of our problem all have the same domain of permissible values, $\mathcal{D} = \{1, \dots, d\}$, and all constraints will be on k variables, for some fixed integers $d, k \geq 2$. Given a k-tuple of variables, $(x_1, \dots, x_k)$, a *restriction* on $(x_1, \dots, x_k)$ is a k-tuple of values $R = (\delta_1, \dots \delta_k)$, where each $\delta_i \in \mathcal{D}$. A set of restrictions on a k-tuple $(x_1, \dots, x_k)$ is called a *constraint* (or a clause). An assignment of values to the variables of a constraint C *satisfies* C if that assignment is not one of the restrictions in C. A CSP consists of a set of variables and a collection of constraints on subsets of those variables. An assignment of values to all variables in a CSP satisfies that CSP if every constraint is simultaneously satisfied. A CSP is *satisfiable* if there is at least one such satisfying assignment. The *degree* of a variable is the number of constraints in which it lies.

A *subproblem* of a CSP $\mathcal{I}$ is a CSP which is obtained by removing some of the variables and some of the constraints from $\mathcal{I}$, where, of course, if a variable x is removed, then every constraint containing x is also removed. When there is no possibility of confusion we often use, for example, $\mathcal{I} - \{C_1, C_2\}$ to denote the subproblem obtained by deleting the constraints C_1 and C_2 from $\mathcal{I}$ and $\mathcal{I} - \{x_1, x_2\}$ to denote the subproblem obtained by deleting the variables x_1 and x_2 from $\mathcal{I}$, along with any constraints containing them.

Recall that a k-uniform hypergraph is a generalization of a graph, where each edge contains k vertices. The *constraint hypergraph* of a CSP is the k-uniform hypergraph whose vertices correspond to the variables and whose edges correspond to the k-tuples of variables which have (nonempty) constraints. Of course, when $k = 2$, the constraint hypergraph is simply a graph, and so we often call it the *constraint graph.*

We define $\Omega^{d,k,t}$ to be the set of CSPs in which every variable has domain $\{1, \dots, d\}$, every constraint has k variables and t restrictions, and no two constraints use the same k-tuple of variables.

The random model: Specify c, n, d, k, t, and let $M = cn$. First choose a random constraint hypergraph with n vertices and M edges of size k, where each such hypergraph is equally likely. Next, for each edge e, we choose a random constraint on the k variables of e, with domains $\mathcal{D} = \{1, \dots, d\}$, uniformly from among all constraints with exactly t restrictions.

Note that every member of $\Omega^{d,k,t}$ with n variables and M clauses is equally likely to be chosen. We use $\mathcal{F}^{d,k,t}_{n,M}$ to denote a random CSP drawn from this model. We say that a property holds a.s. if the probability that it holds tends to 1 as n tends to infinity.

Remark. Alternatively, we could have chosen the constraint hypergraph by making an independent choice for each potential edge and deciding to put it in the hypergraph with probability $p = \frac{c \times k!}{n^{k-1}}$. We denote the resulting random CSP by $\mathcal{F}_{n,p}^{d,k,t}$. This model is, in many senses, equivalent to $\mathcal{F}_{n,M}^{d,k,t}$, as we describe in Appendix B. In particular, Lemma 25 implies that all of the theorems in this paper translate to $\mathcal{F}_{n,p}^{d,k,t}$. We will make use of the equivalence of these models in the proofs of Lemmas 15 and 16.

2.2. Resolution complexity. For a Boolean CNF formula F, a *resolution refutation* of F with length r is a sequence of clauses $C_1, \ldots, C_r = \emptyset$ such that each C_i is either a clause of F or is derived from two earlier clauses $C_j, C_{j'}$ for $j, j' < i$ by the following rule: $C_j = (A \vee x), C_{j'} = (B \vee \overline{x})$, and $C_i = (A \vee B)$, for some variable x. The *resolution complexity* of F, denoted $\mathbf{RES}(F)$, is the length of the shortest resolution refutation of F. (If F is satisfiable, then $\mathbf{RES}(F) = \infty$.)

Mitchell [32] discusses two natural ways to extend the notion of resolution complexity to the setting of a CSP. These two measures of resolution complexity are denoted $\mathbf{C-RES}$ and $\mathbf{NG-RES}$. The latter appears on the surface to be the most natural extension in that it extends resolution rules to the setting of a CSP and then carries them out. $\mathbf{C-RES}$, on the other hand, converts a CSP to a Boolean CNF formula and then carries out CNF resolution on that formula. Mitchell shows that, for every CSP instance $\mathcal{I}$, $\mathbf{C-RES}(\mathcal{I}) \leq \text{poly}(\mathbf{NG-RES}(\mathcal{I}))$, whereas there are many choices for $\mathcal{I}$ for which the converse is not true. Furthermore, all commonly used resolution-type CSP algorithms correspond nicely to the $\mathbf{C-RES}$ complexity of the input, but there are some that do not correspond to the $\mathbf{NG-RES}$. For that reason, we focus in this paper on the $\mathbf{C-RES}$ complexity, as did Mitchell in [31].

Given an instance $\mathcal{I}$ of a CSP in which every variable has domain $\{1, \ldots, d\}$, we construct a Boolean CNF formula CNF($\mathcal{I}$) as follows. For each variable x of $\mathcal{I}$, there are d variables in CNF($\mathcal{I}$), denoted $x : 1, x : 2, \ldots, x : d$, and there is a *domain clause* $(x : 1 \vee \cdots \vee x : d)$. For each restriction $(\delta_1, \ldots, \delta_k)$ on variables $(x_1, \ldots, x_k)$ in any constraint of $\mathcal{I}$, CNF($\mathcal{I}$) has a *conflict clause* $(\overline{x_1 : \delta_1} \vee \cdots \vee \overline{x_k : \delta_k})$. It is easy to see that CNF($\mathcal{I}$) has a satisfying assignment iff $\mathcal{I}$ does—if $\mathcal{I}$ has a satisfying assignment, then we produce one for CNF($\mathcal{I}$) by setting $x : \delta$ to True iff $x = \delta$; if CNF($\mathcal{I}$) has a satisfying assignment, then we produce one for $\mathcal{I}$ by setting $x = \delta$, where δ is any one of the values for which $x : \delta$ is True.

Remark. It is natural to consider adding an extra set of constraints for each variable x which specifies that $x : \delta$ can be true for at most one value of δ. But it is easily verified that each of the results in this paper (in particular, Lemma 7) holds regardless of whether we include these clauses; to be specific, we do not include them.

We define the resolution complexity of $\mathcal{I}$, denoted $\mathbf{C-RES}(\mathcal{I})$, to be equal to $\mathbf{RES}(\text{CNF}(\mathcal{I}))$.

In most previous papers bounding the resolution complexity of random instances of SAT or CSP for $k \geq 3$, a key lemma has been to establish that the following two conditions hold a.s. for some constants $\alpha, \zeta > 0$:

(A) Every subproblem on at most αn variables is satisfiable.

(B) Every subproblem on v variables, where $\frac{1}{2}\alpha n \leq v \leq \alpha n$, has at least ζn variables of degree 1.

For SAT, these two facts imply that a.s. the resolution complexity is exponential in n using principles introduced in [13] and refined to easily applied tools in [8, 9]. For more general instances of CSP, one needs to establish an additional fact (which is trivially true for SAT):

(C) If x is a variable of degree 1 in a CSP f, then, letting f' be the subproblem obtained by removing x and its constraint, any satisfying assignment of f' can be extended to a satisfying assignment of f by assigning some value to x.

In our setting, (C) holds if $t < d$, but for $t \geq d$, it is easy to see that it fails: Suppose that the constraint x lies in contains the d restrictions: $(1, 1, 1, \dots, 1, 1)$, $(1, 1, 1, \dots, 1, 2), \dots, (1, 1, 1, \dots, 1, d)$, where x is the last variable in the constraint. Then any satisfying assignment for f' in which all of the other variables of the clause receive 1 cannot be extended to f. For $k \geq 3$ Mitchell's proof [31] applies precisely to the range of t for which (C) holds. For $k = 2$, Mitchell modifies the conditions, replacing "degree 1" by "degree 2" in (B) and (C); this revised condition (C) holds precisely when $t \leq (d-1)/2$.

For higher values of t, we need to replace "degree 1" in condition (B) by a more complicated notion and then prove that something similar to condition (C) still holds. We describe how to do this in the next section, after presenting several necessary definitions.

2.3. Some new boundaries. A constraint C on variables $x_1, \dots, x_k$ *forbids* $x_i : \delta$ if each of the d^{k-1} possible k-tuples $(\delta_1, \dots, \delta_k)$, with $\delta_i = \delta$, is a restriction of C. Such a C is called a *forbidder.* As explained in [5] (and expanded on in [33]), it is the presence of forbidders that causes $\mathbf{C} - \mathbf{RES}(\mathcal{F}^{d,k,t}_{n,M=cn}) = O(1)$ a.s. for all c when $t \geq d^{k-1}$. C *permits* $(x_i : \delta, x_j : \gamma)$ if at least one of the d^{k-2} possible k-tuples $(\delta_1, \dots, \delta_k)$, with $\delta_i = \delta$ and $\delta_j = \gamma$, is not a restriction of C. C is a $(x_i : \delta) \rightarrow (x_j : \gamma)$ *forcer* if C does not permit $(x_i : \delta, x_j : \gamma')$ for any $\gamma' \neq \gamma$, i.e., if each of the $(d-1)d^{k-2}$ possible k-tuples $(\delta_1, \dots, \delta_k)$, with $\delta_i = \delta$ and $\delta_j \neq \gamma$, is a restriction of C. Thus C implies "if $x_i = \delta$, then $x_j = \gamma$." In this case, we say that the forcer C *starts* at x_i (or, more specifically, $x_i : \delta$) and *finishes* at x_j (or $x_j : \gamma$). As predicted by Mitchell [32], it is the presence of forcers that causes $\mathbf{C} - \mathbf{RES}(\mathcal{F}^{d,k,t}_{n,M=cn}) = \text{poly}(n)$ a.s. for large c when $(d-1)d^{k-2} \leq t < d^{k-1}$.

A *path* of length r in a k-uniform hypergraph H is a sequence of r edges $e_1, e_2, \dots, e_r$ such that:

- for $1 \leq i \leq r-1$, $e_i \cap e_{i+1} = x_i$—this is called a *connecting vertex*;
- for all $1 \leq i \leq r-2$ and $j > i+1$, $e_i \cap e_j = \emptyset$;
- there are specified vertices $x_0 \in e_1$ and $x_r \in e_r$, called the *endpoints* of the path.

If $e_1, \dots, e_r$ is a path and there is an edge $e_0 \in H$ whose intersection with the vertices of $e_1, \dots, e_r$ is only $\{x_0, x_r\}$, then $e_0, \dots, e_r$ form a *cycle* in H.

A *pendant path* is a path in which no vertices other than the endpoints lie in any edges of H off the path. In other words, there is no restriction on the degrees of the endpoints, each connecting vertex has degree 2 in H, and every other vertex in the path has degree 1 in H.

A (*pendant*) *path* of length r in a CSP is a sequence of r constraints whose underlying edges form a (pendant) path of length r in the underlying hypergraph. If there are values $\delta_0, \dots, \delta_r$ such that the constraint on each e_i is a $(x_{i-1} : \delta_{i-1}) \rightarrow (x_i : \delta_i)$ forcer, then we say that the (pendant) path is a $(x_0 : \delta_0) \rightarrow (x_r : \delta_r)$ *forcing (pendant) path.* It will be convenient to consider a single variable x to be a forcing path of length zero (note that we trivially have $(x : \delta) \rightarrow (x : \delta)$ for every δ); in this case, both endpoints of the forcing path are considered to be x.

A constraint on the edge e_i of a path is a P *forcer* if it is a $(x_{i-1} : \delta) \rightarrow (x_i, \gamma)$ forcer or a $(x_i : \gamma) \rightarrow (x_{i-1}, \delta)$ forcer for some δ, γ.

For any $\mathcal{I} \in \Omega^{d,k,t}$:

- the *first boundary* of $\mathcal{I}$, denoted by $\mathcal{B}^1(\mathcal{I})$, is the set of nonforbidding constraints of $\mathcal{I}$ which contain at most one variable of degree greater than 1;
- the *second boundary* of $\mathcal{I}$, denoted by $\mathcal{B}^2(\mathcal{I})$, is the set of pendant paths of length 4 in $\mathcal{I}$ which have no P forcers;
- the *third boundary* of $\mathcal{I}$, denoted by $\mathcal{B}^3(\mathcal{I})$, is the set of pendant paths of length 2 where one of the two constraints is a P forcer that starts at the connecting vertex, and the other is not a P forcer that finishes at the connecting vertex.

The *boundary* of $\mathcal{I}$ is $\mathcal{B}(\mathcal{I}) = \mathcal{B}^1(\mathcal{I}) \cup \mathcal{B}^2(\mathcal{I}) \cup \mathcal{B}^3(\mathcal{I})$.

Our main lemma corresponds to conditions (A) and (B) from section 2.2.

LEMMA 7. *Consider any $\mathcal{I} \in \Omega^{d,k,t}$ on n variables, where $t < d^{k-1}$. If, for some $\alpha, \zeta > 0$, we have the following:*

(a) *every subproblem on at most αn variables is satisfiable, and*

(b) *every subproblem $\mathcal{I}'$ on v variables, where $\frac{1}{2}\alpha n \leq v \leq \alpha n$, has $|\mathcal{B}(\mathcal{I}')| \geq \zeta n$, then $\mathbf{C} - \mathbf{RES}(\mathcal{I}) \geq 2^{\Theta(n)}$.*

To prove Lemma 7, we require the following lemma, which corresponds to condition (C) from section 2.2.

LEMMA 8. *Consider any $\mathcal{I} \in \Omega^{d,k,t}$, where $t < d^{k-1}$, and any $X \in \mathcal{B}(\mathcal{I})$. Any satisfying assignment of $\mathcal{I} - X$ can be extended to a satisfying assignment of $\mathcal{I}$.*

Proof. Suppose $X \in \mathcal{B}^1(\mathcal{I})$. Then the lemma follows from the fact that, since $t < d^{k-1}$, X cannot be a forbidding constraint.

Suppose $X \in \mathcal{B}^2(\mathcal{I})$, and consider any satisfying assignment of $\mathcal{I} - X$ where x_0, x_4 are assigned δ_0, δ_4. ($\mathcal{I} - X$ is the subproblem obtained by removing all clauses of X and all variables of X other than the endpoints.) Since e_1 is not an (x_0, x_1) forcer, there are at least two choices for δ_1 such that e_1 permits $(x_0 : \delta_0, x_1 : \delta_1)$. Similarly, there are at least two choices for δ_3 which can be assigned to x_3 so e_4 permits $(x_3 : \delta_3, x_4 : \delta_4)$. We will show that, for at least one of these four choices for the pair (δ_1, δ_3), there is a value δ_2 such that e_2 permits $(x_1 : \delta_1, x_2 : \delta_2)$ and e_3 permits $(x_2 : \delta_2, x_1 : \delta_3)$. If this were not the case, then for every $\delta_2 \in \{1, \dots, d\}$ either (i) e_2 does not permit $(x_1 : \delta_1, x_2 : \delta_2)$ for either of the two choices of δ_1 (this requires $2d^{k-2}$ restrictions) or (ii) e_3 does not permit $(x_2 : \delta_2, x_3 : \delta_3)$ for either of the two choices of δ_3 (this also requires $2d^{k-2}$ restrictions). Thus e_2, e_3 would have a total of at least $2d^{k-1}$ restrictions, which is not possible by hypothesis.

Suppose $X \in \mathcal{B}^3(H)$. Let the endpoints of X be x_0, x_2, the connecting variable of X be x_1, and the constraints of X be C_1, C_2, where C_1 is a forcer starting at x_1 and ending at x_0 and C_2 is not a forcer that starts at x_2 and ends at x_1. Consider any satisfying assignment of $\mathcal{I} - X$ where x_0, x_2 are assigned δ_0, δ_2. There are at least $d - 1$ choices for δ_1 such that C_1 permits $(x_0 : \delta_0, x_1 : \delta_1)$, and there are at least two choices for δ_1 such that C_2 permits $(x_1 : \delta_1, x_2 : \delta_2)$. At least one choice for δ_1 lies in the intersection of these sets, and so the lemma follows. □

With Lemma 8 in hand, the proof of Lemma 7 is straightforward, following Mitchell's framework [31].

Proof of Lemma 7. Consider any resolution refutation of CNF($\mathcal{I}$). Mitchell [31, Lemma 1], proves that hypothesis (a) implies there must be a clause C in the refutation and a subproblem $\mathcal{J}$ of $\mathcal{I}$ on between $\frac{1}{2}\alpha n$ and αn variables such that $\mathcal{J}$ minimally implies C in the following sense: (i) Every satisfying assignment of $\mathcal{J}$ satisfies C, and (ii) for subproblem $\mathcal{J}'$ of $\mathcal{J}$, there is a satisfying assignment of $\mathcal{J}'$ that does not satisfy C.

We will next prove that C must have at least $\zeta n/4$ variables.

Consider any clause $X \in \mathcal{B}^1(\mathcal{J})$; we will show that some variable of X appears in C. To see this, consider any assignment α which satisfies $\mathcal{J} - X$ but does not satisfy C. By Lemma 8, it is possible to extend α to a satisfying assignment α' of $\mathcal{J}$, and, since $\mathcal{J}$ implies C, α' satisfies C. Thus, there is some variable of C that is assigned a value in α' but not in α; that variable must be in X.

Nearly identical arguments show that C must contain a non-end-point variable of every member of $\mathcal{B}^2(\mathcal{J})$ and that C must contain the connecting variable from every member of $\mathcal{B}^3(\mathcal{J})$. No variable can be a non-end-point variable of more than four members of $\mathcal{B}^2(\mathcal{J})$. So C contains at least $|\mathcal{B}^1(\mathcal{J})| + |\mathcal{B}^2(\mathcal{J})|/4 + |\mathcal{B}^3(\mathcal{J})|$ variables. Since by hypothesis (b), $|\mathcal{B}(\mathcal{J})| \geq \zeta n$, C must contain at least $\zeta n/4$ variables, as required.

This allows us to apply the now standard "width lemma" of Ben-Sasson and Wigderson [9, Corollary 3.6], to prove our lemma. In particular, if we let $w_1 = k$ be the maximum clause size in CNF($\mathcal{I}$), and $w_2 \geq \zeta n/4$ be the minimum over all resolution refutations of CNF($\mathcal{I}$) of the maximum clause size in the refutation, then the width lemma states that

$$\mathbf{C} - \mathbf{RES}(\mathcal{I}) = e^{\Omega\left((w_2 - w_1)^2/n\right)} \geq 2^{\Theta(n)}. \qquad \square$$

We close this section with a lemma explaining the significance of $c^*(d, k, t)$.

LEMMA 9. *For $d, k \geq 2$ and $t \geq (d-1)d^{k-2}$, let $c = c^*(d, k, t) = \frac{1}{dk(k-1)}\binom{d^k}{t}/\binom{d^k-(d-1)d^{k-2}}{t-(d-1)d^{k-2}}$. Specify any variable x and value $\delta \in \{1, \dots, d\}$. The expected number of forcers in $\mathcal{F}^{d,k,t}_{n,M=cn}$ starting with $x : \delta$ is 1.*

Proof. Let $L = (d-1)d^{k-2}$. The expected number of constraints containing x is ck. For each of the $d(k-1)$ choices of $x' \neq x, \delta' \in \{1, \dots, d\}$ for a particular constraint containing x, the probability that the constraint forms a $(x\!:\!\delta) \rightarrow (x'\!:\!\delta')$ forcer is $\binom{d^k-L}{t-L}/\binom{d^k}{t}$, as there are exactly $\binom{d^k-L}{t-L}$ choices for such a forcer. Therefore, the expected number of forcers from $x : \delta$ is

$$cdk(k-1) \times \frac{\binom{d^k-L}{t-L}}{\binom{d^k}{t}} = \frac{\binom{d^k}{t}}{dk(k-1)\binom{d^k-L}{t-L}} \times dk(k-1) \times \frac{\binom{d^k-L}{t-L}}{\binom{d^k}{t}} = 1. \qquad \square$$

It is instructive to consider the case $k = d = 2$ and $t = (d-1)d^{k-2} = 1$, which is the more familiar random 2-SAT. Here every 2-clause can be viewed as the union of two forcers, e.g., $(x_1 \vee x_2)$ is equivalent to the conjunction of the two forcers $(x_1 : F) \rightarrow (x_2 : T)$ and $(x_2 : F) \rightarrow (x_1 : T)$. (Of course, we are considering the domain to be {T(rue),F(alse)} rather than $\{1, 2\}$. Note that $c^* = 1$, which is the satisfiability threshold for 2-SAT. The reader who is familiar with random 2-SAT will recognize that the property guaranteed by Lemma 9 corresponds very closely to what happens to cause the random 2-SAT to be unsatisfiable. Thus, it is not surprising that, for general d, k, at $c > c^*$ the forcers alone produce an unsatisfiable formula and that it, like random 2-SAT, has small resolution complexity.

For $d = 2$ and general k, it is easy to see that an $(x : F) \rightarrow (y : T)$ forcer is also an $(y : F) \rightarrow (x : T)$ forcer. Thus, such a forcer implies the 2-clause $(x \vee y)$. Extending this reasoning shows that for $c > c^*$ the forcers alone will contain a random instance of 2-SAT where the number of 2-clauses is above the satisfiability threshold. As mentioned earlier, this was discovered independently by Gao and Culberson [23].

3. Proof of Theorem 1.

We begin with a lemma of a type that has become standard in papers on the resolution complexity of random formulas. It says that a.s.

every subproblem of $\mathcal{F}_{n,M}^{d,k,t}$ with at most αn variables has a very low clause-vertex ratio. Thus, to prove that the conditions of Lemma 7 hold, it suffices to prove that certain types of subproblems must have a high clause-vertex ratio.

LEMMA 10. *Let $c > 0$ and $k \geq 2$, and let H be the random k-uniform hypergraph with n vertices and $m = cn$ edges. Then for any $\delta > 0$ there exists $\alpha = \alpha(c, k, \delta) > 0$ such that a.s. H has no subgraph with $0 < h \leq \lfloor \alpha n \rfloor$ vertices and at least $(\frac{1+\delta}{k-1})h$ edges.*

Proof. This proof follows a straightforward first moment calculation of a type that has been carried out many times in similar settings, starting with Łuczak [30].

Let $\mu = \frac{1+\delta}{k-1}$, $\mathcal{S}_h$ be the number of subgraphs of H with h vertices and *exactly* $\lceil \mu h \rceil$ edges, and set $\mathcal{S} = \sum_{h=1}^{\lfloor \alpha n \rfloor} \mathcal{S}_h$. Note that if $\mathcal{S}_h = 0$, then there are no subgraphs of H with h vertices and *at least* μh edges. To count $\mathbf{E}(S_h)$, we multiply the number of choices of h vertices by the number of choices for $\lceil \mu h \rceil$ of the cn random edges and the probability that each of those random edges lies entirely in that set of h vertices:

$$\mathbf{E}(\mathcal{S}_h) \leq \binom{n}{h} \binom{cn}{\lceil \mu h \rceil} \left(\frac{h}{n}\right)^{k\lceil \mu h \rceil}.$$

This yields:

$$\begin{aligned}
\mathbf{E}(\mathcal{S}) &= \sum_{h=1}^{\lfloor \alpha n \rfloor} \mathbf{E}(\mathcal{S}_h) \\
&\leq \sum_{h=1}^{\lfloor \alpha n \rfloor} \binom{n}{h} \binom{cn}{\lceil \mu h \rceil} \left(\frac{h}{n}\right)^{k\lceil \mu h \rceil} \\
&\leq \sum_{h=1}^{\lfloor \alpha n \rfloor} \left(\frac{en}{h}\right)^{h} \left(\frac{ecn}{\lceil \mu h \rceil}\right)^{\lceil \mu h \rceil} \left(\frac{h}{n}\right)^{k\lceil \mu h \rceil} \\
&\leq \frac{ec}{\mu} \sum_{h=1}^{\lfloor \alpha n \rfloor} \left[\left(\frac{h}{n}\right)^{(k-1)\mu - 1} e^{\mu+1} (c/\mu)^{\mu} \right]^{h} \\
&= \frac{ec}{\mu} \sum_{h=1}^{\lfloor \alpha n \rfloor} \left[\left(\frac{h}{n}\right)^{\delta} c' \right]^{h} \qquad \text{for } c' = e^{\mu+1}(c/\mu)^{\mu} \\
&\leq \frac{ec}{\mu} \left(\sum_{h=1}^{\lfloor \log n \rfloor} \left[\left(\frac{\lfloor \log n \rfloor}{n}\right)^{\delta} c' \right] + \sum_{h=\lfloor \log n \rfloor + 1}^{\lfloor \alpha n \rfloor} \left[\left(\frac{\lfloor \alpha n \rfloor}{n}\right)^{\delta} c' \right]^{\lfloor \log n \rfloor} \right) \\
&\leq O\left(\frac{\log^{1+\delta} n}{n^{\delta}}\right) + \sum_{h=\lfloor \log n \rfloor + 1}^{\lfloor \alpha n \rfloor} O\left(\frac{1}{n^2}\right) \qquad \text{for sufficiently small } \alpha \\
&= o(1). \qquad \square
\end{aligned}$$

The next lemma will allow us to show that subproblems with small boundaries must have a high clause-variable ratio and hence, by the previous lemma, must be large.

LEMMA 11. *Let $r \geq 2$ be a constant and H be a k-uniform hypergraph on n vertices and m edges that does not have any component which is a cycle. Let B_1 be the set of edges which have at most one vertex of degree greater than 1 and B_2 be the set of pendant paths of length r. If $|B_1| + |B_2| \leq n/(72r^2k^3)$, then for $\delta = \frac{1}{3rk^2}$: $m \geq n(\frac{1+\delta}{k-1})$.*

Intuitively, the lemma is clear: If $|B_1| = 0$ and if no vertex has degree greater than 2, then it is easy to see that we would have $m = n/(k-1)$. So, in order for m to not be much bigger, either B_1 must be large or there must be very few vertices of degree greater than 2. If the latter is true and B_1 is small, then H must contain long pendant paths, and so B_2 will be big. Our formal proof is a bit lengthy, and so we defer it to the end of the section.

These two lemmas are enough to prove the first of our main theorems.

Proof of Theorem 1. It suffices to prove that a.s. conditions (a) and (b) of Lemma 7 hold for $\mathcal{F}^{d,k,t}_{n,M=cn}$, where $\alpha = \alpha(c, k, \delta = 1/(12k^2))$ from Lemma 10 and $\zeta = \min(1/(72 \times 16k^3), \alpha/10k)$.

Since $t < (d-1)d^{k-2}$, $\mathcal{F}^{d,k,t}_{n,M}$ has no forcer constraints. Using this fact, our proof would follow immediately from Lemmas 10 and 11, if it were not for the fact that Lemma 11 applies only to hypergraphs with no cycle components.

We begin with condition (a). Suppose that $\mathcal{J}$ is a minimally unsatisfiable subproblem of $\mathcal{F}^{d,k,t}_{n,M}$. Thus, the underlying hypergraph of $\mathcal{J}$ is connected. Furthermore, since $t < (d-1)d^{k-2}$, it is easily verified that the underlying hypergraph of $\mathcal{J}$ cannot be a single cycle. Finally, Lemma 8 implies that $|\mathcal{B}^1(\mathcal{J})| = |\mathcal{B}^2(\mathcal{J})| = 0$. Therefore, since $\mathcal{J}$ has no forcers, Lemma 11 with $r = 4$ applies to the underlying hypergraph of $\mathcal{J}$, and so $\mathcal{J}$ has a clause-variable ratio of at least $(1+\delta)/(k+1)$. Thus Lemma 10 implies that a.s. $\mathcal{F}^{d,k,t}_{n,M}$ has no minimally unsatisfiable subproblems of size at most αn. Therefore a.s. $\mathcal{F}^{d,k,t}_{n,M}$ has no unsatisfiable subproblems of size at most αn.

Next is condition (b). We will use the easy fact, provided as Lemma 24 in Appendix B, that a.s. the underlying random hypergraph of $\mathcal{F}^{d,k,t}_{n,M}$ has fewer than $\log n$ cycles of length at most 4. Suppose, by contradiction, that $\mathcal{J}$ is a subproblem of $\mathcal{F}^{d,k,t}_{n,M}$ with v variables, where $\frac{1}{2}\alpha n \le v \le \alpha n$, and with $|\mathcal{B}^1(\mathcal{J})| + |\mathcal{B}^2(\mathcal{J})| \le \zeta n$. (Since there are no forcers, $|B^3(\mathcal{J})| = 0$.) Let H' be the subhypergraph obtained by removing all of the cycle components from the underlying hypergraph of $\mathcal{J}$. By Lemma 11 (with $r = 4$), H' has at least $|H'|\frac{1+\delta}{k-1}$ edges, and note also that $|H'| \le |\mathcal{J}| \le \zeta n < \alpha n$. By Lemma 10, a.s. every such H' is empty. Thus a.s. for every such subproblem $\mathcal{J}$, every component in the underlying hypergraph of $\mathcal{J}$ is a cycle. Every vertex in such a cycle of length at least 5 must lie in a member of $\mathcal{B}^2(\mathcal{J})$, and every member of $\mathcal{B}^2(\mathcal{J})$ contains fewer than $4k$ vertices; so there are at most $4k\zeta n$ vertices in those cycles. As mentioned above, a.s. there are at most $4 \log n$ vertices which lie in cycles of length at most 4 in $\mathcal{F}^{d,k,t}_{n,M}$. Since $4k\zeta n + 4\log n < \frac{1}{2}\alpha n \le |\mathcal{J}|$, we have a contradiction. □

We now close this section with the proof of Lemma 11.

Proof of Lemma 11. We say that a pendant path p of length at least 1 is *contractible* if (i) both of its endpoints have degree 2 and (ii) p is maximal in the sense that it is not part of a longer pendant path whose endpoints both have degree 2. Let $\mathcal{P}$ be the set of contractible pendant paths in H.

We form a hypergraph H' with no long pendant paths as follows.

For each $p \in \mathcal{P}$ with endpoints x, y, we remove all edges and vertices of p except for x, y and do the following: If x, y do not both lie in some edge outside of p, then we contract x, y into a single vertex. Otherwise, we create a new edge containing x, y and $k-2$ new degree 1 vertices; this edge is called a *reduced edge*, and x, y are its endpoints. Note that, since H has no cycle components, this operation does not create any new contractible paths, and it does not destroy any contractible paths. So there is no need to iterate this process, and we contract every path from $\mathcal{P}$. For convenience, we first contract all paths of length at least r in phase A and then all of the remaining paths in phase B.

The resulting hypergraph is H'. Every nonreduced edge in H' either (i) has a vertex of degree at least 3, (ii) has at least three degree 2 vertices, or (iii) is in B_1.

n' is the number of vertices in H'; s is the number of vertices of degree greater than 1; m' is the number of edges in H'; m_2 is the number of reduced edges; m^* is the number of edges with at least one degree 3 vertex.

Since H has no cycle components, the endpoints of any reduced edge must lie in a nonreduced edge. Since those endpoints have degree 2, each edge can hold the endpoints of at most $k/2$ reduced edges. Therefore, $m_2 \leq m' \cdot \frac{k}{2}/(\frac{k}{2}+1) = m'(k/(k+2))$.

The sum of the degrees of the vertices is $n'+s$ plus the sum of all vertices v with $\deg(v) \geq 3$ of $\deg(v)-2$. Each such vertex v lies in $\deg(v)$ edges, and so by counting $(\deg(v)-2)/\deg(v) \geq \frac{1}{3}$ for each of those edges, it follows that this latter sum is at least $m^*/3$. Therefore, since the sum of the degrees of all vertices is km', we have

$$km' \geq n' + s + m^*/3.$$

Furthermore, by counting the number of degree 1 variables in each edge, we have

$$s \geq n' - (k-3)m' - (m^* + m_2) - 2|B_1|.$$

These two equations combine to yield

$$\begin{aligned} km' &\geq 2n' - (k-2)m' + (m' - 2m^*/3 - m_2) - 2|B_1| \\ &\geq 2n' - (k-2)m' + \frac{1}{3}(m' - m_2) - 2|B_1| \\ &\geq 2n' - m'\left(k - 2 - \frac{2}{3(k+2)}\right) - 2|B_1|, \end{aligned}$$

and so $m' \geq (2n' - 2|B_1|)/(2k-2-\frac{2}{3(k+2)}) \geq n'(\frac{1+2\delta}{k-1}) - 2|B_1|$, since $\delta < \frac{1}{3k(k+2)}$ and $2k-2-\frac{2}{3(k+2)} > 1$.

Now we observe that very few vertices were removed during phase A. Any pendant path of length $l \geq r$ contains at least $l-r+1$ pendant paths of length r. So the total of the lengths of all such paths in H is at most $r|B_2|$. Therefore, the number of vertices in the hypergraph at the end of phase A is at least $n - rk|B_2|$.

Now we consider what happened during phase B. Every time we contracted a contractible path p of length $l < r$ to a vertex, the net loss in edges was l and the net loss of vertices was $(k-1)l-1$, and each time we contracted one to an edge, those net losses were $l-1$ and $(k-1)(l-1)-1$, respectively. Thus, for some v, we lost v vertices and at least $v(r-1)/((r-1)(k-1)-1) > v(1+\frac{1}{rk})/(k-1) \geq v(\frac{1+2\delta}{k-1})$ edges during phase B, since $\delta \leq \frac{1}{2rk}$.

Therefore, the hypergraph remaining at the end of phase A has at least

$$(n - rk|B_2|)\left(\frac{1+2\delta}{k-1}\right) - 2|B_1| \geq n\left(\frac{1+\delta}{k-1}\right) + \frac{n\delta}{k-1} - 3r|B_2| - 2|B_1| > n\left(\frac{1+\delta}{k-1}\right)$$

edges. Since phase A does not increase the number of edges, this proves our Lemma. □

4. Proof of Theorem 2. A Z_q*-configuration* is a collection of q vertex-disjoint forcing paths in $\mathcal{I}$, each with possibly length zero (i.e., a single vertex), plus $q(\frac{1+\gamma}{k-1})$ other edges, each containing k endpoints of the paths, where $\gamma = 1/(300k^2)$.

For $\mathcal{I} \in \Omega^{d,k,t}$ and $t \geq (d-1)k^{d-2}$, let $\mathcal{P} = p_1, \ldots, p_q$ be a collection of forcing paths of $\mathcal{I}$ such that: (i) every vertex lies in exactly one of these paths, and (ii) it is not possible to transform $\mathcal{P}$ into a collection of $q-1$ paths meeting condition (i) by adding another forcer from $\mathcal{I}$. Obviously a collection of paths of length 0, one for each variable of $\mathcal{I}$, satisfies (i), and so some collection exists which satisfies (i) and (ii).

LEMMA 12. *For any $\mathcal{I}, \mathcal{P}$ as described above: If $|\mathcal{B}(\mathcal{I})| < q/(72000k^3)$ and if the underlying hypergraph of $\mathcal{I}$ has no cycle components, then $\mathcal{I}$ contains a Z_q-configuration.*

Proof. Suppose that, among the paths in $\mathcal{P}$, exactly $p_1, \ldots, p_r$ $(r \leq q)$ have at least one edge each; the others have length 0. Consider a path p_i $(1 \leq i \leq r)$, and suppose it has $l \geq 1$ edges. Let x_0 and x_l be the start and end points of this path, respectively; so p_i is a $(x_0\!:\!\delta_0) \to (x_l\!:\!\delta_l)$ forcer for some values δ_0, δ_l. Remove from $\mathcal{I}$ all of the clauses and variables of p_i other than x_0, x_l. Then add $k-2$ new variables and a $(x_0\!:\!\delta_0) \to (x_l\!:\!\delta_l)$ forcer. The new forcer is called a *reduced* forcer. We do this for every $p_i, 1 \leq i \leq r$. The new CSP obtained after these operations is denoted by $\mathcal{I}'$. Note that n', the number of variables in $\mathcal{I}'$, is $q + r(k-1)$. Note also that since $p_1, \ldots, p_q$ are vertex-disjoint, no two reduced forcers in $\mathcal{I}'$ share a vertex.

CLAIM 13. *There is no forcer path of length at least 4 in $\mathcal{I}'$.*

Proof. By contradiction, assume that $p = e_1e_2e_3e_4$ is a forcer path in $\mathcal{I}'$, with u_{i-1} and u_i being the start and end points of e_i, respectively. If e_2 is not a reduced forcer, then adding the forcer e_2 to $\mathcal{P}$ would concatenate the path in $\mathcal{P}$ containing u_1 with the one containing u_2 without violating condition (i). This contradicts condition (ii). If e_2 is a reduced forcer, then e_3 cannot be (since no two reduced forcers share a variable). Thus a similar contradiction arises when we consider adding the forcer e_3 to $\mathcal{P}$. □

CLAIM 14. *Every pendant path of length 10 in $\mathcal{I}'$ has a subpath which is in $\mathcal{B}^2(\mathcal{I}) \cup \mathcal{B}^3(\mathcal{I})$.*

Proof. Let P' be a pendant path in $\mathcal{I}'$. By replacing each reduced edge of P' by its corresponding path from $\mathcal{P}$, we obtain a path P in $\mathcal{I}$. Every nonforcer in P' is a nonforcer in P. Assume $P = e_1, \ldots, e_l$, where $x_i = e_i \cap e_{i+1}$, and that e_a and e_b, $b > a$, are two nonforcers in P', and hence in P, such that there is no other nonforcer between them. If $b - a > 1$, then e_{a+1} is a forcer, and it must start at x_{a+1}; otherwise, $\{e_a, e_{a+1}\} \in \mathcal{B}^3(\mathcal{I})$, and we are done. Similarly, e_{b-1} must be a forcer starting at x_{b-2}; otherwise, $\{e_{b-1}, e_b\} \in \mathcal{B}^3(\mathcal{I})$. But these two imply that along the path $e_{a+1}, \ldots, e_{b-1}$ there is a member of $\mathcal{B}^3(\mathcal{I})$. Thus, we can assume that $b - a = 1$, i.e., that the nonforcers in P' are consecutive. Also, if i is the largest index for which e_i is a nonforcer in P, then $e_le_{l-1}\ldots e_{i+1}$ must be a forcing path going into x_i; otherwise, there is a member of $\mathcal{B}^3(\mathcal{I})$ along this path. Therefore the portions of P' on the sides of these nonforcers form forcing paths. Similar arguments show that if P' has no nonforcers, then it contains at most two forcing paths starting at the endpoints of P', or else P' contains a member of $\mathcal{B}^3(\mathcal{I})$.

By Claim 13, the length of each forcing path is at most 3. Therefore, if P' has length 10, then P' has at least 4 consecutive nonforcers, and so that subpath of P' is in $\mathcal{B}^2(\mathcal{I})$.

Let B_1 be the set of clauses which have at most one variable of degree greater than 1 in $\mathcal{I}'$ and B_2 be the set of pendant paths of length 10 in $\mathcal{I}'$. Note that $|\mathcal{B}^1(\mathcal{I})| \geq |B_1|$. Since no subpath can lie in more than 10 members of B_2, Claim 14 implies that $|B_2| \leq 10(|\mathcal{B}^2(\mathcal{I}) + \mathcal{B}^3(\mathcal{I})|)$. Therefore, $|B_1| + |B_2| \leq 10|\mathcal{B}(\mathcal{I})| \leq q/(7200k^3) < n'/(7200k^3)$, as n', the number of variables in $\mathcal{I}'$, is $q + r(k-1)$. So, applying Lemma 11 with $r = 10$ to the underlying hypergraph of $\mathcal{I}'$, the number of clauses in $\mathcal{I}'$ is at least

$n'(\frac{1+\gamma}{k-1})$, and at least $n'(\frac{1+\gamma}{k-1}) - r \geq q(\frac{1+\gamma}{k-1})$ are not reduced forcers. Those clauses and the paths in $\mathcal{P}$ will form a Z_q-configuration in $\mathcal{I}$. □

Lemma 15. *For any constants $d, k \geq 2$ and $(d-1)d^{k-2} \leq t < d^{k-1}$, and for every $c < c^*(d,k,t)$, there exists $\sigma > 0$, such that a.s. $\mathcal{F}^{d,k,t}_{n,M=cn}$ has no Z_q-configuration with $q \leq \sigma n$.*

Proof. For this proof, it will be convenient to work in the $\mathcal{F}^{d,k,t}_{n,p}$ model described in section 2.1, where each of the $\binom{n}{k}$ potential edges is chosen for the constraint hypergraph with probability $ck!/n^{k-1}$. Lemma 25 in Appendix B shows that proving this model a.s. has no Z_q-configuration with $q \leq \sigma n$ will imply that a.s. neither does $\mathcal{F}^{d,k,t}_{n,M=cn}$.

We compute the expected number of Z_q-configurations. To do so, we suppose that the q forcing paths are ordered $p_1, \ldots, p_q$ when we count the number of ways to choose them. Since the forcing paths of a Z_q-configuration are actually unordered, this produces an overcount, which we correct by dividing by $q!$.

We start with the computations related to the forcing paths: For each i, let $a_i \geq 0$ be the number of forcers in p_i, and set $A = \sum_{i=1}^{q} a_i$. The number of ways to choose the endpoints of the paths is at most n^{2q} (fewer if some of the path lengths are 0). For each p_i, there are at most n^{a_i-1} choices for the connecting variables and d^{a_i+1} choices of values to use on the variables to form a forcing path. Also, for each edge of each p_i, there are $\binom{n}{k-2}$ choices for the set of degree 1 variables. The probability that all of the specified hyperedges exist is $(ck!/n^{k-1})^A$. The probability that the constraints all form the specified forcers is, as we argued in the proof of Lemma 9, $(\binom{d^k-(d-1)d^{k-2}}{t-(d-1)d^{k-2}}/\binom{d^k}{t})^A$.

Now we turn our attention to the additional edges: There are at most $\binom{2q}{k}$ potential edges containing only endpoints of the paths, and we must choose $B = q(\frac{1+\gamma}{k-1})$ of them; there are $\binom{\binom{2q}{k}}{B}$ ways to do so. The probability that the B chosen edges are all present in H is $(ck!/n^{k-1})^B$.

Letting $c = (1-\epsilon)c^*$, this yields

$$\begin{aligned}
\mathbf{E}(|Z_q|) &\leq \frac{n^{2q}}{q!} \times \sum_{a_1,\ldots,a_q \geq 0} n^{A-q} d^{A+q} \binom{n}{k-2}^{A} \left[\frac{(1-\epsilon)c^* k!}{n^{k-1}}\right]^{A} \left[\frac{\binom{d^k-(d-1)d^{k-2}}{t-(d-1)d^{k-2}}}{\binom{d^k}{t}}\right]^{A} \\
&\qquad \times \binom{\binom{2q}{k}}{B} \left(\frac{ck!}{n^{k-1}}\right)^{B} \\
&\leq \frac{n^{2q}}{q!} \binom{\binom{2q}{k}}{B} \left(\frac{ck!}{n^{k-1}}\right)^{B} \times \sum_{a_1,\ldots,a_q \geq 0} \binom{n}{k-2}^{A} n^{A-q} d^{A+q} \left[\frac{(1-\epsilon)(k-2)!}{dn^{k-1}}\right]^{A} \\
&\leq \frac{n^{2q}}{q!} \left(\frac{(2q)^k e}{k!B} \frac{ck!}{n^{k-1}}\right)^{B} \times \sum_{a_1,\ldots,a_q \geq 0} \frac{n^{(k-2)A+A-q} d^{A+q}}{(k-2)!^{A}} \left[\frac{(1-\epsilon)(k-2)!}{dn^{k-1}}\right]^{A} \\
&\leq \frac{n^{2q}}{q!} \left(\frac{(2q)^k ec}{n^{k-1}(q/k-1)}\right)^{q(1+\gamma)/(k-1)} \times \frac{d^q}{n^q} \sum_{a_1,\ldots,a_q \geq 0} (1-\epsilon)^{A} \\
&\leq \left(\frac{\psi q}{n}\right)^{\gamma q} \left[\sum_{i \geq 0} (1-\epsilon)^{i}\right]^{q} \\
&\leq \left(\frac{\psi' q}{n}\right)^{\gamma q},
\end{aligned}$$

where $\psi, \psi' > 0$ are functions of $c, d, k, \epsilon, \gamma$, and hence of c, d, k, t since ϵ, γ can be derived from c, d, k, t. Therefore,

$$\sum_{q=1}^{\sigma n} \mathbf{E}(|Z_q|) \le \sum_{q=1}^{\lfloor \log n \rfloor} \left(\frac{\psi' q}{n}\right)^{\gamma q} + \sum_{q=\lfloor \log n \rfloor+1}^{\sigma n} \left(\frac{\psi' q}{n}\right)^{\gamma q}$$
$$\le O\left(\frac{\log^2 n}{n}\right) + \sum_{q=\lfloor \log n \rfloor+1}^{\sigma n} O(n^{-2}) = o(1)$$

for $\sigma > 0$ sufficiently small that $(\psi'\sigma)^\gamma < e^{-3}$. Thus σ is a function of c, d, k, t, γ and hence of c, d, k, t. □

LEMMA 16. *For $c < c^*(d, k, t)$, and for every constant integer $\theta > 0$, a.s. the number of variables of $\mathcal{F}_{n,M=cn}^{d,k,t}$ that are part of a maximal forcing path of length greater than θ is at most $3\theta d(c/c^*)^\theta$.*

Proof. Assume that $c = (1 - \epsilon)c^*$. We will again work in the $H_{n,p}$ model where $p = c \times k!/n^{k-1}$. Lemma 25 from Appendix B permits us to do so.

For any value of θ, let X_θ be the number of forcing paths of length θ, and let Y_θ be the number of maximal forcing paths of length at least θ. Obviously, X_θ is an upper bound for Y_θ (since for every forcing path of length θ there is a unique maximal forcing path of length at least θ). Our goal is to upper bound Y_θ for constant values of θ and for that we upper bound X_θ. We first compute the expected value of X_θ. We have to choose $\theta+1$ variables for the connecting points and the endpoints of the path; there are $\binom{n}{\theta+1}$ ways to do so. We order them; there are $(\theta+1)!$ ways to do so. Then we choose one of d values for each; there are $d^{\theta+1}$ ways to do so. Then we choose the remaining $k-2$ vertices for each of the θ constraints; there are $\binom{n-\theta-1}{(k-2)\theta}\frac{[(k-2)\theta]!}{(k-2)!^\theta}$ ways to do so. Finally, we multiply by the probability that the edge for each constraint is chosen in the underlying hypergraph and that the random constraints chosen for those edges are the specified forcers; the first of these probabilities is p^θ, and the second is $(dk(k-1)/c^*)^\theta$ (the latter computation uses the same arguments found in the proof of Lemma 9). This yields

$$\mathbf{E}(X_\theta) = \binom{n}{\theta+1}(\theta+1)!d^{\theta+1}\binom{n-\theta-1}{(k-2)\theta}\frac{[(k-2)\theta]!}{(k-2)!^\theta}\left(\frac{(1-\epsilon)(k-2)!}{dn^{k-1}}\right)^\theta$$
$$= \frac{n!}{[n-\theta-1-(k-2)\theta]!} \cdot \frac{(1-\epsilon)^\theta d}{n^{(k-1)\theta}}$$
$$= (1+o(1))nd(1-\epsilon)^\theta \qquad \text{for constant values of } \theta.$$

Now we bound the probability of $X_\theta > 2\mathbf{E}(X_\theta)$ using the second moment method. By Chebychev's inequality, this probability is at most $(\mathbf{E}(X_\theta^2) - \mathbf{E}(X_\theta)^2)/\mathbf{E}(X_\theta)^2$. So to prove that this probability is $o(1)$, it will suffice to prove that $\mathbf{E}(X_\theta^2) \le \mathbf{E}(X_\theta)^2(1+o(1))$.

Consider a fixed forcing path A of length θ. For each $i, j \ge 1$ we bound the number of potential forcing paths B of length θ which have exactly i constraints in common with A and for which these i constraints form j segments in A. To compute this, we first choose the j segments by choosing the vertices of their endpoints from A and the positions of those endpoints in B; there are $\binom{\theta}{2j}^2$ ways to make this selection. Then we match the j segments of A to the j segments of B; there are $j!$ choices for this. Then we select $\theta+1-i-j$ points (the rest of the connecting variables of path

B) and a value for each; there are at most $(nd)^{\theta+1-i-j}$ ways to do this. Then for each of the $\theta - i$ constraints in $B - A$ we select the remaining $k-2$ variables; there are $\binom{n}{(k-2)(\theta-i)}\frac{[(k-2)(\theta-i)!]}{(k-2)!^{(\theta-i)}}$ possible choices. Finally we multiply by the probability that the $\theta - i$ constraints in $B - A$ are selected and are forcers; as in the previous calculation, this probability is $(\frac{(1-\epsilon)(k-2)!}{dn^{k-1}})^{\theta-i}$. For any potential forcing path A of length θ, let Q_A be its indicator variable.

$$\begin{aligned}
\mathbf{E}(X_\theta^2) &= \sum_{A,B} \mathbf{Pr}(Q_A = 1 \cap Q_B = 1)\\
&= \sum_{A} \sum_{B: A\cap B = \emptyset} \mathbf{Pr}(Q_A = 1)\mathbf{Pr}(Q_B = 1) + \sum_{A} \sum_{B: A\cap B \neq \emptyset} \mathbf{Pr}(Q_A = 1 \cap Q_B = 1)\\
&\le \mathbf{E}(X_\theta)^2 + \sum_{A} \mathbf{Pr}(Q_A = 1) \times \sum_{i=1}^{\theta}\sum_{j=1}^{i} \binom{\theta}{2j}^2 j! n^{\theta+1-i-j} d^{\theta+1-i-j}\\
&\qquad \times \binom{n}{(k-2)(\theta-i)} \frac{[(k-2)(\theta-i)!]}{(k-2)!^{(\theta-i)}} \left(\frac{(1-\epsilon)(k-2)!}{dn^{k-1}}\right)^{\theta-i}\\
&\le \mathbf{E}(X_\theta)^2 + \mathbf{E}(X_\theta) 9 \sum_{i=1}^{\theta}\sum_{j=1}^{i} \left(\frac{e^2\theta^2}{4j^2}\right)^{2j} j^j n^{1-j} d^{1-j} (1-\epsilon)^{\theta-i}\\
&\le \mathbf{E}(X_\theta)^2 + \mathbf{E}(X_\theta) \cdot nd(1-\epsilon)^{\theta} \sum_{i=1}^{\theta}\sum_{j=1}^{i} \left(\frac{\alpha\theta^4}{j^3 nd}\right)^{j} (1-\epsilon)^{-i} \quad \text{(for a constant } \alpha > 0)\\
&\le \mathbf{E}(X_\theta)^2 + \mathbf{E}(X_\theta)^2 \cdot (1 + o(1)) \cdot O\left(\frac{1}{n}\right).
\end{aligned}$$

Therefore, a.s. $X_\theta \le 2(1+o(1))nd(1-\epsilon)^\theta$. Thus the number of variables which lie on a maximal forcing path of length at least θ is a.s. at most $2(1+o(1))\theta nd(1-\epsilon)^\theta < 3\theta d(c/c^*)^\theta$. □

Proof of Theorem 2. The proof is nearly identical to that of Theorem 1, this time using Lemmas 12 and 15 rather than Lemmas 11 and 10. We will prove that conditions (a) and (b) of Lemma 7 hold with $\alpha = \frac{1}{2}\sigma$ and $\zeta = \alpha/(4\theta \times 72000k^3)$, where θ is a positive integer such that $3\theta d(c/c^*)^\theta \le \alpha/8$.

We start with condition (a). Let $\mathcal{J}$ be a minimally unsatisfiable subproblem of $\mathcal{F}_{n,M}^{d,k,t}$ and H be the underlying hypergraph of $\mathcal{J}$. Clearly H is connected. Next we show that H cannot be a single cycle. By way of contradiction suppose that H is a cycle with constraints $C_1, \ldots, C_\ell$. Since $t < d^{k-1}$ we have the following: For any constraint C_i and any pair of variable/value $(x : \delta)$, with $x \in C_i$, there is a satisfying assignment of values to the variables of C_i in which x gets value δ. Let $x_1 = C_1 \cap C_2$ and $x_\ell = C_1 \cap C_\ell$, and consider $\mathcal{J} - C_1$. Consider any value $\delta \in \mathcal{D}$. There is a satisfying assignment for C_1 in which x gets δ—let δ_2 be the value assigned to x_2 in that assignment. There is a satisfying assignment for C_2 in which x_2 gets δ_2—let δ_3 be the value assigned to x_3 in that assignment. Repeating this argument yields a satisfying assignment for $\mathcal{J} - C_1$ in which x_1 gets δ. Since this is true of every value δ, there are at least d pairs (δ, δ') in which there is a satisfying assignment for $\mathcal{J} - C_1$ in which x_1 gets δ and x_ℓ gets δ'. Since C_1 contains fewer than $d \times d^{k-2}$ restrictions, at least one of these pairs (δ, δ') is such that there is a satisfying assignment to C_1 in which x_1 gets δ and x_ℓ gets δ'. Therefore, $\mathcal{J}$ is satisfiable, which is a contradiction. Thus H is connected and is not a cycle. Since $\mathcal{J}$ is minimally unsatisfiable, Lemma 8 implies that $|\mathcal{B}(\mathcal{J})| = 0$. So by Lemma 12, $\mathcal{J}$ has a Z_q-configuration, and, by

Lemma 15, that configuration has $q \geq \sigma n$. Since the paths of the Z_q-configuration are vertex-disjoint, we have $|\mathcal{J}| \geq \sigma n > \alpha n$ as required.

Now we prove that condition (b) of Lemma 7 holds. Consider a subproblem $\mathcal{J}$ on $\frac{1}{2}\alpha n \leq v \leq \alpha n$ variables, and let H' be the hypergraph remaining after removing all cycle components from the underlying hypergraph of $\mathcal{J}$.

Case 1. $|H'| \leq \frac{1}{4}\alpha n$. Since $|\mathcal{J}| \geq \frac{1}{2}\alpha n$, the total size of the cycle components is at least $\frac{1}{4}\alpha n$. By Lemma 24 in Appendix B, a.s. at most $\log n$ vertices lie on cycles of size at most 4. Every vertex on any other cycle component lies on a member of $\mathcal{B}^2(\mathcal{J})$, and each member of $\mathcal{B}^2(\mathcal{J})$ contains fewer than $4k$ vertices. So $|\mathcal{B}^2(\mathcal{J})| > \frac{1}{4k}(\frac{1}{4}\alpha n - \log n) > \frac{1}{20k}\alpha n > \zeta n$.

Case 2. $|H'| > \frac{1}{4}\alpha n$. Since $3\theta d(c/c^*)^\theta \leq \alpha/8$, Lemma 16 yields that at least $\alpha n/4 - \alpha n/8 > \alpha n/8$ of the variables in H' do not lie on any forcer paths of length at least θ. Thus, any collection of forcer paths which covers all of the variables of H' must contain at least $\frac{\alpha}{8\theta}n$ paths. So we can apply Lemma 12, where $\mathcal{I}$ is the CSP on H' formed by removing all cycle components from $\mathcal{J}$ and where $\frac{\alpha}{4\theta}n \leq q \leq |\mathcal{I}| \leq \alpha n$. Since $q \leq \alpha n < \sigma n$, Lemma 15 implies that a.s. the entire random CSP has no Z_q-configuration and so neither does H'. Since H' has no cycle components, Lemma 12 implies that $\mathcal{B}(\mathcal{I}) \geq q/(72000k^3) \geq \zeta n$. Every boundary element of $\mathcal{I}$ is also a boundary element of $\mathcal{J}$, and so this establishes condition (b). □

5. Proof of Theorem 3.

We will show that a.s. $\mathcal{F}^{d,k,t}_{n,M}$ contains a small unsatisfiable subproblem with a structure that is inspired by the snakes of [12]. Our proof is similar to the corresponding proof in [12].

A *forbidding cycle* is a $x : \delta \to x' : \delta'$ forcing path along with a $x' : \delta' \to x : \delta''$ forcer where $\delta \neq \delta''$. Thus, there is no satisfying assignment where $x = \delta$. We say that the cycle *forbids* $x : \delta$. Consecutive clauses in the cycle intersect in exactly one variable; such variables are called *connecting variables*.

An *r-flower* is the union of d forcing cycles $\mathcal{C}_1, \ldots, \mathcal{C}_d$ such that: (i) each has exactly r forcers; (ii) each cycle contains a particular variable x; (iii) no other variable lies in more than one of the cycles; (iv) each cycle C_i forbids $x : i$. We call x the *center variable*. Thus, any r-flower is unsatisfiable.

LEMMA 17. *For any constants $d, k \geq 2, d + k > 4$ and $(d-1)d^{k-2} \leq t < d^{k-1}$, and for every constant $c > c^*(d,k,t)$, $\mathcal{F}^{d,k,t}_{n,M=cn}$ a.s. contains all constraints of an r-flower, where $r = \lambda \log n$, for some sufficiently large constant λ.*

Theorem 3 follows immediately since if $\mathcal{F}^{d,k,t}_{n,M}$, contains an r-flower, with $r = \lambda \log n$, then we can use an exhaustive search to prove that the r-flower, and hence $\mathcal{F}^{d,k,t}_{n,M}$, is unsatisfiable in $\exp(r) = \text{poly}(n)$ steps. Such a proof can be simulated by a resolution proof with only a polynomial increase in length, so a.s. $\mathbf{RES}(\mathcal{F}^{d,k,t}_{n,M}) = \text{poly}(n)$. (The case $k = d = 2$, i.e., 2-SAT, is already known [12].)

Proof. For any potential flower A, we let X_A be the indicator variable for the event that the clauses of A all appear in the random CSP. With $X = \sum_A X_A$, it is enough to show that $\mathbf{E}(X^2) \leq \mathbf{E}(X)^2(1+o(1))$. Then the theorem follows easily from the Chebyshev inequality.

First, we compute $\mathbf{E}(X)$. We must choose $s = dr - d + 1$ connecting variables (including the center variable) and the $(k-2)dr$ other variables. There are $s!$ ways to arrange the connecting variables and then $[(k-2)dr]!/(k-2)!^{dr}$ ways to arrange the other variables into the flower. For each C_i, we need to choose some value other than i for the center variable and an arbitrary value for each of the other connecting variables. Then we multiply by the probability of all our forcers being present. We have $c = (1+\epsilon)c^*$ for some $\epsilon > 0$. For fixed variables x, y and values $u, v \in D$, the probability that there exists a $(x\!:\!u) \longrightarrow (y\!:\!v)$ forcer is $p = (1+\epsilon)\frac{(k-2)!}{dn^{k-1}}$, by the same calculations as in Lemma 9.

$$\begin{aligned}\mathbf{E}(X) &= \binom{n}{s} s! \binom{n-s}{(k-2)dr} \frac{[(k-2)dr]!}{(k-2)!^{dr}} \times (d-1)^d d^{(r-1)d} p^{dr}\\ &= (1+o(1))(1+\epsilon)^{dr}\left(\frac{d-1}{d}\right)^r n^{1-d}\\ &= \Omega(n^2)\end{aligned}$$

for sufficiently large λ. Next we compute an upper bound for $\mathbf{E}(X^2)$. Consider a fixed r-flower A and its underlying hypergraph H_A. For each $i, j \geq 1$ we will upper bound the number of potential r-flowers B that have exactly i constraints in common with A where these constraints form j connected components in H_A. (A very loose upper bound will suffice.) First, we consider choosing the j components. At most one component contains the center variable—for each C_i, such a component contains either all of C_i, none of C_i, or the portion of C_i between 2 variables. So there are at most $(2+r^2)^d$ choices for such a component. Each of the other components is specified by 2 variables on the same cycle. Thus, the number of choices for the components of H_A is at most $(2+r^2)^d(dr^2)^{j-1}$. To obtain a very loose upper bound on the number of ways that these components can fit into B, we simply multiply by the number of ways to choose j components from B and then multiply by $j!$ for the number of ways to pair them up with the components of A. Note that, since $t < d^{k-1}$ and d, k are not both 2, no constraint can be a $a : \delta \rightarrow b : \gamma$ forcer for more than one choice of a, b, δ, γ. Therefore, if an edge lies in the underlying hypergraph of both A and B, then its forcer in B must be identical to its forcer in A. Therefore, to choose the rest of B, we choose the remaining at most $s-i-j$ variables and a value for each of them (d values if one of them is the center variable) and then choose $k-2$ nonconnecting variables for each of the remaining clauses. Thus, the total number of potential such r-flowers is at most $((2+r^2)^d(dr^2)^{j-1})^2 j! n^{s-i-j} d^{s-i-j+d-1}\binom{n}{k-2}^{dr-i}$. Therefore, $\mathbf{E}(X^2)$ is

$$\begin{aligned}&\sum_{A,B}\mathbf{Pr}(X_A = 1 \wedge X_B = 1)\\ &= \sum_A \sum_{B:A\cap B=\emptyset}\mathbf{Pr}(X_A=1)\mathbf{Pr}(X_B=1) + \sum_A \sum_{B:H_A\cap H_B\neq\emptyset}\mathbf{Pr}(X_A = 1 \wedge X_B = 1)\\ &< \mathbf{E}(X)^2 + \sum_A \mathbf{Pr}(X_A = 1)\\ &\qquad \times \sum_{i=1}^{s}\sum_{j=1}^{i}\left[\left((2+r^2)^d(dr^2)^{j-1}\right)^2 \times j! n^{s-i-j} d^{s-i-j+d-1}\binom{n}{k-2}^{dr-i} p^{dr-i}\right]\\ &= \mathbf{E}(X)^2 + \mathbf{E}(X)\sum_{i=1}^{s}\left[(2+r^2)^{2d} r^{-4} n^{s-i} d^{s-i+d-3} \times \binom{n}{k-2}^{dr-i} p^{dr-i}\sum_{j=1}^{i}\left(\frac{dr^4 j}{n}\right)^j\right]\\ &\leq \mathbf{E}(X)^2 + \mathbf{E}(X) \times \mathbf{E}(X) \times O(r^{4d-4}) \times \sum_{i=1}^{s}(1+\epsilon)^{-i} O\left(\frac{r^4}{n}\right)\\ &\leq \mathbf{E}(X)^2\left(1 + O\left(\frac{r^{4d}}{n}\right)\right),\end{aligned}$$

which completes the proof since $r = O(\log n)$. □

6. Proofs of Theorems 4 and 5.

We close the paper with the proofs of Theorems 4 and 5. Part (a) of Theorem 4 uses a very standard technique whereby we compute the expected number of satisfying assignments. There are other standard techniques around which to improve this theorem (e.g., the techniques from [29]); we made no attempt to do so in part (a) as our only goal was to show that $\mathcal{F}^{d,k,t}_{n,M=cn}$ is a.s. unsatisfiable for some $c < c^*(d,k,t)$. However, we need to work a bit harder for part (c), and so we use the simplest of the techniques from [29].

Proof of Theorem 4. Part (a). Consider any instance $\mathcal{I}$ chosen from $\mathcal{F}^{d,k,t}_{n,M=cn}$. There are d^n assignments to the variables of $\mathcal{I}$. For each such assignment, the probability that all constraints are satisfied is easily seen to be $((d^k-t)/d^k)^{cn}$. Therefore, the expected number of assignments that satisfy $\mathcal{I}$ is

$$d^n\left(\frac{d^k-t}{d^k}\right)^{cn} = e^{(\ln d - c\ln(d^k/d^k-t))n},$$

which is $o(1)$, if $c > \frac{\ln d}{\ln(d^k/d^k-t)}$. This implies that for such c a.s. $\mathcal{I}$ is unsatisfiable.

Part (b). It is straightforward to verify that the statement holds for $d=2$ and $k\in\{4,5\}$. Also, $c^*(d,k,t) > \frac{1}{dk(k-1)} \times (\frac{d^k}{t})^{(d-1)d^{k-2}} > \frac{d^{(d-1)d^{k-2}}}{dk(k-1)}$. So it is enough to show that for $d\ge 2$, $k\ge 6$ and for $d\ge 3$, $3\le k\le 5$

$$\frac{\ln d}{\ln[d^k/(d^k-t)]} < \frac{d^{(d-1)d^{k-2}}}{dk(k-1)}. \tag{6.1}$$

A simple inductive argument shows that, for $k\ge 6$, $k(k-1)<2^k$ and $k<2^{k-2}-4$, which implies $2k(k-1) < 2^{2^{k-2}-3} \le d^{(d-1)d^{k-2}-3}$. Similarly, for $d\ge 3$ and $k\ge 3$, $2k(k-1) < 3^k$ and $k \le 2\times 3^{k-2}-3$, which implies $2k(k-1) < 3^{2\times 3^{k-2}-3} \le d^{(d-1)d^{k-2}-3}$. Therefore, in both cases

$$\begin{gathered}2dk(k-1)\ln d < d^{(d-1)d^{k-2}-2}\ln d,\\ \frac{2dk(k-1)\ln d}{d^{(d-1)d^{k-2}}} < \frac{\ln d}{d^2} < \frac{(d-1)d^{k-2}}{d^k-(d-1)d^{k-2}}.\end{gathered} \tag{6.2}$$

Using (6.2) and the fact that, for $0<x<1$, $e^x < 1+2x$

$$\begin{aligned}\exp\left(\frac{dk(k-1)\ln d}{d^{(d-1)d^{k-2}}}\right) &\le 1+\frac{(d-1)d^{k-2}}{d^k-(d-1)d^{k-2}}\\ &\le \frac{d^k}{d^k-t},\\ \frac{dk(k-1)\ln d}{d^{(d-1)d^{k-2}}} &< \ln\left(\frac{d^k}{d^k-t}\right),\\ \frac{\ln d}{\ln[d^k/(d^k-t)]} &< \frac{d^{(d-1)d^{k-2}}}{dk(k-1)},\end{aligned}$$

thus establishing (6.1) as required.

Part (c). For the case $d=2, k=3, t=2$, we strengthen the bound from part (a) by applying the so-called "1-flips" technique from [29]. We say that a satisfying assignment is *1-maximal* if, for every variable x with value 1, changing the value of x to 2 will result in a nonsatisfying assignment. It is easy to see that if an instance $\mathcal{I}$ chosen from $\mathcal{F}^{d,k,t}_{n,M=cn}$ is satisfiable, then it has a 1-maximal satisfying assignment; indeed, consider an assignment which, among all satisfying assignments, has the greatest number of variables with value 2.

Consider any instance $\mathcal{I}$ chosen from $\mathcal{F}^{d,k,t}_{n,M=cn}$. For each $0 \le a \le n$, consider one of the $\binom{n}{a}$ value assignments ν to the variables of $\mathcal{I}$ in which exactly a variables have value 1. As described in the proof of part (a), the probability that this is a satisfying assignment is $(6/8)^{cn}$. We condition on the fact that it is a satisfying assignment; the effect of this conditioning is that the M constraints are chosen uniformly at random from among the $\binom{7}{2}\binom{n}{3}$ constraints that are not violated by ν.

For ν to be 1-maximal, it must be the case that, for each variable x with value $\nu(x) = 1$, there is a constraint on x and two other variables, say, y, z, that contains $x = 2, y = \nu(y), z = \nu(z)$ as a restriction; we say that such a constraint *blocks* x. There are $6\binom{n-1}{2}$ possible constraints of this form, 6 for each choice of y, z. Conditional on ν being satisfying, the probability that no constraint blocks x is

$$\binom{\binom{7}{2}\binom{n}{3} - 6\binom{n-1}{2}}{M} \bigg/ \binom{\binom{7}{2}\binom{n}{3}}{M} = e^{-6c/7} + o(1).$$

Given two variables x_1, x_2, with $\nu(x_1) = \nu(x_2) = 1$, the events that at least one constraint blocks x_1 and at least one constraint blocks x_2 are not independent—given that one blocks x_1, it is less likely that that constraint blocks x_2, and so the probability that x_2 is blocked is a bit smaller. However, it is easy to see that this dependence goes in the right direction for our purposes, and so the probability that all a variables that are assigned 1 by ν are blocked is less than $(1 - e^{-6c/7} + o(1))^a$. Therefore, the expected number of 1-maximal satisfying assignments is

$$\sum_{a=0}^{n} \binom{n}{a} \left(\frac{6}{8}\right)^{cn} (1 - e^{-6c/7})^a = \left(\frac{6}{8}\right)^{cn} (2 - e^{-6c/7})^n = \left(\left(\frac{3}{4}\right)^c (2 - e^{-6c/7})\right)^n.$$

For $c > 2.114$ we have $(\frac{3}{4})^c(2 - e^{-6c/7}) < 1$, and so this expected number is $o(1)$. Thus a.s. $\mathcal{I}$ has no 1-maximal satisfying assignments and so $\mathcal{I}$ is unsatisfiable.

(Clearly, this technique will easily give an improvement to the bound in part (a) for any d, k, t. It is not hard to see that further techniques from [29] will obtain even better bounds.) □

Our final proof follows the, now rather standard, technique of using a differential equation analysis to show that a particular algorithm will a.s. find a satisfying assignment. See [1] for a good presentation of this method and survey of some of its most important applications.

Proof of Theorem 5. Recall that our assumption is that $c < c^*(2, 3, 3) = 7/9$ and that we wish to show that $\mathcal{F}^{2,3,3}_{n,M=cn}$ is a.s. satisfiable.

We will make use of the fact that $\mathcal{F}^{2,3,3}_{n,M=cn}$ has a sharp threshold in the sense of Friedgut's theorem [22]. This fact was first proven independently by Creignou and Daudé [16] and by Istrate [27]. These papers each proved special cases of a more general conjecture from [15], which was proved in [17], where Creignou and Daudé classified which members of a large family of random CSPs with domain size two exhibit a sharp threshold.

More formally, this fact says that there is a function $c^*(n)$ such that, for every $\epsilon > 0$, $\mathcal{F}^{2,3,3}_{n,M=(c^*(n)-\epsilon)n}$ is a.s. satisfiable and $\mathcal{F}^{2,3,3}_{n,M=(c^*+\epsilon)n}$ is a.s. unsatisfiable. This implies that if, for some constant c, $\mathcal{F}^{2,3,3}_{n,M=cn}$ is satisfiable with probability at least

γ for some $\gamma > 0$, then $\mathcal{F}^{2,3,3}_{n,M=c'n}$ is a.s. satisfiable for every constant $c' < c$: The only alternative is that $\mathcal{F}^{2,3,3}_{n,M=cn}$ and $\mathcal{F}^{2,3,3}_{n,M=c'n}$ are neither a.s satisfiable nor a.s. unsatisfiable. But this contradicts the existence of $c^*(n)$ since, for $\epsilon = (c - c')/3$, either $c' < c^*(n) - \epsilon$ or $c > c^*(n) + \epsilon$.

Thus, it will suffice to prove that, for every $c < 7/9$, $\mathcal{F}^{2,3,3}_{n,M=cn}$ is satisfiable with probability at least γ for some $\gamma = \gamma(c) > 0$, which we do now.

We consider the following algorithm, which we denote the *unit constraint* (UC).

The initial CSP is the input CSP, which is drawn from $\mathcal{F}^{2,3,3}_{n,M=cn}$. Repeatedly, we select a variable x and assign it a value i. We then modify each constraint C containing x as follows. If C contains any restrictions involving $x : i$, then we form a new constraint C' on the variables of C other than x, by taking each restriction of C that contains $x : i$, removing $x : i$ from that restriction, and placing the shortened restriction in C'. Thus, C' can be thought of as the constraint that is implied by C and setting $x = i$. Note that this might result in a constraint on exactly one variable in which each restriction simply dictates a value which that variable is not allowed to receive. We remove C and, if C contained any restrictions involving $x : i$, we replace it with C', unless:

- If C' is on two variables, say, a and b, and if there is some value j for which C' forbids both $(a = 1, b = j)$ and $(a = 2, b = j)$, then we simplify by replacing C with the constraint whose only variable is b and whose only restriction is (j), i.e., a 1-variable constraint that forbids b from taking the value j. If C' also forbids both $(a = j', b = 1)$ and $(a = j', b = 2)$, then we replace C by two 1-variable constraints which forbid $a = j'$ and $b = j$, respectively. Note that this latter case occurs iff C' contains 3 restrictions (since C' cannot contain more than $t = 3$ restrictions).
- If C has exactly one variable, and if it forbids $x = i$, then C' will contain no variables, so we remove C but do not add C', and we say that we formed a *null constraint*. This indicates that our assignment violated one of the original constraints. However, we will continue to run the algorithm, as this will be convenient for its analysis.

Since no constraint has more than $t = 3$ restrictions, it is easy to see that we will never generate a 1-variable constraint with two restrictions.

We choose x and i as follows:

- If there are any clauses on 1 variable, choose one of them uniformly at random, and set its variable so as to satisfy that clause. (As described above, no such clause will ever contain 2 restrictions, and so there is always a unique such setting for that variable.)
- Otherwise, pick x uniformly at random from all unset variables, and pick i uniformly at random from the domain $\{1, 2\}$.

After r variables have been set, we define the following:

- $C_3(r)$—the number of constraints on 3 variables,
- $H_1(r)$—the number of constraints on 2 variables with 1 restriction,
- $H_2(r)$—the number of constraints on 2 variables with 2 restrictions,
- $C_1(r)$—the number of constraints on 1 variable.

Note that the total number of remaining constraints is the sum of these values since every constraint formed has at least one restriction, and no constraint on 2 variables with 3 restrictions is ever added (since, instead of adding such a constraint, we would add the equivalent pair of constraints each on 1 variable).

CLAIM 18. *For each r, the CSP remaining after r steps of UC is uniformly random from amongst all CSPs with $C_3(r)$ constraints with 3 variables and 3 restrictions,*

$H_1(r)$ constraints with 2 variables and 1 restriction, $H_2(r)$ constraints with 2 variables and 2 restrictions, and $C_1(r)$ constraints with 1 variable and 1 restriction.

Proof. Consider two CSPs H_1 and H_2 each with $C_3(r)$ constraints with 3 variables and 3 restrictions, $H_1(r)$ constraints with 2 variables and 1 restriction, $H_2(r)$ constraints with 2 variables and 2 restrictions, and $C_1(r)$ constraints with 1 variable and 1 restriction. Consider any input CSP F_1 with n variables and with cn constraints, each having 3 variables and 3 restrictions, and any sequence of random choices of variables, such that running UC with input F_1 for r steps with that sequence of random choices will result in H_1. It is trivial to see how to modify F_1 into F_2, also with n variables and with cn constraints each having 3 variables and 3 restrictions, such that running UC with input F_2 for r steps with that same sequence of random choices will result in H_2. (Essentially, you simply replace all original constraints in F_1 that became constraints in H_1 with constraints that will instead become constraints of H_2.) This implies that the probability of ending up with H_1 is the same as the probability of ending up with H_2. This, in turn, implies the claim. □

Next, we consider the expected changes in the first 3 variables after step $r+1$. By examining all $\binom{8}{3}$ possible constraints on 3 variables, it is straightforward (but tedious) to verify that we have the following, regardless of whether step $r+1$ sets the variable of a 1-clause or a uniformly random unset variable:

- $\mathbf{Exp}(C_3(r+1) - C_3(r)) = -\frac{3C_3(r)}{n-r}$,
- $\mathbf{Exp}(H_1(r+1) - H_1(r)) = \frac{9}{7} \times \frac{C_3(r)}{n-r} - \frac{2H_1(r)}{n-r}$,
- $\mathbf{Exp}(H_2(r+1)) - H_2(r)) = \frac{3}{7} \times \frac{C_3(r)}{n-r} - \frac{2H_2(r)}{n-r}$.

Furthermore, the expected number of new 1-variable constraints that are formed during step $r+1$ is

$$F(r) = \frac{9}{7} \times \frac{C_3(r)}{n-r} + \frac{H_1(r)}{n-r} + \frac{2H_2(r)}{n-r}.$$

As is standard with this sort of analysis, our goal is to prove that a.s. $F(r)$ is always less than $1-\zeta$ for some $\zeta > 0$, as this will imply that, with sufficiently high probability, no null constraints are formed, i.e., that a.s. our assignment does not violate any of the original constraints.

Consider the following functions:

- $c_3(x) = c(1-x)^3$,
- $h_1(x) = \frac{9c}{7}x(1-x)^2$, and
- $h_2(x) = \frac{3c}{7}x(1-x)^2$.

Note that their derivatives satisfy

- $c_3'(x) = -\frac{3c_3}{1-x}$,
- $h_1'(x) = \frac{9}{7} \times \frac{c_3(x)}{1-x} - \frac{2h_1(x)}{1-x}$, and
- $h_2'(x) = \frac{3}{7} \times \frac{c_3(x)}{1-x} - \frac{2h_2(x)}{1-x}$

and that $C_3(0) = c_1(0)n = n$, $H_1(0) = h_1(0)n = 0$, and $H_2(0) = h_2(0)n = 0$.

We also need to note that, with very high probability, none of these parameters change much during any one iteration. In particular, it is straightforward to show that the probability of either C_3, H_1, or H_2 changing by more than $\log n$ during any one iteration is less than n^{-10}.

Noting the correspondence between these derivatives and the expected values computed above, Wormald's theorem [36] implies that for any $\alpha > 0$ a.s. for every $r \le (1-\alpha)n$ we have the following:

- $C_3(r) = c_3(r/n)n + o(n)$,

- $H_1(r) = h_1(r/n)n + o(n)$, and
- $H_2(r) = h_2(r/n)n + o(n)$.

(See [1] for a statement of Wormald's theorem and a good discussion of how to apply it in settings like this one.)

Thus, a.s. for every $r \leq (1-\alpha)n$, setting $x = r/n$ we have

$$F(r) = \frac{9}{7} \times \frac{c_3(x)}{1-x} + \frac{h_1(x)}{1-x} + \frac{2h_2(x)}{1-x} + o(1) = \frac{9c}{7}(1-x)\left(1 + \frac{2}{3}x\right) + o(1) \leq \frac{9c}{7} + o(1),$$

over the relevant range of $0 \leq x \leq 1$. Thus, a.s. $F(r) < 1 - \zeta$ for some small constant $\zeta > 0$, so long as $c < 7/9$.

We will run UC until a point where at least αn variables remain unset, for some particular small constant α to be named later. First, we bound the probability of creating a null constraint. The sequence $C_1(r)$ follows the pattern of a random walk on the positive integers, with a barrier at 0 and with drift always bounded above by $-\zeta$. Standard arguments imply that a.s. $\sum_{r=1}^{(1-\alpha)n} C_1(r) \leq Wn$ for some constant W. Note that, during step r, the probability that no null constraint is formed is (if $C_1(r) > 0$) equal to $(1 - \frac{1}{2(n-r)})^{C_1(r)-1} > (1 - \frac{1}{2\alpha n})^{C_1(r)}$. Therefore, the probability that no null constraints are formed at all is at least $(1 - \frac{1}{2\alpha n})^{Wn} = e^{-W/2\alpha} + o(1)$.

Again, using the fact that $C_1(r)$ has negative drift, it is straightforward to show that a.s. there is some $(1-\alpha)n - \log^2 n < r \leq (1-\alpha)n$ such that $C_1(r) = 0$. It will be convenient to halt UC there. With high probability, we are left with $c_3(1-\alpha)n + o(n) < \alpha^3 n$ constraints on 3 variables and $(h_1(1-\alpha) + h_2(1-\alpha))n + o(n) < 2\alpha^2 n$ constraints on 2 variables. Let G be the hypergraph whose vertices are the unset variables and where a group of vertices form a hyperedge iff they are the set of variables covered by a constraint.

It is straightforward to show that this random hypergraph G a.s. does not have a giant component. Perhaps the easiest way to see this is to add a third random vertex to each hyperedge of size 2 and call the resulting 3-uniform hypergraph G'. This leaves us with a random 3-uniform hypergraph on $n' = \alpha n$ vertices and with fewer than $3\alpha n' < n'/12$ hyperedges for $\alpha < 1/36$. It is well known that the threshold for such a random hypergraph to have a giant component is when the number of hyperedges is $n'/6$ and, in particular, that with probability at least γ' for some $\gamma' > 0$, every component of G' will be a tree. This would imply that every component of G is a tree. It is easy to see that if every component of G is a tree, then the formula is satisfiable.

Thus, the probability that the original formula is satisfiable is at least $\gamma' \times e^{-W/2\alpha} + o(1) > 0$, as required. □

Appendix A: A short proof of Theorem 6. Each variable v has two literals: v and $\overline{v}$, and we say that they are *complements* of each other. A literal of a variable in a CNF formula F is *pure* if does not appear in any clause of F. As explained in [2], it suffices to prove the following.

LEMMA 19. *For any $\Delta, \epsilon > 0$, consider a random CNF formula $\mathcal{F}$ on n variables with Δn 3-clauses and $(1-\epsilon)n$ 2-clauses where every such formula is equally likely. A.s.:*

(a) *every subformula on at most αn variables is satisfiable, and*

(b) *every subformula on v variables, where $\frac{1}{2}\alpha n \leq v \leq \alpha n$, has at least ζn pure literals.*

Consider any CNF formula F containing only 2-clauses and 3-clauses. Let H_2 be the graph defined as follows: The vertices of H_2 are the variables of F, and two vertices are joined iff their variables form at least one 2-clause.

An isolated cycle of F is a 2-SAT subformula F' such that (i) F' forms a component of H_2 that is a cycle, (ii) no variable of F' lies in a 3-clause, and (iii) no variable of F' has a pure literal.

A *pendant path* of F is a path of H_2 whose internal vertices each have degree 2 in H_2 and do not lie in any 3-clauses. Consider such a path whose variables are, in order, $x_0, x_1, \ldots, x_l$, and suppose that $C_1, \ldots, C_l$ is the corresponding set of 2-clauses in F. If, for each x_i, the literal of x_i appearing in C_i is the complement of the literal appearing in C_{i+1}, then we say that it is a *forcing path.* Note that such a path is bidirectional in the sense that there are two literals a and b such that, in any satisfying assignment, if $x_0 = a$, then $x_l = b$, and if $x_l = \overline{b}$, then $x_0 = \overline{a}$. Trivially, a single vertex is a forcing path of length 0.

For any $r \geq 1$, a Y_r*-configuration* consists of:

- r forcing paths and
- a collection of t_2 additional 2-clauses and t_3 3-clauses whose variables are all endpoints of the r forcing paths for some t_2, t_3, with $\frac{3}{2}t_2 + 3t_3 \geq \frac{5}{3}r$.

Consider a collection of forcing paths $\mathcal{P} = P_1, \ldots, P_r$ of F such that (i) every variable of F appears on exactly one path and (ii) $\mathcal{P}$ is minimal in the sense that it is impossible to form a collection $P_1, \ldots, P_{r-1}$ satisfying (i) by adding a 2-clause from F to $\mathcal{P}$. Obviously a collection of paths of length 0, one for each variable of F, satisfies (i), and so some collection exists which satisfies (i) and (ii).

Lemma 20. *If F has at most $r/3$ pure literals and no isolated cycles, then F has a Y_r-configuration.*

Proof. We call the clauses of $\mathcal{P}$ *path clauses* and the other clauses in F *nonpath clauses.* Note that every nonpath clause contains only variables that are endpoints of the paths in $\mathcal{P}$. We define a set X of literals as follows: For each P_i of length 0, we place both literals of the variable of P_i into X. For each P_i of length at least 1, and for each endpoint v of P_i, we place the literal of v that does not appear on a clause of P_i into X. Thus, $|X| = 2r$, and any literal of X that does not appear in a nonpath clause is pure.

We form a graph G with vertex set X as follows: Every nonpath 2-clause $(a \vee b)$ forms an edge of G: $x(a)$ is defined to be a if $a \in X$ and the complement of a otherwise; $x(b)$ is defined in the same way; the edge of G is between $x(a)$ and $x(b)$.

Let s be the number of pure literals in F, $t_2 = |E(G)|$ be the number of 2-clauses, and t_3 be the number of 3-clauses.

Claim 21. *Every component of G with either* 1 *or* 2 *literals contains a literal which is either pure or in a* 3*-clause.*

Proof: If the component has 1 literal, then it is either pure or in a 3-clause. So suppose the component has 2 literals and the edge joining them corresponds to the clause $(a \vee b)$. If at least one of a, b is not in X, then the complement of that literal is either pure or in a 3-clause. If a and b are both in X and if their variables are the endpoints of the same path in $\mathcal{P}$, then one of them must be in a 3-clause, or else that path plus $(a \vee b)$ would form an isolated cycle. If a and b are both in X and their variables are the endpoints of different paths of $\mathcal{P}$, then it is easy to see that those two paths plus $(a \vee b)$ form a forcing path. This contradicts the minimality of $\mathcal{P}$, i.e., condition (ii) in the definition of $\mathcal{P}$.

Let ℓ_1 be the number of components with exactly 1 literal and ℓ_2 be the number with exactly 2 literals. The remaining components have $2r - \ell_1 - 2\ell_2$ literals and at least $\frac{2}{3}(2r - \ell_1 - 2\ell_2)$ edges (since the components on those literals each have a size of at least 3). Therefore, $t_2 \geq \ell_2 + \frac{2}{3}(2r - \ell_1 - 2\ell_2)$; i.e. $\frac{3}{2}t_2 \geq 2r - \ell_1 - \frac{1}{2}\ell_2$. By

Claim 18, $3t_3 + s \geq \ell_1 + \ell_2$. These combine to yield:

$$\frac{3}{2}t_2 + 3t_3 + s \geq 2r.$$

Since $s \leq r/3$, F has a Y_r-configuration. □

Lemma 22. *For any $\Delta, \epsilon > 0$, consider a random CNF formula $\mathcal{F}$ on n variables with Δn 3-clauses and $(1-\epsilon)n$ 2-clauses where every such formula is equally likely. There is some constant $\alpha > 0$ such that a.s. F has no Y_r-configuration for any $r \leq \alpha n$.*

Proof. Given r, t_2 we specify $t_3 = \lceil \frac{5}{9}r - \frac{1}{2}t_2 \rceil$ to be the smallest integer t_3 such that $\frac{3}{2}t_2 + 3t_3 \geq \frac{5}{3}r$. Clearly, it suffices to show that a.s. there are no Y_r-configurations with such a pair t_2, t_3. First, we compute the expected number of Y_r-configurations for any choice of t_2, t_3 that are both at least $r/100$.

Consider any list of 2-clauses $C_1, \ldots, C_s$. The probability that they all appear in $\mathcal{F}$ is

$$\frac{\binom{4\binom{n}{2}-s}{(1-\epsilon)n-s}}{\binom{4\binom{n}{2}}{(1-\epsilon)n}} < \left(\frac{1-\epsilon}{2(n-1)}\right)^s < \left(\frac{1-\epsilon'}{2n}\right)^s$$

for some $0 < \epsilon' < \epsilon$.

We have at most $\binom{n}{r}n^r$ choices for the r pairs of endpoints. Suppose that the numbers of 2-clauses in the paths are $l_1, \ldots, l_r$, and set $L = l_1 + \cdots + l_r$. Then there are n^{L-r} choices for the interior variables on the paths and 2^{L+r} choices for the literals. We multiply by the probability that all L of these clauses appear and that there are t_2 other 2-clauses and t_3 3-clauses on the endpoints. This gives us an upper bound of

$$\begin{aligned}
&\sum_{l_1,\ldots,l_r \geq 0} \binom{n}{r} n^L 2^{L+r} \left(\frac{1-\epsilon'}{2n}\right)^L \binom{(1-\epsilon)n}{t_2}\binom{\Delta n}{t_3}\left(\frac{2r}{n}\right)^{2t_2+3t_3} \\
&\leq \left(\frac{2en}{r}\right)^r \left(\frac{en}{t_2}\right)^{t_2} \left(\frac{e\Delta n}{t_3}\right)^{t_3} \left(\frac{2r}{n}\right)^{2t_2+3t_3} \sum_{l_1,\ldots,l_r \geq 0} (1-\epsilon')^L \\
&\leq \left(\frac{\gamma r}{n}\right)^{t_2+2t_3-r} \left(\sum_{l \geq 0}(1-\epsilon')^l\right)^r \qquad \text{for some } \gamma > 0, \text{ since } t_2, t_3 \geq r/100 \\
&\leq \left(\frac{\gamma' r}{n}\right)^{r/9}.
\end{aligned}$$

For some constant $\gamma' > 0$ since $t_2 + 2t_3 - r = \frac{2}{3}(\frac{3}{2}t_2 + 3t_3) - r \geq \frac{2}{3} \times \frac{5}{3}r - r = \frac{r}{9}$.

If $t_2 \leq r/100$, then $t_3 \geq (\frac{5}{9} - \frac{1}{200})r$. For such t_2, we compute the expected number of collections of r vertex-disjoint forcing paths along with t_3 3-clauses on their endpoints. Clearly, if there are no such collections, then there is no Y_r-configuration with those values of t_2, t_3. As above, we upper bound this expected number with

$$\left(\frac{2en}{r}\right)^r \left(\frac{e\Delta n}{t_3}\right)^{t_3} \left(\frac{2r}{n}\right)^{3t_3} \left(\sum_{l \geq 0}(1-\epsilon')^l\right)^r < \left(\frac{\gamma' r}{n}\right)^{r/10},$$

with possibly an increase in γ'. If $t_3 \leq r/100$, then we compute the expected number of collections of r vertex-disjoint forcing paths along with t_2 additional 2-clauses on their endpoints. Clearly, if there are no such collections, then there is no Y_r-configuration with those values of t_2, t_3. Again, this expected number is at most $(\frac{\gamma' r}{n})^{r/10}$. Thus, considering that there are $O(r)$ choices for t_2, t_3, it suffices to show that

$$\sum_{r=1}^{\alpha n} r \left(\frac{\gamma' r}{n}\right)^{r/10} = o(1).$$

The first $\log n$ terms of this sum add up to at most $O(\log n/n^{1/10})$, and if $\alpha < \frac{1}{2\gamma'}$, then the rest add up to at most $\sum_{i \geq \log n} (1/2)^i = o(1)$. □

Lemma 23. *A.s. our random $\mathcal{F}$ has at most* $\log n$ *variables lying on isolated cycles.*

Proof. Consider the subformula F_2 formed by the 2-clauses of $\mathcal{F}$. For any variable v lying in an isolated cycle of $\mathcal{F}$, there must be a sequence of 2-clauses in F_2 of the form: $(v \vee x_1), (\overline{x_1} \vee x_2), \ldots, (\overline{x_i} \vee \overline{v})$. A well-known property of random 2-SAT (see, e.g., [11]) says that a.s. there are at most $\log n$ such variables. □

Proof of Lemma 19. If F' is a minimally unsatisfiable subformula of $\mathcal{F}$, then F' must be connected and F' cannot be an isolated cycle. Therefore F' can have no isolated cycles. Furthermore F' can have no pure literals. Therefore, by Lemma 20, F' must have a Y_r-configuration for some $r \geq 1$. Therefore, by Lemma 22, $\mathcal{F}$ a.s. has no minimally unsatisfiable subformula on at most αn variables, and hence a.s. has no unsatisfiable subformula on at most αn variables. This establishes part (a).

Consider any subformula on v variables, where $\frac{1}{2}\alpha n \leq v \leq \alpha n$. By Lemma 23, $\mathcal{F}$ is a.s. such that, after removing all isolated cycles from such a subformula, we are left with a subformula F' on v' variables, where $\frac{1}{2}\alpha n - \log n \leq v' \leq \alpha n$. It will suffice to show that a.s. every such F' has at least ζn pure literals. By Lemma 22, $\mathcal{F}$ is a.s. such that every subformula on at most αn variables does not have a Y_r-configuration for any $r \geq 1$. Therefore, by Lemma 20, there is some $r \geq 1$ such that F' has at least $r/3$ pure literals and F' has a collection $\mathcal{P}$ of r forcer paths which contain all of its variables.

Well-known properties of random 2-SAT (see, e.g., [11]) imply that there is some $\pi > 0$ such that for every $\theta > 0$ a.s. F has fewer than $e^{-\pi\theta}$ variables that lie on forcing paths of length at least θ. In fact, the same would be true if we removed from the definition of *forcing path* the stipulation that no internal variables lie in any 3-clauses, thus reducing forcing paths to be defined only in terms of the $(1-\epsilon)n$ random 2-clauses of F. Pick θ so that $e^{-\pi\theta} < \alpha/4$. Thus, at least $(\alpha/4)n - \log n$ variables of F' lie on paths in $\mathcal{P}$ of length less than θ. Therefore, $r > \alpha n/(5\theta)$, and so F' has at least ζn pure literals for $\zeta = \alpha/(15\theta)$. This establishes part (b). □

Appendix B: Two simple lemmas. Here we translate two standard facts from random graph theory into the setting of this paper.

Lemma 24. *A.s. the underlying random hypergraph of $\mathcal{F}_{n,M}^{d,k,t}$ has fewer than* $\log n$ *cycles of length at most* 4.

Remark. This statement remains true when "4" is replaced by any constant. It is well known for random graphs, but we can't find the statement for random hypergraphs recorded in the literature. So we include the simple proof here.

Proof. For each constant integer $r \geq 2$, we compute the expected number of cycles of length r, by pretending that the vertices of degree 2 in the cycle are labeled $v_1 \ldots, v_r$, in order around the cycle; this creates an overcount, which we correct by dividing by $2r$, the number of ways to label each cycle. (For $k = 2$, we take $r \geq 3$ since a simple graph contains no 2-cycles; for $r = 2$, we must divide by r instead of $2r$ since there are only 2 ways to label each cycle.)

There are at most n^r choices for $v_1, \dots, v_r$ and at most $\binom{n-r}{k-2}^r$ choices for the other vertices. This specifies the r edges. There are $M^r = (cn)^r$ choices for which random edges correspond to the edges of the cycle. The probability that each such random edge is the desired one is $\binom{n}{k}^{-r}$. So the expected number of cycles of length r is

$$\frac{1}{2r} n^r \binom{n-r}{k-2}^r (cn)^r \binom{n}{k}^{-r} = O(1).$$

(For $r = 2$ we replace $\frac{1}{2r}$ by $\frac{1}{r}$.) Thus, the expected number of cycles of length $2 \le r \le 4$ is $O(1)$. So by Markov's inequality, the probability that this number is at least $\log n$ is $O(1/\log n) = o(1)$ as required. □

Remark. With more work, one can show that the probability is much lower than $O(1/\log n)$; but that is not needed here.

Our second lemma shows how the $\mathcal{F}_{n,M}^{d,k,t}$ and $\mathcal{F}_{n,p}^{d,k,t}$ models are, in many senses, equivalent and, in particular, allows us to use the $\mathcal{F}_{n,p}^{d,k,t}$ model in the proofs of Lemmas 15 and 16.

We say that a property A of CSPs in $\Omega^{d,k,t}$ is *monotone increasing* if for every $F_1, F_2 \in \Omega^{d,k,t}$ with every constraint of F_1 also in F_2, if F_1 has A, then so does F_2. A is *monotone decreasing* if the same holds whenever every constraint of F_2 is also in F_1. A is *monotone* if it is either monotone increasing or monotone decreasing.

For example, it is easy to see that the properties considered in the statements of Lemmas 15 and 16 are both monotone decreasing.

Lemma 25. *Let A be any monotone property of CSPs in $\Omega^{d,k,t}$, and let $c > 0$ be any positive constant. A holds a.s. for $\mathcal{F}_{n,p}^{d,k,t}$, with $p = c \times k!/n^{k-1}$ iff for every real constant x, A holds a.s. for $\mathcal{F}_{n,M}^{d,k,t}$, with $M = \lceil cn + x\sqrt{n} \rceil$.*

In particular, taking $x = 0$ allows us to show that A holds a.s. in $\mathcal{F}_{n,M}^{d,k,t}$ by proving that it holds a.s. in $\mathcal{F}_{n,p}^{d,k,t}$, as we do in the proofs of Lemmas 15 and 16. The proof is very straightforward and follows similar proofs in, e.g., [10, 28].

Proof. We assume that A is monotone increasing (the monotone decreasing case is nearly identical).

Suppose that $\mathcal{F}_{n,p}^{d,k,t}$ a.s. has A. Fix any real x, and set $M = \lceil cn + x\sqrt{n} \rceil$. Let $\gamma(n) = \mathbf{Pr}(\mathcal{F}_{n,M}^{d,k,t}$ does not have $A)$. The probability that the number of edges in $\mathcal{F}_{n,p}^{d,k,t}$ is at most M is well known to be at least a positive constant $g(x)$, since this number is a binomial variable with mean cn. By the monotonicity of A, the probability that $\mathcal{F}_{n,p}^{d,k,t}$ does not have A is at least $g(x) \times \gamma(n)$. Therefore, $\lim_{n\to\infty} \gamma(n) = 0$, as required.

For the other direction, suppose that, for every real constant x, A holds a.s. for $\mathcal{F}_{n,M}^{d,k,t}$, with $M = \lceil cn + x\sqrt{n} \rceil$. For any $\epsilon > 0$, there exists $x_1 < 0 < x_2$ such that the probability that the number of edges in $\mathcal{F}_{n,p}^{d,k,t}$ is in $\lceil cn + x_1\sqrt{n} \rceil, \dots, \lceil cn + x_2\sqrt{n} \rceil$ is at least $1 - \epsilon$. Therefore, the probability that $\mathcal{F}_{n,p}^{d,k,t}$ does not have A is at most $\epsilon + o(1)$. Since this is true for every $\epsilon > 0$, $\mathcal{F}_{n,p}^{d,k,t}$ a.s. has A. (Note that this part did not require A to be monotonic.) □

Acknowledgments. We thank Joe Culberson and Yong Gao for spotting an error in Theorem 4 of the conference version of this paper [34]. We also thank two anonymous referees for a very careful reading and many suggested improvements in the presentation. Most of this research was completed while the first author was a visiting researcher at Microsoft Research and the second author was with Department of Computer Science, University of Toronto.

A MIN-MAX THEOREM ON TOURNAMENTS*

XUJIN CHEN†, XIAODONG HU†, AND WENAN ZANG‡

Abstract. We present a structural characterization of all tournaments $T = (V, A)$ such that, for any nonnegative integral weight function defined on V, the maximum size of a feedback vertex set packing is equal to the minimum weight of a triangle in T. We also answer a question of Frank by showing that it is NP-complete to decide whether the vertex set of a given tournament can be partitioned into two feedback vertex sets. In addition, we give exact and approximation algorithms for the feedback vertex set packing problem on tournaments.

Key words. min-max relation, feedback vertex set, tournament, packing, covering

1. Introduction.

A rich variety of combinatorial optimization problems falls within the general framework of packing and covering in hypergraphs. A *hypergraph* is a pair $\mathcal{H} = (V, \mathcal{E})$, where V is a finite set and $\mathcal{E}$ is a family of subsets of V. Elements of V and $\mathcal{E}$ are called the *vertices* and *edges* of $\mathcal{H}$, respectively. A *vertex cover* of $\mathcal{H}$ is a vertex subset that intersects all edges of $\mathcal{H}$. Let w be a nonnegative integral weight function defined on V. A family $\mathcal{S}$ of edges (repetition is allowed) of $\mathcal{H}$ is called a *w-packing* of $\mathcal{H}$ if each $v \in V$ belongs to at most $w(v)$ members of $\mathcal{S}$. Let $\nu_w(\mathcal{H})$ denote the maximum size of a w-packing of $\mathcal{H}$, and let $\tau_w(\mathcal{H})$ denote the minimum total weight of a vertex cover. Clearly $\nu_w(\mathcal{H}) \leq \tau_w(\mathcal{H})$; this inequality, however, need not hold equality in general. We say that $\mathcal{H}$ is *Mengerian* if the min-max relation $\nu_w(\mathcal{H}) = \tau_w(\mathcal{H})$ is satisfied for any nonnegative integral function w defined on V. Many celebrated results and conjectures in combinatorial optimization can be rephrased by saying that certain hypergraphs are Mengerian (see section 79.1 of [19]), so Mengerian hypergraphs have been subjects of extensive research. As conjectured by Edmonds and Giles [9, 18] and proved recently by Ding, Feng, and Zang [4], the problem of recognizing Mengerian hypergraphs is NP-hard in general, and hence it cannot be solved in polynomial time unless $NP = P$. In this paper we study a special class of Mengerian hypergraphs; our work is a continuation of those done in [1, 2, 3, 5, 6].

Let $G = (V, E)$ be a graph (directed or undirected), and let $\mathcal{C}_G = (V, \mathcal{E})$, where $\mathcal{E}$ consists of $V(C)$, for all induced cycles C in G. Throughout this paper, by a cycle in a digraph we always mean a directed one. In [6], Ding and Zang obtained a structural description of all undirected graphs G for which $\mathcal{C}_G$ is Mengerian. Due to the long list of forbidden structures, to find a good characterization of all digraphs G with Mengerian $\mathcal{C}_G$ seems to be extremely difficult. While this characterization problem

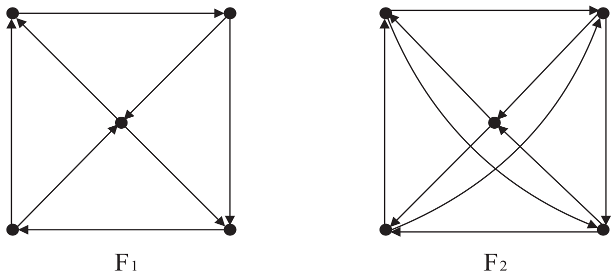

Fig. 1. *Forbidden subtournaments F_1 and F_2, where the two arcs not shown in F_1 may take any directions.*

remains open in general, it was completely solved on tournaments by Cai, Deng, and Zang [1], where a *tournament* is an orientation of an undirected complete graph.

Theorem 1.1 ([1]). *Let T be a tournament. Then hypergraph $\mathcal{C}_T$ is Mengerian if and only if T has no subtournament isomorphic to F_1 nor F_2.*

(Note that F_2 is the tournament in which every vertex is incident with precisely two incoming arcs and two outgoing arcs.) One objective of this paper is to establish a closely related min-max relation which is motivated as follows.

Every hypergraph $\mathcal{H} = (V, \mathcal{E})$ is naturally associated with another hypergraph $b(\mathcal{H}) = (V, \mathcal{E}')$, where $\mathcal{E}'$ consists of all minimal (with respect to set inclusion) vertex covers of $\mathcal{H}$. Usually $b(\mathcal{H})$ is called the *blocker* of $\mathcal{H}$. Although in general the blocker of a Mengerian hypergraph does not have to be Mengerian (see section 79.2 of [19]), the famous max-flow-min-cut theorem and a Fulkerson theorem [11] (see p. 115 of [18]) assert that both the hypergraph of r-s paths in a graph and its blocker are Mengerian; so are the hypergraph of r-arborescences and its blocker by Edmonds' disjoint arborescence theorem [7] and Fulkerson's optimum arborescence theorem [12]. Recently, Chen et al. [3] managed to characterize all undirected graphs G for which $b(\mathcal{C}_G)$ is Mengerian; it turns out that $b(\mathcal{C}_G)$ is Mengerian if and only if $\mathcal{C}_G$ is. So a natural question is to ask: What is the blocker version of Theorem 1.1?

Theorem 1.2. *Let T be a tournament. Then hypergraph $b(\mathcal{C}_T)$ is Mengerian if and only if T has no subtournament isomorphic to F_1 nor F_2 (see Figure 1).*

An immediate corollary of Theorems 1.1 and 1.2 is the following.

Corollary 1.3. *Let T be a tournament. Then $b(\mathcal{C}_T)$ is Mengerian if and only if $\mathcal{C}_T$ is.*

Let us define a few terms before presenting an equivalent of the above statements. Let $G = (V, E)$ be a digraph with a nonnegative integral weight $w(v)$ on each vertex v. A *feedback vertex set* (FVS) of G is a vertex subset that intersects each cycle in G, and a *w-FVS packing* of G is a collection $\mathcal{F}$ of minimal FVSs (repetition is allowed) such that each vertex v is contained in at most $w(v)$ members of $\mathcal{F}$. Similarly, a *w-cycle packing* of G is a collection $\mathcal{C}$ of induced cycles (repetition is allowed) such that each vertex v is contained in at most $w(v)$ members of $\mathcal{C}$. The *weight* of a cycle (resp., an FVS) is the sum of weights of all vertices in this cycle (resp., FVS). Observe that every minimal FVS of G uniquely corresponds to an edge of $b(\mathcal{C}_G)$, and vice versa. So there is $1-1$ correspondence between a *w-FVS packing* of G and a w-packing of $b(\mathcal{C}_G)$ and $1-1$ correspondence between a *w-cycle packing* of G and a w-packing of $\mathcal{C}_G$. Moreover, if G is a tournament, then every cycle in a cycle packing is a triangle (a cycle of length three), and hence a cycle packing is actually a triangle packing.

Let $\boldsymbol{Z}_+$ denote the set of nonnegative integers. Then Theorems 1.1 and 1.2 can be restated as follows.

THEOREM 1.4. *The following three statements are equivalent for a tournament* $T = (V, A)$*:*

(i) *For any weight function* $w \in \mathbf{Z}_+^V$*, the minimum weight of an FVS in* T *is equal to the maximum size of a* w*-triangle packing of* T*;*

(ii) *for any weight function* $w \in \mathbf{Z}_+^V$*, the minimum weight of a triangle in* T *is equal to the maximum size of a* w*-FVS packing of* T*;*

(iii) T *has no subtournament isomorphic to* F_1 *nor* F_2*.*

It is worthwhile pointing out that the above statement (i) is closely related to the famous Lucchesi–Younger theorem [15], which, when restricted to a planar digraph $G = (V, E)$, is equivalent to saying that for any $w \in \mathbf{Z}_+^E$ the minimum weight of a feedback arc set in G is equal to the maximum size of a cycle packing of G, where a *feedback arc set* of G is a set of arcs that intersects each cycle in G; statement (ii) is closely related to the well-known Woodall conjecture [20] on packing feedback arc sets and the Edmonds–Giles conjecture [8, 17] on packing directed cut covers.

Given a digraph $G = (V, E)$ with a nonnegative integral weight $w(v)$ on each vertex v, the *FVS packing problem* is to find a w-FVS packing of maximum size in G. In connection with this problem, Frank suggested the following question.

Question 1.5 ([10]). Given a digraph G, can we decide in polynomial time whether each vertex of G can be colored by red or blue so that every cycle contains at least one red vertex and at least one blue vertex? Or is this an NP-complete problem?

Our next theorem states that Frank's problem is NP-complete even when G is restricted to a tournament.

THEOREM 1.6. *It is NP-complete to decide whether the vertex set of a given tournament can be partitioned into two feedback vertex sets.*

We shall also present algorithms for the FVS packing problem.

THEOREM 1.7. *The FVS packing problem on a tournament* $T = (V, A)$ *with no* F_1 *nor* F_2 *can be solved exactly in* $O(|V|^4)$ *time.*

For the problem on a general tournament, we shall give an approximation algorithm.

THEOREM 1.8. *The FVS packing problem on a general tournament can be approximated within a factor of* $2/5$.

The remainder of this paper is organized as follows: In section 2, we give a proof of Theorem 1.2, which relies heavily on the structural description of tournaments with no F_1 nor F_2 obtained in [1]. In section 3, we prove Theorem 1.6 by using the so-called NOT-ALL-EQUAL 3-SATISFIABILITY problem as the source problem. In section 4, we present an exact algorithm for the FVS packing problem on tournaments with no F_1 nor F_2 and describe a 2/5-approximation algorithm for the problem on general tournaments. In section 5, we conclude this paper with some open problems.

2. Min-max relation.

The purpose of this section is to prove Theorem 1.2. We break the proof into a series of lemmas and shall implicitly and frequently use the fact that a vertex subset of a tournament is an FVS if and only if it intersects every triangle. As usual, a digraph G is called *strongly connected* if, for any two vertices x and y, there exist a (directed) path from x to y and a (directed) path from y to x in G. Our proof relies heavily on the following structural description obtained in [1].

LEMMA 2.1 ([1]). *Let* $T = (V, A)$ *be a strongly connected tournament. Then* T *has no subtournament isomorphic to* F_1 *nor* F_2 *if and only if* V *can be partitioned into* $V_1, V_2, \ldots, V_k$ *for some* $3 \le k \le |V|$*, which have the following properties:*

(i) *For any* i, j *with* $1 \le i \le j-2 \le k-2$*, each arc between* V_i *and* V_j *is directed from* V_j *to* V_i*.*

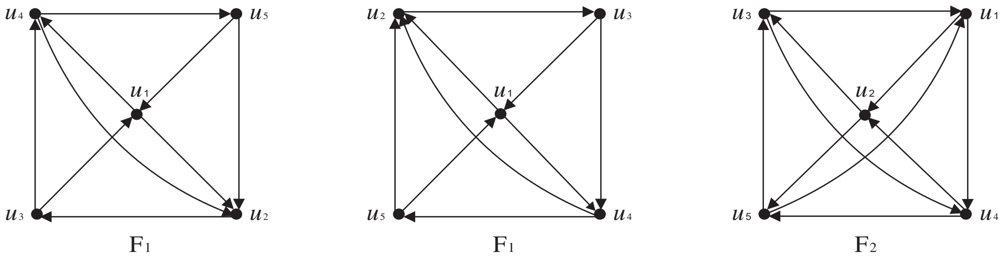

FIG. 2. *Three triangles $u_1u_2u_3u_1$, $u_2u_3u_4u_2$, and $u_1u_4u_5u_1$ in F_1 and F_2.*

(ii) *For any triangle $xyzx$ in T, there exists an i with $1 \le i \le k-2$ such that $x \in V_i$, $y \in V_{i+1}$, and $z \in V_{i+2}$ (renaming x, y, and z if necessary).*

We make two remarks on the above lemma: First, for notational convenience, the order of the indices used in the above partition $V_1, V_2, \ldots, V_k$ is precisely the reverse of the one used in [1]. Second, as depicted in Figure 2, the vertices of both F_1 and F_2 can be labeled as $u_1, u_2, \ldots, u_5$ such that $\{u_1, u_2, u_3\}$, $\{u_2, u_3, u_4\}$, and $\{u_1, u_4, u_5\}$ are vertex sets of three triangles. Using these triangles, we can immediately see the sufficiency.

Let $T = (V, A)$ be a tournament and $u, v \in V$. The arc in T with tail u and head v is written as (u, v) and called the arc from u to v. For any subtournament K of T, let $V(K)$ and $A(K)$ denote the vertex set and arc set of K, respectively. For any vertex u of T, let $T\backslash u$ denote the tournament obtained from T by deleting u, and let $T\langle u\rangle$ denote the tournament obtained from T by introducing a new vertex u' and then adding arcs in such a way that

$$(1^*)\qquad \text{for each } v \in V - \{u\},\ (u', v) \text{ is an arc in } T\langle u\rangle \text{ if and only if } (u, v) \text{ is an arc in } T.$$

(There is no direction constraint on the arc between u and u'.) We propose to call u' the *image* of u and call $T\langle u\rangle$ an *augmentation of* T (*with respect to* u). It can be seen from (1^*) that

$$(2^*)\qquad \text{no triangle in } T\langle u\rangle \text{ contains } \{u, u'\}.$$

LEMMA 2.2. *Let $T\langle u\rangle$ be an augmentation of a tournament $T = (V, A)$. If T contains no F_1 nor F_2, then neither does $T\langle u\rangle$.*

Proof. Assume the contrary: $T\langle u\rangle$ contains a subtournament F isomorphic to F_1 or F_2. Let u' be the image of u. Then F contains both u and u', for otherwise, by (1^*), $V(F\backslash u') \cup \{u\}$ would induce a subtournament in T isomorphic to F, which is a contradiction.

(1) We may assume that T is strongly connected.

Suppose not, let K be the strongly connected component of $T\langle u\rangle$ that contains F (such K is available since F is strongly connected). Then $K\backslash u'$ is strongly connected, for otherwise the vertex set of $K\backslash u'$ can be partitioned into X and Y such that all arcs between X and Y are directed to Y. Without loss of generality, we assume that $u \in X$. Since u' is the image of u, all arcs in K between $X \cup \{u'\}$ and Y are directed to Y, contradicting the strong connectivity of K. Since K is an augmentation of $K\backslash u'$ (with respect to u), we get (1); otherwise, replace T by $K\backslash u'$ and $T\langle u\rangle$ by K.

It follows from (1) that the vertex set V of T admits a partition $V_1, V_2, \ldots, V_k$ with properties (i) and (ii) as described in Lemma 2.1. Suppose $u \in V_h$. Let us partition the vertex set $V \cup \{u'\}$ of $T\langle u\rangle$ into k sets V'_i such that $V'_h = V_h \cup \{u'\}$ and $V'_j = V_j$ for all other j with $1 \le j \le k$. From (1*), we see that the partition $V'_1, V'_2, \dots, V'_k$ satisfies (i) in Lemma 2.1 with respect to $T\langle u\rangle$. Since F is contained in $T\langle u\rangle$, Lemma 2.1 guarantees the existence of a triangle $xyzx$ in $T\langle u\rangle$ that violates (ii) in the lemma with respect to the partition $V'_1, V'_2, \dots, V'_k$. Note that $\{x, y, z\}$ contains at most one of u and u' by (2*). Set $Q = \{x, y, z\}$ if $u' \notin \{x, y, z\}$ and $Q = (\{x, y, z\} - \{u'\}) \cup \{u\}$ otherwise. Then Q would induce a triangle in T that violates Lemma 2.1(ii) with respect to the partition $V_1, V_2, \dots, V_k$, which is a contradiction. □

Let $T = (V, A)$ be a tournament, and let $S \subseteq V$. We shall use the following notations in our proof:

$$(3^*) \qquad \mathscr{D}_S := \{C : C \text{is a triangle in } T \text{ and } |V(C) \cap S| = 2\},$$

$$(4^*) \qquad \mathscr{F}_S := \{C : C \text{ is a triangle in } T,\ V(C) \subseteq S, \text{ and } |V(C) \cap V(C')| \le 1 \text{ for every } C' \in \mathscr{D}_S\},$$

$$(5^*) \qquad \mathscr{F}^+_S := \{C : C \text{ is a triangle in } T,\ V(C) \subseteq S, \text{ and } |V(C) \cap V(C')| = 2 \text{ for some } C' \in \mathscr{D}_S\}.$$

Let $\mathscr{C}$ be a collection of some triangles in T. Write $V(\mathscr{C}) = \cup_{C \in \mathscr{C}} V(C)$. It follows from the definition that $V(\mathscr{D}_S) - S \ne \emptyset$ if $\mathscr{D}_S \ne \emptyset$ and that $V(\mathscr{F}_S) \cup V(\mathscr{F}^+_S) \subseteq S$.

LEMMA 2.3. *Let $T = (V, A)$ be a tournament with no subtournament isomorphic to F_1 nor F_2. Suppose S is a subset of V such that $\mathscr{D}_S \ne \emptyset$ and that $|S \cap V(C)| \ge 2$ for every triangle C of T. Then there exists $R \subseteq S$ such that $|R \cap V(C)| = 1$ for every triangle $C \in \mathscr{D}_S$. Moreover, given S, such an R can be found in $O(|V|^3)$ time.*

Proof. Let us first construct an undirected graph G with vertex set S as follows: uv is an edge of G if and only if there is a triangle C in T such that $\{u, v\} = S \cap V(C)$. If G is a bipartite graph, let R be one color class of G, and then R is as desired. So we assume that G is nonbipartite and aim to reach a contradiction. To this end, let $x_1 x_2 \dots x_{2l+1} x_1$ be the shortest odd cycle of G. From the construction of G, we see that, for every i with $1 \le i \le 2l + 1$, there exists a vertex y_i in $V - S$ such that $\{x_i, x_{i+1}, y_i\}$ induces a triangle, denoted by $\triangle_i$, in $\mathscr{D}_S$. Note that y_i's may not be distinct.

Let T_0 denote the subtournament of T induced by vertex subset $\{x_i, y_i : 1 \le i \le 2l + 1\}$. Then

(1) $\triangle_i$, for $i = 1, 2, \dots, 2l + 1$, are $2l + 1$ triangles in T_0, where $x_{2l+2} = x_1$.

Let us perform a sequence of $2l + 1$ augmentations in the following iterative way: $T_i := T_{i-1}\langle y_i\rangle$; that is, T_i is an augmentation of T_{i-1} with respect to y_i, for $i = 1, 2, \dots, 2l+1$. Let y'_i be the image of y_i involved in the construction of T_i, and let C_i denote the triangle $y'_i x_i x_{i+1} y'_i$ if $\triangle_i = y_i x_i x_{i+1} y_i$ and $y'_i x_{i+1} x_i y'_i$ otherwise. Since $\{x_1, x_2, \dots, x_{2l+1}\} \cap \{y_1, y_2, \dots, y_{2l+1}\} = \emptyset = \{y'_1, y'_2, \dots, y'_{2l+1}\} \cap \{y_1, y_2, \dots, y_{2l+1}\}$, and since $x_1, x_2, \dots, x_{2l+1}, y'_1, y'_2, \dots, y'_{2l+1}$ are distinct vertices, by (1) we have

(2) C_i, for $i = 1, 2, \dots, 2l + 1$, are $2l + 1$ triangles in T_{2l+1}, with the property that no vertex of T_{2l+1} is contained in more than two of them.

Since T_0 is a subtournament of T, it contains no F_1 nor F_2. Repeated applications of Lemma 2.2 yield the following:

(3) For any $0 \le i \le 2l + 1$, tournament T_i contains no F_1 nor F_2.

Let us make one more simple observation.

(4) For any $0 \le i \le 2l + 1$, every triangle in T_i contains at least two vertices from $\{x_1, x_2, \dots, x_{2l+1}\}$.

To justify (4), we apply induction on i. For $i = 0$, since $S \cap V(T_0) = \{x_1, x_2, \dots, x_{2l+1}\}$ and $|S \cap V(C)| \ge 2$ for every triangle C of T_0 (by hypothesis), the desired statement follows. Suppose we have established the assertion for T_{i-1}. Let us proceed to the induction step for T_i. Let $xyzx$ be an arbitrary triangle in T_i. Set $Q = \{x, y, z\}$ if $y'_i \notin \{x, y, z\}$ and $Q = (\{x, y, z\} - \{y'_i\}) \cup \{y_i\}$ otherwise. It follows from (1*) and (2*) that Q induces a triangle in T_{i-1}. So it contains at least two vertices from $\{x_1, x_2, \ldots, x_{2l+1}\}$ by induction hypothesis. We can thus deduce that the triangle $xyzx$ also contains at least two vertices from $\{x_1, x_2, \ldots, x_{2l+1}\}$ as y_i and y'_i are both outside $\{x_1, x_2, \ldots, x_{2l+1}\}$. So (4) is proved.

It can be seen from (2) that the minimum size of an FVS of T_{2l+1} is at least $l+1$. In view of (3), Theorem 1.1 (which is equivalent to Theorem 1.4(i)) guarantees the existence of at least $l+1$ vertex-disjoint triangles in T_{2l+1}. By (4), each of these $l+1$ triangles contains at least two vertices from $\{x_1, x_2, \ldots, x_{2l+1}\}$. Hence the size of $\{x_1, x_2, \ldots, x_{2l+1}\}$ is at least $2(l+1)$, which is a contradiction.

Since there are $O(|V|^3)$ triangles altogether in T, it takes $O(|V|^3)$ time to find the edge set of G. From the proof we see that G is a bipartite graph. Since the two color classes of G can be obtained in linear time by using depth first search, R can be found in $O(|V|^3)$ time. □

LEMMA 2.4. *Let $T = (V, A)$ be a tournament with no subtournament isomorphic to F_1 nor F_2. Suppose S is a subset of V that contains at least two vertices from every triangle in T. Then $V(C) \nsubseteq V(\mathscr{D}_S)$ for every triangle $C \in \mathscr{F}_S$.*

Proof. We may assume that T is strongly connected; otherwise, we turn to consider the strongly connected components of T separately. Thus V admits a partition $V_1, V_2, \ldots, V_k$ as described in Lemma 2.1. For every $v \in V$, we use $l(v)$ to denote the index i such that $v \in V_i$. Let $D = (V, B)$ be the digraph obtained from T by deleting all arcs from V_j to V_i with $i \leq j-2$; in other words, $(u, v) \in B$ if and only if $(u, v) \in A$ and $|l(u) - l(v)| \leq 1$. So each arc (u, v) in D falls into precisely one of the following three categories: We call (u, v) an *upward* arc if $l(u) = l(v) - 1$, a *downward* arc if $l(u) = l(v) + 1$, and a *level* arc if $l(u) = l(v)$. By Lemma 2.1(ii), we have the following:

(1) D contains no triangle. A (directed) path in D is called *upward* if it consists of three vertices and two upward arcs. It follows from Lemma 2.1 that an upward path P in D corresponds to a triangle in T (induced by $V(P)$), and vice versa. By the hypothesis on S, we get

(2) $|V(P) \cap S| \geq 2$ for any upward path P in D. We prove the lemma by contradiction. Assume the contrary: $\{a, b, c\} \subseteq V(\mathscr{D}_S)$ for some triangle $abca \in \mathscr{F}_S$. Suppose $i = l(a) = l(b) - 1 = l(c) - 2$ for some $1 \leq i \leq k-2$. Then (4*) guarantees the existence of three triangles $xx'x''x$, $yy'y''y$, and $zz'z''z$ in $\mathscr{D}_S$ such that $a \in \{x, x', x''\}$, $b \in \{y, y', y''\}$, and $c \in \{z, z', z''\}$ and that

(3) $xx'x''$, $yy'y''$, and $zz'z''$ are upward paths; that is, $l(x) = l(x') - 1 = l(x'') - 2$, $l(y) = l(y') - 1 = l(y'') - 2$, and $l(z) = l(z') - 1 = l(z'') - 2$.

Since each upward path in D corresponds to a triangle in T, it follows from (4*) that

(4) no upward path in D can go through two vertices in $\{a, b, c\}$ and a vertex in $V - S$. In particular, for any $u \in V - S$ and $v \in \{a, b, c\}$ with $|l(u) - l(v)| = 1$, the arc between u and v is downward unless $v \in \{a, c\}$ and $l(u) = i + 1$.

Using (1), (3), (4), and the fact $|\{x, x', x''\} \cap S| = |\{y, y', y''\} \cap S| = |\{z, z', z''\} \cap S| = 2$ (by (3*)), we can enumerate all possible configurations of the three triangles $xx'x''x$, $yy'y''y$, and $zz'z''z$, which are described in (5), (6), and (7), respectively; see Figure 3 for an illustration, where vertices in S are indicated by black points and those outside S by small circles.

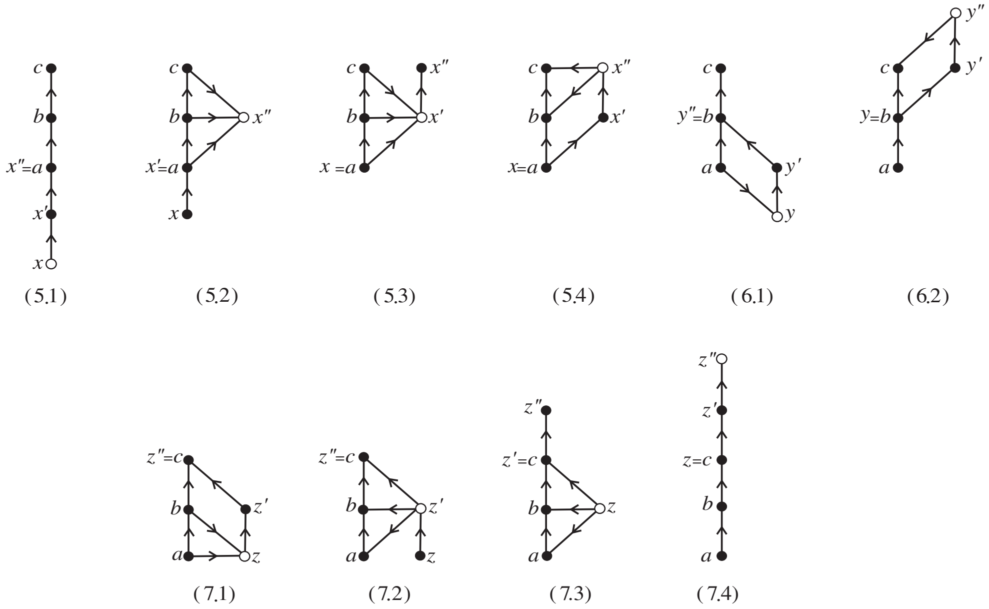

FIG. 3. *Possible configurations of triangles $xx'x''x$, $yy'y''y$, and $zz'z''z$.*

(5) For triangle $xx'x''x$, exactly one of the following holds:

(5.1) $x \in V_{i-2} - S$, $x' \in V_{i-1} \cap S$, $x'' = a \in V_i \cap S$;

(5.2) $x \in V_{i-1} \cap S$, $x' = a \in V_i \cap S$, $x'' \in V_{i+1} - S$, and downward $(c, x'') \in B$, level $(b, x'') \in B$;

(5.3) $x = a \in V_i \cap S$, $x' \in V_{i+1} - S$, $x'' \in V_{i+2} \cap S$, and downward $(c, x') \in B$, level $(b, x') \in B$;

(5.4) $x = a \in V_i \cap S$, $x' \in V_{i+1} \cap S$, $x'' \in V_{i+2} - S$, and downward $(x'', b) \in B$, level $(x'', c) \in B$.

(6) For triangle $yy'y''y$, exactly one of the following holds:

(6.1) $y \in V_{i-1} - S$, $y' \in V_i \cap S$, $y'' = b \in V_{i+1} \cap S$, and downward $(a, y) \in B$;

(6.2) $y = b \in V_{i+1} \cap S$, $y' = V_{i+2} \cap S$, $y'' \in V_{i+3} - S$, and downward $(y'', c) \in B$.

(7) For triangle $zz'z''z$, exactly one of the following holds:

(7.1) $z \in V_i - S$, $z' \in V_{i+1} \cap S$, $z'' = c \in V_{i+2} \cap S$, and downward $(b, z) \in B$, level $(a, z) \in B$;

(7.2) $z \in V_i \cap S$, $z' \in V_{i+1} - S$, $z'' = c \in V_{i+2} \cap S$, and downward $(z', a) \in B$, level $(z', b) \in B$;

(7.3) $z \in V_{i+1} - S$, $z' = c \in V_{i+2} \cap S$, $z'' \in V_{i+3} \cap S$, and downward $(z, a) \in B$, level $(z, b) \in B$;

(7.4) $z = c \in V_{i+2} \cap S$, $z' \in V_{i+3} \cap S$, $z'' \in V_{i+4} - S$.

(8) The following statements hold:

(8.1) Either (5.1) or (6.1) fails;

(8.2) either (6.2) or (7.4) fails;

(8.3) either (5.4) or (6.2) fails;

(8.4) either (6.1) or (7.1) fails.

To justify (8.1), suppose to the contrary that both (5.1) and (6.1) hold. Using (1) and path $x'x''y = x'ay$, we get level $(x', y) \in B$, which in turn gives upward $(x, y) \in B$ (as path $xx'y$ does not correspond to a triangle in D). Thus xyy' is an upward path with x, y outside S, contradicting (2). Hence we have (8.1). Similarly, the violation of (8.2) (resp., (8.3), (8.4)) would give $\{(y'', z'), (y'', z'')\} \subseteq B$ (resp., $\{(x'', y'), (x'', y'')\} \subseteq B$, $\{(y', z), (y, z)\} \subseteq B$) and upward path $y'y''z''$ (resp., $x'x''y''$, yzz'), contradicting (2) again.

(9) The following statements hold:

(9.1) Either (5.1) or (7.1) fails;

(9.2) either (5.4) or (7.4) fails.

Indeed, if both (5.1) and (7.1) hold, then, using (1) and path $x'az$, we have upward $(x', z) \in B$ and hence have the upward path $xx'z$ with $\{x, z\} \subseteq V - S$, contradicting (2). Similarly, if both (5.4) and (7.4) hold, then $(x'', z') \in B$, and so the upward path $x''z'z''$ contradicts (2).

(10) The following statements hold:

(10.1) Either (5.4) or (7.2) fails;

(10.2) either (5.3) or (7.1) fails.

Indeed, if both (5.4) and (7.2) hold, then, using (1) and path $z'ax'$, we have level $(z', x') \in B$. In view of path $z'x'x''$, we further have upward $(z', x'') \in B$. Thus $zz'x''$ contradicts (2). Similarly, if both (5.3) and (7.1) hold, then we have level $(z', x') \in B$ and upward $(z, x') \in B$. It follows that the upward path $zx'x''$ contradicts (2).

(11) The following statements hold:

(11.1) Either (5.4) or (7.3) fails;

(11.2) either (5.2) or (7.1) fails.

Indeed, if both (5.4) and (7.3) hold, then, using (1) and paths $x''cz''$ and zax', we have upward $(x'', z'') \in B$ and level $(z, x') \in B$, respectively. Using path $zx'x''$, we obtain upward $(z, x'') \in B$. Thus the upward path $zx''z''$ contradicts (2). Similarly, if both (5.2) and (7.1) hold, then we have $\{(x, z), (z', x''), (z, x'')\} \subseteq B$. Thus the upward path xzx'' contradicts (2).

(12) Either (5.4) or (6.2) holds.

Suppose otherwise; then from (6) and (5), we see that (6.1) and one of (5.1)–(5.3) hold. In view of (8.1), we further conclude that (5.2) or (5.3) holds. From (5.2) and (5.3), it follows that $\{u\} = \{x', x''\} \cap V_{i+1} \subseteq V - S$ and $(b, u) \in B$ is level. Using (1) and path $y'y''u$, we have upward $(y', u) \in B$ and hence the upward path $yy'u$ with $\{y, u\} \subseteq V - S$, contradicting (2).

(13) Either (6.1) or (7.1) holds.

Suppose otherwise; then (6) and (7) imply that (6.2) and one of (7.2)–(7.4) hold. Using (8.2), we further conclude that (7.2) or (7.3) holds. By (7.2) and (7.3), we have $\{u\} = \{z, z'\} \cap V_{i+1} - S$ and level $(u, b) \in B$. Using (1) and path $uby' = uyy'$, we get upward $(u, y') \in B$ and hence upward path $uy'y''$, which contradicts (2).

(14) (6.2) holds (so (6.1) fails).

Suppose otherwise; (6.2) fails (so (6.1) holds by (6)). It follows from (12) and (8.4) that (5.4) holds and (7.1) fails. Hence, by (7), one of (7.2), (7.3), and (7.4) holds, which leads to a contradiction to one of (10.1), (11.1), and (9.2).

It follows from (14) and (13) that (7.1) holds, which, together with (9.1) and (10.2), implies that neither (5.1) nor (5.3) holds. Moreover, the combination of (14) and (8.3) yields the failure of (5.4). Thus from (5) we see that (5.2) holds, contradicting (11.2). □

Lemma 2.5. *Let $T = (V, A)$ be a tournament with no subtournament isomorphic to F_1 nor F_2. Suppose S is a subset of V such that $\mathscr{D}_S \cup \mathscr{F}_S \neq \emptyset$ and that $|S \cap V(C)| \geq 2$ for every triangle C of T. Then there exists $R \subseteq S$ such that $|R \cap V(C)| = 1$ for every triangle C in $\mathscr{D}_S \cup \mathscr{F}_S$. Moreover, given S, such an R can be found in $O(|V|^3)$ time.*

Proof. We prove by contradiction. Assume (T, S) is a counterexample with minimum $|S|$. It follows instantly from Lemma 2.3 that $\mathscr{F}_S \neq \emptyset$. Let C_0 be a triangle in $\mathscr{F}_S$. Then Lemma 2.4 guarantees the existence of some $v \in V(C_0)$ with $v \notin V(\mathscr{D}_S)$. By considering $(T, S - \{v\})$, we deduce from the minimality of S that there exists $R \subseteq S - \{v\}$ which contains exactly one vertex from each triangle in $\mathscr{D}_{S-\{v\}} \cup \mathscr{F}_{S-\{v\}}$. Note that $C_0 \in \mathscr{D}_{S-\{v\}}$. So $|R \cap V(C)| = 1$ for every triangle C in $\mathscr{D}_S \cup \mathscr{F}_S$, which is a contradiction.

Let $s_1, s_2, \ldots, s_k$ be all of the vertices in S. We apply the following algorithm to S. While $i \leq k$, do: set $S = S - \{s_i\}$ if s_i is contained in no triangle C such that $|V(C) \cap S| = 2$.

Since there are $O(|V|^2)$ triangles altogether in T containing s_i, each iteration takes $O(|V|^2)$ time, and hence the whole algorithm runs in $O(|V|^3)$ time. Let S' denote the resulting S. From the above proof, we see that $\mathscr{F}_{S'} = \emptyset$ and that $\mathscr{D}_{S'} = \mathscr{D}_S \cup \mathscr{F}_S$, where S is the initial one. By Lemma 2.3 (with S' in place of S over there), we can find a subset R of S' in $O(|V|^3)$ time, such that $|R \cap V(C)| = 1$ for every triangle $C \in \mathscr{D}_{S'}$. This R is clearly as desired. $\square$

Now we are ready to establish the min-max relation.

Proof of Theorem 1.2. We shall actually show that statements (ii) and (iii) in Theorem 1.4 are equivalent. For convenience, we use the following notations in our proof. Given a tournament $T = (V, A)$ and a weight function $w \in \mathbf{Z}_+^V$, let τ_w denote the minimum weight of a triangle in T, and let ν_w denote the maximum size of a w-FVS packing of T. Recall that we always have

(1) $\nu_w \leq \tau_w$.

(ii)⇒(iii) Suppose the contrary: $T = (V, A)$ contains a subtournament F isomorphic to F_1 or F_2. Define $w \in \boldsymbol{Z}_+^V$ as $w(v) = 1$ for each $v \in V$. Then $\tau_w = 3$. It is easy to see that each FVS of T contains at least two vertices in F. Since $|V(F)| = 5$, we have $\nu_w \leq 2$. Hence $\tau_w \neq \nu_w$, contradicting (ii).

(iii)⇒(ii) Let $T = (V, A)$ be a tournament with no F_1 nor F_2. To prove that $\nu_w = \tau_w$ for any $w \in \boldsymbol{Z}_+^V$, we apply induction on $|V|$.

The min-max relation holds trivially when $|V| \leq 3$. So we proceed to the induction step and assume that we have already proved the assertion for any tournament with no F_1 nor F_2 and with fewer vertices than T.

To establish the induction step, we apply induction on τ_w. Clearly, $\tau_w = \nu_w$ if $\tau_w = 0$. So we assume $\tau_w > 0$ and distinguish between two cases.

Case 1. $w(z) \geq \tau_w$ for some vertex $z \in V$. Set $w' = w|_{V-\{z\}}$. By the induction hypothesis on $T \backslash z$ (with respect to the weight function w'), we get $\nu_{w'} = \tau_{w'}$. So it can be seen that

- either $T \backslash z$ is acyclic,
- or there exists a w'-FVS packing $\mathcal{S}'$ of $T \backslash z$ with size τ_w (for $\tau_{w'} \geq \tau_w$).

In the former case, define $\mathcal{S}$ to be the multiset consisting of τ_w copies of $\{z\}$; in the latter case, define $\mathcal{S} := \{S' \cup \{z\} : S' \in \mathcal{S}'\}$. Then $\mathcal{S}$ is a collection of FVSs of T with size τ_w, which clearly yields a w-FVS packing of T with size τ_w (by the assumption of case 1). So by (1) we have $\nu_w = \tau_w$.

Case 2. $w(z) < \tau_w$ for any vertex $z \in V$. Set $S := \{v \in V : w(v) \geq 1\}$. It follows from the assumption of the present case that

(2) $|S \cap V(C)| \geq 2$ for every triangle C in T.

In view of (2), the set of triangles of T is the disjoint union of three sets $\mathscr{D}_S$, $\mathscr{F}_S$, and $\mathscr{F}_S^+$ (recall (3*)–(5*)). It follows from the definition of $\mathscr{F}_S^+$ that

(3) all triangles C with $\sum_{v \in V(C)} w(v) = \tau_w$ are contained in $\mathscr{D}_S \cup \mathscr{F}_S$.

By Lemma 2.5, there exists $R \subseteq S$ such that $|R \cap V(C)| = 1$ for every triangle C in $\mathscr{D}_S \cup \mathscr{F}_S$. From the definition of $\mathscr{F}_S^+$, we see that R is an FVS of T. Set $\delta = \min\{w(v) : v \in R\}$. Then $\delta \geq 1$. Define $w' \in \boldsymbol{Z}_+^V$ as $w'(v) = w(v) - \delta|R \cap \{v\}|$ for all $v \in V$.

(4) $\tau_{w'} = \tau_w - \delta$.

To justify (4), it suffices to show that $|R \cap V(C)| \leq 2$ for every $C \in \mathscr{F}_S^+$ (by (3) and the selection of R). It is the case since any such C shares with some triangle in $\mathscr{D}_S$ two vertices, one of which is in $S - R$. So (4) follows.

By the induction hypothesis on $\tau_{w'}$ and by (4), T has a w'-FVS packing $\mathcal{S}$ of size $\tau_w - \delta$. Clearly, $\{R, R, \ldots, R\} \cup \mathcal{S}$ is a collection of FVSs of T with size τ_w, where the multiplicity of R is δ. This collection clearly yields a w-FVS packing of T with size τ_w. So by (1) we have $\nu_w = \tau_w$.

Combining the above two cases, we complete the proof of the induction step and hence our min-max theorem. □

3. NP-completeness.

For convenience, let us call the problem addressed in Theorem 1.6 the *partition problem.* We show its NP-completeness in this section.

Proof of Theorem 1.6. Clearly, the partition problem is in NP. To prove the assertion, we appeal to the following Not-All-Equal 3-Satisfiability problem (Not-All-Equal-3SAT): Given n Boolean variables $\lambda_1, \lambda_2, \ldots, \lambda_n$ and m clauses $c_1, c_2, \ldots, c_m$ in CNF, each of which contains exactly three literals (variables or their negation), determine whether there exists an assignment of Boolean values to the variables such that for each clause at least one literal is true and at least one literal is false. It was shown by Schaefer [16] that Not-All-Equal-3SAT is NP-complete. Our objective is to reduce Not-All-Equal-3SAT to the partition problem.

For this purpose, let $\lambda_1, \lambda_2, \ldots, \lambda_n$ be the set of variables, and let $c_1, c_2, \ldots, c_m$ be the set of clauses in an arbitrary instance of Not-All-Equal-3SAT. We propose to construct a tournament T with $5n + 3m + 3$ vertices such that the vertex set of T can be partitioned into two FVSs if and only if $c_1 \wedge c_2 \wedge \cdots \wedge c_m$ is satisfiable (with respect to Not-All-Equal-3SAT). The construction goes as follows (see Figures 4 and 5 for an illustration):

(i) To every variable λ_i, $1 \leq i \leq n$, we associate a tournament X_i with vertex set

$$V(X_i) = \{x_i^h : h = 1, 2, 3, 4, 5\}$$

and arc set

$$A(X_i) = \{(x_i^g, x_i^h) : 1 \leq g < h \leq 5 \text{ and } (g, h) \notin \{(1,5), (2,4)\}\} \cup \{(x_i^5, x_i^1), (x_i^4, x_i^2)\};$$

(ii) to every clause $c_j = c_j^1 \vee c_j^2 \vee c_j^3$, $1 \leq j \leq m$, we associate a triangle $Z_j = z_j^1 z_j^2 z_j^3 z_j^1$;

(iii) let $V := (\cup_{i=1}^n V(X_i)) \cup V(Y) \cup (\cup_{j=1}^m V(Z_j))$, where $Y = y_1 y_2 y_3 y_1$ is a triangle, and all X_i's, Y, and Z_j's are pairwise disjoint;

(iv) to every $z = z_l^k \in \cup_{j=1}^m V(Z_j)$, $1 \leq k \leq 3$, $1 \leq l \leq m$, we associate an arc α_z from z_l^k to x_i^1 if $c_l^k = \lambda_i$ and from z_l^k to x_i^5 if $c_l^k = \bar{\lambda}_i$;

(v) let A be the disjoint union of $\cup_{i=1}^n A(X_i)$, $A(Y)$, $\cup_{j=1}^m (A(Z_j) \cup \{\alpha_z : z \in V(Z_j)\})$, and $\{(u, v) : u \text{ and } v \text{ satisfy one of (a)–(e)}\}$:

(a) $u \in V(X_i)$, $v \in V(X_{i'})$, and $i < i'$;

(b) $u \in \cup_{i=1}^n V(X_i)$ and $v \in V(Y)$;

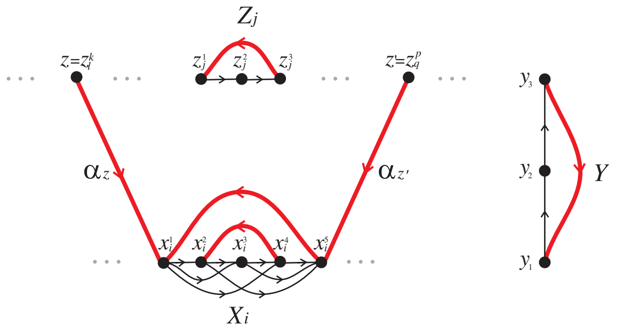

FIG. 4. *An illustration of constructions* (i)–(iv), *where* $c_l^k = \lambda_i$ *and* $c_q^p = \bar{\lambda}_i$.

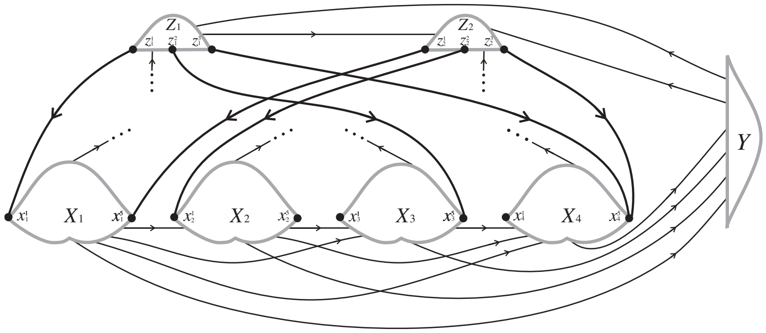

FIG. 5. *Tournament* T *resulting from the instance* $(\lambda_1 \vee \bar{\lambda}_3 \vee \bar{\lambda}_4) \wedge (\bar{\lambda}_1 \vee \lambda_2 \vee \bar{\lambda}_4)$.

(c) $u \in \cup_{i=1}^{n} V(X_i)$, $v \in \cup_{j=1}^{m} V(Z_j)$, and α_v is not directed to u;
(d) $u \in V(Y)$ and $v \in \cup_{j=1}^{m} V(Z_j)$;
(e) $u \in V(Z_j)$, $v \in V(Z_{j'})$, and $j < j'$.

The construction is completed. It is easy to see that the construction can be accomplished in polynomial time, and the resulting digraph $T = (V, A)$ is a tournament. The tournament T resulting from the NOT-ALL-EQUAL-3SAT instance with $n = 4$, $m = 2$, $c_1 = \lambda_1 \vee \bar{\lambda}_3 \vee \bar{\lambda}_4$, and $c_2 = \bar{\lambda}_1 \vee \lambda_2 \vee \bar{\lambda}_4$ is illustrated in Figure 5.

Let us define a linear order $\prec$ on the vertex set of T as follows: $x_1^1 \prec x_1^2 \prec x_1^3 \prec x_1^4 \prec x_1^5 \prec x_2^1 \prec x_2^2 \prec x_2^3 \prec x_2^4 \prec x_2^5 \prec \cdots \prec x_n^1 \prec x_n^2 \prec x_n^3 \prec x_n^4 \prec x_n^5 \prec y_1 \prec y_2 \prec y_3 \prec z_1^1 \prec z_1^2 \prec z_1^3 \prec z_2^1 \prec z_2^2 \prec z_2^3 \prec \cdots \prec z_m^1 \prec z_m^2 \prec z_m^3$. Observe

(1) Set

$$\begin{aligned} B := {} & \{(x_i^5, x_i^1), (x_i^4, x_i^2) : 1 \le i \le n\} \cup \{(y_3, y_1)\} \\ & \cup \{(z_j^3, z_j^1) : 1 \le j \le m\} \cup \{\alpha_z : z \in \cup_{j=1}^{m} V(Z_j)\}. \end{aligned}$$

(In Figure 4, the arcs in B are bold lined.) Then for any $u, v \in V$ with $u \prec v$, arc $(v, u) \in A$ if and only if $(v, u) \in B$;

(2) for every $1 \le i \le n$, there are four triangles

$$X_i^1 = x_i^2 x_i^3 x_i^4 x_i^2 \text{and } X_i^h = x_i^1 x_i^h x_i^5 x_i^1,\ h = 2, 3, 4,$$

altogether in tournament X_i; and

(3) for every $z \in \cup_{j=1}^{m} V(Z_j)$, there are three triangles Y_z^i, $i = 1, 2, 3$, altogether in T through α_z and y_i.

It follows from (1) that every triangle in T contains one or two arcs in B. Furthermore, since no two arcs in $B - \{\alpha_z : z \in \cup_{j=1}^m V(Z_j)\}$ have a common end, from the construction of T and (2) we see that

(4) every triangle of T is either in $\{X_i^h : 1 \le h \le 4, 1 \le i \le n\} \cup \{Y\} \cup \{Z_j : 1 \le j \le m\}$ or contains α_z for some $z \in \cup_{j=1}^m V(Z_j)$.

Now we are ready to show that the vertex set of T can be partitioned into two FVSs if and only if the Not-All-Equal-3SAT instance $c_1 \wedge c_2 \wedge \cdots \wedge c_m$ is satisfiable.

Sufficiency. Suppose there is a truth assignment for $\{\lambda_1, \lambda_2, \ldots, \lambda_n\}$ such that each clause c_j, $1 \le j \le m$, contains at least one true literal and at least one false literal. Set

- $X := \{x_i^1 : \lambda_i \text{ is true}, 1 \le i \le n\} \cup \{x_i^5 : \lambda_i \text{ is false}, 1 \le i \le n\}$;
- $\bar{X} := \{x_i^1 : \lambda_i \text{ is false}, 1 \le i \le n\} \cup \{x_i^5 : \lambda_i \text{ is true}, 1 \le i \le n\}$;
- $Z := \{z \in \cup_{j=1}^m V(Z_j) : \alpha_z = (z, x), x \in X\}$; and
- $\bar{Z} := \cup_{j=1}^m V(Z_j) - Z = \{z \in \cup_{j=1}^m V(Z_j) : \alpha_z = (z, x), x \in \bar{X}\}$.

It is easy to see that

(5) $|X \cap V(X_i^h)| = |\bar{X} \cap V(X_i^h)| = 1$ for every $h = 2, 3, 4$ and $1 \le i \le n$;

(6) for every $z \in \cup_{j=1}^m V(Z_j)$, if the head of α_z is in X (resp., $\bar{X}$), then its tail is in Z (resp., $\bar{Z}$); and

(7) V is the disjoint union of two sets
   - $S_1 := X \cup \bar{Z} \cup \{x_i^2 : 1 \le i \le n\} \cup \{y_1\}$ and
   - $S_2 := \bar{X} \cup Z \cup \{x_i^3, x_i^4 : 1 \le i \le n\} \cup \{y_2, y_3\}$.

We claim that both S_1 and S_2 are FVSs of T. To justify this, let C be an arbitrary triangle C of T. Let us show that C meets both S_1 and S_2. By (5) and (6), the statement holds if $C \in \{X_i^h : h = 2, 3, 4;\ 1 \le i \le n\}$ or if C contains some α_z. If $C = X_i^1$ for some $1 \le i \le n$, then we derive from (2) and (7) that $x_i^2 \in V(C) \cap S_1$ and $x_i^3 \in V(C) \cap S_2$. If $C = Y$, then $y_1 \in V(C) \cap S_1$ and $y_2 \in V(C) \cap S_2$. So by (4) it remains to consider the case when $C = Z_j$ for some $1 \le j \le m$. Recall that c_j^h is true and c_j^i is false for some $1 \le h \ne i \le 3$. From (iv) and the definitions of X and $\bar{X}$, we deduce that $x \in X$ and $x' \in \bar{X}$, where (z_j^h, x) and (z_j^i, x') are arcs associated to z_j^h and z_j^i, respectively, as described in (iv). It follows from (6) and (7) that $z_j^h \in Z \cap V(C) \subseteq S_2 \cap V(C)$ and $z_j^i \in \bar{Z} \cap V(C) \subseteq S_1 \cap V(C)$. Therefore both S_1 and S_2 are FVSs of T, as claimed. By (7), we are done.

Necessity. Suppose the vertex set of T can be partitioned into two FVSs S_1 and S_2. For $1 \le i \le n$, set λ_i to be true if $x_i^1 \in S_1$ and false otherwise. Let us show that this assignment enables every c_j, $1 \le j \le m$, to contain at least one true literal and at least one false literal. To this end, we first show that

(8) $|\{x_i^1, x_i^5\} \cap S_1| = |\{x_i^1, x_i^5\} \cap S_2| = 1$ for all $1 \le i \le n$.

Indeed, by (2), we have $x_i^g \in S_1 \cap V(X_i^1)$ and $x_i^h \in S_2 \cap V(X_i^1)$ for some $2 \le g \ne h \le 4$. This, in turn, implies that $\{x_i^1, x_i^5\} \cap S_2 \ne \emptyset$ and $\{x_i^1, x_i^5\} \cap S_1 \ne \emptyset$ by considering triangles $X_i^g = x_i^1 x_i^g x_i^5 x_i^1$ and $X_i^h = x_i^1 x_i^h x_i^5 x_i^1$. So (8) is established.

Next we observe that

(9) $|\{x, z\} \cap S_1| = |\{x, z\} \cap S_2| = 1$ for all $\alpha_z = (z, x)$ with $z \in \cup_{j=1}^m V(Z_j)$ and $x \in \{x_i^1, x_i^5 : 1 \le i \le n\}$.

Indeed, by (iii) and the definition of S_1 and S_2, triangle $y_1 y_2 y_3 y_1$ contains $y_g \in S_1$ and $y_h \in S_2$ for some $1 \le g \ne h \le 3$. Recall (3), T contains triangles $Y_z^i = x y_i z x$, $i = 1, 2, 3$. Now using triangles Y_z^g and Y_z^h, we obtain $\{x, z\} \cap S_2 \ne \emptyset$ and $\{x, z\} \cap S_1 \ne \emptyset$. Hence (9) holds.

For $1 \le j \le m$, by (ii) triangle Z_j contains some $z_j^g \in S_1$ and $z_j^h \in S_2$. Suppose (z_j^g, x) and (z_j^h, x') are arcs associated to z_j^g and z_j^h, respectively, as described in (iv), where $\{x, x'\} \subseteq \{x_i^1, x_i^5 : 1 \leq i \leq n\}$. It follows from (9) that $x \in S_2$ and $x' \in S_1$. Suppose $x \in \{x_i^1, x_i^5\}$ for some $1 \leq i \leq n$.

- If $x = x_i^1$, then, by (iv), $c_j^g = \lambda_i$ is false as $x_i^1 \notin S_1$;
- if $x = x_i^5$, then, by (8), $x_i^1 \in S_1$. So λ_i is true, and hence, by (iv), $c_j^g = \bar{\lambda}_i$ is false.

Therefore c_j^g is false (in either case). Similarly, it can be deduced from $x' \in S_1$ that c_j^h is true. Hence c_j contains both false literal c_j^g and true literal c_j^h; equivalently, $c_1 \wedge c_2 \wedge \cdots \wedge c_m$ is satisfiable, completing the proof. □

4. Algorithms. For simplicity, we use the same notations as introduced before. In particular, given a tournament $T = (V, A)$ and a weight function $w \in \mathbf{Z}_+^V$, let τ_w denote the minimum weight of a triangle in T, and let ν_w denote the maximum size of a w-FVS packing of T.

For the case when T contains no F_1 nor F_2, we present the following algorithm for finding an optimal w-FVS packing of size ν_w.

Algorithm Opt_Pack OPTIMAL_FVS_PACKING

```
Input   A tournament $T = (V, A)$ with no $F_1$ nor $F_2$ and a weight $w \in \boldsymbol{Z}_+^V$
Output  A maximum $w$-FVS packing $\mathcal{S}$ of $T$ with $|\mathcal{S}| = \nu_w$
  1. $\tau_w \leftarrow$ the minimum weight of a triangle in $T$
  2. if $\tau_w = 0$ or $T$ is acyclic, then return $\mathcal{S} \leftarrow \emptyset$
  3. if $\exists\, z \in V$ with $w(z) \geq \tau_w$, then
  4.     if $T \backslash z$ is acyclic, then return $\mathcal{S} \leftarrow \{S_i : S_i = \{z\},\ i = 1, 2, \ldots, \tau_w\}$
  5.                 else $\{S_i : 1 \leq i \leq \tau_{w|_{V-\{z\}}}\} \leftarrow$ Opt_Pack$(T \backslash z, w|_{V-\{z\}})$
                          return $\mathcal{S} \leftarrow \{\{z\} \cup S_i : 1 \leq i \leq \tau_w\}$
  6. $S \leftarrow \{v \in V : w(v) \geq 1\}$, $R \leftarrow$ a subset of $S$ with $|R \cap V(C)| = 1$ for all
     $C \in \mathscr{D}_S \cup \mathscr{F}_S$
  7. $\delta \leftarrow \min\{w(v) : v \in R\}$, $w'(v) \leftarrow w(v) - \delta|R \cap \{v\}|$ for all $v \in V$
  8. return $\mathcal{S} \leftarrow \{S_i : S_i = R,\ i = 1, 2, \ldots, \delta\} \cup$ Opt_Pack$(T, w')$
```

Remark. Note that $\mathcal{S}$ is a collection of FVSs of T with size ν_w, which obviously yields a w-FVS packing of T with the same size.

THEOREM 4.1. *Let $T = (V, A)$ be a tournament with no F_1 nor F_2. Then Algorithm* OPTIMAL_FVS_PACKING *solves the FVS packing problem on T exactly in $O(|V|^4)$ time.*

Proof. The correctness of the algorithm follows instantly from the proof of Theorem 1.2. Let us now estimate the time complexity of the algorithm.

Note that either in steps 3–5 one vertex z is eliminated from our consideration or in step 7 the weight of at least one vertex becomes zero (from nonzero one). So the whole algorithm takes $O(|V|)$ iterations. From Lemma 2.5, we can conclude that each iteration takes $O(|V|^3)$ time. Hence the total running time of the algorithm is $O(|V|^4)$. □

Let us proceed to the FVS packing problem on a general tournament T. For this general case, we can easily obtain a 1/3-approximation algorithm: Set $R = \emptyset$. While T contains a triangle C, do: let v be a vertex in $V(C)$ of maximum weight. Set $R = R \cup \{v\}$ and $T = T \backslash v$. Obviously, $\{R, R, \ldots, R\}$, where the multiplicity of R is $\min\{w(v) : v \in R\}$, is an FVS packing in the original T with size at least $\frac{1}{3}\nu_w$. By exploiting the structural characterization given in our min-max theorem and using the above exact algorithm as a subroutine, we can obtain a better approximation algorithm based on the subgraph removal technique.

Algorithm Apx_Pack APPROXIMATE_FVS_PACKING

```
Input   A tournament $T = (V, A)$ and a weight $w \in \boldsymbol{Z}_+^V$
Output  A $w$-FVS packing $\mathcal{S}$ of $T$ with $|\mathcal{S}| \geq \frac{2}{5}\nu_w$
   1. $\tau_w \leftarrow$ the minimum weight of a triangle in $T$, $R \leftarrow \emptyset$
   2. if $\tau_w = 0$ or $T$ is acyclic, then return $\mathcal{S} \leftarrow \emptyset$
   3. while $T$ contains a subtournament $F$ isomorphic to $F_1$ or $F_2$ do
   4.         $v \leftarrow$ a vertex in $V(F)$ of maximum weight, $R \leftarrow R \cup \{v\}$, $T \leftarrow T \backslash v$
   5. end-while
   6. $\mathcal{S}' = \{S_i : 1 \leq i \leq \tau_{w|_{V(T)}}\} \leftarrow$ Opt_Pack$(T, w|_{V(T)})$, $\delta \leftarrow \min\{w(v) : v \in R\}$
   7. if $\mathcal{S}' = \emptyset$, then return $\mathcal{S} \leftarrow \{S_i : S_i = R, i = 1, 2, \ldots, \delta\}$
   8.             else return $\mathcal{S} \leftarrow \{S_i \cup R : i = 1, 2, \ldots, \min\{\tau_{w|_{V(T)}}, \delta\}\}$
```

Remark. Again $\mathcal{S}$ is a collection of FVSs of T, which obviously yields a w-FVS packing of T with the same size.

THEOREM 4.2. *Let $T = (V, A)$ be an arbitrary tournament. Then Algorithm* APPROXIMATE_FVS_PACKING *approximates the FVS packing problem on T within a factor of* $2/5$ *in $O(|V|^4)$ time.*

Proof. Clearly, $\mathcal{S}$ is a collection of FVSs of T. To get the approximation ratio, it suffices to prove that

(1) $|\mathcal{S}| \geq \frac{2}{5}\nu_w$.

For this purpose, we turn to show that

(2) $\delta \geq \frac{2}{5}\nu_w$ if $\delta > 0$.

To justify (2), let u be a vertex in R with $w(u) = \delta$. Suppose u is added to R because of subtournament F (recall the while-loop of the algorithm), and suppose $\mathcal{S}^*$ is a w-FVS packing of T with size ν_w. Since we need to delete at least two vertices in F in order to destroy all triangles in F, each FVS in $\mathcal{S}^*$ contains at least two vertices in F. From the definition of a w-FVS packing, we deduce that $2|\mathcal{S}^*| \leq \sum_{v \in V(F)} w(v)$. Since u is a vertex with maximum weight in F and $|V(F)| = 5$, we have $2\nu_w = 2|\mathcal{S}^*| \leq 5w(u) = 5\delta$, yielding (2).

To establish (1), we may assume $\tau_w > 0$, for otherwise the statement holds trivially. So we have $\delta > 0$ when $R \neq \emptyset$. If $\mathcal{S}' = \emptyset$, then it follows from (2) and step 7 of the algorithm that (1) holds. Otherwise, $\tau_{w|_{V(T)}}$ in step 6 of the algorithm is at least $\tau_w (\geq \nu_w)$. Thus from step 8 of the algorithm we can also conclude (1).

It was shown in [1] that F in step 3 can be obtained in $O(|V|^2)$ time if it exists. Thus we deduce from Theorem 4.1 that APPROXIMATE_FVS_PACKING runs in $O(|V|^4)$ time. □

It is easy to see that Theorems 1.7 and 1.8 follow from the above two theorems, respectively.

5. Concluding remarks.

In this paper we have characterized all tournaments T with Mengerian hypergraph $b(\mathcal{C}_T)$. Coincidently, $b(\mathcal{C}_T)$ is Mengerian if and only if $\mathcal{C}_T$ is. Major open problems in this research direction are to characterize all digraphs G with Mengerian $\mathcal{C}_G$ and those with Mengerian $b(\mathcal{C}_G)$. The arc versions of these problems are equally interesting. While these problems are extremely hard in general, Guenin and Thomas [14] successfully characterized all digraphs that pack, where a digraph G *packs* if for any subdigraph H of G the maximum number of disjoint cycles is equal to the minimum number of vertices in a feedback vertex set in H. Guenin strongly believes that the blocker version of their theorem holds on exactly the same digraphs.

Conjecture 5.1 ([13]). *A digraph G packs if and only if for any subdigraph H of G the maximum number of disjoint feedback vertex sets is equal to the length of the shortest cycle in H.*

We close this paper by the aforementioned Woodall's conjecture on packing feedback arc sets.

Conjecture 5.2 ([20]). *In any planar digraph the maximum number of disjoint feedback arc sets is equal to the length of the shortest cycle.*

Certainly, these two beautiful conjectures deserve arduous research efforts.

Acknowledgment. The authors are grateful to two anonymous referees for their invaluable comments and suggestions.

THE POWER OF STRONG FOURIER SAMPLING: QUANTUM ALGORITHMS FOR AFFINE GROUPS AND HIDDEN SHIFTS[*]

CRISTOPHER MOORE[†], DANIEL ROCKMORE[‡], ALEXANDER RUSSELL[§], AND LEONARD J. SCHULMAN[¶]

Abstract. Many quantum algorithms, including Shor's celebrated factoring and discrete log algorithms, proceed by reduction to a *hidden subgroup problem*, in which an unknown subgroup H of a group G must be determined from a quantum state ψ over G that is uniformly supported on a left coset of H. These hidden subgroup problems are typically solved by *Fourier sampling*: the quantum Fourier transform of ψ is computed and measured. When the underlying group is nonabelian, two important variants of the Fourier sampling paradigm have been identified: the *weak standard method*, where only representation *names* are measured, and the *strong standard method*, where full measurement (i.e., the row and column of the representation, in a suitably chosen basis, as well as its name) occurs. It has remained open whether the strong standard method is indeed stronger, that is, whether there are hidden subgroups that can be reconstructed via the strong method but *not* by the weak, or any other known, method. In this article, we settle this question in the affirmative. We show that hidden subgroups H of the q-hedral groups, i.e., semidirect products $\mathbb{Z}_q \ltimes \mathbb{Z}_p$, where $q \mid (p-1)$, and in particular the affine groups A_p, can be information-theoretically reconstructed using the strong standard method. Moreover, if $|H| = p/\text{polylog}(p)$, these subgroups can be fully reconstructed with a polynomial amount of quantum and classical computation. We compare our algorithms to two weaker methods that have been discussed in the literature—the "forgetful" abelian method, and measurement in a random basis—and show that both of these are weaker than the strong standard method. Thus, at least for some families of groups, it is crucial to use the full power of representation theory and nonabelian Fourier analysis, namely, to measure the high-dimensional representations in an *adapted basis* that respects the group's subgroup structure. We apply our algorithm for the hidden subgroup problem to new families of cryptographically motivated *hidden shift problems*, generalizing the work of van Dam, Hallgren, and Ip on shifts of multiplicative characters. Finally, we close by proving a simple closure property for the class of groups over which the hidden subgroup problem can be solved efficiently.

Key words. quantum computation, hidden subgroup problem, Fourier analysis, group representations

1. The hidden subgroup problem.

One of the principal quantum algorithmic paradigms is the use of the abelian Fourier transform to discover a function's hidden periodicities. In the examples relevant to quantum computing, an oracle function f defined on an abelian group G has "hidden periodicity" if there is a "hidden" subgroup H of G so that f is precisely invariant under translation by H or, equivalently, f is constant on the cosets of H and takes distinct values on distinct cosets. The *hidden*

subgroup problem is the problem of determining the subgroup H from such a function. Algorithms for these problems typically adopt the approach detailed below, called *Fourier sampling* [3].

Step 1. Prepare two registers, the first in a uniform superposition over the elements of a group G and the second with the value zero, yielding the state

$$\psi_1 = \frac{1}{\sqrt{|G|}} \sum_{g \in G} |g\rangle \otimes |0\rangle \,.$$

Step 2. Calculate (or, if it is an oracle, query) the function f defined on G and XOR it with the second register. This entangles the two registers and results in the state

$$\psi_2 = \frac{1}{\sqrt{|G|}} \sum_{g \in G} |g\rangle \otimes |f(g)\rangle \,.$$

Step 3. Measure the second register. This produces a uniform superposition over one of f's level sets, i.e., the set of group elements g for which $f(g)$ takes the measured value f_0. As the level sets of f are the cosets of H, this puts the first register in a uniform distribution over superpositions on one of those cosets, namely cH, where $f(c) = f_0$ for some f_0. Moreover, it disentangles the two registers, resulting in the state $\psi_3 \otimes |f_0\rangle$, where ψ_3 is a so-called *coset state*,

$$\psi_3 = |cH\rangle = \frac{1}{\sqrt{|H|}} \sum_{h \in H} |ch\rangle \,.$$

Alternately, since the value f_0 we observe has no bearing on the algorithm, we can use the formulation in which the environment, rather than the user, measures f. In that case, tracing over f yields a mixed state with density matrix

$$\rho_H = \frac{1}{[G:H]} \sum_{f_0} |\psi_3\rangle \langle\psi_3| = \frac{1}{|G|} \sum_{c} |cH\rangle \langle cH| \,,$$

i.e., a classical mixture consisting of one pure state ψ_3 for each coset. Kuperberg refers to this as the *coherent* hidden subgroup problem [18].

Step 4. Carry out the quantum Fourier transform on ψ_3 or ρ_H and measure the result.

For example, in Simon's algorithm [26], the "ambient" group G over which the Fourier transform is performed is $\mathbb{Z}_2^n$, f is an oracle with the promise that $f(x) = f(x+y)$ for some y, and $H = \{0, y\}$ is a subgroup of order 2. In Shor's factoring algorithm [25] G is the group $\mathbb{Z}_n^*$, where n is the number we wish to factor, $f(x) = r^x \bmod n$ for a random $r < n$, and H is the subgroup of $\mathbb{Z}_n^*$ of index order(r). (However, since $|\mathbb{Z}_n^*|$ is unknown, Shor's algorithm actually performs the transform over $\mathbb{Z}_q$, where q is polynomially bounded by n; see [25] or [11, 12].)

These are all abelian instances of the *hidden subgroup problem* (HSP). Interest in *nonabelian* versions of the HSP evolved from the relation to the elusive Graph Automorphism problem: if one could efficiently solve the HSP over the symmetric group S_n, this would yield an efficient quantum algorithm for graph automorphism (see, e.g., Jozsa [16] for a review). This was the impetus behind the development of the first nonabelian quantum Fourier transform [2] and is, in part, the reason that the nonabelian HSP has remained such an active area of research in quantum algorithms.

In general, we will say that the HSP for a family of groups G has a *Fourier sampling* algorithm if a procedure similar to that outlined above works. Specifically, the algorithm prepares a coset state as defined above,

$$|cH\rangle = \frac{1}{\sqrt{|H|}} \sum_{h \in H} |ch\rangle \,,$$

over a random coset cH of the hidden subgroup H, computes the (quantum) Fourier transform of this state, and measures the result. After a polynomial number of such trials, a polynomial amount of classical computation, and, perhaps, a polynomial number of classical queries to the function h to confirm the result, the algorithm produces a set of generators for the subgroup H with high probability.

When G is abelian, measuring a state's Fourier transform has a clear meaning: one observes the frequency χ with probability equal to the squared magnitude of the transform at that frequency. In the case where G is a *nonabelian* group, however, in order to define a full measurement it is necessary to select bases for each representation of G. (We explain this in more detail below.) The subject of this article is the relationship between this choice of basis and the information gleaned from the measurement: are some bases more useful for computation than others?

Since we are typically interested in exponentially large groups, we will take the size of our input to be $n = \log |G|$. Throughout, "polynomial" means polynomial in n and thus polylogarithmic in $|G|$.

1.1. Nonabelian hidden subgroup problems. Although a number of interesting results have been obtained on the nonabelian HSP, the groups for which efficient solutions are known remain woefully few. On the positive side, Roetteler and Beth [22] give an algorithm for the wreath product $\mathbb{Z}_2^k \wr \mathbb{Z}_2$. Ivanyos, Magniez, and Santha [15] extend this to the more general case of semidirect products $K \ltimes \mathbb{Z}_2^k$, where K is of polynomial size, and also give an algorithm for groups whose commutator subgroup is of polynomial size. Friedl, Ivanyos, Magniez, Santha, and Sen [8] solve a problem they call hidden translation and thus generalize this further to what they call "smoothly solvable" groups: these are solvable groups whose derived series is of constant length and whose abelian factors are each the direct product of an abelian group of bounded exponent and one of polynomial size. (See also section 8.)

In another vein, Ettinger and Høyer [6] show that the HSP is solvable for the dihedral groups in an *information-theoretic* sense; namely, a polynomial number of quantum queries to the function oracle gives enough information to reconstruct the subgroup, but the best known reconstruction algorithm takes exponential time. More generally, Ettinger, Høyer, and Knill [7] show that for *arbitrary* groups the HSP can be solved information-theoretically with a finite number of quantum queries. However, their algorithm calls for a quantum measurement for each possible subgroup, and since there might be $|G|^{\Omega(\log |G|)}$ of these, it requires an exponential number of quantum operations.

Our current understanding of the HSP, then, divides group families into three classes.

I. *Fully reconstructible.* Subgroups of a family of groups $\{G_i\}$ are *fully reconstructible* if the HSP can be solved with high probability by a quantum circuit of size polynomial in $\log |G_i|$.

II. *Information-theoretically reconstructible.* Subgroups of a family of groups $\{G_i\}$ are *information-theoretically reconstructible* if the solution to the HSP for G_i is determined information-theoretically by the fully measured result of a quantum circuit of size polynomial in $\log |G_i|$.

III. *Quantum information-theoretically reconstructible.* Subgroups of a family of groups $\{G_i\}$ are *quantum information-theoretically reconstructible* if the solution to the HSP for G_i is determined by the quantum state resulting from a quantum circuit of polynomial size in $\log |G_i|$, in the sense that there exists a positive operator-valued measurement (POVM) that yields the subgroup H with constant probability but where it may or may not be possible to carry out this POVM with a quantum circuit of polynomial size.

In each case, the quantum circuit has oracle access to a function $f : G \to S$, for some set S, with the property that f is constant on each left coset of a subgroup H and distinct on distinct cosets.

In this language, then, subgroups of abelian groups are fully reconstructible, while the result of [7] shows that subgroups of arbitrary groups are quantum information-theoretically reconstructible. The other work cited above has labored to place specific families of nonabelian groups into the more algorithmically meaningful classes I and II.

1.2. Nonabelian Fourier transforms. In this section we give a brief review of nonabelian Fourier analysis but only to the extent needed to set down notation. We refer the reader to [9, 24] for a more complete exposition.

Fourier analysis over a finite abelian group A expresses a function $\phi : A \to \mathbb{C}$ as a linear combination of homomorphisms $\chi : A \to \mathbb{C}$. If $A = \mathbb{Z}_p$, for example, these are the familiar basis functions $\chi_t : z \mapsto \omega_p^{tz}$, where ω_p denotes the pth root of unity $\mathrm{e}^{2\pi i/p}$. Any function $\phi : A \to \mathbb{C}$ can be uniquely expressed as a linear combination of these χ_t, and this change of basis is the Fourier transform.

When G is a nonabelian group, however, this same procedure cannot work: in particular, there are not enough homomorphisms of G into $\mathbb{C}$ to span the space of all $\mathbb{C}$-valued functions on G. To define a sufficient basis, the representation theory of finite groups considers more general functions, namely homomorphisms from G into groups of unitary matrices.

A *representation* of a finite group G is a homomorphism $\rho : G \to \mathrm{U}(d)$, where $\mathrm{U}(d)$ denotes the group of unitary $d \times d$ matrices (with entries from $\mathbb{C}$); the dimension $d = d_\rho$ is referred to as the *dimension* of ρ. If $\rho : G \to \mathrm{U}(d)$ is a representation, a subspace W of $\mathbb{C}^d$ is said to be *invariant* if $\rho(g)(W) \subset W$ for all g. A representation is said to be *irreducible* if the only invariant subspaces are the trivial subspaces $\mathbb{C}^d$ and $\{\vec{0}\}$.

For a function $\phi : G \to \mathbb{C}$ and an irreducible representation ρ, $\hat{\phi}(\rho)$ denotes *the Fourier transform of* ϕ *at* ρ and is defined by

$$\hat{\phi}(\rho) = \sqrt{\frac{d_\rho}{|G|}} \sum_g \phi(g)\rho(g).$$

Note that ϕ takes values in $\mathbb{C}$ while ρ is matrix-valued. It is a fact that a finite group has a finite number of distinct irreducible representations up to isomorphism (i.e., up to a unitary change of basis). The *Fourier transform* of a function $\phi : G \to \mathbb{C}$ is then the collection of matrices $\hat{\phi}(\rho)$, taken over all nonisomorphic irreducible representations ρ.

Fixing a group G and a subgroup H, we shall focus primarily on the functions

$\varphi_c : G \to \mathbb{C}$ of the form

$$\varphi_c(g) = \begin{cases} 1/\sqrt{|H|} & \text{if } g \in cH, \\ 0 & \text{otherwise,} \end{cases}$$

corresponding to the first register of the state ψ_3 resulting from Step 3 above, which is a uniform superposition over the coset cH. The Fourier transform of such a function is

$$\widehat{\varphi_c}(\rho) = \sqrt{\frac{d_\rho}{|G||H|}}\, \rho(c) \cdot \sum_{h \in H} \rho(h).$$

Note, as above, that $\widehat{\varphi_c}(\rho)$ is a $d_\rho \times d_\rho$ matrix.

For any subgroup H, the sum $\sum_h \rho(h)$ is precisely $|H|$ times a projection operator (see, e.g., [13]); we write

$$\sum_h \rho(h) = |H|\, \pi_H(\rho).$$

With this notation, we can express $\widehat{\varphi_c}(\rho)$ as $\sqrt{n_\rho}\, \rho(c) \cdot \pi_H(\rho)$, where $n_\rho = d_\rho |H|/|G|$. For a $d \times d$ matrix M, we let $\|M\|$ denote the matrix norm given by

$$\|M\|^2 = \mathbf{tr}\left(M^\dagger M\right) = \sum_{ij} |M_{ij}|^2,$$

where $M^\dagger$ denotes the conjugate transpose of M. Then the probability that we observe the representation ρ is

$$\begin{aligned} \|\widehat{\varphi_c}(\rho)\|^2 &= \left\|\sqrt{n_\rho}\, \rho(c)\, \pi_H(\rho)\right\|^2 \\ &= n_\rho \left\|\pi_H(\rho)\right\|^2 \\ &= n_\rho\, \mathbf{rk}\, \pi_H(\rho), \end{aligned} \tag{1}$$

where $\mathbf{rk}\, \pi_H(\rho)$ denotes the rank of the projection operator $\pi_H(\rho)$. See [13] for more discussion.

1.3. Weak vs. strong sampling and the choice of basis. Hallgren, Russell, and Ta-Shma [13] show that by measuring only the *names* of representations—the so-called *weak standard method* in the terminology of [10]—it is possible to reconstruct normal subgroups (and thus solve the HSP for *Hamiltonian groups*, all of whose subgroups are normal). More generally, this method reconstructs the *normal core* of a subgroup, i.e., the intersection of all its conjugates. On the other hand, they show that this is insufficient to solve Graph Automorphism, since even in an information-theoretic sense this method cannot distinguish between the trivial subgroup of S_n and subgroups of order 2 consisting of the identity and an involution.

Therefore, in order to solve the HSP for nonabelian groups, we need to measure not just the name of the representation we are in but also the row and column. In order for this measurement to be well defined, we need to choose a basis for $\mathrm{U}(d_\rho)$ for each ρ. Grigni, Schulman, Vazirani, and Vazirani [10] call this the *strong standard method*. They show that if we measure using a uniformly *random* basis, then trivial and nontrivial subgroups are still information-theoretically indistinguishable. However, they leave open the question of whether the strong standard method with a clever choice of basis, rather than a random one, allows us to solve the HSP in nonabelian groups, yielding an algorithm for Graph Automorphism.

Indeed, from a computational perspective the representation theory of a finite group G does distinguish certain "preferred" bases, those which give the matrices $\rho(g)$ unusually structured or sparse form. In particular, Moore, Rockmore, and Russell [20] showed that so-called *adapted bases* yield highly efficient algorithms for the quantum Fourier transform.

1.4. Contributions of this paper. As stated above, [13] and [10] leave an important open question, namely, whether there are cases where the strong standard method, with the proper choice of basis, offers an advantage over a simple abelian transform or the weak standard method. We settle this question in the affirmative. Our results deal primarily with the *q-hedral* groups, i.e., semidirect products of the form $\mathbb{Z}_q \ltimes \mathbb{Z}_p$, where $q \mid (p-1)$, and in particular the *affine* groups $A_p \cong \mathbb{Z}_p^* \ltimes \mathbb{Z}_p$.

We begin in section 3 by focusing on full reconstructibility. We define the *hidden conjugate problem* (HCP) as follows: given a group G, a nonnormal subgroup H, and a function which is promised to be constant on the cosets of some conjugate $H^b = bHb^{-1}$ of H (and distinct on distinct cosets), determine the subgroup H^b by finding an element $c \in G$ so that $H^c = H^b$. We adopt the above classification (fully, information-theoretically, quantum information-theoretically) for this problem in the natural way. Then we show that given a subgroup of sufficiently small (but still exponentially large) index, hidden conjugates in A_p are fully reconstructible (Theorem 1). This almost immediately implies that, for prime $q = (p-1)/\text{polylog}(p)$, subgroups of the q-hedral groups $\mathbb{Z}_q \ltimes Z_p$ are fully reconstructible (Theorem 2).

Section 4 concerns itself with information-theoretic reconstructibility. We generalize the results of Ettinger and Høyer on the dihedral group and show that hidden conjugates of any subgroup are information-theoretically reconstructible in the affine groups and, more generally, the q-hedral groups for all q (Theorem 3). We then show that we can identify the order, and thus the conjugacy class, of a hidden subgroup, and this implies that all subgroups of the affine and q-hedral groups are information-theoretically reconstructible (Theorem 5).

The results of sections 3 and 4 rely crucially on measuring the high-dimensional representations of the affine and q-hedral groups in a well-chosen basis, namely an *adapted* basis that respects the group's subgroup structure. We show in section 5 that we lose information-theoretic reconstructibility if we measure in a *random* basis instead. Specifically, we need an exponential number of measurements to distinguish conjugates of small subgroups of A_p. This establishes for the first time that the strong standard method is indeed stronger than measuring in a random basis: some bases provide much more information about the hidden subgroup than others.

For some nonabelian groups, the HSP can be solved with a "forgetful" approach, where we erase the group's nonabelian structure and perform an abelian Fourier transform instead. In section 6 we show that this is not the case for the affine groups. Specifically, if we treat A_p as a direct product rather than a semidirect one, its conjugate subgroups become indistinguishable.

As an application, in section 7 we consider *hidden shift* problems. In the setting we consider, one must reconstruct a "hidden shift" $s \in \mathbb{Z}_p$ from an oracle $f_s(x) = f(x-s)$, where f is any function that is constant on the (multiplicative) cosets of a known multiplicative subgroup of $\mathbb{Z}_p^*$. These functions have been studied in some depth for their pseudorandom properties, and several instances have been suggested as cryptographically strong pseudorandom generators. By associating f_s with its isotropy subgroup, and using our reconstruction algorithm to find that subgroup, we give an efficient quantum algorithm for the hidden shift problem in the case where $f(x)$ is a function of x's multiplicative order mod r for some $r = \text{polylog}(p)$. This generalizes the work of van Dam, Hallgren, and Ip [4], who give an algorithm for hidden shift problems in the case where f is precisely a multiplicative character.

Finally, in section 8 we show that the set of groups for which the HSP can be solved in polynomial time has the following closure property: if $\mathcal{H} = \{H_n\}$ is a family of groups for which we can efficiently solve the HSP and $\mathcal{K} = \{K_n\}$ is a family of groups for which $|K_n| = \text{polylog}(|H_n|)$, we can also efficiently solve the HSP for the family $\{G_n\}$, where each G_n is any extension of K_n by H_n. This subsumes the results of [13] on Hamiltonian groups, and also those of [15] on groups with commutator subgroups of polynomial size.

We note that subsequent to this work, Bacon, Childs, and van Dam [1] found additional algorithms for the HSP in the affine groups. Their approach uses the "pretty good measurement," which they showed is optimal for certain cases of the HSP (see also [21]). Their work extends to a number of other group families, such as the Heisenberg groups.

2. The affine and *q*-hedral groups. Let A_p be the *affine group*, consisting of ordered pairs $(a, b) \in \mathbb{Z}_p^* \times \mathbb{Z}_p$, where p is prime, under the multiplication rule $(a_1, b_1) \cdot (a_2, b_2) = (a_1a_2, b_1 + a_1b_2)$. A_p can be viewed as the set of affine functions $f_{(a,b)} : \mathbb{Z}_p \to \mathbb{Z}_p$ given by $f_{(a,b)} : x \mapsto ax + b$ where multiplication in A_p is given by function composition. Structurally, A_p is a semidirect product $\mathbb{Z}_p^* \ltimes \mathbb{Z}_p \cong \mathbb{Z}_{p-1} \ltimes \mathbb{Z}_p$. Its subgroups can be described as follows:

- Let $N \cong \mathbb{Z}_p$ be the normal subgroup of size p consisting of elements of the form $(1, b)$. Geometrically, this is the set of affine functions with slope 1.
- Let $H \cong \mathbb{Z}_p^* \cong \mathbb{Z}_{p-1}$ be the nonnormal subgroup of size $p - 1$ consisting of the elements of the form $(a, 0)$. Geometrically, this is the set of lines passing through the origin.
- For each $b \in \mathbb{Z}_p$, the conjugate subgroup $H^b = (1, b) \cdot H \cdot (1, -b)$ consists of elements of the form $(a, (1 - a)b)$. In the action on $\mathbb{Z}_p$, H^b is the stabilizer of b; geometrically, H^b is the set of lines intersecting the diagonal at (b, b).
- If $a \in \mathbb{Z}_p^*$ has order q, where q divides $p - 1$, let $N_q \cong \mathbb{Z}_q \ltimes \mathbb{Z}_p$ be the normal subgroup consisting of all elements of the form (a^t, b). Geometrically, N^q is the set of lines whose slope is a power of a.
- Similarly, if $a \in \mathbb{Z}_p$ has order q, let H_q be the nonnormal subgroup $H_q = \langle (a, 0) \rangle$ of size q. Then H_q consists of the elements of the form $(a^t, 0)$, and its conjugates $H_q^b = (1, b) \cdot H_q \cdot (1, -b)$ consist of the elements of the form $(a^t, (1-a^t)b)$. Geometrically, these are the subsets of H and H^b, respectively, consisting of lines whose slope is a power of a.

Construction of the representations of A_p requires that we fix a generator γ of $\mathbb{Z}_p^*$. Define $\log : \mathbb{Z}_p^* \to \mathbb{Z}_{p-1}$ to be the isomorphism $\log \gamma^t = t$. Let ω_p denote the pth root of unity $e^{2\pi i/p}$. Then A_p has $p - 1$ one-dimensional representations σ_s, namely the representations of $\mathbb{Z}_p^* \cong \mathbb{Z}_{p-1}$ given by $\sigma_t((a, b)) = \omega_{p-1}^{t \log a}$. In addition, A_p has one $(p - 1)$-dimensional representation ρ given by

$$\rho((a, b))_{j,k} = \begin{cases} \omega_p^{bj}, & k = aj \bmod p, \\ 0 & \text{otherwise}, \end{cases} \quad 1 \le j, k < p, \tag{2}$$

where the indices i and j are elements of $\mathbb{Z}_p^*$. See [24, section 8.2] for a more detailed discussion.

Similarly, given a prime p and a divisor q of $p-1$, we consider the *q-hedral groups*, namely semidirect products $\mathbb{Z}_q \ltimes \mathbb{Z}_p$. These embed in A_p in a natural way, namely, as the normal subgroups N_q defined above. The *dihedral* groups are the special case where $q = 2$.

The representations of $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ include the q one-dimensional representations of $\mathbb{Z}_q$ given by $\sigma_\ell((a^t, b)) = \omega_q^{\ell t}$ for $\ell \in \mathbb{Z}_q$ and the $(p-1)/q$ distinct q-dimensional representations ρ_k given by

$$\rho_k((a^u, b))_{s,t} = \begin{cases} \omega_p^{ka^s b}, & t = s + u \bmod q, \\ 0 & \text{otherwise} \end{cases}$$

for each $0 \leq s, t < q$. Here k ranges over the elements of $\mathbb{Z}_p^*/\mathbb{Z}_q$, or, to put it differently, k takes values in $\mathbb{Z}_p^*$, but ρ_k and $\rho_{k'}$ are isomorphic if k and k' are in the same coset of $\langle a \rangle$.

The representations of the affine and q-hedral groups are related as follows. The restriction of the $(p-1)$-dimensional representation ρ of A_p to N_q is reducible and is isomorphic to the direct product of the ρ_k. Moreover, if we measure ρ in a *Gel'fand–Tsetlin* basis such as (2) which is *adapted* to the tower of subgroups

$$A_p > N_q > \{1\},$$

then ρ becomes block-diagonal, with $(p-1)/q$ blocks of size q, and these blocks are exactly the representations ρ_k of N_q. (See [20] for an introduction to adapted bases and their uses in quantum computation.) We will use this fact in sections 4 and 5 below.

The affine and q-hedral groups are *metacyclic* groups, i.e., extensions of a cyclic group $\mathbb{Z}_p$ by a cyclic group $\mathbb{Z}_q$. In [14], Høyer shows how to perform the nonabelian Fourier transform over such groups (up to an overall phase factor) with a polynomial, i.e., polylog(p), number of elementary quantum operations.

3. Full reconstructibility. In this section we show that conjugates of sufficiently large subgroups of the affine groups are fully reconstructible in polynomial time. For some values of p and q, this allows us to completely solve the HSP for the q-hedral group $\mathbb{Z}_q \ltimes \mathbb{Z}_p$.

THEOREM 1. *Let p be prime and let q be a divisor of $p-1$ for which $(p-1)/q =$ polylog(p). Then the hidden conjugates H_q^b of H_q in A_p are fully reconstructible.*

Proof. First, consider the maximal nonnormal subgroup $H = \langle(\gamma, 0)\rangle$, where γ is a generator of $\mathbb{Z}_p^*$. Carrying out Steps 1 through 3 of the Fourier sampling procedure outlined in the introduction results in a state ψ_3 over the group G which is uniformly supported on a random left coset of the conjugate H^b. Using the procedure of [14], we now compute the quantum Fourier transform of this state over A_p in the basis (2). The associated projection operator is

$$\pi_{H^b}(\rho)_{j,k} = \frac{1}{p-1}\,\omega_p^{b(j-k)}$$

for $1 \leq j, k < p$. This is a circulant matrix of rank 1. More specifically, every column is some root of unity times the vector

$$(u_b)_j = \frac{1}{p-1}\,\omega_p^{bj},$$

$1 \leq j < p$. This is also true of $\rho(c) \cdot \pi_{H^b}(\rho)$; since $\rho(c)$ has one nonzero entry per column, left multiplying by $\rho(c)$ simply multiplies each column of $\pi_{H^b}(\rho)$ by a phase. Note that in this case

$$n_\rho = d_\rho |H|/|G| = (p-1)/p = 1 - 1/p,$$

and so by (1) we observe the $(p-1)$-dimensional representation ρ with overwhelming probability $1 - 1/p$.

Assuming that we observe ρ, we perform another change of basis: namely, we Fourier transform each column by left multiplying $\rho(cH)$ by the unitary matrix

$$Q_{\ell,j} = \frac{1}{\sqrt{p-1}} \, \omega_{p-1}^{-\ell j}.$$

In terms of quantum operations, we apply the quantum Fourier transform over $\mathbb{Z}_{p-1}$ to the row register, while leaving the column register unchanged. We can now infer b by measuring the frequency ℓ. Specifically, we observe a given value of ℓ with probability

$$(3) \qquad P(\ell) = \left| \frac{1}{p-1} \sum_{j=1}^{p-1} \omega_p^{bj} \omega_{p-1}^{-\ell j} \right|^2 = \frac{1}{(p-1)^2} \left| \sum_{j=1}^{p-1} \mathrm{e}^{2i\theta j} \right|^2 = \frac{1}{(p-1)^2} \frac{\sin^2 (p-1)\theta}{\sin^2 \theta},$$

where

$$\theta = \left(\frac{b}{p} - \frac{\ell}{p-1} \right) \pi.$$

Now note that for any b there is an ℓ such that $|\theta| \leq \pi/(2(p-1))$. Since

$$(2x/\pi)^2 \leq \sin^2 x \leq x^2$$

for $|x| \leq \pi/2$, this gives $P(\ell) \geq (2/\pi)^2$.

Recall that the probability that we observed the $(p-1)$-dimensional representation ρ in the first place is $n_\rho = 1 - 1/p$. Thus if we measure ρ, the column, and then ℓ and then guess that b minimizes $|\theta|$, we will be correct with constant probability. This can be boosted to high probability, i.e., $1 - o(1)$, by repeating the experiment a polynomial number of times. Alternately, we can use a POVM rather than the von Neumann measurement presented here and obtain the correct value of b with high probability in a single measurement [1].

Now consider the more general case, where the hidden subgroup is a conjugate of the subgroup H_q of order q. For convenience, let $\langle (a, 0) \rangle$ be a generator for H_q; then a given conjugate H_q^b consists of the elements of the form $(a^t, (1 - a^t)b)$. We have

$$\pi_{H_q^b}(\rho)_{j,k} = \frac{1}{q} \begin{cases} \omega_p^{b(j-k)}, & k = a^t j \text{ for some } t, \\ 0 & \text{otherwise} \end{cases}$$

for $1 \leq j, k < p$. In other words, the nonzero entries are those for which j and k lie in the same coset of $\langle a \rangle \subset \mathbb{Z}_p^*$. The rank of this projection operator is thus the number of cosets equal to the index $(p-1)/q$ of $\langle a \rangle$ in $\mathbb{Z}_p^*$. Since n_ρ is now q/p, we again observe ρ with probability

$$n_\rho \, \mathbf{rk} \, \pi_{H_q}(\rho) = (p-1)/p = 1 - 1/p.$$

Following the same procedure as before, we carry out a partial measurement on the columns of ρ and then Fourier transform the rows. After changing the variable of summation from t to $-t$ and adding a phase shift of $\mathrm{e}^{-i\theta(p-1)}$ inside the $|\cdot|^2$, we obtain the probability that we observe a frequency ℓ conditional on finding ourselves in the kth column:

$$P(\ell) = \left| \frac{1}{\sqrt{q(p-1)}} \sum_{t=0}^{q-1} \omega_p^{b(a^t k \bmod p)} \omega_{p-1}^{-\ell(a^t k \bmod p)} \right|^2 = \frac{1}{q(p-1)} \left| \sum_{t=0}^{q-1} \mathrm{e}^{2i\theta(a^t k \bmod p)} \right|^2 . \tag{4}$$

Now note that the terms in the sum are of the form $\mathrm{e}^{i\phi}$, where (assuming without loss of generality that θ is positive)

$$\phi \in [-\theta(p-1), \theta(p-1)].$$

If we again take ℓ so that $|\theta| \leq \pi/(2(p-1))$, then $\phi \in [-\pi/2, \pi/2]$ and all the terms in the sum have nonnegative real parts. We will obtain a lower bound on the real part of the sum by showing that a constant fraction of the terms have $\phi \in (-\pi/3, \pi/3)$ and thus have real part more than 1/2. This is the case whenever $a^t k \in (p/6, 5p/6)$, and so it is sufficient to prove the following lemma.

LEMMA 1. *Let a have order $q = p/\mathrm{polylog}(p)$ in $\mathbb{Z}_p^*$, where p is prime. Then at least $(1/3 - o(1))q$ of the elements in the coset $\langle a \rangle k$ are in the interval $(p/6, 5p/6)$.*

Proof. We will prove this using *Gauss sums*, which quantify the interplay between the characters of $\mathbb{Z}_p$ and the characters of $\mathbb{Z}_p^*$. In particular, Gauss sums establish bounds on the distribution of powers of a. Specifically, if a has order q in $\mathbb{Z}_p^*$, then for any integer $k \not\equiv 0 \bmod p$ we have

$$\sum_{t=0}^{q-1} \omega_p^{a^t k} = O(p^{1/2}) = o(p).$$

(See [17] and Appendix A.)

Now suppose s of the elements x in $\langle a \rangle k$ are in the set $(p/6, 5p/6)$, for which $\mathrm{Re}\, \omega_p^x \geq -1$, and the other $q - s$ elements are in $[0, p/6] \cup [5p/6, p)$, for which $\mathrm{Re}\, \omega_p^x \geq 1/2$. Thus we have

$$\mathrm{Re} \sum_{t=0}^{q-1} \omega_p^{a^t k} \geq \ (q/2) - \ (3s/2).$$

If $s \leq (1/3 - \epsilon)q$ for any $\epsilon > 0$, this is $\Theta(q)$, a contradiction. ∎

Now that we know that a fraction $1/3 - \epsilon$ of the terms in (4) have real part at least 1/2 and the others have real part at least 0, we can take $\epsilon = 1/12$ (say) and write

$$P(\ell) \geq \frac{1}{q(p-1)} \left(\frac{q}{8}\right)^2 = \frac{1}{64} \frac{q}{p-1} = \frac{1}{\mathrm{polylog}(p)}.$$

Thus we observe the correct frequency with polynomially small probability, and this can be boosted to high probability by a polynomial number of repetitions. ∎

As we will now show, Theorem 1 implies that we can completely solve the HSP for certain q-hedral groups.

THEOREM 2. *Let p and q be prime with $q = (p-1)/\mathrm{polylog}(p)$. Then subgroups of the q-hedral group $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ are fully reconstructible.*

Proof. First, note that we can fully reconstruct H if it is nontrivial and normal. We do this by reconstructing the normal core of H,

$$C(H) = \bigcap_{\gamma \in G} \gamma H \gamma^{-1},$$

using the techniques of [13] (the weak standard method). The q-hedral groups have the special property that nonnormal subgroups contain no nontrivial normal subgroups; in particular, if H is nonnormal, then $C(H)$ is the trivial subgroup. Thus by reconstructing $C(H)$, we either learn that $H = C(H)$ or learn that H is either trivial or nonnormal. Furthermore, if H is trivial, we will learn this by checking our reconstruction against the oracle f and finding that it is incorrect. Therefore, it suffices to consider the nonnormal subgroups.

If q is prime, then the nonnormal subgroups of $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ are all conjugate to a single subgroup $K \cong \mathbb{Z}_q$, as any such subgroup has the form $\{(a, (1-a)z) \mid a \in \mathbb{Z}_q < \mathrm{Aut}(\mathbb{Z}_p) \cong \mathbb{Z}_p^*\}$; in this case the HSP reduces to the HCP for K. While one can construct a proof similar to that of Theorem 1 directly for the q-hedral groups, it is convenient to embed them in A_p using the isomorphisms $N_q \cong \mathbb{Z}_q \ltimes \mathbb{Z}_p$ and $H_q \cong K$ and appeal to Theorem 1.

Now suppose we have an oracle $f : \mathbb{Z}_q \times \mathbb{Z}_p \to S$. We extend this to an oracle f' on A_p as follows. Choose a generator $\gamma \in \mathbb{Z}_p^*$ and one of the $q-1$ elements $a \in \mathbb{Z}_p^*$ of order q, and let

$$f' : A_p \to S \times \langle a \rangle,$$

where

$$f'((a,b)) = \left(f\left(\left(\left\lfloor \frac{\log a}{(p-1)/q} \right\rfloor, b \right) \right), a^q \right),$$

recalling that $\log \gamma^t = t$. The second component of f' serves to distinguish the cosets of N_q from each other, while the first component maps each coset of N_q to $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ with the element of $\mathbb{Z}_q$ written additively, rather than multiplicatively. (This last step is not strictly necessary—after all, we could have written the elements of A_p in additive form in the first place—but it can be carried out with Shor's algorithm for the discrete logarithm [25].) This reduces the HCP for K (and therefore the HSP) on $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ to the HCP for H_q on A_p, completing the proof. □

As an example of Theorem 2, if q is a *Sophie Germain* prime, i.e., one for which $p = 2q + 1$ is also a prime, we can completely solve the HSP for $\mathbb{Z}_q \ltimes \mathbb{Z}_p$.

4. Information-theoretic reconstructibility. In this section, we show that *all* subgroups of the affine and q-hedral groups, regardless of their size, are information-theoretically reconstructible. We start by considering the HCP for subgroups H_q in A_p. Then in Theorem 5 we show that we can identify the conjugacy class of a hidden subgroup and therefore the subgroup itself. This generalizes the results of Ettinger and Høyer [6], who show information-theoretic reconstructibility for the dihedral groups, i.e., the case $q = 2$.

THEOREM 3. *Let p be prime and let q divide $p-1$. Then the hidden conjugates of H_q in A_p are information-theoretically reconstructible.*

Proof. Suppose $a \in \mathbb{Z}_p^*$ has order q. Recall that H_q and its conjugates H_q^b are maximal in the subgroup $N_q \cong \mathbb{Z}_q \ltimes \mathbb{Z}_p$. We wish to show that there is a measurement whose outcomes, given two distinct values of b, have large (i.e., $1/\text{polylog}(p)$) total variation distance. First, we perform a series of partial measurements as follows:

(i) Measure the name of the representation of A_p. If this is not ρ, try again. Otherwise, continue.

(ii) Measure the name of the representation ρ_k of N_q inside ρ.

(iii) Measure the column of ρ_k.

(iv) Perform a POVM with q outcomes, in each of which the row $s \in \mathbb{Z}_q$ is u or $(u+1) \bmod q$.

As in Theorem 1, we measure the $(p-1)$-dimensional representation of A_p in a chosen basis. Recall that in the adapted basis (2) the restriction of ρ to N_q is block-diagonal, where the $(p-1)/q$ blocks are the q-dimensional representations ρ_k of N_q. Therefore, the projection operator $\pi_{H_q^b}(\rho)$ is block-diagonal, and each of its blocks is one of the projection operators $\pi_{H_q^b}(\rho_k)$. Summing ρ_k over $H_q^b = \{(a^t, (1-a^t)b)\}$ gives

$$\left(\pi_{H_q^b}(\rho_k)\right)_{s,t} = \frac{1}{q}\,\omega_p^{k(a^s-a^t)b}$$

for $0 \le s,t < q$. This is a matrix of rank 1, where each column (even after left multiplication by $\rho_k(c)$) is some root of unity times the vector $(u_k)_s = (1/q)\ \omega_p^{ka^s b}$. Since $n_\rho = q/p$, the probability that we observe a particular ρ_k is q/p. Since $\pi_{H_q^b}(\rho)$ has $(p-1)/q$ blocks of this kind, it has rank $(p-1)/q$, and the total probability that we observe ρ is $(p-1)/p = 1-1/p$ as before.

Then these four partial measurements determine k, remove the effect of the coset, and determine that the row has one of two values, u or $u+1$. Up to an overall phase we can write this as a two-dimensional vector:

$$\frac{1}{\sqrt{2}}\begin{pmatrix} \omega_p^{ka^u b} \\ \omega_p^{ka^{u+1} b} \end{pmatrix}.$$

Our only goal in doing this is to create a one-qubit state where the relative phase between the two basis vectors depends on the conjugate b. Moreover, the relative phase is multiplied by the irrep label k, which is uniformly random. As a result, the typical angle between the states corresponding to any two distinct cosets b, b' will be $\Omega(1)$, and a simple measurement yields a constant variation distance between them.

To make this precise, apply the Hadamard transform

$$\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$$

and measure according to the resulting basis. The probability that we observe the first or second basis vector is then $\cos^2\theta$ and $\sin^2\theta$, respectively, where $\theta = (ka^u(a-1)b\pi)/p$. Now when we observe a q-dimensional representation ρ_k of N_k, the observed label k is uniformly distributed over $\mathbb{Z}_p^*/\mathbb{Z}_q$. Moreover, when we perform the POVM in step (iv) above, the u we observe is uniformly distributed over $\mathbb{Z}_q$. It follows that the coefficient $m = ka^u(u-1)$ is uniformly distributed over $\mathbb{Z}_p^*$. For any two distinct b, b', the total variation distance is then

$$\frac{1}{2(p-1)}\sum_{m\in\mathbb{Z}_p^*}\left(\left|\cos^2\frac{\pi mb}{p} - \cos^2\frac{\pi mb'}{p}\right| + \left|\sin^2\frac{\pi mb}{p} - \sin^2\frac{\pi mb'}{p}\right|\right).$$

This we rewrite

$$\frac{1}{p-1}\sum_{m\in\mathbb{Z}_p^*}\left|\cos^2\frac{\pi mb}{p}-\cos^2\frac{\pi mb'}{p}\right|$$

$$=\frac{1}{2(p-1)}\sum_{m\in\mathbb{Z}_p}\left|\cos\frac{2\pi mb}{p}-\cos\frac{2\pi mb'}{p}\right|$$

$$\geq\frac{1}{4(p-1)}\sum_{m\in\mathbb{Z}_p}\left(\cos\frac{2\pi mb}{p}-\cos\frac{2\pi mb'}{p}\right)^2$$

$$=\frac{p}{4(p-1)}>\frac{1}{4}.$$

(Adding the $m=0$ term contributes zero to the sum in the second line. In the third line we use the facts that $|x|\leq x^2/2$ for all $|x|\leq 2$, the average of $\cos^2 x$ is $1/2$, and the two cosines have zero inner product.)

Since the total variation distance between any two distinct conjugates is bounded below by a constant, we can distinguish between the p different conjugates with only $O(\log p)=\text{poly}(n)$ samples. Thus, hidden conjugates in A_p are information-theoretically reconstructible, completing the proof. □

By embedding the q-hedral groups in A_p as in Theorem 2, we can generalize Theorem 3 to the q-hedral groups (q not necessarily prime) as follows. Let p be prime, let q be a divisor of $p-1$, and let q' be a divisor of q. The q-hedral group $\mathbb{Z}_q\ltimes\mathbb{Z}_p$ has a unique normal subgroup $K\cong\mathbb{Z}_{q'}\ltimes\mathbb{Z}_p$, in which there is a maximal subgroup $H_{q'}$ of order q'. Moreover, all nonnormal subgroups of order q' are conjugates of $H_{q'}$.

THEOREM 4. *If p,q,q', and $H_{q'}$ are as above, then the hidden conjugates of $H_{q'}$ in $\mathbb{Z}_q\ltimes\mathbb{Z}_p$ are information-theoretically reconstructible.*

We now wish to information-theoretically reconstruct all subgroups of the affine and q-hedral groups. We can do this by using the fact that, except for normal subgroups, there is a unique conjugacy class of each order q', namely the conjugates of $H_{q'}$. Thus if we can determine the order of H, this determines its conjugacy class, and we can information-theoretically reconstruct which conjugate it is using, Theorem 3 or Theorem 4.

THEOREM 5. *Subgroups of the q-hedral groups $\mathbb{Z}_q\ltimes\mathbb{Z}_p$, including the affine groups A_p, are information-theoretically reconstructible.*

Proof. As in Theorem 2, we can (fully) reconstruct normal subgroups, and so it suffices to consider nonnormal subgroups H. As discussed above, if we can determine $|H|=q'$, then we know that it is one of the conjugates of $H_{q'}$, and we can reconstruct it information-theoretically using Theorem 3 or Theorem 4.

Now let the oracle be $f:\mathbb{Z}_q\ltimes\mathbb{Z}_p\to S$, and let $p_1^{\alpha_1}\ldots p_k^{\alpha_k}$ be the prime factorization of q, in which case $k\leq\sum_i\alpha_i=O(\log q)$. For each $i\in\{1,\ldots,k\}$ and each $\alpha\in\{0,\ldots,\alpha_i\}$, we will determine if $p_i^\alpha\mid|H|$, and taking the largest such α for each i gives the prime factorization of $|H|$.

To do this, for each $i\in[k]$ and $1\leq\alpha\leq\alpha_i$, let $\Upsilon_i^\alpha:\mathbb{Z}_q\ltimes\mathbb{Z}_p\to\mathbb{Z}_{q/p_i^\alpha}$ be the homomorphism given by

$$\Upsilon_i^\alpha:(a,b)\mapsto a^{p_i^\alpha}.$$

Then let

$$A_i^{\alpha_i} = \ker \Upsilon_i^\alpha = \{\gamma \in \mathbb{Z}_q \ltimes \mathbb{Z}_p \mid \gamma^{p_i^{\alpha_i}} = \mathbf{1}\},$$

where $\mathbf{1}$ denotes the identity element of $\mathbb{Z}_q \ltimes \mathbb{Z}_p$. $A_i^{\alpha_i}$ is the subgroup of $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ consisting of all elements whose orders are a multiple of p_i^α. Now consider the function

$$f' : \mathbb{Z}_q \ltimes \mathbb{Z}_p \to S \times \mathbb{Z}_{q/p_i^\alpha}$$

given by

$$f'(\gamma) = (f(\gamma), \Upsilon_i^\alpha(\gamma))\,.$$

Observe that f' is constant (and distinct) on the left cosets of $H \cap A_i^\alpha$ and, furthermore, the subgroup $H \cap A_i^\alpha$ has order p^α if and only if p^α divides $|H|$. We may then determine if $H \cap A_i^\alpha$ has order p^α by assuming that it does, reconstructing H with Theorem 4 using f' as the oracle, and checking the result against the original oracle f. This allows us to determine the prime factorization of $|H|$ as desired, and the theorem follows. □

As in the dihedral case [6], we know of no polynomial-time algorithm which can reconstruct the most likely b from these queries. However, Kuperberg [18] gives a quantum algorithm for the HSP in the dihedral group, and more generally the hidden shift problem, that runs in subexponential ($e^{O(\log^{1/2} p)}$) time. Since we can reduce the HSP on $\mathbb{Z}_q \ltimes \mathbb{Z}_p$ to a hidden shift problem by focusing on two cosets of $\mathbb{Z}_p$, this algorithm applies to the q-hedral groups as well.

5. Random vs. adapted bases.

In Theorems 3 and 5, we measured the high-dimensional representation ρ in a specific basis which is adapted to the subgroup structure of A_p and the q-hedral groups. In contrast, we show in this section that if we measure ρ in a *random* basis instead, then for all but the largest values of q we need an exponential number of measurements in order to information-theoretically distinguish conjugate subgroups from each other.

THEOREM 6. *Let p be prime and let q be a divisor of $p-1$ for which $q < p^{1-\epsilon}$ for some $\epsilon > 0$. Let $P_b(v)$ be the probability that we observe a basis vector v in the Fourier basis if the hidden subgroup is H_q^b. If we measure ρ in a random basis, then for any two b, b', with high probability the ℓ_1 distance between these probability distributions is exponentially small. In particular, there exists $\beta > 0$, depending only on ϵ, such that*

$$\sum_v |P_b(v) - P_{b'}(v)| < p^{-\beta}.$$

Thus it takes an exponentially large number of measurements to distinguish the conjugates H_q^b and $H_q^{b'}$.

Proof. Since we observe the high-dimensional representation ρ with probability $1-1/p$, it suffices to consider the ℓ_1 distance summed over the $d_\rho = p-1$ basis vectors of ρ. In fact, we will show that $P_b(v)$ is exponentially close to the uniform distribution for all b.

Write $\pi = \pi_{H_q^b}(\rho)$. Then the probability that we observe a given basis vector v, conditioned on observing ρ, is

$$P_b(v) = \frac{1}{\mathbf{rk}\,\pi} |\pi \cdot v|^2\,.$$

If v is uniformly random with norm 1, the expectation of $|\pi \cdot v|_2^2$ is $(\mathbf{rk}\,\pi)/d_\rho$, and so the expectation of $P_b(v)$ is $1/d_\rho$. We will use the following lemma to show that when $\mathbf{rk}\,\pi$ is sufficiently large, $P_b(v)$ is tightly concentrated around this expectation.

LEMMA 2. *Let π be a projection operator of rank r in a d-dimensional space, and let v be a random d-dimensional vector of unit length. Then for all* $0 < \delta < 2$,

$$\Pr\left[\left||\pi \cdot v|_2^2 - \frac{r}{d}\right| > \delta\frac{r}{d}\right] < 4\mathrm{e}^{-r\delta^2/48}.$$

Proof. We use an argument similar to [10]. We can think of a random d-dimensional complex vector v as a random $2d$-dimensional real vector of the same length, and we can think of this in turn as

$$v_i = \frac{w_i}{\sum_{i=1}^{2d} w_i^2},$$

where the w_i are independent Gaussian variables with zero mean and unit variance. By choosing a basis in which π projects onto the first r (complex) components of v, we have

$$|\pi \cdot v|_2^2 = \frac{\sum_{i=1}^{2r} w_i^2}{\sum_{i=1}^{2d} w_i^2} = \frac{r}{d}\frac{(1/2r)\sum_{i=1}^{2r} w_i^2}{(1/2d)\sum_{i=1}^{2d} w_i^2}.$$

Now we use the following Chernoff bound, which can be derived from the moment generating function. For any t, we have

$$\Pr\left[\left|\left(\frac{1}{t}\sum_{i=1}^{t} w_i^2\right) - 1\right| > \epsilon\right] < 2\left[(1+\epsilon)^{1/2}\,\mathrm{e}^{-\epsilon/2}\right]^t.$$

For $|\epsilon| < 1/2$, we have $\ln(1+\epsilon) < \epsilon - \epsilon^2/3$, and this becomes

$$\Pr\left[\left|\left(\frac{1}{t}\sum_{i=1}^{t} w_i^2\right) - 1\right| > \epsilon\right] < 2\mathrm{e}^{-t\epsilon^2/6}. \tag{5}$$

Now, for any a, b, if $|a/b - 1| > \delta$, where $\delta < 2$, then either $|a - 1| > \delta/4$ or $|b - 1| > \delta/4$. Taking the union bound over these events where $a = (1/2r)\sum_{i=1}^{2r} w_i^2$ and $b = (1/2d)\sum_{i=1}^{2d} w_i^2$, setting $\epsilon = \delta/4$ and $t = 2r \le 2d$ in (5) gives the stated bound. □

Setting $d = d_\rho$ and $r = \mathbf{rk}\,\pi$, Lemma 2 and the union bound imply that, for any constant $A > \sqrt{48}$, if

$$\delta = A\sqrt{\frac{\log d_\rho}{\mathbf{rk}\,\pi}}, \tag{6}$$

then, with high probability, for all d_ρ basis vectors v we have

$$\left|P_b(v) - \frac{1}{d_\rho}\right| < \frac{\delta}{d_\rho}.$$

Summing over all v, this implies that the ℓ_1 distance between $P_b(v)$ and the uniform distribution is at most δ. Now recall that $\mathbf{rk}\ \pi = (p-1)/q$. If $q < p^{1-\epsilon}$, then $\mathbf{rk}\ \pi > p^{\epsilon}$, and (6) gives $\delta < p^{-\beta}$, where $\beta = \epsilon/3$, say. Since $P_b(v)$ is within δ of the uniform distribution for all b, doubling the constant A and using the triangle inequality completes the proof. □

Several remarks are in order. First, just as for the dihedral group, we can information-theoretically distinguish conjugate subgroups if we use a random basis *within* each q-dimensional block of ρ. The problem is that rather than having this block-diagonal structure, a random basis cuts across these blocks, mixing different "frequencies" ρ_k and canceling out the useful information. To be more precise, a random basis is not adapted to the subgroup structure of A_p; it does not "know" that ρ decomposes into a direct sum of the ρ_k when restricted to N_q.

Second, it is worth noting that for the values of q for which we have an algorithm for full (as opposed to information-theoretic) reconstruction, namely $q = p/\text{polylog}(p)$, a random basis works as well, since the ℓ_1 distance δ becomes $1/\text{polylog}(p)$. Based on the strong evidence from representation theory that some bases are much better for computation than others, we conjecture that, for some families of groups, adapted bases allow full reconstruction while random bases do not; but this remains an open question.

Third, while we focused above on distinguishing conjugate subgroups from each other, in fact our proof shows that if $q < p^{1-\epsilon}$, a random basis is incapable of distinguishing H_q from the *trivial* subgroup. In contrast, Theorems 3 and 5 show that an adapted basis allows us to do this.

6. Failure of the abelian Fourier transform.

In [6] the abelian Fourier transform over $\mathbb{Z}_2 \times \mathbb{Z}_p$ is used in a reconstruction algorithm for the dihedral groups. Using this sort of "forgetful" abelian Fourier analysis it is similarly information-theoretically possible to reconstruct subgroups of the q-hedral groups when q is small enough.

However, it does not seem possible to reconstruct subgroups of A_p using the abelian Fourier transform. In particular, we show in this section that if we think of the affine group as a direct product $\mathbb{Z}_p^* \times \mathbb{Z}_p$ rather than a semidirect product, then the conjugates of the maximal subgroup become indistinguishable. This is not surprising, since in an abelian group conjugates are identical by definition, but it helps illustrate that nonabelian HSPs require nonabelian approaches (most naturally, in our view, representation theory).

Let us consider the HCP for the maximal subgroup $H = \langle(\gamma, 0)\rangle$, where γ is a generator of $\mathbb{Z}_p^*$. In that case, the characters of $\mathbb{Z}_p^* \times \mathbb{Z}_p$ are simply $\rho_{k,\ell}(\gamma^t, b) = \omega_{p-1}^{kt}\omega_p^{\ell b}$. Summing these over $H_q = \{(z, (1-z)b \mid z \in \mathbb{Z}_p^*\}$ shows that we observe the character (k, ℓ) with probability

$$P(k,\ell) = \frac{1}{p\,(p-1)^2}\left|\sum_{t\in\mathbb{Z}_{p-1}} \omega_{p-1}^{kt}\omega_p^{\ell(1-\gamma^t)b}\right|^2$$

$$= \frac{1}{p\,(p-1)^2}\left|\sum_{x\in\mathbb{Z}_p^*} \omega_{p-1}^{k\log_\gamma x}\omega_p^{-\ell x b}\right|^2 .$$

This is the inner product of a multiplicative character with an additive one, which is another Gauss sum. In particular, assuming $b \neq 0$, we have

$$\begin{aligned} P(0,0) &= 1/p, \\ P(0,\ell \neq 0) &= 1/(p\,(p-1)^2), \\ P(k \neq 0, 0) &= 0, \\ P(k \neq 0, \ell \neq 0) &= 1/(p-1)^2 \end{aligned}$$

(see Appendix A). Since these probabilities do not depend on b, the different conjugates H^b with $b \neq 0$ are indistinguishable from each other. Thus it appears essential to use the nonabelian Fourier transform and the high-dimensional representations of A_p.

7. Hidden shift problems. Using the natural action of the affine group on $\mathbb{Z}_p$, we can apply our algorithm for the HCP studied above to a natural family of *hidden shift problems*. Specifically, let M be a multiplicative subgroup of $\mathbb{Z}_p^*$ of index $r > 1$, let S be some set of $r+1$ symbols, and let $f : \mathbb{Z}_p \to S$ be a function for which

$$f(x) = f(mx) \Leftrightarrow m \in M$$

for every $x \in \mathbb{Z}_p$. Observe that f is constant on the (multiplicative) cosets of M and takes distinct values on distinct cosets; to put it differently, $f(x)$ is an injective function of the multiplicative order of x mod r. Furthermore, $f(0) \neq f(x)$ for any nonzero x. The hidden shift problem associated with f is the problem of determining an unknown element $s \in \mathbb{Z}_p$ given oracle access to the shifted function

$$f_s(x) = f(x - s).$$

Such functions have remarkable pseudorandom properties, and have been proposed as pseudorandom generators for cryptographic purposes, where s acts as the seed to generate the sequence (see, e.g., [5]).

The special case when $f : \mathbb{Z}_p \to \mathbb{C}$ is a *Legendre symbol*, that is, a multiplicative character of $\mathbb{Z}_p^*$ extended to all of $\mathbb{Z}_p$ by setting $f(0) = 0$, was studied by van Dam, Hallgren, and Ip [4]. They give efficient quantum algorithms for these hidden shift problems for all characters of $\mathbb{Z}_p^*$. Their algorithms, however, make explicit use of the complex values taken by the character, whereas the algorithms we present here depend only on the symmetries of the underlying function f; in particular, in our case f can be an arbitrary injective function from a multiplicative character into a set S. On the other hand, their algorithms are efficient for characters of any order, while our algorithms require that r be at most polylogarithmic in p.

Returning to the general problem defined above, let $\mathcal{F}(\mathbb{Z}_p, S)$ denote the collection of S-valued functions on $\mathbb{Z}_p$. Note that the affine group A_p acts on the set $\mathcal{F}(\mathbb{Z}_p, S)$ by assigning $\alpha \cdot g(x) = g(\alpha^{-1}(x))$ for each $\alpha \in A_p$ and $g \in F(\mathbb{Z}_p, S)$. In particular, $f_s = (1, s) \cdot f$.

Now note that the isotropy subgroup of f, namely the subgroup of A_p that fixes the cosets of M, is precisely $H_q = \langle (a, 0) \rangle$, where $a \in \mathbb{Z}_p^*$ has order $q = (p-1)/r$. As we have $f_s = (1, s) \cdot f$, the isotropy subgroup of f_s is the conjugate subgroup $H_q^s = (1, s) \cdot H_q \cdot (1, -s)$. Now observe that if we define $F_s : A_p \to (\mathbb{Z}_p)^p$ so that $F_s(\alpha)$ is the p-tuple $(\alpha f_s(0), \alpha f_s(1), \ldots, \alpha f_s(p-1))$, then

$$F_s(\alpha) = F_s(\beta) \Leftrightarrow \alpha^{-1}\beta \in H_q^s; \tag{7}$$

i.e., F_s is constant precisely on the left cosets of H_q^s. Evidently, then, the solution to the HCP given by the oracle F_s determines the solution to the hidden shift problem given by f_s. Unfortunately, the *values* of the oracle F_s are of exponential size—we cannot afford to evaluate $\alpha f_s(x)$ for all $x \in \mathbb{Z}_p$. The same symmetry expressed in (7), however, can be obtained efficiently by selecting an appropriate subset $R = \{x_1, \dots, x_m\} \subset \mathbb{Z}_p$ and considering the oracle that samples αf_s on R, that is,

$$F_s^R(\alpha) = (\alpha f_s(x_1), \dots, \alpha f_s(x_m)).$$

Of course, we have $\alpha f_s = \beta f_s \Rightarrow F_s^R(\alpha) = F_s^R(\beta)$ regardless of R; the difficulty is finding a small set R for which $F_s^R(\alpha) = F_s^R(\beta) \Rightarrow \alpha f_s = \beta f_s$. We show below that a set of $O(\log p)$ elements selected uniformly at random from $\mathbb{Z}_p$ has this property with high probability.

Considering that $\alpha f_s(x) = \alpha \cdot (1, s) \cdot f(x)$, it suffices to show that if $\alpha f \neq \beta f$, then

$$\Pr_x[\alpha f(x) = \beta f(x)] \leq 1/2,$$

where x is selected uniformly at random in $\mathbb{Z}_p$. Note that for affine functions α and β and an element $x \in \mathbb{Z}_p$ for which $\beta^{-1}(x) \neq 0$,

$$\alpha f(x) = \beta f(x) \;\Leftrightarrow\; \frac{\alpha^{-1}(x)}{\beta^{-1}(x)} \in M.$$

The function $\alpha^{-1}(x)/\beta^{-1}(x)$ is a *fractional linear transform*, i.e., the ratio of two linear functions; such functions are the discrete analogues of the Möbius transformations in the complex plane. As in the complex case, the fractional linear transform $\gamma(x)/\delta(x)$ is a bijection on the projective space $\mathbb{Z}_p \cup \{\infty\}$ unless γ and δ share a root, or, equivalently, there is a scalar $z \in \mathbb{Z}_p^*$ such that $\gamma(x) = z\delta(x)$. If $\alpha^{-1}(x)/\beta^{-1}(x)$ is injective, we can immediately conclude that

$$\Pr_x[\alpha f(x) = \beta f(x)] \leq |M|/(p-1) = 1/r \leq 1/2.$$

Otherwise, $\alpha^{-1}(x)/\beta^{-1}(x) = z$ for some scalar z. Since $\alpha f \neq \beta f$, however, in this case we must have $z \in \mathbb{Z}_p^* \setminus M$. In particular, $f(zy) \neq f(y)$ for any $y \neq 0$, and so

$$\Pr_x[\alpha f(x) = \beta f(x)] = 1/p,$$

since this occurs only at the unique root x of $\alpha^{-1}(x) = 0$.

In either case, then, αf and βf differ on at least half the elements of $\mathbb{Z}_p$ whenever α and β belong to different cosets of H_q^s. It follows that if $R \subset \mathbb{Z}_p$ consists of m elements chosen independently and uniformly at random from $\mathbb{Z}_p$, we have

$$\Pr_R\left[\forall x \in R, \alpha f(x) = \beta f(x)\right] \leq 1/2^m$$

for any $\alpha, \beta \in A_p$ with $\alpha^{-1}\beta \notin H_q$. Taking a union bound over all pairs of left cosets of H_q,

$$\Pr_R\left[\exists \alpha, \beta \in A_p : \alpha^{-1}\beta \notin H_q \; \forall x \in R, \alpha f(x) = \beta f(x)\right] \leq \left(\frac{p(p-1)}{|H_q|}\right)^2 \frac{1}{2^m}.$$

Selecting $m = 5 \log p$ ensures that this probability is less than $1/p$.

Since we showed in section 3 that we can identify a hidden conjugate of H_q whenever H_q is of polylogarithmic index in $\mathbb{Z}_p^*$, this provides an efficient solution to the hidden shift problem so long as $p/q = \operatorname{polylog}(p)$.

8. Closure under extending small groups. In this section we show that for any polynomial-size group K and any H for which we can solve the HSP, we can also solve the HSP for any extension of K by H, i.e., any group G with $K \lhd G$ and $G/K \cong H$. (Note that this is more general than split extensions, i.e., semidirect products $H \ltimes K$.) This includes the case discussed in [13] of Hamiltonian groups, since all such groups are direct products (and hence extensions) by abelian groups of the quaternion group Q_8 [23]. It also includes the case discussed in [8] of groups with commutator subgroups of polynomial size, such as extra-special p-groups, since in that case $K = G'$ and $H \cong G/G'$ is abelian. Indeed, our proof is an easy generalization of that in [8].

Theorem 7. *Let H be a group for which hidden subgroups are fully reconstructible and K a group of polynomial size in* $\log |H|$. *Then hidden subgroups in any extension of K by H, i.e., any group G with $K \lhd G$ and $G/K \cong H$, are fully reconstructible.*

Proof. We assume that G and K are encoded in such a way that multiplication can be carried out in classical polynomial time. We fix some transversal $t(h)$ of the left cosets of K. First, note that any subgroup $L \subseteq G$ can be described in terms of (i) its intersection $L \cap K$, (ii) its projection $L_H = L/(L \cap K) \subseteq H$, and (iii) a representative $\eta(h) \in L \cap (t(h) \cdot K)$ for each $h \in L_H$. Then each element of L_H is associated with some left coset of $L \cap K$, i.e., $L = \bigcup_{h \in L_H} \eta(h) \cdot (L \cap K)$. Moreover, if S is a set of generators for $L \cap K$ and T is a set of generators for L_H, then $S \cup \eta(T)$ is a set of generators for L.

We can reconstruct S in classical polynomial time simply by querying the function h on all of K. Then $L \cap K$ is the set of all k such that $f(k) = f(1)$, and we construct S by adding elements of $L \cap K$ to it one at a time until they generate all of $L \cap K$.

To identify L_H, as in [8] we define a new function f' on H consisting of the unordered collection of the values of f on the corresponding left coset of K:

$$f'(h) = \{f(g) \mid g \in t(h) \cdot K\}.$$

Each query to f' consists of $|K| = \text{poly}(n)$ queries to f. The level sets of f' are clearly the cosets of L_H, and so we reconstruct L_H by solving the HSP on H. This yields a set T of generators for L_H.

It remains to find a representative $\eta(h)$ in $L \cap (t(h) \cdot K)$ for each $h \in T$. We simply query $f(g)$ for all $g \in t(h) \cdot K$ and set $\eta(h)$ to any g such that $f(g) = f(1)$. Since $|T| = O(\log |H|) = \text{poly}(n)$, this can be done in polynomial time, completing the proof. □

Unfortunately, we cannot iterate this construction more than a constant number of times, since doing so would require a superpolynomial number of queries to f for each query of f'. If K has superpolynomial size, it is not clear how to obtain $\eta(h)$, even when H has only two elements. Indeed, this is precisely the difficulty with the dihedral group.

9. Conclusion and directions for further work. We have shown that the "strong standard method," applied with adapted bases, solves certain nonabelian HSPs in quantum polynomial time that cannot be solved using measurements in random bases or "forgetful" abelian approaches.

While we are still very far from an algorithm for HSP in the symmetric group S_n or for Graph Automorphism, a global understanding of the power of strong Fourier sampling remains an important goal. Perhaps the next class of groups to try beyond the affine and q-hedral groups are matrix groups such as $\text{PSL}_2(p)$, whose maximal subgroups are isomorphic to A_p, and which include one of the infinite families of finite simple groups.

Appendix A. Notes on exponential sums. The basic *Gauss sum* bounds the inner products of additive and multiplicative characters of $\mathbb{F}_p$, the finite field of prime cardinality p. Definitive treatments appear in [19, section 5] and [17]. Considering $\mathbb{F}_p$ as an additive group with p elements, we have p additive characters $\chi_s : \mathbb{F}_p \to \mathbb{C}$, for $s \in \mathbb{F}_p$, given by $\chi_s : z \mapsto \omega_p^{sz}$, where, as above, $\omega_p = \mathrm{e}^{2\pi i/p}$ is a primitive pth root of unity. Likewise considering the elements of $\mathbb{F}_p^* = \mathbb{F}_p \setminus \{0\}$ as a multiplicative group, we have $p-1$ characters $\psi_t : \mathbb{F}_p^* \to \mathbb{C}$, for $t \in \mathbb{F}_p^*$, given by $\psi_t : g^z \mapsto \omega_{p-1}^{tz}$, where $\omega_{p-1} = \mathrm{e}^{2\pi i/(p-1)}$ is a primitive $(p-1)$th root of unity and g is a multiplicative generator for the (cyclic) group $\mathbb{F}_p^*$.

With this notation the basic Gauss sum is the following.

THEOREM 8. *Let χ_s be an additive character and ψ_t a multiplicative character of $\mathbb{F}_p$. If $s \neq 0$ and $t \neq 1$, then*

$$\Big| \sum_{z \in \mathbb{F}_p^*} \chi_s(z)\, \psi_t(z) \Big| = \sqrt{p}.$$

Otherwise

$$\sum_{z \in \mathbb{F}_p^*} \chi_s(z)\psi_t(z) = \begin{cases} p-1 & \textit{if } s = 0,\ t = 1, \\ -1 & \textit{if } s = 0,\ t \neq 1, \\ 0 & \textit{if } s \neq 0,\ t = 1. \end{cases}$$

See [19, section 5.11] for a proof.

This basic result has been spectacularly generalized. In the body of the paper we require bounds on additive characters taken over multiplicative subgroups of $\mathbb{F}_p^*$. Such sums are discussed in detail in [17]. The specific bound we require is the following.

THEOREM 9. *Let χ_t be a nontrivial additive character of $\mathbb{F}_p$ and $a \in \mathbb{F}_p^*$ an element of multiplicative order q. Then*

$$\sum_{z=0}^{q-1} \chi_t(a^z) = \begin{cases} O(p^{1/2}) & \textit{if } q \geq p^{2/3}, \\ O(p^{1/4}q^{3/8}) & \textit{if } p^{1/2} \leq q \leq p^{2/3}, \\ O(p^{1/8}q^{5/8}) & \textit{if } p^{1/3} \leq q \leq p^{1/2}. \end{cases}$$

See [17, section 2] for a proof.

Note that in the body of the paper, we use $\mathbb{Z}_p$ to denote the additive group of integers modulo p and $\mathbb{Z}_p^*$ to denote the multiplicative group of integers modulo p.

Acknowledgments. We are grateful to Wim van Dam, Julia Kempe, Greg Kuperberg, Frederic Magniez, Martin Rötteler, and Miklos Santha for helpful conversations and to Sally Milius and Tracy Conrad for their support.

EFFICIENT TESTING OF BIPARTITE GRAPHS FOR FORBIDDEN INDUCED SUBGRAPHS*

NOGA ALON†, ELDAR FISCHER‡, AND ILAN NEWMAN§

Abstract. Alon et. al. [N. Alon, E. Fischer, M. Krivelevich, and M. Szegedy, *Combinatorica*, 20 (2000), pp. 451–476] showed that every property that is characterized by a finite collection of forbidden induced subgraphs is ϵ-testable. However, the complexity of the test is *double-tower* with respect to $1/\epsilon$, as the only tool known to construct such tests uses a variant of Szemerédi's regularity lemma. Here we show that any property of *bipartite* graphs that is characterized by a finite collection of forbidden induced subgraphs is ϵ-testable, with a number of queries that is polynomial in $1/\epsilon$. Our main tool is a new "conditional" version of the regularity lemma for binary matrices, which may be interesting on its own.

Key words. property testing, graph algorithms, approximation, regularity lemma

1. Introduction.

Property testing, first started in [6] and [17], deals with the following general question: Given a property P and an input which is assumed to come in the form of an oracle, how many queries to the input are required to distinguish between an input which satisfies P and an input which is ϵ-far (in the normalized Hamming distance) from any input that satisfies P? Property testing in general, and the investigation of graph testing that was started in [14], in particular, has become an active research area in recent years (see, for example, [14, 3, 8, 15, 1, 4] and the surveys [16, 9]). In particular, it was shown in [3] that every property that is characterized by a finite collection of forbidden induced subgraphs is ϵ-testable, that is, one can distinguish between graphs that satisfy it and graphs that are ϵ-far from satisfying it, with a number of queries that is bounded by a function of ϵ only, and is independent of the size of the input graph. However, the complexity of the test is *double-tower* with respect to $1/\epsilon$, as the only tool known to prove this testability is a variant of Szemerédi's regularity lemma.

More recently, Alon and Shapira [1, 4] initiated a study of those graph properties that are characterized by forbidden subgraphs and can be tested "very efficiently" in the sense that they can be tested with only $poly(1/\epsilon)$ many queries. In [1] it is shown that the property of not containing a given subgraph (where the subgraph is not necessarily induced) is testable with a number of queries polynomial in $1/\epsilon$ if and

only if the forbidden subgraph is bipartite. In the context of testing digraphs for a forbidden structure, [4] contains a similar (but more complex) classification. The only known upper bounds for the cases where the number of queries is not polynomial are the tower (or worse) functions that result from Szemerédi's regularity lemma and its variants.

Here we concentrate on graph properties that are characterized by a finite family of forbidden induced subgraphs. For general graphs, the only known upper bound is the tower of towers; it was obtained from the proof in [3] that this is testable at all. We consider here the special case of *bipartite* input graphs and show, in contrast to the above, that any property of bipartite graphs that is characterized by a finite collection of forbidden induced subgraphs is ϵ-testable with a number of queries that is polynomial in $1/\epsilon$.

Our main tool is a new "conditional" version of the regularity lemma for binary matrices (Lemma 1.6 below), which may be interesting on its own. We combine this with some methods similar to those of [11] to obtain the desired result ([11] is an expanded version of the results from [10] about matrix-poset properties, while this paper expands the results from [10] about testing of bipartite graphs; the original bounds in [10] for bipartite graphs, while better than the previously known tower of towers, were not polynomial in $1/\epsilon$).

Our results are stated for graphs that are already given with a bipartition of their vertices (with the definition of a forbidden subgraph also relating to subgraphs with a compatible bipartition). However, in the case of bipartite input graphs whose bipartition is not given in advance (and general induced forbidden subgraphs), we can first use the approximate bipartition oracle given in [14] to reduce that setting to our setting.

We now note that the study of such bipartite graph properties is an extension of the poset model studied in [11], in which the testability of properties is related to the logical complexity of their description (for the purpose here a *model* is the language in which the properties are expressed, so a model is essentially identifiable with its family of expressible properties). In this case the poset is the 2-dimensional $n \times n$ grid, which as a poset is the product of two n-size total orders (lines). The language (syntax) includes the poset relation, the label unary relation (being labeled "1"), and in addition, the relations $row(x_1, x_2)$ which state that x_1 is on the same row as x_2, and similarly $col(x_1, x_2)$ for columns. $\forall$-properties in this model are properties that can be described by a finite formula over a fixed number of variables with only $\forall$-quantifiers in prenex normal form. Such properties would then correspond to exactly the properties that are characterized by a finite collection of forbidden submatrices (in a manner similar to what was done in [11] for the $\forall$-poset model). We call this model the "submatrix model." The submatrix model is closely related to a submodel of the (not always testable) $\forall\exists$-poset model, defined in [11].

The model "submatrix" includes some interesting properties. In particular, the permutation-invariant properties in it are tightly connected to bipartite graph properties that are characterized by a collection of forbidden induced subgraphs.

Definition 1.1. *For a finite collection F of $0/1$ matrices, we denote by $\mathcal{S}_F$ all $0/1$-matrices that do not contain as a submatrix any row and/or column permutation of a member of F.*

Observation 1.2. *Every bipartite graph property (where a bipartite graph is identified with its adjacency matrix in the usual way) that is characterized by a finite collection of forbidden induced subgraphs is equivalent to a property $\mathcal{S}_F$ for some finite set F of matrices. In addition, every $\mathcal{S}_F$-property in the "submatrix" model is* *equivalent to a bipartite graph property as above.*

It is important to note that here we discuss forbidden *induced* subgraphs. Not having a forbidden subgraph (rather than induced subgraph) is a monotone decreasing property. In this case, the test for the property is trivial, by density. For a large enough density, a Zarankiewicz (see [21], [13]) type theorem asserts that the answer "No" is correct (as the graph will have a large enough complete bipartite graph), while if the density is low then the answer is trivially "Yes," as the graph is close to the empty (edgeless) one. A thorough treatment of this case is found in [1]. The main result in the present paper is the following.

THEOREM 1.3. *Let F be a fixed finite collection of $0/1$ matrices. Property $\mathcal{S}_F$ is $(\epsilon, poly(\frac{1}{\epsilon}))$-testable for every $\epsilon > 0$, by a 2-sided error algorithm.*

The test above, however, is not only 2-sided but also very computation-intensive (despite this computation using only a relatively small set of queries as data). Using some additional tools we then derive a 1-sided error test which is also efficient in terms of its running time.

THEOREM 1.4. *Let F be a fixed finite collection of $0/1$ matrices. Property $\mathcal{S}_F$ is $(\epsilon, poly(\frac{1}{\epsilon}))$-testable for every $\epsilon > 0$, by a one sided error algorithm whose running time is polynomial in the time it takes to make the queries.*

The derivation of Theorem 1.4 from the main tool used in Theorem 1.3 is done in two stages, in sections 5 and 6. To present the test proving Theorem 1.3, we will need some machinery.

Let M be a 0/1-labeled, $n \times n$ matrix (to simplify notation we restrict ourselves to square matrices, but all arguments and theorems in this paper hold word-for-word for rectangular $n \times m$ matrices as well). We denote by $R(M)$ and $C(M)$ the set of rows and the set of columns of M, respectively. For an integer r, an *r-partition* of M is a partition of the set $R(M)$ into $r' \leq r$ parts $\{R_1, \ldots, R_{r'}\}$ and a partition of the set $C(M)$ into $r'' \leq r$ parts $\{C_1, \ldots, C_{r''}\}$. Each submatrix of the form $R_i \times C_j$ will be called a block (note that the coordinate sets defining the blocks do not necessarily consist of consecutive matrix coordinates). The weight of the (i, j) block is defined as $\frac{1}{n^2}|R_i||C_j|$. We also define similar weights for the R_i's and C_j's, e.g., $w(R_i) = \frac{1}{n}|R_i|$.

For a block B of a 0/1-matrix M and $\delta \geq 0$, we say that B is *δ-homogeneous* if all but a δ-fraction of its values are identical. If B is δ-homogeneous we call the value that appears in at least a $1-\delta$ fraction of the places the *δ-dominant* value of B. Note that this value is also α-dominant for any $\delta < \alpha < 1/2$. We say that a value is the *dominant* value of B if it is simply the majority value in B.

DEFINITION 1.5. *Let $\mathcal{P} = \{R_1, \ldots R_{r'}\} \times \{C_1, \ldots C_{r''}\}$ be an r-partition of M, and let $\delta > 0$. We say that $\mathcal{P}$ is a (δ, r)*-partition *if the total weight of the δ-homogeneous blocks is at least $1 - \delta$.*

The key result is that an input that does not admit some (δ, r)-partition can be rejected easily, because it will then contain many copies of every possible $k \times k$ matrix (including the forbidden ones) as submatrices.

LEMMA 1.6. *Let k be fixed. For every $\delta > 0$ and an $n \times n$, $0/1$-matrix M with $n > (k/\delta)^{O(k)}$, either M has a (δ, r)-partition for $r = r(\delta, k) \leq (k/\delta)^{O(k)}$, or for every $0/1$-labeled $k \times k$ matrix B, a $(g(\delta, k) \geq (\delta/k)^{O(k^2)})$-fraction of the $k \times k$ submatrices of M are B.*

This lemma allows us to reduce the testing problem to matrices that admit a (δ, r)-partition for certain δ, r; as for matrices that do not admit such partitions, the lemma asserts that querying a random submatrix will find a counterexample with sufficiently high probability. We note that the lemma is essentially a conditional version of Szemerédi's regularity lemma ([19]; see also [7, Chapter 7]), as a (δ, r)-partition is in particular a regular partition in the sense of Szemerédi of the corresponding bipartite graph. The improvement over directly using the regularity lemma is achieved because of this conditioning. The proof of the lemma will be presented in section 4.

We then construct a test for matrices admitting a (δ, r)-partition. This test will be very similar to the 2-sided boolean matrix poset test in [11]. However, the situation in the poset test is that the partition can be fixed in advance, while in our case there is the problem of "learning" enough of the partition by sampling. The main tool for doing so is Lemma 2.3 below. For stating it we need some more definitions, which are described in section 2 along with the framework of the proof of Theorem 1.3.

The plan of the paper is as follows. Section 2 includes some preliminaries, as well as a proof of Theorem 1.3 from two main lemmas—Lemma 1.6 above and Lemma 2.3 which is stated there. The lemmas themselves are proven in sections 4 and 3, respectively. We then turn to proving Theorem 1.4. This is done in two stages. First, a special case is proven in section 5, and then this case is used as a lemma in section 6 to prove the full result. In both stages we need the main tool that was used in the proof of Theorem 1.3, namely, Lemma 1.6. Finally, section 7 contains some concluding open problems.

2. Partitions, signatures, and Theorem 1.3. Assume that M has a (δ, r)-partition. We have no hope, of course, of finding it using $O(1)$ many queries, as we cannot even sample a single point from every matrix row. Hence, we will need to define the "high-level features" of the (δ, r)-partitions of M that can be detected by sampling.

In the following, whenever we refer to a δ-fraction of the members of a *weighted* set Q, we mean a subset Q', the total weight of whose members is δ (where we assume that the total weight of the members of Q is normalized to be 1). Let M be a matrix with a (δ, r)-partition $\mathcal{P}$ defined by the row partition $\{R_1, \ldots, R_s\}$ and the column partition $\{C_1, \ldots, C_t\}$, $s, t \leq r$. Then $\mathcal{P}$ naturally defines a high-level pattern which is an $s \times t$ matrix of the dominant labels of the blocks.

Definition 2.1. *Let $\mathcal{P}$ be a partition as above, and let P be a $0/1$-labeled, $s \times t$ matrix. A block $R_i \times C_j$ is called* δ-good *with respect to P if it is δ-homogeneous and its dominant label is $P_{i,j}$. P is called a* δ-pattern *of $\mathcal{P}$ if all but at most a δ-fraction of the weighted blocks in $\mathcal{P}$ are δ-good with respect to P.*

It is immediate from the definition that if a partition has a δ-good pattern of size $s \times t$, then it is a (δ, r)-partition with $r = \max\{s, t\}$. Conversely, if $\mathcal{P}$ is a (δ, r)-partition, then it has an $r \times r$ δ-pattern (by possibly introducing empty blocks). As the block sizes of a (δ, r)-partition need not be fixed, we will also need information about the weights of R_i and C_j, $(i, j) \in [s] \times [t]$.

Definition 2.2. *Let M be an $n \times n$ matrix with a (δ, r)-partition $\mathcal{P}$ defined by the row partition $\{R_1, \ldots, R_s\}$ and the column partition $\{C_1, \ldots, C_t\}$. Then a* δ-signature *of $\mathcal{P}$ is an $s \times t$, $0/1$-labeled matrix P and two sequences $\{\alpha_i\}_1^s, \{\beta_i\}_1^t$, where P is a δ-pattern of $\mathcal{P}$, and in addition $\sum_{i=1}^s |\frac{|R_i|}{n} - \alpha_i| \leq \delta$ and $\sum_{j=1}^t |\frac{|R_j|}{n} - \beta_j| \leq \delta$.*

Note that the signature of a partition is closed under permutations of rows and columns; namely, any row/column permutation of P with the respective permutations of $\{\alpha_i\}_1^s$ and $\{\beta_i\}_1^t$ is also a δ-signature of any matrix for which P is a δ-signature. Moreover, a signature of M is also a signature of all row/column permutations of M.

The signature of a partition has sufficient properties for constructing a test as we shall see in the proof of Theorem 1.3. The following also asserts that it can be approximated by sampling.

Lemma 2.3. *Let $\delta < 1/81$ and assume that an $n \times n$, 0/1-matrix M has a (δ, r)-partition. By making $q = (r/\delta)^{O(1)}$ many queries, a $26\delta^{1/6}$-signature of a $(16\delta^{1/6}, 10r^2/(4\delta^{1/3}) + 1)$-partition can be found, with success probability $\frac{3}{4}$.*

We note that a test for a much closer approximation of the original (δ, r)-partition can also be deduced from [14], with exponentially worse running time and query complexity. The proof of Lemma 2.3 is given in section 3. We end the discussion by showing that together with Lemma 1.6 this indeed implies a 2-sided error test.

Proof of Theorem 1.3. Assume that we want to ϵ-test M for a permutation-invariant collection of forbidden induced $k \times k$ submatrices. Blocks will now correspond to partition-blocks: Let $\delta = (\frac{\epsilon}{300})^6$, and let $g = g(\delta, k)$, $r = r(\delta, k)$ be those of Lemma 1.6. For $4/g = (k/\epsilon)^{O(k^2)}$ iterations, independently, we choose k random rows and k random columns of M and query all k^2 points in the $k \times k$ matrix that is defined by them. If we find a counterexample in the queried points we answer "No" and terminate the algorithm, and otherwise we continue. Let E_1 denote the event that M has no (δ, r)-partition and yet the algorithm continues. For inputs with a (δ, r)-partition, this event (by definition) never happens, while for other inputs, by Lemma 1.6, the probability of this event is bounded by $\frac{1}{12}$.

We now work under the assumption that M has a (δ, r)-partition and use the algorithm given in Lemma 2.3 to try finding an $\frac{\epsilon}{8}$-signature of an $(\frac{\epsilon}{8}, 10r^2/4(\frac{\epsilon}{300})^2 + 1)$-partition by sampling $(r/\delta)^{O(1)} = (k/\epsilon)^{O(k)}$ queries. Let P with $\{\alpha_i\}_1^s$ and $\{\beta_i\}_1^t$ be the signature obtained by the algorithm, and let E_2 be the event that it is not an $\frac{\epsilon}{8}$-signature of an $(\frac{\epsilon}{8}, 10r^2/4(\frac{\epsilon}{300})^2 + 1)$-partition of M. If M in fact did not have a (δ, r)-partition, then this event has the same probability as E_1 (which is bounded by $\frac{1}{12}$), and otherwise by Lemma 2.3 the probability of E_2 is bounded by $\frac{1}{4}$.

We now form an $n \times n$ matrix M_Q that represents our knowledge of M: We partition the rows of M_Q into s parts of weights $\{\alpha_i\}_1^s$ and the columns into t parts of weights $\{\beta_i\}_1^t$. For every block of P, we set every entry of the corresponding block of M_Q to have the same label as in P. Now, let $\mathcal{M}_{Q,\epsilon}$ be the set of all matrices that can be obtained from M_Q by changing at most $\epsilon n^2/2$ entries in any possible way. We check if any of the members of $\mathcal{M}_{Q,\epsilon}$ has the property $\mathcal{S}_F$. If there is such a member, the algorithm answers "Yes." Otherwise, if every member $\mathcal{M}_{Q,\epsilon}$ contains a permutation of a forbidden submatrix, then the answer is "No." Note that this last phase of the algorithm involves no additional queries and is just a computation phase.

To see that the algorithm is correct we first note that if a counterexample is found in the first phase of the algorithm, then the input M does not have the property with probability 1. Hence the algorithm can err only in the second phase.

We claim that unless E_2 happened the following hold: (a) some row/column permutation of M is a member of $\mathcal{M}_{Q,\epsilon}$, and (b) every two members of $\mathcal{M}_{Q,\epsilon}$ are of distance at most ϵn^2. Indeed, assume that the signature that has been found is an $\frac{\epsilon}{8}$-signature of an $(\frac{\epsilon}{8}, 10r^2/4(\frac{\epsilon}{300})^2 + 1)$-partition of M. Then M_Q can be obtained from M by changing at most an $\frac{\epsilon}{8}$-fraction of the entries in each $\frac{\epsilon}{8}$-good block, followed by changing any of the entries in the non–$\frac{\epsilon}{8}$-homogeneous blocks, and finally changing entries that are in strips around every block to compensate for the inaccuracy of the size sequences of the signature (whose sizes sum up to no more than $\frac{\epsilon}{8}$ for the rows and $\frac{\epsilon}{8}$ for the columns). The first two types of changes contribute at most an $\frac{\epsilon}{8}$-fraction of changes to the whole matrix each, and the last type contributes at most an $\frac{\epsilon}{4}$-fraction of changes. Thus M is at most $\epsilon n^2/2$-far from M_Q, and, in particular, M is in $\mathcal{M}_{Q,\epsilon}$. This proves (a), while (b) follows automatically from the definition of $\mathcal{M}_{Q,\epsilon}$ and the triangle inequality.

Hence, we may assume that with probability at least $\frac{3}{4}$ (which is the lower bound on E_2 not happening), the $\frac{\epsilon}{8}$-signature is computed correctly and (a) and (b) above are satisfied. We conclude that if M has the property then certainly some member of $\mathcal{M}_{Q,\epsilon}$ will have the property (as M itself is such a member by (a)), and thus the algorithm will accept. On the other hand, if M is more than ϵn^2-far from having the property, then no member of $\mathcal{M}_{Q,\epsilon}$ can have the property by (b).

Clearly the query complexity of the test is $O(k/\epsilon)^{O(k^2)}$, which for a fixed family F (and hence a fixed k) is polynomial in ϵ. □

The above test, while using only a constant number of queries, has a bad dependence of the calculation time on the input size (this can be alleviated somewhat, but in light of the following we omit the details). Unfortunately, this dependence is such that the automatic conversion by Alon of 2-sided tests to 1-sided ones, described in [15, Appendix D], will not work here. Instead we will go on a different route to show that a (δ, r)-partition of the matrix not only contains the necessary information about its farness from our property, but also implies the existence of many witnesses. But first, we turn back to the proofs of Lemmas 2.3 and 1.6.

3. (δ, r)-partitions, row similarity, and the proof of Lemma 2.3.

Our goal here is to show that by sampling $(r/\delta)^{O(1)}$ entries in M, one can detect the signature of a (δ', r')-partition, if a (δ, r)-partition exists. For this we need a representation of a partition in a "local" way, which is asserted by Claims 3.2 and 3.3. To do this, we relate the notion of a (δ, r)-partition to relative distances between rows and columns. For the rest of this section we assume that δ is smaller than 1/81.

For two vectors $u, v \in \{0,1\}^m$ let $\mu(u,v) = \frac{1}{m}|\{i|\ u_i \neq v_i\}|$; namely, $\mu(u,v)$ is the normalized Hamming distance between the two vectors. We will use the following definitions.

DEFINITION 3.1. *Let M be an $n \times n$ matrix. We set $E^R(\mu(r_i, r_j))$ to be the expected value of $\mu(r_i, r_j)$, where r_i, r_j are two rows of M chosen at random. Similarly let $E^C(\mu(c_i, c_j))$ denote the respective quantity where c_i, c_j are two columns chosen at random.*

*Given a set of vectors V (usually either the set of rows or the set of columns of M) and a partition $V_0, \dots, V_s$ of V, we say that the partition is a (δ, r)-*clustering of *V if $s \le r$, $|V_0| \le \delta|V|$, and for every $1 \le i \le r$ and $u, v \in V_i$ we have $\mu(u,v) \le \delta$.*

Finally, for a partition block B and a row u that intersects B, let $u|_B$ be the restriction of u to the columns in B.

There is a close correlation between (δ, r)-partitions of M and (δ, r)-clusterings of its rows and columns, as the following two claims show.

CLAIM 3.2. *Let M be a $0/1$, $m \times m$ matrix, and assume that M has a (δ, r)-partition. Then there exist a $(4\delta^{1/3}, r)$-clustering of the rows of M as well as a $(4\delta^{1/3}, r)$-clustering of the columns of M.*

CLAIM 3.3. *Let M be a $0/1$, $m \times m$ matrix, and assume that $\{R_0, \dots, R_s\}$ and $\{C_0, \dots, C_t\}$ are (δ^2, r)-clusterings, for $r = \max\{s, t\}$, of the set of rows and the set of columns, respectively. Then these clusterings also form a $(4\delta, r+1)$-partition of M.*

Moreover, for the above $R_0, \dots, R_s$ and $C_0, \dots, C_t$, a 4δ-signature for the partition is given by the sequences $\alpha_i = w(R_i)$, $i = 0, \dots, s$, $\beta_i = w(C_i)$, $i = 0, \dots, t$, and the $s \times t$ matrix P, where the (i,j) entry of P corresponds to the block $R_i \times C_j$ and its label is the dominant label of this block.

Before we prove the two claims we need two simple observations that in some sense correspond to the case "$r = 1$" of the claims.

OBSERVATION 3.4. *Let A be a $0/1$ matrix. If A is δ-homogeneous, then $E^R(\mu(r_i, r_j)) \leq 2\delta$ and $E^C(\mu(r_i, r_j)) \leq 2\delta$.*

Proof. As A is δ-homogeneous, we may assume without loss of generality that A contains less than a δ fraction of 0's. Hence, choosing two rows at random and picking a random place i in both, the probability that they are not both "1" in this place is at most 2δ. Thus the expectation of the fraction of the number of places where they differ is bounded by 2δ, and this expectation is exactly $E^R(\mu(r_i, r_j))$. The proof for $E^C(\mu(r_i, r_j))$ is analogous. □

OBSERVATION 3.5. *If A is a $0/1$ matrix such that $E^R(\mu(r_i, r_j)) < \delta$ and $E^C(\mu(c_i, c_j)) < \delta$, then A is 4δ-homogeneous.*

Proof. Assume on the contrary that A is not 4δ-homogeneous. This implies that when choosing two points from A independently and uniformly at random, with probability at least 4δ, they will not have the same label. This is also a lower bound on the fraction of the 2×2 submatrices that contain both 0's and 1's, as any two points with different labels can be extended to such a submatrix. On the other hand, if $E^R(\mu(r_i, r_j)) < \delta$, then with probability more than $1 - 2\delta$ both rows of a uniformly random 2×2 submatrix are identical, as this matrix can be expressed as choosing two random places from two random rows. By the same token, if $E^R(\mu(c_i, c_j)) < \delta$, then with probability more than $1 - 2\delta$ the two columns of a random 2×2 matrix are identical. Together these would have implied that less than a 4δ fraction of the 2×2 submatrices have both 0's and 1's, which is a contradiction. □

Proof of Claim 3.2. Assume that M has a (δ, r)-partition defined by the row partition $R_1, \ldots, R_s$ and the column partition $C_1, \ldots, C_t$, $s, t \leq r$. Assume that B is a δ-homogeneous block that contains the rows of R_i. Then by Observation 3.4, $E^R(u|_B, v|_B) \leq 2\delta$ for two rows chosen at random from R_i. For a non$-$ δ-homogeneous block, this expression is at most 1. Let $w_i = w(R_i) = |R_i|/m$, $i = 1, \ldots, s$, and let $E_i(\mu(u, v))$ be the expectation of $\mu(u, v)$, where u, v are two rows chosen uniformly at random from R_i. Then the above implies that $\Sigma_{i=1}^{r} w_i E_i(\mu(u, v)) \leq (1-\delta)2\delta + \delta \cdot 1 \leq 3\delta$, as this sum goes over all blocks and there is at least a $(1-\delta)$ fraction of 0/1-blocks contributing at most 2δ each.

Now this implies that the total weight of the R_i's for which $E_i(\mu(u, v)) \geq \delta^{2/3}$ is at most $3\delta^{1/3}$. Let R_0 be the union of all these R_i's. Let $R_1, \ldots, R_{r'}$ be all other R_i's, after renumbering. For every $i = 1, \ldots, r'$, by our assumption, $E_i(\mu(u, v)) < \delta^{2/3}$ for randomly chosen u, v, so there is an $r_i \in R_i$ for which for at least a $(1 - \delta^{1/3})$ fraction of the v's in R_i, $\mu(r_i, v) < \delta^{1/3}$. Hence if we define for $1 \leq i \leq r'$ the set $R'_i = \{v \in R_i | \mu(v, r_i) < \delta^{1/3}\}$ and then define $R'_0 = \bigcup_{i=1}^{r'} (R_i \setminus R'_i) \cup R_0$, we obtain that $R'_0, \ldots, R'_{r'}$ is indeed a $(4\delta^{1/3}, r)$-clustering for the rows of M. The proof for the existence of a clustering of the columns is analogous. □

Proof of Claim 3.3. By the assumptions of the claim, $|R_0| < \delta^2 n$. Also, for any $i \geq 1$ and any two rows $u, v \in R_i$, $\mu(u, v) \leq \delta^2$. Thus for $i = 1, \ldots, s$, $E_i(\mu(u, v)) \leq \delta^2$, where E_i is the expectation when u, v are chosen at random from R_i. Hence for the above partition into rows, $\Sigma_{i=0}^{s} \frac{|R_i|}{m} E_i(\mu(u, v)) \leq 2\delta^2$ (as for each $i > 1$ the corresponding term in this average is at most δ^2, and for $i = 0$ the weight of the term is at most δ^2). Similarly we get the analogous inequality for columns. Let $\mathcal{P}$ be the partition of M into blocks that is defined by the cross product of the two partitions above.

Recall that $\frac{|R_i|}{m}$, $\frac{|C_i|}{m}$ are the weights $w(R_i), w(C_i)$ of the corresponding sets. Also, for a block B, let $E_R(\mu(u|_B, v|_B))$, respectively, $E_C(\mu(u|_B, v|_B))$, be the expectation of $\mu(\cdot, \cdot)$ for two rows u, v, respectively, columns, chosen at random from B. By the law of complete probability, $\Sigma_{i=0}^{s} w(R_i) \cdot E_i(\mu(u,v)) = E_B(E_R(\mu(u|_B, v|_B)))$, where in the right-hand side the outer expectation is on blocks of $\mathcal{P}$ chosen according to their weights, and the inner expectation is on rows chosen at random in the block. Hence, the fact that $\Sigma_{i=0}^{s} w(R_i) E_i(\mu(u,v)) \leq 2\delta^2$ implies that the total weight of all blocks B for which $E_R(\mu(u|_B, v|_B)) > \delta$ is bounded by 2δ. By the same argument, for at most a 2δ fraction of the blocks $E_C(\mu(u|_B, v|_B)) > \delta$. Hence, for at least a $1-4\delta$ fraction of the blocks (weighted by the block weights), both $E_R(\mu(u|_B, v|_B)) \leq \delta$ and $E_C(\mu(u|_B, v|_B)) \leq \delta$. However, by Observation 3.5 above, each such block is 4δ-homogeneous, and hence at most a 4δ fraction of the blocks (measured by weights) are not 4δ-homogeneous. This implies that $\mathcal{P}$ is a $(4\delta, r+1)$-partition. Also, by definition, a pattern for this partition is any one that has, for each block, the $(1-4\delta)$-dominant label of this block if there is one, or an arbitrary value otherwise. Moreover, as α_i, β_i are the exact weights of the parts in the partition, we get a 4δ-signature for it by definition. □

We are now ready to present the testing algorithm that yields Lemma 2.3. We start with a trivial observation about approximating distances.

Claim 3.6. *Let $u, v \in \{0,1\}^n$, $\gamma < 1$. Choose randomly and independently (with repetitions) m elements of $[n]$, naming the resulting (multi)set $L = \{l_1, \dots, l_m\}$. Let $\tilde{\mu}(u,v) = \frac{1}{m}\sum_{k=1}^{m} |u(l_k) - v(l_k)|$, where $u(i)$ and $v(i)$ are the ith coordinates of u and v, respectively. Then $|\mu(u,v) - \tilde{\mu}(u,v)| \leq \gamma$ with probability at least $1 - 2exp(-\gamma^2 m)$.*

Proof. The proof is immediate by a Chernoff-type inequality (see, e.g., [5, Corollary A.1.7]). □

We next construct a testing algorithm for an approximate notion of clustering. Testing algorithms for clustering were already investigated in [2]; here we will use a simple self-contained proof for an algorithm that gives an approximation in a very weak sense.

Lemma 3.7. *There exists an approximate oracle algorithm that makes $(r/\delta)^{O(1)}$ bit queries (queries of one coordinate of one vector) to a set V of vectors over $\{0,1\}^n$, such that if V has a (δ, r)-clustering then the algorithm provides a $(4\delta, 10r^2/\delta)$-clustering of V as follows.*

The algorithm makes $(r/\delta)^{O(1)}$ queries in a preprocessing step, and with probability at least 0.9 provides a clustering oracle for V in the following sense: There exists a $(4\delta, 10r^2/\delta)$-clustering $V'_0, \dots, V'_t$ of V, such that for every specified $v \in V$ the algorithm can make $(r/\delta)^{O(1)}$ additional queries to provide an index $0 \leq i_v \leq t$, where it is guaranteed that for at least a $(1-4\delta)$ fraction of the vectors $v \in V$ the provided i_v will satisfy $v \in V_{i_v}$.

Proof. Suppose that $V_0, \dots, V_s$ is a (δ, r)-clustering of V. The algorithm starts by selecting uniformly at random $r' = 10r^2/\delta$ vectors $v_1, \dots, v_{r'}$ from V. With probability at least 0.95 (assuming that r is large enough) the situation is that for every $1 \leq i \leq r$ for which $|V_i| \geq \delta|V|/r$, we have picked at least one vector from V_i.

We now pick uniformly at random (with repetitions) $l = (10r' \log r')/\delta$ coordinates from $1, \dots, n$, and let $\tilde{\mu}(\cdot,\cdot)$ denote the corresponding approximated distance. Claim 3.6 implies that for every $v, v' \in V$, the probability for $|\mu(v,v') - \tilde{\mu}(v,v')| > \frac{1}{2}\delta$ is bounded by $\delta/20r'$, and so with probability at least 0.95 the situation is that for at least a $(1-\delta)$ fraction of the vectors $v \in V$, $|\mu(v,v_i) - \tilde{\mu}(v,v_i)| \leq \frac{1}{2}\delta$ for every $1 \leq i \leq r'$.

Assuming that both of the above events occurred (which is the case with probability at least 0.9), we define $V'_0, \dots, V'_{r'}$ as follows. Every vector v that belongs to V_0, or that belongs to a V_i of size $|V_i| < \delta/r$, or such that there exists some v_i for which

$|\mu(v,v_i) - \tilde{\mu}(v,v_i)| > \frac{1}{2}\delta$, is placed in V'_0. For every other vector we let i be the index for which $\tilde{\mu}(v,v_i)$ is minimal (or the smallest such index if there exist several values that minimize $\tilde{\mu}(v,v_i)$), and define v to be in V'_i.

We claim that $V'_0,\dots,V'_{r'}$ is indeed a $(4\delta,r')$-clustering. First, it is easy to see that $|V'_0| \le 3\delta|V| < 4\delta|V|$ from the assumption on the size of V_0, and the guarantee that we have on the number of vectors for which the distance was not well approximated. Now, if $u,v \in V'_i$ for some $1 \le i \le r'$, then we first note that $\mu(u,v_i) \le 2\delta$. This is because if we denote by $1 \le j \le r$ the index for which $u \in V_j$, then we have $\mu(u,v_i) \le \tilde{\mu}(u,v_i) + \frac{1}{2}\delta \le \tilde{\mu}(u,v_j) + \frac{1}{2}\delta \le \mu(u,v_j) + \delta \le 2\delta$. The same goes for proving that $\mu(v,v_i) \le 2\delta$, and so by the triangle inequality $\mu(u,v) \le 4\delta$. This concludes the claim about $V'_0,\dots,V'_{r'}$.

We now describe the remainder of the algorithm: After choosing $v_1,\dots,v_{r'}$ and the l coordinates as above, the algorithm now queries each of these coordinates from each v_i, and by this concludes the preprocessing stage. For the oracle stage, given a vector $v \in V$ the algorithm queries all the l chosen coordinates of v, and then calculates $\tilde{\mu}(v,v_i)$ for every i. The algorithm then outputs the index i that minimizes this, or the smallest such index in case there is more than one. It is clear that the algorithm gives the correct index for every vector that is not in V'_0, whose size is bounded by 4δ, concluding the proof. □

We note here that we could also use the above to find an approximate oracle for a $(4\delta,r)$-clustering (instead of a $(4\delta,10r^2/\delta)$-clustering), by trying to get from the set of queried vectors a subset V' for which all but at most a 3δ fraction of the members of V are δ-close to a member of V' (and verifying the validity of V' using a polynomial number of additional queries). This would also improve the dependencies in Lemma 2.3, but we omit it as our proofs already ensure the polynomial dependence on ϵ without this improvement.

We are now ready to describe the algorithm that proves Lemma 2.3, by finding with probability $\frac{3}{4}$ a signature of a $(16\delta^{1/6}, 10r^2/(4\delta^{1/3})+1)$-partition of M, if M has a (δ,r)-partition.

Algorithm Sig.

- By Claim 3.2, there exists a $(4\delta^{1/3},r)$-clustering of the rows. We perform the preprocessing stage of the algorithm provided by Lemma 3.7 to obtain an approximate oracle for a $(16\delta^{1/3}, 10r^2/(4\delta^{1/3}))$-clustering of the set of rows of M; we denote it by $R'_0,\dots,R'_{r'}$ for $r' = 10r^2/(4\delta^{1/3})$. Similarly, we obtain an approximate oracle for a $(16\delta^{1/3},r')$-clustering $C'_0,\dots,C'_{r'}$ of the columns.
- We now choose uniformly and independently at random (with repetitions) a (multi)set R of $l = (100r'\log r')/\delta$ rows of M, and for each of these we use the clustering oracle for $R'_0,\dots,R'_{r'}$. For $1 \le i \le r'$, we set α_i to be the number of rows from R for which the oracle answered "i," divided by l. We do the analogous operation for a set C of l columns M that were uniformly and independently chosen (this time with respect to the oracle for $C'_0,\dots,C'_{r'}$), and use it to set β_i for $1 \le i \le r'$. Both α_0 and β_0 are set to 0, as the above oracles never correctly detect that a row is in R'_0 or a column is in C'_0.
- Finally, for every $1 \le i \le r'$ and $1 \le j \le r'$ we look at the intersections of all the rows in R which the oracle located in R'_i, and all the columns in C which the oracle located in C'_j. We query the entries of M at the intersections of the set of sampled rows R and the set of sampled columns C, and we set $P_{i,j}$ to be the value (0 or 1) that has the majority of appearances in these queries.

We now claim that this algorithm satisfies the assertion of Lemma 2.3. First, we note that with probability at least 0.8, the oracles for both the clustering of the rows and the clustering of the columns are valid, as guaranteed by Lemma 3.7. In turn this guarantees that $R'_0, \dots, R'_{r'}$ and $C'_0, \dots, C'_{r'}$ form a $(16\delta^{1/6}, r'+1)$-partition of M, by Claim 3.3. Also, each of the following occurs with probability at least 0.99:

- The difference between every α_i and the total fraction of the rows of M for which the oracle would output "i" is at most δ/r'. This implies that $\sum_{i=0}^{r'} |\frac{|R'_i|}{n} - \alpha_i| \le 2 \cdot 16\delta^{1/3} + r' \cdot \delta/r' < 33\delta^{1/3}$.
- Similarly to the above, $\sum_{i=0}^{r'} |\frac{|C'_i|}{n} - \beta_i| < 33\delta^{1/3}$. With the previous item this means that for all but at most a $10\delta^{1/6}$ fraction of the pairs (i,j), both $|\frac{|R'_i|}{n} - \alpha_i| \le 7\delta^{1/6}$ and $|\frac{|C'_j|}{n} - \beta_j| \le 7\delta^{1/6}$.
- The fraction of appearances of "1" in the values taken under consideration when calculating $P_{i,j}$ differs from the fraction of appearances in the intersections of all rows assigned to "i" and all columns assigned to "j" (by the oracles) by no more than δ. In addition, by the previous item for all but at most a $10\delta^{1/6}$ fraction of the pairs (i,j), the above fraction differs by no more than $14\delta^{1/6}$ from the fraction of appearances of "1" in $R'_i \times C'_j$, and so (if δ is small enough) for the $16\delta^{1/6}$-homogeneous blocks among these, $P_{i,j}$ will get the correct value. Hence, the (weighted) fraction of wrong $P_{i,j}$ labels is no more than $16\delta^{1/6} + 10\delta^{1/6} = 26\delta^{1/6}$.

Therefore, with probability at least $\frac{3}{4}$ all the above occurs (including the two oracles being valid), and a $26\delta^{1/6}$-signature of a $16\delta^{1/6}$-partition is obtained. □

As a final remark, the proof of Lemma 1.6, given in the next section, also uses an interim lemma about clusterings, Lemma 4.1 below. One could save further on the number of queries in the main theorem if the notion of (δ, r)-clustering would be used throughout instead of the notion of (δ, r)-partitions, but it would still be polynomial (not linear) in ϵ. However, the notion of (δ, r)-partitions is more intuitive and could have applications outside the scope of this work, so we use it instead.

4. Proof of Lemma 1.6. We use the same definition of a (δ, r)-clustering (for sets of rows or columns) as we used in the previous section. Claim 3.3, which was proved above, implies that if A has a $(\delta^2/16, t)$-clustering for both its rows and its columns, then A admits a $(\delta, t+1)$-partition. Therefore, the following lemma immediately implies Lemma 1.6. Moreover, it follows that Lemma 1.6 is true even if we insist on the forbidden submatrices also obeying the order of the rows and the columns of the input matrix (which is ignored for our use of a matrix as representing a bipartite graph).

LEMMA 4.1. *Let k be a fixed integer and let $\delta > 0$ be a small real. For every $n \times n$, 0/1-matrix A, with $n > (k/\delta)^{O(k)}$, either A admits (δ, r)-clusterings for both the rows and columns with $r \le (k/\delta)^{O(k)}$, or for every $k \times k$, 0/1 matrix F, at least a $(\delta/k)^{O(k^2)}$ fraction of the $k \times k$ (ordered) submatrices of A are copies of F.*

We should also note that the above estimate is essentially tight, as shown by a random $n \times n$ matrix A, where each entry is independently chosen to be 1 with probability 2δ, and 0 with probability $1 - 2\delta$. The expected number of copies of the $k \times k$ all 1 matrix in such a matrix is only a $(2\delta)^{k^2}$ fraction of the total number of $k \times k$ submatrices, and it is not difficult to check that with high probability A does not have a $(\delta, o(n))$-clustering for either its rows or its columns.

We will prove the lemma only for the clustering of the columns, because the proof for rows is virtually identical. We make no attempt to optimize the absolute constants and omit all floor and ceiling signs to simplify the presentation. In order to prove the above lemma, we first need the following simple corollary of Sauer's lemma [18, 20].

LEMMA 4.2. *For every $t > 10k$, every $t \times t^{2k-1}$ binary matrix M with no two identical columns contains every possible $k \times k$ binary matrix as a submatrix.*

Proof. By Sauer's lemma [18, 20], every set of $s = 1 + \sum_{i=0}^{k-1} \binom{t}{i}$ consecutive columns of M contains a $k \times 2^k$ submatrix that has no two identical columns (and so contains all 2^k possible binary vectors as columns). Note that $s < t^{k-1}$ and $s(1 + (k+1)\binom{t}{k}) \leq t^{2k-1}$. Thus M can be partitioned into at least $1 + (k+1)\binom{t}{k}$ blocks of size $t \times s$, each consisting of s consecutive columns. Considering these $1 + (k+1) \cdot \binom{t}{k}$ pairwise disjoint consecutive blocks, we now find in each of them a $k \times 2^k$ submatrix with no identical columns. Considering now the set of k rows in each such submatrix, we obtain by the pigeonhole principle k such submatrices of size $k \times 2^k$, all having the same set of rows, such that their column sets are contained in disjoint intervals (according to the column order of M), one following the other. This implies the desired result, as we can choose from each of the submatrices a desired column and thus construct any given $k \times k$ matrix. □

We now turn to the proof of Lemma 4.1. Fix δ and k, and suppose that n is large enough (as a function of δ and k, to be chosen later). Let t be the smallest integer for which $(1 - \frac{1}{2}\delta)^t t^{4k-2} < 0.1$. A simple computation shows that $t = O(\frac{k}{\delta}\log(\frac{k}{\delta}))$. Define $T = t^{2k-1}$ and suppose that A is an $n \times n$ matrix with 0/1 entries which does not have a δ-clustering of the columns of size T. We have to show that in this case A must contain many copies of every $k \times k$ matrix F.

Indeed, let S be a random set of columns of A obtained by choosing, randomly, uniformly, and independently (with repetitions) $\tau = 5T/\delta$ columns of A. We assume that $n > 10(\frac{5T}{\delta})^2$. Note that, in particular, for such an n, with probability at least 9/10 no column is chosen more than once.

CLAIM 4.3. *With probability at least* 0.9*, S contains a subset S' of T columns so that the Hamming distance between any pair of them is at least $\frac{1}{2}\delta n$.*

Proof. Let us choose the members of S one by one and construct, greedily, a subset S' of S consisting of columns so that the Hamming distance between any pair of them is at least $\frac{1}{2}\delta n$ as follows. The first member of S belongs to S', and for all $i > 1$, the ith chosen column of S is added to S' if its Hamming distance from every previous member of S' is at least $\frac{1}{2}\delta n$. Since, by assumption, there is no (δ, T)-clustering of the columns of A, as long as the cardinality of S' is smaller than T, the probability that the next chosen member of S will be added to S' is at least δ (given any history of the previous choices); otherwise it would mean that the balls of radius $\frac{1}{2}\delta n$ around the members of S' form a δ-clustering. It thus follows that the probability that by the end of the procedure the cardinality of S' will still be smaller than T is at most the probability that a binomial random variable with parameters $5T/\delta$ and δ will have value at most T. Hence this probability is smaller than 0.1, which implies the assertion of the claim. □

The usefulness of S' as above is shown by the following claim.

CLAIM 4.4. *Let S' be a fixed set of T columns of A for which the pairwise Hamming distance is at least $\frac{1}{2}\delta n$. Then, if we choose a random set R of t rows of A by choosing them independently and uniformly at random, with probability at least* 0.9 *all the projections of the members of S' on the rows in R are distinct.*

Proof. Let S' be a fixed set of T columns of A so that the Hamming distance between every pair is at least $\frac{1}{2}\delta n$. For any two fixed columns $c_1, c_2 \in S'$ and a random row r we have that the probability that $c_1[r] = c_2[r]$ is at most $1 - \frac{1}{2}\delta$, where $c[j]$ denotes the jth coordinate of c. Hence, the expected number of pairs of members of S' whose projections on R are identical is at most $\binom{T}{2}(1-\frac{1}{2}\delta)^t < 0.1$, where the last inequality follows from the choice of t. The desired result follows. □

We can now conclude the proof of Lemma 4.1 as follows. Fix F to be any $k \times k$, 0/1 matrix. Choosing a random $t \times \tau$ submatrix C of A is just like choosing a set R of t random rows and a set S of τ random columns. By Claim 4.3, with probability at least 0.9, the set S of τ columns contains a subset of the columns S' of size T that has pairwise distances at least $\frac{1}{2}\delta n$. Given that this happens, by Claim 4.4 with probability 0.9 all the t projections of S' on the t rows of C are distinct. Hence with probability at least 0.8 (the probability that both events above hold) Lemma 4.2 ensures that C contains F as a submatrix.

Now choosing a random $k \times k$ submatrix of A can be viewed as first choosing a random $t \times \tau$ matrix C as above and then choosing a random subset of k columns and k rows in C. Hence the probability that such a random $k \times k$ matrix will be identical to F is at least $0.8/(\binom{t}{k}\binom{\tau}{k}) = (\frac{\delta}{k})^{O(k^2)}$.

5. Unfoldable graphs and 1-sided testing.

To construct a 1-sided test that is polynomial in ϵ, one would like to use the following scheme. First, the case where there is no (δ, r)-partition (for the appropriate parameters) is covered also for 1-sided algorithms by Lemma 1.6. Now, assuming that M is ϵ-far from $\mathcal{S}_F$ and has a (δ, r)-partition, using Lemma 2.3, we can find a submatrix Q that has a (δ', r)-partition with a signature similar to a (δ', r)-partition of M. We would like to show that in this case Q contains a member of F which will provide a witness for rejecting M.

However, having a Q with the same signature as a matrix M that is ϵ-far from $\mathcal{S}_F$ still does not imply that Q contains a member of F, because some of the partition blocks of Q may not be homogeneous and so their behavior may depend on n (this was circumvented in the 2-sided algorithm by checking all $n \times n$ matrices that are compatible with the signature). One way to solve this would be to use a Ramsey-like lemma like the one used in [11] to get rid of nonhomogeneous blocks, but this would create an exponential blow-up in the number of queries.

Here we take a different approach. First, in this section we prove the existence of the test only for the case where it is enough for Q to have only one row and one column from every cluster of the partition of M, and so the issue of homogeneity becomes moot. Later, we will use this special case as a lemma to prove the general case.

Definition 5.1. *A matrix M is called* unfoldable *if it contains no two identical rows and no two identical columns. Equivalently, an unfoldable bipartite graph is one that has no two vertices (on the same side) with exactly the same set of neighbors.*

A family F of matrices is called unfoldable *if all its members are unfoldable.*

The main lemma that we will prove in this section essentially states that properties definable by unfoldable matrices are testable.

Lemma 5.2. *For every ϵ, k, and a family F of unfoldable $k \times k$ or smaller matrices, there exists $\delta = (\epsilon/k)^{O(k^2)}$ such that if an $n \times n$ matrix M, where $n > (k/\epsilon)^{O(k)}$, is ϵ-far from the property $\mathcal{S}_F$, then M contains at least δn^{2k} distinct submatrices containing members of F (up to permutations).*

What we will need to use for the general case is the following corollary. In the next section we will use it on the *signature* of M to avoid dealing at all with blocks of M that are not homogeneous.

Corollary 5.3. *For every ϵ, k, and a family F of unfoldable $k \times k$ or smaller matrices, there exists $\delta = (\epsilon/k)^{O(k^2)}$ such that if an $n \times n$ matrix M, where $n > (k/\epsilon)^{O(k)}$, is ϵ-far from the property $\mathcal{S}_F$, then for every set X of δn^2 entries, M*

contains a member of F (up to permutations) that does not include any entry from X.

Proof. Every set X can clearly intersect at most $|X| \cdot \binom{n-1}{k-1}^2 < |X| n^{2k-2}$ submatrices of M. Hence, if $|X| < \delta n^2$, then Lemma 5.2 implies that, in particular, there exists a copy of a forbidden submatrix which does not intersect X. □

To prove Lemma 5.2, and also for the next section, it is more convenient to work with partitions into equally sized blocks.

Definition 5.4. *An r-partition of an $n \times n$ matrix M is called an* r-equipartition *if the size of all the sets R_i and C_j lie between $\lfloor n/r \rfloor$ and $\lceil n/r \rceil$. In an analogous manner we define a* (δ, r)-equipartition.

Note that for (δ, r)-equipartitions, a δ-signature essentially holds no more information than the δ-pattern it includes. The conditional existence of (δ', r')-equipartitions follows from that of (δ, r)-partitions by the following simple lemma.

Lemma 5.5. *For $\delta < \frac{1}{4}$, if a matrix M admits a (δ, r)-partition, then it admits also a $(\sqrt{\delta} + 3\delta, r/\delta)$-equipartition.*

Proof. For simplicity we assume that $l = \delta n/r$ is an integer. We repartition the original (δ, r)-partition of M in the following manner. From every R_i whose size is at least l we randomly and uniformly pick $s = \lfloor |R_i|/l \rfloor$ disjoint subsets $R_{i,1}, \ldots, R_{i,s}$ of size l. We call the matrix rows not picked for any $R_{i,x}$ by this procedure *leftover rows.* We now arbitrarily partition the set of leftover rows into disjoint sets of size l. We then perform the analogous procedure for the columns of the matrix M.

Now for every i and j such that $R_i \times C_j$ was δ-homogeneous, every block $R_{i,p} \times C_{j,t}$ will be $\sqrt{\delta}$-homogeneous with probability at least $1 - \sqrt{\delta}$. To see this assume without loss of generality that $R_i \times C_j$ has at most a δ-fraction of 1's. Then, for any fixed p, t, a random submatrix $R_{i,p} \times C_{j,t}$ of $R_i \times C_j$ has the same expected average value of its entries as the average value for $R_i \times C_j$, which is at most δ. Hence, by the Markov inequality, the probability that $R_{i,p} \times C_{j,t}$ will have more than a $\sqrt{\delta}$ fraction of 1's is at most $\sqrt{\delta}$. This probability is, however, the failure probability of $R_{i,p} \times C_{j,t}$ being $\sqrt{\delta}$-homogeneous.

Thus, there is a choice of the repartitions above for which the number of blocks $R_{i,p} \times C_{j,t}$ that come from δ-homogeneous blocks $R_i \times C_j$ but are not themselves $\sqrt{\delta}$-homogeneous is not more than $\sqrt{\delta}(n/l)^2$.

Also, since the original partition was δ-homogeneous, there are no more than $\delta(n/l)^2$ blocks $R_{i,p} \times C_{j,t}$ that come from blocks of the original partition that are not δ-homogeneous. Finally, there are the blocks that are related to leftover rows and columns. From the procedure it follows that there are no more than $lr \le \delta n$ leftover rows and no more than lr leftover columns. Thus the total number of such blocks is no more than $2\delta(n/l)^2$.

Counting all the above we obtain a total of not more than $(\sqrt{\delta} + 3\delta)(n/l)^2$ blocks that are not $\sqrt{\delta}$-homogeneous, and so the same bound holds also for non-$(\sqrt{\delta} + 3\delta)$-homogeneous blocks. □

Lemma 5.6. *Let k be fixed. For every $0 < \delta < \frac{1}{4}$ and any $n \times n$, $0/1$-matrix M, with $n > (k/\delta)^{O(k)}$, either M has a (δ, t)-equipartition for $t = t(\delta, k) \le (k/\delta)^{O(k)}$, or for every $0/1$-labeled $k \times k$ matrix B, an $h(\delta, k) \ge (\delta/k)^{O(k^2)}$ fraction of the $k \times k$ submatrices of M are B.*

Proof. We set $h(\delta, k) = g(\delta^2/16, k)$ and $t(\delta, k) = 16r(\delta, k)/\delta^2$, where g and r are the functions of Lemma 1.6. If M does not contain an h fraction of $k \times k$ submatrices that are identical to B, then it admits a $(\delta^2/16, r)$-partition as per Lemma 1.6. But then this implies that M admits a (δ, t)-equipartition by Lemma 5.5. □

The following lemma is the main technical tool, showing that the existence of a (δ, r)-partition (for the appropriate parameters) implies a dichotomy between being close to $\mathcal{S}_F$ and containing many forbidden matrices from F.

Lemma 5.7. *Let F be an unfoldable family of $k \times k$ or smaller matrices. Furthermore, let M be a matrix, and let P be an $\epsilon/8$-pattern of an $(\epsilon/8, t)$-equipartition of M for $t > 4k^2$. If P is $\epsilon/2$-close to $\mathcal{S}_F$, then M itself is ϵ-close to $\mathcal{S}_F$, while if P is $\epsilon/2$-far from $\mathcal{S}_F$, then M contains at least $\Omega(n/t)^{2k}$ distinct $k \times k$ matrices containing members of F (up to permutations).*

Proof. Let $R_1, \ldots, R_t$ and $C_1, \ldots, C_t$ be the $(\epsilon/8, t)$-equipartition of M, and let P be the corresponding $(\epsilon/8)$-pattern. If P is indeed $\epsilon/2$-close to $\mathcal{S}_F$, then let P' be the $\epsilon/2$-close matrix containing no members of F. Now modify M by setting every entry of M to be identical to the entry of P' corresponding to its block in the $(\epsilon/8, t)$-equipartition. Denote the modified matrix by M'. M' is ϵ-close to M, because the modified entries can only correspond to either entries where P and P' differed (a total of at most $\epsilon/2n^2$ entries), or entries that correspond to blocks that are not good with respect to P (at most $\epsilon/8n^2$), or entries that correspond to good blocks (at most $\epsilon/8n^2$, as in every good block the corresponding entry of P is $\epsilon/8$-dominant). Now since F is unfoldable, M' cannot contain members of F unless all their rows are in distinct R_i and all their columns are in distinct C_j. But then because P' contains no member of F, neither does M'.

We now assume that P is $\epsilon/2$-far from containing no member of F, and calculate the probability that a uniformly random $k \times k$ submatrix A of M is not a member of F. For simplicity we assume that t divides n. Recalling that $t > 4k^2$ we first note that with probability at least $\frac{1}{2}$ this matrix has no two rows in the same R_i and no two columns in the same C_j. Now, we condition the distribution of A on this event and note that it is identical to the one resulting from the following procedure: First choose uniformly, randomly, and independently a row $r_i \in R_i$ for every $1 \leq i \leq t$ and a column $c_j \in C_j$ for every $1 \leq j \leq t$. Denoting this matrix by Q, now let A be a uniformly random $k \times k$ submatrix of Q.

Because P is an $(\epsilon/8)$-pattern of the equipartition, no more than an $\epsilon/8$ fraction of the entries of M that make up Q come from blocks which are not $\epsilon/8$-good with respect to P. For an entry $Q_{i,j}$ of Q that does come from an $\epsilon/8$-good block $R_i \times C_j$, with probability at least $1 - \epsilon/8$ the value of $Q_{i,j}$ is identical to $P_{i,j}$. This implies that for the random set of entries of M that makes up Q, the expectation of the fraction of entries $Q_{i,j}$ that are consistent with the corresponding $P_{i,j}$ is at least $1 - \epsilon/4$. Hence, with probability at least $\frac{1}{2}$ the matrix Q is $\epsilon/2$-close to P, and so contains a member of F. Now conditioned on this event, the probability that A contains the forbidden submatrix is at least t^{-2k}. Putting all the above together using Bayes's law, the unconditional probability that a uniformly random A contains a forbidden submatrix is at least $t^{-2k}/4$, completing the proof. □

We can now put together the proof of Lemma 5.2 that concludes this section.

Proof of Lemma 5.2. If M is ϵ-far from $\mathcal{S}_F$ (where F is unfoldable), then there are two possible cases for M. Either it contains an $(\epsilon/8, t)$-equipartition for $t(\epsilon/8, k)$ as in Lemma 5.6, or M does not contain such an equipartition.

In the second case, Lemma 5.6 ensures that an $(\epsilon/k)^{O(k^2)}$ fraction of the $k \times k$ matrices are identical to an arbitrary member of F, so we are done.

In the first case, let P be an $\epsilon/8$-pattern of the equipartition of M. By Lemma 5.7 P itself cannot be $\epsilon/2$-close to $\mathcal{S}_F$ (as this would contradict the assumption that

M is ϵ-far from $\mathcal{S}_F$), and so P is $\epsilon/2$-far from $\mathcal{S}_F$. But then Lemma 5.7 implies that there is at least an $\Omega(t^{-2k}) = (\epsilon/k)^{O(k^2)}$ fraction of the $k \times k$ submatrices of M, such that each of these $k \times k$ submatrices contains members from F, as required. □

6. 1-sided testing for general bipartite graphs.

Given a family F of forbidden submatrices that may contain foldable ones, we will first construct a family $\tilde{F}$ that is related to F and is unfoldable.

Definition 6.1. *For a matrix A, we define the* folding *of A as the matrix $\tilde{A}$ resulting from A after removing all duplicate rows and columns, keeping only one of each.*[1]

For a family of matrices F, we define the folding *of F as the family $\tilde{F}$ consisting of all the foldings of the members of A.*

The main technical tool here is proven similarly to Lemma 5.7, but here we actually use Corollary 5.3 for the signature first, to address the possibility of having some nonhomogeneous blocks in our equipartition.

Lemma 6.2. *Let F be a family of $k \times k$ or smaller matrices, and let $\tilde{F}$ be the folding of F. Furthermore, let M be a matrix, and let P be a δ-pattern of a (δ, t)-equipartition of M, for $t \geq (k/\epsilon)^{O(k)}$ and $\delta = (\epsilon/k)^{O(k^2)}$. If P is $\epsilon/2$-close to $\mathcal{S}_{\tilde{F}}$, then M itself is ϵ-close to $\mathcal{S}_F$, while if P is $\epsilon/2$-far from $\mathcal{S}_{\tilde{F}}$, then M contains at least $\Omega(n/kt)^{2k}$ distinct $k \times k$ matrices containing members of F (up to permutations).*

Proof. Let $R_1, \ldots, R_t$ and $C_1, \ldots, C_t$ be the (δ, t)-equipartition of M. If P is indeed $\epsilon/2$-close to $\mathcal{S}_{\tilde{F}}$, then let P' be the $\epsilon/2$-close matrix containing no members of $\tilde{F}$. Now modify M by setting every entry of M to be identical to the entry of P' corresponding to its block in the (δ, t)-equipartition. Denote the modified matrix by M'. As in the proof of Lemma 5.7, it is not hard to see that M' is ϵ-close to M. Now M' cannot contain a member of F (up to permutations) unless P' contains a folding of this member, which is a contradiction as $\tilde{F}$ is the folding of F.

We now assume that P is $\epsilon/2$-far from containing no member of $\tilde{F}$ and calculate the probability that a uniformly random $k \times k$ submatrix A of M is not a member of F. For simplicity we assume that t divides n. We note that the distribution of picking a uniformly random $k \times k$ submatrix A is identical to the distribution of the following procedure: First choose uniformly, randomly, and independently k distinct rows $r_{i,1}, \ldots, r_{i,k} \in R_i$ for every $1 \leq i \leq t$, and k distinct columns $c_{j,1}, \ldots, c_{j,k} \in C_j$ for every $1 \leq j \leq t$. Denoting this matrix by Q, we now let A be a uniformly random $k \times k$ submatrix of Q.

Since P is a δ-pattern of the equipartition, the probability that a random entry x in M is equal to $P_{i,j}$ given that $x \in R_i \times C_j$ and that $R_i \times C_j$ is δ-good is at least $1 - \delta$. Thus, for a δ-good block, with probability at most δ its intersection with Q is not a $k \times k$ matrix whose entries are all identical to the corresponding label of P. Because P is a δ-pattern of the equipartition, the expectation of the number of blocks $R_i \times C_j$ for which their intersection with Q is not a $k \times k$ matrix whose entries are all identical to the corresponding label of P is no more than $2k^2\delta t^2$. We let X denote the set of entries of P corresponding to all such bad blocks. Let E be the event that $|X| \leq 8k^2\delta t^2$. Clearly E occurs with probability at least 3/4.

By Corollary 5.3, for X as above and the matrix P, there is a member of $\tilde{F}$ in P whose entries are disjoint from X (for an appropriate choice of the coefficient

[1] Note that if we remove one of two or more identical rows, the identity relations between columns remain exactly the same, and conversely the identity relations between rows remain exactly the same if we remove duplicate columns. Hence, the order in which we remove duplicates does not affect $\tilde{A}$ apart from a possible permutation in its rows and columns.

in the O notation in the expression of δ, and in the lower bound condition on t). However, if P contains a copy of a member $\tilde{B}$ of $\tilde{F}$ whose entries are disjoint from X, then Q contains the member B of F whose folding is $\tilde{B}$. Now conditioned on the event E, the probability that A contains the forbidden submatrix is at least $(kt)^{-2k}$. Putting all of the above together using Bayes's law, the unconditional probability that a uniformly random A contains a forbidden submatrix is at least $(kt)^{-2k}/4$, completing the proof. □

This allows us to conclude with the lemma yielding the 1-sided test.

Lemma 6.3. *For every ϵ and k there exists $\eta = (\epsilon/k)^{O(k^4)}$ such that if an $n \times n$ matrix M where $n > (k/\epsilon)^{O(k^3)}$ is ϵ-far from the property $\mathcal{S}_F$, where F is a family of $k \times k$ or smaller matrices, then M contains at least ηn^{2k} distinct submatrices containing members of F (up to permutations).*

Proof. We set $\delta = (\epsilon/k)^{O(k^2)}$ as required from Lemma 6.2 and set $t = t(\delta, k) = (k/\epsilon)^{O(k^3)}$ as per Lemma 5.6. Now if M is ϵ-far from $\mathcal{S}_F$, then either M contains a (δ, t)-equipartition or it does not.

In the second case, Lemma 5.6 ensures that there is a $(\delta/k)^{O(k^2)} = (\epsilon/k)^{O(k^4)}$ fraction of the $k \times k$ matrices, such that each of these matrices is identical to an arbitrary member of F, so we are done.

In the first case, let P be a δ-pattern of the equipartition of M. By Lemma 6.2 P itself cannot be $\epsilon/2$-close to $\mathcal{S}_{\tilde{F}}$ (as this would contradict the assumption that M is ϵ-far from $\mathcal{S}_F$), and so P is $\epsilon/2$-far from $\mathcal{S}_{\tilde{F}}$. But then Lemma 6.2 implies that M contains at least an $\Omega((tk)^{-2k}) \geq (\epsilon/k)^{O(k^4)}$ fraction of the $k \times k$ submatrices of M that contain members from F, as required. □

Corollary 6.4. *The property $\mathcal{S}_F$ is ϵ-testable with $(\epsilon/k)^{O(k^4)}$ many queries.*

Proof. Using the η of Lemma 6.3, select independently $3/\eta$ uniformly random $k \times k$ submatrices of M, and for each of them, check whether it contains a member of F. □

7. Open problems.

More general combinatorial structures. A long standing question in graph property testing is that of whether there exists a test for the property of a (general) graph being triangle-free, whose number of queries is less than a tower function in ϵ. Noting the "conditional regularity" nature of Lemma 1.6 here, one would hope for an analogue that will work for triangles. However, formulating such an analogue is not as simple as it seems: Gowers [12] constructed a bipartite (hence triangle-free) graph in which there is a tower lower bound on the size of the smallest regular partition. Hence, the only hope would be of finding a partition in which most of the nonregular pairs are somehow labeled as "irrelevant" for the existence of a triangle in the graph. This still remains open; we already know, however, by [1] that, unlike the case of bipartite graphs, a polynomial dependency (in $1/\epsilon$) is not possible for this case.

Another interesting open question would be to formulate a lemma in the spirit of Lemma 1.6 for higher dimensional matrices that would in turn correspond to r-partite r-uniform hypergraphs. Here too there is probably no avoiding the existence of "irrelevant" portions for which there is no regularity. Take, for example, any 3-dimensional matrix which is constant along the last dimension; it does not contain, for example, the $2 \times 2 \times 2$ matrix that is all zero apart from exactly one entry, while it may still not admit any relatively small regular partition.

Matrices with row and column order. This direction seems at the moment more accessible than those outlined above. It would be interesting to test a matrix for the property of not containing a member of a forbidden family of submatrices, with the same row and column orders (i.e., containing a nontrivial row or column permutation of a forbidden matrix is now allowed). Lemma 1.6 also holds for this framework, so the missing part would be "untangling" the sets of rows and columns in the resulting partition, in order to prove from this partition that one need only consider a set of possible input matrices that can be calculated from a small sample (as in the proof of Theorem 1.3).

Nonbinary matrices. It would also be interesting to prove the result for matrices that are not binary. It is enough to look at matrices with a fixed finite alphabet, because one does not need to distinguish between the different labels that do not appear in the finite set of forbidden matrices F.

Again "full conditional regularity" cannot be guaranteed, but this problem might be a little more accessible (though perhaps with a no longer polynomial dependence of the number of queries on ϵ). A possible course of attack could be to start by partitioning into blocks, each containing less than the full set of labels, and continue by recursively classifying each block as either "repartitionable" or "homogeneous" in a way somewhat reminiscent of what was done (more easily) in [11, 10] for poset properties.

Acknowledgment. We wish to thank Eyal Rozenberg for the discussion concerning an inaccuracy in an earlier version of the proof of Theorem 1.4. We also wish to thank two anonymous referees for their thoughtful comments.

OBSERVING BRANCHING STRUCTURE THROUGH PROBABILISTIC CONTEXTS*

NANCY LYNCH†, ROBERTO SEGALA‡, AND FRITS VAANDRAGER§

Abstract. Probabilistic automata (PAs) constitute a general framework for modeling and analyzing discrete event systems that exhibit both nondeterministic and probabilistic behavior, such as distributed algorithms and network protocols. The behavior of PAs is commonly defined using schedulers (also called adversaries or strategies), which resolve all nondeterministic choices based on past history. From the resulting purely probabilistic structures, trace distributions can be extracted, whose intent is to capture the observable behavior of a PA. However, when PAs are composed via an (asynchronous) parallel composition operator, a global scheduler may establish strong correlations between the behavior of system components and, for example, resolve nondeterministic choices in one PA based on the outcome of probabilistic choices in the other. It is well known that, as a result of this, the (linear-time) trace distribution precongruence is not compositional for PAs. In his 1995 Ph.D. thesis, Segala has shown that the (branching-time) probabilistic simulation preorder is compositional for PAs. In this paper, we establish that the simulation preorder is, in fact, the coarsest refinement of the trace distribution preorder that is compositional. We prove our characterization result by providing (1) a context of a given PA $\mathcal{A}$, called the *tester*, which may announce the state of $\mathcal{A}$ to the outside world, and (2) a specific global scheduler, called the *observer*, which ensures that the state information that is announced is actually correct. Now when another PA $\mathcal{B}$ is composed with the tester, it may generate the same external behavior as the observer only when it is able to simulate $\mathcal{A}$ in the sense that whenever $\mathcal{A}$ goes to some state s, $\mathcal{B}$ can go to a corresponding state u, from which it may generate the same external behavior. Our result shows that probabilistic contexts together with global schedulers are able to exhibit the branching structure of PAs.

1. Introduction.

Labeled transition systems (automata) are studied extensively within concurrency theory as underlying operational models of concurrent systems [27]: a system is described as a state machine whose transitions are labeled by *actions*, where each action describes potential communication with the external environment. An important aspect of concurrency theory is the study of relationships between systems, namely equivalence and preorder relations, with the objective of understanding whether a system can be used in place of another one or as an implementation of some

more abstract description. Several relations are studied in the literature, but the most important classes of relations are represented by simulations and bisimulations [27] and by language (trace) inclusion and equivalence [17]. An extensive classification of existing relations appears in [12], where, in particular, relations are classified as either *branching*, which observe the places where nondeterminism is resolved, or *linear*, which are insensitive to the actual places where nondeterminism is resolved. For instance, language inclusion and language equivalence are linear relations, while simulations and bisimulations are branching relations.

During the last fifteen years there has been a growing interest in the extension of concurrent models with probabilities, mainly motivated by the fact that several applications included randomized behaviors. Some of the most relevant proposals of operational models with probability and nondeterminism are reactive, generative, and stratified systems [13], concurrent labeled Markov chains [15], alternating automata [40, 29], probabilistic automata (PAs) [32], and probabilistic reactive modules [10]. Extensive comparative studies that include these models appear in [36, 4, 35].

Simulation, bisimulation, and language inclusion relations have been extended to the probabilistic case as well. In particular, [22] defines strong bisimulation on reactive systems, [34] defines strong and weak simulation and bisimulation relations on PAs, including a notion of branching bisimulation, [15] defines strong bisimulation on labeled concurrent Markov chains, [29] defines strong and weak bisimulation on alternating automata, and [2] defines branching bisimulation on alternating automata. Although the above definitions are quite different, it turns out that they can all be seen in a uniform way by viewing reactive systems, labeled concurrent Markov chains, and alternating automata as special cases of PAs [35]. For extensive comparative studies we refer the reader again to [36, 4, 35].

In this paper we are interested in extensions of language inclusion to the probabilistic case. On ordinary nondeterministic automata the resolution of nondeterminism produces sequences of alternating states and actions called *executions*; then, by restricting those sequences to visible actions, we obtain the so-called *traces*. Implementation and equivalence of nondeterministic automata can be defined in terms of inclusion and equality of sets of traces. This approach was first proposed in the context of process algebras [17] and is used extensively in the area of I/O automata [25].

An attempt to extend language inclusion to PAs appears in [31], where it is proposed that the probabilistic extension of a trace should be a probability measure over traces. Indeed, the resolution of nondeterminism on PAs produces a stochastic process that induces a probability measure over executions (a *probabilistic execution*), and the restriction of a probabilistic execution to the externally visible actions leads to a probability measure over traces (a *trace distribution*). Then, the proposal of [31] is to compare PAs based on inclusion and equality of sets of trace distributions. This is consistent with ordinary nondeterministic automata since an execution can be seen as a probabilistic execution that assigns probability 1 to a single element, and similarly a trace can be seen as a trace distribution that assigns probability 1 to a single element.

There are several arguments in favor of the point of view that probabilistic executions in PAs should play the role that executions play in ordinary nondeterministic automata, and thus in favor of the notion of trace distribution as well. One element is that this point of view leads to the definition of *weak transitions*, used to extend weak simulations and bisimulation to the probabilistic case. Another element of evidence comes from the area of distributed algorithms, where the probability of termination of an algorithm is studied under any scheduling policy: in this context a scheduler is the entity that resolves nondeterminism, for example, by choosing the order in which processes take steps, and a probabilistic execution is the natural object where the probability of termination can be computed, as demonstrated by several case studies [23, 30, 1, 39, 20, 28, 6] and by the ongoing research on automatic verification tools for probabilistic systems [16]. Finally, again in the area of distributed algorithms, the approach of [31] to language inclusion turns out to be useful for the modular analysis of complex algorithms [30].

An important requirement for an implementation relation on systems is *compositionality*, that is, the relation is preserved by parallel composition. For labeled transition systems, the trace, simulation, and bisimulation preorders are all compositional [17, 27]. For PAs, various simulation and bisimulation preorders are known to be compositional [34]. A problem with the trace-based relations proposed in [31] is that they are not compositional; that is, they are not preserved by parallel composition. A typical solution to the problem, followed by [31], is to define a notion of *trace distribution precongruence* as the coarsest precongruence included in the trace distribution inclusion. Unfortunately, such implicit definition does not provide much insight about the structure of the relation. For this reason, there have been several attempts to characterize it in more concrete terms. In [32] trace distribution precongruence is characterized in terms of the set of trace distributions observable in a certain *principal context*—a rudimentary PA that makes very limited nondeterministic and probabilistic choices; in [33] a testing scenario is proposed. However, these indirect characterizations still do not provide much insight into the structure of trace distribution precongruence; for example, they do not explain its branching structure. Indeed, trace distribution precongruence is not a linear relation since it distinguishes ordinary nondeterministic automata that are trace equivalent.

In this paper, we provide an explicit characterization of the trace distribution precongruence, $\leq_{DC}$, for PAs, which completely explains its branching structure. Namely, we show that $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ iff there exists a *weak probabilistic (forward) simulation relation* from $\mathcal{P}_1$ to $\mathcal{P}_2$. Moreover, we provide a similar characterization of $\leq_{DC}$ for nondeterministic automata in terms of the existence of a weak (nonprobabilistic) simulation relation. It was previously known that simulation relations are sound for $\leq_{DC}$ [32], for both nondeterministic and probabilistic automata; we show the surprising fact that they are also *complete*. That is, we show that, for both nondeterministic and probabilistic automata, probabilistic contexts can observe all the distinctions that can be expressed using simulation relations.

Our proofs of completeness rely on special contexts for PAs, called *testers*. The tester of a PA $\mathcal{P}$, under the action of an appropriate scheduler, can reveal the branching structure of $\mathcal{P}$ via a trace distribution. Such a scheduler is called an *observer scheduler*. Informally, the tester $\mathcal{C}$ of a PA $\mathcal{P}$ announces the outcome of each probabilistic choice of $\mathcal{P}$ by performing an action with the name of the state reached, and flips coins to propose and announce how $\mathcal{P}$ should resolve its nondeterministic choices. The ability of another PA $\mathcal{P}'$ to comply with the requirements of $\mathcal{C}$, that is, that the trace distribution induced by the observer scheduler is also a trace distribution of $\mathcal{P}'\|\mathcal{C}$ (the parallel composition of $\mathcal{P}'$ and $\mathcal{C}$), reveals whether $\mathcal{P}'$ has at least the same possibilities for solving nondeterministic choices as $\mathcal{P}$. If $\mathcal{P} \leq_{DC} \mathcal{P}'$, then we extract a probabilistic forward simulation from $\mathcal{P}$ to $\mathcal{P}'$ by observing how $\mathcal{P}'\|\mathcal{C}$ produces the trace distribution induced by the observer scheduler.

An interesting observation about tester automata is that probabilistic choices of a PA are observed via nondeterministic choices of the tester automaton, while nondeterministic choices of a PA are observed via probabilistic choices of the tester automaton. Thus, the branching structure of a PA is observed via a probabilistic context.

The rest of the paper is structured as follows. Sections 2 and 3 contain basic definitions and results for nondeterministic and probabilistic automata, respectively, and for the preorders we consider. These sections contain no new material, but recall definitions and theorems from the literature. For a more leisurely introductions see [25, 26, 38, 36]. Section 4 introduces the concept of tester automaton and the scheduler for a PA $\mathcal{P}$ and its tester that reveals the structure of $\mathcal{P}$. Sections 5 and 6 contain, respectively, our characterization results for nondeterministic and probabilistic automata. Since the proof of the characterization result for the general case of PAs with internal actions is highly complex, we first present a proof for the special case of nondeterministic automata without internal actions (section 5.1). Then we successively show how we can also handle internal actions (section 5.2) and probabilistic choice (section 6.1) before dealing with the general case of PAs with internal actions (section 6.2). Section 7 contains our conclusions.

2. Definitions and basic results for nondeterministic automata.

In this section we recall definitions and basic results for nondeterministic automata. We impose a few restrictions to avoid confusion and unnecessary complications in the rest of the paper. For more information the reader is referred to [25, 26].

2.1. Nondeterministic automata, executions, and traces.

A *nondeterministic automaton* is a tuple $\mathcal{A} = (Q, \bar{q}, E, H, D)$, where

- Q is a countable set of *states*,
- $\bar{q} \in Q$ is a *start state*,
- E is a countable set of *external actions*,
- H is a countable set of *internal (hidden) actions* with $E \cap H = \emptyset$, and
- $D \subseteq Q \times (E \cup H) \times Q$ is a *transition relation*.

We denote $E \cup H$ by A, and we refer to it as the set of *actions*. We denote a transition (q, a, q') of D by $q \xrightarrow{a} q'$. We write $q \rightarrow q'$ if $q \xrightarrow{a} q'$ for some a, and we write $q \rightarrow$ if $q \rightarrow q'$ for some q'.

We assume finite branching: for each state q the number of pairs (a, q') such that $q \xrightarrow{a} q'$ is finite. We denote the elements of a nondeterministic automaton $\mathcal{A}$ by $Q_{\mathcal{A}}, \bar{q}_{\mathcal{A}}, E_{\mathcal{A}}, H_{\mathcal{A}}, D_{\mathcal{A}}, A_{\mathcal{A}}, \xrightarrow{a}_{\mathcal{A}}$. Often we use the name $\mathcal{A}$ for a generic nondeterministic automaton; in this case, we usually omit the subscripts, writing simply Q, $\bar{q}$, E, H, D, A, and $\xrightarrow{a}$. We extend this convention to allow indices and primes as well; thus, the set of states of a nondeterministic automaton $\mathcal{A}'_i$ is denoted by Q'_i.

Remark 2.1. In the definition of nondeterministic automaton above, we have imposed some restrictions that are not strictly necessary for this paper but rather avoid unnecessary complications. The restriction on the cardinality of the sets of states and actions is imposed to ensure that a nondeterministic automaton has at most countably many finite execution fragments (see definition later), which simplifies the use of measure theory later. The finite branching restriction is imposed to simplify the construction of the tester automaton in section 4; however, the results of this paper generalize to countable branching at the cost of adding complexity to the proofs (cf. Remark 4.5). We have also chosen to define nondeterministic automata with a single initial state rather than a set of initial states. Sets of initial states do not add any technical insight, but they complicate notation slightly.

An *execution fragment* of a nondeterministic automaton $\mathcal{A}$ is a finite or infinite sequence $\alpha = q_0a_1q_1a_2q_2\cdots$ of alternating states and actions, starting with a state and, if the sequence is finite, ending in a state, where each $(q_i, a_{i+1}, q_{i+1}) \in D$. State q_0, the first state of α, is denoted by *fstate*(α). If α is a finite sequence, then the last state of α is denoted by *lstate*(α). An *execution* of $\mathcal{A}$ is an execution fragment whose first state is the start state $\bar{q}$. We let *frags*$(\mathcal{A})$ denote the set of execution fragments of $\mathcal{A}$ and *frags*$^*(\mathcal{A})$ the set of finite execution fragments. Similarly, we let *execs*$(\mathcal{A})$ denote the set of executions of $\mathcal{A}$ and *execs*$^*(\mathcal{A})$ the set of finite executions.

Execution fragment α is a *prefix* of execution fragment α', denoted by $\alpha \leq \alpha'$, if sequence α is a prefix of sequence α'. Finite execution fragment $\alpha_1 = q_0a_1q_1\cdots a_kq_k$ and execution fragment α_2 can be concatenated if *fstate*$(\alpha_2) = q_k$. In this case the *concatenation* of α_1 and α_2, $\alpha_1 \frown \alpha_2$, is the execution fragment $q_0a_1q_1\cdots a_k\alpha_2$. Given an execution fragment α and a finite prefix α', $\alpha \rhd \alpha'$ (read as "α after α'") is defined to be the unique execution fragment α'' such that $\alpha = \alpha' \frown \alpha''$.

The *trace* of an execution fragment α of a nondeterministic automaton $\mathcal{A}$, written *trace*$_{\mathcal{A}}(\alpha)$, or just *trace*(α) when $\mathcal{A}$ is clear from context, is the sequence obtained by restricting α to the set of external actions of $\mathcal{A}$. For a set S of executions of a nondeterministic automaton $\mathcal{A}$, *traces*$_{\mathcal{A}}(S)$, or just *traces*(S) when $\mathcal{A}$ is clear from context, is the set of traces of the executions in S. We say that β is a trace of a nondeterministic automaton $\mathcal{A}$ if there is an execution α of $\mathcal{A}$ with *trace*$(\alpha) = \beta$. Let *traces*$(\mathcal{A})$ denote the set of traces of $\mathcal{A}$. We define the *trace preorder* relation on nondeterministic automata as follows: $\mathcal{A}_1 \leq_T \mathcal{A}_2$ iff $E_1 = E_2$ and *traces*$(\mathcal{A}_1) \subseteq$ *traces*$(\mathcal{A}_2)$. We use $\equiv_T$ to denote the kernel of $\leq_T$. That is, $\mathcal{A}_1 \equiv_T \mathcal{A}_2$ iff $\mathcal{A}_1 \leq_T \mathcal{A}_2$ and $\mathcal{A}_2 \leq_T \mathcal{A}_1$. A similar convention will be adopted to denote the kernels of other preorder relations used in the paper.

If $\beta \in A^*$, then $q \overset{\beta}{\Longrightarrow} q'$ iff there exists an execution fragment α such that *fstate*$(\alpha) = q$, *lstate*$(\alpha) = q'$, and *trace*$(\alpha) =$ *trace*(β). (Here and elsewhere, we abuse notation slightly by extending the *trace* function to arbitrary sequences.) We call $q \overset{\beta}{\Longrightarrow} q'$ a *weak transition*. If β is the empty sequence, then we write alternatively $q \Longrightarrow q'$. Observe that the definition of $q \overset{\beta}{\Longrightarrow} q'$ depends only on the external actions that occur in β. We have chosen to define weak transitions for any sequence β, including internal actions as well, for notational convenience in later definitions.

We let *tr* range over either transitions or weak transitions. For a transition $tr = (q, a, q')$, we denote q by *source*(tr) and q' by *target*(tr).

2.2. Composition. We define composition of nondeterministic automata by synchronizing them on common external actions. There are several ways to do this, but the simplest approach that is followed in several papers is to synchronize nondeterministic automata on common actions and impose the restriction that no internal action of a component is an action of the other component as well. This restriction can easily be eliminated, for example, by renaming internal actions if necessary.

Nondeterministic automata $\mathcal{A}_1$ and $\mathcal{A}_2$ are *compatible* if $H_1 \cap A_2 = A_1 \cap H_2 = \emptyset$. The *(parallel) composition* of compatible nondeterministic automata $\mathcal{A}_1$ and $\mathcal{A}_2$, denoted by $\mathcal{A}_1 \| \mathcal{A}_2$, is the nondeterministic automaton $\mathcal{A} \triangleq (Q_1 \times Q_2, (\bar{q}_1, \bar{q}_2), E_1 \cup E_2, H_1 \cup H_2, D)$, where D is the set of triples (q, a, q') such that, for $i \in \{1, 2\}$,

$$a \in A_i \Rightarrow (\pi_i(q), a, \pi_i(q')) \in D_i \quad \text{and} \quad a \notin A_i \Rightarrow \pi_i(q) = \pi_i(q'),$$

where π_i is the projection function on states of $\mathcal{A}$ defined by $\pi_i(q_1, q_2) = q_i$.

Let α be an execution fragment of $\mathcal{A}_1 \| \mathcal{A}_2$, $i \in \{1, 2\}$. Then $\pi_i(\alpha)$, the ith projection of α, is the sequence obtained from α by projecting each state onto its

ith component, and removing each action not in A_i together with its following state. Sometimes we denote this projection by $\alpha\lceil\mathcal{A}_i$.

PROPOSITION 2.2. *Let $\mathcal{A}_1$ and $\mathcal{A}_2$ be nondeterministic automata, with $\mathcal{A}_1 \leq_T \mathcal{A}_2$. Then, for each nondeterministic automaton $\mathcal{C}$ compatible with both $\mathcal{A}_1$ and $\mathcal{A}_2$, $\mathcal{A}_1\|\mathcal{C} \leq_T \mathcal{A}_2\|\mathcal{C}$.*

2.3. Simulation relations. We define two kinds of simulation relations: forward simulations, which provide a step-by-step correspondence, and weak forward simulations, which are insensitive to the occurrence of internal steps. Namely, relation $R \subseteq Q_1 \times Q_2$ is a *forward simulation* (resp., *weak forward simulation*) from $\mathcal{A}_1$ to $\mathcal{A}_2$ iff $E_1 = E_2$ and both of the following hold:

1. $\bar{q}_1 \; R \; \bar{q}_2$.
2. If $q_1 \; R \; q_2$ and $q_1 \xrightarrow{a} q_1'$, then there exists q_2' such that $q_2 \xrightarrow{a} q_2'$ (resp., $q_2 \overset{a}{\Longrightarrow} q_2'$) and $q_1' \; R \; q_2'$.

We write $\mathcal{A}_1 \leq_F \mathcal{A}_2$ (resp., $\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$) when there is a forward simulation (resp., a weak forward simulation) from $\mathcal{A}_1$ to $\mathcal{A}_2$. It is easy to prove that both $\leq_F$ and $\leq_{wF}$ are preorders, that is, reflexive and transitive. Since all simulation relations in this paper are forward simulations, we often omit the word "forward."

PROPOSITION 2.3. *Let $\mathcal{A}_1$ and $\mathcal{A}_2$ be nondeterministic automata. Then*

1. *if $\mathcal{A}_1 \leq_F \mathcal{A}_2$, then $\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$;*
2. *if $H_1 = H_2 = \emptyset$, then $\mathcal{A}_1 \leq_F \mathcal{A}_2$ iff $\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$;*
3. *if $\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$, then $\mathcal{A}_1 \leq_T \mathcal{A}_2$.*

Proof. The proof is standard; for instance, see [26]. ☐

2.4. Tree-structured automata. We say that a nondeterministic automaton is *tree-structured* if each state is reached via (i.e., occurs as a final state of) a unique execution.

The *unfolding* of nondeterministic automaton $\mathcal{A}$, denoted by *Unfold*$(\mathcal{A})$, is the tree-structured nondeterministic automaton $\mathcal{B}$ obtained from $\mathcal{A}$ by unfolding its transition graph into a tree. Formally,

- $Q_{\mathcal{B}} = \mathit{execs}^*(\mathcal{A})$,
- $\bar{q}_{\mathcal{B}} = \bar{q}_{\mathcal{A}}$,
- $E_{\mathcal{B}} = E_{\mathcal{A}}$,
- $H_{\mathcal{B}} = H_{\mathcal{A}}$, and
- $D_{\mathcal{B}} = \{(\alpha, a, \alpha a q) \mid (\mathit{lstate}(\alpha), a, q) \in D_{\mathcal{A}}\}$.

PROPOSITION 2.4. $\mathcal{A} \equiv_F \mathit{Unfold}(\mathcal{A})$.

Proof. See [26]. It is easy to check that the relation R, where $\alpha \; R \; q$ iff $\mathit{lstate}(\alpha) = q$, is a forward simulation from *Unfold*$(\mathcal{A})$ to $\mathcal{A}$ and that the inverse relation of R is a forward simulation from $\mathcal{A}$ to *Unfold*$(\mathcal{A})$. ☐

PROPOSITION 2.5. $\mathcal{A} \equiv_T \mathit{Unfold}(\mathcal{A})$.

Proof. The proof follows by Proposition 2.4 and Proposition 2.3, parts 1 and 3. ☐

3. Definitions and basic results for probabilistic automata.

3.1. Preliminaries and notation on measure theory. We recall a few basic definitions and notation for measure theory that can be retrieved from any standard book on the subject (e.g., [11]).

A *σ-field* over a set X is a set $\mathcal{F} \subseteq 2^X$ that contains the empty set and is closed under complement and countable union. A pair $(X, \mathcal{F})$, where $\mathcal{F}$ is a σ-field over X, is called a *measurable space.* A *measure* on a measurable space $(X, \mathcal{F})$ is a function $\mu : \mathcal{F} \to [0, \infty]$ such that $\mu(\emptyset) = 0$ and μ is countably additive: for each countable family $\{C_i\}_i$ of pairwise disjoint elements of $\mathcal{F}$, $\mu(\cup_i C_i) = \sum_i \mu(C_i)$. A *probability measure* on $(X, \mathcal{F})$ is a measure μ on $(X, \mathcal{F})$ such that $\mu(X) = 1$. A *subprobability measure* on $(X, \mathcal{F})$ is a measure μ on $(X, \mathcal{F})$ such that $\mu(X) \leq 1$. A *discrete probability measure* on a set X is a probability measure μ on $(X, 2^X)$. A *discrete subprobability measure* on X is a subprobability measure μ on $(X, 2^X)$. We denote the set of discrete probability measures and discrete subprobability measures on X by $\mathit{Disc}(X)$ and $\mathit{SubDisc}(X)$, respectively. We denote the *support* of a discrete measure μ, that is, the set of elements of X that have nonzero measure, by $\mathit{supp}(\mu)$. We let $\delta(q)$ denote the *Dirac measure* for q, the discrete probability measure that assigns probability 1 to $\{q\}$. Finally, if X is nonempty and finite, then $\mathcal{U}(X)$ denotes the *uniform distribution* over X, the discrete measure that assigns probability $1/|X|$ to each element of X. Given two discrete probability measures μ_1, μ_2 on $(X, 2^X)$ and $(Y, 2^Y)$, respectively, we denote by $\mu_1 \times \mu_2$ the *product measure*, that is, the measure on $(X \times Y, 2^{(X \times Y)})$ such that $\mu_1 \times \mu_2((x, y)) = \mu_1(x)\mu_2(y)$ for each $x \in X, y \in Y$.

Sometimes it is useful to know the probability μ of some event C, knowing that some other event C' takes place. We call this the measure of C *conditional* on C' and denote it by $\mu(C \mid C')$. Such probability is defined to be 0 if $\mu(C') = 0$, and $\mu(C \cap C')/\mu(C')$ otherwise.

A function $f : X \to Y$ is said to be *measurable* from $(X, \mathcal{F}_X)$ to $(Y, \mathcal{F}_Y)$ if the inverse image of each element of $\mathcal{F}_Y$ is an element of $\mathcal{F}_X$, that is, for each $C \in F_Y$, $f^{-1}(C) \in \mathcal{F}_X$. In such a case, given a measure μ on $(X, \mathcal{F}_X)$, the function $f(\mu)$ defined on $\mathcal{F}_Y$ by $f(\mu)(C) = \mu(f^{-1}(C))$ for each $C \in \mathcal{F}_Y$ is a measure on $(Y, \mathcal{F}_Y)$ and is called the *image measure* of μ under f.

Given a countable collection of measures $\{\mu_i\}_i$ on $(X, \mathcal{F}_X)$ and a countable collection $\{p_i\}_i$ of real numbers in $[0, \infty)$, denote by $\sum_i p_i \mu_i$ a new function μ such that, for each element $C \in \mathcal{F}_X$, $\mu(C) = \sum_i p_i \mu_i(C)$. We state a few elementary properties.

PROPOSITION 3.1. *The following hold:*

1. $\sum_i p_i \mu_i$ *is a measure on* $(X, \mathcal{F}_X)$.
2. *If each* μ_i *is a (sub)probability measure and* $\sum_i p_i = 1$*, then* $\sum_i p_i \mu_i$ *is a (sub)probability measure.*
3. *If* f *is a measurable function from* $(X, \mathcal{F}_X)$ *to* $(Y, \mathcal{F}_Y)$*, then* $f(\sum_i p_i \mu_i) = \sum_i p_i f(\mu_i)$.

3.2. PAs, executions, and traces. A *probabilistic automaton (PA)* is a tuple $\mathcal{P} = (Q, \bar{q}, E, H, D)$, where all components are exactly as for nondeterministic automata, except that the following holds:

- D, the *transition relation*, is a subset of $Q \times (E \cup H) \times \mathit{Disc}(Q)$.

We define A as before. Also, we use the name $\mathcal{P}$ for a generic PA, and we refer to its components by writing simply Q, $\bar{q}$, E, H, D, A, and $\xrightarrow{a}$. We extend this convention to allow indices and primes as well; thus, the set of states of a PA $\mathcal{P}'_i$ is denoted by Q'_i. We denote a transition (q, a, μ) by $q \xrightarrow{a} \mu$. We assume finite branching: for each state q the number of pairs (a, μ) such that $q \xrightarrow{a} \mu$ is finite. Given a transition $tr = (q, a, \mu)$, we denote q by $\mathit{source}(tr)$ and μ either by $\mathit{target}(tr)$ or by μ_{tr}.

Thus, a PA differs from a nondeterministic automaton in that a transition leads to a probability measure over states rather than to a single state. A nondeterministic automaton can be viewed as a special case of a PA, where the last component of each transition is a Dirac measure. Conversely, we can associate a nondeterministic automaton with each PA by replacing transition relation D by the relation D' given by

$$(q, a, q') \in D' \Leftrightarrow (\exists \mu)[(q, a, \mu) \in D \wedge \mu(q') > 0].$$

Using this correspondence, notions such as execution fragments and traces carry over from nondeterministic automata to PAs.[1] For instance, an execution fragment of a PA is simply an execution fragment of its associated nondeterministic automaton. Along the same lines we write $q \overset{a}{\to} q'$ whenever there exists a measure μ such that $q \overset{a}{\to} \mu$ and $q' \in \mathit{supp}(\mu)$.

An execution fragment of a PA is the result of resolving nondeterministic as well as probabilistic choices; however we are interested also in the outcome of the resolution of nondeterministic choices only. We can think of resolving nondeterminism by unfolding the transition relation of a PA and then choosing only one transition at each point. From the formal point of view it is more convenient to define a function, called a *scheduler*, that chooses transitions based on the past history (i.e., the current position in the unfolding of the transition relation).

A *scheduler* for a PA $\mathcal{P}$ is a function $\sigma : \mathit{frags}^*(\mathcal{P}) \to \mathit{SubDisc}(D)$ such that $\mathit{tr} \in \mathit{supp}(\sigma(\alpha))$ implies $\mathit{source}(\mathit{tr}) = \mathit{lstate}(\alpha)$. A scheduler σ is said to be *deterministic* if for each finite execution fragment α either $\sigma(\alpha)(D) = 0$ or else $\sigma(\alpha) = \delta(\mathit{tr})$ (the Dirac measure for tr) for some $\mathit{tr} \in D$. A scheduler σ is *memoryless* if it depends only on the last state of its argument, that is, for each pair α_1, α_2 of finite execution fragments, if $\mathit{lstate}(\alpha_1) = \mathit{lstate}(\alpha_2)$, then $\sigma(\alpha_1) = \sigma(\alpha_2)$.

Informally, $\sigma(\alpha)$ describes the rule for choosing a transition after α has occurred. The rule itself may be randomized. Since $\sigma(\alpha)$ is a subprobability measure, it is possible that with some nonzero probability no transition is chosen, which corresponds to terminating the computation (with what in nondeterministic automata is called a finite execution fragment). Deterministic schedulers are not allowed to use randomization in their choices, while memoryless schedulers are not allowed to look at the past history in their choices. Deterministic and memoryless schedulers are easier to analyze compared to general schedulers, and several properties (e.g., reachability) can be studied by referring to deterministic memoryless schedulers only. Note that a deterministic memoryless scheduler can be represented alternatively as a partial function from Q to D.

A scheduler σ and a discrete probability measure over states μ induce a measure ϵ on the σ-field generated by cones of execution fragments as follows. If α is a finite execution fragment, then the *cone* of α is defined by $C_\alpha = \{\alpha' \in \mathit{frags}(\mathcal{P}) \mid \alpha \leq \alpha'\}$. The measure ϵ of a cone C_α is defined to be $\mu(q)$ if $\alpha = q$ for some state $q \in Q$, and if α is of the form $\alpha' a' q'$, it is defined by the recursive equation

$$\epsilon(C_\alpha) = \epsilon(C_{\alpha'}) \sum_{\mathit{tr} \in D(a')} \sigma(\alpha')(\mathit{tr}) \mu_{\mathit{tr}}(q'), \tag{1}$$

where $D(a')$ denotes the set of transitions of D that are labeled by a'. Roughly speaking, the measure of a cone C_α equals the probability of doing α when using σ to resolve nondeterminism. Standard measure theoretical arguments ensure that ϵ is well defined. We call the measure ϵ a *probabilistic execution fragment* of $\mathcal{P}$, and we say that ϵ is *generated* by σ and μ. We also denote by $\epsilon_{\sigma,\mu}$ the probabilistic execution fragment generated by σ and μ.

[1] The correspondence between nondeterministic automata and PAs is worked out in great detail in [4].

Proposition 3.2. *Let σ be a scheduler and μ be a discrete probability measure over states. Then fstate$(\epsilon_{\sigma,\mu}) = \mu$.*

Proof. The proof follows immediately by definition of $\epsilon_{\sigma,\mu}$ after observing that the inverse image under *fstate* of a state q is the set C_q. □

We call the measure *fstate*(ϵ) the *first state* of ϵ. If *fstate*(ϵ) is the Dirac measure over the start state $\bar{q}$, then ϵ is called a *probabilistic execution.* We often write $\epsilon_{\sigma,q}$ for $\epsilon_{\sigma,\delta(q)}$, and we say that $\epsilon_{\sigma,q}$ is generated by σ and q.

Example 3.1 (the cone construction is rich). The cone construction produces a very rich set of measurable events. The event "action a occurs at least once," that is, the set of execution fragments where an action a occurs at least once, is measurable since it can be expressed as a union of cones and there are at most countably many cones in a PA. Similarly the event "action a occurs at least n times" is measurable for any natural number n. The event "action a occurs exactly n times" is measurable since it is the intersection of "action a occurs at least n times" with the complement of "action a occurs at least $n + 1$ times." Also the event "action a occurs finitely (infinitely) many times" is measurable since it is the countable union (intersection) of "action a occurs exactly (at least) n times." Similar arguments hold for occurrences of states rather than actions.

Any singleton set is measurable since for an infinite execution fragment α the set $\{\alpha\}$ is the intersection of the cones of all its finite prefixes, while for a finite execution fragment α the set $\{\alpha\}$ is the intersection of C_α with the complement of the union of the cones of the extensions of α. Thus, also the set of finite execution fragments is measurable, and the set of infinite execution fragments is measurable as well.

Observe that the probability of a finite execution fragment α is the probability that α occurs and then the computation terminates. Thus, the probability of the set of finite execution fragments represents the probability of termination in a probabilistic execution fragment. This leads to the idea that a probabilistic execution fragment should be called *finite* if the probability of the set of finite execution fragments is 1.

We now show how to obtain a probability measure over traces from a probabilistic execution fragment. The measurable space is the pair $(E^* \cup E^\omega, \mathcal{F})$, where $\mathcal{F}$ is the σ-field generated by cones of traces. More precisely, the cone of a finite trace β is defined by $C_\beta = \{\beta' \in E^* \cup E^\omega \mid \beta \leq \beta'\}$, where $\leq$ denotes the prefix ordering on sequences. It is easy to check that the *trace* function is measurable since the inverse image of a cone C_β is a union of cones, specifically those cones C_α such that $\beta \leq \mathit{trace}(\alpha)$, and since there are countably many finite execution fragments in a PA.

Given a probabilistic execution fragment ϵ, we define the *trace distribution* of ϵ, *tdist*(ϵ), to be the image measure of ϵ under *trace*. We denote the set of trace distributions of probabilistic executions of a PA $\mathcal{P}$ by *tdists*$(\mathcal{P})$. We define the *trace distribution preorder* relation on PAs by $\mathcal{P}_1 \leq_D \mathcal{P}_2$ iff $E_1 = E_2$ and *tdists*$(\mathcal{P}_1) \subseteq$ *tdists*$(\mathcal{P}_2)$.

An example of a measurable set of traces that is used extensively throughout the paper is the set $E^*a(E^* \cup E^\omega)$ of traces in which a specific action a occurs. We denote this set by $\diamond a$. The inverse image under *trace* of $\diamond a$ can be expressed as a disjoint union of cones of executions, namely the cones of the minimal executions with trace in $\diamond a$. Thus, we have the following proposition, whose elementary proof is omitted.

Proposition 3.3. *Let η be the trace distribution of a probabilistic execution ϵ of a PA $\mathcal{P}$, and let Θ_a be the set of finite executions of $\mathcal{P}$ with a single occurrence of* *action a whose last transition is labeled by a. Then*

$$\eta(\diamond a) = \sum_{\alpha \in \Theta_a} \epsilon(C_\alpha). \tag{2}$$

3.3. Combined, weak, and hyper transitions. We define three new kinds of transitions that play crucial roles in the paper. Informally, a combined transition is a convex combination of transitions that are labeled by the same action, a weak combined transition abstracts from internal computation and is obtained by performing several, possibly zero, combined transitions, while a hyper-transition is a generalization of combined transitions and weak combined transitions where the starting point is a measure over states rather than a single state.

3.3.1. Combined transitions. Let $\{q \xrightarrow{a} \mu_i\}_{i\in I}$ be a collection of transitions of a PA $\mathcal{P}$, and let $\{p_i\}_{i\in I}$ be a collection of probabilities such that $\sum_{i\in I} p_i = 1$. Then the triple $(q, a, \sum_{i\in I} p_i\mu_i)$ is called a *combined transition* of $\mathcal{P}$.

3.3.2. Weak transitions. Consider a probabilistic execution fragment ϵ of a PA $\mathcal{P}$, with first state $\delta(q)$, that assigns probability 1 to the set of all finite execution fragments with trace *trace*(β) for some $\beta \in A^*$. Let μ be the discrete measure on Q defined by $\mu(q') = \epsilon(\{\alpha \mid \mathit{lstate}(\alpha) = q'\})$. Then $q \overset{\beta}{\Longrightarrow} \mu$ is a *weak combined transition* of $\mathcal{P}$. We refer to ϵ as a *representation* of $q \overset{\beta}{\Longrightarrow} \mu$. Observe that the measure μ can be seen alternatively as the image measure of ϵ under *lstate*. This is an abuse of notation because *lstate* is not defined for infinite execution fragments; however, since ϵ assigns measure 1 to the set of finite execution fragments, we can extend the definition of *lstate* to infinite execution fragments for this purpose: for instance, we define the last state of any infinite execution fragment to be $\bar{q}$.

The notion of weak combined transition that we have just defined for PAs is a conservative extension of the corresponding notion defined for nondeterministic automata. Indeed, it is routine to check that whenever $q \overset{\beta}{\Longrightarrow} q'$ is a weak transition of a nondeterministic automaton $\mathcal{A}$, then $q \overset{\beta}{\Longrightarrow} \delta(q')$ is a weak combined transition of $\mathcal{A}$ viewed as a PA.

PROPOSITION 3.4. *Let $\{tr_i = (q, a, \mu_i)\}_{i\in I}$ be a collection of weak combined transitions of a PA $\mathcal{P}$, and let $\{p_i\}_{i\in I}$ be probabilities such that $\sum_{i\in I} p_i = 1$. Then $(q, a, \sum_{i\in I} p_i\mu_i)$, written $\sum_{i\in I} p_i tr_i$, is a weak combined transition of $\mathcal{P}$.*

Proof. For each $i \in I$, let ϵ_i be a representation of tr_i, and σ_i be a scheduler that, together with state q, induces ϵ_i. We omit the index set I in the rest of the proof. For each finite execution fragment α, let $N(\alpha) \triangleq \sum_i p_i\epsilon_i(C_\alpha)$. Define a new scheduler σ as follows:

$$\sigma(\alpha) = \begin{cases} \displaystyle\sum_i \frac{p_i\epsilon_i(C_\alpha)}{N(\alpha)}\sigma_i(\alpha) & \text{if } N(\alpha) > 0, \\ \text{arbitrary} & \text{otherwise.} \end{cases}$$

Informally, the weight that $\sigma(\alpha)$ gives to the choice $\sigma_i(\alpha)$ is the normalized probability with which σ_i contributes to the generation of α. Let ϵ be the probabilistic execution fragment induced by σ and q. Let α be a finite execution fragment of $\mathcal{P}$. We first prove by induction on the length of α that $\epsilon(C_\alpha) = N(\alpha)$. The base case is trivial since $\epsilon(C_q) = 1$ and for each i, $\epsilon_i(C_q) = 1$, which implies $N(q) = \sum_i p_i\epsilon_i(C_q) = 1$; similarly, for each state $q' \neq q$, $\epsilon(C_{q'}) = 0$ and for each i, $\epsilon_i(C_{q'}) = 0$. For the inductive step, let $\alpha = \alpha'a'q'$. If $\epsilon(C_{\alpha'}) = 0$, then, by induction, $N(\alpha') = \sum_i p_i\epsilon_i(C_{\alpha'}) = 0$, which implies that for each i, $p_i\epsilon_i(C_{\alpha'}) = 0$. By the definition of the measure of a cone, in (1), $\epsilon(C_\alpha) = 0$. Furthermore, for each i, if $p_i = 0$, then $p_i\epsilon_i(C_\alpha) = 0$ trivially, and if $p_i > 0$, then $\epsilon_i(C_{\alpha'}) = 0$, and by definition of measure of a cone, in (1), $\epsilon_i(C_\alpha) = 0$, which implies $p_i\epsilon_i(C_\alpha) = 0$. Thus, $N(\alpha) = 0$ as needed. If $\epsilon(C_{\alpha'}) > 0$, then, by the definition of the measure of a cone, in (1),

$$\epsilon(C_\alpha) = \epsilon(C_{\alpha'}) \sum_{tr \in D(a')} \sigma(\alpha')(tr)\mu_{tr}(q').$$

By the induction hypothesis, $N(\alpha') > 0$. Thus, by expanding $\sigma(\alpha')(tr)$ with the definition of σ, we obtain

$$\epsilon(C_\alpha) = \epsilon(C_{\alpha'}) \sum_{tr \in D(a')} \left(\sum_i \frac{p_i\epsilon_i(C_{\alpha'})}{N(\alpha')}\sigma_i(\alpha')(tr) \right) \mu_{tr}(q').$$

By standard algebraic manipulations (exchanges of sums and rearrangements of constants) we obtain

$$\epsilon(C_\alpha) = \frac{\epsilon(C_{\alpha'})}{N(\alpha')} \sum_i \sum_{tr \in D(a')} p_i\epsilon_i(C_{\alpha'})\sigma_i(\alpha')(tr)\mu_{tr}(q').$$

By induction, $\epsilon(C_{\alpha'}) = N(\alpha')$. Thus, by simplifying (removing) the leftmost term and rearranging constants, we obtain

$$\epsilon(C_\alpha) = \sum_i p_i \left(\epsilon_i(C_{\alpha'}) \sum_{tr \in D(a')} \sigma_i(\alpha')(tr)\mu_{tr}(q') \right).$$

Finally, by the definition of the measure of a cone, in (1), we get the desired equation

$$\epsilon(C_\alpha) = N(\alpha) = \sum_i p_i\epsilon_i(C_\alpha).$$

Thus, $\epsilon = \sum_i p_i\epsilon_i$. Since each ϵ_i assigns probability 1 to the set of finite execution fragments of $\mathcal{P}$ with trace *trace*(a), then so does ϵ. Furthermore, by Proposition 3.1.3, *lstate*$(\epsilon) = \sum_i p_i$ *lstate*(ϵ_i). That is, ϵ is a representation of a weak combined transition $(q, a, \sum_i p_i \textit{ lstate}(\epsilon_i))$, which, since *lstate*$(\epsilon_i) = \mu_i$, is the triplet $(q, a, \sum_i p_i \mu_i)$. Hence, $\sum_i p_i tr_i$ is a weak combined transition of $\mathcal{P}$. □

3.3.3. Hyper-transitions. Let $\mathcal{P}$ be a PA with $a \in A$, and let $\mu \in \textit{Disc}(Q)$. For each $q \in \textit{supp}(\mu)$, suppose that $q \xrightarrow{a} \mu_q$ is a combined transition of $\mathcal{P}$. Let μ' be $\sum_{q \in \textit{supp}(\mu)} \mu(q)\mu_q$. Then $\mu \xrightarrow{a} \mu'$ is called a *hyper-transition* of $\mathcal{P}$. Also, let $\beta \in A^*$, and for each $q \in \textit{supp}(\mu)$, suppose that $q \overset{\beta}{\Longrightarrow} \mu_q$ is a weak combined transition of $\mathcal{P}$. Let μ' be $\sum_{q \in \textit{supp}(\mu)} \mu(q)\mu_q$. Then $\mu \overset{\beta}{\Longrightarrow} \mu'$ is called a *weak hyper-transition* of $\mathcal{P}$.

We now prove two technical properties of weak hyper-transitions. The first property gives an alternative definition of weak hyper-transition and is used to prove the second property; the second property states that weak hyper-transitions can be concatenated. It will be used in section 6.2.

PROPOSITION 3.5. *There is a weak hyper-transition $\mu \overset{\beta}{\Longrightarrow} \mu'$ iff there is a scheduler σ such that $\epsilon_{\sigma,\mu}$ assigns probability 1 to the set of finite execution fragments with trace β, and lstate$(\epsilon_{\sigma,\mu}) = \mu'$. We say that $\epsilon_{\sigma,\mu}$ represents $\mu \overset{\beta}{\Longrightarrow} \mu'$.*

Proof. Let $\{q_i\}_I$ be an enumeration of the states in *supp*(μ). We prove the two implications separately.

$\Rightarrow$ For each i let σ_i be a scheduler such that ϵ_{σ_i,q_i} represents $q_i \overset{\beta}{\Longrightarrow} \mu_i$ and $\mu' = \sum_I \mu(q_i)\mu_i$. Let σ be a new scheduler defined as follows:

$$\sigma(\alpha) = \begin{cases} \sigma_i(\alpha) & \text{if } \mathit{fstate}(\alpha) = q_i \text{ for some } i \in I, \\ 0 & \text{otherwise.} \end{cases}$$

We first prove that $\epsilon_{\sigma,\mu} = \sum_i \mu(q_i)\epsilon_{\sigma_i,q_i}$ by demonstrating that $\epsilon_{\sigma,\mu}(C_\alpha) = \sum_i \mu(q_i)\epsilon_{\sigma_i,q_i}(C_\alpha)$ for each finite execution fragment α. The proof is by induction on the length of α. For the base case, let $\alpha = q$ for some state q. By the definition of the measure of a cone, $\epsilon_{\sigma,\mu}(C_\alpha) = \mu(q)$, and, for each i, $\epsilon_{\sigma_i,q_i}(C_\alpha)$ is 1 if $q = q_i$ and 0 otherwise. Thus, $\epsilon_{\sigma,\mu}(C_q) = \sum_i \mu(q_i)\epsilon_{\sigma_i,q_i}(C_q)$ trivially. For the inductive step, let α be $\alpha' a q$. If $\mathit{fstate}(\alpha') \notin \mathit{supp}(\mu)$, then trivially $\epsilon_{\sigma,\mu}(C_\alpha) = 0$ and, for each i, $\epsilon_{\sigma_i,q_i}(C_\alpha) = 0$. Thus, $\epsilon_{\sigma,\mu}(C_\alpha) = \sum_i \mu(q_i)\epsilon_{\sigma_i,q_i}(C_\alpha)$. If $\mathit{fstate}(\alpha') \in \mathit{supp}(\mu)$, then let j be the index of $\mathit{fstate}(\alpha')$. By the definition of the measure of a cone, $\epsilon_{\sigma,\mu}(C_\alpha) = \epsilon_{\sigma,\mu}(C_{\alpha'}) \sum_{tr\in D(a)} \sigma(\alpha')(tr)\mu_{tr}(q)$. By induction and the definition of σ,

$$\epsilon_{\sigma,\mu}(C_\alpha) = \sum_i \mu(i)\epsilon_{\sigma_i,q_i}(C_{\alpha'}) \sum_{tr\in D(a)} \sigma_j(\alpha')(tr)\mu_{tr}(q).$$

Since only $\epsilon_{\sigma_j,q_j}(C_{\alpha'})$ may be different from 0, we get

$$\epsilon_{\sigma,\mu}(C_\alpha) = \mu(q_j)\epsilon_{\sigma_j,q_j}(C_{\alpha'}) \sum_{tr\in D(a)} \sigma_j(\alpha')(tr)\mu_{tr}(q) = \mu(q_j)\epsilon_{\sigma_j,q_j}(C_\alpha).$$

For the same reason, $\sum_i \mu(q_i)\epsilon_{\sigma_i,q_i}(C_\alpha) = \mu(q_j)\epsilon_{\sigma_j,q_j}(C_\alpha)$. Thus, $\epsilon_{\sigma,\mu}(C_\alpha) = \sum_i \mu(i)\epsilon_{\sigma_i,q_i}(C_\alpha)$, as needed.

Since each ϵ_{σ_i,q_i} assigns probability 1 to the set of finite execution fragments with trace β, then also $\epsilon_{\sigma,\mu}$ assigns probability 1 to the set of finite execution fragments with trace β. Furthermore, by Proposition 3.1.3, $\mathit{lstate}(\epsilon_{\sigma,\mu}) = \sum_i \mu(q_i)\mathit{lstate}(\epsilon_{\sigma_i,q_i}) = \mu'$. Thus, $\mathit{lstate}(\epsilon_{\sigma,\mu})$ represents $\mu \overset{\beta}{\Longrightarrow} \mu'$.

$\Leftarrow$ Let σ be a scheduler that represents $\mu \overset{\beta}{\Longrightarrow} \mu'$. For each i, let $\sigma_i = \sigma$. Observe that for each finite execution fragment α,

$$\epsilon_{\sigma,\mu}(C_\alpha) = \mu(\mathit{fstate}(\alpha))\epsilon_{\sigma,\mathit{fstate}(\alpha)}(C_\alpha).$$

Thus, as in the previous case, $\epsilon_{\sigma,\mu} = \sum_i \mu(i)\epsilon_{\sigma_i,q_i}$. Let $q_i \overset{\beta}{\Longrightarrow} \mu_i$ be the weak transition represented by ϵ_{σ_i,q_i}. Since $\mu' = \mathit{lstate}(\epsilon_{\sigma,\mu})$ and for each i, $\mu_i = \mathit{lstate}(\epsilon_{\sigma_i,q_i})$, by Proposition 3.1.3, $\mu' = \sum_i \mu(q_i)\mu_i$. This suffices. □

PROPOSITION 3.6. *Suppose that* $\mu_1 \overset{\beta_1}{\Longrightarrow} \mu_2$ *and* $\mu_2 \overset{\beta_2}{\Longrightarrow} \mu_3$ *are weak hyper-transitions of a PA* $\mathcal{P}$. *Then* $\mu_1 \overset{\beta_1\beta_2}{\Longrightarrow} \mu_3$ *is a weak hyper-transition of* $\mathcal{P}$.

Proof. Let ϵ_1 and ϵ_2 be the probabilistic execution fragments that represent $\mu_1 \overset{\beta_1}{\Longrightarrow} \mu_2$ and $\mu_2 \overset{\beta_2}{\Longrightarrow} \mu_3$, respectively, and let σ_1 and σ_2 be the schedulers that generate ϵ_1 and ϵ_2, respectively. Let $N(\alpha) \triangleq \epsilon_1(C_\alpha) + \sum_{\alpha' < \alpha} \epsilon_1(\alpha')\epsilon_2(C_{\alpha \triangleright \alpha'} \mid C_{\alpha' \triangleright \alpha'})$, where we recall that $\epsilon_2(C_{\alpha \triangleright \alpha'} \mid C_{\alpha' \triangleright \alpha'})$ denotes the probability of $C_{\alpha \triangleright \alpha'}$ conditional on $C_{\alpha' \triangleright \alpha'}$. Define a new scheduler σ as follows:

$$\sigma(\alpha) = \begin{cases} \frac{\epsilon_1(C_\alpha)\sigma_1(\alpha) + \sum_{\alpha' \leq \alpha} \epsilon_1(\alpha')\epsilon_2(C_{\alpha \triangleright \alpha'} | C_{\alpha' \triangleright \alpha'})\sigma_2(\alpha \triangleright \alpha')}{N(\alpha)} & \text{if } N(\alpha) > 0, \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

Informally, σ is a scheduler that represents a concatenation of ϵ_1 and ϵ_2. A finite execution fragment α can be reached in the concatenation of ϵ_1 and ϵ_2 either because ϵ_1 reaches it or because ϵ_1 terminates at a prefix of α from which ϵ_2 continues. The scheduler σ from α should behave according to σ_1 whenever α is reached in ϵ_1, and according to σ_2, with the appropriate argument, whenever α is reached in ϵ_2. The schedules from α must be weighted by the probabilities with which ϵ_1 and ϵ_2 lead to α. The term $N(\alpha)$ is a normalization factor whose computation is just technical. In the formal proof we have to show that σ is indeed a scheduler (in other words, the value of N is correct), and that σ generates the representation of $\mu_1 \overset{\beta_1\beta_2}{\Longrightarrow} \mu_3$. These proofs are mainly detailed algebraic manipulations. An interesting point of the proof is (4), which expresses the probability of a finite execution fragment in the concatenation of ϵ_1 and ϵ_2 in terms of the probabilities of finite execution fragments of ϵ_1 and ϵ_2.

We show that σ is a scheduler. That is, for each finite execution fragment α, $\sigma(\alpha)(D) \le 1$, or equivalently, $\epsilon_1(C_\alpha)\sigma_1(\alpha)(D)+\sum_{\alpha' \le \alpha}\epsilon_1(\alpha')\epsilon_2(C_{\alpha\triangleright\alpha'} \mid C_{\alpha'\triangleright\alpha'})\sigma_2(\alpha\triangleright\alpha')(D) \le N(\alpha)$, where the left-hand term is the numerator of the definition of σ applied to D. Since σ_2 is a scheduler, we know that $\sigma_2(\alpha\triangleright\alpha')(D) \le 1$. Also, observe that $\epsilon_1(C_\alpha)\sigma_1(\alpha)(D) = \epsilon_1(C_\alpha - \{\alpha\})$. Thus, it suffices to show that $\epsilon_1(C_\alpha - \{\alpha\}) + \sum_{\alpha' \le \alpha}\epsilon_1(\alpha')\epsilon_2(C_{\alpha\triangleright\alpha'} \mid C_{\alpha'\triangleright\alpha'}) \le N(\alpha)$. We separate from the sum the term with $\alpha' = \alpha$ and observe that $\epsilon_2(C_{\alpha\triangleright\alpha} \mid C_{\alpha\triangleright\alpha}) \le 1$. The new inequality, which suffices for our purposes, is $\epsilon_1(C_\alpha - \{\alpha\}) + \epsilon_1(\{\alpha\}) + \sum_{\alpha' < \alpha}\epsilon_1(\alpha')\epsilon_2(C_{\alpha\triangleright\alpha'} \mid C_{\alpha'\triangleright\alpha'}) \le N(\alpha)$. However, since $\epsilon_1(C_\alpha - \{\alpha\}) + \epsilon_1(\{\alpha\}) = \epsilon_1(C_\alpha)$, the inequality above is $N(\alpha) \le N(\alpha)$, which is trivially true.

Let ϵ be the probabilistic execution fragment generated by σ and μ_1. We show that ϵ represents $\mu_1 \overset{\beta_1\beta_2}{\Longrightarrow} \mu_3$ in three steps. First we show by induction on the length of a finite execution fragment α that $\epsilon(C_\alpha) = N(\alpha)$. The base case is trivial since $N(q) = \epsilon_1(C_q)$ by definition of N, and $\epsilon_1(C_q) = \epsilon(C_q) = \mu_1(q)$ by definition of ϵ_1 and ϵ since both measures are generated by μ_1. For the inductive step, let $\alpha = \alpha' a' q'$. If $\epsilon(C_{\alpha'}) = 0$, then by the definition of the measure of a cone, in (1), $\epsilon(C_\alpha) = 0$. We show that $N(\alpha) = 0$ as well. By induction, since $\epsilon(C_{\alpha'}) = 0$, $N(\alpha') = 0$. By definition of N, $\epsilon_1(C_{\alpha'}) = 0$, and $\epsilon_1(\alpha'')\epsilon_2(C_{\alpha'\triangleright\alpha''} \mid C_{\alpha''\triangleright\alpha''}) = 0$ for each $\alpha'' < \alpha'$. Then, by the definition of a conditional measure and of a measure of a cone, $\epsilon_1(C_\alpha) = 0$ and $\epsilon_1(\alpha'')\epsilon_2(C_{\alpha\triangleright\alpha''} \mid C_{\alpha''\triangleright\alpha''}) = 0$ for each $\alpha'' < \alpha'$. By $\epsilon_1(C_{\alpha'}) = 0$, also $\epsilon_1(\alpha') = 0$, and hence $\epsilon_1(\alpha')\epsilon_2(C_{\alpha\triangleright\alpha'} \mid C_{\alpha'\triangleright\alpha'}) = 0$. We have shown that all the terms of the definition of $N(\alpha)$ are 0, and thus $N(\alpha) = 0$ as needed. If $\epsilon(C_{\alpha'}) > 0$, then by expanding σ with its definition in (1), the definition of the measure of a cone, we get that $\epsilon(C_\alpha)/\epsilon(C_{\alpha'})$ equals

$$\sum_{tr \in D(a)} \frac{\epsilon_1(C_{\alpha'})\sigma_1(\alpha')(tr) + \sum_{\alpha'' \le \alpha'}\epsilon_1(\alpha'')\epsilon_2(C_{\alpha'\triangleright\alpha''} \mid C_{\alpha''\triangleright\alpha''})\sigma_2(\alpha' \triangleright \alpha'')(tr)}{N(\alpha')}\mu_{tr}(q').$$

By induction, $\epsilon(C_{\alpha'}) = N(\alpha')$, and thus the two terms can be simplified in the equation above. Then, by rearranging terms algebraically, we get

$$\epsilon(C_\alpha) = \sum_{tr \in D(a)} \epsilon_1(C_{\alpha'})\sigma_1(\alpha')(tr)\mu_{tr}(q')$$

$$+ \sum_{\alpha'' \le \alpha'} \epsilon_1(\alpha'') \sum_{tr \in D(a)} \epsilon_2(C_{\alpha'\triangleright\alpha''} \mid C_{\alpha''\triangleright\alpha''})\sigma_2(\alpha' \triangleright \alpha'')(tr)\mu_{tr}(q').$$

By the definition of the measure of a cone, the first term above is $\epsilon_1(C_\alpha)$. With a similar argument, after applying the definition of a conditional measure and distinguishing the cases where $\epsilon_2(C_{\alpha'' \rhd \alpha''}) = 0$, the second term above is $\sum_{\alpha'' \leq \alpha'} \epsilon_1(\alpha'')\epsilon_2(C_{\alpha \rhd \alpha''} \mid C_{\alpha'' \rhd \alpha''})$. Thus, we get

$$\epsilon(C_\alpha) = \epsilon_1(C_\alpha) + \sum_{\alpha'' \leq \alpha'} \epsilon_1(\alpha'')\epsilon_2(C_{\alpha \rhd \alpha''} \mid C_{\alpha'' \rhd \alpha''}).$$

Then it is enough to observe that the right-hand side of the equation above is $N(\alpha)$ since $\alpha'' \leq \alpha'$ iff $\alpha'' < \alpha$.

Second we show that for each finite execution fragment α,

$$\epsilon(\alpha) = \sum_{\alpha' \leq \alpha} \epsilon_1(\alpha')\epsilon_2(\alpha \rhd \alpha' \mid C_{\alpha' \rhd \alpha'}). \tag{4}$$

Observe that, by the definition of the cone σ-field, $\epsilon(\alpha) = \epsilon(C_\alpha) - \sum_{a \in A, q \in Q} \epsilon(C_{\alpha a q})$. By replacing the ϵ measures of cones with the definition of N in the equation above, we get

$$\begin{aligned}\epsilon(\alpha) = \epsilon_1(C_\alpha) &+ \sum_{\alpha' < \alpha} \epsilon_1(\alpha')\epsilon_2(C_{\alpha \rhd \alpha'} \mid C_{\alpha' \rhd \alpha'}) \\ &- \sum_{a \in A, q \in Q} \left(\epsilon_1(C_{\alpha a q}) + \sum_{\alpha' < \alpha a q} \epsilon_1(\alpha')\epsilon_2(C_{\alpha a q \rhd \alpha'} \mid C_{\alpha' \rhd \alpha'}) \right).\end{aligned}$$

We now use the terms $\epsilon_1(C_\alpha)$ and $-\sum_{a \in A, q \in Q} \epsilon_1(C_{\alpha a q})$ in the equation above to derive $\epsilon_1(\alpha)$, and similarly we use part of the other two terms to derive the following:

$$\epsilon(\alpha) = \epsilon_1(\alpha) + \sum_{\alpha' < \alpha} \epsilon_1(\alpha')\epsilon_2(\alpha \rhd \alpha' \mid C_{\alpha' \rhd \alpha'}) - \sum_{a \in A, q \in Q} \epsilon_1(\alpha)\epsilon_2(C_{\alpha a q \rhd \alpha} \mid C_{\alpha \rhd \alpha}).$$

Observe that the third term in the equation above is $\epsilon_1(\alpha)\epsilon_2((C_{\alpha \rhd \alpha} - \{\alpha \rhd \alpha\}) \mid C_{\alpha \rhd \alpha})$. Thus, by adding and subtracting the term $\epsilon_1(\alpha)\epsilon_2(\alpha \rhd \alpha \mid C_{\alpha \rhd \alpha})$ and rearranging algebraically, we get

$$\epsilon(\alpha) = \sum_{\alpha' \leq \alpha} \epsilon_1(\alpha')\epsilon_2(\alpha \rhd \alpha' \mid C_{\alpha' \rhd \alpha'}) + \epsilon_1(\alpha)\left(1 - \epsilon_2(C_{\alpha \rhd \alpha} \mid C_{\alpha \rhd \alpha})\right).$$

If $\epsilon_1(\alpha) = 0$, then (4) follows trivially. If $\epsilon_1(\alpha) > 0$, then, since ϵ_1 represents $\mu_1 \overset{\beta_1}{\Longrightarrow} \mu_2$, $\mu_2(q) > 0$, where q is *lstate*(α). Since ϵ_2 is generated by σ_2 and μ_2, $\epsilon_2(C_q) = \mu_2(q) > 0$. By definition of $\rhd$, $\alpha \rhd \alpha = q$, and thus $\epsilon_2(C_{\alpha \rhd \alpha}) > 0$. By the definition of the conditional measure, $\epsilon_2(C_{\alpha \rhd \alpha} \mid C_{\alpha \rhd \alpha}) = 1$, which leads again to (4).

Third we show that ϵ represents $\mu_1 \overset{\beta_1\beta_2}{\Longrightarrow} \mu_3$. Let α be such that $\epsilon(\alpha) > 0$. By (4) there exists a prefix α' of α such that $\epsilon_1(\alpha') > 0$ and $\epsilon_2(\alpha' \rhd \alpha) > 0$. Then *trace*$(\alpha') = \beta_1$ and *trace*$(\alpha \rhd \alpha') = \beta_2$. Thus, *trace*$(\alpha) = \beta_1\beta_2$. Let μ be *lstate*(ϵ). We are left to show that $\mu = \mu_3$. Consider a state q of Q. By the definition of an image measure and (4), $\mu(q) = \sum_{\alpha \mid lstate(\alpha) = q} \sum_{\alpha' \leq \alpha} \epsilon_1(\alpha')\epsilon_2(\alpha \rhd \alpha' \mid C_{\alpha' \rhd \alpha'})$. The sum above can be restructured as follows:

$$\mu(q) = \sum_{\alpha'} \sum_{\alpha \mid fstate(\alpha) = lstate(\alpha'), lstate(\alpha) = q} \epsilon_1(\alpha')\epsilon_2(\alpha \mid C_{\alpha' \rhd \alpha'}).$$

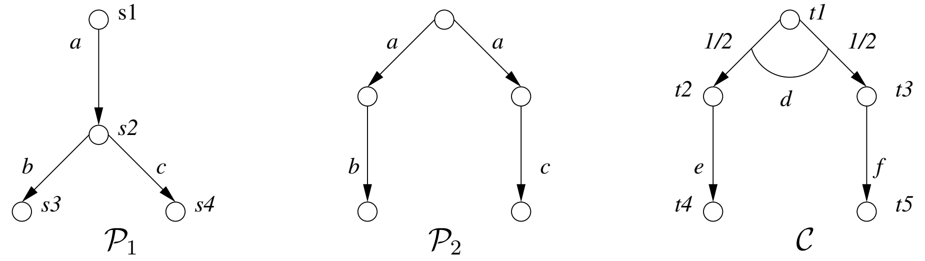

FIG. 3.1. *Trace distribution inclusion is not preserved by composition (without communication).*

We further partition the sums over $lstate(\alpha')$, thus getting

$$\mu(q) = \sum_{q' \in Q} \sum_{\alpha' | lstate(\alpha') = q'} \sum_{\alpha | fstate(\alpha) = q', lstate(\alpha) = q} \epsilon_1(\alpha')\epsilon_2(\alpha \mid C_{q'}).$$

Observe that, since $\mu_2 = lstate(\epsilon_1)$, if $\mu_2(q') = 0$, then there is no α' with last state q' such that $\epsilon_1(\alpha') > 0$. Thus we can restrict the first sum to those q' such that $\mu_2(q') > 0$. Also, if $\mu_2(q') > 0$, we have already concluded before that $\epsilon_2(C_{\alpha' \rhd \alpha'}) = \mu_2(q')$. Thus, we get

$$\mu(q) = \sum_{q' \in Q | \mu_2(q') > 0} \sum_{\alpha' | lstate(\alpha') = q'} \sum_{\alpha | fstate(\alpha) = q', lstate(\alpha) = q} \epsilon_1(\alpha')\epsilon_2(\alpha)/\mu_2(q').$$

Observe that the two inner sums can be exchanged. By definition of μ_2 it follows that $\sum_{\alpha' | lstate(\alpha') = q'} \epsilon_1(\alpha') = \mu_2(q')$. Thus, we get

$$\mu(q) = \sum_{q' \in Q | \mu_2(q') > 0} \sum_{\alpha | fstate(\alpha) = q', lstate(\alpha) = q} \epsilon_2(\alpha).$$

Following the same argument that we used to restrict the sum over q', we can remove such restriction, and thus we can remove the most external sum, leading to $\mu(q) = \sum_{\alpha | lstate(\alpha) = q} \epsilon_2(\alpha)$, which is the definition of $\mu_3(q)$. □

3.4. Composition. Two PAs, $\mathcal{P}_1$ and $\mathcal{P}_2$, are *compatible* if $H_1 \cap A_2 = A_1 \cap H_2 = \emptyset$. The *(parallel) composition* of two compatible PAs $\mathcal{P}_1$ and $\mathcal{P}_2$, denoted by $\mathcal{P}_1 \| \mathcal{P}_2$, is the PA $\mathcal{P} = (Q_1 \times Q_2, (\bar{q}_1, \bar{q}_2), E_1 \cup E_2, H_1 \cup H_2, D)$, where D is the set of triples $(q, a, \mu_1 \times \mu_2)$ such that, for $i \in \{1, 2\}$,

$$a \in A_i \Rightarrow (\pi_i(q), a, \mu_i) \in D_i \quad \text{and} \quad a \notin A_i \Rightarrow \mu_i = \delta(\pi_i(q)).$$

Let ϵ be a probabilistic execution (fragment) of $\mathcal{P}_1 \| \mathcal{P}_2$ and let $i \in \{1, 2\}$. Define $\pi_i(\epsilon)$, the ith projection of ϵ, to be the image measure under π_i of ϵ. It is easy to verify that the projection function is measurable. When convenient, we denote a projection by $\epsilon \lceil \mathcal{P}_i$, where $\mathcal{P}_i$ is the PA that appears in the ith position.

PROPOSITION 3.7. *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be compatible PAs, and let ϵ be a probabilistic execution (fragment) of $\mathcal{P}_1 \| \mathcal{P}_2$. Then for each $i \in \{1, 2\}$, $\pi_i(\epsilon)$ is a probabilistic execution (fragment) of $\mathcal{P}_i$.*

Proof. The proof follows by Propositions 4.3.4 and 4.3.5 of [32]. □

The trace distribution preorder is not preserved by composition [34, 37], as is shown by the following example.

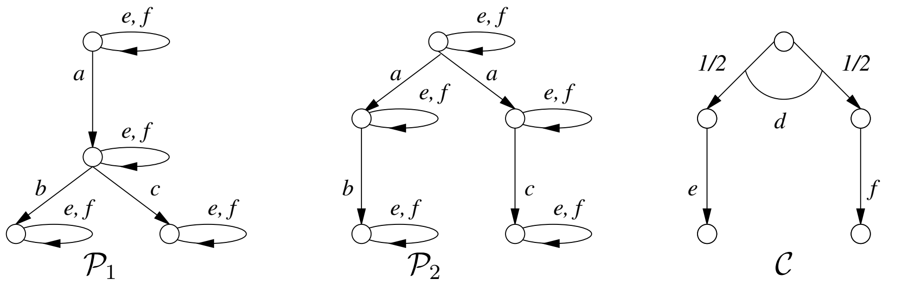

FIG. 3.2. *Trace distribution inclusion is not preserved by composition (with communication).*

Example 3.2 (failure of compositionality). Consider the two (nondeterministic) automata $\mathcal{P}_1$ and $\mathcal{P}_2$ of Figure 3.1. The two automata are trace equivalent, and it is easy to see that they are also trace distribution equivalent. Now consider the compositions $\mathcal{P}_1\|\mathcal{C}$ and $\mathcal{P}_2\|\mathcal{C}$, where $\mathcal{C}$ is the PA of Figure 3.1 and we assume that the actions of $\mathcal{C}$ are not shared with $\mathcal{P}_1$ and $\mathcal{P}_2$. It is possible to build a probabilistic execution of $\mathcal{P}_1\|\mathcal{C}$ as follows: first a is scheduled followed by d; then e or f is scheduled, depending on the outcome state of the transition labeled by d; finally, b or c is scheduled, depending on whether e or f was scheduled. Formally, we consider the probabilistic execution induced by the deterministic memoryless scheduler specified by the following partial function, where a transition is denoted by the unique action labeling it:

Q_1	$Q_\mathcal{C}$	$D_{\mathcal{P}_1\|\mathcal{C}}$
s_1	t_1	a
s_2	t_1	d
s_2	t_2	e
s_2	t_3	f
s_2	t_4	b
s_2	t_5	c

Thus, in the resulting trace distribution there is a total correlation between e, b and f, c, respectively. The same trace distribution cannot be obtained from $\mathcal{P}_2\|\mathcal{C}$ because after scheduling the transition labeled by a we are already bound to b or c, and thus the occurrence of b or c cannot be correlated to e or f in this case.

Example 3.2 may appear pathological since, in the probabilistic execution of $\mathcal{P}_1\|\mathcal{C}$ that correlates the choices between e and f and between b and c, a nondeterministic choice of $\mathcal{P}_1$ is resolved based on information that is not available to $\mathcal{P}_1$. This may lead us to propose a naive solution to the nonpreservation of trace distribution inclusion by parallel composition, where we require that each PA in a parallel composition be able to resolve its nondeterministic choices based on local knowledge only. However, a more elaborate example shows that this naive idea also does not work.

Example 3.3 (failure of compositionality). Consider the two automata $\mathcal{P}_1$ and $\mathcal{P}_2$ of Figure 3.2, which are essentially the automata of Example 3.2 where self-loop transitions labeled by e and f are added to each state. In this case the context $\mathcal{C}$ synchronizes with $\mathcal{P}_1$ and $\mathcal{P}_2$ on actions e and f, and $\mathcal{P}_1$ is able to learn which of e or f occurs, thus determining the correlation with b and c based on local knowledge only.

The solution of resolving nondeterminism based on local knowledge is adopted in [10] for a probabilistic extension of reactive modules; however, the idea of [10] cannot be extended easily to PAs because of key structural differences in the models: in PAs there is a total interleaving of the transitions taken by different PAs in a parallel composition, while in probabilistic reactive modules there are several independent *atoms* that are not forced to interleave. A direct adaptation of the idea of [10] to PAs would require drastic modifications of the model that go beyond the scope of this paper: transitions would have to be labeled by sets of actions and be structured in such a way that each action affects different parts of the state.

An alternative approach, followed in [32] and adopted in this paper, consists of defining a new *trace distribution precongruence* relation, denoted by $\leq_{DC}$, as the coarsest precongruence (for parallel composition) that is included in the trace distribution preorder $\leq_D$, and finding alternative characterizations of $\leq_{DC}$. It is known from [32] that there exists a simple context, called the *principal context*, that is sufficiently powerful to distinguish all PAs that are not in the trace distribution precongruence relation; alternatively, a testing scenario is proposed in [33].

In this paper we characterize $\leq_{DC}$ in terms of probabilistic simulation relations. Another simple alternative characterization of $\leq_{DC}$ that is useful for our study is given by the following proposition.

PROPOSITION 3.8. *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be PAs. Then $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ iff for every PA $\mathcal{C}$ that is compatible with both $\mathcal{P}_1$ and $\mathcal{P}_2$, $\mathcal{P}_1\|\mathcal{C} \leq_D \mathcal{P}_2\|\mathcal{C}$.*

Proof. Define relation $\sqsubseteq$ such that $\mathcal{P}_1 \sqsubseteq \mathcal{P}_2$ iff for every PA $\mathcal{C}$ that is compatible with both $\mathcal{P}_1$ and $\mathcal{P}_2$, $\mathcal{P}_1\|\mathcal{C} \leq_D \mathcal{P}_2\|\mathcal{C}$.

Let $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ and let $\mathcal{C}$ be a PA compatible with both $\mathcal{P}_1$ and $\mathcal{P}_2$. Since $\leq_{DC}$ is a precongruence by definition, then $\mathcal{P}_1\|\mathcal{C} \leq_{DC} \mathcal{P}_2\|\mathcal{C}$. Since, again by definition, $\leq_{DC}$ is included in $\leq_D$, then $\mathcal{P}_1\|\mathcal{C} \leq_D \mathcal{P}_2\|\mathcal{C}$. Thus, $\mathcal{P}_1 \sqsubseteq \mathcal{P}_2$, which implies that $\leq_{DC}$ is included in $\sqsubseteq$.

Conversely, observe that $\sqsubseteq$ is reflexive and transitive, and thus a preorder relation. Observe also that, by using a trivial context $\mathcal{C}$ with no external actions and no transitions, $\sqsubseteq$ is included in $\leq_D$. Finally, using the associativity of parallel composition, observe that $\sqsubseteq$ is preserved by parallel composition, and thus is a precongruence. This means that $\sqsubseteq$ is a precongruence included in $\leq_D$. Since $\leq_{DC}$ is the coarsest precongruence included in $\leq_D$, we get that $\sqsubseteq$ is included in $\leq_{DC}$. □

3.5. Simulation relations. The definitions of forward simulation and weak forward simulation in section 2 can be extended naturally to PAs [34]. However, Segala has shown [31] that the resulting simulations are not complete for $\leq_{DC}$, and has defined new candidate simulations. These new simulations relate states to probability measures on states.

In order to define the new simulations formally, we need two new concepts. First we show how to *lift* a relation between sets to a relation between measures over sets [18]. Let $R \subseteq X \times Y$. The *lifting* of R is a relation $R' \subseteq \mathit{Disc}(X) \times \mathit{Disc}(Y)$ such that $\mu_X \; R' \; \mu_Y$ iff there is a function $w : X \times Y \to [0,1]$ that satisfies the following:

1. If $w(x,y) > 0$, then $x \; R \; y$.
2. For each $x \in X$, $\sum_{y \in Y} w(x,y) = \mu_X(x)$.
3. For each $y \in Y$, $\sum_{x \in X} w(x,y) = \mu_Y(y)$.

We abuse notation slightly and denote the lifting of a relation R by R as well. Second, we define a *flattening* operation that converts a measure μ in $\mathit{Disc}(\mathit{Disc}(X))$ into a measure $\mathit{flatten}(\mu)$ in $\mathit{Disc}(X)$. Namely, we define $\mathit{flatten}(\mu) = \sum_{\rho \in \mathit{supp}(\mu)} \mu(\rho)\rho$.

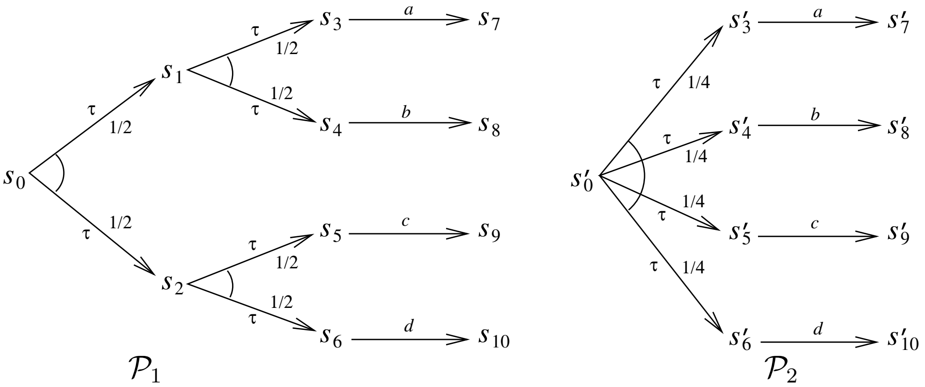

FIG. 3.3. *A forward probabilistic simulation between two PAs.*

We now define simulations for PAs. A relation $R \subseteq Q_1 \times Disc(Q_2)$ is a *probabilistic forward simulation* (resp., *weak probabilistic forward simulation*) from PA $\mathcal{P}_1$ to PA $\mathcal{P}_2$ iff $E_1 = E_2$ and both of the following hold:

1. $\bar{q}_1 \; R \; \delta(\bar{q}_2)$.
2. For each pair q_1, μ_2 such that $q_1 \; R \; \mu_2$ and each transition $q_1 \xrightarrow{a} \mu'_1$, there exists a measure $\xi'_2 \in Disc(Disc(Q_2))$ such that $\mu'_1 \; R \; \xi'_2$ and such that $\mu_2 \xrightarrow{a} \mathit{flatten}(\xi'_2)$ (resp., $\mu_2 \overset{a}{\Longrightarrow} \mathit{flatten}(\xi'_2)$) is a hyper-transition (resp., a weak hyper-transition) of $\mathcal{P}_2$.

We write $\mathcal{P}_1 \leq_{PF} \mathcal{P}_2$ (resp., $\mathcal{P}_1 \leq_{wPF} \mathcal{P}_2$) whenever there is a probabilistic forward simulation (resp., a weak probabilistic forward simulation) from $\mathcal{P}_1$ to $\mathcal{P}_2$.

Example 3.4 (forward probabilistic simulation). Figure 3.3 gives an example of two PAs that are in the kernel of probabilistic forward simulation. However, there would be no simulation from $\mathcal{P}_1$ to $\mathcal{P}_2$ if we did not allow states to be related to measures over states. The probabilistic forward simulation R from $\mathcal{P}_1$ to $\mathcal{P}_2$ relates each state of $\mathcal{P}_1$ with the Dirac measure over its primed version of $\mathcal{P}_2$, relates s_1 with the uniform measure over s'_3 and s'_4, and relates s_2 with the uniform measure over s'_5 and s'_6. The transition from s_0 can be simulated from s'_0 by scheduling the only transition enabled. Indeed, the target measure $\mathcal{U}(s'_3, s'_4, s'_5, s'_6)$ is the flattening of $\mathcal{U}(\mathcal{U}(s'_3, s'_4), \mathcal{U}(s'_5, s'_6))$, and it is easy to check that $\mathcal{U}(s_1, s_2) \; R \; \mathcal{U}(\mathcal{U}(s'_3, s'_4), \mathcal{U}(s'_5, s'_6))$.

Note that a forward simulation between nondeterministic automata is a probabilistic forward simulation between the two automata viewed as PAs, as described next.

PROPOSITION 3.9. *Let $\mathcal{A}_1$ and $\mathcal{A}_2$ be nondeterministic automata. Then*

1. *$\mathcal{A}_1 \leq_F \mathcal{A}_2$ iff $\mathcal{A}_1 \leq_{PF} \mathcal{A}_2$, and*
2. *$\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$ iff $\mathcal{A}_1 \leq_{wPF} \mathcal{A}_2$.*

Proof. The left-to-right inclusions are easy since, given a (weak) forward simulation R from $\mathcal{A}_1$ to $\mathcal{A}_2$, it is routine to check that the relation $R' \triangleq \{(q_1, \delta(q_2)) \mid q_1 \; R \; q_2\}$ is a (weak) probabilistic forward simulation from $\mathcal{A}_1$ to $\mathcal{A}_2$.

For the converse implication, let R be a (weak) probabilistic forward simulation from $\mathcal{A}_1$ to $\mathcal{A}_2$. Define a relation $R' \triangleq \{(q_1, q_2) \mid \exists_\mu q_1 \; R \; \mu, q_2 \in supp(\mu)\}$. We show that R' is a (weak) forward simulation from $\mathcal{A}_1$ to $\mathcal{A}_2$.

The start condition is trivial since $\bar{q}_1 \; R \; \delta(\bar{q}_2)$, and thus $\bar{q}_1 \; R' \; \bar{q}_2$. For the step condition, let $q_1 \; R' \; q_2$, and let $q_1 \xrightarrow{a} q'_1$. By the definition of R', there exists a measure

μ such that $q_1 \; R \; \mu$ and $q_2 \in \mathit{supp}(\mu)$. Since R is a (weak) forward simulation, there exists a hyper-transition $\mu \xrightarrow{a} \mu'$ (a weak hyper-transition $\mu \overset{a}{\Longrightarrow} \mu'$), where μ' is the flattening of some measure μ'' such that $\delta(q_1') \; R \; \mu''$. By the definition of hyper-transition, there is a combined transition $q_2 \xrightarrow{a} \mu_2$ (a weak combined transition $q_2 \overset{a}{\Longrightarrow} \mu_2$) such that $\mathit{supp}(\mu_2) \subseteq \mathit{supp}(\mu')$. For the strong case, let $q_2 \xrightarrow{a} q_2'$ be one of the transitions of D_2 that are combined in $q_2 \xrightarrow{a} \mu_2$. Then, $q_2' \in \mathit{supp}(\mu_2)$. For the weak case, consider a scheduler σ that generates $q_2 \overset{a}{\Longrightarrow} \mu_2$, and build a new scheduler σ' that on input α stops (does not return any transition) if $\sigma(\alpha)$ stops with some nonzero probability and chooses any transition in $\mathit{supp}(\sigma(\alpha))$ that reduces the distance from a stopping point otherwise. This leads to a weak transition $q_2 \overset{a}{\Longrightarrow} q_2'$, where $q_2' \in \mathit{supp}(\mu_2)$. We now show that $q_1' \; R' \; q_2'$, which suffices. Since $q_2' \in \mathit{supp}(\mu_2)$, and since $\mathit{supp}(\mu_2) \subseteq \mathit{supp}(\mu')$, then $q_2' \in \mathit{supp}(\mu')$. Since $\mu' = \mathit{flatten}(\mu'')$, then q_2' is also in the support of some measure $\rho \in \mathit{supp}(\mu'')$. Thus, $q_1' \; R \; \rho$, and, by the definition of R', $q_1' \; R' \; q_2'$, as needed. □

PROPOSITION 3.10. *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be PAs. Then the following hold:*

1. *If $\mathcal{P}_1 \leq_{PF} \mathcal{P}_2$, then $\mathcal{P}_1 \leq_{wPF} \mathcal{P}_2$.*
2. *If $H_1 = H_2 = \emptyset$, then $\mathcal{P}_1 \leq_{PF} \mathcal{P}_2$ iff $\mathcal{P}_1 \leq_{wPF} \mathcal{P}_2$.*
3. *If $\mathcal{P}_1 \leq_{wPF} \mathcal{P}_2$, then $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$.*

Proof. The first item follows from the fact that a combined transition is a special case of a weak combined transition; the second item follows from the fact that in the absence of internal actions a weak combined transition is a combined transition. The proof of the third item is quite involved, and we refer the reader to Proposition 8.7.1 of [32]. The main idea is to use the weak probabilistic forward simulation from $\mathcal{P}_1$ to $\mathcal{P}_2$ to build, for each probabilistic execution of $\mathcal{P}_1$, a corresponding probabilistic execution of $\mathcal{P}_2$ with the same trace distribution. □

3.6. Tree-structured PAs. A *path* of a PA $\mathcal{P}$ is a finite sequence $\gamma = q_0 a_1 \mu_1 q_1 a_2 \mu_2 q_2 \ldots q_n$ of alternating states, actions, and distribution over states, starting with the start state of $\mathcal{P}$ such that for each nonfinal i, $q_i \xrightarrow{a_{i+1}} \mu_{i+1}$ and $q_{i+1} \in \mathit{supp}(\mu_{i+1})$. We write $\mathit{lstate}(\gamma)$ to denote q_n and $\mathit{paths}(\mathcal{P})$ for the set of all paths of $\mathcal{P}$. We say that $\mathcal{P}$ is *tree-structured* if each state is reached via a unique path. Tree-structured PAs are characterized uniquely by the property that all states are reachable, the start state does not occur in the target of any transition, and each of the other states occurs in the target of exactly one transition. Tree-structured nondeterministic automata are also characterized uniquely by this property, albeit for a different notion of transition.

If a PA is tree-structured, then its underlying nondeterministic automaton is also tree-structured. The following example shows that the converse does not hold.

Example 3.5 (non–tree-structured PAs). Figure 3.4 shows a PA that is not tree-structured, as state q' can be reached via two different paths. The underlying nondeterministic automaton is tree-structured, however, since the only way to reach state q' is via the execution qaq'.

The *unfolding* of a PA $\mathcal{P}$, denoted by $\mathit{Unfold}(\mathcal{P})$, is the tree-structured PA $\mathcal{Q}$ obtained from $\mathcal{P}$ by unfolding its transition graph into a tree. Formally,

- $Q_{\mathcal{Q}} = \mathit{paths}(\mathcal{P})$,
- $\bar{q}_{\mathcal{Q}} = \bar{q}_{\mathcal{P}}$,
- $E_{\mathcal{Q}} = E_{\mathcal{P}}$,
- $H_{\mathcal{Q}} = H_{\mathcal{P}}$, and
- $D_{\mathcal{Q}} = \{(\gamma, a, \mu) \mid (\exists \mu')[(\mathit{lstate}(\gamma), a, \mu') \in D_{\mathcal{P}} \wedge (\forall q \in \mathit{supp}(\mu'))[\mu'(q) = \mu(\gamma a \mu' q)]]\}$.

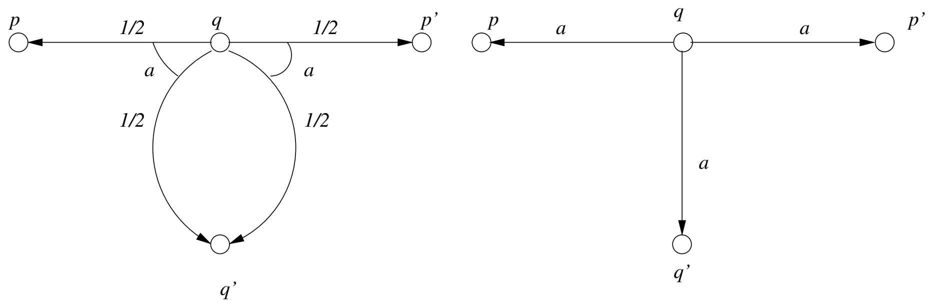

FIG. 3.4. *The PA on the left is not tree-structured even though its underlying nondeterministic automaton on the right is.*

PROPOSITION 3.11. $\mathcal{P} \equiv_{PF}$ *Unfold*$(\mathcal{P})$.

Proof. It is easy to check that the relation R, where $\alpha \; R \; \delta(q)$ iff *lstate*$(\alpha) = q$ is a probabilistic forward simulation from *Unfold*$(\mathcal{P})$ to $\mathcal{P}$ and that the "inverse" of R, that is, the relation R' such that $q \; R' \; \delta(\alpha)$ iff *lstate*$(\alpha) = q$, is a probabilistic forward simulation from $\mathcal{P}$ to *Unfold*$(\mathcal{P})$. □

PROPOSITION 3.12. $\mathcal{P} \equiv_{DC}$ *Unfold*$(\mathcal{P})$.

Proof. The proof follows by Proposition 3.11 and Proposition 3.10, parts 1 and 3. □

3.7. Truncations and continuations. We now define two simple constructions on probabilistic execution fragments that will be useful for our proofs. Specifically, we define the truncation of a probabilistic execution fragment, which is the result of stopping the computation at some designated points, and the continuation of a probabilistic execution fragment, which represents the rest of a probabilistic execution fragment after some finite execution fragment has occurred.

Let ϵ be a probabilistic execution fragment of a PA $\mathcal{P}$, generated by some scheduler σ, and let Θ be a set of finite execution fragments of $\mathcal{P}$. Define the *truncation of* ϵ *at* Θ to be the same as ϵ except that no transition is scheduled from all the Θ places, that is, the probabilistic execution fragment ϵ', with the same start state as ϵ, generated by a new scheduler σ' such that $\sigma'(\alpha) = \sigma(\alpha)$ if $\alpha \notin \Theta$ and $\sigma'(\alpha)(D) = 0$ if $\alpha \in \Theta$.

PROPOSITION 3.13. *The definition of truncation of a probabilistic execution fragment* ϵ *is independent of the choice of the inducing scheduler.*

Proof. Let μ be the first state of ϵ, and let σ_1, σ_2 be two schedulers that, together with μ, induce ϵ. Let Θ be a set of finite execution fragments of $\mathcal{P}$, and let σ'_1, σ'_2 be the schedulers built from σ_1, σ_2, respectively, according to the definition of truncation. Let ϵ_1, ϵ_2 be the induced probabilistic execution fragments, and suppose by contradiction that $\epsilon_1 \neq \epsilon_2$. Then there exists a finite execution α such that $\epsilon_1(C_\alpha) \neq \epsilon_2(C_\alpha)$. Consider such a finite execution α of minimum length. Observe that $|\alpha| > 0$ since $\epsilon(C_q) = \epsilon_1(C_q) = \epsilon_2(C_q) = \mu(q)$ for each state $q \in Q$. Thus, $\alpha = \alpha' a' q'$ for some α', a', q', where $\epsilon_1(C_{\alpha'}) = \epsilon_2(C_{\alpha'})$. We distinguish two cases.

Case 1. If $\alpha' \in \Theta$, then, by the definitions of σ'_1 and σ'_2, $\sigma'_1(\alpha')(D) = \sigma'_2(\alpha')(D) = 0$. Thus, $\epsilon_1(C_\alpha) = \epsilon_2(C_\alpha) = 0$, a contradiction.

Case 2. If $\alpha' \notin \Theta$, then, by the definitions of σ'_1 and σ'_2, $\sigma'_1(\alpha') = \sigma_1(\alpha')$ and

$\sigma_2'(\alpha') = \sigma_2(\alpha')$. Then,

$$\begin{aligned}
\epsilon_1(C_\alpha) &= \epsilon_1(C_{\alpha'}) \textstyle\sum_{tr \in D(a')} \sigma_1'(\alpha')(tr)\mu_{tr}(q') \quad \text{(by (1))}\\
&= \epsilon_2(C_{\alpha'}) \textstyle\sum_{tr \in D(a')} \sigma_1(\alpha')(tr)\mu_{tr}(q')\\
&\qquad \text{(by } \sigma_1'(\alpha') = \sigma_1(\alpha'),\ \epsilon_1(C_{\alpha'}) = \epsilon_2(C_{\alpha'})\text{)}\\
&= \epsilon_2(C_{\alpha'}) \textstyle\sum_{tr \in D(a')} \sigma_2(\alpha')(tr)\mu_{tr}(q') \quad \text{(by } \sigma_1 \text{ and } \sigma_2 \text{ induce } \epsilon\text{)}\\
&= \epsilon_2(C_{\alpha'}) \textstyle\sum_{tr \in D(a')} \sigma_2'(\alpha')(tr)\mu_{tr}(q') \quad \text{(by } \sigma_2'(\alpha') = \sigma_2(\alpha')\text{)}\\
&= \epsilon_2(C_\alpha) \quad \text{(by (1))},
\end{aligned}$$

again a contradiction. □

Let ϵ be a probabilistic execution fragment of a PA $\mathcal{P}$, generated by a scheduler σ, and let α be a finite execution fragment with $\mathit{fstate}(\alpha) \in \mathit{supp}(\mathit{fstate}(\epsilon))$. Define $\epsilon \rhd \alpha$, the *continuation of ϵ after prefix α*, to be the probabilistic execution fragment generated by the following scheduler σ' from $\mathit{lstate}(\alpha)$:

$$\sigma'(\alpha') = \begin{cases} \sigma(\alpha \frown \alpha') & \text{if } \mathit{fstate}(\alpha') = \mathit{lstate}(\alpha),\\ 0 & \text{otherwise,} \end{cases}$$

where by 0 we denote the identically 0 function.

PROPOSITION 3.14. *The definition of $\epsilon \rhd \alpha$ is independent of the choice of the inducing scheduler.*

Proof. The proof proceeds in a manner similar to that of Proposition 3.13. Let μ be the first state of ϵ, and let σ_1, σ_2 be two schedulers that, together with μ, induce ϵ. Let q' be $\mathit{lstate}(\alpha)$. Let σ_1', σ_2' be the schedulers built from σ_1, σ_2, respectively, according to the definition of $\epsilon \rhd \alpha$. Let ϵ_1, ϵ_2 be the induced probabilistic execution fragments from q', and suppose by contradiction that $\epsilon_1 \neq \epsilon_2$. Then there exists a finite execution α' such that $\epsilon_1(C_{\alpha'}) \neq \epsilon_2(C_{\alpha'})$. Consider such a finite execution α' of minimum length. Observe that $|\alpha'| > 0$ since $\epsilon(C_{q'}) = \epsilon_1(C_{q'}) = \epsilon_2(C_{q'}) = 1$ and, for each state $q'' \neq q'$, $\epsilon(C_{q''}) = \epsilon_1(C_{q''}) = \epsilon_2(C_{q''}) = 0$. Thus, $\alpha' = \alpha'' a'' q''$ for some α'', a'', q'', where $\epsilon_1(C_{\alpha''}) = \epsilon_2(C_{\alpha''})$. We distinguish two cases.

Case 1. If $\mathit{fstate}(\alpha'') \neq q'$, then, by the definitions of ϵ_1 and ϵ_2, $\epsilon_1(C_{\alpha'}) = \epsilon_2(C_{\alpha'}) = 0$, a contradiction.

Case 2. If $\mathit{fstate}(\alpha'') = q'$, then, by the definitions of σ_1' and σ_2', $\sigma_1'(\alpha'') = \sigma_1(\alpha \frown \alpha'')$ and $\sigma_2'(\alpha'') = \sigma_2(\alpha \frown \alpha'')$. Then,

$$\begin{aligned}
\epsilon_1(C_{\alpha'}) &= \epsilon_1(C_{\alpha''}) \textstyle\sum_{tr \in D(a'')} \sigma_1'(\alpha'')(tr)\mu_{tr}(q'') \quad \text{(by (1))}\\
&= \epsilon_2(C_{\alpha''}) \textstyle\sum_{tr \in D(a'')} \sigma_1(\alpha \frown \alpha'')(tr)\mu_{tr}(q'')\\
&\qquad \text{(by } \sigma_1'(\alpha'') = \sigma_1(\alpha \frown \alpha'') \text{ and } \epsilon_1(C_{\alpha''}) = \epsilon_2(C_{\alpha''})\text{)}\\
&= \epsilon_2(C_{\alpha''}) \textstyle\sum_{tr \in D(a'')} \sigma_2(\alpha \frown \alpha'')(tr)\mu_{tr}(q'') \quad \text{(by } \sigma_1 \text{ and } \sigma_2 \text{ induce } \epsilon\text{)}\\
&= \epsilon_2(C_{\alpha''}) \textstyle\sum_{tr \in D(a'')} \sigma_2'(\alpha'')(tr)\mu_{tr}(q'') \quad \text{(by } \sigma_2'(\alpha'') = \sigma_2(\alpha \frown \alpha'')\text{)}\\
&= \epsilon_2(C_{\alpha'}) \quad \text{(by (1))},
\end{aligned}$$

again a contradiction. □

The following proposition relates the continuation of ϵ after some prefix α with ϵ itself. In practice it states that $\epsilon \rhd \alpha$ is closely related to $\epsilon \mid C_\alpha$.

PROPOSITION 3.15. *Let ϵ be a probabilistic execution fragment of a PA $\mathcal{P}$, and let α be a finite execution fragment of $\mathcal{P}$. Then, for each finite execution α' with $\mathit{lstate}(\alpha) = \mathit{fstate}(\alpha')$, $\epsilon(C_{\alpha \frown \alpha'}) = \epsilon(C_\alpha) \cdot (\epsilon \rhd \alpha)(C_{\alpha'})$.*

Proof. The proof follows easily by induction on the length of α' from the definition of the probability of a cone. □

4. Tester automata and observer schedulers.

The proofs of our completeness results rely on a special context for a PA, which we call its *tester PA*. The tester automaton, $\mathit{tester}(\mathcal{P})$, of a PA $\mathcal{P}$ can observe the states that $\mathcal{P}$ goes through and the transitions that are scheduled during a probabilistic execution. This information is revealed by means of externally visible transitions of $\mathit{tester}(\mathcal{P})$ with the help of a specific scheduler, called the *observer*, which synchronizes $\mathcal{P}$ with its tester. In this section we present the constructions of the tester and observer and prove some results about the resulting trace distributions.

Informally, the tester of a PA $\mathcal{P}$ is a PA $\mathcal{C}$ whose states include a distinguished start state, all the states of $\mathcal{P}$, and all the transitions of $\mathcal{P}$. Automaton $\mathcal{C}$ has a special transition from its own start state, $\bar{q}_{\mathcal{C}}$, to the start state of $\mathcal{P}$, $\bar{q}_{\mathcal{P}}$, labeled by $\bar{q}_{\mathcal{P}}$. Also, from every state q of $\mathcal{P}$, $\mathcal{C}$ has a uniform transition labeled by ch ("choose") to the set of transitions of $\mathcal{P}$ that begin in state q. Finally, for every transition tr of $\mathcal{P}$ and every state q in the support of μ_{tr}, $\mathcal{C}$ has a transition labeled by q from tr to q.

DEFINITION 4.1. *The* tester PA *of a PA $\mathcal{P}$, denoted by $\mathit{tester}(\mathcal{P})$, is a PA $\mathcal{C} = (Q_{\mathcal{C}}, \bar{q}_{\mathcal{C}}, E_{\mathcal{C}}, H_{\mathcal{C}}, D_{\mathcal{C}})$, where*

- $Q_{\mathcal{C}} = \{\bar{q}_{\mathcal{C}}\} \cup Q_{\mathcal{P}} \cup D_{\mathcal{P}}$,
- $E_{\mathcal{C}} = Q_{\mathcal{P}} \cup \{ch\}$,
- $H_{\mathcal{C}} = \emptyset$, *and*
- $D_{\mathcal{C}} = \{(\bar{q}_{\mathcal{C}}, \bar{q}_{\mathcal{P}}, \delta(\bar{q}_{\mathcal{P}}))\} \cup$
  $\{(q, ch, \mathcal{U}(\{tr \in D_{\mathcal{P}} \mid \mathit{source}(tr) = q\})) \mid q \in Q_{\mathcal{P}} \wedge q \rightarrow\} \cup$
  $\{(tr, q, \delta(q)) \mid tr \in D_{\mathcal{P}}, q \in \mathit{supp}(\mu_{tr})\}$.

Observe that the tester of an ordinary nondeterministic automaton enables at most one transition from each state, and dually, the tester of an automaton that enables at most one transition from each state is a nondeterministic automaton. This observation, together with the results that we prove later in the paper, imply that a fully probabilistic context is enough to observe the branching structure of a nondeterministic automaton.

PROPOSITION 4.2. *The following hold:*

1. *The tester of a nondeterministic automaton is fully probabilistic; that is, it enables at most one transition from each state.*
2. *The tester of a fully probabilistic automaton is a nondeterministic automaton; that is, it contains only transitions whose target measures are Dirac.*

Proof. For the first item, observe that the only states of $\mathit{tester}(\mathcal{P})$ that may enable more than one transition are of the form $tr \in D_{\mathcal{P}}$, which enable one transition for each state in $\mathit{supp}(\mu_{tr})$; however, the size of $\mathit{supp}(\mu_{tr})$ is 1 in a nondeterministic automaton.

For the second item, observe that the only states of $\mathit{tester}(\mathcal{P})$ that may enable non-Dirac transitions are of the form $q \in Q_{\mathcal{P}}$, which may enable a transition labeled by ch to a uniform measure over the set of transitions enabled from q in $\mathcal{P}$; however, there is at most one transition enabled from q in a fully probabilistic automaton. □

We assume without loss of generality that a PA $\mathcal{P}$ and its tester do not have any actions in common (otherwise we can simply rename states of $\mathcal{P}$ to achieve our goal), and thus $\mathcal{P}$ and its tester are compatible.

Since $\mathit{tester}(\mathcal{P})$ and $\mathcal{P}$ share no actions, merely composing $\mathit{tester}(\mathcal{P})$ with $\mathcal{P}$ does not ensure that $\mathit{tester}(\mathcal{P})$ faithfully emulates the behavior of $\mathcal{P}$. However, an appropriate scheduler can synchronize the two automata and ensure such an emulation, which will be sufficient for our purposes. Given a PA $\mathcal{P}$, we define a specific scheduler σ for $\mathcal{P}\|tester(\mathcal{P})$, called the *observer* of $\mathcal{P}$, that synchronizes the two automata so that the internal structure of $\mathcal{P}$ is visible in the trace. Specifically, the scheduler σ starts by scheduling the transition of $tester(\mathcal{P})$ from the start state of $tester(\mathcal{P})$ to the start state of $\mathcal{P}$, leading to state $(\bar{q}, \bar{q})$, which is of the form (q, q). Then σ repeats the following as long as $q \rightarrow$:

1. Schedule the *ch* transition of $tester(\mathcal{P})$, thus choosing a transition *tr* of $\mathcal{P}$.
2. Schedule transition *tr* of $\mathcal{P}$, leading $\mathcal{P}$ to a new state q'.
3. Schedule the transition of $tester(\mathcal{P})$ labeled by the state q', resulting in the state (q', q'), which is again of the form (q, q).

DEFINITION 4.3. *The* observer *of a PA $\mathcal{P}$, which we denote by observer$(\mathcal{P})$, is a deterministic (almost memoryless) scheduler for $\mathcal{P}\|tester(\mathcal{P})$ that bases its decisions on the last state and sometimes the last action of its argument according to the following table. Here, $\mathcal{C}$ denotes tester$(\mathcal{P})$, q is any state such that $q \rightarrow$, tr is any transition in $D_{\mathcal{P}}$, and q' is any state in μ_{tr}.*

$Q_{\mathcal{P}}$	$Q_{tester(\mathcal{P})}$	Last action	$D_{\mathcal{P}\|tester(\mathcal{P})}$
$\bar{q}_{\mathcal{P}}$	$\bar{q}_{tester(\mathcal{P})}$		$\bar{q}_{\mathcal{P}}$-labeled transition of $tester(\mathcal{P})$
q	q		*ch*-labeled transition of $tester(\mathcal{P})$
q	*tr*	*ch*	transition *tr* of $\mathcal{P}$
q'	*tr*	not *ch*	q'-labeled transition of $tester(\mathcal{P})$

Scheduler $observer(\mathcal{P})$ and start state $(\bar{q}_{\mathcal{P}}, \bar{q}_{tester(\mathcal{P})})$ induce a trace distribution for $\mathcal{P}\|tester(\mathcal{P})$ where all states and external actions of $\mathcal{P}$ appear explicitly.

DEFINITION 4.4. *The* observation *of a PA $\mathcal{P}$, denoted by observation$(\mathcal{P})$, is the trace distribution induced by observer$(\mathcal{P})$ and $(\bar{q}_{\mathcal{P}}, \bar{q}_{tester(\mathcal{P})})$.*

Remark 4.5. The *ch*-labeled transitions of a tester are defined to lead to uniform measures over states of $tester(\mathcal{P})$ that represent transitions of $\mathcal{P}$. This is well defined since we have assumed that nondeterministic and probabilistic automata are finite branching. From the technical point of view, however, the proofs of this paper rely on the fact that the transitions labeled by *ch* assign nonzero probability (not necessarily the same probability) to each one of the options that are available in a nondeterministic choice. Thus, it would be possible to remove the finite branching restriction from the definition of automata and modify the definition of a tester automaton so that, whenever there are countably many transitions from a state q, the corresponding *ch*-labeled transition of the tester assigns a nonuniform measure to the transitions enabled from q, for example, a Poisson distribution after enumerating all possible transitions enabled from q. We have chosen not to deal with countable branching automata in this paper because it would complicate proofs without adding much insight.

We state and prove some properties of $observation(\mathcal{P})$. The first property, given in (5), says that the cone of traces beginning with the starting state of $\mathcal{P}$ has probability 1. The second property, (6), says that for any state q of $\mathcal{P}$ from which some transition is enabled and for each finite trace β of $\mathcal{P}\|tester(\mathcal{P})$, the probability of the cone of traces beginning with βq is the same as the probability of the cone beginning with $\beta q\, ch$; that is, once βq occurs, the probability that *ch* follows is 1. The third property, (7), says that for any state q of $\mathcal{P}$ and for each finite trace β of $\mathcal{P}\|tester(\mathcal{P})$, the probability of the cone of traces beginning with $\beta q\, ch$ is the same as the sum of the probabilities of the cones beginning with $\beta q\, ch\, \beta'$, where β' represents one single step of $\mathcal{P}$ from q; that is, once *ch* occurs, one of the transitions of $\mathcal{P}$ that are enabled from q is exposed. The right-hand side of (7) consists of two parts dealing with external and internal transitions, respectively.

PROPOSITION 4.6. *The trace distribution $\eta = observation(\mathcal{P})$ induced by the observer of a PA $\mathcal{P}$ satisfies the following three properties, for all finite traces β of $\mathcal{P}\|tester(\mathcal{P})$ and for all states q of $\mathcal{P}$:*

$$\eta(C_{\bar{q}}) = 1, \tag{5}$$

$$q \rightarrow \quad \Longrightarrow \quad \eta(C_{\beta q}) = \eta(C_{\beta q\, ch}), \tag{6}$$

$$\eta(C_{\beta q\, ch}) = \sum_{(a,q') \mid a \in E, q \xrightarrow{a} q'} \eta(C_{\beta q\, ch\, aq'}) + \sum_{q' \mid (\exists a) a \in H, q \xrightarrow{a} q'} \eta(C_{\beta q\, ch\, q'}). \tag{7}$$

Proof. Equation (5) follows from the fact that $observer(\mathcal{P})$ schedules action $\bar{q}$ immediately. Equation (6) follows from the fact that, after scheduling action q, thus leading to a state of the form (q, q), $observer(\mathcal{P})$ immediately schedules action ch if q enables at least one transition. Equation (7) follows from the fact that, after scheduling ch, $observer(\mathcal{P})$ schedules one of the transitions of $\mathcal{P}$ that are enabled from q, say $q \xrightarrow{a} \mu$, followed by a transition of $tester(\mathcal{P})$ labeled by a state in $supp(\mu)$. □

The following technical properties will be needed in the proofs of section 6. The first property, in (8), says that the probability of observing a state q' reachable in a tree-structured PA $\mathcal{P}$ with a single transition, say tr, from another state q is the probability of observing q, divided by the number of transitions enabled from q, and multiplied by the probability of reaching q' in tr, the only transition that may lead to q' since $\mathcal{P}$ is tree-structured. Indeed, q' can be observed only if q is observed (probability of observing q), the transition tr is chosen (factor $1/k$ since transitions are chosen uniformly), and the chosen transition leads to q'. The second property, (9), is similar to the first one, where the probability of observing q and scheduling the transition tr is replaced by the probability of observing any state in the target of tr.

PROPOSITION 4.7. *Let $\mathcal{P}$ be a tree-structured PA, and let η be $observation(\mathcal{P})$. Let $tr = (q, a, \mu)$ be a transition of $\mathcal{P}$. Let k be the number of transitions that are enabled from q in $\mathcal{P}$, and let q' be a state in $supp(\mu)$. Then the following properties hold:*

$$\eta(\diamond q') = \frac{\eta(\diamond q)}{k} \mu(q'), \tag{8}$$

$$\eta(\diamond q') = \left(\sum_{q'' \in supp(\mu)} \eta(\diamond q'') \right) \mu(q'). \tag{9}$$

Proof. Let σ be the observer of $\mathcal{P}$, and let ϵ_σ be the probabilistic execution induced by σ. Since $\mathcal{P}$ is tree-structured, the set Θ_q contains a single execution α. Indeed, by the definition of tree-structured, there is only one execution in $\mathcal{P}$ ending with state q, and σ simply interleaves this execution with transitions labeled by ch, by the names of the transitions of $\mathcal{P}$ that are needed to reach q, and by the names of the states that are reached. Similarly, $\Theta_{q'}$ contains a single execution α'.

Once state q is reached, σ schedules action ch, reaching state tr of $tester(\mathcal{P})$ with probability $1/k$. Then, σ schedules transition tr, reaching state q' in $\mathcal{P}$ with probability $\mu(q')$, and finally σ schedules the transition of $tester(\mathcal{P})$ labeled by q'. Thus, $\epsilon_\sigma(C_{\alpha'}) = \epsilon_\sigma(C_\alpha)(1/k)\mu(q')$. Then (8) follows by (2).

By summing over *supp*(μ) in (8), we get

$$\sum_{q'' \in supp(\mu)} \eta(\diamond q'') = \frac{\eta(\diamond q)}{k} \sum_{q'' \in supp(\mu)} \mu(q''). \tag{10}$$

Observe that $\sum_{q'' \in supp(\mu)} \mu(q'') = 1$. Hence, (10) simplifies to

$$\sum_{q'' \in supp(\mu)} \eta(\diamond q'') = \frac{\eta(\diamond q)}{k}. \tag{11}$$

Substitution of (11) into (8) gives us (9), as needed. □

5. Characterizations of $\leq_{DC}$ for nondeterministic automata.

In this section, we present our characterization theorems for $\leq_{DC}$ for nondeterministic automata: Theorem 5.2 characterizes $\leq_{DC}$ in terms of $\leq_F$, for nondeterministic automata without internal actions, and Theorem 5.4 characterizes $\leq_{DC}$ in terms of $\leq_{wF}$, for arbitrary nondeterministic automata. In each case, we prove the result first for tree-structured nondeterministic automata and then extend it to the non–tree-structured case via unfolding. The interesting direction for each of these results is the completeness direction, showing that $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ implies the existence of a simulation relation from $\mathcal{A}_1$ to $\mathcal{A}_2$.

The strategy that we use to prove our completeness results is also applied in many other full abstraction results; see, for example, [5, 14]. By Proposition 3.8, $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ implies that $\mathcal{A}_1 \leq_D \mathcal{A}_2$ for all contexts $\mathcal{C}$. Thus it suffices to construct a specific context $\mathcal{C}$ with the property that the trace distributions of $\mathcal{A}_1 \| \mathcal{C}$ contain all information about $\mathcal{A}_1$ that is preserved by the simulation preorder. More specifically, we compose $\mathcal{A}_1$ with the context $\mathcal{C} = \mathit{tester}(\mathcal{A}_1)$ and consider just a single trace distribution of the composed system, namely $\mathit{observation}(\mathcal{A}_1)$, the one generated by $\mathit{observer}(\mathcal{A}_1)$. We show, for any other nondeterministic automaton $\mathcal{A}_2$, that if the composition $\mathcal{A}_2 \| \mathit{tester}(\mathcal{A}_1)$ generates the trace distribution $\mathit{observation}(\mathcal{A}_1)$, then $\mathcal{A}_2$ actually simulates $\mathcal{A}_1$ in a strong sense. Namely, whenever $\mathcal{A}_1$ reaches some state q_1, $\mathcal{A}_2$ can reach a corresponding state q_2 from which it generates the same trace distribution. The formalities of the proof are intricate, in part because states of $\mathcal{A}_1$ also show up as states of $\mathit{tester}(\mathcal{A}_1)$ and within the trace distribution of $\mathit{observation}(\mathcal{A}_1)$. In the proof we try to be very explicit about the roles of states of $\mathcal{A}_1$, but we also warn the reader to be alert to this potential source of confusion.

5.1. Nondeterministic automata without internal actions.

We begin by considering nondeterministic automata without internal actions. We first consider tree-structured nondeterministic automata.

PROPOSITION 5.1. *Let $\mathcal{A}_1$, $\mathcal{A}_2$ be nondeterministic automata without internal actions such that $\mathcal{A}_1$ is tree-structured. Then $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ implies $\mathcal{A}_1 \leq_F \mathcal{A}_2$.*

Proof. Assume that $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$. Let $\mathcal{C}$ be $\mathit{tester}(\mathcal{A}_1)$ and η be $\mathit{observation}(\mathcal{A}_1)$, that is, the trace distribution of $\mathcal{A}_1 \| \mathcal{C}$ induced by the scheduler $\mathit{observer}(\mathcal{A}_1)$. Since $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ implies $\mathcal{A}_1 \| \mathcal{C} \leq_D \mathcal{A}_2 \| \mathcal{C}$, Proposition 3.8 implies that η is also a trace distribution of $\mathcal{A}_2 \| \mathcal{C}$. That is, there exists a probabilistic execution ϵ of $\mathcal{A}_2 \| \mathcal{C}$, induced by some scheduler σ_2, such that $\mathit{tdist}(\epsilon) = \eta$.

For each state q_1 in Q_1, let Θ_{q_1} be the set of finite executions of $\mathcal{A}_2 \| \mathcal{C}$ whose last transition is labeled by q_1. For each state q_2 of $\mathcal{A}_2$, let Θ_{q_1,q_2} be the set of executions in Θ_{q_1} whose last state is the pair (q_2, q_1).

Define a relation R on $Q_1 \times Q_2$ as follows: $q_1 \; R \; q_2$ iff there exists a finite execution α in Θ_{q_1,q_2} such that $\epsilon(C_\alpha) > 0$. We claim that R is a forward simulation from $\mathcal{A}_1$ to $\mathcal{A}_2$.

For the start condition, we must show that $\bar{q}_1 \; R \; \bar{q}_2$. Consider the start state $(\bar{q}_2, \bar{q}_\mathcal{C})$ of $\mathcal{A}_2 \| \mathcal{C}$. Since there are no internal actions in $\mathcal{A}_2$ or $\mathcal{C}$, and since, by (5) from Proposition 4.6, $\eta(C_{\bar{q}_1}) = 1$, the only action that is scheduled initially by σ_2 is $\bar{q}_1$, leading to state $(\bar{q}_2, \bar{q}_1)$. Thus, the finite execution $\alpha = (\bar{q}_2, \bar{q}_\mathcal{C})\bar{q}_1(\bar{q}_2, \bar{q}_1)$ is an element of $\Theta_{\bar{q}_1,\bar{q}_2}$ such that $\epsilon(C_\alpha) > 0$, as needed.

For the step condition, assume $q_1 \; R \; q_2$ and let $q_1 \xrightarrow{a}_1 q_1'$ be a transition of $\mathcal{A}_1$, which we denote by *tr* for convenience. We exhibit a matching transition $q_2 \xrightarrow{a}_2 q_2'$.

By the definition of R, there exists a finite execution α in Θ_{q_1,q_2} such that $\epsilon(C_\alpha) > 0$. Since Θ_{q_1,q_2} is a subset of Θ_{q_1}, by definition of Θ_{q_1}, $\mathit{trace}(\alpha) = \beta q_1$ for some finite trace β. Therefore, $\eta(C_{\beta q_1}) > 0$. Since q_1 enables at least one transition in $\mathcal{A}_1$, specifically transition *tr*, (6) from Proposition 4.6 implies that $\eta(C_{\beta q_1 \, ch}) = \eta(C_{\beta q_1})$. Then, since $\mathcal{A}_2$ and $\mathcal{C}$ have no internal actions, σ_2 schedules action *ch* from α with probability 1.

By the definition of *tester*$(\mathcal{A}_1)$, the transition labeled by *ch* leaving from state q_1 of $\mathcal{C}$ leads to state *tr* with probability > 0. Hence, $\epsilon(C_{\alpha \, ch \, (q_2, tr)}) > 0$. By (7) from Proposition 4.6, where only the first term of the right-hand side is nonzero due to the absence of internal actions, $\eta(C_{\beta q_1 \, ch}) = \sum_{(a,q') | a \in E, q_1 \xrightarrow{a} q'} \eta(C_{\beta q_1 \, ch \, a q'})$. Hence, σ_2 must extend $\alpha \, ch \, (q_2, tr)$ with two steps labeled by an action and a state of $\mathcal{A}_1$, respectively, where the action and the state are compatible with one of the transitions of $\mathcal{A}_1$ that are enabled from q_1. Since state *tr* of $\mathcal{C}$ enables only action q_1', and since, by the tree-structure of $\mathcal{A}_1$, a is uniquely determined by q_1', the action and state scheduled by σ_2 are a and q_1'. Therefore, there exists a state q_2' of $\mathcal{A}_2$ such that the execution $\alpha' = \alpha \, ch \, (q_2, tr) a (q_2', tr) q_1' (q_2', q_1')$ is an execution in $\Theta_{q_1',q_2'}$ such that $\epsilon(C_{\alpha'}) > 0$. Then $q_1' \; R \; q_2'$ and $q_2 \xrightarrow{a} q_2'$, as needed. □

Now we present our result for general (non–tree-structured) nondeterministic automata without internal actions.

THEOREM 5.2. *Let $\mathcal{A}_1$, $\mathcal{A}_2$ be nondeterministic automata without internal actions. Then $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ iff $\mathcal{A}_1 \leq_F \mathcal{A}_2$.*

Proof. First we prove soundness of forward simulations:

$$\begin{aligned} \mathcal{A}_1 \leq_F \mathcal{A}_2 \quad &\Rightarrow \quad \mathcal{A}_1 \leq_{PF} \mathcal{A}_2 \quad \text{(Proposition 3.9.1)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_{wPF} \mathcal{A}_2 \quad \text{(Proposition 3.10.1)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad \text{(Proposition 3.10.3).} \end{aligned}$$

Next we establish completeness:

$$\begin{aligned} \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_F \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad \text{(Proposition 2.4)} \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_{DC} \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad \text{(as in soundness proof)} \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_{DC} \mathcal{A}_2 \quad (\leq_{DC} \text{ is transitive}) \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_F \mathcal{A}_2 \quad \text{(Proposition 5.1)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_F \mathit{Unfold}(\mathcal{A}_1) \leq_F \mathcal{A}_2 \quad \text{(Proposition 2.4)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_F \mathcal{A}_2 \quad (\leq_F \text{ is transitive}). \qquad \square \end{aligned}$$

5.2. Nondeterministic automata with internal actions. Next we extend the results of section 5.1 to nondeterministic automata that may include internal actions. The proofs are analogous to those in section 5.1. The difference is that, in several places in the proof of Proposition 5.3, we need to reason about multistep extensions of executions instead of single-step extensions. Again, we begin with tree-structured nondeterministic automata.

Proposition 5.3. *Let $\mathcal{A}_1$, $\mathcal{A}_2$ be nondeterministic automata such that $\mathcal{A}_1$ is tree-structured. Then $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ implies $\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$.*

Proof. Assume that $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$. Let $\mathcal{C}$ be $\mathit{tester}(\mathcal{A}_1)$ and η be $\mathit{observation}(\mathcal{A}_1)$, that is, the trace distribution of $\mathcal{A}_1 \| \mathcal{C}$ induced by the scheduler $\mathit{observer}(\mathcal{A}_1)$. Define the scheduler σ_2, the probabilistic execution ϵ, and the Θ sets as in the proof of Proposition 5.1.

The definition of R is slightly different: $q_1 \; R \; q_2$ iff there exists a state q_2' such that $q_2 \implies q_2'$ and there exists $\alpha \in \Theta_{q_1,q_2'}$ such that $\epsilon(C_\alpha) > 0$. We claim that R is a weak forward simulation from $\mathcal{A}_1$ to $\mathcal{A}_2$.

For the start condition, we must show that $\bar{q}_1 \; R \; \bar{q}_2$. By Item 1 of Proposition 4.6, $\eta(C_{\bar{q}_1}) = 1$. This means that there exists a finite execution fragment α of $\mathcal{A}_2 \| \mathcal{C}$ with trace $\bar{q}_1$ that ends with action $\bar{q}_1$ such that $\epsilon(C_\alpha) > 0$. By definition of $\mathcal{C}$, the last state of α is $(q_2, \bar{q}_1)$ for some state q_2 satisfying $\bar{q}_2 \implies q_2$. By definition of R, $\bar{q}_1 \; R \; \bar{q}_2$, as needed.

For the step condition, assume $q_1 \; R \; q_2$ and let $q_1 \xrightarrow{a}_1 q_1'$ be a transition of $\mathcal{A}_1$, which we denote by tr. We exhibit a matching weak transition $q_2 \overset{a}{\implies}_2 q_2'$.

By definition of R, there exists a state q_2'' of $\mathcal{A}_2$ such that $q_2 \implies q_2''$, and there exists a finite execution α in $\Theta_{q_1,q_2''}$ such that $\epsilon(C_\alpha) > 0$. Since $\Theta_{q_1,q_2''}$ is a subset of Θ_{q_1}, by definition of Θ_{q_1}, $\mathit{trace}(\alpha) = \beta q_1$ for some finite trace β. Therefore, $\eta(C_{\beta q_1}) > 0$. Since q_1 enables at least one transition in $\mathcal{A}_1$, specifically transition tr, (6) from Proposition 4.6 implies that $\eta(C_{\beta q_1 \, ch}) = \eta(C_{\beta q_1})$. Thus, there exists an execution fragment α' of $\mathcal{A}_2 \| \mathcal{C}$ with trace ch such that $\epsilon(C_{\alpha \frown \alpha'}) > 0$. Furthermore, since, by definition of $\mathcal{C} = \mathit{tester}(\mathcal{A}_1)$, the transition of $\mathcal{C}$ labeled by ch that leaves from state q_1 leads to state tr with nonzero probability, we can assume that the last state of α' is of the form (q', tr) for some state q' of $\mathcal{A}_2$.

Recall from above that $\eta(C_{\beta q_1 \, ch}) > 0$. By (7) from Proposition 4.6, $\eta(C_{\beta q_1 \, ch}) = \sum_{(a,q') | a \in E, q \xrightarrow{a} q'} \eta(C_{\beta q_1 \, ch \, aq'}) + \sum_{q' | (\exists a) a \in H, q_1 \xrightarrow{a} q'} \eta(C_{\beta q_1 \, ch \, q'})$. Hence, σ_2 must extend $\alpha \frown \alpha'$ in such a way that the first or the first two external actions are compatible with one of the transitions of $\mathcal{A}_1$ that are enabled from q_1. (The number of external actions depends on whether the compatible transition of $\mathcal{A}_1$ is labeled by an internal or external action.) Since state tr of $\mathcal{C}$ enables only action q_1', and since, by the tree-structure of $\mathcal{A}_1$, a is uniquely determined by q_1', the first or first two external actions of $\mathcal{A}_2 \| \mathcal{C}$ scheduled by σ_2 are either q_1' or aq_1', depending on whether a is internal or external. Thus, there exists an execution fragment α'' of $\mathcal{A}_2 \| \mathcal{C}$, with trace $\mathit{trace}(aq_1')$, such that $\epsilon(C_{\alpha \frown \alpha' \frown \alpha''}) > 0$. Furthermore, we can assume that the last transition of α'' is labeled by q_1' (simply truncate α'' otherwise).

Let (q_2', q_1') be the last state of α''. Then, $\alpha \frown \alpha' \frown \alpha'' \in \Theta_{q_1',q_2'}$, thus showing that $q_1' \; R \; q_2'$. It remains to show that $q_2 \overset{a}{\implies} q_2'$. For this, it suffices to recall that $q_2 \implies q_2''$ and observe that $q_2'' \overset{a}{\implies} q_2'$ since the execution fragment $(\alpha' \frown \alpha'') \lceil \mathcal{A}_2$ has trace $\mathit{trace}(a)$, first state q_2'', and last state q_2'. ◻

Using the same approach as before, we may eliminate the assumption in Proposition 5.3 that $\mathcal{A}_1$ is tree-structured.

Theorem 5.4. *Let $\mathcal{A}_1$, $\mathcal{A}_2$ be nondeterministic automata. Then $\mathcal{A}_1 \leq_{DC} \mathcal{A}_2$ iff $\mathcal{A}_1 \leq_{wF} \mathcal{A}_2$.*

Proof. This proof is analogous to that of Theorem 5.2. First we prove soundness of weak forward simulations:

$$\begin{aligned} \mathcal{A}_1 \leq_{wF} \mathcal{A}_2 \quad &\Rightarrow \quad \mathcal{A}_1 \leq_{wPF} \mathcal{A}_2 \quad \text{(Proposition 3.9.2)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad \text{(Proposition 3.10.3).} \end{aligned}$$

Now we prove completeness:

$$\begin{aligned} \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_F \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \quad \text{(Proposition 2.4)} \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_{DC} \mathcal{A}_1 \leq_{DC} \mathcal{A}_2 \\ & \quad \text{(as in proof Theorem 5.2, soundness part)} \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_{DC} \mathcal{A}_2 \quad (\leq_{DC} \text{ is transitive}) \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{A}_1) \leq_{wF} \mathcal{A}_2 \quad \text{(Proposition 5.3)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_F \mathit{Unfold}(\mathcal{A}_1) \leq_{wF} \mathcal{A}_2 \quad \text{(Proposition 2.4)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_{wF} \mathit{Unfold}(\mathcal{A}_1) \leq_{wF} \mathcal{A}_2 \quad \text{(Proposition 2.3.1)} \\ &\Rightarrow \quad \mathcal{A}_1 \leq_{wF} \mathcal{A}_2 \quad (\leq_{wF} \text{ is transitive}). \quad \square \end{aligned}$$

6. Characterizations of $\leq_{DC}$ for PAs.

Now we present our characterization theorems for $\leq_{DC}$ for PAs: Theorem 6.3 characterizes $\leq_{DC}$ in terms of $\leq_{PF}$, for PAs without internal actions, and Theorem 6.5 characterizes $\leq_{DC}$ in terms of $\leq_{wPF}$, for arbitrary PAs. Again, we give the results first for tree-structured PAs and extend them by unfolding. As before, the interesting direction is the completeness direction, showing that $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ implies the existence of a simulation relation from $\mathcal{P}_1$ to $\mathcal{P}_2$. Our proofs of completeness for PAs are analogous to those for nondeterministic automata.

6.1. PAs without internal actions.

We first consider tree-structured PAs.

PROPOSITION 6.1. *Let $\mathcal{P}_1$, $\mathcal{P}_2$ be PAs without internal actions such that $\mathcal{P}_1$ is tree-structured. Then $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ implies $\mathcal{P}_1 \leq_{PF} \mathcal{P}_2$.*

Proof. Assume that $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$. Let $\mathcal{C}$ be $\mathit{tester}(\mathcal{P}_1)$ and η be $\mathit{observation}(\mathcal{P}_1)$, that is, the trace distribution of $\mathcal{P}_1 \| \mathcal{C}$ induced by the scheduler $\mathit{observer}(\mathcal{P}_1)$. Define the scheduler σ_2, the probabilistic execution ϵ, and the Θ sets as in the proof of Proposition 5.1.

Define a relation R as follows: $q_1 \; R \; \mu_2$ iff $\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha) > 0$ and for each state $q_2 \in Q_2$,

$$\mu_2(q_2) = \frac{\sum_{\alpha \in \Theta_{q_1,q_2}} \epsilon(C_\alpha)}{\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha)}. \tag{12}$$

That is, the measure μ_2 describes probabilities of the various Θ_{q_1,q_2}'s relative to Θ_{q_1}. Note that the equation above is well defined since, by the tree-structure of $\mathcal{P}_1$, all the cones represented by Θ_{q_1} are disjoint, and thus $\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha) \leq 1$. We claim that R is a probabilistic forward simulation from $\mathcal{P}_1$ to $\mathcal{P}_2$.

Before proving that R is a probabilistic forward simulation we make several observations:

1. Relation R is a function from Q_1 to $\mathit{Disc}(Q_2)$. Indeed, if $\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha) > 0$, then there exists exactly one measure that satisfies (12). Furthermore, given the construction of η and the fact that $\mathcal{P}_1$ is tree-structured (i.e., all states are reachable), every state q_1 of Q_1 occurs with some positive probability in η. Thus, since η is induced by ϵ, $\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha) > 0$ for all states q_1 of Q_1.
2. If $q_1 \; R \; \mu_2$, then, for each state $q_2 \in Q_2$ and each execution $\alpha \in \Theta_{q_1,q_2}$,

$$\epsilon(C_\alpha) > 0 \quad \Rightarrow \quad q_2 \in \mathit{supp}(\mu_2). \tag{13}$$

That is, the execution α occurs with nonzero probability in ϵ only if μ_2 assigns nonzero probability to q_2. This property is a direct consequence of (12).

3. For each transition $q_1 \xrightarrow{a} \mu'_1$ of $\mathcal{P}_1$, the following equation holds:

$$\mu'_1(q'_1) = \frac{\sum_{\alpha\in\Theta_{q'_1}} \epsilon(C_\alpha)}{\sum_{q\in supp(\mu'_1)\,,\,\alpha\in\Theta_q} \epsilon(C_\alpha)}. \tag{14}$$

That is, the relative probabilities of the states of $supp(\mu'_1)$ in ϵ are given by μ'_1. This result follows by instantiating (9) from Proposition 4.7 with $q_1 \xrightarrow{a} \mu'_1$ to derive the probability of a state q'_1 in the support of μ'_1, and by replacing the diamond expressions according to (2) from Proposition 3.3.

4. For each transition $tr = q_1 \xrightarrow{a} \mu'_1$ of $\mathcal{P}_1$, the following equation holds:

$$\sum_{\alpha\in\Theta_{q_1}} \epsilon(C_\alpha) = k \sum_{q\in supp(\mu'_1)\,,\,\alpha\in\Theta_q} \epsilon(C_\alpha), \tag{15}$$

where k is the number of transitions of $\mathcal{P}_1$ enabled from q_1. That is, the probability of reaching q_1 in ϵ is k times the probability of reaching q_1 and scheduling tr. Informally, transition tr is scheduled only if state q_1 is reached and the outcome of the following transition labeled by ch is tr, which happens with probability $1/k$. The reason why $\sum_{q\in supp(\mu'_1)\,,\,\alpha\in\Theta_q} \epsilon(C_\alpha)$ is the probability of reaching q_1 and scheduling tr is that states from $supp(\mu'_1)$ can occur only after q_1 has occurred and tr is reached (see the definition of tester automaton and of observer of a tester automaton), and furthermore states from $supp(\mu'_1)$ occur with probability 1 once tr is reached (see (7) from Proposition 4.6).

This follows by instantiating (8) from Proposition 4.7 with tr, replacing the diamond expressions according to (2) from Proposition 3.3, summing over $supp(\mu'_1)$, observing that $\sum_{q'_1\in supp(\mu'_1)} \mu'_1(q'_1) = 1$, and deriving $\sum_{\alpha\in\Theta_{q_1}} \epsilon(C_\alpha)$ from the resulting equation.

We are now ready to show that R is a probabilistic forward simulation. For the start condition, we must show that $\bar{q}_1 \; R \; \delta(\bar{q}_2)$.

Consider the start state $(\bar{q}_2, \bar{q}_{\mathcal{C}})$ of $\mathcal{P}_2\|\mathcal{C}$. Since there are no internal actions in $\mathcal{P}_2$ or $\mathcal{C}$, and since, by (5) from Proposition 4.6, $\eta(C_{\bar{q}_1}) = 1$, the only action that is scheduled initially by σ_2 is $\bar{q}_1$, leading to state $(\bar{q}_2, \bar{q}_1)$ with probability 1. Thus, the finite execution $\alpha = (\bar{q}_2, \bar{q}_{\mathcal{C}})\bar{q}_1(\bar{q}_2, \bar{q}_1)$ is an element of $\Theta_{\bar{q}_1,\bar{q}_2}$ such that $\epsilon(C_\alpha) = 1$, and, by definition of R, $\bar{q}_1 \; R \; \delta(\bar{q}_2)$, as needed.

For the step condition, assume that $q_1 \; R \; \mu_2$ and let $q_1 \xrightarrow{a}_1 \mu'_1$ be a transition of $\mathcal{P}_1$, which we denote by tr. We must exhibit a probability measure $\xi'_2 \in Disc(Disc(Q_2))$ and a hyper-transition $\mu_2 \xrightarrow{a}_2 \mu''_2$, matching the given transition, where $\mu''_2 = \mathit{flatten}(\xi'_2)$ and $\mu'_1 \; R \; \xi'_2$. We do this by deriving a transition tr_α of $\mathcal{P}_2$ for each execution α of Θ_{q_1} and by combining the tr_α's appropriately into transitions tr_q, for each state $q \in supp(\mu_2)$, that are the basis for the required hyper-transition. The tr_α transitions are derived from η; the construction considers only those α's for which $\epsilon(C_\alpha) > 0$. The other α's can be treated arbitrarily.

Consider an execution α of Θ_{q_1} such that $\epsilon(C_\alpha) > 0$. By property (13), $\alpha \in \Theta_{q_1,q_2}$ for some state q_2 in $supp(\mu_2)$. Since Θ_{q_1,q_2} is a subset of Θ_{q_1}, by definition of Θ_{q_1}, $trace(\alpha) = \beta q_1$ for some finite trace β. Therefore, $\eta(C_{\beta q_1}) > 0$. Since q_1 enables at least one transition in $\mathcal{P}_1$, specifically transition tr, (6) from Proposition 4.6 implies that $\eta(C_{\beta q_1\, ch}) = \eta(C_{\beta q_1})$. Then, since $\mathcal{P}_2$ and $\mathcal{C}$ have no internal actions, σ_2 schedules action *ch* from α with probability 1.

By definition of $\mathcal{C} = \mathit{tester}(\mathcal{P}_1)$, the transition labeled by *ch* leaving from state q_1 of $\mathcal{C}$ leads to state *tr* with probability > 0. Hence, $\epsilon(C_{\alpha\, ch\,(q_2,tr)}) > 0$. By (7) from Proposition 4.6, where only the first term of the right-hand side is nonzero due to the absence of internal actions, $\eta(C_{\beta q_1\, ch}) = \sum_{(a,q')|a\in E, q_1 \xrightarrow{a} q'} \eta(C_{\beta q_1\, ch\, aq'})$. Hence, σ_2 must extend $\alpha\, ch\,(q_2, tr)$ with two steps labeled by an action and a state of $\mathcal{P}_1$, respectively, where the action and the state are compatible with one of the transitions of $\mathcal{P}_1$ that are enabled from q_1. Since state *tr* of $\mathcal{C}$ enables only actions in $\mathit{supp}(\mu_1')$, and since, by the tree-structure of $\mathcal{P}_1$, a is uniquely determined by μ_1', the action that is scheduled is a, and the state that is scheduled is a state in $\mathit{supp}(\mu_1')$. Thus, $\sigma_2(\alpha\, ch\,(q_2, tr))$ returns a probability measure over transitions labeled by a. This measure identifies a combined transition of $\mathcal{P}_2$ labeled by a that leaves from q_2, which we denote by tr_α.

Now, using the tr_α transitions, we define a combined transition from each state in the support of μ_2. Namely, for each state $q \in \mathit{supp}(\mu_2)$, let tr_q be the combined transition of $\mathcal{P}_2$ defined by

$$tr_q \triangleq \sum_{\alpha\in\Theta_{q_1,q}} \frac{\epsilon(C_\alpha)}{\sum_{\alpha'\in\Theta_{q_1,q}} \epsilon(C_{\alpha'})} tr_\alpha. \tag{16}$$

Informally, each element of $\Theta_{q_1,q}$ is an execution that contributes to the emulation of transition $q_1 \xrightarrow{a}_1 \mu_1'$ from q. Equation (16) computes tr_q, the overall contribution to the emulation from q, by averaging over all elements of $\Theta_{q_1,q}$. We could prove that $\Theta_{q_1,q}$ contains only one element α' such that $\epsilon(C_{\alpha'}) > 0$ and simplify (16) accordingly. However, this simplification is not necessary for the proof. Now we define the measure $\mu_2'' \in \mathit{Disc}(Q_2)$:

$$\mu_2'' \triangleq \sum_{q\in \mathit{supp}(\mu_2)} \mu_2(q)\mu_{tr_q}. \tag{17}$$

Then, by construction, $\mu_2 \xrightarrow{a} \mu_2''$ is a hyper-transition of $\mathcal{P}_2$.

It remains to define a probability measure $\xi_2' \in \mathit{Disc}(\mathit{Disc}(Q_2))$ such that $\mu_2'' = \mathit{flatten}(\xi_2')$ and $\mu_1'\ R\ \xi_2'$.

For each $q \in \mathit{supp}(\mu_1')$, let μ_q be the unique measure such that $q\ R\ \mu_q$. We can identify μ_q because R is a function. Define $\xi_2' \in \mathit{Disc}(\mathit{Disc}(Q_2))$ such that, for each $q \in \mathit{supp}(\mu_1')$, $\xi_2'(\mu_q) = \sum_{q'\in \mathit{supp}(\mu_1')|\mu_{q'}=\mu_q} \mu_1'(q')$. Then $\mu_1'\ R\ \xi_2'$ by the definition of ξ_2'.

It remains to show that $\mu_2'' = \mathit{flatten}(\xi_2')$, that is, that $\mu_2'' = \sum_{\rho\in \mathit{supp}(\xi_2')} \xi_2'(\rho)\rho$. From the definition of ξ_2' and of the flatten operator, it suffices to show that for every $q_2 \in Q_2$,

$$\mu_2''(q_2) = \sum_{q\in \mathit{supp}(\mu_1')} \mu_1'(q)\mu_q(q_2). \tag{18}$$

To prove (18) we first claim that the following equation is valid for each pair of states q_1, q_2 of $\mathcal{P}_1$ and $\mathcal{P}_2$, respectively, if k denotes the number of transitions of $\mathcal{P}_1$ that are enabled from q_1:

$$\sum_{\alpha\in\Theta_{q_1}} \epsilon(C_\alpha)\mu_{tr_\alpha}(q_2) = k \sum_{q\in \mathit{supp}(\mu_1'),\, \alpha\in\Theta_{q,q_2}} \epsilon(C_\alpha). \tag{19}$$

Informally, the left-hand side of (19) represents the probability of scheduling q_1 and then reaching q_2 according to the transition tr_α, without considering the outcome of the transition labeled by *ch*. The right-hand side, on the other hand, computes the probability of scheduling q_1, scheduling *ch* and reaching μ_1', and then scheduling tr_α and reaching q_2. State μ_1' is reached by *ch* with probability $1/k$, which justifies the k factor in the right-hand side.

To prove (19), consider an execution $\alpha \in \Theta_{q,q_2}$, where $q \in \mathit{supp}(\mu_1')$. Since q always occurs after q_1, execution α can be split into $\alpha' \frown \alpha''$, where $\alpha' \in \Theta_{q_1}$. Furthermore, $\mathit{trace}(\alpha'') = \mathit{ch}\, aq$, and since there are no internal actions in $\mathcal{P}_2$ and $\mathcal{C}$, α is the unique extension of α' that is in Θ_{q,q_2}. In particular,

$$\alpha'' = (q', q_1)\; \mathit{ch}\; (q', tr)a(q_2, tr)q(q_2, q)$$

for some state q' of $\mathcal{P}_2$, and $\epsilon(C_\alpha) = \epsilon(C_{\alpha'})(1/k)\mu_{tr_{\alpha'}}(q_2)$. Thus, each summand on the right-hand side of (19) has a corresponding summand on the left-hand side that differs by a factor of k, and the correspondence relation is an injection. If the correspondence is not a bijection, then the α terms that are left out on the left-hand side are such that $\mu_{tr_\alpha}(q_2) = 0$ (otherwise an extension in Θ_{q,q_2} for some q exists). This suffices.

We now consider the left-hand side of (18). Consider the definition of μ_2'' given by (17). By expanding $\mu_2(q)$ according to the definition of μ_2 given by (12), and expanding $\mu_{tr}(q_2)$ according to the definition of μ_{tr} given by (16), we obtain

$$\mu_2''(q_2) = \sum_{q \in \mathit{supp}(\mu_2)} \frac{\sum_{\alpha \in \Theta_{q_1,q}} \epsilon(C_\alpha)}{\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha)} \frac{\sum_{\alpha \in \Theta_{q_1,q}} \epsilon(C_\alpha)\mu_{tr_\alpha}(q_2)}{\sum_{\alpha \in \Theta_{q_1,q}} \epsilon(C_\alpha)}.$$

By cross-simplifying the top-leftmost and bottom-rightmost factors, and by factoring the left denominator out of the sum, we obtain

$$\mu_2''(q_2) = \frac{\sum_{q \in \mathit{supp}(\mu_2)} \sum_{\alpha \in \Theta_{q_1,q}} \epsilon(C_\alpha)\mu_{tr_\alpha}(q_2)}{\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha)}.$$

By property (13), we can rewrite the numerator as follows:

$$\mu_2''(q_2) = \frac{\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha)\mu_{tr_\alpha}(q_2)}{\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha)}.$$

By multiplying numerator and denominator by k, applying (19) to the numerator, and applying (15) to the denominator, we obtain

$$\mu_2''(q_2) = \frac{\sum_{q \in \mathit{supp}(\mu_1')\,,\, \alpha \in \Theta_{q,q_2}} \epsilon(C_\alpha)}{\sum_{q \in \mathit{supp}(\mu_1')\,,\, \alpha \in \Theta_q} \epsilon(C_\alpha)}. \tag{20}$$

We now consider the right-hand side of (18). By applying (14) and (12) to the two factors of the right-hand side of (18), and by simplifying common factors algebraically, we obtain

$$\sum_{q \in \mathit{supp}(\mu_1')} \mu_1'(q)\mu_q(q_2) = \frac{\sum_{q \in \mathit{supp}(\mu_1')\,,\, \alpha \in \Theta_{q,q_2}} \epsilon(C_\alpha)}{\sum_{q \in \mathit{supp}(\mu_1')\,,\, \alpha \in \Theta_q} \epsilon(C_\alpha)}. \tag{21}$$

Now (18) follows by direct combination of (20) and (21). ◻

Interestingly, the probabilistic forward simulation that we constructed in the above proof is functional. Functional simulations are usually called *refinement mappings* [21, 26]. Write $\mathcal{P}_1 \leq_{PR} \mathcal{P}_2$ if there exists a functional probabilistic forward simulation from $\mathcal{P}_1$ to $\mathcal{P}_2$. Then we can state the following new proposition, which is a probabilistic version of Proposition 3.12 in [26].

PROPOSITION 6.2. *Let $\mathcal{P}_1$, $\mathcal{P}_2$ be PAs without internal actions such that $\mathcal{P}_1$ is tree-structured. Then $\mathcal{P}_1 \leq_{PF} \mathcal{P}_2$ iff $\mathcal{P}_1 \leq_{PR} \mathcal{P}_2$.*

Proof. It is enough to observe that each state q_1 of $\mathcal{P}_1$ occurs with some positive probability in the trace distribution η of the proof of Proposition 6.1. ◻

As usual, we may eliminate the assumption that $\mathcal{P}$ is tree-structured.

THEOREM 6.3. *Let $\mathcal{P}_1$, $\mathcal{P}_2$ be PAs without internal actions. Then $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ iff $\mathcal{P}_1 \leq_{PF} \mathcal{P}_2$.*

Proof. First we prove the soundness of probabilistic forward simulations:

$$\begin{aligned} \mathcal{P}_1 \leq_{PF} \mathcal{P}_2 \quad &\Rightarrow \quad \mathcal{P}_1 \leq_{wPF} \mathcal{P}_2 \quad \text{(Proposition 3.10.1)} \\ &\Rightarrow \quad \mathcal{P}_1 \leq_{DC} \mathcal{P}_2 \quad \text{(Proposition 3.10.3).} \end{aligned}$$

Now we prove completeness:

$$\begin{aligned} \mathcal{P}_1 \leq_{DC} \mathcal{P}_2 \quad &\Rightarrow \quad \mathit{Unfold}(\mathcal{P}_1) \leq_{DC} \mathcal{P}_1 \leq_{DC} \mathcal{P}_2 \quad \text{(Proposition 3.12)} \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{P}_1) \leq_{DC} \mathcal{P}_2 \quad (\leq_{DC} \text{ is transitive}) \\ &\Rightarrow \quad \mathit{Unfold}(\mathcal{P}_1) \leq_{PF} \mathcal{P}_2 \quad \text{(Proposition 6.1)} \\ &\Rightarrow \quad \mathcal{P}_1 \leq_{PF} \mathit{Unfold}(\mathcal{P}_1) \leq_{PF} \mathcal{P}_2 \quad \text{(Proposition 3.11)} \\ &\Rightarrow \quad \mathcal{P}_1 \leq_{PF} \mathcal{P}_2 \quad (\leq_{PF} \text{ is transitive}). \quad ◻ \end{aligned}$$

6.2. PAs with internal actions. Again, we start with tree-structured PAs.

PROPOSITION 6.4. *Let $\mathcal{P}_1$, $\mathcal{P}_2$ be PAs with $\mathcal{P}_1$ tree-structured. Then $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ implies $\mathcal{P}_1 \leq_{wPF} \mathcal{P}_2$.*

Proof. Assume that $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$. Define the tester PA $\mathcal{C}$ of $\mathcal{P}_1$, the observer σ_1, the trace distribution η, the scheduler σ_2, the probabilistic execution ϵ, and the Θ sets as in the proof of Proposition 5.1. Define relation R according to (12) as in the proof of Proposition 6.1. Observe that formulas (13), (14), and (15) hold for the same reasons as before. Define a new relation R' as follows: $q_1 \; R' \; \mu_2$ iff there exists a measure μ_2' such that $\mu_1 \implies \mu_2'$ and $q_1 \; R \; \mu_2'$. Observe that trivially $R {\subseteq} R'$. We show that R' is a weak probabilistic forward simulation from $\mathcal{P}_1$ to $\mathcal{P}_2$.

For the start condition, we must show that $\bar{q}_1 \; R' \; \delta(\bar{q}_2)$. By Item 1 of Proposition 4.6, $\eta(C_{\bar{q}_1}) = 1$. This means that $\sum_{\alpha \in \Theta_{\bar{q}_1} | \mathit{trace}(\alpha) = \bar{q}_1} \epsilon(C_\alpha) = 1$. Let $\Theta'_{\bar{q}_1}$ be the set of elements of $\Theta_{\bar{q}_1}$ with trace $\bar{q}_1$, and let ϵ' be the truncation of ϵ to $\Theta'_{\bar{q}_1}$. Then ϵ' assigns probability 1 to the set of finite execution fragments with trace $\bar{q}_1$. Furthermore, observing that all elements of $\Theta'_{\bar{q}_1}$ are not prefixes of each other, we derive $\epsilon'(C_\alpha) = \epsilon'(\{\alpha\})$ for each $\alpha \in \Theta'_{\bar{q}_1}$. Finally, observing that each element of $\Theta_{\bar{q}_1} - \Theta'_{\bar{q}_1}$ is not a prefix of any element of $\Theta'_{\bar{q}_1}$, we derive $\epsilon'(C_\alpha) = \epsilon'(\{\alpha\}) = 0$ for each $\alpha \in \Theta_{\bar{q}_1} - \Theta'_{\bar{q}_1}$. Let μ_2' be $\mathit{lstate}(\epsilon')$. By the definition of a weak hypertransition, $\delta(\bar{q}_2) \implies \mu_2'$. We show that $\bar{q}_1 \; R \; \mu_2'$, which suffices. Consider a state q_2 of $\mathcal{P}_2$. By definition of μ_2', definition of $\Theta_{\bar{q}_1, q_2}$, and the fact that $\mathit{supp}(\epsilon') \subseteq \Theta_{\bar{q}_1}$, $\mu_2'(q_2) = \sum_{\alpha \in \Theta_{\bar{q}_1, q_2}} \epsilon'(\{\alpha\})$. Then the result follows immediately by observing that this equation corresponds to (12) since $\epsilon'(\{\alpha\}) = \epsilon'(C_\alpha)$ when $\alpha \in \Theta_{\bar{q}_1}$ and since $\sum_{\alpha \in \Theta_{\bar{q}_1}} \epsilon(C_\alpha) = 1$.

For the step condition, assume that $q_1 \; R' \; \mu_2$, and let $q_1 \xrightarrow{a}_1 \mu_1'$ be a transition of $\mathcal{P}_1$, which we denote by tr. By definition of R', there exists a measure μ_2' such that $\mu_2 \Longrightarrow \mu_2'$ and $q_1\ R\ \mu_2'$. We now show that there exists a measure ξ_2' and a measure $\mu_2'' = \mathit{flatten}(\xi_2')$ such that $\mu_1\ R\ \xi_2'$ and $\mu_2' \overset{a}{\Longrightarrow} \mu_2''$. Then $\mu_1\ R'\ \xi_2'$, and by Proposition 3.6, $\mu_2 \overset{a}{\Longrightarrow} \mu_2''$.

The proof of existence of ξ_2' and μ_2'' proceeds exactly as in the case of Proposition 6.1 except for the definition of the tr_α transitions. Thus, in the rest of the proof we construct the tr_α's and prove that (19) still holds.

We introduce a special *conditional* construction that is needed for the definition of the tr_α's. Let $\mathcal{C}_{tr}$ be the same as $\mathcal{C}$ except that the transition $q_1 \overset{ch}{\rightarrow} \mu$, where μ is uniquely determined by q_1, is replaced by $q_1 \overset{ch}{\rightarrow} \delta(tr)$. Given a scheduler σ for $\mathcal{P}_2\|\mathcal{C}$, define the scheduler $\sigma \mid tr$ for $\mathcal{P}_2\|\mathcal{C}_{tr}$ that is the same as σ except that transition $q_1 \overset{ch}{\rightarrow} \delta(tr)$ of $\mathcal{C}_{tr}$ is chosen whenever σ chooses $q_1 \overset{ch}{\rightarrow} \mu$. Given a probabilistic execution fragment ϵ' of $\mathcal{P}_2\|\mathcal{C}$, generated by some scheduler σ, define $\epsilon' \mid tr$ to be the result of $\sigma \mid tr$ applied to $\mathcal{P}\|\mathcal{C}_{tr}$ from the start state of ϵ'. The intuition behind $\epsilon' \mid tr$ is that we study ϵ' under the condition that tr is the outcoming state of $\mathcal{C}$ whenever $q_1 \overset{ch}{\rightarrow} \mu$ is scheduled. Then, the following two properties are valid:

1. $(\epsilon' \mid tr)\lceil\mathcal{P}_2$ is a probabilistic execution fragment of $\mathcal{P}_2$.
2. For each finite execution fragment α of $\mathcal{P}_2\|\mathcal{C}$ where state tr occurs and such that $\mathit{fstate}(\alpha)$ is not of the form $(\cdot, tr)$, $(\epsilon' \mid tr)(C_\alpha) = k\epsilon(C_\alpha)$, where k is the size of $\mathit{supp}(\mu)$.

The first item follows immediately from Proposition 3.7, given that $\epsilon' \mid tr$ is a probabilistic execution fragment of $\mathcal{P}_2\|\mathcal{C}_{tr}$. The second item follows directly from the definition of probability of a cone, since in ϵ' the probability associated with the edge $q\ ch\ (\cdot, tr)$ is $1/k$ while in $\epsilon' \mid tr$ the probability of the same edge is 1.

We now define the tr_α's. Consider an execution α of Θ_{q_1} such that $\epsilon(C_\alpha) > 0$. Let ϵ^1 be the truncation of ϵ at all the points in $\cup_{q\in \mathit{supp}(\mu_1')}\Theta_q$, which is a probabilistic execution of $\mathcal{P}_2\|\mathcal{C}$ by definition. Let ϵ^1_α be $\epsilon^1 \triangleright \alpha$, which is a probabilistic execution fragment of $\mathcal{P}_2\|\mathcal{C}$ by definition. Finally, let ϵ^2_α be $(\epsilon^1_\alpha \mid tr)\lceil\mathcal{P}_2$, which is a probabilistic execution fragment of $\mathcal{P}_2$ by Property 1.

By definition of Θ_{q_1}, $\mathit{trace}(\alpha) = \beta q_1$ for some finite trace β. Therefore, $\eta(C_{\beta q_1}) > 0$. Since q_1 enables at least one transition in $\mathcal{P}_1$, specifically transition tr, (6) from Proposition 4.6 implies that $\eta(C_{\beta q_1\, ch}) = \eta(C_{\beta q_1})$. Thus, action ch occurs as the first external action with probability 1 in μ^1_α.

By (7) from Proposition 4.6, if the occurrence of action ch leads $\mathcal{C}$ to state tr, then an action in $\mathit{supp}(\mu_1')$ occurs eventually in ϵ with probability 1, leading $\mathcal{C}$ to a state in $\mathit{supp}(\mu_1')$, which is a truncation point according to the definition of ϵ^1. Thus, the probability of termination in $\epsilon^1_\alpha \mid tr$ is 1, as well as the probability of termination in ϵ^2_α; that is, ϵ^2_α assigns probability 1 to the set of finite executions. Furthermore, given that action a is uniquely determined by μ_1' ($\mathcal{P}_1$ is tree-structured), again by (7) from Proposition 4.6 all finite executions α' with $\epsilon^2_\alpha(\alpha') > 0$ have trace $\mathit{trace}(a)$. Thus, ϵ^2_α is a representation of a weak combined transition labeled by a from $\mathit{lstate}(\alpha)\lceil\mathcal{P}_2$. Denote such transition by tr_α.

We are left to show that (19) still holds. That is,

$$\sum_{\alpha\in\Theta_{q_1}} \epsilon(C_\alpha)\mu_{tr_\alpha}(q_2) = k \sum_{q\in \mathit{supp}(\mu_1')\,,\, \alpha\in\Theta_{q,q_2}} \epsilon(C_\alpha).$$

We consider first the term $\mu_{tr_\alpha}(q_2)$. From the definition of tr_α and of weak combined transition we get

$$\mu_{tr_\alpha}(q_2) = \sum_{\alpha' \mid lstate(\alpha') = q_2} \epsilon^2_\alpha(\alpha').$$

By applying the definition of projection, and using the fact that $\epsilon^1_\alpha \mid tr$ assigns probability 1 to the set of finite executions, we get

$$\mu_{tr_\alpha}(q_2) = \sum_{\alpha' \mid lstate(\alpha' \lceil \mathcal{P}_2) = q_2} (\epsilon^1_\alpha \mid tr)(\alpha').$$

Given that the truncation points of ϵ^1 are all at the $\cup_{q \in supp(\mu'_1)} \Theta_q$ points, the only finite executions α' that have nonzero probability are such that $\alpha \frown \alpha'$ is in some set Θ_q. Furthermore, given that no execution in $\cup_{q \in supp(\mu'_1)} \Theta_q$ is a prefix of another (our PAs are tree-structured and all actions in $supp(\mu'_1)$ occur in different branches), the probabilities of the finite executions can be replaced by the probabilities of their cones, thus getting

$$\mu_{tr_\alpha}(q_2) = \sum_{q \in supp(\mu'_1)} \sum_{\alpha' \mid \alpha \frown \alpha' \in \Theta_{q,q_2}} (\epsilon^1_\alpha \mid tr)(C_{\alpha'}).$$

By property 2 we can get rid of the conditional on tr by introducing a k factor, thus getting

$$\mu_{tr_\alpha}(q_2) = \sum_{q \in supp(\mu'_1)} \sum_{\alpha' \mid \alpha \frown \alpha' \in \Theta_{q,q_2}} k \epsilon^1_\alpha(C_{\alpha'}). \tag{22}$$

By replacing $\mu_{tr_\alpha}(q_2)$ according to (22) in the left-hand side of (19) and by rearranging terms algebraically, we obtain

$$\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha) \mu_{tr_\alpha}(q_2) = k \sum_{q \in supp(\mu'_1)} \sum_{\alpha \in \Theta_{q_1}} \sum_{\alpha' \mid \alpha \frown \alpha' \in \Theta_{q,q_2}} \epsilon(C_\alpha) \epsilon^1_\alpha(C_{\alpha'}).$$

By using that $\epsilon^1_\alpha = \epsilon^1 \triangleright \alpha$ (by definition) and Proposition 3.15, the two probabilities in the equation above can be grouped into $\epsilon(C_{\alpha \frown \alpha'})$. By observing that all elements in Θ_{q,q_2}, with $q \in supp(\mu'_1)$, have a prefix in Θ_{q_1}, the intermediate sum can be removed, thus getting

$$\sum_{\alpha \in \Theta_{q_1}} \epsilon(C_\alpha) \mu_{tr_\alpha}(q_2) = k \sum_{q \in supp(\mu'_1)} \sum_{\alpha \in \Theta_{q,q_2}} \epsilon(C_\alpha),$$

which is (19), as needed. □

THEOREM 6.5. *Let $\mathcal{P}_1$, $\mathcal{P}_2$ be PAs. Then $\mathcal{P}_1 \leq_{DC} \mathcal{P}_2$ iff $\mathcal{P}_1 \leq_{wPF} \mathcal{P}_2$.*

Proof. Soundness of weak probabilistic forward simulations follows immediately from Proposition 3.10. Completeness is established as follows:

$$\begin{aligned}
\mathcal{P}_1 \leq_{DC} \mathcal{P}_2 \quad &\Rightarrow \quad \mathit{Unfold}(\mathcal{P}_1) \leq_{DC} \mathcal{P}_1 \leq_{DC} \mathcal{P}_2 \quad \text{(Proposition 3.12)} \\
&\Rightarrow \quad \mathit{Unfold}(\mathcal{P}_1) \leq_{DC} \mathcal{P}_2 \quad (\leq_{DC} \text{ is transitive}) \\
&\Rightarrow \quad \mathit{Unfold}(\mathcal{P}_1) \leq_{wPF} \mathcal{P}_2 \quad \text{(Proposition 6.4)} \\
&\Rightarrow \quad \mathcal{P}_1 \leq_{PF} \mathit{Unfold}(\mathcal{P}_1) \leq_{wPF} \mathcal{P}_2 \quad \text{(Proposition 3.11)} \\
&\Rightarrow \quad \mathcal{P}_1 \leq_{wPF} \mathit{Unfold}(\mathcal{P}_1) \leq_{wPF} \mathcal{P}_2 \quad \text{(Proposition 3.10)} \\
&\Rightarrow \quad \mathcal{P}_1 \leq_{wPF} \mathcal{P}_2 \quad (\leq_{wPF} \text{ is transitive}). \quad \square
\end{aligned}$$

7. Concluding remarks. We have characterized the trace distribution precongruence for nondeterministic and probabilistic automata, with and without internal actions, in terms of four kinds of simulation relations, $\leq_F$, $\leq_{wF}$, $\leq_{PF}$, and $\leq_{wPF}$. In particular, this shows that probabilistic contexts are capable of observing all the distinctions that can be expressed using these simulation relations. Our main technical contribution is the definition of special contexts, called testers, that, under the action of an appropriate scheduler, can reveal the branching structure of a PA via a trace distribution. Some technical improvements are possible. For example, our finite branching restriction can be relaxed to countable branching, simply by replacing uniform distributions in the tester automata by other distributions such as exponential distributions. In that case, however, calculations become more complicated. We have also considered nondeterministic and probabilistic automata with countably many states and actions. Again, this restriction can be relaxed at the cost of complicating the definition of the σ-field of execution fragments: the generators would be arbitrary unions of cones, and the measure of a union of cones would be just the sum of the measures of each single cone. Indeed, discrete transitions and discrete schedulers ensure that there are at most countably many cones with nonzero measure.

Although in this paper we reach a point where we have a full understanding of trace distribution precongruence as a branching relation, a natural question is whether it is possible to define linear probabilistic extensions of language inclusion. A potential approach is to consider ordinary traces paired with their maximal or minimal probabilities under all schedulers, but the induced preorder relations do not appear to be interesting. Another approach, followed in [19], is to extend classical testing preorders by considering the maximal and minimal probabilities of success of a test; however, even in such case the resulting precongruence is characterized in terms of simulation relations that, although weaker than the relations studied in this paper, are still branching relations. Other approaches ensure compositionality of trace distribution inclusion by restricting parallel composition so that the nondeterminism of each component is resolved based only on externally visible behavior of the other components. This approach is investigated in [10] in a synchronous model. In [8, 7], an asynchronous switched probabilistic input/output automaton model (PIOA) is presented, which uses a token structure to eliminate global nondeterministic choices. This token structure ensures that, at any point in time, there is at most one active component in a system and this unique component determines the next active component. Thus, global scheduling is performed jointly by all local schedulers, which have access to local information only. A notion of switched probabilistic systems is defined, which are switched PIOAs paired with sets of *acceptable* I/O schedulers. A trace-style semantics for switched probabilistic systems is given, using the notion of likelihood assignments. This semantics is shown to be compositional with respect to a parallel operator that combines local I/O schedulers into a joint I/O scheduler. Thus, the approach of [8, 7] can be characterized as *schedule-and-compose*, where local nondeterministic choices are resolved before the components are placed in parallel. In [7] also a similar strategy is pursued, but without the token structure. Instead, several axioms are imposed on the reactive and generative transition structures, so that branching occurs only when it is meant to be globally visible (i.e., the branches carry different visible action labels). These axioms capture a local-oblivious assumption on adversaries, which is well known in the area of randomized consensus [9, 3]. The model is proven to be compositional with respect to a schedule-and-compose operator similar to that in [8].

Acknowledgment. We are grateful to Erik de Vink for numerous detailed observations and suggestions for improvements.

GEOMETRIC SEPARATORS AND THEIR APPLICATIONS TO PROTEIN FOLDING IN THE HP-MODEL[*]

BIN FU[†] AND WEI WANG[‡]

Abstract. We develop a new method for deriving a geometric separator for a set of grid points. Our separator has a linear structure, which can effectively partition a grid graph. For example, we prove that for a grid graph G with a set of n points P in a two-dimensional grid, there is a separator with at most $1.129\sqrt{n}$ points in P that partitions G into two disconnected grid graphs each with at most $\frac{2n}{3}$ points. Our separator theorem for grid graphs has a significantly smaller upper bound than that was obtained for the general planar graphs in [H. N. Djidjev and S. M. Venkatesan, *Acta Inform.*, 34 (1997), pp. 231–234]. The protein folding problem in the HP-model is to put a sequence, consisting of two characters H and P, in a d-dimensional grid to have maximal number of HH-contacts, where an HH-contact is a pair of non-consecutive H letters that are put at two grid points of distance 1. Our separator is then applied to develop an exact algorithm for the protein-folding problem in the HP-model, which is NP-hard both in both two and three dimensions [B. Berger and T. Leighton, *J. Comput. Biol.*, 5 (1998), pp. 27–40; P. Crescenzi et al., *J. Comput. Biol.*, 5 (1998), pp. 423–465]. We design a $2^{O(n^{1-\frac{1}{d}}\log n)}$ time algorithm for the d-dimensional protein folding problem in the HP-model. In particular, our algorithm has $O(2^{6.145\sqrt{n}\log n})$ and $O(2^{6.913n^{\frac{2}{3}}\log n})$ computational time in two and three dimensions, respectively.

Key words. separator, protein folding, time complexity, algorithm

1. Introduction.

Geometric separators are fundamental tools in algorithm design for solving many geometric problems. Lipton and Tarjan [24] showed a well-known geometric separator for planar graphs. Their result has been elaborated on by many authors [9, 15, 2, 10]. The following best known separator theorem for planar graphs was proved by Djidjev and Venkatesan [10].

Theorem 1 (see [10]). *Any planar graph of n vertices has a vertex subset of cardinality* $\leq 1.97\sqrt{n}$ *whose removal separates the graph into two components each having at most* $\frac{2n}{3}$ *vertices.*

Spielman and Teng [38] showed a $\frac{3}{4}$-separator with size $1.82\sqrt{n}$ for planar graphs. Separators for more general graphs were presented in, e.g., [16, 3, 32]. Planar graph separators were applied to derive some $2^{O(\sqrt{n})}$-time algorithms for certain NP-hard problems about planar graphs by Lipton and Tarjan [25] and Ravi and Hunt [35]. Those problems include computing a maximum independent set, a minimum vertex cover, and three-colorings of a planar graph, and the number of satisfying truth assignments to a planar 3CNF formula [23].

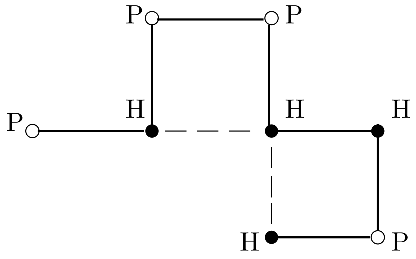

FIG. 1. *The sequence PHPPHHPH is put on the 2D grid. There are two H-H contacts marked by the dotted lines.*

Some other forms of the geometric separators were studied by Miller, Teng, and Vavasis [26], Miller and Thurston [27] and Smith and Wormald [37]. For a set of regular geometric objects such as circles, rectangles, etc., if every point on the plane is covered by at most k objects, the set of the objects is called a k-thick system. Some $O(\sqrt{k \cdot n})$ size separators for k-thick systems and the algorithms for finding them were derived in [27, 26, 37]. Smith and Wormald [37] applied their separators to develop algorithms for some geometric problems such as the planar travelling salesman and the Steiner tree problems (e.g., see [37]). Those problems usually have input points with fixed geometric positions in space.

Finding a minimal size separator, which maintains a similar balance partition condition like one of those mentioned above (e.g., each side of the separator has at most $\frac{2n}{3}$ points), for a grid graph is also an interesting combinatorial problem. Using special geometric properties of grid points, we develop a method for obtaining a separator with a smaller size for grid points via controlling the distances from the grid points to the separator line.

A set of grid points on the plane forms a grid graph by adding edges to every two grid points with distance 1. A grid graph is also a planar graph. In the protein folding of the HP-model, the 20 letter alphabet of amino acids is reduced to a two letter alphabet, namely H and P. H represents hydrophobic amino acids, whereas P represents polar or hydrophilic amino acids. Two monomers form a contact in some specific conformation if they are not consecutive, but occupy neighboring positions in the conformation (i.e., the distance vector between their positions in the conformation is a unit vector). A conformation with minimal energy is just a conformation with the maximal number of contacts between nonconsecutive H-monomers (see Figure 1). The protein folding problem in the HP-model is to find the conformation for any HP-sequence with minimal energy. The protein folding problem in the HP-model is an interesting and challenging problem that deals with a puzzle in the grids. The problem is to put a sequence, consisting of two characters H and P, in a d-dimensional grid to have the the maximal number of HH-contacts. As the input of the protein folding problem is only a sequence of letters, the locations of those letters in space are unknown and will be determined by the algorithm. For this reason, we do not know whether the separator theorems, such as Theorem 1, can be applied to the protein folding problem. We derive a separator theorem for the grid graph with a significantly smaller upper bound on the number of points on the separator than that obtained for planar graphs. Our result is stated as the following theorem.

THEOREM 2. *For a set P of n grid points on the two-dimensional (2D) plane, there is a line on the plane and a subset $Q \subseteq P$ of cardinality $\leq 1.129\sqrt{n}$ such that each half-plane determined by the line contains at most $\frac{2}{3}n$ points of P, and every two* *points $p_1, p_2 \in P$ on the different sides of the line have distance > 1, unless at least one of p_1, p_2 is in Q.*

Furthermore, we also provide $O(n^2)$ possible locations to find such a line based on the folding region within a fixed $n \times n$ square. This makes it possible to use the separator theorem in the algorithm for the protein folding problem, even though the locations of the letters are not known. The approximation method in searching for the separator region highly depends on the linear structure of the separator. We derive a similar separator for three-dimensional (3D) grid points, which is also applied to the 3D protein folding problem.

The lower bounds of $1.555\sqrt{n}$ and $1.581\sqrt{n}$ for the $\frac{2}{3}$-separator like that in Theorem 2 for the planar graph were proved by Djidev and Venkatesan [10] and Smith and Wormald [37], respectively. However, we develop a new approach and obtain an upper bound on the separator for a grid graph with a size smaller than their lower bounds. This shows that our smaller-sized separator for grid graphs cannot be directly obtained from that for planar graphs.

Our development of the separator technology is motivated by finding fast exact algorithms for the protein folding problem. A protein can be folded into a specific 3D structure, which is uniquely determined by the sequence of amino acids. Its 3D structure determines its function. Protein structure prediction with computational technology is one of the most significant problems in bioinformatics.

A simplified representation of proteins is a lattice conformation, which is a self-avoiding sequence in Z^3. An important representative of lattice models is the HP-model, which was introduced in [20, 21]. This problem was proven to be NP-hard both on two and three dimensions [6, 8].

Some algorithms for this problem have been developed based on heuristic, genetic, Monte Carlo, branch, and bound methods (e.g., [39, 40, 41, 36, 30, 33, 18, 19, 31, 22, 34, 5, 4]). Although many experimental results were reported for testing sequences of small lengths, we have not seen any theoretical analysis about upper bounds on the computational time of the algorithms. Another approach is to develop polynomial time approximation algorithms for protein folding in the HP-model, [17, 1, 28]. Hart and Istrail [17] showed a polynomial time $\frac{3}{8}$-approximation algorithm for the 3D protein folding in the HP-model and Newman [28] derived a polynomial time $\frac{1}{3}$-approximation algorithm for the 2D problem, improving the $\frac{1}{4}$-approximation algorithm in [17].

If the first letter of an HP-sequence is fixed at a position of a 2D plane (or 3D space), we have at least 2^{n-1} (3^{n-1}) ways and at most $3^{n-1}(5^{n-1})$ ways to put the rest of the letters on the plane (in the space, resp.). The computational time of our algorithm is bounded by $2^{O(n^{\frac{1}{2}} \log n)}$ $(2^{O(n^{\frac{2}{3}} \log n)}$ $)$ in two dimensions (in three dimensions, resp.). As the average number of amino acids of proteins is between 400 and 600, if an algorithm could solve the protein structure prediction problem with ≤ 1000 amino acids, it would be able to satisfy most of the application demands. Our effort is a theoretical step toward this target. Our algorithm is a divide-and-conquer approach, which is based on our geometric separator for separating the points in a d-dimensional grid.

The paper is organized as follows. In sections 2 and 3, we develop the separator theory. In sections 4 and 5, we apply the separators to the protein folding problem in the HP-model. In section 2, we show a class of easy separators on a set of d-dimensional grid points. This kind of separator is used in section 4 to obtain a $2^{O(n^{1-1/d} \log n)}$-time algorithm for the d-dimensional protein folding problem in the HP-model. In section 3, we develop sharp separators in both two and three dimensions. Those separators are used to obtain faster algorithms for the protein folding problem in section 5. Precisely, those separators help us reduce the constant factor in the exponents of the computational complexity of the protein folding problem.

In this paper, we only apply the separators for grid points to the protein folding problem in the HP-model. When developing algorithms for some geometric problems with the input of a set of points in the Euclidean space, we can select a set of grid points to characterize the distribution of the input points. This brings more applications of separators for grid points. A series of advances [11, 7, 13, 12] has been made along this line of the separator technology, which starts from the earlier version [14] of this paper. The method of this paper was extended and applied to a class of other NP-hard geometric problems by Fu [11], improving their exact algorithms to $2^{O(\sqrt{n})}$-time from $n^{O(\sqrt{n})}$-time. Those problems include the problems of disk covering, maximum independent set, minimum vertex cover, and minimum dominating set on disk graphs. An efficient sublinear time randomized algorithm was developed in [12] for finding separators. The method was also applied to derive an approximation algorithm for a geometric problem [7] that has application in digital image half-toning.

2. An easy separator for grid points.

Given a set of n grid points P, we will show that there is a hyperplane (denoted by $P_{r,a}$ for some r with $1 \le r \le d$ and an integer a in the definition below), which contains $O(n^{1-\frac{1}{d}})$ grid points from P, to partition P into two parts of at most $c(d)n$ grid points on each side, where $0 < c(d) < 1$ and $c(d)$ is a constant for fixed d. The separator in this section has a self-contained proof and is used in deriving an $n^{O(n^{1-\frac{1}{d}})}$-time algorithm for the protein folding problem in the HP-model in section 4. Let the dimensional number d be fixed. We need the following terms.

Definition 3.

- *For a set A, $|A|$ denotes the number of elements in A.*
- *The integer set is represented by $Z = \{\cdots, -2, -1, 0, 1, 2, \cdots\}$. For integers i and j, integer interval $[i, j] = \{i, i+1, \cdots, j\}$. For integers $x_1, \cdots, x_d$, $(x_1, \cdots, x_d)$ is a d-dimensional grid point.*
- *For two points p_1, p_2 with the same dimension,* $\mathrm{dist}(p_1, p_2)$ *is the Euclidean distance between them.*
- *An r-plane is the set $P_{r,a} = \{(x_1, \cdots, x_{r-1}, a, x_{r+1}, \cdots, x_d) | x_1, \cdots, x_{r-1}, x_{r+1}, \cdots, x_d \in Z\}$, which has all of the elements in Z^d with the rth component being a fixed value a.*
- $P_{r,<a} = \{(x_1, \cdots, x_{r-1}, x_r, x_{r+1}, \cdots, x_d) | x_1, \cdots, x_{r-1}, x_r, x_{r+1}, \cdots, x_d \in Z$ and $x_r < a\}$.
- $P_{r,>a} = \{(x_1, \cdots, x_{r-1}, x_r, x_{r+1}, \cdots, x_d) | x_1, \cdots, x_{r-1}, x_r, x_{r+1}, \cdots, x_d \in Z$ and $x_r > a\}$.
- $P_{r,\le a} = Pr_{r,<a} \cup P_{r,a}$*, and* $P_{r,\ge a} = P_{r,>a} \cup P_{r,a}$.
- *For a set of points S in the d-dimensional space and $1 \le r \le d$ and $a \in Z$, define $S(r, < a) = \{(x_1, \cdots, x_d) \in S | x_r < a\}$, $S(r, = a) = \{(x_1, \cdots, x_d) \in S | x_r = a\}$, and $S(r, > a) = \{(x_1, \cdots, x_d) \in S | x_r > a\}$.*
- *For $0 < c < 1$ and a set S in the d-dimensional space, a $P_{r,a}$ is a c-balanced-separator if $|S(r, < a)| \le c \cdot |S|$ and $|S(r, > a)| \le c \cdot |S|$.*

Theorem 4. *For a set S of n grid points in the d-dimensional space, there is a $c(d)$-balanced-separator P^* that contains at most $\le c'(d)n^{1-\frac{1}{d}}$ points from S, where $0 < c(d) < 1$, $0 < c'(d)$ and both $c(d)$ and $c'(d)$ are constants for a fixed dimensional number d.*

Proof. We will construct a series of sets $S = S_0 \supseteq S_1 \supseteq S_2 \supseteq \cdots \supseteq S_t$ such that $t \le d-1$ and $|S_i| \ge \frac{1}{2}|S_{i-1}|$ for $i = 1, 2, \ldots, t$. The construction of P^* starts from Stage 0 and can go up to Stage d.

Stage 0: Let $S_0 = S$ and $r = 1$. Enter Stage 1. **End of Stage 0.**

Stage $\boldsymbol{r}$ $\boldsymbol{(1 \le r \le d-1)}$: Let Q_r contain all of $P_{r,a}$ such that $P_{r,a}$ is a $\frac{3}{4}$-balanced-separator for S_{r-1}. At most $\frac{1}{4}$ of the elements in S_{r-1} with smallest a values (for the rth component) stay to the left of all the $\frac{3}{4}$-balanced separators and at most $\frac{1}{4}$ of the elements in S_{r-1} with largest a values (for the rth component) stay to the right of all the $\frac{3}{4}$-separators. The set $\cup_{P_{r,a} \in Q_r} P_{r,a}$ has at least $\frac{1}{2}$ of the elements from S_{r-1}. Thus, Q_r is not empty. If a $P_{r,a}$ in Q_r contains no more than $n^{1-\frac{1}{d}}$ elements from S, let $P^* = P_{r,a}$ and terminate the construction. We have $|S_{r-1}| \ge \frac{1}{2^{r-1}}|S|$ and

$$|S(r, < a)| \le |S_{r-1}(r, < a)| + |S - S_{r-1}| \le \frac{3}{4}|S_{r-1}| + |S| - |S_{r-1}| \tag{1}$$

$$= |S| - \frac{1}{4}|S_{r-1}| \le \left(1 - \frac{1}{2^{r+1}}\right)|S| \le \left(1 - \frac{1}{2^d}\right)|S|. \tag{2}$$

Similarly, $|S(r, > a)| \le (1 - \frac{1}{2^d})|S|$.

If every $P_{r,a} \in Q_r$ has $> n^{1-\frac{1}{d}}$ elements from S, $|Q_r| \le n^{\frac{1}{d}}$ because $|\cup_{P_{r,a} \in Q_r} (P_{r,a} \cap S)| \le |S| = n$ and all planes in Q_r are disjoint from each other. It is easy to see that there is an integer interval $[c_1, c_2]$ such that $Q_r = \{P_{r,a} | a \in [c_1, c_2]\}$. Let $S_r = \cup_{P_{r,a} \in Q_r} (P_{r,a} \cap S_{r-1})$. We have $S_r \subseteq S_{r-1}$ and $|S_r| \ge |S_{r-1}|/2$ (because $[c_1, c_2]$ is the set of all the integers a such that $P_{r,a}$ is a $\frac{3}{4}$-balanced-separator). Let $r = r + 1$ and go to the next stage. **End of stage $\boldsymbol{r}$.**

Stage $\boldsymbol{d}$: Assume that for each r with $1 \le r \le d-1$, Q_r has no plane $P_{r,a}$ with elements $\le n^{1-\frac{1}{d}}$ from S. Hence, $|Q_r| \le n^{\frac{1}{d}}$ for $1 \le r \le d-1$. If a is fixed, every $p \in P_{r,a}$ has the rth component equal to a. Therefore, $\{x_r | x_r$ is the rth component of some $p \in P_{r,a}$ for some $P_{r,a} \in Q_r\}$ has $\le n^{\frac{1}{d}}$ elements since $|Q_r| \le n^{\frac{1}{d}}$ $(1 \le r \le d-1)$. This implies that for every $P_{d,a}$,

$$|\{p | p \in P_{r,a_r} \text{ for some } P_{r,a_r} \in Q_r \ (r = 1, \ldots, d-1) \text{ and } p \in P_{d,a}\}| \le (n^{\frac{1}{d}})^{d-1} = n^{\frac{d-1}{d}}.$$

As $|S_{d-1}| \ge \frac{|S|}{2^{d-1}} = \frac{1}{2^{d-1}} n$, there are at least $\frac{\frac{1}{2}|S_{d-1}|}{n^{1-\frac{1}{d}}} \ge \frac{1}{2^d} \cdot n^{\frac{1}{d}}$ many $P_{d,a}$'s to be $\frac{3}{4}$-balanced-separators for S_{d-1}. One of them has at most $\frac{|S|}{\frac{1}{2^d} n^{\frac{1}{d}}} = 2^d n^{1-\frac{1}{d}}$ elements from S. Let P^* be such a $P_{d,a}$. As $|S_{d-1}| \ge \frac{1}{2^{d-1}}|S|$, we have

$$|S(d, < a)| \le |S_{d-1}(d, < a)| + |S - S_{d-1}| \le \frac{3}{4}|S_{d-1}| + |S| - |S_{d-1}| \tag{3}$$

$$= |S| - \frac{1}{4}|S_{d-1}| \le \left(1 - \frac{1}{2^{d+1}}\right)|S|. \tag{4}$$

Similarly, we also have $|S(d, > a)| \le (1 - \frac{1}{2^{d+1}})|S|$. **End of stage $\boldsymbol{d}$.** □

For a d-dimensional cube that contains n grid points, its edge length is $n^{\frac{1}{d}}$. Every hyperplane $P_{r,a}$ which intersects the cube shares $n^{\frac{d-1}{d}}$ grid points with the cube. This shows that it is impossible to improve the upper bound on the number of points on the separator to $o(n^{\frac{d-1}{d}})$. In the next section, we shows that we can improve the separator by a constant factor. Theorem 4 indicates that the balanced separator can be found among $O(dn)$ axis-parallel hyperplanes.

3. Sharp separators for grid points.

We will improve the quality of the separator obtained in the previous section. The following lemma is a well-known fact (see [29]) that will be used for deriving our new separator. Our reduced upper bound on the number of points on the separator is from the following fact: For a set P of 2D grid points with the centerpoint o (see Lemma 5), a random line through o has the largest expected number of points of P with distance $\leq a$ to the line when the points in P are tightly arranged in the grid points inside a circle with the least radius. This is also true in the higher dimensional space.

LEMMA 5. *For an n-element set P in the d-dimensional space, there is a point q with the property that any half-space that does not contain q covers at most $\frac{d}{d+1}n$ elements of P. (Such a point q is called a centerpoint of P.)*

DEFINITION 6. *For a grid point (i, j) on the 2D plane, its grid square is a 1×1 square with four corner points $(i-\frac{1}{2}, j-\frac{1}{2}), (i-\frac{1}{2}, j+\frac{1}{2}), (i+\frac{1}{2}, j-\frac{1}{2})$, and $(i+\frac{1}{2}, j+\frac{1}{2})$. For a 3D grid point (i, j, k), its grid cube is a $1 \times 1 \times 1$ cube with eight corner points in $\{(i+\alpha, j+\beta, k+\gamma) | \alpha, \beta, \gamma \in \{-\frac{1}{2}, \frac{1}{2}\}\}$.*

3.1. 2D separators.

LEMMA 7. (1) *A circle of radius r contains at most $\pi(r + \frac{\sqrt{2}}{2})^2$ grid points.*

(2) *A circle of radius r on the 2D plane has at least $\pi r^2 - 4\sqrt{2}\pi r$ grid points inside it.*

(3) *A circle of radius $\frac{1}{\sqrt{\pi}}\sqrt{n} + 4\sqrt{2}$ has at least n grid points in it.*

(4) *For every line segment L of length m, the number of grid points with distance $\leq a$ to at least one point of L is $\leq (2a + \sqrt{2})(m + 2a + \sqrt{2})$.*

(5) *For every line L and fixed $a > 0$, there are at most $(2a+\sqrt{2})(\sqrt{2}n+2a+\sqrt{2})$ grid points inside an $n \times n$ square with $\leq a$ distance to L.*

Proof. (1) If a grid point p is inside a circle C of radius r at center o, the 1×1 grid square with center at p is inside a circle C' of radius $r + \frac{\sqrt{2}}{2}$ at the same center o. The number of those 1×1 grid squares for the grid points inside C is no more than the area size of the circle C'.

(2) Let C_1, C, and C_2 be three circles on the plane with the same center. Their radii are $r - \sqrt{2}, r$, and $r + \sqrt{2}$, respectively. Every 1×1 grid square intersecting C's boundary is outside C_1 and inside C_2. The number of grid squares intersecting C's boundary is no more than $\pi(r + \sqrt{2})^2 - \pi(r - \sqrt{2})^2 = 4\sqrt{2}\pi r$.

(3) Let $r = \frac{1}{\sqrt{\pi}}\sqrt{n} + 4\sqrt{2}$. It is straightforward to verify that $\pi r^2 - 4\sqrt{2}\pi r > n$. Apply (2).

(4) If a point p has $\leq a$ distance to L, every point in the 1×1 grid square with center at p has distance $\leq a + \frac{\sqrt{2}}{2}$ to L. The number of those 1×1 squares with centers at points of distance $\leq a$ to L is no more than $2(a + \frac{\sqrt{2}}{2})(m + 2a + \sqrt{2})$.

(5) The length of a line L inside an $n \times n$ square is $\leq \sqrt{2}n$. Apply (4). □

DEFINITION 8. *Assume that $a > 0$ and that p_0, p are two points on the plane. Define $Pr_2(a, p_0, p)$ to be the probability that a point p has $\leq a$ perpendicular distance to a random line L through the point p_0.*

LEMMA 9. *Let $a > 0$ be a constant and $\delta > 0$ be a small constant. Let P be a set of points in a 2D grid. Assume that all the points of P are inside a circle of radius r with center at point o. For a random line passing through o, the expected number of points in P with distance $\leq a$ to L is bounded by $4ar + \delta r$ for all large r.*

Proof. Assume that $p = (x, y)$ is a point of P and that L is a random line passing through the center $o = (x_0, y_0)$. Let C be the circle of radius r at center o such that C covers all the points in P. Let C' be the circle of radius $r' = r + \frac{\sqrt{2}}{2}$ at the same center o. It is easy to see that every unit square with center at a point in P is inside C'. The probability that a point p has distance $\leq a$ to L is $\frac{2\arcsin\frac{a}{\mathrm{dist}(o,p)}}{\pi}$.

Let $\epsilon > 0$ be a small constant which will be determined later. Select r_0 to be large enough such that for every point p with $\mathrm{dist}(o,p) \geq r_0$, $\arcsin\frac{a}{\mathrm{dist}(o,p)} < (1+\epsilon)\frac{a}{\mathrm{dist}(o,p)}$ and $\frac{1}{\mathrm{dist}(o,p')} < \frac{1+\epsilon}{\mathrm{dist}(o,p)}$ for every point p' with $\mathrm{dist}(p',p) \leq \frac{\sqrt{2}}{2}$. Let P_1 be the set of all the points p in P such that $\mathrm{dist}(o,p) < r_0$. By Lemma 7, the number of grid points in P_1 is no more than $\pi(r_0+\frac{\sqrt{2}}{2})^2$. For each point $p \in P_1$, $Pr_2(a,o,p) \leq 1$. For every point $p \in P - P_1$, $Pr_2(a,o,p) = \frac{2\arcsin\frac{a}{\mathrm{dist}(o,p)}}{\pi} \leq \frac{(1+\epsilon)2a}{\pi\mathrm{dist}(o,p)}$.

The expected number of points in P with distance $\leq a$ to a random line through the point o is

$$\sum_{p\in P} Pr_2(a,o,p) = \sum_{p\in P_1} Pr_2(a,o,p) + \sum_{p\in P-P_1} Pr_2(a,o,p) \tag{5}$$

$$\leq \sum_{p\in P_1} 1 + \sum_{p\in P-P_1} \frac{2\arcsin\frac{a}{\mathrm{dist}(o,p)}}{\pi} \tag{6}$$

$$< \pi\left(r_0+\frac{\sqrt{2}}{2}\right)^2 + \sum_{p\in P-P_1}\frac{(1+\epsilon)2a}{\pi\mathrm{dist}(o,p)} \tag{7}$$

$$\leq \pi\left(r_0+\frac{\sqrt{2}}{2}\right)^2 + \frac{2a(1+\epsilon)^2}{\pi}\int\int_{C'}\frac{1}{\mathrm{dist}(o,p)}d_xd_y \tag{8}$$

$$= \frac{2a(1+\epsilon)^2}{\pi}\int_0^{2\pi}\int_0^{r'}\frac{\rho}{\rho}d_\rho d_\theta + \pi\left(r_0+\frac{\sqrt{2}}{2}\right)^2 \tag{9}$$

$$= 4a(1+\epsilon)^2r' + \pi\left(r_0+\frac{\sqrt{2}}{2}\right)^2 \tag{10}$$

$$< 4ar + \delta r \text{ for all large } r \text{ by selecting } \epsilon \text{ small enough.} \tag{11}$$

We use the transformation $x = \rho\cos\theta + x_0, y = \rho\sin\theta + y_0$ to convert the integral at (8) to that at (9) above. □

THEOREM 10. *Let $a > 0$ be a constant and $\epsilon > 0$ be a small constant. For a set P of n grid points in a 2D grid, there is a line L such that P has at most $(\frac{4a}{\sqrt{\pi}})\cdot\sqrt{n}+\epsilon\sqrt{n}$ points with distance $\leq a$ to L, and each half-plane divided by L has at most $\frac{2}{3}n$ points from P.*

Proof. Assume that the centerpoint of P is at the point o (see Lemma 5). We are going to estimate the upper bound for the expected number of points in P that have $\leq a$ distances to a random line L through o.

Let $r = \frac{1}{\sqrt{\pi}}\sqrt{n} + 4\sqrt{2}$. By Lemma 7, the circle C at center o with radius r contains at least n grid points. Let f be a one-to-one mapping from P to the set of grid points inside C such that $f(p) = p$ for every $p \in P$ with $\mathrm{dist}(o,p) \leq r$. Therefore, f moves those points of P outside the circle C to the inside. It is easy to see that if $\mathrm{dist}(o,p_1) \leq \mathrm{dist}(o,p_2)$, then, $Pr_2(a,o,p_1) \geq Pr_2(a,o,p_2)$. The expected number of points in P with $\leq a$ distance to L is $\sum_{p\in P} Pr_2(a,o,p)$.

By Lemma 9, $\sum_{p\in P} Pr_2(a,o,p) \leq \sum_{p\in P} Pr_2(a,o,f(p)) \leq 4ar+\delta r = \frac{4a}{\pi}\sqrt{n}+\epsilon\sqrt{n}$ by selecting a small δ. □

3.2. 3D separators. The technology used in the previous section can be easily extended to the 3D grid. We give a brief proof for the case in the 3D space.

LEMMA 11. *Let $a = \sqrt{3}$. (1) A sphere of radius r has at least $\frac{4}{3}\pi r^3 - \frac{4}{3}\pi(6ar^2 + 2a^3)$ grid points. (2) A sphere of radius $(\frac{3}{4\pi})^{\frac{1}{3}} n^{\frac{1}{3}} + 7a$ contains at least n grid points.*

Proof. (1) Let $r_1 = r + a$, and let $r_2 = r - a$. The volume difference between the sphere of radius r_1 and the sphere of radius r_2 is $\frac{4}{3}\pi(6ar^2 + 2a^3)$, which is larger or equal to the number of unit grid cubes intersecting the boundary of the sphere of radius r. (2) For $r = (\frac{3}{4\pi})^{\frac{1}{3}} n^{\frac{1}{3}} + 7a$, we have $\frac{4}{3}\pi r^3 - \frac{4}{3}\pi(6ar^2 + 2a^3) \geq n$. □

DEFINITION 12. *Assume that $a > 0$ and that p_0, p are two points in the 3D Euclidean space. Define $Pr_3(a, p_0, p)$ to be the probability that the point p has $\leq a$ perpendicular distance to a random plane L through the point p_0 in the 3D space.*

Assume that both a and p_0 are fixed. We want to compute $Pr_3(a, p_0, p)$, which depends on the parameter a and the distance between p_0 and p. Without loss of generality, we assume that p_0 is the origin point $(0, 0, 0)$ and $p = (x, 0, 0)$, where $x = \text{dist}(p_0, p)$. A random plane through the origin point is uniquely determined by its normal vector (u, v, w) with $u \geq 0$. The distance between p to the plane with normal vector (u, v, w) is equal to xu. If the distance is at most a, then $u \leq \frac{a}{x}$. The set $G_{p,a} = \{(u, v, w) | u^2 + v^2 + w^2 = 1 \text{ and } 0 \leq u \leq \frac{a}{x}\}$ contains all the normal vectors of those planes (through the origin) such that p has distance at most a to each of them. The set $G_{p,a}$ is a subarea of the half-sphere $H_1 = \{(u, v, w) | u^2 + v^2 + w^2 = 1 \text{ and } 0 \leq u\}$ with center at the origin point and radius 1. If a is fixed and x is large, the area size of $G_{p,a}$ can be computed by the formula

$$\int_0^{\frac{a}{x}} 2\pi\sqrt{1 - y^2} d_y = \frac{2\pi a}{x} + O\left(\frac{a^2}{x^2}\right).$$

Since the area size of a half-sphere of radius 1 is 2π, the probability that p has distance at most a to a random plane through the origin is

$$Pr_3(a, p_0, p) = \frac{\text{the area size of } G_{p,a}}{\text{the area size of } H_1} = \frac{\frac{2\pi a}{x} + O(\frac{a^2}{x^2})}{2\pi} = \frac{a}{x} + O\left(\frac{a^2}{x^2}\right).$$

The above formula for computing $Pr_3(a, p_0, p)$ corrects a mistake that we made in the extended abstract of this paper [14]. It also gives a slightly different upper bound for the exact algorithm for the folding problem in the 3D space reported in [14].

LEMMA 13. *Let $a > 0$ be a constant and let $\delta > 0$ be a small constant. Let P be a set of points in a 3D grid. Assume that all the points of P are inside a sphere of radius r with center at point o. For a random plane passing through o, the expected number of points in P with distance at most a to L is bounded by $2\pi ar^2 + \delta r^2$ for all large r.*

Proof. The proof is very similar to that of Lemma 9. Let S be the sphere with radius r at center $o = (x_0, y_0, z_0)$ such that it contains all the points in P. Let S' be the sphere of radius $r' = r + \frac{\sqrt{3}}{2}$ at the same center of S. All unit cubes with center at points in P are inside S'.

The expected number of points in P with distance $\leq a$ to a random plane through o is $\sum_{p=(x,y,z)\in P} Pr_3(a, o, p)$, which has the main part $\int\int\int_{S'} \frac{a}{\text{dist}(a,o,p)} d_x d_y d_z$. By the transformation $x = \rho \sin\theta \cos\alpha + x_0, y = \rho \sin\theta \cos\alpha + y_0, z = \rho \sin\theta + z_0$, we have $\int\int\int_{S'} \frac{a}{\text{dist}(a,o,p)} d_x d_y d_z = \int_0^{r'} \int_0^{\pi} \int_0^{2\pi} \frac{a\rho^2 \sin\theta}{\rho} d_\alpha d_\theta d_\rho = 2\pi a r'^2$. □

THEOREM 14. *Let $a > 0$ be a constant and let $\epsilon > 0$ be a small constant. For a set P of n points in a 3D grid, there is a plane L such that P has at most*

$(2\pi a(\frac{3}{4\pi})^{2/3}) \cdot n^{2/3} + \epsilon n^{2/3}$ points with distance at most a to L, and each half-space divided by L has at most $\frac{3}{4}n$ points from P.

Proof. By Lemma 11, the sphere of radius $(\frac{3}{4\pi})^{\frac{1}{3}}n^{\frac{1}{3}} + 7\sqrt{3}$ contains at least n grid points. Moving points of P into the sphere, which has center at the centerpoint of P (see Lemma 5), from the outside increases the probability to have distance $\leq a$ to a random plane through the sphere center. By Lemma 13, the expected number of points in P with distance $\leq a$ to a random plane is $(2\pi a(\frac{3}{4\pi})^{2/3}) \cdot n^{2/3} + \epsilon n^{2/3}$ for all large n via selecting small δ. □

4. An application of the easy separators to the protein folding problem.

We apply the easy separators to the protein folding problem in the HP-model, and obtain the first subexponential time algorithm for it. We have already shown that there is a small set of letters with size $O(n^{1-\frac{1}{d}})$ on a hyperplane to partition the folding problem of n letters into 2 smaller problems of $\leq c(d)n$ letters, where $0 < c(d) < 1$, $c(d)$ is a constant for fixed d, and n is the size of the input (the number of H and P characters). The 2 smaller problems are recursively solved, and their solutions are merged to derive the solution to the original problem. As the separator has only $O(n^{1-\frac{1}{d}})$ letters, there are at most $n^{O(n^{1-\frac{1}{d}})}$ cases to partition the problem.

DEFINITION 15.

- *For a d-dimensional point $(x_1, \cdots, x_d)$, define $||(x_1, \cdots, x_d)|| = \sum_{i=1}^{d} |x_i|$.*
- *For a set Σ of letters, a Σ-sequence is a sequence of letters from Σ. For example, $PHPPHHPH$ is an $\{H, P\}$-sequence. For a sequence S of length n and $1 \leq i \leq n$, $S[i]$ is the ith letter of S and $S[i,j]$ denotes the subsequence $S[i]S[i+1] \cdots S[j]$. If $[i_1, j_1], [i_2, j_2], \cdots, [i_t, j_t]$ are pairwise disjoint intervals inside $[1,n]$, we call $S[i_1, j_1], S[i_2, j_2], \cdots, S[i_t, j_t]$ disjoint subsequences of S. For a set of integers $A = \{i_1 < i_2 < \cdots < i_k\}$, define $S[A] = S[i_1]S[i_2] \cdots S[i_k]$.*
- *A self-avoiding arrangement f for a sequence S of length n in the d-dimensional grid is a one-to-one mapping from $\{1, 2, \cdots, n\}$ to Z^d such that $||f(i) - f(i+1)|| = 1$ for $i = 1, 2, \ldots, n-1$. For the disjoint subsequences $S[i_1, j_1], \cdots, S[i_k, j_k]$ of S, a partial self-avoiding arrangement of S on $S[i_1, j_1], \cdots, S[i_k, j_k]$ is a partial function f from $\{1, 2, \cdots, n\}$ to Z^d such that f is defined on $\cup_{t=1}^{k}[i_t, j_t]$, and f can be extended to a (full) self-avoiding arrangement of S on Z^d.*
- *For a grid self-avoiding arrangement, its contact map is the graph $G_f = (1, 2, \cdots, n, E)$, where the edge set $E = \{(i,j) : |i-j| > 1 \text{ and } ||f(i) - f(j)|| = 1\}$.*
- *A rectangular region R in a d-dimensional space is the intersection of a finite number of sets $P_1, P_2, \cdots, P_k$, where $P_i = P_{r,<a}$ or $P_i = P_{r,>a}$ with $1 \leq r \leq d$ and $a \in Z$ for $i = 1, \ldots, k$.*
- *A rectangular region R in a d-dimensional space is of size $m_1 \times m_2 \times \cdots \times m_d$ if $m_i = max\{x_i - x_i' | (x_1, \cdots, x_d), (x_1', \cdots, x_d') \in R\} + 1$ for $i = 1, \ldots, d$.*

As we are going to describe our algorithm recursively, we use the following term to characterize the problem. A d-dimensional *multisequence folding problem F* is formulated as follows.

The inputs are

1. a list of disjoint subsequences $S_1, S_2, \cdots, S_k$ of sequence S_0 ($S_t = S_0[i_t, j_t]$ for $t = 1, \ldots, k$),
2. a rectangular region R, where all of the k $\{H, P\}$-sequences are going to be arranged,

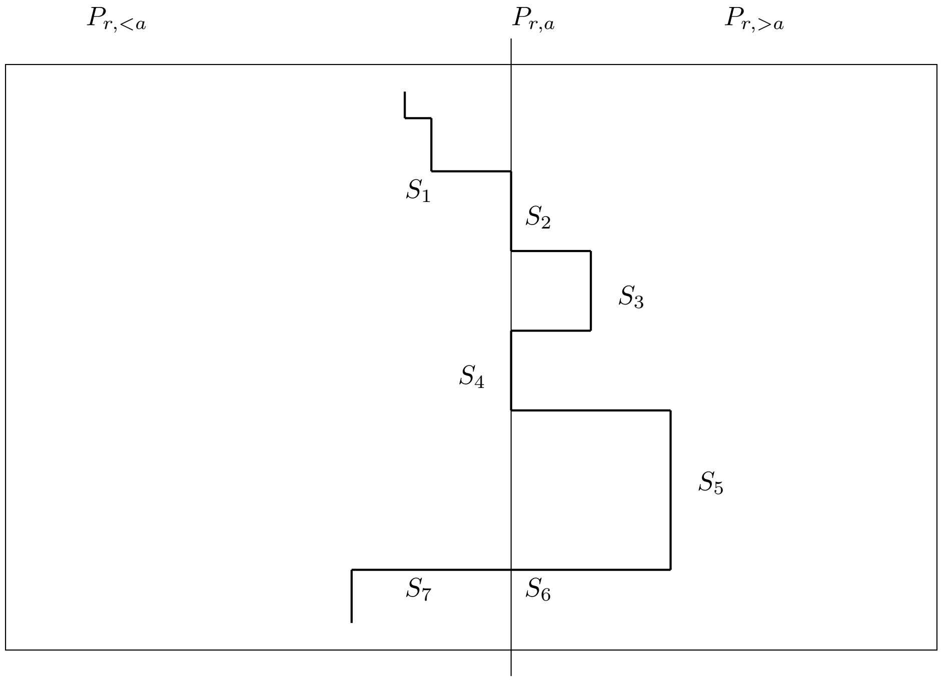

FIG. 2. *The hyperplane $P_{r,a}$ partitions a sequence into 3 groups of disjoint subsequences $\{S_1, S_7\}, \{S_2, S_4, S_6\}$, and $\{S_3, S_5\}$ in $P_{r,<a}, P_{r,a}$, and $P_{r,>a}$, respectively. (Notice that S_6 is a point that is the intersection between the two lines.)*

3. a series of k pairs of points in R: $(p_1, q_1), (p_2, q_2), \cdots, (p_k, q_k)$, in which points $p_t \in R$ and $q_t \in R$ are the positions for putting the first and the last letters of S_t, respectively,
4. a set of available points to put the letters from the k sequences, and
5. a set of $\{H, P\}$ points, which already have letters H and P from $S_0[([1, n] - \cup_{t=1}^{k}[i_t, j_t])]$.

The output is a partial self-avoiding arrangement f of S_0 on $S_1, \cdots, S_k$ in the rectangular region R that satisfies $f(i_t) = p_t, f(j_t) = q_t\,(t = 1, 2, \ldots, k)$ and has the maximal number of H-H contacts, where $f(i)$ is an available point for each $i \in \cup_{t=1}^{k}[i_t, j_t]$. H-H contacts may happen between two available neighbor positions or between an available position and a nonavailable position after the arrangement.

A hyperplane $P_{r,a}$ partitions a multisequence folding problem F into two multisequence folding problems F_1 and F_2 in regions $R \cap P_{r,\leq a}$ and $R \cap P_{r,\geq a}$, respectively, by fixing some letters on $P_{r,a}$ (see Figure 2). Furthermore, the available points of F_1 (F_2, resp.) are the intersection of F's available points with $P_{r,<a}$ ($P_{r,>a}$, resp.).

Algorithm

```
(a) Input a $d$-dimensional multisequence folding problem $F$ (as defined above);
(b)     For each subset $S$ of $\leq c'(d) \cdot n^{\frac{d-1}{d}}$ letters from $S_1, \cdots, S_k$
            For every plane $P_{r,a}$ (with nonempty intersection with $R$) and
              For every arrangement of $S$ at available points on $P_{r,a} \cap R$
(c)           Begin
(d)             For each partition (by $P_{r,a}$) making $F$ into problems $F_1$ and $F_2$ of
                    size $\leq c(d)n$
```

```
(e)                 Begin
(f)                     Solve $F_1$ and $F_2$ recursively using this algorithm (use the brute
                        force method when the problem size is small);
(g)                     Merge the solutions to $F_1$ and $F_2$ to get a potential solution
                        for $F$;
(h)                 End
(i)           End
(j) Output the solution for $F$ with the maximal number of $H$-$H$ contacts among
      all of the potential solutions for $F$;
```

End of the Algorithm

LEMMA 16. *There is an* $(nm)^{O(n^{1-\frac{1}{d}})}$*-time algorithm for the d-dimensional multisequence folding problem with an* $m_1 \times m_2 \times \cdots \times m_d$ *rectangular region in the HP-model, where* $m = \max\{\max\{m_i | i = 1, \ldots, d\}, 2\}$ *and the dimension* d *is assumed to be a constant.*

Proof. By Theorem 4, the folding problem is partitioned into two problems with a separator of size $\leq c'(d) \cdot n^{1-\frac{1}{d}}$ elements. For each $1 \leq r \leq d$, we have at most m planes $P_{r,a}$ that have a nonempty intersection with the $m_1 \times m_2 \cdots \times m_d$ rectangular region. There are at most $d \cdot m$ ways to select the separator plane. If the plane has at most t letters, there are at most $d \cdot m \cdot n^t m^{(d-1)t} = dn^t m^{(d-1)t+1}$ ways to select the plane and the position for the letters and put those letters at the selected position on the plane. Thus, the loop (c)–(i) is repeated $\leq dn^t m^{(d-1)t+1}$ times.

For disjoint subsequences $S_1, \cdots, S_k$ of S_0 inside a rectangular region R, we fix $t \leq c'(d) \cdot n^{1-\frac{1}{d}}$ letters from $S_1, \cdots, S_k$ on the hyper plane $P_{r,a}$ and partition them into three groups of subsequences of S_0 which are in $R \cap P_{r,<a}$, $R \cap P_{r,=a}$, and $R \cap P_{r,>a}$, respectively (see Figure 2). For each subsequence from $R \cap P_{r,<a}$ or $R \cap P_{r,>a}$, we fix the positions for its two endpoints under all possible cases. The subsequences in $R \cap P_{r,<a}$ will not affect those in $R \cap P_{r,>a}$. We have at most 2^{t+1} ways to fix the endpoints of those sequences in $R \cap P_{r,<a}$ and $R \cap P_{r,>a}$. Therefore, the loop (e)–(h) is repeated $\leq 2^{t+1}$ times.

Let $T(m, n)$ be the computational time of our algorithm, where n is the length of S_0 and m is defined as in the lemma. We have the following recursive relationship for the total time of the algorithm:

$$T(m, n) \leq 2 \cdot d \cdot m^{(d-1)c'(d)n^{1-\frac{1}{d}}+1} \cdot n^{c'(d)n^{1-\frac{1}{d}}} \cdot 2^{c'(d)n^{1-\frac{1}{d}}+1} \cdot T(m, c(d)n),$$

where $0 < c(d) < 1$ and $0 < c'(d)$ are constants for fixed d. Expanding the inequality recursively, we have $T(m, n) = (nm)^{O(n^{1-\frac{1}{d}})}$. □

THEOREM 17. *There is a* $2^{O(n^{1-\frac{1}{d}} \log n)}$*-time algorithm for the d-dimensional protein folding problem in the HP-model for fixed d.*

Proof. The folding problem can be put into an $n \times n \times \cdots \times n$ rectangular region in the d-dimensional space by fixing the two middle letters in two central neighbor points in the region. By Lemma 16, we have an $n^{O(n^{1-\frac{1}{d}})} = 2^{O(n^{1-\frac{1}{d}} \log n)}$-time algorithm. □

5. Application of the sharp separators to the protein folding problem.

In the previous section, we show that the d-dimensional folding problem is computable in $O(2^{e(d)n^{1-\frac{1}{d}}})$ time, where $e(d)$ is constant for fixed d. We will reduce the constant $e(d)$ in this section using the sharp separators.

5.1. 2D folding algorithm. It is easy to see that Theorem 10 implies Theorem 2 by setting $a = \frac{1}{2}$. Assume that our input HP-sequence has n_0 letters and the optimal folding is inside an $m \times m$ square. Select a parameter $\epsilon > 0$. Add some points evenly on the four edges of the $m \times m$ square, so that every two neighbor points have distance $\leq \epsilon$. Those points are called *ϵ-regular points.* Every line segment connecting two ϵ-regular points is called an *ϵ-regular line segment.* An ϵ-regular line is a line containing two ϵ-regular points.

LEMMA 18. *Let $\epsilon > 0$ be a constant. Every line segment L_1 inside the $m \times m$ square has an ϵ-regular segment L_2 such that for every point $p_1 \in L_1$, there is a point $p_2 \in L_2$ with $\operatorname{dist}(p_1, p_2) \leq \epsilon$, and for every point $q_2 \in L_2$, there is a point $q_1 \in L_1$ with $\operatorname{dist}(q_1, q_2) \leq \epsilon$.*

Proof. Assume E_1, E_2, E_3, and E_4 are the four edges of the $m \times m$ square. Assume L_1 intersects two of them inside the square at two points p_i and p_j of edges E_i and $E_j (i \neq j)$, respectively. Select the ϵ-regular point q_i closest to p_i from the edge E_i, and q_j closest to p_j from E_j. The ϵ-regular line segment L_2 results from connecting q_i and q_j. Every point p in L_1 has another point $p' \in L_2$ with distance $\leq \max(\operatorname{dist}(p_i, q_i), \operatorname{dist}(p_j, q_j)) \leq \epsilon$, and every point q in L_2 has another point in $q' \in L_1$ with distance $\leq \max(\operatorname{dist}(p_i, q_i), \operatorname{dist}(p_j, q_j)) \leq \epsilon$. □

LEMMA 19. *Let a and ϵ be positive constants. Let P be a set of n points in a $2D$ grid. There is an ϵ-regular line L such that there are $\leq (\frac{2}{3} + \epsilon)n$ points of P on each of the two half-planes, and $\leq 4(a + \epsilon)\frac{\sqrt{n}}{\sqrt{\pi}}$ points of P with distance $\leq a$ to L.*

Proof. Let $\delta > 0$ be a small constant. By Theorem 10, there is a line L such that the number of points of P with distance $a + \delta$ to it is bounded by $4(a + \delta)\frac{\sqrt{n}}{\sqrt{\pi}}$, and each side of L has at most $\frac{2}{3}n$ points in P. By Lemma 18, there is a line L' close to L such that every point in L has another point in L' with distance $\leq \delta$ and every point in L' has another point in L with distance $\leq \delta$. Every point with distance $\leq a$ to the line L' has distance $\leq a + \delta$ to L. Therefore, the number of points in P with distance $\leq a$ to L' is bounded by $4(a + \epsilon)\frac{\sqrt{n}}{\sqrt{\pi}}$, and each half-plane divided by L has at most $(\frac{2}{3} + \epsilon)n$ points in P if δ is small enough. □

LEMMA 20. *For some constants $c_0, \epsilon > 0$, there is an $O(m^{c_0 \log n} n_0^{(6.145 - \epsilon)\sqrt{n}})$-time algorithm for the $2D$ multisequence folding problem F in an $m \times m$ square, where n is the sum of the lengths of the input disjoint subsequences of S_0 and n_0 is the length of S_0.*

Proof. Let $a = 1/2$, $c = 2/3 + \delta$, and $d = \frac{4(a+\delta)}{\sqrt{\pi}}$, where $\delta > 0$ is a small constant which will be fixed later. We assume $m > 1$ and n is large. Let P be an optimal arrangement for the problem F. By Lemma 19, there is a line L such that P has at most $d\sqrt{n}$ points with distance $\leq 1/2$ to L, and each half-plane has at most cn points from P. The letters that stay at those positions with $\leq \frac{1}{2}$ distance to L form a separator for P. For every two letters at different sides of L that have a contact (their distance is 1), at least one of them has distance $\leq \frac{1}{2}$ to L. The algorithm is based on such a separator and is similar to that used in the previous section to find such an optimal solution P.

The number of δ-regular points at every edge of the $m \times m$ square is bounded by $\frac{m}{\delta}$. The total number of δ-regular lines is bounded by $u_1 = \binom{4}{2}(\frac{m}{\delta})^2$. By Stirling's formula, we have $(d\sqrt{n})! > \frac{(d\sqrt{n})^{d\sqrt{n}}}{2^{d\sqrt{n}}}$. There are $u_2 = \binom{n}{0} + \binom{n}{1} + \cdots \binom{n}{d\sqrt{n}} < d\sqrt{n}\frac{n^{d\sqrt{n}}}{(d\sqrt{n})!} < (\frac{2}{d})^{d\sqrt{n}} \cdot d\sqrt{n} \cdot n^{\frac{1}{2}d\sqrt{n}}$ ways to select $\leq d\sqrt{n}$ letters from those n letters among the input disjoint subsequences of S_0.

Assume k $(\leq d\sqrt{n})$ letters $S_0[i_1], S_0[i_2], \cdots, S_0[i_k]$ $(1 \leq i_1 < i_2 < \cdots < i_k \leq n)$ are fixed from the disjoint subsequences of S_0. By Lemma 7, there are at most

$\beta = (2a+\sqrt{2})(\sqrt{2}m+2a+\sqrt{2})$ positions (inside the $m \times m$ square) to put the letter $S_0[i_1]$ such that it has distance $\le a$ to L.

By Lemma 7, after the letter $S_0[i_j]$ is put at a grid point, there are at most $(2a+\sqrt{2})((i_{j+1}-i_j+2a)+2a+\sqrt{2}) \le (2a+\sqrt{2})(1+4a+\sqrt{2})(i_{j+1}-i_j)$ ways to arrange $S_0[i_{j+1}]$ so that its position has at most distance a to a point in L. Let $\alpha = (2a+\sqrt{2})(1+4a+\sqrt{2})$. After the position of the letter $S_0[i_1]$ is fixed, there are at most $\prod_{j=1}^{j=k-1}(\alpha(i_{j+1}-i_j))$ ways to put $S_0[i_2], S_0[i_3], \cdots, S_0[i_k]$ along the separation line with distance $\le a$. Since $k \le d\sqrt{n}$ and $1 \le i_1 < i_2 < \cdots < i_k \le n_0$,

$$\prod_{j=1}^{j=k-1} \left(\alpha\left(i_{j+1}-i_j\right)\right) \le \left(\alpha\left(\frac{n_0}{k-1}\right)\right)^{k-1} \tag{12}$$

$$\le \left(\alpha\left(\frac{n_0}{k}\right)\right)^{k} \tag{13}$$

$$\le \left(\alpha\left(\frac{n_0}{d\sqrt{n}}\right)\right)^{d\sqrt{n}} \tag{14}$$

$$\le \left(\frac{\alpha}{d}\right)^{d\sqrt{n}} n_0^{d\sqrt{n}} n^{-\frac{1}{2}d\sqrt{n}}. \tag{15}$$

The inequality (12) follows from the well-known fact that for positive variables $y_1, \cdots, y_{k-1}$ and fixed h with $y_1+\cdots+y_{k-1} \le h$, the product $\prod_{t=1}^{k-1} y_k$ is maximal when $y_1 = y_2 = \cdots = y_{k-1} = \frac{h}{k-1}$. The number of ways to arrange the k letters along the separation line (with distance $\le a$ to L) is bounded by

$$u_3 = \beta\left(\frac{\alpha}{d}\right)^{d\sqrt{n}} n_0^{d\sqrt{n}} n^{-\frac{1}{2}d\sqrt{n}}.$$

We have $T(n) \le u_1 \cdot u_2 \cdot u_3 \cdot T(cn)$. It implies that

$$T(n) \le \left(\frac{mn}{\delta}\right)^{c_0 \log n} 2^{c_0\sqrt{n}} n_0^{d(\frac{1}{1-\sqrt{c}})\sqrt{n}} = O(m^{c_0 \log n} n_0^{(6.145-\epsilon)\sqrt{n}})$$

by selecting constants ϵ, δ small enough and c_0 large enough. □

THEOREM 21. *There is an $O(n^{6.145\sqrt{n}})$-time algorithm for the 2D protein folding problem in the HP-model.*

Proof. Fix the two middle letters at the two central neighbor positions of an $n \times n$ square. Let the folding be inside the $n \times n$ square, and apply Lemma 20. □

5.2. 3D folding algorithm.

The technology used in the previous section can be easily extended to a 3D grid. We give a brief proof for the case in the 3D space.

Put some regular points on each side of the six faces of an $m \times m \times m$ cube (the folding region) so that every point on each face has $\le \epsilon$ distance to one regular point. Recall that these points are called ϵ-regular points. Every three ϵ-regular points determine a plane, called an ϵ-regular plane.

LEMMA 22. *Let a and ϵ be positive constants. Let P be a set of n points in a 3D grid. There is an ϵ-regular plane such that there are $\le (\frac{3}{4}+\epsilon)n$ points on each side of the plane and $2\pi(a+\epsilon)(\frac{3}{4\pi})^{2/3}n^{2/3}$ points with distance at most a to it.*

Proof. Let L be the plane of Theorem 14. Let H be the area of the intersection between plane L and the six faces of the $m \times m \times m$ cube that contains all the points in P. Let p_1 and p_2 be the two points in H with the maximal distance. Let p_3 be the point in H with the largest perpendicular distance to the line p_1p_2. Let p_1', p_2'

and p'_3 be the δ-regular noncollinear points such that p'_i has distance $\leq \delta$ to p_i for $i = 1, 2, 3$. Use the δ-regular plane determined by p'_1, p'_2, and p'_3 (by selecting δ small enough). $\square$

LEMMA 23. *For some positive constant c_0 and $\epsilon > 0$, there exists an $O(m^{c_0 \log n} n^{-6.9128 n^{2/3}} n_0^{(13.8258-\epsilon) n^{2/3}})$-time algorithm for the 3D multisequence folding problem in an $m \times m \times m$ cube, where n is the sum of the lengths of the input disjoint subsequences of S_0 and n_0 is the length of S_0.*

Proof. Let $a = 1/2$, $c = 3/4 + \delta$, and $d = 2\pi(a + \delta)(\frac{3}{4\pi})^{2/3}$. As in the proof of Lemma 20, let $u_1 = \binom{8}{3}(\frac{m}{\delta})^6$, let $u_2 = (\frac{2}{d})^{dn^{2/3}} \cdot dn^{2/3} \cdot n^{\frac{1}{3} dn^{2/3}}$, and let $u_3 = \beta'(\frac{\alpha'}{d})^{2dn^{\frac{2}{3}}} n^{-\frac{4}{3} dn^{\frac{2}{3}}} n_0^{2dn^{\frac{2}{3}}}$, where α' and β' are similar to the α and β in the proof of Lemma 20. We have $T(n) \leq u_1 \cdot u_2 \cdot u_3 \cdot T(cn)$. This implies that $T(n) = (mn)^{c_0 \log n} 2^{c_0 n^{\frac{2}{3}}} n^{-\frac{d}{(1-c^{2/3})} n^{2/3}} n_0^{\frac{2d}{(1-c^{2/3})} n^{2/3}}$ for some constant $c_0 > 0$. $\square$

THEOREM 24. *There is an $O(n^{6.913 n^{2/3}})$-time algorithm for the 3D protein folding problem in the HP-model.*

Proof. Fix the two middle letters at the two central neighbor positions of an $n \times n \times n$ cube. Let the folding be inside the $n \times n \times n$ cube, and apply Lemma 23. $\square$

6. Conclusions.

We develop an efficient method to obtain an effective separator for a set of grid points. For a set of 2D (3D) grid points, the separator is controlled by a line (plane, resp.) L and a distance a to L. The region of the separator consists of those points with distance at most a to L. The distance parameter a provides us with a flexible way to control the width of the separator region. The separators are used in obtaining a subexponential time algorithm for the protein folding problem in the HP-model. Using the linear structure of the separator, we can find the approximate separator region by checking $O(n^2)$ $(O(n^6))$ possible locations in developing the algorithm for the 2D (3D, resp.) protein folding problem in the HP-model. These algorithms for the protein folding problem have a nontrivial upper bound, but they are not practical enough for implementation. The separators developed in this paper have been found to have more applications in a series of recent papers [11, 7, 13, 12].

Acknowledgments. We are grateful to Mahdi Abdelguerfi, Padmanabhan Mahadevan, and Seth Pincus for helpful discussions during this research. We thank the anonymous referees for helpful comments and for pointing out an error in the earlier version. We are also grateful to Zhixiang Chen and Ming Li for their suggestions for improving the presentation of this paper. The first author would also like to thank Chanda Yadavalli for introducing him to the area of bioinformatics.

POPULAR MATCHINGS[*]

DAVID J. ABRAHAM[†], ROBERT W. IRVING[‡], TELIKEPALLI KAVITHA[§], AND KURT MEHLHORN[¶]

Abstract. We consider the problem of matching a set of *applicants* to a set of *posts*, where each applicant has a *preference list*, ranking a nonempty subset of posts in order of preference, possibly involving ties. We say that a matching M is *popular* if there is no matching M' such that the number of applicants preferring M' to M exceeds the number of applicants preferring M to M'. In this paper, we give the first polynomial-time algorithms to determine if an instance admits a popular matching and to find a largest such matching, if one exists. For the special case in which every preference list is strictly ordered (i.e., contains no ties), we give an $O(n+m)$ time algorithm, where n is the total number of applicants and posts and m is the total length of all of the preference lists. For the general case in which preference lists may contain ties, we give an $O(\sqrt{n}m)$ time algorithm.

Key words. matchings, bipartite graphs, one-sided preference lists

AMS subject classification. 68W40

DOI. 10.1137/06067328X

1. Introduction.

An instance of the *popular matching problem* is a bipartite graph $G = (\mathcal{A} \cup \mathcal{P}, E)$ and a partition $E = E_1 \dot{\cup} E_2 \dots \dot{\cup} E_r$ of the edge set. We call the nodes in $\mathcal{A}$ *applicants*, the nodes in $\mathcal{P}$ *posts*, and the edges in E_i the edges of rank i. If $(a,p) \in E_i$ and $(a,p') \in E_j$, with $i < j$, we say that *a prefers p to p'*. If $i = j$, we say that a is *indifferent* between p and p'. This ordering of posts adjacent to a is called a's *preference list*. We say that preference lists are *strictly ordered* if no applicant is indifferent between any two posts on his/her preference list. More generally, if applicants can be indifferent between posts, we say that preference lists contain *ties*.

A *matching* M of G is a set of edges, no two of which share an end point. A node $u \in \mathcal{A} \cup \mathcal{P}$ is either *unmatched* in M or *matched* to some node, denoted by $M(u)$ (i.e., $(u, M(u)) \in M$). We say that an applicant a *prefers* matching M' to M if (i) a is matched in M' and unmatched in M or (ii) a is matched in both M' and M, and a prefers $M'(a)$ to $M(a)$. M' is *more popular than* M, denoted by $M' \succ M$, if the number of applicants that prefer M' to M exceeds the number of applicants that prefer M to M'.

DEFINITION 1.1. *A matching M is* popular *if and only if there is no matching M' that is more popular than M.*

Example 1.1. Figure 1.1 shows the preference lists for an example instance in which $\mathcal{A} = \{a_1, a_2, a_3\}$, $\mathcal{P} = \{p_1, p_2, p_3\}$, and each applicant prefers p_1 to p_2 and p_2

FIG. 1.1. *An instance for which there is no popular matching.*

to p_3. Consider the three symmetrical matchings $M_1 = \{(a_1, p_1), (a_2, p_2), (a_3, p_3)\}$, $M_2 = \{(a_1, p_3), (a_2, p_1), (a_3, p_2)\}$, and $M_3 = \{(a_1, p_2), (a_2, p_3), (a_3, p_1)\}$. It is easy to verify that none of these matchings is popular, since $M_1 \prec M_2$, $M_2 \prec M_3$, and $M_3 \prec M_1$. In fact, this instance admits no popular matching, the problem being, of course, that the *more popular than* relation is not acyclic.

The *popular matching problem* is to determine if a given instance admits a popular matching and to find such a matching, if one exists. We remark that popular matchings may have different sizes, and a largest such matching may be smaller than a maximum-cardinality matching. The *maximum-cardinality popular matching problem* then is to determine if a given instance admits a popular matching and to find a *largest* such matching, if one exists.

In this paper, we use a novel characterization of popular matchings to give an $O(\sqrt{n}m)$ time algorithm for the maximum-cardinality popular matching problem, where n is the number of nodes, and m is the number of edges. For instances with strictly ordered preference lists, we give an $O(n + m)$ time algorithm. No polynomial time algorithms were known previously.

Related previous work. The bipartite matching problem with a graded edge set is well-studied in the economics literature; see, for example, [1, 19, 21]. It models some important real-world markets, including the allocation of graduates to training positions [10] and families to government-owned housing [20]. Instances of these markets are restrictions of stable marriage instances [5, 7], in which members of one side of the market (posts) are indifferent between members of the other side of the market (applicants).

The notion of popular matching was originally introduced by Gardenfors [6] in the context of the full stable marriage problem. It is well known that every stable marriage instance admits a weakly stable matching (one for which there is no pair who strictly prefer each other to their partners in the matching). In fact, there can be an exponential number of weakly stable matchings, and so Gardenfors considered the problem of finding one with additional desirable properties, such as popularity. Gardenfors showed that, when preference lists are strictly ordered, every stable matching is popular. He also showed that, when preference lists contain ties, there may be no popular matching.

For the problem setup considered in this paper, various other definitions of optimality have been studied. For example, a matching M is *Pareto optimal* [2, 1, 19] if there is no matching M' such that (i) some applicant prefers M' to M and (ii) no applicant prefers M to M'. In particular, such a matching has the property that no coalition of applicants can collectively improve their allocation (say, by exchanging posts with one another) without requiring some other applicant to be worse off. This is the weakest reasonable definition of optimality—see [2] for an algorithmically oriented exposition. Stronger definitions exist: A matching is *rank-maximal* [11] if it allocates the maximum number of applicants to their first choice and then, subject to this, the maximum number to their second choice, and so on. Rank-maximal matchings always exist and may be found in time $O(\min(n, C\sqrt{n})m)$ [11], where C is the maximum edge rank used in the matching. Finally, we mention *maximum-utility* matchings, which maximize $\sum_{(a,p)\in M} u_{a,p}$, where $u_{a,p}$ is the utility of allocating post p to applicant a. Maximum-utility matchings can be found through an obvious transformation to the maximum-weight matching problem. Neither rank-maximal nor maximum-utility matchings are necessarily popular.

Preliminaries. For exposition purposes, we create a unique *last resort* post $l(a)$ for each applicant a and assign the edge $(a, l(a))$ higher rank than any edge incident on a. In this way, we can assume that every applicant is matched, since any unmatched applicant can be allocated to his/her last resort. From now on then, matchings are *applicant-complete*, and the size of a matching is just the number of applicants not matched to their last resort. We may also assume that instances have no gaps—so if an applicant a is incident to a rank i edge, then a is also incident to edges of all ranks smaller than i.

Organization of the paper. In section 2 we develop an alternative characterization of popular matchings, under the assumption that preference lists are strictly ordered. We then use this characterization as the basis of a linear-time algorithm to solve the maximum-cardinality popular matching problem. In section 3 we consider preference lists with ties and give an $O(\sqrt{n}m)$ time algorithm for the maximum-cardinality popular matching prblem. In section 4 we give some empirical results on the probability that a popular matching exists. Finally, the preliminary version of this paper motivated the study of several other questions related to popular matchings. We end by summarizing this recent work.

2. Strictly ordered preference lists.

In this section, we restrict our attention to strictly ordered preference lists, both to provide some intuition for the more general case and because we can solve the popular matching problem in only linear time. This last claim is not immediately clear, since Definition 1.1 potentially requires an exponential number of comparisons to even check that a given matching is popular. We begin this section then by developing an equivalent (though efficiently checkable) characterization of popular matchings.

2.1. Characterizing popular matchings.

For each applicant a, let $f(a)$ denote the first-ranked post on a's preference list (i.e., $(a, f(a)) \in E_1$). We call any such post p an *f-post* and denote by $f(p)$ the set of applicants a for which $f(a) = p$.

Example 2.1. Figure 2.1 gives the preference lists for an instance with six applicants and six posts that we shall use to illustrate the results in this section. The f-posts for this instance are p_1, p_2, and p_3, and $f(p_1) = \{a_1, a_2\}$, $f(p_2) = \{a_3, a_4, a_5\}$, and $f(p_3) = \{a_6\}$. Note that we use l_i as an abbreviation for $l(a_i)$.

The following lemma gives the first of three conditions necessarily satisfied by a popular matching.

LEMMA 2.1. *Let M be any popular matching. Then for every f-post p,* (i) *p is matched in M, and* (ii) *$M(p) \in f(p)$.*

a_1	:	p_1	p_2	p_3	l_1
a_2	:	p_1	p_5	p_4	l_2
a_3	:	p_2	p_1	p_3	l_3
a_4	:	p_2	p_3	p_6	l_4
a_5	:	p_2	p_6	p_4	l_5
a_6	:	p_3	p_2	p_5	l_6

FIG. 2.1. *An illustrative example.*

a_1	:	$\mathbf{p_1}$	p_2	p_3	$\underline{l_1}$
a_2	:	$\mathbf{p_1}$	$\underline{p_5}$	p_4	l_2
a_3	:	$\mathbf{p_2}$	p_1	p_3	$\underline{l_3}$
a_4	:	$\mathbf{p_2}$	p_3	$\underline{p_6}$	l_4
a_5	:	$\mathbf{p_2}$	$\underline{p_6}$	p_4	l_5
a_6	:	$\mathbf{p_3}$	p_2	$\underline{p_5}$	l_6

FIG. 2.2. *The f-posts and s-posts for the example instance.*

Proof. Every f-post p must be matched in M, for otherwise we can promote any $a \in f(p)$ to p, thereby constructing a matching more popular than M. Suppose for a contradiction then that p is matched to some $M(p) \notin f(p)$. Select any $a_1 \in f(p)$, let $a_2 = M(p)$, and since all f-posts are matched in M, let $a_3 = M(f(a_2))$. We can again construct a matching more popular than M, this time by (i) demoting a_3 to $l(a_3)$, (ii) promoting a_2 to $f(a_2)$, and then (iii) promoting a_1 to p. □

Example 2.2. According to Lemma 2.1, we can be sure that, if a popular matching exists for our example instance, then posts p_1, p_2, and p_3 are matched, and $M(p_1) \in \{a_1, a_2\}$, $M(p_2) \in \{a_3, a_4, a_5\}$, and $M(p_3) = a_6$.

For each applicant a, let $s(a)$ denote the first non-f-post on a's preference list (note that $s(a)$ must exist, due to the introduction of $l(a)$). We call any such post p an *s-post* and remark that f-posts are disjoint from s-posts.

Example 2.3. Figure 2.2 shows the preference lists for our example instance with the f-posts and s-posts highlighted. The bold entry in each preference list is the f-post and the underlined entry is the s-post.

In the next two lemmas, we show that a popular matching can only allocate an applicant a to either $f(a)$ or $s(a)$.

LEMMA 2.2. *Let M be any popular matching. Then for every applicant a, $M(a)$ can never be strictly between $f(a)$ and $s(a)$ on a's preference list.*

Proof. Suppose for a contradiction that $M(a)$ is strictly between $f(a)$ and $s(a)$. Since a prefers $M(a)$ to $s(a)$, we have that $M(a)$ is an f-post. Furthermore, M is a popular matching, so a belongs to $f(M(a))$ (by Lemma 2.1), thereby contradicting the assumption that a prefers $f(a)$ to $M(a)$. □

LEMMA 2.3. *Let M be a popular matching. Then for every applicant a, $M(a)$ is never worse than $s(a)$ on a's preference list.*

Proof. Suppose for a contradiction that a_1 prefers $s(a_1)$ to $M(a_1)$. If $s(a_1)$ is unmatched in M, we can promote a_1 to $s(a_1)$, thereby constructing a matching more popular than M. Otherwise, let $a_2 = M(s(a_1))$, and let $a_3 = M(f(a_2))$ (note that $a_2 \neq a_3$, since f-posts and s-posts are disjoint). We can again construct a matching more popular than M, this time by (i) demoting a_3 to $l(a_3)$, (ii) promoting a_2 to $f(a_2)$, and then (iii) promoting a_1 to $s(a_1)$. □

The three necessary conditions we have just derived form the basis of the following preliminary characterization.

LEMMA 2.4. *A matching M is popular if and only if*

(i) *every f-post is matched in M, and*

(ii) *for each applicant a, $M(a) \in \{f(a), s(a)\}$.*

Proof. Any popular matching necessarily satisfies conditions (i) and (ii) (by Lemmas 2.1–2.3). It remains to show that, together, these conditions are sufficient.

Let M be any matching satisfying (i) and (ii), and suppose for a contradiction that there is some matching M' that is more popular than M. Let a be any applicant that prefers M' to M, and let $p' = M'(a)$ (note that p' is distinct for each such a). Now, since a prefers p' to $M(a)$, it follows from condition (ii) that $M(a) = s(a)$. So,

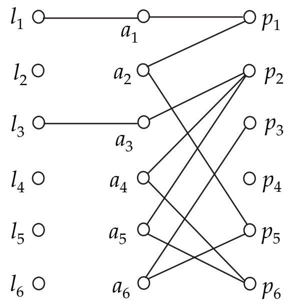

FIG. 2.3. *The reduced graph G' for the example instance.*

p' is an f-post, which by condition (i) must be matched in M, say, to a'. But then $p' = f(a')$ (by condition (ii) and since f-posts and s-posts are disjoint), and so a' prefers M to M'.

Therefore, for every applicant a that prefers M' to M, there is a distinct corresponding applicant a' that prefers M to M'. Hence, M' is not more popular than M, giving the required contradiction. □

Given an instance graph $G = (\mathcal{A} \cup \mathcal{P}, E)$, we define the *reduced graph* $G' = (\mathcal{A} \cup \mathcal{P}, E')$ as the subgraph of G containing two edges for each applicant a: one to $f(a)$ and the other to $s(a)$. We remark that G' need not admit an applicant-complete matching, since $l(a)$ is now isolated whenever $s(a) \neq l(a)$.

Example 2.4. Figure 2.3 shows the reduced graph for our example instance.

Lemma 2.4 gives us that M is a popular matching of G if and only if every f-post is matched in M, and M belongs to the graph G'. Recall that all popular matchings are applicant-complete through the introduction of last resorts. Hence, the following characterization is immediate.

THEOREM 2.5. *M is a popular matching of G if and only if*

(i) *every f-post is matched in M, and*

(ii) *M is an applicant-complete matching of the reduced graph G'.*

Example 2.5. By applying Theorem 2.5 to the reduced graph of Figure 2.3, it may be verified that our example instance admits four popular matchings, two of size 5 and two of size 4, as listed below. (Clearly, in the matchings of size 5, a_3 is matched with his last resort in the reduced graph, and in those of size 4, a_1 is also matched with his last resort.)

$$\begin{aligned}
M_1 &= \{(a_1,p_1),(a_2,p_5),(a_4,p_2),(a_5,p_6),(a_6,p_3)\},\\
M_2 &= \{(a_1,p_1),(a_2,p_5),(a_4,p_6),(a_5,p_2),(a_6,p_3)\},\\
M_3 &= \{(a_2,p_1),(a_4,p_2),(a_5,p_6),(a_6,p_3)\},\\
M_4 &= \{(a_2,p_1),(a_4,p_6),(a_5,p_2),(a_6,p_3)\}.
\end{aligned}$$

2.2. Algorithmic results. Figure 2.4 contains an algorithm for solving the popular matching problem. The correctness of this algorithm follows immediately from the characterization in Theorem 2.5. We remark only that at the termination of the loop, every f-post must be matched, since $f(a)$ is unique for each applicant a, and f-posts are disjoint from s-posts. We now show a linear-time implementation of this algorithm.

It is clear that the reduced graph G' of G can be constructed in $O(n+m)$ time. G' has $O(n)$ edges, since each applicant has degree 2, and so it is also clear that the

```

    $M := \emptyset$;
    **while** some post $p$ has degree 1
        $a$ := unique applicant adjacent to $p$;
        $M := M \cup \{(a, p)\}$;
        $G' := G' - \{a, p\}$;    // *remove a and p from G'*
    **while** some post $p$ has degree 0
        $G' := G' - \{p\}$;
    // *Every post now has degree at least* 2
    // *Every applicant still has degree* 2
    **if** $|\mathcal{P}| < |\mathcal{A}|$ **then**
        **return** *"no applicant-complete matching"*;
    **else**
        // *G' decomposes into a family of disjoint cycles*
        $M'$ := any maximum-cardinality matching of $G'$;
        **return** $M \cup M'$.
```

FIG. 2.5. *Linear-time algorithm for finding an applicant-complete matching in G'.*

loop phase requires only $O(n)$ time. It remains to show how we can efficiently find an applicant-complete matching of G' or determine that no such matching exists.

One approach involves computing a maximum-cardinality matching M of G' and then testing if M is applicant-complete. However, using the Hopcroft–Karp algorithm for maximum-cardinality matching [9], this would take $O(n^{3/2})$ time, which is superlinear, whenever m is $o(n^{3/2})$. Consider then the algorithm in Figure 2.5.

This algorithm begins by repeatedly matching a degree 1 post p with the unique applicant a adjacent to p. No subsequent augmenting path can include p (since it is matched and has degree 1), so we can remove both a and p from consideration. It is not hard to see that this loop can be implemented to run in $O(n)$ time, using, for example, degree counters and lazy deletion. After this, we remove any degree 0 posts, so that all remaining posts have degree at least 2, while all remaining applicants still have degree exactly 2. Now, if $|\mathcal{P}| < |\mathcal{A}|$, G' cannot admit an applicant-complete matching by Hall's marriage theorem [8]. Otherwise, we have that $|\mathcal{P}| \geq |\mathcal{A}|$, and $2|\mathcal{P}| \leq \sum_{p \in \mathcal{P}} \deg(p) = 2|\mathcal{A}|$. Hence, it must be the case that $|\mathcal{A}| = |\mathcal{P}|$, and every post has degree exactly 2. G' therefore decomposes into a family of disjoint cycles, and we need only to walk over these cycles, choosing every second edge.

We summarize the preceding discussion in the following lemma.

LEMMA 2.6. *We can find a popular matching, or determine that no such matching exists, in $O(n + m)$ time.*

We now consider the maximum-cardinality popular matching problem. Let $\mathcal{A}_1$ be the set of all applicants a with $s(a) = l(a)$, and let $\mathcal{A}_2 = \mathcal{A} - \mathcal{A}_1$. Our target matching must satisfy conditions (i) and (ii) of Theorem 2.5 and, among all such matchings, allocate the fewest $\mathcal{A}_1$-applicants to their last resort.

We begin by constructing G' and testing for the existence of an applicant-complete matching M of $\mathcal{A}_2$-applicants to posts (using the applicant-complete matching algorithm in Figure 2.5). If no such M exists, then G admits no popular matching by Theorem 2.5. Otherwise, we remove all edges from G' that are incident on a last resort post and exhaustively augment M, each time matching an additional $\mathcal{A}_1$-applicant with his/her first-ranked post. If any $\mathcal{A}_1$-applicants are unmatched at this point, we simply allocate them to their last resort. Finally, we ensure that every f-post is matched, as in the popular matching algorithm in Figure 2.4. It is clear that the resulting matching is a maximum-cardinality popular matching, and so we comment only on the time complexity of augmenting M.

Note that an alternating path Q from an unmatched applicant a is completely determined (since applicants have degree 2). If we are able to augment along this path, then no subsequent augmenting path can contain a node in Q, since such a path would necessarily terminate at a, which is already matched. Otherwise, if there is no augmenting path from a, then it is not hard to see that again no subsequent augmenting path can contain a node in Q. This means we only need to visit and mark each node at most once, leading to the following result.

Theorem 2.7. *For instances with strictly ordered preference lists, we can find a maximum-cardinality popular matching, or determine that no such matching exists, in $O(n + m)$ time.*

3. Preference lists with ties.

In this section, we relax our assumption that preference lists are strictly ordered and consider problem instances with ties. We begin by developing a generalization of the popular matching characterization, similar to Theorem 2.5. Using this characterization, we then go on to give an $O(\sqrt{n}m)$ time algorithm for solving the maximum-cardinality popular matching problem. Note that we cannot hope for a linear-time algorithm here, since, for the special case where all edges have rank one, the problem of finding a popular matching is equivalent to the problem of finding a maximum-cardinality bipartite matching. Thus the popular matching problem is at least as hard as the maximum-cardinality bipartite matching problem when preference lists contain ties.

3.1. Characterizing popular matchings.

For each applicant a, let $f(a)$ denote the *set* of first-ranked posts on a's preference list. Again, we refer to all such posts p as *f-posts* and denote by $f(p)$ the set of applicants a for which $p \in f(a)$.

It may no longer be possible to match *every* f-post p with an applicant in $f(p)$ (as in Lemma 2.1), since, for example, there may now be more f-posts than applicants. Below then, we work towards generalizing this key lemma.

Let M be a popular matching of some instance graph $G = (\mathcal{A} \cup \mathcal{P}, E)$. We define the *first-choice graph* of G as $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$, where E_1 is the set of all rank-one edges.

Example 3.1. Figure 3.1 gives an example instance that we use as an illustration in this section. Ties in the preference lists are indicated by parentheses.

The graph G_1 for this instance is shown in Figure 3.2.

For instances with strictly ordered preference lists, Lemma 2.1 is equivalent to requiring that every f-post is matched in $M \cap E_1$ (note that f-posts are the only posts with nonzero degree in G_1). But since applicants have a unique first choice in

a_1	:	$(p_1$	$p_2)$	p_4	l_1
a_2	:	p_1	$(p_2$	$p_5)$	l_2
a_3	:	p_2	$(p_4$	$p_6)$	l_3
a_4	:	p_2	p_1	p_3	l_4
a_5	:	p_4	p_3	p_2	l_5
a_6	:	$(p_5$	$p_6)$	p_1	l_6

FIG. 3.1. *An example with ties in the preference lists.*

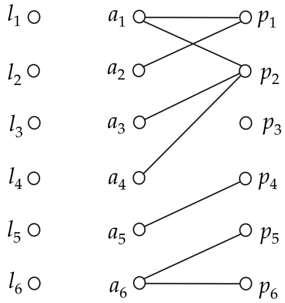

FIG. 3.2. *The graph G_1 for the example instance with ties.*

this context, Lemma 2.1 is also equivalent to the weaker condition that $M \cap E_1$ is a maximum matching of G_1. The next lemma shows that this weaker condition must also be satisfied when ties are permitted.

LEMMA 3.1. *Let M be a popular matching. Then $M \cap E_1$ is a maximum matching of G_1.*

Proof. Suppose for a contradiction that $M_1 = M \cap E_1$ is not a maximum matching of G_1. Then M_1 admits an augmenting path $Q = \langle a_1, p_1, \ldots, p_k \rangle$ with respect to G_1. It follows that $M(a_1) \notin f(a_1)$, and either p_k is unmatched in M, or $M(p_k) \notin f(p_k)$. We now show how to use Q to construct a matching M' that is more popular than M. Begin with $M' = M \setminus \{(a_1, M(a_1))\}$. There are two cases:

(i) *p_k is unmatched in M'.* Since both a_1 and p_k are unmatched in M', we augment M' with Q. In this new matching, a_1 is matched with p_1 (where $p_1 \in f(a_1)$), while all other applicants in Q remain matched to one of their first-ranked posts. Hence M' is more popular than M.

(ii) *p_k is matched in M'.* Let $a_{k+1} = M'(p_k)$, and note that $p_k \notin f(a_{k+1})$. Remove (a_{k+1}, p_k) from M', and then augment M' with Q. Select any $p_{k+1} \in f(a_{k+1})$. If p_{k+1} is unmatched in M', we promote a_{k+1} to p_{k+1}. Otherwise, we demote $a = M'(p_{k+1})$ to either $l(a)$ (if $a \neq a_1$) or back to $M(a_1)$ (if $a = a_1$), after which we can promote a_{k+1} to p_{k+1}. It is clear from this that at least one of a_1 and a_{k+1} prefers M' to M. Also, at most one applicant (that is, a) prefers M to M', though in this case *both* a_1 and a_{k+1} prefer M'. Hence, M' is more popular than M. □

Example 3.2. In our example, we see from Figure 3.2 and Lemma 3.1 that posts p_1, p_2, and p_4 and applicants a_5 and a_6 must be matched in any popular matching M. Furthermore, we deduce that $M(p_1) \in \{a_1, a_2\}$, $M(p_2) \in \{a_1, a_3, a_4\}$, $M(p_4) = a_5$, and $M(a_6) \in \{p_5, p_6\}$.

We now begin working towards a generalized definition of $s(a)$. For instances with strictly ordered preference lists, $s(a)$ is equivalent to the first post in a's preference

a_1	:	$(\mathbf{p_1}$	$\mathbf{p_2})$	p_4	$\underline{l_1}$
a_2	:	$\mathbf{p_1}$	$(p_2$	$\underline{p_5})$	l_2
a_3	:	$\mathbf{p_2}$	$(p_4$	$\underline{p_6})$	l_3
a_4	:	$\mathbf{p_2}$	p_1	$\underline{p_3}$	l_4
a_5	:	$\mathbf{p_4}$	$\underline{p_3}$	p_2	l_5
a_6	:	$(\underline{\mathbf{p_5}}$	$\underline{\mathbf{p_6}})$	p_1	l_6

FIG. 3.3. *An example with ties in the preference lists.*

list that has degree 0 in G_1. However, since Lemma 2.1 no longer holds, $s(a)$ may now contain any number of surplus f-posts. It will help us to know which f-posts *cannot* be included in $s(a)$, and for this we use the following well known ideas from bipartite matching theory.

Let M_1 be a maximum matching of some bipartite graph $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$. (Note that we are using notation that matches our use of this theory—so $M_1 = M \cap E_1$, and G_1 is the graph G restricted to rank-one edges.) Using M_1, we can partition $A \cup \mathcal{P}$ into three disjoint sets: A node v is *even* (respectively, *odd*) if there is an even (respectively, odd) length alternating path (with respect to M_1) from an unmatched node to v. Similarly, a node v is *unreachable* if there is no alternating path from an unmatched node to v. Denote by $\mathcal{E}$, $\mathcal{O}$, and $\mathcal{U}$ the sets of even, odd, and unreachable nodes, respectively. The Gallai–Edmonds decomposition lemma, covered in detail in [13], gives some fundamental relationships between maximum matchings and this type of node partition.

LEMMA 3.2 (Gallai–Edmonds decomposition). *Let $\mathcal{E}$, $\mathcal{O}$, and $\mathcal{U}$ be the node sets defined by G_1 and M_1 above. Then*

(a) *$\mathcal{E}$, $\mathcal{O}$, and $\mathcal{U}$ are pairwise disjoint. Every maximum matching in G_1 partitions the node set into the same partition of even, odd, and unreachable nodes.*

(b) *In any maximum-cardinality matching of G_1, every node in $\mathcal{O}$ is matched with some node in $\mathcal{E}$, and every node in $\mathcal{U}$ is matched with another node in $\mathcal{U}$. The size of a maximum-cardinality matching is $|\mathcal{O}| + |\mathcal{U}|/2$.*

(c) *No maximum-cardinality matching of G_1 contains an edge between two nodes in $\mathcal{O}$ or a node in $\mathcal{O}$ and a node in $\mathcal{U}$. Also, there is no edge in G_1 connecting a node in $\mathcal{E}$ with a node in $\mathcal{U}$.*

Example 3.3. In our example, it may be verified from a maximum matching, say, $\{(a_1, p_2), (a_2, p_1), (a_5, p_4), (a_6, p_5)\}$, in Figure 3.2, that $\mathcal{E} = \{a_1, a_2, a_3, a_4, p_3, p_5, p_6, l_1, l_2, l_3, l_4, l_5, l_6\}$, $\mathcal{O} = \{a_6, p_1, p_2\}$, and $\mathcal{U} = \{a_5, p_4\}$.

Now, since M_1 is a maximum-cardinality matching of G_1, Lemma 3.2(b) gives us that every odd or unreachable post p in G_1 must be matched in M to some applicant in $f(p)$. Such posts cannot be members of $s(a)$, and so we define $s(a)$ to be the set of top-ranked posts in a's preference list that are *even* in G_1 (note that $s(a) \neq \emptyset$, since $l(a)$ is always even in G_1). This definition coincides with the one in section 2, since degree 0 posts are even, and whenever every applicant has a unique first choice, posts with nonzero degree (i.e., f-posts) are odd or unreachable.

Example 3.4. Figure 3.3 displays the preference lists for our example instance, annotated as before, with the f-posts in bold and the s-posts underlined. Note that, when ties are present, f-posts and s-posts may coincide, as occurs here for applicant a_6.

Recall that our original definition of $s(a)$ led to Lemmas 2.2 and 2.3, which restrict the set of posts to which an applicant can be matched in a popular matching. We now show that the generalized definition leads to analogous results here.

LEMMA 3.3. *Let M be a popular matching. Then for every applicant a, $M(a)$ can never be strictly between $f(a)$ and $s(a)$ on a's preference list.*

Proof. Suppose for a contradiction that $M(a)$ is strictly between $f(a)$ and $s(a)$. Then since a prefers $M(a)$ to any post in $s(a)$ and because posts in $s(a)$ are the top-ranked even nodes in G_1, it follows that $M(a)$ must be an odd or unreachable node of G_1. By Lemma 3.2(b), odd and unreachable nodes are matched in every maximum matching of G_1. But since $M(a) \notin f(a)$, $M(a)$ is unmatched in $M \cap E_1$. Hence M is not a maximum matching on rank-one edges, and so by Lemma 3.1, M is not a popular matching. □

LEMMA 3.4. *Let M be a popular matching. Then for every applicant a, $M(a)$ is never worse than $s(a)$ on a's preference list.*

Proof. Suppose for a contradiction that $M(a_1)$ is strictly worse than $s(a_1)$. Let p_1 be any post in $s(a_1)$. If p_1 is unmatched in M, we can promote a_1 to p_1, thereby constructing a matching more popular than M. Otherwise, let $a_2 = M(p_1)$. There are two cases:

(a) $p_1 \notin f(a_2)$. Select any post $p_2 \in f(a_2)$, and let $a_3 = M(p_2)$ (note that p_2 must be matched in M, for otherwise Lemma 3.1 is contradicted). We can again construct a matching more popular than M, this time by (i) demoting a_3 to $l(a_3)$, (ii) promoting a_2 to p_2, and then (iii) promoting a_1 to p_1.

(b) $p_1 \in f(a_2)$. Now, since $p_1 \in s(a_1)$ as well, it must be the case that p_1 is an even post in G_1. It follows then that G_1 contains (with respect to $M \cap E_1$) an even length alternating path $Q' = \langle p_1, a_2, \ldots, p_k \rangle$, where p_k is unmatched in $M \cap E_1$ (note that p_k may be matched in M though). Now, let $Q = \langle a_1, p_1, a_2, \ldots, p_k \rangle$ (i.e., a_1 followed by Q'), and let $M' = M \setminus \{(a_1, M(a_1)\}$. The remaining argument follows the proof of Lemma 3.1. If p_k is unmatched in M', $M' \oplus Q$ is more popular than M. Otherwise, p_k is matched in M'. Let $a_{k+1} = M'(p_k)$, and note that $p_k \notin f(a_{k+1})$. Remove (a_{k+1}, p_k) from M', and then augment M' with Q. Select any $p_{k+1} \in f(a_{k+1})$. If p_{k+1} is unmatched in M', we promote a_{k+1} to p_{k+1}. Otherwise, we demote $a = M'(p_{k+1})$ to either $l(a)$ (if $a \neq a_1$) or back to $M(a_1)$ (if $a = a_1$), after which we can promote a_{k+1} to p_{k+1}. It is clear from this that at least one of a_1 and a_{k+1} prefers M' to M. Also, at most one applicant (that is, a) prefers M to M', though in this case *both* a_1 and a_{k+1} prefer M'. Hence, M' is more popular than M. □

The three necessary conditions we have just derived form the basis of the following preliminary characterization.

LEMMA 3.5. *A matching M is popular in G if and only if*

(i) *$M \cap E_1$ is a maximum matching of G_1, and*

(ii) *for each applicant a, $M(a) \in f(a) \cup s(a)$.*

Proof. Any popular matching necessarily satisfies conditions (i) and (ii) (by Lemmas 3.1, 3.3, and 3.4). It remains to show that, together, these conditions are sufficient.

Let M be any matching satisfying conditions (i) and (ii), and suppose for a contradiction that there is some matching M' that is more popular than M. Let a be any applicant that prefers M' to M. We want to show that there is a distinct corresponding applicant a' that prefers M to M'.

The graph $H = (M \oplus M') \cap E_1$ consists of disjoint cycles and paths, each alternating between edges in $M \cap E_1$ and edges in $M' \cap E_1$. We claim that $M'(a)$ must be contained in a *nonempty path* Q of H. First, note that $M'(a)$ is an odd or unreachable node in G_1, since a prefers $M'(a)$ to $M(a)$, and $M(a) \in s(a)$ is a top-ranked even

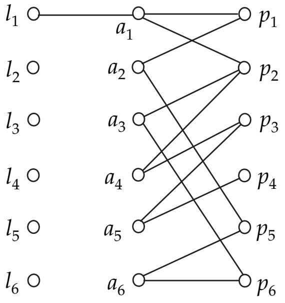

FIG. 3.4. *The reduced graph G' for the example instance with ties.*

node of G_1 in a's preference list. So by condition (i) and Lemma 3.2(b), $M'(a)$ is matched in $M \cap E_1$. However, $M'(a) \neq M(a)$, so $M'(a)$ is not isolated in H. Also, $M'(a)$ cannot be in a cycle, since a is unmatched in $M \cap E_1$. Therefore, $M'(a)$ belongs to some nonempty path Q of H.

Now, one end point of Q must be a (if $M'(a) \in f(a)$) or $M'(a)$ (otherwise). So for each such applicant a, there is a distinct nonempty path Q. Since $M'(a)$ is odd or unreachable, every post p in Q is also odd or unreachable. It follows from Lemma 3.1 that all such posts must be matched in $M \cap E_1$, and so the other end point of Q is an applicant, say, a'. It is easy to see then that a' prefers M to M', since $M(a') \in f(a')$, while $M'(a) \notin f(a')$.

Therefore, for every applicant a that prefers M' to M, there is a distinct corresponding applicant a' that prefers M to M'. Hence, M' is not more popular than M, giving the required contradiction. $\square$

Given an instance graph $G = (\mathcal{A} \cup \mathcal{P}, E)$, we define the *reduced graph* $G' = (\mathcal{A} \cup \mathcal{P}, E')$ as the subgraph of G containing edges from each applicant a to posts in $f(a) \cup s(a)$. We remark that G' need not admit an applicant-complete matching, since $l(a)$ is now isolated whenever $s(a) \neq \{l(a)\}$.

Example 3.5. Figure 3.4 shows the reduced graph for our example instance.

Lemma 3.5 gives us that M is a popular matching of G if and only if M is a maximum matching on rank-one edges, and M belongs to the graph G'. Recall that all popular matchings are applicant-complete through the introduction of last resorts. Hence, the following characterization is immediate.

THEOREM 3.6. *M is a popular matching of G if and only if*

(i) *$M \cap E_1$ is a maximum matching of G_1, and*

(ii) *M is an applicant-complete matching of the reduced graph G'.*

Example 3.6. By applying Theorem 3.6 to the reduced graph of Figure 3.4, it may be verified that our example instance admits five popular matchings, two of size 6 and three of size 5, as listed below. (Clearly, in the three matchings of size 5, a_1 is matched with his last resort l_1 in the reduced graph.)

$$M_1 = \{(a_1, p_1), (a_2, p_5), (a_3, p_2), (a_4, p_3), (a_5, p_4), (a_6, p_6)\},$$
$$M_2 = \{(a_1, p_2), (a_2, p_1), (a_3, p_6), (a_4, p_3), (a_5, p_4), (a_6, p_5)\},$$
$$M_3 = \{(a_2, p_1), (a_3, p_2), (a_4, p_3), (a_5, p_4), (a_6, p_5)\},$$
$$M_4 = \{(a_2, p_1), (a_3, p_2), (a_4, p_3), (a_5, p_4), (a_6, p_6)\},$$
$$M_5 = \{(a_2, p_1), (a_3, p_6), (a_4, p_2), (a_5, p_4), (a_6, p_5)\}.$$

```
Popular matching ($G = (\mathcal{A} \cup \mathcal{P}, E)$)
  1. Construct the graph $G' = (\mathcal{A} \cup \mathcal{P}, E')$, where $E' = \{(a, p) \mid p \in f(a) \cup s(a),\ a \in \mathcal{A}\}$.
  2. Compute a maximum matching $M_1$ on rank-one edges; i.e., $M_1$ is a maximum
     matching in $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$.
     ($M_1$ is also a matching in $G'$ because $E' \supseteq E_1$)
  3. Delete all edges in $G'$ connecting two nodes in the set $\mathcal{O}$ or a node in $\mathcal{O}$ with a node
     in $\mathcal{U}$, where $\mathcal{O}$ and $\mathcal{U}$ are the sets of odd and unreachable nodes of $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$.
     Determine a maximum matching $M$ in the modified graph $G'$ by augmenting $M_1$.
  4. If $M$ is not applicant-complete, then declare that there is no popular matching in
     $G$.
     Else return $M$.
```

FIG. 3.5. *An $O(\sqrt{n}m)$ popular matching algorithm for preference lists with ties.*

3.2. Algorithmic results. In this section, we present the algorithm popular matching (see Figure 3.5) for solving the popular matching problem. This algorithm is based on the characterization given in Theorem 3.6 and is similar to the algorithm for computing a rank-maximal matching [11].

The following lemma is necessary for the correctness of our algorithm.

LEMMA 3.7. *Algorithm popular matching returns a maximum matching M on rank-one edges.*

Proof. Since M is obtained from M_1 by successive augmentations, every node matched by M_1 is also matched by M. Nodes in $\mathcal{O}$ and $\mathcal{U}$ are matched by M_1 (by Lemma 3.2(b)). Hence, nodes in $\mathcal{O}$ and $\mathcal{U}$ are matched in M.

First, we claim that G' has no edges of rank greater than one incident on nodes in $\mathcal{O}$ and nodes in $\mathcal{U} \cap \mathcal{P}$. Let us consider any odd or unreachable node in $\mathcal{P}$. This is never a candidate for $s(a)$, and hence no edge of the type $(a, p), p \in s(a)$, is incident on such a node. For odd nodes that belong to $\mathcal{A}$, it is the case that they have first-ranked posts that are even, and so $s(a) \subseteq f(a)$. This proves our claim.

So the edges that we removed in step 3 are rank-one edges, and these edges cannot be used by any maximum matching of G_1, by Lemma 3.2(c). (So no popular matching of G can use these edges.) Now the only neighbors of nodes in $\mathcal{O}$ are the even nodes of G_1 (call this set $\mathcal{E}$), and similarly, the only neighbors of nodes in $\mathcal{U} \cap \mathcal{P}$ are nodes in $\mathcal{U} \cap \mathcal{A}$ (by our edge deletions in step 3 and Lemma 3.2(c)). This means that M must match all of the nodes in $\mathcal{O}$ with nodes in $\mathcal{E}$ and all of the nodes in $\mathcal{U} \cap \mathcal{P}$ with nodes in $\mathcal{U} \cap \mathcal{A}$.

So M has at least $|\mathcal{O}| + |\mathcal{U} \cap \mathcal{P}| = |\mathcal{O}| + |\mathcal{U}|/2$ edges of rank one. So M is a maximum matching on rank-one edges (by Lemma 3.2(b)). □

Thus the matching returned by the algorithm popular matching is both an applicant-complete matching in G' and a maximum matching on rank-one edges. The correctness of the algorithm now follows from Theorem 3.6.

It is easy to see that the running time of our algorithm is $O(\sqrt{n}m)$: We use the algorithm of Hopcroft and Karp [9] to compute a maximum matching in G_1 and identify the set of edges E' and construct G' in $O(\sqrt{n}m)$ time. We then repeatedly augment M_1 (by the Hopcroft–Karp algorithm) to obtain M. This gives us the following result.

LEMMA 3.8. *We can find a popular matching, or determine that no such matching exists, in $O(\sqrt{n}m)$ time.*

It is now a simple matter to solve the maximum-cardinality popular matching problem. Let us assume that the instance $G = (\mathcal{A} \cup \mathcal{P}, E)$ admits a popular matching. (Otherwise, we are done.) We now want an applicant-complete matching in G' that is a maximum matching on rank-one edges and which maximizes the number of applicants not matched to their last resort.

Let M' be an arbitrary popular matching in G. We know that M' belongs to the graph G'. Remove all edges of the form $(a, l(a))$ from G' (and M'). Let H denote the resulting subgraph of G'. Note that M' is still a maximum matching on rank-one edges, since no rank-one edge has been deleted from M' or G', but M' need not be a maximum matching in the graph H. Determine a maximum matching N in H by augmenting M'. N is a matching in G' that

(i) is a maximum matching on rank-one edges and

(ii) matches the maximum number of non-last-resort posts.

N need not be a popular matching. Determine a maximum matching M in G' by augmenting N. The matching M will be applicant-complete. Since M is obtained from N by successive augmentations, all posts that are matched by N are still matched by M. Hence, it follows that M is a popular matching that maximizes the number of applicants not matched to their last resort.

The following theorem is therefore immediate.

THEOREM 3.9. *We can find a maximum-cardinality popular matching, or determine that no such matching exists, in* $O(\sqrt{n}m)$ *time.*

4. Concluding remarks. In order to obtain an idea of the probability that a popular matching exists, we performed some simulations. The factors that affect this probability are the number of applicants, the number of posts, the lengths of the preference lists, and the number, size, and position of ties in these lists.

To keep this empirical investigation manageable, we restricted our attention to cases where the numbers of applicants and posts are equal, represented by n, and all preference lists have the same length k. We characterized the ties by a single parameter t, the probability that an entry in a preference list is tied with its predecessor.

Tables 4.1 and 4.2 contain the results of simulations carried out on randomly generated instances with $n = 10$ and $n = 100$, respectively. We set t to a sequence of values in the range 0.0–0.8. For $n = 10$ we allowed k to take all possible values $(1, \ldots, 10)$, and for $n = 100$ we investigated the cases $k = 1, \ldots, 10$ and $k = 20, 30, \ldots, 100$. We generated 1000 random instances in each case. In both cases, the table shows the number of instances admitting a popular matching.

TABLE 4.1
Proportion of instances with a popular matching for $n = 10$.

		t				
		0.0	0.2	0.4	0.6	0.8
k	1	1000	1000	1000	1000	1000
	2	986	988	996	997	1000
	3	898	941	962	983	996
	4	759	846	929	979	999
	5	681	811	915	979	998
	6	636	786	888	976	1000
	7	578	737	893	978	1000
	8	565	738	909	985	1000
	9	553	759	906	980	1000
	10	556	725	890	979	1000

Table 4.2
Proportion of instances with a popular matching for $n = 100$.

		t				
		0.0	0.2	0.4	0.6	0.8
k	1	1000	1000	1000	1000	1000
	2	997	1000	999	1000	1000
	3	884	956	985	990	1000
	4	519	807	925	946	974
	5	204	534	806	863	879
	6	64	346	685	782	798
	7	20	192	534	705	721
	8	8	90	436	628	672
	9	3	39	309	578	670
	10	2	28	243	531	675
	20	0	0	53	346	787
	30	0	0	37	302	776
	40	0	1	37	314	781
	50	0	0	44	291	791
	60	0	1	49	318	775
	70	0	2	36	304	780
	80	0	1	63	280	801
	90	0	0	38	306	776
	100	0	1	51	302	759

These results, and others not reported in detail here, give rise to the following observations:

- When $t = 0.0$, i.e., there are no ties, the likelihood of a popular matching declines rapidly as k increases and, for large n, is negligible except for very small values of k.
- Not surprisingly, increasing the value of t, and therefore the likely number and length of ties, increases the probability of a popular matching.
- For fixed n and t, increasing k initially reduces the likelihood of a popular matching, but beyond a certain range this effect all but disappears.

Thus popular matchings do exist with good probability when the chance of ties in the preference lists is high, which is likely to happen in real-world problems.

In fact, since the preliminary version of this paper [3] appeared, Mahdian [14] has shown that a popular matching exists with high probability, when (i) preference lists are randomly constructed and (ii) the number of posts is a small multiplicative factor larger than the number of applicants.

Of course, for a given instance, it still may be the case that a popular matching does not exist. Recently, McCutchen [16] considered the problem of finding a *least-unpopular* matching, where the unpopularity of a matching M is defined as the maximum ratio over all matchings M' of the number of applicants preferring M' to M to the number of applicants preferring M to M'. This definition of unpopularity makes the problem NP-hard; however, it is not clear if this is the case for other reasonable definitions.

The preliminary version also motivated the study of several other questions related to popular matchings. Manlove and Sng [15] have generalized the algorithms of sections 2.2 and 3.2 to the case where each post has an associated *capacity*, indicating the number of applicants that it can accommodate. (They described this in the equivalent context of the house allocation problem.) They gave an $O(\sqrt{C}n_1 + m)$ time algorithm for the no-ties case and a $O((\sqrt{C} + n_1)m)$ time algorithm when ties are allowed, where n_1 is the number of applicants, m, as usual, is the total length of all preference lists, and C is the total capacity of all of the posts.

In [17] Mestre designed an efficient algorithm for the *weighted* popular matching problem, where each applicant is assigned a priority or weight, and the definition of popularity takes into account the priorities of the applicants. In this case the algorithm for the no-ties version has $O(n + m)$ complexity, and for the version that allows ties, the complexity is $O(\min(k\sqrt{n}, n)m)$, where k is the number of distinct weights assigned to applicants.

In [12], Kavitha and Shah give faster randomized algorithms for the popular matching problem (for problem instances where preference lists contain ties) and a weighted version of the rank-maximal matching problem. Their popular matching algorithm runs in expected time $O(n^\omega)$, where $\omega < 2.376$ is the best exponent for matrix multiplication—this algorithm reduces the popular matching problem to the bipartite perfect matching problem and uses the $O(n^\omega)$ algorithm for the latter problem [18]. The reduction works as follows: In the graph G' (the reduced graph, refer to section 3.2), let us first delete posts which are isolated; now each post in G' is either an odd or unreachable post in G_1 or it is a most preferred even post in G_1. Note that these two sets are disjoint. Let there be k_1 posts of the first type and k_2 posts of the second type. Add $k_1 + k_2 - |\mathcal{A}|$ new nodes to $\mathcal{A}$, and make each of these new nodes adjacent to each of the k_2-posts of the second type (that is, most preferred even posts in G_1). It is easy to see that there is a perfect matching in this resulting graph if and only if there is an applicant-complete matching in G' that is a maximum matching on rank-one edges. Thus it follows that the popular matching problem and the bipartite perfect matching problem have equivalent time complexities.

Finally, in the preliminary version of this paper, we described the following open problem. Suppose we have an instance that admits a popular matching, but we already have a nonpopular matching M_0 in place. Since the *more popular than* relation is not transitive, it may be that no *popular* matching is more popular than M_0. We define a *voting path* then as a sequence of matchings $\langle M_0, M_1, \dots, M_k\rangle$ such that M_i is more popular than M_{i-1} for all $1 \leq i \leq k$, where M_k is popular.

Even though the *more popular than* relation is not acyclic, we were able to show that, for every matching M_0, (i) there is a voting path beginning at M_0 and (ii) the shortest such path has length at most 3. The open problem was to give an efficient algorithm for computing a shortest-length voting path from a given matching. Recently, Abraham and Kavitha [4] have shown that there is always such a voting path of length at most 2 and have given a linear-time algorithm to find one.

Acknowledgments. We thank David Manlove for directing us to previous work in the area and commenting on an early draft. We also thank Julian Mestre for correcting our description of Gardenfors' original results on popular matching.

A GEOMETRIC APPROACH TO INFORMATION-THEORETIC PRIVATE INFORMATION RETRIEVAL*

DAVID WOODRUFF† AND SERGEY YEKHANIN†

Abstract. A *t-private* private information retrieval (PIR) scheme allows a user to retrieve the ith bit of an n-bit string x replicated among k servers, while any coalition of up to t servers learns no information about i. We present a new geometric approach to PIR and obtain the following: (1) A t-private k-server protocol with communication $O(\frac{k^2}{t} \log k\ n^{1/\lfloor (2k-1)/t \rfloor})$, removing the kt term of previous schemes. This answers an open question of [Y. Ishai and E. Kushilevitz, in *Proceedings of the* 31*st ACM Symposium on Theory of Computing*, 1999, pp. 79–88]. (2) A 2-server protocol with $O(n^{1/3})$ communication, polynomial preprocessing, and online work $O(n/\log^r n)$ for any constant r. This improves the $O(n/\log^2 n)$ work of [A. Beimel, Y. Ishai, and T. Malkin, *J. Cryptology*, 17 (2004), pp. 125–151]. (3) Smaller communication for *instance hiding* [D. Beaver, J. Feigenbaum, J. Kilian, and P. Rogaway, *J. Cryptology*, 10 (1997), pp. 17–36; Y. Ishai and E. Kushilevitz, in *Proceedings of the* 31*st ACM Symposium on Theory of Computing*, 1999, pp. 79–88], PIR with a polylogarithmic number of servers, and *robust* PIR [A. Beimel and Y. Stahl, in *Proceedings of the* 3*rd Conference on Security in Communications Networks (SCN* 2002*)*, Lecture Notes in Comput. Sci. 2576, Springer, Berlin, 2003, pp. 326–341].

1. Introduction.

Private information retrieval (PIR) was introduced in a seminal paper by Chor et al. [11]. In such a scheme a server holds an n-bit string $x \in \{0,1\}^n$, representing a database, and a user holds an index $i \in [n] = \{1, \ldots, n\}$. At the end of the protocol the user should learn x_i, and the server should learn nothing about i. A trivial solution is for the server to send the user x. While private, the *communication complexity* is linear in n. In contrast, in a nonprivate setting, there is a protocol with only $\log n + 1$ bits of communication. This raises the question of how much communication is really necessary to achieve privacy.

Unfortunately, if information-theoretic privacy is required, then there is no better solution than the trivial one [11]. To get around this, Chor et al. [11] suggested replicating the database among $k > 1$ noncommunicating servers. In this setting, one can do substantially better. Indeed, Chor et al. [11] gave a protocol with complexity $O(n^{1/3})$ for as few as two servers and an $O(k^2 \log k\ n^{1/k})$ solution for the general case. Ambainis [1] then extended the $O(n^{1/3})$ protocol to achieve $O(2^{k^2} n^{1/(2k-1)})$ complexity for every k. Later, Beimel et al. [7] reduced the communication to $2^{\tilde{O}(k)} n^{\frac{2 \log \log k}{k \log k}}$. Finally, in a recent paper Yekhanin [27] presented a 3-server protocol with $O(n^{\epsilon})$ communication for some tiny $\epsilon < 10^{-7}$. Combining the results of [27] and [7], one gets k server protocols with $2^{\tilde{O}(k)} n^{\frac{\delta \log \log k}{k \log k}}$ communication for a small $\delta > 0$ and every k.

Yekhanin [27] has also shown that under a certain plausible number-theoretic conjecture one can achieve $n^{o(1)}$ communication complexity with as few as three servers. The best lower bound is $c \log n$ for a constant $c > 1$ [18, 24, 25]. Stronger lower bounds are known in certain restricted models [5, 16, 14, 24, 20]. For a survey, see [13, 23].

A drawback of all of these solutions is that if any two servers communicate, they can completely recover i. This motivates the notion of a *privacy threshold* t, $1 \le t \le k$, which limits the number of servers that might collude in order to get any information about i. That is, the joint view of any t servers should be independent of i. The case $t > 1$ was addressed in [11, 15, 6]. It is not known whether the techniques of [7] and [27] (that yield the best upper bounds in the 1-private case) can be extended to obtain t-private protocols for arbitrary values of k and $1 \le t \le k$. The best t-private protocols prior to our work were due to Beimel and Ishai [6]. They achieve communication complexity of: $O\big(\binom{k}{t} \frac{k^2}{t} n^{1/\lfloor (2k-1)/t \rfloor}\big)$. Since this bound grows rapidly with t, in [15] the following is asked:

Can one avoid the $\binom{k}{t}$ overhead induced by our use of replication-based secret sharing?

We give a scheme with communication $O\big(\frac{k^2}{t} \log k \ n^{1/\lfloor (2k-1)/t \rfloor}\big)$ for any t and thus answer this question in the affirmative.

Our upper bound is of considerable interest in the *oracle instance-hiding* scenario [3, 4]. In this setting there is a function $F_m : \{0,1\}^m \to \{0,1\}$ held by k oracles. The user has $P \in \{0,1\}^m$ and wants to privately retrieve $F_m(P)$, even if up to t of the oracles collude. The user's computation, let alone the total communication, should be polynomial in m. For $k = \frac{m}{c \log m}$ and constant t, running our PIR scheme on the truth table of F_m gives a scheme with total communication $\tilde{O}(m^{ct/2+2})$. This improves the previous bound of $\tilde{O}(m^{ct/2+2+t})$ (see [15]) by a factor of m^t. When $m = \log n$, this is exactly the problem of PIR with $k = \Omega(\log n / \log\log n)$, for which we obtain the best known bound.

Another application of our techniques is k-out-of-l *robust* PIR [9]. In this scenario a user should be able to recover x_i even if after sending his queries, up to $l - k$ servers do not respond. Previous bounds for this problem include $O(kn^{1/k} l \log l)$ and $2^{\tilde{O}(k)} n^{\frac{\delta \log\log k}{k \log k}} l \log l$ [9] for a small constant $\delta > 0$. The first bound has a better dependence on k, while the second has a better dependence on n. We improve upon the former with a k-out-of-l robust protocol with communication $O(kn^{1/(2k-1)} l \log l)$.

Another concern with the abovementioned solutions is the *time complexity* of the servers per query. Beimel, Ishai, and Malkin [8] show, among other things, that if two servers are given polynomial-time preprocessing, then during the online stage they can respond to queries with $O(n/\log^2 n)$ work, while preserving $O(n^{1/3})$ total communication. By combining a balancing technique similar to that in [10] with a specially designed 2-server protocol in our language, we can reduce the work to $O(n/\log^r n)$ for any constant $r > 0$.

Finally, we believe that an important advantage of our PIR protocols is the simple geometric intuition behind them. The novel technique that we introduce has already found additional applications in the area of secure multiparty computation [2], and we expect further applications to follow.

1.1. Omitted from this version. The original version of this paper [26] contained a section with alternative geometric proofs of some of the upper bounds of Beimel et al. [7] for 1-private k-server PIR protocols. The initial argument of [7] involves a highly nontrivial recursion and is fairly hard to follow. Our proofs shed new light on the nature of these protocols. However, after the original paper [26] was published, these results were superseded by [27] and are therefore omitted from this version.

1.2. Our techniques. The general idea behind our protocols is the idea of polynomial interpolation. As in several previous works, we model the database as a degree-d polynomial $F \in \mathbb{F}_q[z_1, \ldots, z_m]$ with $m = O(dn^{1/d})$. The polynomial F is chosen in such a way that for some encoding $E : [n] \to \mathbb{F}_q^m$ (which is independent of F) we have $F(E(i)) = x_i$ for every $i \in [n]$. The user wants to retrieve the value $F(P)$ for $P = E(i)$ while keeping the identity of P private. To this end the user randomly selects a low-dimensional affine curve (in many cases this is simply an affine line) $\chi \subseteq \mathbb{F}_q^m$ containing the point P and discloses certain points on χ to the servers. Each server computes and returns the value of F and the values of *partial derivatives* of F at the point that it is given. Finally, the user reconstructs the restriction of F to χ. In particular, the user obtains the desired value of $F(P)$. The idea of polynomial interpolation has been used previously in the PIR literature [3, 11, 4]; however, we significantly extend and improve upon earlier techniques through the use of partial derivatives and curves.

A possible high level interpretation of our results is to say that we modify the protocols of [15], replacing the replication-based secret-sharing scheme by a more efficient Shamir's scheme [21]. A discussion of certain merits of replication-based secret sharing (that come at a price of increased communication) can be found in [12]. For another use of derivatives in polynomial-based secret-sharing schemes, see [22].

1.3. Outline. In section 2 we introduce our notation and provide some necessary definitions. In section 3 we describe a 1-private PIR protocol on a line. We also discuss the robustness of our protocol. Section 4 deals with t-private PIR protocols on a curve for arbitrary t and discusses applications to instance hiding. In section 5 we present our construction of PIR protocols with preprocessing.

2. Preliminaries. By default, variables λ_h take values in a finite field $\mathbb{F}_q$, and variables P, V, V^j, Q, and Q^j take values in $\mathbb{F}_q^m$. Let W be an element of $\mathbb{F}_q^m$. We use the subscript W_l to denote the lth component of W.

A k-server PIR protocol involves k servers $\mathcal{S}_1, \ldots, \mathcal{S}_k$, each holding the same n-bit string x (the database), and a user $\mathcal{U}$ who knows n and wants to retrieve some bit x_i, $i \in [n]$, without revealing i. We restrict our attention to *one-round,* information-theoretic PIR protocols.

Definition. [7] A t-private PIR protocol is a triplet of algorithms $\mathcal{P} = (\mathcal{Q}, \mathcal{A}, \mathcal{C})$. At the beginning of the protocol, the user $\mathcal{U}$ invokes $\mathcal{Q}(k, n, i)$ to pick a randomized k-tuple of queries $(q_1, \ldots, q_k)$, along with an auxiliary information string aux. It sends each server $\mathcal{S}_j$ the query q_j and keeps aux for later use. Each server $\mathcal{S}_j$ responds with an answer $a_j = \mathcal{A}(k, j, x, q_j)$. (We can assume without loss of generality that the servers are deterministic; hence, each answer is a function of a query and a database.) Finally, $\mathcal{U}$ computes its output by applying the reconstruction algorithm $\mathcal{C}(k, n, a_1, \ldots, a_k, aux)$. A protocol as above should satisfy the following requirements:

- *Correctness.* For any k, n, $x \in \{0,1\}^n$ and $i \in [n]$, the user outputs the correct value of x_i with probability 1 (where the probability is over the randomness of $\mathcal{Q}$).
- *t-Privacy.* Each collusion of up to t servers learns no information about i. Formally, for any k, n, $i_1, i_2 \in [n]$, and every $T \subseteq [k]$ of size $|T| \leq t$ the

distributions $\mathcal{Q}_T(k, n, i_1)$ and $\mathcal{Q}_T(k, n, i_2)$ are identical, where $\mathcal{Q}_T$ denotes concatenation of jth outputs of $\mathcal{Q}$ for $j \in T$.

The *communication complexity* of a PIR protocol $\mathcal{P}$, denoted $C_{\mathcal{P}}(n, k)$, is a function of k and n measuring the total number of bits communicated between the user and k servers, maximized over all choices of $x \in \{0,1\}^n$, $i \in [n]$, and random inputs.

In all our protocols we represent the database x by a multivariate polynomial $F(z_1, \ldots, z_m)$ over a finite field. The important parameters of the polynomial F are its degree-d and the number of variables m. A very similar representation has been used previously in [7]. The polynomial F represents x in the following sense: with every $i \in [n]$ we associate a point $E(i) \in \mathbb{F}_q^m$; the polynomial F satisfies

$$\forall i \in [n], \quad F(E(i)) = x_i.$$

We use the assignment function $E : [n] \to \mathbb{F}_q^m$ from [7]. Let $E(1), \ldots, E(n)$ denote n distinct points of Hamming weight[1] d with coordinate values from the set $\{0,1\} \subset \mathbb{F}_q$. Such points exist if $\binom{m}{d} \geq n$. Therefore $m = O(dn^{1/d})$ variables are sufficient. Define

$$F(z_1, \ldots, z_m) = \sum_{i=1}^{n} x_i \prod_{E(i)_l = 1} z_l$$

($E(i)_l$ is the lth coordinate of $E(i)$.) Since each $E(i)$ is of weight d, the degree of F is d. Each assignment $E(i)$ to the variables z_i satisfies exactly one monomial in F (whose coefficient is x_i); thus, $F(E(i)) = x_i$.

Our constructions rely heavily on the notion of a derivative of a polynomial over a finite field. Recall that for $f(\lambda) = a_0 + \sum_{i=1}^{d} a_i \lambda^i \in \mathbb{F}_q[\lambda]$ the derivative is defined by $f'(\lambda) = \sum_{i=1}^{d} i a_i \lambda^{i-1}$. Higher order derivatives are defined recursively by $f^{(s)}(\lambda) = \left(f^{(s-1)}(\lambda)\right)'$.

We conclude the section with two technical lemmas.

Lemma 1. *Let $f \in \mathbb{F}_q[\lambda]$ and let s be an integer smaller than the characteristic of $\mathbb{F}_q$. Suppose $f(\lambda_0) = f'(\lambda_0) = \cdots = f^{(s)}(\lambda_0) = 0$; then $(\lambda - \lambda_0)^{s+1} \mid f$.*

Proof. See Lemma 6.51 in [17]. □

Lemma 2. *Suppose $\{\lambda_h\}, \{v_h^0\}, \{v_h^1\}$ are elements of $\mathbb{F}_q$, where $h \in [s]$ and $\{\lambda_h\}$ are distinct; then there exists at most one polynomial $f(\lambda) \in \mathbb{F}_q[\lambda]$ of degree $\leq 2s - 1$ such that $f(\lambda_h) = v_h^0$ and $f'(\lambda_h) = v_h^1$.*

Proof. Assume there exist two such polynomials $f_1(\lambda)$ and $f_2(\lambda)$. Consider their difference $f = f_1 - f_2$. Clearly, $f(\lambda_h) = f'(\lambda_h) = 0$ for all $h \in [s]$. Therefore, by Lemma 1,

$$\prod_{h=1}^{s} (\lambda - \lambda_h)^2 \;\Bigg|\; f(\lambda).$$

This divisibility condition yields $f(\lambda) = 0$ since the degree of f is at most $2s - 1$. □

3. PIR on the line.

We start this section with a PIR protocol of [11]. This protocol has a simple geometric interpretation and has served as the starting point for our work.

Theorem 3 (see [11]). *There exists a 1-private k-server PIR protocol with communication complexity $O(k^2 \log k \; n^{1/(k-1)})$.*

[1] The Hamming weight of a vector is defined to be the number of nonzero coordinates.

Protocol description. Consider a finite field $\mathbb{F}_q$, where $k < q \leq 2k$. Let $\lambda_1, \ldots, \lambda_k \in \mathbb{F}_q$ be distinct and nonzero. Set $d = k - 1$. Let $P = E(i)$. The user wants to retrieve $F(P)$.

$\mathcal{U}$	:	Picks $V \in \mathbb{F}_q^m$ uniformly at random.
$\mathcal{U} \to \mathcal{S}_h$	:	$P + \lambda_h V$.
$\mathcal{U} \leftarrow \mathcal{S}_h$	:	$F(P + \lambda_h V)$.

Privacy. It is immediate to verify that the input $(P + \lambda_h V)$ of each server $\mathcal{S}_i$ is distributed uniformly over $\mathbb{F}_q^m$. Thus the protocol is private.

Correctness. We need to show that values $F(P + \lambda_h V)$ for $h \in [k]$ suffice to reconstruct $F(P)$. Consider the line $L = \{P + \lambda V \mid \lambda \in \mathbb{F}_q\}$ in the space $\mathbb{F}_q^m$. Let $f(\lambda) = F(P + \lambda V)$ be the restriction of F to L. Clearly, $f \in \mathbb{F}_q[\lambda]$ is a univariate polynomial of degree at most $d = k - 1$. Note that $f(\lambda_h) = F(P + \lambda_h V)$. Thus $\mathcal{U}$ knows the values of $f(\lambda)$ at k points and therefore can reconstruct $f(\lambda)$. It remains to note that $F(P) = f(0)$.

Complexity. The user sends each of k servers a length-m vector of values in $\mathbb{F}_q$. Recall that $m = O(dn^{1/d})$ and $k < q \leq 2k$. Thus the total communication from the user to all the servers is $O(k^2 \log k \; n^{1/(k-1)})$. Each $\mathcal{S}_h$ responds with a single value from $\mathbb{F}_q$, which does not affect the asymptotic communication of the protocol.

In the protocol above there is an obvious imbalance between the communication from the user to the servers and vice versa. The next theorem extends the technique of Theorem 3 to fix this imbalance and obtain a better communication complexity.

THEOREM 4. *There exists a* 1*-private k-server PIR protocol with communication complexity* $O(k^2 \log k \; n^{1/(2k-1)})$.

Protocol description. We use the standard mathematical notation $\frac{\partial F}{\partial z_l}\big|_Q$ to denote the value of the partial derivative of F with respect to z_l at point Q. Let $\lambda_1, \ldots, \lambda_k \in \mathbb{F}_q$ be distinct and nonzero. Set $d = 2k - 1$. Let $P = E(i)$. The user wants to retrieve $F(P)$.

$\mathcal{U}$	:	Picks $V \in \mathbb{F}_q^m$ uniformly at random.
$\mathcal{U} \to \mathcal{S}_h$	:	$P + \lambda_h V$.
$\mathcal{U} \leftarrow \mathcal{S}_h$	:	$F(P + \lambda_h V), \frac{\partial F}{\partial z_1}\Big|_{P + \lambda_h V}, \ldots, \frac{\partial F}{\partial z_m}\Big|_{P + \lambda_h V}.$

Privacy. The proof of privacy is identical to the proof from Theorem 3.

Correctness. Again, consider the line $L = \{P + \lambda V \mid \lambda \in \mathbb{F}_q\}$. Let $f(\lambda) = F(P + \lambda V)$ be the restriction of F to L. Clearly, $f(\lambda_h) = F(P + \lambda_h V)$. Thus the user knows the values $\{f(\lambda_h)\}$ for all $h \in [k]$. However, this time the values $\{f(\lambda_h)\}$ do not suffice to reconstruct the polynomial f, since the degree of f may be up to $2k - 1$. The main observation underlying our protocol is that knowing the values of partial derivatives $\frac{\partial F}{\partial z_1}\big|_{P + \lambda_h V}, \ldots, \frac{\partial F}{\partial z_m}\big|_{P + \lambda_h V}$, the user can reconstruct the value of $f'(\lambda_h)$. The proof is a straightforward application of the chain rule:

$$\frac{\partial f}{\partial \lambda}\bigg|_{\lambda_h} = \frac{\partial F(P + \lambda V)}{\partial \lambda}\bigg|_{\lambda_h} = \sum_{l=1}^{m} \frac{\partial F}{\partial z_l}\bigg|_{P + \lambda_h V} V_l.$$

Thus the user can reconstruct $\{f(\lambda_h)\}$ and $\{f'(\lambda_h)\}$ for all $h \in [k]$. Combining this observation with Lemma 2, we conclude that the user can reconstruct f and obtain $F(P) = f(0)$.

Complexity. The user sends each of k servers a length-m vector of values in $\mathbb{F}_q$. Servers respond with length-$(m+1)$ vectors of values in $\mathbb{F}_q$. Recall that $m = O(dn^{1/d})$ and $q \leq 2k$. Thus the total communication is $O(k^2 \log k \; n^{1/(2k-1)})$.

3.1. Application to robust PIR. We review the definition of robust PIR [9].

Definition 5. *A k-out-of-l PIR protocol is a 1-private PIR protocol with the additional property that the user always computes the correct value of x_i from any k out of l of the answers.*

As noted in [9], robust PIR has applications to servers which may hold different versions of a database, as long as some k have the latest version and there is a way to distinguish these k. Another application is to servers with varying response times. Previous bounds for this problem include $O(kn^{1/k} l \log l)$ and $2^{\tilde{O}(k)} n^{\frac{\delta \log \log k}{k \log k}} l \log l$ [9] for a small constant $\delta > 0$. The first bound has a better dependence on k, while the second has a better dependence on n. We improve upon the former with a k-out-of-l robust protocol with communication $O(kn^{1/(2k-1)} l \log l)$.

Indeed, in the protocol above, if for l servers we set the field size $q > l$ and the degree $\deg F = 2k-1$, then from any k servers' answers, we can reconstruct f as before. We conclude that the following theorem holds.

Theorem 6. *For all $k \leq l$ there exists a k-out-of-l robust PIR with communication complexity $O(kn^{1/(2k-1)} l \log l)$.*

4. PIR on the curve. Now we proceed to t-private PIRs for general t.

Theorem 7. *For all $t \leq k$ there exists a t-private k-server PIR protocol with communication complexity $O\big(\frac{k^2}{t} \log k \; n^{1/\lfloor \frac{2k-1}{t} \rfloor}\big)$.*

Protocol description. Again, consider $\mathbb{F}_q$, where $k < q \leq 2k$, and let $\lambda_1, \ldots, \lambda_k \in \mathbb{F}_q$ be distinct and nonzero. Set $d = \lfloor \frac{2k-1}{t} \rfloor$. Let $P = E(i)$. The user wants to retrieve $F(P)$.

$$\boxed{\begin{array}{lcl} \mathcal{U} & : & \text{Randomly picks } V^1, \ldots, V^t \in \mathbb{F}_q^m. \\ \mathcal{U} \rightarrow \mathcal{S}_h & : & Q^h = P + \lambda_h V^1 + \lambda_h^2 V^2 + \ldots + \lambda_h^t V^t. \\ \mathcal{U} \leftarrow \mathcal{S}_h & : & F(Q^h), \left.\frac{\partial F}{\partial z_1}\right|_{Q^h}, \ldots, \left.\frac{\partial F}{\partial z_m}\right|_{Q^h}. \end{array}}$$

Privacy. We need to show that for every $T \subseteq [k]$, where $|T| \leq t$, the collusion of servers $\{\mathcal{S}_h\}_{h \in T}$ learns no information about the point $P = E(i)$. The joint input of servers $\{\mathcal{S}_h\}_{h \in T}$ is $\{P + \lambda_h V^1 + \cdots + \lambda_h^t V^t\}_{h \in T}$. Since the coordinates are shared independently, it suffices to show that for each $l \in [m]$ and $V_l^j \in \mathbb{F}_q$ chosen independently and uniformly at random, the values $\{P_l + \lambda_h V_l^1 + \cdots + \lambda_h^t V_l^t\}_{h \in T}$ disclose no information about P_l. The last statement follows immediately from the fact that for any distinct $\lambda_0, \ldots, \lambda_t \in \mathbb{F}_q$ and arbitrary $u_0, \ldots, u_t \in \mathbb{F}_q$ there exists a unique polynomial $f(\lambda) \in \mathbb{F}_q[\lambda]$ of degree up to t such that $f(\lambda_i) = u_i$ for all i. One other way to argue privacy is to observe that our queries can be obtained by independently secret sharing each of the m coordinates of P according to Shamir's scheme [21].

Correctness. Consider the curve $\chi = \{P + \lambda V^1 + \cdots + \lambda^t V^t \mid \lambda \in \mathbb{F}_q\}$. Let $f(\lambda) = F(P + \lambda V^1 + \cdots + \lambda^t V^t)$ be the restriction of F to χ. Obviously, f is a univariate polynomial of degree at most $2k-1$. By definition, we have $f(\lambda_h) = F(Q^h)$; thus $\mathcal{U}$ knows the values $\{f(\lambda_h)\}$ for all $h \in [k]$. Now we shall see how knowing the values of partial derivatives $\left.\frac{\partial F}{\partial z_1}\right|_{Q^h}, \ldots, \left.\frac{\partial F}{\partial z_m}\right|_{Q^h}$ $\mathcal{U}$ reconstructs the value of $f'(\lambda_h)$.

Again, the reconstruction is a straightforward application of the chain rule:

$$\left.\frac{\partial f}{\partial \lambda}\right|_{\lambda_h} = \left.\frac{\partial F(P+\lambda V^1+\cdots+\lambda^t V^t)}{\partial \lambda}\right|_{\lambda_h} = \sum_{l=1}^{m} \left.\frac{\partial F}{\partial z_l}\right|_{Q^h} \left.\frac{\partial}{\partial \lambda}(P_l+\lambda V_l^1+\cdots+\lambda^t V_l^t)\right|_{\lambda_h}.$$

Thus $\mathcal{U}$ can reconstruct $\{f(\lambda_h)\}$ and $\{f'(\lambda_h)\}$ for all $h \in [k]$. Combining this observation with Lemma 2, we conclude that the user can reconstruct f and obtain $F(P) = f(0)$.

Complexity. As in the protocol of Theorem 4, $\mathcal{U}$ sends each of k servers a length-m vector of values in $\mathbb{F}_q$, and servers respond with length-$(m+1)$ vectors of values in $\mathbb{F}_q$. Here $m = O(dn^{1/d})$ and $q \leq 2k$. Thus the total communication is $O\big(\frac{k^2}{t}\log k\; n^{1/\lfloor\frac{2k-1}{t}\rfloor}\big)$.

4.1. Application to instance hiding. As noted in the introduction, in the instance-hiding scenario [3, 4] there is a function $F_m : \{0,1\}^m \to \{0,1\}$ held by k oracles. The user has a point $P \in \{0,1\}^m$ and should learn $F_m(P)$. Further, the view of up to t oracles should be independent of P. When $k = \frac{m}{c\log m}$, we have the following improvement upon the best known $\tilde{O}(m^{ct/2+2+t})$ communication bound of [15].

THEOREM 8. *Let $c, t > 0$, and suppose that t is an integer. Then for any $m > 0$ there is an oracle instance-hiding scheme with $k = \frac{m}{c\log m}$ oracles and communication and computation $\tilde{O}(m^{ct/2+2})$, where $\tilde{O}(f) = O(f\log^{O(1)} f)$.*

Proof. Using the above protocol on the truth table of F_m, the communication is

$$O\left(\frac{k^2}{t}\log k n^{1/\lfloor(2k-1)/t\rfloor}\right) = \tilde{O}\left(m^2\cdot(2^m)^{(\lfloor(2k-1)/t\rfloor)^{-1}}\right) = \tilde{O}(m^{ct/2+2}).$$

It is also easy to see that $\mathcal{U}$ runs in time which is quasi-linear in the communication. □

5. PIR with preprocessing. To measure the efficiency of an algorithm with preprocessing, we use the definition of *work* in [8] which counts the number of precomputed bits and database bits that need to be read in order to respond to a query. We note that, as mentioned in [8], this definition of work may be more appropriate for proving lower bounds than for upper bounds. However, as in that paper, the actual amount of work in the unit-cost RAM model[2] of our scheme is linear in the number of bits read.

The goal of this section is to prove the following theorem.

THEOREM 9. *There exists a 2-server PIR protocol with $O(n^{1/3})$ communication,* poly(n) *preprocessing, and $O(n/(\log n)^r)$ server work for any constant r.*

The reader may wonder what happens if we consider larger values of r in this theorem. To simplify the presentation of this section, we defer the discussion of this to Remark 11.

We need a lemma about preprocessing polynomials $F \in \mathbb{F}_p[z_1, \ldots, z_m]$. We assume the number of variables m is tending to infinity, while the degree of F is constant. This lemma is similar to Theorem 3.1 of [8]. The main idea is to write the input polynomial F as a sum of poly(m) polynomials G each over disjoint monomials. We do this in such a way that each G involves only a logarithmic number of variables. Thus we can precompute G on all possible assignments. As the different G are over disjoint

[2] Recall that in the unit-cost RAM model each field operation can be performed in constant time.

monomials, to evaluate $F(V)$ we simply read one precomputed answer for each G and sum them up.

LEMMA 10. *Let F be a homogeneous degree-d polynomial in $\mathbb{F}_p[z_1, \ldots, z_m]$. Using* $\mathrm{poly}(m)$ *preprocessing time, for all $V \in \mathbb{F}_p^m$, $F(V)$ can be computed with $O(m^d/\log^d m)$ work.*

Proof. Partition $[m]$ into $\alpha = m/\log m$ disjoint sets $D_1, \ldots, D_\alpha$ of size $\log m$. For every sequence $1 \le t_1, \ldots, t_d \le \alpha$, let $F_{D_{t_1},\ldots,D_{t_d}}$ denote the sum of all monomials of F of the form $cz_{i_1} \cdots z_{i_d}$ for some $c \in \mathbb{F}_p$ and $i_1 \in D_{t_1}, \ldots, i_d \in D_{t_d}$. The following is the preprocessing algorithm.

```
Preprocess(F):
1. For each polynomial $F_{D_{t_1},\ldots,D_{t_d}}$,
     Evaluate $F_{D_{t_1},\ldots,D_{t_d}}$ on all $W \in \mathbb{F}_p^m$
     for which $\mathrm{Supp}(W) \subseteq \cup_i D_{t_i}$.
```

Time Complexity. There are $\alpha^d = (m/\log m)^d$ polynomials $F_{D_{t_1},\ldots,D_{t_d}}$. For each polynomial, there are at most $p^{d \log m} = \mathrm{poly}(m)$ different W whose support is in $\cup_i D_{t_i}$. Thus the total time of the algorithm is $\mathrm{poly}(m)$.

For a set $S \subseteq [m]$, let $V|_S$ denote the point $V' \in \mathbb{F}_p^m$ with $V'_j = V_j$ for $j \in S$ and $V'_j = 0$ otherwise. The following describes how to compute $F(V)$.

```
Evaluate($F, V$):
1. $\sigma \leftarrow 0$.
2. For each polynomial $F_{D_{t_1},\ldots,D_{t_d}}$,
     $\sigma \leftarrow \sigma + F_{D_{t_1},\ldots,D_{t_d}}(V|_{\cup_i D_{t_i}})$.
3. Output $\sigma$.
```

Correctness. This is immediate from

$$F(V) = \sum_{t_1,\ldots,t_d} F_{D_{t_1},\ldots,D_{t_d}}(V|_{\cup_i D_{t_i}}).$$

Work. The sum is over $\alpha^d = (m/\log m)^d$ polynomials $F_{D_{t_1},\ldots,D_{t_d}}$, each with a precomputed answer, and thus the total work is $O(m^d/\log^d m)$. □

5.1. Two server protocol. We start with the intuition underlying our 2-server preprocessing protocol. Suppose the servers were to represent the database as a degree-d polynomial F in $m = \Theta(n^{1/d})$ variables, where $d = 2r + 1$ is an arbitrary odd constant. Proceeding as in the protocol of section 3, the user sends each server a point on a random line L through his point of interest. To reconstruct $F|_L$, the user needs the evaluation of F on his query points, together with all partial derivatives of F up to order r. The observation is that each partial derivative computed by the servers is either a zero polynomial or a polynomial of degree at least $d - r = r + 1$ in at most m variables, and therefore we can apply Lemma 10 to achieve low server work.

However, while the user is sending only $O(m)$ bits to the servers, the servers' answers are of size $O(m^r)$. To fix this, we use a balancing technique similar to that in [10]. Each server partitions the database into t databases F_j, each of size n/t, for some parameter t. Each database will be represented as a degree-d polynomial in $m = O((n/t)^{1/d})$ variables. The user sends t points to each server, one for each database. Suppose the user wants $F_u(P)$. For the $t-1$ databases F_j, $j \neq u$, that do not interest the user, the user sends random V^j and $-V^j$ to servers 1 and 2, respectively. On the other hand, for the database F_u that contains the value of interest, the user proceeds as in the protocol of section 3. The servers compute the lists of partial derivatives for each database, as before, but instead of sending them back, they send the *sum* of each partial derivative over all t databases. We show this information is sufficient for the user to reconstruct $F_u(P)$. The total work will be $O(n/\log^{r+1} n)$, and by carefully choosing t, we can keep the communication at $O(n^{1/3})$.

Consider a prime field[3] $\mathbb{F}_p$ for some $\max(2, r) < p < 2\max(2, r)$. Such a prime p exists by Bertrand's postulate [19]. $\mathcal{S}_1$ and $\mathcal{S}_2$ preprocess as follows.

```
Preprocessing phase($x$):
1. $s \leftarrow \frac{r-1}{3r}$, $t \leftarrow n^s$.
2. Partition $x$ into $t$ databases $\mathrm{DB}_1, \ldots, \mathrm{DB}_t$, each
   containing $n^{1-s}$ elements.
3. Represent $\mathrm{DB}_j$ as a homogeneous polynomial $F_j$
   of degree $d = 2r + 1$ with $m = O\left(n^{(1-s)/d}\right)$ vars.
4. For $a = 0, \ldots, r$, for $j \in [t]$, and for $l_1, \ldots, l_a \in [m]$,
   compute Preprocess$\left(\frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\right)$.
```

Let DB_u be the database containing x_i. Assume the user wants $F_u(P)$. Let $\delta_{\alpha,\beta}$ be 1 if $\alpha = \beta$ and 0 otherwise.

```
$\mathcal{U}$                      : Randomly picks $V^1, \ldots, V^t \in \mathbb{F}_p^m$.
$\mathcal{U} \rightarrow \mathcal{S}_h$ : For $j \in [t]$, $Q^{h,j} = (-1)^{h+1} V^j + \delta_{j,u} P$.
$\mathcal{U} \leftarrow \mathcal{S}_h$  : $\forall a \in \{0, \ldots, r\}$ and $l_1, \ldots, l_a \in [m]$,
                             $\sum_{j=1}^t \frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\Big|_{Q^{h,j}} =$
                             $\sum_{j=1}^t$ Evaluate$\left(\frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}, Q^{h,j}\right)$
```

Correctness. Since d is odd, for all V

$$\frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{-V} = (-1)^{a+1} \frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{V}.$$

It follows that for all a and all $j \neq u$,

$$\sum_{l_1,\ldots,l_a} \frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{V^j} + \sum_{l_1,\ldots,l_a} \frac{(-1)^a \partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{-V^j} = 0.$$

Put $f(\lambda) = (F_u)|_{P+\lambda V^u}$, and define $g(\lambda) = f(\lambda) + f(-\lambda)$. We then have

$$\begin{aligned}
&\sum_j \sum_{l_1,\ldots,l_a} \frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{Q^{1,j}} V_{l_1}^u \cdots V_{l_a}^u + \frac{(-1)^a \partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{Q^{2,j}} V_{l_1}^u \cdots V_{l_a}^u \\
&= \sum_{l_1,\ldots,l_a} \frac{\partial^a F_u}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{P+V^u} V_{l_1}^u \cdots V_{l_a}^u + \frac{(-1)^a \partial^a F_u}{\partial z_{l_1} \cdots \partial z_{l_a}}\bigg|_{P-V^u} V_{l_1}^u \cdots V_{l_a}^u \\
&= f^{(a)}(1) + (-1)^a f^{(a)}(-1) = g^{(a)}(1).
\end{aligned}$$

[3] In section 5 we base our protocols on prime fields $\mathbb{F}_p$ and do not consider general finite fields $\mathbb{F}_q$. We do this to avoid issues related to subtle properties of derivatives of orders greater than one in finite fields of small characteristic. Another possible solution to this problem is to use Hasse derivatives (referred to as hyperderivatives in [17]) instead of usual derivatives. This allows for protocols over arbitrary finite fields.

Thus $\mathcal{U}$ can compute $g(1), g^{(1)}(1), \dots, g^{(r)}(1)$ from the answers. Since every monomial of g has even degree, for $\gamma = \lambda^2$ we can define $h(\gamma) = g(\lambda)$ for a degree-r polynomial h. Using that

$$\frac{dg}{d\lambda} = \frac{dh}{d\gamma} \cdot \frac{d\gamma}{d\lambda} = 2\lambda \frac{dh}{d\gamma},$$

a simple induction shows that from $g^{(0)}(1), \dots, g^{(r)}(1)$, $\mathcal{U}$ can get $h^{(0)}(1), \dots, h^{(r)}(1)$. The claim is that these values determine h. Indeed, if $h_1 \neq h_2$ agree on these values, then by Lemma 1,

$$(\gamma - 1)^{r+1} \;\Big|\; (h_1 - h_2),$$

which contradicts that $h_1 - h_2$ has degree at most r. Hence the user obtains $h(0) = g(0) = 2f(0) = 2F(P)$, and thus $F(P)$ since the characteristic $p > 2$.

Privacy. Since the V^j are independent and uniformly random, so are the $Q^{1,j}$ and the $Q^{2,j}$. Thus the view of each of $\mathcal{S}_1$, $\mathcal{S}_2$ is independent of P.

Communication. $\mathcal{U}$ sends $O(tm) = O(n^{s+(1-s)/(2r+1)}) = O(n^{(r-1)/(3r)+1/(3r)}) = O(n^{1/3})$ bits. $\mathcal{S}_1, \mathcal{S}_2$ respond with $O(m+m^2+\cdots+m^r) = O(m^r) = O(n^{(1-s)r/(2r+1)}) = O(n^{1/3})$ bits.

Server work. Notice that the work is dominated by the calls to $\mathsf{Evaluate}$. For any $a \in \{0, \dots, r\}$, any $l_1, \dots, l_a \in [m]$, and any $j \in [t]$, the polynomial $\frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}$ is either 0 or has degree $2r + 1 - a$ and at most m variables. Thus for any V, $\mathsf{Evaluate}(\frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}, V)$ can be computed in $O(m^{2r+1-a}/\log^{2r+1-a} m)$ time. As the number of such $\frac{\partial^a F_j}{\partial z_{l_1} \cdots \partial z_{l_a}}$ is $O(m^a)$, it follows that the time for all calls to $\mathsf{Evaluate}$ per DB is

$$\sum_a O\left(\frac{m^a m^{2r+1-a}}{\log^{2r+1-a} m}\right) = \frac{O(m^d)}{\log^{r+1} m} = \frac{O(n^{1-s})}{\log^{r+1} n}.$$

Thus the total work over all n^s DBs is $O(n/\log^{r+1} n)$.

Remark 11. Now we consider what happens if r is allowed to grow with n. In step 3 of the preprocessing phase we now need the number of variables m to be $\Theta(dn^{1-s})$, where the degree $d = 2r + 1$. Step 4 takes $(r + 1)tm^{O(d)}\text{poly}(\log p)$ time, which is $\text{poly}(n, d^d)$. This step is still efficient provided that $d = O\big(\frac{\log n}{\log \log n}\big)$.

However, in the protocol the communication is now $\Theta((tm+m^r) \log p) = d^{\Theta(d)} n^{1/3}$. This is larger than the desired $O(n^{1/3})$ communication for any superconstant value of d, and thus any superconstant value of r. Similarly, the server work increases by a $d^{\Theta(d)}$ factor. It is an interesting open question to reduce the server work while preserving $O(n^{1/3})$ total communication.

Acknowledgment. Sergey Yekhanin would like to express his deep gratitude to Madhu Sudan for introducing him to the problem and for many helpful discussions during this work.

STABILITY OF MULTIVALUED CONTINUOUS CONSENSUS*

LIOR DAVIDOVITCH†, SHLOMI DOLEV†, AND SERGIO RAJSBAUM‡

Abstract. Multivalued consensus functions defined from a vector of inputs over the set V of possible input values (and possibly from the previous input and output values) to a single output are investigated. The consensus functions are designed to tolerate t faulty inputs. Two classes of multivalued consensus functions are defined, the *exact value* and the *range value*, which require the output to be one of the nonfaulty inputs or in the range of the nonfaulty inputs, respectively. The *instability* of consensus functions is examined, counting the maximal number of output changes along a geodesic path of input changes, a path in which each input is changed at most once. Lower and upper bounds for the instability of multivalued consensus functions as a function of n, the number of sensors, t, and $|V|$ are presented. A new technique for obtaining such lower bounds, using edgewise simplex subdivision, is presented.

Key words. consensus, stability

1. Introduction.

The interest in sensor networks and the way they may control the behavior of a system, such as a vehicle, airplane, satellite, or other device, is rapidly growing. The *agreement* functions used to ensure smooth and stable control while reflecting the changes in the environment are of great interest. An abstraction of many agreement functions is the *consensus* problem, where a set of n processors get input values from some set V and must agree on a value. There is always a nontrivial *validity* requirement that specifies restrictions on the decided value as a function of the input values and the failure pattern of the execution. Consensus is a fundamental problem in distributed computing that has been widely studied for more than two decades due to its theoretical and practical interest (e.g., [2, 7, 14]).

Research on consensus has concentrated on the *one-shot* setting, where processors start with their input values and have to solve consensus once. Often, distributed systems need to solve consensus repeatedly, on inputs received one after the other. Thus, researchers have also investigated *continuous* versions of consensus[1] where processors have to adapt their consensus decisions continuously (e.g., [3, 8, 13]).

Although consensus algorithms are generally associated with distributed systems, this need not necessarily be the case. In fact, it is sufficient that the system has multiple sensors. For instance, typical situations where continuous consensus problems arise are in cases of systems that read values from replicated sensors [12]. A fault-tolerant consensus algorithm is needed to decide on a single reading because sensors

[1] Sometimes called *long-lived* consensus.

usually do not give the exact same reading of a physical parameter, or because some sensors can fail. Although in the simplest version of consensus, which is the one most often considered in theory, the validity requirement is that a decided value must have been read by at least one sensor, in many real settings it is desired that the decided value be a value that has been produced by a majority of the sensors. These and other nontrivial validity requirements are possible, but they all imply that as the readings of the sensors change because the physical parameters that are sampled change, the consensus value will have to change. In the extreme case, all sensors can change their readings from one single value to another, forcing the consensus decision to change accordingly.

Although the consensus value may change several times during the repeated executions of a consensus algorithm, we prefer continuous consensus algorithms that are *stable*, i.e., in which the number of times the decision value is changed is as small as possible. Usually averaging functions are used in an independent way from sample to sample, sometimes combined with agreement protocols (e.g., [15]), and hence there is no attempt to maximize stability. There are several reasons for preferring a stable consensus system (more are described in [8]). Some sensors are discrete and are used to control actuators, which may also be discrete. There is the possible operational amplification of decision changes, say turning an engine on and off. The energy or other resources consumed are sometimes proportional to the number of transitions; e.g., turning an engine on and off takes energy and time, and reduces its lifetime; some related work in VLSI (very large scale integration) is [5, 16]. Our results have an independent purely mathematical interest for analyzing discrete functions over vectors of inputs; they may also be useful for studying problems (e.g., [11]) about the number of influencing variables in Boolean functions.

In [8] we initiated a study of the stability of continuous consensus systems for the case of a binary set V of inputs (i.e., $|V| = 2$). We defined an abstract formalization of a continuous consensus system and the stability measures. This formalization, presented in section 2, is not tied to any specific model of computation, in order to understand the basic stability issues. Moreover, it is also valid for nondistributed consensus systems. We considered *memoryless* systems, where consecutive one-shot consensus executions are independent, versus the stability of systems that can keep memory of previous executions. We also studied the stability of *symmetric* systems, where decisions are taken solely on the basis of the distribution of the different input values, but not on what a specific sensor produced as a particular input value. We characterized the stability of systems according to their memory and symmetry properties, proving tight upper and lower bounds for the various cases.

Results. In this paper we extend the results of [8] to the case of a multivalued set V of inputs (i.e., $|V| \geq 2$). It turns out that this generalization makes all the above variants of the problem much harder. Some of them are much more interesting than those of the binary case; in particular, one of the results here uses topological techniques for high-dimensional complexes.

Let n be the number of sensors, and let t be the number of sensors that may give a wrong value. The validity requirement of [8] is that if fewer than $t + 1$ inputs are equal to a value b, then the consensus value is not b; hence, the decision value is a value of a correct sensor. Another natural validity requirement for a multivalued consensus system is that the decision should be between two correct sensor values. Thus we study the following two classes of systems:

Exact value system (EV): the decision is the value of a correct sensor.

Range value system (RV): the decision is in the range of the correct sensor values.

First we identify the combinations of values of $n, v = |V|, t$ for which systems of these classes exist. We prove that an EV system can be defined if and only if $n \geq vt+1$, and that an RV system can be defined if and only if $n \geq 2t + 1$.

We define the *instability* of a consensus system as the maximal number of changes to the consensus value along any *geodesic path*—a sequence of changes to the input values, where any input value changes at most once. Our choice to examine a geodesic path is motivated by the intuition of condition changes that are monitored by the different sensors. Note that for every (memoryless) consensus algorithm there is an input change that yields an output change, and therefore if the above input is allowed to be changed $k > 1$ times, then obviously the number of changes to the output is at least k. We would like to nullify this phenomenon when we evaluate consensus algorithms, and therefore we choose the geodesic path (see [8] for a further discussion on the motivation of the settings). The instability of a consensus system with memory is analyzed proving that it is n in the cases where n is the smallest possible value, namely $n = vt + 1$, and that the instability may go down until it becomes 1 when $n \geq v^2t+1$. The investigation of the rest of the cases for EV systems results in bounds for a range of stability values as a function of n, v, and t.

Lower bounds on the instability of memoryless systems are obtained for symmetric functions. The lower bounds are achieved using a technique to subdivide a simplex from [9] and Sperner's lemma. This can be seen as a generalization of Lemma 2 in [10]: In the one-dimensional case, the input values may be ordered in a line from one extreme to the other, where two consecutive input vectors differ in exactly one input. In the case of several dimensions, the border between the different extreme values is a simplex. We also present an upper bound for a memoryless symmetric system [6], which is about a factor of 2 away from our lower bound. An interesting open question is how to close this gap.

Organization. The rest of the paper is organized as follows. In the next section, we define the system settings and the problem definitions. The case of systems with memory is addressed in section 3. Memoryless systems are considered in section 4.

2. The model. We start with a definition of a multivalued continuous consensus system which extends the definitions for the binary case of [8]. See [8] for a detailed discussion of the motivation of this system, and for applications to specific distributed computing models. Briefly, the system captures a situation where a system (which may be distributed, but not necessarily) gets inputs from sensors, runs some consensus algorithm to agree on one of the sensors' values, gets another vector of sensor values, runs a consensus algorithm on them, and so on. We consider only the state of the system at the beginning of each such round, i.e., when it gets inputs from the sensors. Also, we consider the value decided by the consensus algorithm at the end of each one of these phases. We are not interested in the details of how the consensus algorithm works. Our goal is to find the minimum number of decision value changes that the algorithm will make over the repeated invocations of the consensus algorithm. Thus, we assume that the consensus algorithm decides the same value in every execution starting in the same state and with the same vector of sensor values.

We will use the following notation. Consider a set $V = \{0, 1, \ldots, v-1\}$ of possible sensor values, and an integer $n > 0$ representing the number of sensors. Then $\vec{x}$ is a vector of n values from V, i.e., in V^n. Also, $\vec{x}\,[i]$ is the ith element of $\vec{x}$. We denote the ith vector in a sequence of vectors by $\vec{x}_i$. Thus, $\vec{x}_i\,[j]$ stands for the jth element of the ith vector in a series of vectors. For a vector $\vec{x}$, $\#b(\vec{x})$ is the number of entries of $\vec{x}$ that are equal to b.

2.1. Continuous consensus systems and instability. A multivalued *continuous consensus system* D, called for short a *system*, is defined by a 6-tuple, D $= \langle n, v, t, S, \tau, f\rangle$, where

- $n > 1$ is an integer representing the number of sensors;
- $v > 1$ is an integer specifying the size of the set V of valid sensors' inputs, $V = \{0, 1, \ldots, v-1\}$;
- $t \geq 0$ is a fault tolerance integer parameter;
- S is a set of *states*, which includes a special *initial state*, s_0;
- τ is a transition function, $\tau : V^n \times S \to S$;
- f is a *decision* function $f : V^n \times S \to V$ such that $f(\vec{x}, s)$ is equal to one of the entries of $\vec{x}$, for every $s \in S$.

An *input vector* is any vector $\vec{x} \in V^n$. Any sequence of input vectors, $\vec{x}_0, \vec{x}_1, \vec{x}_2, \ldots$, induces a unique *execution* of the system, $(\vec{x}_0, s_0) \to (\vec{x}_1, s_1) \to (\vec{x}_2, s_2) \to \cdots$, where for every i, $s_{i+1} = \tau(\vec{x}_i, s_i)$. The *ith output* for the execution is $f(\vec{x}_i, s_i)$. Note that the sequence of input vectors uniquely determines a sequence of output values, $f(\vec{x}_0, s_0), f(\vec{x}_1, s_1), \ldots$.

We use the term *path* for a sequence of input vectors $\vec{x}_0, \vec{x}_1, \ldots$. A component k *changes in the path* if the path contains two vectors $\vec{x}_i, \vec{x}_j$ which differ in their kth components, i.e., such that $\vec{x}_i[k] \neq \vec{x}_j[k]$. A *geodesic path* is a path in which each component k changes at most once. For simplicity, we shall assume, w.l.o.g., that in every step of a geodesic path exactly one input value will be changed. Notice that a geodesic path can be of length at most n, since the vectors of the geodesic paths we consider in this paper are of dimension n.

Definition 2.1. *The* instability *of the system* D *is the largest number of decision changes for any* geodesic *input path.*

The fault-tolerant parameter t represents the largest number of input values in a vector $\vec{x}$ that may be wrong. It is desirable that the decision function f choose an input value that is not wrong. If we require that the value b decided by f in $\vec{x}$ appear at least $t+1$ in $\vec{x}$, then b is certainly not wrong. A system satisfying this requirement is denoted EV, formally, as follows.

Definition 2.2 (exact value system). *A system* D *is* exact value *if for any input vector $\vec{x}$ and any system state s, if $f(\vec{x}, s) = b$, then $\#b(\vec{x}) \geq t+1$.*

This is the natural generalization to the requirement of the binary case [8]. In the case of a multivalued consensus system, we may consider also a different requirement: that if the value b is decided by f, then there are at least $t+1$ values greater than or equal to b in $\vec{x}$ and at least $t+1$ values less than or equal to b in $\vec{x}$. Hence, the decided value is between two correct values; i.e., there are at least *two* sensors, p_i and p_j, such that their inputs, $\vec{x}[i]$ and $\vec{x}[j]$, satisfy $\vec{x}[i] \leq b \leq \vec{x}[j]$. Such a system is denoted RV, as follows.

Definition 2.3 (range value system). *A system* D *is* range value *if for any input vector $\vec{x}$ and any system state s, if $f(\vec{x}, s) = b$, then $\sum_{b' \geq b} \#b'(\vec{x}) \geq t+1$ and $\sum_{b' \leq b} \#b'(\vec{x}) \geq t+1$.*

These constraints ensure that if b is the consensus value, then there are at least two nonfaulty sensors, p_i and p_j, such that their inputs, $\vec{x}[i]$ and $\vec{x}[j]$, satisfy $\vec{x}[i] \leq b \leq \vec{x}[j]$. We use RV to denote a range value consensus system.

Note that any EV system is also an RV system. For binary input systems (where $|V| = 2$), an RV system is also an EV system.

2.2. The scope for exact and range value systems. Before we continue describing our results, we need to describe the combination of the parameters n, v, and t for which an exact or a range value system exists. First we show that for any n, v, t for which $n \geq vt+1$, an exact value system can be defined, and for every such defined EV it holds that $n \geq vt+1$. This result generalizes the binary case of [8], in which the analogous condition is $n \geq 2t+1$.

LEMMA 2.4. *An exact value system* EV *can be defined if and only if $n \geq vt+1$.*

Proof. Consider an exact value system EV $= \langle n, v, t, S, \tau, f\rangle$, and assume for contradiction that $n \leq vt$. Then there exists a vector $\vec{x} = 0^{\alpha_0}1^{\alpha_1}\cdots(v-1)^{\alpha_{v-1}}$, with $\alpha_i \leq t$ for every i, since $n \leq vt$; that is, $\#b(\vec{x}) < t+1$ for every $b \in V$. Taking $\vec{x}$ as the first input vector of a path to EV, Definition 2.2 of an exact value system requires that $f(\vec{x}, s_0)$ be equal to some value b with $\#b(\vec{x}) \geq t+1$, a contradiction.

Now, assume that $n \geq vt+1$. Then, every input vector $\vec{x}$ must have at least one value b with $\#b(\vec{x}) \geq t+1$ (otherwise $n \leq vt$). Define an exact value system EV $= \langle n, v, t, S, \tau, f\rangle$ with $S = \{0\}$, $\tau(\cdot, 0) = 0$, and f choosing such a value b, e.g., $f(\vec{x}, 0) = b$ such that b is the smallest value with $\#b(\vec{x}) \geq t+1$. □

For range value systems, RV must satisfy $n \geq 2t+1$, and if $n \geq 2t+1$, then an RV system can be defined, as follows.

LEMMA 2.5. *A range value system* RV *can be defined if and only if $n \geq 2t+1$, with $v > 1$.*

Proof. Consider a range value system RV $= \langle n, v, t, S, \tau, f\rangle$, and assume for contradiction that $n \leq 2t$. Consider the input vector $\vec{x} = 0^t1^{n-t}$. For any $b \in \{0, 1, \ldots, v-1\}$, either $\sum_{b' \geq b} \#b'(\vec{x}) < t+1$ or $\sum_{b' \leq b} \#b'(\vec{x}) < t+1$. Taking $\vec{x}$ as the first input vector of a path to RV, Definition 2.3 of a range value system requires that $f(\vec{x}, s_0)$ be equal to some value b with $\sum_{b' \geq b} \#b'(\vec{x}) \geq t+1$ and $\sum_{b' \leq b} \#b'(\vec{x}) \geq t+1$, a contradiction.

Now, assume that $n \geq 2t+1$. Then, every input vector $\vec{x}$ has a value b such that $\sum_{b' \geq b} \#b'(\vec{x}) \geq t+1$ and $\sum_{b' \leq b} \#b'(\vec{x}) \geq t+1$. To see this consider the distribution of values of $\vec{x}$, $\#i(\vec{x}) = \alpha_i$, for $0 \leq i \leq v-1$, and let $\vec{y}$ be the lexicographically ordered input values of $\vec{x}$:

$$\vec{y} = 0^{\alpha_0}1^{\alpha_1}\cdots(v-1)^{\alpha_{v-1}}.$$

Then, if b is the value in the middle of this sequence, meaning $b = \vec{y}[\lceil \frac{n}{2} \rceil]$, we get the desired property $\sum_{b' \geq b} \#b'(\vec{x}) \geq t+1$ and $\sum_{b' \leq b} \#b'(\vec{x}) \geq t+1$, since $n \geq 2t+1$. And we can define an exact value system EV $= \langle n, v, t, S, \tau, f\rangle$ with $S = \{0\}$, $\tau(\cdot, 0) = 0$, and f, choosing a value b, so that $f(\vec{x}, 0) = b$. □

3. Stability of systems with memory.

In section 3.1 we study the instability of an EV or RV system with the minimal number of sensors according to Lemmas 2.4 and 2.5. We also show that when the number of sensors is big enough, an EV system can be defined whose instability is 1. The case of a general n is considered in section 3.2. Then, in section 4, we study a system that cannot keep any memory from previous input vectors, and from its previous decisions.

It is convenient to visualize the input vector $\vec{x}$ as a bar chart, where every bar relates to a possible input value b, and the height of that bar is $\#b\,(\vec{x})$. By definition, an input value may be the consensus value of an EV system only if the height of the bar is at least $t+1$. This is exemplified in Figure 3.1.

3.1. The extreme cases of n.

We will first consider the extreme case in which n is the minimal possible number of sensors: $vt+1$ for EV systems, as shown in Lemma 2.4, and $2t+1$ for RV systems, as shown in Lemma 2.5. We prove that the instability of the system in this case is n; that is, it is possible to force any system to

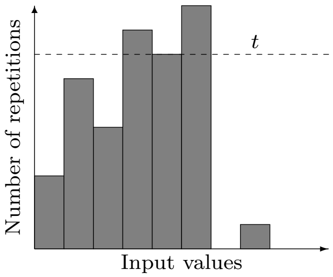

FIG. 3.1. *A visualization of the input vector as a bar chart—every bar represents an input value, and its height is the number of repetitions of that value within the input vector. The dashed line represents height of* t*. Notice that only two input values are a valid consensus value.*

change its decision with each input change. The second extremum is where n is very large. In Lemma 3.4 we will show that when n is large enough, we can build an EV system that changes its decision only once.

LEMMA 3.1. *For every* EV *system* D *with* $n = vt + 1$*, instability*(D) $= vt + 1$.

Proof. Obviously *instability*(D) $\leq n = vt+1$, since any geodesic path is of length at most n, and hence at most n decision value changes can occur.

To prove that *instability*(D) $= n = vt + 1$, we construct a geodesic path of length $vt + 1$ that produces $vt + 1$ changes in system D. We will start with the input vector $\vec{x}_0 = (01 \dots (v-1))^t 0$, and to get $\vec{x}_{i+1}$, switch the input value of the $(i + 1)$th sensor from i mod v to $i + 1$ mod v. The geodesic path can be illustrated as follows:

$$\begin{array}{ll}
(012\dots(v-2)(v-1))^1(012\dots(v-1))^{t-1}0 & \to \\
(112\dots(v-2)(v-1))^1(012\dots(v-1))^{t-1}0 & \to \\
(122\dots(v-2)(v-1))^1(012\dots(v-1))^{t-1}0 & \to \\
(123\dots(v-2)(v-1))^1(012\dots(v-1))^{t-1}0 & \to \\
\dots & \to \\
(123\dots(v-1)(v-1))^1(012\dots(v-1))^{t-1}0 & \to \\
(123\dots(v-1)0)^1(01\dots(v-1))^{t-1}0 & \to \\
\dots & \to \\
(123\dots(v-1)0)^2(01\dots(v-1))^{t-2}0 & \to \\
\dots & \to \\
(123\dots(v-1)0)^t0 & \to \\
(123\dots(v-1)0)^t1. &
\end{array}$$

Notice that $\#b(\vec{x_0}) = t$ for $b \neq 0$ and $\#0(\vec{x_0}) = t + 1$. Since the only input value that appears more than t times is 0, the consensus value must be 0. In general, a simple induction shows that $\#b(\vec{x}_i) = t$ for $b \neq i$ mod v and $\#b(\vec{x}_i) = t + 1$ for $b = i$ mod v. Therefore, the consensus value in $\vec{x}_i$ is i mod v, and there is a consensus value change with each new input vector; i.e., *instability*(D) $= n$. □

The previous result generalizes the result in [8], where it was proved that when $n = 2t + 1$ and $v = 2$ the instability of the system is n.

LEMMA 3.2. *For every* RV *system* D *with* $n = 2t+1$ *and any* $v \geq 2$*, instability*(D) $= 2t + 1$.

Proof. Consider the system D over the restricted set of input values $\{0, 1\} \subseteq V$. When restricted to binary input values, any RV system is also an EV system. Since here $n = 2t + 1$, then by Lemma 3.1 *instability*(D) $= 2t + 1$. □

It is easy to see that, for any EV system D with $v > 1$, there is a geodesic path that forces it to make at least one decision change. This, actually, holds for any continuous consensus system D, as follows.

LEMMA 3.3. *For every system* D *with* $v > 1$*, it holds that instability*(D) ≥ 1.

Proof. Consider a geodesic path starting in $\vec{x}_0 = 0^n$ and ending in $\vec{x}_n = 1^n$ obtained by switching one value at a time from 0 to 1. By the definition of a continuous consensus system, $f(\vec{x}_0, s_0) \in \{\vec{x}[i] \mid 1 \leq i \leq n\} = \{0\}$, and therefore $f(\vec{x}_0, s_0) = 0$. For symmetric reasons $f(\vec{x}_n, s_n) = 1$. Thus, there is at least one change to the consensus value. □

In Lemma 3.1 we considered the instability of an EV system for the smallest possible value of n, namely $n = vt + 1$ (Lemma 2.4 proved that this is the smallest value), and showed that the instability is the largest possible, namely n. There is no upper bound for the number of sensors, since for every $n \geq vt + 1$ there exists an exact value system. However, we prove next that for $n \geq v^2 t + 1$ there exists a system with the smallest possible instability, namely 1, matching the trivial lower bound of Lemma 3.3. To prove it, we describe a simple system, MS. Also, we show that for $n < v^2 t + 1$ no system can achieve an instability of 1.

For its initial state, the system MS decides on the most frequent value in $\vec{x}_0$. The system MS remembers in its state its last consensus value, c, and a vector $\vec{h}$ that records in $\vec{h}[b]$, for each $b \in V$, how many times an input value has switched to b. Then, MS will keep its previous decision, c, unless forced to change; that is, it will change decision only if $\#c(\vec{x}) = t$ in the current input vector $\vec{x}$. In this case, if there is a value b such that $\vec{h}[b] \geq t + 1$, it will decide b, since then no more changes will occur. Otherwise, it will decide on the most frequent value in $\vec{x}$ (if there is more than one most frequent value, it will decide on the smallest one).

To compute $\vec{h}$ the system must remember also the previous input vector; actually it must remember only the multiplicity of each input value in the previous input vector, and not the position in the vector of each value. Thus, for a vector $\vec{x}$, let $bar(\vec{x})$ be the vector of dimension v such that $bar(\vec{x})[b]$ is equal to the number of times $\vec{x}[i] = b$, over $1 \leq i \leq n$. This is illustrated in Figure 3.1. Therefore, the current state is of the form $\tilde{s} = \{bar(\vec{x}_{prev}), c, \vec{h}\}$. For example, if the current state is $\tilde{s} = \{(4, 5, 1), 1, (2, 0, 1)\}$, then the input vector contains four inputs with value 0, five inputs with value 1, and one input with value 2; the consensus value is 1; and two input values were changed to 0 and one input to 2 in the input path $\vec{x}_0 \to \vec{x}_1 \to \vec{x}_2 \to \vec{x}_3$ (since there have been three changes to the input values, the path is of length 3). Formally, the system is defined as follows, where $\tilde{s} = \{bar(\vec{x}_{prev}), c, \vec{h}\}$:

$$f(\vec{x}, \tilde{s}) = \begin{cases} \operatorname{maxarg}_{b \in V} \{\#b(\vec{x})\} & \text{if } \tilde{s} = s_0, \\ \begin{cases} \operatorname{maxarg}_{b \in V} \left\{\vec{h}[b]\right\} & \text{if } \exists b,\ \vec{h}[b] \geq t+1, \\ \operatorname{maxarg}_{b \in V} \{\#b(\vec{x})\} & \text{otherwise,} \end{cases} & \\ & \text{if } \#c(\vec{x}) \leq t, \\ c & \text{if } \#c(\vec{x}) \geq t+1, \end{cases}$$

$$\tau(\vec{x}, \tilde{s}) = \begin{cases} \{bar(\vec{x}), f(\vec{x}, \tilde{s}), (0, \dots, 0)\} & \text{if } \tilde{s} = s_0, \\ \left\{bar(\vec{x}), f(\vec{x}, \tilde{s}), \vec{h} + \sum_{b=0}^{v-1} \vec{\delta}_b \max\{0, bar(\vec{x})[b] - bar(\vec{x}_{prev})[b]\}\right\} & \\ & \text{otherwise,} \end{cases}$$

where

$$\vec{\delta}_m[k] = \begin{cases} 1, & m = k, \\ 0, & m \neq k, \end{cases}$$

$$\operatorname*{maxarg}_{b\in V}\{g(b)\} = \min\{b \mid b \in V,\, g(b) = \max\{g(b) \mid b \in V\}\}\,.$$

This system is a generalization of the system BP, described in [8]. We will prove that for a large enough number of sensors, the instability of this system is 1.

LEMMA 3.4. *When $n \geq v^2t+1$, instability*(MS) $= 1$.

Proof. Lemma 3.3 implies that *instability*(MS) ≥ 1. Therefore, we will prove that *instability*(MS) ≤ 1 when $n \geq v^2t+1$. We will do so by proving that MS changes value at most once in any geodesic path.

Consider any geodesic path $\vec{x}_0 \to \vec{x}_1 \to \cdots$. We already know that for some value b_0, $\#b_0(\vec{x}_0) \geq vt+1$; otherwise for every $b \in V$, $\#b(\vec{x}_0) \leq vt$ and $n \leq v^2t$, a contradiction. Now, assume that b_0 is the one which appears the largest number of times in $\vec{x}_0$. In particular, $\#b_0(\vec{x}_0) \geq vt+1$. Then, $f(\vec{x}_0, s_0) = b_0$. Notice that f will not change its decision before it gets an input vector with t entries equal to b_0. Consider the first time this happens (otherwise no consensus value changes occur, and we are done), say in $\vec{x}_i$. It follows that at least $(v-1)t+1$ entries equal to b_0 have changed to other values, in $\vec{x}_0 \to \vec{x}_1 \to \cdots \to \vec{x}_i$, since $\#b_0(\vec{x}_i) = t$ and $\#b_0(\vec{x}_0) \geq vt+1$. Each time a value changes from b_0 to some other value, b, one unit is added to $\vec{h}[b]$. Therefore, after $(v-1)t+1$ entries equal to b_0 have changed to other values, at least one entry of $\vec{h}$, say c, gets incremented at least $t+1$ times (there are $v-1$ values different from b_0); that is, $\vec{h}[c] \geq t+1$ at the end of the path $\vec{x}_0 \to \vec{x}_1 \to \cdots \to \vec{x}_i$. Then f will decide on such a value c with $\vec{h}[c] \geq t+1$. No more decision changes will occur, because there are $t+1$ entries in the input vector that are equal to c and have already changed value in the past, and the path is geodesic. □

3.2. The general case. We will call a vector such as $\vec{h}$ in the system MS an *accumulator vector*. Notice that for any geodesic input path P we can define an accumulator vector associated with each of the vectors of P. The accumulator records the number of times each value has been changed. That is, initially $\vec{h} = 0^v$, and if one input bit changes from some value b to b', then $\vec{h}[b']$ is incremented by 1. Thus, an accumulator vector is independent of the EV system used and is defined even if the system does not actually use it; it is just a device that we use to reason about the system. The following lemma captures the importance of $\vec{h}$, and it will be useful for proving lower bounds. Here by *optimal* we mean that the system delays a change to the consensus value while possible. More formally, if the consensus value is b, then an optimal system will not change the consensus value until $\#b(\vec{x}) \leq t$. Notice that for any nonoptimal system D there exists an optimal system D$'$ which holds *instability*(D$'$) $\leq$ *instability*(D), i.e., a system which behaves exactly like D except for delaying a change to the consensus value.

LEMMA 3.5. *Let* D *be an optimal* EV *system. Consider an input vector $\vec{x}$ at the end of a geodesic input path P, and the corresponding vector $\vec{h}$. Assume that the consensus value in $\vec{x}$ is b. There is a geodesic path extending P that causes at least one consensus change to* D *if and only if $\vec{h}[b] \leq t$.*

Proof. If $\vec{h}[b] \leq t$, then at most t entries of $\vec{x}$ that are equal to b have already changed in P. The total number of entries equal to b is $\#b(\vec{x}) \geq t+1$, since b is the decision in $\vec{x}$. So we can extend P by switching one by one entries that are equal to b to some other value until we get an input vector $\vec{x}_1$ with $\#b(\vec{x}_1) = t$, and at some point during this path the decision will have to change.

If there is a geodesic path extending P that causes at least one consensus change to D, then clearly $\vec{h}[b] \leq t$, because otherwise at least $t+1$ entries of $\vec{x}$ that are equal to b have already changed in P, and hence a vector $\vec{x}_1$ in any geodesic extension to

P will have $\#b(\vec{x}_1) \geq t+1$, and D does not need to change its decision ever (since it is optimal). ◻

LEMMA 3.6. *For any* EV *system* D, *if* $n \leq v^2 t$, *then instability*(D) ≥ 2.

Proof. We prove that for any exact value system D there is a geodesic path that causes two decision changes. Let $\vec{x}_0 = 0^{\alpha_0} 1^{\alpha_1} \cdots b_i^{\alpha_i} \cdots (v-1)^{\alpha_{v-1}}$, with $\alpha_i \leq vt$ for all $0 \leq i \leq v-1$. Assume $f(\vec{x}_0, s_0) = b_j$ for some j. Then we produce a geodesic path starting in $\vec{x}_0$, by switching one by one $\alpha_j - t \leq (v-1)t$ inputs that are equal to b_j to other values, in a round-robin manner (first to 0, then to 1, ..., then to $v-1$, then to 0, and so on). Eventually, a decision change must occur, at the latest when there are only t entries equal to b_j. Let us call $\vec{x}_{l_1}$ the input vector when a decision change occurs for the first time, and $\vec{h}_{l_1}$ the corresponding accumulator. Then,

$$bar(\vec{x}_{l_1}) = (\alpha_0 + \beta_0, \alpha_1 + \beta_1, \ldots, t + \Delta, \ldots, \alpha_{v-1} + \beta_{v-1}),$$

$$\vec{h}_{l_1} = (\beta_0, \beta_1, \ldots, 0, \ldots, \beta_{v-1}),$$

where $\sum_{i=0,\, i \neq j}^{v-1} \beta_i \leq \alpha_j - t$ and $\Delta \geq 0$. It follows from Lemma 3.5 that whatever the consensus decision is in $\vec{x}_{l_1}$, say b_k ($\neq b_j$), we can continue changing input values, from b_k to other values until we get an input vector with t entries equal to b_k, and force one more decision change. This is since $\vec{h}_{l_1}[k] = \beta_k \leq \lceil \frac{\alpha_j - t}{v-1} \rceil \leq t$. ◻

A concept similar to the accumulator vector is the *consensus accumulator vector*. Such a vector holds for each input value b the number of input values changed *from a consensus value* to b. Notice that if $\vec{h}$ is an accumulator vector and $\vec{\bar{h}}$ is a consensus accumulator vector of the same path, then for any b it holds that $\vec{\bar{h}}[b] \leq \vec{h}[b]$.

We now prove our main upper bound result for EV systems with memory. For any vector $\vec{y}$, define $|\vec{y}|$ to be the $\sum_i \vec{y}[i]$, and $\max \vec{y}$ to be $\max_i \vec{y}[i]$. We will use the fact that $|\vec{h}| \geq vt+1$ implies $\max \vec{h} \geq t+1$, and then apply Lemma 3.5.

LEMMA 3.7. *Let* $x = \lceil \frac{n-vt}{v-1} \rceil$ *and* $y = \lceil \frac{n-vt}{v} \rceil$. *Then instability*(MS) $\leq \lfloor \frac{vt-y}{x} \rfloor + 2$.

Proof. Consider a geodesic path $P = \vec{x}_0 \to \vec{x}_1 \to \cdots$. We will first claim that $\max bar(\vec{x}_0) \geq y+t$. Otherwise,

$$n = |bar(\vec{x}_0)| = \sum_{b \in V} bar(\vec{x}_0)[b] \leq v(y+t-1) = v\left(\left\lceil \frac{n-vt}{v} \right\rceil - 1\right) + vt < (n-vt) + vt = n.$$

Therefore, MS will decide in $\vec{x}_0$ on a value b such that $bar(\vec{x}_0)[b] \geq y+t$. Let $\vec{x}_{i_1}$ be the first vector in P where MS changes its decision, and $\vec{\bar{h}}_{i_1}$ the corresponding consensus accumulator. Since MS changes its decision when only t entries are equal to b, it follows that at least y inputs must have changed to get to $\vec{x}_{i_1}$. That is,

$$|\vec{\bar{h}}_{i_1}| \geq y.$$

We will now claim that $\max bar(\vec{x}_{i_1}) \geq x+t$. Otherwise, since $\#b(\vec{x}_{i_1}) = t$, then

$$\begin{aligned} n = |bar(\vec{x}_{i_1})| &= \sum_{b' \in V} bar(\vec{x}_{i_1})[b'] \leq t + (v-1)(x+t-1) \\ &= t + (v-1)\left(\left\lceil \frac{n-vt}{v-1} \right\rceil + t - 1\right) \\ &< t + (n-vt) + (v-1)t = n. \end{aligned}$$

In general, consider the sequence of input vectors at which the subsequent consensus value changes occur, $\vec{x}_{i_2}, \vec{x}_{i_3}, \ldots$, with the corresponding consensus accumulators,

$\vec{h}_{i_2}, \vec{h}_{i_3}, \ldots$. Notice that in each such vector $\vec{x}_{i_j}$ there is at least one value b such that $\#b(\vec{x}_{i_j}) = t$, namely, b is the consensus value in $\vec{x}_{i_{j-1}}$. Thus, $\max bar(\vec{x}_{i_j}) \geq x + t$, and hence MS will decide on a value d in $\vec{x}_{i_j}$ such that $bar(\vec{x}_{i_j})[d] \geq x + t$. Thus, at least x entries equal to d must change to get to $\vec{x}_{i_{j+1}}$:

$$|\vec{h}_{i_{j+1}}| \geq |\vec{h}_{i_j}| + x \geq y + jx,$$

$$\max bar(\vec{x}_{i_j}) \geq x + t.$$

For any j, let b_j denote the consensus value at $\vec{x}_{i_j}$. Let $\vec{h}_{i_{c+1}}$ be the consensus accumulator vector after the last change to the consensus value, and let $\vec{h}_{i_c}$ be the consensus accumulator after the *previous* consensus change. If there is a value $b \in V$ for which $\vec{h}_{i_c}[b] > t$, then by the definition of MS the consensus value would change to such a value, and by Lemma 3.5 there would not be a change of the consensus value from b_c to b_{c+1}. Therefore, for all $b \in V$, $\vec{h}_{i_c}[b] > t$, and so $|\vec{h}_{i_c}| \leq vt$.

Since

$$y + (c-1)x \leq |\vec{h}_{i_c}| \leq |\vec{h}_{i_c}| \leq vt$$

we have that

$$c \leq \left\lfloor \frac{vt - y}{x} \right\rfloor + 1.$$

Thus the total number of consensus changes is at most $c + 1$ (one change from $\vec{x}_0$ to $\vec{x}_{i_1}$, and c changes after that), and we get the desired result *instability*(MS) $\leq \lfloor \frac{vt-y}{x} \rfloor + 2$. □

Consider the extreme cases for the previous lemma. First, let $n = v^2 t$, so we have $x = vt$ and $y = t(v-1)$. We get *instability*(MS) $\leq \lfloor \frac{vt - t(v-1)}{vt} \rfloor + 2$, and hence *instability*(MS) $\leq \lfloor \frac{1}{v} \rfloor + 2 = 2$, which matches the lower bound of Lemma 3.6. Second, let $n = vt + 1$, so we have $x = 1$, $y = 1$. We get *instability*(MS) $\leq \lfloor \frac{vt-1}{1} \rfloor + 2 = vt + 1$, which matches the lower bound of Lemma 3.1.

Summarizing the stability results for EV. The next theorem summarizes the results obtained for EV systems with memory. Let *instability*(EV) denote the smallest instability over all EV systems.

THEOREM 3.8.

1. *When* $vt + 1 < n < v^2 t$, *instability*(EV) $\leq \lfloor \frac{vt-y}{x} \rfloor + 2$, *where* $x = \lceil \frac{n-vt}{v-1} \rceil$ *and* $y = \lceil \frac{n-vt}{v} \rceil$.
2. *Otherwise,*

$$\textit{instability}\,(\text{EV}) = \begin{cases} vt+1 & \textit{if } n = vt+1, \\ 2 & \textit{if } n = v^2 t, \\ 1 & \textit{if } n \geq v^2 t + 1. \end{cases}$$

4. Stability of symmetric memoryless systems. In this section we turn to investigating the case in which no memory is kept by the system from previous input vectors and from previous decisions; that is, we assume a *memoryless* system D $= \langle n, v, t, S, \tau, f \rangle$, where $S = \{s_0\}$. Hence instead of $f(\vec{x}, s_0)$ we simply write $f(\vec{x})$ for any input vector $\vec{x}$. Furthermore, we assume that the system is *symmetric*, meaning that the decision function is oblivious to the order of the input values; i.e., for any two input vectors $\vec{x}, \vec{y}$, $bar(\vec{x}) = bar(\vec{y})$ implies $f(\vec{x}) = f(\vec{y})$. Thus, f is a function of just $\#i(\vec{x})$ for every $i \in V$. We study in this section the corresponding function $\tilde{f}$ defined on the set A,

$$A = \{(\alpha_0, \alpha_1, \ldots, \alpha_{v-1}) \mid \alpha_i \in \mathbb{N} \cup \{0\},\ \alpha_0 + \alpha_1 + \cdots + \alpha_{v-1} = n\}\,.$$

We also define $\tilde{f} : A \to V$ in terms of f as follows:

$$\tilde{f}(\alpha_0, \alpha_1, \ldots, \alpha_{v-1}) = f(0^{\alpha_0} 1^{\alpha_1} \cdots (v-1)^{\alpha_{v-1}}).$$

4.1. Overview of the lower bound. The lower bound proof is a generalization of the one in [10], from dimension 1 to higher dimensions. The proof uses Sperner's lemma, a well-known result that generalizes the graph connectivity notion to higher dimensions. See, e.g., [4] for a proof, and see, e.g., [1] for a recent application to distributed computing.

In dimension 1, Sperner's lemma says that if the vertices of a path are colored with $0, 1$, with 0 coloring one end-vertex and 1 coloring the other, then at least one edge will have its two vertices colored with different colors. More generally, if the vertices of a connected graph are colored with 0, 1 such that at least one vertex is colored with 0 and at least one vertex is colored with 1, then at least one edge of the graph will have its two vertices colored with different colors.

In general, a *k-simplex* is a set of $k+1$ vertices; the *dimension* k of the simplex is equal to its number of vertices minus one. For $j \leq k$, a j-face of a k-simplex is a subset of $j+1$ of its vertices. A 0-face is just a vertex. A *complex* is a set of simplexes closed under containment. It is often convenient to assume that these vertices are points in space and that the simplex is the convex hull of these points. A *subdivision* of a simplex is a partition of the simplex into simplices, such that the union of the dividing simplices equals the original simplex, and any two dividing simplices intersect at most in a common face. A *Sperner coloring* of a subdivided k-simplex $\mathcal{S}$ is an assignment of colors $\{0, \ldots, k\}$ to its vertices such that the $k+1$ corners are assigned the $k+1$ distinct colors, and the vertices in the subdivision of a face of $\mathcal{S}$ are assigned colors from the corners of that face.

In our proof we put the input vectors of A in a space of dimension v. The input vectors in which one component is n and all the rest are zero form a simplex, in fact a $(v-1)$-simplex. The points corresponding to all other input vectors are convex combinations of the above vertices and therefore reside within the simplex. We use Sperner's lemma to conclude that there is a dividing simplex such that its v vertices have v distinct decision values.

There are several ways to define such a subdivision, and fortunately we found in [9] a subdivision that serves us well, in that for every dividing subsimplex of dimension $v-1$ there is a geodesic path of length vt whose input vectors correspond to the vertices of the subsimplex. In particular, we have such a path in the dividing simplex that has different function values for each of its vertices.

We illustrate the instability lower bound for the case of $v = 3$. This should give the reader a more intuitive view of the general proof.

When $v = 3$, the set A can be used as vertices of a subdivision of a 2-simplex—or, in other words, a solid flat triangle. This triangle can be divided into subsimplices (subtriangles) such that the vertices of a subtriangle represent input vectors that are adjacent, in the sense that they can result from each other by a change of a single input value. The vertices will be colored by the consensus value of a given input vector, and using Sperner's lemma, we will find a subtriangle for which the colors of

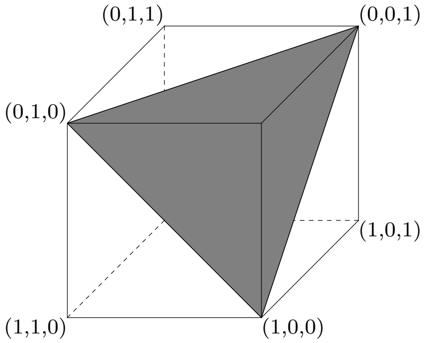

FIG. 4.1. *A* 2*-simplex defined over* $(1,0,0)$*,* $(0,1,0)$*, and* $(0,0,1)$*.*

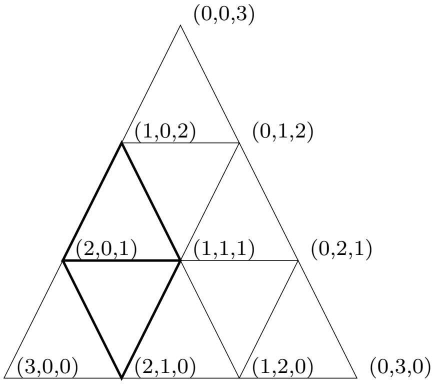

FIG. 4.2. *Subdivision of a* 2*-simplex—the emphasized subsimplices represent the two types of subsimplices.*

its vertices are pairwise different. This subtriangle will imply a geodesic path with $3t+1$ changes to the consensus value.

LEMMA 4.1. *Let* D *be a symmetric memoryless* EV *system with* $v = 3$*. Then* *instability*(D) $\geq 3t+1$.

Proof. Every point of A is in the 2-simplex $\mathcal{S}$, defined by the vectors $(n,0,0)$, $(0,n,0)$, and $(0,0,n)$. A k-simplex is defined by $k+1$ linearly independent vectors, $\vec{v}_0,\ldots,\vec{v}_k$, and is defined as $\left\{\vec{x} = \sum_{i=0}^{k} \lambda_i \vec{v}_i \;\middle|\; \lambda_i \geq 0,\ \sum_{i=0}^{k} \lambda_i = 1\right\}$. Figure 4.1 describes a 2-simplex.

We will use the points of A to subdivide $\mathcal{S}$. Every subsimplex in the subdivision will be defined by $\vec{a}_0, \vec{a}_1, \vec{a}_2 \in A$, where either $\vec{a}_0-(1,0,0) = \vec{a}_1-(0,1,0) = \vec{a}_2-(0,0,1)$ or $\vec{a}_0+(1,0,0) = \vec{a}_1+(0,1,0) = \vec{a}_2+(0,0,1)$. For example, the subsimplex defined by $(2,0,1)$, $(1,1,1)$, and $(1,0,2)$ is of the first type, whereas the simplex defined by $(1,1,1)$, $(2,0,1)$, and $(2,1,0)$ is of the second type (see Figure 4.2). The subdivision that corresponds to the case where $n=3$ is demonstrated in Figure 4.2. We will color every vertex $\vec{a}$ with the color $\tilde{f}(\vec{a})$. Since $\#i(\vec{a}) = 0$ implies that $f(\vec{a}) \neq i$, the coloring is a Sperner coloring, and hence there must exist a subsimplex in the subdivision so that every vertex of the subsimplex is colored by a different color.

Let $\vec{a}_0$, $\vec{a}_1$, and $\vec{a}_2$ be the vertices of that subsimplex. Let j_i be defined by $f(\vec{a}_i) = j_i$, $i = 0,1,2$. Then $\#j_i(\vec{a}_i) > t$. Since the subsimplex is of one of the two types above, for any pair $\vec{a}_k, \vec{a}_l$ we have $\#b(\vec{a}_l) - 1 \leq \#b(\vec{a}_k) \leq \#b(\vec{a}_l) + 1$ for all b.

Hence for every $k, b \in \{0,1,2\}$, $\#b(\vec{a}_k) \geq t$.

We will examine the case where the given subsimplex is of the first type. We say that an input vector $\vec{x}$ *corresponds* to vector $\vec{a} \in A$ if and only if $bar(\vec{x}) = \vec{a}$, namely $\#i(\vec{x}) = \vec{a}[i]$ for any $0 \leq i \leq v-1$. Assume, w.l.o.g., $\vec{a}_0 - (1,0,0) = \vec{a}_1 - (0,1,0) = \vec{a}_2 - (0,0,1)$. Thus, $\vec{a}_0 + (-1,1,0) = \vec{a}_1$, which means that a vector of n input values of the sensors that corresponds to $\vec{a}_1$ can be reached from a vector of n input values of the sensors that corresponds to $\vec{a}_0$ by switching the input value of one sensor from 0 to 1. Generally, if the input vector $\vec{x}$ corresponds to $\vec{a}_i$, then changing the input value of one sensor from i to $(i+1) \bmod 3$ will change the value of the decision function and result in a new input vector that corresponds to $\vec{a}_{(i+1) \bmod 3}$.

Since for any $k, b \in \{0,1,2\}$ it holds that $\#b(\vec{a}_k) \geq t$, then a vector corresponding to $\vec{a}_0$ will be some permutation of $(012)^t\vec{z}$. We can examine a geodesic path which starts with $(012)^t\vec{z}$, which corresponds to $\vec{a}_0$. The path continues for the next $3t$ steps, at every step changing the value of the ith sensor from $i \bmod 3$ into $(i+1) \bmod 3$, thus achieving $3t$ value changes. The path ends with the input vector $(120)^t\vec{z}$. We can continue the geodesic path to $(120)^t k^{n-3t}$, where $f((120)^t\vec{z}) \neq k$, thus yielding $3t+1$ value changes.

The case where the simplex is of the second kind is analogous. □

4.2. Lower bound for memoryless systems. We will now prove that for any EV system D with a symmetric function f, *instability*(D) $\geq vt+1$. To do so, we will use the *edgewise subdivision of a simplex*, defined in [9] (see the appendix for details).

Let $\mathcal{S}$ be a d-simplex, spanned by $\vec{V}_0, \vec{V}_1, \ldots, \vec{V}_d$. An edgewise subdivision is a function that, given an integer k, transforms every point $\vec{X} \in \mathcal{S}$ into a color scheme M, which is defined by a matrix as follows:

$$M = \begin{pmatrix} \chi_{1,0} & \chi_{1,1} & \cdots & \chi_{1,j} \\ \chi_{2,0} & \chi_{2,1} & \cdots & \chi_{2,j} \\ \vdots & \vdots & \ddots & \vdots \\ \chi_{k,0} & \chi_{k,1} & \cdots & \chi_{k,j} \end{pmatrix},$$

where $j \leq d$. Each entry of the matrix is a nonnegative integer from 0 through d, the columns are pairwise different, and the entries appear in nondecreasing order when read like English text:

$$\chi_{1,0} \leq \chi_{1,1} \leq \cdots \leq \chi_{1,j} \leq \chi_{2,0} \leq \cdots \leq \chi_{k,j}.$$

The color scheme defines $j+1$ independent vectors $\vec{V}_0^*, \vec{V}_1^*, \ldots, \vec{V}_j^*$, where $\vec{V}_l^* = \frac{1}{k}\sum_{i=1}^{k} \vec{V}_{\chi_{i,l}}$, which span a j-simplex. By applying the function to every point $\vec{X} \in \mathcal{S}$, we obtain a subdivision of $\mathcal{S}$ into subsimplices, some of which are d-simplices. [9] proves that the above simplices indeed form a subdivision of $\mathcal{S}$, and that every point $\vec{X}$ resides within the simplex it defines.

Recall that

$$\vec{\delta}_m[k] = \begin{cases} 1, & m = k, \\ 0, & m \neq k. \end{cases}$$

LEMMA 4.2. *Let $\mathcal{S}$ be the $(v-1)$-simplex, spanned by $\vec{V}_0, \vec{V}_1, \ldots, \vec{V}_{v-1}$, where $\vec{V}_i = n \cdot \vec{\delta}_i$. Let $\vec{a}$ be a vertex of any $(v-1)$-simplex in the edgewise subdivision of $\mathcal{S}$ using $k = n$. Then for every $0 \leq i \leq v-1$, $\vec{a}[i]$ is an integer. Moreover, $\sum_{i \in V} \vec{a}[i] = n$.*

Proof. Let $\vec{a}$ correspond to a column j in some color scheme M. Then,

$$\vec{a}\left[i\right] = \frac{1}{n}\sum_{l=1}^{n} \vec{V}_{\chi_{l,j}}\left[i\right] = \frac{1}{n}\sum_{l=1}^{n} n \cdot \vec{\delta}_{\chi_{l,j}}\left[i\right] = \sum_{l=1}^{n} \vec{\delta}_{\chi_{l,j}}\left[i\right].$$

Since $\vec{\delta_l}\left[m\right]$ is always an integer, then $\vec{a}\left[i\right]$ is also an integer. Finally,

$$\sum_{i \in V} \vec{a}\left[i\right] = \sum_{i \in V}\sum_{l=1}^{n} \vec{\delta}_{\chi_{l,j}}\left[i\right] = n. \qquad \square$$

Lemma 4.2 implies that for every vertex $\vec{a}$ of a $(v-1)$-simplex of the edgewise n-subdivision of $\mathcal{S}$, $\vec{a} \in A$. We will color every vertex $\vec{a}$ of the subdivision with $\tilde{f}(\vec{a})$. Since it holds that for every $\vec{a} \in A$ such that $\tilde{f}(\vec{a}) = b$, $\#b(\vec{a}) \geq t+1 > 0$, then the coloring is a Sperner coloring, and according to Sperner's lemma there must exist in the subdivision a subsimplex $\mathcal{S}^*$ such that all its vertices' colors are different.

We will now introduce the concept of a geodesic path over a subsimplex. A path over a subsimplex is a sequence of vertices of the subsimplex. The elements of a vertex are its coordinates at a point in A. A geodesic path over a subsimplex is a path in which any element is *increased* at most once. We refer only to increments, since we would like to allow a geodesic loop—a path which begins and ends at the same vertex. A geodesic path with minimal changes is a geodesic path for which two consecutive vertices differ only in two entries: one increased by 1, the other decreased by 1.

Notice that the above definition does not ensure that a geodesic path with minimal changes over a subsimplex will necessarily correspond to a geodesic path of input values: For example, the geodesic path $(5,0,0) \to (4,1,0) \to (4,0,1)$ does not correspond to any geodesic path of input values. However, when all the entries are positive there is always a corresponding geodesic path of input values.

Lemma 4.3. *Let $\mathcal{S}$ be a d-simplex spanned by $\vec{V_0}, \vec{V_1}, \ldots, \vec{V_d}$ such that for every $0 \leq i \leq d$, $\vec{V_i} = n \cdot \vec{\delta_i}$. Let $\mathcal{S}^*$ be a d-simplex of the edgewise subdivision of $\mathcal{S}$ using the integer n, where $\mathcal{S}^*$ is spanned by $\vec{V}_0^*, \vec{V}_1^*, \ldots, \vec{V}_d^*$. Then $\vec{V}_0^* \to \vec{V}_1^* \to \cdots \to \vec{V}_d^* \to \vec{V}_0^*$ is a geodesic path with minimal changes.*

Proof. Let M be the color scheme corresponding to $\mathcal{S}^*$ such that for every $0 \leq j \leq d$, $\vec{V}_j^* = \frac{1}{n}\sum_{i=1}^{n} \vec{V}_{\chi_{i,j}}$. Consider a scan S of M in the following way: Each row is scanned from left to right, and then the next row is scanned in the same order, until reaching the rightmost element in the last row. Namely, the scan order is $S = \chi_{1,0} \to \chi_{1,1} \to \cdots \to \chi_{1,d} \to \chi_{2,0} \to \cdots \to \chi_{n,d}$. By the definition of M, there are exactly d color changes along S. Namely, every color $0 \leq b \leq d-1$ changes to $b+1$ exactly once. Since, by the definition of M, no two successive columns are identical, then for every column $0 \leq j \leq d-1$ there is exactly one row i such that $\chi_{i,j} \neq \chi_{i,j+1}$. Moreover, $\chi_{i,j+1} = \chi_{i,j} + 1$. Therefore, exactly one color $c_j = \chi_{i,j}$ is changed when moving from column j to column $j+1$. Note further that we have already accounted for d color changes along S, and since all those color changes were of the form $\chi_{i,j} \neq \chi_{i,j+1}$, we can conclude that for every $1 \leq i \leq n-1$, $\chi_{i,d} = \chi_{i+1,0}$.

For every $0 \leq j \leq d-1$,

$$\begin{aligned}\vec{V}_{j+1}^* - \vec{V}_j^* &= \frac{1}{n}\sum_{i=1}^{n} \vec{V}_{\chi_{i,j+1}} - \frac{1}{n}\sum_{i=1}^{n} \vec{V}_{\chi_{i,j}} \\ &= \frac{1}{n}\sum_{i=1}^{n} (\vec{V}_{\chi_{i,j+1}} - \vec{V}_{\chi_{i,j}}) = \frac{1}{n}(\vec{V}_{c_j+1} - \vec{V}_{c_j})\end{aligned}$$

$$= \frac{1}{n}(n \cdot \vec{\delta}_{c_j+1} - n \cdot \vec{\delta}_{c_j}) = \vec{\delta}_{c_j+1} - \vec{\delta}_{c_j}.$$

Now examine the end of the path:

$$\begin{aligned}\vec{V}_0^* - \vec{V}_d^* &= \frac{1}{n}\sum_{i=1}^{n} \vec{V}_{\chi_{i,0}} - \frac{1}{n}\sum_{i=1}^{n} \vec{V}_{\chi_{i,d}} \\ &= \frac{1}{n}\vec{V}_{\chi_{1,0}} + \frac{1}{n}\sum_{i=1}^{n-1}(\vec{V}_{\chi_{i+1,0}} - \vec{V}_{\chi_{i,d}}) - \frac{1}{n}\vec{V}_{\chi_{n,d}} \\ &= \frac{1}{n}(\vec{V}_{\chi_{1,0}} - \vec{V}_{\chi_{k,d}}) = \frac{1}{n}(\vec{V}_0 - \vec{V}_d) \\ &= \frac{1}{n}(n \cdot \vec{\delta}_0 - n \cdot \vec{\delta}_d) = \vec{\delta}_0 - \vec{\delta}_d.\end{aligned}$$

Thus $\vec{V}_0^* \rightarrow \vec{V}_1^* \rightarrow \cdots \rightarrow \vec{V}_d^* \rightarrow \vec{V}_0^*$ is a path with minimal changes.

When passing the path from $\vec{V}_j^*$ to $\vec{V}_{j+1}^*$, there are only two changes in the elements of $\vec{V}_j^*$: $\vec{V}_j^*[c_j]$ is decreased by 1, and $\vec{V}_j^*[c_j+1]$ is increased by 1. Since the colors $c_0, c_1, \ldots, c_{d-1}$ are a permutation of the colors $0, 1, \ldots, d-1$, it follows that along the path $\vec{V}_0^* \rightarrow \vec{V}_1^* \rightarrow \cdots \rightarrow \vec{V}_d^*$ the 0th element is decreased once, the dth element is increased once, and for each $1 \leq i \leq d-1$ the ith element is increased once and decreased once. When passing from $\vec{V}_d^*$ to $\vec{V}_0^*$ the dth element is decreased once and the 0th element is increased once. Therefore, $\vec{V}_0^* \rightarrow \vec{V}_1^* \rightarrow \cdots \rightarrow \vec{V}_d^* \rightarrow \vec{V}_0^*$ is a geodesic path. ◻

Now we can prove the main theorem, given next.

THEOREM 4.4. *For every* EV *system* D *with a symmetric function f, instability*(D) $\geq vt + 1$.

Proof. $\tilde{f}$ is defined over A, which subdivides $\mathcal{S}$ using the edgewise subdivision (Lemma 4.2). We will use $\tilde{f}$ to color the vertices in A. According to Sperner's lemma, there is a $(v-1)$-simplex in the subdivision so that the colors of its vertices are pairwise different. Let $\vec{a}_0, \vec{a}_1, \ldots, \vec{a}_{v-1} \in A$ be the vertices spanning $\mathcal{S}$.

According to Lemma 4.3, $\vec{a}_0 \rightarrow \vec{a}_1 \rightarrow \cdots \rightarrow \vec{a}_{v-1} \rightarrow \vec{a}_0$ is a geodesic path with minimal changes. This means that for any b, the bth element is increased only once. Given that this path is a loop, every element is decreased only once (since every element should be increased and decreased an equal number of times), which means that for any i, j it holds that $\vec{a}_j[b] - 1 \leq \vec{a}_i[b] \leq \vec{a}_j[b] + 1$. Since for every b there is a vertex $\vec{a}_{i_b}$ such that $f(\vec{a}_{i_b}) = b$, then $\vec{a}_{i_b}[b] \geq t+1$, and hence for any k, b it holds that $\vec{a}_k[b] \geq t$.

Let c_j be the color that changes between $\vec{a}_j$ and $\vec{a}_{(j+1) \bmod v}$ for every $0 \leq j \leq v-1$. Now, for every step i we start with an input vector corresponding to $\vec{a}_{i \bmod v}$ and will switch an input value $c_{i \bmod v}$ to $(c_{i \bmod v} + 1) \bmod v$, thus arriving at an input vector corresponding to $\vec{a}_{(i+1) \bmod v}$. We can repeat these steps vt times, in total changing t input values from c_j to $c_{(j+1) \bmod v}$ for any $0 \leq j \leq v-1$. Hence, after vt steps only t input values were changed to $f(\vec{a}_0)$, so changing all the input values yet unchanged to some $b \neq f(\vec{a}_0)$ will result in another change to the consensus value, thus resulting in a total of $vt + 1$ changes to the consensus value. ◻

4.3. Instability upper bound, MLS system. We now describe a memoryless symmetric EV system MLS, and prove that its instability is a factor of two away from the lower bound presented in the previous section. An interesting open question is how to close this gap. Since MLS is memoryless and symmetric, it is defined solely by its decision function f_{MLS}. We will define f_{MLS} as follows:

$$f_{MLS}(\vec{x}) = \min \{ b \mid \#b(\vec{x}) \geq t+1 \}.$$

Namely, f_{MLS} decides upon the smallest value possible.

LEMMA 4.5. *Instability*(MLS) $\geq \min\{n, 2(v-1)(t+1)\}$.

Proof. We will prove the lemma by providing a geodesic path which yields $\min\{n, 2(v-1)(t+1)\}$ changes to the consensus value.

We will first assume that $n \geq 2(v-1)(t+1)$, and start with an input vector $\vec{x}_0 = 0^{t+1}1^{t+1} \dots (v-2)^{t+1}(v-1)^{n-(v-1)(t+1)}$. Notice that $\#\,(v-1)\,(\vec{x}_0) = n - (v-1)(t+1) \geq (v-1)(t+1)$. Since $\#0(\vec{x}_0) = t+1$, $f_{MLS}(\vec{x}_0) = 0$. Next, we switch one input value from 0 to $v-1$. Now $\#0(\vec{x}_0) = t$, and therefore the consensus value will change to 1. When we switch an input value from $v-1$ to 0, the consensus value will change back to 0. We will repeat these two steps t times, and on the $(t+1)$th time we will not change an input value from $v-1$ to 0. Notice that up until here we have changed the input value of $t+1$ sensors from 0, and of t sensors from $v-1$, and ended up with an input vector $\vec{x}_{2t+1}$, where $\#0(\vec{x}_{2t+1}) = t$. Next, we switch input values from 1 to $v-1$ and back again in the same fashion, and so forth. The geodesic path achieved this way is as follows:

$$\begin{array}{lccc}
0^{t+1}1^{t+1}2^{t+1} \dots (v-2)^{t+1}(v-1)^{n-(v-1)(t+1)} & \rightarrow & \cdots & \rightarrow \\
(v-1)^{t+1}1^{t+1}2^{t+1} \dots (v-2)^{t+1}0^{t}(v-1)^{n-(v-1)(t+1)-t} & \rightarrow & \cdots & \rightarrow \\
(v-1)^{2t+2}2^{t+1} \dots (v-2)^{t+1}0^{t}1^{t}(v-1)^{n-(v-1)(t+1)-2t} & \rightarrow & \cdots & \rightarrow \\
\vdots & & & \\
(v-1)^{(v-1)(t+1)}0^{t}1^{t} \dots (v-2)^{t}(v-1)^{n-(v-1)(2t+1)}. & & &
\end{array}$$

Every step yields $2t+1$ changes to the consensus value, resulting in a total sum of $(v-1)(2t+1)$ changes. Notice that at the end of the current path $\#i(\vec{x}_{(v-1)(2t+1)}) = t$ for every $0 \leq i \leq v-2$, thus $f_{MLS}(\vec{x}_{(v-1)(2t+1)}) = v-1$. Next, we will switch one input value from $v-1$ to $v-2$. As a result, $\#(v-2)(\vec{x}_{(v-1)(2t+1)+1}) = t+1$, and the consensus value changes to $v-2$. We can repeat this step by changing an input value from $v-1$ to $v-3$, then from $v-1$ to $v-4$, and so forth, resulting in $v-1$ more changes to the consensus value, and a total sum of $2(v-1)(t+1)$ changes. The end of the geodesic path is as follows:

$$\begin{array}{lc}
\mathcal{Z}(v-1)^{n-(v-1)(2t+1)} & \longrightarrow \\
\mathcal{Z}(v-2)(v-1)^{n-(v-1)(2t+1)-1} & \longrightarrow \\
\mathcal{Z}(v-2)(v-3)(v-1)^{n-(v-1)(2t+1)-2} & \longrightarrow \\
\mathcal{Z}(v-2)(v-3) \dots 0(v-1)^{n-2(v-1)(t+1)}, &
\end{array}$$

where

$$\mathcal{Z} = (v-1)^{(v-1)(t+1)}0^{t}1^{t} \dots (v-2)^{t}.$$

Now, let us consider the case where $n < 2(v-1)(t+1)$.

If $(v-1)(2t+1) \leq n < 2(v-1)(t+1)$, then $\#(v-1)(\vec{x}_0) \geq (v-1)t$. In this case, we can take the first $(v-1)(2t+1)$ steps described above, ending with $\vec{x}_{(v-1)(2t+1)} = \mathcal{Z}(v-1)^{n-(v-1)(2t+1)}$. There are exactly $n-(v-1)(2t+1) < v-1$ input values which equal $v-1$ and have not been changed yet. Therefore, we can follow the above $n-(v-1)(2t+1)$ steps (of the second group of steps), and yield a total of n changes to the consensus value.

If $n<(v-1)(2t+1)$, then let $\alpha=\lfloor\frac{n}{2t+1}\rfloor$, $\beta=n-\alpha(2t+1)<2t+1$. We will start the geodesic path with the input vector $\vec{x}_0=0^{t+1}1^{t+1}\dots(\alpha-1)^{t+1}\alpha^{\lceil\frac{\beta}{2}\rceil}(v-1)^{\alpha t+\lfloor\frac{\beta}{2}\rfloor}$. Notice that $\alpha<v-1$, and since $n\geq vt+1$ and $v\geq 2$, then $\alpha\geq 1$. Now, we change an input value from 0 to α, thus changing the consensus value from 0 to 1, and then change an input value from $v-1$ to 0, thus changing the consensus value from 1 to 0. We repeat these two steps $t-\lceil\frac{\beta}{2}\rceil+1$ times. Next, we change an input value from 0 to $v-1$, thus changing the consensus from 0 to 1, and then change an input value from $v-1$ to 0, changing the consensus value from 1 to 0. We repeat these two steps $\lceil\frac{\beta}{2}\rceil-1$ times, and then change an input value once from 0 to $v-1$. Now, given $\#0(\vec{x}_{2t+1})=t$, for every $1\leq b\leq\alpha$ it holds that $\#b(\vec{x}_{2t+1})=t+1$, and there are $(\alpha-1)t+\lfloor\frac{\beta}{2}\rfloor$ input values which can be changed from $v-1$ to another value. For the next $(\alpha-1)(2t+1)$ steps we change first an input value from 1 to $v-1$ and back from $v-1$ to 1 (t times) plus one change of an input value from 1 to $v-1$, we change an input value from 2 to $v-1$ and back from $v-1$ to 2 (t times) plus one change of an input value from 2 to $v-1$, etc. Every change leads to a change in the consensus value. After the $(\alpha-1)(2t+1)$th step, there are β input values left which can be changed: $\lfloor\frac{\beta}{2}\rfloor$ input values which can be changed from $v-1$ to another value, and $\lceil\frac{\beta}{2}\rceil$ input values which can be changed from α to another value. Finally, we change an input value from α to $v-1$, and then from $v-1$ to α, repeating these two steps $\lfloor\frac{\beta}{2}\rfloor$ times. If necessary (if β is odd), we change an input value from α to $v-1$. The total geodesic path is as follows:

$$\begin{array}{ll}
0^{t+1}1^{t+1}2^{t+1}\dots(\alpha-1)^{t+1}\alpha^{\lceil\frac{\beta}{2}\rceil}(v-1)^{\alpha t+\lfloor\frac{\beta}{2}\rfloor} & \longrightarrow\ \cdots\ \longrightarrow \\
\alpha^{t-\lceil\frac{\beta}{2}\rceil+1}0^{\lceil\frac{\beta}{2}\rceil}1^{t+1}2^{t+1}\dots(\alpha-1)^{t+1}\alpha^{\lceil\frac{\beta}{2}\rceil}0^{t-\lceil\frac{\beta}{2}\rceil+1}(v-1)^{(\alpha-1)t+\beta-1} & \longrightarrow\ \cdots\ \longrightarrow \\
\alpha^{t-\lceil\frac{\beta}{2}\rceil+1}(v-1)^{\lceil\frac{\beta}{2}\rceil}1^{t+1}2^{t+1}\dots(\alpha-1)^{t+1}\alpha^{\lceil\frac{\beta}{2}\rceil}0^{t}(v-1)^{(\alpha-1)t+\lfloor\frac{\beta}{2}\rfloor} & \longrightarrow\ \cdots\ \longrightarrow \\
\alpha^{t-\lceil\frac{\beta}{2}\rceil+1}(v-1)^{\lceil\frac{\beta}{2}\rceil+t+1}2^{t+1}\dots(\alpha-1)^{t+1}\alpha^{\lceil\frac{\beta}{2}\rceil}0^{t}1^{t}(v-1)^{(\alpha-2)t+\lfloor\frac{\beta}{2}\rfloor} & \longrightarrow\ \cdots\ \longrightarrow \\
\vdots & \\
\alpha^{t-\lceil\frac{\beta}{2}\rceil+1}(v-1)^{\lceil\frac{\beta}{2}\rceil+(\alpha-1)(t+1)}\alpha^{\lceil\frac{\beta}{2}\rceil}0^{t}1^{t}2^{t}\dots(\alpha-1)^{t}(v-1)^{\lfloor\frac{\beta}{2}\rfloor} & \longrightarrow\ \cdots\ \longrightarrow \\
\alpha^{t-\lceil\frac{\beta}{2}\rceil+1}(v-1)^{2\lceil\frac{\beta}{2}\rceil+(\alpha-1)(t+1)}0^{t}1^{t}2^{t}\dots(\alpha-1)^{t}\alpha^{\lfloor\frac{\beta}{2}\rfloor}. &
\end{array}$$

Since every input value changed along the geodesic path, and since every change to an input value resulted in a change to the consensus value, the instability is n. □

LEMMA 4.6. *Instability*(MLS) $\leq 2(v-1)(t+1)$.

Proof. Let $P=\vec{x}_0\rightarrow\vec{x}_1\rightarrow\cdots\rightarrow\vec{x}_n$ be a geodesic path. The number of decision value changes in P is equal to the sum of the times the decision changes to a higher value plus the times it changes to a lower value, i.e., $\#\uparrow+\#\downarrow$. We next show that each one of these quantities is at most $(v-1)(t+1)$, which proves the lemma.

To compute $\#\uparrow$, notice that if the decision d changes to a higher value, then it must be the case that an input bit equal to d changes: In the current input $\vec{x}_i$ we must have $\#d(\vec{x}_i)=t+1$ while $\#d(\vec{x}_{i+1})=t$. Now

$$\#\uparrow=\sum_{d=0}^{v-2}\#\uparrow_d,$$

where $\#\uparrow_d$ denotes the number of changes of a decision from d to a higher value. Consider the first time, $\vec{x}_j$, where the decision is d and the change in $\vec{x}_{j+1}$ is to a higher value. We have $\#d(\vec{x}_j) = t + 1$, and therefore the total number of changes from d to a higher value is at most $t + 1$ (since once this happens, $t + 1$ inputs equal to d have changed and thus are fixed in a geodesic path).

To compute $\# \downarrow$, observe that if the decision d changes in $\vec{x}_i$ to a smaller value d', then it must be the case that a value changes to d': $\#d'(\vec{x}_i) = t$ and $\#d'(\vec{x}_{i+1}) = t+1$. This can happen at most $t + 1$ times for each such d' in a geodesic path (once this happens there are $t + 1$ entries with value d' fixed). There are $(v - 1)$ such values d', so the total number of such changes is at most $(v - 1)(t + 1)$. □

COROLLARY 4.7. *Instability*(MLS) $= \min\{n, 2(v - 1)(t + 1)\}$.

Appendix. Edgewise subdivision. In [9] an edgewise subdivision of a d-simplex is suggested, which uses an abacus model of the simplex. In this appendix, we summarize the method described in [9], and its main results.

Let $\vec{V}_0, \vec{V}_1, \ldots, \vec{V}_d$ be independent vectors which define a d-simplex $\mathcal{S}$ in $\mathbb{R}^d$. Every point $\vec{X} \in \mathcal{S}$ can be described by $\lambda_0, \lambda_1, \ldots, \lambda_d$ nonnegative real numbers which sum to 1, so that

$$\vec{X} = \sum_{i=0}^{d} \lambda_i \cdot \vec{V}_i.$$

These are called *the barycentric coordinates* of $\vec{X}$. We may portray them graphically by drawing the unit interval as a rectangle with regions colored from 0 through d, making sure to arrange the colors from left to right, so that λ_i is the fraction of points with color i. Figure A.1 illustrates this for $d = 7$ and the point with barycentric coordinates $(0.26, 0.11, 0.07, 0.11, 0.19, 0.08, 0.04, 0.14)$. The coordinates of the dividing lines are displayed above the rectangle. They are provided by the partial sums $0 = B_0, B_1, \ldots, B_d, B_{d+1} = 1$ with $B_i = \lambda_0 + \lambda_1 + \cdots + \lambda_{i-1}$. B_1 through B_d can be any nondecreasing sequence in the unit interval.

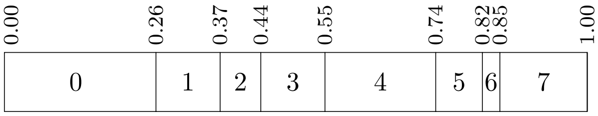

FIG. A.1. *The rectangle represents the unit interval with points colored from* 0 *to* 7.

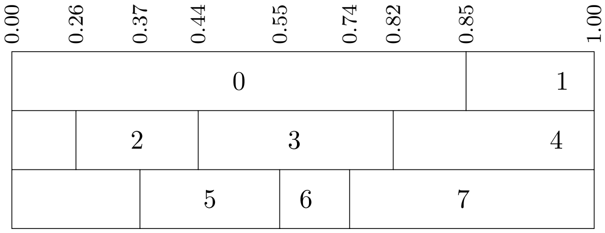

FIG. A.2. *The rectangle in Figure* A.1 *is chopped into three pieces, which are stacked and expanded.*

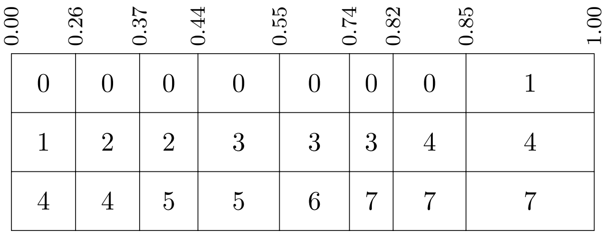
Suppose we chop the rectangle in Figure A.1 into k pieces of equal width, stack them on top of each other, and expand the scale by factor of k in the horizontal direction (see Figure A.2). The coordinates of the dividing lines are obtained by



0	0	0	0	0	0	0	1
1	2	2	3	3	3	4	4
4	4	5	5	6	7	7	7

FIG. A.3. *Each row is cut vertically by the coordinates, and each region keeps the original color of its points.*

multiplying the coordinates of the earlier dividing lines by k and discarding the integer part, keeping only the fractional part. We discard any duplications, letting $j+2$ be the number of distinct values remaining. Call these numbers $0 = C_0, C_1, \ldots, C_j, C_{j+1} = 1$, making sure to sort them in increasing order. We extend the dividing lines vertically until they span the entire stack, and label each region by its color (see Figure A.3).

The number of regions of each stack is $j + 1$. Forgetting the positions of the vertical dividing lines, we get a matrix,

$$M = \begin{pmatrix} \chi_{1,0} & \chi_{1,1} & \cdots & \chi_{1,j} \\ \chi_{2,0} & \chi_{2,1} & \cdots & \chi_{2,j} \\ \vdots & \vdots & \ddots & \vdots \\ \chi_{k,0} & \chi_{k,1} & \cdots & \chi_{k,j} \end{pmatrix},$$

of $k(j+1)$ color entries. We call $M = M(\vec{X}, k)$ a *color scheme* because it determines the combinatorics but not the geometry of the coloring. The matrices that may occur are those whose entries are drawn from the set $\{0, 1, \ldots, d\}$, whose entries are in nondecreasing order when read like English text,

$$\chi_{1,0} \leq \chi_{1,1} \leq \cdots \leq \chi_{1,j} \leq \chi_{2,0} \leq \cdots \leq \chi_{k,j},$$

and whose columns are pairwise different.

For every k, not necessarily distinct, colors χ_1 through χ_k we introduce the notation

$$\vec{V}_{\chi_1,\chi_2,\ldots,\chi_k} = \frac{1}{k}(\vec{V}_{\chi_1} + \vec{V}_{\chi_2} + \cdots + \vec{V}_{\chi_k}).$$

Now we can define for every $0 \leq l \leq j$, $\vec{V}_l^* = \vec{V}_{\chi_{1,l},\chi_{2,l},\ldots,\chi_{k,l}}$, where each vector corresponds to a column in the color scheme $M = M(\vec{X}, k)$. In [9] it is proved that these vectors are independent, thus spanning a j-simplex. Let $\mathcal{S}_M$ denote the simplex spanned by the vectors corresponding to M. Then the *k-edgewise subdivision* of $\mathcal{S}$ consists of all the simplices defined this way by points of $\mathcal{S}$:

$$\text{Esd}_k(\mathcal{S}) = \left\{\mathcal{S}_M \mid M = M(\vec{X}, k),\ \vec{X} \in \mathcal{S}\right\}.$$

[9] proves that not only is $\text{Esd}_k(\mathcal{S})$ a subdivision of $\mathcal{S}$, but also for every $\vec{X} \in \mathcal{S}$ it holds that $\vec{X} \in \mathcal{S}_{M(\vec{X},k)}$.

Acknowledgment. It is a pleasure to thank Ronen Peretz, Nir Shavit, and Yuri Vasilevski for their comments.

PARAMETRIC DUALITY AND KERNELIZATION: LOWER BOUNDS AND UPPER BOUNDS ON KERNEL SIZE[*]

JIANER CHEN[†], HENNING FERNAU[‡], IYAD A. KANJ[§], AND GE XIA[¶]

Abstract. Determining whether a parameterized problem is kernelizable and has a small kernel size has recently become one of the most interesting topics of research in the area of parameterized complexity and algorithms. Theoretically, it has been proved that a parameterized problem is kernelizable if and only if it is fixed-parameter tractable. Practically, applying a data reduction algorithm to reduce an instance of a parameterized problem to an equivalent smaller instance (i.e., a kernel) has led to very efficient algorithms and now goes hand-in-hand with the design of practical algorithms for solving $\mathcal{NP}$-hard problems. Well-known examples of such parameterized problems include the VERTEX COVER problem, which is kernelizable to a kernel of size bounded by $2k$, and the PLANAR DOMINATING SET problem, which is kernelizable to a kernel of size bounded by $335k$. In this paper we develop new techniques to derive upper and lower bounds on the kernel size for certain parameterized problems. In terms of our lower bound results, we show, for example, that unless $\mathcal{P} = \mathcal{NP}$, PLANAR VERTEX COVER does not have a problem kernel of size smaller than $4k/3$, and PLANAR INDEPENDENT SET and PLANAR DOMINATING SET do not have kernels of size smaller than $2k$. In terms of our upper bound results, we further reduce the upper bound on the kernel size for the PLANAR DOMINATING SET problem to $67k$, improving significantly the $335k$ previous upper bound given by Alber, Fellows, and Niedermeier [*J. ACM*, 51 (2004), pp. 363–384]. This latter result is obtained by introducing a new set of reduction and coloring rules, which allows the derivation of nice combinatorial properties in the kernelized graph leading to a tighter bound on the size of the kernel. The paper also shows how this improved upper bound yields a simple and competitive algorithm for the PLANAR DOMINATING SET problem.

1. Introduction.

Many practical algorithms for $\mathcal{NP}$-hard problems start by applying data reduction subroutines to the input instances of the problem. The hope is that after the data reduction phase the instance of the problem has shrunk to a moderate size. This makes the applicability of a second phase, such as a branch-and-bound phase, to the resulting instance more feasible. Weihe showed in [41] how a practical preprocessing algorithm for a variation of the DOMINATING SET problem, called the RED/BLUE DOMINATING SET problem, resulted in breaking up input instances of the problem into much smaller instances. Abu-Khzam, Langston, and Shanbhag [2], in their implementation of algorithms for the VERTEX COVER problem,

observed the following: "In many cases, reduction was so effective that it eliminated the core completely, and with it the need for decomposition and search." Similar success was reported with DOMINATING SET as well [3].

On the other hand, many applications seek solutions of very small sizes to fairly large input instances of $\mathcal{NP}$-hard problems. This has been the main concern for the area of parameterized computation. A *parameterized problem* is a set of instances of the form (x, k), where x is the input instance and k is a nonnegative integer called the *parameter*. A parameterized problem is said to be *fixed-parameter tractable* [17] if there is an algorithm that solves the problem in time $f(k)|x|^c$, where c is a fixed constant and $f(k)$ is a recursive function. The development of efficient parameterized algorithms has provided a new approach for practically solving problems that are theoretically intractable. For example, parameterized algorithms for the $\mathcal{NP}$-hard problem VERTEX COVER [9, 13] have found applications in biochemistry [10], and variants thereof are applicable to problems arising in chip manufacturing [11, 21, 24], while parameterized algorithms in computational logic [35] have provided an effective method for solving practical instances of the ML TYPE-CHECKING problem, which is complete for the class EXPTIME [30].

The notion of a parameterized problem being parameterized tractable, and of the problem having a good data reduction algorithm, turns out to be very closely related. Informally speaking, a *kernelization*—precisely defined below—is a data reduction procedure that reduces an instance of the problem to another (smaller) instance called the *kernel*.

It has been proved that a parameterized problem is fixed-parameter tractable if and only if the problem is kernelizable [18].

Designing efficient parameterized algorithms and constructing kernels of reasonable sizes have recently been two of the main topics of research in the area of parameterized computation. More specifically, constructing a problem kernel has become one of the main components in the design of an efficient parameterized algorithm for a problem [9, 11, 12, 13], and designing efficient parameterized algorithms for a parameterized problem now goes hand-in-hand with the construction of a problem kernel of a moderate size for the problem. Two of the most celebrated problems that have been receiving a lot of attention recently from both perspectives are the VERTEX COVER and PLANAR DOMINATING SET problems. After a long sequence of algorithms, the VERTEX COVER problem can be solved in time $O(1.274^k + kn)$ [14]. Moreover, the VERTEX COVER problem enjoys a kernel of size bounded by $2k$, and reducing this bound further seems to be a very challenging task, since it would probably lead to an approximation algorithm for the problem of ratio smaller than 2—a result believed by many people to be unlikely. The PLANAR DOMINATING SET problem as well has undergone some extensive study which culminated in a recent algorithm solving the problem in time $O(2^{15.13\sqrt{k}} + n^3)$ [25]. Recently, and after many strenuous efforts, it was shown that the PLANAR DOMINATING SET problem has a problem kernel of size $335k$ that is computable in $O(n^3)$ time [5]. The question of whether such a bound on the problem kernel could be significantly improved remains open.

In this paper we develop new techniques to derive upper and lower bounds on the kernel size for certain parameterized problems. We define the notion of *duality* of a parameterized problem. Many parameterized tractable problems are the dual of parameterized intractable problems (see [19, 34, 38]). As an example, consider the VERTEX COVER and INDEPENDENT SET problems. If n denotes the number of vertices in the whole graph G, then it is well known that (G, k) is a YES-instance of VERTEX

COVER if and only if (G, k_d), where $k_d = n-k$, is a YES-instance of INDEPENDENT SET. In this sense, INDEPENDENT SET is the parametric dual problem of VERTEX COVER. While VERTEX COVER is fixed-parameter tractable on general graphs, INDEPENDENT SET is not [17]. Similarly, while DOMINATING SET is fixed-parameter intractable on general graphs, its parametric dual, called NONBLOCKER, is fixed-parameter tractable; see [15]. The landscape changes when we turn our attention towards special graph classes, e.g., problems on *planar graphs* [6]. Here, for example, both INDEPENDENT SET and DOMINATING SET are fixed-parameter tractable. In fact, and in contrast to what was stated above, there are very many problems for which both the problem itself and its dual are fixed-parameter tractable. This is also true for problems on graphs of bounded genus, as well as on graphs of bounded degree.

The beauty of problems which, together with their dual problems, are fixed-parameter tractable is that this constellation allows for, from an algorithmic standpoint, a two-sided attack on the original problem. This two-sided attack enabled us to derive lower bounds on the kernel size for such problems (under classical complexity assumptions). For example, we show that unless $\mathcal{P} = \mathcal{NP}$, PLANAR VERTEX COVER does not have a kernel of size smaller than $4k/3$, and PLANAR INDEPENDENT SET and PLANAR DOMINATING SET do not have kernels of size smaller than $2k$. To the authors' knowledge, this is the first group of results establishing lower bounds on the kernel size of parameterized problems. We also show that some lower bound results obtained using the techniques devised in this paper are sharp by exhibiting a family of graph classes on which the lower bound on the kernel size of the restricted $\mathcal{NP}$-hard VERTEX COVER problem approaches the upper bound $2k$ with an arbitrary precision.

Whereas the lower bounds on the kernel size for PLANAR VERTEX COVER and PLANAR INDEPENDENT SET come close to the known upper bounds of $2k$ and $4k$ on the kernel size for the two problems, respectively, the lower bound derived for PLANAR DOMINATING SET is still very far from the $335k$ upper bound on the problem kernel, which was given by Alber, Fellows, and Niedermeier [5]. To bridge this gap, we investigate the problem of finding a kernel of smaller size for the PLANAR DOMINATING SET problem and derive better upper bounds on the problem kernel for the problem. We improve the reduction rules proposed in [5] and introduce new rules that *color* the vertices of the graph, enabling us to observe many new combinatorial properties of its vertices. These properties allow us to prove a much stronger bound on the number of vertices in the reduced graph. We show that the PLANAR DOMINATING SET problem has a kernel of size $67k$ that is computable in $O(n^3)$ time. This is a significant improvement over the results in [5]. Finally, we show how the resulting bound on the kernel size yields a very simple algorithm for the PLANAR DOMINATING SET problem that beats some previous algorithms for the problem, and whose running time even comes close to some of the recently proposed algorithms.

2. Preliminaries.

A graph G is said to be *planar* if G can be embedded on the plane such that no two edges in G cross. It is well known that deciding whether a graph is planar and constructing a planar embedding of the graph in such case can be done in linear time [31]. The number of edges in a planar graph with n vertices for $n \geq 3$ is bounded by $3n - 6$ [16].

A dominating set in a graph G is a set of vertices D such that every vertex in G is either in D or adjacent to at least one vertex in D. The size of a dominating set D is the number of vertices in D. A *minimum dominating set* of G is a dominating set with the minimum size. We will denote by $\gamma(G)$ the size of a minimum dominating set in G. The PLANAR DOMINATING SET problem, abbreviated PLANAR-DS henceforth, is the following: given a planar graph G and a positive integer k, either construct a dominating set for G of size at most k or report that no such dominating set exists. It is well known that the PLANAR-DS problem is $\mathcal{NP}$-complete [27].

A *parameterized problem* P is a subset of $\Sigma^* \times N$, where Σ is a fixed alphabet and N is the set of all nonnegative integers. Therefore, each instance of the parameterized problem P is a pair (I, k), where the second component k is called the *parameter*. The language $L(P)$ is the set of all YES-instances of P. We say that the parameterized problem P is *fixed-parameter tractable* [17] if there is an algorithm that decides whether an input (I, k) is a member of $L(P)$ in time $f(k)|I|^c$, where c is a fixed constant and $f(k)$ is a recursive function independent of the input length $|I|$. The class of all fixed-parameter tractable problems is denoted by FPT.

A mapping $s : \Sigma^* \times N \to N$ is called a *size function* for a parameterized problem P if

- $0 \leq k \leq s(I, k)$,
- $s(I, k) \leq |I|$, and
- $s(I, k) = s(I, k')$ for all appropriate k, k' *(independence)*. Hence, we can also write $s(I)$ for $s(I, k)$.

A problem P together with its size function s is denoted (P, s). The *dual problem* P_d of P is the problem whose corresponding language (i.e., the set of YES-instances) $L(P_d) = \{(I, s(I) - k) \mid (I, k) \in L(P)\}$. The dual of the dual of a problem (with a given size function) is again the original problem. We give some examples below.

d-HITTING SET

Given: A hypergraph $G = (V, E)$ with *edge degree* bounded by d, i.e., for all $e \in E$, $|e| \leq d$.

Parameter: k.

Question: Is there a *hitting set* of size at most k, i.e.,

$$\exists C \subseteq V, |C| \leq k, \quad \forall e \in E, C \cap e \neq \emptyset?$$

The special case in which $d = 2$ corresponds to the VERTEX COVER problem in undirected graphs. Let $L(d\text{-HS})$ denote the language of d-HITTING SET. Taking as size function $s(G) = |V|$, it is clear that the dual problem obeys $(G, k_d) \in L(d\text{-HS}_d)$ if and only if G has an *independent set* of cardinality k_d.

DOMINATING SET

Given: A (simple) graph $G = (V, E)$.

Parameter: k.

Question: Is there a *dominating set* of size at most k, i.e.,

$$\exists D \subseteq V, |D| \leq k, \quad \forall v \in V \setminus D \; \exists w \in D, (w, v) \in E?$$

Taking as size function $s(G) = |V|$, it is clear that the dual problem obeys $(G, k_d) \in L(\text{DS}_d)$ if and only if G has a *nonblocker set* (i.e., the complement of a dominating set) of cardinality k_d.

Generally speaking, it is easy to "correctly" define the dual of a problem for the so-called selection problems as formalized in [7]. The concept of duality is less clear, say, for weighted graph problems (with the slight exception of ROMAN DOMINATION; see [22]). Also, different graph parameterizations like treewidth seem to possess no natural dualization.

A *kernelization (reduction)* for a parameterized problem P with size function s is a polynomial-time computable reduction which maps an instance (I, k) onto (I', k') such that (1) $s(I') \leq g(k)$ (g is a recursive function), (2) $k' \leq k$, and (3) $(I, k) \in L(P)$

if and only if $(I', k') \in L(P)$. I' is called the *problem kernel* of I. It is known (see [18]) that a parameterized problem is fixed-parameter tractable if and only if it has a kernelization. Of special interest to us in this paper are problems with *linear kernels* in which $g(k) = \alpha k$ for some constant $\alpha > 0$. Such small kernels are known for many important graph problems restricted to planar graphs.

3. Lower bounds on kernel size.

Practice in the study of parameterized algorithms has suggested that improved kernelization can lead to improved parameterized algorithms. Many efforts have been made towards obtaining smaller kernels for well-known $\mathcal{NP}$-hard parameterized problems (see, for example, [5, 13, 18]). A natural question to ask along this line of research is about the limit of polynomial-time kernelization. In this section we develop techniques for deriving lower bounds on the kernel size for certain well-known $\mathcal{NP}$-hard parameterized problems.

3.1. General lower bound results.

THEOREM 3.1. *Let (P, s) be an $\mathcal{NP}$-hard parameterized problem (with size function s). Suppose that P admits an αk kernelization and its dual P_d admits an $\alpha_d k_d$ kernelization, where $\alpha, \alpha_d \geq 1$. If $(\alpha - 1)(\alpha_d - 1) < 1$, then $\mathcal{P} = \mathcal{NP}$.*

Proof. Suppose that the assumption of the theorem is true, and let $r(\cdot)$ denote the assumed linear kernelization reduction for P. Similarly, let $r_d(\cdot)$ be the linear kernelization reduction for P_d. Consider the following reduction R, which on input (I, k) of P performs the following:

```
    **if** $k \leq \frac{\alpha_d}{\alpha+\alpha_d} s(I)$ **then** compute $r(I, k)$;
    **else** compute $r_d(I, s(I) - k)$.
```

Let (I', k') be the instance computed by the reduction R. If $k \leq \frac{\alpha_d}{\alpha+\alpha_d} s(I)$, then $s(I') \leq \alpha k \leq \frac{\alpha\alpha_d}{\alpha+\alpha_d} s(I)$. Otherwise,

$$\begin{aligned} s(I') &\leq \alpha_d k_d \\ &= \alpha_d(s(I) - k) \\ &< \alpha_d \left(s(I) - \frac{\alpha_d}{\alpha + \alpha_d} s(I) \right) \\ &= \frac{\alpha\alpha_d}{\alpha + \alpha_d} s(I). \end{aligned}$$

Since $(\alpha - 1)(\alpha_d - 1) < 1$, or equivalently $\frac{\alpha\alpha_d}{\alpha+\alpha_d} < 1$, by repeatedly applying R (at most polynomially many times), the problem P can be solved in polynomial time. This completes the proof. □

The condition "$\alpha, \alpha_d \geq 1$" in the previous theorem is not crucial in the light of the following lemma.

LEMMA 3.2. *Let (P, s) be a parameterized problem such that P admits a kernelization $r(\cdot)$ with $s(r(I, k)) \leq \alpha k$ for some $\alpha < 1$. Then P is in $\mathcal{P}$.*

Proof. According to our definition of the size function, we have $s(I') \geq k'$ for each instance (I', k'). This is particularly true for the parameter k' of the problem kernel instance $I' = r(I, k)$. Therefore, $k' \leq \alpha k$ for some $\alpha < 1$. By repeated kernelization, we arrive at a problem with an arbitrarily small parameter and, hence, of arbitrarily small size. In fact, we need $\mathcal{O}(\log k)$ many such kernelizations, each of them requiring polynomial time. It follows that the given problem can be decided in polynomial time. □

Remark. The assumption that $s(I) \geq k$ is crucial here. As a concrete "counter-example," consider the *decision tree problem*, specified by n objects $X = \{x_1, \ldots, x_n\}$,

t boolean tests $T = \{T_1, \dots, T_t\}$, and a parameter k. In this setting, a decision tree is a binary tree B whose leaves are (uniquely) labeled with objects and whose inner nodes are labeled with tests such that on the path from the root to the leaf labeled x_i, tests are performed that uniquely distinguish x_i from all other objects. The overall length of all paths from the root to each leaf is usually considered as the cost function. The question is whether there exists a decision tree with cost bounded by k. This problem is known to be $\mathcal{NP}$-complete (see [32]).

If $n = 2^\ell$, the decision tree with optimal cost is surely the complete binary tree (possibly not attainable with the given set of tests), since it is optimally balanced. Hence, we have $k > n \log_2 n$ (otherwise, an algorithm can simply answer NO); this can be seen as a trivial kernelization algorithm. Therefore, $n \in o(k)$. This can be interpreted as giving the (to our knowledge) first natural parameterized problem having a sublinear kernel. On the other hand, this relation also implies that $s(I, k) < k$ is true here, so that the previous lemma does not lead to a contradiction with the known $\mathcal{NP}$-hardness result.

The problem here is the seemingly innocuous choice of the size function as being $n = |X|$. Observe that any "reasonable" encoding of an instance would rather use $n \log n$ bits, since each element of X would need to get a name. This way, the problem would disappear.

3.2. Concrete lower bound results. From Theorem 3.1 and assuming $\mathcal{P} \neq \mathcal{NP}$, we immediately obtain Corollaries 3.3–3.8.

COROLLARY 3.3. *For any $\epsilon > 0$, there is no $(4/3-\epsilon)k$ kernel for* PLANAR VERTEX COVER.

Proof. The four-color theorem implies a $4k$-kernelization for PLANAR INDEPENDENT SET, which is the dual problem of PLANAR VERTEX COVER. □

COROLLARY 3.4. *For any $\epsilon > 0$, there is no $(2-\epsilon)k$ kernel for* PLANAR INDEPENDENT SET. *This result remains true if we restrict the problem to graphs of maximum degree bounded by three, or even to planar graphs of maximum degree bounded by three (both problems are $\mathcal{NP}$-hard).*

Proof. The general VERTEX COVER problem, which is the dual of the INDEPENDENT SET problem, has a $2k$-kernelization [13] (based on a result of Nemhauser and Trotter). This kernelization is both planarity and bounded-degree preserving. □

COROLLARY 3.5. *For any $\epsilon > 0$, there is no $(3/2-\epsilon)k$-kernelization for* VERTEX COVER *restricted to triangle-free planar graphs (this problem is still $\mathcal{NP}$-hard* [40, *Chapter* 7]*).*

Proof. Based on a theorem by Grötzsch (which can be turned into a polynomial-time coloring algorithm; see [29]), it is known that planar triangle-free graphs are 3-colorable. This implies a $3k$ kernel for INDEPENDENT SET restricted to this graph class, which gives the result. Observe that the mentioned $2k$-kernelization for VERTEX COVER on general graphs preserves planarity and triangle-freeness, which implies that this restriction of the problem has a $2k$-kernelization. □

COROLLARY 3.6. *For any $\epsilon > 0$, there is no $(335/334-\epsilon)k_d$ kernel for* PLANAR NONBLOCKER.

Proof. A $335k$ kernel for PLANAR-DS was derived in [5]. □

COROLLARY 3.7. *For any $\epsilon > 0$, there is no $(2-\epsilon)k$ kernel for* PLANAR-DS. *This remains true when further restricting the graph class to planar graphs of maximum degree three (the problem is still $\mathcal{NP}$-hard).*

Proof. In [20], a $2k_d$-kernelization for NONBLOCKER on general graphs which preserves planarity and degree bounds was derived (see also [37, Thm. 13.1.3]). □

Corollary 3.8 (see [15]). *For any $\epsilon > 0$, there is no $(2-\epsilon)k$ kernel for* dominating set on cubic graphs. This is interesting, since that case is the best match between upper and lower bounds for domination problems.

The above results open a new line of research and prompt us to ask whether we can find examples of problems such that the derived kernel sizes are optimal (unless $\mathcal{P} = \mathcal{NP}$), and whether we can close the gaps between the upper bounds and lower bounds on the kernel size. According to our previous discussion, planar vertex cover on triangle-free graphs is our "best match": we know how to derive a kernel of size $2k$ and (assuming $\mathcal{P} \neq \mathcal{NP}$) we know that no kernel smaller than $3k/2$ exists. On the other hand, the $335k$ upper bound on the kernel size for planar-DS [5] is very far from the $2k$ lower bound proved above. In the next sections, we improve this upper bound to $67k$ in an effort to bridge the huge gap between the upper bound and lower bound on the kernel size for this problem. This allows us to state the following corollary.

Corollary 3.9. *Assuming $\mathcal{P} \neq \mathcal{NP}$, there is no $(67/66-\epsilon)k_d$ kernel for* planar nonblocker *for any choice of $\epsilon > 0$.*

Remark. Since "Euler-type" theorems exist for graphs of bounded genus g, it can be shown that there is a constant c_g such that each graph of genus g is c_g-colorable. Therefore, lower bounds on the kernel sizes of vertex cover on graphs of genus g can be derived. For triangle-free graphs of genus g, Thomassen has shown that the corresponding constant c'_g is in $\mathcal{O}(g^{1/3}(\log g)^{-2/3})$ (see [28, 39]).

Remark. Recently, Fomin and Thilikos [26] were able to extend the linear kernel result for dominating set to graphs on surfaces of bounded genus. Therefore, our lower bound results extend to these more general graph classes as well.

3.3. Can we improve on the lower bounds?

In the following, we reproduce a construction that is essentially due to Paul Seymour.[1] This construction shows that the lower bound results obtained using the techniques devised in this section can be sharp for certain problems.

Consider the following family $\mathcal{G}_n$ of graph classes. A graph G is in $\mathcal{G}_n$ if and only if it satisfies the following two conditions.

1. $G = (V, E)$ can be partitioned into $2n+1$ mutually disjoint independent sets, i.e., $V = I_1 \cup \cdots \cup I_{2n+1}$, $I_i \cap I_j = \emptyset$ for all $1 \leq i < j \leq 2n+1$, and the induced graphs $G[I_i]$ contain no edges.
2. The edge set E can be partitioned into $2n+1$ groups $E_1, \ldots, E_{2n+1}$ such that
$$E_i = E(G[I_i \cup I_{i \bmod (2n+1)+1}]).^2$$

Figure 1 provides an example of a graph in $\mathcal{G}_n$.

Since each of these classes is closed under taking induced subgraphs, we can deduce by the Nemhauser–Trotter kernelization [13] the following lemma.

Lemma 3.10. vertex cover *restricted to $\mathcal{G}_n$ admits a kernel of size $2k$ (within $\mathcal{G}_n$).*

Since the graphs in $\mathcal{G}_n$ are "nearly bipartite," we have the following result.

Lemma 3.11. independent set *restricted to $\mathcal{G}_n$ admits a kernel of size $(2 + 1/n)k_d$ (within $\mathcal{G}_n$).*

Proof. Let $G = (V, E) \in \mathcal{G}_n$ with an independent set decomposition $V = I_1 \cup \cdots \cup I_{2n+1}$ that certifies this membership. To simplify the notation, we assume that

[1] Personal communication (2005).

[2] We assume that the graph G is given with a certificate of membership in $\mathcal{G}_n$, which is a partitioning of its vertex set into the $2n+1$ subsets.

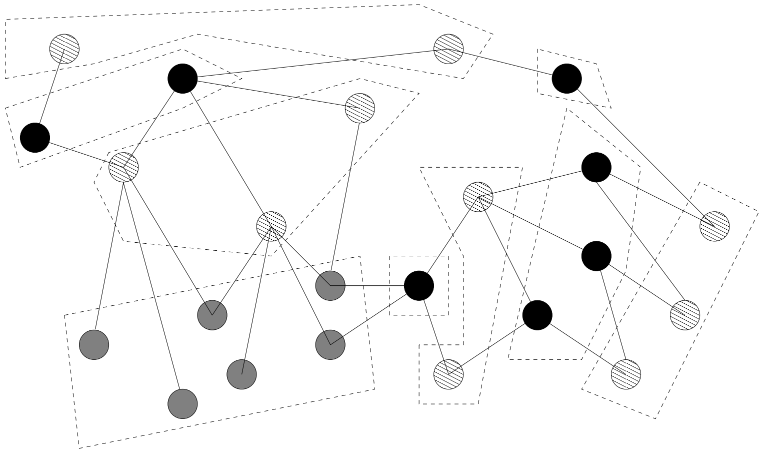

FIG. 1. *An example of a graph in $\mathcal{G}_n$.*

additions and subtractions of indices are all performed modulo $2n+1$. Consider the sets

$$J_i = I_i \cup I_{i+2} \cup \cdots \cup I_{i-3}, \quad 1 \le i \le 2n+1.$$

J_i greedily collects "every second" set starting at I_i so that each set J_i forms an independent set of G. It can be easily verified that

$$\sum_{i=1}^{2n+1} |J_i| = n|V|.$$

This shows that there exists an index i for which the set J_i contains at least a fraction $n/(2n+1)$ of all the vertices. Moreover, such a J_i can be found in polynomial time. Therefore, we can answer YES straightaway whenever we are given a graph $G = (V, E) \in \mathcal{G}_n$ with a parameter $k_d \le (n/(2n+1))|V|$, as an instance of INDEPENDENT SET. This means that we have $|V| < (2+1/n)k_d$ for all the remaining instances. □

THEOREM 3.12. *For each n,* VERTEX COVER *restricted to $\mathcal{G}_n$ is $\mathcal{NP}$-complete.*

Proof. Membership in $\mathcal{NP}$ is inherited from the general VERTEX COVER problem. We will show that 3-SAT is polynomial-time reducible to VERTEX COVER restricted to $\mathcal{G}_n$. We highlight the main elements in the reduction here and leave the verification of some of the details to the interested reader.

Let $\mathcal{C} = \{C_1, \ldots, C_m\}$ be a collection of clauses. Without loss of generality, we can assume that $|C_i| = 3$ for all $1 \le i \le m$. Let ℓ_i^j refer to the jth literal in clause C_i, i.e., $\ell_i^j = y_i^j$ or $\ell_i^j = \bar{y}_i^j$ for some variable $y_i^j \in X = \{x_1, \ldots, x_r\}$.

We construct a graph $G = (V, E) \in \mathcal{G}_n$ as follows. For each variable x_i, we introduce a cycle $(v_i^1, \ldots, v_i^{4n+2})$ of even length. Clearly, $2n+1$ of these vertices will be in any feasible vertex cover. For each clause C_i, we introduce a cycle $(u_i^1, \ldots, u_i^{2n+1})$ of odd length. Clearly, $n+1$ of these vertices will be in any feasible vertex cover. Summarizing, the graph described so far will have at least $r(2n+1) + m(n+1)$ vertices in any feasible cover. Since we will now add more edges to this graph, the lower bound on the size of the vertex cover will still be valid. At the same time, we will maintain the property that $I_j = \{v_i^j, v_i^{j+2n+1} \mid 1 \le i \le r\} \cup \{u_i^j \mid 1 \le i \le m\}$, where $1 \le j \le 2n+1$, are all independent sets.

If $\ell_i^1 = y_i^1 = x_q$, then we will make u_i^1 adjacent to v_q^2. If $\ell_i^2 = y_i^2 = x_q$, then we will make u_i^2 adjacent to v_q^{2n+2}. If $\ell_i^3 = y_i^3 = x_q$, then we will make u_i^3 adjacent to v_q^2.

If $\ell_i^1 = \bar{y}_i^1 = \bar{x}_q$, then we will make u_i^1 adjacent to v_q^{2n+3}. If $\ell_i^2 = \bar{y}_i^2 = \bar{x}_q$, then we will make u_i^2 adjacent to v_q^1. If $\ell_i^3 = \bar{y}_i^3 = \bar{x}_q$, then we will make u_i^3 adjacent to v_q^{2n+3}.

Now, if x_i is set to true in a satisfying assignment of the given 3-SAT instance, then we put v_i^j into the vertex cover if and only if j is even. If x_i is set to false in a satisfying assignment of the given 3-SAT instance, then we put v_i^j into the vertex cover if and only if j is odd. It is not difficult to verify that a satisfying assignment of $\mathcal{C}$ can be translated into a feasible vertex cover of size $r(2n+1)+m(n+1)$.

The same identification of vertices from v_i^j with variable settings allows us to translate a feasible vertex cover of size $r(2n+1)+m(n+1)$ into a satisfying assignment for the given 3-SAT instance. □

COROLLARY 3.13. *Unless $\mathcal{P} = \mathcal{NP}$, the* VERTEX COVER *problem restricted to $\mathcal{G}_n$ does not have a kernel of size $(2-\epsilon)k$ for any $\epsilon > 0$.*

Proof. This follows from Lemma 3.11 and Theorem 3.1. □

Remark. The above corollary shows that the lower bound results on the kernel size for VERTEX COVER restricted to $\mathcal{G}_n$ obtained using the techniques in this paper are tight. It also shows that it is unlikely that the VERTEX COVER problem on general graphs admits a kernelization of size $(2-\epsilon)k$ with the property that the produced kernel is a subgraph of the original graph, the reason being that such a kernelization would also be a kernelization for the vertex cover problem restricted to the class $\mathcal{G}_n$ with the same kernel bound.

3.4. A possible two-sided attack for exact algorithms. With problems having both FPT algorithms for their primal and for their dual parameterizations, we have the possibility of converting both algorithms into a nonparameterized algorithm. This is like attacking the problem from two sides. This means that we can use either of the two FPT algorithms, depending on "to which side" our concrete problem instance is closer.

THEOREM 3.14. *Let (P, s) be a parameterized problem and P_d its dual. Assume that both P and P_d are in FPT. Let f be a monotone function. Assume that there is an algorithm A that solves an instance (I, k) of P in time $\mathcal{O}(f(\beta k)p(s(I)))$ for some polynomial p, and that A_d is an algorithm that solves an instance (I, k_d) of P_d in time $\mathcal{O}(f(\beta_d k_d)p_d(s(I)))$ for a polynomial p_d.*

Then, there is an algorithm A' for solving the nonparameterized problem instance I running in time

$$\mathcal{O}\left(f\left(\frac{\beta\beta_d}{\beta+\beta_d}s(I)\right)p'(s(I))\right),$$

for some polynomial p'.

Proof. The idea is to use algorithm A as long as it is better than using A_d. This means that we have to compare

$$f(\beta k) \quad \text{to} \quad f(\beta_d(s(I)-k_d)).$$

Since f is monotone, this means we can simply compare

$$\beta k \quad \text{to} \quad \beta_d(s(I)-k_d).$$

Some simple algebra shows that we can have the following algorithm A' for the nonparameterized problem P, given an instance I:

```
for all parameter values $k$ do:
if $k \leq \frac{\beta_d}{\beta+\beta_d}s(I)$ then compute $A(I,k)$;
else compute $A_d(I, s(I)-k)$;
output the 'best' of all computed solutions.
```

Considering the boundary case $k = \frac{\beta_d}{\beta+\beta_d}s(I)$ gives the claimed worst-case running time. Here, $p'(j) = j(p(j)+p_d(j))$. □

Unfortunately, we currently lack good examples that prove this approach superior to published (problem-tailored) exact algorithms.

4. Reduction and coloring rules.

In this section we show how to improve the upper bound on the kernel size for the PLANAR-DS problem to $67k$. In the remainder of the paper we will always assume that the graph we are dealing with is planar.

In this section we present an $O(n^3)$ time preprocessing scheme that reduces the graph G to a graph G' such that $\gamma(G) = \gamma(G')$ and such that given a minimum dominating set for G', a minimum dominating set for G can be constructed in linear time. We will color the vertices of the graph G with two colors: black and white. Initially, all vertices are colored black. Informally speaking, white vertices will be those vertices for which we know for sure when we color them that there exists a minimum dominating set for the graph excluding all of them. The black vertices are all other vertices. Note that it is possible for white vertices to be in some minimum dominating set, but the point is that there exists at least one minimum dominating set that excludes all white vertices. Hence, the black-and-white coloring is only an auxiliary structure and not part of the problem definition. We start with the following definitions that are adopted from [5] with minor additions and modifications.

For a vertex v in G denote by $N(v)$ the set of neighbors of v, and by $N[v]$ the set $N(v) \cup \{v\}$. By removing a vertex v from G, we mean removing v and all the edges incident on v from G. For a vertex v in G, we partition its set of neighbors $N(v)$ into three sets: $N_1(v) = \{u \in N(v) \mid N(u) - N[v] \neq \emptyset\}$; $N_2(v) = \{u \in N(v) - N_1(v) \mid N(u) \cap N_1(v) \neq \emptyset\}$; and $N_3(v) = N(v) - (N_1(v) \cup N_2(v))$. For two vertices v and w we define $N(v,w) = N(v) \cup N(w)$ and $N[v,w] = N[v] \cup N[w]$. We partition $N(v,w)$ into three sets: $N_1(v,w) = \{u \in N(v,w) \mid N(u) - N[v,w] \neq \emptyset\}$; $N_2(v,w) = \{u \in N(v,w) - N_1(v,w) \mid N(u) \cap N_1(v,w) \neq \emptyset\}$; and $N_3(v,w) = N(v,w) - (N_1(v,w) \cup N_2(v,w))$.

DEFINITION 4.1. *Let $G = (V,E)$ be a plane graph. A region $R(v,w)$ between two vertices v and w is a closed subset of the plane with the following properties:*

1. *The boundary of $R(v,w)$ is formed by two simple paths P_1 and P_2 in G which connect v and w, and the length of each path is at most three.*
2. *All vertices that are strictly inside (i.e., not on the boundary) the region $R(v,w)$ are from $N(v,w)$.*

For a region $R = R(v,w)$, let $V[R]$ denote the vertices in R; i.e.,

$$V[R] := \{u \in V \mid u \textit{ sits inside or on the boundary of } R\}.$$

Let $V(R) = V[R] - \{v,w\}$.

DEFINITION 4.2. *A region $R = R(v,w)$ between two vertices v and w is called* simple *if all vertices in $V(R)$ are common neighbors of both v and w; that is, $V(R) \subseteq N(v) \cap N(w)$.*

We introduce the following definition.

DEFINITION 4.3. *A region $R = R(v,w)$ between two vertices v and w is called* quasi-simple *if $V[R] = V[R'] \cup R^+$, where $R' = R'(v,w)$ is a simple region between v and w, and R^+ is a set of white vertices satisfying the following conditions.*

1. *Every vertex of R^+ sits strictly inside R'.*
2. *Every vertex of R^+ is connected to v and not connected to w, and is also connected to at least one vertex on the boundary of R' other than v.*

A vertex in $V(R)$ is called a *simple* vertex if it is connected to both v and w; otherwise it is called *nonsimple*. The set of vertices R^+, which consists of the nonsimple vertices in $V(R)$, will be referred to as $R^+(v, w)$.

For a vertex $u \in V$, denote by $B(u)$ the set of black vertices in $N(u)$ and by $W(u)$ the set of white vertices in $N(u)$. We describe next the reduction and coloring rules to be applied to the graph G. The reduction and coloring rules are applied to the graph until the application of any of them does not change the structure of the graph or the color of any vertex in the graph. The first two reduction rules, Rules 1 and 2, are slight modifications of Rules 1 and 2 introduced in [5]. The only difference is that in the current paper they are applied only to black vertices, and not to all the vertices as in [5].

Rule 1 (see [5]). If $N_3(v) \neq \emptyset$ for some black vertex v, then remove the vertices in $N_2(v) \cup N_3(v)$ from G and add a new white vertex v' and an edge (v, v') to G.

Rule 2 (see [5]). If $N_3(v, w) \neq \emptyset$ for two black vertices v, w and if $N_3(v, w)$ cannot be dominated by a single vertex in $N_2(v, w) \cup N_3(v, w)$, then we distinguish the following two cases.

Case 1. If $N_3(v, w)$ can be dominated by a single vertex in $\{v, w\}$, then (1) if $N_3(v, w) \subseteq N(v)$ and $N_3(v, w) \subseteq N(w)$, remove $N_3(v, w)$ and $N_2(v, w) \cap N(v) \cap N(w)$ from G and add two new white vertices z, z' and the edges $(v, z), (w, z), (v, z'), (w, z')$ to G; (2) if $N_3(v, w) \subseteq N(v)$ and $N_3(v, w) \not\subseteq N(w)$, remove $N_3(v, w)$ and $N_2(v, w) \cap N(v)$ from G and add a new white vertex v' and the edge (v, v') to G; and (3) if $N_3(v, w) \subseteq N(w)$ and $N_3(v, w) \not\subseteq N(v)$, remove $N_3(v, w)$ and $N_2(v, w) \cap N(w)$ from G and add a new white vertex w' and the edge (w, w') to G.

Case 2. If $N_3(v, w)$ cannot be dominated by a single vertex in $\{v, w\}$, then remove $N_2(v, w) \cup N_3(v, w)$ from G and add two new white vertices v', w' and the edges (v, v'), (w, w') to G.

Rule 3. For each black vertex v in G, if there exists a black vertex $x \in N_2(v) \cup N_3(v)$, color x white and remove the edges between x and all other white vertices in G.

Rule 4. For every two black vertices v and w, if $N_3(v, w) \neq \emptyset$, then for every black vertex $x \in N_2(v, w) \cup N_3(v, w)$ that does not dominate all vertices in $N_3(v, w)$, color x white and remove all the edges between x and the other white vertices in G.

Rule 5. For every quasi-simple region $R = R(v, w)$ between two vertices v and w, if v is black, then for every black vertex $x \in N_2(v, w) \cup N_3(v, w)$ strictly inside R that does not dominate all vertices in $N_2(v, w) \cup N_3(v, w)$ strictly inside R, color x white and remove all the edges between x and the other white vertices in G.

Rule 6. For every two white vertices u and v, if $N(u) \subseteq N(v)$ and $u \in N_2(w) \cup N_3(w)$ for some black vertex w, then remove v.

Rule 7. For every black vertex v, if every vertex $u \in W(v)$ is connected to all the vertices in $B(v)$, then remove all the vertices in $W(v)$ from G.

Rule 8. For every two black vertices v and w, let $W(v, w) = W(v) \cap W(w)$. If $|W(v, w)| \geq 2$ and there is a degree-2 vertex $u \in W(v, w)$, then remove all vertices in $W(v, w)$ except u, add a new degree-2 white vertex u', and connect u' to both v and w.

Figure 2 illustrates Rules 4, 6, and 8.

A graph G is said to be *reduced* if every vertex in G is colored white or black and

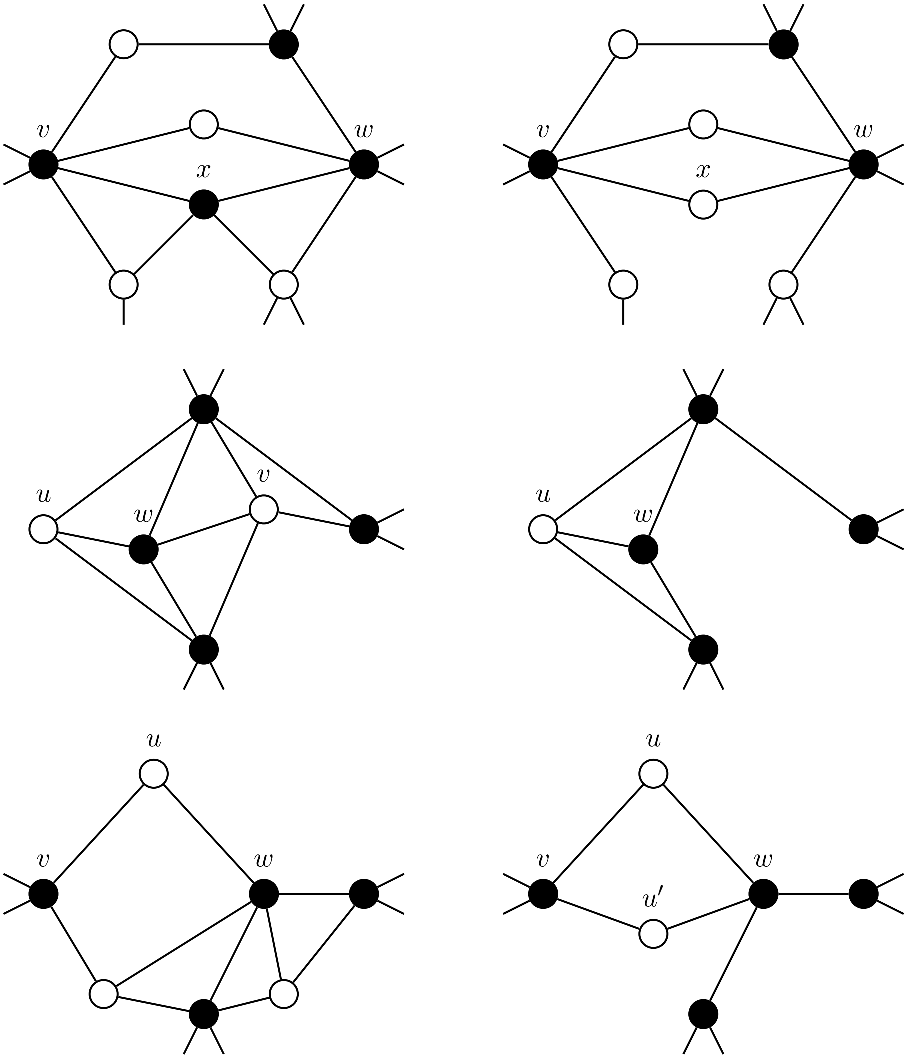

FIG. 2. *Illustrations of Rule* 4 *(top figure), Rule* 6 *(middle figure), and Rule* 8 *(bottom figure).*

the application of Rules 1–8 leaves the graph G unchanged. That is, the application of any of the above rules does not change the color of any vertex in G, nor does it change the structure of G. We have the following theorem.

THEOREM 4.4. *Let G be a planar graph with n vertices. Then in time $O(n^3)$ we can construct a planar graph G' from G such that* (1) *G' is reduced,* (2) $\gamma(G') = \gamma(G)$, (3) *there exists a minimum dominating set for G' that excludes all white vertices of G', and* (4) *from a minimum dominating set for G' a minimum dominating set for G can be constructed in linear time.*

Proof. Given a graph G, we first color all its vertices black. We then apply Rules 1–8 given above until the application of any of these rules leaves G unchanged. Let G' be the resulting graph. Then G' is reduced by the definition of a reduced graph. Alber, Fellows, and Niedermeier [5] noted that each successful application of Rules 1 and 2 (i.e., an application that changes the structure of the graph G) reduces the number of vertices in the graph by at least one. Hence, the total number of applications of these two rules is bounded by n. By looking at Rules 3–7, it is easy to see that each of these rules either reduces the number of vertices in G by at least one or changes the color of at least one black vertex to white without adding any new vertices to the graph. Moreover, none of Rules 1–7 increases the number of edges in the graph. If we look at Rule 8, it is not difficult to see that each successful application of this rule reduces the number of edges in the graph by at least 1. This is true since in a successful application of the rule either $|W(v,w)| > 2$ (and in this case the numbers of vertices and edges decrease after the application of the rule) or $|W(v,w)| = 2$ and there is a vertex in $W(v,w)$ of degree larger than 2 (otherwise the application of the rule does not change the structure of the graph), and hence the removal of $W(v,w)$ decreases the number of edges in the graph. Noting that the number of edges in a planar graph is linear in the number of vertices and that the application of the rules becomes unnecessary if the graph does not contain any black vertices, we conclude that the total number of successful applications of the operations in Rules 1–8 is $O(n)$. Alber, Fellows, and Niedermeier [5] also showed that Rules 1 and 2 can be executed in time $O(n^2)$ when the graph is planar. Similarly, one can show that Rules 3–8 can also be executed in $O(n^2)$ time (we leave the verification of this simple fact to the interested reader). This, together with the fact that the total number of successful applications of all the rules is $O(n)$, implies that the time needed to construct G' is $O(n^3)$.

To show parts (2) and (3) of the theorem, we prove that after the execution of any of the rules, the resulting graph satisfies conditions (2) and (3) in the theorem. The proof will then follow by an inductive argument on the number of applications of the rules. Denote by H the graph before a rule is executed, and by H' the resulting graph after the rule is executed. Denote by D a minimum dominating set for H excluding all white vertices in H. Initially, $H = G$, and all vertices in H are black. Thus, H trivially satisfies conditions (2) and (3) in the theorem. Suppose now that one of the rules is executed on a graph H satisfying conditions (2) and (3) in the theorem to yield the graph H'. We need to show that H' satisfies conditions (2) and (3) as well.

Suppose that Rule 1 is executed. The same argument used in [5] shows that $\gamma(H) = \gamma(H')$.[3] What is left is showing that H' has a minimum dominating set consisting only of black vertices. Let D be a minimum dominating set for H consisting of black vertices. Since $N_3(v) \neq \emptyset$, D must contain a vertex in $N_2(v) \cup N_3(v) \cup \{v\}$. If D contains a vertex in $N_2(v) \cup N_3(v)$, then clearly this vertex can be replaced by v which is black. Thus we can assume that D contains v and no vertex in $N_3(v) \cup N_2(v)$. Then D is also a dominating set for H' consisting only of black vertices, and since $\gamma(G) = \gamma(H) = \gamma(H')$, D is a minimum dominating set for H'. It follows that H' satisfies conditions (2) and (3). The proof of Rule 2 is of the same flavor.

If Rule 3 is executed, then the black vertices in the set $N_2(v) \cup N_3(v)$, where v is black, will be colored white, and the edges between the white vertices are removed. It suffices to show that after the coloring of one vertex x in $N_2(v) \cup N_3(v)$ white and removing the edges between x and the other white vertices, conditions (2) and (3) still hold (the same argument can then be applied repetitively to every such vertex). By our inductive hypothesis, before the application of Rule 3 to H, H had a minimum dominating set D of size equal to $\gamma(G)$ that excludes all white vertices in H. If D contains x, we can replace x by v and have a minimum dominating set of H consisting only of black vertices in H. Thus, we can assume, without loss of generality, that D

[3] The fact that this statement holds true can be easily verified by the reader.

does not include x. Since x is the only vertex whose color has changed to white, D consists only of black vertices in H'. Moreover, it is not difficult to see that D is also a dominating set in H' since the edges removed from H are not used to dominate any vertices in H (these edges were incident on vertices that are not in D). Since by removing edges from the graph the size of the minimum dominating set can only increase, we conclude that D is a minimum dominating set for H' excluding all white vertices, and $\gamma(H') = \gamma(H) = \gamma(G)$.

Suppose Rule 4 is executed. Similarly, we need only show that conditions (2) and (3) still hold after a vertex x has been colored white. If D contains x, then by the assumption in Rule 4, x does not dominate all the vertices in $N_3(v,w)$, and D must also contain at least another vertex x' in $N_2(v,w) \cup N_3(v,w) \cup \{v,w\}$ to dominate $N_3(v,w)$. This is true since only vertices in $N_2(v,w) \cup N_3(v,w) \cup \{v,w\}$ can dominate vertices of $N_3(v,w)$. In such a case we can replace x and x' by v and w and have a minimum dominating set that consists only of black vertices in H. Since x is the only vertex whose color has changed to white, D excludes all white vertices in H'. It is easy to see that the edges that connect white vertices in H are not used by D to dominate any vertex. By an argument similar to the above, it follows that D is a minimum dominating set for H' excluding all white vertices in H', and $\gamma(H') = |D| = \gamma(H) = \gamma(G)$.

Suppose Rule 5 is executed and a vertex x is colored white. Let $R = R(v,w)$ be the quasi-simple region that was being processed in the rule, and note that all the vertices in $R^+(v,w)$ are connected to v. Let the boundary of R be (v,y,w,z,v). Let D be a dominating set for H consisting only of black vertices. If D contains x, then by the assumption in Rule 5, x does not dominate all the vertices in $N_2(v,w) \cup N_3(v,w)$ strictly inside R, and D must contain another black vertex $x' \in R(v,w)$ in $N_2(v,w) \cup N_3(v,w) \cup \{v,w,y,z\}$ to dominate the vertices in $N_2(v,w) \cup N_3(v,w)$ that are strictly inside R. Observe that, by the definition of a quasi-simple region, the only vertex that can be dominated by x and not by v is w. We distinguish the following cases.

Case 1. $x' = v$. Since at least one vertex $r \in \{y,w,z\}$ must be black (w is connected to both y and z, and no edges exist between white vertices; thus it is not possible for all the vertices in $\{y,w,z\}$ to be white) and since all the vertices in $\{y,w,z\}$ dominate w, we can replace x by r (note that x is dominated by v) to obtain a dominating set consisting of black vertices that excludes x.

Case 2. $x' \neq v$. If x' does not dominate w, then x' must be one of those vertices in R^+ that connect only to v and to the vertices on the boundary of R other than w. Since all such boundary vertices are dominated by v, and x' is dominated by v as well, we can replace x' by v in D, and the case reduces to Case 1 above. If x' dominates w, then we can replace x by v to get a dominating set consisting of black vertices that excludes x.

Thus, we can assume, without loss of generality, that D does not include x. Since x is the only vertex whose color has changed to white, D consists only of black vertices in H'. By an argument similar to that above, it follows that D is a minimum dominating set for H' excluding all white vertices in H', and $\gamma(H') = |D| = \gamma(H) = \gamma(G)$.

Suppose Rule 6 is executed and a vertex v is removed as described in the rule. Let D be a minimum dominating set for H excluding all white vertices in H. Thus D does not contain v. Since v is the only vertex removed, and no vertices are colored, it follows that D is a dominating set for H' excluding all white vertices in H'. What is left is proving that D is a minimum dominating set for H'. Suppose that H' has a minimum dominating set D' of size strictly smaller than D. Then D' has to cover u, and hence D' contains either u or a neighbor of u in H'. If D' contains u, since every neighbor of u is also a neighbor of w, and u is a neighbor of w, $(D' \cup \{w\}) - \{u\}$ is a minimum dominating set for H of size smaller than D, a contradiction (note that since w is a neighbor of u, w is a neighbor of v as well and hence dominates v). On the other hand, if D' contains a neighbor of u, since $N(u) \subseteq N(v)$, D' also contains a neighbor of v in H and hence dominates v. Thus, D' is a dominating set for H of size smaller than D, a contradiction. It follows that $|D| = \gamma(H') = \gamma(H) = \gamma(G)$.

Suppose that Rule 7 is executed on a black vertex v and all vertices in $W(v)$ were removed as described in the rule. Let D be a minimum dominating set for H excluding all white vertices in H. Thus, D does not contain any vertex in $W(v)$. Since the vertices in $W(v)$ are the only vertices that were removed, and no vertices in the graph were colored, it follows that D is a dominating set for H' excluding all white vertices in H'. What is left is proving that D is a minimum dominating set for H'. Suppose that H' has a minimum dominating set D' of size strictly smaller than D. Then D' has to cover v. Hence D' contains either v or a neighbor of v in $B(v)$ because all the vertices in $W(v)$ were removed. In either case, D' dominates all the removed vertices in $W(v)$ in H, since every vertex in $W(v)$ is adjacent to all vertices in $B(v)$. Therefore D' is also a dominating set for H of size smaller than D, a contradiction. It follows that $|D| = \gamma(H') = \gamma(H) = \gamma(G)$.

To prove the statement for Rule 8, let D be a minimum dominating set for H excluding all white vertices in H. Again, D is a dominating set for H' excluding all white vertices in H'. Let D' be a minimum dominating set for H' and suppose, to get a contradiction, that $|D'| < |D|$. Without loss of generality, we can assume that D' contains either v or w (or both); otherwise, to dominate u and u', D' has to contain both u and u', which can be replaced by v and w. Now D' is also a dominating set for H of smaller size than D, a contradiction. It follows that D is a minimum dominating set for H' excluding all white vertices in H', and $\gamma(H') = \gamma(H) = \gamma(G)$.

To prove part (4) of the theorem, note the following: (1) from a minimum dominating set for G' one can construct in $O(n)$ time a minimum dominating set for G' containing only black vertices (this can be achieved by associating, during the reduction phase, with the vertices colored white the black vertices that can replace them) and (2) a minimum dominating set for G' consisting only of black vertices is also a minimum dominating set for G. This completes the proof. □

5. A problem kernel. Let G be a reduced graph, and let D be a minimum dominating set for G consisting of black vertices such that $|D| = k$. In this section, we will show that the number of vertices n in G is bounded by $67k$. The following definitions are adopted from [5].

Given any dominating set D in a graph G, a *D-region* decomposition of G is a set $\Re$ of regions between pairs of vertices in D such that the following hold.

1. For any region $R = R(v, w)$ in $\Re$, no vertex in D is in $V(R)$. That is, a vertex in D can only be an endpoint of a region in $\Re$.
2. No two distinct regions R_1, $R_2 \in \Re$ intersect. However, they may touch each other by having common boundaries.

Note that all the endpoints of the regions in a D-region decomposition are vertices in D. For a D-region decomposition $\Re$, define $V[\Re] = \bigcup_{R \in \Re} V[R]$. A D-region decomposition is *maximal* if there is no region R such that $\Re^{'} = \Re \cup R$ is a D-region decomposition with $V[\Re] \subsetneq V[\Re^{'}]$.

For a D-region decomposition $\Re$, associate a planar graph $G_{\Re}(V_{\Re}, E_{\Re})$ with possible multiple edges, where $V_{\Re} = D$, and such that there is an edge between two vertices v and w in $G_{\Re}$ if and only if $R(v,w)$ is a region in $\Re$. A planar graph with multiple edges is called *thin* if there is a planar embedding of the graph such that for any two edges e_1 and e_2 between two distinct vertices v and w in the graph, there must exist two more vertices which sit inside the disjoint areas of the plane enclosed by e_1 and e_2.

Alber, Fellows, and Niedermeier [5] showed that the number of edges in a thin graph of n vertices is bounded by $3n-6$. They also showed that for any plane graph G and a dominating set D of G, there exists a maximal D-region decomposition for G such that $G_{\Re}$ is thin. Since the maximal D-region decomposition in [5] starts with any dominating set D and is not affected by the color a vertex can have, the same results in [5] hold true for our reduced graph G whose vertices are colored black/white, and with a minimum dominating set D consisting of only black vertices. The above discussion is summarized in the following proposition.

PROPOSITION 5.1. *Let G be a reduced graph and D a dominating set of G consisting of black vertices. Then there exists a maximal D-region decomposition $\Re$ of G such that $G_{\Re}$ is thin.*

COROLLARY 5.2. *Let G be a reduced graph with a minimum dominating set D consisting of k black vertices, and let $\Re$ be a maximal D-region decomposition of G such that $G_{\Re}$ is thin. Then the number of regions in $\Re$ is bounded by $3k-6$.*

Proof. The number of regions in $\Re$ is the number of edges in $G_{\Re}$. Since $G_{\Re}$ has $|D| = k$ vertices, by [5], the number of edges in $G_{\Re}$ is bounded by $3k-6$. □

In the remainder of this section, $\Re$ will denote a maximal D-region decomposition of G such that $G_{\Re}$ is thin. Let u and v be two vertices in G. We say that u and v are *boundary-adjacent* if (u,v) is an edge on the boundary of some region $R \in \Re$. For a vertex $v \in G$, denote by $N^*(v)$ the set of vertices that are boundary-adjacent to v. Note that for a vertex $v \in D$, since v is black, by Rule 3, all vertices in $N_2(v) \cup N_3(v)$ must be white. Note also that, by the definition of a D-region decomposition, all the endpoints of the regions in $\Re$ are vertices in D, and hence are colored black.

PROPOSITION 5.3. *Let $v \in D$. The following are true.*

(a) *(Lemma 6, [5].) Every vertex $u \in N_1(v)$ is in $V[\Re]$.*

(b) *The vertex v is an endpoint of a region $R \in \Re$. That is, there exists a region $R = R(x,y) \in \Re$ such that $v = x$ or $v = y$.*

(c) *Every vertex $u \in N_2(v)$ which is not in $V[\Re]$ is connected only to v and to vertices in $N^*(v)$.*

Proof. The proof of part (a) appears in [5].

To prove (b), suppose, to get a contradiction, that v is not the endpoint of any region in $\Re$. Since $v \in D$, and by the definition of a region, v must be outside every region in $\Re$. Now v must have a vertex in $N_1(v)$; otherwise, all vertices in $N(v)$ would be white and hence removed by Rule 7 (we assume, without loss of generality, that G does not contain any isolated vertices). Let $u \in N_1(v)$. By part (a) above, u must belong to some region $R = R(x,y)$. Observe that u must be on the boundary of R; otherwise v would be a vertex in $V[R]$. Again, by the definition of a region, u is either boundary-adjacent to x or to y. Suppose, without loss of generality, that u is boundary-adjacent to x. But then the degenerated region formed by (x,u,v) does not cross $\Re$ (it only touches R), contradicting the maximality of $\Re$.

To prove part (c), let u be a vertex in $N_2(v)$ and note that u is white, and suppose that u is connected to a vertex $w \neq v$ such that $w \notin N^*(v)$. Note that w must be in $N_1(v)$ (otherwise w would be white and u and w cannot be adjacent) and hence, by part (a) above, must belong to some region $R = R(x, y)$. Since $u \notin V[\Re]$, w cannot be inside R and hence is on the boundary of R. Moreover, by the definition of a region, w must be boundary-adjacent to either x or y. Without loss of generality, assume w is boundary-adjacent to x. Now $w \notin N^*(v)$, so w cannot be boundary-adjacent to v, and $x \neq v$. Consider the degenerated region formed by (v, u, w, x). This region cannot cross any region in $\Re$; otherwise it crosses it via (u, w), and u would be in $V[\Re]$. But this contradicts the maximality of $\Re$ since $u \notin V[\Re]$. ▯

Let x be a vertex in G such that $x \notin V[\Re]$. Then by part (b) in Proposition 5.3, $x \notin D$. Thus, $x \in N(v)$ for some black vertex $v \in D \subseteq V[\Re]$. By part (a) in Proposition 5.3, $x \notin N_1(v)$, and hence, $x \in N_2(v) \cup N_3(v)$. By Rule 3, the color of x must be white. Let $R = R(v, w)$ be a region in $V[\Re]$ of which v is an endpoint (such a region must exist by part (b) of Proposition 5.3). We distinguish two cases.

Case A. $x \in N_3(v)$. Since v is black, by Rule 1, this is only possible if $deg(x) = 1$ and $N_2(v) = \emptyset$ (in this case x will be the white vertex added by the rule). In such a case it can be easily seen that we can flip x and place it inside R without affecting the planarity of the graph.

Case B. $x \in N_2(v)$. Note that in this case $N_3(v) = \emptyset$ by Rule 1 (otherwise $N_2(v) \cup N_3(v)$ would be removed), and x is only connected to v and $N^*(v)$ by part (c) of Proposition 5.3. If $deg(x) = 2$, by a similar argument to Case A above, x can be flipped and placed inside R.

According to the above discussion, it follows that the vertices in G can be classified into two categories: (1) those vertices that are in $V[\Re]$ and (2) those that are not in $V[\Re]$, which are those vertices of degree larger than 2 that belong to $N_2(v)$ for some vertex $v \in D$ and in this case must be connected only to vertices in $N^*(v)$. To bound the number of vertices in G we need to bound the number of vertices in the two categories. We start with the vertices in category (2).

Let O denote the set of vertices in category (2). Note that all vertices in O are white, and no two vertices u and v in O are such that $N(u) \subseteq N(v)$. To see why the latter statement is true, note that every vertex in O must be in $N_2(w)$ for some black vertex $w \in D$. So if $N(u) \subseteq N(v)$, then by Rule 6, v would have been removed from the graph. To bound the number of vertices in O, we will bound the number of vertices in O that are in $N_2(v)$ where $v \in D$. Let us denote this set by $N^\dagger(v)$. Let $N^*_\dagger(v)$ be the set of vertices in $N^*(v)$ that are neighbors of vertices in $N^\dagger(v)$. Note that every vertex in $N^\dagger(v)$ has degree ≥ 3 and is connected only to v and to $N^*_\dagger(v)$, and that no two vertices x and y in $N^\dagger(v)$ are such that $N(x) \subseteq N(y)$.

ASSUMPTION 5.4. *For the sake of counting the number of vertices in $N^\dagger(v)$, it is safe to assume that* (1) *every vertex in $N^\dagger(v)$ has degree exactly* 3*;* (2) *no two vertices x and y in $N^\dagger(v)$ are such that $N(x) \subseteq N(y)$; and* (3) *vertices in $N^\dagger(v)$ are only connected to v and to vertices in $N^*_\dagger(v)$.*

Proof. Since properties (2) and (3) are already satisfied by the vertices in $N^\dagger(v)$, we need only show how we can make the vertices in $N^\dagger(v)$ satisfy property (1) without reducing their number and without affecting properties (2) and (3). To satisfy property (1), we will remove some edges between vertices in $N^\dagger(v)$ and $N^*_\dagger(v)$ without affecting the other properties. This can be done as follows. List the vertices in $N^\dagger(v)$ in an arbitrary order $\langle u_1, \ldots, u_r\rangle$. Start by picking u_1; then choose any two neighbors of u_1 in $N^*_\dagger(v)$ and remove all edges that join u_1 to all its neighbors other than v and these two chosen neighbors. Inductively, suppose we have processed vertex u_{i-1}; we process vertex u_i as follows. Pick two neighbors w_1^i and w_2^i of u_i in $N^*_\dagger(v)$ such that no vertex in $\{u_1, \ldots, u_{i-1}\}$ has both w_1^i and w_2^i as its picked neighbors. Delete all the edges that join u_i to all vertices other than v, w_1^i, and w_2^i. We need to show that it is always possible to carry out this step. Suppose not, and let i be the smallest index such that this is not possible. It is easy to verify using the facts that every vertex in $N^\dagger(v)$ has degree larger than 2, no two vertices x and y are such that $N(x) \subseteq N(y)$, and that $i > 3$. Note that it must be the case that $deg(u_i) > 3$; otherwise, since this step cannot be carried out, the only two neighbors of u_i other than v must be neighbors of some other vertex $u_j \in \{u_1, \ldots, u_{i-1}\}$, and hence we would have $N(u_i) \subseteq N(u_j)$ for some $u_j \in \{u_1, \ldots, u_{i-1}\}$, contradicting the properties satisfied by category-(2) vertices as discussed above. Let a, b, c be three neighbors of u_i other than v. Since this step cannot be carried out successfully, there must exist three distinct vertices $u_p, u_q, u_s \in \{u_1, \ldots, u_{i-1}\}$ such that $\{a, b\} \subset N(u_p)$, $\{a, c\} \subset N(u_q)$, and $\{b, c\} \subset N(u_s)$. Consider the subgraph H of G induced by the set of vertices $\{v, u_p, u_q, u_s, u_i, a, b, c\}$. Then the following is true about the vertices in H: (1) $u_i, u_p, u_q, u_s, a, b, c$ are neighbors of v in H; (2) v, a, b, c are neighbors of u_i in H; (3) v, a, b are neighbors of u_p in H; (4) v, a, c are neighbors of u_q in H; (5) v, b, c are neighbors of u_s in H; (6) v, u_i, u_p, u_q are neighbors of a in H; (7) v, u_i, u_p, u_s are neighbors of b in H; and (8) v, u_i, u_q, u_s are neighbors of c in H. Using all this information, it is not difficult to verify that H is nonplanar (identify vertex a with vertex b along the path (a, u_p, b) to obtain a copy of $K_{3,3}$), contradicting the planarity of G. This completes the proof. □

PROPOSITION 5.5. $|N^\dagger(v)| \leq 3/2|N^*_\dagger(v)|$.

Proof. To simplify the counting, by Assumption 5.4, we can assume that every vertex in $N^\dagger(v)$ has degree exactly 3; no two vertices x and y in $N^\dagger(v)$ are such that $N(x) \subseteq N(y)$; and vertices in $N^\dagger(v)$ are connected only to v and $N^*_\dagger(v)$. Let x be the number of vertices in $N^*_\dagger(v)$, and let $f(x) = |N^\dagger(v)|$. We will show that $f(x) \leq 3/2(x-1)$. We proceed by induction on x. If $x = 1$, it is clear that $f(x) = 0 \leq 3/2(x-1)$ since by Assumption 5.4, each vertex in $N^\dagger(v)$ has degree exactly 3. If $x = 2$, then clearly $f(x) \leq 1 \leq 3/2(x-1)$ since at most one vertex can be connected to v and the two vertices in $N^*_\dagger(v)$ without violating properties (1)–(3) in Assumption 5.4. If $x = 3$, then $f(x) \leq 3$ since at most three vertices can be connected to $N^*_\dagger(v)$ without violating properties (1)–(3) in Assumption 5.4, each connected to v and to two other vertices in $N^*_\dagger(v)$. Inductively, suppose that if $N^*_\dagger(v)$ contains y vertices with $3 \leq y < x$, then the number of vertices $f(y)$ in $N^\dagger(v)$ satisfies $f(y) \leq 3/2(y-1)$. Suppose now that $|N^*_\dagger(v)| = x$. Let u be a vertex in $N^\dagger(v)$, and let a, b be its neighbors in $N^*_\dagger(v)$. The vertex u is called *hollow* if the interior of the region enclosed by (u, a, v, b, u) contains no vertices of $N^*_\dagger(v)$. If every vertex in $N^\dagger(v)$ is hollow, then it is clear that $f(x) \leq x \leq 3/2(x-1)$ for $x > 3$, and the bound $f(x) = x$ is attained when there are x vertices in $N^\dagger(v)$, and every vertex u in $N^\dagger(v)$ is adjacent to v and the two neighbors a and b in $N^*_\dagger(v)$ immediately to the left and right in the clockwise (or counterclockwise) ordering, respectively, of u in the embedding. Suppose now that there is a vertex $u \in N^\dagger(v)$ such that u is not hollow. The edges (u, a), (u, v), (u, b), (v, a), (v, b) separate the plane into three faces: F_1 enclosed by the cycle (u, a, v, u), F_2 enclosed by the cycle (u, v, b, u), and F_3, the outer face determined by the cycle (u, a, v, b, u). Let x_1 be the number of vertices in $N^*_\dagger(v)$ that are in F_1 including the boundary, x_2 the number in F_2, and x_3 the number in F_3. Note that $1 \leq x_1 < x$ since $a \in F_1$ and $b \notin F_1$, $1 \leq x_2 < x$ since $b \in F_2$ and $a \notin F_2$, and $2 \leq x_3 < x$ since a and b are in F_3 and at least one vertex in $N^*_\dagger(v)$ is not in F_3 since u is hollow, and hence the interior of the face (u, a, v, b, u) contains at least one vertex in $N^*_\dagger(v)$. Moreover, $x_1 + x_2 + x_3 = x + 2$, since a and b are the only vertices counted twice when we add the vertices in $N^*_\dagger(v)$ that are in F_1, F_2, and F_3. Now every vertex in $N^\dagger(v)$ is either (1) connected to two vertices in $N^*_\dagger(v)$ in F_1, (2) connected to two vertices in $N^*_\dagger(v)$ in F_2, or (3) connected to two vertices in $N^*_\dagger(v)$ in F_3. Note that vertex u satisfies property (3). Since $x_1, x_2, x_3 < x$, by the inductive hypothesis, the number of vertices satisfying (1) is bounded by $f(x_1) \leq 3/2(x_1 - 1)$, the number of vertices satisfying (2) is bounded by $f(x_2) \leq 3/2(x_2 - 1)$, and the number of vertices satisfying (3) is bounded by $f(x_3) \leq 3/2(x_3 - 1)$. Now $f(x) \leq f(x_1) + f(x_2) + f(x_3) \leq 3/2(x_1 + x_2 + x_3) - 9/2 = 3x/2 - 3/2 = 3/2(x - 1)$. This completes the proof. □

LEMMA 5.6. *The number of vertices in category* (2) *(i.e., the number of vertices not in* $V[\Re]$*) is bounded by* $18k$.

Proof. Let v and w be any two distinct vertices in D and observe the following. First, $N^\dagger(v) \cap N^\dagger(w) = \emptyset$, because if $u \in N^\dagger(v) \cap N^\dagger(w)$, then (v, u, w) would be a degenerated region with $u \notin V[\Re]$ contradicting the maximality of $\Re$. Second, from the first observation it follows that $w \notin N^*_\dagger(v)$ and $v \notin N^*_\dagger(w)$, and in general no vertex $a \in D$ belongs to $N^*_\dagger(b)$ for any vertex $b \in D$; otherwise, there exists a vertex $u \in N^\dagger(v)$ that is connected to w, and hence $u \in N^\dagger(v) \cap N^\dagger(w)$, contradicting the first observation. Third, $N^*_\dagger(v) \cap N^*_\dagger(w) = \emptyset$; otherwise, there exists a vertex $u \in N^*_\dagger(v) \cap N^*_\dagger(w)$ that is connected to a category-(2) vertex $a \in N^\dagger(v)$ (or $b \in N^\dagger(w)$), and the degenerated region (v, a, u, w) (or (w, b, u, v)) would contain the vertex $a \notin \Re$ (or $b \notin \Re$), contradicting the maximality of $\Re$.

Let B be the number of vertices not in D that are boundary-adjacent to vertices in D (i.e., in $N^*(v) - D$ for some $v \in D$). Combining the above observations with Proposition 5.5, it follows that the number of category-(2) vertices is

$$\sum_{v \in D} |N^\dagger(v)| \leq \frac{3}{2} \sum_{v \in D} |N^*_\dagger(v)| \leq 3B/2.$$

According to the definition of a region, each region in $\Re$ has at most six vertices on its boundary, two of which are vertices in D. Thus, each region in $\Re$ can contribute with at most four vertices to B. Note that from the above discussion no vertex $a \in D$ belongs to $N^*_\dagger(b)$ for any vertex $b \in D$, and hence the endpoints of the regions do not contribute to B. By Corollary 5.2, the number of regions in $\Re$ is bounded by $3k - 6$. It follows that $B \leq 12k - 24$, and hence the number of category-(2) vertices is bounded by $18k - 36 < 18k$. This completes the proof. □

To bound the number of vertices in category (1), fix a region $R(v, w)$ between $v, w \in D$. We have the following lemma whose proof is technical and based on case-by-case structural analysis. The proof of the lemma appears in the appendix.

LEMMA 5.7 (see Lemma A.5 in the appendix). *Let* $R = R(v, w)$ *be a region in* $V[\Re]$. *The number of vertices in* $V(R)$ *is bounded by* 16.

THEOREM 5.8. *The number of vertices in* G *is bounded by* $67k$.

Proof. By Lemma 5.6, the number of category-(2) vertices in G is bounded by $18k$. Using this bound, we can assume that each region in $\Re$ is nice. By Corollary 5.2, the number of regions in $\Re$ is bounded by $3k - 6$. According to Lemma 5.7, the number of vertices in $V(R)$, where $R \in \Re$ is a nice region, is bounded by 16. It follows that the number of vertices in $V(\Re)$ is bounded by $48k - 96$. Thus, the number of vertices in $V[\Re]$, and hence in category (1), is bounded by $48k - 96$ plus the number of vertices in D which are the endpoints of the regions in $\Re$. Therefore the number of vertices in $V[\Re]$ is bounded by $49k - 96$, and the total number of vertices in G is bounded by $67k - 96 < 67k$. This completes the proof. □

THEOREM 5.9. *Let G be a planar graph with n vertices. Then in time $O(n^3)$, computing a dominating set for G of size bounded by k can be reduced to computing a dominating set of size bounded by k for a planar graph G' of $n' < n$ vertices, where $n' \leq 67k$.*

Proof. According to Theorem 4.4, in time $O(n^3)$ we can construct a reduced graph G' from G, where $\gamma(G') = \gamma(G)$, and such that a dominating set for G can be constructed from a dominating set for G' in linear time. Moreover, the graph G' has no more than n vertices. If G has a dominating set of size bounded by k, then G' has a dominating set of size bounded by k (since $\gamma(G) = \gamma(G')$), and by Theorem 5.9, we must have $n' \leq 67k$. If this is the case, then we can work on computing a dominating set for G' of size bounded by k, from which a dominating set for G can be easily computed. If this is not the case, then G does not have a dominating set of size bounded by k, and the answer to the input instance is negative. This completes the proof. □

6. A simple algorithm. In this section we present a simple algorithm for determining whether a graph G has a dominating set of size bounded by k.

Let $G = (V, E)$ be a planar graph given with an embedding in the plane. The *layer decomposition* of G with respect to the embedding is a partitioning of V into disjoint layers $(L_1, \ldots, L_r)$ defined inductively as follows. Layer L_1 is the set of vertices that lie on the outer face of G, and layer L_i is the set of vertices that lie on the outer face of $G - \bigcup_{j=1}^{i-1} L_j$ for $1 < i \leq r$. It is well known that a layer decomposition of a planar graph G can be computed in linear time in the number of vertices in the graph [4].

A *separator* in a graph G is a set of vertices S whose removal disconnects G. If $(L_1, \ldots, L_r)$ is a layer decomposition of G, then clearly the vertices in any layer L_i form a separator in G, separating the vertices in layers $L_1, \ldots, L_{i-1}$ from those in layers $L_{i+1}, \ldots, L_r$. Let (G, k) be an instance of the PLANAR-DS problem. By Theorem 5.9, we can assume that G is reduced and that the number of vertices n of G satisfies $n \leq 67k$. Let $(L_1, \ldots, L_r)$ be a layer decomposition of G. Let $c > 0$ be a constant which will be determined later, and set $l = \lceil c\sqrt{k} \rceil$. Consider the families of layers F_i, $i = 1, \ldots, l$, where F_i consists of layers $L_i, L_{i+l}, L_{i+2l}, \ldots$. Assume for now that the number of layers $r \geq l$. We will show later how to handle the situation when this is not the case. The families F_i, $i = 1, \ldots, l$, are disjoint, and each family forms a separator separating the graph into connected components that will be called *chunks*, where each chunk consists of at most l consecutive layers. Since these l families are disjoint and partition the layers into l groups, and since the graph has at most $67k$ vertices, there exists an index $1 \leq \mu \leq l$, such that the number of vertices in F_μ is bounded by $67k/l$. Again, observe that the removal of F_μ from G separates G into chunks, each consisting of at most l consecutive layers. Let these chunks be $G_1, \ldots, G_s$.

The basic idea behind the algorithm is to apply a simple divide-and-conquer strategy by removing the vertices in the family F_μ to split the graph into chunks, then to compute a minimum dominating set for the resulting chunks using the algorithm introduced in [33], which is a variation of Baker's algorithm [8]. To do this, for each vertex v in the F_μ, we "guess" whether v is in the minimum dominating set for G or not (basically, what we mean by guessing is enumerating all sequences corresponding to the different possibilities). For each guess of all the vertices in F_μ, we will solve the corresponding instance with respect to that guess. It was shown in [33] how this guessing process can be achieved using at most three statuses per vertex. Hence, guessing the vertices in F_μ can be done by enumerating at most $3^{|F_\mu|} \leq 3^{67k/l}$

ternary sequences. After guessing each vertex in the separator and updating the graph accordingly, the instance becomes an instance of a variation of the minimum dominating set problem due to the constraints placed on some of the vertices in the graph. Kanj and Perković introduced an algorithm in [33], which is a variation of Baker's algorithm [8], to solve this problem. The algorithm introduced in [33] solves this problem on the chunks in time $O(27^{d+1}n)$, where d is the maximum number of layers in a chunk (i.e., the maximum depth of a chunk). Noting that $d \leq l$ and that $n \leq 67k$, we conclude that after guessing all the vertices in F_μ, the problem can be solved in time $O(27^l k)$. If the number of layers r in G is less than l, we can simply call the algorithm in [33] directly on G to solve the problem in time $O(27^l k)$. The algorithm is given in Figure 3 below.

It is not difficult to verify that the running time of the algorithm is $O(3^{67k/l} \cdot 27^l \cdot k + n^3)$, where the $O(n^3)$ time is the time taken to reduce G to its kernel. Niedermeier and Rossmanith showed how to get rid of the k factor corresponding to the kernel size in the running time of such algorithms [36]. Using their techniques, the running time of the algorithm becomes $O(n^3 + 3^{67k/l} \cdot 27^l)$. We choose c, and hence l, so that the above expression is minimized. It can be shown that the expression is minimized when $c = \sqrt{67/3}$, and the running time of the algorithm becomes $O(n^3 + 2^{45\sqrt{k}})$.

```
Algorithm. DS-SOLVER
Input: a planar graph $G$ of $n$ vertices, and a parameter $k$
Output: a dominating set $D$ of size $\leq k$ in case it exists;

1. use the results in Theorem 5.9 to kernelize $G$;
2. if the number of vertices $n$ of $G$ is $> 67k$ then
       Stop("$G$ does not have a dominating set of size $\leq k$");
3. let $c = \sqrt{67/3}$; $l = \lceil c\sqrt{k} \rceil$;
4. if the number of layers in $G$ is $< l$ then
       use the algorithm in [33] to solve the problem in time $O(2^{45\sqrt{k}}k)$; Stop;
5. let $F_\mu$ be a separator of size $\leq 67k/l$ separating the graph into chunks
   $G_1, \ldots, G_s$ each consisting of at most $l$ consecutive layers;
6. for each assignment to the vertices in $F_\mu$ do
       update $D$;
       split the graph into its components;
       compute a minimum dominating set $D'$ for the resulting graph using the
       algorithm in [33];
       $D = D \cup D'$;
7. output the smallest dominating set constructed in step 6 in case its size is
   bounded by $k$; otherwise return ("$G$ does not have a dominating set of size
   $\leq k$").
```

FIG. 3. *A simple algorithm solving* PLANAR-DS.

THEOREM 6.1. *In time $O(n^3 + 2^{45\sqrt{k}})$, it can be determined whether or not a planar graph on n vertices has a dominating set of size bounded by k.*

Theorem 6.1 shows that our algorithm for solving the PLANAR-DS problem is competitive with the previous algorithms using the similar technique of layer decomposition of a planar graph [4, 33]. The above algorithm improves the original $O(2^{70\sqrt{k}}n)$ time algorithm given in [4] for the problem. At the same time, our algorithm is much simpler than the algorithms in [4, 23, 25, 33], illustrating the power of kernelization in the process of designing efficient algorithms for parameterized $\mathcal{NP}$-hard problems. Finally, after a kind of race resulting in better and better algorithms [4, 23, 25, 33], Fomin and Thilikos recently presented an $O(n^3 + 2^{15.13\sqrt{k}})$ time algorithm to solve the PLANAR-DS problem based on the concept of branchwidth [25], the best treewidth based algorithm being only slightly worse [23].

7. Summary and extensions. In this paper we exhibited the first lower bound results on kernel sizes and, motivated by these findings, we strived to improve on the (still huge) constants involved in the known linear kernel for PLANAR-DS.

Are there other, possibly more sophisticated arguments for showing lower bounds on kernel sizes? In particular, it would be interesting to have arguments ruling out, for example, the existence of a kernel of size $o(k^3)$ in a situation when a kernel of size $\mathcal{O}(k^3)$ has been obtained. The algebra we used in the proof of Theorem 3.1 does not extend to such cases.

We mention that the concept of a black-and-white graph we used for deriving the kernel upper bound results for PLANAR-DS also allows us to exhibit a small kernel for a variation of the DOMINATING SET problem, called the RED/BLUE DOMINATING SET problem, as studied by Weihe [41]: Given a graph $G = (V, E)$, with V partitioned into $V_{\text{red}} \cup V_{\text{blue}}$, and a positive integer k, is there a *red/blue dominating set* $D \subseteq V_{\text{red}}$ with $|D| \leq k$, i.e., $V_{\text{blue}} \subseteq N(D)$? Namely, if we consider the red vertices as "black" in our notation and the blue vertices as "white," and if we reanalyze our reduction rules, we can state the following corollary.

COROLLARY 7.1. PLANAR RED/BLUE DOMINATING SET *admits a problem kernel of size* $67k$.

As exhibited in [4, 23], the possibly better known FACE COVER problem can be solved with the help of PLANAR RED/BLUE DOMINATING SET, by introducing "face vertices." However, we are still investigating if we could claim a small kernel for FACE COVER, since we are not keeping the (face) structure of the original problem. Notice that a cubic kernel was derived in [1, Thm. 1]. Based on this sort of problem kernel, we could then arrive at an $O^*(c^{\sqrt{k}})$ algorithm for FACE COVER that is significantly better than what was obtained in [4], close to being competitive with [23], along the lines of the preceding section.

Appendix. In this section we prove Lemma 5.7. We first start with some observations and preliminary results.

Fix a region $R(v, w)$ between $v, w \in D$. Without loss of generality, assume the boundary of R is determined by the two paths (v, v_1, w_1, w) and (v, v_2, w_2, w). Note that all vertices in $V(R)$ belong to $N(v, w)$, and that v_1, $v_2 \in N^*(v)$ and $w_1, w_2 \in N^*(w)$. If there is a degree-1 vertex x connected to v (resp., w), then this vertex is in $N_3(v)$ (resp., $N_3(w)$) and must be colored white by Rule 3. Similarly, if there exists a degree-2 vertex y that is connected to v and either v_1 or v_2 (resp., w and either w_1 or w_2), then y is in $N_2(v)$ (resp., $N_2(w)$) and must be colored white by Rule 3. Now if a degree-1 white vertex is connected to v, then since the vertices in $N^\dagger(v)$ are white and are neighbors of v, by Rule 6 we must have $N^\dagger(v) = \emptyset$. During the process of counting the number of vertices in $N^\dagger(v)$, we bounded the number of vertices in $N^\dagger(v)$ by $3|N^*(v)|/2$. This can be looked at as each vertex in $N^*(v)$ contributing 3/2 vertices to $|N^\dagger(v)|$. So if a degree-1 white vertex is connected to v (note that at most one degree-1 vertex can be connected to v), this means that $N^*(v)$ which contains at least two vertices will not contribute to the number of vertices in $N^\dagger(v)$, and hence, the bound on $|N^\dagger(v)|$ will be decreased by at least three. Similarly, if a degree-2 white vertex is connected to v and v_1 (or v_2) (again, note that there can be at most one degree-2 vertex connected to v and to v_1 (or v_2)), then no vertex in $N^\dagger(v)$ can be connected to v_1 (or v_2). This can be regarded as a reduction to the bound on $|N^\dagger(v)|$ by 3/2. Thus, if we use the upper bound on the number of vertices in category (2) computed above, we may assume without loss of generality that no degree-1 vertex is connected to v or w and that no degree-2 vertex is connected to v and v_1, v and v_2,

w and w_1, or w and w_2. We will also assume that the boundary of a region $R(v, w)$ consists of exactly six distinct vertices; that is, the region is not a degenerated region. The case of a degenerated region obviously yields a better bound on the number of vertices in the region. Let us call a region with all the above properties *nice*. We start with the following propositions.

Proposition A.1. *If there is no simple black vertex strictly inside a quasi-simple region $R = R(v, w)$, then $V(R)$ contains at most two simple white vertices.*

Proof. Suppose, to get a contradiction, that $V(R)$ contains more than two simple white vertices, and let a, b, and c be three such vertices. Since all three vertices are simple, one vertex must be engulfed within the area determined by v, w, and the other two vertices. Suppose that b is situated within the area (v, a, w, c, v). Since, by the assumption of the proposition, all the simple vertices strictly inside $V(R)$ must be white, and since all the nonsimple vertices inside $V(R)$ (i.e., vertices in R^+) are white by definition, and since no edges exist between white vertices, it follows that the white simple vertex b, engulfed by the area (v, a, w, c, v), is connected only to v and w and hence has degree 2. Note that the color of both v and w must be black since there are simple white vertices that are connected to both v and w. Now $|W(v, w)| > 2$ because $\{a, b, c\} \subseteq W(v, w)$. But this makes Rule 8 applicable, contradicting the fact that G is reduced. This completes the proof. ∎

Proposition A.2. *Let $R = R(v, w)$ be a quasi-simple region where the color of v is black; then $V(R)$ has at most four simple vertices.*

Proof. Suppose first that R has six or more simple vertices. Let S be the set of those simple vertices that are strictly inside R. Then $|S| \geq 4$. Since the vertices in S are simple and hence connect to both v and w, it is obvious that no vertex lying strictly inside R can dominate all vertices in S. Since S is a subset of those vertices in $N_2(v, w) \cup N_3(v, w)$ that are strictly inside R, it follows that no vertex that is strictly inside R can dominate all vertices in $N_2(v, w) \cup N_3(v, w)$. Now all vertices that lie strictly inside R belong to $N_2(v, w) \cup N_3(v, w)$; thus, by Rule 5, all vertices strictly inside R must be white. Noting that $|S| \geq 4$, and that all the vertices in S are simple white vertices, this contradicts Proposition A.1.

Suppose now that R has five simple vertices. Let a, b, and c be the three simple vertices that lie strictly inside R. By an argument similar to the above, we can assume that vertex b is engulfed within the area determined by v, a, w, and c. Again all the vertices strictly inside R must belong to $N_2(v, w) \cup N_3(v, w)$. Since a does not dominate c, and vice versa, it follows that a and c are colored white by Rule 5. Now a, b, and c are the only simple vertices strictly inside R, but by Proposition A.1, no three simple white vertices can be contained in R. This forces b to be black and to be connected to both a and c (otherwise b would be colored white by Rule 5). Now all other nonsimple vertices in R must be connected to the boundary and hence cannot be connected to b (all the vertices other than a and c which can be connected to b have to belong to the area engulfed by (v, a, w, c) and cannot be connected to the boundary). Thus, $W(b) = \{a, c\}$, and every vertex in $W(b)$ is connected to all vertices in $B(b) = \{v, w\}$ (note that since a and c are white and are connected to w, w must be black). By Rule 7, $W(b) = \{a, c\}$ should have been removed at this point, a contradiction. Therefore, R has at most four simple vertices and the proof is complete. ∎

Proposition A.3. *Let (v, y, w, z, v) be the boundary of a quasi-simple region $R = R(v, w)$, and suppose that v and y are black. Then there can be at most one white vertex in $R^+ = R^+(v, w)$ that is connected to both v and y.*

Proof. Suppose, to get a contradiction, that there are at least two white vertices in R^+ that are connected to both v and y. Since all the vertices in R^+ are white and hence cannot be connected together, there must exist two white vertices a and b in R^+ satisfying that the area engulfed by (v, a, y, v) is empty, and that the area engulfed by (v, b, y, v) contains only the vertex a. Clearly, the degree of a is exactly 2, and a belongs to $N_2(v) \cup N_3(v)$. Now since both a and b are connected to both v and y, we have $N(a) \subseteq N(b)$. Given the fact that v is black, this is a contradiction to Rule 6. □

Proposition A.4. *Let $R = R(v, w)$ be a quasi-simple region, and suppose that v is black. Let (v, y, w, z, v) be the boundary of R. If*

(a) *there are no simple vertices strictly inside R or*

(b) *there are simple vertices strictly inside R and all vertices in $R^+ = R^+(v, w)$ are connected to y,*

then $V(R) \cup \{w\}$ contains at most three white vertices. Moreover, if there are three white vertices in $V(R) \cup \{w\}$, then either $R^+ \neq \emptyset$ or there is a simple black vertex interior to R.

Proof. To prove that part (a) implies the statement of the proposition, suppose that there are no simple vertices lying strictly inside R. Then clearly all the white vertices in $V(R)$ come from $R^+ \cup \{y, z\}$. If y is white, then no vertex in R^+ can be connected to y because the vertices in R^+ are all white. On the other hand, since $R^+ \subseteq N_2(v) \cup N_3(v)$, if y is black, by Proposition A.3, at most one white vertex in R^+ can be connected to y, and similarly if z is black. Since every vertex in R^+ has to be connected to either y or z by the definition of a quasi-simple region, it follows from the above that $V(R)$ contains at most two white vertices, and hence $V(R) \cup \{w\}$ contains at most three white vertices. Now when $V(R) \cup \{w\}$ contains three white vertices, w must be white, and hence, y and z are black. Thus, the two white vertices other than w in $V(R) \cup \{w\}$ come from R^+, and $R^+ \neq \emptyset$.

To prove part (b), note first that, by Proposition A.2, the number of simple vertices in R including y and z is bounded by four. We will assume that the number of simple vertices in R is exactly four. The cases when there are less than four simple vertices in R are simpler and yield the desired bound. Let a and b be the other two simple vertices, and assume that the four simple vertices y, a, b, z appear in the preceding sequence in a clockwise order around v. Observe that the white vertices in $V(R)$ come from $R^+ \cup \{y, a, b, z\}$. Also observe that since all the vertices in R^+ are connected to y by the hypothesis of part (b), either y is white and R^+ is empty or y is black and by Proposition A.3, R^+ contains at most one vertex. It follows that the number of white vertices in $R^+ \cup \{y\}$ is bounded by one. Now suppose to get a contradiction that $V(R) \cup \{w\}$ contains four white vertices. Since no two white vertices are connected and since all vertices in $\{a, b, z\}$ are connected to w, w must be black, and all three vertices a, b, and z must be white. But then the degree of b is exactly 2, and $|W(v, w)| > 2$, contradicting Rule 8. To complete the proof, supposing that $V(R) \cup \{w\}$ contains exactly three white vertices, we need to show that either $R^+ \neq \emptyset$ or there exists a simple black vertex inside R. Suppose, to get a contradiction, that $R^+ = \emptyset$ and the interior vertices to R, a, b, are all white. Then w must be black in this case, and either y or z is white. Without loss of generality, assume y is white. Since there are no edges between white vertices, the degree of a must be 2, and $\{y, a, b\} \subseteq W(v, w)$, again a contradiction to Rule 8. □

Lemma A.5 (see Lemma 5.7). *Let $R = R(v, w)$ be a nice region in $V[\Re]$. The number of vertices in $V(R)$ is bounded by* 16.

Proof. Every vertex in $V(R)$ is in $N(v,w)$, and hence is connected to either v or w. We distinguish two cases.

Case 1. $N_3(v,w)=\emptyset$. In this case every vertex in $V(R)-\{v_1,v_2,w_1,w_2\}$ has to be connected to at least one vertex in $\{v_1,v_2,w_1,w_2\}$ because v_1,v_2,w_1,w_2 are the only vertices in $V(R)$ that possibly belong to $N_1(v,w)$. Since R is nice, the vertices in $V(R)-\{v_1,v_2,w_1,w_2\}$ can be classified into the following categories, where a vertex is assigned to the first category that it satisfies:

(i) vertices connected to v and v_1, but not connected to w_1;
(ii) vertices connected to v and w_1;
(iii) vertices connected to v and w_2;
(iv) vertices connected to v and v_2;
(v) vertices connected to w and w_2, but not connected to v_2;
(vi) vertices connected to w and v_2;
(vii) vertices connected to w and v_1; and
(viii) vertices connected to w and w_1.

Note that one of categories (ii) and (vii) must be empty; otherwise, according to our placement of the vertices in the categories, we have two distinct vertices in $V(R)$ other than v_1 and w_1: one of them is connected to v and w_1 and the other to w and v_1, contradicting the planarity of the graph. Similarly, one of categories (iii) and (vi) must be empty. Without loss of generality, assume that categories (iii) and (vii) are empty. If, in addition, either category (ii) or category (vi) is empty, then the situation becomes simpler, leading to a better bound on the number of vertices in $V(R)$. Thus, we will assume that both categories (ii) and (vi) are nonempty. Note also that since R is nice, no vertex interior to R has degree 2, and every vertex in category (i) must be connected to some vertex interior to R. Since category (ii) is nonempty, and by the planarity of G, a vertex in category (i) can be connected only to vertices in category (ii). Moreover, since the vertices in category (i) are connected only to v and to neighbors of v including v_1 (since these vertices can be connected only to v and to vertices in category (ii)), all these vertices belong to $N_2(v)\cup N_3(v)$. Since v is black, by Rule 3, all vertices in category (i) must be white. Now the vertices in categories (i) and (ii), plus v, v_1, and w_1, form a quasi-simple region between v and w_1, $Q_1=R(v,w_1)$. Moreover, all the vertices in $V(Q_1)$, except those in category (i), are simple vertices because all vertices in $V(Q_1)$, except those in category (i), have to be connected to both v and w_1. Since v is black (all the endpoints of regions in $\Re$ are black), by Proposition A.2, the number of vertices in $V(Q_1)$ except those vertices in category (i) is bounded by 4. Now we bound the number of vertices in category (i). Every vertex in category (i) is white and is connected to v and v_1. If category (i) is nonempty, then v_1 must be black, and the vertices in category (i) are white vertices in $Q_1^+(v,w_1)$ that are connected to v and v_1. It follows from Proposition A.3 that the number of vertices in category (i) is bounded by 1. This shows that the number of vertices in $V(Q_1)$ is bounded by 5. By symmetry, the number of vertices in $V(Q_2)$, where Q_2 is the quasi-simple region between w and v_2 consisting of the vertices in categories (v) and (vi), plus the vertices w, w_2, v_2, is bounded by 5. Now we bound the number of vertices in categories (iv) and (viii). We have the following claim.

Claim. The number of vertices in category (iv) (resp., category (viii)) is bounded by 2. Moreover, at most one vertex in category (iv) (resp., category (viii)) is white.

Consider the vertices in category (iv). Suppose that there are three or more vertices in category (iv), and let a_1, a_2, a_3 be three vertices in category (iv) such that no vertex is engulfed in the area of the embedding determined by (v,a_1,v_2), a_1

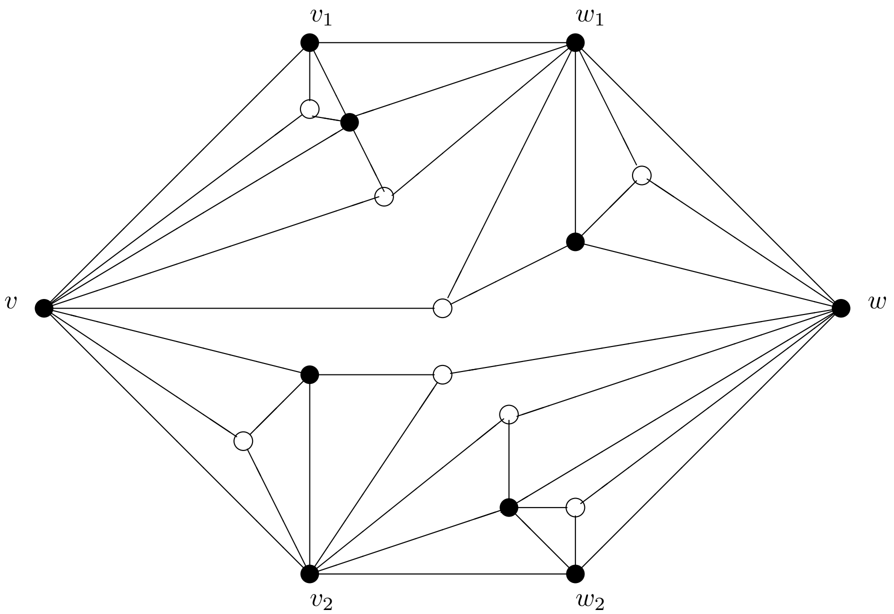

FIG. 4. *Illustration of a possible worst-case scenario for Case* 1. *Empty circles represent white vertices, and filled circles black vertices.*

is the only vertex engulfed in the area determined by (v, a_2, v_2), and a_1 and a_2 are the only two vertices engulfed in the area determined by (v, a_3, v_2). Now a_1 and a_2 must belong to $N_2(v) \cup N_3(v)$. Since v is black, it follows from Rule 3 that a_1 and a_2 must be white and that no edge exists between a_1 and a_2. But this means that $N(a_1) \subseteq N(a_2)$, and since $a_1 \in N_2(v)$ and v is black, according to Rule 6, this leads to a contradiction. It follows that at most two vertices can be in category (iv). By symmetry, at most two vertices can be in category (viii). Note also that it follows from the above proof that if there are exactly two vertices a_1 and a_2 in category (iv) (resp., category (viii)), then at most one vertex in $\{a_1, a_2\}$ can be white. This proves the claim.

Now the vertices in $V(R)$ consist of vertices of $V(Q_1)$, vertices of $V(Q_2)$, category (iv) and category (viii) vertices, and the two vertices v_2 and w_1 (in case these two vertices were not included in any of the other categories). It follows that the number of vertices in R is bounded by 16. See Figure 4 for an illustration of such a possible scenario.

Case 2. $N_3(v, w) \neq \emptyset$. Let X be the set of white vertices in $N_2(v, w)$ that are in $V(R)$, Y the set of black vertices in $N_2(v, w) \cup N_3(v, w)$ that are in $V(R)$, and Z the set of white vertices in $N_3(v, w)$ that are in $V(R)$. We first make a few observations.

Observation 1. $|X| \leq 7$. We first show that $|X| \leq 8$. Remove the vertices in $N_3(v, w)$ interior to R; then define categories (i)–(viii) as above. Similar to Case 1, we can assume that the vertices in categories (i) and (ii), plus the vertices v, v_1, and w_1, form a quasi-simple region $Q_1 = R(v, w_1)$, and that those in categories (v) and (vi), plus the vertices w, w_2, and v_2, form a quasi-simple region $Q_2 = R(w, v_2)$. Since $X \subseteq N_2(v, w)$, every vertex in X must belong to one of categories (i)–(viii) or possibly to the set $\{v_1, v_2, w_1, w_2\}$. From the definition of categories (i) and (ii), vertices in category (i) form the set $Q_1^+ = Q_1^+(v, w_1)$ in the quasi-simple region Q_1, and all the vertices in Q_1^+ are connected to v_1. Now add the vertices in $N_3(v, w)$ back, and note that no black vertex in $N_3(v,w)$ that is not connected to w_1 resides in Q_1. The reason is that such a vertex would be in $N_2(v) \cup N_3(v)$ (otherwise, this vertex will have to be connected to w_1—the only vertex in Q_1 possibly not in $N(v)$) and hence colored white by Rule 3. Now Q_1 plus the set of black vertices in $N_3(v,w)$ that reside in Q_1, minus the set of white vertices in $N_3(v,w)$ that reside in Q_1, satisfies condition (b) in Proposition A.4, and the number of white vertices in Q_1 is bounded by 3. Since no two white vertices are connected together and hence the presence of the white vertices from $N_3(v,w)$ in Q_1 cannot increase the number of possible white vertices in Q_1, we conclude that the number of white vertices in Q_1 that are not in $N_3(v,w)$, and hence, the number of vertices in X that belong to Q_1, is bounded by 3. Similarly, the number of vertices in X that belong to Q_2 is bounded by 3. Moreover, the statement of the claim in Case 1 carries in a straightforward manner to Case 2, and categories (iv) and (viii) contain at most one white vertex each. It follows that the number of white vertices in the set X is bounded by 8. Now if $|X| = 8$, then both Q_1 and Q_2 (plus the black vertices in $N_3(v,w)$ that reside in Q_1 and Q_2) contain three white vertices. Since Q_1 contains exactly three white vertices, by Proposition A.4, either $Q_1^+ \neq \emptyset$, or Q_1 must contain an interior black vertex. If $Q_1^+ \neq \emptyset$, since R is nice, the vertex in Q_1^+ must be connected to some vertex interior to Q_1 which must be black because the vertices in Q_1^+ are white. Therefore, if Q_1 contains exactly three white vertices, then there must exist an interior black vertex p in Q_1. Similarly, there must exist an interior black vertex q in Q_2. Since both p and q are black and are in $N_2(v,w) \cup N_3(v,w)$, by Rule 4, p and q must dominate all vertices in $N_3(v,w) \neq \emptyset$. In particular, p which is interior to Q_1 must dominate q which is interior to Q_2. This is a contradiction to the planarity of the graph. It follows that $|X| \leq 7$.

Observation 2. Every vertex in Y must dominate all vertices in $N_3(v,w)$.

This observation follows from Rule 4 since the vertices in Y are black and are a subset of $N_2(v,w) \cup N_3(v,w)$.

Let H be the graph obtained from G by identifying the vertex v with w along the path (v, v_1, w_1, w). Clearly, H is planar. Let u be the resulting vertex by this identification. Let Y' be the set of vertices in Y that are in H, and let $y = |Y'|$. Similarly, let Z' be the set of vertices in Z that are in H, and let $z = |Z'|$. Observe that the vertex u is connected to all the vertices in Y' and Z' in H, and that the only vertices that have been removed by this identification are boundary vertices to R that belong to $\{v_1, v_2, w_1, w_2\}$.

Observation 3. If $y > 1$ and $z > 1$, then the number of vertices in $V(R)$ is bounded by 16.

Suppose that $y > 1$ and $z > 1$. If $y > 2$, since every vertex in Y' must dominate the vertices in Z', it follows that the subgraph of H induced by the set of vertices $Y' \cup Z' \cup \{u\}$ contains a copy of $K_{3,3}$, contradicting the planarity of H (the vertices in Y' form the first bipartition, and the other vertices form the second bipartition). Suppose now that $y = 2$. If $z > 2$, then similarly, the subgraph induced by $Z' \cup \{u\} \cup Y'$ contains a copy of $K_{3,3}$ (the vertices in $Y' \cup \{u\}$ form the first bipartition, and those in Z' form the second bipartition). Suppose now that $y = z = 2$. Then the number of vertices in $X \cup Y' \cup Z'$ is bounded by 11. Since $|V(R)| \leq |X \cup Y' \cup Z' \cup \{v_1, v_2, w_1, w_2\}|$, it follows that the number of vertices in $V(R)$ is bounded by 16.

Now we distinguish the following two subcases.

Subcase 2.1. $z \leq 1$. Let $Y_1 = Y' \cap N_2(v,w)$ be the set of black vertices in Y' that are in $N_2(v,w)$, $y_1 = |Y_1|$, $Y_2 = Y' - Y_1$ be the set of black vertices in Y' that are in $N_3(v,w)$, and $y_2 = |Y_2|$. Note that every vertex in Y' must be connected to all vertices in $Y_2 \cup Z$ by Rule 4. If $y = y_1 + y_2 < 5$, then since $z \leq 1$ and the number of vertices in X is bounded by 7 by Observation 1, the number of vertices in $V(R)$ is bounded by 16. So we can assume that $y \geq 5$. If $y_2 + z \geq 4$, then the subgraph induced by the vertices $\{u\} \cup Y_2 \cup Z$ is a copy of K_5. Thus, $y_2 + z < 4$. If $y_2 + z = 3$, then the subgraph induced by the bipartition $(Y_2 \cup Z, Y_1 \cup \{u\})$ contains a copy of $K_{3,3}$, whereas if $y_2 + z = 2$, then the subgraph induced by the bipartition $(\{u\} \cup Y_2 \cup Z, Y_1)$ contains a copy of $K_{3,3}$. Suppose now that $y_2 + z = 1$. If $y_1 \leq 4$, then $y + z \leq 5$, and hence, the number of vertices in R is bounded by 16. Assume now that $y_1 \geq 5$. Let p be the vertex in $Y_2 \cup Z$; then p is connected to all vertices in Y_1 in H and hence in G. Moreover, every vertex in Y_1 is connected to either v or w (or both) in G. Since $y_1 \geq 5$, there must exist at least three vertices in Y_1 that are connected to either v or to w in G. Let these vertices be p_1, p_2, and p_3, and assume, without loss of generality, that these vertices are connected to v. Since p_1, p_2, and p_3, are also connected to p, there must exist a vertex in $\{p_1, p_2, p_3\}$, say p_2, that is interior to the region determined by v, p, and the other two vertices. But $p_2 \in Y_1 \subseteq N_2(v, w)$, and hence p_2 must be connected to the boundary of R (because p_2 must be connected to some vertex in $N_1(v, w)$), a contradiction. Thus, the number of vertices in $V(R)$ is bounded by 16.

Subcase 2.2. $y \leq 1$. If $z \leq 4$, then $y + z \leq 5$, and given that $|X| \leq 7$ by Observation 1, the total number of vertices in $V(R)$ is bounded by 16. Suppose now that $z \geq 5$. Observe first that $Y \neq \emptyset$; otherwise, $N_2(v, w) \cup N_3(v, w)$ consists of only white vertices, and $N_3(v, w)$, which contains at least five white vertices ($Z \subseteq N_3(v, w)$), could not be dominated by a single vertex in $N_2(v, w) \cup N_3(v, w)$. This would make Rule 2 applicable, a contradiction. Let p_1, p_2, p_3, p_4, and p_5 be vertices in Z. Since each of these vertices must be connected to either w or v, at least three vertices in $\{p_1, p_2, p_3, p_4, p_5\}$ are connected to either v or w. Suppose, without loss of generality, that $\{p_1, p_2, p_3\}$ are connected to v, and note that by Observation 2, every vertex in Y must be connected to all vertices in Z. If $|Y| \geq 2$, then $(\{v\} \cup Y, \{p_1, p_2, p_3\})$ would be a copy of $K_{3,3}$. Suppose now that $|Y| = 1$, and let q be the single vertex in Y. Since p_1, p_2, p_3 are white and belong to $N_3(v, w)$, these vertices can connect only to vertices in $\{v, q, w\}$. Again, by planarity, at least one vertex in $\{p_1, p_2, p_3\}$ is not connected to w and hence must be of degree 2. But then $|W(v, q)| \geq 3$, and $W(v, q)$ contains a degree-2 vertex. This contradicts Rule 8.

It follows that in all cases the number of vertices in $V(R)$ is bounded by 16. This completes the proof. □

DISTRIBUTION-FREE PROPERTY-TESTING*

SHIRLEY HALEVY[†] AND EYAL KUSHILEVITZ[†]

Abstract. We consider the problem of distribution-free property-testing of functions. In this setting of property-testing, the distance between functions is measured with respect to a *fixed but unknown* distribution D on the domain. The testing algorithms are given oracle access to random sampling from the domain according to this distribution D. This notion of distribution-free testing was previously defined, but no distribution-free property-testing algorithm was known for any (non-trivial) property. We present the first such distribution-free property-testing algorithms for two of the central problems in this field. The testers are obtained by extending some known results (from "standard," uniform distribution, property-testing): (1) A distribution-free testing algorithm for low-degree multivariate polynomials with query complexity $O(d^2 + d \cdot \epsilon^{-1})$, where d is the total degree of the polynomial. The same approach that is taken for the distribution-free testing of low-degree polynomials is shown to apply also to several other problems; (2) a distribution-free monotonicity testing algorithm for functions $f : [n]^d \to A$ for low dimensions (e.g., when d is a constant) with query complexity similar to the one achieved in the uniform setting. On the negative side, we prove an exponential gap between the query complexity required for uniform and distribution-free monotonicity testing in the high-dimensional case.

Key words. property-testing, distribution-free property-testing, low-degree testing, monotonicity testing, distribution-free testing lower bounds

1. Introduction.

The classical notion of *decision problems* requires an algorithm to distinguish objects having some property $\mathcal{P}$ from those objects which do not have the property. *Property-testing* is a relaxation of decision problems, where algorithms are only required to distinguish objects having the property $\mathcal{P}$ from those which are at least "ϵ-far" from every such object. The notion of property-testing was introduced by Rubinfeld and Sudan [46] for the general case and was first studied in the context of combinatorial properties by Goldreich, Goldwasser, and Ron [25]. Since then it has attracted a considerable amount of attention. Property-testing algorithms were introduced for problems in graph theory (see, e.g., [2, 25, 28, 41]), monotonicity testing (see, e.g., [12, 16, 17, 21, 22, 24, 31]), and other properties (see, e.g., [1, 4, 5, 6, 7, 8, 10, 13, 14, 15, 18, 20, 26, 32, 34, 35, 39, 40, 42, 43, 45]).[1] The main goal of property-testing algorithms is to avoid "reading" the whole object, which requires complexity at least linear in the size of its representation, i.e., to make the decision by reading a small, possibly selected at random, fraction of the input (e.g., a fraction of size polynomial in $1/\epsilon$ and polylogarithmic in the size of the representation) and still having a good (say, at least 2/3) probability of success.

A crucial component in the definition of property-testing is that of the *distance* between two objects. For the purpose of this definition, it is common to think of objects as being *functions* over some domain $\mathcal{X}$. For example, a graph G may be

[1] The reader is referred to surveys by Ron [44], Goldreich [23], and Fischer [19] for a presentation of some of this work, including some connections between property-testing and other topics.

thought of as a function $f_G : V \times V \rightarrow \{0,1\}$ indicating for each possible edge e whether it exists in the graph. The distance between functions f and g is then measured by considering the set $\mathcal{X}_{f \neq g}$ of all points x where $f(x) \neq g(x)$ and comparing the size of this set $\mathcal{X}_{f \neq g}$ to that of $\mathcal{X}$;[2] equivalently, one may introduce a uniform distribution over $\mathcal{X}$ and measure the probability of picking $x \in \mathcal{X}_{f \neq g}$. Note that property-testing algorithms access the input function (object) via *membership queries* (i.e., the algorithm gives a value x from the domain and gets as an answer $f(x)$).[3]

It is natural to consider situations where not all the points of the domain are equivalently important. For example, when dealing with graph properties it is possible that removing or adding some edges may be more expensive than removing or adding others, depending on various factors of the problem (and not only on the number of edge removals and additions). We are interested in taking these differences between the edges into consideration when measuring the distance between a given graph and the property (which is not the case when dealing with standard uniform testing). In other words, we wish to put different weights (probabilities) on different elements of the domain. That is, our goal is to generalize the definition of distance between two functions, to deal with arbitrary probability distributions D over $\mathcal{X}$, by utilizing the probability measure of $\mathcal{X}_{f \neq g}$ according to D. Ideally, one would hope to get *distribution-free* property-testing algorithms (in short, distribution-free testers). A distribution-free tester for a given property $\mathcal{P}$ accesses the function using membership queries, as above, and by randomly sampling the *fixed but unknown* distribution D (this mimics similar definitions from *learning theory* and is implemented via an oracle access to D; see, e.g., [37]).[4] As before, the testing algorithm is required to accept the given function f with probability at least $\frac{2}{3}$ if f satisfies the property $\mathcal{P}$, and to reject it with probability at least $\frac{2}{3}$ if f is at least ϵ-far from $\mathcal{P}$ with respect to the distribution D.

Another natural question that arises when dealing with distribution-free testing, beyond the mere existence of such testers, is whether the testing (if possible) can always be accomplished using the same query complexity as in the uniform setting, or is there an inherent gap between the query complexity required for the different settings?

This definition of distance with respect to an arbitrary distribution D was already considered in the context of property-testing [25]. However, it is important to notice that the transformation of uniform testers into distribution-free ones is not straightforward. Many of the previously known testers use the fact that an object that is far from satisfying the property in question contains many small witnesses of this fact. As a result, many of the uniform testers use random sampling of the input object in order to find such a witness. On the other hand, when dealing with distribution-free property-testing, it is possible that an object contains very few such witnesses (hence, is very close to the property with respect to the uniform distribution), while at the same time is very far from the property with respect to some arbitrary distribution D.

[2] We usually compare objects of the same size, and hence a common definition for the distance between two objects is $|\mathcal{X}_{f \neq g}|$ (instead of $\frac{|\mathcal{X}_{f \neq g}|}{\mathcal{X}}$). However, defining the distance as described above is more suitable when dealing with general distribution measures.

[3] For example, in the case of a graph G, represented as a function f_G as described above, the algorithm gives a pair (u_1, u_2) and receives an answer of whether the edge (u_1, u_2) exists in the graph G or not.

[4] More precisely, distribution-free property-testing is the analogue of the PAC+MQ model of learning (that was studied by the learning theory community mainly via the EQ+MQ model); standard property-testing is the analogue of the uniform+MQ learning model.

Indeed, to the best of our knowledge, no distribution-free property-testing algorithm was known for any (nontrivial) property (besides testing algorithms that follow from the existence of proper learning algorithms in learning theory [25]). Moreover, discouraging impossibility results, due to [25], show that for many graph-theoretic properties (for which testers that work with respect to the uniform distribution are known) no such distribution-free algorithm exists. As a result, most previous work focused on testing algorithms for the uniform distribution; some of these algorithms can be generalized to deal with certain (quite limited) classes of distributions (e.g., product distributions [25]), and very few can be modified to be testers with respect to any *known* distribution (as was observed by [19] regarding the tester presented in [39]), but none is shown to be a distribution-free tester.

We start by reviewing some of the central problems, studied in the context of property-testing, which are relevant to our work.

Low-degree tests for polynomials. The first problem studied in the field of property testing is that of low-degree testing for multivariate polynomials over a finite field, where one wishes to test whether a given function can be represented by a multivariate polynomial of total degree d, or it is ϵ-far from any such polynomial. Later, the problem of low-degree testing played a central role in the development of probabilistic checkable proofs (PCPs), where the goal is to probabilistically verify the validity of a given proof. For the problem of low-degree testing, Rubinfeld and Sudan [46] presented a tester with query complexity of $O(d^2 + d \cdot \epsilon^{-1})$. This test was further analyzed in [11]. The reader is also referred to [13], where a linearity test (which tests whether a given function acts as a homomorphism between groups) is presented, and to [3, 9, 10, 26, 36] for other related work.

Monotonicity testing. Monotonicity has also been the subject of a significant amount of work in the property-testing literature (see, e.g., [12, 16, 17, 18, 21, 22, 24]). In monotonicity testing, the domain $\mathcal{X}$ is usually the d-dimensional cube $[n]^d$. A partial order is defined on this domain in the natural way (for $\vec{y}, \vec{z} \in [n]^d$, we say that $\vec{y} \leq \vec{z}$ if each coordinate of $\vec{y}$ is bounded by the corresponding coordinate of $\vec{z}$).[5] A function f over the domain $[n]^d$ is *monotone* if whenever $\vec{z} \geq \vec{y}$, then $f(\vec{z}) \geq f(\vec{y})$. Testing algorithms were developed to deal with both the low-dimensional and the high-dimensional cases (with respect to the uniform distribution over the domain). In what follows, we survey some of the known results on this problem which are most relevant to our work:

- *The low-dimensional case.* In this case, d is considered to be small compared to n (and, in fact, it is typically a constant); a successful algorithm for this case is typically one that is polynomial in $1/\epsilon$ and in $\log n$. The first paper to deal with this case is by Ergün et al. [17], who presented an $O(\frac{\log n}{\epsilon})$ algorithm for the line (i.e., the case $d = 1$) and showed that this query complexity cannot be achieved without using membership queries (that is, such query complexity cannot be achieved using only queries of the function at randomly drawn points of the domain; we have to allow the tester to make queries at points of its choice, computed based on the information it learned during the previous steps of its execution). This algorithm was generalized for any fixed d in [12]. For the case $d = 1$, there is a lower bound showing that testing monotonicity (for some constant ϵ) indeed requires $\Omega(\log n)$ queries [18].
- *The high-dimensional case.* In this case, d is considered as the main parameter (and n might be as low as 2); a successful algorithm is typically one that

[5] In the case $d = 1$ this yields a linear order.

is polynomial in $1/\epsilon$ and d. This case was first considered by Goldreich et al. [24], who showed an algorithm for testing monotonicity of functions from the Boolean ($n = 2$) d-dimensional hypercube to a Boolean range using $O(\frac{d}{\epsilon})$ queries. This result was generalized in [16] to arbitrary values of n, showing that $O(\frac{d\cdot\log^2 n}{\epsilon})$ queries suffice for testing monotonicity of general functions over $[n]^d$, which is the best known result so far.

- *Other related work.* Lower bounds for monotonicity testing of functions $f : \{0,1\}^d \to \{0,1\}$ (i.e., Boolean functions over $[n]^d$ for $n = 2$) were shown by Fisher et al. in [21]: an $\Omega(\sqrt{d})$ lower bound for nonadaptive, one-sided error algorithms, and an $\Omega(\log d)$ lower bound for nonadaptive two-sided error algorithms (these bounds imply the corresponding adaptive lower bounds of $\Omega(\log d)$ and $\Omega(\log\log d)$, respectively). These authors also considered graphs other than the hypercube, proving, for example, that testing monotonicity with a constant (depending only on $\frac{1}{\epsilon}$) number of queries is possible for certain classes of graphs.

1.1. Our contributions. Our main positive contributions are distribution-free testers for the two properties mentioned above: low-degree multivariate polynomials and low-dimensional monotone functions. Both testers use query complexity similar to that known for the uniform setting. We also show that the low-degree test is a special case of a general scheme for a wider class of properties including properties such as dictatorship and junta functions [20, 43]. These algorithms are the first known distribution-free testers for nontrivial properties. By presenting these algorithms, we answer a natural question that has been raised explicitly by Fischer [19, subsection 9.3] and is implicit in [25]. We emphasize that our algorithms work for any distribution D without having any information about D.

On the negative side, we show that, although in the uniform setting testing of Boolean functions defined over the Boolean hypercube can be done using query complexity that is polynomial in $\frac{1}{\epsilon}$ and in the dimension d, in the distribution-free setting such testing requires a number of queries that is exponential in d. We elaborate below.

Distribution-free low-degree testing for polynomials (and more). We consider a generalization of the notion of self-correctors for single functions (see [13]) to classes of functions (this was previously introduced in [46]). We observe that if the property in question has such a self-corrector, then the existence of a uniform tester implies the existence of a distribution-free one. This approach yields distribution-free testers for a variety of properties, among which is the property of low-degree multivariate polynomials (see section 3).

In addition, for the problem of testing low-degree multivariate polynomials, we show how to generalize the tester presented in [46] to a distribution-free tester with the same (up to a multiplicative factor of 2) query complexity ($O(d^2+d\cdot\epsilon^{-1})$) without using self-correctors. The algorithm and its analysis are presented in subsection 3.1.

Distribution-free monotonicity testing in the low-dimensional case. We present a distribution-free monotonicity tester in the low-dimensional hypercube case with query complexity of $O(\frac{\log^d n\cdot 2^d}{\epsilon})$. This is done by first considering the one-dimensional case (the "line"). In this case, we prove that an algorithm of [17] can be slightly modified to handle the distribution-free case with the same query complexity of $O(\frac{\log n}{\epsilon})$. Our proof is presented for the sake of completeness and it shares similar ideas with the original proof [17] for the uniform case (although it is possible to modify the original analysis for the distribution-free case). We then show how to appropriately generalize this algorithm to deal with higher (yet low compared to n) dimensions (a similar generalization was used in [12] for the uniform distribution case). The tester for the one-dimensional case and its generalization for higher dimensions appear in section 4.

It is typical for known property-testing algorithms to be quite simple, and it is in the analysis of why these algorithms work that the property $\mathcal{P}$ in question requires understanding; indeed, Goldreich and Trevisan [29] proved that in certain settings this is an inherent phenomenon: they essentially showed (with respect to the uniform distribution) that any graph-theoretic property that can be tested can also be tested (with a small penalty in the complexity) by a "generic" algorithm that samples a random subgraph and decides whether it has some property. Our work is no different in this aspect: our algorithms are similar to previously known algorithms, and our main contribution is their analysis, in particular, the analysis for the distribution-free case. Moreover, it is somewhat surprising that our distribution-free testers do not require dramatically different techniques than those used in the construction and analysis of previous algorithms (that work for the uniform distribution case). We remark, however, that although all the distribution-free testers presented in this work can be viewed as variations of testers for the uniform distribution, in each of the problems the modification of the uniform distribution test is different.[6]

Lower bound for distribution-free monotonicity testing in the high-dimensional case. In section 5, we show that while $O(\frac{d}{\epsilon})$ queries suffice for testing monotonicity of Boolean functions in the uniform case [24], in the distribution-free case it requires a number of queries that is exponential in the dimension d (that is, there exists a constant c such that $\Omega(2^{cd})$ queries are required for the testing). Hence, such testing is infeasible in the high-dimensional case. Our lower bound can be trivially extended to deal with monotonicity testing of Boolean functions that are defined over the domain $[n]^d$ for general values of n. By this, we show another gap between the query complexity of uniform and distribution-free testers for a natural testing problem.

Organization. In section 2, we formally define the notions used in this work. In section 3, we deal with properties that have both a uniform tester and a property self-corrector; then, in subsection 3.1, we present an alternative distribution-free tester for low-degree multivariate polynomials that does not use the notion of property self-correctors. Section 4 describes the distribution-free monotonicity tester for the low-dimensional case, and section 5 describes the lower bound on the query complexity of distribution-free monotonicity testing in the high-dimensional case. Finally, section 6 presents some open questions with respect to property-testing in general and distribution-free testing in particular.

2. Definitions.

We start by formally defining the notion of being ϵ-far from a property $\mathcal{P}$, with respect to a given distribution D defined over the domain $\mathcal{X}$, and of distribution-free testing. Assume that the range of the functions in question is $\mathcal{A}$.

DEFINITION 2.1. *Denote by $\mathcal{F}_{\mathcal{A}}^{\mathcal{X}}$ the set of all functions $f : \mathcal{X} \to A$. A* property *$\mathcal{P}$ is a subset $\mathcal{P} \subseteq \mathcal{F}_{\mathcal{A}}^{\mathcal{X}}$. We say that f* satisfies *$\mathcal{P}$ if $f \in \mathcal{P}$.*

DEFINITION 2.2. *Let $\mathcal{X}$ be a domain and D be a distribution measure defined over $\mathcal{X}$. The D-*distance *between functions $f, g \in \mathcal{F}_{\mathcal{A}}^{\mathcal{X}}$ is defined by $dist_D(f, g) \overset{def}{=} \Pr_{x\sim D}\{f(x) \neq g(x)\}$.*

*The D-*distance *of a function f from a property $\mathcal{P}$ is $dist_D(f, \mathcal{P}) \overset{def}{=} \inf_{g\in\mathcal{P}} dist_D(f, g)$.*

[6] Indeed, in light of [25], there can be no generic transformation of uniform distribution testers into distribution-free ones.

We say that f is (ϵ, D)-far from a property $\mathcal{P}$ *if $dist_D(f, \mathcal{P}) \geq \epsilon$. Similarly, we say that f is* (ϵ, D)-close to a property $\mathcal{P}$ *if $dist_D(f, \mathcal{P}) \leq \epsilon$.*

When the distribution in question is the uniform distribution over $\mathcal{X}$, we either use U instead of D or (if clear from the context) we omit any reference to the distribution; e.g., the phrase "f is ϵ-far from $\mathcal{P}$" refers to distance according to the uniform distribution.

Next, we define the notion of a distribution-free tester for a given property $\mathcal{P}$.

DEFINITION 2.3. *A* distribution-free two-sided error tester *for a property $\mathcal{P}$ is a probabilistic oracle machine M, which is given a distance parameter $\epsilon > 0$, an oracle access to an arbitrary function $f : \mathcal{X} \to \mathcal{A}$, and an oracle access to sampling of a fixed but unknown distribution D over $\mathcal{X}$, and satisfies the following two conditions:*

1. *If f satisfies $\mathcal{P}$, then* $\Pr\{M^{f,D} = \textit{ Accept}\} \geq \frac{2}{3}$.
2. *If f is (ϵ, D)-far from $\mathcal{P}$, then* $\Pr\{M^{f,D} = \textit{ Accept}\} \leq \frac{1}{3}$.

All our testers, like many previously known testers, have one-sided error; i.e., they always accept any function satisfying the property $\mathcal{P}$ in question.

DEFINITION 2.4. *A* distribution-free one-sided error tester *for a property $\mathcal{P}$ is a probabilistic oracle machine M, which is given a distance parameter $\epsilon > 0$, an oracle access to an arbitrary function $f : \mathcal{X} \to \mathcal{A}$, and an oracle access to sampling of a fixed but unknown distribution D over $\mathcal{X}$, and satisfies the following two conditions:*

1. *If f satisfies $\mathcal{P}$, then* $\Pr\{M^{f,D} = \textit{ Accept}\} = 1$.
2. *If f is (ϵ, D)-far from $\mathcal{P}$, then* $\Pr\{M^{f,D} = \textit{ Accept}\} \leq \frac{1}{3}$.

The definition of a uniform distribution (two-sided or one-sided error) tester for a property $\mathcal{P}$ can be derived from the previous definitions by omitting the sampling oracle (since the tester can sample in the uniform distribution by itself) and by measuring distance with respect to the uniform distribution.

Notice that, because the distribution D in question is arbitrary, there is a difference between satisfying $\mathcal{P}$ and having distance 0 from $\mathcal{P}$. That is, it is possible that there are two distinct functions f and g such that $dist_D(f, g) = 0$. Specifically, it is possible that $f \in \mathcal{P}$ and $g \notin \mathcal{P}$. Since the notion of testing is meant to be a relaxation of the notion of decision problems, it is required that the algorithm accept (with probability at least $\frac{2}{3}$) functions that satisfy $\mathcal{P}$, but it may reject functions that have distance 0 from $\mathcal{P}$ (but do not satisfy $\mathcal{P}$). In addition, note that membership queries allow the algorithm to query the value of the input function also in points with probability 0 (which is also the case with membership queries in learning theory).[7] This definition of distribution-free testing was previously introduced in [25].

3. Distribution-free testing of properties with self-corrector. In this section, we focus on a specific class of properties for which the existence of a uniform tester implies the existence of a distribution-free one. These properties are characterized by the fact that we are able to efficiently "correct" every object that is close to the property. That is, given a function f that is close to a property $\mathcal{P}$, we are able to efficiently compute (with high probability), in every point x of the domain, the correct value of the function $g \in \mathcal{P}$ that is close to the input function f. We refer to this ability as "property self-correction." First, we formally define the notion of a property self-correction (it has already been defined implicitly and used in [38, 46]), and then introduce a general scheme for obtaining distribution-free testers for a variety of properties that satisfy these conditions.

[7] It is not known whether membership queries are essential in general for testing even in the uniform case (see [44]); this is known only for specific problems such as monotonicity testing (see [17]).

The notion of a property self-corrector is a generalization of the notion of self-correctors for functions that was introduced by Blum, Luby, and Rubinfeld in [13]. A self-corrector for a specific function f is a randomized algorithm that, given oracle access to a function g which is ϵ-close to f, is able to compute the value $f(x)$ in every point x of the domain. This definition can be generalized to classes of functions, specifically demanding that all the functions in the class are self-correctable using the same algorithm.

DEFINITION 3.1. *An ϵ'* self-corrector *for a property $\mathcal{P}$ is a probabilistic oracle machine M, which is given an oracle access to an arbitrary function $f : \mathcal{X} \rightarrow \mathcal{A}$ and satisfies the following conditions:*

- *If $f \in \mathcal{P}$, then $\Pr\{M^f(x) = f(x)\} = 1$ for every $x \in \mathcal{X}$.*
- *If there exists a function $g \in \mathcal{P}$ such that $dist_U(f, g) \leq \epsilon'$ (i.e., f is ϵ'-close to $\mathcal{P}$), then $\Pr\{M^f(x) = g(x)\} \geq \frac{2}{3}$ for every $x \in \mathcal{X}$.*

Note that the definition of a property self-corrector refers to distance measured only with respect to the uniform distribution; however, we still use these correctors for the construction of distribution-free testers. Observe that a necessary condition for the existence of an ϵ-self-corrector for a property $\mathcal{P}$ is that for every function f such that $dist_U(f, \mathcal{P}) \leq \epsilon$ (i.e., f is ϵ-close to $\mathcal{P}$ with respect to the uniform distribution), there exists a *unique* function $g \in \mathcal{P}$ that is ϵ-close to $\mathcal{P}$. Notice that the property of monotonicity does not fulfill this requirement.[8] Hence, the distribution-free monotonicity tester that is presented in the next section requires a different approach.

Next, in Figure 3.1 we describe our general distribution-free testing scheme. Let $\mathcal{P}$ be a property, let $T_{\mathcal{P}}$ be a uniform distribution tester for $\mathcal{P}$ with query complexity Q_T that has one-sided error, and let $C_{\mathcal{P}}$ be an ϵ' property self-corrector for $\mathcal{P}$ with query complexity Q_C. Let $\epsilon \leq \epsilon'$, and $f : \mathcal{X} \rightarrow A$.

```
Tester$_D(\epsilon)$
Run $T^f_{\mathcal{P}}(\epsilon)$. If $T^f_{\mathcal{P}}(\epsilon)$ = FAIL, then return FAIL.
Repeat $\frac{2}{\epsilon}$ times:
    Choose $x \in_D \mathcal{X}$.
    Repeat twice: Run $C^f_{\mathcal{P}}(x)$; If $f(x) \neq C^f_{\mathcal{P}}(x)$, then return FAIL.
return PASS
```

FIG. 3.1. *Generalized distribution-free testing scheme.*

THEOREM 3.2. *Algorithm Tester$_D(\epsilon)$ is a one-sided error distribution-free tester for $\mathcal{P}$ with query complexity $Q_T(\epsilon) + \frac{4}{\epsilon} \cdot Q_C$.*

Proof. It is obvious that the query complexity of the algorithm Tester$_D(\epsilon)$ is indeed as required. Hence, we have only to prove the correctness of the algorithm. To do so, we prove the following two facts:

- If $f \in \mathcal{P}$, then f is accepted by the algorithm with probability 1.
- If f is (ϵ, D)-far from $\mathcal{P}$, then f is rejected by Tester$_D(\epsilon)$ with probability at least $\frac{2}{3}$.

If f is indeed in $\mathcal{P}$, then it passes the uniform test with probability 1, and the value returned by the self-corrector is always identical to the value of f. Hence, f is accepted by the algorithm. Assume, from now on, that f is (ϵ, D)-far from $\mathcal{P}$. We distinguish between two possibilities as follows:

[8] Consider, for example, the following function $f : [n] \rightarrow \{0, 1\}$: Set $f(i) = 0$ if i is even, and set $f(i) = 1$ if i is odd. f is $\frac{1}{2}$-far from monotone, and it is $\frac{1}{2}$-close to $O(n)$ monotone functions.

- If f is (ϵ, U)-far from $\mathcal{P}$, then the probability that it passes the uniform test is at most $\frac{1}{3}$.
- If f is (ϵ, U)-close to $\mathcal{P}$, then there exists a function $g \in \mathcal{P}$ such that $dist(f, g) \leq \epsilon$. However, since $dist_D(f, \mathcal{P}) \geq \epsilon$, we deduce that $dist_D(f, g) \geq \epsilon$ (in other words, $\Pr_{x \sim D}\{f(x) \neq g(x)\} \geq \epsilon$). If f was accepted by the algorithm, then one of the two following events happened: Either we failed to sample a point in which f and g differ, or we succeeded in sampling such a point x, but both executions of the self-corrector failed to compute the value $g(x)$. The probability of the first event is at most $(1-\epsilon)^{\frac{2}{\epsilon}} \leq \frac{1}{e}^2 \leq \frac{1}{6}$ and, by the definition of a property self-corrector, the probability of the second event is at most $\frac{1}{3}^2 = \frac{1}{9}$. Therefore, the total probability that f is accepted by the algorithm is at most $\frac{1}{3}$.

Hence, in both cases the probability that f is accepted by the algorithm is at most $\frac{1}{3}$. □

Remark 3.3. We used the assumption that there exists a uniform distribution tester for the property $\mathcal{P}$ that has one-sided error. However, the same transformation can be applied also when the uniform distribution tester has two-sided error, except that the resulting distribution-free tester also has two-sided error.

This scheme implies the existence of distribution-free property testers for a few properties. Among these properties are low-degree multivariate polynomials (which will be the focus of the next subsection) and junta and dictatorship functions. A function $f : \{0,1\} \to \{0,1\}$ is said to be a k-junta if there exists a subset of $\{x_1, \ldots, x_n\}$ of size k that determines the value of f (i.e., f is independent of the other variables). A special case of juntas are dictatorship functions, where a single variable determines the value of the function. These properties (and other related properties) have uniform distribution testers, as was shown in [46, 20, 43]. In addition, they are subsets of the class of low-degree polynomials (for example, k-juntas are a special case of degree k multivariate polynomials) and thus are self-correctable [38, 46]. Therefore, the scheme described in this section gives distribution-free testers for these properties.

Remark 3.4. Given two properties $\mathcal{P}$ and $\mathcal{P}'$ such that $\mathcal{P}' \subseteq \mathcal{P}$, the fact that $\mathcal{P}$ is testable in the uniform distribution does not imply that $\mathcal{P}'$ is thus testable (to see this observe that every property is a subset of the class of all functions that is clearly testable). However, the fact that $\mathcal{P}$ is self-correctable implies that $\mathcal{P}'$ is self-correctable (using the same correction algorithm).

3.1. An alternative distribution-free test for low-degree multivariate polynomials. In this subsection, we present a distribution-free test for the property of low-degree multivariate polynomials that does not use property self-correctors. This test is obtained by modifying the known uniform tester presented by [46]. Hence, it might be used, along with other distribution-free testing algorithms, to deduce a general transformation of uniform testers into distribution-free ones (in case such a distribution-free tester exists).

We first define the problem formally. Let F be a finite field. In the problem of low-degree testing, with respect to the uniform distribution, the tester is given access to a function $f : F^m \to F$, a distance parameter ϵ, and a degree d, and has to decide whether f is a multivariate polynomial of total degree d, or is at least ϵ-far (with respect to the uniform distribution) from any degree d multivariate polynomial (i.e., one has to change the values of at least $\epsilon \times |F|^m$ points in order to transform f into a degree d multivariate polynomial; this implies that for every degree d multivariate polynomial g, the probability that a *uniformly* drawn point x has a value $g(x)$ different than $f(x)$ is at least ϵ). Rubinfeld and Sudan [46] presented a tester for this problem with query complexity $O(d^2 + d \cdot \epsilon^{-1})$. We show how to modify this tester to a distribution-free one with the same query complexity (up to a factor of 2).

Basic tool. Fix some value for d and assume from now on that $|F| > 10d$. To describe the testers (both the one for the uniform distribution and our distribution-free one), we use the following terminology from [46]:

- A *line* in F^m is a set of $10d + 1$ points of the form $\{x, x + h, \ldots, x + 10dh\}$ for some $x, h \in F^m$. The line defined by x and h is denoted $\ell_{x,h}$.
- We say that a line $\ell_{x,h}$ *is an f-polynomial* if there exists a univariate polynomial $P_{x,h}(i)$ of degree d such that $f(x + ih) = P_{x,h}(i)$ for every $0 \leq i \leq 10d$.

Notice that if f is a multivariate polynomial of total degree at most d, then for every x and h, the line $\ell_{x,h}$ is an f-polynomial.[9] Given the values of f on a line $\ell_{x,h}$, testing whether this line is an f-polynomial can be done as follows:

- Find, using interpolation, a univariate polynomial $P(i)$ of degree d, consistent with the values of f at the $d+1$ points $x, x+h, \ldots, x+dh$ (i.e., $P(i) = f(x+hi)$ for every $0 \leq i \leq d$).
- Check, for every $(d + 1) \leq i \leq 10d$, that $f(x + ih) = P(i)$. If so, accept; otherwise reject.

We show how this basic test is used to build a uniform and a distribution-free low-degree test.

Low-degree test for the uniform distribution. The low-degree test for the uniform distribution works by randomly sampling $O(d+\epsilon^{-1})$ lines (i.e., by uniformly choosing $x, h \in F^m$) and checking that each of these lines is an f-polynomial. The correctness of this algorithm follows immediately from the following theorem (see [46, Theorem 9]).

THEOREM 3.5 (see [46, Theorem 9]). *There exists a constant c_U such that for $0 \leq \delta \leq \frac{1}{c_U \cdot d}$, if f is a function from F^m to F, such that all but at most a δ fraction of the lines $\{\ell_{x,h} | x, h \in F^m\}$ are f-polynomials, then there exists a polynomial $g : F^m \to F$ of total degree at most d such that $dist_U(f, g) \leq (1 + o(1))\delta$ (provided that $|F| > 10d$).*

Distribution-free low-degree testing algorithm. Denote the class of multivariate polynomials of total degree d by $\mathcal{P}^d_{deg}$. We show that the tester described above can be modified into a distribution-free tester for low-degree multivariate polynomials. That is, we present an algorithm with query complexity $O(d^2 + d \cdot \epsilon^{-1})$ that, given a distance parameter ϵ, a degree parameter d, and access to random sampling of F^m according to D and to membership queries of a function $f : F^m \to F$, distinguishes, with probability at least $\frac{2}{3}$, between the case that f is in $\mathcal{P}^d_{deg}$ and the case that f is (ϵ, D)-far from $\mathcal{P}^d_{deg}$.

The natural generalization of the uniform distribution tester above for the distribution-free case would be to replace the sampling of the tested lines by sampling according to the distribution D; i.e., sample the $O(d + \epsilon^{-1})$ lines by choosing $x \sim D$ and $h \sim U$ and check that these lines are f-polynomials. However, we could not show that this modification actually works. Instead, the algorithm we present consists of two stages: In the first stage, we simply run the uniform distribution test as is and check that the function f is ϵ-close to $\mathcal{P}^d_{deg}$ with respect to the uniform distribution;

[9] To see this, assume $f(x) = \Sigma_j a_j \Pi_{l=1}^{d_j} x_{k_l^j}$, where a_j is the coefficient of the jth term in f, d_j is the degree ($d_j \leq d$), and k_l^j is the index of the lth variable in that term. In this case, for every fixed $x = (x_1, \ldots, x_m)$ and $h = (h_1, \ldots, h_m)$, the value $f(x + ih) = \Sigma_j a_j \Pi_{l=1}^{d_j}(x_{k_l^j} + ih_{k_l^j})$, which, of course, is a degree d univariate polynomial in i.

the second stage is the generalization suggested above. This combined strategy is presented in Figure 3.2 and analyzed below.

```
Poly($\epsilon, d$)

Set $k \triangleq \max\{\epsilon^{-1}, c_U \cdot d\}$.
Repeat $5k$ times:
    • Choose $x, h \in_U F^m$. If the line $\ell_{x,h}$ is not an $f$-polynomial, return FAIL.
    • Choose $x \in_D F^m$, $h \in_U F^m$. If the line $\ell_{x,h}$ is not an $f$-polynomial, return FAIL.
return PASS
```

FIG. 3.2. *Distribution-free low-degree tester.*

THEOREM 3.6. *Algorithm Poly*(ϵ, d) *is a distribution-free one-sided error tester for* $\mathcal{P}^d_{deg}$*; its query complexity is* $O(d^2 + d \cdot \epsilon^{-1})$.

The correctness of the algorithm relies on the following lemma.

LEMMA 3.7. *Let* c_U *be the constant from Theorem* 3.5. *For every* $0 \leq \delta \leq \frac{1}{c_U \cdot d}$, *if* f *is a function from* F^m *to* F *such that*

- $\Pr_{x,h \sim U}\{\ell_{x,h}$ *is not an* f*-polynomial*$\} \leq \delta$, *and*
- $\Pr_{x \sim D, h \sim U}\{\ell_{x,h}$ *is not an* f*-polynomial*$\} \leq \delta$,

then there exists a polynomial $g : F^m \to F$ *of total degree at most* d *such that* $dist_D(f, g) \leq \frac{\delta}{1-40\delta} = (1 + o(1))\delta$ *(provided that* $|F| > 10d$*).*

Proof. We prove that if f satisfies the two conditions for $0 \leq \delta \leq \frac{1}{c_U \cdot d}$, then it is indeed $(\frac{\delta}{1-40\delta}, D)$-close to $\mathcal{P}^d_{deg}$. For the purpose of the analysis, we construct a function g based on f in the same way as in [46, proof of Theorem 9]:

- For every $x, h \in F^m$, denote by $P_{x,h}(i)$ the univariate polynomial that satisfies $P_{x,h}(i) = f(x + ih)$ for at least $6d$ of the values $i \in \{0, \ldots, 10d\}$. If no such polynomial exists, define $P_{x,h}$ to be an "error." Notice that there can be at most one such polynomial, since every two polynomials that satisfy the demand have to agree on at least $2d$ points, implying that they are identical.
- For every $x \in F^m$, define $g(x) = \text{plurality}_h\{P_{x,h}(0)\}$, where the plurality is taken over all values of h for which $P_{x,h}$ is not an error ($g(x)$ is well defined for every x since, by [46, Lemma 12], $\Pr_{h_1,h_2 \sim U}\{P_{x,h_1}(0) = P_{x,h_2}(0)\} \geq 1 - 20\delta$.

It was shown that the function g is indeed a degree d multivariate polynomial (see [46, proof of Theorem 9] and notice that f satisfies the condition of that theorem). Moreover, for every $x \in F^m$, $i \in \{0, \ldots, 10d\}$, $\Pr_{h \sim U}[g(x + ih) = P_{x,h}(i)] \geq 1 - 40\delta$ (see [46, Corollary 13]).

To complete the proof, it remains to show that $dist_D(f, g) \leq \frac{\delta}{1-40\delta}$. Let B be the set of x's that satisfy $f(x) \neq P_{x,h}(0)$ for at least a $1 - 40\delta$ fraction of the h's in F^m (including the values of h for which $P_{x,h}$ was defined to be an error). Notice that if $x \notin B$, then $f(x) = P_{x,h}(0)$ for more than a 40δ fraction of the h's in F^m (this is due to the fact that $f(x) \neq P_{x,h}(0)$ for less than a $1 - 40\delta$ fraction of the h's, and hence it has to be equal to $P_{x,h}(0)$ for more than a 40δ fraction of the h's). Therefore, for every $x \notin B$, we can claim the following:

1. $g(x) = P_{x,h}(0)$ for at least a $1 - 40\delta$ fraction of the h's (this holds for every x, and thus for every $x \notin B$). Denote this fraction by g_x.
2. $f(x) = P_{x,h}(0)$ for more than a 40δ fraction of the h's in F^m. Denote this fraction by f_x.

Therefore, for at least one value of h both $f(x) = P_{x,h}(0)$ and $g(x) = P_{x,h}(0)$ (otherwise, $f_x + g_x > 1$, since $g_x \geq 1 - 40\delta$ and $f_x > 40\delta$). Hence, for every $x \notin B$, we get $f(x) = g(x)$. Let us bound the probability of picking a point in B according to the distribution D as follows:

$$\delta \geq \Pr_{x \sim D, h \sim U}\{\ell_{x,h} \text{ is not an } f\text{-polynomial}\} \geq (1 - 40\delta) \Pr_{x \sim D}\{x \in B\},$$

where the first inequality is due to the second condition of the lemma, and the second inequality follows the previous discussion, implying that

$$\Pr_{x \sim D}\{x \in B\} \leq \frac{\delta}{1 - 40\delta}. \qquad \square$$

Proof of Theorem 3.6. To prove that the algorithm is indeed a distribution-free tester for $\mathcal{P}^d_{deg}$, we prove the following two facts:

1. If f is in $\mathcal{P}^d_{deg}$, then the algorithm accepts f with probability 1.
2. If f is (ϵ, D)-far from $\mathcal{P}^d_{deg}$, then the algorithm $Poly(\epsilon, d)$ rejects f with probability at least $\frac{2}{3}$.

As explained before, if f is indeed a multivariate polynomial of total degree d, then every line is an f-polynomial. Hence, it follows that such an f is accepted by the tester with probability 1. Assume from now on that f is (ϵ, D)-far from $\mathcal{P}^d_{deg}$. Notice that, by the definition of $k = \max\{\epsilon^{-1}, c_U \cdot d\}$, for $\epsilon' = \frac{1}{k}$, f is (ϵ', D)-far from $\mathcal{P}^d_{deg}$. By Lemma 3.7, either $\Pr_{x,h \sim U}\{\ell_{x,h}$ is not an f-polynomial$\} > \frac{\epsilon'}{2+40\epsilon'}$, or $\Pr_{x \sim D, h \sim U}\{\ell_{x,h}$ is not an f-polynomial$\} > \frac{\epsilon'}{2+40\epsilon'}$ (otherwise, it follows that there exists a degree d polynomial g such that $dist_D(f,g) \leq \frac{\epsilon'}{(2+40\epsilon')\cdot(1-40\frac{\epsilon'}{2+40\epsilon'})} = \frac{\epsilon'}{2} < \epsilon'$, contradicting the fact that the D-distance of f from any such polynomial is at least ϵ'). Assume that the first event occurs. Therefore, the probability that a randomly chosen line $\ell_{x,h}$ is an f-polynomial is at most $(1 - \frac{\epsilon'}{2+40\epsilon'})$. Hence, the probability that the algorithm accepts f is at most $(1 - \frac{\epsilon'}{2+40\epsilon'})^{5k} = (1 - \frac{1}{2k+40})^{5k} \leq \frac{1}{e}^2 \leq \frac{1}{3}$ (the first inequality follows from the fact that c_U, the constant of Theorem 3.5, is at least 100, implying that $k \geq 100$). Similarly, if the second event occurs, the probability that a randomly chosen line $\ell_{x,h}$, where $x \sim D$ and $h \sim U$, is an f-polynomial is at most $(1 - \frac{\epsilon'}{2+40\epsilon'})$. Hence, as before, the probability that the algorithm accepts f is at most $(1 - \frac{\epsilon'}{2+40\epsilon'})^{5k} \leq \frac{1}{3}$. $\square$

4. Distribution-free monotonicity testing on the *d*-dimensional cube.

In this section, we present monotonicity testers for the d-dimensional hypercube with respect to an arbitrary distribution D. As before, we assume D to be fixed but unknown and, other than the ability to sample according to D, we assume no knowledge of D. For simplicity, we begin our discussion with the case $d = 1$, and show that, given access to random sampling according to D and to membership queries, there is a distribution-free tester for monotonicity over $[n]$, whose query complexity is $O(\frac{\log n}{\epsilon})$ (the algorithm for the case $d = 1$ is presented without proof). In subsection 4.2, we generalize this algorithm to a distribution-free tester for monotonicity over the d-dimensional hypercube, whose query complexity is $O(\frac{\log^d n \cdot 2^d}{\epsilon})$ (this algorithm for the case $d = 1$ is the basic algorithm shown in subsection 4.1).

We begin with a few notations and definitions. Denote by $[n]$ the set $\{1, \ldots, n\}$ and by $[n]^d$ the set of d-tuples over $[n]$. For every two points $\vec{i}$ and $\vec{j}$ in $[n]^d$ we say that $\vec{i} \leq \vec{j}$ if for every $1 \leq k \leq d$, $i_k \leq j_k$. Let $(A, <_A)$ be some linear order.

DEFINITION 4.1. *We say that a function* $f : [n]^d \to A$ *is* monotone *if for every* $\vec{i}$ *and* $\vec{j}$ *if* $\vec{i} \leq \vec{j}$, *then* $f(\vec{i}) \leq_A f(\vec{j})$.

DEFINITION 4.2. *Let* $f : [n]^d \to A$ *be a function. A pair* $(\vec{i}, \vec{j})$ *is said to be an* f-violation *if* $\vec{i} < \vec{j}$ *and* $f(\vec{i}) >_A f(\vec{j})$.

Let D be any distribution on $[n]^d$, and let S be a subset of $[n]^d$. Define $\Pr_D\{\vec{i}\} \overset{\text{def}}{=} \Pr_{X \sim D}\{X = \vec{i}\}$ and $\Pr_D\{S\} \overset{\text{def}}{=} \sum_{\vec{i} \in S} \Pr_D\{\vec{i}\}$.

4.1. Testing monotonicity for the line ($d = 1$). We consider the case $d = 1$. Our algorithm is a variant of the algorithm presented in [17] for testing monotonicity (with respect to the uniform distribution). The analysis for the special case $d = 1$ shares some of the ideas presented in the proof of [17] and is omitted; it can be obtained as a special case of the general proof that appears in the next subsection. The algorithm works in phases; in each phase a center point is selected according to the distribution D (in the original algorithm, the center point is selected uniformly), and the algorithm looks for a violation of the monotonicity with this center point. The search for a violation is done by randomly sampling in growing neighborhoods of the center point. In other words, in the case $d = 1$, the only change made in the original algorithm in order to adjust it to be distribution-free is that the choice of center points is made according to D. However, the search for violations remains unchanged. It is important to observe that, when dealing with an arbitrary distribution, there is no connection between the distance of the function from monotone and the number of pairs that form a violation of monotonicity (unlike the case of testing with respect to the uniform distribution, when a small number of violations implies closeness to monotonicity). Hence, the correctness of the algorithm for the uniform distribution does not imply its correctness for the general case.

As stated above, we present a tester for monotonicity in the one-dimensional case with query complexity $O(\frac{\log n}{\epsilon})$. The algorithm appears in Figure 4.1 and is a special case of the algorithm for general d that is proved in the next subsection. A separate correctness proof for the case $d = 1$ can be found in [30].

```
Algorithm-monotone-1-dim$_D(f, \epsilon)$:
repeat $\frac{2}{\epsilon}$ times
   choose $i \in_D [n]$
   for $k \leftarrow 0 \ldots \lceil \log i \rceil$ do
      repeat 8 times
         choose $a \in_U [2^k]$
         if $f(i - a) >_A f(i)$ then return FAIL
   for $k \leftarrow 0 \ldots \lceil \log(n - i) \rceil$ do
      repeat 8 times
         choose $a \in_U [2^k]$
         if $f(i) >_A f(i + a)$ then return FAIL
return PASS
```

FIG. 4.1. *Distribution-free monotonicity tester for* $d = 1$.

Remark 4.3. In the journal version of [17], an additional testing algorithm for monotonicity on the line, called Sort-Check-II, is presented. This algorithm can also be transformed into a distribution-free monotonicity tester over the line. However, we do not know if it can be generalized to higher dimensions.

4.2. Distribution-free monotonicity testing for general *d*. In the previous section, we saw how to test monotonicity over the one-dimensional hypercube (the line) when the distance is measured with respect to an arbitrary distribution D.

Next, we show how to generalize this algorithm to the d-dimensional case and prove its correctness. We begin by adjusting the definitions and notations of the previous section to the d-dimensional case. Notice that, unlike in the one-dimensional case, in the d-dimensional case $[n]^d$ is a partial order (not every two points are comparable). Denote by $\vec{i}$ the point $i_1, \dots, i_d \in [n]^d$. For every two points $\vec{i}$ and $\vec{a}$, we denote by $\vec{i} + \vec{a}$ (respectively, $\vec{i} - \vec{a}$) the point $i_1 + a_1, \dots, i_d + a_d$ (respectively, $i_1 - a_1, \dots, i_d - a_d$), where every coordinate smaller than 1 is set to 1 and every coordinate larger than n is set to n.

We will show that, given access to random sampling according to D and to membership queries, there is a distribution-free tester for monotonicity, whose query complexity is $O(\frac{\log^d n \cdot 2^d}{\epsilon})$. The algorithm is presented in Figure 4.2.

```
Algorithm monotone-d-dim$_D(d, f, \epsilon)$:
repeat $\frac{2}{\epsilon}$ times
  choose $\vec{i} \in_D [n]^d$
   for $k_1 \leftarrow 0 \cdots \lceil \log i_1 \rceil$ do
        ⋮
     for $k_d \leftarrow 0 \dots \lceil \log i_d \rceil$ do
       repeat $4 \cdot 2^d$ times
         choose $\vec{a} \in_U [2^{k_1}] \times \cdots \times [2^{k_d}]$
         if $f(\vec{i} - \vec{a}) >_A f(\vec{i})$ then return FAIL
  for $k_1 \leftarrow 0 \dots \lceil \log(n - i_1) \rceil$ do
        ⋮
     for $k_d \leftarrow 0 \dots \lceil \log(n - i_d) \rceil$ do
       repeat $4 \cdot 2^d$ times
         choose $\vec{a} \in_U [2^{k_1}] \times \cdots \times [2^{k_d}]$
         if $f(\vec{i}) >_A f(\vec{i} + \vec{a})$ then return FAIL
return PASS
```

FIG. 4.2. *Distribution-free monotonicity tester for general d.*

THEOREM 4.4. *Algorithm monotone-d-*$\mathrm{dim}_D(d, f, \epsilon)$ *is a one-sided error distribution-free monotonicity tester over* $[n]^d$ *with query complexity* $O(\frac{\log^d n \cdot 2^d}{\epsilon})$.

To prove the above theorem, we need the following lemmas.

LEMMA 4.5. *Let* $f : [n]^d \to A$ *be a function, and let* $S \subseteq [n]^d$ *be a set. If for every* f*-violation* $(\vec{i}, \vec{j})$ *either* $\vec{i} \in S$ *or* $\vec{j} \in S$, *then there exists a monotone function* f' *that differs from* f *only on points in* S.

Proof. We will show that, by modifying the value of f only on points in S, we can obtain a monotone function f'. Define $\bar{S} = [n]^d \setminus S$. The construction of f' is done through the following iterative process. In each step, modify the value of one of the points $\vec{i} \in S$ that has not yet been modified and so that the values of all the points below it (i.e., all $\vec{k} < \vec{i}$) have already been set. The process ends after redefining the values of all the points in S.

The value of point $\vec{i} \in S$ is set in the following manner. We distinguish between two cases: $\vec{i} = (1, \dots, 1)$ and $\vec{i} \in [n]^d \setminus (1, \dots, 1)$. If $\vec{i} = (1, \dots, 1)$, then we set $f'(\vec{i}) = f(\vec{i})$ if $S = [n]^d$, and $f'(\vec{i}) = \min_{\vec{j}:\vec{i}<\vec{j},\vec{j}\in\bar{S}}\{f(\vec{j})\}$ otherwise. If $\vec{i} \in S \setminus (1, \dots, 1)$, we set $f'(i) = \max_{\vec{j}:\vec{j}<\vec{i}}\{f(\vec{j})\}$ (note that the maximum is taken over *all* points smaller than $\vec{i}$ and not only those in S) . The values of points in $\bar{S}$ are unchanged (i.e., for all these points $f'(\vec{i}) = f(\vec{i})$).

It is left to prove that f' is indeed monotone, or equivalently, that there are no f'-violations. Consider a pair of points $\vec{i}, \vec{j}$ such that $\vec{i} < \vec{j}$; we will prove that $f'(\vec{i}) \leq_A f'(\vec{j})$. There are three possible cases.

Case 1. $\vec{i}, \vec{j} \in \bar{S}$. Since f' equals f for all points not in S, and there were no f-violations with both endpoints in $\bar{S}$, then $f'(\vec{i}) = f(\vec{i}) \leq_A f(\vec{j}) = f'(\vec{j})$.

Case 2. $\vec{j} \in S$ and $\vec{i} \in [n]^d$. By the construction of f', the value of $f'(\vec{j})$ was set after the value at point $\vec{i}$ had already been set (since $\vec{i} < \vec{j}$), and therefore $f'(\vec{i}) \leq_A f'(\vec{j})$.

Case 3. $\vec{i} \in S$ and $\vec{j} \in \bar{S}$. Assume towards a contradiction that $(\vec{i}, \vec{j})$ is an f'-violation; moreover, let $(\vec{i}, \vec{j})$ be the minimal such pair (in lexicographic order). Since we already know that there are no f'-violations other than the ones referred to in this case, this is the minimal f'-violation. By the definition of f', clearly if $\vec{i} = (1, \ldots, 1)$, then $f'(\vec{i}) = \min_{\vec{j}: \vec{i} < \vec{j}, \vec{j} \in \bar{S}} \{f(\vec{j})\}$ and therefore $f'(\vec{i}) \leq_A f(\vec{j}) = f'(\vec{j})$. Hence $\vec{i} \neq (1, \ldots, 1)$. By the construction of f', the value of $f'(\vec{i})$ is the maximal value of f' at points $\vec{k}$ such that $\vec{k} < \vec{i}$. Thus $f'(\vec{i}) = f'(\vec{k})$ for some $\vec{k} < \vec{i}$, implying that $(\vec{k}, \vec{j})$ is also an f'-violation, contradicting the minimality of $(\vec{i}, \vec{j})$. □

A similar argument was used in [16]. An immediate conclusion of the above lemma is the following.

Lemma 4.6. *Let $f : [n]^d \to A$ be a function (ϵ, D)-far from monotone. Given $S \subseteq [n]^d$, if for every f-violation $(\vec{i}, \vec{j})$ either $\vec{i} \in S$ or $\vec{j} \in S$, then $\Pr_D\{S\} \geq \epsilon$.*

Definition 4.7. *For an f-violation $(\vec{i}, \vec{j})$, we say that $\vec{i}$ is* active *in this violation if*

$$|\{\vec{k} \ : \ \vec{i} < \vec{k} < \vec{j} \ , \ f(\vec{i}) >_A f(\vec{k})\}| \ \geq \ \frac{|\{\vec{k} : \vec{i} < \vec{k} < \vec{j}\}|}{2}.$$

That is, $\vec{i}$ is active in an f-violation $(\vec{i}, \vec{j})$ if, for at least half of the points $\vec{i} < \vec{k} < \vec{j}$, $(\vec{i}, \vec{k})$ is also an f-violation (i.e., $f(\vec{i}) >_A f(\vec{k})$). Similarly, $\vec{j}$ is active *in this violation if*

$$|\{\vec{k} \ : \ \vec{i} < \vec{k} < \vec{j} \ , \ f(\vec{k}) >_A f(\vec{j})\}| \ \geq \ \frac{|\{\vec{k} : \vec{i} < \vec{k} < \vec{j}\}|}{2}.$$

Lemma 4.8. *For every f-violation $(\vec{i}, \vec{j})$, at least one of $\vec{i}$ and $\vec{j}$ is active in $(\vec{i}, \vec{j})$.*

Proof. Let $(\vec{i}, \vec{j})$ be an f-violation. Namely, $\vec{i} < \vec{j}$ and $f(\vec{i}) >_A f(\vec{j})$. For every $\vec{i} < \vec{k} < \vec{j}$, if $f(\vec{i}) \leq_A f(\vec{k})$ (i.e., $(\vec{i}, \vec{k})$ is not an f-violation), then $f(\vec{k}) >_A f(\vec{j})$ (since $(A, <_A)$ is a linear order), and hence $(\vec{k}, \vec{j})$ is an f-violation. Similarly, if $(\vec{k}, \vec{j})$ is not an f-violation, then $(\vec{i}, \vec{k})$ is. Therefore, each of the points between $\vec{i}$ and $\vec{j}$ forms an f-violation with either $\vec{i}$ or $\vec{j}$. □

Define the active set of f (denoted A_f) as the set of all points that are active in some f-violation. Applying Lemma 4.6 to the set A_f, if f is (ϵ, D)-far from monotone, then $\Pr_D\{A_f\} \geq \epsilon$. We now prove Theorem 4.4.

Proof of Theorem 4.4. Clearly, the query complexity of the algorithm is $O(\frac{\log^d n \cdot 2^d}{\epsilon})$. It is left to show that this algorithm is indeed a distribution-free one-sided error monotonicity tester. To prove this, the following two facts have to be shown: (a) If f is monotone, it is accepted by the algorithm with probability 1; and (b) if f is (ϵ, D)-far from monotone, it is rejected by the algorithm with probability at least $\frac{2}{3}$.

As for (a), it follows immediately from the definition of the algorithm. Therefore, assume from now on that f is (ϵ, D)-far from monotone; we prove that f is rejected with probability at least $\frac{2}{3}$. Our algorithm may fail to detect that f is not monotone if either one of the following two events occurs:

1. None of the $\frac{2}{\epsilon}$ points $\vec{i}$ sampled by the algorithm according to D are in A_f.

2. The algorithm picked at least one point $\vec{i} \in A_f$, but failed to detect that $\vec{i}$ belongs to some f-violation.

The probability of the first event is at most $(1-\epsilon)^{\frac{2}{\epsilon}} \leq \frac{1}{e^2} \leq \frac{1}{6}$. To estimate the probability of the second event, let $\vec{i}$ be a point in A_f and assume, without loss of generality, that there exists $\vec{j}$ such that $(\vec{i},\vec{j})$ is an f-violation and $\vec{i}$ is active in this violation. Denote by k_l, $1 \leq l \leq d$, the minimal value such that $i_l + 2^{k_l} \geq j_l$. By the minimality of k_l, it follows that $j_l - i_l > \frac{1}{2} \cdot 2^{k_l}$ and therefore $(j_1 - i_1) \cdot \ldots \cdot (j_d - i_d) > \frac{1}{2^d} \cdot 2^{k_1} \cdot \ldots \cdot 2^{k_d}$. Since $\vec{i}$ is active in the f-violation $(\vec{i},\vec{j})$, at least half of the values between $\vec{i}$ and $\vec{j}$ form an f-violation with $\vec{i}$. Therefore at least $\frac{1}{2^{d+1}}$ of the values $\vec{a}$ in $[2^{k_1}] \times \cdots \times [2^{k_d}]$ will reveal a violation of monotonicity. Since for every possible value for $k_1, \ldots, k_d$ we sample $4 \cdot 2^d$ points in $[2^{k_1}] \times \cdots \times [2^{k_d}]$, the probability that no f-violation is detected is at most $(1 - \frac{1}{2^{d+1}})^{4 \cdot 2^d} = (1 - \frac{1}{2^{d+1}})^{2 \cdot 2^{d+1}} \leq \frac{1}{e^2} \leq \frac{1}{6}$. Therefore, the total probability of the algorithm failing to detect a violation, and hence to accept f, is at most $\frac{1}{3}$. □

Remark 4.9. A similar distribution-free monotonicity tester can be shown for Boolean functions of the form $f : B \to \{0,1\}$, where $(B, <_B)$ is a partial order that can be described as an "almost balanced" tree (i.e., a tree of depth $O(\log n)$ when $n = |B|$); monotonicity testing of functions defined over trees was also studied in [21], where a constant time algorithm was presented for testing Boolean functions defined over trees. The testing is again performed in stages. In each stage, as before, the tester selects a center point x according to the distribution D in question and starts looking for a violation of monotonicity with that center point. However, in this case, we distinguish between two possibilities: If $f(x) = 0$, then the tester uniformly samples $O(\log n)$ points in the path from x to the root (the tester can actually read the whole path using $O(\log n)$ queries). Otherwise, if $f(x) = 1$, then the tester uniformly samples $O(1)$ points in growing neighborhoods of x, where the neighborhoods are defined to be trees rooted at x, and at each time we increase the depth of the tree by 1 (thereby at most doubling the size of the tree).

The correctness proof of the tester uses the same ideas, with the following adjustment. For every violation of monotonicity (i,j), where $i < j$ (necessarily $f(i) = 1$ and $f(j) = 0$), we say that i is heavy in this violation if at least a $1 - \frac{1}{O(\log n)}$ fraction of the values in the path from i to j are 0, and we say that j is heavy if at least a $\frac{1}{O(\log n)}$ fraction of the vertices in the path from i to j are 1. Using arguments similar to those used in the above proof, it is easy to show that this is indeed a one-sided error monotonicity tester.

5. A lower bound for distribution-free monotonicity testing in the high-dimensional case.

In this section we show that distribution-free testing of Boolean functions, defined over the Boolean hypercube $\{0,1\}^d$, requires a number of queries that is exponential in the dimension. In subsection 5.1, we give an overview of the lower bound proof and present the families of functions used in this proof. Then, for simplicity, we first prove, in subsection 5.2, the lower bound for one-sided error testing, and later in subsection 5.3 we extend our lower bound for the two-sided error case.

Hereafter, we identify any point $x \in \{0,1\}^d$ with the corresponding set $x \subseteq [d]$. This allows us to apply set theory operations, such as union and intersection, to points.

In addition, for any two points $p, p' \in \{0,1\}^{\frac{d}{2}}$, denote by $p||p'$ the point $x \in \{0,1\}^d$, that is, the concatenation of p and p' (i.e., it is identical to p in its first $\frac{d}{2}$ coordinates and to p' in its last $\frac{d}{2}$ coordinates). Given a point $x \in \{0,1\}^d$, we say that $p \in \{0,1\}^{\frac{d}{2}}$ is the prefix of x if $x = p||p'$ for some p'. For every two points $x, y \in \{0,1\}^d$, denote by $H(x,y)$ the Hamming distance between x and y. For every point x, define $U(x) \stackrel{\text{def}}{=} \{y : y \geq x, |y| \leq \frac{d}{2}\}$; similarly define $L(x) \stackrel{\text{def}}{=} \{y : y \leq x, |y| > \frac{d}{2}\}$. Denote by $B^d_{\lambda d}$ the set of points in $\{0,1\}^d$ of weight λd, that is, $B^d_{\lambda d} = \{x \in \{0,1\}^d : |x| = \lambda d\}$. We always assume that d is divisible enough and $\lambda \cdot d$ is an integer.

5.1. Overview of the construction. To prove the lower bound on the query complexity, we show that any two-sided error distribution-free monotonicity tester with subexponential query complexity is unable to distinguish between monotone functions and functions that are $\frac{1}{2}$-far from monotone. To this aim, we consider two families $\mathcal{F}_1$ and $\mathcal{F}_2$ of pairs (f, D_f), where f is a Boolean function and D_f is a probability distribution corresponding to f, both defined over $\{0,1\}^d$, such that the following three requirements are satisfied:

1. Every function in $\mathcal{F}_1$ is monotone. Hence, every tester has to accept every pair $(f, D_f) \in \mathcal{F}_1$ with probability at least $\frac{2}{3}$.
2. Every function f in $\mathcal{F}_2$ is $\frac{1}{2}$-far from monotone with respect to D_f. Therefore, every tester has to reject every pair $(f, D_f) \in \mathcal{F}_2$ with probability at least $\frac{2}{3}$ (regardless of the choice of the distance parameter ϵ).
3. There exists a constant c such that no algorithm A that makes fewer than 2^{cd} membership queries and samples the distribution less than 2^{cd} times satisfies that
   - A accepts every pair (f, D_f) in $\mathcal{F}_1$ with probability at least $\frac{2}{3}$.
   - A rejects every pair (f, D_f) in $\mathcal{F}_2$ with probability at least $\frac{2}{3}$.

We conclude that there exists no two-sided error distribution-free tester for monotonicity of Boolean functions defined over $\{0,1\}^d$ with subexponential query complexity. (A similar approach was previously used for lower bound proofs in property-testing with respect to the uniform distribution [28]. However, since the previous proofs considered the uniform distribution setting, the two families in those proofs consist of functions and not pairs of functions and distributions.)

In the rest of this subsection, we describe the two families of functions (and the corresponding distributions), $\mathcal{F}_1$ and $\mathcal{F}_2$, defined over $\{0,1\}^d$. Let $\alpha < \frac{1}{32}$ be a parameter used for the construction of both families and define $m \stackrel{\text{def}}{=} 2^{\alpha d}$. In the construction, we use a set $\mathcal{M} \subset B^{d/2}_{(1/4-\alpha)\cdot d}$ of size $2m$ such that every two points in $\mathcal{M}$ are "far apart." This property of $\mathcal{M}$ will be used in the proof that the third requirement is satisfied. We first define the exact requirements from such a set $\mathcal{M}$ and claim its existence.

Lemma 5.1. *There exists a set $\mathcal{M} \subset B^{d/2}_{(1/4-\alpha)\cdot d}$ that satisfies the following conditions:*

- $|\mathcal{M}| = 2m$.
- $H(p, p') > 2\alpha d$ *for every two distinct points* $p, p' \in \mathcal{M}$.

Proof. First, note that the second condition of the lemma is equivalent to asking that $|p \cap p'| < (\frac{1}{4} - 2\alpha)d$ for every two distinct points $p, p' \in \mathcal{M}$. This holds since $H(p,p') = 2((\frac{1}{4} - \alpha)d - |p \cap p'|)$; hence, $|p \cap p'| < (\frac{1}{4} - 2\alpha)d$ iff $H(p,p') > 2\alpha d$.

We show that a randomly drawn set of $2m$ points in $B^{d/2}_{(1/4-\alpha)\cdot d}$ satisfies the small intersection condition with nonzero probability. Let P be the probability that two randomly drawn points $x, y \in B^{d/2}_{(1/4-\alpha)\cdot d}$ have intersection of size at least $(\frac{1}{4} - 2\alpha)d$.

By the union bound, the probability that a set of $2m$ randomly drawn points does not satisfy the small intersection condition is at most $4m^2P$. We prove the existence of such a set $\mathcal{M}$ by showing that $4m^2P < 1$. It is also possible to see P as the probability for a given point $x \in B^{d/2}_{(1/4-\alpha)\cdot d}$ that a randomly drawn point $y \in B^{d/2}_{(1/4-\alpha)\cdot d}$ has an intersection of size at least $(\frac{1}{4} - 2\alpha)d$ with x, and hence

$$\begin{aligned} P &= \frac{\sum_{i=(\frac{1}{4}-2\alpha)d}^{(\frac{1}{4}-\alpha)d} \binom{(\frac{1}{4}-\alpha)d}{i}\binom{(\frac{1}{4}+\alpha)d}{(\frac{1}{4}-\alpha)d-i}}{\binom{\frac{d}{2}}{(\frac{1}{4}-\alpha)d}} < (\alpha d+1)\frac{\binom{(\frac{1}{4}-\alpha)d}{(\frac{1}{4}-2\alpha)d}\binom{(\frac{1}{4}+\alpha)d}{\alpha d}}{\binom{\frac{d}{2}}{(\frac{1}{4}-\alpha)d}} \\ &= \frac{(\alpha d+1)((\frac{1}{4}-\alpha)d)!^2((\frac{1}{4}+\alpha)d)!^2}{\frac{d}{2}!((\frac{1}{4}-2\alpha)d)!(\frac{1}{4}d)!(\alpha d)!^2}. \end{aligned}$$

A simple calculation, based on Stirling formula, shows that $P < \frac{1}{4m^2}$ for sufficiently large d, implying the claimed result. To see this, we write

$$\begin{aligned} P &< \frac{(\alpha d+1)\cdot((\frac{1}{4}-\alpha)d)!^2((\frac{1}{4}+\alpha)d)!^2}{\frac{d}{2}!((\frac{1}{4}-2\alpha)d)!(\frac{1}{4}d)!(\alpha d)!^2} \\ &\approx \frac{(\alpha d+1)(2\pi)\cdot((\frac{1}{4}-\alpha)d\cdot((\frac{1}{4}-\alpha)d)^{2(\frac{1}{4}-\alpha)d}\cdot e^{-2(\frac{1}{4}-\alpha)d})}{(2\pi)^{\frac{5}{2}}\cdot\left(\sqrt{\frac{d}{2}}\cdot\frac{d}{2}^{\frac{d}{2}}\cdot e^{-\frac{d}{2}}\right)\cdot\left(\sqrt{(\frac{1}{4}-2\alpha)d}\cdot\left(\left(\frac{1}{4}-2\alpha\right)d\right)^{(\frac{1}{4}-2\alpha)d}\cdot e^{-(\frac{1}{4}-2\alpha)d}\right)} \\ &\quad\cdot\frac{((\frac{1}{4}+\alpha)d\cdot((\frac{1}{4}+\alpha)d)^{2(\frac{1}{4}+\alpha)d}\cdot e^{-2(\frac{1}{4}+\alpha)d})}{\left(\sqrt{\frac{d}{4}}\cdot(\frac{d}{4})^{\frac{d}{4}}\cdot e^{-\frac{d}{4}}\right)\cdot(\alpha d\cdot(\alpha d)^{2\alpha d}\cdot e^{-2\alpha d})} \\ &= \frac{(\alpha d+1)(\frac{1}{16}-\alpha^2)\cdot((\frac{1}{4}-\alpha)d)^{2(\frac{1}{4}-\alpha)d}\cdot((\frac{1}{4}+\alpha)d)^{2(\frac{1}{4}+\alpha)d}\cdot e^{-d}}{\sqrt{\frac{\pi}{4}\cdot((\frac{1}{4}-2\alpha)d)}\frac{d}{2}^{\frac{d}{2}}\cdot\frac{d}{4}^{\frac{d}{4}}\cdot\alpha\cdot\left(\left(\frac{1}{4}-2\alpha\right)d\right)^{(\frac{1}{4}-2\alpha)d}\cdot e^{-d}\cdot(2\alpha d)^{2\alpha d}} \\ &= \frac{(\alpha d+1)(\frac{1}{16}-\alpha^2)\cdot(\frac{1}{4}-\alpha)^{2(\frac{1}{4}-\alpha)d}\cdot(\frac{1}{4}+\alpha)d^{2(\frac{1}{4}+\alpha)d}}{\sqrt{\frac{\pi}{4}\cdot(\frac{1}{4}-2\alpha)}\cdot\alpha\cdot\frac{d}{2}^{\frac{d}{2}}\cdot\frac{d}{4}^{\frac{d}{4}}(\frac{1}{4}-2\alpha)^{(\frac{1}{4}-2\alpha)d}\cdot\alpha^{2\alpha d}}. \end{aligned}$$

For $\alpha < \frac{1}{32}$, we have $P < \frac{1}{4m^2}$. □

Using a set $\mathcal{M}$, as in Lemma 5.1, we define the two families. For each pair (f, D_f), we first define the function $f : \{0,1\}^d \to \{0,1\}$ and then, based on the definition of f, we define the corresponding distribution D_f over $\{0,1\}^d$.
